Abstract

Our main technical contribution is a polynomial-time determinisation procedure for history-deterministic Büchi automata, which settles an open question of Kuperberg and Skrzypczak, 2015. A key conceptual contribution is the lookahead game, which is a variant of Bagnol and Kuperberg's token game, in which Adam is given a fixed lookahead. We prove that the lookahead game is equivalent to the 1-token game. This allows us to show that the 1-token game characterises history-determinism for semantically-deterministic Büchi automata, which paves the way to our polynomial-time determinisation procedure.

1 Introduction

History-deterministic (HD) automata are non-deterministic automata in which the non-determinism can be resolved "on the fly", based only on the prefix of the word read so far [6, 15]. This concept can be formalised using the history-determinism game (HD game), in which two players Adam and Eve make alternating moves choosing letters and transitions, thus constructing a word and a run of the automaton on it, respectively. Eve wins if the run is accepting or if the word is not in the language, and hence Eve's winning strategy will successfully resolve non-determinism by constructing an accepting run on the fly, for all words in the language. An automaton is then defined to be history-deterministic if Eve has a winning strategy in the game.

Henzinger and Piterman [11] introduced HD automata because of their potential to speed up key algorithmic tasks in verification and synthesis, such as language containment and strategy synthesis. In language containment, we ask whether all executions of an

implementation $\mathcal{A}$ satisfy a specification $\mathcal{H}$. If $\mathcal{H}$ is non-deterministic then the problem is **PSPACE**-hard, but if $\mathcal{H}$ is HD then it is more tractable, because it amounts to checking that $\mathcal{H}$ simulates $\mathcal{A}$. This can be done in polynomial time if the parity index of $\mathcal{H}$ is fixed [8, Theorem 3] and in quasi-polynomial time otherwise [18, Theorem 20]. Henzinger and Piterman had originally dubbed HD automata as good-for-games automata in their work because games whose winning conditions are represented by an HD automaton can be solved efficiently without automaton determinisation [11, Theorem 3.1], a well-known computational bottleneck in synthesis.

1.1 Related work

Key questions studied for HD parity automata include recognising them, their succinctness relative to deterministic automata, minimisation, and determinisation.

Recognising History-Deterministic Automata via Games. Kuperberg and Skrzypczak [14] gave a polynomial time algorithm to recognise HD co-Büchi automata, and Bagnol and Kuperberg [3] gave a polynomial time algorithm to recognise HD Büchi automata. These algorithms have been conceptually unified by Boker, Kuperberg, Lehtinen, and Skrzypczak [5] to be based on the 2-token game introduced by Bagnol and Kuperberg [3], leading to the 2-token conjecture.

▶ **Conjecture 1** (The 2-token conjecture [3, 5]). *A parity automaton is HD if and only if Eve wins the 2-token game on it.*

Proving the 2-token conjecture would imply that recognising HD parity automata of fixed parity index can be done in polynomial time. In contrast, the best upper bound currently known for the problem is **EXPTIME**, dating back to Henzinger and Piterman [11]. In the general case, when the parity index is not fixed, a lower bound of **NP**-hardness has been achieved only very recently [18].

Bagnol and Kuperberg [3] introduced the k-token game as a tool to characterise the conceptually more complex HD game. Like in the HD game, in the k-token game for $k \geq 1$, two players Adam and Even make alternating moves choosing letters and transitions, but in addition, in every round, after Eve chooses a transition, Adam also chooses k transitions. As a result, Adam constructs a word and k runs, Eve constructs a run, and Eve wins if her run is accepting or all of Adam's k runs are rejecting. A key insight in Bagnol and Kuperberg's work [3] is that the 2-token game is equivalent to the k-token game for all $k \geq 2$.

▶ **Theorem 2** ([3]). *Eve wins the 2-token game on a parity automaton if and only if for all $k \geq 2$, Eve wins the k-token game on it.*

Bagnol and Kuperberg's proof that the 2-token game characterises history-determinism for Büchi automata exploits this insight, by showing that if Adam wins the HD game on a Büchi automaton then he can win the k-token game for some k that is doubly-exponential in the size of the automaton, and hence also the 2-token game.

Boker et al. [5] have used an analogous, but more involved, argument to show that the 2-token game also characterises history-determinism for co-Büchi automata, combining Theorem 2 with the algorithm of Kuperberg and Skrzypczak [14] to recognise HD co-Büchi automata efficiently, which was based on the so-called Joker game. The Joker game is similar to the 1-token game but, additionally, Adam has the power to (finitely many times) "play Joker" by choosing a transition from Eve's token instead of a transition from his token, and Eve wins if her run is accepting, or Adam's run is rejecting, or Adam has played Joker infinitely many times.

Kuperberg and Skrzypczak's algorithm uses Joker games in their polynomial time algorithm to recognise HD co-Büchi automata, but to date, it was not known if Joker games characterise history-determinism on co-Büchi or Büchi automata, or on parity automata in general.

Succinctness and minimisation of HD automata. Kuperberg and Skrzypczak [14] proved that HD co-Büchi automata are exponentially more succinct than deterministic co-Büchi automata [14], which is tight [15, Theorem 4.1]. Abu Radi and Kupferman [1] showed that transition-based HD co-Büchi automata can be minimised in polynomial time and that they have canonicity. In contrast, minimisation of state-based HD Büchi or HD co-Büchi automata is **NP**-complete [22, Theorem 1]. Minimisation of transition-based Büchi automata is easily seen to be in **NP**, but the exact complexity is open.

Determinisation of HD Büchi automata. Kuperberg and Skrzypczak [14] also proved that every HD Büchi automaton with n states has an equivalent deterministic Büchi automaton with at most n^2 states. However, it is not known if HD Büchi automata are strictly more succinct than deterministic Büchi automata.

The determinisation procedure of Kuperberg and Skrzypczak for an HD Büchi automaton $\mathcal{H}$ involves carefully analysing the simulation game between $\mathcal{H}$ and an equivalent deterministic Büchi automaton of exponential size. At a high level, the procedure iteratively modifies the simulation game and the automaton $\mathcal{H}$, eventually yielding an equivalent game of quadratic size, from which a deterministic Büchi automaton of quadratic size can be extracted, but the procedure itself runs in exponential time.

Kuperberg and Skrzypczak also gave a non-deterministic polynomial-time procedure for determinisation of HD Büchi automata, which guesses a deterministic Büchi automaton of quadratic size and then checks for language equivalence [14, Theorem 10]. They left the exact complexity of determinisation for HD Büchi automata open, in particular, the question of whether HD Büchi automata can be determinised in polynomial time.

1.2 Our Contributions

- We introduce the k-lookahead game, a variant of the 1-token game, in which Adam's transition on his token is delayed by k steps, thus giving him a lookahead of k. We prove that the 1-token game is equivalent to the k-lookahead game.

  ▶ **Theorem A.** *For every parity automaton $\mathcal{A}$, Eve wins the 1-lookahead game on $\mathcal{A}$ if and only if she wins the k-lookahead game on $\mathcal{A}$.*

  The 1-token game is syntactically equivalent to the 1-lookahead game. Theorem A thus demonstrates that the 1-token game is already quite powerful, and it is analogous to Theorem 2 of Bagnol and Kuperberg.
- With Theorem A as a key tool, we show that the 1-token game characterises history-determinism on semantically-deterministic Büchi automata. These are automata in which, for every state, all transitions labelled by the same letter lead to language-equivalent states [20].

  ▶ **Theorem B.** *A semantically-deterministic Büchi automaton is history-determinsitic if and only if Eve wins the 1-token game on it.*

  A consequence of Theorem B is that Joker games characterise history-determinism on Büchi automata (Theorem 19). Since Joker games have smaller arenas than 2-token games, this leads to a more efficient algorithm for recognising HD Büchi automata (Lemma 20).

- We give a parity automaton with priorities 1, 2, and 3 on which Eve wins the Joker game but that is not HD (Theorem 23). This implies that the Joker game does not characterise history-determinism for parity automata and that Theorem B does not extend to parity automata.
- We give a polynomial time determinisation procedure for HD Büchi automata, thus resolving an open question of Kuperberg and Skrzypczak [14].
  ▶ **Theorem C.** *There is a polynomial-time procedure that converts every HD Büchi automaton with n states into an equivalent deterministic Büchi automaton with n^2 states.*
  Our determinisation procedure is inspired by that of Kuperberg and Skrzypczak [14], but rather than working with the simulation game between the automaton and a deterministic automaton of exponential size, thanks to Theorem B, we can work with the 1-token game instead. This results in an algorithm that is conceptually simpler and that runs in polynomial time.
- We also give a technique to reduce game-based characterisations of history-determinism to universal automata (automata that accept all words). Hence to prove the 1-token game characterisation of history-determinism for semantically-deterministic (SD) Büchi automata, it suffices to prove it for universal SD Büchi automata (Theorem 11). Likewise, to prove the 2-token conjecture for parity automata, it suffices to prove it for universal parity automata (Theorem 13).

2 Preliminaries

We let $\mathbb{N} = \{0, 1, 2, \cdots\}$ to be the set of natural numbers. For two natural numbers i, j such that $i < j$, we write $[i, j]$ to denote the set of integers $\{i, i+1, \ldots, j\}$, and $[j]$ to denote $[0, j]$. An *alphabet* Σ is a finite set of *letters*. We use Σ^* and Σ^ω to denote the set of words of finite and countably infinite length over Σ, respectively. We also let ε be the unique word of length 0. A language $\mathcal{L} \in \Sigma^\omega$ is a set of infinite words. For a finite word $u \in \Sigma^*$ and a language $\mathcal{L}$, we define $u^{-1}\mathcal{L}$ to be $\{w \mid uw \in \mathcal{L}\}$.

2.1 Games

Game arenas. An *arena* is a directed graph $G = (V, E)$ with vertices partitioned into $V_\forall$ and $V_\exists$ between two players Adam and Eve, respectively. Additionally, a vertex $v_0 \in V_\forall$ is designated as the initial vertex. We say that vertices in $V_\exists$ are owned by Eve and those in $V_\forall$ are owned by Adam.

A *play* on this arena is an infinite path starting at v_0 and it is formed as follows. A play starts with a token at v_0 and it proceeds for infinitely many rounds. At each round, the player who owns the vertex on which the token is currently placed chooses an outgoing edge, and the token is moved along this edge to the next vertex for another round of play. This creates an infinite path in the arena, which we call a play of G.

A *game* $\mathcal{G}$ consists of an arena $G = (V, E)$ and a winning condition given by a language $L \subseteq E^\omega$. We say that Eve *wins a play* ρ in G if $\rho \in L$, and Adam wins otherwise. A *strategy* for Eve in such a game $\mathcal{G}$ is a function from the set of plays that end at an Eve's vertex to an outgoing edge from that vertex. Eve's strategy is said to be winning if any play produced while she plays according to this strategy is winning for her. We say that Eve *wins the game* if she has a winning strategy. Winning strategies are defined for Adam analogously, and we say that Adam wins the game if he has a winning strategy. In this paper we deal with ω-regular games, which are known to be determined [17, 10], i.e., each game has a winner. Two games are *equivalent* if they have the same winner.

Parity games. An $[i,j]$-*parity game* $\mathcal{G}$ is played over a finite game arena $G = (V, E)$, with the edges of G labelled by a priority function $\chi : E \to [i,j]$ for some $i, j \in \mathbb{N}$ with $i < j$, and $i = 0$ or $i = 1$. A play ρ in the arena of $\mathcal{G}$ is winning for Eve if and only if the highest edge priority that occurs infinitely often is even. It is well known that parity games can be solved in polynomial time when the interval $[i,j]$ is fixed, and in quasi-polynomial time otherwise [7, 13, 16].

2.2 Automata

Parity automata. An $[i,j]$-*non-deterministic parity automaton* $\mathcal{A} = (Q, \Sigma, q_0, \Delta)$ consists of a finite directed graph with edges labelled by letters in Σ and *priorities* in $[i,j]$ for some $i, j \in \mathbb{N}$ with $i < j$. These edges are called *transitions*, which are elements of the set $\Delta \subseteq Q \times \Sigma \times [i,j] \times Q$, and the vertices of this graph are called *states*, which are elements of the set Q. Each automaton has a designated *initial state* $q_0 \in Q$. For states $p, q \in Q$ and a letter $a \in \Sigma$, we use $p \xrightarrow{a:c} q$ to denote a transition from p to q on the letter a that has the priority c.

A *run* on an infinite word w in Σ^ω is an infinite path in the automaton, starting at the initial state and following transitions that correspond to the letters of w in sequence. We write that such a run is *accepting* if it *satisfies the parity condition*, i.e., the highest priority occurring infinitely often amongst the transitions of the run is even, and a word w in Σ^ω is accepting if the automaton has an accepting run on w. The *language* of an automaton $\mathcal{A}$, denoted by $\mathcal{L}(\mathcal{A})$, is the set of words that it accepts. We write that the automaton $\mathcal{A}$ *recognises* a language $\mathcal{L}$ if $\mathcal{L}(\mathcal{A}) = \mathcal{L}$. A language $\mathcal{L} \subseteq \Sigma^\omega$ is *ω-regular* if it is recognised by some parity automaton. A parity automaton $\mathcal{A}$ is *deterministic* if for any given state in $\mathcal{A}$ and any given letter in Σ, there is at most one outgoing transition from that state on that letter.

We write that $[i,j]$, with $i = 0$ or 1, is the parity index of $\mathcal{A}$. A *Büchi* (resp. co-Büchi) automaton is a $[1,2]$ (resp. $[0,1]$) parity automaton. A *safety automaton* is one where all transitions have priority 0.

We write $(\mathcal{A}, q)$ to denote the automaton $\mathcal{A}$ with q as its initial state, and $\mathcal{L}(\mathcal{A}, q)$ to denote the language it recognises. Two states p and q in $\mathcal{A}$ are *equivalent* if $\mathcal{L}(\mathcal{A}, p) = \mathcal{L}(\mathcal{A}, q)$.

History-determinism. The (HD game) is a two player turn-based game between Adam and Eve, who take alternating turns to select a letter and a transition in the automaton (on that letter), respectively. After the game ends, the sequence of Adam's choices of letters is an infinite word, and the sequence of Eve's choices of transitions is a run on that word. Eve wins the game if her run is accepting or Adam's word is rejecting, and we say that an automaton is HD if Eve has a winning strategy in the history-determinism game.

▶ **Definition 3** (History-determinism game). *Given a parity automaton $\mathcal{A} = (Q, \Sigma, q_0, \Delta)$, the* history-determinism game *of $\mathcal{A}$ is defined between the players Adam and Eve as follows, with positions in Q. The game starts at q_0 and proceeds for infinitely many rounds. For each $i \in \mathbb{N}$, round i starts at a position $q_i \in Q$, and proceeds as follows:*

1. *Adam selects a letter $a_i \in \Sigma$;*
2. *Eve selects a transition $q_i \xrightarrow{a_i:c_i} q_{i+1} \in \Delta$.*

The new position is q_{i+1} from where round $(i+1)$ is played. Thus, the play of a history-determinism game can be seen as Adam constructing a word letter-by-letter, and Eve constructing a run transition-by-transition on the same word. Eve wins such a play if the following holds: if Adam's word is in $\mathcal{L}(\mathcal{A})$, then Eve's run is accepting.

If Eve wins the history-determinism game on $\mathcal{A}$, then we say that $\mathcal{A}$ is *history-deterministic*.

Semantic-determinism. Let $\mathcal{A}$ be a parity automaton. A transition δ from p to q on a letter a in $\mathcal{A}$ is called *language-preserving* if $\mathcal{L}(\mathcal{A}, q) = a^{-1}\mathcal{L}(\mathcal{A}, p)$. We say that a parity automaton is *semantically-deterministic*, SD for short, if all transitions in it are language-preserving. The following lemma can be shown by a simple inductive argument on the length of words.

▶ **Lemma 4.** *If a parity automaton is SD then all states in the automaton that can be reached from a fixed state q upon reading a finite word u accept the language $u^{-1}\mathcal{L}(\mathcal{A}, q)$.*

SD automata were introduced by Kuperberg and Skrzypczak as residual automata [14]. We follow Abu Radi, Kupferman, and Leshkowitz [21] by calling them SD automata instead.

2.3 Games on Automata

Simulation and simulation-like games (such as token games [3]) are fundamental amongst the techniques we use in this paper. We define these games below.

Simulation and stepahead simulation.

▶ **Definition 5** (Simulation game). *Given two parity automata $\mathcal{A} = (P, \Sigma, p_0, \Delta_A)$ and $\mathcal{B} = (Q, \Sigma, q_0, \Delta_B)$, the* simulation game *between $\mathcal{B}$ and $\mathcal{A}$ is a two player game played between Eve and Adam as follows, with positions in $P \times Q$. The game starts at (p_0, q_0), and proceeds for infinitely many rounds. For each $i \geq 0$, round i starts at position (p_i, q_i) and proceeds as follows:*

1. *Adam selects a letter $a_i \in \Sigma$;*
2. *Adam selects a transition $p_i \xrightarrow{a_i:c'} p_{i+1}$ in $\mathcal{A}$;*
3. *Eve selects a transition $q_i \xrightarrow{a_i:c} q_{i+1}$ in $\mathcal{B}$.*

At the end of a play of the simulation game, the letters selected by Adam in sequence form a word, while the sequence of his selected transitions and the sequence of Eve's selected transitions form runs on that word in $\mathcal{A}$ and $\mathcal{B}$, respectively. We say Eve wins the game if her run in $\mathcal{B}$ is accepting or Adam's run in $\mathcal{A}$ is rejecting. If Eve has a strategy to win the simulation game, then we say that $\mathcal{B}$ simulates *$\mathcal{A}$.*

The *stepahead simulation* game between $\mathcal{B}$ and $\mathcal{A}$ is defined similarly to the simulation game, except the orders of move in each round are changed as follows: Adam selects a letter first, then Eve selects a transition on $\mathcal{B}$, and then Adam selects a transition on $\mathcal{A}$. The winning condition is identical, which is that Eve's run on $\mathcal{B}$ is accepting if Adam's run on $\mathcal{A}$ is accepting. If Eve wins the stepahead simulation game between $\mathcal{B}$ and $\mathcal{A}$, then we say that $\mathcal{B}$ *step-ahead simulates* $\mathcal{A}$.

Token games. k-token games are similar to stepahead simulation games, but are played on a single automaton, and Adam constructs k runs instead of one. The winning objective of Eve requires her to construct an accepting run if one of k Adam's runs is accepting.

▶ **Definition 6** (k-token game). *The* k-token game *on a non-deterministic parity automaton $\mathcal{A} = (Q, \Sigma, q_0, \Delta)$ is defined between the players Adam and Eve as follows, with positions in $Q \times Q^k$. The game starts at $(q_0, (q_0)^k)$ and proceeds in ω many rounds. For each $i \in \mathbb{N}$, the round i starts at a position $(q_i, (p_i^1, p_i^2, \cdots, p_i^k)) \in Q \times Q^k$, and proceeds as follows.*

1. *Adam selects a letter $a_i \in \Sigma$.*
2. *Eve selects a transition $q_i \xrightarrow{a_i:c} q_{i+1} \in \Delta$.*
3. *Adam selects k transitions $p_i^1 \xrightarrow{a_i:c'_1} p_{i+1}^1, p_i^2 \xrightarrow{a_i:c'_2} p_{i+1}^2, \cdots p_i^k \xrightarrow{a_i:c'_k} p_{i+1}^k \in \Delta$.*

The new position is $(q_{i+1}, (p_{i+1}^1, p_{i+1}^2, \cdots, p_{i+1}^k))$, from where round $(i+1)$ begins.

Thus, in a play of the k-token game on $\mathcal{A}$, Eve constructs a run and Adam k runs, all on the same word. Eve wins such a play if the following holds: if one of Adam's k runs is accepting, then Eve's run is accepting.

Observe that the stepahead-simulation game between $\mathcal{A}$ and itself is equivalent to the 1-token game on $\mathcal{A}$.

Joker games. *Joker games* are defined similar to 1-token games, but additionally in each round, Adam can choose to play *Joker* and choose a transition from Eve's position instead of a transition from his position. The winning condition for Eve is the following: If Adam's sequence of transitions satisfies the parity conditions and Adam has played finitely many Jokers, then Eve's run is accepting as well.

▶ **Definition 7** (Joker games). *The* Joker game *on a non-deterministic parity automaton $\mathcal{A} = (Q, \Sigma, q_0, \Delta)$ is defined between the players Adam and Eve as follows, with positions in $Q \times Q$. The game starts at (q_0, q_0) and proceeds in ω many rounds. For each $i \in \mathbb{N}$, the round i starts at a position $(q_i, p_i) \in Q \times Q$, and proceeds as follows.*

1. *Adam selects a letter $a_i \in \Sigma$.*
2. *Eve selects a transition $q_i \xrightarrow{a_i:c_i} q_{i+1} \in \Delta$*
3. *Adam either selects a transitions $p_i \xrightarrow{a_i:c'_i} p_{i+1}$, or plays Joker and selects a transition $q_i \xrightarrow{a_i:c'_i} p_{i+1}$.*

The new position is (q_{i+1}, p_{i+1}), from where round $(i+1)$ begins.

Eve wins such a play if the following holds: if Adam plays finitely many Jokers and his sequence of transitions satisfies the parity condition, then Eve's run is accepting.

The following observations are easy to see.

▶ **Lemma 8.** *If $\mathcal{A}$ is an HD parity automaton, and if $\mathcal{B}$ is a parity automaton such that $\mathcal{L}(\mathcal{B}) \subseteq \mathcal{L}(\mathcal{A})$, then we have:*

1. *Eve wins the Joker game on $\mathcal{A}$ and the k-token game on $\mathcal{A}$, for all $k \geq 1$;*
2. *$\mathcal{A}$ simulates and step-ahead simulates $\mathcal{B}$.*

Proof. Fix a winning strategy σ for Eve in the HD game of $\mathcal{A}$. Consider the strategy for Eve in the above games, in which she follows σ based on the letters Adam chooses, ignoring the rest of his moves. Then Eve constructs an accepting run whenever the word constructed by Adam is accepting. In particular, if Adam constructs an accepting run in the k-token game or the (stepahead) simulation game, then his word must be in $\mathcal{L}(\mathcal{A})$, implying Eve's run is accepting as well.

Similarly, in a play of the Joker game, suppose Adam plays finitely many Jokers and his sequence of transitions satisfies the parity condition. Let i be the last round where Adam played a Joker. Then there is an accepting run on Adam's word, which can be obtained by concatenating Eve's run until round $(i-1)$ with Adam's run from round i. This implies that Adam's word is in $\mathcal{L}(\mathcal{A})$, once again implying that Eve's run is accepting. ◀

2.4 History-Deterministic Automata and Simulation

Let $\mathcal{L}$ be an ω-regular language and let $\mathcal{F}_{\mathcal{L}}$ be the set of automata whose recognized languages are subsets of $\mathcal{L}$, that is $\mathcal{F}_{\mathcal{L}} = \{\mathcal{A} \mid \mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}\}$. For $\mathcal{A}, \mathcal{B} \in \mathcal{F}_{\mathcal{L}}$, we define $\mathcal{A} \preceq \mathcal{B}$ to hold if $\mathcal{B}$ simulates $\mathcal{A}$. This relation $\preceq$ is called the *simulation preorder* because it is reflexive and transitive. Lemma 8 implies that every HD automaton $\mathcal{H}$ that recognises $\mathcal{L}$ is a *greatest* element in $\mathcal{F}_{\mathcal{L}}$ with respect to the simulation preorder, that is, we have $\mathcal{A} \preceq \mathcal{H}$ for all $\mathcal{A}$ such that $\mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}(\mathcal{H})$. We show that the converse also holds.

▶ **Lemma 9.** *Let $\mathcal{L}$ be an ω-regular language and let $\mathcal{F}_{\mathcal{L}} = \{\mathcal{A} \mid \mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}\}$. Then, an automaton $\mathcal{H}$ in $\mathcal{F}_{\mathcal{L}}$ is greatest w.r.t. the simulation preorder if and only if $\mathcal{H}$ recognises $\mathcal{L}$ and it is history-deterministic.*

Proof. We only need to prove the forward implication, since the backward implication follows from Lemma 8. Let $\mathcal{H} \in \mathcal{F}_{\mathcal{L}}$ be such that $\mathcal{A} \preceq \mathcal{H}$ for all automata $\mathcal{A}$ that satisfy $\mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}$. Fix $\mathcal{D}$ to be a deterministic parity automaton that recognises $\mathcal{L}$ (such a $\mathcal{D}$ always exists, see [9, Theorem 1.19 and 3.11]). Then, in particular, we have $\mathcal{D} \preceq \mathcal{H}$. Observe that this implies $\mathcal{L}(\mathcal{H}) \supseteq \mathcal{L}(\mathcal{D}) = \mathcal{L}$, and since $\mathcal{L}(\mathcal{H}) \subseteq \mathcal{L}$, we get that $\mathcal{L}(\mathcal{H}) = \mathcal{L}$.

We proceed to show that Eve wins the HD game on $\mathcal{H}$. Fix σ to be a winning strategy for Eve in the simulation game between $\mathcal{H}$ and $\mathcal{D}$. We use σ to construct a winning strategy in the HD game on $\mathcal{H}$ as follows. During the letter game on $\mathcal{H}$, Eve keeps a corresponding play of the simulation game between $\mathcal{H}$ and $\mathcal{D}$, where Adam is playing the same letters as the HD game and choosing the unique transitions available to him. Then Eve chooses transitions according to σ in the HD game and in the simulation game in her memory. This way, whenever Adam's word w in the HD game is in $\mathcal{L}(\mathcal{H}) = \mathcal{L}$, then the unique run in $\mathcal{D}$ on w is accepting, and hence, Eve's run in the HD game on $\mathcal{H}$ must be accepting as well. ◀

We make explicit a corollary of the above lemma.

▶ **Corollary 10** ([11, Theorem 4])**.** *If a nondeterministic parity automaton $\mathcal{A}$ simulates a language-equivalent history-deterministic automaton $\mathcal{H}$ then $\mathcal{A}$ is history-deterministic.*

Proof. Let $\mathcal{L}(\mathcal{A}) = \mathcal{L}(\mathcal{H}) = \mathcal{L}$. From Lemma 9, we know that $\mathcal{H}$ is a greatest element in $\mathcal{F}_{\mathcal{L}}$, and $\mathcal{H} \preceq \mathcal{A}$ implies that $\mathcal{A}$ is a greatest element in $\mathcal{F}_{\mathcal{L}}$ as well. It follows from Lemma 9 that $\mathcal{A}$ is history-deterministic. ◀

3 Sufficient to think about Universal Automata

In the next section, we will show that 1-token games characterise history-determinism on semantically-deterministic Büchi automata (Theorem B). In order to show this, we start by reducing this result to the restriction where our automata are universal (Theorem 11), i.e., recognise all words in the language. A very similar reduction also shows that proving the 2-token conjecture for universal parity is sufficient to conclude the 2-token conjecture for parity automata (Theorem 19).

▶ **Theorem 11.** *The following statements are equivalent:*

1. *For any semantically-deterministic Büchi automaton $\mathcal{A}$, Eve wins the 1-token game on $\mathcal{A}$ if and only if $\mathcal{A}$ is history-deterministic.*
2. *For any semantically-deterministic Büchi automaton $\mathcal{U}$ with $\mathcal{L}(\mathcal{U}) = \Sigma^\omega$, Eve wins the 1-token game on $\mathcal{U}$ if and only if $\mathcal{U}$ is history-deterministic.*

We shall use the following fact shown by Boker, Henzinger, Lehtinen, and Prakash to prove Theorem 11 [4].

▶ **Lemma 12** ([4])**.** *A non-deterministic parity automaton $\mathcal{A}$ is history-deterministic if and only if it simulates all deterministic safety automata $\mathcal{S}$ with $\mathcal{L}(\mathcal{S}) \subseteq \mathcal{L}(\mathcal{A})$.*

A proof of Lemma 12 can be found in the full version [2]. We now show Theorem 11.

Proof sketch for Theorem 11. It is clear that 1 implies 2. For the other direction, suppose 2 holds. Let $\mathcal{A}$ be a semantically-deterministic automaton that is not HD. We will show that Adam wins the 1-token game on $\mathcal{A}$.

From Lemma 12, we know that there is a deterministic safety automaton $\mathcal{S}$ such that $\mathcal{A}$ does not simulate $\mathcal{S}$ and $\mathcal{L}(\mathcal{S}) \subseteq \mathcal{L}(\mathcal{A})$. Consider the product safety automaton $\mathcal{P}$ of $\mathcal{S}$ and $\mathcal{A}$ which recognises the language $\mathcal{L}(\mathcal{P}) = \mathcal{L}(\mathcal{S})$. We then complete $\mathcal{P}$ by adding an accepting sink state f, and transitions to f from all states q on letters a such that q did not have an outgoing transition on a in $\mathcal{P}$. We call this automaton $\mathcal{U}$. It is clear that $\mathcal{L}(\mathcal{U}, p) = \Sigma^\omega$ for all states p in $\mathcal{U}$, and hence $\mathcal{U}$ is SD. We show that Adam wins the HD game on $\mathcal{U}$, by using his winning strategy in the simulation game between $\mathcal{A}$ and $\mathcal{S}$ (recall that $\mathcal{P}$ was constructed by taking product of $\mathcal{S}$ and $\mathcal{A}$). The hypothesis implies that Adam wins the 1-token game on $\mathcal{U}$. We then show that we can adapt a winning strategy for Adam on 1-token game of $\mathcal{U}$ to one for the 1-token game on $\mathcal{A}$, by simply "projecting" his strategy to the $\mathcal{A}$ component: note that since $\mathcal{S}$ is deterministic, in plays of the 1-token game on $\mathcal{U}$, Eve's and Adam's states have the same $\mathcal{S}$-component at the start of each round. ◀

An almost word-by-word identical proof to above also shows that the 2-token conjecture can be reduced to the case where the automata are universal.

▶ **Theorem 13.** *The following statements are equivalent:*

1. *For any non-deterministic parity automaton $\mathcal{A}$, Eve wins the 2-token game on $\mathcal{A}$ if and only if $\mathcal{A}$ is history-deterministic.*
2. *For any non-deterministic parity automaton $\mathcal{U}$ with $\mathcal{L}(\mathcal{U}) = \Sigma^\omega$, Eve wins the 2-token game on $\mathcal{U}$ if and only if $\mathcal{U}$ is history-deterministic.*

4 When 1-Token Game is Enough

In this section, we will show the following result.

▶ **Theorem B.** *A semantically-deterministic Büchi automaton is history-determinsitic if and only if Eve wins the* 1*-token game on it.*

Towards this, we first introduce k-lookahead games, which are variants of 1-token games where Adam is given a lookahead of k.

4.1 Lookahead Games

Let us briefly recall how a round of the 1-token game on a parity automaton $\mathcal{A}$ works. In each round, Adam selects a letter, then Eve selects a transition on that letter on her token, and then Adam selects a transition on that letter on his token. The winning condition for Eve is that at the end of the play, either Eve's run is accepting or Adam's run is rejecting. This is very close to the simulation game between $\mathcal{A}$ and itself, except that the order of the moves in which Eve and Adam select transitions has been reversed. One can, however, see the 1-token game as a simulation game, where Adam picks the transition for round i in round $(i+1)$. Or equivalently, we can construct an automaton $\mathsf{Delay}(\mathcal{A})$ such that any non-determinism on $\mathcal{A}$ is "delayed" by one step, and then the 1-token game on $\mathcal{A}$ is equivalent to the simulation game between $\mathcal{A}$ and $\mathsf{Delay}(\mathcal{A})$. This insight was used by Prakash and Thejaswini to give an algorithm for deciding history-determinism of one-counter nets, by reducing the 1-token game to a simulation game [19]. Below we give a construction Delay on parity automata that delays the non-determinism by one-step, inspired by a similar construction for one-counter nets [19, Lemma 11].

▶ **Definition 14.** *For any non-deterministic parity automaton $\mathcal{A} = (Q, \Sigma, q_0, \Delta)$, the automaton* $\mathsf{Delay}(\mathcal{A})$ *is constructed so that it runs "one letter behind" $\mathcal{A}$, by storing a letter in its state space. More formally,* $\mathsf{Delay}(\mathcal{A}) = (Q', \Sigma, s, \Delta')$*, where $Q' = Q \times \Sigma \cup \{s\}$, and s is the initial state. The set of transitions Δ' is the union of the following sets of transitions.*

1. $\{(s \xrightarrow{a:0} (q_0, a)) \mid a \in \Sigma\}$.
2. $\{((p, a) \xrightarrow{a':c} (q, a')) \mid \ (p \xrightarrow{a:c} q) \in \Delta\}$.

Observe that $\mathsf{Delay}(\mathcal{A})$ accepts the same language as $\mathcal{A}$. The following lemma is easy to prove, since the expanded game arenas of the 1-token game on $\mathcal{A}$, and the simulation game between $\mathcal{A}$ and $\mathsf{Delay}(\mathcal{A})$ are equivalent, with identical winning conditions.

▶ **Lemma 15.** *For every non-deterministic parity automaton $\mathcal{A}$, Eve wins the 1-token game on $\mathcal{A}$ if and only if $\mathcal{A}$ simulates* $\mathsf{Delay}(\mathcal{A})$*.*

Furthermore, we can also show that Eve wins the 1-token game on $\mathsf{Delay}(\mathcal{A})$ if Eve wins the 1-token game on $\mathcal{A}$, by simply "delaying" her winning strategy in the 1-token game on $\mathcal{A}$.

▶ **Lemma 16.** *If Eve wins the 1-token game on an automaton $\mathcal{A}$, then Eve wins the 1-token game on* $\mathsf{Delay}(\mathcal{A})$*.*

An iterative application of Lemmas 15 and 16 gives us the following corollary.

▶ **Corollary 17.** *If Eve wins the 1-token game on a parity automaton $\mathcal{A}$, then $\mathcal{A}$ simulates* $\mathsf{Delay}^k(\mathcal{A})$ *for all $k \in \mathbb{N}$.*

Proof. Note that simulation relation is transitive, i.e., if $\mathcal{A}_0$ simulates $\mathcal{A}_1$ and $\mathcal{A}_1$ simulates $\mathcal{A}_2$, then $\mathcal{A}_0$ simulates $\mathcal{A}_2$. Suppose Eve wins the 1-token game on $\mathcal{A}$. From Lemma 16, induction gives us that Eve wins the 1-token game on $\mathsf{Delay}^k(\mathcal{A})$ for all $k \in \mathbb{N}$. From Lemma 15, we see that $\mathsf{Delay}^k(\mathcal{A})$ simulates $\mathsf{Delay}^{k+1}(\mathcal{A})$ for all $k \in \mathbb{N}$. Combining this with transitivity of simulation, we get that $\mathcal{A}$ simulates $\mathsf{Delay}^k(\mathcal{A})$ for all $k \in \mathbb{N}$. ◀

Call the simulation game between $\mathcal{A}$ and $\mathsf{Delay}^k(\mathcal{A})$ as the *k-lookahead game* on $\mathcal{A}$. Note that the 1-token game of $\mathcal{A}$ is then equivalent to the 1-lookahead game of $\mathcal{A}$. Corollary 17 can thus be restated as the following theorem.

▶ **Theorem A.** *For every parity automaton $\mathcal{A}$, Eve wins the 1-lookahead game on $\mathcal{A}$ if and only if she wins the k-lookahead game on $\mathcal{A}$.*

4.2 Games to Characterise History-Determinism

We now proceed to show Theorem B. From Theorem 11, we know that it suffices to only consider SD Büchi automata that are universal. The following lemma shows that every universal SD Büchi automaton is history-deterministic with sufficient lookahead.

▶ **Lemma 18.** *Let $\mathcal{U}$ be a semantically-deterministic Büchi automata such that $\mathcal{L}(\mathcal{U}) = \Sigma^\omega$. Then, there is a K such that* $\mathsf{Delay}^K(\mathcal{U})$ *is history-deterministic.*

Proof sketch. We let $K = 2^n$, where n is the number of states of $\mathcal{A}$. The crucial observation is that since $\mathcal{L}(\mathcal{U}, q) = \Sigma^\omega$ for any state q in $\mathcal{U}$, any finite word u that has length at least 2^n must have a run from q that passes through an accepting transition. Eve thus wins the history-determinism game on $\mathsf{Delay}^K(\mathcal{U})$ by exploiting the lookahead of K to take at least one accepting transition every K steps. The run of Eve's token then has infinitely many accepting transitions and hence is accepting, as desired. ◀

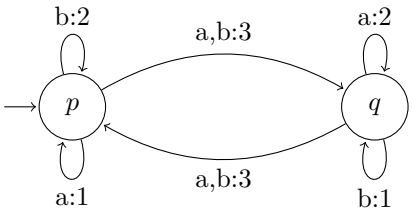

Figure 1 An [1,3]-automaton $\mathcal{A}$ that is not HD but on which Eve wins the Joker game.

We can now prove Theorem B.

Proof of Theorem B. The forward implication is clear by Lemma 8. For the backward direction, suppose that Eve wins the 1-token game on $\mathcal{A}$. Due to Theorem 11, we may assume that $\mathcal{A}$ is universal. Then, from Lemma 18, we know that there is a K such that $\mathsf{Delay}^K(\mathcal{A})$ is history-deterministic. If Eve wins the 1-token game on $\mathcal{A}$, then from Lemma 15, we know that $\mathcal{A}$ simulates $\mathsf{Delay}^K(\mathcal{A})$. But since $\mathsf{Delay}^K(\mathcal{A})$ is language equivalent to $\mathcal{A}$, we get from Corollary 10 that $\mathcal{A}$ is HD as well. ◀

Having shown that the 1-token game on a semantically-deterministic Büchi automaton $\mathcal{A}$ is equivalent to the HD game on $\mathcal{A}$, we are able to show that Joker games characterise history-determinism on Büchi automata. We also get an alternate proof of Bagnol and Kuperberg's result of 2-token games characterising history-determinism of Büchi automata as a corollary.

▶ **Theorem 19.** *For every Büchi automaton $\mathcal{A}$, the following statements are equivalent.*

1. *$\mathcal{A}$ is history-deterministic.*
2. *Eve wins the Joker game on $\mathcal{A}$.*
3. *Eve wins the 2-token game on $\mathcal{A}$.*

We prove Theorem 19 by reducing it to SD automata [2, Lemma 33], similar to Bagnol and Kuperberg [3, Lemma 16].

Joker games on a Büchi automaton have smaller arenas than 2-token games. As a result, we get a more efficient algorithm to recognise HD Büchi automata.

▶ **Lemma 20.** *Given a non-deterministic Büchi automaton $\mathcal{A} = (Q, \Sigma, q_0, \Delta)$, we can decide whether it is history-deterministic in time $\mathcal{O}(|\Sigma|^2|Q|^3|\Delta|)$.*

▶ Remark 21. While we have proven Theorem B by reducing it to universal automata for the sake of simplicity of arguments, one can also give a more direct proof. Such a direct proof involves arguing that if an automaton $\mathcal{A}$ is not history-deterministic, then there is a K exponential in the size of $\mathcal{A}$ such that $\mathcal{A}$ does not simulate $\mathsf{Delay}^K(\mathcal{A})$. It then follows from Lemma 15 that Eve loses the 1-token game on $\mathcal{A}$, as desired.

To argue that $\mathcal{A}$ does not simulate $\mathsf{Delay}^K(\mathcal{A})$, we reason based on the size of Adam's strategy in the history-determinism game on $\mathcal{A}$. Adam, in the simulation game between $\mathcal{A}$ and $\mathsf{Delay}^K(\mathcal{A})$, can pick letters according to his strategy in the history-determinism game on $\mathcal{A}$, thus ensuring Eve produces a rejecting run on her token. At the same time, Adam can exploit the lookahead in $\mathsf{Delay}^K(\mathcal{A})$ to construct an accepting run on his token, thus winning the simulation game between $\mathcal{A}$ and $\mathsf{Delay}^K(\mathcal{A})$.

We end this section by showing that unlike Büchi automata, Joker games do not characterise history-determinism on parity automata.

▶ **Example 22.** Consider the $[1,3]$-automaton $\mathcal{A}$ shown in Figure 1. Note that $\mathcal{A}$ accepts all words in $\{a,b\}^\omega$, and is SD. It is easy to see that the automaton $\mathcal{A}$ is not history-deterministic, since Adam can win the history-determinism game on $\mathcal{A}$ by choosing the letter a when Eve's token is at p, and b when her token is at q. This forces Eve to never see an even transition, causing her run to be rejecting.

Eve wins the Joker game on $\mathcal{A}$, however. Consider the strategy of Eve where she switches states if her and Adam's tokens are at different states, and otherwise stays at the same state. For Adam to win, Adam must play only finitely many Jokers, and construct an accepting run, which requires him to eventually stay in the same state. But then, Eve's strategy will ensure that Eve's and Adam's run are eventually identical, thus ensuring Adam cannot win the Joker game of $\mathcal{A}$.

▶ **Theorem 23.** *Joker games do not characterise history-determinism on (semantically-deterministic) parity automata.*

5 Determinising HD Büchi Automata in Polynomial Time

In this section, we present a polynomial time determinisation procedure for HD Büchi automata with only a quadratic state-space blowup. Our procedure combines ideas from the exponential-time procedure given by Kuperberg and Skrzypczak [14] with our 1-token game characterisation of history-determinism on SD Büchi automata.

▶ **Theorem C.** *There is a polynomial-time procedure that converts every HD Büchi automaton with n states into an equivalent deterministic Büchi automaton with n^2 states.*

Let $\mathcal{H}$ be an HD Büchi automaton. Kuperberg and Skrzypczak's procedure relies on carefully analysing the simulation game between $\mathcal{H}$ and an equivalent deterministic Büchi automaton $\mathcal{D}$ whose states are the subsets of $\mathcal{H}$. Their procedure iteratively makes modifications to $\mathcal{H}$ and $\mathcal{D}$ based on the structure of Eve's winning strategies in this game or, more precisely, the progress measures [12] or the signatures [23] of the vertices in this game, which they call ranks [14]. The end result of their procedure is a relation between states of $\mathcal{H}$ and states of $\mathcal{D}$ that correspond to sets containing a singleton in $\mathcal{H}$. A product construction based on this relation allows them to construct an equivalent determinsitic Büchi automaton whose number of states is quadratic in the number of states of $\mathcal{A}$.

The reason Kuperberg and Skrzypczak work with the simulation game between $\mathcal{H}$ and $\mathcal{D}$ is that it characterises the history-determinism of $\mathcal{H}$. A non-deterministic automaton is HD if and only if it simulates an equivalent deterministic one, as shown by Hezinger and Piterman [11, Theorem 4]. Our result on 1-token games characterising history-determinism (Theorem B) allows us to instead work with the 1-token game on $\mathcal{H}$. This results in a conceptually simpler procedure that works in polynomial time.

We present our algorithm in two steps. First, we introduce HD Büchi automata that have a sprint self-simulation, and we give a polynomial time determinisation procedure for them. The procedure involves a quadratic state-space blowup. Then, we give a polynomial time iterative procedure to transform $\mathcal{H}$ into an equivalent HD Büchi automaton of the same size that has a sprint self-simulation. Overall, this gives us a polynomial time procedure to determinise HD Büchi automata with a quadratic state-space blowup.

5.1 Determinising Automata with Sprint Self-Simulation

In this subsection, we describe what automata with sprint self-simulation are and give a polynomial time determinisation procedure for such HD Büchi automata. The key concept here is the *sprint simulation* relation between two Büchi automata, characterised by the *sprint*

step-ahead simulation game. This game is similar to the step-ahead simulation game, but the winning condition for Eve is that she must see an accepting transition before Adam does, i.e., she is in a sprint with Adam to see an accepting transition in the step-ahead simulation game first. Sprint step-ahead simulation (game) would be a more accurate phrase, but for brevity, we shorten it to just sprint simulation (game).

▶ **Definition 24.** *For two non-deterministic Büchi automata* $\mathcal{A} = (Q, \Sigma, q_0, \Delta_A)$ *and* $\mathcal{B} = (P, \Sigma, p_0, \Delta_B)$*, the* sprint simulation game *between* $\mathcal{A}$ *and* $\mathcal{B}$ *is played on the set of positions* $Q \times P$ *and it proceeds in rounds. In each round* $i = 0, 1, 2, \ldots$*, from position* (q_i, p_i)*, the two players Adam and Eve make the following choices:*

1. *Adam chooses a letter* $a_i \in \Sigma$*;*
2. *Eve chooses a transition* $\delta_i = (q_i \xrightarrow{a_i:c_i} q_{i+1}) \in \Delta_A$*;*
3. *Adam chooses a transition* $\delta'_i = (p_i \xrightarrow{a_i:c'_i} p_{i+1}) \in \Delta_B$*.*

The new position is (q_{i+1}, p_{i+1})*. At every round* i*, if transition* δ_i *is accepting then Eve wins the game, and otherwise, if the transition* δ'_i *is accepting then Adam wins the game. If neither* δ_i *nor* δ'_i *are accepting transitions, then the game continues for another round. Eve wins every infinite play.*

Observe that if Eve wins the sprint simulation game then she can do so by a positional strategy, because the objective for Eve is a disjunction of a safety and a reachability objective, which can be seen as a $[0, 1]$-parity game. If Eve has a winning strategy in the above game, we say that $\mathcal{A}$ sprint simulates $\mathcal{B}$. The sprint simulation relation is transitive, i.e., if $\mathcal{A}$ sprint simulates $\mathcal{B}$ and $\mathcal{B}$ sprint simulates $\mathcal{C}$, then $\mathcal{A}$ sprint simulates $\mathcal{C}$ [2, Lemma 36].

▶ Remark 25. The sprint simulation relation is similar to the 'dependency' relation introduced by Kuperberg and Skrzypczak [14, Definition 30]. While the sprint simulation relation is between two Büchi automata, dependency relation is derived from the sprint simulation game between a Büchi automaton and an equivalent exponential-sized deterministic Büchi automaton.

We say that an HD Büchi automaton $\mathcal{H}$ has a *sprint self-simulation* if it is semantically-deterministic and for every state p in $\mathcal{H}$, there is a language-equivalent state q, such that $(\mathcal{H}, p)$ sprint simulates $(\mathcal{H}, q)$. When $\mathcal{H}$ is clear from the context, we will just say that p sprint simulates q. For the rest of this subsection, fix $\mathcal{H} = (Q, \Sigma, q_0, \Delta)$ to be an HD Büchi automaton that has a sprint self-simulation. The following lemma follows from transitivity of sprint simulation.

▶ **Lemma 26.** *For every state* p *in* $\mathcal{H}$*, there is a language-equivalent state* q *such that* p *sprint simulates* q *and* q *sprint simulates itself.*

Proof. Fix a state p in $\mathcal{H}$. Then, there is a language-equivalent state q_0 in $\mathcal{H}$ such that p sprint simulates q_0. If q_0 does not sprint simulates itself, there is another language-equivalent q_1 such that q_0 sprint simulates q_1. Repeating this argument, we get a sequence of states $q_0, q_1, q_2, \ldots$, such that q_i sprint simulates q_{i+1}. Since, there are finitely many states in $\mathcal{H}$, there are two natural numbers $i < j$ such that $q_i = q_j$. Due to transitivity of sprint simulation [2, Lemma 36], it follows that p sprint simulates q_i and q_i sprint simulates itself, as desired. ◀

Let us call a state q *sprint deterministic* if the automaton $\mathcal{H}$ can be determinised by deleting transitions to get a deterministic subautomaton $\mathcal{F}_q$ so that the following holds: for all finite words w that have a run in $\mathcal{H}$ starting at q going through an accepting transition,

the unique run on w in $\mathcal{F}_q$ from q also sees an accepting transition. Thus, for states q that are sprint deterministic, there is a uniform strategy that achieves the objective of seeing an accepting transition as soon as possible on all words. We say that the automaton $\mathcal{F}_q$ as above is a witness for sprint determinism of q.

▶ **Lemma 27.** *A state q in $\mathcal{H}$ is sprint deterministic if and only if q sprint simulates itself. Moreover, there is a deterministic subautomaton $\mathcal{F}$ that can be computed in polynomial time and is a witness for all sprint deterministic states.*

Lemmas 26 and 27 above tell us that every state in $\mathcal{H}$ is either sprint deterministic, or it sprint simulates a state that is sprint deterministic. Fix a subautomaton $\mathcal{F}$ from Lemma 27, and a positional Eve strategy τ in the step-ahead simulation game from (p, q) for all pairs of states (p, q) such that p sprint simulates q.

The deterministic automaton $\mathcal{D}$ that is language-equivalent to $\mathcal{H}$ is then constructed to consist of pairs of states (p, q) such that p and q are language equivalent, p sprint simulates q, and q is sprint deterministic. Note that the pair of such states can be found in polynomial time, since checking for language containment on HD Büchi automata [18, Corollary 17] and deciding the winner of sprint simulation game can be done in polynomial time. Furthermore, for each state p in $\mathcal{H}$, we know from Lemmas 26 and 27 that there is a state q in $\mathcal{H}$ such that (p, q) is a state in $\mathcal{D}$. We let the initial state d_0 be (q_0, r_0) for some r_0 such that $(q_0, r_0) \in \mathcal{D}$.

At a state (q, p), the transitions in $\mathcal{D}$ from the second component p are chosen according to transitions from $\mathcal{F}$, while transitions from q are chosen via the positional Eve strategy τ. When an accepting transition $q \xrightarrow{a:2} q'$ is taken on the first component, we update the second component deterministically to be p' such that (q', p') is a state in $\mathcal{D}$. Or, equivalently, q' and p' are language equivalent, q' sprint simulates p', and p' is sprint deterministic. The priorities of transitions in $\mathcal{D}$ are the priorities of transitions of the first component.

We show the correctness of our construction using the definition of sprint simulation game and the fact that $\mathcal{H}$ is semantically-deterministic.

▶ **Lemma 28.** *The automaton $\mathcal{D}$ accepts the same language as $\mathcal{H}$.*

Proof. $\mathcal{L}(\mathcal{D}) \subseteq \mathcal{L}(\mathcal{H})$: If ρ is an accepting run of a word w in $\mathcal{D}$, then the projection of ρ on the first component is an accepting run in $\mathcal{H}$ as well.

$\mathcal{L}(\mathcal{H}) \subseteq \mathcal{L}(\mathcal{D})$: We show that for each state (p, q) in $\mathcal{D}$, if $w \in \mathcal{L}(\mathcal{H}, p)$ then the run from (p, q) on w in $\mathcal{D}$ sees an accepting transition eventually. We can then conclude by induction and the semantic determinism of $\mathcal{H}$ that runs of $\mathcal{D}$ on all accepting words in $\mathcal{L}(\mathcal{H})$ contain infinitely many accepting transitions each, and hence are accepting. To see this, let $w \in \mathcal{L}(\mathcal{H}, p)$ and let ρ_D be the run of $\mathcal{D}$ on w from (p, q). By construction of $\mathcal{D}$, we know that q is language-equivalent to p. Since q is sprint deterministic, the second component of ρ_D in $\mathcal{D}$ must contain an accepting transition on w eventually. But since p sprint simulates q, the run on the first component of ρ_D contains an accepting transition as well, as desired. ◀

5.2 Towards Automata with Sprint Self-Simulation

We now present a polynomial time algorithm to convert an HD Büchi automaton into an equivalent HD Büchi automaton that has a sprint self-simulation. Throughout this subsection, let $\mathcal{H} = (Q, \Sigma, q_0, \Delta)$ be an HD Büchi automaton.

We say that $\mathcal{H}$ is *good* if $\mathcal{H}$ is semantically-deterministic and Eve wins the Joker game from all states in $\mathcal{H}$. Every HD Büchi automaton $\mathcal{H}$ can be converted to an equivalent good HD Büchi automaton in polynomial time: we fix a winning strategy τ for Eve on the Joker game on $\mathcal{H}$, and consider the subautomaton $\mathcal{H}_N$ consisting of transitions that Eve takes according to τ [2, Lemma 38]. We thus assume without loss of generality that $\mathcal{H}$ is good.

To get an HD Büchi automaton equivalent to $\mathcal{H}$ and that has a sprint self-simulation, we iteratively make modifications to $\mathcal{H}$ based on the ranks of the 1-token game on $\mathcal{H}$. We first give a description of the 1-token game on a Büchi automaton as a $[0,2]$-parity game, and briefly recall the properties of ranks that we need on such games.

▶ **Definition 29.** *For a semantically-deterministic Büchi automaton $\mathcal{B} = (Q, \Sigma, q_0, \Delta)$, define the $[0,2]$-parity game $G_1(\mathcal{B}) = (V, E)$ as follows:*

- *The set of vertices V consists of the set $V = V_1 \cup V_2 \cup V_3$, where:*
  1. $V_1 = \{(p,q) \mid$ *p, q are states reachable from q_0 upon reading the same word $w\}$*
  2. $V_2 = \{(p,a,q) \mid (p,q) \in V_1\}$
  3. $V_3 = \{(p',q,a) \mid (p,a,q) \in V_2$ *and* $p \xrightarrow{a} p' \in \Delta\}$

  Eve's vertices are $V_\exists = V_2$, while Adam's vertices are $V_\forall = V_1 \cup V_3$
- *The set of edges E is the union of following sets:*
  1. $E_1 = \{(p,q) \to (p,a,q) \mid a \in \Sigma\}$ *(Adam chooses a letter)*
  2. $E_2 = \{(p,a,q) \to (p',q,a) \mid p \xrightarrow{a:c} p' \in \Delta\}$ *(Eve chooses a transition on her token)*
  3. $E_3 = \{(p',q,a) \to (p',q') \mid q \xrightarrow{a:c} q' \in \Delta\}$ *(Adam chooses a transition on his token)*
- *The priority function Ω is defined as follows. All elements in E_1 are assigned priority 0, while edges $(p,a,q) \to (p',q,a)$ in E_2 are assigned priority 2 if the transition $\delta = p \xrightarrow{a:c} p'$ in $\mathcal{B}$ is accepting (or equivalently, $c = 2$), and 0 otherwise. The edge $(p',q,a) \to (p',q')$ in E_3 is assigned priority 1 if the transition $q \xrightarrow{a:c} q'$ is accepting, and 0 otherwise.*

Observe that since $\mathcal{H}$ is SD, we have $\mathcal{L}(\mathcal{H}, p) = \mathcal{L}(\mathcal{H}, q)$ if (p,q) is a vertex in $G_1(\mathcal{H})$.

Ranks. We now define the ranks of a $[0,2]$-parity game $\mathcal{G}$. For each vertex v in $\mathcal{G}$, $\mathrm{rank}(v)$ is the largest number of 1's that Adam can guarantee Eve will see before seeing a 2 in the play (or only 0's) starting from v.

Observe that Eve wins such a parity game from every position if and only if the ranks of all the vertices are bounded. If this is the case, then there is a positional winning strategy τ, using which Eve can guarantee that she sees at most $\mathrm{rank}(v)$ many 1's before seeing a 2 (or seeing 0's forever) [23, Lemma 8] in every play. We will call such a strategy *optimal*. For $[0,2]$-parity games with n vertices and m edges, an optimal strategy can be computed in time $\mathcal{O}(mn)$ [12, Theorem 11].

The following property of ranks follows from their definition.

▶ **Lemma 30.** *Let $\mathcal{G}$ be a $[0,2]$-parity game, and let $v \xrightarrow{e} u$ be an edge in $\mathcal{G}$, such that either v belongs to Adam, or the edge e is prescribed by Eve's optimal strategy τ. Then the edge e has priority 2 or $\mathrm{rank}(v) \geq \mathrm{rank}(u)$. Furthermore, this inequality is strict if e has priority 1.*

Consider the 1-token game $G_1(\mathcal{H})$, and the ranks of its vertices. Note that for a vertex (q,p) in $G_1(\mathcal{H})$, we have $\mathrm{rank}(q,p) = 0$ if and only if q sprint simulates p. Define, for each state $q \in \mathcal{H}$, its optimal rank $\mathrm{opt}(q)$ to be the minimum rank of a vertex of the form (q,p) in $G_1(\mathcal{H})$. Note that if $\mathrm{opt}(q) = 0$ for all states $q \in \mathcal{H}$, then $\mathcal{H}$ has a sprint self-simulation. Thus, our iterative procedure focuses on reducing the optimal ranks for all states until they are all 0. We describe this procedure below.

Iterating towards a sprint self-simulation. Set $\mathcal{H}_0 = \mathcal{H}$. For each $i \geq 0$, perform the following three steps on $\mathcal{H}_i$ until $\mathcal{H}_{i+1} = \mathcal{H}_i$.

1. For all vertices $(p,q) \in G_1(\mathcal{H}_i)$, compute the optimal ranks $\mathrm{opt}_i(p)$ in $G_1(\mathcal{H}_i)$.
2. Obtain $\mathcal{H}'_i$ from $\mathcal{H}_i$ by removing all transitions $q \xrightarrow{a:1} q'$ with $\mathrm{opt}_i(q) < \mathrm{opt}_i(q')$.
3. Obtain $\mathcal{H}_{i+1}$ from $\mathcal{H}'_i$, by making all transitions $q \xrightarrow{a:1} q'$ with $\mathrm{opt}_i(q) > \mathrm{opt}_i(q')$ accepting.

We show that for each i, both $\mathcal{H}'_i$ and $\mathcal{H}_{i+1}$ are good HD Büchi automata that are equivalent to $\mathcal{H}_i$ [2, Lemmas 39 and 40]. By a simple induction, we get that each $\mathcal{H}_i$ for $i \geq 0$ is a good HD Büchi automaton equivalent to $\mathcal{H}$.

Note that in steps 2 and 3, we are either removing rejecting transitions or making rejecting transitions accepting, and hence this procedure terminates after at most $|\Delta|$ iterations. Let $\mathcal{H}^*$ be the automaton obtained after the procedure terminates. Since $\mathcal{H}^*$ is good, we know that it is SD. The next lemma thus shows that $\mathcal{H}^*$ has a sprint self-simulation.

▶ **Lemma 31.** *For all states p in $\mathcal{H}^*$, there is a language-equivalent state q in $\mathcal{H}^*$ such that p sprint simulates q.*

Proof. Assume, to the contrary, that there exists a state p such that $\text{opt}^*(p) = \text{rank}^*(p, q) > 0$. Fix an optimal winning strategy τ for Eve in $G_1(\mathcal{H}^*)$. Consider a finite play ρ of $G_1(\mathcal{H}^*)$ from (p, q) where Eve is playing according to τ, Adam chooses an accepting transition in his token at some point, while Eve is unable to. Then by monotonicity of ranks (Lemma 30), we know that rank^* strictly decreases across ρ at some point. Then, there must be a rejecting transition across which the quantity opt^* decreases as well. But since such transitions would have been made accepting in step 3 of the iteration, we get a contradiction. ◀

From the polynomial time determinisation construction for HD Büchi automata that have a sprint self-simulation presented in Section 5.1, we get a polynomial time determinisation procedure for HD Büchi automata. This concludes the proof of Theorem C.

6 Discussion

Our paper has shown two key results on HD Büchi automata: a 1-token game based characterisation of history-determinism for semantically-deterministic Büchi automata, and a polynomial time determinisation procedure. In the process of obtaining these results, we developed several novel techniques that we believe to be equally exciting and insightful. We finish by remarking some implications of our results and techniques, and natural future directions that our work points to.

Our first technique, presented in Section 3, reduces game based characterisations of history-determinism on parity automata to parity universal automata. But the history-determinism game on such an automaton is just a parity game, since Adam's word is always accepting. The 2-token conjecture thus reduces, by Theorem 13, to showing that this parity game is equivalent to the 2-token game. This seems easy enough to show at first glance, but it proves to be (unsurprisingly) difficult. This result also shows that the difficulty in proving or disproving the 2-token conjecture arises not from the language an automaton recognises, but rather from the structure of the automaton.

We also introduced lookahead games, and showed that k-lookahead games are equivalent to 1-token games for all $k \geq 1$ (Theorem A). This shows that the 1-token games are quite powerful, in the same sense that 2-token games are powerful due to them being equivalent to k-token games for all $k \geq 2$. While our 1-token game characterisation of history-determinism on SD Büchi automata does not extend to parity automata (Theorem 23), one can combine the two different approaches to give the 2-token game more power, both in the form of lookahead and more tokens. It would be interesting to consider such games to try extending the 2-token conjecture beyond Büchi and co-Büchi automata.

Our algorithm to determinise HD Büchi automata involves a quadratic blowup. However, we do not know whether this is tight. In fact, it is still open if HD Büchi automata are strictly more succinct than determinstic Büchi automata. Nevertheless, we are hopeful that our algorithm can offer some insights on how to make progress on this problem.

Let us end with a problem highlighted by Boker and Lehtinen in their recent survey [6, Section 6.3.2]. In all the existing game-based characterisations which are used to recognise HD automata efficiently, including ours (Theorem B), it is not clear how we can naturally convert a winning strategy for Eve from the 2-token game or the Joker game to a winning strategy in the HD game. Our algorithm to determinise HD Büchi automata, however, can be seen as one: starting with a winning strategy for Eve in the Joker game, we construct a strategy in the HD game that requires linear memory, thus obtaining a deterministic automaton of quadratic size. But the proof of correctness of our algorithm relies on Theorem B. Towards a more pure strategy-transfer argument, where ideally an algorithm for strategy transfer also proves a game-based characterisation of history-determinism, our algorithm comes tantalisingly close. Indeed, proving that the automaton constructed in Step 2 preserves the relevant invariants [2, Lemma 39] is the only place where we use the fact that we started with an HD automaton. We believe that trying to get rid of this assumption, in order to give an alternative strategy-transfer proof for the 1-token game characterisation of history-determinism on SD Büchi automata, could lead to crucial insights towards better understanding HD (Büchi) automata and token games.

Abstract

We lift metrics over words to metrics over word-to-word transductions, by defining the distance between two transductions as the supremum of the distances of their respective outputs over all inputs. This allows to compare transducers beyond equivalence.

Two transducers are *close* (*resp.* k-close) with respect to a metric if their distance is finite (*resp.* at most k). Over integer-valued metrics computing the distance between transducers is equivalent to deciding the closeness and k-closeness problems. For common integer-valued edit distances such as, Hamming, transposition, conjugacy and Levenshtein family of distances, we show that the closeness and the k-closeness problems are decidable for functional transducers. Hence, the distance with respect to these metrics is also computable.

Finally, we relate the notion of distance between functions to the notions of diameter of a relation and index of a relation in another. We show that computing edit distance between functional transducers is equivalent to computing diameter of a rational relation and both are a specific instance of the index problem of rational relations.

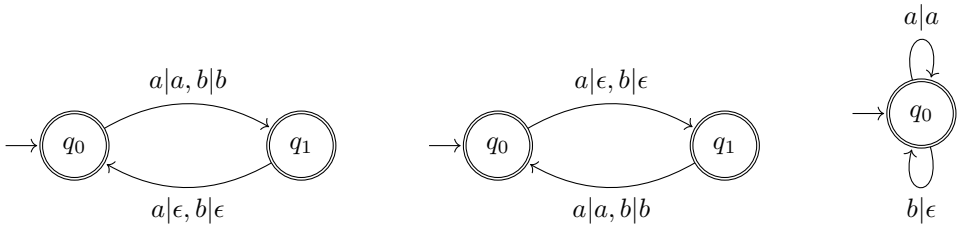
1 Introduction

For meaningfully comparing two words (or sequences, vectors, functions, etc.), it is often necessary to have a measure that quantifies their (dis)similarity. It usually consists of associating a nonnegative integer to two words that indicates how different they are from each other. This usually defines a distance between words, the most popular of which are edit distances. It is the minimum number of edit operations required to transform one word into another. These operations typically include inserting or deleting a letter, substituting a letter with another, swapping adjacent letters (transpositions), and cyclic shifts. Edit distances are studied in coding [29, 41], parsing [2], speech recognition [33, 1], molecular biology [18, 24] etc. Interesting combinatorial problems on words such as the computation of longest common subsequences can be reduced to computing edit distances [6]. For a detailed overview of the history and applications of edit distances, see [27].

The notion of distance between two words can be lifted naturally to distance between a word and a set of words, or between two sets of words, and so on. There is a long line of research of this kind: computing the edit distance between two languages – usually defined as the smallest distance between any two pairs from the respective sets. It could be between a word and a regular language [42, 4], two regular languages [31], a regular language and itself [25], or a regular language and a context-free language [21]. In all these settings there are efficient algorithms for computing the edit distances.

In this paper we study the distance between two word-to-word functions (transductions) given by finite state transducers, i.e., automata with output. Finite state transducers are used in a variety of software and hardware systems such as encoders, decoders, demuxers, spell checkers, text normalizers, schema translators, template code generators, etc.



(a) $\mathcal{T}_1$. **(b)** $\mathcal{T}_2$. **(c)** $\mathcal{T}_3$.

Figure 1 $\mathcal{T}_1$ outputs letters at the odd positions, $\mathcal{T}_2$ outputs letters at the even positions and $\mathcal{T}_3$ outputs only a's.

Our aim is to develop a framework to meaningfully compare two transductions beyond equivalence. Consider the functions given by the transducers in Figure 1. The transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ output the letters at the odd and even positions respectively, while the transducer $\mathcal{T}_3$ erases b's in the input. If we were to find the odd one among these three functions, arguably $\mathcal{T}_3$ will be picked, with the length of the respective output on any input deviating significantly from that of the others. Our aim is to define a measure that quantifies such distances.

If we have a metric to compare the output words, we can extend it to transductions as follows. The distance between two transductions is the least upper bound of the distances between their respective outputs on any input word. We assume that their domains are the same, and we set the distance to infinity if this is not the case. We say that two transductions are close if their distance is finite, and they are k-close if their distance is at most k. We may simply say that two transducers are close (or k-close) instead, to mean that the transductions defined by these transducers are close (or k-close).

We are interested in the following question: *Given two finite state transducers, are the transductions defined by them close (or simply are the transducers close)?* Clearly, deciding closeness is a boundedness problem. We show closeness as well as k-closeness are decidable for various edit distance metrics, in particular Hamming (letter-to-letter substitutions), transposition (swapping adjacent letters), conjugacy (only cyclic shifts) and Levenshtein family of distances – Longest common subsequence (insertion and deletion), Levenshtein (insertion, deletion and substitution), and Damerau-Levenshtein (insertion, deletion, substitution and adjacent transposition). It turns out that computing distance between transducers is equivalent to deciding closeness and k-closeness over integer-valued metrics (see Proposition 3.6). Hence for the edit distances mentioned above, the distance between transducers is computable.

A related notion is that of *diameter* of a relation. We define it to be the supremum of the distance of every pair in the relation. We are interested in computing the diameter of rational relations over words, that is those given by (not necessarily functional) finite state transducers. A rational relation is said to have *bounded diameter* (*resp.* k-bounded diameter) if the diameter of the relation is finite (*resp.* at most k). It turns out that for every pair of transductions $\mathcal{T}_1$ and $\mathcal{T}_2$ there is a rational relation R such that for every metric, the diameter of R is same as the distance between $\mathcal{T}_1$ and $\mathcal{T}_2$. In fact, the converse is also true by virtue of Nivat's theorem (see Theorem 3.23).

Another related notion is that of the *index of a rational relation in the composition closure of another*. Let R, S be a rational relation over words. The index of R in the composition closure of S is defined to be the smallest integer k such that the relation R is contained in the k-fold composition of S. If such a k exists we say that R has the *finite index property* in the composition closure of S. We show that the finite index property is undecidable for arbitrary rational relations. However, if S is a metrizable relation (see Definition 3.18) w.r.t. the edit distances mentioned above, the index of R in the composition closure of S is computable.

Our decision procedure for k-closeness involves designing a weighted automaton that counts the number of edit operations for transforming one output to the other. We need to check whether there are input instances for which the weight is more than k. We extract a finite state automaton of size exponential in k that achieves this (see Proposition 3.11). This is a generic approach independent of the particular edit operations. However for Hamming and transposition distances, we have a direct polynomial time procedure for deciding k-closeness (see full version).

Recall that deciding closeness of transductions is same as deciding whether the diameter of a rational relation R is bounded. For the latter, consider a transducer recognising R. It turns out that if there are loops in this transducer that produce nonconjugate words (that are not cyclic shifts of each other) then such loops can be iterated to get unbounded diameter/distance. Thus a crucial ingredient in our decision procedure is checking for conjugacy of loops, which is decidable [3]. For boundedness w.r.t. Levenshtein distances, we show that this is also a sufficient condition (see Claim 4.9). For conjugacy distance, we show that the diameter of a rational relation R is bounded if and only if every pair in R is conjugate (see Proposition 4.6). Notice that this is not the case for arbitrary relations. In the case of Hamming distance, which only includes substitutions, we show that it is sufficient to check if the pairs of words generated by the loops after some shifted delay are identical (see Claim 4.11). This also holds true for transposition distance, but additionally, we also need to check if the words are permutations of each other (see Claim 4.12).

1.1 Related Work

The *adjacent functions* in [34] is an analogous definition for closeness between transductions with respect to prefix distance. Two functions $f, g : A^* \to B^*$ are *adjacent* if $\sup\{ d_p(f(w), g(w)) \mid w \in dom(f) \cap dom(g) \} < \infty$. Here, $d_p(u, v) = |u| + |v| - 2\max\{|z| \mid u, v \in zA^*\}$ denotes the *prefix distance* between two words u and v. The adjacency of two rational functions is used in deciding the sequentiality of a function. It is decidable to check if two given rational functions are adjacent or not (Proposition 1 of [34]).

Another problem that is similar in spirit is the *robustness problem*. We say a transducer $\mathcal{T}$ is *robust* w.r.t. a distance d if there is a nontrivial relation R between the distance between two input words (say $d(u, v)$) and distance between their corresponding outputs on $\mathcal{T}$ (say $d(\mathcal{T}(u), \mathcal{T}(v))$). For instance, R could be *Lipschitz continuity* – there is some $k > 0$ such

that $d(\mathcal{T}(u), \mathcal{T}(v)) \leq k \cdot d(u, v)$, or *locally Lipschitz continuity* – there exists $b, k > 0$ such that if $d(u, v) < b$ then $d(\mathcal{T}(u), \mathcal{T}(v)) \leq k \cdot d(u, v)$, etc. Sometimes, weaker notions of distance are considered (for instance by dropping the triangle inequality), and respective distances are called *cost* or *similarity* functions. The work [35] solves the locally Lipschitz continuity problem for sequential and unambiguous transducers using reversal bounded counter automata. The problem is shown to be undecidable for Lipschitz continuity even for deterministic transducers and the decidability is shown for the class that has a bound on the delay between input and output words [23].

Frougny and Sakarovitch studied rational relations with bounded delay [20], which is actually our diameter problem for rational relations when the distance over words is measured by their length difference. A problem related to the diameter of a rational relation is *almost reflexivity* of rational relations studied in [11]. A relation $R \subseteq A^* \times A^*$ is k-reflexive, for some integer $k \leq \infty$, if every element u of the domain is at a distance at most k from some element of the range v, with $(u, v) \in R$, and vice versa. The relation R is almost reflexive if $k < \infty$. It is shown undecidable to check if a deterministic rational relation is almost reflexive, or k-reflexive, for any given integer k, with respect to the following – Hamming, prefix, suffix, subword and Levenshtein edit distances. It is shown decidable for synchronized rational relation w.r.t. Hamming distance.

In 1966, Brzozowski raised the question of *finite power property* on regular languages – it takes a regular language L as input and asks whether there exists some positive integer n such that $(L + \epsilon)^n = L^*$. It was solved in 1979 by Hashiguchi [22] and Simon [37], independently. We study the *finite index property* of a rational relation in the iterative composition of another relation. Notice that the finite index property is different from the finite power property in two respects. One, it is over relations and not languages, and secondly and more importantly, the iteration is obtained by relation composition and not concatenation.

1.2 Organisation of the Paper

In § 2, we recall the definitions of finite state transducers, metrics on words and edit distances. In § 3, we define the notion of distance between transducers, the diameter of a rational relation, and the index of a rational relation in another. We also establish the relation between these notions and state our results in this section. In § 4, we give the connections with conjugacy and the proof arguments remaining from § 3. Finally, we conclude in § 5 with a short discussion on future directions. Proofs omitted are provided in the full version.

2 Preliminaries

Let A^* denote the set of all finite words over the alphabet A. We use $|w|$ to denote the length of the word w. Let $w[i\,..\,j]$ denote the factor of w from index i to j where $1 \leq i \leq j \leq |w|$. A transduction is a function from words to words.

2.1 Finite State Transducers

The simplest form of a transducer is a deterministic finite state machine whose each transition and each final state is labelled by a possibly empty *output word*. Formally, a *sequential transducer* $\mathcal{T} = \langle \mathcal{A}, \lambda, o \rangle$ with input alphabet A and output alphabet B is a *deterministic* finite state automaton $\mathcal{A}$ with two associated output functions $\lambda : \Delta \to B^*$ and $o : F \to B^*$ where Δ and F are the set of transitions and the set of accepting states of $\mathcal{A}$ respectively.

On an input word that is accepted by the automaton, we concatenate the output words produced by the transitions in the unique run of the machine and finally append the end-of-input word of the final state to obtain the output of the machine. That is to say, if $\rho = \delta_1 \cdots \delta_n$ is the successful run of $\mathcal{A}$ on a word $w \in A^*$, the *output* of $\mathcal{T}$ on w, denoted by $\mathcal{T}(w)$, is the word $\lambda(\rho) \cdot o(q)$ where $\lambda(\rho) = \lambda(\delta_1) \cdots \lambda(\delta_n)$ and q is accepting state reached by the run. Let $L(\mathcal{A})$ denote the set of words accepted by $\mathcal{A}$, called the *language* of $\mathcal{A}$ or the *domain* of $\mathcal{T}$ (denoted as $dom(\mathcal{T})$). We can see that $\mathcal{T}$ defines a function from $dom(\mathcal{T})$ to B^*. Functions defined by sequential transducers are called *sequential*. In the literature, they are known as *subsequential functions*, introduced by Schützenberger [36]. Transducers given in Figure 1 are sequential.

If we allow the finite state automaton $\mathcal{A}$ to be nondeterministic, then $\mathcal{T}$ no longer defines a function, but a binary relation on $A^* \times B^*$. Such relations are called *rational*. If the relation is a function, then the transducer is called *functional*, and the corresponding functions are called *rational functions*. We can restrict the nondeterminism and still compute all rational functions. A finite state automaton is *unambiguous* if on each input word the machine has at most one run. It is a well-known fact in the theory of transducers that all *rational functions* are computed by finite state transducers whose underlying automata are unambiguous [10]. Such transducers are called *unambiguous transducers*. Clearly sequential functions are a strict subset of rational functions. For instance, the function "output the input word if the last letter of the input is an a, otherwise the empty word" is rational but not sequential.

There exist generalisations of rational functions where the underlying automaton is a two-way finite state automaton or equivalently a finite state automaton with registers (corresponding functions are called *regular* [17, 5]), or two-way finite state automaton with pebbles (polyregular functions [8, 9]). An overview of the classical theory of transducers is given in [19]. In this paper, we restrict our attention to one-way functional transducers.

2.2 Metric on Words, Edit Distances

Simply put, a metric on a set is used to measure distance between any two elements of the set. A *metric on words* over the alphabet A is a function $d : A^* \times A^* \to [0, \infty]$ such that for any words u, v and w in A^*, $d(u, v) = 0 \iff u = v$ (*separation*), $d(u, v) = d(v, u)$ (*symmetry*), and $d(u, v) \leq d(u, w) + d(w, v)$ (*triangle inequality*).

A metric is *integer-valued* if it has range $\mathbb{N} \cup \{\infty\}$. A trivial metric on words is the *discrete metric* – distance between words u and v, denoted by $d_\infty(u, v)$, is 0 if $u = v$ and ∞ otherwise. Another straightforward distance on words is the absolute difference of their lengths (denoted as d_{len}). This is a *pseudo-metric* since the distance between two distinct words can be zero, i.e., does not satisfy the separation property of a metric.

An important class of metrics in the context of word transducers is *edit distances*. Loosely speaking, *edits* are operations that transform words, such as *inserting a letter*, *deleting a letter*, *substitutions (letter-to-letter)*, *adjacent transpositions* (swapping adjacent letters), *left and right shifts* etc. For a fixed set of edit operations C, the edit distance with respect to C between words u and v, is the minimum number of edits in C required to transform u to v if it is possible, and ∞ otherwise. The common edit distances and their corresponding operations are recalled in Table 1. Since many of these operations are obtained by combinations of the others, we can relate these metrics. The notation $d_1 \leq d_2$ is an abbreviation for $d_1(u, v) \leq d_2(u, v)$ for all words u, v. We can also relate the metrics up to boundedness (See [14] for a detailed introduction). Let $\alpha : \mathbb{N} \to \mathbb{N}$ be a *correction* function. Usual examples are increments (e.g. $x \mapsto x + 2$), scaling (e.g. $x \mapsto 2 \cdot x$) etc. We extend α to the domain $\mathbb{N} \cup \{\infty\}$ by letting $\alpha(\infty) = \infty$. We write $d_1 \lesssim d_2$ to mean that there is some α such that

Table 1 Edit Distances.

Edit Distance	Denotation	Allowed Operations
Hamming distance	d_h	letter-to-letter substitutions
Transposition distance	d_t	swapping adjacent letters
Conjugacy distance	d_c	left and right cyclic shifts
Levenshtein edit distance	d_l	insertions, deletions, and substitutions
Longest Common Subsequence	d_{lcs}	insertions and deletions
Damerau-Levenshtein distance	d_{dl}	insertions, deletions, substitutions and adjacent transpositions

$d_1 \leq \alpha \circ d_2$. Clearly, if $d_1 \leq d_2$ then $d_1 \lesssim d_2$. If $d_1 \lesssim d_2$ and $d_2 \lesssim d_1$, we write $d_1 \approx d_2$ (this is known as the cost equivalence or the boundedness equivalence). If two functions f and g are cost-equivalent then f and g are bounded over precisely the same family of subsets (See Proposition 1 of [14]).

▶ **Lemma 2.1.** *The metrics defined in Table 1 are related as follows:*

1. $d_{len} \leq d \leq d_\infty$, *for each edit distance metric* $d \in \{d_l, d_h, d_t, d_c, d_{lcs}, d_{dl}\}$
2. $d_l \approx d_{lcs} \approx d_{dl}$
3. $d_l \leq d_h \lesssim d_t$
4. $d_l \lesssim d_c$
5. d_c *and* d_t *as well as* d_c *and* d_h *are incomparable, i.e.,* $d_h \not\lesssim d_c, d_c \not\lesssim d_h$ *and* $d_t \not\lesssim d_c, d_t \not\lesssim d_c$

3 Distance between Transductions

In this section we define the notion of distance between two rational functions, diameter of a rational relation, and index of a rational relation in another. We establish the relation between these notions and state our results.

3.1 Comparing Transducers

We lift a metric over words to the class of word-to-word functions as follows.

▶ **Definition 3.1** (Metric on transductions). *Let d be a metric on words over the alphabet B. Given two partial functions $\mathcal{T}, \mathcal{S} : A^* \to B^*$, we define*

$$d(\mathcal{T}, \mathcal{S}) = \begin{cases} \sup\{\, d(\mathcal{T}(w), \mathcal{S}(w)) \mid w \in dom(\mathcal{T})\} & \text{if } dom(\mathcal{T}) = dom(\mathcal{S}) \\ \infty & \text{otherwise} \end{cases}$$

▶ **Proposition 3.2.** *d is a metric on transductions.*

▶ Remark 3.3. We can define a notion of distance between word-to-word relations in the above manner, however this distance will not be a metric. In particular $d(R, R)$ will not be 0 for a relation R that is not a (partial) function.

▶ **Example 3.4.** Consider the sequential transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ in Figure 1. The transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ output the letters at the odd and even positions respectively. For any input word u, $||\mathcal{T}_1(u)| - |\mathcal{T}_2(u)|| \leq 1$. Hence $d_{len}(\mathcal{T}_1, \mathcal{T}_2) = 1$. For input word $(ab)^n$ where $n > 1$, the outputs produced by $\mathcal{T}_1$ and $\mathcal{T}_2$ are a^n and b^n respectively. Since n substitutions are required to convert a^n to b^n, $d_l(a^n, b^n) = n$. Therefore, $d_h(\mathcal{T}_1, \mathcal{T}_2) = \infty$ as well as $d_l(\mathcal{T}_1, \mathcal{T}_2) = \infty$.

Table 2 Problems about distance between two transducers w.r.t. the metric d.

Problem	Input	Question
Distance Problem	transducers $\mathcal{T}, \mathcal{S}$	$d(\mathcal{T}, \mathcal{S})$?
Closeness Problem	transducers $\mathcal{T}, \mathcal{S}$	Is $d(\mathcal{T}, \mathcal{S}) < \infty$?
k-Closeness Problem	integer k, transducers $\mathcal{T}, \mathcal{S}$	Is $d(\mathcal{T}, \mathcal{S}) \leq k$?

▶ **Example 3.5.** The sequential transducer $\mathcal{T}_4$ in Figure 2 replaces each block of 0's by a single 0 and each block of 1's by a single 1. Similarly, $\mathcal{T}_5$ substitutes a block of 0's by a single 1 and a block of 1's by a single 0. The output words produced by the transducers on any input word is an alternate sequence of 0's and 1's. If $\mathcal{T}_4$ outputs 010, then $\mathcal{T}_5$ produces its complement, i.e., 101. The Hamming distance between $\mathcal{T}_4$ and $\mathcal{T}_5$ is ∞, but the Levenshtein distance is 2.

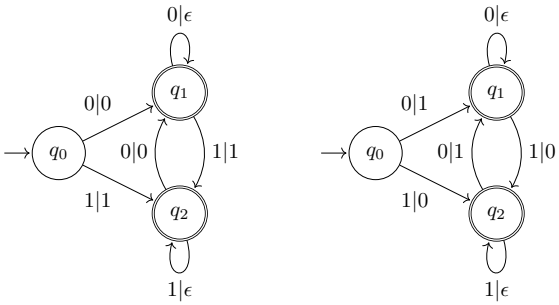


Figure 2 $\mathcal{T}_4$ (left) outputs 0 & 1 for each block of 0's & 1's *resp.* whereas $\mathcal{T}_5$ (right) outputs 1 & 0 for each block of 0's & 1's *resp.*

Let d be a distance on words. The value $d(\mathcal{T}, \mathcal{S})$ is an upper bound on how dissimilar the outputs of transducers $\mathcal{T}$ and $\mathcal{S}$ can be on any input. It is natural to ask the computational and boundedness problems given in Table 2.

Closeness and k-closeness are respectively a boundedness and an upper bound problem on distance.

▶ **Proposition 3.6.** *Let d be an integer-valued metric. The distance problem w.r.t. d is computable if and only if k-closeness and closeness problems w.r.t. d are decidable.*

Proof. Clearly, if we can compute the distance w.r.t. d then we can decide k-closeness as well as closeness. For the other direction, given two transducers, we first check if they are close and if it is we perform an exponential search – check if they are k-close for $k = 2^0, 2^1, 2^2, \ldots$ till it fails and subsequently perform a binary search on the interval $[2^n, 2^{n+1}]$, $n \in \mathbb{N}$ that contains the distance. ◀

We say two transducers $\mathcal{T}$ and $\mathcal{S}$ are *close* (*resp.* k*-close*, for $k \geq 0$) w.r.t. d if $d(\mathcal{T}, \mathcal{S}) < \infty$ (*resp.* $d(\mathcal{T}, \mathcal{S}) \leq k$). Closeness with respect to the discrete metric d_∞ is precisely the equivalence problem. Closeness w.r.t. the length metric d_{len} can be characterised in terms of delay as follows.

▶ **Proposition 3.7.** *Given two transducers $\mathcal{T}_1, \mathcal{T}_2$ with identical domain, $d_{len}(\mathcal{T}_1, \mathcal{T}_2)$ is finite iff there exists a $k \in \mathbb{N}$ such that on any input word w, the difference in lengths of the partial outputs of $\mathcal{T}_1, \mathcal{T}_2$ on any prefix of w is bounded by k.*

In the case of edit distances, closeness means that the output of $\mathcal{T}_1$ can be converted to the output of $\mathcal{T}_2$ by doing a bounded number of edits.

▶ Remark 3.8. From Definition 3.1, it is easy to verify that Lemma 2.1 holds for transducers as well. If $d_1 \lesssim d_2$, then it is easy to see that if transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ are *not* close w.r.t. d_1, then they are not close w.r.t. d_2 either.

The problems in Table 2 for unambiguous transducers with identical domains can be reduced to that for sequential transducers by considering the cartesian product of the unambiguous transducers. Given two unambiguous transducers $\mathcal{T}_1$ and $\mathcal{T}_2$, we obtain the sequential transducers $\mathcal{T}_1'$ and $\mathcal{T}_2'$ as follows. The input automata for $\mathcal{T}_1'$ and $\mathcal{T}_2'$ are the same, call it $\mathcal{A}$, which is the cartesian product of the input automata of $\mathcal{T}_1$ and $\mathcal{T}_2$. By treating the transitions of the cartesian product as the input alphabet, we get input determinism. The output functions of $\mathcal{T}_1'$ and $\mathcal{T}_2'$ are lifted from T_1 and T_2 respectively.

▶ **Proposition 3.9.** *Let d be a distance on words. For each pair of unambiguous transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ with identical domain, there exist a DFA $\mathcal{A}$ and output functions λ_1', o_1' and λ_2', o_2' such that $d(\mathcal{T}_1, \mathcal{T}_2) = d(\mathcal{T}_1', \mathcal{T}_2')$ where the sequential transducer $\mathcal{T}_i' = \langle \mathcal{A}, \lambda_i', o_i' \rangle$, $i \in \{1, 2\}$. Furthermore, the size of the automaton $\mathcal{A}$ is polynomial in the size of $\mathcal{T}_1$ and $\mathcal{T}_2$.*

Given two transductions $\mathcal{T}$ and $\mathcal{S}$, we define a distance function that maps each word w to the distance between their outputs on w.

▶ **Definition 3.10** (Distance function)**.** *The* distance function $f^d_{\mathcal{T},\mathcal{S}} : A^* \to \mathbb{N} \cup \{\infty\}$ *of $\mathcal{T}$ and $\mathcal{S}$ is $f^d_{\mathcal{T},\mathcal{S}}(w) = d(\mathcal{T}(w), \mathcal{S}(w))$ if $w \in dom(\mathcal{T}) \cap dom(\mathcal{S})$; otherwise $f^d_{\mathcal{T},\mathcal{S}}(w) = \infty$.*

Transducers $\mathcal{T}$ and $\mathcal{S}$ are close w.r.t. a metric d if their domains are the same and their distance function $f^d_{\mathcal{T},\mathcal{S}}$ is *limited* (i.e.,$< \infty$ on its domain). Similarly k-closeness w.r.t. d of $\mathcal{T}$ and $\mathcal{S}$ reduces to k-limitedness of $f^d_{\mathcal{T},\mathcal{S}}$. Limitedness problems are well-studied in the context of weighted automata [28, 12]. Therefore, when the distance function $f^d_{\mathcal{T},\mathcal{S}}$ is computable by a $(\min, +)$-automaton, the distance between $\mathcal{T}$ and $\mathcal{S}$ is computable due to Proposition 3.6.

However, there are distance functions that are not computable by weighted automata. Let $A = \{a, b\}$. Consider the sequential transducers $\mathcal{T}_1, \mathcal{T}_2 : A^* \to A^*$ with the domain a^*b^* defining the functions $a^pb^q \mapsto a^p$, $a^pb^q \mapsto a^q$ respectively ($\mathcal{T}_1$ outputs the a's and erases the b's, $\mathcal{T}_2$ erases a's and renames the b's as a's). It is easily checked that their distance function w.r.t. the Levenshtein family ($d \in \{d_l, d_{lcs}, d_{dl}\}$) is $f^d_{\mathcal{T}_1,\mathcal{T}_2} : a^pb^q \mapsto |p - q|$.

If $f : A^* \to \mathbb{N} \cup \{\infty\}$ is a function computed by weighted automata ($(\min, +)$ or $(\max, +)$ or B-automata [13]), then $L_{f \leq k} = \{w \in A^* \mid f(w) \leq k\}$ is regular for each $k \leq \mathbb{N}$. Hence the function $f^d_{\mathcal{T}_1,\mathcal{T}_2}$ is not realised by any of them (consider the language $L_{f^d_{\mathcal{T}_1,\mathcal{T}_2} \leq k}$). In fact, it can be shown that the function $f^d_{\mathcal{T}_1,\mathcal{T}_2}$ is not computed even upto boundedness [15].

To compute k-closeness w.r.t. any of the edit distances, it is not necessary to compute the distance function precisely. The k-approximation of the distance function $f^d_{\mathcal{T},\mathcal{S}}$ is the function $\lceil f^d_{\mathcal{T},\mathcal{S}} \rceil^{\leq k} : w \mapsto f^d_{\mathcal{T},\mathcal{S}}(w)$ if $f^d_{\mathcal{T},\mathcal{S}}(w) \leq k$ and ∞ otherwise.

▶ **Proposition 3.11.** *If $\mathcal{T}$ and $\mathcal{S}$ are close w.r.t. the length metric, then the approximation $\lceil f^d_{\mathcal{T},\mathcal{S}} \rceil^{\leq k}$ for a metric $d \in \{d_l, d_{lcs}, d_{dl}, d_h, d_t, d_c\}$ is computed by a distance automaton for each $k \in \mathbb{N}$.*

To check if $\mathcal{T}$ and $\mathcal{S}$ are k-close, we check if they have the same domain and they are close w.r.t. the length metric (otherwise they are neither close nor k-close). If so, we check if the domain of T is same as the domain of $\lceil f^d_{\mathcal{T},\mathcal{S}} \rceil^{\leq k}$. Thus we get:

▶ **Corollary 3.12.** *Let d be any metric from Table 1, and $\mathcal{T}$ and $\mathcal{S}$ be any functional transducers. It is decidable if $\mathcal{T}$ and $\mathcal{S}$ are k-close w.r.t. d.*

Table 3 Problems about diameter of a rational relation w.r.t. the metric d.

Problem	Input	Question
Diameter Problem	rational relation R	$dia_d(R)$?
Bounded Diameter Problem	rational relation R	Is $dia_d(R) < \infty$?
k-Bounded Diameter Problem	integer k, rational relation R	Is $dia_d(R) \leq k$?

3.2 Diameter of a Rational Relation

▶ **Definition 3.13** (Diameter of a Rational Relation w.r.t. a distance d). *The diameter of a rational relation R with respect to a distance d, denoted by $dia_d(R)$, is the supremum of the distance of the related words in R.*

$$dia_d(R) = \sup \{ d(u, v) \mid (u, v) \in R \}$$

Similar to the questions asked in Table 2, we can ask the questions given in Table 3 about diameter of a rational w.r.t. a metric d. We say a rational relation has *bounded (resp. k-bounded) diameter w.r.t. a distance d* if the diameter of the relation w.r.t. d is finite (*resp.* $\leq k$). A rational relation with *bounded delay* is precisely those relations with bounded diameter w.r.t. a length metric. Relations with 0-delay are called *length-preserving relations* [16] where any two related words are of equal length. It is decidable to check if a rational relation has bounded delay or 0-delay [20].

Relations bounded w.r.t. the discrete metric are simply those with only identical pairs. It is decidable to determine if a rational relation R is identity. First, check if R is length-preserving. If so, we can construct a letter-to-letter transducer for R based on Eilenberg and Schützenberger's theorem [16] stating that a length-preserving rational relation over $A^* \times B^*$ is a rational subset of $(A \times B)^*$, or equivalently, it can be realised by a letter-to-letter transducer whose transitions are labelled with elements of $A \times B$. Finally, validate this transducer for identity by examining the labels of each transition.

3.3 Index of a Rational Relation in a Composition Closure

Consider two rational relations R over $A^* \times B^*$ and S over $B^* \times C^*$. The composition $S \circ R$ over $A^* \times C^*$ is defined by $(S \circ R)(u) = S(R(u)) = \bigcup_{v \in R(u)} S(v)$.

▶ **Definition 3.14** (Composition closure of a Rational Relation). *Let S be a rational relation over $A^* \times A^*$. Let $S^{(n)}$ denote the composition of S with itself $n \geq 0$ times ($S^{(0)}$ is taken to be the identity relation), and let $S^{\leq (n)}$ denotes the composition of S with itself at most n times, i.e., $S^{\leq (n)} = S^{(0)} \cup S^{(1)} \cup \cdots S^{(n)}$.*

The composition closure *of S, denoted as $S^{(*)}$, is defined as $S^{(*)} = \bigcup_{i \geq 0} S^{(i)}$.*

Notice that we use parenthesis around the superscript to indicate that the base operation is composition, and not concatenation.

▶ **Definition 3.15** (Index of a Rational Relation in a Composition Closure). *Let S be a rational relation over $A^* \times A^*$. An* index *of a rational relation R in the composition closure of S, denoted as Index(R, S), is the smallest integer k such that R is contained in $S^{\leq (k)}$.*

▶ **Example 3.16.** Consider a relation S over $\{a, b\}^* \times \{a, b\}^*$ that deletes the first a if exists on any input. Fix an integer $k > 0$ and let R be the relation that deletes the first k a's from the input if exists. The index of R in $S^{(*)}$ is k since for any input word $u \in A^*$, $R(u) \in S^{\leq (k)}(u)$.

Table 4 Problems about the index of a rational relation in the composition closure of another.

Problem	Input	Question
Index Problem	rational relation R, S	Index(R, S)?
Bounded (or Finite) Index Problem	rational relation R, S	Is Index$(R, S) < \infty$?
k-Bounded Index Problem	integer k, rational relation R, S	Is Index$(R, S) \leq k$?

Consider another relation R' that deletes all a's from the input. Since $R'(a^{k+1}) \notin S^{\leq(k)}(a^{k+1})$ for any $k > 0$, the index of R' in $S^{(*)}$ is ∞.

As seen in the case of the distance and diameter problem, we can ask questions in Table 4 about the index of a rational relation in the composition closure of a relation. We say a rational relation R has *bounded (resp. k-bounded)* index in the composition closure of a rational relation S if the index of R in $S^{(*)}$ is finite (*resp.* $\leq k$).

Deciding the boundedness of the index problem for an arbitrary rational relation is difficult.

▶ **Lemma 3.17.** *It is undecidable to check if a rational relation has a bounded index in the composition closure of an arbitrary rational relation.*

However, we show that the index problem is decidable w.r.t. a large class of rational relations defined below.

▶ **Definition 3.18** (Metrizable Relation)**.** *Let S be a rational relation over $A^* \times A^*$. Let $d_S : A^* \times A^* \to \mathbb{N} \cup \{\infty\}$ be the distance between two vertices in the graph of S, i.e., for any two words u and v, $d_S(u, v)$ is the smallest i such that $v \in S^{(i)}(u)$, and ∞ otherwise.*

We say S is a d-metrizable relation *for a metric d if $d_S \approx d$.*

▶ **Proposition 3.19.** *Let R be a rational relation and S be a d-metrizable relation for an integer-valued metric d for which $d_{len} \lesssim d$. If boundedness of diameter w.r.t. d is decidable for a rational relation, then Index(R, S) is computable.*

Proof. Similar to distance problem, the index problem is computable iff bounded index and k-bounded index problems are decidable. For a rational relation R and d-metrizable relation S, we show that Index$(R, S) < \infty$ iff $dia_d(R) < \infty$ as follows.

$$
\begin{aligned}
dia_d(R) < \infty &\iff \exists k \in \mathbb{N} \text{ s.t. } \forall (u, v) \in R, d(u, v) \leq k \\
&\iff \exists k' \in \mathbb{N} \text{ s.t. } \forall (u, v) \in R, d_S(u, v) \leq k' && \text{(Since } d_S \approx d\text{)} \\
&\iff \forall (u, v) \in R, v \in S^{\leq(k')}(u) && \text{(Definition of } d_S\text{)} \\
&\iff \text{Index}(R, S) < \infty
\end{aligned}
$$

Therefore, if the boundedness of diameter w.r.t. d is decidable for a rational relation, then we can decide if Index$(R, S) < \infty$. If so, then it suffices to decide if Index$(R, S) \leq k$ for $k = 0, 1, \ldots$ and output the smallest k as the index of R in the composition closure of S.

Since $dia_d(R) < \infty$ and $d_{len} \lesssim d$, the rational relation R has a bounded delay. Similarly, S also has a bounded delay since for all $(u, v) \in S$, $d_S(u, v) = 1 \Rightarrow \exists k \in \mathbb{N}$ s.t. $d(u, v) \leq k$ (since $d_S \approx d$) $\Rightarrow \exists k' \in \mathbb{N}$ s.t. $d_{len}(u, v) \leq k'$ (since $d_{len} \lesssim d$). Since S has bounded delay, for any $k \in \mathbb{N}$, $S^{(k)}$ also has bounded delay. It is known that emptinesss and set difference of two rational relations with bounded delay is decidable (Corollary 2 of [20]). For any $k \in \mathbb{N}$, deciding Index$(R, S) \leq k$ reduces to checking if $R \subseteq S^{\leq(k)}$ (or equivalently, $R \setminus S^{\leq(k)} = \emptyset$), and hence decidable. ◀

A close and (almost) dual notion is that of a metric that defines a rational relation.

▶ **Definition 3.20** (Rationalizable Distance). *A distance d on words is* rationalizable *if the relation $S_d = \{(u, v) \mid d(u, v) = 1\}$, called the* distance relation *of d, is rational.*

▶ **Example 3.21.** Consider the hamming distance d_h. We can construct a rational relation $S_h = \{(u, v) \mid u \text{ and } v \text{ differ only in exactly one position}\}$. For example, let $A = \{a, b\}$ and $S_h(aba) = \{bba, aaa, abb\}$. For this, construct a transducer that nondeterministically chooses a position and replaces the input letter with other letters in the alphabet. Similarly, the distance relation of the length metric $S_{len} = \{(u, v) \mid ||u| - |v|| = 1\}$ is also rational.

In fact, we have the following result about the rationalizability of edit distances referred in Table 1.

▶ **Proposition 3.22.** *Every edit distance $d \in \{d_l, d_h, d_t, d_c, d_{lcs}, d_{dl}\}$ is rationalizable.*

3.4 Reductions between Distance, Diameter and Index Problems

We show that the distance problem of two rational functions is mutually reducible to the diameter problem of a rational relation, which in turn is mutually reducible to the index problem of a rational relation in the composition closure of a metrizable relation. Thus, their closeness and boundedness problems are also interreducible.

The correspondence between distance and diameter follows from Nivat's theorem:

▶ **Theorem 3.23** ([32]). *Let A and B be alphabets. The following conditions are equivalent.*

1. *R is a rational relation over $A^* \times B^*$.*
2. *There exist an alphabet C, two alphabetic morphisms $\phi : C^* \to A^*$ and $\psi : C^* \to B^*$ and a regular language $L \subset C^*$ such that $R = \{(\phi(w), \psi(w)) \mid w \in L\}$*

From Proposition 3.9 and (2) ⇒ (1) in the above theorem, it follows that distance of two rational functions reduces to the diameter of a rational relation. Now, given a rational relation R, we can create two functional transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ in the following way. The domain for these transducers corresponds to the set L in Theorem 3.23. For each transition in $\mathcal{T}_1$ and $\mathcal{T}_2$ that involves an input alphabet symbol σ, we set the outputs to be $\phi(\sigma)$ and $\psi(\sigma)$ in Theorem 3.23, respectively. Consequently, $\mathcal{T}_1$ and $\mathcal{T}_2$ consist of the sets $\{\phi(w) \mid w \in L\}$ and $\{\psi(w) \mid w \in L\}$ respectively. Since the domain of these transducers is identical, the distance between $\mathcal{T}_1$ and $\mathcal{T}_2$ with respect to any distance d, $d(\mathcal{T}_1, \mathcal{T}_2) = \sup\{\, d(\phi(w), \psi(w)) \mid w \in L \,\}$, that is equivalent to the diameter of R w.r.t. the distance d.

The correspondence between diameter and index for rationalizable distances is stated in the following proposition.

▶ **Proposition 3.24.** *The diameter of a rational relation R w.r.t. a rationalizable distance d is equal to the index of the rational relation R in the composition closure of the distance relation of d.*

Proof. Assume that the diameter of a relation R w.r.t. a distance d is ∞. We claim that the index of R in $S_d^{(*)}$ is also ∞ where S_d is the distance relation of d. Suppose not, i.e., let $k < \infty$ be the index of R in $S_d^{(*)}$. Thus, $\forall (u, v) \in R$, $v \in S_d^{\leq (k)}(u)$. Since S_d is the distance relation of d, $\forall (u, v) \in R$, $d(u, v) \leq k$. However, this contradicts the fact that $dia_d(R) = \infty$. Hence, the index of R in $S_d^{(*)}$ is infinite. Similarly, we can prove the other direction. Now, suppose the diameter of R w.r.t. d is finite, i.e.,

$$\begin{aligned}
\text{diameter of } R \text{ w.r.t. } d \text{ is } k < \infty &\iff \forall (u, v) \in R, d(u, v) \leq k \\
&\iff \forall (u, v) \in R, v \in S_d^{\leq (k)}(u) \\
&\iff \text{index of } R \text{ in } S_d^{(*)} \text{ is } k.
\end{aligned}$$

◀

3.5 Decidability Results

We study the problems stated in Tables 2, 3 and 4 and show that they are decidable for the metrics in Table 1. The index problems stated in Table 4 are undecidable in general (see Lemma 3.17), but is decidable for d-metrizable relations for metrics d given in Table 1.

Recall that, w.r.t. a metric d, distance problem is computable if and only if both closeness and k-closeness are decidable (see Proposition 3.6). We have shown that the k-closeness is decidable for all the metrics in Table 2 (Corollary 3.12). Hence to show the decidability of all the problems in Table 2, it suffices to show the decidability of the closeness problem. Furthermore, thanks to the inter-reductions described above (see § 3.4), the decidability of Table 3 follows as well as the decidability for the problems in Table 4 for the rationalizable distance. Moreover, the index of a rational relation in the composition closure of a d-metrizable relation for a metric d given in Table 2 is computable by Proposition 3.19.

It only remains to prove that closeness is decidable for edit distances in Table 1. This is stated below, and proved in the following section.

▶ **Theorem 3.25.** *Let d be any metric from Table 1, and $\mathcal{T}$ and $\mathcal{S}$ be any functional transducers. It is decidable if $\mathcal{T}$ and $\mathcal{S}$ are close w.r.t. d.*

4 Closeness for Edit Distances

In this section, we show that closeness is decidable for all the edit distances in Table 1. The first step is to check if the domain of the transducers are the same. This reduces to checking the equivalence of the underlying automata. For sequential transducers, the underlying automaton is a DFA, while for unambiguous transducers, the underlying automaton is an unambiguous NFA. Checking the equivalence of two unambiguous automata can be done in polynomial time [39], while it is PSPACE in the case of ambiguous automata [40]. Therefore, from now on, we assume that the domains of the transducers given as input to the closeness problem are identical.

Proposition 3.9 allows us to state the distance and closeness problems more abstractly in terms of an automaton over pairs of words. The proposition asserts that distance and closeness problems of two given sequential or unambiguous transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ can be reduced to the corresponding problem for a DFA $\mathcal{A}$ with two sets of output functions λ_1, o_1 and λ_2, o_2. We can combine the output functions to output a pair of words. That is to say, let $\lambda : \Delta \to B^* \times B^*$ be defined as $\lambda(\delta) = (\lambda_1(\delta), \lambda_2(\delta))$, where $\delta \in \Delta$ and Δ is the set of transitions of $\mathcal{A}$. Similarly let $o(p) = (o_1(p), o_2(p))$, where $p \in F$ and F is the set of accepting states of $\mathcal{A}$. Henceforth, we can assume that we are given a DFA $\mathcal{A}$ with the output functions λ and o, denoted as the sequential transducer $\mathcal{T}$. Since the input words are inconsequential for computing the distance, we can convert the transducer $\mathcal{T}$ to an automaton $\mathcal{A}$ that accepts a set of pairs of output words over $B^* \times B^*$, i.e., $L(\mathcal{A}) = \{(u, v) \in B^* \times B^* \mid (u, v) = \mathcal{T}(w), w \in dom(\mathcal{T})\}$. Clearly, transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ are close w.r.t. d if and only if there exist an integer $k \geq 0$ such that $\forall (u, v) \in L(\mathcal{A})$, $d(u, v) \leq k$.

Conjugacy of words plays an important role in closeness problems. A pair of words (u, v) is *conjugate* if there exist words x and y (possibly empty) such that $u = xy$ and $v = yx$ or equivalently, u and v are cyclic shifts of one another. For example, $(aaab, aaba)$ is a conjugate pair where $x = a$ and $y = aab$. Conjugacy relation is an equivalence relation on the set of words. A set of pairs is *conjugate* if each pair in the set is conjugate.

▶ **Lemma 4.1.** *Let $\mathcal{T}_1$ and $\mathcal{T}_2$ be two sequential transducers that define a function from A^* to B^*. If $\mathcal{T}_1$ and $\mathcal{T}_2$ are close w.r.t. a metric $d \in \{d_l, d_h, d_t, d_c, d_{lcs}, d_{dl}\}$, then every loop in the trim automaton over $B^* \times B^*$, that accepts set of all pairs of output words of $\mathcal{T}_1$ and $\mathcal{T}_2$ on any input, generates only conjugate pair of words.*

Proof. This proof is adaptation of a related result in [3]. Let $\mathcal{A}$ be a trim automaton that realises the pair of output words of transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ on any input. Since $\mathcal{T}_1$ and $\mathcal{T}_2$ are close w.r.t. d, there exist an integer $k \geq 0$ such that $\forall (u, v) \in L(\mathcal{A})$, $d(u, v) \leq k$. Let (u, v) be a pair labelled in a loop rooted at some state q. Hence (u^ℓ, v^ℓ) for each $\ell \geq 0$ is also a pair in a loop rooted at q. We can safely assume that $|u| = |v|$, otherwise the edit distance will be unbounded as each iteration will increase the edit distance by a difference in length of u and v (Item 1 of Lemma 2.1).

Since $\mathcal{A}$ is trimmed, there exists a path from an initial state q_0 to q and from q to a final state q_f. Let (α_0, β_0) be a pair labelled in a path from q_0 to q, and let (α_1, β_1) be a pair labelled in a path from q to q_f. Thus, pair $(\alpha_0, \beta_0)(u^\ell, v^\ell)(\alpha_1, \beta_1)$ belongs to $L(\mathcal{A})$ where $\ell = 2^k$ (some value much larger than k). Since ℓ is much larger than k and $d(\alpha_0 u^\ell \alpha_1, \beta_0 v^\ell \beta_1) \leq k$, there exist large portions of u's and v's that match. Therefore, we can infer that u is a factor of vv, and v is a factor of uu.

Since v is an infix of uu, the following holds. There exist words x, y, p and q such that $v = xy$ and $u = px = yq$. Since $|u| = |v|$, length of p and length of y are the same, that implies $p = y$ (since $u = px = yq$). Therefore, $u = yx$. Hence u and v are conjugate words. Since the pair (u, v) was arbitrary, any pair generated by a loop in $\mathcal{A}$ is conjugate. ◀

4.1 Closeness w.r.t. Levenshtein distances and Conjugacy

In this subsection, we decide closeness w.r.t. Levenshtein family of distances – Levenshtein, Damerau-Levenshtein, and LCS distances – and conjugacy distance. Levenshtein family of distances are all equivalent with respect to closeness problems by Lemma 2.1 and Remark 3.8.

We have already seen that given two unambiguous transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ with identical domains, there exists an automaton $\mathcal{A}$ over $B^* \times B^*$ that accepts a set of all pairs of output words of $\mathcal{T}_1$ and $\mathcal{T}_2$ on any input. Thus, we can state the distance and closeness problems in terms of rational expressions over $B^* \times B^*$.

We define *pairs over the alphabet* B to be the set $B^* \times B^*$ with the pointwise concatenation $(u, v) \cdot (u', v') = (u \cdot u', v \cdot v')$. A *rational expression of pairs* over the alphabet B is a rational expression over the alphabet $\{(b, b') \mid b, b' \in (B \cup \{\epsilon\})\}$ that generates a subset of pairs over B. From the automaton $\mathcal{A}$ over $B^* \times B^*$, using state elimination method ([26], Lecture 9), we can construct the rational expression of pairs E for the output pairs generated by the transducer $\mathcal{T}_1$ and $\mathcal{T}_2$ on any input. We can lift the metric d to expressions by letting $d(E) = \sup\{d(u, v) \mid (u, v) \in L(E)\}$. Clearly $d(E) = d(\mathcal{T}_1, \mathcal{T}_2)$. Thus, the distance and closeness problems of sequential and unambiguous transducers reduce to the corresponding problems for a rational expression of pairs. Henceforth we assume that we are given a rational expression of pairs.

In the context of conjugacy distance, the closeness of a rational expression necessarily implies that every pair in the expression is conjugate. Otherwise, if there exists a pair $(u, v) \in L(E)$ such that u is not conjugate to v, then $d_c(u, v) = \infty$, thus $d_c(E) = \infty$. In fact, this is also a sufficient condition. The proof relies on the results from [3] that studies the conjugacy of rational expression over pairs of words. It crucially uses the notion of a *common witness* of a set of pairs.

▶ **Definition 4.2** (Common Witness of a Set of Pairs). *A* witness *of pair of conjugate words* (u, v) *is a word* z *such that either* $uz = zv$ *(called an* inner witness*) or* $zu = vz$ *(called an* outer witness*). A* common witness *of a set of pairs is a word* z *such that either* z *is an inner witness of every pair in the set, or* z *is an outer witness of every pair in the set.*

Lyndon and Schützenberger gave a characterisation of conjugacy of a pair of words, stated as a pair of words is conjugate if and only if it has both inner and outer witness (Proposition 1.3.4 of [30]). In [3], it is generalised to a set of pairs as follows.

▶ **Theorem 4.3** ([3]). *Let $M = (\alpha_0, \beta_0)G_1^*(\alpha_1, \beta_1)\cdots G_k^*(\alpha_k, \beta_k)$ be a set of pairs where $G_1, \ldots, G_k$, $k > 0$ are arbitrary sets of pairs of words, and $(\alpha_0, \beta_0), \ldots, (\alpha_k, \beta_k)$ are arbitrary pairs of words. The set M is conjugate iff M has a common witness.*

Existence of a common witness bounds the conjugacy distance of an expression as follows.

▷ Claim 4.4. If a rational expression over pairs E has a common witness z, then $d_c(E) \leq |z|$.

Proof. Since E has a common witness, either $\forall(u, v) \in L(E)$, $uz = zv$, or $\forall(u, v) \in L(E)$, $zu = vz$. WLOG, assume that $\forall(u, v) \in L(E)$, $uz = zv$. Now, for any pair $(u, v) \in L(E)$:

1. If $|u| > |z|$, then z is a prefix of u and suffix of v and hence $(u, v) = (zp, pz)$ for some word $p \in A^*$. Therefore $d_c(u, v) \leq |z|$ since v can be obtained by $|z|$ left cyclic shifts of u.
2. Otherwise, when $|u| \leq |z|$, the number of cyclic shifts required to transform u to v (note that u and v are conjugate since they have a witness) is less than $|u| \leq |z|$. ◁

A rational expression is *sumfree* if it does not use sum (i.e., $+$). In [3], it is shown that if a common witness exists, it is computable for a sumfree rational expression over pairs of words. It is folklore that every rational expression is equivalent to a sum of sumfree expressions [3]. The proposition below implies that to show closeness for a sum of sumfree expressions, it suffices to show closeness for each of its constituent sumfree expressions.

▶ **Proposition 4.5.** *Let $E = E_1 + \cdots + E_k, k \geq 1$ be a rational expression of pairs. Then $d(E) = \max(d(E_1), \ldots, d(E_k))$ for all word metrics d.*

An expression is conjugate if every pair generated by the expression is conjugate. The following proposition characterises closeness w.r.t. conjugacy distance.

▶ **Proposition 4.6.** *A rational expression over pairs of words is close w.r.t. conjugacy distance if and only if the expression is conjugate. Furthermore, the closeness w.r.t. conjugacy distance is decidable.*

Proof. One direction is trivial. Assume E to be an arbitrary rational expression of pairs and is conjugate. Let $E = E_1 + E_2 + \cdots + E_k$ where $E_1, E_2, \ldots, E_k$ are sumfree expressions. Since E is conjugate, each of its sumfree constituents E_i for $1 \leq i \leq k$ is also conjugate. Using Theorem 4.3, each E_i has a common witness, say z_i. From Claim 4.4, $d_c(E_i) \leq z_i$. Therefore, $d_c(E)$ is close w.r.t. conjugacy distance by Proposition 4.5. Hence, to decide closeness of E w.r.t. conjugacy distance, it suffices to check if E is conjugate. This reduces to checking if a common witness exists for each sumfree constituent. It is shown to be decidable in [3]. ◀

Now consider the case of Levenshtein distances. From Lemma 4.1, if an expression is close w.r.t. Levenshtein distances, it is necessary that every pair generated by a Kleene star in the expression needs to be conjugate. Using common witness, we show that it is also a sufficient condition.

▷ Claim 4.7. If a rational expression of pairs E has a common witness z, then $d_l(E) \leq 2|z|$.

Proof. The proof is similar to Claim 4.4. Since E has a common witness, either $\forall(u, v) \in L(E)$, $uz = zv$, or $\forall(u, v) \in L(E)$, $zu = vz$. WLOG, assume that $\forall(u, v) \in L(E)$, $uz = zv$. For any pair $(u, v) \in L(E)$, $|u| = |v|$ since $uz = zv$. There are two cases, either $|u| > |z|$ or $|u| \leq |z|$. If $|u| > |z|$, then z is a prefix of u and suffix of v and hence $(u, v) = (zp, pz)$ for some word p. Therefore, $d_l(E) \leq 2|z|$ by deleting z in the beginning and insert z at the end of u. Suppose $|u| \leq |z|$, the number of edits required to transform u to v is less than $|u| + |v| \leq 2|u| \leq 2|z|$. ◁

▶ **Proposition 4.8.** *Closeness of a rational expression w.r.t. Levenshtein distance is decidable.*

Proof. Given an arbitrary rational expression, there is an equivalent sum of sumfree expression. From Proposition 4.5, to show closeness for a sum of sumfree expressions, it suffices to show closeness for each of its constituent sumfree expressions. The general form of a sumfree expression $E = (\alpha_0, \beta_0)E_1^*(\alpha_1, \beta_1) \cdots E_k^*(\alpha_k, \beta_k)$ where $k \in \mathbb{N}$, for $0 \leq j \leq k$, (α_j, β_j) is a (possibly empty) pair of words, and for each $1 \leq i \leq k$, E_i is a sumfree expression.

▷ Claim 4.9. A sumfree expression $E = (\alpha_0, \beta_0)E_1^*(\alpha_1, \beta_1) \cdots E_k^*(\alpha_k, \beta_k)$ is close w.r.t. Levenshtein distance if and only if each E_i^* for $1 \leq i \leq k$ is conjugate.

Proof. From Lemma 4.1, if E is close w.r.t. Levenshtein edit distance then each E_i^* is conjugate. For the other direction, if each E_i^* is conjugate, then each E_i^* has a common witness, say z_i, by Theorem 4.3. From Claim 4.7, $d_l(E_i^*) \leq 2|z_i|$. Further, $d_l(E) \leq \sum_{j\in\{0\ldots k\}} d_l(\alpha_j, \beta_j) + \sum_{i\in\{1\ldots k\}} d_l(E_i^*) = \sum_{j\in\{0\ldots k\}} d_l(\alpha_j, \beta_j) + 2\sum_{i\in\{1\ldots k\}} z_i$, hence finite. This implies that if each E_i^* in E is conjugate, then $d_l(E)$ is finite. ◁

Therefore, checking the closeness of a rational expression w.r.t. Levenshtein distances reduces to checking the existence of a common witness of each Kleene star in its sumfree constituents, and thus decidable. ◀

For a sumfree rational expression, a witness, if exists, can be computed in polynomial time [3], and thus closeness w.r.t. Levenshtein and conjugacy distances are decidable in polynomial time. However, converting a rational expression to a sum of sumfree rational expressions can cause an exponential blow-up both in the number of summands and the size of each summand [3].

4.2 Closeness w.r.t. Hamming and Transposition distances

▶ **Theorem 4.10.** *Closeness w.r.t. Hamming and Transposition distance are decidable for functional transducers.*

Given two functional transducers, check if their domains are the same. If not, the distance is ∞ hence they are not close. Assume they have an identical domain. By Proposition 3.9, it suffices to consider two sequential transducers with a common underlying DFA. Let $\mathcal{T}_1 = \langle \mathcal{A}, \lambda_1, o_1 \rangle$ and $\mathcal{T}_2 = \langle \mathcal{A}, \lambda_2, o_2 \rangle$ be two sequential transducers. WLOG, we make the following assumptions.

1. (Property $\star$) Automaton $\mathcal{A}$ is trimmed, i.e., all states are accessible (reachable from the initial state) and coaccessible (from each state there is a path to some final state).
2. (Property ‡) $\mathcal{T}_1$ and $\mathcal{T}_2$ produce output words of identical length; otherwise the Hamming as well as transposition distance will be ∞. We can check this property: rename all the output letters in $\mathcal{T}_1$ and $\mathcal{T}_2$ to a and check their equivalence.
3. The delay between partial outputs of $\mathcal{T}_1$ and $\mathcal{T}_2$ is at most $k \in \mathbb{N}$ (By Proposition 3.7).

Let Q and $F \subseteq Q$ be the set of states and final states of $\mathcal{A}$ respectively, and let $q_0 \in Q$ be the initial state. For states $p, q \in Q$, Let $M_{p,q}$ be the set of pairs (u, v) such that there is a run ρ from p to q and $u = \lambda_1(\rho)$ and $v = \lambda_2(\rho)$. Extending this notation, for a state $q_f \in F$, let M'_{q,q_f} be the set of pairs (u, v) such that $u = u' \cdot o_1(q_f), v = v' \cdot o_2(q_f)$ and $(u', v') \in M_{q,q_f}$.

Let q be a state of the automaton. If (α, β) and (α', β') are two pairs in $M_{q_0,q}$, then $|\alpha| - |\beta| = |\alpha'| - |\beta'|$, or else one of the pairs in $\{(\alpha\alpha'', \beta\beta''), (\alpha'\alpha'', \beta'\beta'')\}$ will have different lengths, where (α'', β'') is some pair in M_{q,q_f}, for some $q_f \in F$, guaranteed by Property $(\star)$.

Therefore with each state q, we can associate the delay of a run reaching it, called the *delay at* q, denoted by ∂_q, as $|\alpha| - |\beta|$. Clearly $\partial_q \leq k$. By a symmetric argument, if (α, β) and (α', β') are two pairs in M_{q,q_f}, where q_f is some final state, then $|\alpha| - |\beta| = |\alpha'| - |\beta'| = -\partial_q$. This also implies that for all $(u, v) \in M_{q,q}$, $|u| = |v|$.

For each state q, either $M_{q,q} = \{(\epsilon, \epsilon)\}$, or $M_{q,q}$ is infinite. Let q be a state for which $M_{q,q}$ is nonempty. For a delay $\partial \in \mathbb{Z}$, a pair $(u, v) \in M_{q,q}$ where $n = |u| > \partial$, we define the interior of the pair (u, v) as

$$\mathit{interior}_\partial(u, v) = \begin{cases} (u[1 \dots n - \partial], v[\partial + 1 \dots n]) & \text{if } \partial \geq 0 \\ (u[\partial + 1 \dots n], v[1 \dots n - \partial]) & \text{if } \partial < 0 \end{cases}$$

For example, $\mathit{interior}_1(abc, def) = (ab, ef)$ and $\mathit{interior}_{-1}(abc, def) = (bc, de)$. We also define the *Left-Border* and *Right-Border* of the pair (u, v) as

$$\mathit{lborder}_\partial(u, v) = \begin{cases} v[1 \dots \partial] & \text{if } \partial \geq 0 \\ u[1 \dots \partial] & \text{if } \partial < 0 \end{cases} \qquad \mathit{rborder}_\partial(u, v) = \begin{cases} u[n - \partial + 1 \dots n] & \text{if } \partial \geq 0 \\ v[n - \partial + 1 \dots n] & \text{if } \partial < 0 \end{cases}$$

▷ Claim 4.11. Hamming distance between $\mathcal{T}_1$ and $\mathcal{T}_2$ is unbounded if and only if there exists a state $q \in Q$ and $(u, v) \in M_{q,q}$ such that $|u| = |v| > \partial_q$, and $u' \neq v'$ where $(u', v') = \mathit{interior}_{\partial_q}(u, v)$.

Proof. The Figure 3 depicts the situation described by (2).

($\leftarrow$): Assume there exists a state $q \in Q$ and $(u, v) \in M_{q,q}$ such that $|u| = |v| > \partial_q$, and $u' \neq v'$ where $(u', v') = \mathit{interior}_{\partial_q}(u, v)$. Let $(\alpha_0, \beta_0) \in M_{q_0,q}$ and $(\alpha_1, \beta_1) \in M_{q,q_f}$. Consider the pair $(u_i = \alpha_0 u^i \alpha_1, v_i = \beta_0 v^i \beta_1)$, $i \geq 1$ (shown in Figure 4). Since $u' \neq v'$, we can deduce that $d_h(u_i, v_i) \geq i$. Hence $d_h(\mathcal{T}_1, \mathcal{T}_2) = \infty$.

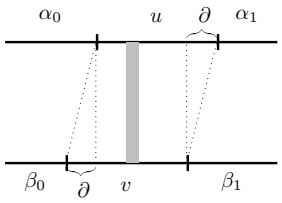

Figure 3 An edit in the interior of u and v.

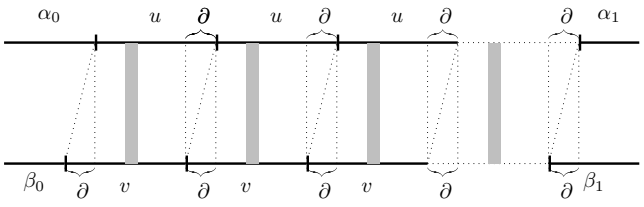

Figure 4 Words that require an arbitrarily large number of edits.

($\rightarrow$): Assume $d_h(\mathcal{T}_1, \mathcal{T}_2) = \infty$. Assume $\mathcal{A}$ has n states and the maximum length of an output produced on any transition or at the end-of-input is ℓ. Choose a run ρ of $\mathcal{A}$ such that the distance between the outputs produced on $\rho = \delta_1 \cdots \delta_m$, $m > 0$ is at least $((k+2)n+1)\ell$. We can associate each edit in $\lambda_1(\rho)$ with the transition δ_i such that the edit happens in

$\lambda_1(\delta_i)$. Since there are $((k+2)n+1)\ell$ edits, there are at least $(k+2)n+1$ transitions in ρ whose output words are edited. Associate each transition with its source state. By pigeonhole principle, there is a state q such that $\rho = \rho_1 \cdot \rho_2 \cdot \rho_3$ where

1. ρ_1 is a run from the initial state q_0 to q,
2. ρ_2 is a run from q to itself,
3. ρ_3 is a run from q to a final state q_f, and
4. there are at least $(k+1)$ edits in the factor $\lambda_1(\rho_2)$.

Let $u = \lambda_1(\rho_2)$ and $v = \lambda_2(\rho_2)$. Clearly $|u| = |v|$ and $|u| \geq (k+1)$. Since the edits in u are at least $k+1$, there is a position on which the pair $\mathit{interior}_{\partial_q}(u,v)$ differ. ◁

Next we show closeness w.r.t. transposition distance. We write $u \equiv v$ to denote that words u and v are permutations of each other. The *alphabetic vector* of a word over the alphabet A, denoted by $\vec{u}$, is the sequence $(|w|_{a_i})_{a_i \in A}$ for some fixed ordering of A. It is easy to observe that two words are permutations of each other if their alphabetic vectors are the same.

▷ Claim 4.12. Transposition distance between $\mathcal{T}_1$ and $\mathcal{T}_2$ is unbounded if and only if one of the following holds

1. There is a pair $(u,v) \in M'_{q_0,q_f}$, $q_f \in F$ such that $u \not\equiv v$.
2. There exists a state $q \in Q$ and $(u,v) \in M_{q,q}$ such that $|u| = |v| > \partial_q$, and $u' \neq v'$ where $(u',v') = \mathit{interior}_{\partial_q}(u,v)$.
3. There exists a state $q \in Q$ such that $M_{q,q}$ is infinite, and for each pair $(u,v) \in M_{q,q}$ of length at least $|\partial_q|$, $\mathit{interior}_{\partial}(u,v)$ is identical. Further, there are pairs $(u,v) \in M_{q,q}$ and $(\alpha,\beta) \in M_{q_0,q}$ (*resp.* M_{q,q_f}) such that: If $\partial_q \geq 0$, then $\alpha \not\equiv \beta \cdot \mathit{lborder}(u,v)$ (*resp.* $\mathit{rborder}(u,v) \cdot \alpha \not\equiv \beta$), and if $\partial_q < 0$, then $\alpha \cdot \mathit{lborder}(u,v) \not\equiv \beta$ (*resp.* $\alpha \not\equiv \mathit{rborder}(u,v) \cdot \beta$).

Proof. ($\leftarrow$): It is obvious that if Item 1 is true, then the transposition distance between $\mathcal{T}_1$ and $\mathcal{T}_2$ is unbounded. Therefore we assume that the output pairs of the transducers are permutations of each other. For Item 2, the proof is the same as in Claim 4.11. Next we consider Item 3. The cases are symmetric. Assume that there exist a pair $(u,v) \in M_{q,q}$, $(\alpha,\beta) \in M_{q_0,q}$, and WLOG $\partial_q \geq 0$ such that $\alpha \not\equiv \beta \cdot \mathit{lborder}(u,v)$. Let (α',β') be some pair in M_{q,q_f}. Consider the pair $(u_i = \alpha u^i \alpha', v_i = \beta v^i \beta')$, $i \geq 1$.

Let $(x,x) = \mathit{interior}_{\partial_q}(u,v)$, $z_1 = \mathit{lborder}(u,v)$, $z_2 = \mathit{rborder}(u,v)$. By assumption $\alpha \not\equiv \beta z_1$, and hence $z_2\alpha' \not\equiv \beta'$. Since interior of (u,v) is (x,x), we can deduce that $\alpha z_2 \alpha' \equiv \beta z_1 \beta'$. Therefore $\vec{\alpha} - \beta\vec{z_1} = z_2\vec{\alpha'} - \vec{\beta'}$. This means that the transpositions have to cancel out the differences in the vectors at each end of the word. We can prove by induction that it requires at least $|x|$ transpositions to mitigate a difference of 1, while keeping the alphabetic vector of the middle portion the same. Hence we deduce that $d_t(u_i,v_i) \geq i$.

($\rightarrow$): If $d_t(\mathcal{T}_1,\mathcal{T}_2) \in \infty$, either there is a pair of outputs (u,v) such that $d_t(u,v) = \infty$ (This is Item 1), or all the output pairs are permutations of each other and there is an infinite set of pairs $S = \{(u_i,v_i) \mid i > 0\}$ such that $d_t(u_i,v_i) \geq i$.

In the latter case, we show that either Item 2 or Item 3 holds. We say the set S is *error-bounded* if there is an $r > 0$ such that u_i and v_i differ in at most r positions. Clearly, there are sets with bounded errors on which d_t is infinite. We do case analysis.

If there is an infinite set of pairs $S = \{(u_i,v_i) \mid i > 0\}$ such that $d_t(u_i,v_i) \geq i$ that is *not* error-bounded, we proceed as in the proof of Claim 4.11 and obtain Item 2 by pigeonhole principle.

If the set of all output pairs is error-bounded, then clearly for states q such that $M_{q,q}$ is infinite, the interior of all the sufficiently large pairs in $M_{q,q}$ are identical. Moreover since the output pairs are permutations of each other there is a state q such that $|M_{q,q}| = \infty$ and there is a partial run from q_0 to q (or a partial run from q to q_f) whose output words are not permutations of each other. ◁

Claim 4.11 and Claim 4.12 can be verified for $\mathcal{T}_1$ and $\mathcal{T}_2$ in polynomial time. Thus, closeness of sequential and unambiguous transducers w.r.t. hamming and transposition distance is decidable in polynomial time.

5 Discussion and Conclusion

It is shown that distance between two rational functions w.r.t. common edit distances is computable. The related notions of diameter of a rational relation, and the index of a rational relation in the composition closure of another are also computable. We leave open the question of finding the precise computational complexity of the problems in Tables 2, 3 and 4.

The current decision procedure for closeness w.r.t. conjugacy and Levenshtein family of distances proceeds through the analysis of rational expressions. One could directly work on automata, but it is not enough to check for the conjugacy of simple cycles, as there can be complex strongly connected components. In such cases, a decidability proof for conjugacy can be achieved by utilizing Simon's factorization forests [38] and checking the conjugacy of the factorization trees inductively. Sumfree expressions are doing this in essence, circumventing the need to construct the transition monoids.

Lifting these notions to infinite words, and two-way transducers is an immediate next step. Distance between one-way transducers could be seen as the diameter of a rational relation obtained by the cartesian product. However, when the transducers $\mathcal{T}, \mathcal{S}$ are two-way or polyregular, the relation $\{(\mathcal{T}(w), \mathcal{S}(w)) \mid w \in dom(\mathcal{T})\}$ need not be rational. It remains to develop techniques for checking the conjugacy of non-rational relations.

An interesting question is: given two functional transducers $\mathcal{T}_1$ and $\mathcal{T}_2$ with bounded distance, does there exist a transducer $\mathcal{T}$ such that $\mathcal{T}_2$ is equivalent to a cascading composition of $\mathcal{T}_1$ and $\mathcal{T}$? This is often called the *repair problem* and is well-studied between two regular languages [7].

Abstract

The ω-regular separability problem for Büchi VASS coverability languages has recently been shown to be decidable, but with an EXPSPACE lower and a non-primitive recursive upper bound – the exact complexity remained open. We close this gap and show that the problem is EXPSPACE-complete. A careful analysis of our complexity bounds additionally yields a PSPACE procedure in the case of fixed dimension ≥ 1, which matches a pre-established lower bound of PSPACE for one dimensional Büchi VASS. Our algorithm is a non-deterministic search for a witness whose size, as we show, can be suitably bounded. Part of the procedure is to decide the existence of runs in VASS that satisfy certain non-linear properties. Therefore, a key technical ingredient is to analyze a class of systems of inequalities where one variable may occur in non-linear (polynomial) expressions.

These so-called singly non-linear systems (SNLS) take the form $\boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x)$, where $\boldsymbol{A}(x)$ and $\boldsymbol{b}(x)$ are a matrix resp. a vector whose entries are polynomials in x, and $\boldsymbol{y}$ ranges over vectors in the rationals. Our main contribution on SNLS is an exponential upper bound on the size of rational solutions to singly non-linear systems. The proof consists of three steps. First, we give a tailor-made quantifier elimination to characterize all real solutions to x. Second, using the root separation theorem about the distance of real roots of polynomials, we show that if a rational solution exists, then there is one with at most polynomially many bits. Third, we insert the solution for x into the SNLS, making it linear and allowing us to invoke standard solution bounds from convex geometry.

Finally, we combine the results about SNLS with several techniques from the area of VASS to devise an EXPSPACE decision procedure for ω-regular separability of Büchi VASS.

1 Introduction

Vector addition systems with states (VASS) are one of the most popular and well-studied models of concurrent systems. A d-dimensional VASS consists of finitely many control states and d counters. Transitions between control states can increment or decrement the d counters, but importantly, one can only take a transition if the new counter values remain non-negative.

Separability problems. In recent years, a strong focus of the research on VASS was on *separability problems* [2, 5, 6, 8–11, 15–17, 31]. Here, we label the transitions of the input VASS $\mathcal{V}_1$, $\mathcal{V}_2$ by letters, which gives rise to languages L_1 and L_2. Then, we ask whether there exists a language S, from some class $\mathcal{S}$ of allowed separators, such that $L_1 \subseteq S$ and $L_2 \cap S = \emptyset$. Here, $\mathcal{S}$ is typically the class of regular languages.

An important motivation for studying separability problems is that separators can be viewed as certificates for disjointness, and thus the non-existence of a run in the product of $\mathcal{V}_1$ and $\mathcal{V}_2$. Such certificates are crucial for understanding safety verification for infinite-state systems, where the difficult part is to prove the non-existence of a run (the existence of a run is usually easy to show). In particular, certificates for non-existence are often the ingredient that is conceptually hardest to come by. For example, in the case of reachability in VASS, the KLM decomposition [18, 19, 22, 26] and Leroux's Presburger-definable inductive invariants [21] can be viewed as such certificates. Regular separators could play a similar role in alternative approaches to reachability.

In addition to understanding certificates, the recent attention on separability has led to other applications. For example, work on separability by bounded languages has led to a general framework to address unboundedness problems for VASS [8]. Moreover, separability results were used in an algorithm for deciding inclusion between unambiguous VASS [7].

With the recent contribution by Keskin and Meyer [16] (together with earlier decidability results for subclasses and variants [2, 5, 6, 8–11]), proving regular separability decidable for (finite-word) VASS, the *decidability* status of regular separability has largely been settled. However, concerning *complexity*, regular separability is far from understood, with few results: So far, the only exact complexity results are PSPACE-completeness for (succintly represented) one-dimensional VASS [9], EXPSPACE-completeness for VASS coverability languages [10], and Ackermann-completeness for VASS reachability languages [16].

Büchi VASS. A particularly challenging problem is (ω-)regular separability in Büchi VASS [2]. In a Büchi VASS $\mathcal{V}$, the language $L(\mathcal{V})$ consists of *infinite words* induced by runs that visit some final state infinitely often. As demonstrated by Baumann, Meyer, and Zetzsche [2], Büchi VASS behave quite differently in terms of regular separability from their finite-word counterpart, coverability languages of VASS [10]. Nevertheless, Baumann, Meyer, and Zetzsche proved decidability of regular separability for Büchi VASS [2]. However, the complexity remained open: Their algorithm requires at least Ackermannian time (because it constructs Karp-Miller graphs), and the only known lower bound is EXPSPACE.

Challenge: Non-linear constraints. Improving the complexity established in [2] is challenging due to the characterization of inseparability there: Inseparability is equivalent to the existence of a constellation of runs, called an *inseparability flower*, that must satisfy a *non-linear constraint*, meaning a constraint that is not expressible in linear arithmetic (i.e. first-order logic of $(\mathbb{Z}; +, <, 0, 1)$ or $(\mathbb{Q}; +, <, 0, 1)$). Essentially, such a flower is a triple

(α, β, γ) of cyclic runs such that (among other linear inequalities) the counter effect of the combined run $\alpha\beta\gamma$ is a scalar multiple of the counter effect of just α. In other words, we are looking for runs with effects $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{Z}^n$ such that

$$\exists x \in \mathbb{Q}\colon \boldsymbol{v} = x \cdot \boldsymbol{u} \ . \tag{1}$$

Detecting runs with such constraints is difficult: There are powerful generic EXPSPACE algorithms for detecting runs that satisfy unboundedness conditions [12], linear constraints [1], or variants of computation tree logic (CTL) [4]. However, condition (1) falls in neither of those categories.

In fact, we are not aware of any algorithmic approach to solving systems of linear inequalities with constraints of type (1) (let alone inside algorithms for VASS). There is a result by Gurari & Ibarra [13] showing that integral feasibility of systems of equalities $\boldsymbol{A} \cdot \boldsymbol{y} = \boldsymbol{b}(x)$ can be decided in NP, where $\boldsymbol{b}(x)$ is a vector containing in each component a quotient of polynomials in x. However, these do not seem to capture (1): By moving the denominators from $\boldsymbol{b}(x)$ to the left-hand side, one obtains equations where every variable from $\boldsymbol{y}$ is multiplied with the same polynomial over x. However, for (1), we need to multiply a *subset* of the linear variables (namely, those in $\boldsymbol{u}$) with a polynomial (namely, x). The same is true for the logic of *almost linear arithmetic* due to Weispfenning [32], whose existential fragment is also solvable in NP. Here, the definable sets are finite unions of solution sets of Gurari & Ibarra.

Furthermore, it is not even clear how to detect inseparability flowers by invoking reachability in VASS (even though this would only yield an Ackermann upper bound): To some extent, algorithms for reachability permit non-linear constraints – for example, using standard tricks, it is decidable whether one can reach a configuration with counter values (m, n) such that $n \leq 2^m$. However, the condition in (1) does not even seem to be captured by such methods.

Contribution. Our main result is that regular separability in Büchi VASS is EXPSPACE-complete, and PSPACE-complete in fixed dimension ≥ 1. The key technical ingredient is a method that we expect to be of independent interest: We develop a procedure for solving systems of linear inequalities with a single non-linear variable, which we call *singly non-linear systems of inequalities* (SNLS). We use our results about SNLS to show that if an inseparability witness exists, then there is one where all runs have at most doubly exponential length, yielding an EXPSPACE procedure. In fixed dimension, we obtain singly exponential bounds, leading to a PSPACE procedure.

Step I: Singly non-linear systems of inequalities. Intuitively, a singly non-linear system of inequalities (SNLS) is a system of inequalities that is linear in all but one variable. This means, there is one variable x that may appear in arbitrary polynomials, but all others can only occur linearly. More precisely, an SNLS is a system of inequalities of the form

$$\boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x), \quad \boldsymbol{y} \geq \boldsymbol{0} \ , \tag{2}$$

where $\boldsymbol{A}(x) \in \mathbb{Z}[x]^{m \times n}$ is an $m \times n$ matrix over the ring $\mathbb{Z}[x]$ of integer polynomials in x, $\boldsymbol{b}(x) \in \mathbb{Z}[x]^m$ is a vector of polynomials from $\mathbb{Z}[x]$, and $\boldsymbol{y}$ ranges over $\mathbb{Q}^n$. Notice that here indeed, x can be freely multiplied with itself and other variables, whereas the expression on the left-hand side must be linear in each component of $\boldsymbol{y}$.

Our main result about SNLS is that if a system as in (2) has a solution $(x, \boldsymbol{y}) \in \mathbb{Q} \times \mathbb{Q}^n$, then it has a solution where all numbers (numerators and denominators) are bounded exponentially in the description size of $\boldsymbol{A}(x)$ and $\boldsymbol{b}(x)$, even if numbers in the description are encoded in binary. This implies in particular that feasibility of SNLS is in NP.

In the proof, we first show that the set of all $x \in \mathbb{Q}$ for which there is a solution $(x, \boldsymbol{y})$ can be described by a Boolean combination Φ of polynomial constraints of the form $p(x) \geq 0$, for polynomials $p \in \mathbb{Z}[x]$. This amounts to a quantifier elimination procedure for a class of first-order formulas in the ordered field $(\mathbb{Q}; +, \cdot, <, 0, 1)$. This is perhaps surprising, since this structure does not admit quantifier elimination in general [24, Theorem 2].

Let us give a geometric explanation how we arrive at the constraints $\Phi(x)$: For each choice of x, the SNLS $\boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x),\ \boldsymbol{y} \geq \boldsymbol{0}$ defines a polyhedron. It is a standard fact in convex geometry that such a polyhedron has a point on a minimal face, and moreover this point can be expressed as the inverse of a submatrix of $\boldsymbol{A}(x)$ multiplied with $\boldsymbol{b}(x)$. This expression can then be plugged back into $\boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x)$ to obtain a set of polynomial constraints on x, subject to a particular determinant being non-zero. The latter non-zero condition can as well be expressed as a polynomial constraint.

We then show that Φ has a small solution: In one case, a rational root of one of the polynomials p is a solution – these can be bounded by the *Rational Root Theorem*. The other case is that the solution x lies strictly between two roots $r_1 < r_2$ of participating polynomials. But then one can observe that any rational number between those roots is a solution (if no other root lies between r_1 and r_2). Using the *Root Separation Theorem* (specifically, Rump's Bound [27]), which lower-bounds the size of such intervals (r_1, r_2), we can then conclude that such an interval must contain a rational number with small numerator and denominator.

Once we exhibit a small x, we can plug it into $\boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x)$ to obtain a system of linear inequalities. Then we use standard bounds to obtain a small (i.e. exponential) solution $\boldsymbol{y} \in \mathbb{Q}^n$. It should be noted that while our result about SNLS concerns rational solutions, we apply it in the case where $\boldsymbol{b}(x) \geq \boldsymbol{0}$, which means a rational solution can be turned into an integral solution by multiplying a common denominator.

Step II: Rackoff-like bounds. After establishing the solution bound for SNLS, we use this result in the context of Büchi VASS to show the existence of inseparability witnesses that are small, i.e. consist of runs that are at most doubly exponential in length. Here, we use an adaptation of the Rackoff technique [28] similar to the proofs of Habermehl [14] and Atig & Habermehl [1]. In [1], it is shown that runs satisfying (restricted) linear inequalities can be detected in EXPSPACE. For this, they use a Rackoff-style induction to bound the length of such runs. We devise a similar Rackoff-style induction to work with SNLS instead of ordinary linear inequalities. Different compared to the earlier works is the fact that our witnesses contain ω-counters, which may change when invoking the induction hypothesis. Moreover, we need to use a result of Demri on selective unboundedness [12, Theorem 4.6] (in EXPSPACE in the general case and PSPACE in fixed dimension) to check the coverability of our witnesses.

2 Preliminaries

Büchi VASS. A *Büchi vector addition system with states (Büchi VASS)* of dimension $d \in \mathbb{N}$ over an alphabet Σ is a tuple $\mathcal{V} = (Q, q_0, \Sigma, T, F)$. It consists of a finite set of states Q, an initial state $q_0 \in Q$, a set of final states $F \subseteq Q$, and a finite set of transitions $T \subseteq Q \times \Sigma^* \times \mathbb{Z}^d \times Q$. The size of the Büchi VASS is $|\mathcal{V}| := |Q| + |F| + \sum_{(q,w,\delta,q') \in T} \big(|w| + \|\delta\|_2\big)$. By $\|\delta\|_2$, we mean the size of the binary encoding of δ. Since we only consider Büchi VASS in this paper, we often simply call them VASS. If $d = 0$, we call $\mathcal{V}$ a *Büchi automaton*.

The semantics of the Büchi VASS is defined over its *configurations*, which are elements of $Q \times \mathbb{N}^d$. The *initial configuration* of $\mathcal{V}$ is $(q_0, \boldsymbol{0})$. We lift the transitions of the Büchi VASS to a relation over configurations $\to \subseteq Q \times \mathbb{N}^d \times \Sigma^* \times Q \times \mathbb{N}^d$ as follows: $(q, \boldsymbol{m}) \xrightarrow{w} (q', \boldsymbol{m}')$ if there is $(q, w, \delta, q') \in T$ such that $\boldsymbol{m}' = \boldsymbol{m} + \delta$. A *run* of the Büchi VASS is a (possibly infinite) sequence of configurations of the form $\sigma = (p_0, \boldsymbol{m}_0) \xrightarrow{w_1} (p_1, \boldsymbol{m}_1) \xrightarrow{w_2} \cdots$.

A run σ is *accepting* if it starts from the initial configuration and visits final states infinitely often, meaning there are infinitely many configurations $(q, \boldsymbol{m})$ in σ with $q \in F$. The run is said to be *labeled* by the word $w = w_0 w_1 \cdots$ in Σ^ω. The *language* $L(\mathcal{V})$ of the Büchi VASS consists of all infinite words that label an accepting run.

An infinite-word language $L \subseteq \Sigma^\omega$ is called *regular* if it is accepted by a Büchi automaton. As we only consider infinite-word languages, we just call them languages.

Arithmetic. Our approach to regular separability in Büchi VASS rests on a result about solutions to singly non-linear systems of inequalities. This also requires some terminology.

We define the integers, rationals, polynomials, and matrices together with the operations we need to perform on them. Let $a \in \mathbb{Z}$ be an integer. Its size $\|a\|_2 = |bin(a)|$ is the length of its binary encoding. We also use $\|a\|_1$ to denote the size of the unary encoding. This is the absolute value plus an extra bit for the sign. A polynomial with integer coefficients $p \in \mathbb{Z}[x]$ is a sum $\sum_{i=0}^{k} a_i x^i$ with $a_0, \ldots, a_k \in \mathbb{Z}$ and $a_k \neq 0$ if $k > 0$. We define $\|p\|_1 = \sum_{i=0}^{k} \|a_i\|_1$ and similar for $\|p\|_2$. The *degree* of the polynomial is $\deg(p) = k$, its *maximal coefficient* is $\mathrm{maxc}(p) = \max_{i \in [0,k]} \|a_i\|_1$. Note that $\|p\|_1 \leq (\deg(p) + 1) \cdot \mathrm{maxc}(p)$. A real number $r \in \mathbb{R}$ with $p(r) = 0$ is called a *root* of the polynomial. Let S be a set with a size function $\| - \|$ defined on it. We consider matrices $\boldsymbol{A} \in S^{m \times n}$ over S, and define their size $\|\boldsymbol{A}\|$ by summing up the sizes of the entries. We use $row(\boldsymbol{A}) = m$ and $col(\boldsymbol{A}) = n$. When $S = \mathbb{Z}[x]$, we also use $\deg(\boldsymbol{A})$ for the highest degree of a polynomial in $\boldsymbol{A}$ and $\mathrm{maxc}(\boldsymbol{A})$ for the maximal coefficient of a polynomial in $\boldsymbol{A}$. Pairs $(s_1, s_2) \in S \times S$ form a special case with size $\|(s_1, s_2)\| = \|s_1\| + \|s_2\|$. In particular, a rational number $t \in \mathbb{Q}$ is a pair $t = \frac{a}{b}$ of integers $a, b \in \mathbb{Z}$ with $\|t\|_1 = \|a\|_1 + \|b\|_1$, and similar for $\|t\|_2$.

We perform addition $a + b$ and multiplication $a \cdot b$ among integers, rationals, polynomials, and matrices. These operations can be executed in time polynomial in $\|a\|_2 + \|b\|_2$. The same holds for the comparison $a \geq b$ among integers and rationals. We also add, multiply, and compare integers and rationals with $-\infty$ and ∞. The definitions are as expected.

3 Main results

A language $R \subseteq \Sigma^\omega$ is said to *separate* languages $L_1, L_2 \subseteq \Sigma^\omega$, if $L_1 \subseteq R$ and $R \cap L_2 = \emptyset$. We call L_1 and L_2 *regular separable*, denoted by $L_1 \mid L_2$, if there is a separator R that is a regular language. The problem we address is the *regular separability problem* for Büchi VASS:

Given Two VASS $\mathcal{V}_1$ and $\mathcal{V}_2$ over some alphabet Σ.

Question Does $L(\mathcal{V}_1) \mid L(\mathcal{V}_2)$ hold?

We also consider the variants of this problem where the inputs are of fixed dimension: For a fixed number $d \in \mathbb{N} \setminus \{0\}$, the *$d$-dimensional regular separability problem* for Büchi VASS is the same problem as above, except that the input VASS $\mathcal{V}_1$ and $\mathcal{V}_2$ are restricted to be of dimension at most d. Our first main result is the following:

▶ **Theorem 3.1.** *The regular separability problem for Büchi VASS is* EXPSPACE*-complete. Moreover, the d-dimensional regular separability problem is* PSPACE*-complete for all $d \geq 1$.*

As mentioned above, the proof is based on a small model property for what we call singly non-linear systems of inequalities. We expect this result to be of independent interest. Formally, a *singly non-linear system (SNLS)* is a system of inequalities of the form

$$\boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x) \wedge \boldsymbol{y} \geq \boldsymbol{0} \ .$$

Here, $\boldsymbol{A}(x) \in \mathbb{Z}[x]^{m \times n}$ is an $m \times n$ matrix over the set of polynomials with integer coefficients in variable x, and $\boldsymbol{b} \in \mathbb{Z}[x]^m$ is a vector of polynomials. We also write an SNLS as $\mathcal{S} = (\boldsymbol{A}(x), \boldsymbol{b}(x))$, or $\mathcal{S}(x, \boldsymbol{y})$ to emphasize the variables. A *solution* to $\mathcal{S}$ is a pair $(t, \boldsymbol{s}) \in \mathbb{Q} \times \mathbb{Q}^n$ that satisfies $\boldsymbol{A}(t) \cdot \boldsymbol{s} \geq \boldsymbol{b}(t) \wedge \boldsymbol{s} \geq \boldsymbol{0}$. If a solution exists, we call the system *feasible*.

Our second main result is a bound on the size of least solutions.

▶ **Theorem 3.2.** *If the SNLS $\mathcal{S}$ is feasible, then it has a solution $(t, \boldsymbol{s})$, where all components of $\boldsymbol{s}$ have the same denominator, with $\|t\|_1, \|\boldsymbol{s}\|_1 \in (col(\mathcal{S}) \cdot \deg(\mathcal{S}) \cdot \mathrm{maxc}(\mathcal{S}))^{\mathcal{O}(\deg(\mathcal{S})^2 \cdot row(\mathcal{S})^4)}$.*

Theorem 3.2 implies that a feasible system $\mathcal{S}$ always has a solution of size at most singly exponential in $\|\mathcal{S}\|_1$. This gives an upper bound on the complexity of feasibility.

▶ **Corollary 3.3.** *Feasibility of SNLS is in* NP.

The reader may have noted that SNLS are more general than the non-linear systems we are confronted with when checking separability. There are at least two arguments in support of the generalization. First, non-linearity is not well-understood, and we believe a class of systems that admits an efficient algorithm for checking feasibility will find its applications. Second, the generalization only adds little complexity to the proof or, phrased differently, the special case already needs most considerations.

Organization. The remainder of the paper is organized as follows. In Section 4, we prove Theorem 3.2 and in Section 5, we show Theorem 3.1.

4 Singly Non-Linear Systems

In this section, we prove Theorem 3.2.

Some notation. By $\boldsymbol{A}(t)$ or $eval(\boldsymbol{A}(x), t)$ we mean the matrix with rational entries that results from $\boldsymbol{A}(x)$ by evaluating all polynomials at t. Let $\boldsymbol{A} \in R^{n \times n}$ be a square matrix over some ring R. In our exposition, we will consider matrices over the rings $\mathbb{Z}$, $\mathbb{Q}$, and $\mathbb{Z}[x]$. We write $\det(\boldsymbol{A})$ for the determinant, and recall that if R is a field (such as $\mathbb{Q}$), then $\boldsymbol{A}$ is invertible if and only if $\det(\boldsymbol{A}) \neq 0$. The *adjugate* (also called *classical adjoint*) of $\boldsymbol{A}$ is the matrix $\mathrm{adj}(\boldsymbol{A}) \in R^{n \times n}$ with $\mathrm{adj}(\boldsymbol{A})[j, i] = (-1)^{i+j} \det(\boldsymbol{A}_{ij})$, where $\boldsymbol{A}_{ij}$ is the matrix obtained from $\boldsymbol{A}$ by removing the i-th row and the j-th column. It is well-known that then $\boldsymbol{A} \cdot \mathrm{adj}(\boldsymbol{A}) = \det(\boldsymbol{A}) \cdot \boldsymbol{I}$, where $\boldsymbol{I}$ is the identity matrix in dimension n. In particular, if $\boldsymbol{A}$ is invertible, its inverse can be computed as $\boldsymbol{A}^{-1} = \frac{\mathrm{adj}(\boldsymbol{A})}{\det(\boldsymbol{A})}$ [20, Chapter XIII, Prop. 4.16].

In upper bound arguments, we will use the well-known Leibniz formula for determinants, which says $\det(\boldsymbol{A}) = \sum_{\sigma \in S_n} \mathrm{sgn}(\sigma) \cdot \prod_{i=1}^{n} \boldsymbol{A}[i, \sigma(i)]$ [20, Chapter XIII, Prop. 4.6]. Here, S_n is the set of all permutations of $[1, n]$ and $\mathrm{sgn}(\sigma) \in \{-1, 1\}$ is the sign of $\sigma \in S_n$.

Bounding solutions. For the proof of Theorem 3.2, we proceed in two steps. We first show that if an SNLS $\mathcal{S}(x, \boldsymbol{y})$ is feasible, then we find a small rational t for x such that the system $\mathcal{S}(t, \boldsymbol{y})$ is feasible. This system is the result of evaluating all polynomials in $\mathcal{S}$ at t, and thus having only $\boldsymbol{y}$ as the variables.

▶ **Lemma 4.1.** *If the SNLS $\mathcal{S}(x, \boldsymbol{y})$ is feasible, then there is a number $t \in \mathbb{Q}$ with $\|t\|_1 \in (col(\mathcal{S}) \cdot \deg(\mathcal{S}) \cdot \mathrm{maxc}(\mathcal{S}))^{\mathcal{O}(\deg(\mathcal{S}) \cdot row(\mathcal{S})^3)}$ such that $\mathcal{S}(t, \boldsymbol{y})$ is feasible.*

Lemma 4.1 is non-trivial and will occupy almost this entire section. To explain our approach, note that the feasibility of $\mathcal{S}(x, \boldsymbol{y})$ is equivalent to the feasibility of $\exists \boldsymbol{y}.\mathcal{S}(x, \boldsymbol{y})$. Our first step is to eliminate the quantifier and determine a new formula $\Phi(x)$ in which $\boldsymbol{y}$ no longer occurs and that is equivalent to the previous one over the rationals, $\exists \boldsymbol{y}.\mathcal{S}(x, \boldsymbol{y}) \models|_{\mathbb{Q}} \Phi(x)$. The equivalence says that for every $t \in \mathbb{Q}$, we have $t \models \exists \boldsymbol{y}.\mathcal{S}(x, \boldsymbol{y})$ if and only if $t \models \Phi(x)$.

The second step for Lemma 4.1 is to show that if the new formula holds, then we find a small solution for t. To this end, we will apply the Root Separation Theorem, which provides a lower bound on the distance between distinct real roots of polynomials. After establishing Lemma 4.1, we obtain Theorem 3.2 (at the end of this section) by taking the t provided by Lemma 4.1, and pair it with the $\boldsymbol{s} \in \mathbb{Q}^n$, which must exist according to the quantifier elimination done in the first step of Lemma 4.1.

4.1 Quantifier Elimination

We show how to remove the quantifier from $\exists \boldsymbol{y}.\mathcal{S}(x, \boldsymbol{y})$ with a tailor-made quantifier elimination algorithm. The fact that quantifier elimination is possible in this setting came as a surprise to us, given the non-linear nature and the setting of rationals. For example, the real closed field $(\mathbb{R}; +, \cdot, <, 0, 1)$ admits quantifier elimination by a classical result of Tarski [25, Theorem 3.3.15], but this is not true for the ordered field $(\mathbb{Q}; +, \cdot, <, 0, 1)$ of rationals [24, Theorem 2] (see [25, p. 71–72] for a simple example). This means, there are first-order formulas over $(\mathbb{Q}; +, \cdot, <, 0, 1)$ that have no quantifier-free equivalent. However, we show that if we existentially quantify the linear variables in the formulas induced by SNLS, then those quantifiers can be eliminated.

The precise formulation of the result needs some notation. A *lower bound constraint* has the form $p(x) \geq 0$ or $p(x) > 0$ with $p \in \mathbb{Z}[x]$ a polynomial with integer coefficients. The formula $\Phi(x)$ that we want to obtain takes the form $\bigvee_{i \in I} \bigwedge_{j \in J_i} \Phi_{i,j}(x)$, where the formulae $\Phi_{i,j}(x)$ are lower bound constraints. We call it a DNFLB, short for *disjunctive normal form with lower bound constraints as the literals*. We may also omit x and write Φ. We use $\deg(\Phi)$ and $\operatorname{maxc}(\Phi)$ for the maximal degree resp. coefficient of a polynomial in Φ.

▶ **Theorem 4.2.** *For every SNLS $\mathcal{S}(x, \boldsymbol{y})$, there is a DNFLB $\Phi(x)$ with $\exists \boldsymbol{y}.\mathcal{S}(x, \boldsymbol{y}) \models|_{\mathbb{Q}} \Phi(x)$, $\deg(\Phi) \in \mathcal{O}(row(\mathcal{S}) \cdot \deg(\mathcal{S}))$, and $\operatorname{maxc}(\Phi) \in (col(\mathcal{S}) \cdot \deg(\mathcal{S}) \cdot \operatorname{maxc}(\mathcal{S}))^{\mathcal{O}(row(\mathcal{S})^2)}$.*

Since our intention is to bound the solutions t to variable x, the given estimations on the degree and the maximal coefficient suffice for us. The proof actually gives an algorithm to compute Φ which runs in time exponential in the dimension of $\mathcal{S}$, but we do not need the effectiveness here. In the proof of Theorem 4.2, we will use a standard fact about polyhedra:

▶ **Lemma 4.3.** *Suppose $\boldsymbol{D} \in \mathbb{Q}^{m \times n}$ and $\boldsymbol{c} \in \mathbb{Q}^m$. If the system $\boldsymbol{D} \cdot \boldsymbol{x} \geq \boldsymbol{c}$ has a solution in $\mathbb{Q}^n$, then there is a solution $\boldsymbol{s} \in \mathbb{Q}^n$ that also satisfies $\boldsymbol{D}' \cdot \boldsymbol{s} = \boldsymbol{c}'$, where $(\boldsymbol{D}', \boldsymbol{c}')$ is a subset of the rows of $(\boldsymbol{D}, \boldsymbol{c})$ such that $\operatorname{rank}(\boldsymbol{D}') = \operatorname{rank}(\boldsymbol{D})$.*

Proof. By well-known decomposition theorems about polyhedra, a polyhedron $P = \{\boldsymbol{s} \in \mathbb{Q}^n \mid \boldsymbol{D} \cdot \boldsymbol{s} \geq \boldsymbol{c}\}$ is non-empty if and only if it has a non-empty minimal face [30, Theorem 8.5]. Moreover, minimal faces can be characterized as exactly the sets of the form $\{\boldsymbol{s} \in \mathbb{Q}^n \mid \boldsymbol{D}' \cdot \boldsymbol{s} = \boldsymbol{c}'\}$, where $(\boldsymbol{D}', \boldsymbol{c}')$ is a subset of the rows of $(\boldsymbol{D}, \boldsymbol{c})$ such that $\boldsymbol{D}'$ has the same rank as $\boldsymbol{D}$ [30, Theorem 8.4]. ◀

We are ready to prove Theorem 4.2:

Proof of Theorem 4.2. Let $\mathcal{S}(x, \boldsymbol{y}) = \boldsymbol{A}(x) \cdot \boldsymbol{y} \geq \boldsymbol{b}(x) \wedge \boldsymbol{y} \geq \boldsymbol{0}$. To fix the dimension, let $\boldsymbol{A} \in \mathbb{Z}[x]^{m \times n}$. We can equivalently write the SNLS as $\mathcal{S}'(x, \boldsymbol{y}) = \boldsymbol{D}(x) \cdot \boldsymbol{y} \geq \boldsymbol{c}(x)$ with

$$\boldsymbol{D}(x) \;=\; \begin{pmatrix} \boldsymbol{A}(x) \\ \boldsymbol{I}_n \end{pmatrix} \in \mathbb{Z}[x]^{(m+n)\times n} \qquad \boldsymbol{c}(x) \;=\; \begin{pmatrix} \boldsymbol{b}(x) \\ \boldsymbol{0}_n \end{pmatrix} \in \mathbb{Z}[x]^{m+n} \;,$$

i.e. we glue the $n \times n$ identity matrix $\boldsymbol{I}_n$ to the bottom of $\boldsymbol{A}(x)$ and extend $\boldsymbol{b}(x)$ by n zeros.

Assume $\mathcal{S}'$ is feasible and the solution for x is $t \in \mathbb{Q}$. By Lemma 4.3 and since $\boldsymbol{D}(t)$ has rank n, we can select a subset of n rows of $\boldsymbol{D}(t)$ and of $\boldsymbol{c}(t)$ such that the smaller system has a solution, even with equality. More formally, for any subset $R \subseteq [1, m+n]$, denote by $\boldsymbol{D}_R(t)$ (resp. $\boldsymbol{c}_R(t)$) the matrix (resp. vector) obtained by selecting only the rows in R from $\boldsymbol{D}(t)$ (resp. $\boldsymbol{c}(t)$). Then Lemma 4.3 tells us that there is an $\boldsymbol{s} \in \mathbb{Q}^n$ with $\boldsymbol{D}_R(t) \cdot \boldsymbol{s} = \boldsymbol{c}_R(t)$, where $\boldsymbol{D}_R(t)$ has rank n. In particular, $\boldsymbol{D}_R(t)$ is invertible and thus $\det(\boldsymbol{D}_R(t)) \neq 0$. The fact that $\boldsymbol{D}_R(t)$ is invertible allows us to write $\boldsymbol{s} = \boldsymbol{D}_R(t)^{-1} \cdot \boldsymbol{c}_R(t)$, which will be key for our quantifier elimination. The argumentation shows that for every $t \in \mathbb{Q}$, $\exists \boldsymbol{y}.\mathcal{S}'(t, \boldsymbol{y})$ is equivalent to the condition

$$\bigvee_{\substack{R \subseteq [1, m+n] \\ |R| = n}} \det(\boldsymbol{D}_R(t)) \neq 0 \;\wedge\; \boldsymbol{D}(t) \cdot \boldsymbol{D}_R(t)^{-1} \cdot \boldsymbol{c}_R(t) \geq \boldsymbol{c}(t) \;. \tag{3}$$

Here, of course, we only know that $\boldsymbol{D}_R(t)^{-1}$ exists when $\det(\boldsymbol{D}_R(t)) \neq 0$. To express (3) using polynomials, we employ the identity $\boldsymbol{D}_R(t)^{-1} = \frac{\operatorname{adj}(\boldsymbol{D}_R(t))}{\det(\boldsymbol{D}_R(t))}$ whenever $\boldsymbol{D}_R(t)$ is invertible (equivalently, whenever $\det(\boldsymbol{D}_R(t)) \neq 0$). Thus, the set of all t with $\exists \boldsymbol{y}\colon \mathcal{S}'(t, \boldsymbol{y})$ can be defined by the following DNFLB Φ:

$$\begin{aligned} \bigvee_{\substack{R \subseteq [1, m+n] \\ |R| = n}} & \Big(\det(\boldsymbol{D}_R(x)) > 0 \;\wedge\; \boldsymbol{D}(x) \cdot \operatorname{adj}(\boldsymbol{D}_R(x)) \cdot \boldsymbol{c}_R(x) \geq \det(\boldsymbol{D}_R(x)) \cdot \boldsymbol{c}(x) \Big) \\ & \vee \Big(\det(\boldsymbol{D}_R(x)) < 0 \;\wedge\; \boldsymbol{D}(x) \cdot \operatorname{adj}(\boldsymbol{D}_R(x)) \cdot \boldsymbol{c}_R(x) \leq \det(\boldsymbol{D}_R(x)) \cdot \boldsymbol{c}(x) \Big) \;, \end{aligned} \tag{4}$$

where indeed all conditions are of the form $p(x) \geq 0$ or $p(x) > 0$ for some polynomials p. Note that here, we distinguish the cases $\det(\boldsymbol{D}_R(x)) < 0$ and $\det(\boldsymbol{D}_R(x)) > 0$ because moving a negative $\det(\boldsymbol{D}_R(x))$ to the other side of the inequality changes $\geq$ to $\leq$. Moreover, note that (in contrast to (3)) in the formulation (4), all terms are well-defined, independenly of whether the current choice of R makes $\boldsymbol{D}_R(x)$ invertible or not. To be precise, we obtain the DNFLB by subtracting the right-hand sides of the inequalities from the left-hand sides and multiplying the result by -1 to invert the inequality where necessary. The above form will suffice to give an estimate on the maximal degree and the maximal coefficient.

It is now clear that the coefficients (resp. degrees) appearing in Φ are exponential (resp. polynomial) in the bitsize of $\mathcal{S}$. The precise bounds promised in the Theorem are straightforward to deduce from standard bounds on determinants, see the full version for details. ◀

4.2 Root Separation

To show Lemma 4.1, it remains to be shown that any feasible DNFLB $\Phi(x)$ has a solution that is exponentially bounded. The key observation is that if r and r' are adjacent roots of a polynomial $p(x) \in \mathbb{Z}[x]$ and a constraint $p(x) \geq 0$ or $p(x) > 0$ is satisfied for some t for x with $r < t < r'$, then any number t' in the open interval (r, r') will also satisfy the constraint: The polynomial does not change its sign between r and r'. Thus, we can think of $\mathbb{R}$ as being split into (i) roots of p and (ii) intervals between roots of p (and the infinite intervals below

the smallest and above the largest root). Then whether $t \in \mathbb{Q}$ satisfies $p(x) \geq 0$ or $p(x) > 0$ only depends on which of those parts of $\mathbb{R}$ the number t belongs to. This remains true if we refine this decomposition of $\mathbb{R}$ according to *all* polynomials occurring in Φ.

In order to construct rational numbers with small numerator and denominator in intervals (r, r'), we will rely on a Root Separation Theorem, saying that polynomial roots are not too close. More specifically, we use Rump's Bound [27, Theorem 8.5.5]:

▶ **Theorem 4.4** (Rump's Bound [27, Theorem 8.5.5]). *Suppose $r, r' \in \mathbb{R}$ are distinct roots of a polynomial $p(x) \in \mathbb{Z}[x]$ with degree $d \in \mathbb{N}$. Then $|r - r'| > (d^{d+1}(1 + \|p(x)\|_1)^{2d})^{-1}$.*

We will also use an elementary fact about rational roots of integral polynomials. It is known as the Rational Root Theorem or Integral Root Test [20, Chapter IV, Prop. 3.3]:

▶ **Lemma 4.5** (Rational Root Theorem [20, Chapter IV, Prop. 3.3]). *Let $p(x) = c_n x^n + \cdots + c_0 \in \mathbb{Z}[x]$ be a polynomial. If $r = a/b$ is a root of p with a, b co-prime, then a divides c_0 and b divides c_n. In particular, $|a|, |b| \leq \mathrm{maxc}(p)$.*

Finally, we need a standard bound on all real roots of a polynomial [27, Corollary 8.3.2]. This is known as Cauchy's bound.

▶ **Lemma 4.6** (Cauchy's Bound [27, Corollary 8.3.2]). *If $r \in \mathbb{R}$ is a root of a polynomial $p \in \mathbb{Z}[x]$, then $|r| \leq 1 + \|p\|_1$.*

Let $r_1 < \cdots < r_k \in \mathbb{R}$ be all the real roots of polynomials occurring in Φ. Observe that if $t \in \mathbb{Q}$ satisfies $\Phi(x)$ and $t \in (r_i, r_{i+1})$, then any rational number in (r_i, r_{i+1}) must satisfy $\Phi(x)$, because none of the polynomials in Φ changes its sign between r_i and r_{i+1}. This allows us to bound a rational solution, by distinguishing the following cases:

1. Suppose $\Phi(x)$ is satisfied by some rational root r_i of p in Φ. Write $r_i = \frac{a}{b}$ with a, b co-prime. Then the Rational Root Theorem (Lemma 4.5) implies $|a|, |b| \leq \mathrm{maxc}(p)$.
2. Suppose $\Phi(x)$ has a rational solution in some interval (r_i, r_{i+1}). Since r_i and r_{i+1} are the roots of some polynomials p, q in $\Phi(x)$, as observed above, any rational number in (r_i, r_{i+1}) is also a solution to $\Phi(x)$. Note that r_i, r_{i+1} are roots of $p(x) \cdot q(x)$ and thus by Theorem 4.4, we have $|r_i - r_{i+1}| > \frac{1}{b}$ for some $b \in \mathbb{Z}$ that is exponentially bounded. Thus, there is an integer $a \in (br_i, br_{i+1})$. Note that then $\frac{a}{b}$ belongs to the interval (r_i, r_{i+1}) and thus satisfies $\Phi(x)$. Moreover, by the Cauchy Bound (Lemma 4.6), we also have an exponential bound $U \in \mathbb{R}$ on $|r_i|, |r_{i+1}|$ and thus on $|a| \leq |b|U$.
3. Suppose $\Phi(x)$ has a rational solution t outside of $[r_1, r_k]$. If $t > r_k$ then every rational number in $[r_k, \infty)$ is also a solution. Moreover, by Lemma 4.6, any rational number t' with $t' > 1 + \|p\|_1$ for every polynomial p occurring in Φ can be chosen, e.g. $t' = 2 + c$, where $c = \max\{\|p\|_1 \mid p \text{ polynomial in } \Phi\}$. On the other hand, if $t < r_1$, then $t' = -(2 + c)$ is a solution by an analogous argument.

This proves that any feasible $\Phi(x)$ has a rational solution that is exponentially bounded, which is what we will use in our application to Büchi VASS. The precise bounds of Lemma 4.1 are shown in the full version.

Proof sketch for Theorem 3.2. For showing Theorem 3.2, we can now use the fact that if $t \in \mathbb{Q}$ admits a solution $(t, \boldsymbol{s})$, then by our argument in the proof of Theorem 4.2, $\boldsymbol{s}^* := \frac{\mathrm{adj}(D_R(t))}{\det(D_R(t))} \cdot \boldsymbol{c}_R(t)$ is also a solution, for some subset $R \subseteq [1, m+n]$. This means that we can apply the bound on t and the bounds on $\mathrm{adj}(\boldsymbol{D}_R(x))$ and $\det(\boldsymbol{D}_R(x))$ established in the proof of Theorem 4.2 to bound the solution $\boldsymbol{s}^*$. We can ensure that all components of $\boldsymbol{c}_R(t)$ have the same denominator by increasing the bit size at most $\deg(\mathcal{S})$-fold. If we compute $\boldsymbol{s}^*$ starting from such a vector, we get an $\boldsymbol{s}^*$ where all components have the same denominator.

Since the entries in $\boldsymbol{D}_R$ all appear in $\mathcal{S}$ and it is well-known that the determinant has polynomial bit size in the bit size of a matrix, it follows that there exists a solution $(t, \boldsymbol{s})$ of polynomial bit size. The precise bounds promised in Theorem 3.2 are derived in the full version.

5 ω-Regular Separability

We use the results from Section 4 to prove Theorem 3.1. Note that the lower bounds in Theorem 3.1 easily follow from [2]. First, that paper already shows PSPACE-completeness of regular separability for one-dimensional Büchi VASS, which yields the PSPACE lower bound for fixed dimension ≥ 1. In fact, their argument also yields EXPSPACE-hardness in the general case: The full version [3, Appendix E.1] describes a simple reduction from intersection emptiness of one-dimensional VASS that accept by final state to regular separability of Büchi VASS, and the construction is the same in higher dimension. This yields EXPSPACE-hardness of regular separability of Büchi VASS, since intersection emptiness of VASS of arbitrary dimension that accept by final state is EXPSPACE-hard [23].

It remains to prove the upper bounds in Theorem 3.1. To adequately formulate our proofs, we need to introduce additional VASS-related concepts.

More on Büchi VASS. Let $\mathcal{V} = (Q, q_0, \Sigma, T, F)$ be a Büchi VASS. Consider a (possibly infinite) run $\sigma = (p_0, \boldsymbol{m}_0) \xrightarrow{w_1} (p_1, \boldsymbol{m}_1) \xrightarrow{w_2} \cdots$ of $\mathcal{V}$. The sequence of transitions in σ is called a *path* and has the form $\rho = (p_0, w_1, \delta_1, p_1)(p_1, w_2, \delta_1, p_2)\ldots$. If a path is finite and the source state of its first transition coincides with the target state of its last transition, then we call it a *loop*. Since a run is uniquely determined by the start configuration and its sequence of transitions, we also denote a run by $\sigma = (p_0, \boldsymbol{m}_0).\rho$. If σ is finite and $(p_\ell, \boldsymbol{m}_\ell)$ is its last configuration, then we sometimes write $\sigma = (p_0, \boldsymbol{m}_0).\rho.(p_\ell, \boldsymbol{m}_\ell)$ to emphasize this. The *effect* $\delta(\rho)$ of some finite path $\rho = (p_0, w_1, \delta_1, p_1)\ldots(p_{\ell-1}, w_\ell, \delta_\ell, p_\ell)$ is the sum of all induced counter changes, formally $\delta(\rho) = \sum_{1 \leq i \leq \ell} \delta_i$.

Recall that configurations of the Büchi VASS $\mathcal{V}$ are elements of the set $Q \times \mathbb{N}^d$. We call the second component in a configuration the *counter valuation* and refer to the i-th entry as the *value of counter* i. For a configuration cf and a set of counters $I \subseteq [1, d]$ we also use $cf[I]$ to denote the counter valuation of cf restricted to the counters in I. A configuration $(q, \boldsymbol{m})$ is *coverable* in $\mathcal{V}$ if there is a run starting in the initial configuration $(q_0, \boldsymbol{0})$ and reaching a configuration $(q, \boldsymbol{m}')$ with $\boldsymbol{m}' \geq \boldsymbol{m}$. Here, $\geq$ is defined component-wise.

Moreover we also consider a set of *extended configurations* $Q \times \mathbb{N}_\omega^d$, where $\mathbb{N}_\omega = \mathbb{N} \cup \{\omega\}$. Here ω is used to represent a counter value that has become unbounded. For an extended configuration $(q, \boldsymbol{m})$ we use $\omega(q, \boldsymbol{m}) \subseteq [1, d]$ to denote the set of counters valued ω in $\boldsymbol{m}$. Comparisons and arithmetic operations between integer values and ω behave as expected, treating ω as ∞. Formally, $\omega \geq \omega$, $\omega \geq z$, and $\omega + z = \omega$ for all $z \in \mathbb{Z}$. The *size* of an extended configuration is $|(q, \boldsymbol{m})| = \log_2 |Q| + \|\boldsymbol{m}\|_2 + d$, where the extra bit per counter encodes whether it has value ω or not. We also use the size of a unary encoding $\|(q, \boldsymbol{m})\|_1 = |Q| + \|\boldsymbol{m}\|_1 + d$.

The transition relation is also lifted to extended configurations in the expected manner. Formally, for $(q, \boldsymbol{m})$, $(q', \boldsymbol{m}') \in Q \times \mathbb{N}_\omega^d$ we have $(q, \boldsymbol{m}) \xrightarrow{w} (q', \boldsymbol{m}')$ if there is a transition $(q, w, \delta, q') \in T$ such that $\boldsymbol{m}' = \boldsymbol{m} + \delta$, where addition between elements of $\mathbb{N}_\omega^d$ and $\mathbb{Z}^d$ is defined component-wise. Furthermore, our definitions of runs, paths, loops, etc. carry over to *extended* versions over the set of extended configurations in a straightforward way. More precisely, an *extended run* is a sequence of extended configurations $cf_1 \xrightarrow{w_1} cf_2 \xrightarrow{w_2} \cdots$, an *extended path* is the underlying sequence of transitions of an extended run, and an *extended*

loop is a finite extended path starting and ending in the same state. To cover an extended configuration, intuitively, the ω-counters need to become unbounded, and the remaining counters need to be covered. Formally, an extended configuration $(q, \boldsymbol{m})$ is *coverable* in $\mathcal{V}$ if for every $k \in \mathbb{N}$ there is a run starting in the initial configuration $(q_0, \mathbf{0})$ and reaching a configuration $(q, \boldsymbol{m}_k) \in Q \times \mathbb{N}^d$ such that $\boldsymbol{m}_k[j] \geq k$ for every counter $j \in \omega(q, \boldsymbol{m})$ and $\boldsymbol{m}_k[i] \geq \boldsymbol{m}[i]$ for every counter $i \in [1, d] \setminus \omega(q, \boldsymbol{m})$.

Finally, we sometimes want to restrict only some counters of the VASS to stay non-negative. In this case, we consider extended configurations in $Q \times \mathbb{Z}_\omega^d$, where $\mathbb{Z}_\omega = \mathbb{Z} \cup \{\omega\}$. We say an extended run $\sigma = cf.\rho$ *remains non-negative* on counters $I \subseteq [1, d]$ if $cf'[I] \subseteq \mathbb{N}^{|I|}$ for all extended configurations cf' on σ.

Dyck Language. Towards the EXPSPACE upper bound of Theorem 3.1, a first step is to reduce the separability problem to a variant where one language is fixed to the Dyck language. The Dyck language D_n with n-letters is defined over the alphabet $\Sigma_n = \{a_i, \bar{a}_i \mid i \in [1, n]\}$. It contains those words w where, for every prefix v with $w = v.u$, we have at least as many letters a_i as $\bar{a}_i$. Thus, the letters behave like VASS counters and, indeed, the Dyck language is accepted by a single-state VASS $\mathcal{D}_n$ with n counters that increments the i-th counter upon seeing letter a_i and decrements the i-th counter upon seeing $\bar{a}_i$. If a VASS is defined over the Dyck alphabet Σ_n, we also call it n-visible. We will sometimes treat an n-visible VASS of dimension d as a $(d+n)$-dimensional VASS, and refer to the additional n counters as external. Note that this amounts to forming the product with $\mathcal{D}_n$. Given a path ρ, we use $\varphi(\rho)$ for the effect on the external counters in this product construction. Moreover, we write $\delta\varphi(\rho)$ to denote the combined effect on both internal and external counters, i.e. the $(d+n)$-dimensional vector $(\delta(\rho), \varphi(\rho))$.

To avoid an exponential blow-up, our reduction uses a variant of VASS whose transitions are labeled by compressed words. Essentially, the reduction takes $\mathcal{V}_1$ and $\mathcal{V}_2$ and produces a VASS $\mathcal{V}$ that is a product of $\mathcal{V}_1$ and $\mathcal{V}_2$. Moreover, it acts on its counters like $\mathcal{V}_1$; the input labels of $\mathcal{V}$ correspond to the counter updates of $\mathcal{V}_2$. Since the latter are binary-encoded, the new VASS will have binary encoded input words. Let us make this precise. A *label-compressed VASS* (lcVASS) $\mathcal{V}$ is a VASS, where the transitions are of the form $(p, a^m, \delta, q) \in Q \times \Sigma^* \times \mathbb{Z}^d \times Q$, where $a \in \Sigma$ and $m \in \mathbb{N}$ is given in binary. Thus, for an lcVASS $\mathcal{V}$, we define its *size* as $|\mathcal{V}| = |Q| + |F| + \sum_{(q,a^m,\delta,q') \in T} (\log_2(m) + \|\delta\|_2)$. The reduction that fixes the Dyck language is captured by the following lemma.

▶ **Lemma 5.1** ([2, Lemma 3.4]). *Given $\mathcal{V}_1$ and $\mathcal{V}_2$ over Σ, we can compute in time polynomial in $|\mathcal{V}_1| + |\mathcal{V}_2|$ an n-visible lcVASS $\mathcal{V}$ so that $L(\mathcal{V}_1) \,|\, L(\mathcal{V}_2)$ if and only if $L(\mathcal{V}) \,|\, D_n$. Here, n is the dimension of $\mathcal{V}_2$.*

The polynomial time bound is not mentioned in [2], but the simple construction they use (from [11]) clearly implies this bound. The latter separability problem $L(\mathcal{V}) \,|\, L(D_n)$ has been studied closely in [2] as well. They first show that $\mathcal{V}$ can be transformed so as to make the language $L(\mathcal{V})$ pumpable. For the resulting VASS, they show that $L(\mathcal{V}) \,|\, L(D_n)$ holds if and only if the so called Karp-Miller graph of $\mathsf{KM}(\mathcal{V})$ does not contain an inseparability witness. Unfortunately, the transformation required for pumpability involves another Karp-Miller graph construction, and therefore does not fit into the space bound we aim for (said graph can be of Ackermannian size in the worst case). Instead, we reformulate the witness.

▶ **Definition 5.2.** *Let $\mathcal{V}$ be an n-visible d-dimensional VASS. An* inseparability bloom *for $\mathcal{V}$ is a tuple $❀ = (q_f, I, \alpha, \beta, \gamma)$ with q_f a final state, loops α, β, γ starting and ending in q_f, and a partition of the counters $\Omega \uplus I = [1, d+n]$ so that*

(i) *for all* $\rho = \alpha, \beta, \gamma$*, we have* $\delta\varphi(\rho)[I] \geq 0$*,*
(ii) $\delta(\alpha) + \delta(\beta) + \delta(\gamma) \geq 0$
(iii) $\varphi(\alpha) + \varphi(\beta) \geq 0$*,*
(iv) *there is a* $t \in \mathbb{Q}$ *with* $\varphi(\alpha) + \varphi(\beta) + \varphi(\gamma) = t \cdot \varphi(\alpha)$*.*

The size *of the bloom is* $|❀| = \log_2 |Q| + |I| + |\alpha| + |\beta| + |\gamma|$*.*

A stem for ❀ *is an extended run* $cf.\sigma$ *of the product VASS* $\mathcal{V} \times \mathcal{D}_n$ *with the following properties: It ends in an extended configuration* $cf' = (q_f, \boldsymbol{m})$ *for some* $\boldsymbol{m} \in \mathbb{N}_\omega^{d+n}$ *with* $\Omega \subseteq \omega(cf')$*, and the counters in* $I \setminus \omega(cf)$ *remain non-negative when executing* σ *from* cf *resp.* α*,* β*, and* γ *from* cf'*.*

An inseparability flower $—❀ = (cf.\sigma, ❀)$ *consists of an inseparability bloom and a suitable stem. The size is* $|—❀| = \|cf\|_1 + |\sigma| + |❀|$*. The flower is* coverable *if the extended configuration* cf *is coverable in the product VASS* $\mathcal{V} \times \mathcal{D}_n$*.*

The following can be derived from the results in [2], refer to the full version for the details.

▶ **Lemma 5.3.** *Let* $\mathcal{V}$ *be* n*-visible. We have* $L(\mathcal{V}) \not| D_n$ *if and only if some inseparability flower is coverable.*

Our main result is the following. Note: the unary counter encoding strengthens the bound.

▶ **Theorem 5.4.** *If an inseparability flower is coverable in an* n*-visible lcVASS* $\mathcal{V}$ *of dimension* d*, then there is one of size at most* $|—❀| = 2^{|\mathcal{V}|^{\mathcal{O}((d+n)^2)}}$*.*

Main algortihm. We now have all ingredients to formulate the algorithm that proves the upper bounds in Theorem 3.1. We first describe the EXPSPACE upper bound. Given $\mathcal{V}_1$ and $\mathcal{V}_2$ whose languages we wish to separate, we first compute the lcVASS $\mathcal{V}$ using Lemma 5.1. This takes poly time. The task is to check $L(\mathcal{V}) \,|\, D_n$, where n is the dimension of $\mathcal{V}_2$. Using Lemma 5.3, we have to find an inseparability flower for $\mathcal{V}$ that is coverable. Theorem 5.4 bounds the size of the flowers we have to consider. We thus use non-determinism to find a flower of bounded size followed by a somewhat involved coverability check. Savitch's theorem [29] turns the non-deterministic algorithm into a deterministic one.

We detect a flower of bounded size as follows. We first guess the final state $q_f \in F$ and the partitioning of the counters $I \uplus \Omega$. With this information, we can guess the stem.

Towards obtaining a suitable stem, we start by guessing an extended configuration cf, whose non-ω-entries are at most doubly exponentially large. We can store such configurations in exponential space. If $\Omega \subseteq \omega(cf)$ fails, we abort. We now guess a path σ of doubly exponential length from cf to a configuration cf'. As we proceed, we store the length of the path, which only needs exponential space. We abort, if one of the following happens while guessing σ: a counter from $I \setminus \omega(cf)$ becomes negative, σ becomes too long, or the last state on σ is different from q_f. If we have not aborted until now, we have determined $cf.\sigma.cf'$ that may serve as a stem for a bloom with final state q_f and partition $I \uplus \Omega$.

Given the stem, we can finish the construction of the bloom by guessing the cycles $\rho = \alpha, \beta, \gamma$. The reason we proceed in this order is the following. The cycles are too long to be stored in exponential space. Instead, we check the non-negativity required by a stem on-the-fly, while constructing the cycles. To do so, we need the configuration cf', which we can store upon finishing the guess of σ above. While guessing the cycles, we store their length and the numbers $\delta(\rho)$ and $\varphi(\rho)$. It is readily checked that these numbers are bounded by

$$2^{|\mathcal{V}|} \cdot 2^{|\mathcal{V}|^{\mathcal{O}((d+n)^2)}} = 2^{|\mathcal{V}|^{\mathcal{O}((d+n)^2)}}.$$

This means we can store them in exponential space. We abort, if one of the following applies: an intermediate valuation becomes negative on $I \setminus \omega(cf)$, the path becomes too long, or the last state is different from q_f. We compute the operations and comparisons required by (i) to (iv) in Definition 5.2. For (iv), we start with counter $d+1$ and store the quotient $\frac{\varphi(\alpha)[d+1]+\varphi(\beta)[d+1]+\varphi(\gamma)[d+1]}{\varphi(\alpha)[d+1]}$ as the rational number t. As the numerator and denominator will be at most doubly exponential, we can store the number in exponential space. For the remaining entries, we only perform the required comparison. As noted above, they can be executed in polynomial time. If a comparison fails, we reject. If we have not rejected up to now, we have determined an inseparability flower while using space $|\mathcal{V}|^{\mathcal{O}((d+n)^2)} \leq 2^{|\mathcal{V}|\cdot\mathcal{O}((d+n)^2)} = 2^{poly(|\mathcal{V}_1|+|\mathcal{V}_2|)}$.

It remains to check whether this flower is coverable. There are two challenges. First, since cf is extended, we have a combination of a simultaneous unboundedness and a coverability problem. Second, the non-ω-entries in cf may be doubly exponentially large. We reduce the problem to simultaneous unboundedness, which is in EXPSPACE as shown by Demri [12, Theorem 4.6(I)]. The reduction uses a simple gadget that subtracts the counter valuation to be covered and, if succcessful, makes a new target counter j unbounded. In the end we check simultaneous unboundedness of $\omega(cf) \cup \{j\}$. To handle the large values, we utilize Lipton's construction [23], which allows a VASS to simulate EXPSPACE-computations. As a remark, simultaneous unboundedness cannot be expressed by a polynomial-sized formula in Yen's logic [33], a fact that was first observed in [12], which means we cannot just invoke the bounds in [1].

For the PSPACE upper bound, we merely need to observe that in fixed dimension, all our bounds on counter values become singly exponential. Moreover, for the gadget that subtracts counter values, we do not need the Lipton construction, as we can subtract exponentially bounded values directly using transitions. Finally, in fixed dimension, the simultaneous unboundedness check is also possible in PSPACE, as shown by Demri [12, Theorem 4.6(II)].

The remainder of the paper proves Theorem 5.4. SNLS help us deal with Constraint (iv).

6 Proof of Theorem 5.4

In this section we fix an n-visible lcVASS $\mathcal{V} = (Q, q_0, \Sigma_n, T, F)$. Note that since $\mathcal{V}$ is label-compressed, the effect on the external counters $\varphi(\rho)$ for a path ρ is also compressed. This matches the effect $\delta(\rho)$, which is anyway encoded in binary.

The proof is Rackoff-like, and we explain the analogy as we proceed. Like in Rackoff's upper bound for coverability [28], we reason over all (extended) configurations. Unlike Rackoff, however, we do not look at short covering sequences from a given configuration, but rather at small flowers rooted in said configuration. To bound the size while maximizing over all configurations, we measure each flower's size without considering the configuration it is rooted in. We therefore define the *flower bound*

$$\mathcal{B}_{\mathcal{V}} \;=\; \max_{cf} \min\{|\sigma| + |❀| \mid (cf.\sigma, ❀) \text{ is an inseparability flower}\}\ .$$

Theorem 5.4 is an immediate consequence of the following.

▶ **Lemma 6.1.** $\mathcal{B}_{\mathcal{V}} \leq 2^{|\mathcal{V}|^{\mathcal{O}((d+n)^2)}}$.

Step I: From length bounds to flower size bounds. Before we prove Lemma 6.1, let us see how it implies Theorem 5.4. Notice that Lemma 6.1 makes a statement about the lengths of the runs σ, α, β, γ, whereas Theorem 5.4 also promises a small starting configuration cf. Thus, it remains to construct a small starting configuration.

Proof of Theorem 5.4. To begin, assume $—❀ = (cf.\sigma, ❀)$ is coverable. By Lemma 6.1, there is another flower $(cf.\sigma', ❀')$ that is rooted in the same extended configuration and satisfies $|\sigma'| + |❀'| \leq \mathcal{B}_\mathcal{V}$. The extended configuration cf may not obey the desired bound. Thus, we replace it by cf' defined by $\omega(cf') = \omega(cf)$ and $cf'[j] = \min\{cf[j], \mathcal{B}_\mathcal{V} \cdot 2^{|\mathcal{V}|}\}$ for all $j \in I \setminus \omega(cf)$. Here, we keep the ω-entries, and for each non-ω-counter, we take the value of cf unless it is larger than $\mathcal{B}_\mathcal{V} \cdot 2^{|\mathcal{V}|}$, in which case we truncate to this value. We now claim that $—❀' = (cf'.\sigma', ❀')$ is still a coverable inseparability flower, and its size is at most doubly exponential (satisfying the desired bound). Coverability is immediate by $cf' \leq cf$. We also have $\|cf'\|_1 \leq 2^{2^{\mathcal{O}(|\mathcal{V}|)}}$. To be an inseparability flower, we have to check that the counters whose values we truncated when moving from cf to cf' remain non-negative while executing σ, and also $\sigma.\rho$ with $\rho = \alpha, \beta, \gamma$. This, however, is clear by the fact that $\sigma.\rho$ has length at most $\mathcal{B}_\mathcal{V}$, and each transition can subtract at most $2^{|\mathcal{V}|}$ tokens. As we have this budget available in cf', the run remains non-negative. ◀

In the remainder of the section, we prove Lemma 6.1. Similar to Rackoff's proof for coverability, we generalize the notion of flowers to admit negative counter values. Then we use an induction on the number of non-negative counters to establish a bound on the length of shortest generalized flowers. Let $i \in [0, d+n]$, $❀ = (q_f, I, \alpha, \beta, \gamma)$ a bloom, and $\Omega = [1, d+n] \setminus I$. We call an extended run $cf.\sigma$ of $\mathcal{V} \times \mathcal{D}_n$ an *i-stem for* $❀$, if it ends in an extended configuration cf' with $cf' = (q_f, \boldsymbol{m}')$ for some $\boldsymbol{m}'$, $\Omega \subseteq \omega(cf)$, and the counters in $([1, i] \cap I) \setminus \omega(cf)$ remain non-negative when executing σ from cf resp. α, β, and γ from cf' in $\mathcal{V} \times \mathcal{D}_n$. Here, we use $[1, 0] = \emptyset$. We call a pair $(cf.\sigma, ❀)$ consisting of an i-stem and an inseparability bloom an *i-inseparability flower*. Note that a $(d+n)$-inseparability flower is an inseparability flower as in Definition 5.2. We say the flower is *b-bounded* with $b \in \mathbb{N} \setminus \{0\}$, if the counters in $([1, i] \cap I) \setminus \omega(cf)$ are bounded by b along $cf.\sigma.\rho$ for all $\rho = \alpha, \beta, \gamma$. We wish to establish an estimate on the following function f, note that $f(d+n) = \mathcal{B}_\mathcal{V}$:

$$f(i) = \max_{cf} \min\{|\sigma| + |❀| \mid (cf.\sigma, ❀) \text{ is an } i\text{-inseparability flower}\} .$$

Step II: From value bounds to length bounds. Similar to Rackoff's proof, we will bound $f(i+1)$ in terms of $f(i)$, which will then yield the bound on $\mathcal{B}_\mathcal{V} = f(n+d)$. However, there is a key difference to Rackoff's proof: When constructing runs that, in the first $i+1$ coordinates stay non-negative, Rackoff argues that if such a run only uses counter values in $[0, b]$ on the first $i+1$ coordinates, then there is such a run of length at most $|Q| \cdot (b+1)^{i+1}$: whenever a combination of values in $[0, b]$ (and a control state) repeats, we can cut out the infix in between. Hence, *value bounds yield length bounds*. Our setting requires a different argument: Simply cutting out infixes in α, β, γ might spoil the properties (ii), (iii), and (iv) of i-inseparability flowers. Instead, we use our results on SNLS to obtain length bounds from value bounds. The technique is similar to some other generalizations of Rackoff's result by Yen [33, Lemma 3.5] Habermehl [14, Lemma 3.2] and Atig and Habermehl [1, Lemma 5]. However, the following proof also needs to work with non-linear constraints (which are also not present in Demri's extension of Rackoff's result [12]).

▶ **Lemma 6.2.** *Let $—❀ = (cf.\sigma, ❀)$ be a b-bounded i-inseparability flower. Then there is an i-inseparability flower $—❀' = (cf.\sigma', ❀')$ with $|\sigma'| + |❀'| \leq (2^{|\mathcal{V}|} \cdot |Q| \cdot b)^{\mathcal{O}((d+n)^6)}$.*

Proof. Let $—❀ = (cf.\sigma, ❀)$ be a b-bounded i-inseparability flower with $❀ = (q_f, I, \alpha, \beta, \gamma)$. Let Ω be the complement of I. Let $\widehat{cf}$ be the extended configuration reached by $cf.\sigma$.

Let $D = ([1, i] \cap I) \setminus \omega(cf)$ be the counters we wish to keep non-negative. By a *D-loop*, we mean an extended run $cf_1.\tau.cf_2$ of $\mathcal{V} \times \mathcal{D}_n$ where τ is a loop, $cf_1[D] = cf_2[D]$, and $cf_1[\Omega] = cf_2[\Omega]$. The D-loop is called *irreducible* if it does not contain further D-loops. By

the pigeonhole principle, any run that is longer than $u_{len} = |Q| \cdot (b+1)^{|D \cup \Omega|}$ contains a D-loop. This means the length of an irreducible D-loop is at most u_{len}. Moreover, these loops can have at most $2 \cdot 2^{|\mathcal{V}|} \cdot u_{len}$ distinct effects on each counter, where the leading 2 is for the distinction between positive and negative values. This analysis yields an upper bound of $u_{num} = (2^{|\mathcal{V}|+1} \cdot u_{len})^{d+n}$ on the number of irreducible D-loops with distinct effects. We show how to construct a flower as promised in the lemma.

We begin by cutting out irreducible D-loops from σ, yielding σ' of length at most u_{len}. The extended configuration cf' reached by $cf.\sigma'$ coincides with $\widehat{cf}$ on the ω-entries and on the non-ω-entries for D.

Next, we want to shorten $\rho = \alpha, \beta, \gamma$. To this end, we first decompose them into irreducible D-loops. We assume all such D-loops have distinct effects, otherwise we pick a representative. With the previous analysis, the result is $\rho_0, \rho_1, \ldots, \rho_v$ with $v \leq u_{num}$. Here, ρ_0 is the loop on the final state into which the irreducible D-loops $\rho_1, \ldots, \rho_v$ are inserted. Note that ρ_0 is not necessarily a D-loop. What we know, however, is that ρ_0 has a non-negative effect on the counters in I, due to Condition (i) in the definition of inseparability blooms. Since we want to be able to insert all the D-loops directly into ρ_0, the latter should still contain the same starting configurations for such loops as ρ, at least when only considering the counters in $D \cup \Omega$. Therefore we cannot guarantee that ρ_0 contains no D-loops, because cutting all of them out might reduce the number of such configurations visited by ρ_0. However, ρ_0 still has length at most u_{len}^2 by the following argument. If we mark in ρ_0 the first occurrence of each element from $Q \times [0,b]^{D \cup \Omega}$, then each infix leading from one such marker to the next has at most length u_{len}, because longer infixes still contain a D-loop that has no marked configuration and can therefore be removed. Since there are at most $|Q \times [0,b]^{D \cup \Omega}| = |Q| \cdot (b+1)^{|D \cup \Omega|} = u_{len}$ markers, we obtain the stated length bound of u_{len}^2 for ρ_0.

A vector $\boldsymbol{x} \in \mathbb{N}^v$ with $\boldsymbol{x}[0] > 0$ and $\boldsymbol{x}[j] \geq 0$ for $1 \leq j \leq v$ can now be turned into a run $\rho_{\boldsymbol{x}}$ by glueing together $\boldsymbol{x}[j]$-many instances of ρ_j. Note that also the base loop ρ_0 may be repeated. As the order of the transitions does not influence the effect of the run, $\delta\varphi(\rho) = \delta\varphi(\rho_{\boldsymbol{y}})$ holds, where $\boldsymbol{y} = \Psi(\rho)$ is the so-called Parikh vector that counts the occurrences of irreducible loops in ρ. As a consequence, we can directly define the effect on the vector $\boldsymbol{x}$, namely $\delta\varphi(\boldsymbol{x}) = \sum_{i=0}^{v} \boldsymbol{x}[j] \cdot \delta\varphi(\rho_j) \in \mathbb{Z}^{d+n}$.

With irreducible D-loops at hand, we can formulate the search for a small bloom as an SNLS. We define the vectors $\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta, \boldsymbol{x}_\gamma$, and the following constraints:

$$\begin{aligned}
\boldsymbol{x}_\alpha[0], \boldsymbol{x}_\beta[0], \boldsymbol{x}_\gamma[0] &\geq 1 & \delta(\boldsymbol{x}_\alpha + \boldsymbol{x}_\beta + \boldsymbol{x}_\gamma)[1,d] &\geq 0 \\
\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta, \boldsymbol{x}_\gamma &\geq 0 & \varphi(\boldsymbol{x}_\alpha + \boldsymbol{x}_\beta)[d+1, d+n] &\geq 0 \\
\delta\varphi(\boldsymbol{x}_\alpha)[I], \delta\varphi(\boldsymbol{x}_\beta)[I], \delta\varphi(\boldsymbol{x}_\gamma)[I] &\geq 0 & (\varphi(\boldsymbol{x}_\alpha + \boldsymbol{x}_\beta + \boldsymbol{x}_\gamma) - t \cdot \varphi(\boldsymbol{x}_\alpha))[d+1, d+n] &= 0
\end{aligned}$$

The constraints on the left say that we repeat the base loops at least once, and the remaining loops a non-negative number of times. The last constraint is Condition (i) in the definition of blooms. The constraints on the right correspond to the Conditions (ii) to (iv).

It is readily checked that $(\Psi(\alpha), \Psi(\beta), \Psi(\gamma))$ solves the SNLS. This means Theorem 3.2 applies and yields a small rational solution. To turn it into an integer solution, we observe that our SNLS is monotonic in the sense that if $(\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta, \boldsymbol{x}_\gamma)$ is a solution, so is $(k\boldsymbol{x}_\alpha, k\boldsymbol{x}_\beta, k\boldsymbol{x}_\gamma)$ for any $k \geq 1$. We multiply the rational solution by the common denominator to obtain the integer solution $(\boldsymbol{x}'_\alpha, \boldsymbol{x}'_\beta, \boldsymbol{x}'_\gamma)$ with the associated loops α', β', γ'.

We argue that $\multimap^{\text{❀}'} = (cf.\sigma', \text{❀}')$ with $\text{❀}' = (q_f, I, \alpha', \beta', \gamma')$ is an i-inseparability flower. Remember that cf' is the configuration reached by $cf.\sigma'$. As cf and I have not changed, the only thing we have to show is the non-negativity for the counters in D. For σ', this follows from the non-negativity of σ, and the fact that we only cut-out D-loops. For $\rho' = \alpha', \beta', \gamma'$,

which are executed from cf', we argue as follows. The base loop ρ_0 has the same effect on the D-counters as ρ, because we obtained ρ_0 by cutting-out D-loops from ρ. The effect of ρ on even the entire set I is non-negative due to Condition (i) for blooms. This means if one repetition of ρ_0 stays non-negative from cf', arbitrarily many repetitions will. The one repetition stays non-negative, because ρ was non-negative from $\widehat{cf}$ (the extended configuration reached by $cf.\sigma$), and cf' coincides with $\widehat{cf}$ on D. Since the D-loops that we glue into ρ_0 come with a valuation of the counters in D, and this valuation keeps them non-negative in ρ, the entire ρ' stays non-negative.

We analyze the complexity of our system $\mathcal{S}$. It has at most $row(\mathcal{S}) \in \mathcal{O}(d+n)$ many rows, and note that the non-negativity constraints do not count towards the rows. There are at most $col(\mathcal{S}) \in \mathcal{O}(u_{num})$ many columns. The degree is $\deg(\mathcal{S}) = 1$. The maximal coefficient is bounded from above by the largest possible loop effect, $\max(\mathcal{S}) \leq 2^{|\mathcal{V}|} \cdot u_{len}^2$. Then, Theorem 3.2 gives us rational solutions $\boldsymbol{x}_\alpha, \boldsymbol{x}_\beta, \boldsymbol{x}_\gamma$ of the form $\boldsymbol{x}_\rho[i] = \frac{a}{K}$, meaning K is the common denominator of all entries, with

$$\begin{aligned}
\|\boldsymbol{x}_\rho\|_1 &\in (col(\mathcal{S}) \cdot \deg(\mathcal{S}) \cdot \max(\mathcal{S}))^{\mathcal{O}(\deg(\mathcal{S})^2 \cdot row(\mathcal{S})^4)} \\
&= (\mathcal{O}(u_{num}) \cdot 2^{|\mathcal{V}|} \cdot u_{len}^2)^{\mathcal{O}((d+n)^4)} \\
&= (\mathcal{O}((2^{|\mathcal{V}|+1} \cdot u_{len})^{d+n}) \cdot 2^{|\mathcal{V}|} \cdot u_{len}^2)^{\mathcal{O}((d+n)^4)} \\
&= (2^{|\mathcal{V}|} \cdot u_{len})^{\mathcal{O}((d+n)^5)} = (2^{|\mathcal{V}|} \cdot |Q| \cdot (b+1))^{\mathcal{O}((d+n)^6)} \\
&= (2^{|\mathcal{V}|} \cdot |Q| \cdot b)^{\mathcal{O}((d+n)^6)} .
\end{aligned}$$

We already argued that the integer vectors $K\boldsymbol{x}_\alpha$, $K\boldsymbol{x}_\beta$, $K\boldsymbol{x}_\gamma$ are also solutions with runs α', β', γ'. Since each entry of these vectors is smaller than $(2^{|\mathcal{V}|} \cdot |Q| \cdot b)^{\mathcal{O}((d+n)^6)}$, and we have at most $u_{num} = (2^{|\mathcal{V}|} \cdot |Q| \cdot (b+1))^{\mathcal{O}((d+n)^2)}$ many loops with maximal size $u_{len}^2 = |Q|^2 \cdot (b+1)^{2(d+n)}$, we get

$$\begin{aligned}
|\rho'| &\leq (2^{|\mathcal{V}|} \cdot |Q| \cdot b)^{\mathcal{O}((d+n)^6)} \cdot (2^{|\mathcal{V}|} \cdot |Q| \cdot (b+1))^{\mathcal{O}((d+n)^2)} \cdot |Q|^2 \cdot (b+1)^{2(d+n)} \\
&= (2^{|\mathcal{V}|} \cdot |Q| \cdot b)^{\mathcal{O}((d+n)^6)} .
\end{aligned}$$

◀

Step III: Rackoff-style induction. We now give the bound on $f(i)$ that we need to prove Lemma 6.1. In the base case, no counter has to remain non-negative and so we have a 1-bounded 0-inseparability flower. We employ the bound from Lemma 6.2.

▶ **Lemma 6.3.** $f(0) = (2^{|\mathcal{V}|}|Q|)^{\mathcal{O}((d+n)^6)}$.

In the induction step, and as in Rackoff's result, the bound takes the form of a recurrence.

▶ **Lemma 6.4.** $f(i+1) \leq (2^{|\mathcal{V}|} \cdot f(i))^{\mathcal{O}((d+n)^6)}$.

Proof. Consider an $(i+1)$-inseparability flower $—❀ = (cf.\sigma, ❀)$ with $❀ = (q_f, I, \alpha, \beta, \gamma)$ and $\Omega = [1, d+n] \setminus I$. Let $r(i) = 2^{|\mathcal{V}|} \cdot f(i)$ serve as an abbreviation. We proceed by a case distinction. If $—❀$ is $r(i)$-bounded, then Lemma 6.2 provides another $(i+1)$-inseparability flower $(cf.\sigma', ❀')$ with $|\sigma'| + |❀'| \leq (2^{|\mathcal{V}|} \cdot |Q| \cdot r(i))^{\mathcal{O}((d+n)^6)} = (2^{|\mathcal{V}|} \cdot f(i))^{\mathcal{O}((d+n)^6)}$. This satisfies the bound stated in the lemma.

If $—❀$ is not $r(i)$-bounded, then $\sigma.\rho$ with $\rho = \alpha, \beta, \gamma$ exceeds $r(i)$. We identify the first moment when this happens, say after ρ_1 and for the $(i+1)$-th counter. The case where the run exceeds the bound already in σ is simpler. The run decomposes into

$$cf \xrightarrow{\sigma} cf_1 \xrightarrow{\rho_1} cf' \xrightarrow{\rho_2} cf_2 .$$

We argue that also $(cf'.\rho_2, ❀)$ is an $(i+1)$-flower, which means $cf'.\rho_2$ is an $(i+1)$-stem for ❀. Since ρ is a loop, it returns to q_f. We have $\omega(cf) = \omega(cf')$ and since $\Omega \subseteq \omega(cf)$, we get $\Omega \subseteq \omega(cf')$. As ❀ is a bloom, ρ has a non-negative effect on the counters in I. This means $cf_1[I] \leq cf_2[I]$, and so the counters in $([1, i+1] \cap I) \setminus \omega(cf')$ remain non-negative when executing α, β, γ from cf_2 as they did from cf_1. Also ρ_2 remains non-negative from cf', because ρ remained non-negative from cf_1.

Since $(cf'.\rho_2, ❀)$ is an $(i+1)$-flower, it is an i-flower. The induction hypothesis yields another i-flower $—❀' = (cf'.\sigma', ❀')$ with $|\sigma'| + |❀'| \leq f(i)$. Let $❀' = (q'_f, I', \alpha', \beta', \gamma')$ and let Ω' be the complement of I'.

We argue that $—❀'$ is actually an $(i+1)$-flower. If the counter $i+1$ that exceeds the bound $r(i)$ does not belong to I', there is nothing to show. Otherwise, even $\sigma'.\alpha'.\beta'.\gamma'$ in succession could subtract at most $f(i) \cdot 2^{|\mathcal{V}|} = r(i)$ tokens from counter $i+1$. Since this counter carries more than $r(i)$ tokens, this leaves us with a positive balance.

We show that also $(cf.\sigma.\rho_1.\sigma', ❀')$ is an $(i+1)$-flower, meaning $cf.\sigma.\rho_1.\sigma'$ is an $(i+1)$-stem for ❀'. We have $\omega(cf) = \omega(cf')$ and so $\Omega' \subseteq \omega(cf')$ implies $\Omega' \subseteq \omega(cf)$. It remains to show that the counters in $([1, i+1] \cap I') \setminus \omega(cf)$ remain non-negative. Consider the prefix $\sigma.\rho_1$ executed from cf. For the counters that also belong to I, non-negativity holds as $—❀$ is an $(i+1)$-flower. Assume there was a counter in $([1, i+1] \cap I') \setminus \omega(cf)$ that did not belong to I. Then it belonged to Ω. But as $\Omega \subseteq \omega(cf)$, we had a contradiction. For the suffix σ' executed from cf', and for α', β', γ', non-negativity holds as $—❀'$ is an $(i+1)$-flower.

To estimate the size of the newly constructed flower rooted in cf, we assume $\sigma.\rho_1$ does not repeat configurations on the first $(i+1)$-counters. If it does, we cut out the infix and adapt the values of the counters that are allowed to fall below zero. Then the length of $\sigma.\rho_1$ is bounded by $|Q| \cdot r(i)^{i+1}$, and we have

$$|\sigma.\rho_1.\sigma'| + |❀'| \leq |Q| \cdot r(i)^{i+1} + f(i) \leq \ (2^{|\mathcal{V}|} \cdot f(i))^{\mathcal{O}(i+1)} \leq (2^{|\mathcal{V}|} \cdot f(i))^{\mathcal{O}((d+n)^6)} \ . \qquad ◀$$

It remains to solve the recurrence. Let $a = 2^{|\mathcal{V}|}$ and $b = \mathcal{O}((d+n)^6)$. We have

$$f(d+n) = (a \dots (a \cdot f(0))^b \dots)^b \leq (a^{d+n} \cdot f(0))^{b^{d+n}} \ .$$

Since $f(0) = (2^{|\mathcal{V}|} \cdot |Q|)^{\mathcal{O}((d+n)^6)}$, we obtain the promised $\mathcal{B}_\mathcal{V} = f(d+n) \leq 2^{|\mathcal{V}|^{\mathcal{O}((d+n)^2)}}$.

Abstract

We present results concerning the expressiveness and decidability of a popular graph learning formalism, graph neural networks (GNNs), exploiting connections with logic. We use a family of recently-discovered decidable logics involving "Presburger quantifiers". We show how to use these logics to measure the expressiveness of classes of GNNs, in some cases getting exact correspondences between the expressiveness of logics and GNNs. We also employ the logics, and the techniques used to analyze them, to obtain decision procedures for verification problems over GNNs. We complement this with undecidability results for static analysis problems involving the logics, as well as for GNN verification problems.

1 Introduction

Graph Neural Networks (GNNs) have become the most common model for learning functions that work on graph data. Like traditional neural networks, GNNs consist of a layered architecture where layer $k+1$ takes as input the output of layer k. Each layer computes a function from graph vertices to a vector of numerical values – the *feature vector*. Computation of the feature vector at layer $k+1$ for a node u is based on aggregating vectors for layer k of nodes v that are related to u in the source graph: for example aggregating vectors associated to nodes adjacent to u in the graph. In an aggregation, the vectors of the previous vectors may be transformed using linear functions. A layer can perform multiple aggregations – corresponding to different linear functions – and then combine them to get the feature vector for the next layer. The use of graph structure ensures that the computation of the network is *invariant*: depending only on the input graph and the node up to isomorphism. There are many variations of GNN. One key design choice is the kind of aggregation used - one can use "local aggregation", over the neighbors of a node, or aggregation over all nodes in the graph. A second design choice is the kind of numerical functions that can be applied to vector components, in particular the kind of *activation functions* that can be applied at each layer: e.g. ReLU, sigmoid, piecewise linear functions.

An important issue in the study of graph learning is the *expressiveness* of a learning model. What kinds of computations can a given type of GNN express? The first results in this line were about the *separating power of a graph learning model*: what pairs of nodes can be distinguished using GNNs within a certain class. For example, it is known that the separating power of standard GNN models is limited by the Weisfeiler-Leman (WL) test [16].

A finer-grained classification would characterize the functions computed by GNNs within a certain class, in terms of some formalism that is easier to analyze. Such characterizations are referred to as *uniform expressiveness results* and there has been much less work in this area. [1] provides a classification of a class of GNNs in terms of *modal logic*. The main result in [1] is a characterization of the classifiers expressible in first-order logic that can be performed with a GNN having only *local aggregation* and *truncated* ReLU *activations* over *undirected graphs*. They also provide a lower bound on the expressiveness of GNNs having in addition a "global aggregator", that sums over all nodes in the graph.

In this work we continue the line of work on uniform expressiveness. Our work improves on the state of the art in a number of directions:

- *From first order expressiveness to general expressiveness* In contrast to [1], we provide logical characterizations of *all* the functions that can be computed by certain GNN formalisms, not just the intersection with first-order logic. To do this we utilize logics that go beyond first order, but which are still amenable to analysis.
- *From expressiveness to verification* While we deal with GNNs that go beyond first-order logic, we can still obtain characterizations in a logic where the basic satisfiability problems are decidable. This provides us with decidability of a number of natural verification problems related to GNNs. In doing this, we show a surprising link between GNNs and recently-devised decidable logics going beyond first-order logic, so-called *Presburger logics*.
- *From undirected graphs to directed graphs* While prior work focused on undirected graphs, we explore how the expressiveness characterizations vary with GNNs that can recognize directionality of graph edges. The aim is to show that the logical characterizations and decidability are often independent of the restriction to undirected graphs.
- *From bounded to unbounded activations* We explore the impact of the activation functions. We begin with the case of *bounded activation functions*, like the truncated ReLU of [1], and establish characterizations and decidability results for GNNs using this function. We show both some contrasts and some similarity to the case of *unbounded activation functions*, including the standard ReLU. Here some, but not all, of the corresponding decidability results fail.

Related work. Logics have been used to characterized the separating power of GNN languages ("non-uniform expressiveness") for a number of years: see [8] for an overview. The recent [9] provides logical characterizations of GNNs with piecewise linear activations. The logic is not decidable; indeed our undecidability results imply that one cannot capture such GNNs with a decidable logic.

We employ logical characterizations to gain insight on two basic verification problems – whether a given classification can be achieved on some nodes or on all nodes. There is prior work on verification of GNNs, but it focuses on more complex (but arguably more realistic) problems, adversarial robustness. The closest paper to ours is the recent [14], which formalizes a broad set of problems related to verifying that the output is in a certain region in Euclidean space. [14] provides both decidability and undecidability theorems, but they are incomparable to ours both in the results and in the techniques. For example Theorem 1 of [14] shows undecidability of a satisfiability problem where we verify that certain nodes

output a particular value, over GNNs which always distinguish a node from its neighbor. Theorem 2 of [14] shows a decidability result with a different kind of specification, where the degree of input graphs is bounded.

Recently, logics that combine uninterpreted relations with Presburger arithmetic have been applied to the analysis of transformers – transducers that process strings [4, 2]. Since this is outside of the context of general graphs, the details of the logics that are employed are a bit different than those we consider, and the focus is not on the decidability border.

Organization. We formalize our GNN model and the basic logics we study in Section 2. We present results on logical characterizations of GNNs with "bounded activation functions" – like the truncated ReLU of [1]. We apply these characterizations to get decidability results. Section 4 turns to the case of unbounded activation functions, which includes the traditional ReLU function. Here we provide lower bounds for expressiveness, and then turn to the implications for decidability. Section 5 gives conclusions and discusses several open issues and directions for future work. For space reasons, *many details of the constructions and proofs are deferred to the full version, which is available on arxiv.*

2 Preliminaries

Let $\mathbb{N}$, $\mathbb{N}^+$, $\mathbb{Z}$, and $\mathbb{Q}$ be the set of natural numbers, positive natural numbers, integers, and rational numbers, respectively. For $p, q \in \mathbb{Z}$ and $p \leq q$, $[p\,, q]$ is the set of integers between p and q, including p and q. For $r \in \mathbb{Q}$, $\lceil r \rceil$ is the smallest integer greater than or equal to r.

For a function f mapping from $\mathbb{Q}$ to $\mathbb{Q}$ and a vector $b \in \mathbb{Q}^m$, $f(b)$ denotes that f is applied to each entry of b.

▶ **Definition 1.** *An* n-graph *is a tuple* $\left\langle V, E, \{U_c\}_{1 \leq c \leq n} \right\rangle$*, where* $n \in \mathbb{N}$ *is the number of vertex colors;* V *is a nonempty finite set of vertices;* $E \subseteq V \times V$ *is a set of edges; each* $U_c \subseteq V$ *is the set of* c*-colored vertices.*

Note that we allow self-loops in graphs, and a graph is by default a *directed graph.* For a graph $\mathcal{G}$, we say that $\mathcal{G}$ is a *undirected graph* if for all $v, u \in V$, $(v, u) \in E$ if and only if $(u, v) \in E$. For a vertex $v \in V$, we let $\mathcal{N}_{\text{out},\mathcal{G}}(v) := \{u |\ (v, u) \in E\}$ and refer to this as the set of *out-neighbors of* v. The set of *in-neighbors of* v, denoted $\mathcal{N}_{\text{in},\mathcal{G}}(v)$ are defined analogously.

Graph Neural Networks. We use a standard notion of "aggregate-combine" graph neural networks with rational coefficients. The only distinction from the usual presentation is that we allow GNNs to work over directed graphs, with separate aggregations over incoming and outgoing edges, while traditional GNNs work on undirected graphs.

▶ **Definition 2.** *An* n-graph neural network (GNN) *is a tuple*

$$\left\langle \{d_\ell\}_{0 \leq \ell \leq L}, \{f^\ell\}_{1 \leq \ell \leq L}, \{C^\ell\}_{1 \leq \ell \leq L}, \{A^\ell_x\}_{\substack{1 \leq \ell \leq L \\ x \in \{out,in\}}}, \{R^\ell\}_{1 \leq \ell \leq L}, \{b^\ell\}_{1 \leq \ell \leq L} \right\rangle,$$

where $L \in \mathbb{N}^+$ *is the number of layers; each* $d_\ell \in \mathbb{N}^+$*, called the* dimension *of the* ℓ^{th} *layer, requiring* $d_0 := n$*, the number of colors; each* $f^\ell : \mathbb{Q} \to \mathbb{Q}$*, the* activation function *of the* ℓ^{th} *layer; each* $C^\ell, A^\ell_x, R^\ell \in \mathbb{Q}^{d_\ell \times d_{\ell-1}}$*, the* coefficient matrices *of the* ℓ^{th} *layer; and* $b^\ell \in \mathbb{Q}^{d_\ell}$*, the* bias vector *of the* ℓ^{th} *layer.*

All the coefficients are rational. In order to have an effective representation of a GNN, we will also *assume that the activation functions are computable.*

▶ **Definition 3.** *For an n-GNN $\mathcal{A}$ and an n-graph $\mathcal{G}$, the* computation of $\mathcal{A}$ on $\mathcal{G}$ *is a sequence of* derived feature functions $\left\{\xi^{\ell}_{\mathcal{G}} : V \to \mathbb{Q}^{d_\ell}\right\}_{0\leq\ell\leq L}$ *defined inductively: for $\ell = 0$, if $v \in U_c$, then the c^{th} entry of $\xi^0_{\mathcal{G}}(v)$ is 1; otherwise, the entry is 0. For $1 \leq \ell \leq L$,*

$$\xi^{\ell}_{\mathcal{G}}(v) \;:=\; f^{\ell}\left(C^{\ell}\xi^{\ell-1}_{\mathcal{G}}(v) + \sum_{x\in\{out,in\}}\left(A^{\ell}_{x}\sum_{u\in\mathcal{N}_{x,\mathcal{G}}(v)}\xi^{\ell-1}_{\mathcal{G}}(u)\right) + R^{\ell}\sum_{u\in V}\xi^{\ell-1}_{\mathcal{G}}(u) + b^{\ell}\right).$$

For $v \in V$, $\xi^{\ell}_{\mathcal{G}}(v)$ is called the ℓ-feature vector of v, *and $\xi^{\ell}_{\mathcal{G},i}(v)$ is the i^{th} entry of $\xi^{\ell}_{\mathcal{G}}(v)$.*

That is, we compute the feature values of a node v at layer $\ell + 1$ by adding several components. One component aggregates over the ℓ-layer feature vector from the outgoing neighbors of v, and applies a linear transformation. Another component does the same for the incoming neighbors of v, a third does this for every node in the graph, while another applies a transformation to the ℓ-layer feature vector of v itself. The linear transformation can be different for each component, and in particular can be a zero matrix that just drops that component. The final component of the sum is the bias vector.

When the graph $\mathcal{G}$ is clear from the context, we omit it and simply write $\xi^{\ell}(v)$ and $\xi^{\ell}_{i}(v)$, and similarly when the graph $\mathcal{G}$ is clear from the context, write $\mathcal{N}_{\text{out}}(v)$ and $\mathcal{N}_{\text{in}}(v)$ for the in-neighbors and out-neighbors.

Note that in most presentations of GNNs, one deals with only undirected edges. The above definition degenerates in that setting to two aggregations per layer, with the aggregation over all nodes often referred to in the literature as the *global readout*.

In some presentations of GNNs, a *classification function*, which associates a final Boolean decision to a node, is included in the definition. In our case, we have separated out the classification function as an independent component in defining the expressiveness: see the last part of the preliminaries.

Classes of activation functions. Following prior work on analysis of GNNs, some of our results will deal with activation functions that are bounded in value:

▶ **Definition 4.** *We say that the function $f : \mathbb{Q} \to \mathbb{Q}$ is* eventually constant, *if there exists $t_{\mathsf{left}}, t_{\mathsf{right}} \in \mathbb{Q}$ satisfying $t_{\mathsf{left}} < t_{\mathsf{right}}$, called the* left and right thresholds of f, *such that for every $x \leq t_{\mathsf{left}}$, $f(x) = f(t_{\mathsf{left}})$; for every $x \geq t_{\mathsf{right}}$, $f(x) = f(t_{\mathsf{right}})$.*

A standard eventually constant function is the *truncated* ReLU *function*, which is 0 for negative reals, 1 for x greater than 1, and x otherwise [1]. There are other eventually constant functions that are used in practice: for example, the linear approximation of standard bounded functions used in graph learning, like the Sigmoid activation function. We will be interested in functions that are defined on the reals, but which preserve the rationals. The definition of eventually constant extends to such a function in the obvious way.

For a GNN with eventually constant activation functions, we use $\left\{t^{\ell}_{\mathsf{left}}\right\}_{1\leq\ell\leq L}$ and $\left\{t^{\ell}_{\mathsf{right}}\right\}_{1\leq\ell\leq L}$ to denote the left and right thresholds of the GNN's activation functions.

We also consider *unbounded activation functions*, such as the *standard* ReLU *function*, which is x for non-negative reals and 0 for negative reals.

Flavors of GNN. For a GNN $\mathcal{A}$, we say that $\mathcal{A}$ is *outgoing-only*, denoted by $\mathcal{O}$, if for every $1 \leq \ell \leq L$, A^{ℓ}_{in} is a zero matrix. $\mathcal{A}$ is *bidirectional*, denoted by $\mathcal{B}$, if there is no restriction on A^{ℓ}_{in}. $\mathcal{A}$ is *local*, denoted by $\mathcal{L}$, if for every $1 \leq \ell \leq L$, R^{ℓ} is a zero matrix. In the usual GNN terminology, this would mean that *there is no global readout*. $\mathcal{A}$ is

global, denoted by $\mathcal{G}$, if global readout is allowed. $\mathcal{A}$ is *eventually constant*, denoted by $\mathcal{C}$, if for $1 \leq \ell \leq L$, f^ℓ is an eventually constant function. Our results outside of eventually constant will deal with either *piecewise linear* activations, denoted $\mathcal{PW}$, truncated ReLU activations, denoted TrReLU, or standard ReLU activations. We use the following naming, $(\mathcal{O}|\mathcal{B})(\mathcal{L}|\mathcal{G})(\mathcal{C}|\mathcal{PW}|\mathsf{TrReLU}|\mathsf{ReLU})$-GNN, for the set of GNNs satisfying constraints given by the prefix. For example, $\mathcal{OLC}$-GNN is the set of outgoing-only, local, and eventually constant GNNs; $\mathcal{BGPW}$-GNN is the set of GNNs allowing both incoming and outgoing, global readout, and piecewise linear activations.

Classifiers and Boolean semantics. Our GNNs define vector-valued classification functions on nodes. But for comparing with expressiveness and in defining verification problems, we will often use a derived function from nodes to Booleans. We do this by thresholding at the end – below we use .5 for convenience, but other choices do not impact the results.

▶ **Definition 5.** *For a L-layer n-GNN $\mathcal{A}$, an n-graph $\mathcal{G}$, and a vertex $v \in V$, we say that $\mathcal{A}$* accepts *the tuple $\langle \mathcal{G}, v \rangle$, if $\xi^L_{\mathcal{G},1}(v) \geq 0.5$.*

Note that the global readout component can interact with the activation functions f^ℓ, which can behave very differently on translated values due to non-linearity – think of a typical f^ℓ as a piecewise linear function. Global readout can also interact with the classification threshold, pushing some values above the threshold while leaving others below.

Two-variable Modal Logic with Presburger Quantifiers. We review logic with Presburger quantifiers. The basic idea is to combine a decidable logic on uninterpreted structures, like two-variable logic or guarded logic, with the ability to perform some arithmetic on the number of elements. There are several formalisms in the literature that combine Presburger arithmetic with a decidable uninterpreted logic, some originating many years ago [11]. We will rely on a recent logic from [3], but we will need several variations of the underlying idea here.

▶ **Definition 6.** *A* Presburger quantifier *is of the form:*

$$\mathcal{P}(x) \;:=\; \sum_{i=1}^{k} \lambda_i \cdot \#_y[\varphi_i(x,y)] \;\circledast\; \delta,$$

where $\delta \in \mathbb{Z}$; each $\lambda_i \in \mathbb{Z}$; each $\varphi_i(x,y)$ is a formula with free variables x and y; $\circledast$ is one of $=$, $\neq$, $\leq$, $\geq$, $<$, or $>$. Note that $\mathcal{P}(x)$ has one free variable x.

We give the semantics of these quantifiers inductively, assuming a semantics for $\varphi_i(x,y)$. Given a graph $\mathcal{G}$ and a vertex $v \in V$, we say that $\mathcal{P}(x)$ holds in $\mathcal{G}, x/v$, denoted by $\mathcal{G} \models \mathcal{P}(v)$, if the following (in)equality holds in $\mathbb{Z}$.

$$\sum_{i=1}^{k} \lambda_i \cdot |\{u \in V |\ \mathcal{G} \models \varphi_i(v,u)\}| \;\circledast\; \delta$$

▶ Remark 7. Note that each Presburger quantifier can be rewritten as a Boolean combination of expressions which *only use the inequality symbol $\geq$ as $\circledast$*. For example, $(\#_y[\varphi(x,y)] = \delta)$ and $(\#_y[\varphi(x,y)] \geq \delta) \wedge \neg(\#_y[\varphi(x,y)] \geq \delta + 1)$ are semantically equivalent. Therefore it is sufficient to consider Presburger quantifiers which only use the inequality symbol $\geq$.

▶ Remark 8. We will make use of Presburger quantifiers that allow for rational coefficients of the form:

$$\widetilde{\mathcal{P}}(x) \;:=\; \kappa_0 + \sum_{i=1}^{k} \kappa_i \cdot \#_y[\varphi_i(x,y)] \;\circledast\; \lambda_0 + \sum_{i=1}^{\ell} \lambda_i \cdot \#_y[\psi_i(x,y)],$$

where each $\kappa_i, \lambda_i \in \mathbb{Q}$. This is a shorthand for the Presburger quantifier:

$$\mathcal{P}(x) \;:=\; \sum_{i=1}^{k} (D\kappa_i) \cdot \#_y[\varphi_i(x,y)] + \sum_{i=1}^{\ell} (-D\lambda_i) \cdot \#_y[\psi_i(x,y)] \;\circledast\; D(\lambda_0 - \kappa_0),$$

where D is the least common multiplier of the denominators of the coefficients in $\widetilde{\mathcal{P}}(x)$.

▶ **Definition 9.** *We give the syntax of* two-variable modal logic with Presburger quantifiers (MP^2) *over vocabulary τ. Formulas will have exactly one free variable, denoted x below:*

- *$\top$ is an MP^2 formula.*
- *for a unary predicate $U \in \tau$, $U(x)$ is an MP^2 formula.*
- *if $\varphi(x)$ is an MP^2 formula, then so is $\neg\varphi(x)$.*
- *if $\varphi_1(x)$ and $\varphi_2(x)$ are MP^2 formulas, then so is $\varphi_1(x) \wedge \varphi_2(x)$.*
- *if $\{\varphi_i(x)\}_{1\le i\le k}$ is a set of MP^2 formulas and $\{\epsilon_i(x,y)\}_{1\le i\le k}$ is a set of* guard atoms*, of form $E(x,y)$, $E(y,x)$, or $\top$, then $\left(\sum_{i=1}^{k} \lambda_i \cdot \#_y[\epsilon_i(x,y) \wedge \varphi_i(y)] \;\circledast\; \delta\right)$ is also an MP^2 formula. $\{\epsilon_i(x,y)\}_{1\le i\le k}$ are the* guards *of the formula. Consistent with the restriction we announced on the logic, we consider the result as a formula with free variable x: if all ϵ_i are $\top$ it returns either every node or no node.*

The semantics of the Boolean connectives is as usual, while the semantics of the Presburger quantifiers is given by Definition 6.

An MP^2 formula $\varphi(x)$ is an n-formula if its vocabulary consists of n unary predicates. We use abbreviations $\vee$ and $\to$ as usual. Note that the guarded universal quantifier $\forall y\, E(x,y) \to \varphi(y)$ can be expressed as $(1 \cdot \#_y[E(x,y) \wedge \neg\varphi(y)] = 0)$, and the guarded existential quantifier $\exists y\, E(x,y) \wedge \varphi(y)$ can be expressed as $(1 \cdot \#_y[E(x,y) \wedge \varphi(y)] \ge 1)$.

The logic MP^2 combines Presburger arithmetic and quantification over the model. Thus one might worry that it has an undecidable satisfiability problem. And indeed, we will show this: see Theorem 29. An idea to gain decidability is to impose that the quantification is *guarded* – again, the underlying idea is from [3]. The logic $\mathcal{L}$-MP^2 (or "*local* MP^2") is obtained by excluding $\top$ as a guard. Analogously to what we did with GNNs, we use $\mathcal{L}$ to indicate that quantification is "local".

The logic $\mathcal{L}$-MP^2 is contained in the following logic, defined in [3]:

▶ **Definition 10.** *The syntax of the* guarded fragment of two-variable logic with Presburger quantifiers (GP^2) *over colored graph vocabulary τ starts with arbitrary atoms over the vocabulary, with the usual connective closure and the following rules for quantifiers:*

- *if $\varphi(x)$ is a GP^2 formula, then so are $\forall x\, \epsilon(x) \to \varphi(x)$ and $\exists x\, \epsilon(x) \wedge \varphi(x)$, where ϵ is either $U(x)$ or $x = x$ for some unary predicate $U \in \tau$.*
- *if $\varphi(x,y)$ is a GP^2 formula, then so are $\forall x\, \epsilon(x,y) \to \varphi(x,y)$ and $\exists x\, \epsilon(x,y) \wedge \varphi(x,y)$, where $\epsilon(x,y)$ is one of $E(x,y)$ or $E(y,x)$.*
- *if $\{\varphi_i(x,y)\}_{1\le i\le k}$ is a set of GP^2 formulas and $\{\epsilon_i(x,y)\}_{1\le i\le k}$ is a set of formulas, each of form $E(x,y)$ or $E(y,x)$, then $\left(\sum_{i=1}^{k} \lambda_i \cdot \#_y[\epsilon_i(x,y) \wedge \varphi_i(x,y)] \;\circledast\; \delta\right)$ is also a GP^2 formula.*

The main difference between the logic $\mathcal{L}$-MP^2 and the logic above is that the former is "modal", restricting to one-variable formulas, and allowing two variables only in the guards. While in the logic above we can build up more interesting two variable formulas, for example conjoining two guards.

We will make use of the following prior decidability result:

▶ **Theorem 11** ([3], Theorem 10). *The finite satisfiability problem of* GP^2 *is decidable.*

From this we easily derive the decidability of $\mathcal{L}$-MP^2:

▶ **Corollary 12.** *The finite satisfiability problem of* $\mathcal{L}$-MP^2 *is decidable.*

Notions of expressiveness for GNNs and MP^2 Formulas. Recalling that we have a node-to-Boolean semantics available for both logical formulas and GNNs (via thresholding), we use the term *n-specification* for either a n-GNN or a n-MP^2 formula.

▶ **Definition 13.** *If S_1, S_2 are n-GNNs, they are said to be* equivalent *if they accept the same nodes within n-graphs. If S_1 is a GNN and S_2 a node formula in some logic, we say S_1 and S_2 are equivalent if for every n-graph $\mathcal{G}$ and vertex $v \in V$, S_1 accepts $\langle \mathcal{G}, v \rangle$ if and only if $\mathcal{G}, v$ satisfies S_2.*

The notions of two languages of specifications being equally expressive, or equally expressive over undirected graphs, is defined in the obvious way:

Verification Problems for GNNs. We focus on two verification problems. The first is the most obvious analog of satisfiability for GNNs, whether it accepts some node of some graph:

▶ **Definition 14.** *For an n-GNN $\mathcal{A}$, we say that $\mathcal{A}$ is* satisfiable*, if there exist an n-graph $\mathcal{G}$ and a vertex $v \in V$, such that $\mathcal{A}$ accepts $\langle \mathcal{G}, v \rangle$.*

We will also consider a variation of the problem which asks whether a GNN accepts every node of some graph:

▶ **Definition 15.** *For an n-GNN $\mathcal{A}$, we say that $\mathcal{A}$ is* universally satisfiable*, if there exist an n-graph $\mathcal{G}$, such that for every vertex $v \in V$, $\mathcal{A}$ accepts $\langle \mathcal{G}, v \rangle$.*

Two GNNs $\mathcal{A}$ and $\mathcal{B}$ are equivalent if they accept the same tuples. Note that, like satisfiability and unlike universal satisfiability, this does not require a quantifier alternation. For brevity we will not state results for equivalence, but *it can easily be seen that both our positive and negative results on satisfiability also apply to equivalence.*

3 Characterization and decidability of GNNs with eventually constant activation functions

In this section, we only consider GNNs with eventually constant activations. In Section 3.1, we establish a key tool to analyzing these GNNs: we show that the set of possible activation values is finite, and one can compute an overapproximation of this set. We use this for two purposes. First we give a decidability result for GNNs with eventually constant activations and only local aggregation, and then we show that even with global aggregation we get an equivalence of the GNNs in expressiveness with a logic.

In Section 3.2, we show that the finite satisfiability of MP^2 is undecidable. Using the expressiveness characterization, this will imply that satisfiability problems for global GNNs are undecidable. These results were presented for GNNs and logics on directed graphs. In Section 3.3 we use the logical characterizations to show that they also apply to the standard setting for GNNs of undirected graphs.

3.1 Decidability of satisfiability problems for GNNs with eventually constant functions, via logic

We now come to one of the crucial definitions in the paper, the spectrum of a GNN.

▶ **Definition 16.** *For a $\mathcal{BGC}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$, the* ℓ-spectrum *of $\mathcal{A}$, denoted by $\mathcal{S}^\ell$, is the set $\left\{\xi^\ell(v) \middle| \text{ for every } n\text{-graph } \mathcal{G} \text{ and vertex } v \in V\right\}$.*

That is, the ℓ-spectrum is the range of the feature vectors computed at layer ℓ, as we range over all input graphs and nodes. We show that the spectrum is actually finite, and a finite superset is computable:

▶ **Theorem 17.** *For every $\mathcal{BGC}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$, the ℓ-spectrum of $\mathcal{A}$ is finite. We can compute a finite superset of the ℓ-spectrum from the specification of $\mathcal{A}$.*

We give some intuition for the proof. Our effective overapproximation of the spectrum will simulate the computation of the GNN, and will be defined inductively on the layers. Recall that a $\mathcal{BLC}$-GNN is given by dimensions $\{d_\ell\}_{0\leq\ell\leq L}$, activation functions $\left\{f^\ell\right\}_{1\leq\ell\leq L}$, coefficient matrices for transforming the prior node value $\left\{C^\ell\right\}_{1\leq\ell\leq L}$, coefficient matrices for local aggregation $\left\{A^\ell_x\right\}_{\substack{1\leq\ell\leq L\\ x\in\{\text{out},\text{in}\}}}$, coefficient matrices for global readout $\left\{R^\ell\right\}_{1\leq\ell\leq L}$, and bias vectors $\left\{b^\ell\right\}_{1\leq\ell\leq L}$.

▶ **Definition 18.** *For a $\mathcal{BLC}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$, the set $\uparrow\mathcal{S}^\ell$ is defined as follows:*

$$
\begin{aligned}
\uparrow\mathcal{S}^0 &:= \{0,1\}^{d_0}\\
\uparrow\mathcal{S}^\ell_s &:= \left\{ f^\ell\left(C^\ell s + \sum_{x\in\{out,in\}} A^\ell_x \sum_{s'\in\uparrow\mathcal{S}^{\ell-1}} s' n^{A,s'}_x + R^\ell \sum_{s'\in\uparrow\mathcal{S}^{\ell-1}} s' n^{R,s'} + b^\ell\right) \middle| \; n^{A,s'}_x, n^{R,s'} \in \mathbb{N} \right\}\\
\uparrow\mathcal{S}^\ell &:= \bigcup_{s\in\uparrow\mathcal{S}^{\ell-1}} \uparrow\mathcal{S}^\ell_s
\end{aligned}
$$

We show that the set $\uparrow\mathcal{S}^\ell$ overapproximates the ℓ-spectrum:

▶ **Lemma 19.** *For every n-$\mathcal{BLC}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$, for every n-graph $\mathcal{G}$ and vertex $v \in V$, there exists $s \in \uparrow\mathcal{S}^\ell$, such that $\xi^\ell(v) = s$.*

It is quite straightforward to see that every element of the spectrum is captured. It is an overapproximation because different integers that we sum in an inductive step may not be realized in the same graph.

We can show by induction on the number of the layers that the set is finite – regardless of computability of the activation functions!

▶ **Lemma 20.** *For every n-$\mathcal{BLC}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$, $\uparrow\mathcal{S}^\ell$ has finite size and can be computed.*

In the inductive step, we have a finite set of rationals, thus some fixed precision. We take some integer linear combinations and we will obtain an infinite set of values, but only finitely many between the left and right thresholds of the eventually constant activations. Thus when we apply the activation functions to these values, we will get a finite set of rational values – since the activation functions map rationals to rationals.

▶ Remark 21. The restriction to rational coefficients is crucial in the argument. Consider the following 1-layer 1-$\mathcal{BL}$TrReLU-GNN. The dimensions are $d_0 = d_1 = 1$; the coefficient matrix C^1 is a zero matrix; $\left(A^1_{\text{out}}\right)_{1,1} = \sqrt{2}$; $\left(A^1_{\text{in}}\right)_{1,1} = -1$; the bias vector b^1 is a zero vector. It is not difficult to see that its 1-spectrum is $\left\{\mathsf{TrReLU}\left(\sqrt{2}k_1 - k_2\right) \middle| \; k_1, k_2 \in \mathbb{N}\right\}$, whose size is infinite since $\sqrt{2}$ is irrational.

▶ Remark 22. Even simple GNNs may have exponential size spectra. For example, let $\mathcal{A}_k$ be a 1-layer 1-$\mathcal{BL}$TrReLU-GNN defined as follows: the dimensions are $d_0 = d_1 = 1$; the coefficient matrices C^1 and A^1_{in} are zero matrices; $\left(A^1_{\text{out}}\right)_{1,1} = k^{-1}$; the bias vector b^1 is a zero vector. By definition, its 1-spectrum is $\left\{ik^{-1} \middle| \; i \in [0\,, k]\right\}$, whose size is $k+1$. But the description of $\mathcal{A}_k$ is only linear in $\log k$.

For GNNs with truncated ReLU and only local aggregation, there is a matching upper bound, as discussed after Theorem 25.

We now give several applications of the spectrum result. First we can use the finiteness of the spectrum to get a characterization of the expressiveness of $\mathcal{BGC}$-GNN and logic:

▶ **Theorem 23.** *For every n-$\mathcal{BGC}$-GNN $\mathcal{A}$, there exists an n-MP^2 formula $\Psi_{\mathcal{A}}(x)$, effectively computable from the description of $\mathcal{A}$, such that $\mathcal{A}$ and $\Psi_{\mathcal{A}}(x)$ are equivalent. In the case we start with an n-$\mathcal{BLC}$-GNN, the formula we obtain is in n-$\mathcal{L}$-MP^2.*

This expressiveness equivalence will be useful in getting further decidability results, as well as separations in expressiveness, for GNNs. The idea of the proof of the theorem is that we have only finitely many elements in the overapproximation set to worry about, so we can fix each in turn and write a formula for each.

Recall that finite satisfiability of $\mathcal{L}$-MP^2 is decidable by Corollary 12. Combining this with Theorem 23 we get decidability of satisfiability for $\mathcal{BLC}$-GNN:

▶ **Theorem 24.** *The satisfiability problem for $\mathcal{BLC}$-GNNs is decidable.*

A more realistic analysis of complexity requires stronger assumptions on the activation functions. For now we note only one special case, where everything is a truncated ReLU:

▶ **Theorem 25.** *For $\mathcal{BLC}$-GNNs with truncated* ReLU *activations, the satisfiability problem is* PSPACE*-complete. It is* NP*-complete when the number of layers is fixed.*

We briefly discuss the PSPACE upper bound argument. We can show that for an arbitrary input graph, there are only exponentially many activation values, each representable with a polynomial number of bits. We also show, via an "unravelling construction", a common technique use in analysis of modal and guarded logics [12, 7], that a satisfying model can be taken to be a tree of polynomial depth and branching. These two facts immediately give an elementary bound, since we could guess the tree and the activation values. We can improve to PSPACE by exploring a satisfying tree-like model on-the-fly: again, this is in line with the PSPACE algorithm for modal logic [12].

The PSPACE lower bound is established by embedding the description logic $\mathcal{ALC}$ into $\mathcal{L}$-MP^2. PSPACE-hardness will follow from this, since concept satisfiability problem of $\mathcal{ALC}$ with one role is PSPACE-hard [15]. The NP upper bound will use the same on-the-fly algorithm as in the PSPACE case, just observing that for fixed depth it can be implemented in NP. A direct encoding of SAT gives the lower bound.

The following converse to Theorem 23 shows that the logic is equally expressive as the GNN model:

▶ **Theorem 26.** *For every n-MP^2 formula $\Psi(x)$, there exists an n-$\mathcal{BGC}$TrReLU-GNN $\mathcal{A}_\Psi$, such that $\Psi(x)$ and $\mathcal{A}_\Psi$ are equivalent. If we start with an n-$\mathcal{L}$-MP^2 formula, we obtain an n-$\mathcal{BLC}$TrReLU-GNN.*

The idea of the proof is induction on the formula structure. For each subformula there will be an entry of a feature vector for the GNN which represents the subformula, in the sense that – for the final layer – its value is 1 if the subformula holds, or 0 otherwise. We will have an entry for each subformula at every iteration, but as we progress to later layers of the GNN, more of these entries will be correct with respect to the corresponding subformula. In an inductive case for a Presburger quantifier that uses some coefficients λ_i, the corresponding matrix will be multiplying certain quantifies by λ_i. Note that this translation is polynomial time, thus the size of the corresponding GNN is polynomial in the formula.

Putting together the two translation results, we have:

▶ **Corollary 27.** *The logic MP^2 and $\mathcal{BGC}$-GNNs are expressively equivalent, as are $\mathcal{L}$-MP^2 and $\mathcal{BLC}$-GNNs.*

The translations also tell us that *the expressiveness of GNNs with truncated* ReLU *is the same as that of GNNs with arbitrary eventually constant activations* – provided we use the Boolean semantics based on thresholds.

Recall from Corollary 12 that finite satisfiability for the richer logic GP^2, allowing unguarded unary quantification and containing $\mathcal{L}$-MP^2, is decidable. Using this and the expressiveness characterization gives decidability of universal satisfiability for these GNNs:

▶ **Theorem 28.** *The universal satisfiability problem of $\mathcal{BLC}$-GNNs is decidable.*

3.2 Undecidability of MP^2, and of GNNs with truncated ReLU and global readout

Note that we claimed that the spectrum is finite for GNNs with eventually constant activations, even when they have global readout. And we could compute a finite overapproximation of the spectrum. But in our decidability argument for $\mathcal{BLC}$-GNN, we required further the ability to decide membership in the spectrum for any fixed rational, and for this we utilized decidability of the logic. So what happens to decidability of the GNNs – or the corresponding logic – when global readout is allowed? We show undecidability of finite satisfiability for the logic MP^2, and of the corresponding GNN satisfiability problem. First for the logic:

▶ **Theorem 29.** *The finite satisfiability problem of MP^2 is undecidable.*

For the proof we apply an approach based on ideas in [3], using a reduction from Hilbert's tenth problem.

▶ **Definition 30.** *A* simple equation system *ε (with n variables and m equations) is a set of m equations of one of the forms $v_{i_1} = 1$, $v_{i_1} = v_{i_2} + v_{i_3}$, or $v_{i_1} = v_{i_2} \cdot v_{i_3}$, where $1 \leq i_1, i_2, i_3 \leq n$. We say the system ε is solvable if it has a solution in $\mathbb{N}$.*

▶ **Lemma 31.** *For every simple equation system ε with n variables and m equations, there exists an $(n+m)$- MP^2 formula $\Psi_\varepsilon(x)$ such that ε has a solution in $\mathbb{N}$ if and only if $\Psi_\varepsilon(x)$ is finitely satisfiable.*

Since the solvability (over $\mathbb{N}$) of simple equation systems is undecidable, Theorem 29 follows. From the theorem and Corollary 27 we obtain undecidability of static analysis for GNNs with global readout:

▶ **Theorem 32.** *The satisfiability problem of $\mathcal{BG}$TrReLU-GNNs is undecidable.*

We give the reduction used in Lemma 31, leaving the verification for the reader. The vocabulary of the constructed formulas $\Psi_\varepsilon(x)$, where ϵ is the simple equation system, consists of unary predicates P_i and U_j, where $1 \leq i \leq m$ and $1 \leq j \leq n$. For $1 \leq i \leq m$, we define $\varphi_i(x)$ depending on the i^{th} equation in ε.

- If the equation is $v_j = 1$, then $\varphi_i(x) := (\#_y[P_i(y) \wedge U_j(y)] = 1)$.
- If the equation is $v_{j_1} = v_{j_2} + v_{j_3}$, then $\varphi_i(x) := (\#_y[\psi_i(y)] - \#_y[\top] = 0)$ where

$$\begin{aligned}\psi_i(y) \;:=\; & (P_i(y) \wedge (U_{j_2}(y) \vee U_{j_3}(y)) \rightarrow (\#_x[E(y,x) \wedge P_i(x) \wedge U_{j_1}(x)] = 1)) \;\wedge \\ & (P_i(y) \wedge U_{j_1}(y) \rightarrow (\#_x[E(x,y) \wedge P_i(x) \wedge (U_{j_2}(x) \vee U_{j_3}(x))] = 1))\,.\end{aligned}$$

- If the equation is $v_{j_1} = v_{j_2} \cdot v_{j_3}$, then $\varphi_i(x) := (\#_y[\psi_i(y)] - \#_y[\top] = 0)$ where

$$\begin{aligned}\psi_i(y) \;:=\; & (P_i(y) \wedge U_{j_2}(y) \rightarrow (\#_x[E(y,x) \wedge P_i(x) \wedge U_{j_1}(x)] - \#_x[P_i(x) \wedge U_{j_3}(x)] = 0)) \;\wedge \\ & (P_i(y) \wedge U_{j_1}(y) \rightarrow (\#_x[E(x,y) \wedge P_i(x) \wedge U_{j_2}(x)] = 1))\,.\end{aligned}$$

We now define $\Psi_\varepsilon(x)$:

$$\begin{aligned}\psi^{disj}(x) \;&:=\; \bigwedge_{1 \leq i_1 < i_2 \leq m} (\#_y[P_{i_1}(y) \wedge P_{i_2}(y)] = 0) \;\wedge \bigwedge_{1 \leq j_1 < j_2 \leq n} (\#_y[U_{j_1}(y) \wedge U_{j_1}(y)] = 0) \\ \psi^{eq}(x) \;&:=\; \bigwedge_{\substack{1 \leq i_1 < i_2 \leq m \\ 1 \leq j \leq n}} (\#_y[P_{i_1}(y) \wedge U_j(y)] - \#_y[P_{i_2}(y) \wedge U_j(y)] = 0) \\ \Psi_\varepsilon(x) \;&:=\; \psi^{disj}(x) \wedge \psi^{eq}(x) \wedge \bigwedge_{1 \leq i \leq m} \varphi_i(x).\end{aligned}$$

Using a similar reduction, we obtain undecidability for universal satisfiability:

▶ **Theorem 33.** *The universal satisfiability problem of $\mathcal{BG}$TrReLU-GNNs is undecidable.*

3.3 Variations for the undirected case

Thus far we have been dealing with both logics and GNNs that work over directed graphs. We now show that all of the prior results apply to undirected graphs, the standard setting for GNNs.

We can enforce undirectedness within the larger decidable logic GP^2 to obtain decidability:

▶ **Corollary 34.** *The finite satisfiability problem of $\mathcal{L}$-MP^2 over undirected graphs is decidable.*

By reducing to decidability in the logic $\mathcal{L}$-MP^2, we can show that the satisfiability problem for GNNs on undirected graphs – that is, the standard notion of GNN – is decidable.

▶ **Theorem 35.** *The satisfiability problem of $\mathcal{BLC}$-GNNs over undirected graphs is decidable.*

▶ **Theorem 36.** *The universal satisfiability problem of $\mathcal{BLC}$-GNNs over undirected graphs is decidable.*

We can also revise our undecidability results for global GNNs to the undirected case, thus giving undecidability for the usual notion of GNN with global readout. This is done with the same reduction from solvability of simple equation systems to the finite satisfiability of MP^2, which we can show works over undirected graphs.

▶ **Theorem 37.** *The finite satisfiability problem of* MP^2 *over undirected graphs is undecidable.*

▶ **Theorem 38.** *The satisfiability problem of* $\mathcal{BG}$TrReLU-GNN*s over undirected graphs is undecidable.*

▶ **Theorem 39.** *The universal satisfiability problem of* $\mathcal{BG}$TrReLU-GNN*s over undirected graphs is undecidable.*

4 GNNs with unbounded activation functions

In this section, we consider GNNs with unbounded activations, such as the standard ReLU. Since we have already shown that global aggregation leads to undecidability even in the bounded case, in this section *we will only deal with GNNs having only local aggregation*. In Section 4.1 we show that the universal satisfiability problem of $\mathcal{BL}$ReLU-GNN is undecidable, a contrast to the case with eventually constant activation functions. In the process, we introduce a logic that also helps with understanding expressiveness of this class of GNNs.

In Section 4.2, we turn to the satisfiability problem, and give a partial positive result about decidability. Here we will not use the logic directly, but rather use components from decidability proofs for Presburger logics [3]. We will use the idea of representing the possible values of activations which was also used in the case of decidability for eventually constant activations. But in this case we will be representing an infinite set of values, using Presburger formulas.

4.1 (Un)decidability of GNNs with unbounded activation functions

We prove the undecidability of the universal satisfiability problem of $\mathcal{BL}$ReLU-GNN. Here we will use logic again. We will not obtain an expressiveness characterization, but merely a logic that embeds in $\mathcal{BL}$ReLU-GNNs: local two-variable modal logic with two-hop Presburger quantifiers ($\mathcal{L}$-M2P^2), which is the extension of MP^2 where the guards are conjunctions of at most two binary predicates.

▶ **Definition 40.** *The syntax of* local two-variable modal logic with two-hop Presburger quantifiers ($\mathcal{L}$-M2P^2) *over vocabulary* τ *is defined inductively:*

- $\top$ *is a* $\mathcal{L}$-M2P^2 *formula.*
- *for a unary predicate* $U \in \tau$, $U(x)$ *is a* $\mathcal{L}$-M2P^2 *formula.*
- *if* $\varphi(x)$ *is a* $\mathcal{L}$-M2P^2 *formula, then so is* $\neg\varphi(x)$.
- *if* $\varphi_1(x)$ *and* $\varphi_2(x)$ *are* $\mathcal{L}$-M2P^2 *formulas, then so is* $\varphi_1(x) \wedge \varphi_2(x)$.
- *if* $\{\varphi_i(x)\}_{1\leq i\leq k} \cup \{\varphi'_i(x)\}_{1\leq i\leq k'}$ *is a set of* $\mathcal{L}$-M2P^2 *formulas,* $\{\epsilon_i(x,z,y)\}_{1\leq i\leq k}$ *is a set of guard formulas, each of form* $E(x,z) \wedge E(z,y)$, $E(x,z) \wedge E(y,z)$, $E(z,x) \wedge E(z,y)$, *or* $E(z,x) \wedge E(y,z)$, *and* $\{\epsilon'_i(x,y)\}_{1\leq i\leq k'}$ *is another set of guard formulas, each of form* $E(x,y)$ *or* $E(y,x)$, *then*
  $\left(\sum_{i=1}^{k} \lambda_i \cdot \#_{z,y}[\epsilon_i(x,z,y) \wedge \varphi_i(y)] + \sum_{i=1}^{k'} \lambda'_i \cdot \#_y[\epsilon'_i(x,y) \wedge \varphi'_i(y)] \circledast \delta\right)$
  is also a $\mathcal{L}$-M2P^2 *formula. The numbers* $\delta, \lambda_i, \lambda'_i$, *and the comparison* $\circledast$ *are as in the standard Presburger quantifier definition.*

The idea is that we can still count a linear combination of cardinalities of the number of nodes satisfying a given lower-level formula that are one-hop away from the current node – as in $\mathcal{L}$-MP^2. Optionally, we can add on a linear combination of the number of two-hop paths that lead to a node satisfying other lower-level formulas.

The semantics of the formulas is given inductively, with the only step that is different from the usual cases being for the quantification, which is the obvious one. We call these *two-hop Presburger quantifiers*. We can apply a similar proof technique as in Theorem 26 to show that the $\mathcal{L}$-M2P^2 are expressible using $\mathcal{BL}$ReLU-GNNs.

▶ **Theorem 41.** *For every n-$\mathcal{L}$-M2P^2 formula $\Psi(x)$, there exists an n-$\mathcal{BL}$ReLU-GNN $\mathcal{A}_\Psi$, such that $\Psi(x)$ and $\mathcal{A}_\Psi$ are equivalent.*

Note that we do not claim an expressive equivalence here. Nevertheless this containment of the logic in the GNN class is useful, since we can show undecidability of the logic by reduction from the halting problem of two-counter machines, which is known to be undecidable [13].

▶ **Definition 42.** *A* two-counter machine *$\mathcal{M}$ is a finite list $d_1 \dots d_n$ of instructions having one of the forms* `INC` (c_i), `IF` $(c_i = 0)$ `GOTO` (j), *or* `HALT`, *where $i \in \{0, 1\}$ and $1 \leq j \leq n$.*

A configuration *is a tuple $\langle q, c_0, c_1\rangle$, where $1 \leq q \leq n$ and $c_0, c_1 \in \mathbb{N}$. We say $\langle q', c_0', c_1'\rangle$ is the* successor configuration *of $\langle q, c_0, c_1\rangle$ if, letting d_q be the q^{th} instruction of the machine:*

- *If d_q is* `INC` (c_i), *then $q' = q + 1$, $c_i' = c_i + 1$, and $c_{1-i}' = c_{1-i}$.*
- *If d_q is* `IF` $(c_i = 0)$ `GOTO` (j), *if $c_i = 0$, then $q' = j$, $c_0' = c_0$, and $c_1' = c_1$; otherwise, $q' = q + 1$, $c_i' = c_i - 1$, and $c_{1-i}' = c_{1-i}$.*

Note that if d_q is `HALT`, *there is no successor. This configuration is called a halting configuration.*

The computation *of the machine is a (possibly infinite) sequence of configurations where the first is $\langle 1, 0, 0\rangle$, consecutive pairs are in the succcessor relationship above, the last configuration is a halting configuration. The machine* halts *if its computation is a finite sequence.*

The reduction is by encoding the computation of a two-counter machine into the graph directly. We have illustrated it in Figure 1. Each configuration is encoded as a height 1 tree, which is denoted by a dashed box. Its line number is represented by the unary predicate Q_i realized by the root vertex, and the values of the counters are represented by the number of "labeled leaves" – those with predicate C_0 or C_1 being true. There are edges connected to the roots of each configuration, which encode the computation sequence. Then it is possible to assert the (in)equality between the number of leaves of some root and the root of the successor tree, which encodes the condition of a valid transition.

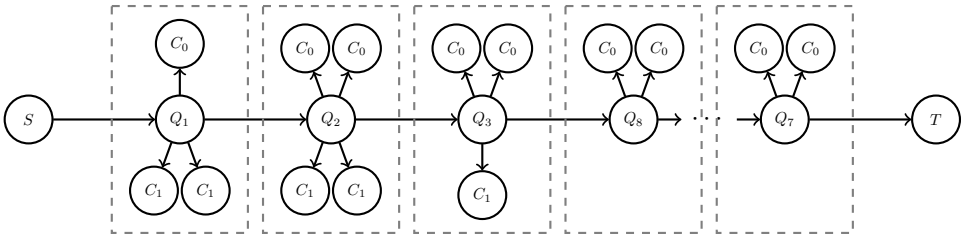

Figure 1 An example of the encoding of the computation of the two-counter machines to directed graphs.

▶ **Lemma 43.** *For every two-counter machine $\mathcal{M}$ with n instructions, there exists an $(n + 5)$-$\mathcal{L}$-M2P^2 formula $\Psi_\mathcal{M}(x)$ such that $\mathcal{M}$ halts if and only if $\forall x\ \Psi_\mathcal{M}(x)$ is finitely satisfiable.*

Since the halting problem of two-counter machines is undecidable, and $\mathcal{L}$-M2P^2 formulas can be translted to $\mathcal{BL}$ReLU-GNNs, we obtain the undecidability of the universal satisfibility problem of $\mathcal{BL}$ReLU-GNN, by reduction from $\mathcal{L}$-M2P^2.

▶ **Theorem 44.** *The universal satisfiability problem of* $\mathcal{BL}$ReLU-GNN*s is undecidable.*

We will later show that this holds also for undirected graphs: see Theorem 52 below.

We can also use the logic to get an expressiveness separation for GNNs: By Theorem 41 to show that $\mathcal{BL}$ReLU-GNNs can do more than $\mathcal{BLC}$-GNNs, it is sufficient to show that there is a $\mathcal{L}$-M2P^2 formula that is not given by a $\mathcal{BLC}$-GNN:

▶ **Lemma 45.** $\mathcal{L}$-M2P^2 *is strictly more expressive than* $\mathcal{BLC}$-GNN*.*

The following results are direct consequences of the lemma above and the logical characterization in the prior section:

▶ **Corollary 46.** $\mathcal{L}$-M2P^2 *is strictly more expressive than* $\mathcal{L}$-MP^2*.*

▶ **Corollary 47.** $\mathcal{BL}$ReLU-GNN *is strictly more expressive than* $\mathcal{BLC}$-GNN*.*

We comment on the proof of Lemma 45. We claim that the property "the number of two-hop paths from the vertex v to the green vertices is the same as the number of two-hop paths from v to the blue vertices" gives the separation. It is easy to express in the two-hop logic. To show that no $\mathcal{BLC}$-GNN can express it, we construct a sequence of pairs of graphs, each with a special node, such that the property holds in the special node of the first graph and fails in the special node of the second, while for every $\mathcal{BLC}$-GNN $\mathcal{A}$, for any sufficiently large pairs of graphs in this sequence, the special nodes are indistinguishable by $\mathcal{A}$. The graphs are as follows:

▶ **Definition 48.** *For* $n_1, n_2 \in \mathbb{N}$*, the* (n_1, n_2)-bipolar graph $\langle V, E, U_1, U_2 \rangle$ *is an undirected* 2*-graph defined as follows.*

$$
\begin{aligned}
U_1 &:= \{v_{1,i} |\ 1 \leq i \leq n_1\} \\
U_2 &:= \{v_{2,i} |\ 1 \leq i \leq n_2\} \\
V &:= U_1 \cup U_2 \cup \{v_0, v_1, v_2\} \\
\widetilde{E} &:= \{(v_0, v_1), (v_0, v_2)\} \cup \{(v_1, v_{1,i}) |\ 1 \leq i \leq n_1\} \cup \{(v_2, v_{2,i}) |\ 1 \leq i \leq n_2\} \\
E &:= \widetilde{E} \cup \left\{ (u, v) \,\middle|\, (v, u) \in \widetilde{E} \right\}
\end{aligned}
$$

See Figure 2.

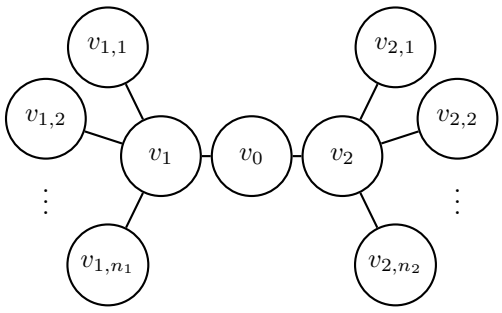

Figure 2 (n_1, n_2)-bipolar graph.

It is easy to see that these graphs with the distinguished nodes v_0 and v_0' disagree on the property, and we can also show that eventually no $\mathcal{BLC}$-GNN can distinguish them:

▶ **Lemma 49.** *For each 2-$\mathcal{BLC}$-GNN $\mathcal{A}$, there exist a threshold $n_{\mathcal{A}} \in \mathbb{N}$, such that for every $n_1, n_2 \geq n_{\mathcal{A}}$, the following properties hold. Let $\mathcal{G}$ be the $(n_{\mathcal{A}}, n_{\mathcal{A}})$-bipolar graph and $\mathcal{G}'$ be the (n_1, n_2)-bipolar graph. For every $0 \leq \ell \leq L$,*

- $\xi^{\ell}_{\mathcal{G}}(v_0) = \xi^{\ell}_{\mathcal{G}'}(v'_0)$, $\xi^{\ell}_{\mathcal{G}}(v_1) = \xi^{\ell}_{\mathcal{G}'}(v'_1)$, *and* $\xi^{\ell}_{\mathcal{G}}(v_2) = \xi^{\ell}_{\mathcal{G}'}(v'_2)$.
- *for* $1 \leq i \leq n_{\mathcal{A}}$ *and* $1 \leq j \leq n_1$, $\xi^{\ell}_{\mathcal{G}}(v_{1,1}) = \xi^{\ell}_{\mathcal{G}}(v_{1,i}) = \xi^{\ell}_{\mathcal{G}'}(v'_{1,j})$.
- *for* $1 \leq i \leq n_{\mathcal{A}}$ *and* $1 \leq j \leq n_2$, $\xi^{\ell}_{\mathcal{G}}(v_{2,1}) = \xi^{\ell}_{\mathcal{G}}(v_{2,i}) = \xi^{\ell}_{\mathcal{G}'}(v'_{2,j})$.

Above $\xi^{\ell}_{\mathcal{G}}$ refers to the ℓ^{th} derived feature function of the GNN $\mathcal{A}$ over the graph $\mathcal{G}$.

Thus far the results in this section are stated for directed graphs. We explain briefly why the undecidability and expressiveness separation results on GNNs with unbounded activation functions apply also to undirected graphs. For the expressiveness results, note that the graphs that we constructed in the proof of Lemma 45 are undirected. Hence the expressiveness gap between $\mathcal{BL}$ReLU-GNN and $\mathcal{BLC}$-GNN still exists for the undirected case.

▶ **Theorem 50.** *$\mathcal{BL}$ReLU-GNN is strictly more expressive over undirected graphs than $\mathcal{BLC}$-GNN.*

To obtain the undecidability of the universal satisfiability problem over undirected graphs of $\mathcal{BL}$ReLU-GNN, we again reduce from two-counter machines, but now with a modification to guarantee the direction of the transition.

▶ **Lemma 51.** *For every two-counter machine $\mathcal{M}$ with n instructions, there exists an $(n+8)$-$\mathcal{L}$-M2P^2 formula $\Psi_{\mathcal{M}}(x)$ such that $\mathcal{M}$ halts if and only if $\forall x\ \Psi_{\mathcal{M}}(x)$ is finitely satisfiable over undirected graphs.*

We cannot apply the exact encoding from Figure 1 and Lemma 43 here, because in that encoding we distinguished the predecessor and successor configurations by the direction of edges. Here, we sketch the trick that overcomes the lack of direction in the edges. We will utilize the predicates from the proof of Lemma 43: in particular we will have a predicate Q and an associated notion of Q vertex as in that proof.

We introduce three fresh unary predicates I_0, I_1, and I_2 to label the configuration's index modulo 3. We add an extra clause to the formula to guarantee that each element has exactly one of these three index labels. The elements in each 1-level tree will have the same index, in the sense of satisfying the same index predicates. Finally, for each Q vertex v with index i, there exists at most one Q vertex v' with index $(i+1 \bmod 3)$, such that v and v' are connected; there exists at most one Q vertex v'' with index $(i-1 \bmod 3)$, such that v and v' are connected. Therefore we can modify the formula which identifies the successor and predecessor based on the index, rather than the direction of the edges, and show that the two-counter machine halts if and only if the modified formula is finitely satisfiable over undirected graphs.

▶ **Theorem 52.** *The universal satisfiability problem of $\mathcal{BL}$ReLU-GNNs over undirected graphs is undecidable.*

4.2 Decidability of satisfiability for "modal" GNNs with unbounded activation functions

Thus the situation for universal satisfiability contrasts with the eventually constant case. What about the *satisfiability problem*? We do not know whether it is decidable for GNNs with piecewise linear activations, or even with just ReLU. We can see that even simple unbounded activation functions produce unbounded spectra, so the proof technique in the truncated case certainly will not work. For example, consider the following 1-layer 1-$\mathcal{BL}$ReLU-GNN.

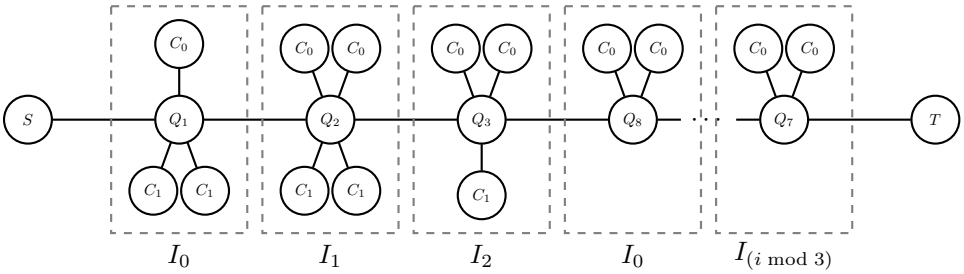

Figure 3 An example of the encoding of the computation of a two-counter machines in undirected graphs.

The dimensions are $d_0 = d_1 = 1$; the coefficient matrices C^1 and A^1_{in} are zero matrices; $\left(A^1_{\text{out}}\right)_{1,1} = 1$; the bias vector b^1 is a zero vector. It is not difficult to see that the value of $\xi^1_1(v)$ is the number of out-neighbors of v. Hence, the 1-spectrum of this GNN is the set of natural numbers.

We present a decidability result for the "modal version": aggregation over nodes connected by outgoing edges only, within a directed graph:

▶ **Theorem 53.** *The satisfiability problem of $\mathcal{OLPW}$-GNNs is decidable.*

Analogously to what we did in the eventually constant case, we describe all the possible values of a given activation function. Unlike in the eventually constant case, this will not be a finite set, but it will be *semi-linear*: that is, describable using a formula of Presburger arithmetic. We will first review the notion of semi-linear set that we use, where we modify the standard notion to deal with rational numbers. We then show that the set of all possible values output by a GNN is a semi-linear set.

For $a_0 \in \mathbb{Q}^k$ and $A = \{a_1, a_2, \ldots, a_m\}$ a finite subset of $\mathbb{Q}^k$, we define:

$$\mathbb{N}\text{-}\mathsf{Span}(a_0, A) := \left\{ a_0 + \sum_{1 \le i \le m} n_i a_i \;\middle|\; n_i \in \mathbb{N} \right\}.$$

A set $S \subseteq \mathbb{Q}^k$ is a *linear set*, if there is $a_0 \in \mathbb{Q}^k$ and a finite set $A \subseteq \mathbb{Q}^k$, such that S is $\mathbb{N}\text{-}\mathsf{Span}(a_0, A)$. The pair (a_0, A) is called *the basis of* S. A *semi-linear set* is a finite union of linear sets. A basis of a semi-linear set $\bigcup_{1 \le i \le k} \mathbb{N}\text{-}\mathsf{Span}\left(a^k_0, A^k\right)$ is the set $\left\{\left(a^1_0, A^1\right), \left(a^2_0, A^2\right), \ldots, \left(a^k_0, A^k\right)\right\}$.

For semi-linear sets $S_1, S_2, S \subseteq \mathbb{Q}^k$, we use the following operators:

$$T(S) := \{T(a) |\ a \in S\} \qquad \text{where } T : \mathbb{Q}^k \to \mathbb{Q}^m \text{ is an affine transformation}$$

$$\mathsf{KleeneStar}(S) := \left\{ \sum_{s \in S'} s \;\middle|\; \text{For every finite multi-subset } S' \text{ of } S \right\}$$

We recall that in the context of integers, both operators are known to preserve semi-linearity and the basis of the resulting semi-linear set can be computed. See, e.g., [5, 10, 6]. The arguments adapt easily to our rational setting, thus *we assume below that we have an algorithm for pushing semi-linear representations through these operators.*

We consider piecewise linear functions, defined by a sequence $((I_1, f_1), \ldots, (I_p, f_p))$ where $I_1 \cup \cdots \cup I_p$ is a partition of $\mathbb{Q}$ into p intervals and each $f_i : \mathbb{Q} \to \mathbb{Q}$ is an affine function. The sequence $((I_1, f_1), \ldots, (I_p, f_p))$ defines a function where x is mapped to $f_i(x)$ if x is in

the interval I_i. We apply a piecewise linear function on some fixed components of a vector, which is captured by the following notation. For a piecewise linear function $f : \mathbb{Q} \to \mathbb{Q}$, a rational vector $a \in \mathbb{Q}^k$ and $K \subseteq [1, k]$, we write $f_K(a)$ to denote the vector $b \in \mathbb{Q}^k$ where $b_i = f(a_i)$ for every $i \in K$ and $b_i = a_i$ for every $i \notin K$. In other words, $f_K(a)$ only applies the function f on the components in K and the identity function on the components outside K. Similar to affine transformation and Kleene star, *piecewise linear functions also preserve semi-linearity and the basis of the resulting semi-linear sets can be computed.* Again, we can easily adapt the argument in [6] to our rational setting.

To prove Theorem 53, we need two more definitions. Let $\mathcal{A}$ be a L-layer $\mathcal{OLPW}$-GNN. Let $d_0, d_1, \ldots, d_L$ be the dimension of the layers. We denote by $\mathbb{Q}^{[d_0,d_1,\ldots,d_{\ell-1}]}$ the Cartesian product $\mathbb{Q}^{d_0} \times \mathbb{Q}^{d_1} \ldots \times \mathbb{Q}^{d_{\ell-1}}$. Given an element m of this product, the i^{th} component of m, denoted by $m[i]$, is the projection of m to $\mathbb{Q}^{d_i}$.

For a graph $\mathcal{G}$, vertex $v \in V$, and $0 \leq \ell \leq L$, the *ℓ-history of v in $\mathcal{G}$* (w.r.t. $\mathcal{A}$), denoted by $\mathsf{hist}^{\ell}_{\mathcal{G}}(v) \in \mathbb{Q}^{[d_0,d_1,\ldots,d_\ell]}$, is the tuple that collects the first $(\ell+1)$ feature vectors of v. Formally, for $0 \leq i \leq \ell$, $\left(\mathsf{hist}^{\ell}_{\mathcal{G}}(v)\right)[i] = \xi^i_{\mathcal{G}}(v)$. When the graph $\mathcal{G}$ is clear from the context, we omit it and simply write $\mathsf{hist}^{\ell}(v)$. The *ℓ-history-space* of $\mathcal{A}$ is the set of all possible histories.

We now state our representation theorem, which immediately implies Theorem 53:

▶ **Theorem 54.** *For every $\mathcal{OLPW}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$, the ℓ-history-space is semi-linear, and its basis can be effectively computed.*

We contrast the theorem with Theorem 17. There we could only overapproximate the spectrum, because we could not determine which numbers from previously layers were simultaneously realizable. By inductively maintaining the entire history at each node, we have enough information to resolve these questions of consistency, and compute an *exact* representation of the semantic object, not just an overapproximation.

The rest of this section is devoted to the proof of Theorem 54. We will first explain the intuition behind it. Let $\mathcal{A}$ be a L-layer $\mathcal{OLPW}$-GNN, as in Definition 2. Let $\mathcal{G}$ be a graph and v be a vertex. Recall that for every $1 \leq \ell \leq L$, the ℓ-feature vector of v is:

$$\xi^{\ell}(v) \;:=\; f^{\ell}\left(C^{\ell}\xi^{\ell-1}(v) + A^{\ell}_{\text{out}} \sum_{u \in \mathcal{N}_{\text{out}}(v)} \xi^{\ell-1}(u) + b^{\ell}\right).$$

We can rewrite it in terms of history:

$$\mathsf{hist}^{\ell}(v)[0] \;= \xi^0(v), \tag{1}$$

and for each $1 \leq i \leq \ell$:

$$\mathsf{hist}^{\ell}(v)[i] \;= f^i\left(C^i \cdot \mathsf{hist}^{\ell}(v)[i-1] \;+\; A^i_{\text{out}} \cdot \left(\sum_{u \in \mathcal{N}_{\text{out}}(v)} \mathsf{hist}^{\ell-1}(u)\right)[i-1] \;+\; b^i\right). \tag{2}$$

Thus, the ℓ-history of v can be computed by applications of sum, affine transformations, and piecewise linear functions on the sum of the history of its out-neighbors.

We formalise this intuition in the following paragraphs. For each $0 \leq \ell \leq L$, we define the set $\mathcal{H}^{\ell}$:

$$\mathcal{H}^0 \;:=\; \{0,1\}^{d_0}$$
$$\mathcal{H}^{\ell} \;:=\; \bigcup_{e \in \{0,1\}^{d_0}} \mathsf{proj}_{\ell} \circ T_{\ell} \circ T_{\ell-1} \circ \ldots \circ T_{0,e} \circ \mathsf{KleeneStar}\left(\mathcal{H}^{\ell-1}\right),$$

where the definition and intuition of each $\mathsf{proj}_{\ell}, T_{\ell}, \ldots, T_1, T_{0,e}$ is as follows.

- Intuitively $\mathsf{KleeneStar}\left(\mathcal{H}^{\ell-1}\right)$ captures the term $\sum_{u\in\mathcal{N}_{\text{out}}(v)} \mathsf{hist}^{\ell-1}(u)$ in Equation (2).
- $T_{0,e} : \mathbb{Q}^{[d_0,\ldots,d_{\ell-1}]} \to \mathbb{Q}^{[d_0,\ldots,d_{\ell-1},d_0]}$ is an affine transformation that maps a to (a, e), i.e., it simply "pads" e into a.
- For each $1 \leq i \leq \ell$, the transformation $T_i : \mathbb{Q}^{[d_0,\ldots,d_{\ell-1},d_0,\ldots,d_{i-1}]} \to \mathbb{Q}^{[d_0,\ldots,d_{\ell-1},d_0,\ldots,d_{i-1},d_i]}$ computes the vector $\mathsf{hist}^{\ell}(v)[i]$ defined in Equation (2) and pads it at the end. Formally, T_i maps a to (a, c) where $c = f^i\left(C^i a[\ell+i-1] + A^i_{\text{out}} a[i-1] + b^i\right)$.
- Finally, $\mathsf{proj}_\ell : \mathbb{Q}^{[d_0,\ldots,d_{\ell-1},d_0,\ldots,d_\ell]} \to \mathbb{Q}^{[d_0,\ldots,d_\ell]}$ is a projection that projects out the first ℓ components.

We can show that $\mathcal{H}^\ell$ is a semi-linear set, and this captures the ℓ-history-space, as stated formally in Lemma 55. Note that Theorem 53 follows easily from the lemma and the computability of the basis of $\mathcal{H}^\ell$.

▶ **Lemma 55.** *For every $\mathcal{OLPW}$-GNN $\mathcal{A}$ and $0 \leq \ell \leq L$,*

1. *$\mathcal{H}^\ell$ is a semi-linear set.*
2. *For every $s \in \mathbb{Q}^{[d_0,d_1,\ldots,d_\ell]}$, the following are equivalent.*
   - *$h \in \mathcal{H}^\ell$*
   - *There exists a graph $\mathcal{G}$ and vertex $v \in V$ such that $\mathsf{hist}^{\ell}(v) = h$.*

Proof. The first item follows immediately from the fact that $\mathcal{H}^0$ is semi-linear and the operators Kleene star, affine transformations and piecewise linear functions all preserve semi-linearity.

We now prove the second item by induction on ℓ. The base case $\ell = 0$ is trivial.

For the induction hypothesis, we assume that the lemma holds for $\ell - 1$. We show that $h \in \mathcal{H}^\ell$ if and only if there is a graph $\mathcal{G}$ and a vertex v such that $\mathsf{hist}^{\ell}(v) = h$.

We start with the "only if" direction. Suppose $h \in \mathcal{H}^\ell$. By definition, there is $e \in \{0,1\}^{d_0}$ and a finite multi-subset $\{\{h_1, h_2, \ldots, h_k\}\}$ of $\mathcal{H}^{\ell-1}$ such that:

$$h = \mathsf{proj}_\ell \circ T_\ell \circ T_{\ell-1} \circ \ldots \circ T_{0,e}\left(h_1 + h_2 + \cdots + h_k\right)$$

By the induction hypothesis, there exist graphs $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_k$ and vertices $v_1, v_2, \ldots, v_k$ such that $\mathsf{hist}^{\ell-1}_{\mathcal{G}_i}(v_i) = h_i$ for every $1 \leq i \leq k$.

Let $\mathcal{G}$ be the graph obtained by taking the disjoint union of $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_k$ and adding a fresh vertex v. Recalling that $\xi^0_{\mathcal{G}}(v)$ can achieve an arbitrary combination of $\{0,1\}$ vectors, based on the colors of v, we set the colors so that $\xi^0_{\mathcal{G}}(v) = e$. We have an outgoing edge from v to v_i for each $1 \leq i \leq k$. It is routine to verify that the ℓ-history of v is precisely h. Note that *because $\mathcal{A}$ is outgoing-only, the edge from v to v_i has no effect on the $(\ell-1)$-history of v_i*. Thus $\mathsf{hist}^{\ell-1}_{\mathcal{G}}(v_i) = \mathsf{hist}^{\ell-1}_{\mathcal{G}_i}(v_i)$

For the "if" direction, let $\mathcal{G}$ be a graph and v be a vertex. Let $v_1, \ldots, v_k$ be the out-neighbors of v. By definition, for each $1 \leq i \leq \ell$:

$$\mathsf{hist}^{\ell}_{\mathcal{G}}(v)[i] \;=\; f^i\left(C^i \cdot \mathsf{hist}^{\ell}_{\mathcal{G}}(v)[i-1] \;+\; A^i_{\text{out}} \cdot \left(\sum_{u\in\mathcal{N}_{\text{out}}(v)} \mathsf{hist}^{\ell-1}_{\mathcal{G}}(u)\right)[i-1] \;+\; b^i\right).$$

It is routine to verify that:

$$\mathsf{hist}^{\ell}_{\mathcal{G}}(v) \;=\; \mathsf{proj}_\ell \circ T_\ell \circ T_{\ell-1} \circ \ldots \circ T_{0,e}\left(\mathsf{hist}^{\ell-1}_{\mathcal{G}}(v_1) + \mathsf{hist}^{\ell-1}_{\mathcal{G}}(v_2) + \cdots + \mathsf{hist}^{\ell-1}_{\mathcal{G}}(v_k)\right),$$

where $e = \xi^0_{\mathcal{G}}(v)$. Therefore, $\mathsf{hist}^{\ell}_{\mathcal{G}}(v) \in \mathcal{H}^\ell$. ◀

5 Discussion

This work extends the exploration of the relationship between aggregate-combine GNNs and logic, with exact characterizations of expressiveness for GNNs with eventually constant activation functions, and embedding a logic into the GNNs with standard ReLU activations. We also obtain both decidability and undecidability results, some using the logical characterizations and some by porting the techniques used for decidability of the logics to apply directly on the GNNs. Perhaps the main take-away, echoing the theme of [1], is that Presburger logics and the techniques for analyzing them can be relevant to GNNs.

We have left open one major technical problem: the decidability of satisfiability for standard GNNs using the ReLU activation function. Here we have proven decidability only for the "outgoing-only" variant. We also do not know whether the undecidability results we have proven – e.g. for standard GNNs with global readout – still hold for the variants with outgoing-only aggregation. Thus, for all we know, the most crucial dividing line for decidability could revolve around outgoing-only vs bidirectional aggregation, rather than (e.g.) local vs global aggregation or truncation vs non-truncation in the activation function.

Looking at broader open issues, we focused here on some very basic verification problems on GNNs: can a certain classification be achieved? But it is clear that our techniques apply to many other logic-based verification problems; for example, it can be applied to determine whether a GNN can achieve a certain classification on a graph satisfying a certain sentence – provided that the sentence is also in one of our decidable logics.

We have not focused on complexity in this paper. Of course, for the broad class of GNNs with eventually constant activation functions, it is difficult to talk about complexity bounds. For GNNs based on truncated ReLU and local aggregation, we have shown satisfiability is PSPACE-complete, and is NP-complete for a fixed number of layers. The finer-grained complexity analysis for other decidability results is left for future work.

Our work provides motivation for exploring the properties of Presburger logics over relational structures and their connections with GNNs beyond the setting here, which considers only graphs with discrete feature values from a fixed set. In our ongoing work we are adapting our techniques to deal with GNNs whose feature values are *unbounded integers*, specified by an initial semi-linear set.

Abstract

Characterisations theorems serve as important tools in model theory and can be used to assess and compare the expressive power of temporal languages used for the specification and verification of properties in formal methods. While complete connections have been established for the linear-time case between temporal logics, predicate logics, algebraic models, and automata, the situation in the branching-time case remains considerably more fragmented. In this work, we provide an *automata-theoretic characterisation* of some important branching-time temporal logics, namely CTL* and ECTL* interpreted on arbitrary-branching trees, by identifying two variants of *Hesitant Tree Automata* that are proved equivalent to those logics. The characterisations also apply to *Monadic Path Logic* and the bisimulation-invariant fragment of *Monadic Chain Logic*, again interpreted over trees. These results widen the characterisation landscape of the branching-time case and solve a forty-year-old open question.

1 Introduction

Temporal logics [49] play a pivotal role in the *formal verification* of complex systems [50]. Serving as *specification languages*, they provide a framework to express and reason about time-dependent properties, capturing the intricate behaviours and interactions of system components over time. Commonly, these languages are classified into two categories: *linear-time logics*, which emphasise properties spanning the entirety of a computation, and *branching-time logics*, specifically tailored to address the non-deterministic and concurrent nature of behaviours. Well-established representatives of the former include *Linear-Time Temporal Logic* (LTL) [61, 62], its full ω-regular extension ELTL [84], and the finite-horizon variant

$\mathrm{LTL_f}$ [32]. Important members of the second category, instead, belong to the families of *Dynamic Logics* [30, 35] and *Computation Tree Logics*, including CTL [21, 16, 24, 17, 22], CTL* [23, 25], ECTL* [80], $\mathrm{CTL^*_f}$ [79], and $\mathrm{ECTL^*_f}$ [74]. Additionally, more expressive but lower-level languages, like μ-Calculus [42], have been considered, which suitably extend classic modal logic with monadic fix-point operators, contributing to the rich tapestry of specification languages in the field of formal verification and synthesis.

The semantics of these temporal logics are typically formalised, at the meta-level, through various flavour of *predicate logic*, frequently *First-Order Logic* (FO) or *Second-Order Logic* (SO), interpreted over either *linearly-ordered structures*, such as finite and infinite words [60], or *branching structures*, like Kripke structures [43], labelled transition systems [40], and their tree unwindings. In tandem with this, the rich body of literature on automata-theoretic techniques [75] for words and trees, originated from [41, 56, 57, 66], has proven invaluable to provide effective technical tools for the solution of related *model-checking* [18, 2, 81, 47, 27], *satisfiability* [81, 26, 78, 6, 47], and *synthesis* [15, 63, 69] decision problems. Predicate logics and automata theory offer, in addition, a rich and coherent arsenal of tools to evaluate and compare the expressive power, as well as the computational properties, of temporal languages, as witnessed by numerous *characterisation theorems*. These results provide a dual perspective on the topic, which enhance our ability to navigate the intricate landscape of language fragments and allow us to assess their pros (*e.g.*, elementary complexity of decision problems) and cons (*e.g.*, limitations on the expressive power).

The initial seminal result in this context is Kamp's theorem [39, 31, 67, 68], which establishes the equivalence of LTL and FO over infinite words. The result also extends to $\mathrm{LTL_f}$ and FO on finite words [19]. A direct link has been drawn between FO-*definability* and *recognition* by *counter-free finite-state automata*, in both the finite [52] and infinite [48, 71, 72, 59] cases, by means of the notions of *star-free language*, *aperiodic language*, and *aperiodic syntactic monoid* (see [70], for finite words, and [58], for the infinite ones). Together these results provide a complete characterisation of the expressive power of LTL and $\mathrm{LTL_f}$ in terms of predicate logics and automata. A parallel correspondence exists between ELTL and $\mathrm{ELTL_f}$, the *Monadic Second-Order Logic* (MSO) and its *weak (finite-quantification) fragment* (WMSO), and regular automata on infinite and finite words. Notably, the equivalence between WMSO and regular automata [8, 20, 76], followed by the equivalence between MSO and ω-regular automata [9, 10, 51, 14], stands among the first results connecting the two fields of model theory and automata theory.

The landscape for branching-time temporal logics is considerably more intricate, due to the complex topology of the models and additional factors, such as *bisimulation invariance* [77] and *counting quantifiers* [29], and it is not as clear and complete as the linear-time counterpart. A significant milestone in this setting is the full correspondence between μ-Calculus, the *bisimulation-invariant* fragment of MSO interpreted over trees, and *(Symmetric) Alternating Parity Tree Automata* [38]. This result generalises the already known connection between the latter two formalisms [64]. Another noteworthy connection has been shown to exist between the *alternation-free* fragment of μ-Calculus (AFμ-Calculus), the bisimulation-invariant fragments of WMSO over bounded-branching trees, and *(Symmetric) Alternating Weak Tree Automata* [1, 37] (see [28, 11, 12, 13], for the unbounded-branching case), which extends previous partial results [45, 65]. The above equivalences lift also to the general case, by incorporating counting quantifiers into the temporal logics [37, 36]. The scenario in other cases appears significantly more fragmented. In recent developments, the equivalence between CTL and *(Symmetric) Hesitant Linear Tree Automata* [7] was proved. Nonetheless, as of today, no corresponding fragment of MSO has been identified. By contrast, several variants

of CTL* have been linked to the *path* and *chain* fragments of MSO since the eighties, although no automata characterisation has been provided thus far. For instance, it was shown in [34] that, on binary trees, CTL* is equivalent to *Monadic Path Logic* (MPL) [33]. Similar correspondences have been established in [74] for CTL^*_{f}, ECTL*, and ECTL^*_{f}, which equate, respectively, to FO, *Monadic Chain Logic* (MCL), and its weak fragment (WMCL). The result concerning CTL* was later extended to arbitrary-branching trees, addressing both bisimulation-invariance [54] and counting quantifiers [55]. As far as we know, no similar results are available for the other three logics. Finally, the recently introduced *Monadic Tree Logic* (MTL) [3] together with its variants have yet to find a correspondence either with temporal logics or with automata.

The objective of this work is to provide an *automata-theoretic characterisation* of CTL* and ECTL*, by identifying two specific classes of alternating tree automata that are expressively equivalent to those logics (the used technique extends seamlessly to the finite-horizon variants). A first result is the proof of the equivalence of the *symmetric variant* of classic ranked *Hesitant Tree Automata* (HTA) [47] with both ECTL* and the bisimulation-invariant fragment of MCL. To this end, for technical convenience, we employ two intermediate formalisms. On the one hand, to prove the equivalence between HTA and ECTL*, we use a *syntactic variant* of ECTL*, called *Computation Dynamic Logic* (CDL), alongside its counting version (CCDL). In ECTL* temporal operators are specified by means of right-linear grammars, while CDL uses finite automata on finite words for the same purpose incorporated into the dynamic modalities. Moreover, while the path subformulae in ECTL* are part of the alphabet of the grammar, in CDL they are specified by means of a testing function over the set of states of the automaton. It is straightforward to move from one formalism to the other by means of a linear-time translation. This logic essentially lifts to the branching-time realm the *Linear Dynamic Logic* (LDL) proposed in [32, 83]. On the other hand, we consider a *first-order extension* [82] of HTAs (HFTA) and show them equivalent to MCL by proving a closure property under *chain projections*. The final result, then, follows from the equivalence between HTAs and the bisimulation-invariant fragment of HFTA. As a second result, we first identify the *graded extension* of HTAs (HGTA), together with its counter-free restriction (HGTA_{cf}), and then prove their equivalence with CCDL and CCTL*, respectively. While for the definition of HGTA the standard notion of counting modalities smoothly applies, introducing HGTA_{cf} proves quite more intricate. We show, indeed, that a naive application of counter-freeness in the context of tree-automata leads to a class of languages that are not CTL* definable. To overcome this problem, we identify the crucial *mutual-exclusion* property of a HGTA that constrains the automaton branching-behaviours. This property, together with counter-freeness of the automaton linear behaviours, provides an apt definition of HGTA_{cf}, something that was previously only hypothesised in [54, 55]. The above characterisations holds also under bisimulation-invariance assumptions. Specifically, HTA_{cf} is equivalent to both CTL* and the bisimulation-invariant fragment of MPL. All these results, coupled with the algebraic characterisation of tree languages provided in [74], brings the expressiveness landscape for branching-time temporal logics to the same level as their linear-time counterpart, thus closing a forty-year-old open question posed in [73, 74].

2 Preliminaries

Let $\mathbb{N}$ be the set of natural numbers. For $i, j \in \mathbb{N}$ with $i \leq j$, $[i, j]$ denotes the set of natural numbers k such that $i \leq k \leq j$. For a finite or infinite word ρ over some alphabet, $|\rho|$ is the length of ρ ($|\rho| = \omega$ if ρ is infinite) and for all $0 \leq i < |\rho|$, $\rho(i)$ is the $(i+1)$-th letter of ρ.

Kripke Trees and Tree Languages. Given a non-empty set of directions D, a tree T (with set of directions in D) is a non-empty subset of D^* which is prefix closed (i.e., for each $w \cdot d \in T$ with $d \in D$, $w \in T$). Elements of T are called nodes and the empty word ε is the root of T. For $w \in T$, a *child* of w in T is a node in T of the form $w \cdot d$ for some $d \in D$. For $w \in T$, the *subtree of* T *rooted at node* w is the tree consisting of the nodes of the form w' such that $w \cdot w' \in T$. A *subtree of* T is a tree T' such that for some $w \in T$, T' is a subset of the subtree of T rooted at w. A *path* of T is a subtree π of T which is totally ordered by the child-relation (i.e., each node of π has at most one child in π). In the following, a path π of T is also seen as a word over T in accordance to the total ordering in π induced by the child relation. A *chain* of T is a subset of a path of T. A tree is *non-blocking* if each node has some child. A non-blocking tree T is infinite, and maximal paths in T are infinite as well.

For an alphabet Σ, a Σ-labelled tree is a pair (T, Lab) consisting of a tree and a labelling $Lab : T \mapsto \Sigma$ assigning to each node in T a symbol in Σ. A *tree-language* over Σ is a set of Σ-labeled trees. In this paper, we consider formalisms whose specifications denote *tree-languages* over a given alphabet Σ. For the easy of presentation, we assume that the labeled trees of a tree-language are non-blocking. All the results of this paper can be easily adapted to the general case, where the non-blocking assumption is relaxed. For a finite set AP of atomic propositions, a *Kripke tree* over AP is a non-blocking 2^{AP}-labelled tree.

Automata over Infinite and Finite Words. We first recall the class of parity nondeterministic automata on infinite words (parity NWA for short) which are tuples $\mathcal{A} = \langle \Sigma, Q, \delta, q_I, \Omega \rangle$, where Σ is a finite input alphabet, Q is a finite set of states, $\delta : Q \times \Sigma \mapsto 2^Q$ is the transition function, $q_I \in Q$ is an initial state, and $\Omega : Q \mapsto \mathbb{N}$ is a parity acceptance condition over Q assigning to each state a natural number (color). Given a word ρ over Σ, a *path* of $\mathcal{A}$ over ρ is a word π over Q of length $|\rho| + 1$ ($|\rho| + 1$ is ω if ρ is infinite) such that $\pi(i+1) \in \delta(\pi(i), \rho(i))$ for all $0 \leq i < |\rho|$. A *run* over ρ is a path over ρ starting at the initial state. The NWA $\mathcal{A}$ is *counter-free* if for all $n > 0$, states $q \in Q$ and finite words ρ over Σ, the following holds: if there is a path from q to q over ρ^n, then there is also a path from q to q over ρ.

A run π of $\mathcal{A}$ over an infinite word ρ is *accepting* if the highest color of the states appearing infinitely often along π is even. The ω-language $\mathsf{L}(\mathcal{A})$ accepted by $\mathcal{A}$ is the set of infinite words ρ over Σ such that there is an accepting run π of $\mathcal{A}$ over ρ.

A parity acceptance condition $\Omega : Q \mapsto \mathbb{N}$ is a *Büchi* (resp., *coBüchi*) condition if there is an even (resp., odd) color $n \in \mathbb{N}$ such that $\Omega(Q) \subseteq \{n-1, n\}$. A *Büchi* (resp., *coBüchi*) NWA is a parity NWA whose acceptance condition is Büchi (resp., coBüchi).

We also consider NWA over finite words (NWA_f for short) which are defined as parity NWA but the parity condition Ω is replaced with a set $F \subseteq Q$ of accepting states. A run π over a finite word is *accepting* if its last state is accepting.

3 Branching-Time Temporal Logics

In this section, we recall syntax and semantics of Counting-CTL* (CCTL* for short) [55], which extends the classic branching-time temporal logic CTL* [25] with counting operators. Moreover, we introduce a novel branching-time temporal logic more expressive than CCTL*, called *Counting Computation Dynamic Logic* (CCDL for short). CCDL can be viewed as a branching-time extension of Linear Dynamic Logic (LDL) [32]. However, unlike LDL, we consider NWA_f over finite words, instead of regular expressions, as the building blocks of formulae. This approach is similar to the one adopted in [83] for Visibly Linear Dynamic Logic, a context-free extension of LTL.

The Logic CCTL*. The syntax of CCTL* is given by specifying inductively the set of *state formulae* φ and the set of *path formulae* ψ over a given finite set AP of atomic propositions:

$$\varphi ::= \top \mid p \mid \neg\varphi \mid \varphi \wedge \varphi \mid \mathtt{E}\psi \mid \mathtt{D}^n\varphi$$
$$\psi ::= \varphi \mid \neg\psi \mid \psi \wedge \psi \mid \mathtt{X}\,\psi \mid \psi\,\mathtt{U}\,\psi$$

where $p \in \mathrm{AP}$, $\mathtt{X}$ and $\mathtt{U}$ are the standard "next" and "until" temporal modalities, $\mathtt{E}$ is the existential path quantifier, and $\mathtt{D}^n$ is the counting operator with $n \in \mathbb{N} \setminus \{0\}$. The language of CCTL* consists of the state formulae of CCTL*. Standard CTL* is the fragment of CCTL* where the counting operators $\mathtt{D}^n$ with $n > 1$ are disallowed, and standard LTL [61] corresponds to the set of path formulae of CTL* where the path quantifiers are disallowed.

Given a Kripke tree $\mathcal{T} = (\mathrm{T}, \mathit{Lab})$ (over AP), a node w of T, an infinite path π of T, and $0 \leq i < |\pi|$, the satisfaction relations $(\mathcal{T}, w) \models \varphi$, for a state formula φ, (meaning that φ holds at node w of $\mathcal{T}$), and $(\mathcal{T}, \pi, i) \models \psi$, for a path formula ψ, (meaning that ψ holds at position i of the path π in $\mathcal{T}$) are defined as usual:

$$\begin{array}{ll}
(\mathcal{T}, w) \models p & \Leftrightarrow p \in \mathit{Lab}(w);\\
(\mathcal{T}, w) \models \mathtt{E}\psi & \Leftrightarrow (\mathcal{T}, \pi, 0) \models \psi \text{ for some infinite path } \pi \text{ of } T \text{ starting at node } w;\\
(\mathcal{T}, w) \models \mathtt{D}^n\varphi & \Leftrightarrow \text{there are at least } n \text{ distinct children } w' \text{ of } w \text{ in T s.t. } (\mathcal{T}, w') \models \varphi;\\
(\mathcal{T}, \pi, i) \models \varphi & \Leftrightarrow (\mathcal{T}, \pi(i)) \models \varphi;\\
(\mathcal{T}, \pi, i) \models \mathtt{X}\,\psi & \Leftrightarrow (\mathcal{T}, \pi, i+1) \models \psi;\\
(\mathcal{T}, \pi, i) \models \psi_1\,\mathtt{U}\,\psi_2 & \Leftrightarrow \text{for some } j \geq i\text{: } (\mathcal{T}, \pi, j) \models \psi_2 \text{ and } (\mathcal{T}, \pi, k) \models \psi_1 \text{ for all } i \leq k < j.
\end{array}$$

Note that $\mathtt{D}^1\varphi$ corresponds to $\mathtt{EX}\,\varphi$. A Kripke tree $\mathcal{T}$ satisfies (or is a model of) a state formula φ, written $\mathcal{T} \models \varphi$, if $\mathcal{T}, \varepsilon \models \varphi$. The tree-language $\mathsf{L}(\varphi)$ of φ is the set of models of φ. For an LTL formula ψ and an infinite word ρ over 2^{AP}, ρ satisfies ψ, written $\rho \models \psi$, if $\mathcal{T}_\rho \models \mathtt{E}\psi$, where $\mathcal{T}_\rho$ is a trivial tree-encoding of ρ. For an LTL formula ψ, $\mathsf{L}(\psi)$ denotes the set of infinite words over 2^{AP} satisfying ψ.

The New Logic CCDL. Like CCTL*, the syntax of CCDL is composed of *state formulae* φ and *path formulae* ψ over a given finite set AP of atomic propositions, defined as follows:

$$\varphi ::= \top \mid p \mid \neg\varphi \mid \varphi \wedge \varphi \mid \mathtt{E}\psi \mid \mathtt{D}^n\varphi$$
$$\psi ::= \varphi \mid \neg\psi \mid \psi \wedge \psi \mid \langle\mathcal{A}\rangle\psi$$

where $p \in \mathrm{AP}$ and $\langle\mathcal{A}\rangle$ is the *existential sequencing* modality applied to a *testing* $\mathrm{NWA_f}$ $\mathcal{A}$. We define a *testing* $\mathrm{NWA_f}$ $\mathcal{A} = \langle 2^{\mathrm{AP}}, \mathrm{Q}, \delta, q_I, \mathrm{F}, \tau\rangle$ as consisting of an $\mathrm{NWA_f}$ $\langle 2^{\mathrm{AP}}, \mathrm{Q}, \delta, q_I, \mathrm{F}\rangle$ over finite words over 2^{AP} and a test function τ mapping states in Q to CCDL path formulae. Intuitively, along an infinite path π of a Kripke tree, the testing automaton accepts the labeling of a (possibly empty) infix $\pi(i)\dots\pi(j-1)$ of π if the embedded $\mathrm{NWA_f}$ has an accepting run $q_i \dots q_j$ over the labeling of such an infix so that, for each position $k \in [i, j]$, the formula $\tau(q_k)$ holds at position k along π. A test function τ is *trivial* if it maps each state to $\top$. We also use the shorthand $[\mathcal{A}]\psi \triangleq \neg\langle\mathcal{A}\rangle\neg\psi$ (*universal sequencing* modality). The language of CCDL consists of the state formulae of CCDL. We also consider the *bisimulation-invariant* fragment CDL of CCDL where the counting operators $\mathtt{D}^n$ with $n > 1$ are disallowed. Given a Kripke tree $\mathcal{T} = (\mathrm{T}, \mathit{Lab})$, an infinite path π of T, and $0 \leq i < |\pi|$, the semantics of modality $\langle\mathcal{A}\rangle$ is defined as follows, where $\mathcal{A} = \langle 2^{\mathrm{AP}}, \mathrm{Q}, \delta, q_I, \mathrm{F}, \tau\rangle$:

$(\mathcal{T}, \pi, i) \models \langle\mathcal{A}\rangle\psi \quad \Leftrightarrow$ for some $j \geq i$, $(i, j) \in \mathrm{R}_{\mathcal{A}}(\mathcal{T}, \pi)$ and $(\mathcal{T}, \pi, j) \models \psi$

where $\mathrm{R}_{\mathcal{A}}(\mathcal{T}, \pi)$ is the set of pairs (i, j) with $j \geq i$ such that there is an accepting run $q_i \dots q_j$ of the $\mathrm{NWA_f}$ embedded in $\mathcal{A}$ over $\mathit{Lab}(\pi(i)) \dots \mathit{Lab}(\pi(j-1))$ and, for all $k \in [i, j]$, it holds that $(\mathcal{T}, \pi, k) \models \tau(q_k)$. The notions of a model and tree-language of a CCDL formula are defined as for CCTL*.

Embedding of CCTL* into CCDL. The logic CCTL* can be easily embedded into CCDL as follows. Let $\mathcal{A}$ be the testing $\mathrm{NWA_f}$ having trivial tests and accepting all and only the words of length 1, and for CCDL path formulae ψ_1, ψ_2, let $\mathcal{A}_{\psi_1,\psi_2} = \langle 2^{\mathrm{AP}}, \{q_1, q_2\}, \delta, q_1, \{q_2\}, \tau \rangle$ be the testing $\mathrm{NWA_f}$ where, for all $a \in 2^{\mathrm{AP}}$, $\delta(q_1, a) = \{q_1, q_2\}$, $\delta(q_2, a) = \emptyset$, $\tau(q_1) = \psi_1$, and $\tau(q_2) = \psi_2$. Then, the next and until formulae $\mathtt{X}\,\psi_1$ and $\psi_1\,\mathtt{U}\,\psi_2$ can be expressed as follows: $\mathtt{X}\,\psi_1 \equiv \langle \mathcal{A} \rangle \psi_1$ and $\psi_1\,\mathtt{U}\,\psi_2 \equiv \psi_2 \vee \langle \mathcal{A}_{\psi_1,\psi_2} \rangle \top$.

4 Alternating Tree Automata

In this section, we recall the class of parity *alternating tree automata with first-order constraints* (FTA for short), introduced in [82] to provide an automata-theoretic characterization of MSO interpreted on arbitrary labeled trees. Moreover, we also recall the class of *graded alternating tree automata* (GTA for short), a subclass of FTA, which was introduced in [44] and allows for expressing counting modal requirements on the child relation of an input tree. The transition relation of both FTA and GTA is based on constraints on the set of states Q written as formulae in a suitable language, called *one-step logic*. The *one-step interpretations* of such formulae over Q are pairs (S, I), where S is an arbitrary (possibly infinite) non-empty set and I is a mapping $\mathrm{I} : \mathrm{S} \mapsto 2^{\mathrm{Q}}$, assigning to each element of S a subset of Q. Intuitively, the pair (S, I) describes the local behaviour of the automaton on reading a node w of the input tree. The set S corresponds to the set of children of the current input node w and, for each $w' \in \mathrm{S}$, $\mathrm{I}(w')$ is the set of states associated with the copies of the automaton which are sent to the child w' of w.

One-Step Logic for GTA. The one-step relation of GTA is specified by means of formulae θ of one-step positive graded modal logic over Q, we call *graded* Q-*constraints*, defined as:

$\theta ::= \top \mid \bot \mid \theta \vee \theta \mid \theta \wedge \theta \mid \Diamond_k \alpha \mid \Box_k \alpha$

where $k \in \mathbb{N} \setminus \{0\}$ and α is a *positive* Boolean formula over Q. The atomic formulae $\Diamond_k \alpha$ and $\Box_k \alpha$ are called Q-*atoms*. The atom $\Diamond_1 \alpha$ (resp., $\Box_1 \alpha$) is also denoted by $\Diamond \alpha$ (resp., $\Box \alpha$). A formula θ is *symmetric* if the atoms occurring in θ are of the form $\Diamond \alpha$ or $\Box \alpha$.

The satisfaction relation $(\mathrm{S}, \mathrm{I}) \models \theta$ for a one-step interpretation (S, I) over Q is inductively defined as follows (we omit the clauses for positive Boolean connectives which are standard):

- $(\mathrm{S}, \mathrm{I}) \models \Diamond_k \alpha$ if $|\{s \in \mathrm{S} \mid \mathrm{I}(s) \models \alpha\}| \geq k$;
- $(\mathrm{S}, \mathrm{I}) \models \Box_k \alpha$ if $|\{s \in \mathrm{S} \mid \mathrm{I}(s) \not\models \alpha\}| < k$.

If $(\mathrm{S}, \mathrm{I}) \models \theta$, we say that (S, I) is a model of θ. Intuitively, for an alternating automaton $\mathcal{A}$ with set of states Q, the atom $\Diamond_k \alpha$ requires that at the current input node w, there are at least k children of w and, for each of such nodes w', (**) there is a subset $\mathrm{Q}' \subseteq \mathrm{Q}$ satisfying α such that a copy of $\mathcal{A}$ is sent to node w' in state q, for each $q \in \mathrm{Q}'$. For an atom $\Box_k \alpha$, the previous condition (**) is required to hold for all but at most $k - 1$ children w' of w.

One-Step Logic for FTA. The one-step language $\mathrm{FOE}_1^+(\mathrm{Q})$ of positive first-order formulae with equality and monadic predicates over Q and first-order variables in Vr_1 is given by the sentences (formulae without free variables) generated by the following grammar:

$\theta ::= \top \mid \bot \mid q(x) \mid x = y \mid x \neq y \mid \theta \vee \theta \mid \theta \wedge \theta \mid \exists x.\, \theta \mid \forall x.\, \theta$

where $q \in \mathrm{Q}$ and $x, y \in \mathrm{Vr}_1$. An $\mathrm{FOE}_1^+(\mathrm{Q})$-sentence θ is called *first-order* Q-*constraint*; θ is *symmetric* if it does not contain equality and inequality atomic formulae. In FTA, these constraints allow formulae that refer to the children of a node of a tree by means of explicit first-order variables.

Given a one-step interpretation (S, I) over Q and an assignment $V : Vr_1 \to S$ of the first-order variables, the satisfaction relation $(S, I), V \models \theta$ is defined in a standard way. For sentences θ, this relation is independent of V, and we simply write $(S, I) \models \theta$. Note that graded Q-constraints can be trivially expressed in $FOE_1^+(Q)$, and first-order Q-constraints θ are *monotonic*, i.e., for all one-step interpretations (S, I) and (S, I') such that $I(s) \subseteq I'(s)$ for each $s \in S$, it holds that $(S, I) \models \theta$ entails $(S, I') \models \theta$. A *minimal model* of θ is a model (S, I) of θ such that there is no model (S, I') of θ with $I' \neq I$ and $I'(s) \subseteq I(s)$ for each $s \in S$.

Parity GTA and Parity FTA. A *parity* GTA $\mathcal{A}$ is a tuple $\mathcal{A} = \langle \Sigma, Q, \delta, q_I, \Omega \rangle$, where Σ, Q, q_I, and Ω are defined as for parity NWA, while the transition function δ is a mapping from $Q \times \Sigma$ to the set of graded Q-constraints. The set $\mathsf{Atoms}(\mathcal{A})$ is the set of Q-atoms occurring in the transition function of $\mathcal{A}$. Parity FTA $\mathcal{A} = \langle \Sigma, Q, \delta, q_I, \Omega \rangle$ are defined similarly but the transition function δ is of the form $\delta : Q \times \Sigma \mapsto FOE_1^+(Q)$. A GTA (resp., FTA) $\mathcal{A} = \langle \Sigma, Q, \delta, q_I, \Omega \rangle$ is *symmetric* if for all $(q, a) \in Q \times \Sigma$, the constraint $\delta(q, a)$ is symmetric. GTA (resp., FTA) $\mathcal{A}$ operate over non-blocking Σ-labeled trees (T, Lab). A run of $\mathcal{A}$ over (T, Lab) is a $(Q \times T)$-labeled tree $\mathsf{r} = (T_\mathsf{r}, Lab_\mathsf{r})$, where each node of T_r labelled by (q, w) describes a copy of $\mathcal{A}$ that is in state q reading the node w of T. Moreover, we require that:

- $Lab_\mathsf{r}(\varepsilon) = (q_I, \varepsilon)$ (initially, the automaton is in state q_I reading the root of the input T);
- for each node $y \in T_\mathsf{r}$ with $Lab_\mathsf{r}(y) = (q, w)$ and denoted by S_w the set of children of node w in the input T, there is a one-step interpretation (S_w, I) over Q satisfying $\delta(q, Lab(w))$ such that the set of labels associated with the children of y in T_r consists of the pairs (q', w') with $w' \in S_w$ and $q' \in I(w')$.

The run r is accepting if, for all infinite paths π starting from the root, the infinite sequence of states in $Lab_\mathsf{r}(\pi(0))Lab_\mathsf{r}(\pi(1))\ldots$ satisfies the parity acceptance condition Ω. The language $\mathsf{L}(\mathcal{A})$ accepted by $\mathcal{A}$ is the tree-language over Σ consisting of the non-blocking Σ-labeled trees (T, Lab) such that there is an accepting run of $\mathcal{A}$ over (T, Lab).

Dualization. For a graded Q-constraint θ, the *dual* $\widetilde{\theta}$ of θ is obtained from θ by exchanging $\vee$ with $\wedge$, $\top$ with $\bot$, and Q-atoms $\Diamond_k \alpha$ with $\Box_k \widetilde{\alpha}$, and vice versa, where $\widetilde{\alpha}$ is obtained from α by exchanging $\vee$ with $\wedge$. For example, the dual of $\Diamond_{k_1}(q_0 \vee q_1) \wedge \Box_{k_2} q_2$ is $\Box_{k_1}(q_0 \wedge q_1) \vee \Diamond_{k_2} q_2$. Similarly, the dual $\widetilde{\theta}$ of a first-order Q-constraint θ is obtained from θ by exchanging $\vee$ with $\wedge$, $\top$ with $\bot$, $x = y$ with $x \neq y$, and existential quantification $\exists x$ with universal quantification $\forall x$. For a parity GTA (resp., parity FTA) $\mathcal{A} = \langle \Sigma, Q, \delta, q_I, \Omega \rangle$, the *dual automaton* of $\mathcal{A}$ is the parity GTA (resp., parity FTA) $\widetilde{\mathcal{A}} = \left\langle \Sigma, Q, \widetilde{\delta}, q_I, \widetilde{\Omega} \right\rangle$, where for all $(q, a) \in Q \times \Sigma$, $\widetilde{\Omega}(q) = \Omega(q) + 1$ and $\widetilde{\delta}(q, a)$ is the dual of $\delta(q, a)$. By [82, 12], the following holds.

▶ **Proposition 4.1** ([82, 12]). *Let $\mathcal{A}$ be a parity* GTA *(resp., parity* FTA*). Then, the dual automaton of $\mathcal{A}$ is a parity* GTA *(resp., parity* FTA*) accepting the complement of* $\mathsf{L}(\mathcal{A})$.

5 Automata Characterisations of CDL and CCTL*

In this section, we provide effective automata-theoretic characterisations of the logics CCDL and CCTL*. We first consider the graded version of the class of *hesitant alternating tree automata* (HTA, for short), the latter being a well-known formalism introduced in [47] as an optimal automata-theoretic framework for model checking and synthesis of CTL*. We show that the graded version of HTA (HGTA for short) characterises the logic CCDL. In order to capture the logic CCTL*, we consider a subclass of HGTA obtained by enforcing a counter-freeness requirement on the linear-time behaviour of the automaton along an existential component together with an additional condition (we call *mutual-exclusion property*) on the alphabet of the linearization word automaton.

In the following, for a GTA $\mathcal{A}$ and a set $\mathrm{A} \subseteq \mathsf{Atoms}(\mathcal{A})$, we denote by $\mathsf{Con}(\mathrm{A})$ (resp., $\mathsf{Dis}(\mathrm{A})$) the conjunction (resp., disjunction) of the atoms occurring in A. As usual, the empty conjunction is $\top$ and the empty disjunction is $\bot$.

Hesitant GTA. An *hesitant* GTA (HGTA for short) is a tuple $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$, where $\langle \Sigma, \mathrm{Q}, \delta, q_I, \Omega \rangle$ is a parity GTA, $\mathsf{H} = \langle \mathrm{Q}_1, \ldots, \mathrm{Q}_n \rangle$ is an *ordered* tuple of non-empty pairwise disjunct subsets Q_i of Q (called *components* of $\mathcal{A}$) which form a partition of Q, and $\mathsf{H}_\exists$ is a subset of the components in H (the so called *existential components*). Thus, like HTA [47], there is an ordered partition of Q into disjoint sets $\mathrm{Q}_1, \ldots, \mathrm{Q}_n$. Moreover, each component Q_i is classified as *transient*, *existential*, or *universal*, and the following holds:

- *transient requirement*: for each transient component Q_i and $(q, a) \in \mathrm{Q}_i \times \Sigma$, $\delta(q, a)$ only refers to states in components Q_j such that $j < i$;
- *existential requirement*: for each existential component Q_i and $(q, a) \in \mathrm{Q}_i \times \Sigma$, $\delta(q, a)$ can be rewritten as a disjunction of conjunctions of the form $\Diamond q' \wedge \mathsf{Con}(\mathrm{A})$, where $q' \in \mathrm{Q}_i$ and the atoms in A only refer to states in components Q_j such that $j < i$;
- *universal requirement*: for each universal component Q_i and $(q, a) \in \mathrm{Q}_i \times \Sigma$, $\delta(q, a)$ can be rewritten as a conjunction of disjunctions of the form $\Box q' \vee \mathsf{Dis}(\mathrm{A})$, where $q' \in \mathrm{Q}_i$ and the atoms in A only refer to states in components Q_j such that $j < i$;
- *hesitant acceptance requirement*: for each existential (resp., universal) component Q_i, the restriction Ω_{Q_i} of Ω to the set Q_i is a Büchi condition (resp., coBüchi condition).

The first three requirements ensure that every infinite path of a run of $\mathcal{A}$ gets trapped within some existential or universal component Q_i. The existential requirement establishes that from each existential state $q \in \mathrm{Q}_i$, exactly one copy is sent to a child of the current input node in component Q_i (all the other copies move to states with order lower than i). The universal requirement corresponds to the dual of the existential requirement. Finally, the hesitant acceptance requirement ensures that for each infinite path π of a run that gets trapped into an existential (resp., universal) component, π is accepting iff π visits infinitely many times states with even color (resp., π visits finitely many times states with odd color).

▶ **Example 5.1.** Let $\mathrm{AP} = \{p\}$ and φ_p be the CTL* formula $\mathtt{EX}\, p$ asserting that the root of the given Kripke tree has a child where p holds. We consider the tree-language L_2 consisting of the Kripke trees $\mathcal{T}$ such that there is an infinite path π from the root so that p never holds along π and at the even positions $2i$, φ_p holds at node $\pi(2i)$. L_2 requires counting modulo 2 and cannot be expressed in CCTL*. The language L_2 is recognised by the HGTA $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \langle \mathrm{Q}_1, \mathrm{Q}_2 \rangle, \{\mathrm{Q}_2\}, \Omega \rangle$ consisting of three states having colour 0: the existential states q_I and q having the same and highest order ($\mathrm{Q}_2 = \{q_I, q\}$) and the transient state q_p ($\mathrm{Q}_1 = \{q_p\}$). Moreover, (i) $\delta(q_p, \{p\}) = \top$ and $\delta(q_p, \emptyset) = \bot$, (ii) $\delta(q_I, \emptyset) = \Diamond q \wedge \Diamond q_p$ and $\delta(q_I, \{p\}) = \bot$, and (iii) $\delta(q, \emptyset) = \Diamond q_I$ and $\delta(q, \{p\}) = \bot$.

Linearization. Fix an HGTA $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$. Given a component Q_i of $\mathcal{A}$ and $\mathrm{A} \subseteq \mathsf{Atoms}(\mathcal{A})$, the set A *is lower than* Q_i if the atoms in A only refer to states with order $j < i$. For each existential (resp., universal) component Q_i and $q \in \mathrm{Q}_i$, we introduce a Büchi (resp., coBüchi) NWA $\mathcal{A}_{\mathrm{Q}_i, q}$ over the alphabet $\Sigma \times \mathsf{Atoms}(\mathcal{A})$. Intuitively, $\mathcal{A}_{\mathrm{Q}_i, q}$ encodes the *modular* behaviour of $\mathcal{A}$ starting at state q, which is composed of the behaviour along Q_i (which is linear-time when Q_i is existential), plus additional moves that lead to states with order lower than i: the input alphabet $\Sigma \times \mathsf{Atoms}(\mathcal{A})$ keeps track of these additional moves. When Q_i is universal, then $\mathcal{A}_{\mathrm{Q}_i, q}$ can be viewed as a universal tree automaton.

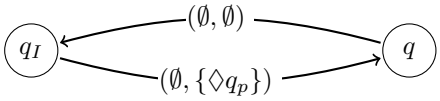
▶ **Definition 5.2** (Linearization word automata). *For each non-transient component* Q_i *of* $\mathcal{A}$ *and* $q \in \mathrm{Q}_i$*, we denote by* $\mathcal{A}_{\mathrm{Q}_i,q}$ *the parity* NWA $\mathcal{A}_{\mathrm{Q}_i,q} = \langle \Sigma \times 2^{\mathsf{Atoms}(\mathcal{A})}, \mathrm{Q}_i, \delta_{\mathrm{Q}_i}, q, \Omega_{\mathrm{Q}_i} \rangle$ *where for all* $q' \in \mathrm{Q}_i$*,* $a \in \Sigma$*, and* $\mathrm{A} \subseteq \mathsf{Atoms}(\mathcal{A})$*,* $\delta_{\mathrm{Q}_i}(q', (a, \mathrm{A}))$ *is defined as follow:*

- *Case* Q_i *is existential:* $q'' \in \delta_{\mathrm{Q}_i}(q', (a, \mathrm{A}))$ *if there is conjunction* ξ *in the disjunctive normal form of* $\delta(q', a)$ *such that* $\xi = \Diamond q'' \wedge \mathsf{Con}(\mathrm{A})$ *(note that* A *is lower than* Q_i*).*
- *Case* Q_i *is universal:* $q'' \in \delta_{\mathrm{Q}_i}(q', (a, \mathrm{A}))$ *if there is disjunction* ξ *in the conjunctive normal form of* $\delta(q', a)$ *such that* $\xi = \Box q'' \vee \mathsf{Dis}(\mathrm{A})$ *(note that* A *is lower than* Q_i*).*

Let Υ_{Q_i} *be the set of elements* $\mathrm{A} \subseteq \mathsf{Atoms}(\mathcal{A})$ *s.t.* $\delta_{\mathrm{Q}_i}(q', (a, \mathrm{A})) \neq \emptyset$ *for some* $(q', a) \in \mathrm{Q}_i \times \Sigma$*.*

▶ Remark 5.3. Note that the transition function of $\mathcal{A}_{\mathrm{Q}_i,q}$ is independent of q, and $\mathcal{A}_{\mathrm{Q}_i,q}$ is a Büchi (resp., coBüchi) NWA if Q_i is existential (resp., universal). We can equate the parity NWA $\mathcal{A}_{\mathrm{Q}_i,q}$ to the parity NWA over the alphabet $\Sigma \times \Upsilon_{\mathrm{Q}_i}$ which is obtained from $\mathcal{A}_{\mathrm{Q}_i,q}$ by restricting the transition function to the alphabet $\Sigma \times \Upsilon_{\mathrm{Q}_i}$. In the following, we write $\mathcal{A}_{\mathrm{Q}_i,q}$ to denote this automaton. Observe that each set of atoms $\mathrm{A} \in \Upsilon_{\mathrm{Q}_i}$ is lower than Q_i.

If we consider the HGTA $\mathcal{A}$ of Example 5.1, the Büchi NWA $\mathcal{A}_{\mathrm{Q}_2,q_I}$ associated with the existential component Q_2 is illustrated below. Note that $\Upsilon_{\mathrm{Q}_2} = \{\emptyset, \{\Diamond q_p\}\}$.



Let us fix an HGTA $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$ with $\mathsf{H} = \langle \mathrm{Q}_1, \ldots, \mathrm{Q}_n \rangle$. For each graded Q-constraint θ, we denote by $\mathcal{A}^\theta$ the HGTA $\langle \Sigma, \mathrm{Q} \cup \{\theta\}, \delta_\theta, \theta, \mathsf{H}_\theta, \mathsf{H}_\exists, \Omega \cup (\theta \to 0) \rangle$ where for the states in Q, δ_θ agrees with δ, for the initial state θ, $\delta_\theta(\theta, a) = \theta$ for all $a \in \Sigma$, and $\mathsf{H}_\theta = \langle \mathrm{Q}_1, \ldots, \mathrm{Q}_n, \{\theta\} \rangle$. Note that $\{\theta\}$ is a transient component with highest order. Thus, from the root of the input tree, $\mathcal{A}^\theta$ send copies of $\mathcal{A}$ to the children of the root according to the constraint θ. By construction, for each existential state q of an HGTA $\mathcal{A}$, we obtain the following characterisation of the language $\mathsf{L}(\mathcal{A}^q)$, where $\mathcal{A}^q$ is the HGTA obtained from $\mathcal{A}$ by setting q as initial state instead of q_I, in terms of the linearization of $\mathcal{A}$.

▶ **Proposition 5.4.** *Let* $\mathcal{A}$ *be an* HGTA*,* Q_i *be an existential component of* $\mathcal{A}$*, and* $q \in \mathrm{Q}_i$*. Then, for each input* $\mathcal{T} = (\mathrm{T}, Lab)$*,* $\mathcal{T} \in \mathsf{L}(\mathcal{A}^q)$ if and only if *there is an infinite path* π *of* $\mathcal{T}$ *starting at the root and an infinite word* $\rho \in \mathsf{L}(\mathcal{A}_{\mathrm{Q}_i,q})$ *such that* ρ *is of the form* $\rho = (Lab(\pi(0)), \mathrm{A}_0)(Lab(\pi(1)), \mathrm{A}_1) \ldots$ *and for each* $i \geq 0$*,* $\mathcal{T}_{\pi(i)} \in \mathsf{L}(\mathcal{A}^{\mathsf{Con}(\mathrm{A}(i))})$*, where* $\mathcal{T}_{\pi(i)}$ *is the labelled subtree of* $\mathcal{T}$ *rooted at node* $\pi(i)$*.*

Counter-free HGTA**.** In order to capture CCTL*, we introduce a subclass of HGTA obtained by enforcing additional conditions. By Proposition 5.4 and the equivalence of LTL and Büchi *counter-free* NWA [19], a natural condition consists in requiring that for each non-transient component Q_i of the HGTA and state $q \in \mathrm{Q}_i$, the NWA $\mathcal{A}_{\mathrm{Q}_i,q}$ is counter-free (*counter-freeness requirement*).[1] However, this condition is not sufficient for characterising the logic CCTL*. A counterexample is the HGTA $\mathcal{A}$ of Example 5.1 which clearly satisfies the counter-freeness requirement but recognises a tree-language which is not expressible in CCTL*. We introduce an additional condition (*mutual-exclusion property*) on the alphabets of the linearization automata (see Definition 5.5 below). A *Counter-free* HGTA ($\mathrm{HGTA}_{\mathrm{cf}}$ for short) is an HGTA satisfying both the counter-free requirement and the mutual-exclusion condition.

[1] Note that the property of an NWA to be counter-free is independent of the initial state.

▶ **Definition 5.5.** *An* HGTA $\mathcal{A}$ *satisfies the* mutual-exclusion property *if for each non-transient component* Q_i *and for all* $\mathrm{A}, \mathrm{A}' \in \Upsilon_{\mathrm{Q}_i}$ *such that* $\mathrm{A} \neq \mathrm{A}'$*, it holds that there exists an atom* $\mathsf{atom} \in \mathrm{A}$ *and an atom* $\mathsf{atom}' \in \mathrm{A}'$ *such that* $\mathsf{L}(\mathcal{A}^{\mathsf{atom}})$ *is the complement of* $\mathsf{L}(\mathcal{A}^{\mathsf{atom}'})$*. Note that if* Υ_{Q_i} *is a singleton, then the previous property is fulfilled.*

Evidently, if $\mathcal{A}$ satisfies the mutual-exclusion condition, then for each non-transient component Q_i and for all $\mathrm{A}, \mathrm{A}' \in \Upsilon_{\mathrm{Q}_i}$ such that $\mathrm{A} \neq \mathrm{A}'$, it holds that $\mathsf{L}(\mathcal{A}^{\mathsf{Con}(\mathrm{A})}) \cap \mathsf{L}(\mathcal{A}^{\mathsf{Con}(\mathrm{A}')}) = \emptyset$. Intuitively, the mutual-exclusion condition requires that along a non-transient component Q_i, the distinct moves $\mathrm{A} \in \Upsilon_{\mathrm{Q}_i}$ (these moves lead to components with order lower than i) are mutually exclusive. Let us consider again the HGTA $\mathcal{A}$ of Example 5.1. Since $\Upsilon_{\mathrm{Q}_2} = \{\emptyset, \{\Diamond q_p\}\}$, by Definition 5.5, $\mathcal{A}$ does not satisfy the mutual-exclusion condition. Note that $\mathsf{Con}(\emptyset) = \top$ and $\mathsf{Con}(\{\Diamond q_p\}) = \Diamond q_p$. Hence, $\mathsf{L}(\mathcal{A}^{\top}) \cap \mathsf{L}(\mathcal{A}^{\mathsf{Con}(\{\Diamond q_p\})}) = \mathsf{L}(\mathcal{A}^{\mathsf{Con}(\{\Diamond q_p\})}) = \mathsf{L}(\mathtt{EX}\, p) \neq \emptyset$.

The dual $\widetilde{\mathcal{A}}$ of an HGTA $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$ is the tuple $\left\langle \Sigma, \mathrm{Q}, \widetilde{\delta}, q_I, \mathsf{H}, \widetilde{\mathsf{H}_\exists}, \widetilde{\Omega} \right\rangle$, where $\widetilde{\delta}$ and $\widetilde{\Omega}$ are defined as for the dual of an arbitrary parity GTA and $\widetilde{\mathsf{H}_\exists}$ consists of the universal components of $\mathcal{A}$. By construction and Proposition 4.1, the considered subclasses of GTA are closed under Boolean language operations.

▶ **Proposition 5.6.** HGTA *(resp.,* $\mathrm{HGTA}_{\mathrm{cf}}$*) and* HGTA *satisfying the mutual-exclusion property are effectively closed under Boolean language operations.*

Enforcing the Mutual-exclusion Property. By exploiting dualization, an HGTA $\mathcal{A}$ can be converted into an equivalent HGTA $\mathcal{A}_s$ satisfying the mutual-exclusion condition. Intuitively, $\mathcal{A}_s$ is obtained by merging in a syntactical and *modular* way $\mathcal{A}$ with a renaming of the dual HGTA $\widetilde{\mathcal{A}}$.

▶ **Proposition 5.7.** *Given an* HGTA $\mathcal{A}$*, one can construct an* HGTA $\mathcal{A}_s$ *such that* $\mathcal{A}_s$ *satisfies the mutual-exclusion condition and* $\mathsf{L}(\mathcal{A}_s) = \mathsf{L}(\mathcal{A})$*.*

Note that the translation in Proposition 5.7 changes the second component Υ_{Q_i} of the alphabets of the linearization automata. Since counter-free NWA are not closed under inverse projection, the construction does not preserve the counter-freeness property. For example, for the HGTA of Example 5.1, the translation replaces the edge from q to q_I with label $(\emptyset, \emptyset)$ of the NWA $\mathcal{A}_{\mathrm{Q}_2, q_I}$ with two edges from q to q_I: one with label $(\emptyset, \{\Diamond q_p\})$ and the other one with label $(\emptyset, \{\Box q'_p\})$ where $\mathsf{L}(\mathcal{A}^{\mathsf{Con}(\{\Box q'_p\})}) = \mathsf{L}(\neg \mathtt{EX}\, p)$. The resulting NWA is not counter-free.

5.1 From Automata to Logics and Back

In this section, we show that the class of HGTA and the logic CCDL are effectively equivalent, and the class of $\mathrm{HGTA}_{\mathrm{cf}}$ effectively characterizes CCTL*. We start with the translations from automata to logics.

▶ **Theorem 5.8.** *Let* $\mathcal{A}$ *be an* HGTA *(resp., an* $\mathrm{HGTA}_{\mathrm{cf}}$*) over* 2^{AP}*. Then, one can construct a* CCDL *(resp.,* CCTL**) formula* $\varphi_{\mathcal{A}}$ *such that* $\mathsf{L}(\varphi_{\mathcal{A}}) = \mathsf{L}(\mathcal{A})$*. Moreover,* $\varphi_{\mathcal{A}}$ *is a* CDL *(resp. a* CTL**) formula if* $\mathcal{A}$ *is symmetric.*

Proof. We focus on the translation from $\mathrm{HGTA}_{\mathrm{cf}}$ $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$ to CCTL*. For each $q \in \mathrm{Q}$, we construct a CCTL* formula φ_q such that $\mathsf{L}(\varphi_q) = \mathsf{L}(\mathcal{A}^q)$ and φ_q is a CTL* formula if $\mathcal{A}$ is symmetric. Thus, by setting $\varphi_{\mathcal{A}} \triangleq \varphi_{q_I}$, Theorem 5.8 directly follows. The proof is by induction on the order ℓ of the component Q_ℓ such that $q \in \mathrm{Q}_\ell$. We distinguish

the cases where q is transient, existential, or universal. The transient case is easy and the universal case follows from the existential case by a dualization argument. Now, assume that q is existential. Let us consider the Büchi NWA $\mathcal{A}_{\mathrm{Q}_\ell,q}$ over $2^{\mathrm{AP}} \times \Upsilon_{\mathrm{Q}_\ell}$ as defined in Definition 5.2. Recall that $\mathcal{A}_{\mathrm{Q}_\ell,q}$ is counter-free. Moreover, $\Upsilon_{\mathrm{Q}_\ell} \subseteq 2^{\mathsf{Atoms}(\mathcal{A})}$ contains only elements A such that states occurring in the atoms of A have order j lower than ℓ. Thus, by the induction hypothesis, for each $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$, one can build a CCTL* formula φ_{A} such that $\mathsf{L}(\mathcal{A}^{\mathsf{Con}(\mathrm{A})}) = \mathsf{L}(\varphi_{\mathrm{A}})$. Hence, since $\mathcal{A}$ satisfies the mutual-exclusion condition, the following holds:

Claim 1. For all $\mathrm{A}, \mathrm{A}' \in \Upsilon_{\mathrm{Q}_\ell}$ such that $\mathrm{A} \neq \mathrm{A}'$, $\mathsf{L}(\varphi_{\mathrm{A}}) \cap \mathsf{L}(\varphi_{\mathrm{A}'}) = \emptyset$.

For each $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$, let p_{A} be a fresh atomic proposition. We denote by $\mathrm{AP}_{\mathtt{ex}}$ the extension of AP with these fresh propositions. Moreover, let $\mathcal{A}_{\mathtt{ex},\mathrm{Q}_\ell,q}$ be the Büchi NWA over $2^{\mathrm{AP}_{\mathtt{ex}}}$ having the same set of states, initial state, acceptance condition as $\mathcal{A}_{\mathrm{Q}_\ell,q}$ and whose transition function $\delta_{\mathtt{ex},\mathrm{Q}_\ell}$ is obtained from the transition function δ_{Q_ℓ} of $\mathcal{A}_{\mathrm{Q}_\ell,q}$ as follows: for all $q' \in \mathrm{Q}_\ell$ and $a_{\mathtt{ex}} \in 2^{\mathrm{AP}_{\mathtt{ex}}}$, if $a_{\mathtt{ex}}$ is of the form $a \cup \{p_{\mathrm{A}}\}$, for some $a \in 2^{\mathrm{AP}}$ and $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$, (i.e., $a_{\mathtt{ex}}$ contains a unique proposition in $\mathrm{AP}_{\mathtt{ex}} \setminus \mathrm{AP}$), then $\delta_{\mathtt{ex},\mathrm{Q}_\ell}(q', a_{\mathtt{ex}}) = \delta_{\mathrm{Q}_\ell}(q', (a, \mathrm{A}))$; otherwise, $\delta_{\mathtt{ex},\mathrm{Q}_\ell}(q', a_{\mathtt{ex}}) = \emptyset$. Being $\mathcal{A}_{\mathrm{Q}_\ell,q}$ counter-free, $\mathcal{A}_{\mathtt{ex},\mathrm{Q}_\ell,q}$ is clearly counter-free as well. Thus, by [19], one can construct an LTL formula ψ over $\mathrm{AP}_{\mathtt{ex}}$ such that $\mathsf{L}(\psi) = \mathsf{L}(\mathcal{A}_{\mathtt{ex},\mathrm{Q}_\ell,q})$. Since $\mathsf{L}(\mathcal{A}^{\mathsf{Con}(\mathrm{A})}) = \mathsf{L}(\varphi_{\mathrm{A}})$ for all $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$, by construction and Proposition 5.4, we obtain the following characterization of the tree-language $\mathsf{L}(\mathcal{A}^q)$.

Claim 2. For each Kripke tree $\mathcal{T} = (\mathrm{T}, \mathit{Lab})$, $\mathcal{T} \in \mathsf{L}(\mathcal{A}^q)$ iff there is an infinite path π of $\mathcal{T}$ from the root and an infinite word ρ over $2^{\mathrm{AP}_{\mathtt{ex}}}$ such that $\rho \models \psi$ and, for all $j \geq 0$, (i) $\rho(j) \cap \mathrm{AP} = \mathit{Lab}(\pi(j))$, (ii) for all $p_{\mathrm{A}} \in \rho(j)$, $(\mathcal{T}, \pi(j)) \models \varphi_{\mathrm{A}}$, and (iii) there is a unique $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$ such that $p_{\mathrm{A}} \in \rho(j)$.

Note that since $\mathsf{L}(\psi) = \mathsf{L}(\mathcal{A}_{\mathtt{ex},\mathrm{Q}_\ell,q})$, by construction, point (iii) in Claim 2 follows from the fact that $\rho \models \psi$. By exploiting the always modality $\mathtt{G}$ ($\mathtt{G}\,\xi$ is a shorthand of $\neg(\top\,\mathtt{U}\,\neg\xi)$) and both conjunction and disjunction, w.l.o.g. we can assume that the LTL formula ψ is in negation normal form, i.e., negation is applied only to atomic propositions. Now, let $f(\psi)$ be the CCTL* path formula over AP obtained from ψ by replacing each literal of the form p_{A} (resp., $\neg p_{\mathrm{A}}$), where $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$, with the CCTL* state formula φ_{A} (resp., $\bigvee_{\mathrm{A}' \in \Upsilon_{\mathrm{Q}_\ell} \setminus \{\mathrm{A}\}} \varphi_{\mathrm{A}'}$). Finally, let us consider the CCTL* state formula φ_q defined as follows:

$\varphi_q \triangleq \mathtt{E}(f(\psi) \wedge \mathtt{G} \bigvee_{\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}} \varphi_{\mathrm{A}})$.

Note that the second conjunct in the state formula φ_q ensures that, for the infinite path π selected by the path quantifier $\mathtt{E}$ and for each $j \geq 0$, the state formula φ_{A} holds at node $\pi(j)$ for some $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$. We show that a Kripke tree $\mathcal{T} = (\mathrm{T}, \mathit{Lab})$ satisfies φ_q iff the characterization of $\mathsf{L}(\mathcal{A}^q)$ in Claim 2 holds. Hence, the result follows.

We shall now focus on the left-right implication of the equivalence (the right-left implication is similar). Thus, assume that $\mathcal{T} \models \varphi_q$. Hence, there exists an infinite path π of $\mathcal{T}$ from the root and an infinite sequence $\nu = \mathrm{A}_0, \mathrm{A}_1, \ldots$ over $\Upsilon_{\mathrm{Q}_\ell}$ such that $(\mathcal{T}, \pi, 0) \models f(\psi)$ and for each $j \geq 0$, $(\mathcal{T}, \pi(j)) \models \varphi_{\mathrm{A}_j}$. Let $\mathit{Lab}(\pi) \otimes \nu$ be the infinite word over $2^{\mathrm{AP}_{\mathtt{ex}}}$ defined as follows for all $j \geq 0$: $(\mathit{Lab}(\pi) \otimes \nu)(j) = \mathit{Lab}(\pi(j)) \cup \{p_{\mathrm{A}_j}\}$. By Claim 2, it suffices to show that $\mathit{Lab}(\pi) \otimes \nu \models \psi$. To this purpose, we show by structural induction that for each $j \geq 0$ and subformula θ of ψ if $(\mathcal{T}, \pi, j) \models f(\theta)$, then $(\mathit{Lab}(\pi) \otimes \nu, j) \models \theta$. Since the formula ψ is in negation normal form, by the induction hypothesis, the unique non-trivial case is when θ is either of the form p_{A} or of the form $\neg p_{\mathrm{A}}$ for some $\mathrm{A} \in \Upsilon_{\mathrm{Q}_\ell}$.

- $\theta = p_{\mathrm{A}}$: hence, $f(\theta) = \varphi_{\mathrm{A}}$. Since $(\mathcal{T}, \pi, j) \models f(\theta)$ and $(\mathcal{T}, \pi(j)) \models \varphi_{\mathrm{A}_j}$, by Claim 1, it follows that $\mathrm{A} = \mathrm{A}_j$, i.e. $\theta = p_{\mathrm{A}_j}$. Hence, $(\mathit{Lab}(\pi) \otimes \nu, j) \models \theta$, and the result follows.
- $\theta = \neg p_{\mathrm{A}}$: hence $f(\theta) = \bigvee_{\mathrm{A}' \in \Upsilon_{\mathrm{Q}_\ell} \setminus \{\mathrm{A}\}} \varphi_{\mathrm{A}'}$. Since $(\mathcal{T}, \pi, j) \models f(\theta)$ and $(\mathcal{T}, \pi(j)) \models \varphi_{\mathrm{A}_j}$, by Claim 1, $\mathrm{A} \neq \mathrm{A}_j$. Hence, $(\mathit{Lab}(\pi) \otimes \nu, j) \models \theta$, and we are done. ◀

From Logics to Automata. As to the translation from CCTL* to $\mathrm{HGTA}_{\mathrm{cf}}$, in order to ensure the mutual-exclusion property of the resulting $\mathrm{HGTA}_{\mathrm{cf}}$, we need a restricted syntactic form of CCTL* formulae, which is still expressively complete. A CCTL* formula is in *simple form* if each occurrence of the path quantifier $\mathtt{E}$ is immediately preceded by the counter modality $\mathtt{D}^1$ (note that $\mathtt{D}^1$ corresponds to the standard $\mathtt{EX}$ modality of CTL*). Formally, the set of state formulae φ of CCTL* in simple form is defined according to the following syntax: $\varphi ::= \top \mid p \mid \neg\varphi \mid \varphi \wedge \varphi \mid \mathtt{D}^1\mathtt{E}\psi \mid \mathtt{D}^n\varphi$. One can easily show that the simple form is indeed expressively complete.

▶ **Theorem 5.9.** *Given a* CCDL *(resp.,* CCTL*) formula φ, one can construct an equivalent* HGTA *(resp.,* $\mathrm{HGTA}_{\mathrm{cf}}$*) $\mathcal{A}_\varphi$ such that $\mathsf{L}(\mathcal{A}_\varphi) = \mathsf{L}(\varphi)$. Moreover, $\mathcal{A}_\varphi$ is symmetric if φ is a* CDL *(resp., a* CTL*) formula.*

Proof. We focus on the translation from CCTL* to $\mathrm{HGTA}_{\mathrm{cf}}$. Fix a CCTL* formula Φ. W.l.o.g., we can assume that Φ is in simple form. As in the case of the alternating hesitant automata for CTL* [47], we construct the automaton by induction on the structure of Φ. With each state subformula φ of Φ we associate an $\mathrm{HGTA}_{\mathrm{cf}}$ $\mathcal{A}_\varphi$ over $\Sigma = 2^{\mathrm{AP}}$ such that $\mathsf{L}(\mathcal{A}_\varphi) = \mathsf{L}(\varphi)$. The cases where φ is an atomic proposition, or the root operator of φ is the counting modality $\mathtt{D}^n$ are straightforward. The cases where the root operator of φ is a Boolean connective directly follow from Proposition 5.6. Now, assume that $\varphi = \mathtt{E}\psi$ for some path formula ψ. Let $\mathsf{max}(\psi)$ be the set of state subformulae of ψ of the form $\mathtt{E}\xi$ or $\mathtt{D}^n\xi$ which are not preceded by the modality $\mathtt{E}$ or the counting modality in the syntax tree of ψ. Since ψ is in simple form, $\mathsf{max}(\psi)$ is of the form $\{\mathtt{D}^{n_1}\varphi_1, \ldots, \mathtt{D}^{n_k}\varphi_k\}$ for some $k \geq 0$, where $\varphi_1, \ldots, \varphi_k$ are CCTL* formulae in simple form. Note that if ψ is a CTL* formula, then $n_1 = \ldots = n_k = 1$. By the induction hypothesis, for each $i \in [1,k]$, one can construct an $\mathrm{HGTA}_{\mathrm{cf}}$ $\mathcal{A}_i = \langle 2^{\mathrm{AP}}, \mathrm{Q}_i, \delta_i, q_{I\,i}, \mathsf{H}_i, \mathsf{H}_{\exists,i}, \Omega_i\rangle$ such that $\mathsf{L}(\mathcal{A}_i) = \mathsf{L}(\varphi_i)$. For each $i \in [1,k]$, let $\widetilde{\mathcal{A}}_i = \left\langle 2^{\mathrm{AP}}, \widetilde{\mathrm{Q}}_i, \widetilde{\delta}_i, \widetilde{q}_{I\,i}, \widetilde{\mathsf{H}}_i, \widetilde{\mathsf{H}}_{\exists,i}, \widetilde{\Omega}_i\right\rangle$ be a renaming of the dual automaton of $\mathcal{A}_i$.

Let $\mathrm{AP}_{\mathtt{ex}}$ be an extension of AP obtained by adding for each state formula $\mathtt{D}^{n_i}\varphi_i$ a fresh proposition p_i. Then, the path formula ψ can be viewed as an LTL formula $\psi_{\mathtt{ex}}$ over $\mathrm{AP}_{\mathtt{ex}}$. By [19], one can build a Büchi *counter-free* NWA $\mathcal{N}_\psi = \langle 2^{\mathrm{AP}_{\mathtt{ex}}}, \mathrm{Q}, \delta, q_I, \Omega\rangle$ s.t. $\mathsf{L}(\mathcal{N}_\psi) = \mathsf{L}(\psi_{\mathtt{ex}})$. By construction, we easily deduce the following characterization of $\mathsf{L}(\varphi) = \mathsf{L}(\mathtt{E}\psi)$:

Claim 1: for each Kripke tree $\mathcal{T} = (\mathrm{T}, Lab)$, $\mathcal{T} \in \mathsf{L}(\varphi)$ *iff* there exists an infinite path π of $\mathcal{T}$ from the root and an infinite word ρ over $2^{\mathrm{AP}_{\mathtt{ex}}}$ such that $\rho \in \mathsf{L}(\mathcal{N}_\psi)$ and the following holds for each $i \geq 0$: (i) $\rho(i) \cap \mathrm{AP} = Lab(\pi(i))$, (ii) for each $\ell \in [1,k]$ such that $p_\ell \in \rho(i)$, $(\mathcal{T}, \pi(i)) \models \mathtt{D}^{n_\ell}\varphi_\ell$, and (iii) for each $\ell \in [1,k]$ such that $p_\ell \notin \rho(i)$, $(\mathcal{T}, \pi(i)) \models \neg\mathtt{D}^{n_\ell}\varphi_\ell$.

We define $\mathcal{A}_\varphi$ as follows: $\mathcal{A}_\varphi$ simulates the Büchi NWA $\mathcal{N}_\psi$ along a guessed infinite path of the input tree from the root and starts additional copies of the $\mathrm{HGTA}_{\mathrm{cf}}$ $\mathcal{A}_1, \ldots, \mathcal{A}_k, \widetilde{\mathcal{A}}_1, \ldots, \widetilde{\mathcal{A}}_k$. According to Claim 1, these copies guarantee that whenever the NWA $\mathcal{N}_\psi$ assumes that proposition p_ℓ labels (resp., p_ℓ does not label) the current node along the guessed path, then $\mathtt{D}^{n_\ell}\varphi_\ell$ holds (resp., $\mathtt{D}^{n_\ell}\varphi_\ell$ does not hold) at this node. The components of $\mathcal{A}$ consist of the existential component Q (the set of states of the Büchi counter-free NWA $\mathcal{N}_\psi$) and the components of the $\mathrm{HGTA}_{\mathrm{cf}}$ automata $\mathcal{A}_i$ and $\widetilde{\mathcal{A}}_i$ for each $i \in [1,k]$. Moreover, the existential component Q has highest order and the ordering of the components of $\mathcal{A}_i$ (resp., $\widetilde{\mathcal{A}}_i$) is preserved for each $i \in [1,k]$. For the transition function δ_φ of $\mathcal{A}_\varphi$, we have that for states in Q_i (resp., $\widetilde{\mathrm{Q}}_i$), δ_φ agrees with the corresponding δ_i (resp., $\widetilde{\delta}_i$). For states $q \in \mathrm{Q}$ and $a \in 2^{\mathrm{AP}}$, $\delta_\varphi(q,a)$ is defined as follows, where for each $\mathrm{I} \subseteq [1,k]$, $\mathrm{I}(a)$ denotes the subset of $\mathrm{AP}_{\mathtt{ex}}$ given by $a \cup \bigcup_{\ell\in\mathrm{I}}\{p_\ell\}$:

$$\delta_\varphi(q,a) \triangleq \bigvee_{\mathrm{I}\subseteq[1,k]} \bigvee_{q'\in\delta(q,\mathrm{I}(a))} (\Diamond q' \wedge \bigwedge_{\ell\in\mathrm{I}} \Diamond_\ell q_{I_i} \wedge \bigwedge_{\ell\in[1,k]\setminus\mathrm{I}} \Box_\ell \widetilde{q}_{I_i})$$

By construction, the induction hypothesis, and Claim 1, $\mathcal{A}_\varphi$ is an HGTA satisfying the mutual-exclusion property such that $\mathsf{L}(\mathcal{A}_\varphi) = \mathsf{L}(\varphi)$. It remains to show that for each $q \in \mathrm{Q}$, the Büchi NWA $\mathcal{A}_{\mathrm{Q},q}$ over the alphabet $2^{\mathrm{AP}} \times \Upsilon_{\mathrm{Q}}$ (see Definition 5.2) driven by the existential component Q of $\mathcal{A}_\varphi$ is counter-free. Let us consider the mapping g assigning to each $a_{\mathtt{ex}} \in 2^{\mathrm{AP}_{\mathtt{ex}}}$ the pair $(a, \bigcup_{\ell\in\mathrm{I}}\{\Diamond_\ell q_{I_i}\} \cup \bigcup_{\ell\in[1,k]\setminus\mathrm{I}}\{\Box_\ell \widetilde{q}_{I_i}\})$, where $a = \mathrm{AP} \cap a_{\mathtt{ex}}$ and I is the set of indexes in $j \in [1,k]$ such that $p_j \in a_{\mathtt{ex}}$. Clearly, g is a bijection between $2^{\mathrm{AP}_{\mathtt{ex}}}$ and $2^{\mathrm{AP}} \times \Upsilon_{\mathrm{Q}}$. Moreover, for the transition functions δ_{Q} and δ of $\mathcal{A}_{\mathrm{Q},q}$ and $\mathcal{N}_\psi$, respectively, it holds that, for each $(a,\mathrm{A}) \in 2^{\mathrm{AP}} \times \Upsilon_{\mathrm{Q}}$ and $q' \in \mathrm{Q}$, $\delta_{\mathrm{Q}}(q',(a,\mathrm{A})) = \delta(q', g^{-1}(a,\mathrm{A}))$, where g^{-1} is the inverse of g. Thus, since $\mathcal{N}_\psi$ is counter free, $\mathcal{A}_{\mathrm{Q},q}$ is counter free as well, and the result follows. ◀

6 Automata Characterisation of Monadic Chain Logic (MCL)

Monadic Chain Logic (MCL) is the fragment of MSO over Kripke trees where monadic second-order quantification is restricted to sets of nodes which forms chains, *i.e.* a subset of a path. In this section, we provide an automata-theoretic characterisation of MCL in terms of a subclass of parity FTA, called *Hesitant* FTA (HFTA for short), which represents the FTA counterpart of hesitant GTA. Moreover, we show that the bisimulation-invariant fragment of MCL and CDL are expressively equivalent.

The class of HFTA**.** An HFTA is a tuple $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega\rangle$, where $\langle \Sigma, \mathrm{Q}, \delta, q_I, \Omega\rangle$ is an FTA and H and $\mathsf{H}_\exists$ are defined as for HGTA. Moreover, we require that $\mathcal{A}$ satisfies the transient requirement and the hesitant acceptance requirement of HGTA and the following variants of the existential and universal requirements of HGTA:

- for each existential component Q_i and $(q,a) \in \mathrm{Q}_i \times \Sigma$, $\delta(q,a)$ is a disjunction of formulae of the form $\exists x.\,(q'(x) \wedge \theta(x))$ where $q' \in \mathrm{Q}_i$ and $\theta(x)$ only refers to states in lower components Q_j with $j < i$ (*first-order existential requirement*);
- for each universal component Q_i and $(q,a) \in \mathrm{Q}_i \times \Sigma$, $\delta(q,a)$ is a conjunction of formulae of the form $\forall x.\,(q'(x) \vee \theta(x))$ where $q' \in \mathrm{Q}_i$ and $\theta(x)$ only refers to states in lower components Q_j with $j < i$ (*first-order universal requirement*).

HFTA can be easily translated into equivalent MCL sentences.

▶ **Theorem 6.1.** *Given an* HFTA $\mathcal{A}$ *over* 2^{AP}*, one can construct in polynomial time an* MCL *sentence* $\varphi_{\mathcal{A}}$ *over* AP *such that* $\mathsf{L}(\varphi_{\mathcal{A}}) = \mathsf{L}(\mathcal{A})$.

Chain Projection. Like HGTA, the tree-languages accepted by HFTA are closed under Boolean operations. Thus, in the translation of MCL formulae into equivalent parity HFTA, the only non-trivial part concerns the treatment of MCL existential quantification. For this purpose, we define an operation on tree languages that captures the semantics of MCL existential quantification. Let L be a tree language over 2^{AP} and $p \in \mathrm{AP}$. The *chain projection of* L *over* p, denoted by $\exists^{\mathsf{c}} p.\mathsf{L}$, is the language consisting of the Kripke trees (T, Lab) over $\mathrm{AP} \setminus \{p\}$ such that there is an infinite path π of T from the root and a Kripke tree $(\mathrm{T}, Lab') \in \mathsf{L}$ so that: $Lab'(w) = Lab(w)$, for each $w \in \mathrm{T} \setminus \pi$, and $Lab'(w) \setminus \{p\} = Lab(w)$, otherwise.

We show that HFTA are effectively closed under chain projection, i.e., for each HFTA $\mathcal{A}$ over 2^{AP} and $p \in \mathrm{AP}$, one can construct an HFTA accepting $\exists^{\mathsf{C}} p.\mathsf{L}(\mathcal{A})$. The proof is divided in two steps. In the first step, we define a subclass of HFTA, called HFTA that *are nondeterministic in one path* (see Definition 6.3), whose closure under chain projection can be easily established (see Proposition 6.4). Then, in the second step, we show that an HFTA can be converted into an equivalent HFTA that is nondeterministic in one path.

We now introduce this subclass of automata. By exploiting the known notion of *basic formula* [82, 12], we first define a fragment of the one-step language $\mathrm{FOE}_1^+(\mathrm{Q})$ for a given non-empty set Q. A Q-*type* is a (possibly empty) set $\mathrm{A} \subseteq \mathrm{Q}$. It defines the first-order constraint $\mathtt{t}(\mathrm{A})(x) \triangleq \bigwedge_{q \in \mathrm{A}} q(x)$. Note that $\mathtt{t}(\mathrm{A})(x)$ is $\top$ if A is empty. Let $\mathtt{T}_\exists$ and $\mathtt{T}_\forall$ be two sets of Q-type. The *basic formula for the pair* $(\mathtt{T}_\exists, \mathtt{T}_\forall)$, denoted $\theta^{=}(\mathtt{T}_\exists, \mathtt{T}_\forall)$, is the $\mathrm{FOE}_1^+(\mathrm{Q})$ sentence defined as follows, where $\mathtt{T}_\exists = \{\mathrm{A}_1, \ldots, \mathrm{A}_n\}$ for some $n \geq 0$ and for variables $z_1, \ldots, z_k$, $\mathtt{diff}(z_1, \ldots, z_k) \triangleq \bigwedge_{i \neq j} z_i \neq z_j$:

$$\exists x_1 \ldots \exists x_n. \Big(\mathtt{diff}(x_1, \ldots, x_n) \wedge \bigwedge_{i=1}^{n} \mathtt{t}(\mathrm{A}_i)(x_i) \wedge \forall y. \big(\mathtt{diff}(x_1, \ldots, x_n, y) \rightarrow \bigvee_{\mathrm{A} \in \mathtt{T}_\forall} \mathtt{t}(\mathrm{A})(y)\big)\Big).$$

Intuitively, $\theta^{=}(\mathtt{T}_\exists, \mathtt{T}_\forall)$ asserts that there are n-distinct elements $s_1, \ldots, s_n$ of the given domain S such that each s_i satisfies the Q-type A_i of the existential part $\mathtt{T}_\exists$, and every other element of the domain satisfies some Q-type in the universal part $\mathtt{T}_\forall$.

▶ **Definition 6.2.** *Let* $\mathrm{Q}' \subseteq \mathrm{Q}$ *with* $\mathrm{Q}' \neq \emptyset$. *A basic formula* $\theta^{=}(\mathtt{T}_\exists, \mathtt{T}_\forall)$ *is* Q'-functional in one direction *if there exists* $\mathrm{A} \in \mathtt{T}_\exists$ *such that* A *is a singleton consisting of an element in* Q', *and for each* $\mathrm{B} \in (\mathtt{T}_\exists \setminus \{\mathrm{A}\}) \cup \mathtt{T}_\forall$, B *does not contain elements in* Q'. *A first-order* Q-*constraint is* Q'-functional in one direction *if it is the disjunction of basic formulae which are* Q'-*functional in one direction.*

Intuitively, when the local behaviour of an HFTA $\mathcal{A}$ at the current input node w is driven by a constraint θ that is Q'-functional in one direction, then there is a child w' of w such that exactly one copy of $\mathcal{A}$ is sent to w'. Moreover, the state of this copy is in Q' and the states of the copies sent to the children of w distinct from w' are in $\mathrm{Q} \setminus \mathrm{Q}'$.

▶ **Definition 6.3.** *An* HFTA $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$ *is* nondeterministic in one path *if the initial state* q_I *belongs to some existential component* Q_ℓ *of* $\mathcal{A}$ *and the following hold:*

1. *for each* $q \in \mathrm{Q}_\ell$ *and* $a \in \Sigma$, $\delta(q, a)$ *is* Q_ℓ-*functional in one direction;*
2. *for each* $\mathcal{T} \in \mathsf{L}(\mathcal{A})$ *and for each infinite path* π *of* $\mathcal{T}$ *from the root, there is an accepting run* $r = (\mathrm{T}_r, Lab_r)$ *of* $\mathcal{A}$ *over* $\mathcal{T}$ *s.t. for each input node* $w \in \pi$, *there is exactly one node* y *of* r *reading* w, *i.e., such that* $Lab_r(y) = (q, w)$ *for some state* q; *moreover,* $q \in \mathrm{Q}_\ell$.

Let $\Sigma = 2^{\mathrm{AP}}$, $p \in \mathrm{AP}$, $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$ be an HFTA that is nondeterministic in one path, and Q_ℓ be the existential component such that $q_I \in \mathrm{Q}_\ell$. We consider the HFTA $\exists^{\mathsf{C}} p.\mathcal{A} = \langle 2^{\mathrm{AP} \setminus \{p\}}, \mathrm{Q}, \delta', q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$, where the transition function δ' is defined as follows for all $q \in \mathrm{Q}$ and $a \in 2^{\mathrm{AP} \setminus \{p\}}$: $\delta'(q, a) = \delta(q, a)$ if $q \notin \mathrm{Q}_\ell$, and $\delta'(q, a) = \delta(q, a) \vee \delta(q, a \cup \{p\})$ otherwise. Hence, on all the states which are not in the existential component Q_ℓ, $\exists^{\mathsf{C}} p.\mathcal{A}$ behaves as $\mathcal{A}$. On the states in Q_ℓ, the projection automaton guesses whether in the simulated run of $\mathcal{A}$, proposition p marks the current input node or not, and proceeds according to the guess and the transition function of $\mathcal{A}$. By Definition 6.3, we easily obtain the following result.

▶ **Proposition 6.4.** *Let* $\mathcal{A}$ *be an* HFTA *over* 2^{AP} *that is nondeterministic in one path and* $p \in \mathrm{AP}$. *Then,* $\mathsf{L}(\exists^{\mathsf{C}} p.\mathcal{A}) = \exists^{\mathsf{C}} p.\mathsf{L}(\mathcal{A})$.

From HFTA to HFTA that are nondeterministic in one path. We now show that HFTA can be effectively translated into equivalent HFTA that are nondeterministic in one path. We first establish a preliminary result on the one-step logic $\mathrm{FOE}_1^+(\mathrm{Q})$ for a given non-empty set Q.

▶ **Definition 6.5.** *Let θ be a first-order* Q*-constraint and θ_s be a first-order $(\mathrm{Q} \cup 2^{\mathrm{Q}})$-constraint which is 2^{Q}-functional in one direction. We say that θ_s simulates θ if the following hold:*

- *for each minimal model (S, I) of θ and for each $s \in \mathrm{S}$, $(\mathrm{S}, \mathrm{I}[s \to \{\mathrm{I}(s)\}])$ is a model of θ_s;*
- *for each minimal model (S, I) of θ_s, let $s \in \mathrm{S}$ be the unique element in S such that $\mathrm{I}(s)$ is of the form $\{\mathrm{Q}'\}$ for some $\mathrm{Q}' \in 2^{\mathrm{Q}}$. Then, the pair $(\mathrm{S}, \mathrm{I}[s \to \mathrm{Q}'])$ is a model of θ;*

where the mappings $\mathrm{I}[s \to \{\mathrm{I}(s)\}]$ and $\mathrm{I}[s \to \mathrm{Q}']$ are defined in the obvious way.

Since each first-order Q-constraint is effectively equivalent to a disjunction of basic formulae [12], we easily obtain the following result.

▶ **Proposition 6.6.** *Let θ be a first-order* Q*-constraint. Then, one can construct a first-order $(\mathrm{Q} \cup 2^{\mathrm{Q}})$-constraint θ_s which is 2^{Q}-functional in one direction and simulates θ.*

Fix an HFTA $\mathcal{A} = \langle \Sigma, \mathrm{Q}, \delta, q_I, \mathsf{H}, \mathsf{H}_\exists, \Omega \rangle$ with $\mathsf{H} = \langle \mathrm{Q}_1, \ldots, \mathrm{Q}_n \rangle$. We construct in two stages an equivalent HFTA $\mathtt{Sim}(\mathcal{A})$ that is nondeterministic in one path. First, by a kind of powerset construction, we construct an automaton $\mathcal{A}_{\mathtt{PATH}}$ that is nondeterministic in one path but the acceptance condition of the existential component $Pow_{\mathcal{A}}$ containing the initial state is not a Büchi condition but an ω-regular set over the infinite sequences on $Pow_{\mathcal{A}}$. In the second stage of the construction, we show how the ω-regular condition can be converted into a standard Büchi condition by equipping the "macro" states in $Pow_{\mathcal{A}}$ with additional information. Intuitively, given an input tree (T, Lab) accepted by $\mathcal{A}$, the automaton $\mathcal{A}_{\mathtt{PATH}}$ simulates the behaviour of $\mathcal{A}$ along an accepting run r over (T, Lab) by guessing an infinite path π of the input tree from the root and proceeding as follows:

- in the input nodes $w \notin \pi$, $\mathcal{A}_{\mathtt{PATH}}$ simply simulates the behaviour of $\mathcal{A}$ along r;
- in the input nodes $w \in \pi$, $\mathcal{A}_{\mathtt{PATH}}$ keeps track in its "macro" state (a state in the existential component $Pow_{\mathcal{A}}$) of the states of $\mathcal{A}$ associated with the copies of $\mathcal{A}$ that read w along r. Thus, in the run of $\mathcal{A}_{\mathtt{PATH}}$, there is a unique infinite path ν from the root associated with the guessed input path π, and ν "collects" the set of parallel paths ν_r of the simulated run of $\mathcal{A}$ associated with the input path π. In order to check the acceptance condition on the individual parallel paths ν_r, an infinite sequence of "macro" states ρ must allow to distinguish the individual infinite paths over Q grouped by ρ. Thus, like in [82], a "macro" state associated with an input node w is a set of pairs (q_p, q): the pair (q_p, q) represents a copy of $\mathcal{A}$ in state q at node w along the simulated run r which has been generated by a copy of $\mathcal{A}$ in state q_p reading the parent node of w in the input tree.

Formally, we denote by $Pow_{\mathcal{A}}$ the subset of $2^{\mathrm{Q} \times \mathrm{Q}}$ consisting of the sets of pairs (q, q') of $\mathcal{A}$-states such that the order of q' is equal or lower than the order of q (*order requirement*). A $Pow_{\mathcal{A}}$*-path* ν is an infinite word $\nu = \mathrm{P}_0\mathrm{P}_1 \ldots$ over $Pow_{\mathcal{A}}$ such that the following conditions are fulfilled: (i) $\mathrm{P}_0 = \{(q_I, q_I)\}$ (*initialisation*), and (ii) for all $i \geq 0$ and $(q_i, q_{i+1}) \in \mathrm{P}_{i+1}$, there is an element of P_i of the form (q_{i-1}, q_i) (*consecution*). An $\mathcal{A}$*-path* of ν is a maximal (possibly finite) non-empty sequence $q_0 q_1 \ldots$ of $\mathcal{A}$-states such that $(q_{i-1}, q_i) \in \mathrm{P}_i$ for all $1 \leq i < |\nu|$. The $Pow_{\mathcal{A}}$-path ν is $\mathcal{A}$-accepting if all infinite $\mathcal{A}$-paths of ν satisfy the parity condition Ω of $\mathcal{A}$. The automaton $\mathcal{A}_{\mathtt{PATH}}$ is then given by $\mathcal{A}_{\mathtt{PATH}} = \langle \Sigma, \mathrm{Q} \cup Pow_{\mathcal{A}}, \delta_{\mathtt{PATH}}, \{(q_I, q_I)\}, \mathsf{H}_{\mathtt{PATH}}, \mathsf{H}_\exists \cup \{Pow_{\mathcal{A}}\}, \Omega \rangle$ where $\mathsf{H}_{\mathtt{PATH}} = \langle \mathrm{Q}_1, \ldots, \mathrm{Q}_n, Pow_{\mathcal{A}} \rangle$ (the existential component $Pow_{\mathcal{A}}$ has highest order) and $\delta_{\mathtt{PATH}}$ is defined as follows:

- for all $q \in \mathrm{Q}$ and $a \in \Sigma$, $\delta_{\mathtt{PATH}}(q, a) = \delta(q, a)$;

- for all $\mathrm{P} \in \mathit{Pow}_{\mathcal{A}}$ and $a \in \Sigma$, if P is empty, then $\delta_{\mathtt{PATH}}(\mathrm{P}, a) = \exists x.\, \mathrm{P}(x)$; otherwise, let us consider the first-order $(\mathrm{Q} \times \mathrm{Q})$-constraint θ given by $\bigwedge_{(q_p,q)\in \mathrm{P}} \delta_q(q, a)$, where $\delta_q(q, a)$ is obtained from $\delta(q, a)$ by replacing each predicate $q'(y)$ occurring in $\delta(q, a)$ with $(q, q')(y)$. By Proposition 6.6, one can construct a first-order $((\mathrm{Q} \times \mathrm{Q}) \cup \mathit{Pow}_{\mathcal{A}})$-constraint θ_s which is $\mathit{Pow}_{\mathcal{A}}$-functional in one direction and simulates θ. Then, $\delta_{\mathtt{PATH}}(\mathrm{P}, a)$ is obtained from θ_s by replacing each predicate $(q, q')(y)$ occurring in θ_s associated with an element of $\mathrm{Q} \times \mathrm{Q}$ with q'. Note that $\delta_{\mathtt{PATH}}(\mathrm{P}, a)$ satisfies the first-order existential requirement and is $\mathit{Pow}_{\mathcal{A}}$-functional in one direction.

Note that in the definition of $\mathcal{A}_{\mathtt{PATH}}$, no acceptance condition is defined for the macro states in $\mathit{Pow}_{\mathcal{A}}$ (the parity condition Ω inherited by $\mathcal{A}$ is defined only on the states in Q). By construction and Proposition 6.6, for each run r of $\mathcal{A}_{\mathtt{PATH}}$ over an input $(\mathrm{T}, \mathit{Lab})$ and every infinite path π of r starting at the root, either π is associated with a $\mathit{Pow}_{\mathcal{A}}$-path ν (in this case, we say that π is accepting if ν is accepting) or π gets trapped into some non-transient component of $\mathcal{A}$ (in this case, acceptance of π is determined by the parity condition Ω). We denote by $\mathsf{L}(\mathcal{A}_{\mathtt{PATH}})$ the set of input trees $(\mathrm{T}, \mathit{Lab})$ such that there is a run of $\mathcal{A}_{\mathtt{PATH}}$ over $(\mathrm{T}, \mathit{Lab})$ whose infinite paths starting at the root are all accepting. By construction and Proposition 6.6, we easily deduce the following crucial result.

▶ **Lemma 6.7.** *$\mathcal{A}_{\mathtt{PATH}}$ is nondeterministic in one path and $\mathsf{L}(\mathcal{A}_{\mathtt{PATH}}) = \mathsf{L}(\mathcal{A})$.*

Construction of the Automaton $\mathtt{Sim}(\mathcal{A})$. Let F_{B} (resp., $\mathrm{F}_{\mathsf{coB}}$) be the set of states in the existential (resp., universal) components of $\mathcal{A}$ having even (resp., odd) color. Fix a $\mathit{Pow}_{\mathcal{A}}$-path ν. By the order requirement, each infinite $\mathcal{A}$-path of ν gets trapped into an existential or universal component of $\mathcal{A}$. Thus, by the hesitant acceptance requirement of HFTA, the $\mathit{Pow}_{\mathcal{A}}$-path ν is $\mathcal{A}$-accepting if and only if for each infinite $\mathcal{A}$-*path* π of ν, the following holds: if π gets trapped into an existential component, then π visits *infinitely* many times some state in F_{B} (*Büchi condition*); otherwise (i.e., π gets trapped into an universal component), π visits *finitely* many times all the states in $\mathrm{F}_{\mathsf{coB}}$ (*coBüchi condition*).

It is known that coBüchi alternating word automata (AWA) over infinite words can be converted in quadratic time into equivalent Büchi AWA by means of the so called *ranking construction* [46]. We adapt the ranking construction and the Miyano-Hayashi construction [53] (for converting a Büchi AWA into an equivalent Büchi NWA) for providing a characterisation of acceptance of $\mathit{Pow}_{\mathcal{A}}$-paths ν by a classical Büchi condition on an extension of ν obtained by adding to each macro-state visited by ν additional finite-state information. Hence, we obtain the following result.

▶ **Theorem 6.8.** *For the given* HFTA $\mathcal{A}$*, one can construct an* HFTA $\mathtt{Sim}(\mathcal{A})$ *that is nondeterministic in one path and such that* $\mathsf{L}(\mathtt{Sim}(\mathcal{A})) = \mathsf{L}(\mathcal{A})$.

By Theorem 6.8 and Proposition 6.4, we obtain the following result.

▶ **Corollary 6.9.** *The class of* HFTA *is effectively closed under chain projection.*

An HFTA with transition function δ is in *normal form* if over existential (resp., universal) components Q_ℓ, $\delta(q, a)$ (resp., the dual of $\delta(q, a)$) is Q_ℓ-functional in one direction for all $q \in \mathrm{Q}_\ell$ and $a \in \Sigma$. Since the constructions for the Boolean language operations and the construction for the closure under chain projection (Theorem 6.8 and Proposition 6.4) preserve the normal form, we deduce the following result.

▶ **Theorem 6.10.** *Given an* MCL *sentence φ, one can construct an* HFTA $\mathcal{A}_\varphi$ *in normal form such that* $\mathsf{L}(\mathcal{A}_\varphi) = \mathsf{L}(\varphi)$.

We exploit the normal form for showing that CDL (or, equivalently, the class of symmetric HGTA) provides a characterisation of the bisimulation-fragment of MCL. It is known [82, 12] that for each FTA $\mathcal{A}$, one can construct a symmetric FTA $\mathcal{A}_S$ such that if $\mathsf{L}(\mathcal{A})$ is bisimulation-closed, then $\mathcal{A}$ and $\mathcal{A}_S$ accept the same tree-language. By adapting the construction given in [82, 12], we can show that a similar result holds for HFTA in normal form versus symmetric HGTA. Hence, by Theorems 5.8 and 5.9 and Theorem 6.10, we deduce the following result.

▶ **Theorem 6.11.** *The bisimulation-invariant fragment of* MCL*,* CDL*, and the class of symmetric* HGTA *are expressively equivalent in a constructive way.*

7 Conclusion

This work provides automata-theoretic characterisations of branching-time temporal logics, mainly focusing on CTL* and CDL, the latter being a syntactic variant of the already known ECTL*. Specifically, we prove the equivalence between the symmetric variant of classic ranked Hesitant Tree Automata (HTA) and both CDL and the bisimulation-invariant fragment of Monadic Chain Logic (MCL). The full MCL, instead, is proved equivalent to a first-order variant of HTAs. In addition, we close a longstanding gap in the expressiveness landscape of branching-time logics, by providing an automata-theoretic characterisation of CTL*. This is obtained via a generalisation to tree-languages of the notion of counter-freeness, originally introduced in the context of word languages. The generalisation essentially decomposes an HTA into a number of counter-free word automata, one for each level of the state decomposition of the HTA. This decomposition, however, works correctly only when the HTA satisfies the additional property of mutual-exclusion. The property requires that different sets of automaton states, active at the same time on a given node of the input tree, must accept different subtrees. Both mutual-exclusion and counter-freeness seem to be essential to capture a meaningful notion of counter-freeness for tree automata. Together these results bring the expressiveness landscape for branching-time temporal logics to almost the same level as their linear-time counterparts.

There are few open questions remaining. In particular, while Theorem 6.11 establishes the equivalence between the bisimulation invariant fragment of MCL and CDL, the precise relationship between CCDL (hence, ECTL*) and full MCL still remains unsettled. In addition, techniques similar to those used in this work may also be applicable to obtain a characterisation of Monadic Tree Logic (MTL), a fragment of MSO where quantified variables range over subtrees [3], and of Substructure Temporal Logic (STL), a temporal logic where one can implicitly predicate over substructure/subtrees [4, 5]. The restriction that variables range over trees, indeed, seem to be tightly connected with the notion of counter-freeness. The difficulty in this case is that counter-free HTAs would not suffice, since both MTL and STL are strictly more expressive than CTL*, and a meaningful definition of decomposition into word automata of a non-hesitant tree automaton is not immediately obvious.

Abstract

Models of computations over the integers are equivalent from a computability and complexity theory point of view by the (effective) Church-Turing thesis. It is not possible to unify discrete-time models over the reals. The situation is unclear but simpler for continuous-time models, as there is a unifying mathematical model, provided by ordinary differential equations (ODEs). Each model corresponds to a particular class of ODEs. For example, the General Purpose Analog Computer model of Claude Shannon, introduced as a mathematical model of analogue machines (Differential Analyzers), is known to correspond to polynomial ODEs. However, the question of a robust complexity theory for such models and its relations to classical (discrete) computation theory is an old problem. There was some recent significant progress: it has been proved that (classical) time complexity corresponds to the length of the involved curves, i.e. to the length of the solutions of the corresponding polynomial ODEs. The question of whether there is a simple and robust way to measure space complexity remains. We argue that space complexity corresponds to precision and conversely.

Concretely, we propose and prove an algebraic characterisation of **FPSPACE**, using *continuous* ODEs. Recent papers proposed algebraic characterisations of polynomial-time and polynomial-space complexity classes over the reals, but with a discrete-time: those algebras rely on discrete ODE schemes. Here, we use classical (continuous) ODEs, with the classic definition of derivation and hence with the more natural context of continuous-time associated with ODEs. We characterise both the case of polynomial space functions over the integers and the reals. This is done by proving two inclusions. The first is obtained using some original polynomial space method for solving ODEs. For the other, we prove that Turing machines, with a proper representation of real numbers, can be simulated by continuous ODEs and not just discrete ODEs. A major consequence is that the associated space complexity is provably related to the numerical stability of involved schemas and the associated required precision. We obtain that a problem can be solved in polynomial space if and only if it can be simulated by some numerically stable ODE, using a polynomial precision.

1 Introduction

Recently, there has been a renewed interest in models of computations over the reals and their associated complexity classes. The fact that these models appear in complexity issues of deep learning models (a.k.a. neural networks) partially explains it. For example, various

51st International Colloquium on Automata, Languages, and Programming (ICALP 2024).

problems, such as the training of fully connected neural networks, have been proved to be a $\exists\mathbb{R}$-complete problem [2, 3]. Complexity classes like **FIXP** were introduced to discuss the complexity of continuous functions' fixed points in various contexts, such as game theory [32]. These classes and statements are related to discrete-time models of computation over the reals.

For discrete-time models of computations over the reals, the most famous approaches are computable analysis, based on the Turing machine model in [55] and [59] and algebraic models such as the Blum Shub Smale (BSS) model of computation [9, 8]. The class $\exists\mathbb{R}$ corresponds to the (constant-free, equivalently uniform) non-deterministic time of the BSS model of computation. Numerous decision problems were proved recently to be in this class. Both models were tailored for very different applications and it is well-known we cannot unify existing models with the equivalent of a Church-Turing thesis. For example, computable functions in a computable analysis model need to be continuous, while the BSS model intends to consider functions and problems over the polynomials that are not. It is also explained by the fact that some models have not been introduced with the idea of corresponding to actual physical machines but also to discuss abstract complexity (lower and upper bounds) for associated problems. Notice that some characterisations of complexity classes corresponding to **PSPACE** have been obtained [10, 11] in the BSS model.

Among models of computation over the reals, we can also distinguish continuous-time models. This includes models of old, first-ever-built computers, such as the Differential Analysers [57]. A famous mathematical model of such machines is the General Purpose Analog Computer model of Claude Shannon [53]. It covers many historical machines and today's analogue devices [56, 58] too. It also includes various recent approaches and models from deep learning such as Neural ODEs [26, 44] with many variants. In the context of continuous-time, the situation is clearer than with discrete-time models, as there is a unifying way to describe these models, provided by Ordinary Differential Equations (ODEs). Each model corresponds to a particular class of ODEs. For example, the GPAC corresponds to polynomial ODEs [37], and Neural ODEs are made by selecting the best solution among a parameterised class of ODEs: see, e.g. [44].

Even if particular classes of ODEs can describe such models, defining a robust and well-defined computation theory for continuous-time computations is not an easy problem: see [21] for the most recent survey. In short, the problem with time complexity is that considering the time variable as a measure of time is not robust: a curve can always be re-parameterised using a change of variable. The problem with space complexity is similar: reparameterisation corresponds to a change of time variable, but also of space-variable, introducing space and time contractions: See e.g. [21, 17]. Furthermore, many problems for simple dynamical systems are known to be undecidable, hence forbid **PSPACE**-completeness: see [38] and [39].

There was a recent breakthrough in [19, 17], where the authors relate time with the length of the solution curve of an ODE. Polynomial ODEs and their projections are known to cover a very wide class of functions, including all common functions or functions that can be built from them [35]. As the length of a curve is preserved under reparameterization, considering the length solves the issue of a possible change of variable. The authors prove that for polynomial ODEs, this is polynomially related to the time required to solve an ODE, hence providing a robust notion of time for ODEs. These statements and underlying constructions, which allow the simulation of Turing machines, led to solving several open problems: the existence of a universal ODE [20], the proof of the Turing-completeness of chemical reactions [33], or statements about the hardness of several dynamical systems problems [39].

The question of whether we can give a simple equivalent defining *space complexity* remains. We argue here that space complexity is polynomially related and conversely to the numerical stability of ODEs and their associated precision. We prove that a problem can be solved in polynomial space iff it can be simulated by some numerically stable ODE, using a polynomial precision. We prove this holds both for classical complexity over the discrete (functions over the integers) and also for space complexity for real functions in the model of computable analysis.

▶ Remark 1. In the literature, there are two possible definitions for **FPSPACE**, according to whether functions with non-polynomial size values are allowed or not. In this article, when we talk about **FPSPACE**, we always assume the outputs remain of polynomial size. Otherwise, the class is not closed by composition: the issue is about the usual convention of not counting the input and output as part of the total space used. Given f computable in polynomial space and g in logarithmic space, $f \circ g$ (and $g \circ f$) is computable in polynomial space. But, if exponential size output is allowed, this is not true: the issue is that if we assumed only f and g to be computable in polynomial space, the first might give an output of exponential size.

These questions of providing characterisations of classical complexity using ODEs can also be seen from the so-called "implicit complexity" point of view. Having "simple" characterisations of computability and complexity classes is useful for various fundamental and applied science fields. We are interested here in "algebraic" characterisations of those classes: we want to define them as the smallest set $[f_1, \ldots, f_k; o_1, \ldots, o_l]$ where the f_i are functions, closed under the operators o_j. For example, the set of computable functions over the integers is well-known to be: $[0, 1, \pi^i_k;$ *composition, minimisation, primitive recursion*$]$. Implicit complexity aims at giving similar algebras for classes of complexity theory: a reference survey is [27, 28]. The main benefit is to avoid the use of the framework of Turing machines, which is rather heavy and not necessarily well-known outside fundamental computer science. Several characterisations for **PTIME** over the integers were proposed. The first is due to Cobham in [29], but relies on explicit *ad hoc* bounds. Other approaches have then been proposed, see surveys [27, 28]. Recently, Bournez and Durand in [13] suggested an algebra using the so-called "linear-length" discrete ODEs. Instead of having explicit bounds, the linearity of the involved discrete ODE guarantees polynomial time complexity.

Using a similar approach, Blanc and Bournez in [4] and in [5] extended the constructions to a characterisation of **PTIME** for function over the reals. The latter extended the result to **PSPACE**, defining *robust* ODEs. However, those models rely on discrete ODEs (a.k.a. finite differences), which are discrete-time and less natural than continuous ODEs. We review all those results in Section 3.2.

This paper can be related to [19, 17]: the authors of these articles provide a characterisation of **PTIME** with *continuous* ODEs, establishing that time complexity corresponds to the length of the involved curve, i.e. the motto **time complexity = length**. Here, we get a motto of the form **space complexity = precision**.

Some of our constructions have similarities with the statements in [7]. In the later paper, various robustness concepts are introduced and it is proven that they lead to tractability. See the references in [7] for similar robustness statements. Robustness can also be associated with a dual motivation: the authors of [40] introduced a concept of robust undecidability, while here, we want a concept of robustness leading to tractability.

This is not the first time **FPSPACE** is characterised using continuous ODEs. However, the existing characterisation [34, 14] is obtained with complicated conditions on ODEs, while we have a simpler statement linking complexity to precision in a direct manner. Notice that

the latter approach dealt with polynomial ODEs, while we do not restrict to polynomial ODEs. We obtain our statements by revisiting the approach of the latter papers but working over a compact domain and dealing with error correction more finely.

Intuitively, this can also be read as being in **PSPACE** for an ODE is consistent with having an attractor easily discretisable when there is one. We can also define the notion of robustness, as the insensitivity to "small" perturbations.

While discussing all these issues, we propose an algebraic characterisation of **PSPACE**, using *continuous* ODEs with the following algebra ($\mathbb{RCD}$ is for Robust Continuous Differential) (Schema *robust ODE* is formally defined in Definition 9):

$$\mathbb{RCD} = [0, 1, \pi_i^k, +, -, \times, \tanh, \cos, \pi, \frac{x}{2}, \frac{x}{3}; \textit{composition}, \textit{robust ODE}].$$

For a function $\mathbf{f} : \mathbb{R}^d \to \mathbb{R}^{d'}$ sending every integer $\mathbf{n} \in \mathbb{N}^d$ to the vicinity of some integer of $\mathbb{N}^d$, say at distance less than $1/4$, we write $\mathrm{DP}(f)$ for its discrete part: this is the function from $\mathbb{N}^d \to \mathbb{N}^{d'}$ mapping $\mathbf{n} \in \mathbb{N}^d$ to the integer rounding of $\mathbf{f}(n)$. For a class $\mathcal{C}$ of such functions, we write $\mathrm{DP}(\mathcal{C})$ for the class of the discrete parts of the functions of $\mathcal{C}$.

▶ **Theorem 2.** $\mathrm{DP}(\mathbb{RCD}) = \mathbf{FPSPACE} \cap \mathbb{N}^{\mathbb{N}}$.

We also provide a characterisation of functions over the reals computable in polynomial space, inspired by [5]. This is obtained by adding a limit schema *ELim* to $\mathbb{RCD}$. If we consider $\overline{\mathbb{RCD}} = [0, 1, \pi_i^k, +, -, \times, \tanh, \cos, \pi, \frac{x}{2}, \frac{x}{3}; \textit{composition}, \textit{robust ODE}, \textit{ELim}]$ then:

▶ **Theorem 3** (Generic functions over the reals). $\overline{\mathbb{RCD}} \cap \mathbb{R}^{\mathbb{R}} = \mathbf{FPSPACE} \cap \mathbb{R}^{\mathbb{R}}$
More generally: $\overline{\mathbb{RCD}} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}} = \mathbf{FPSPACE} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^d}$.

We organise the article as follows. In Section 2, we recall the concept of dynamical systems and discuss some associated complexity issues. We introduce the concept of robust ODE and prove that a robust ODE can be solved in polynomial space (Theorem 11). This is obtained, using an original method for solving ODE, optimising space, inspired by Savitch's theorem. This provides one direction of all the above theorems. The other direction is the object of the following sections, starting from Section 3. We first recall some previous results on discrete ODEs in Section 3. Using extensions of constructions from [5], we then prove that we can simulate a Turing machine using robust continuous ODEs in Section 4. This is obtained by simulating some discrete ODEs using continuous ODEs, dealing with error corrections, and using the fact that the functions are robust to a controlled error. The main result of Section 3 is Theorem 42. It states we can simulate Turing machines robustly with continuous ODEs when space remains polynomial. This theorem leads to the proof of Theorem 2 in Section 4. In Section 5, we prove Theorem 3. In Section 6, we conclude and discuss future works.

Some basic concepts

When we say that a function over the real is computable this is always in the sense of computable analysis: see e.g. [59, 46, 23]. A reference book for issues related to complexity theory in computable analysis is [46].

We assume some basic familiarities with dynamical systems. See [41] for a monography on the theory of dynamical systems from a mathematical point of view. Formally, a *discrete-time dynamical system* is given by a set D, called the *domain* and some (possibly partial) function $\mathbf{u}$ from D to D. A trajectory of the system is a sequence $\mathbf{f}(t)$ evolving according to $\mathbf{u}$: that is $\mathbf{f}(t+1) = \mathbf{u}(\mathbf{f}(t))$ for all t. A *continuous-time dynamical system* is given by a set $D \subseteq \mathbb{R}^d$ and some ODE of the form

$$\mathbf{f}' = \mathbf{u}(\mathbf{f}(t)) \tag{1}$$

on D. A trajectory starting from $\mathbf{f}_0$ is a solution of the associated Initial Value Problem (IVP), given by (1) and initial condition $\mathbf{f}(0) = \mathbf{f}_0$. A dynamical system can equivalently be described by its flow: $\Phi(\mathbf{f}_0, t)$ gives the position of the dynamics at time t, for an initial position $\mathbf{f}(0) = \mathbf{f}_0$. It satisfies the flow property

$$\Phi(\mathbf{f}_0, 0) = \mathbf{f}_0 \quad \Phi(\mathbf{f}_0, t + t') = \Phi(\Phi(\mathbf{f}_0, t), t'). \tag{2}$$

The dynamics or the flow can be parametrised by some $\mathbf{x}$: $\mathbf{u}$ is also some function of $\mathbf{x}$ and the flow function is $\Phi_{\mathbf{x}}(\mathbf{f}_0, t)$.

In the long run, dynamical systems may exhibit attractors. We refer to [48] for discussions of many possible ways of defining this concept, and to [51] for a characterisation of the hardness of computing attractors from a computable analysis point of view. Somehow, our coming results state that the uncomputability discussed in [51] is intrinsically due to the non-numerical stability of the considered dynamical systems there.

2 Dynamical systems and associated complexity issues

2.1 Some complexity results on graphs

We need to discuss the hardness of solving IVP, or equivalently of computing $\Phi(y, t)$. For pedagogical reasons, we first discuss the case of a simple setting, namely the case of a (deterministic) directed graph. Indeed, observe that a discrete-time dynamical system (D, u) can also be seen as a particular (deterministic) directed graph $G = (V, \to)$, where, in the general case, V is not necessarily finite: G corresponds to $V = D$ and $\to$ to the graph of the function u, i.e. $\mathbf{x}_t \to \mathbf{x}_{t+1}$ iff $\mathbf{x}_{t+1} = \mathbf{u}(\mathbf{x}_t)$. The obtained graph is deterministic because any vertex has an outdegree 1. Starting from some point $\mathbf{x}_0$, there is at most one possible path, and consequently, for a given time T, we can talk about its position at time t, i.e. $\Phi(\mathbf{x}_0, T)$ is Tth element of this path: (as usual in complexity theory, the length of some integer x is the length of its binary representation, denoted by $\ell(x)$).

▶ **Proposition 4** (The case of finite graphs). *Let $s(n) \geq \log(n)$ be space-constructible. Assume the vertices of $G = (V, \to)$ can be encoded in binary using words of length $s(n)$. Assume the relation $\to$ is decidable using a space polynomial in $s(n)$. Then,*

- *given the encoding of $\mathbf{u} \in V$ and of $\mathbf{v} \in V$, we can decide whether there is some path from $\mathbf{u}$ to $\mathbf{v}$, in a space polynomial in $s(n)$.*
- *given the encoding of $\mathbf{u} \in V$, and integer T in binary, we can compute $\Phi(\mathbf{u}, T)$, in a space polynomial in $s(n)$ and the length of T.*

The second item is even a characterisation of the complexity of the problem. Indeed, the converse is true: If, given the encoding of $\mathbf{u} \in V$, and integer T in binary, we can compute $\Phi(\mathbf{u}, T)$, in a space polynomial in $s(n)$ and the length of T, then as $\to$ is given by $\Phi(., 1)$, then $\to$ is decidable using a space polynomial in $s(n)$.

Proof. It is well-known that for finite graphs, given a directed graph $G = (V, \to)$ and some vertices $\mathbf{u}, \mathbf{v} \in V$, determine whether there is some path between $\mathbf{u}$ and $\mathbf{v}$ in G, denoted by $\mathbf{u} \xrightarrow{*} \mathbf{v}$ is in NLOGSPACE: the rough idea is to guess non-deterministically the intermediate nodes. The formal proof is detailed in [54]. The same algorithm, working over representations

of vertices, when vertices are encoded using words of length $s(n)$ will work in NSPACE($s(n)$) (with the addition of the binary encoding of T if for the second item, if it bigger than $s(n)$). We then observe that NSPACE($s(n)$) = SPACE($s(n)$) from Savitch's theorem, recalled below. ◀

▶ **Theorem 5** (Savitch's theorem, [54, Theorem 8.5]). *For any space-constructible*[1] *function* $s : \mathbb{N} \to \mathbb{N}$ *with* $s(n) \geq \log n$*, we have* NSPACE($s(n)$) $\subseteq$ SPACE($s^2(n)$)*.*

Recall that the key argument of the proof of Theorem 5 is to express the question as a recursive procedure (expressing reachability in less than 2^t steps, called $CANYIELD(\mathbf{x}, \mathbf{y}, t)$ in [54]) guaranteeing the required space complexity: we write that relation $CANYIELD(\mathbf{x}, \mathbf{y}, t)$ is relation $\mathbf{x} \to \mathbf{y}$ when $t = 1$, and is relation $\exists \mathbf{z}$ such that $CANYIELD(\mathbf{x}, \mathbf{z}, t/2)$ and $CANYIELD(\mathbf{z}, \mathbf{y}, t/2)$ otherwise. If one prefers, this can also be understood as "guessing" some intermediate node $\mathbf{z}$.

▶ Remark 6 (Attractor point of view). We presented the above statement in terms of computing the flow $\Phi(\mathbf{x}, T)$. This could alternatively be interpreted in terms of attractors. Indeed, when the above hypothesis holds, then the dynamics is captured by a graph. In the long run, in particular, if T is greater than the number of vertices, any trajectory loops (i.e. reaches an attractor). The above statement could then also be read as the fact that such an attractor is then polynomial space computable.

2.2 Solving efficiently ODEs: what is known

This idea leads to an original method for solving ODEs. At least, this is original for the numerical analysis literature, as far as we know. A recent survey about computability and complexity issues for solving ODEs is [39]. In short: First, it is important to distinguish the case where we want to solve the ODE on a bounded (hence a compact) domain, from the case of the full domain $\mathbb{R}$: in the latter case, we might ask questions about the evolution of the system on the long run, which is harder. Over a compact domain, it is known that there exists some polynomial-time computable function $u : [-1, 1] \times [0, 1] \to \mathbb{R}$ such that $f' = u(f, t)$ has no computable solution, even over $[0, \delta]$, for any $\delta > 0$: see [45, 50, 1]. The involved ODE has no unique solution. It is known over compact or non-compact domains that if unicity holds, then its solution is computable [30, 31, 52]. However, the complexity can be arbitrarily high [46, 47]. If we want to get to tractability, then some regularity hypotheses must be assumed. A classical hypothesis is to assume the ODE to be Lipschitz.

Over a compact domain, it has been observed in several references (see e.g. [46]) that a careful analysis of Euler's method proves that, if $u : B(0, 1) \times [0, 1] \to \mathbb{R}^n$, with $B(0, 1) \subseteq \mathbb{R}^n$, is a polynomial time computable (right-)Lipschitz function then any solution $f : [0, 1] \to B(0, 1)$ of $f' = u(f, t)$ must be **FPSPACE**: see the discussions around Theorem 3.2 in [39] with several references. Kawamura has proved in [42] that there exists a polynomial-time computable function $u : [-1, 1] \times [0, 1] \to \mathbb{R}$, which satisfies a Lipschitz condition, such that the unique solution $f : [0, 1] \to \mathbb{R}$ takes values in $[-1, 1]$ and computing it leads to a **PSPACE**-complete problem. Hence, the question of solving ODEs over a compact domain in polynomial time corresponds to the question **PTIME** = **PSPACE** [42], even for $\mathcal{C}^\infty$-functions [43].

[1] As proved in [54], this hypothesis can be avoided, at the price of a slightly more complicated proof.

However, all these results are over compact domains, and dealing with non-compact domains, i.e. in the long run, is harder. **PSPACE** membership is not true, as this is possible to simulate any Turing machine by some finite-dimensional polynomial ODE [38] over a non-compact domain. This led to many undecidability results for analytic, and even very simple ODEs: see e.g. [38]. A possible way to analyse efficiency is to analyse the complexity of the solution assuming a bound on the function's growth (i.e. using parameterised complexity). It was proved in [16] that one can solve a polynomial ODE in polynomial time assuming a bound on $\mathbf{Y}(T) = \max_{0\leq t\leq T} \|\mathbf{f}(t)\|$. The result for polynomial ODEs was later improved in [49], where it is proved that the time T and parameter $\mathbf{Y}$ can be replaced by a single parameter, namely the length of the curve for polynomial ODEs. Furthermore, this parameter does not need to be given as input to the algorithm. This is a key argument for one direction of the motto "time complexity = length" we mentioned above. To get polynomial-time complexity over a non-compact domain, it is also mandatory not to use most classical methods from numerical analysis.

The same happens when discussing space complexity: a non-classical method is required to guarantee polynomial space complexity in the long run. No such method has yet been proposed, and this is the purpose of the coming subsection. Actually, for space complexity, in addition to all the problems mentioned, in all the above space or time analyses, the problem is that the complexity is (possibly implicitly) dependent on the Lipschitz constant or the length of the solution. In a system as simple as linear dynamics, the state at time T depends in Lipchitz way from the state at time 0, and the number of additional bits required to guarantee some precision 2^{-n} growth linearly with T. But the problem is that in a space polynomial in the input size, T has no reason to remain polynomial (consider, for example, a system simulating a Turing machine, as we will consider soon). Hence, the required precision is possibly exponential in the input size.

▶ Remark 7. The above comments can be interpreted informally as the fact that "most" (this could be "generic" in the sense of [51], i.e. (effective) descriptive theory) dynamical systems are intrinsically unstable, and an error method introduced at some step can make the method unavoidably incorrect in the long run unless we have a means to "guess" what will happen.

▶ Remark 8 (Attractor point of view). We presented the above statement in terms of computing the flow $\Phi(\mathbf{f}_0, T)$. But, this could alternatively be interpreted in terms of attractors. The point is that computing the attractors of a given dynamical system is hard in general, as this involves long-run behaviours. This explains all the undecidability results obtained in [51], even for very simple dynamics. However, as we will see, this is also explained by the fact that the latter paper discusses numerically unstable systems.

2.3 Solving efficiently ODEs: a space efficient method

This leads to an alternative approach to optimize space complexity: this can be seen as either using a non-deterministic algorithm that "guesses" the correct intermediate positions of the dynamics or, from the proof of Savitch's theorem approach, as an original recursive method to solve ODEs. As far as we know, we have never seen such a method discussed in the literature for solving ODEs.

Concretely: from the flow property, a strategy to compute $\Phi(\mathbf{f}_0, T)$ is either to use a particular numerical method if T is small, says smaller than $\Delta > 0$. Otherwise, we know that $\Phi(\mathbf{f}_0, T) = \Phi(\mathbf{z}, T/2)$, where $\mathbf{z} = \Phi(\mathbf{f}_0, T/2)$. This always holds, so if we can compute both quantities, we will solve the problem. The difficulty is that we cannot precisely compute $\mathbf{z}$ in

practice, but some numerical approximation $\widetilde{\mathbf{z}}$. If the system is numerically stable, we may assume this strategy works. The case when this strategy will not work is if the trajectory starting from $\widetilde{\mathbf{z}}$, for the second half of the work from time $T/2$ to T, has a behaviour different from the one starting in $\mathbf{z}$: in other words, if there is a high instability somewhere, namely in $\mathbf{z}$.

This leads to the following concept: we write $\mathbf{a} =_\epsilon \mathbf{b}$ for $\|\mathbf{a} - \mathbf{b}\| \leq \epsilon$ for conciseness.

▶ **Definition 9** (Robust (continuous) ODE). *A function* $\mathbf{f} : \mathbb{R}^{d+1} \to \mathbb{R}^{d'}$ *is robustly ODE definable (from initial condition* $\mathbf{g}$*, and dynamic* $\mathbf{u}$*) if*

1. *it corresponds to the solution of the following continuous ODE:*

$$\mathbf{f}(0, \mathbf{x}) = \mathbf{g}(\mathbf{x}) \quad \text{and} \quad \frac{\partial \mathbf{f}(t, \mathbf{x})}{\partial t} = \mathbf{u}(\mathbf{f}(t, \mathbf{x}), t, \mathbf{x}), \tag{3}$$

2. *and there is some rational* $\Delta > 0$*, and some polynomial* p *such that the schema (3) is (polynomially) numerically stable on* $[0, \Delta]$*: for all integer* n*, considering* $\eta(n) = p(n + \ell(\lceil \mathbf{x} \rceil))$ *we can compute* $\mathbf{f}(t, \mathbf{x})$ *at precision* 2^{-n} *by working a precision* $2^{-\eta(n)}$*: if you consider any solution of* $\tilde{\mathbf{x}} =_{2^{-\eta(n)}} \mathbf{x}$*,* $\tilde{\mathbf{f}}(0, \tilde{\mathbf{x}}) =_{2^{-\eta(n)}} \mathbf{g}(\mathbf{x})$ *and* $\frac{\partial \tilde{\mathbf{f}}(t, \tilde{\mathbf{x}})}{\partial t} =_{2^{-\eta(n)}} \mathbf{u}(\tilde{\mathbf{f}}(t, \tilde{\mathbf{x}}), t, \tilde{\mathbf{x}})$ *then* $\tilde{\mathbf{f}}(t, \tilde{\mathbf{x}}) =_{2^{-n}} \mathbf{f}(t, \mathbf{x})$ *when* $0 \leq t \leq \Delta$*.*
3. *For* $t \geq \Delta$*, we can compute* $\mathbf{f}(t, \mathbf{x})$ *at precision* 2^{-n} *by computing some approximation* $\widetilde{\mathbf{f}(t/2, \mathbf{x})}$ *of* $\mathbf{f}(t/2, \mathbf{x})$ *at precision* $2^{-\eta(n)}$*, i.e. of* $\Phi(\mathbf{g}(x), t/2)$*, and then some approximation of* $\Phi(\widetilde{\mathbf{f}(t/2, \mathbf{y})}, t/2)$*, working at precision* $2^{-\eta(n)}$*.*

▶ Remark 10. For more clarity, and conciseness, we will assume in the proofs that $d = d' = 1$, as it can be easily extended to more general cases.

▶ **Theorem 11.** *Consider an IVP as in the previous definition. If* $\mathbf{g}$ *and* $\mathbf{u}$ *are computable in polynomial space, then the solution* $\mathbf{f}$ *can be computed in polynomial space.*

Proof. From definitions and above arguments, all bits of $\Phi(\mathbf{y}, t)$ can be computed non-deterministically with precision n (i.e. at 2^{-n}) using computations with precision $\eta(n)$, hence is in $\mathbf{NPSPACE} = \mathbf{PSPACE}$. From the argument of the proof of Savitch's theorem, this can also be turned into a deterministic polynomial space recursive algorithm. ◀

The above theorem is the key argument to obtain one direction of our main theorems. We now go in the reverse direction. This requires talking about discrete ODEs, and some previous constructions.

3 Discrete ODEs: some previous results and constructions

3.1 Preliminary

We will use the concept of discrete ODE defined as follows (notice that we will write $\frac{\delta \mathbf{f}}{\delta n}$ for discrete derivation, by opposition of the classical $\frac{\partial \mathbf{f}}{\partial n}$ to help to distinguish discrete vs continuous ODEs.)

▶ **Definition 12** (Discrete derivation, notation δ). *For* $\mathbf{f} : \mathbb{N} \to \mathbb{R}^d \to \mathbb{R}^{d'}$*, the* discrete derivation *of* $\mathbf{f}$ *is* $\frac{\delta \mathbf{f}}{\delta n}(n, \mathbf{x}) = \mathbf{f}(n + 1, \mathbf{x}) - \mathbf{f}(n, \mathbf{x})$*.*

▶ Remark 13. We use the terminology "discrete ODE", as in [12, 13]. This concept has various names in other communities: this is also called *finite differences*, *difference equations*, sometimes *discretized ODE*, and the associated theory is sometimes called *discrete calculus*,

umbral calculus in other communities . Sometimes, some of the statements seem to be rediscovered with other names, but as far as we know, the idea of computing with discrete ODEs can be associated with [12, 13], and we follow the terminology used there: we refer to the discussions and references in [13] for the references and some discussions about the various names used in literature for similar concepts.

3.2 Algebraic characterisation with discrete ODEs: state of the art

In this subsection, we review some of the results already obtained using discrete ODEs.

▶ Remark 14. Notice that we do not need any of these statements directly, even if we will sometimes reuse some of their constructions (and some of their ideas).

Characterising PTIME over the integers. The concept of derivation along the length was introduced in [12]. A characterisation of **FPTIME** for functions over the integers has then been obtained in [12]:

▶ **Theorem 15** (Functions over the integers [12]). $\mathbb{LDL} \cap \mathbb{N}^{\mathbb{N}} = \mathbf{FPTIME} \cap \mathbb{N}^{\mathbb{N}}$, *for* $\mathbb{LDL} = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \times, sg(x)$; *composition, linear length ODE*$]$, *with* π_i^k *the projection function, and* $sg(x)$ *is 0 for* $x < 0$ *and 1 for* $x > 0$.

Toward the real numbers: characterising real sequences. Later, we introduced in [4]

▶ **Definition 16** (Operation $ELim$). *Given* $\tilde{\mathbf{f}} : \mathbb{R}^d \times \mathbb{N} \to \mathbb{R}^{d'} \in \mathbb{LDL}^\bullet$ *such that for all* $\mathbf{x} \in \mathbb{R}^d$, $n \in \mathbb{N}$, $\|\tilde{\mathbf{f}}(\mathbf{x}, 2^n) - \mathbf{f}(\mathbf{x})\| \leq 2^{-n}$ *for some function* $\mathbf{f}$, *then* $ELim(\tilde{\mathbf{f}})$ *is the (uniquely defined) corresponding function* $\mathbf{f} : \mathbb{R}^d \to \mathbb{R}^{d'}$.

and then we considered the class

$$\overline{\mathbb{LDL}^\bullet} = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \times, \overline{\text{cond}}(x), \frac{x}{2}; \textit{composition, linear length ODE, ELim}],$$

with $\overline{\text{cond}}(x)$ a sigmoid valuing 0 when $x < \frac{1}{4}$ and 1 when $x > \frac{3}{4}$. We proved this provides a characterisation of functions from $\mathbb{N}$ to $\mathbb{R}$ computable in polynomial time.

▶ **Theorem 17** (Sequences of reals [4]). $\overline{\mathbb{LDL}^\bullet} = \mathbf{FPTIME} \cap \mathbb{R}^{\mathbb{N}}$.

Characterisation of PTIME and PSPACE for functions over the real with discrete ODEs. We later succeeded in obtaining a characterisation of functions over the real computable in polynomial time and even space.

▶ **Theorem 18** (**FPTIME**, Generic functions over the reals [5]).
$\overline{\mathbb{LDL}^\circ} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}} = \mathbf{FPTIME} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^d}$, *with*
$\overline{\mathbb{LDL}^\circ} = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \tanh, \frac{x}{2}, \frac{x}{3}; \textit{composition, linear length ODE, ELim}]$.

Consider the following schema:

▶ **Definition 19** (Robust Discrete ODE [5]). *A bounded function* $\mathbf{f}$ *is robustly ODE definable if:*

1. *it corresponds to the solution of the following discrete ODE:*

$$\mathbf{f}(0, \mathbf{x}) = \mathbf{g}(\mathbf{x}) \quad \textit{and} \quad \frac{\delta \mathbf{f}(t, \mathbf{x})}{\delta t} = \mathbf{u}(\mathbf{f}(t, \mathbf{x}), \mathbf{h}(t, \mathbf{x}), t, \mathbf{x}), \tag{4}$$

2. *where the schema* (4) *is (polynomially) numerically stable: there exists some polynomial* p *such that, for all integer* n*, writing* $\eta(n) = p(n + \ell(\mathbf{y}))$*, if you consider any solution of* $\tilde{\mathbf{y}} =_{2^{-\eta(n)}} \mathbf{y}$ *and* $\tilde{\mathbf{h}}(x, \tilde{\mathbf{y}}) =_{2^{-\eta(n)}} \mathbf{h}(x, \tilde{\mathbf{y}})$*, and* $\tilde{\mathbf{f}}(0, \tilde{\mathbf{y}}) =_{2^{-\eta(n)}} \mathbf{g}(\mathbf{y})$ *and* $\frac{\partial \tilde{\mathbf{f}}(x,\tilde{\mathbf{y}})}{\partial x} =_{2^{-\eta(n)}} \mathbf{u}(\tilde{\mathbf{f}}(x, \tilde{\mathbf{y}}), \tilde{\mathbf{h}}(x, \tilde{\mathbf{y}}), x, \tilde{\mathbf{y}})$ *then* $\tilde{\mathbf{f}}(x, \tilde{\mathbf{y}}) =_{2^{-n}} \mathbf{f}(x, \mathbf{y})$*.*

We recall the notion of *essential linearity*: The idea is to measure the degree, similarly to the classical notion of degree in polynomial expression, but considering all subterms that are within the scope of a tanh function contributes to 0 to the degree. Then, essential linearity corresponds to linearity with this concept of degree.

▶ **Definition 20** ([4])**.** *The degree* $\deg(x, P)$ *of a term* P *in* $x \in V$ *is defined inductively as follows:*

- $\deg(x, x) = 1$ *and for* $x' \in V \cup \mathbb{Z}$ *such that* $x' \neq x$*,* $\deg(x, x') = 0$*;*
- $\deg(x, P + Q) = \max\{\deg(x, P), \deg(x, Q)\}$*;*
- $\deg(x, P \times Q) = \deg(x, P) + \deg(x, Q)$*;*
- $\deg(x, \tanh(P)) = 0$*.*

A polynomial expression P *is essentially constant in* x *if* $\deg(x, P) = 0$*.*

A vectorial function (resp. a matrix or a vector) is said to be a polynomial expression if all its coordinates (resp. coefficients) are, and *essentially constant* if all its coefficients are.

▶ **Definition 21** ([4])**.** *A polynomial expression* $\mathbf{g}(\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y})$ *is essentially linear in* $\mathbf{f}(x, \mathbf{y})$ *if it is of the form:* $\mathbf{A}[\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}] \cdot \mathbf{f}(x, \mathbf{y}) + \mathbf{B}[\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}]$ *where* $\mathbf{A}$ *and* $\mathbf{B}$ *are polynomial expressions essentially constant in* $\mathbf{f}(x, \mathbf{y})$*.*

▶ Remark 22. A robust discrete ODE is said to be *linear* if $\mathbf{u}$ is essentially linear in $\mathbf{f}$ and $\mathbf{h}$.

Consider
$\overline{\mathbb{RLD}^\circ} = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \tanh, \frac{x}{2}, \frac{x}{3}; \textit{composition}, \textit{robust linear ODE}, \textit{ELim}]$.

▶ **Theorem 23** (**FPSPACE**, Generic functions over the reals [5])**.**
$\overline{\mathbb{RLD}^\circ} \cap \mathbb{R}^{\mathbb{R}} = \mathbf{FPSPACE} \cap \mathbb{R}^{\mathbb{R}}$
More generally: $\overline{\mathbb{RLD}^\circ} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}} = \mathbf{FPSPACE} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^d}$.

Notice that previous classes mix functions with integer and real arguments. Furthermore, they all involve some various types of discrete ODEs. We need to avoid all these issues, as we consider only continuous ODEs.

3.3 Simulating a discrete ODE using a continuous ODE

We first prove that it is possible to simulate a discrete ODE with a continuous ODE. The underlying idea can be attributed to [22], and has been improved in many ways by several authors. We present here the basic ideas, reformulated in our context. A more precise analysis will come (Proposition 39).

▶ **Definition 24** ("Ideal iteration trick", [22])**.** *Consider the following initial value problem for a discrete ODE, given by functions* $\mathbf{g}$ *and* $\mathbf{u}$*:*

$$\begin{cases} \mathbf{f}(0, \mathbf{x}) = \mathbf{g}(\mathbf{x}) \\ \dfrac{\delta \mathbf{f}}{\delta t}(t, \mathbf{x}) = \mathbf{u}(\mathbf{f}(t, \mathbf{x}), t, \mathbf{x}) \end{cases} \tag{5}$$

Then, let $\mathbf{G}(\mathbf{v}, t, \mathbf{x}) = \mathbf{u}(\mathbf{v}, t, \mathbf{x}) + \mathbf{v}$*, and consider the (continuous) IVP:*

$$\begin{cases} \mathbf{y}_1(0, \mathbf{x}) = \mathbf{y}_2(0, \mathbf{x}) = \mathbf{g}(\mathbf{x}) \\ \mathbf{y}_1' = c(\mathbf{G}(r(\mathbf{y}_2), r(t), \mathbf{x}) - \mathbf{y}_1)^3 \theta(\sin(2\pi t)) \\ \mathbf{y}_2' = c(r(\mathbf{y}_1) - \mathbf{y}_2)^3 \theta(-\sin(2\pi t)) \end{cases} \tag{6}$$

where c *a constant,* $\theta(x) = 0$ *if* $x \leq 0$ *and* $\theta(x) > 0$ *if* $x > 0$*. We abusively write* $r(\mathbf{y})$ *for the application of function* $r : \mathbb{R} \to \mathbb{R}$ *componentwise on vector* $\mathbf{y}$*. Here,* r *is a rounding function: we mean, by construction,* G *preserves the integers, and* r *is a function that maps a real value close to some integer to this integer: assume, say, that for* $z \in [n - \frac{1}{4}, n + \frac{1}{2}]$*,* $r(z) = n$*, for any integer* $n \in \mathbb{Z}$*.*

▶ Remark 25. We do not need to specify what $r(z)$ values for a z not in such an interval: the following reasoning remains correct, whatever it is.

Then, the solution of continuous ODE (6) simulates in a continuous way the discrete ODE (5): Indeed, $\mathbf{y}_1$ corresponds to the actual computation of the iterates of $\mathbf{G}$ (and hence computes the successive values of $\mathbf{f}$) and $\mathbf{y}_2$ acts as a "memory" equation. Let us detail how it works.

▶ Remark 26. We describe here an "ideal" computation, as $\theta(x)$ is exacly 0 when $x \leq 0$, and $r(z)$ is exactly some integer on suitable domains. Later in the paper, we will deal with a not-so-ideal θ and r.

Initially, $\mathbf{f}(0, \mathbf{x}) = \mathbf{y}_1(0, \mathbf{x}) = \mathbf{y}_2(0, \mathbf{x}) = \mathbf{g}(\mathbf{x})$. For $t \in [0, 1/2]$, we have $\theta(-\sin(2\pi t)) = 0$, and hence $\mathbf{y}_2' = 0$, so $\mathbf{y}_2$ is fixed and kept at value $\mathbf{g}(\mathbf{x})$ for $t \in [0, \frac{1}{2}]$. Consequently, for $t \in [0, 1/2]$, $r(\mathbf{y}_2)$ is also fixed and kept at value $\mathbf{g}(\mathbf{x})$, and $r(t)$ is also fixed and kept at value 0. Consequently, on this interval, if we write $C(t) = c\theta(\sin(2\pi t))$, then the dynamics of $\mathbf{y}_1$ is given by

$$\mathbf{y}_1' = C(t)(\mathbf{G}(\mathbf{g}(\mathbf{x}), 0, \mathbf{x}) - \mathbf{y}_1)^3 \tag{7}$$

▶ **Lemma 27** (Analysis of ODE (7))**.** *The solution* $\mathbf{y}_1(t, \mathbf{x})$ *of ODE* (7) *is converging to* $G(\mathbf{g}(\mathbf{x}), 0, \mathbf{x})$ *for any initial condition. Furthermore, for any initial condition* $\mathbf{y}_1(0, \mathbf{x}) \neq G(\mathbf{g}(\mathbf{x}), 0, \mathbf{x})$*, we have* $\left\|\mathbf{y}_1(\frac{1}{2}, \mathbf{x}) - \mathbf{G}(\mathbf{g}(x), 0, \mathbf{x})\right\| \leq \frac{\sqrt{2}}{2\sqrt{\int_0^{\frac{1}{2}} C(z)dz}}$*. In particular, for any* $m \in \mathbb{N}$*, we can select constant* c *such that for any initial condition* $\mathbf{y}_1(0, \mathbf{x})$*,* $\left\|\mathbf{y}_1(\frac{1}{2}, \mathbf{x}) - \mathbf{G}(\mathbf{g}(x), 0, \mathbf{x})\right\| \leq 2^{-m}$*.*

Consequently, $\mathbf{y}_1(t, \mathbf{x})$ will approach $\mathbf{G}(\mathbf{g}(\mathbf{x}), 0, \mathbf{x}) = \mathbf{f}(1, \mathbf{x})$ on this interval. Thus, $\mathbf{y}_1(\frac{1}{2}, \mathbf{x}) =_\epsilon \mathbf{f}(1, \mathbf{x})$ and $\mathbf{y}_2(\frac{1}{2}, \mathbf{x}) = \mathbf{g}(\mathbf{x})$, for some $\epsilon > 0$, that we can consider less than $\frac{1}{4} = 2^{-2}$, by selecting a big enough constant c (just taking $m = 2$ above). At $t = \frac{1}{2}$, $\mathbf{y}_1$ will hence have simulated one step of discrete ODE (5).

Now, for $t \in [\frac{1}{2}, 1]$ the roles of $\mathbf{y}_1$ and $\mathbf{y}_2$ are exchanged : $\mathbf{y}_1'(t, \mathbf{x}) = 0$, so $\mathbf{y}_1$ is kept fixed, $\mathbf{y}_2$ approaches $r(\mathbf{y}_1) = \mathbf{f}(1, \mathbf{x})$, thus $\mathbf{y}_1(1, \mathbf{x}) =_\epsilon \mathbf{y}_2(1, x) =_\epsilon \mathbf{f}(1, \mathbf{x})$.

By induction, from the same reasoning, we obtain that, for all $n \in \mathbb{N}$, $\mathbf{y}_1(n, \mathbf{x}) =_\epsilon \mathbf{y}_2(n, \mathbf{x}) =_\epsilon \mathbf{f}(n, \mathbf{x})$, and actually, we also have $\mathbf{y}_1(t + \frac{1}{2}, \mathbf{x}) =_\epsilon \mathbf{y}_2(t, \mathbf{x}) =_\epsilon \mathbf{f}(n, \mathbf{x})$ for all $t \in [n, n + \frac{1}{2}]$, for any integer n.

To implement such an ODE, we have to fix a function $\theta(x)$ with the above property. Taking $\mathrm{ReLU}(x) = \max(0, x)$ would satisfy it, but it is not a derivable function, and hence would not lead to a (classical) ODE. We could then take $\theta(x) = 0$ for $x \leq 0$, and $\exp(-1/x)$ for $x > 0$. The point is that such a function is not real analytic. The base functions we

consider in our class $\mathbb{RCD}$ are all real analytic, and real analytic functions are preserved by composition, so we cannot get such a function by compositions from our base functions. Furthermore, it is known that a real analytic function that is constant on some interval (we assumed it is 0 for $x \leq 0$) is constant. Hence, the above-considered function $\theta(x)$ cannot be real analytic. So, implementing this trick cannot be done directly using our base functions, using only compositions.

In Proposition 39, we will do a similar construction, but dealing with errors and not exact functions $\theta(z)$ and $r(x)$. Furthermore, here the purpose of function r was to correct errors around integers, i.e. around $\mathbb{Z}$: this will be possibly around other $\mathbb{Z}\delta = \{n\delta | n \in \mathbb{Z}\}$ for some $\delta > 0$. We will then naturally assume that for $z \in [n\delta - \frac{1}{4}\delta, n\delta + \frac{1}{2}\delta]$, $r(z) = n$, for any integer $n \in \mathbb{Z}$, in order to have a similar reasoning as the one above where $\delta = 1$.

3.4 Encoding of Turing machines configurations

Our proofs rely on some constructions from [5]. Concretely, we need to simulate the execution of a Turing machine (TM) by some dynamical system over the reals. This requires to encode the configurations of a Turing machine into some real numbers. We recall some of the definitions and constructions from [5].

Consider a Turing machine defined by $\mathcal{M} = (\Sigma, Q, I, F, \delta)$, with Σ the working alphabet, Q the set of states, $I, F \subseteq Q$ respectively the sets of initial and final states, $\delta : Q \times \Sigma \to Q \times \Sigma \times \{\leftarrow, \rightarrow\}$ the transition function. For some practical reasons, similar to the ones in [5], we assume that the working alphabet is made of the symbols 1 and 3, and that the blank symbol is symbol 0.

We explicit the encoding we will use. We assume $Q = \{0, 1, \ldots, |Q| - 1\}$. Let

$$\ldots l_{-k} l_{-k+1} \ldots l_{-1} l_0 r_0 r_1 \ldots r_n \ldots.$$

denote the content of the tape of the Turing machine M. In this representation, the head is in front of symbol r_0, and $l_i, r_i \in \{0, 1, 3\}$ for all i. Furthermore, we assume that there are no non-blank symbols between two blank symbols, i.e. that blank symbols, i.e. symbol 0, can only be eventually on the right, or eventually on the left. Such a configuration C can be denoted by $C = (q, l, r)$, where $l, r \in \Sigma^\omega$ are words over alphabet $\Sigma = \{0, 1, 3\}$ and $q \in Q$ denotes the internal state of M.

Now, write $\gamma_{word} : \Sigma^\omega \to \mathbb{R}$ for the function that maps a word $w = w_0 w_1 w_2 \ldots$ to the dyadic (hence real) number $\gamma_{word}(w) = \sum_{n \geq 0} w_n 4^{-(n+1)}$.

The idea is that configuration C can also be encoded by some element $\overline{C} = (q, \overline{l}, \overline{r}) \in \mathbb{N} \times \mathbb{R}^2$, by considering $\overline{r} = \gamma_{word}(r)$ and $\overline{l} = \gamma_{word}(l)$. In other words, we encode the configuration of a bi-infinite tape Turing machine M by real numbers using their radix 4 encoding, but using only digits 1,3. Notice that this lives in $Q \times [0, 1]^2$. Denoting the image of $\gamma_{word} : \Sigma^\omega \to \mathbb{R}$ by $\mathcal{I}$, this even lives in $Q \times \mathcal{I}^2$.

In other words, we consider the following encodings:

$$\gamma_{config}(C) = (q, \overline{l}, \overline{r})$$

with

$$\begin{aligned} \overline{l} &= l_0 4^{-1} + l_{-1} 4^{-2} + \cdots + l_{-k} 4^{-(k+1)} + \ldots \\ \overline{r} &= r_0 4^{-1} + r_1 4^{-2} + \cdots + l_n 4^{-(n+1)} + \ldots \end{aligned}$$

3.5 Revisiting some previous constructions

We denote by $\mathbb{RCD}_*$ the algebra $[0, 1, \pi_i^k, +, -, \times, \tanh, \cos, \pi, \frac{x}{2}, \frac{x}{3}; \textit{composition}]$. This is close to the class $\mathbb{LDL}^\circ = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \tanh, \frac{x}{2}, \frac{x}{3}; \textit{composition}, \textit{linear length ODE}]$, considered in [6, 5], but without the function $\ell(x)$, and without the possiblity of defining functions using linear length ODE (and with multiplication added).

We will reuse some of the construction from [5] (some corrections and more details can be found in [6]) but avoid systematically any use of linear length ODE and the length function $\ell(x)$. Furthermore, the class considered in [5] is mixing functions from the integers to the reals, and from the reals to the reals, and we need to keep only functions over the reals.

The following was stated in [5, Lemma 19].

▶ **Lemma 28.** *We denote by $Y(x, 2^{m+2})$ the function $\frac{1+\tanh(2^{m+2}x)}{2}$. For all integer m, for all $x \in \mathbb{R}$, $|\operatorname{ReLU}(x) - xY(x, 2^{m+2})| \leq 2^{-m}$, where $\operatorname{ReLU}(x) = \max(0, x)$.*

First, we observe that considering $Y(x, z) = \frac{1+\tanh(4xz)}{2}$ would yield a function in $\mathbb{RCD}_*$ with the same property: we avoid the computation of 2^m by a substitution of a variable, and using a multiplication. We then write ReLU-$\mathfrak{s}(Y, x)$ for $xY(x, z)$: we have $|\operatorname{ReLU}\text{-}\mathfrak{s}(2^m, x) - \operatorname{ReLU}(x)| \leq 2^{-m}$.

In particular, this was used to prove we can uniformly approximate the continuous sigmoid functions (when $1/(b-a)$ is in $\mathbb{LDL}^\circ$) defined as $\mathfrak{s}(a, b, x) = 0$ whenever $w \leq a$, $\frac{x-a}{b-a}$ whenever $a \leq x \leq b$, and 1 whenever $b \leq x$. The above trick provides a new version of [5, Lemma 20].

▶ **Lemma 29** (Uniform approximation of any piecewise continuous sigmoid)**.** *Assume $a, b, \frac{1}{b-a}$ is in $\mathbb{RCD}_*$. Then there is some function $\mathcal{C}\text{-}\mathfrak{s}(z, a, b, x) \in \mathbb{RCD}_*$ such that for all integer m,*

$$|\mathcal{C}\text{-}\mathfrak{s}(2^m, a, b, x) - \mathfrak{s}(a, b, x)| \leq 2^{-m}.$$

Proof. Take $\mathcal{C}\text{-}\mathfrak{s}(z, a, b, x) = \frac{(x-a)Y(x-a, z2^{1+c}) - (x-b)Y(x-b, z2^{1+c})}{b-a}$. observing that $(b-a)\,\mathfrak{s}(a, b, x) = \operatorname{ReLU}(x-a) - \operatorname{ReLU}(x-b)$. From triangle inequality, it will hold, choosing c with $\frac{1}{b-a} \leq 2^c$. ◀

The authors of [5] proved the existence of some function corresponding to a continuous (controlled) approximation of the fractional part function: we write by $\{.\}$ the fractional part function.

▶ **Theorem 30** ([5, Lemma 28])**.** *There exists some function $\xi : \mathbb{N}^2 \to \mathbb{R}$ in $\mathbb{LDL}^\circ$ such that for all $n, m \in \mathbb{N}$ and $x \in [-2^n, 2^n]$, whenever $x \in [\lfloor x \rfloor + \frac{1}{8}, \lfloor x \rfloor + \frac{7}{8}]$, $\left|\xi(2^m, 2^n, x) - \{x - \frac{1}{8}\}\right| \leq 2^{-m}$.*

We say that some real function is a real extension of a function over the integers if they coincide for integer arguments. It is not clear that we have an extension over the reals of ξ in our algebra $\mathbb{RCD}_*$, but if we add a real extension of such a function, from the proof of [5, Corollary 22], we obtain the bestiary of functions considered in [5, Corollary 22]: we write $\mathbb{RCD}_* + \xi$ for the algebra where some real extension of function ξ is added as a base function.

▶ **Corollary 31** (A bestiary of functions)**.** *There exist*

1. *$\xi_1, \xi_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto \mathbb{R} \in \mathbb{RCD}_* + \xi$ such that, for all $n, m \in \mathbb{N}$, $\lfloor x \rfloor \in [-2^n + 1, 2^n]$, whenever $x \in [\lfloor x \rfloor - \frac{1}{2}, \lfloor x \rfloor + \frac{1}{4}]$, $|\xi_1(2^m, 2^n, x) - \{x\}| \leq 2^{-m}$, and whenever $x \in [\lfloor x \rfloor, \lfloor x \rfloor + \frac{3}{4}]$, $|\xi_2(2^m, 2^n, x) - \{x\}| \leq 2^{-m}$.*
2. *$\sigma_1, \sigma_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto \mathbb{R} \in \mathbb{RCD}_* + \xi$ such that, for all $n, m \in \mathbb{N}$, $\lfloor x \rfloor \in [-2^n + 1, 2^n]$, whenever $x \in [\lfloor x \rfloor - \frac{1}{2}, \lfloor x \rfloor + \frac{1}{4}]$, $|\sigma_1(2^m, 2^n, x) - \lfloor x \rfloor| \leq 2^{-m}$, and whenever $x \in I_2 = [\lfloor x \rfloor, \lfloor x \rfloor + \frac{3}{4}]$, $|\sigma_2(2^m, 2^n, x) - \lfloor x \rfloor| \leq 2^{-m}$.*

3. $\lambda : \mathbb{N}^2 \times \mathbb{R} \mapsto [0,1] \in \mathbb{RCD}_* + \xi$ *such that for all* $m, n \in \mathbb{N}$, $\lfloor x \rfloor \in [-2^n + 1, 2^n]$, *whenever* $x \in [\lfloor x \rfloor + \frac{1}{4}, \lfloor x \rfloor + \frac{1}{2}]$, $|\lambda(2^m, 2^n, x) - 0| \leq 2^{-m}$, *and whenever* $x \in [\lfloor x \rfloor + \frac{3}{4}, \lfloor x \rfloor + 1]$, $|\lambda(2^m, 2^n, x) - 1| \leq 2^{-m}$.
4. $\bmod_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto [0,1] \in \mathbb{RCD}_* + \xi$ *such that for all* $m, n \in \mathbb{N}$, $\lfloor x \rfloor \in [-2^n + 1, 2^n]$, *whenever* $x \in [\lfloor x \rfloor - \frac{1}{4}, \lfloor x \rfloor + \frac{1}{4}]$, $|\bmod_2(2^m, 2^n, x) - \lfloor x \rfloor \bmod 2| \leq 2^{-m}$.
5. $\div_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto [0,1] \in \mathbb{RCD}_* + \xi$ *such that for all* $m, n \in \mathbb{N}$, $\lfloor x \rfloor \in [-2^n + 1, 2^n]$, *whenever* $x \in [\lfloor x \rfloor - \frac{1}{4}, \lfloor x \rfloor + \frac{1}{4}]$, $|\div_2(2^m, 2^n, x) - \lfloor x \rfloor // 2| \leq 2^{-m}$, *with* // *the integer division.*

Similarly, the equivalent of [5, Lemmas 23,24 and 25] still hold in $\mathbb{RCD}_* + \xi$:

▶ **Lemma 32.** *There exists* $\mathcal{C}$-if $\in \mathbb{RCD}_* + \xi$ *such that,* $l \in [0,1]$, *if we take* $|d' - 0| \leq 1/4$, *then* $|\mathcal{C}\text{-if}(2^m, d', l) - 0| \leq 2^{-m}$, *and if we take* $|d' - 1| \leq 1/4$, *then* $|\mathcal{C}\text{-if}(2^m, d', l) - l| \leq 2^{-m}$.

▶ **Lemma 33.** *Let* $\alpha_1, \alpha_2, \ldots, \alpha_n$ *be some integers, and* $V_1, V_2, \ldots, V_n$ *some constants. We write* $\text{send}(\alpha_i \mapsto V_i)_{i \in \{1,\ldots,n\}}$ *for the function that maps any* $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$ *to* V_i, *for all* $i \in \{1, \ldots, n\}$.

There is some function in $\mathbb{RCD}_* + \xi$, *that we write* $\mathcal{C}\text{-send}(2^m, \alpha_i \mapsto V_i)_{i \in \{1,\ldots,n\}}$, *that maps any* $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$ *to a real at distance at most* 2^{-m} *of* V_i, *for all* $i \in \{1, \ldots, n\}$.

▶ **Lemma 34.** *Let* N *be some integer. Let* $\alpha_1, \alpha_2, \ldots, \alpha_n$ *be some integers, and* $V_{i,j}$ *for* $1 \leq i \leq n$ *some constants, with* $0 \leq j < N$. *We write* $\text{send}((\alpha_i, j) \mapsto V_{i,j})_{i \in \{1,\ldots,n\}, j \in \{0,\ldots,N-1\}}$ *for the function that maps any* $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$ *and* $y \in [j - 1/4, j + 1/4]$ *to* $V_{i,j}$, *for all* $i \in \{1, \ldots, n\}$, $j \in \{0, \ldots, N-1\}$.

There is some function in $\mathbb{RCD}_* + \xi$, *that we write* $\mathcal{C}\text{-send}(2^m, (\alpha_i, j) \mapsto V_{i,j})_{i \in \{1,\ldots,n\}, j \in \{0,\ldots,N-1\}}$, *that maps any* $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$ *and* $y \in [j - 1/4, j + 1/4]$ *to a real at distance at most* 2^{-m} *of* $V_{i,j}$, *for all* $i \in \{1, \ldots, n\}$, $j \in \{0, \ldots, N-1\}$.

Working with one step of a Turing machine

As the proof of [5, Lemmas 30] is done using all the functions provided by these lemmas, we obtain:

▶ **Lemma 35.** *We can construct some function* $\overline{Next}$ *in* $\mathbb{RCD}_* + \xi$ *that simulates one step of* M, *i.e. computing the Next function sending a configuration* $\overline{C}$ *of Turing machine* M *to* $\overline{C'}$, *where* C' *is the next one:* $\|Next(2^m, 2^S, \overline{C}) - \overline{C'}\| \leq 2^{-m}$. *Furthermore, it is robust to errors on its input, up to space* S: *considering* $\|\tilde{C} - \overline{C}\| \leq 4^{-(S+2)}$, $\|Next(2^m, 2^S, \tilde{C}) - \overline{C'}\| \leq 2^{-m}$ *remains true.*

Converting integers an dyadics to words and conversely

The article [5] also defined some functions for converting integers and dyadics to their encoding as words, and conversely. Namely, the following encoding is considered: every digit in the binary expansion of dyadic d is encoded by a pair of symbols in the radix 4 expansion of $\overline{d} \in \mathcal{I} \cap [0,1]$: digit 0 (respectively: 1) is encoded by 11 (resp. 13) if before the "decimal" point in d, and digit 0 (respectively: 1) is encoded by 31 (resp. 33) if after. For example, for $d = 101.1$ in base 2, $\overline{d} = 0.13111333$ in base 4. Conversely, given $\overline{d}$, the article provided a way to construct d. This corresponds to [5, Lemmas 33 and 34]:

▶ **Lemma 36** (From $\mathbb{N}$ to $\mathcal{I}$). *We can construct some function* $Decode : \mathbb{N}^2 \to \mathbb{R}$ *in* $\mathbb{LDL}^\circ$ *that maps* m *and* n *to some point at distance less than* 2^{-m} *from* $\gamma_{word}(\overline{n})$.

▶ **Lemma 37** (From $\mathcal{I}$ to $\mathbb{R}$, and multiplying in parallel)**.** *We can construct some function* $\mathit{EncodeMul} : \mathbb{N}^2 \times [0,1] \times \mathbb{R} \to \mathbb{R}$ *in* $\mathbb{LDL}^\circ$ *that maps* m, 2^S, $\gamma_{word}(\overline{d})$ *and (bounded)* λ *to some real at distance at most* 2^{-m} *from* λd*, whenever* $\overline{d}$ *is of length less than* S*.*

As for ξ, it is not clear that we have some real extensions of these functions in $\mathbb{RCD}_*$: we write $\mathbb{RCD}_* + \xi + \mathit{Decode} + \mathit{Encode}$ for the algebra where some real extension of these functions is added as a base function.

3.6 Constructing the missing functions

We need a way to construct some substitute of "missing functions" (ξ, *Decode* and *EncodeMul*). As all of them are defined using discrete ODEs, an idea is to use a continuous ODE to simulate the respective discrete ODEs: we hence revisit the construction of the ideal iteration trick of Section 3.3, dealing with errors and not exact functions $\theta(z)$ and $r(x)$.

The key is to revisit Lemma 27, and do a more detailed analysis of possible involved errors in dynamics of the form (7). This equation has been studied by various authors in several articles, including [24, 25, 36, 18, 34]. We use the following statement from [34, Lemma 4.5], [14, Lemma 5.2], obtained basically by a case analysis of error propagations in Lemma 27.

▶ **Lemma 38** (Improved error analysis of ODE (7), [34, Lemma 4.5] [14, 5.2])**.** *Consider a point* $b \in \mathbb{R}$*, some* $\gamma > 0$ *some reals* $t_0 < t_1$*, and a function* $\phi : \mathbb{R} \to \mathbb{R}$ *with the property that* $\phi(t) \geq 0$ *for all* $t \geq t_0$ *and* $\int_{t_0}^{t_1} \phi(t)dt > 0$*. Let* $\rho, \delta \geq 0$ *and let* $\overline{b}, E : \mathbb{R} \to \mathbb{R}$ *be functions such that that* $|\overline{b}(t) - b| \leq \rho$ *and* $|E(t)| \leq \delta$ *for all* $t \geq t_0$*. Then the IVP defined by*

$$z' = c(\overline{b}(t) - z)^3\phi(t) + E(t)$$

with the initial condition $z(t_0) = \overline{z}_0$*, where* $\gamma > 0$ *and* $c \geq \frac{1}{2\gamma^2 \int_{t_0}^{t_1} \phi(t)dt}$ *satisfies*

1. $|z(t_1) - b| < \rho + \gamma + \delta(t_1 - t_0)$*, independently of the initial condition* $\overline{z}_0 \in \mathbb{R}$
2. $\min(\overline{z}_0, b - \rho) - \delta(t_1 - t_0) \leq z(t) \leq \max(\overline{z}_0, b + \rho) + \delta(t_1 - t_0)$ *for all* $t \in [t_0, t_1]$.

▶ **Proposition 39** (Simulating a discrete ODE by a continuous ODE)**.** *Assume* $\mathbf{G}$ *is almost constant around* $\mathbb{N}\delta$ *and* r *is a rounding function around* $\mathbb{N}\delta$ *for some* $\delta > 0$*: for* $z \in [n\delta - \frac{1}{4}\delta, n\delta + \frac{1}{2}\delta]$*,* $r(z) = n$*, for any integer* $n \in \mathbb{Z}$*.*

Suppose that, in (6)*, we replace function* $\theta(z)$ *and function* $r(z)$ *by some suitable approximations: we take* $\theta(x) = \mathrm{ReLU}(x)$*,* $\theta_{\epsilon'}(x)$*,* $r_{\epsilon'(z)}$ *such that* $\theta(z) =_{\epsilon'} \theta(z)$*, and* $r_{\epsilon'}(x) =_{\epsilon'}$*, and take constant* c *big enough. Then the solution of the obtained ODE will continuously simulate the discrete ODE* (5)*, with the same bounds as in the analysis in Section 3.3, i.e. with error at most* ϵ *if* ϵ' *is taken sufficiently small. To guarantee* $\epsilon = 2^{-n}$*, it is sufficient to take* $\epsilon' = 2^{-p(n)}$ *and* $\theta_{\epsilon'}(x) = \mathrm{ReLU}\text{-}\mathfrak{s}(2^{p(n)}, x)$ *for some polynomial* p*.*

Proof. The key is that the involved errors additively propagate, from Lemma 38. Namely, they are in $\mathcal{O}(\epsilon')$, but they are then corrected from the reasoning in Section 3.3: rounding function corrects errors or order ϵ whenever its argument is at a distance less than $1/4\delta$ of some $n\delta$ exactly as in the reasoning in Section 3.3 (where $\delta = 1$, even if now it introduces some error ϵ' at every step; but the latter is corrected at the next step). Observe that the involved constant c, is of order 2^n.

More formally, we claim that for all $n \in \mathbb{N}$, $\mathbf{y}_1(n, \mathbf{x}) =_\epsilon \mathbf{y}_2(n, \mathbf{x}) =_\epsilon \mathbf{f}(n, \mathbf{x})$, and $\mathbf{y}_1(t + \frac{1}{2}, \mathbf{x}) =_\epsilon \mathbf{y}_2(t, \mathbf{x}) =_\epsilon \mathbf{f}(n, \mathbf{x})$ for all $t \in [n, n + \frac{1}{2}]$.

For $n = 0$, initially $\mathbf{f}(0, \mathbf{x}) = \mathbf{y}_1(0, \mathbf{x}) = \mathbf{y}_2(0, \mathbf{x}) = \mathbf{g}(\mathbf{x})$. For $t \in [n, n + 1/2]$, we then have $\theta(-\sin(2\pi t)) =_{\epsilon'} 0$, and hence $\mathbf{y}_2' =_{\epsilon'} 0$, so $\mathbf{y}_2$ is kept close to value $\mathbf{g}(\mathbf{x})$ for $t \in [0, \frac{1}{2}]$, with an error less than $\frac{1}{2}\epsilon'$.

Consequently, for $t \in [0, 1/2]$, $r(\mathbf{y}_2)$ is kept close to a constant value $\mathbf{g}(\mathbf{x})$, when an error less than ϵ', if we choose $\epsilon' < \frac{1}{4}\delta$. Meanwhile, $r(t)$ is also at a value close to n with an error lesser than ϵ'.

Consequently, on this interval, if we write $C(t) = c\theta(\sin(2\pi t))$, then the dynamics of $\mathbf{y}_1$ is given by a dynamic of the form of Lemma 38. This lemma states that $\mathbf{y}_1(t, \mathbf{x})$ will approach $\mathbf{G}(\mathbf{g}(\mathbf{x}), 0, \mathbf{x}) = \mathbf{f}(1, \mathbf{x})$ on this interval, with an error of order $\epsilon' + \epsilon' + \frac{1}{2}\epsilon'$.

Here the hypothesis that $\mathbf{G}$ is almost constant around $\mathbb{N}\delta$ means that its value is guaranteed to be at ϵ' from $\mathbf{G}(\mathbf{g}(\mathbf{x}), 0, \mathbf{x})$ on the interval.

Thus, $\mathbf{y}_1(\frac{1}{2}, \mathbf{x}) =_{\epsilon/2} \mathbf{f}(1, \mathbf{x})$, if we choose $\frac{5}{2}\epsilon' < \epsilon/2$. At $t = n + \frac{1}{2}$, $\mathbf{y}_1$ will hence have simulated one step of discrete ODE (5), with an error less than $\epsilon/2$, and $\mathbf{y}_2$ will be close to $\mathbf{g}(\mathbf{x})$ with an error less than $\epsilon' < \epsilon/2$.

Now, for $t \in [n + \frac{1}{2}, n + 1]$ the roles of $\mathbf{y}_1$ and $\mathbf{y}_2$ are exchanged: $\mathbf{y}_1'(t, \mathbf{x}) =_{\epsilon'} 0$, so $\mathbf{y}_1$ is kept almost fixed, with a new error less than $\frac{1}{2}\epsilon'$. In the same time $\mathbf{y}_2$ approaches $r(\mathbf{y}_1) = \mathbf{f}(1, \mathbf{x})$ by Lemma 38, with some new error of order less than $\frac{5}{2}\epsilon' < \epsilon/2$.

Consequently, we get the property at rank $n + 1$. ◀

▶ Remark 40. Observe that, somehow, the idea is that the constructions always replace every function with a function that does not change much locally (i.e. changes in a controlled way). This is the key that provides a robust ODE as in Definition 9, leading to polynomial space complexity by Theorem 11.

In other words, whenever we have some discrete ODE as in (5) defining some function $\mathbf{f}(t, \mathbf{x})$, we can construct some continuous ODE, using only functions from $\mathbb{RCD}_*$, such that one of its projection provides a function $\mathbf{f}(z, t, \mathbf{x})$, with the guarantee $\mathbf{f}(2^n, t, \mathbf{x})$ is 2^{-n} close to $\mathbf{f}(n, \mathbf{x})$, whenever t is close (at a distance less than $1/4$) to some integer n.

This works, as we can obtain such a $r_{\epsilon'}(x)$ from the functions from Corollary 31: Consider $r(x, 2^m) = \sigma_2(2^m, 2^n, x + \frac{1}{4})$ that works over $\lfloor x \rfloor \in [-2^n + 1, 2^n]$, and observe that this is sufficient to apply the trick for the required functions, from the form of the considered discrete ODE in [5].

Except that we have a bootstrap problem: ξ was defined using a discrete ODE in [5], and as the functions from Corollary 31 are defined above using ξ, we cannot apply this reasoning to get function ξ. But the point is that for the special case of ξ, it is easy to construct a function in $\mathbb{RCD}$ that corresponds to some real extension of ξ, as we have functions such as $\sin(x) = \cos(\frac{\pi}{2} - x)$ and π.

▶ **Lemma 41.** *Function ξ has some real extension in $\mathbb{RCD}_*$.*

Proof. If we succeed to obtain a function $i(2^m, 2^n, x)$ that values $\lfloor x \rfloor$ whenever $x \in [\lfloor x \rfloor, \lfloor x \rfloor + \frac{3}{4}]$, we are done, as we can then obtain $\xi(2^m, 2^n, x)$ by considering $\xi(2^m, 2^n, x) = x + \frac{7}{8} - i(2^m, 2^n, x + \frac{7}{8})$.

A possible solution is then the following: consider function $R_e(x) := \mathfrak{s}(x, 0, e/2)$, and then $t_e(x) = (1 - R_e(\sin(2\pi x)))((1 - R_e(\sin(4\pi x)))$. If we put aside some interval of width $e/2$ around $\frac{1}{2}$ and $\frac{7}{8}$ where it takes values in $[0, 1]$, it values 0 on $[\lfloor x \rfloor, \lfloor x \rfloor + \frac{7}{8}]$, and then 1 on $[\lfloor x \rfloor + \frac{7}{8}, \lfloor x \rfloor + 1]$. We can then consider $I_e(t) = 8\int_0^t t_e(x)dx$ (i.e. the solution of ODE $l_e' = 8t_e$), and then $i(t) =_{e.t} l_e(t)$. It is then sufficient to replace $\mathfrak{s}$ by $\mathcal{C}$-$\mathfrak{s}$, in the above expressions, in order to control the error and make it smaller than 2^{-m}. ◀

Consequently, this is true that we can substitute a discrete ODE with a continuous ODE for the required functions *Decode* and *EncodeMul*: just replace ξ in the involved schemas by the above function. Notice that we can also easily get a real extension of the function that maps n to 2^n.

3.7 Working with all steps of a Turing machines

We can then go from one step of a Turing machine, to arbitrarily many steps. We are following the idea of [5], but replacing discrete ODEs with continuous ODEs.

▶ **Theorem 42.** *Consider some Turing machine M that computes some function $f : \Sigma^* \to \Sigma^*$ in some polynomial space $S(\ell(\omega))$ on input ω. One can construct some function $\tilde{f} : \mathbb{N}^2 \times \mathbb{R} \to \mathbb{R}$ in $\mathbb{RCD}$ that does the same: we have $\tilde{f}(2^m, 2^{S(\ell(\omega))}, \gamma_{word}(\omega))$ that is at most 2^{-m} far from $\gamma_{word}(f(\omega))$.*

Proof. We denote by $\mathcal{M}$ the Turing machine computing f. Similarly to the arguments in [5], we can state that there exists a function $Exec$ solution of a robust linear discrete ODE (E) that "computes" the execution of $\mathcal{M}$, with C_{init} the initial configuration :

$$(E) : \begin{cases} Exec(2^m, 0, 2^S, C_{init}) = C_{init} \\ \dfrac{\delta Exec(2^m, t, 2^S, C_{init})}{\delta t} = Next(2^m, 2^S, Exec(2^m, t, 2^S, C_{init})) - Exec(2^m, t, 2^S, C_{init}). \end{cases}$$

For any configuration $\overline{C}$ of $\mathcal{M}$, let write $F(\overline{C})) = F(2^m, 2^S, \overline{C}) = Next(2^m, 2^S, \overline{C}) + \overline{C}$, associated to the righthand side of the above discrete ODE. Denoting by $\tilde{C}$ the errorless encoding of the configuration C, from the constructions of [5] (Lemma 35), it is true that if $\left|\overline{C} - \tilde{C}\right| \leq 4^{-(S+2)}$, then $\left|F(\overline{C}) - F(\tilde{C})\right| \leq 4^{-(S+2)}$. F does not change much locally on the space of configuration. Denoting by S the space of $\mathcal{M}$, and replacing m by $m+2S+4$ as in [5], we have $\left|Next(2^m, 2^S, \overline{C}) - \overline{C}\right| \leq 4^{-(S+2)}$. So at each step of the TM, the error is fixed (and bounded). We can then apply the above arguments (Proposition 39) to simulate continuously (E), with some controlled error: all involved quantities have encoding polynomials in the size of the inputs. ◀

4 Proof of Theorem 2

Proof. $\subseteq$: In this direction, we just need to prove that $\mathbb{RCD}$ contains only functions over the reals that are computable in polynomial space. Indeed, then for a function $\mathbf{f} : \mathbb{R}^d \to \mathbb{R}^{d'}$ sending every integer $\mathbf{n} \in \mathbb{N}^d$ to the vicinity of some integer of $\mathbb{N}^d$, at a distance less than $1/4$, by approximating its value with precision $1/4$ on its input arguments, and taking the closest integer, we will get a function from the integers to the integers, that corresponds to $\mathrm{DP}(f)$, and that will be in $\mathbf{FPSPACE} \cap \mathbb{N}^{\mathbb{N}}$.

This is indeed the case, since i) all the base functions of $\overline{\mathbb{RCD}}$ are in **FPSPACE**: they are even in **FPTIME**, see [46] ii) $\mathbb{R}^{\mathbb{R}} \cap \mathbf{FPSPACE}$ is stable under *composition*. iii) stability under *robust ODE* follows from Theorem 11.

$\supseteq$: In the other direction, we use an argument similar to [5]: namely, as the function is polynomial space computable, this means that there is a polynomial space computable function $g : \mathbb{N}^{d''+1} \to \{1, 3\}^*$ so that on $\mathbf{m}, 2^n$, it provides the encoding $\overline{\phi(\mathbf{m}, n)}$ of some dyadic $\phi(\mathbf{m}, n)$ with $\|\phi(\mathbf{m}, n) - \mathbf{f}(\mathbf{m})\| \leq 2^{-n}$ for all $\mathbf{m}$. The problem is then to decode, compute and encode the result to produce this dyadic. More precisely, from Theorem 42, we get $\tilde{g}$ with

$$|\tilde{g}(2^e, 2^{p(max(\mathbf{m},n))}, Decode(2^e, \mathbf{m}, n)) - \gamma_{word}(g(\mathbf{m}, n))| \leq 2^{-e}$$

for some polynomial p corresponding to the time required to compute g, and $e = \max(p(max(\mathbf{m}, n)), n)$. Then we need to transform the value to the correct dyadic: we mean

$$\tilde{\mathbf{f}}(\mathbf{m}, n) = EncodeMul(2^e, 2^t, \tilde{g}(2^e, 2^t, Decode(2^e, \mathbf{m}, n)), 1),$$

where $t = p(max(\mathbf{m}, n))$, $e = \max(p(max(\mathbf{m}, n)), n)$ provides a solution with $\|\tilde{\mathbf{f}}(\mathbf{m}, 2^n) - \mathbf{f}(\mathbf{m})\| \leq 2^{-n}$. ◀

5 Proof of Theorem 3

Proof. $\subseteq$: To prove that $\overline{\mathbb{RCD}} \subseteq \mathbb{R}^{\mathbb{R}} \cap \mathbf{FPSPACE}$, we only need to add to the previous arguments that $\mathbb{R}^{\mathbb{R}} \cap \mathbf{FPSPACE}$ is also stable under $ELim$.
$\supseteq$: In this direction, we have the same issue as in [5]: the strategy of decoding, working with the Turing machine, and encoding is not guaranteed to work for all inputs. But, we can solve it by using an adaptative barycenter technique as in [5].

We recall the principle here for a function whose domain is $\mathbb{R}$, but it can be generalised to $\mathbb{R}^d$. The idea is to construct some function $\lambda : \mathbb{N}^2 \times \mathbb{R} \to [0,1]$ definable in $\mathbb{RCD}_*$ as in Corollary 31, but with a continuous ODE : Adapting the proof from [5] and using the simulation of ξ in our continuous framework, we can consider $\lambda(2^m, N, x) = \Psi(\Xi(2^{m+1}, N, x - 9/8))$ where $\Psi(x) = \mathcal{C}\text{-}\mathfrak{s}(2^{m+1}, 1/4, 1/2, x)$. In particular, by definition, $\lambda \in \mathbb{RCD}_*$. Thus, by Lemma 30, if $\lambda(2^m, N, x) =_{2^{-m}} 0$, then $\sigma_2(2^m, N, x) =_{2^{-m}} \lfloor x \rfloor$. If $\lambda(2^m, N, x) =_{2^{-m}} 1$, then $\sigma_1(2^m, N, x) =_{2^{-m}} \lfloor x \rfloor$ and if $\lambda(2^m, N, x) \in (0,1)$, then $\sigma_1(2^m, N, x) =_{2^{-m}} \lfloor x \rfloor + 1$ and furthermore $\sigma_2(2^m, N, x) =_{2^{-m}} \lfloor x \rfloor$. So, $\lambda(\cdot, 2^n, x)\mathit{Formula}_1(x, u, M, n) + (1 - \lambda(\cdot, 2^n, n))\mathit{Formula}_2(x, u, M, n)$ and we are sure to be close (up to some bounded error) to some 2^{-m} approximation of a function f. ◀

6 Conclusion

We characterised polynomial space using an algebraically defined class of functions, by using a finite set of basic functions, closure under composition, and a schema for defining functions from robust ODEs. We proposed a concept of robust ODEs solvable in polynomial space. As far as we know, this is an original method for solving ODEs optimising space. It is based on classical constructions such as Savitch's theorem. We extended existing characterisations to a characterisation of functions over the reals and not only over the integers.

The interesting message from our statements is that we provide a clear and simple concept associated with continuous ODEs for space: space corresponds to the precision for numerically stable systems. Hence, compiled with [17], we now know the length of solutions corresponds to time and precision to memory.

Considering future work: We have an algebraically defined class of functions. It remains to know whether this could be transferred at the level of polynomial ODE. We know that the solutions of polynomial ODEs define a very robust class of functions, stable by many operations: sum, products, division, ODE solving, etc: see [35, 15]. Hence, all the base functions we consider in our algebraic class can be turned into polynomial ODEs, by adding some variables. It would be interesting to understand if we could define space complexity directly at the level of polynomial ODEs, using precision.

Recently, another characterisation of **PSPACE** was obtained for polynomial ODEs using rather ad-hoc definitions in [34, 14] and working over a non-compact space. Could our characterisation be put at this simpler class of ODEs, but working with precision? The point is that this characterisation uses unbounded domains, so precision is harder to interpret in their constructions, where the schemas are somehow done to control errors.

Of course, from our statements, adding any **FPSPACE**-computable function over the reals among the base functions would not change the class. However, we did not intend to minimise the number of base functions. For example, $\tanh(t)$ is the solution of the ODE $f' = 1 + f^2$ and $\cos(t)$ can be obtained by the two-dimensional ODE $y_1' = -y_2$, $y_2' = y_1$. Minimising the number of base functions is also left for future work. We believe that even in this setting, proving space complexity corresponds to precision is already significant, independently of this question of a minimal set of base functions.

Function Spaces for Orbit-Finite Sets

Abstract

Orbit-finite sets are a generalisation of finite sets, and as such support many operations allowed for finite sets, such as pairing, quotienting, or taking subsets. However, they do not support function spaces, i.e. if X and Y are orbit-finite sets, then the space of finitely supported functions from X to Y is not orbit-finite. We propose a solution to this problem inspired by linear logic.

[18, §1.4.4]), which inspired some ideas in this paper. R. Stefański would like to thank Samson Abramsky for introducing him to the beautiful world of game semantics and suggesting to study it in the context of this paper.

1 Introduction

The class of orbit-finite sets is a class of sets that contains all finite sets and some infinite sets, but still shares some properties with the class of finite sets. The idea, which dates back to Fraenkel–Mostowski models of set theory, is to begin with an infinite set $\mathbb{A}$ of *atoms* or *urelements*. We think of the atoms as being names, such as Eve or John, and atoms can only be compared with respect to equality. Intuitively speaking, an orbit-finite set is a set that can be constructed using the atoms, such as $\mathbb{A}^2$ or $\mathbb{A}^*$, subject to the constraint that there are finitely many elements up to renaming atoms. For example, $\mathbb{A}^2$ is orbit-finite because it has two elements up to renaming atoms, namely (John, John) and (John, Eve), while $\mathbb{A}^*$ is not orbit-finite, because the length of a sequence is invariant under renaming atoms, and there are infinitely many possible lengths. For a survey on orbit-finite sets, see [5].

The notion of orbit-finiteness can be seen as an attempt to find an appropriate notion of finiteness for the nominal sets of Gabbay and Pitts [20]. This attempt emerged from the study of computational models such as monoids [6] and automata [7] over infinite alphabets. Let us illustrate orbit-finiteness using an automaton example.

▶ **Example 1.1** (An orbit-finite automaton)**.** Let $L \subseteq \mathbb{A}^*$ be the language of words in which the letter from the first position does not appear again. This language contains John · Mark · Mark · Eve, because John does not reappear, but it does not contain John · Mark · John. To recognize this language, we can use a deterministic automaton, which uses its state to remember the first letter. In this automaton, the input alphabet is $\Sigma = \mathbb{A}$ and the state space is $Q = 1 + 1 + \mathbb{A}$. In this state space, there are two special states, namely the initial state and a rejecting error state, and furthermore there is one state for each atom $a \in \mathbb{A}$, which represents a situation where the first letter was a but it has not been seen again yet. This state space is infinite; but it is orbit-finite, since each of the three components in Q represents a single orbit. ⌟

Orbit-finite sets have many advantages, which ensure that they are a good setting for automata theory, and discrete mathematics in general. For example, an orbit-finite set can be represented in a finite way [5], which ensures that it becomes meaningful to talk about algorithms that input orbit-finite sets, such as an emptiness check for an automaton. Also, orbit-finite sets are closed under taking disjoint unions and products, which ensures that natural automata constructions, such as the union of two nondeterministic automata or the product of two deterministic automata can be performed.

However, orbit-finite sets do not have all the closure properties of finite sets. Notably missing is the powerset operation, and more generally taking function spaces. For example, if we look at the powerset of $\mathbb{A}$, then this powerset will not be orbit-finite, since already the finite subsets give infinitely many orbits (two finite subsets of different sizes will be in different orbits). The lack of powersets means that one cannot do the subset construction from automata theory, and in particular deterministic and nondeterministic automata are not equivalent. This non-equivalence was known from the early days of automata for infinite alphabets [16], and in fact, some decision problems, such as equivalence, are decidable for deterministic automata but undecidable for nondeterministic automata [17]. Another construction that fails is converting a deterministic automaton into a monoid [6, p. 221]; this is because function spaces on orbit-finite sets are no longer orbit-finite, as explained in the following example.

▶ **Example 1.2** (Failure of the monoid construction)**.** Let us show that the automaton from Example 1.1 cannot be converted into a monoid. The standard construction would be to define the monoid as the subset $M \subseteq Q \to Q$ of all state transformations, namely the subset generated by individual input letters. Unfortunately, this construction does not work. This is because in order for two input words to give the same state transformation, they need to have the same set of letters that appear in them. In particular, the corresponding set of set transformations is not orbit-finite, for the same reason as why the finite powerset is not orbit-finite. Not only does the standard construction not work, but also this language is not recognized by any orbit-finite monoid. ⌟

An attempt to address this problem was provided in [24, 9], based on *single-use* functions. The idea, which originates in linear types and linear logic, is to restrict the functions so that they use each argument at most once. For example, consider the following two functions that input atoms and output Booleans:

$$a \in \mathbb{A} \mapsto \begin{cases} \text{true} & \text{if } a = \text{John} \\ \text{false} & \text{otherwise} \end{cases} \qquad a \in \mathbb{A} \mapsto \begin{cases} \text{true} & \text{if } a = \text{John or } a = \text{Eve} \\ \text{false} & \text{otherwise} \end{cases}$$

Intuitively, the first function is single-use, since it compares the input atom to John only, while the second function is not single-use, since it requires two comparisons, with John and Eve. Here is another example, which shows that the problems with the monoid construction from Example 1.2 could be blamed on a violation of the single-use condition.

▶ **Example 1.3.** Consider the transition function of the automaton in Example 1.1, which inputs a state in $1 + 1 + \mathbb{A}$ together with an input letter from $\mathbb{A}$, and returns a new state. This function is not single use. Indeed, if the state is in $\mathbb{A}$, then the transition function compares it for equality with the input letter; but if the comparison returns true, another copy of the old state must be kept as the new state for future comparisons. ⌟

If one restricts attention to functions that are single-use, much of the usual robustness of automata theory is recovered, with deterministic automata being equivalent to monoids, and both being equivalent to two-way deterministic automata [9].

Despite the success of the single-use restriction in solving automata problems, one would ideally prefer a more principled approach, in which instead of defining single-use automata, we would define a more general object, namely single-use sets and functions. Then the definitions of automata and monoids, as well theorems speaking about them, should arise automatically as a result of suitable closure properties of the sets and functions.

This approach was pursued in [24], in which a *category* of orbit-finite sets with single-use functions was proposed. In this corresponding category, one can represent the set of all single-use functions between two orbit-finite sets X and Y as a new set, call it $X \Rightarrow Y$, which is also orbit-finite. However, as we will see later in this paper, this proposal is not entirely satisfactory, since it fails to account for standard operations that one would like to perform on function spaces, most importantly partial application (currying). In the language of category theory, the proposal from [24] failed to be a monoidal closed category.

Contributions of this paper. The main contribution of this paper is to propose a notion of single-use sets and functions, which extends the proposal from [24], but which is rich enough to be closed under taking function spaces. More formally, we propose a category of single-use functions between orbit-finite sets equipped with additional metadata, and we prove that a suitable quotient of this category is symmetric monoidal closed (Theorem 4.2).

The main idea is to follow the tradition of linear types, and extend the type system from [24] with a new type constructor &. This way we can distinguish between two kinds of products namely $X \otimes Y$ (in [24] denoted as $X \times Y$) and $X \& Y$. Thanks to this distinction, the function space can be built so that the appropriate operations on functions, namely application and currying, can be implemented in a single-use way.

Our proposed category is strongly inspired by linear types, and the proof that it admits function spaces uses a form of *game semantics* – a tool that we take from programming language theory. However, as far as we know, it is an original idea to have an infinite but orbit-finite base type $\mathbb{A}$, and to observe that all constructions in game semantics are consistent with orbit-finiteness. We believe that the resulting category deserves further study, and that it is an interesting and non-trivial example of a category representing "finite" objects.

Some further adjacent developments – such as an alternative solution to the problem of function spaces, using vector spaces of orbit-finite dimension – are presented in Section 7.

2 Sets with atoms

We begin with a brief introduction to orbit-finite sets. For a more detailed treatment, see [5].

Fix for the rest of this paper a countably infinite set $\mathbb{A}$, whose elements will be called atoms. We assume that $\mathbb{A}$ has no other structure except for equality; we will only be interested in notions which are *equivariant*, i.e. invariant under renaming atoms. For example, $\mathbb{A}$ has only two equivariant subsets, namely the empty and full subsets. On the other hand, the set $\mathbb{A}^2$ has four equivariant subsets ($\emptyset$, $\mathbb{A}^2$, the diagonal and its complement). In order to meaningfully speak about equivariant subsets, we must be able to have an action of atom

renamings on the set, as formalized in the following definition. The finite support condition is a technical condition that ensures that the action is well-behaved; it dates back to the work of Fraenkel and Mostowski, and is explained in the survey texts [20, 5].

▶ **Definition 2.1.** *A* set with atoms *is a set X, equipped with an action of the group of atom renamings, subject to the following* finite support condition: *for every $x \in X$ there is a finite set of atoms, such that if an atom renaming π fixes all atoms in the set, then it also fixes x.*

The idea is that a set with atoms is any kind of object that deals with atoms, such as the set $\mathbb{A}^*$ of all words over the alphabet $\mathbb{A}$, or the family of finite subsets of $\mathbb{A}$. Among such objects, we will be interested in those which are "finite". This will be formalized by saying that there are finitely many orbits, as described below. Define the *orbit* of an element x in a set with atoms to be the elements that can be obtained from x by applying some atom renaming. For example, in the set $\mathbb{A}^2$, the orbit of (John, Eve) contains (Mark, John), but it does not contain (John, John). The orbits form a partition of a set with atoms.

▶ **Definition 2.2.** *A set with atoms is called* orbit-finite *if it has finitely many orbits.*

Typical examples of orbit-finite sets are polynomial expressions such as $\mathbb{A}^4 + \mathbb{A}^3 + \mathbb{A}^3 + 1$. Here, 1 represents the set of zero-length sequences; this set has a unique element which is its own orbit. For example, $\mathbb{A}^3$ has five orbits, because there are five possible ways of choosing a pattern of equalities in a sequence of three names. On the other hand, $\mathbb{A}^*$ has infinitely many orbits, since sequences of different lengths are necessarily in different orbits. The family of finite subsets of $\mathbb{A}$ is also not orbit-finite, because subsets of different sizes are in different orbits. The full powerset $\mathsf{P}\mathbb{A}$ is not even a legitimate object in our setting, because some of its elements, i.e. some subsets of $\mathbb{A}$, violate the finite support condition.

2.1 Finiteness of function spaces

As mentioned above, orbit-finite sets can be seen as a certain generalization of finite sets. They allow some, but not all, operations that can usually be done on finite sets. For example, orbit-finite sets are closed under disjoint unions $X + Y$ and products $X \times Y$. Another good property is that an orbit-finite set has only finitely many equivariant subsets (an equivariant subset is one that is invariant under the action of atom permutations). This is because an equivariant subset is a union of some of the finitely many orbits. This accounts for some of the good computational properties of orbit-finite sets.

If X and Y are orbit-finite sets, the set of equivariant functions $X \to Y$ is always literally finite, because it is an equivariant subset of $X \times Y$. However, as we have seen in Example 1.2, when converting an automaton to a monoid, we want to use the *partial applications* $\delta(-, a)$ of the transition function $\delta : Q \times \Sigma \to Q$; while δ is equivariant, in general, $\delta(-, a)$ is not. But it is *finitely supported*, i.e. invariant under all atom renamings that fix some finite set of atoms that depends only on the function. The issue is that the *finitely supported function space* from X to Y is not orbit-finite.

▶ **Example 2.3.** The function $\mathbb{A} \to \mathbb{A}$ below is finitely supported, because it is invariant under all atom renamings that fix Mark, John, Eve and Bill:

$$f(a) = \begin{cases} \text{Mark} & \text{if } a \in \{\text{John, Eve, Bill}\} \\ a & \text{otherwise} \end{cases}$$

If π is the atom renaming that swaps Mark with Adam, then applying it to the function f defined above gives the function $\pi(f)$ that has the same definition (or source code, if a programming intuition is to be followed), except that Mark is used instead of Adam.

In the case of $\mathbb{A} \to \mathbb{A}$, the finitely supported function space is not orbit-finite. Indeed, the condition $a \in \{\text{John, Eve, Bill}\}$ can be replaced by $a \in X$ for any finite set $X \subset \mathbb{A} \setminus \{\text{Mark}\}$ of exceptional values, and two choices of X of different cardinalities will give us two functions in different orbits. ⌟

3 Single-use sets and functions

The lack of function spaces is the problem addressed in this paper. Our solution builds on the idea from [24, Section 2.2], which is to consider only functions that are single-use. This notion, already illustrated intuitively in the introduction, is formalized in Section 3.1, where we show how it almost, but not quite, achieves function spaces. Then, in the rest of this section, we show how function spaces can be recovered by using a more refined type system.

3.1 Single-use functions over polynomial orbit-finite sets

We do not define the single-use functions on all orbit-finite sets, but only a syntactically defined fragment, namely the *polynomial orbit-finite sets*, which are sets that can be generated from 1 and $\mathbb{A}$ using products $\times$ and disjoint unions $+$. Therefore, we will allow orbit-finite sets like $1 + \mathbb{A}^2$, but we will not allow orbit-finite sets like the set of non-repeating pairs $\{(a, b) \mid a \neq b \in \mathbb{A}\}$ or the set of unordered pairs $\{\{a, b\} \mid a \neq b \in \mathbb{A}\}$. It is an open problem to find a satisfactory definition of single-use functions on all orbit-finite sets. (A simple hack is to use a quotienting construction, similar to Section 4, but what we would really like to do is to identify some extra structure in a set, possibly an action of some yet unknown group or semigroup, which enables us to speak about single-use functions.)

Consider two polynomial orbit-finite sets X and Y. To define which functions $X \to Y$ are single-use, we use an inductive definition. We begin with certain functions that are considered single-use, such as the equality test of type $\mathbb{A} \times \mathbb{A} \to 1 + 1$. These functions are called the *prime functions*, and their full list is given in Figure 1. Next, we combine the prime functions into new ones using three combinators. The first, and most important, combinator is function composition. Then, we have two combinators for the two type constructors: if two functions $f_1 : X_1 \to Y_1$ and $f_2 : X_2 \to Y_2$ are single-use, then the same is true for:

$$\underset{(x_1,x_2)\mapsto(f_1(x_1),f_2(x_2))}{f_1 \times f_2 : X_1 \times X_2 \to Y_1 \times Y_2} \qquad \underset{\text{left}(x_1)\mapsto\text{left}(f_1(x_1))}{\underset{\text{right}(x_2)\mapsto\text{right}(f_2(x_2))}{f_1 + f_2 : X_1 + X_2 \to Y_1 + Y_2}}.$$

Crucially, the list of prime single-use functions does not contain the copying function $a \in \mathbb{A} \mapsto (a, a) \in \mathbb{A}^2$. Therefore, an alternative name for the single-use functions is *copyless*. If we added copying, then we would get all finitely supported functions [24, Lemma 23].

▶ **Example 3.1.** Consider the function of type $\mathbb{A}^3 \to \mathbb{A}$ which inputs a triple (a, b, c) of atoms and returns a if c is equal to Mark, and b otherwise. This function is a single-use function. It is obtained by composing the six functions listed below:

Function	Type after function
Append 1.	$\mathbb{A} \times \mathbb{A} \times \mathbb{A} \times 1$
Replace added 1 with Mark using the constant function.	$\mathbb{A} \times \mathbb{A} \times \mathbb{A} \times \mathbb{A}$
Apply the equality test to the last two components.	$\mathbb{A} \times \mathbb{A} \times (1 + 1)$
Distribute.	$\mathbb{A} \times \mathbb{A} \times 1 + \mathbb{A} \times \mathbb{A} \times 1$
Project to first and second components, respectively.	$\mathbb{A} + \mathbb{A}$
Co-diagonal	$\mathbb{A}$

Table 1 The prime single-use functions for polynomial orbit-finite sets X, Y and Z.

Function	Type	Definition
Functions about $\mathbb{A}$		
equality test	$\mathbb{A} \times \mathbb{A} \to 1 + 1$	$a, b \mapsto$ if $a = b$ then true else false
constant a	$1 \to \mathbb{A}$	$x \mapsto a$
identity	$\mathbb{A} \to \mathbb{A}$	$x \mapsto x$
Functions about $\times$		
commutativity of $\times$	$X \times Y \to Y \times X$	$x \times y \mapsto y \times x$
first projection	$X \times Y \to X$	$x \times y \mapsto x$
second projection	$X \times Y \to Y$	$x \times y \mapsto y$
append 1	$X \to X \times 1$	$x \mapsto x \times ()$
associativity of $\times$	$(X \times Y) \times Z \to X \times (Y \times Z)$	$(x \times y) \times z \mapsto x \times (y \times z)$
Functions about $+$		
first co-projection	$X \to X + Y$	$x \mapsto \mathrm{left}(x)$
second co-projection	$Y \to X + Y$	$y \mapsto \mathrm{right}(y)$
co-diagonal	$X + X \to X$	$\begin{cases} \mathrm{left}(x) \mapsto x \\ \mathrm{right}(x) \mapsto x \end{cases}$
commutativity of $+$	$X + Y \to Y + X$	$\begin{cases} \mathrm{left}(x) \mapsto \mathrm{right}(x) \\ \mathrm{right}(y) \mapsto \mathrm{left}(y) \end{cases}$
associativity of $+$	$(X + Y) + Z \to X + (Y + Z)$	$\begin{cases} \mathrm{left}(\mathrm{left}(x)) \mapsto \mathrm{left}(x) \\ \mathrm{left}(\mathrm{right}(y)) \mapsto \mathrm{right}(\mathrm{left}(y)) \\ \mathrm{right}(z) \mapsto \mathrm{right}(\mathrm{right}(z)) \end{cases}$
Distributivity		
$+$ distributes over $\times$	$X \times (Y + Z) \to (X \times Y) + (X \times Z)$	$\begin{cases} x \times (\mathrm{left}(y)) \mapsto \mathrm{left}(x \times y) \\ x \times (\mathrm{right}(z)) \mapsto \mathrm{right}(x \times z) \end{cases}$

To justify this description, one should also show that the six functions are single-use. Appending 1, distributivity and co-diagonal are prime functions. The other three are obtained by combining prime functions using the combinators. For example, the equality test is paired, using the combinator for $\times$, with the identity on the remaining two atoms. ⌟

The design goal of the single-use restriction is to have orbit-finite function spaces. The rough idea is that a single-use function can only use a bounded number of atoms in its source code, which guarantees orbit-finiteness of the function space.

▶ **Example 3.2.** Consider the functions of type $\mathbb{A} \to 1 + 1$, which can be seen as subsets of the atoms, with $1 + 1$ representing the Booleans.

- The finitely supported functions $\mathbb{A} \to 1 + 1$ correspond to the finite or co-finite subsets of $\mathbb{A}$. Therefore, the set of such functions admits an equivariant bijection with a disjoint union of two copies of the finite powerset $\mathsf{P}_{\mathrm{fin}}\mathbb{A}$, in particular it is not orbit-finite.
- There are four possible single-use functions $\mathbb{A} \to 1 + 1$: (a) always return true; (b) always return false; (c) check for equality with some fixed atom a; (d) check for inequality ($\neq$) with some fixed atom a. Therefore, the set of single-use functions admits an equivariant bijection with the orbit-finite set $1 + 1 + \mathbb{A} + \mathbb{A}$. ⌟

The above example shows that the space of single-use functions of some type $X \to Y$ is orbit-finite, and in fact it can be described using a polynomial orbit-finite set. This is true for every choice of polynomial orbit-finite sets X and Y, as proved in [24, Theorem 5], and illustrated in the following example.

▶ **Example 3.3.** Assume that the input type X is some power of the atoms $\mathbb{A}^k$, and the output type Y does not use atoms, e.g. it is $Y = 1 + 1$. The assumption on the input type can be made without loss of generality using distributivity, while the assumption on the output type is a proper restriction, but it will allow us to skip some technical details of the general construction while retaining the important intuitions. We describe below a type that represents all single-use functions from $\mathbb{A}^k$ to Y; we shall denote it by $\mathbb{A}^k \Rightarrow Y$. Note that $\Rightarrow$ is *not* a primitive type constructor in our grammar of types; it is a notation that stands for the inductive construction below.

This type is defined by induction on k. In the base case of $k = 0$ we simply need to give a value from the output type, and therefore $\mathbb{A}^0 \Rightarrow Y$ is the same as Y. Consider now the induction step of $k > 0$. We observe that a single-use function that inputs $\mathbb{A}^k$ must begin with some equality test, and then continue with one of two single-use functions that have fewer arguments (one for the case when the equality test returns true, and one for the other case). This observation leads to the following definition of the type $\mathbb{A}^k \Rightarrow Y$:

$$\underbrace{\coprod_{i \in \{1,\ldots,k\}} \mathbb{A} \times (\mathbb{A}^{k-1} \Rightarrow Y) \times (\mathbb{A}^{k-1} \Rightarrow Y)}_{\substack{\text{starts by comparing } i\text{-th} \\ \text{coordinate to some constant}}} + \underbrace{\coprod_{i,j \in \{1,\ldots,k\}} (\mathbb{A}^{k-2} \to Y) \times (\mathbb{A}^{k-2} \to Y)}_{\substack{\text{starts by comparing the} \\ i\text{-th and } j\text{-th coordinates}}}.$$

Note that the above representation of the function space is not necessarily unique, i.e. the same function can be represented in several different ways. For example, the order in which equality tests are performed will matter for the representation, but might not matter for the function. This is not something that we worry about; it is dealt with in Section 4. ⌟

Unfortunately, the proposal illustrated in Example 3.3 and described in more detail in [24] does not give a satisfactory solution to the problem of function spaces. The problem is that the set of representations $X \Rightarrow Y$ should also support operations on functions. More specifically, we should be able to indicate single-use operations which do the following:

evaluation: a single-use function from $(X \Rightarrow Y) \times X$ to Y which inputs a representation of a function and applies it to an argument;

composition: a single-use function from $(X \Rightarrow Y) \times (Y \Rightarrow Z)$ to $(X \Rightarrow Z)$ which inputs the representations of two functions and returns a representation of their composition;

currying (i.e. partial application): for each single-use function from $X \times Y$ to Z, there should be a single-use function from X to $Y \Rightarrow Z$ which inputs a first argument and returns a representation of the partially applied function.

Only in the presence of all of these operations can we speak of a function space, and the corresponding category can be called closed. (Composition can be obtained through evaluation and currying, so the essential operations are evaluation and currying.) The following example shows that the currying operation is not single-use, and therefore the space of single-use functions as defined in this section is not closed.

▶ **Example 3.4.** Consider the single-use function

$$f : \mathbb{A} \times \mathbb{A} \to 1 + 1 \qquad (a, b) \mapsto \begin{cases} \text{result of test } a = \text{Mark} & \text{if } b = \text{Eve} \\ \text{result of test } a = \text{John} & \text{otherwise.} \end{cases}$$

The currying of this function, is a new function which maps a first argument $a \in \mathbb{A}$ to the partially applied function $f(a, \_)$. This currying is

$$a \mapsto \begin{cases} b \mapsto b = \text{Eve} & \text{if } a = \text{Mark} \\ b \mapsto b \neq \text{Eve} & \text{if } a = \text{John} \\ b \mapsto \text{false} & \text{otherwise} \end{cases}$$

Recall that in Example 3.2 we showed that the space of single-use functions of type $\mathbb{A} \to 1+1$ can be represented as $1 + 1 + \mathbb{A} + \mathbb{A}$. If we use this representation, then the currying of the function f is not single-use, because we need to compare the input atom a to two constants, Mark and John. If we use the representation from Example 3.3, then the corresponding type will be $\mathbb{A} \otimes (1+1)^2$, but the problems with currying will persist. ⌟

For similar reasons, the function space we proposed above does not support function composition either; it cannot be used to convert automata into single-use monoids since the resulting monoid would need to use function composition as its monoid operation.[1]

3.2 Linear types and single-use functions on them

To solve the problems above, we introduce a more refined type system, which is based on linear types. The main idea is to pay more attention to types in Example 3.3, where we describe a single-use function by specifying the first equality test that it makes, and then giving two descriptions of the functions that will be used in each of the two possible outcomes of the equality test. The main observation is that these two outcomes are mutually exclusive, and therefore we intend to use only one of the two descriptions. For this reason, we will use a type constructor & that comes from linear logic. The intended meaning is that an object of type $X \& Y$ consists of two objects, but with the ability to use only one of them. Since linear logic uses $\otimes$ for the product that we have so far denoted by $\times$, we will also follow that convention. Using these two products, the appropriate type for Example 3.3 becomes:

$$\coprod_{i \in \{1,\ldots,k\}} \mathbb{A} \otimes ((\mathbb{A}^{k-1} \Rightarrow Y) \& (\mathbb{A}^{k-1} \Rightarrow Y)) \quad + \quad \coprod_{i,j \in \{1,\ldots,k\}} (\mathbb{A}^{k-2} \to Y) \& (\mathbb{A}^{k-2} \to Y).$$

Under this definition, the problems from Example 3.4 will be solved, at least for the particular type considered in that example. However, by introducing a new type constructor, we will have to redefine the single-use functions, and then we will have to give a representation of functions that allow this new type constructor, without incurring the need to add any other new type constructors. This is what we will do now.

▶ **Definition 3.5** (Linear types). *A* linear type *is any expression constructed from the atomic types* 1 *and* $\mathbb{A}$ *using three*[2] *binary type constructors* $+, \&$ *and* $\otimes$.

---

[1] This problem is solved in [9] and [24] in a different way, namely by showing that every orbit-finite monoid necessarily divides a single-use monoid, using a Krohn-Rhodes construction. However, this construction is difficult and delicate, in particular it does not work for atoms that have more structure than equality alone. In contrast, the proposal that we give in this paper works for other kinds of atoms, as discussed in Section 6.

[2] We set up our type system without using the multiplicative disjunction $\parr$ of linear logic. This is a common practice in linear type systems, as they are often based on intuitionistic linear logic, rather than classical linear logic (see e.g. [1]). It is also worth mentioning that our type system is in fact *affine* [13, §1.2.1], as we are going to allow discarding the unused values of $\mathbb{A}$. However, since there is no risk of confusion, we have decided to use the name *linear types* for the sake of simplicity.

In our linear types, it is only the products that are differentiated, while + comes in only one version. Here is the intuitive explanation of the difference between the two kinds of products, following Girard [13, §1.1.2]. Having a pair $x \otimes y$ is like having the ability of using both components x and y. On the other hand, having a pair $x\&y$ is like having the ability to use one of the two components, at our choice, but not both at once. For example, the input type of the equality test will be $\mathbb{A} \otimes \mathbb{A}$ not $\mathbb{A}\&\mathbb{A}$, since the test will need to consume both arguments. This intuition can only go so far; for example, it is not entirely clear what "our choice" means. We revisit this intuition in Section 5, where game semantics will be used to indicate who makes which choices.

We think of each linear type X as representing a set $[\![X]\!]$, as defined below:

$$[\![1]\!] = 1 \quad [\![\mathbb{A}]\!] = \mathbb{A} \quad [\![X + Y]\!] = [\![X]\!] + [\![Y]\!] \quad [\![X \otimes Y]\!] = [\![X\&Y]\!] = [\![X]\!] \times [\![Y]\!].$$

All sets that arise in this way will be polynomial orbit-finite sets. Note that the two kinds of product represent the same set, namely the set of pairs in the usual set-theoretic sense. However, the two type constructors will be different, because different functions will be allowed to operate on them. As the expression goes, "the proof of the pudding is in the eating"; in this case the pudding is the types and the eating is the functions.

As we did in Section 3.1, the single-use functions will be defined in terms of prime functions and combinators. The combinators are the same, except that instead of $f_1 \times f_2$ we now have two ways of pairing functions, using $\otimes$ and &. The prime functions are inherited from the previous system, with $\times$ understood as $\otimes$, together with a few new functions for &, as described in Table 2. This is summarized in the following definition.

▶ **Definition 3.6** (Single-use functions). *The class of single-use functions is the least class of functions with the following properties:*

1. *It contains the functions from Tables 1 and 2, with $\times$ in Table 1 understood as $\otimes$;*
2. *It is closed under composition, as well as under combining functions using $+$, $\otimes$ and &.*

Table 2 Prime single-use functions that involve &.

Function	Type	Definition
diagonal	$X \to X\&X$	$x \mapsto x\&x$
first projection	$X\&Y \to X$	$x\&y \mapsto x$
second projection	$X\&Y \to Y$	$x\&y \mapsto y$
& distributes over $\otimes$	$X \otimes (Y\&Z) \to (X \otimes Y)\&(X \otimes Z)$	$x \otimes (y\&z) \mapsto (x \otimes y)\&(x \otimes z)$
& distributes over $+$	$X + (Y\&Z) \to (X\&Y) + (X\&Z)$	$\begin{cases} x\&\mathrm{left}(y) \mapsto \mathrm{left}(x\&y) \\ x\&\mathrm{right}(z) \mapsto \mathrm{right}(x\&z) \end{cases}$

Formally speaking, a single-use function consists of an input linear type X, an output linear type Y, and a function between the sets $[\![X]\!]$ and $[\![Y]\!]$ that is generated using the prime functions and combinators from the above definition. As was the case in Section 3.1, all single-use functions are finitely supported. Therefore, one can think of the single-use functions of type $X \to Y$ as being a subset of the set of all finitely supported functions from $[\![X]\!]$ to $[\![Y]\!]$. This subset is strict: as we will see, the space of single-use functions will be orbit-finite, unlike the space of all finitely supported functions. We will be thinking of the single-use functions as a category.

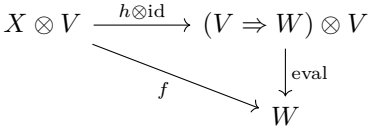
▶ **Definition 3.7** (Category of single-use sets). *The category of single-use sets is:*

1. *The objects are linear types, as per Definition 3.5.*
2. *The morphisms between types X and Y are single-use functions from $[\![X]\!]$ to $[\![Y]\!]$.*

In the very definition of the above category, there is a faithful functor to the category of orbit-finite sets with finitely supported functions. This functor maps objects X to their underlying sets $[\![X]\!]$, which are orbit-finite sets, and it maps morphisms to the corresponding functions. The functions seen to be finitely supported, and the functor is faithful by definition, since the morphisms in Definition 3.7 are defined to be single-use functions.

The main technical result of this paper is that the category of single-use sets has function spaces, as stated in the following theorem. The appropriate product will be $\otimes$, and not &. Since the Cartesian product in our category is & and not $\otimes$, this means that the result we are targeting is symmetric monoidal closed with respect to $\otimes$, and not Cartesian closed. For now, our theorem stops a bit short of saying that the category is monoidal closed, since several different elements of the function space might represent the same function; but we will come back to this in Section 4.

▶ **Theorem 3.8.** *Let V and W be objects (i.e. linear types). There exists an object, denoted by $V \Rightarrow W$, and a morphism (i.e. a single-use function)* $\mathrm{eval} : (V \Rightarrow W) \otimes V \to W$ *with the following property. For every morphism $f : X \otimes V \to W$ there is a (not necessarily unique) morphism $h : X \to (V \Rightarrow W)$ such that the following diagram commutes:*



The above theorem is the main technical contribution of this paper. The difficulty in its proof is finding a representation of the single-use functions that is rich enough to capture all functions, but simple enough to be described by a linear type (in particular, the corresponding set will be orbit-finite). In Section 3.1, when the types did not have "&", we could pull off a relatively simple construction, which was possible mainly due to the strong distributivity rules that allowed converting each type into a normal like $\mathbb{A}^{n_1} + \cdots + \mathbb{A}^{n_\ell}$. In the presence of "&", the distributivity rules are not as strong, and the way in which a single-use program can interact with its input is rather subtle. Our solution is presented in Section 5.

4 Quotienting by partial equivalence relations

A drawback of Theorem 3.8 is that the function space $V \Rightarrow W$ can contain different representations of the same function; this will mean that currying is not unique. To overcome this issue, we use a simple quotient construction, inspired by a classical technique used in realizability semantics of typed λ-calculi (see e.g. [3, Chapter 15]).

Define a *partial equivalence relation* to be a relation that is symmetric and transitive, but not necessarily reflexive. This is the same as (complete) equivalence relation on some subset, hence we may speak of the quotient of a set by a partial equivalence relation (which is an usual quotient of a subset). We will use a partial equivalence on the function space $X \Rightarrow Y$ to: (1) remove objects that do not represent any morphism; (2) identify two objects if they represent the same morphism. After such a quotient, the function space will have unique representations for functions.

▶ **Definition 4.1.** *The* quotiented single-use category *is:*

- *Objects are pairs (linear type X, equivariant partial equivalence relation on $[\![X]\!]$);*
- *The set of morphisms between objects $(X, \sim_X)$ and $(Y, \sim_Y)$ is the quotient of the set of single-use functions from X to Y by*

$$f \sim g \quad :\Longleftrightarrow \quad \forall x, x' \in [\![X]\!],\ x \sim_X x' \Rightarrow f(x) \sim_Y g(x')$$

We can then define the function space object from $(X, \sim_X)$ to $(Y, \sim_Y)$ as $(X \Rightarrow Y, \sim_{X \Rightarrow Y})$ where two elements of $X \Rightarrow Y$ are related by the partial equivalence relation $\sim_{X \Rightarrow Y}$ when the single-use functions they represent are related by the above-defined $\sim$. The quotiented single-use category is also equipped with a tensor product $\otimes$ on its objects.

▶ **Theorem 4.2.** *The quotiented single-use category, equipped with the tensor product $\otimes$, is a monoidal closed category, i.e. it satisfies the conclusions of Theorem 3.8, but, furthermore, the morphism h is unique.*

5 Game semantics

This section is devoted to the proof of Theorem 3.8. To construct the function space $X \Rightarrow Y$, we use game semantics to identify a certain normal form of programs that compute single-use functions. The presentation in this section is self-contained, and does not assume any knowledge of game semantics. We base our notation on [2].[3]

Let us begin with a brief motivation for why game semantics will be useful.

While it is intuitively clear which functions should be allowed as single-use for simple types such as $\mathbb{A} \to 1 + 1$ or $\mathbb{A} \otimes \mathbb{A} \to \mathbb{A} + \mathbb{A}$, these intuitions start to falter when considering more complex types. How can one show that a function is *not* single-use? If one were to use the definition of single-use functions alone, then one would need to rule out any possibility of constructing the function from the primes using the combinators, including constructions that use composition many times, and with unknown intermediate types.

This is the reason why we consider game semantics. It will allow us to give a more principled description of the intuition that pairs of type $X \otimes Y$ can be used on both coordinates, while pairs of type $X \& Y$ can be used on a chosen coordinate only. The idea behind game semantics is to give the description in terms of an interaction between two players:

1. System, who represents the function (we will identify with this player); and
2. Environment, who supplies inputs and requests outputs of the function.

One of the intuitions behind the setup is that if a type $X \& Y$ appears in the input of the function, then it is the System who can choose to use X or Y, while if the type appears in the output, then it is the Environment who makes the choice. (In this paper, we consider functions of first-order types of the form $X \to Y$, where X and Y are linear types that do not use $\to$, and therefore there will be a clear distinction between input and output values.) Before giving a formal definition of game semantics, we give simple example of the interaction.

▶ **Example 5.1.** Consider the two types $X \otimes (Y \& Z)$ and $(X \otimes Y) \& (X \otimes Z)$. Among the prime functions in Table 2, we find distributivity in the direction $\to$, but not in the direction $\leftarrow$. We explain this asymmetry using the interaction between two players System and Environment[4].

Let us first consider the interaction in the direction $\to$. The player Environment begins by requesting an output. Since this output is of type $(X \otimes Y) \& (X \otimes Z)$, this means that Environment can choose to request either of the two types $X \otimes Y$ and $X \otimes Z$. Suppose that Environment requests $X \otimes Y$. Now System needs to react, and produce two elements: one of type X and one of type Y. Both can be obtained from the input; for the second one player System can choose how to resolve the input $Y \& Z$ to get the appropriate value.

[3] Another standard reference for the category of "simple games" upon which we build is [15]. For a recent survey of modern game semantics, see [10].

[4] Observe that in Table 1 the $(+, \otimes)$-distributivity is also only given in one direction. In that case the inverse is, in fact, a single-use function, as it can be constructed from prime functions.

Consider now the interaction in the opposite direction $\leftarrow$. As we will see, System will be unable to react to the behavior of Environment, which demonstrates that there is no distributivity in this direction. The problem is that Environment can begin by requesting an element of type X, since the output type is $X \otimes (Y \& Z)$, while still reserving the possibility to request $Y \& Z$ in the future (because the tensor product $\otimes$ means that both output values need to be produced). To produce this element, System will need choose one of the two coordinates in the input type $(X \otimes Y) \& (X \otimes Z)$, and any of these two choices will be premature, since Environment can then request the opposite choice in the output type. ⌟

As illustrated in the above example, we will use a game to describe the possible behaviours of a function $X \to Y$. The game will be played in an arena, arising from the linear types X and Y, which will tell us what moves are possible for the two players. In each arena, we will be interested in strategies for System, telling us how System should react to Environment's moves. Morally, such a strategy will say how the function reacts to requests in the output type Y and values in the input type X.

Proof scheme for Theorem 3.8. In the remainder of this section, we define the arenas and strategies of our game semantics. Our main Theorem 3.8 will then follow from the two key properties below, that we establish in the technical appendix of the full version.

Representation of single-use functions by strategies: To a strategy in the arena for $X \to Y$, we will assign a single-use function of type $X \to Y$ that it represents. This mapping will be partial, i.e. some ill-behaved strategies will not represent any functions. We will show that the set of strategies in the arena is large enough to represent all single-use functions.

Representation of strategies by a linear type: We shall build a linear type $X \Rightarrow Y$ which can represent all well-formed strategies on the arena for $X \to Y$. In particular, this implies that such strategies form an orbit-finite set. Furthermore, this linear type $X \Rightarrow Y$ will be equipped with single-use evaluation and currying functions, as required.

5.1 Arenas and strategies without constants and equality tests

We begin with a simpler version of the game semantics, in which the arenas and strategies will describe functions that are not allowed to perform equality tests, nor to use constants. These strategies will model functions such as the identity function $\mathbb{A} \to \mathbb{A}$, which directly passes its input to its output, but they will not model the equality test $\mathbb{A} \otimes \mathbb{A} \to 1 + 1$, or the constant functions of type $1 \to \mathbb{A}$. The general idea is to use standard game semantics for linear logic, with an extra feature that we call *register operations*. The register operations will be used to model the way in which atoms are passed from the input to output. For example, in the identity function, Environment will write the input atom into the register, and then System will read the output atom from that register. The following definition of an arena is based on the definition from [2, p. 4], slightly adapted for the context of this paper:

▶ **Definition 5.2** (Arena). *An* arena *consists of:*

1. *A set of* moves*, with each move having an assigned owner, who is either "System" or "Environment", and one of three register operations, which are "none", "read", or "write".*
2. *A set of plays, which a set of finite sequences of moves that is closed under prefixes, and such that in every play, the owner of the first move is Environment, and then the owners alternate between the two players.*

▶ Remark 5.3. In all arenas that we consider, the "read" moves will be owned by System and the "write" moves will be owned by Environment. Therefore, we could simplify the register operations and have just one, called "read/write", whose status is determined by its owner.

In this paper, all the strategies that we consider shall be for player System.

▶ **Definition 5.4.** *A* strategy *in an arena is a subset of plays in the arena, which:*

1. *is closed under prefixes;*
2. *if the strategy contains a play p that ends with a move owned by System, then it also contains all possible plays in the arena that extend p with one move of Environment;*
3. *if the strategy contains a play p that ends with a move owned by Environment, then it contains exactly one play in the arena that extends p with one move of System;*
4. *there is some k such that all plays in the strategy have length at most k;*
5. *every "read" move is directly preceded by a "write" move (in particular a play cannot begin with "read"), and every "write" move is either the last move, or directly succeeded by a "read" move.*

Conditions 2 and 3, which are standard in game semantics (cf. [2, p. 5]), guarantee that the strategy is deterministic and only "ends" when Environment has no moves to play. Let us now comment on the last two conditions, which are not standard.

- The fourth condition is motivated by the idea that we study "finite" types, and there will be no need for unbounded computations[5]
- The last condition will be called the *immediate read condition*. It ensures that there is matching between "read" and "write" moves in plays that do not end with write. Since "write" will always be owned by Environment, the immediate read condition will ensure a matching between "write" and "read" moves.

We now show how to associate to each linear type a corresponding arena, and also how to associate an arena to a function type $X \to Y$ (which is not a linear type in the sense of Definition 3.5) between linear types X and Y. The arenas that we construct so far will not be our final proposal, since the corresponding strategies will not be able to use constants or perform equality tests; this will be fixed in Section 5.2. Before giving a formal definition, we begin with a simple example.

▶ **Example 5.5.** We define an arena for $\mathbb{A} \to \mathbb{A}$. It will be rather impoverished, since the only allowed strategy in it will correspond to the identity function. However, this is consistent with the stage that we are at, where we only consider functions that do not use constants or perform equality tests; for such functions of type $\mathbb{A} \to \mathbb{A}$ the only possibility is the identity.

The arena describes the following interaction between the two players: Environment requests an output, then System requests an input, then Environment grants the input, and finally System grants the output by forwarding the input that was granted. It has 4 moves:

move	owner	register operation
request output	Environment	none
request input	System	none
grant input	Environment	write
grant output	System	read

The plays are defined as all sequences that begin with a move of Environment, alternate between players, use each move only once, and have the following condition: "grant output" can only be played after "request output", and likewise for "grant input" and "request input".

[5] This condition is only meaningful, if there are arenas that admit plays of unbounded length. Since, in this section, all the arenas will be finite this condition will be vacuously true. It will only become relevant in Section 5.2, once we introduce arenas with constants and equality tests.

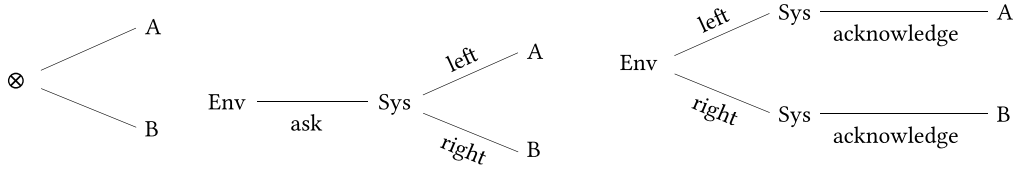


Figure 1 Pictures of the operations $A \otimes B$, $A + B$, $A\&B$ and $A \otimes B$ respectively on arenas. The picture for $\otimes$ is less useful than the next two, since the root node of the tree is not a player, but a node labelled by $\otimes$. The intuition is that the game is played in parallel on both arenas, and therefore a position in it can be visualized as a pair of positions in the two arenas.

A quick inspection of this definition reveals that there is a unique maximal play, where the moves are played in the order from the table, and all other plays are prefixes of this maximal play. Because of the uniqueness of responses, the set of plays is also a strategy. As mentioned at the beginning of this example, the strategy describes the identity function. ⌟

We hope that the above example explains some intuitions about how arenas describe types and strategies describe functions. We now give a formal definition which is compositional: we define arenas for the basic types 1 and $\mathbb{A}$, and then we define operations on arenas that correspond to the type constructors $+$, $\&$, and $\otimes$. We begin with the basic types.

▶ **Definition 5.6** (Arenas for 1 and $\mathbb{A}$)**.**

1. *The arena for the type* 1 *is empty: there are no moves, the only play is the empty sequence.*
2. *The arena for type* $\mathbb{A}$ *has two moves, which must be played one after the other: first player Environment makes a move called "request" that has no register operation, and then player System responds with a move called "grant" that has register operation "read".*

In the above definition, we only described the behaviour of $\mathbb{A}$ when viewed as an output type. To get the input type, where the players are swapped and read is swapped with write, we will use duality, which is another operation on arenas. This operation is defined below, together with other operations that correspond to the type constructors.

▶ **Definition 5.7.** *Let A and B be arenas. We define the following arenas (see also Figure 1):*

$\bar{A}$ *This is called the* dual arena *of A. The moves and plays are the same as in A, except the owners are swapped, and the "read" and "write" register operations are swapped.*

$A + B$ *The moves in this arena are the disjoint union of the moves of A and B, with inherited owners and register operations, plus three extra moves: "ask" owned by Environment, and "left", "right" owned by System. The plays are defined as follows. Player Environment begins with an ask move, then System responds with a left or right move, and the remaining sequence is a play in the arena A or B, depending on whether System chose left or right.*

$A\&B$ *The moves in this arena are the disjoint union of the moves of A and B, with inherited owners and register operations, plus three extra moves: "acknowledge" owned by System, and "left", "right" owned by Environment. The plays are defined as follows. Environment begins by choosing left or right, then System responds with an acknowledge move, and the remaining sequence is a play in either A or B, depending on Environment's choice. (This construction differs slightly from the one from [2, Exercise 1.10] – this is because we want to keep it analogous to the construction for $A + B$.)*

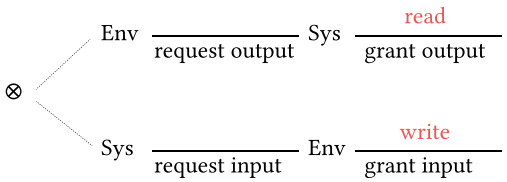
$A \otimes B$ *The moves in this arena are the disjoint union of the moves of A and B, with inherited owners and register operations. A play in this arena is any shuffle of plays in the two arenas A and B. (A shuffle of two words is any word obtained by interleaving them, e.g. shuffles of "abc" and "123" include "a1b23c" and "12ab3c"). By Definition 5.6, we require that the owners of the move alternate in the interleaved sequences. See [2, p.7].*

Equipped with the above definitions, we present our first attempt at assigning arenas to types. In the second item of the following definition, we use the name *library-less*, because our second and final definition of the arena for a function type, as presented in the next section, will be equipped with an extra feature that will be called a library.

▶ **Definition 5.8.** *Let X and Y be linear types.*

- *The* arena for X *is defined by inductively applying the constructions from Definition 5.6 and Definition 5.7 according to the structure of the type.*
- *The* library-less arena for $X \to Y$ *is defined to be (dual of arena of X) $\otimes$ (arena of Y).*

▶ **Example 5.9.** The library-less arena for the identity type $\mathbb{A} \to \mathbb{A}$ is the same as the arena that we explicitly defined in Example 5.5. It can be drawn as the following picture:



As discussed previously, our notion of arenas does not yet take into account some structure on the atoms. This will be fixed in the next section, by modifying the second item in Definition 5.8. On the other hand, the arenas from the first item, for linear types without function types, are already in their final form.

In principle the construction from the second item in Definition 5.8 can be nested, and thus used to assign arenas to higher-order types that can nest $\to$ with the other type constructors. This is how it is usually done in linear logic. However, the construction that we will describe in the next section will be less amenable to nesting, and will use it only to describe functions between types that do not use $\to$.

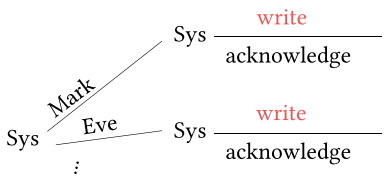
5.2 Arenas and strategies with constants and equality tests

In Section 5.1, we described arenas for functions that did not use the structure of the atoms, i.e. constants and equality tests. We now show how these arenas can be extended to cover this structure. The general idea is to equip the arenas with an extra part, which we call the *library*, that describes the allowed operations on the atoms. (The library as we present it here only contains functions for equality and constants, but in the proof of Theorem 6.2, we will use a library that has other relations beyond equality.)

▶ **Definition 5.10.** *The* library arena *and its parts are defined as follows (cf. Figure 2).*

1. *The* constant choice arena *is the following arena $\mathbb{A} + 1$ moves: first player System chooses an atom, then player Environment plays move with register operation "write".*
2. *The* equality test arena *is an arena which the plays are as follows:*
   a. *first System plays a move with register operation "read";*
   b. *then Environment plays an move with no register operation;*
   c. *then System plays a move with register operation "read";*
   d. *then Environment plays one of two moves, called $=$ and $\neq$, with no register operation.*
3. *The* library arena *is obtained by applying $\otimes$ to infinitely[6] many copies of the constant choice arena and infinitely many copies of the equality test arena.*

The constant choice arena:



The equality test arena:

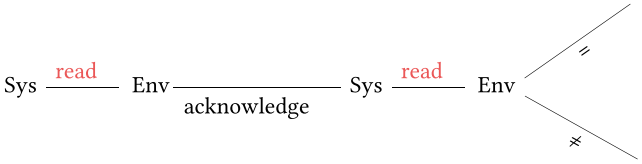


Figure 2 Pictures of the library arenas. We use the convention that the register operations are in red, and the names of the moves, which have no other role than to distinguish them, are in black. Note that the first move in this arena is owned by System, and we assume in Definition 5.2 that the first move is owned by Environment. This is because this arena, like all arenas in Definition 5.10, is not intended to be a stand-alone arena, but only as part of the bigger arena from Definition 5.11 where the first move is indeed owned by Environment.

The library arena is infinite. Taking the tensor product of infinitely many copies of the two arenas ensures that the library arena satisfies the following property, which corresponds to the ! operation from linear logic:

$$\text{library arena} \quad \equiv \quad (\text{constant choice arena}) \otimes (\text{equality test arena}) \otimes (\text{library arena}). \tag{1}$$

In the above, $\equiv$ refers to isomorphism of arenas, which is defined in the natural way: this is a bijection between the moves, which is consistent with the owners, register operations and plays in the expected way. Another property is that the library arena is isomorphic to a tensor product of itself:

$$\text{library arena} \quad \equiv \quad \text{library arena} \otimes \text{library arena}. \tag{2}$$

We are now ready to give the final definition of arenas for functions between linear types, which takes into account the structure of the atoms.

▶ **Definition 5.11** (Function arena). *For linear types X and Y, the arena of $X \to Y$ is*

(library arena) $\otimes$ (dual arena of X) $\otimes$ (arena of Y).

This completes the game semantics of linear types and functions between them. We do not intend to give game semantics for higher-order types, such as functions on functions etc. As a result, we will only be using the dual once, namely for the arena of the input type. Also, note that the read/write operations will be used in a restricted way, as announced in Remark 5.3,

[6] Observe that the shuffle operation from Definition 5.7 can also be used for infinite families of arenas.

namely that the "read" moves will be owned by System and the "write" moves will be owned by Environment. This is because the library arena has this property, the arena for $\mathbb{A}$ has this property, and all operations on arenas that we have defined preserve this property.

As said before, the rest of the proof of Theorem 3.8 takes place in the technical appendix.

6 Beyond equality

So far, we have studied the case when the atoms are equipped with equality only. Consider now a more general case: let $\mathbb{A}$ be any relational structure, i.e. any set equipped with relations (but not functions). For example, we could use the rational numbers with their linear order. Another example would be Presburger arithmetic, i.e. $(\mathbb{N}, +)$. Since we want to have relations only, we think of addition as a ternary relation $x + y = z$. The construction from Section 3 of the single-use category can be generalized to this case; and not only is the definition of the category generic, but the same is true for the proof that function spaces exist.

▶ **Definition 6.1** (Single-use functions over a relational structure). *Let $\mathbb{A}$ be a relational structure. The* single-use category over $\mathbb{A}$ *is defined in the same way as in Definition 3.7, except that the list of prime functions is extended with one prime function $\mathbb{A}^n \to 1 + 1$ for every n-ary relation in the vocabulary of $\mathbb{A}$. (Here, the power $\mathbb{A}^n$ uses $\otimes$.)*

▶ **Theorem 6.2.** *Consider a relational structure $\mathbb{A}$, in which for every $k \in \{0, 1, \ldots\}$ there are finitely many relations of arity k. Then the single-use category over $\mathbb{A}$ satisfies the weak universal property stated in Theorem 3.8.*

In the above statement, "weak" alludes to the non-uniqueness of currying; we could again get a symmetric monoidal closed category by performing the quotient construction of Section 4.

The theorem is proved in the same way as Theorem 3.8. The assumption on the vocabulary is used to ensure that in the corresponding game semantics (cf. Section 5), there are finitely available moves in any given moment, because the vocabulary can only be queried up to the maximal number of atoms in the input, due to the single-use restriction.

Note that this theorem can be applied to any relational structure, including undecidable ones. Clearly, there must be some benefit from assuming that the structure has a decidable first-order theory, which means that there is an algorithm which checks if a first-order sentence is true in the structure. The benefit is that we can check if two morphisms are equal, as expressed in the following theorem, whose assumption applies to structures such as Presburger arithmetic, or the real field $(\mathbb{R}, +, \cdot, \leq)$.

▶ **Theorem 6.3.** *Consider a relational structure $\mathbb{A}$, in which for every $k \in \{0, 1, \ldots\}$ there are finitely many relations in the vocabulary that have arity k. If this structure has a decidable first-order theory, then there is an algorithm for the following problem:*
Input: *Two morphisms, described by expressions using prime functions and combinators.*
Question: *Are they the same morphism?*

7 Further topics

Two-way automata. Theorem 6.3 gives us a reasonable category of single-use functions over a relational structure with a decidable first-order theory. However, the latter property is not the only one needed to ensure that the category is appropriate to automata. If we want to model automata and their decision procedures, we will also need to execute certain fixpoint algorithms, as explained in [5]. In order to allow it, we assume that $\mathbb{A}$ is an *oligomorphic* (see

[5, Definition 3.9]) structure. It is a standard assumption in the theory of sets with atoms, used to ensure that the notion of orbit-finite set is meaningful. Examples of oligomorphic structures include the atoms with equality only, the rational numbers with their linear order, and the Rado graph. Non-examples include Presburger arithmetic and the real field.

▶ **Theorem 7.1.** *Let* $\mathbb{A}$ *be an* oligomorphic *structure with a decidable first-order theory. Then the emptiness problem is decidable for single-use deterministic two-way automata over* $\mathbb{A}$*.*

In the proof of this theorem, we show that the single-use category over an oligomorphic structure $\mathbb{A}$ is *traced* with respect to the coproduct $+$, and use this to model deterministic two-way automata over $\mathbb{A}$. The idea that traced monoidal categories are a natural setting for two-way automata comes from [14].

Orbit-finite dimensional vector spaces. An alternative solution for the problem of function spaces – our central motivation in this paper – is to use vector spaces of orbit-finite dimension. The technical tools for this were developed already in [8]; our contribution here is mainly one of perspective, namely framing it as a symmetric monoidal closed category.

▶ **Theorem 7.2.** *The category of orbit-finitely spanned vector spaces [8, Section VI] is symmetric monoidal closed, with respect to the tensor product.*

▶ Remark 7.3. A similar result was observed in [22, Theorem 3.8], but using the smaller category of vector spaces that admit an orbit-finite basis.

An advantage of the vector space category is its simplicity, and the fact that it is "bigger" in the following sense: The two solutions for function spaces discussed in this paper, namely the single-use solution and the vector space solution, sit on both sides of the classical category of orbit-finite sets, as witnessed by two faithful functors, one from the single-use category to the orbit-finite category, and one from the orbit-finite category to the vector space category. However, there are two limitations of the orbit-finitely spanned vector spaces.

First, the existence of function spaces is dependent on the choice of atoms. Theorem 7.2 works when the atoms have equality only, and it also works when the atoms are equipped with a total order. This is because the dual spaces are orbit-finitely spanned in these cases, as proved in [8, Corollary VI.5]. However, this is no longer the case for other choices of atoms, such as the Rado graph, see [8, Example 9]. This is in contrast to the single-use category, where the existence of function spaces is independent of the choice of atoms.

A second limitation is that unlike the single-use category (cf. Theorem 7.1), the vector space category does not support two-way automata. This is because this category generalizes the orbit-finite category (i.e. it admits a faithful functor from it), and in the orbit-finite category emptiness is undecidable for deterministic two-way automata [17, Theorem 5.3]. This precludes the kind of traced construction that we did in the single-use category. This issue appears already without atoms: the category of finite-dimensional vector spaces is not traced with respect to the sum $\oplus$ of vector spaces.

Related work: categories and λ-calculus. There have been several works using category theory to generalize classical operations on automata, such as the coalgebraic "generalized powerset construction" [23]. The closest to the philosophy that this paper might be the work of Colcombet and Petrişan [11]: it introduces a setting where automata over different categories may be studied and compared (see e.g. [4] for applications). Within this setting, Pradic and the second author have investigated some properties of automata over symmetric monoidal closed categories [18, Sections 1.2.3 and 4.7–4.8].

The latter emerged as part of their research on "implicit automata" [19, 18, 21], which is about relating the expressive power of automata and typed λ-calculi. In [18, Chapter 4], a monoidal closed category of single-use assignments on string-valued registers is built and used to relate a register-based string transducer model to a λ-calculus with linear types. Indeed, symmetric monoidal closed categories are famous for providing denotational semantics for the linear λ-calculus. Similarly, our results here could serve to characterize the languages of words with atoms studied by the first and third author in [9] via some typed λ-calculus.

Conversely, our Theorem 3.8 might also be provable by representing single-use functions as λ-terms (or programs in some richly structured syntactic formalism) instead of strategies over games. Indeed, it is a classical fact that a simple type is inhabited by finitely many linear λ-terms up to β-conversion (when there are no primitive constants), and variations on this fact have been used in the literature to relate automata and λ-calculus [19, 12].

The Structure of Trees in the Pushdown Hierarchy

Arnaud Carayol

Abstract

In this article, we investigate the structure of the trees in the pushdown hierarchy, a hierarchy of infinite graphs having a decidable MSO-theory. We show that a binary complete tree in the pushdown hierarchy must contain at least two different subtrees which are isomorphic. We extend this property to any tree with no leaves and with chains of unary vertices of bounded length. We provided two applications of this result. A first application in formal language theory, gives a simple argument to show that some languages are not deterministic higher-order indexed languages. A second application in number theory shows that the real numbers defined by deterministic higher-order pushdown automata are either rational or transcendental.

2012 ACM Subject Classification Theory of computation → Automata over infinite objects; Theory of computation → Verification by model checking

Keywords and phrases Pushdown hierarchy, Monadic second-order logic, Automatic numbers

Acknowledgements The authors are indebted to Didier Caucal for pointing out the notion of (ℓ, b)-tree implicit in the work [3] and starting this work. The authors would like to thanks the reviewers for their work.

1 Introduction

The pushdown hierarchy (also called the Caucal hierarchy) is a robust hierarchy of infinite directed graphs for which monadic second-order logic (MSO) is decidable. These graphs have a countable set of vertices but their edges and nodes are labeled and colored by finite sets. Such infinite graphs with decidable MSO-theories play an important role in automated program verification as they provide a framework in which the model-checking problem for many relevant properties such as termination and safety is decidable. The robustness of the pushdown hierarchy is witnessed by its numerous characterizations and closure properties (we refer the reader to [21] for a survey).

A first characterization of the pushdown hierarchy is via graph transformations following the original idea of Caucal [10]. Every graph in the pushdown hierarchy can be constructed starting from a finite tree by combining two graph transformations that preserve the decidability of MSO-theories namely MSO-interpretations [12] and graph unfolding [13]. As shown in Figure 1, the pushdown hierarchy consists of two intertwined hierarchies: one of classes of trees $(\mathrm{Tree}_n)_{n\geqslant 0}$ and one of classes of graphs $(\mathrm{Graph}_n)_{n\geqslant 0}$. The class Tree_0 contains all finite trees and for $n \geqslant 0$, Graph_n contains all graphs that can be MSO-interpreted in a tree of Tree_n. The trees in Tree_{n+1} are the unfoldings of the graphs in Graph_n. In particular, Graph_0 contains all finite graphs, Tree_1 contains the regular trees and the graphs in Graph_1 are the prefix-recognizable graphs [9]. This hierarchy is closed under most if not all transformations known to preserve the decidability of MSO-theories [8]. It is in particular closed under MSO-transductions [13] and the Muchnik's iteration [22]. More recently, the pushdown hierarchy was shown to be closed under MSO+$\mathrm{U}^{\mathrm{fin}}$-interpretations in [20].

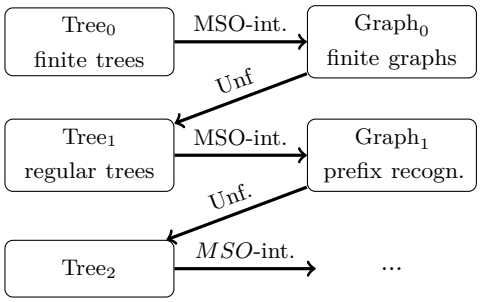

Figure 1 The construction of the pushdown hierarchy using MSO-interpretations and the unfolding operation.

The graphs and trees in the pushdown hierarchy admit several alternative characterizations. The graphs in Graph_n are (up-to isomorphism) the transition graphs of higher-order pushdown automata of order n (see [8]). Higher-order pushdown automata [16] are a generalization of the standard model of pushdown automata which manipulates stacks of stacks at order 2, stacks of stacks of stacks at order 3, ... The deterministic terms in Tree_{n+1} are the solutions of higher-order safe recursion schemes of order-n [10, 15].

These different characterizations make it easy to show that a graph belongs to the pushdown hierarchy. It is rather more complicated to show that a graph does not belong to the pushdown hierarchy. Still the question of characterizing the graphs in this hierarchy has received a lot of attention. There are two main approaches. One approach is to work with higher-order pushdown automata and to develop pumping lemmas for these automata [5, 6, 18, 19]. A second approach is to focus on structural properties of the graphs and to work by induction of the level in the hierarchy using graph transformations [1, 7]. The most involded separation result, namely the separation between trees produced by safe and unsafe recursion schemes was obtained with the first approach [19]. However this approach is much more technically involved and arguably the technical results obtained are less likely to be reusable. In this work, we follow the second approach.

Our starting point is a question asked to the first author by Wolfgang Thomas. He asked whether the pushdown hierarchy contains irrational algebraic numbers such as $\sqrt{2}$. Meaning, does there exists an infinite word (i.e., a unary tree) in the pushdown hierarchy that encodes the expansion of $\sqrt{2}$ in some base $\ell \geqslant 2$? Sadly with this precise statement, the question seems still far out of reach[1]. But the recent work of [3] shows that if we choose to represent a real number in $[0, 1]$ not by its expansion but by a particular tree encoding this expansion, the trees associated with irrational algebraic numbers have strong structural properties: they are deterministic, mostly-complete and all their subtrees are non-isomorphic. The trees representing expansions of real numbers in $[0, 1]$ are implicit in the work of [3] and generalize the definition of automatic real numbers [4]. Indeed they coincide with a generalization of automatic real numbers in which deterministic finite automata are replaced by deterministic higher-order pushdown automata [11].

[1] In this sense, the pushdown hierarchy is known to contain all the rational numbers and all the morphic numbers (and hence all the automatic numbers) in $[0, 1]$. Indeed morphic sequences have been shown to belong to Tree_2 in [10, Proposition 3.2]. Hence the pushdown hierarchy contains expansions of transcendental numbers (see [2]) but is not known to contain the expansions of any irrational algebraic number.

In Section 4 and Section 5, we show that any tree with no leaves and with chains of unary vertices of bounded length in the pushdown hierarchy must contain two different isomorphic subtrees. The main technical ingredient is a precise description of the MSO-interpretations constructing a complete binary tree from a complete binary tree. In Section 6, we give two applications of this result. First, we show how it can be used to show that certain languages such as the language $L_{ww} = \{ww \mid w \in \{0,1\}^*\}$ cannot be accepted by any deterministic higher-order pushdown automaton. Second, we show that a real number in $[0,1]$ represented by a tree in the pushdown hierarchy is either rational or transcendental (i.e., not algebraic). As the real numbers with a tree in Tree_1 are the automatic reals numbers, the result was proved for level 1 in [2]. It was also shown for level 2 in [3].

2 Preliminaries

Notations. Let Σ^* denote the set of all words over the alphabet Σ. We write $u \sqsubseteq v$ if u is a prefix of v and $u \sqsubsetneq v$ if u is a strict-prefix of v. If Σ is equipped with a total order relation, we denote by $<_{\mathrm{lex}}$ the resulting lexicographic ordering on words over Σ.

Infinite graphs and trees. In this article, we consider graphs with countably many vertices with labeled edges and colored vertices. Let Σ be a finite set of edge labels and Θ be a finite set of vertex colors, a graph G labeled by Σ and colored by Θ is a tuple (V, E, C) where V is a countable set of vertices, $E \subseteq V \times \Sigma \times V$ is a set of labeled edges, $C \subseteq \Theta \times V$ is the set of colors. A graph G is deterministic if for all $\sigma \in \Sigma$ and all vertices u, v and v', $u \xrightarrow[G]{\sigma} v$ and $u \xrightarrow[G]{\sigma} v'$ then $v = v'$.

A path π in a graph G from u to v is a sequence $u_0\sigma_0u_1 \cdots \sigma_{n-1}u_n \in V(\Sigma V)^*$ such that $u_0 = u$, $u_n = v$ and $(u_i, \sigma_i, u_{i+1}) \in E$ for $i \in [0, n-1]$. This path is labeled by the word $w = \sigma_0 \cdots \sigma_{n-1}$. We write $u \xrightarrow[G]{w} v$ (or simply $u \xrightarrow{w} v$ if G is clear from the context) to denote the existence of such a path. We extend this notation to a language L over Σ by taking $u \xrightarrow{L} v$ if and only if $u \xrightarrow{w} v$ for some $w \in L$. To improve readability, we write $\longrightarrow$ instead of $\xrightarrow{\Sigma}$, $\longrightarrow^*$ instead of $\xrightarrow{\Sigma^*}$ and $\longrightarrow^+$ instead of $\xrightarrow{\Sigma^+}$.

For two graphs G_1 and G_2, we write $G_1 \sim G_2$ to denote the existence of an isomorphism between G_1 and G_2.

A graph T is a tree if there exists a vertex r called the *root* of T such that there exists a unique path from the root to any vertex. Vertices in a tree are called nodes. A node v is a child of a node u if $u \xrightarrow{\Sigma} v$. In this case, we say that u is the parent of v. A node v is a descendant of u if $u \longrightarrow^* v$ which we also denote by $u \sqsubseteq_T v$. The subtree of a tree T rooted at a node u, denoted by $T_{|u}$, is the tree obtained by restricting T to u and its descendants.

Every node in a deterministic tree is uniquely identified by the label of the unique path from the root to this vertex. As a result, a deterministic tree T labeled by Σ and colored by Θ is determined up-to isomorphism by a mapping from a prefix-closed subset of Σ^* to the subsets of Θ. When reasoning up to isomorphism, we will not distinguish between a deterministic tree and the associated mapping. We always assume that Σ comes with a fixed arbitrary order and hence that the nodes of a deterministic tree can be compared using the lexicographic order.

A complete binary tree is a deterministic tree labeled by $\{0,1\}$ in which every node has two children. The 0-child is called the left-child and the 1-child is called the right-child. For a direction $\gamma \in \{\uparrow, \swarrow, \searrow\}$, we say that v is the γ-successor of u, if v is the parent of u and

$\gamma = \uparrow$ or if v is the left-child (resp. right-child) of u and $\gamma = \swarrow$ (resp. $\gamma = \searrow$). We say that v is in direction γ relative to u, if the γ-successor of u is on the minimal path (ignoring the orientations of the edges) from u to v.

Monadic-second order logic on graphs. We define *monadic-second order logic* (MSO) over graphs with labeled edges and colored nodes as usual. We use lowercase letters $x, y, z, \ldots$ for first order variables and uppercase letters $X, Y, Z, \ldots$ for second order variables. The atomic formulas are $x = y$, $x \in X$, $x \xrightarrow{\sigma} y$ and $\theta(x)$ for σ an edge label and θ a color. MSO-formulas are obtained by applying boolean operators ($\neg$ and $\vee$) and existential quantifiers ($\exists$) over both first and second order variables. To improve readability, we will freely use any definable notion as syntactic sugar: $\forall$, $\Rightarrow$, $X \subseteq Y$, ...

The notion of free variables is defined as usual. We write $\varphi(x_1, \ldots, x_n, X_1, \ldots, X_m)$ when the free variables of a formula φ are among $x_1, \ldots, x_n, X_1, \ldots, X_m$. A closed formula does not have any free variables. For a graph G and a formula $\varphi(x_1, \ldots, x_n, X_1, \ldots, X_m)$, we write $G \models \varphi[u_1, \ldots, u_n, U_1, \ldots, U_m]$ when the graph satisfies the formula if the free variables $x_1, \ldots, x_n, X_1, \ldots, X_m$ are respectively interpreted as $u_1, \ldots, u_n, U_1, \ldots, U_m$ where the u_i's are vertices and U_i's are sets of vertices. The MSO-theory of a graph G is a set of closed formulas satisfied by G. A vertex u of a graph G is MSO-definable in G if there exists a formula $\varphi(x)$ such that u is the only vertex such that $G \models \varphi[u]$. The notion of an MSO-definable set of vertices is defined similarly.

Graph transformations. An *MSO-interpretation* $\mathcal{I}$ (on graphs) is given by a tuple of MSO-formulas $(\delta(x), (\varphi_\sigma(x, y))_{\sigma \in \Sigma}, (\varphi_\theta(x))_{\theta \in \Theta})$ where Σ and Θ are finite sets of labels and colors respectively. An *MSO-recoloring* is a special case of MSO-interpretation which does not erase any vertices (i.e., $\delta(x) = \mathbf{true}$) and preserves all edges (i.e., $\varphi_\sigma(x, y) = x \xrightarrow{\sigma} y$ for $\sigma \in \Sigma$).

An *MSO-transduction* (see [12]) is the composition of a K-copying operation followed by an MSO-interpretation. For a finite set of labels $K = \{k_1, \ldots, k_n\}$, the K-copying operation adds for every vertex u of the graph, fresh vertices $u_1, \ldots, u_n$ as well as edges from u to u_i labeled by k_i for each $i \in [1, n]$.

The *unfolding* of a graph G from a vertex s is the tree denoted by $\mathrm{Unf}(G, s)$ whose vertices consists of all paths in G starting from s and with an edge labeled by a from a path π to a path π' if $\pi' = \pi a t$ for some vertex t. Furthermore a path π, ending at a vertex t of G, is colored in $\mathrm{Unf}(G, s)$ with the same colors as t in G.

3 The pushdown hierarchy

The pushdown hierarchy contains the (possibly infinite) graphs which can be constructed using MSO-interpretations combined with the unfolding operation starting from a finite tree. The pushdown hierarchy consists of two intertwined hierarchies of classes of graphs[2]: one containing trees $(\mathrm{Tree}_n)_{n \in \mathbb{N}}$ and one containing graphs $(\mathrm{Graph}_n)_{n \in \mathbb{N}}$ such that:

- Tree_0 is the class of all finite trees;
- for $n \geqslant 0$, Graph_n is the class of all graphs G such that there exists an MSO-interpretation $\mathcal{I}$ and a tree $T \in Tree_n$ with $G \sim \mathcal{I}(T)$;
- for $n \geqslant 1$, Tree_n is the class of trees such that there exists a graph $G \in \mathrm{Graph}_{n-1}$ and a vertex $u \in G$ such that $T \sim \mathrm{Unf}(G, u)$.

[2] All the graphs we consider are labeled and colored by finite sets: only the set of vertices is infinite.

As both MSO-interpretations and the unfolding (from an MSO-definable vertex) preserve the decidability of MSO-theories [12, 13], it follows that all graphs in the pushdown hierarchy have a decidable MSO-theory [8]. Our main contribution only uses the following closure properties which follow from [8]:

▶ **Theorem 1** ([8]). *The following properties hold:*

1. *For $n \geqslant 0$, for a deterministic tree T in Tree_n and an MSO-recoloring μ, the tree $\mu(T)$ belongs to Tree_n.*
2. *For $n \geqslant 0$, the class Graph_n is closed under MSO-transductions and under restriction to reachable vertices from a given vertex (not necessarily MSO-definable) and Tree_n is closed under taking subtrees.*
3. *For $n \geqslant 1$, every graph $G \in \mathrm{Graph}_n$ is isomorphic to $\mathcal{I}(T)$ for some complete binary tree $T \in \mathrm{Tree}_n$ and some MSO-interpretation $\mathcal{I}$. Furthermore, we can assume that for all nodes $s \neq s'$ of $\mathcal{I}(T)$, s and s' are incomparable for $\sqsubseteq_T$.*

3.1 MSO-interpretations and tree-walking automata

By Property 1 of Theorem 1, every graph in Graph_n can be MSO-interpreted in a complete binary tree. In [7, 8], it is shown that MSO-interpretations applied to deterministic trees can be described using only MSO-recolorings and tree walking automata. To simplify the presentation, we tailor our definitions to complete binary trees (cf. Remark 4).

A *tree-walking automaton* on complete binary trees colored by Θ is a tuple $A = (Q, q_A, F, \Delta)$ where Q is the finite set of states, $q_A \in Q$ is the initial state, $F \subseteq Q \times 2^\Theta$ is the set of accepting conditions and $\Delta \subseteq Q \times 2^\Theta \times \{\uparrow, \swarrow, \searrow\} \times Q$ is the set of transitions. Intuitively, a transition (p, c, γ, q) expresses that if the automaton is in state p on a node u colored by the colors of c, it can move in state q to the γ-successor of u.

A run of a tree-walking automaton A on a complete binary tree T starting from a node u_0 in state q is a finite sequence $q_0 u_0 q_1 u_1 \cdots q_n u_n \in (QV_T)^+$ with $q_0 = q$ and for $i \in [0, n-1]$, there exists a transition $\delta = (q_i, T(u_i), \gamma, q_{i+1}) \in \Delta$ with u_{i+1} the γ-successor of u_i. A run is accepting if $(q_n, T(u_n))$ belongs to F. A tree-walking automaton A *accepts a pair of nodes* (u, v) if there exists an accepting run of A on T from the initial state q_A starting at u and ending in v.

On complete binary trees, tree-walking automata can accept any MSO-definable binary relation provided that the trees are recolored with a suitable MSO-recoloring.

▶ **Proposition 2** ([7, 8]). *For every binary complete tree T and every MSO-formula $\varphi(x, y)$, there exists an MSO-recoloring μ and a tree-walking automaton A_φ which accepts on $\mu(T)$ the pairs of nodes (u, v) such that $T \models \varphi[u, v]$.*

In this article, we need a stronger result in the case when the MSO-formula $\varphi(x, y)$ defines a functional relation (i.e., for each node u, there exists at most one node v such that $T \models \varphi[u, v]$). Under this restriction, we will show that the tree-walking automaton can be chosen to be *deterministic* and *non-backtracking* on T.

A tree-walking automaton is said to be *deterministic* if for all state q and set of colors $c \in 2^\Theta$, $(q, c, \gamma, p) \in \Delta$ and $(q, c, \gamma', p') \in \Delta$ implies that $\gamma = \gamma'$ and $p = p'$. This notion of determinism guarantees that there is at most one run starting from a given node in a given state but it does not forbid the tree-walking automaton from visiting the same node twice. A tree-walking automaton is said to be *non-backtracking* on T if none of its runs on T visits the same node twice. In particular a non-backtracking automaton, when going from u to v, will always follow the shortest path from u to v (ignoring the orientations of the edges).

▶ **Proposition 3.** *For every complete binary tree T and every MSO-formula $\varphi(x, y)$ functional on T, there exist an MSO-recoloring μ and a deterministic and non-backtracking tree-walking automaton A_φ which accepts on $\mu(T)$ the pairs of nodes (u, v) such that $T \models \varphi[u, v]$.*

Proof Sketch. Let A be the non-deterministic tree-walking automaton and μ_A be the MSO-recoloring obtained for $\varphi(x, y)$ in Proposition 2. Our aim is to define a new coloring μ_B that captures the functional behavior of A on T. For this we define, for every node u and every state p of A, $\text{target}(u, p)$ to be the unique node v such that all accepting runs of A on $\mu_A(T)$ starting in state p at u end in v. If no such node v exists, $\text{target}(u, p)$ is undefined. As A accepts a functional relation, if A accepts a pair (u, v) then for the initial state q_A of A, $\text{target}(q_A, u)$ is defined and equal to v.

To define the coloring μ_B, we fix an arbitrary order on the states of A. For each state p of A, we color a node u by the tuple (p, γ, q) if $\text{target}(u, p)$ is defined and equal to v, γ is the direction in $\{\uparrow, \swarrow, \searrow\}$ of v relative to u and q is the smallest state of A such that $\text{target}(u_\gamma, q) = v$ with u_γ the γ-successor of u. Such a state q must exists, as every run from u to v must go through u_γ. This coloring can be defined in MSO as μ_A is MSO-definable.

The deterministic and non-backtracking automaton B has the same states, initial state and acceptance conditions as A. In a state p at a node u colored with a tuple (p, γ, q), the automaton moves in the direction γ to the state q. It is easy to show that B accepts (u, v) on $\mu_B(T)$ if and only if A accepts (u, v) on $\mu_A(T)$ which concludes the proof. ◀

▶ Remark 4. To ease the presentation, we only defined tree-walking automata on binary complete trees but they can be defined to work on general deterministic trees and the results of both Proposition 2 and Proposition 3 generalize to this setting.

As a spin-off result, we obtain a simple proof to an open question of [10, Question b] which asks (when reformulated in the setting of this article) if all deterministic trees in Tree_n can be obtained by replacing general MSO-interpretations by a restricted sub-class called deterministic rational inverse mapping. A *deterministic rational inverse mapping* is an MSO-interpretation in which edges are defined by deterministic tree-walking automata working on deterministic trees (cf. Remark 4) and the colors are obtained by renaming or erasing the existing colors. Only vertices that are source or target of an edge are kept (i.e. $\delta(x) := \exists y, \bigvee_{\sigma \in \Sigma} \varphi_\sigma(x, y) \vee \varphi_\sigma(y, x)$).

By a direct induction on the level of the pushdown hierarchy and using Proposition 3, we obtain the following proposition.

▶ **Proposition 5.** *Every deterministic tree in Tree_n is obtained by a n-fold application of a deterministic inverse rational mapping followed by an unfolding starting with a finite tree.*

4 Trees with no self-similarities in the pushdown hierarchy

A tree is said to have a self-similarity if it contains two different subtrees which are isomorphic. The main contribution of this article is the following theorem.

▶ **Theorem 6.** *Every complete binary tree in the pushdown hierarchy has self-similarities.*

Trees with no self-similarities are called *pure* in this article. To prove Theorem 6, we need to show that the pushdown hierarchy does not contain any pure binary complete tree. Assume toward a contradiction that it does. Let $n_0 \geqslant 0$ denote the smallest level such that either Graph_{n_0} or Tree_{n_0} contain such a tree.

Consider the case where Tree_{n_0} contains some pure complete binary tree T_{pure}. As T_{pure} is infinite, we must have $n_0 \geqslant 1$ and by definition of Tree_{n_0}, the tree T_{pure} is (up-to isomorphism) the unfolding of a graph $G \in \mathrm{Graph}_{n_0-1}$ from some vertex r_G. By Property 2 of Theorem 1, we can assume w.l.o.g. that all the vertices of G are reachable from r_G. As all subtrees of the unfolding of G from r_G are non-isomorphic, every vertex of G must be reachable by exactly one path from r_G. Indeed, if a node s was reachable by two different paths $\pi_1 \neq \pi_2$ from r_G, then the subtrees rooted at π_1 and at π_2 in $\mathrm{Unf}(G, r_G)$ would be isomorphic. This implies that G is a tree. As every tree is isomorphic to its unfolding from its root, the graph G must be isomorphic to T_{pure}. Hence $G \sim T_{\mathrm{pure}}$ is a pure tree in Graph_{n_0-1} which contradicts the definition of n_0.

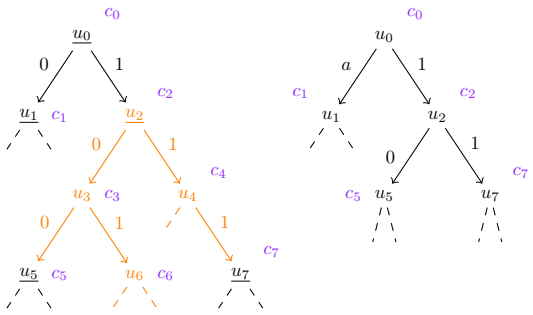

Figure 2 A tree T with a distinguished set of nodes $U = \{u_0, u_1, u_2, u_5, u_7\}$ (on the left) and the induced tree T_U (on the right). The chunk C_{u_2} is highlighted in orange.

It only remains to consider the case where Graph_{n_0} contains a pure binary tree T_{pure} but Tree_{n_0} does not contain any pure complete binary trees. By definition of Graph_{n_0} and by Property 3 of Theorem 1, there must exist a complete binary tree T and an MSO-interpretation $\mathcal{I}$ such that T_{pure} is isomorphic to $\mathcal{I}(T)$. We will show that if an MSO-interpretation is able to produce a pure complete binary tree when applied to some complete binary tree T, then the tree T must be a pure tree *in disguise*.

To formalize what we mean, we recall the notion of embedding in a tree which is illustrated in Figure 2. A set of nodes U in a tree T which contains a unique minimal element induces a tree denoted by T_U. Intuitively this tree is obtained by restricting the tree T to the vertices in U while preserving their colors and inheriting the ancestor relation from T. The label of an edge (u, v) in T_U is the label of the first edge in the unique path from u to v in T. Remark that we present the notion in its most general form but we will mainly work with embedding defining binary complete trees.

▶ **Definition 7.** *An* embedding *in a tree T labeled by Σ is a set of nodes U which contains a unique minimal element for the ancestor relation $\sqsubseteq_T$. This element is called the root of the embedding. This embedding* induces *the tree T_U whose nodes are the elements of U and such that $u \xrightarrow{x} v \in T_U$ if and only if $u \xrightarrow{xw} v \in T$ for some $w \in \Sigma^*$ and there are no $v' \in U$ such that $u \sqsubsetneq v' \sqsubsetneq v$. Moreover the nodes of U have the same colors in T and T_U.*

In Proposition 8, we show that, after applying a suitable MSO-recoloring to the tree T, the resulting tree embeds a pure complete binary tree. This is the main technical contribution of this paper.

▶ **Proposition 8.** *Let T_{pure} and T be two complete binary trees and let $\mathcal{I}$ be an MSO-interpretation such that $T = \mathcal{I}(T)$. If T_{pure} is pure then there exists an MSO-recoloring μ and an embedding $\mathcal{S}_{\mathcal{I}}$ MSO-definable in $\mu(T)$ which induces a pure complete binary tree.*

We defer the proof of this proposition to Section 5, to first show how it can be used to conclude the proof of Theorem 6. By applying Proposition 8, we obtain an MSO-recoloring μ and an embedding $\mathcal{S}_{\mathcal{I}}$ MSO-definable in $\mu(T)$ which induces a pure binary complete tree. The tree $\mu(T)$ belongs to Tree_{n_0} by Property 1 of Theorem 1. To reach a contradiction, we will show that the tree induced by $\mathcal{S}_{\mathcal{I}}$ in $\mu(T)$ belongs to Tree_{n_0}.

▶ **Proposition 9.** *Let $n \geqslant 0$, let T be a deterministic tree in Tree_n and let U be an MSO-definable embedding in T inducing a deterministic tree T_U. The tree T_U belongs to Tree_n.*

Proof Sketch. For $n = 0$, the result is immediate. Hence we assume that $n \geqslant 1$ and furthermore using the closure properties of Theorem 1, we can assume that the root of the embedding is the root of the tree T. Thanks to Property 1 of Theorem 1, we can color the nodes of U in T with a fresh color \$ to obtain a tree $T_{\$}$ also in Tree_n. Consider the following MSO-interpretation $\mathcal{I}$ that produces T_U from $T_{\$}$: it only keeps the vertices colored by \$ and for $x \in \Sigma$, it defines an x-labeled edge between two such vertices u and v if and only if v can be reached from u by a path labeled by a word in $x\Sigma^*$ which does not visit any vertices colored by \$ (except u or v). Furthermore, $\mathcal{I}$ erases the color \$ and preserves all other colors. Clearly, the tree induced by U on T is isomorphic to $\mathcal{I}(T_{\$})$. By definition of Tree_n, the tree $T_{\$}$ is the unfolding of some graph $G \in \mathrm{Graph}_{n-1}$ from some vertex r. The key ingredient is that because $\mathcal{I}(T_{\$})$ is deterministic, the MSO-interpretation $\mathcal{I}$ commutes with the unfolding. It follows that $T_U \sim \mathcal{I}(T_{\$}) \sim \mathrm{Unf}(\mathcal{I}(G), r)$. Hence T_U is isomorphic to the unfolding of the graph $\mathcal{I}(G)$ in Graph_{n-1} and belongs to Tree_n. ◀

By Proposition 9, the tree induced by $\mathcal{S}_{\mathcal{I}}$ in $\mu(T)$ belongs to Tree_{n_0} and by Proposition 8 it is pure which brings the contradiction and conclude the proof of Theorem 6.

Clearly, Theorem 6 does not hold for all trees in the pushdown hierarchy. For instance, the pushdown hierarchy contains infinite unary trees corresponding to non-ultimately-periodic infinite words[3] which are therefore pure. However, Theorem 6 can be extended to any tree that does not contain arbitrary long chains of unary vertices.

▶ **Corollary 10.** *Every tree in the pushdown hierarchy with no leaves and in which the length of all chains of unary vertices is bounded has self-similarities.*

Remark that if we simply ask that there is no infinite chains of unary vertices, Corollary 10 no longer holds. It is possible to construct a pure binary tree in Graph_2 in which all chains of unary vertices are finite. As illustrated in Figure 3, an example of such a tree can be obtained by starting with a copy of the complete binary tree and replacing each node $u = u_1 \cdots u_n \in \{0,1\}^+$ by the finite chain $\bullet \xrightarrow{u_1} \bullet \xrightarrow{u_2} \bullet \cdots \xrightarrow{u_n} \bullet$.

5 Proof of Proposition 8

This section is devoted to proving Proposition 8. For the rest of the section, we fix a complete binary tree T and an MSO-interpretation $\mathcal{I}$ such that $\mathcal{I}(T)$ is a pure complete binary tree. Furthermore for each label $x \in \{0,1\}$, we fix a deterministic and non-backtracking tree-walking automaton A_x with states in Q_x and an MSO-recoloring μ_x such that A_x accepts the pair (u,v) on $\mu_x(T)$ if and only if $u \xrightarrow{x} v$ in $\mathcal{I}(T)$. We assume Q_0 and Q_1 are disjoint and take $Q = Q_0 \uplus Q_1$.

[3] For example, the unary trees representing the morphic words belong to Tree_2 (see [10, Proposition 3.2]).

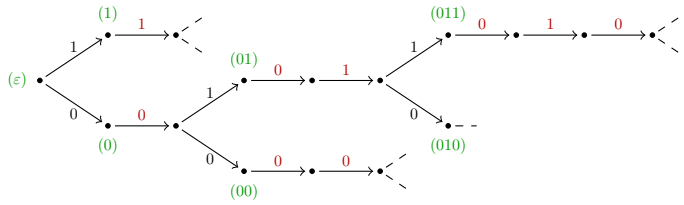

Figure 3 An example of a pure non-complete binary tree in Graph_2. This tree has its edges labeled by $\{0,1\}$. It is obtained by replacing each node $u = u_1 \cdots u_n \in \{0,1\}^+$ of the complete binary tree by a finite line of length $|u|$ in which the i-th edge is labeled by u_i. The corresponding node of the complete binary tree is in green between brackets.

In Subsection 5.1, we define an MSO-definable embedding $\mathcal{S}_\mathcal{I}$ inducing in T a complete binary tree. In Subsection 5.2, we define a MSO-recoloring μ of T. In Subsection 5.3, we show that the binary complete tree induced by $\mathcal{S}_\mathcal{I}$ in $\mu(T)$ is pure.

5.1 Definition of the embedding $\mathcal{S}_\mathcal{I}$

Let us start by remarking that any embedding S in a tree T induces a partition of the nodes of the tree T in regions, we call them chunks. A *chunk* of T is a set of nodes obtained by removing a finite number of subtrees from a subtree of T. Hence a chunk C is described by its *boundary* $(u_0, \ldots, u_n)$ which is a sequence of nodes of T with u_0 the root of the chunk and the $u_1, \ldots, u_n$ are descendants of u_0 which are the pairwise incomparable roots of the subtrees that are removed from $T_{|u_0}$. In other terms, $C = T_{|u_0} \setminus \bigcup_{i\in[1,n]} T_{|u_i}$. We call n the degree of the chunk C.

To every node s in an embedding S, we associate the chunk C_s rooted at s defined by the boundary $(s, s_1, \ldots, s_n)$ where $s_1, \ldots, s_n$ are the children of s in the tree T_S in lexicographical order. This notion is illustrated in Figure 2. The chunks $(C_s)_{s\in S}$ form a partition of the subtree of T rooted at r_S, the root of the embedding S. For our purpose, it is more convenient to obtain a partition of the whole tree T. Hence, we define C_{r_S} by the boundary $(\varepsilon, s_1, \ldots, s_n)$ instead of $(r_S, s_1, \ldots, s_n)$.

The content of a chunk C is the set of nodes kept by the interpretation $\mathcal{I}$ (i.e., $C \cap \mathcal{I}(T)$). We can leverage the fact that $\mathcal{I}(T)$ is a complete binary tree to show that for any chunk with a finite content, the size of the content is bounded by a constant that only depends on the degree of the chunk and on the interpretation $\mathcal{I}$.

▶ **Lemma 11.** *Under the assumptions of this section, for all $m \geqslant 0$, there exists a constant $d \geqslant 0$ depending only on m and on the MSO-interpretation $\mathcal{I}$ such that for each chunk C of degree m, if the content of C is finite, then the size of this content is bounded by d.*

Proof. Let C be a chunk of degree $m \geqslant 0$ with a boundary $(u_0, u_1, \ldots, u_m)$ and let $d := 2(m+1)\max(|Q_0|, |Q_1|)$.

Assume toward a contradiction that C has a finite content U of size $k > d$. As $\mathcal{I}(T)$ is a tree, $\mathcal{I}(T)$ restricted to the content U of C is a forest F with k vertices and hence at most $k-1$ edges. As $\mathcal{I}(T)$ is a complete binary tree, there are at least $2k-(k-1) = k+1$ edges of $\mathcal{I}(T)$ starting in U and ending outside of C. By the pigeonhole principle, at least $\ell > \frac{k+1}{2}$ edges share the same label $x \in \{0,1\}$. Let $(v_1, w_1), \ldots, (v_l, w_l)$ be an enumeration of these edges. As v_i belongs to C and w_i does not, the accepting run of A_x on $\mu_x(T)$ for the pair (v_i, w_i) must cross the boundary of C. By the pigeonhole principle, at least $\frac{\ell}{m+1}$ of these runs cross the boundary of C at the same u_{i_0} with $i_0 \in [0,n]$. As $\frac{\ell}{m+1} > \max(|Q_0|, |Q_1|)$,

there exists two different runs (corresponding to two different edges) reaching u_{i_0} in the same state. This implies that these two different edges must have the same target which contradicts the fact that $\mathcal{I}(T)$ is a tree. ◀

▶ **Definition 12.** *The embedding $\mathcal{S}_\mathcal{I}$ is composed of all nodes u for which both their left and right subtrees contain infinitely many nodes of $\mathcal{I}(T)$.*

Using Lemma 11, we can show that the content of the chunks associated with $\mathcal{S}_\mathcal{I}$ are finite and hence bounded.

▶ **Proposition 13.** *The set $\mathcal{S}_\mathcal{I}$ is an MSO-definable embedding in T defining a complete binary tree. Moreover, for all $s \in \mathcal{S}_\mathcal{I}$, the content of the chunk C_s has size at most d where d is a constant that only depends on $\mathcal{I}$.*

Proof Sketch. For a node u of T, we write $\mathrm{Inf}(u)$ if there are infinitely many nodes of $\mathcal{I}(T)$ below u.

We start by showing that for all node u satisfying $\mathrm{Inf}(u)$, there exist two incomparable descendants v and v' of u such that $\mathrm{Inf}(v)$ and $\mathrm{Inf}(v')$. Assume towards a contradiction that it is not the case for some $u \in T$. Let $v_1, v_2, \dots$ be an enumeration of the descendants v of u for which $\mathrm{Inf}(v)$ holds. For all $i \geqslant 1$, the content of the chunk C_i with boundary (u, v_i) must be finite otherwise it would contain a descendant v of u satisfying $\mathrm{Inf}(v)$ which is incomparable with v_i. By assumption, the v_i's belong to the same infinite branch and hence $T_{|u} = \bigcup_{i \geqslant 1} C_i$. Therefore the size of the content of the C_i's must be unbounded which contradicts Lemma 11.

As the least common ancestor of v and v' belongs to $\mathcal{S}_\mathcal{I}$, we have shown that below every node u satisfying $\mathrm{Inf}(u)$ there exists an element of $\mathcal{S}_\mathcal{I}$. It immediately follows that $\mathcal{S}_\mathcal{I}$ is non-empty and that below each of the two children of an element of $\mathcal{S}_\mathcal{I}$, there exists a unique minimal element in $\mathcal{S}_\mathcal{I}$ (as $\mathcal{S}_\mathcal{I}$ is closed under least common ancestor). This shows that $\mathcal{S}_\mathcal{I}$ induces a complete binary tree. As on deterministic trees the predicate $\mathrm{Inf}(u)$ is MSO-definable, the embedding $\mathcal{S}_\mathcal{I}$ is also MSO-definable.

Using Lemma 11, it only remains to show that content of every chunk C_s for $s \in \mathcal{S}_\mathcal{I}$ is finite. Toward a contradiction, assume that for some $s \in \mathcal{S}_\mathcal{I}$ which is not the root of the embedding, the chunk C_s with boundary (s, s_0, s_1) has an infinite content. There must exist some s' in C_s satisfying $\mathrm{Inf}(s')$ and which is incomparable with both s_0 and s_1. By symmetry, we can assume that s' is in the left subtree of s. In this case, the least common ancestor of s' and s_0 would belong to $\mathcal{S}_\mathcal{I}$ and would be strictly between s and s_0 which would contradict the definition of s_0. The case of the chunk of root of the embedding is treated with similar arguments. ◀

5.2 Definition of the MSO-recoloring μ of the nodes of the embedding

The MSO-recoloring μ will color each vertex $s \in \mathcal{S}_\mathcal{I}$ with a tuple (F_s, π_s, ψ_s) where F_s is the forest obtained by restricting $\mathcal{I}(T)$ to the chunk C_s and π_s and ψ_s are two finite functions describing how to reconnect the forest F_s to the other forests to obtain $\mathcal{I}(T)$.

The forest F_s. For a node $s \in \mathcal{S}_\mathcal{I}$, let $v_1, \dots, v_n$ with $0 \leqslant n \leqslant d$, be an enumeration in lexicographic order of the content of C_s. The nodes of the forest F_s are in $[1, n]$ and for $x \in \{0, 1\}$, $i \xrightarrow{x} j$ in F_s if and only if $v_i \xrightarrow{x} v_j$ in $\mathcal{I}(T)$ and for a color c, i is colored by c in F_s if and only if v_i is colored by c in $\mathcal{I}(T)$.

The partial function π_s. The partial function π_s provides information on the edges that connect the forest F_s to the rest of $\mathcal{I}(T)$. Consider a vertex $i \in [1,n]$ of F_s and a label $x \in \{0,1\}$ such that i has no outgoing x-labeled edge in F_s. Because $\mathcal{I}(T)$ is complete, there is an edge $v_i \xrightarrow{x} v$ in $\mathcal{I}(T)$. The node v is outside of the chunk C_s and hence the unique run of A_x accepting the pair (v_i, v) on $\mu_x(T)$ must exit the chunk through one of its boundaries[4] $\gamma \in \{\text{root}, \text{left}, \text{right}\}$ in a state $q_\gamma \in Q_x$. As A_x follows the minimal path from v_i to v, it crosses the boundary exactly once. The partial function $\pi_s : [1,d] \times \{0,1\} \to \{\text{root}, \text{left}, \text{right}\} \times Q$ associates (i,x) to (γ, q_γ) if the x-labeled edge outgoing from i is missing in F_s and is undefined otherwise.

The partial function ψ_s. The partial function ψ_s provides information on the behavior of the automata A_0 and A_1 when entering the chunk C_s from one of its boundaries. Let $\gamma \in \{\text{root}, \text{left}, \text{right}\}$ be a boundary symbol and let s_γ be the corresponding node in the boundary of C_s. The value of $\psi_s(\gamma, q)$ will provide information on the unique accepting run ρ of A_x on $\mu_x(T)$ starting in state q at s_γ (if it exists). If the run ρ enters C_s and ends at a vertex v_i of the content of C_s, then $\psi_s(\gamma, q)$ is defined to be i. If the run ρ enters C_s and exits through a boundary $\gamma \neq \gamma' \in \{\text{root}, \text{left}, \text{right}\}$ in some state q', then $\psi_s(\gamma, q)$ is defined to be (γ', q'). In all other cases, ψ_s is undefined. As a result ψ_s is a partial mapping $\{\text{root}, \text{left}, \text{right}\} \times Q \to [1,d] \cup (\{\text{root}, \text{left}, \text{right}\} \times Q)$.

▶ **Lemma 14.** *The recoloring μ which colors every $s \in \mathcal{S}_\mathcal{I}$ with the color (F_s, π_s, ψ_s) and leave all other nodes uncolored is MSO-definable.*

5.3 The tree induced by $\mathcal{S}_\mathcal{I}$ on $\mu(T)$ is pure

We start by showing how $\mathcal{I}(T)$ can be reconstructed from the complete binary tree induced by the embedding $\mathcal{S}_\mathcal{I}$ in $\mu(T)$. This tree, denoted E in the following, is essentially the mapping associating to every node $s \in \mathcal{S}_\mathcal{I}$ the tuple (F_s, ψ_s, π_s).

Every node in $\mathcal{I}(T)$ corresponds to a unique node in some forest coloring of E. More precisely, for a node $u \in \mathcal{I}(T)$, the address of u is the unique pair (s,i) such that u is the i-th node in lexicographic order of the content of the chunk C_s. Let $\text{Addr} = \{(s,i) \in \mathcal{S}_\mathcal{I} \times [1,d] \mid E(s) = (F_s, \pi_s, \psi_s) \text{ and } i \in F_s\}$ be the set of all valid addresses.

We now define a deterministic tree R whose nodes are the addresses in Addr and which we will prove to be isomorphic to $\mathcal{I}(T)$ in Proposition 16.

In the tree R, an address $(s,i) \in \text{Addr}$ inherits the colors of the corresponding vertex in F_s. Hence, we define $\mathsf{Colors}(s,i)$ to be $\{\theta \in \Theta \mid E(s) = (F_s, \pi_s, \psi_s) \text{ and } (\theta, i) \in F_s\}$. To define the edges of the tree R, we introduce, for each label $x \in \{0,1\}$, a function Target_x which defines the target of all the x-labeled outgoing edges in R. To define Target_x, we need two auxiliary functions Travel and Follow. These definitions are illustrated in Figure 4.

For $(s,\gamma) \in \mathcal{S}_\mathcal{I} \times \{\text{root}, \text{left}, \text{right}\}$, we define $\mathsf{Travel}(s,\gamma)$ to be equal to (s',γ') if upon leaving C_s by the boundary γ, we enter $C_{s'}$ by its boundary γ'.

For all $s \in \mathcal{S}_\mathcal{I}$, $\gamma \in \{\text{root}, \text{left}, \text{right}\}$ and $q \in Q_x$, $\mathsf{Follow}(s,\gamma,q)$ is recursively defined by (s,j) if $\psi_s(\gamma,q) = j \in [1,d]$ and by $\mathsf{Follow}(s',\gamma'',q')$ if $\psi_s(\gamma,q) = (\gamma',q')$ and $\mathsf{Travel}(s,\gamma') = (s',\gamma'')$. Intuitively, $\mathsf{Follow}(s,\gamma,q)$ gives the address of the end of the run of A_x starting in q at the boundary γ of C_s.

[4] If the boundary of C_s is (s, s_0, s_1), then s correspond to root, s_0 to left and s_1 to right.

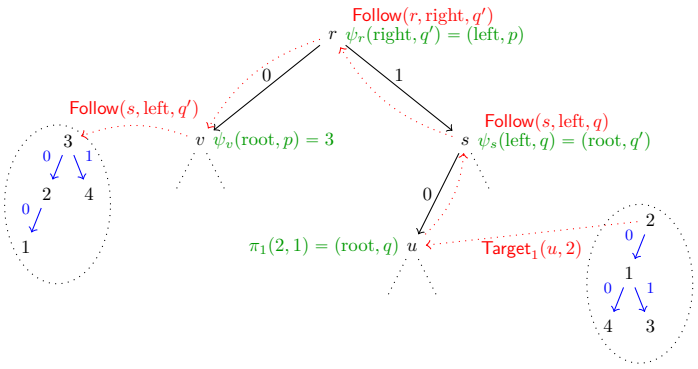

Figure 4 An example of the computation of the function Target. The red path represents the successive recursive calls made when computing $\mathsf{Target}_1(u, 2) = (v, 3)$. As there is no edge from 2 labeled by 1 in F_u, $\mathsf{Target}_1(u, 2)$ calls $\mathsf{Follow}(s, \text{left}, q)$, as $\mathsf{Travel}(u, \text{root}) = (s, \text{left})$ following the function $\pi_1(2, 1) = (\text{root}, q)$. In turn, $\mathsf{Follow}(s, \text{left}, q)$ calls $\mathsf{Follow}(r, \text{right}, q')$ as $\psi_s(\text{left}, q) = (\text{root}, q)$ and $\mathsf{Travel}(s, \text{root}) = (r, \text{right})$. It then proceeds to call $\mathsf{Follow}(s, \text{left}, q')$ as before, which follows $\psi_v(\text{root}, p) = 3$ ending the run on the vertex 3 of the forest F_v.

For $x \in \{0, 1\}$, $\mathsf{Target}_x(s, i)$ is defined to be (s, j) if $i \xrightarrow{x} j$ belongs to F_s otherwise, the x-labeled outgoing edge from i is missing from the forest F_s and $\pi_s(i, x)$ is defined and equal to some $(\gamma, q) \in \{\text{root}, \text{left}, \text{right}\} \times Q_x$ and $\mathsf{Target}_x(s, i)$ is taken to be $\mathsf{Follow}(s', \gamma', q)$ where $(s', \gamma') = \mathsf{Travel}(s, \gamma)$.

▶ **Lemma 15.** *For two addresses (s_u, i_u) and $(s_v, i_v) \in$ Addr respectively corresponding to nodes u and v in $\mathcal{I}(T)$, we have $\mathsf{Target}_x(s_u, i_u) = (s_v, i_v)$ if and only if $u \xrightarrow{x} v$ in $\mathcal{I}(T)$. Furthermore, as the tree-walking automaton A_x is non-backtracking in T, for all $s \in \mathcal{S}_\mathcal{I}$ such that $s \sqsubseteq s_u$ and $s \sqsubseteq s_v$, the recursive calls to* Follow *made when computing $\mathsf{Target}_x(s_u, i_u)$ will all stay below s.*

From this lemma, it follows that the tree R is isomorphic to $\mathcal{I}(T)$.

▶ **Proposition 16.** *The deterministic binary tree R with nodes in* Addr *and defined by* Colors, Target_0 *and* Target_1 *is isomorphic to $\mathcal{I}(T)$.*

We use this reconstruction of $\mathcal{I}(T)$ in E presented above to show that any self-similarity in E would lead to a self-similarity in $\mathcal{I}(T)$ which is impossible by assumption.

▶ **Proposition 17.** *Under the assumptions of this section, for the MSO-recoloring μ and the MSO-definable embedding $\mathcal{S}_\mathcal{I}$ defined previously, the deterministic binary tree E induced by $\mathcal{S}_\mathcal{I}$ on $\mu(T)$ does not have any self-similarities.*

Proof. Assume toward a contradiction that E has a self-similarity and let $s_1 \neq s_2$ be two nodes of E such that $E_{|s_1} \sim E_{|s_2}$. Recall that the nodes of E are the elements of $\mathcal{S}_\mathcal{I}$ and that the ancestor relation $\sqsubseteq_E$ coincide with the ancestor relation $\sqsubseteq_T$ of T on $\mathcal{S}_\mathcal{I} \times \mathcal{S}_\mathcal{I}$. In the following, we say that an address $(t, i) \in$ Addr is below a node s of E if t is descendant of s in E (or equivalently in T).

▷ Claim 18. There exists an address $(t, j) \in$ Addr below s_1 such that all the descendants of (t, j) in the tree R of Proposition 16 have an address below s_1.

Proof. For a label $x \in \{0,1\}$, consider the set X_x of addresses (s,i) below s_1 such that $\mathsf{Target}_x(s,i)$ is not below s_1. By definition of Target_x, there exists $\gamma \in \{\text{left}, \text{right}\}$ such that for all $(s,i) \in X_x$, $\mathsf{Target}_x(s,i)$ must be equal to $\mathsf{Follow}(s_1,\gamma,q)$ for some q. By the pigeonhole principle, X_x is of size at most $|Q_x|$ as otherwise we would have two addresses in X_x with the same value of Target_x which would contradict the fact that R is a tree.

The set Y of addresses (s,i) having a descendant (in R) in the finite set $X_0 \cup X_1$ is itself finite. Let k be the maximal depth of an $s \in E$ such that $(s,i) \in Y$ for some i. As s_1 belongs to $\mathcal{S}_{\mathcal{I}}$, we have by definition of $\mathcal{S}_{\mathcal{I}}$ that there are infinitely many vertices of $\mathcal{I}(T)$ below s_1 in T. Let Z be the corresponding set of addresses. Remark that all these addresses are necessarily below s_1 as if a node $r \in \mathcal{I}(T)$ has an address (s,i) then s is the greatest ancestor of r which belongs to $\mathcal{S}_{\mathcal{I}}$. Hence as Z is infinite, it must contain an element (t,j) with t at depth greater than k in T. By definition of the depth k, this implies that all descendants of (t,j) in R are below s_1. ◁

As $E_{|s_1}$ and $E_{|s_2}$ are isomorphic, there exists a (unique) bijection h that maps every node s of $E_{|s_1}$ to the corresponding node $h(s)$ in $E_{|s_2}$. Let $t' = h(t)$ be the node corresponding to t in $E_{|s_2}$. In particular, t and t' have the same color in R and hence (t',j) is an address in Addr. We claim that $T_1 = R_{|(t,j)}$ is isomorphic to $T_2 = R_{|(t',j)}$ which will bring the contradiction as $R \sim \mathcal{I}(T)$ is assumed to be pure. To see this, consider two descendants (t_1,j_1) and (t_2,j_2) of (t,j) such that $(t_1,j_1) \xrightarrow[R]{x} (t_2,j_2)$ and hence $\mathsf{Target}_x(t_1,j_1) = (t_2,j_2)$. By definition of (t,j), we have that both t_1 and t_2 are below s_1. The recursive calls to Follow made when computing $\mathsf{Target}_x(t_1,j_1)$ stay inside the subtree $E_{|s_1}$ (cf. Lemma 15). As $E_{|s_2}$ is isomorphic to $E_{|s_1}$, we have that $\mathsf{Target}_x(h(t_1),j_1) = (h(t_2),j_2)$. This implies our claim and conclude the proof. ◀

6 Applications

In this section, we leverage the well-known connection between the deterministic trees in the pushdown hierarchy and the trees defined by deterministic higher-order pushdown automata (presented in Subsection 6.1) to give two applications of our main results: one in formal language theory in Subsection 6.2 and one in number theory in Subsection 6.3.

6.1 Higher-order pushdown automata

Higher-order pushdown automata are a generalization of the standard model of pushdown automata. To simplify the presentation, we only define formally higher-order pushdown automata of order 2. We refer the reader to [15] for a definition at all orders.

An order-2 pushdown automaton works on a stack of stacks, called an order-2 stack. We start by defining order-1 and order-2 stacks and the operation to manipulate them. Let Γ be a stack alphabet and let $\perp \notin \Gamma$ be a distinguished bottom of stack symbol. An order-1 stack is a sequence $\perp\gamma_1 \dots \gamma_n \in \perp\Gamma^*$, denoted by $[\,\gamma_1 \dots \gamma_n\,]_1$. The symbol γ_n is the top-most symbol of the stack and $[\,]_1$ is called the empty order-1 stack. An order-2 stack is a non-empty sequence $s_1, \dots, s_n$ of order-1 stacks denoted by $[\,s_1, \dots, s_n\,]_2$. The order-1 stack s_n is the top-most order-1 stack and $[\,[\,]_1\,]_2$ is the empty order-2 stack.

We now define operations on order-2 stacks. For every symbol $\gamma \in \Gamma$, the operation push_γ pushes the symbol γ on the top-most order-1 stack (i.e., $\mathrm{push}_\gamma([\,s_1, \dots, [\,\gamma_1, \dots, \gamma_m\,]_1\,]_2) = [\,s_1, \dots, [\,\gamma_1, \dots, \gamma_m, \gamma\,]_1\,]_2$). The operation pop_1 removes the top-most symbol of the top-most order-1 stack provided that $m \geqslant 1$ (i.e., $\mathrm{pop}_1([\,s_1, \dots, [\,\gamma_1, \dots, \gamma_m\,]_1\,]_2)$ is undefined if

$m = 0$ and is equal to $[\, s_1, \ldots, [\, \gamma_1, \ldots, \gamma_{m-1} \,]_1 \,]_2$ if $m \geqslant 1$). The operation copy_2 copies the top-most order-1 stack (i.e., $\mathrm{copy}_2([\, s_1, \ldots, s_n \,]_2) = [\, s_1, \ldots, s_n, s_n \,]_2$). Finally, the operation pop_2 removes the top-most order-1 stack, if the order-2 stack is not reduced to one order-1 stack (i.e., $\mathrm{pop}_2([\, s_1, \ldots, s_n \,]_2) = [\, s_1, \ldots, s_{n-1} \,]_2$).

An order-2 pushdown automaton P (with ε-transitions) is defined by a tuple (Q, q_0, Σ, Δ) where Q is a finite set of states, $q_0 \in Q$ is the initial state, Σ is a finite set of input symbols, Δ is the set of transitions of the form $(p, \gamma, \sigma, \mathrm{op}, q)$ with $p, q \in Q$, $\gamma \in \Gamma \cup \{\bot\}$, $\sigma \in \Sigma \cup \{\varepsilon\}$ and op an operation in $\{\mathrm{pop}_1, \mathrm{push}_\gamma, \mathrm{pop}_2, \mathrm{copy}_2\}$. We furthermore assume that states of P can be partitioned into $Q_\Sigma \uplus Q_\varepsilon$ such that states in Q_Σ (resp. in Q_ε) are only the source of transitions labeled by Σ (resp. labeled by ε). The automaton is said to be deterministic if for all $q \in Q$, $\gamma \in \Gamma \cup \{\bot\}$ and $\sigma \in \Sigma \cup \{\varepsilon\}$, there exists at most one transition in Δ starting with (q, γ, σ) and if there exists a transition starting with (q, γ) labeled by ε then it is the only transition starting with (q, γ).

A configuration of an order-2 pushdown automaton is a pair (q, s) with $q \in Q$ and s an order-2 stack. For $\sigma \in \Sigma \cup \{\varepsilon\}$, the automaton P induces a relation $\xrightarrow[P]{\sigma}$ between the configurations of P defined by: $(p, s) \xrightarrow[P]{\sigma} (q, s')$ if there exists a transition $(p, \gamma, \sigma, \mathrm{op}, q)$ with $s' = \mathrm{op}(s)$ and γ is the top-most symbol of the top-most order-1 stack of s. From these relations, we can define the relation $\xRightarrow[P]{w}$ for each $w \in \Sigma^*$ in the usual way. If the automaton P is deterministic, we define for all $w \in \Sigma^*$, $\delta_P(w)$ to be the unique configuration (q, s) (if it exists) such that $(q_0, [\,[\,]_1\,]_2) \xRightarrow[P]{w} (q, s)$ with s a stack and $q \in Q_\Sigma$.

If we fix a set $F \subseteq Q_\Sigma$ of final states, the automaton P accepts the language $L(P)$ of words over Σ defined by $L(P) := \{w \in \Sigma^* \mid (q_0, [\,[\,]_1\,]_2) \xRightarrow[P]{w} (q, s) \wedge q \in F\}$. Figure 5 gives an example of a deterministic order-2 pushdown automaton accepting the language $\{1^n 0^n 1^n \mid n \geqslant 1\}$.

If we fix a finite set Θ of vertex colors and a mapping $\mathrm{Col} : Q_\Sigma \to 2^\Theta$, a deterministic order-2 pushdown automaton P defines a deterministic tree $T(P)$ with edges labeled by Σ and with nodes colored by Θ. This tree is given by the partial function T_P from Σ^* to 2^Θ such that for all $w \in \Sigma^*$, $T_P(w) = \mathrm{Col}(q)$ if $\delta_P(w)$ is defined and equal to (q, s) and is undefined otherwise.

The trees defined in this way are the deterministic trees in the pushdown hierarchy.

▶ **Theorem 19** ([10, 15]). *The deterministic trees in* Tree_n *are the trees defined by deterministic higher-order pushdown automata of order* $n - 1$.

6.2 Deterministic vs non-deterministic higher-order pushdown automata

Let Σ be a finite alphabet. For a language $L \subseteq \Sigma^*$ and a word $w \in \Sigma^*$, recall that the left-quotient of L by w, denoted by $w^{-1}L$, is the set $w^{-1}L := \{u \in \Sigma^* \mid wu \in L\}$. We can leverage Theorem 19 to show that if all the left-quotients of a language are different then this language cannot be accepted by any deterministic higher-order pushdown automaton.

▶ **Theorem 20.** *Let* Σ *be a finite alphabet with at least two symbols and* L *be a language over* Σ*. If for all* $w_1 \neq w_2 \in \Sigma^*$*, we have* $w_1^{-1}L \neq w_2^{-1}L$*, the language* L *cannot be accepted by a deterministic higher-order pushdown automaton of any order. In particular, this is the case for the languages:* $\{ww \mid w \in \Sigma^*\}$*,* $\{w \mid w$ *a palindrome in* $\Sigma^*\}$ *and* $\{w^{f(|w|)} \mid w \in \Sigma^*\}$ *for* $f : \mathbb{N} \to \mathbb{N}$ *strictly increasing.*

Proof Sketch. Let Σ be a finite alphabet with a least two symbols and L be a language over Σ. Assume that for all $w_1 \neq w_2 \in \Sigma^*$, $w_1^{-1}L \neq w_2^{-1}L$.

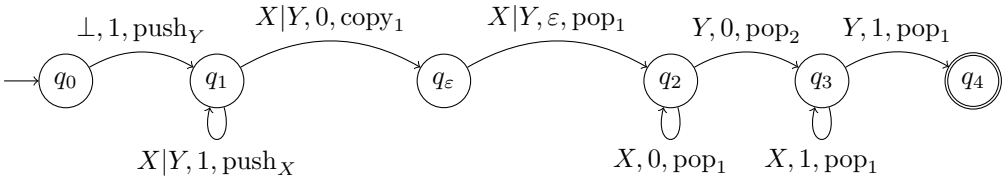

Figure 5 A deterministic higher-order pushdown automaton of order-2 recognizing the language $\{1^n 0^n 1^n \mid n \geqslant 1\}$ with q_0 its initial state and q_4 its final state. Note that the loop on the state q_1 labeled by $X|Y, 1, \text{push}_X$ is actually depicting two transitions: $(q_1, X, 1, \text{push}_X, q_1)$ and $(q_1, Y, 1, \text{push}_X, q_1)$ and similarly for the transitions going from q_1 to q_ε and from q_ε to q_2. For example, the accepting run for the word 110011 is the following $(q_0, [\,[\,]_1\,]_2) \xrightarrow{1} (q_1, [\,[\,Y\,]_1\,]_2) \xrightarrow{1} (q_1, [\,[\,YX\,]_1\,]_2) \xrightarrow{0} (q_\varepsilon, [\,[\,YX\,]_1[\,YX\,]_1\,]_2) \xrightarrow{\varepsilon} (q_2, [\,[\,YX\,]_1[\,Y\,]_1\,]_2) \xrightarrow{0} (q_3, [\,[\,YX\,]_1\,]_2) \xrightarrow{1} (q_3, [\,[\,Y\,]_1\,]_2) \xrightarrow{1} (q_4, [\,[\,]_1\,]_2)$.

Consider the deterministic complete tree $T_L : \Sigma^* \to \{0,1\}$ labeled by Σ and colored by $\{0,1\}$ defined by $T_L(w) = 1$ if and only if $w \in L$. By Theorem 19, T_L belongs to the pushdown hierarchy if and only if L is accepted by a deterministic higher-order pushdown automaton of some order. The assumption of the language L is equivalent to requiring all the subtrees of T_L to be non-isomorphic. Hence T_L does not belong to the pushdown hierarchy by Corollary 10 and our claim follows. ◀

We remark that the language $\{w \mid w \text{ a palindrome in } \Sigma^*\}$ is accepted by a non-deterministic pushdown automaton, the language $\{ww \mid w \in \Sigma^*\}$ is accepted by a non-deterministic order-2 pushdown automaton and $\{w^{|w|} \mid w \in \Sigma^*\}$ is accepted by a non-deterministic order-3 pushdown automaton.

6.3 Real numbers defined by deterministic higher-order pushdown automata

We introduce a generalization of the notion of automatic sequence [4] by replacing the deterministic finite automata used to generate automatic sequences by deterministic higher-order pushdown automata. This generalization follows an approach initiated in [3, 11] and is explicitely mentioned in the conclusion of [11].

Recall that an automatic sequence in base $b \geqslant 2$ is an infinite sequence $\lambda_1\lambda_2\cdots \in \Lambda^\omega$ which is defined using a deterministic finite automaton A over the alphabet $\Sigma_b := \{0, 1, \ldots, b-1\}$. For all $i \geqslant 1$, the automaton outputs the symbol λ_i after having read the decomposition $\langle i \rangle_b$ of i in base b. For the automaton A to output symbols in Λ, we simply associate a symbol in Λ to every state of A using a mapping $\text{Output} : Q \to \Lambda$.

Similarly, a deterministic order-k pushdown automaton P over $\Sigma_b := \{0, \ldots, b-1\}$ equipped with an output function $\text{Output} : Q_\Sigma \to \Lambda$ defines a sequence $\lambda_1\lambda_2\cdots\Lambda^\omega$ if for all $i \geqslant 1$, $\delta_P(\langle i \rangle_b) = (q, s)$ with $\text{Output}(q) = \lambda_i$. If such an automaton exists, the sequence $\lambda_1\lambda_2\cdots \in \Lambda^\omega$ is said to be automatic of order k in base b.

For two bases ℓ and $b \geqslant 2$, a real number in $[0,1]$ is said to be (ℓ, b)-automatic of order-k if it admits an expansion $0.\alpha_1\alpha_2\cdots$ in base ℓ and the sequence $\alpha_1\alpha_2\cdots \in \{0, \ell-1\}^\omega$ is automatic of order-k in base b.

For instance, consider the real number α whose binary expansion is $0.\alpha_1\alpha_2\cdots$ with $\alpha_m = 1$ if $m = 2^{3n} - 2^{2n} + 2^n - 1$ for some $n \geqslant 1$ and $\alpha_m = 0$ otherwise. This number $\alpha = \sum_{n \geqslant 1} 2^{-2^{3n}+2^{2n}-2^n+1}$ is $(2,2)$-automatic of order-2. To see this, remark that for all $n \geqslant 1$,

the binary decomposition of $2^{3n} - 2^{2n} + 2^n - 1$ is $1^n0^n1^n$. Hence an order-2 deterministic pushdown automaton describing the sequence $\alpha_1\alpha_2\dots$ can be obtained by making the deterministic order-2 pushdown automaton presented in Figure 5 complete.

An alternative definition of (ℓ, b)-automatic numbers of order-k can be achieved by considering what we call the (ℓ, b)-tree of the real number. For a real number α with a presentation $0.\alpha_1\alpha_2\cdots$ in base $\ell \geqslant 2$, we can associate its (ℓ, b)-tree T_α which is the deterministic tree whose edges are labeled by $\{0, \dots, b-1\}$ and whose nodes are colored by a unique color in $\{0, \dots, \ell - 1\}$. The domain of the tree T_α is $\{\varepsilon\} \cup [1, \ell - 1][0, \ell - 1]^*$, for all $i \geqslant 1$, $T_\alpha(\langle i \rangle_b) = \alpha_i$ and by convention, $T_\alpha(\varepsilon)$ is taken to be 0. Thanks to Theorem 19, a real number α is (ℓ, b)-automatic of order k if and only if it admits an (ℓ, b)-tree in Tree_{k+1}.

The notion of (ℓ, b)-tree is implicit in the work of [3] where the authors use it to give a sufficient condition for a irrational number to be transcendental.

▶ **Theorem 21** ([3]). *Let $\ell \geqslant 2$, $b \geqslant 2$, $0 \leqslant \alpha \leqslant 1$ a real number and let T_α be an (ℓ, b)-tree for α. If T_α has self-similarities then α is either rational or transcendental.*

By Corollary 10, it immediately follows that:

▶ **Corollary 22.** *For all $\ell \geqslant 2$ and all $b \geqslant 2$, the (ℓ, b)-automatic real number of order k are either rational or transcendental.*

7 Conclusion

In this article, we have shown that every tree in the pushdown hierarchy with no leaves and with chains of unary vertices of bounded length must contain self-similarities. This in particular implies that the trees produced by safe recursion schemes have this property. It is an ongoing work to generalize this property to general unsafe recursion schemes [17]. This would in particular prove that collapsible pushdown automata, a generalization of higher-order pushdown automata cannot be used to generate irrational algebraic numbers [14].

Abstract

This paper provides an NP procedure that decides whether a *linear-exponential system* of constraints has an integer solution. Linear-exponential systems extend standard integer linear programs with exponential terms 2^x and remainder terms (x mod 2^y). Our result implies that the existential theory of the structure $(\mathbb{N}, 0, 1, +, 2^{(\cdot)}, V_2(\cdot,\cdot), \leq)$ has an NP-complete satisfiability problem, thus improving upon a recent ExpSpace upper bound. This theory extends the existential fragment of Presburger arithmetic with the exponentiation function $x \mapsto 2^x$ and the binary predicate $V_2(x, y)$ that is true whenever $y \geq 1$ is the largest power of 2 dividing x.

Our procedure for solving linear-exponential systems uses the method of quantifier elimination. As a by-product, we modify the classical Gaussian variable elimination into a non-deterministic polynomial-time procedure for integer linear programming (or: existential Presburger arithmetic).

1 Introduction

Integer (linear) programming is the problem of deciding whether a system of linear inequalities has a solution over the integers ($\mathbb{Z}$). It is a textbook fact that this problem is NP-complete; however, proof of membership in NP is not trivial. It is established [3, 27] by showing that, if a given system has a solution over $\mathbb{Z}$, then it also has a *small* solution. The latter means that the bit size of all components can be bounded from above by a polynomial in the bit size of the system. Integer programming is an important language that can encode many combinatorial problems and constraints from multiple application domains; see, e.g., [20, 32].

[1] During the work on this paper, DC was a visitor to the Max Planck Institute for Software Systems (MPI-SWS), Kaiserslautern and Saarbrücken, Germany, a visiting fellow at St Catherine's College and a visitor to the Department of Computer Science at the University of Oxford, United Kingdom.

In this paper we consider more general systems of constraints, which may contain not only linear inequalities (as in integer programming) but also constraints of the form $y = 2^x$ (exponentiation base 2) and $z = (x \bmod 2^y)$ (remainder modulo powers of 2). Equivalently, and embedding both new operations into a uniform syntax, we look at a conjunction of inequalities of the form

$$\sum_{i=1}^{n} \left(a_i \cdot x_i + b_i \cdot 2^{x_i} + \sum_{j=1}^{n} c_{i,j} \cdot (x_i \bmod 2^{x_j}) \right) + d \leq 0\,, \tag{1}$$

referred to as an *(integer) linear-exponential system*. In fact, the linear-exponential systems that we consider can also feature equalities $=$ and strict inequalities $<$.[2]

Observe that a linear-exponential system of the form $x_1 = 1 \wedge \bigwedge_{i=1}^{n}(x_{i+1} = 2^{x_i})$ states that x_{n+1} is the tower of 2s of height n. This number is huge, and makes proving an analogue of the small solution property described above a hopeless task in our setting. This obstacle was recently shown avoidable [11], however, and an exponential-space procedure for linear-exponential programs was found, relying on automata-theoretic methods. Our main result is that, in fact, the problem belongs to NP.

▶ **Theorem 1.** *Deciding whether a linear-exponential system over $\mathbb{Z}$ has a solution is in* NP.

We highlight that the choice of the base 2 for the exponentials is for the convenience of exposition: our result holds for any positive integer base given in binary as part of the input.

As an example showcasing the power of integer linear-exponential systems, consider computation of discrete logarithm base 2: given non-negative integers $m, r \in \mathbb{N}$, producing an $x \in \mathbb{N}$ such that $2^x - r$ is divisible by m. As sketched in [14], this problem is reducible to checking feasibility (existence of solutions) of at most $\log m$ linear-exponential systems in two variables, by a binary search for a suitable exponent x. Hence, improving Theorem 1 from NP to PTime for the case of linear-exponential systems with a *fixed* number of variables would require a major breakthrough in number theory. In contrast, under this restriction, feasibility of standard integer linear programs can be determined in PTime [19].

For the authors of this paper, the main motivation for looking at linear-exponential systems stems from logic. Consider the first-order theory of the structure $(\mathbb{N}, 0, 1, +, 2^{(\cdot)}, V_2(\cdot,\cdot), \leq)$, which we refer to as the *Büchi–Semenov arithmetic*. In this structure, the signature $(0, 1, +, \leq)$ of linear arithmetic is extended with the function symbol $2^{(\cdot)}$, interpreted as the function $x \mapsto 2^x$, and the binary predicate symbol V_2, interpreted as $\{(x, y) \in \mathbb{N} \times \mathbb{N} : y$ is the largest power of 2 that divides $x\}$. Importantly, the predicate V_2 can be replaced in this definition with the function $x \bmod 2^y$, because the two are mutually expressible:

$$\begin{aligned} V_2(x, y) &\iff \exists v \left(2 \cdot y = 2^v \wedge 2 \cdot (x \bmod 2^v) = 2^v\right), \\ (x \bmod 2^y) = z &\iff z \leq 2^y - 1 \wedge \left(x = z \vee \exists u \left(V_2(x - z, 2^u) \wedge 2^y \leq 2^u\right)\right). \end{aligned}$$

Above, the subtraction symbol can be expressed in the theory in the obvious way (perhaps with the help of an auxiliary existential quantifier for expressing $x - z$).

Büchi–Semenov arithmetic subsumes logical theories known as Büchi arithmetic and Semenov arithmetic; see Section 2. As a consequence of Theorem 1, we show:

▶ **Theorem 2.** *The satisfiability problem of existential Büchi–Semenov arithmetic is in* NP.

[2] While equalities are considered for convenience only (they can be encoded with a pair of inequalities $\leq$), the addition of $<$ is of interest. Indeed, differently from standard integer programming, one cannot define $<$ in terms of $\leq$, since 2^y is not an integer for $y < 0$. Observe that $(x \bmod 2^y) = 0$ when $y < 0$, because over the reals $(a \bmod m) = a - m \left\lfloor \frac{a}{m} \right\rfloor$, where $\lfloor . \rfloor$ is the floor function.

Theorems 1 and 2 improve upon several results in the literature. The most recent such result is the exponential-space procedure [11] already mentioned above. In 2023, two elementary decision procedures were developed concurrently and independently for integer linear programs with exponentiation constraints ($y = 2^x$), or equivalently for the existential fragment of Semenov arithmetic: they run in non-deterministic exponential time [2] and in triply exponential time [41], respectively. Finally, another result subsumed by Theorem 2 is the membership in NP for the existential fragment of Büchi arithmetic [13].

Theorem 1 is established by designing a non-deterministic polynomial-time decision procedure, which, unlike those in papers [11, 13] but similarly to [2, 41], avoids automata-theoretic methods and instead relies on *quantifier elimination*. This is a powerful method (see, e.g., [9] as well as Section 2) that can be seen as a bridge between logic and integer programming. Presburger [30] used it to show decidability of linear integer arithmetic (and Tarski for real arithmetic with addition and multiplication). For systems of linear equations, quantifier elimination is essentially Gaussian elimination. As a little stepping stone, which was in fact one of the springboards for our paper, we extend the PTIME integer Gaussian elimination procedure by Bareiss [1, 39] into an NP procedure for solving systems of inequalities over $\mathbb{Z}$ (thus re-proving membership of integer linear programming in NP).

A look ahead. The following Section 2 recalls some relevant related work on logical theories of arithmetic. At the end of the paper (Section 9) this material is complemented by a discussion of future research directions, along with several more key references.

The NP procedure for integer programming is given as Algorithm 1 in Section 4. In this extended abstract, we do not provide a proof of correctness or analysis of the running time, but instead compare the algorithm with the classic Gauss–Jordan variable elimination and with Bareiss' method for systems of equations (that is, equalities). Necessary definitions and background information are provided in the Preliminaries (Section 3).

Our core result is an NP procedure for solving linear-exponential systems over $\mathbb{N}$. Its pseudocode is split into Algorithms 2–4. These are presented in the same imperative style with non-deterministic branching as Algorithm 1, and in fact Algorithm 3 relies on Algorithm 1. Section 5 provides a high-level overview of all three algorithms together. To this end, we introduce several new auxiliary concepts: quotient systems and quotient terms, delayed substitution, and primitive linear-exponential systems. After this, technical details of Algorithms 2–4 are given. Section 6 sketches key ideas behind the correctness argument, and the text within this section is thus to be read alongside the pseudocode of Algorithms. An overview of the analysis of the worst-case running time is presented in Section 7. The basic definitions are again those from Preliminaries, and of particular relevance are the subtleties of the action of term substitutions.

Building on the core procedure, in Section 8 we show how to solve in NP linear-exponential systems not only over $\mathbb{N}$ but also over $\mathbb{Z}$ (Theorem 1) and how to decide Büchi–Semenov arithmetic in NP (Theorem 2). The modifications to this procedure that enable proving both results for a different integer base $b > 2$ for the exponentials are given in Appendix A.

2 Arithmetic theories of Büchi, Semenov, and Presburger

In this section, we review results on arithmetic theories that are the most relevant to our study.

Büchi arithmetic is the first-order theory of the structure $(\mathbb{N}, 0, 1, +, V_2(\cdot,\cdot), \leq)$. By the celebrated Büchi–Bruyère theorem [4, 5], a set $S \subseteq \mathbb{N}^d$ is definable in $(\mathbb{N}, 0, 1, +, V_2(\cdot,\cdot), \leq)$ if and only if the representation of S as a language over the alphabet $\{0,1\}^d$ is recognisable

by a deterministic finite automaton (DFA). The theorem is effective, and implies that the satisfiability problem for Büchi arithmetic is in Tower (in fact, Tower-complete) [31, 36]. The situation is different for the existential fragment of this theory. The satisfiability problem is now NP-complete [13], but existential formulae are less expressive [15]. In particular, this fragment fails to capture the binary language $\{10, 01\}^*$. Decision procedures for Büchi arithmetic have been successfully implemented and used to automatically prove many results in combinatorics on words and number theory [35].

Semenov arithmetic is the first-order theory of the structure $(\mathbb{N}, 0, 1, +, 2^{(\cdot)}, \leq)$. Its decidability follows from the classical work of Semenov on sparse predicates [33, 34], and an explicit decision procedure was given by Cherlin and Point [6, 28]. Similarly to Büchi arithmetic, Semenov arithmetic is Tower-complete [8, 29]; however, its existential fragment has only been known to be in NExpTime [2]. The paper [41] provides applications of this fragment to solving systems of string constraints with string-to-integer conversion functions.

Büchi–Semenov arithmetic is a natural combination of these two theories. Differently from Büchi and Semenov arithmetics, the $\exists^*\forall^*$-fragment of this logic is undecidable [6]. In view of this, the recent result showing that the satisfiability problem of existential Büchi–Semenov arithmetic is in ExpSpace [11] is surprising. The proof technique, moreover, establishes the membership in ExpSpace of the extension of existential Büchi–Semenov arithmetic with arbitrary regular predicates given on input as DFAs. Since this extension can express the intersection non-emptiness problem for DFAs, its satisfiability problem is PSpace-hard [22]. The decision procedure of [11] was applied to give an algorithm for solving real-world instances of word equations with length constraints.

Both first-order theories of the structures $(\mathbb{N}, 0, 1, +, \leq)$ and $(\mathbb{Z}, 0, 1, +, \leq)$ are usually referred to as *Presburger arithmetic*, because the decision problems for these theories are logspace inter-reducible, meaning that each structure can be interpreted in the other. The procedures that we propose in this paper build upon a version of the quantifier-elimination procedure for the first-order theory of the structure $(\mathbb{Z}, 0, 1, +, \leq)$. Standard procedures for this theory [9, 26, 38] are known to be suboptimal when applied to the existential fragment: throughout these procedures, the bit size of the numbers in the formulae grow exponentially faster than in, e.g., geometric procedures for the theory [7]. A remedy to this well-known issue was proposed by Weispfenning [39, Corollary 4.3]. We develop his observation in Section 4.

3 Preliminaries

We usually write $a, b, c, \ldots$ for integers, $x, y, z, \ldots$ for integer variables, and $\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}, \ldots$ and $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}, \ldots$ for vectors of those. By $\boldsymbol{x} \setminus y$ we denote the vector obtained by removing the variable y from $\boldsymbol{x}$. We denote linear-exponential systems and logical formulae with the letters $\varphi, \chi, \psi, \ldots$, and write $\varphi(\boldsymbol{x})$ when the (free) variables of φ are among $\boldsymbol{x}$.

For $a \in \mathbb{R}$, we write $|a|$, $\lceil a \rceil$, and $\log a$ for the *absolute value*, *ceiling*, and (if $a > 0$) the *binary logarithm* of a. All numbers encountered by our algorithm are encoded in binary; note that $n \in \mathbb{N}$ can be represented using $\lceil \log(n+1) \rceil$ bits. For $n, m \in \mathbb{Z}$, denote $[n, m] \coloneqq \{n, n+1, \ldots, m\}$. The set $\mathbb{N}$ of non-negative integers contains 0.

Terms. As in Equation (1), a *(linear-exponential) term* is an expression of the form

$$\sum_{i=1}^{n} \left(a_i \cdot x_i + b_i \cdot 2^{x_i} + \sum_{j=1}^{n} c_{i,j} \cdot (x_i \bmod 2^{x_j})\right) + d, \tag{2}$$

where $a_i, b_i, c_{i,j} \in \mathbb{Z}$ are the *coefficients* of the term and $d \in \mathbb{Z}$ is its *constant*. If all b_i and $c_{i,j}$ are zero then the term is said to be *linear*. We denote terms by the letters $\rho, \sigma, \tau, \ldots$, and write $\tau(\boldsymbol{x})$ if all variables of the term τ are in $\boldsymbol{x}$. For a term τ in Equation (2), its 1-norm is $\|\tau\|_1 \coloneqq \sum_{i=1}^{n}(|a_i| + |b_i| + \sum_{j=1}^{n} |c_{i,j}|) + |d|$.

We use the words "system" and "conjunction" of constraints interchangeably. While equalities and inequalities of a linear-exponential system are always of the form $\tau = 0$, $\tau \leq 0$, and $\tau < 0$, for the convenience of exposition we often rearrange left- and right-hand sides and write, e.g., $\tau_1 \leq \tau_2$. In our procedures, linear-exponential systems may contain equalities, inequalities, and also *divisibility constraints* $d \mid \tau$, where τ is a term as in Equation (2), $d \in \mathbb{Z}$ is non-zero, and $\mid$ is the *divisibility predicate*, $\{(d, n) \in \mathbb{Z} \times \mathbb{Z} : n = kd \text{ for some } k \in \mathbb{Z}\}$. We write $\mathit{mod}(\varphi)$ for the (positive) least common multiple of all divisors d appearing in divisibility constraints $d \mid \tau$ of a system φ. For purely syntactic reasons, it is sometimes convenient to see a divisibility constraint $d \mid \tau_1 - \tau_2$ as a *congruence* $\tau_1 \equiv_d \tau_2$, where $d \geq 1$ with no loss of generality. We use the term *divisibility constraint* also for these congruences.

Substitutions. Our procedure uses several special kinds of substitutions. Consider a linear-exponential system φ, a term τ, two variables x and y, and $a \in \mathbb{Z} \setminus \{0\}$.

- We write $\varphi[\tau \,/\, x]$ for the system obtained from φ by replacing every *linear occurrence* of x outside modulo operators with τ. To clarify, this substitution only modifies the "$a_i \cdot x_i$" parts of the term in Equation (2), but not the "$c_{i,j} \cdot (x_i \bmod 2^{x_j})$" parts.
- We write $\varphi[\tau \,/\, x \bmod 2^y]$ and $\varphi[\tau \,/\, 2^x]$ for the system obtained from φ by replacing with τ every occurrence of $(x \bmod 2^y)$ and 2^x, respectively.
- We write $\varphi[[\frac{\tau}{a} \,/\, x]]$ for the *vigorous substitution* of $\frac{\tau}{a}$ for x. This substitution works as follows. **1:** Multiply every equality and inequality by a, flipping the signs of inequalities if $a < 0$; this step also applies to inequalities in which x does not occur. **2:** Multiply both sides of divisibility constraints in which x occurs by a, i.e., $d \mid \tau$ becomes $a \cdot d \mid a \cdot \tau$. **3:** Replace with τ every linear occurrence of $a \cdot x$ outside modulo operators. Note that, thanks to step 1, each coefficient of x in the system can be factorised as $a \cdot b$ for some $b \in \mathbb{Z}$.

We sometimes see substitutions $[\tau \,/\, \tau']$ as first-class citizens: functions mapping systems to systems. When adopting this perspective, $\varphi[\tau \,/\, \tau']$ is seen as a function application.

4 Solving systems of linear inequalities over $\mathbb{Z}$

In this section we present Algorithm 1 (GaussQE), a non-deterministic polynomial time quantifier elimination (QE) procedure for solving systems of linear inequalities over $\mathbb{Z}$, or in other words for integer programming. A constraint (equality, inequality, or divisibility) is *linear* if it only contains linear terms, as defined in Section 3.

We already mentioned in Section 1 that Integer Programming $\in$ NP is a standard result. Intuitively, the range of each variable is infinite, which necessitates a proof that a suitable (and *small*) range suffices; see, e.g., [3, 27, 37]. Methods developed in these references, however, do not enjoy the flexibility of quantifier elimination: e.g., they either do not preserve formula equivalence or are not actually removing quantifiers.

▶ **Theorem 3.** *Algorithm 1 (GaussQE) runs in non-deterministic polynomial time and, given a linear system $\varphi(\boldsymbol{x}, \boldsymbol{z})$ and variables $\boldsymbol{x}$, produces in each non-deterministic branch β a linear system $\psi_\beta(\boldsymbol{z})$ such that $\bigvee_\beta \psi_\beta$ is equivalent to $\exists \boldsymbol{x}\, \varphi$.*

GaussQE is based on an observation by Weispfenning, who drew a parallel between a weak form of QE and Gaussian variable elimination [39]. Based on this observation and relying on an insight by Bareiss [1] (to be discussed below), Weispfenning sketched a non-deterministic procedure for deciding *closed* existential formulae of Presburger arithmetic in polynomial time. Although the idea of weak QE [39] has since been developed further [23], the NP observation has apparently remained not well known.

Algorithm 1 GaussQE: Gauss–Jordan elimination for integer programming.

Input: $\boldsymbol{x}$: sequence of variables; $\varphi(\boldsymbol{x}, \boldsymbol{z})$: system of linear constraints.
Output of each branch (β): system $\psi_\beta(\boldsymbol{z})$ of linear constraints.
Ensuring: $\bigvee_\beta \psi_\beta$ is equivalent to $\exists \boldsymbol{x}\, \varphi$.

1: replace each inequality $\tau \leq 0$ in φ with $\tau + y = 0$, where y is a fresh slack variable
2: $\ell \leftarrow 1$; $\quad s \leftarrow ()$ ▷ *s is an empty sequence of substitutions*
3: **foreach** x in $\boldsymbol{x}$ **do**
4: **if** no equality of φ contains x **then continue**
5: **guess** $ax + \tau = 0$ (with $a \neq 0$) $\leftarrow$ equality in φ that contains x
6: $p \leftarrow \ell$; $\quad \ell \leftarrow a$ ▷ *previous and current lead coefficients*
7: **if** τ contains a slack variable y not assigned by s **then**
8: **guess** $v \leftarrow$ integer in $[0, |a| \cdot mod(\varphi) - 1]$
9: append $[v \,/\, y]$ to s
10: $\varphi \leftarrow \varphi[[\frac{-\tau}{a} \,/\, x]]$
11: divide each constraint in φ by p ▷ *in divisibility constraints, both sides are affected*
12: $\varphi \leftarrow \varphi \wedge (a \mid \tau)$
13: **foreach** equality $\eta = 0$ of φ that contains some slack variable y not assigned by s **do**
14: replace $\eta = 0$ with $\eta[0 \,/\, y] \leq 0$ **if** the coefficient at y is positive **else** with $\eta[0 \,/\, y] \geq 0$
15: apply substitutions of s to φ
16: **foreach** x in $\boldsymbol{x}$ that occurs in φ **do**
17: **guess** $r \leftarrow$ integer in $[0, mod(\varphi) - 1]$
18: $\varphi \leftarrow \varphi[r \,/\, x]$
19: **return** φ

Due to space constraints, we omit the proof of Theorem 3, and explain instead only the key ideas. We first consider the specification of GaussQE, in particular non-deterministic branching. We then recall the main underlying mechanism: Gaussian variable elimination (thus retracing and expanding Weispfenning's observation). After that, we discuss extension of this mechanism to tackle inequalities over $\mathbb{Z}$.

Input, output, and non-determinism. The input to GaussQE is a system φ of linear constraints, as well as a sequence $\boldsymbol{x}$ of variables to eliminate. The algorithm makes non-deterministic guesses in lines 5, 8, and 17. Output of each branch (of the non-deterministic execution) is specified at the top: it is a system ψ_β of linear constraints, in which all variables x in $\boldsymbol{x}$ have been eliminated. For any specific non-deterministic branch, call it β, the output system ψ_β may not necessarily be equivalent to $\exists \boldsymbol{x}\, \varphi$, but the disjunction of all outputs across all branches must be: $\bigvee_\beta \psi_\beta$ has the same set of satisfying assignments as $\exists \boldsymbol{x}\, \varphi$.[3]

The number of non-deterministic branches (individual paths through the execution tree) is usually exponential, but each of them runs in polynomial time. (This is true for all algorithms presented in this paper.) If all variables of the input system φ are included in $\boldsymbol{x}$, then each branch returns a conjunction of numerical assertions that evaluates to true or false.

[3] Formally, an assignment is a map ν from (free) variables to $\mathbb{Z}$. It satisfies a constraint if replacing each z in the domain of ν with $\nu(z)$ makes the constraint a true numerical assertion.

Gaussian elimination and Bareiss' method. Consider a system φ of linear equations (i.e., equalities) over fields, e.g., $\mathbb{R}$ or $\mathbb{Q}$, and let $\boldsymbol{x}$ be a vector of variables that we wish to eliminate from φ. We recall the Gauss–Jordan variable elimination algorithm, proceeding as follows:

01: $\ell \leftarrow 1$
02: **foreach** x in $\boldsymbol{x}$ **do**
03: **if** no equality of φ contains x **then continue**
04: **let** $ax + \tau = 0$ (with $a \neq 0$) $\leftarrow$ an arbitrary equality in φ that contains x
05: $p \leftarrow \ell$; $\ell \leftarrow a$
06: $\varphi \leftarrow \varphi[[\frac{-\tau}{a} \,/\, x]]$
07: divide each constraint in φ by p
08: **return** φ

By removing from this code all lines involving p and ℓ (lines 01, 05 and 07), we obtain a naive version of the procedure: an equation is picked in line 04 and used to remove one of its occurring variables in line 06. Indeed, applying a vigorous substitution $[[\frac{-\tau}{a} \,/\, x]]$ to an equality $bx + \sigma = 0$ is equivalent to first multiplying this equality by the lead coefficient a and then subtracting $b \cdot (ax + \tau) = 0$. The result is $-b\tau + a\sigma = 0$, and x is eliminated.

An insightful observation due to Bareiss [1] is that, after multiple iterations, coefficients accumulate non-trivial common factors. Lines 01, 05, and 07 take advantage of this. Indeed, line 07 divides every equation by such a common factor. Importantly, if all numbers in the input system φ are integers, then the division is without remainder. To show this, Bareiss uses a linear-algebraic argument based on an application of the Desnanot–Jacobi identity (or, more generally, Sylvester's identity) for determinants [1, 10, 21]. Over $\mathbb{Q}$, this makes it possible to perform Gaussian elimination (its "fraction-free one-step" version) in PTime. (This is not the only polynomial-time method; cf. [32, Section 3.3].)

Gaussian elimination for systems of equations can be extended to solving over $\mathbb{Z}$, by introducing divisibility constraints: line 06 becomes $\varphi \leftarrow \varphi[[\frac{-\tau}{a} \,/\, x]] \wedge (a \mid \tau)$. However, while the running time of the procedure remains polynomial, its effect becomes more modest: the procedure reduces a system of linear equations over $\mathbb{Z}$ to an equivalent system of equations featuring variables not in $\boldsymbol{x}$ and multivariate linear congruences that may still contain variables from $\boldsymbol{x}$. To completely eliminate $\boldsymbol{x}$, further computation is required. For our purposes, non-deterministic guessing is a good enough solution to this problem; see the final **foreach** loop in lines 16–18 of GaussQE.

From equalities to inequalities. GaussQE extends Bareiss' method to systems of inequalities over $\mathbb{Z}$. As above, the method allows us to control the (otherwise exponential) growth of the bit size of numbers. Gaussian elimination is, of course, still at the heart of the algorithm (see lines 2–6, 10, and 11), and we now discuss two modifications:

- Line 1 introduces *slack variables* ranging over $\mathbb{N}$. These are internal to the procedure and are removed at the end (lines 13–15).
- In line 5 the equality $ax + \tau = 0$ is selected non-deterministically.

The latter modification is required for the correctness (more precisely: completeness) of GaussQE. Geometrically, for a satisfiable system of inequalities over $\mathbb{Z}$ consider the convex polyhedron of all solutions over $\mathbb{R}$ first. At least one of solutions over $\mathbb{Z}$ must lie in or near a facet of this polyhedron. Line 5 of Algorithm 1 attempts to guess this facet. The amount of slack guessed in line 8 corresponds to the distance from the facet. Observe that if $ax + \tau = 0$ corresponds to an equality of the original system φ, then every solution of φ needs to satisfy $ax + \tau = 0$ exactly, and so there is no slack (lines 8–9 are not taken).

The values chosen for the slack variables in line 8 have, in fact, a counterpart in the standard decision procedures for Presburger arithmetic. When the latter pick a term ρ to substitute, the substitutions in fact introduce $\rho + k$ for k ranging in some $[0, \ell]$, where ℓ depends on $mod(\varphi)$. The amount of slack considered in GaussQE corresponds to these values of k. (Because of this parallel, making the range of guesses in line 8 symmetric, i.e., $|v| \leq |a| \cdot mod(\varphi) - 1$, extends our procedure to the entire existential Presburger arithmetic.)

5 Solving linear-exponential systems over $\mathbb{N}$: an overview

In this section we give an overview of our non-deterministic procedure to solve linear-exponential systems over $\mathbb{N}$. The procedure is split into Algorithms 2–4. A more technical analysis of these algorithms is given later in Section 6.

Whenever non-deterministic Algorithms 1–4 call one another, the return value is always just the output of a single branch, rather than (say) the disjunction over all branches.

Algorithm 2 (LinExpSat). This is the main procedure. It takes as input a linear-exponential system φ without divisibility constraints and decides whether φ has a solution over $\mathbb{N}$. The procedure relies on first (non-deterministically) fixing a linear ordering θ on the exponential terms 2^x occurring in φ (line 2). For technical convenience, this ordering contains a term 2^{x_0}, with x_0 fresh variable, and sets $2^{x_0} = 1$. Variables are iteratively eliminated starting from the one corresponding to the leading exponential term in θ (i.e., the biggest one), until reaching x_0 (lines 3–16). The elimination of each variable is performed by first rewriting the system (in lines 8–14) into a form admissible for Algorithm 3 discussed below. This rewriting introduces new variables, which will never occur in exponentials throughout the entire procedure and are later eliminated when the procedure reaches x_0. Overall, the termination of the procedure is ensured by the decreasing number of exponentiated variables. After LinExpSat rewrites φ, it calls Algorithm 3 to eliminate the currently biggest variable.

Algorithm 3 (ElimMaxVar). This procedure takes as input an ordering θ, a *quotient system induced by* θ and a *delayed substitution*. Let us introduce these notions.

Quotient systems. Let $\theta(\boldsymbol{x})$ be the ordering $2^{x_n} \geq 2^{x_{n-1}} \geq \cdots \geq 2^{x_0} = 1$, where $n \geq 1$. A *quotient system induced by* θ is a system $\varphi(\boldsymbol{x}, \boldsymbol{x}', \boldsymbol{z}')$ of equalities, inequalities, and divisibility constraints $\tau \sim 0$, where $\sim \in \{<, \leq, =, \equiv_d \colon d \geq 1\}$ and τ is an *quotient term (induced by θ)*, that is, a term of the form

$$a \cdot 2^{x_n} + f(\boldsymbol{x}') \cdot 2^{x_{n-1}} + b \cdot x_{n-1} + \tau'(x_0, \ldots, x_{n-2}, \boldsymbol{z}')\,,$$

where $a, b \in \mathbb{Z}$, $f(\boldsymbol{x}')$ is a linear term, and τ' is a linear-exponential term in which the variables from $\boldsymbol{z}'$ do not occur exponentiated. Furthermore, for every variable z' in $\boldsymbol{z}'$, the quotient system φ features the inequalities $0 \leq z' < 2^{x_{n-1}}$. The variables in $\boldsymbol{x}$, $\boldsymbol{x}'$ and $\boldsymbol{z}'$ form three disjoint sets, which we call the *exponentiated variables*, the *quotient variables* and the *remainder variables* of the system φ, respectively. We also refer to the term $b \cdot x_{n-1} + \tau'(x_0, \ldots, x_{n-2}, \boldsymbol{z}')$ as the *least significant part* of the quotient term τ. Importantly, quotient terms are **not** linear-exponential terms.

Here is an example of a quotient system induced by $2^{x_3} \geq 2^{x_2} \geq 2^{x_1} \geq 2^{x_0} = 1$, and having quotient variables $\boldsymbol{x}' = (x_1', x_2')$ and remainder variables $\boldsymbol{z}' = (z_1', z_2')$

$$\begin{aligned} -2^{x_3} + (2 \cdot x_1' - x_2' - 1) \cdot 2^{x_2} + \big\{ -2 \cdot x_2 + 2^{x_1} - (z_1' \bmod 2^{x_1}) \big\} \leq 0, \quad & 0 \leq z_1' < 2^{x_2}, \\ x_1' \cdot 2^{x_2} + \big\{ x_1 + z_2' - 5 \big\} = 0, \quad & 0 \leq z_2' < 2^{x_2}. \end{aligned}$$

The curly brackets highlight the least significant parts of two terms of the system, the other parts being $\pm z'_1$ and $\pm z'_2$ stemming from the inequalities on the right.

Delayed substitution. This is a substitution of the form $[x' \cdot 2^{x_{n-1}} + z' \,/\, x_n]$, where 2^{x_n} is the leading exponential term of θ. Our procedure delays the application of this substitution until x_n occurs linearly in the system φ. One can think of this substitution as an equality $(x_n = x' \cdot 2^{x_{n-1}} + z')$ in φ that must not be manipulated for the time being.

Back to ElimMaxVar, given a quotient system $\varphi(\boldsymbol{x}, \boldsymbol{x'}, \boldsymbol{z'})$ induced by θ and the delayed substitution $[x' \cdot 2^{x_{n-1}} + z' \,/\, x_n]$, the goals of this procedure are to (i) eliminate the quotient variables $\boldsymbol{x'} \setminus x'$; (ii) eliminate all occurrences of the leading exponential term 2^{x_n} of θ and apply the delayed substitution to eliminate the variable x_n; (iii) finally, remove x'. Upon exit, ElimMaxVar gives back to LinExpSat a (non-quotient) linear-exponential system where x_n has been eliminated; i.e., a system with one fewer exponentiated variable.

For steps (i) and (iii), the procedure relies on the Algorithm 1 (GaussQE) for eliminating variables in systems of inequalities, from Section 4. This is where flexibility of QE is important: in line 22 some variables are eliminated and some are not. Step (ii) is instead implemented by Algorithm 4.

Algorithm 4 (SolvePrimitive). The goal of this procedure is to rewrite a system of constraints where x_n occurs exponentiated with another system where all constraints are linear. The specification of the procedure restricts the output further. At its core, SolvePrimitive tailors Semenov's proof of the decidability of the first-order theory of the structure $(\mathbb{N}, 0, 1, +, 2^{(\cdot)}, \leq)$ [34] to a small syntactic fragment, which we now define.

Primitive linear-exponential systems. Let u, v be two variables. A linear-exponential system is said to be (u, v)-*primitive* whenever all its (in)equalities and divisibility constraints are of the form $a \cdot 2^u + b \cdot v + c \sim 0$, with $a, b, c \in \mathbb{Z}$ and $\sim \in \{<, \leq, =, \equiv_d \colon d \geq 1\}$.

The input to SolvePrimitive is a (u, v)-primitive linear-exponential system. This procedure removes all occurrences of 2^u in favour of linear constraints, working under the assumption that $u \geq v$. This condition is ensured when ElimMaxVar invokes SolvePrimitive. The variable u of the primitive system in the input corresponds to the term $x_n - x_{n-1}$, and the variable v stands for the variable x' in the delayed substitution $[x' \cdot 2^{x_{n-1}} + z' \,/\, x_n]$. ElimMaxVar ensures that $x_n - x_{n-1} \geq x'$.

6 Algorithms 2, 3, 4: a walkthrough

Having outlined the interplay between Algorithms 2–4, we move to their technical description, and present the key ideas required to establish the correctness of our procedure for solving linear-exponential systems over $\mathbb{N}$.

6.1 Algorithm 2: the main loop

Let $\varphi(x_1, \ldots, x_n)$ be an input linear-exponential system (with no divisibility constraints). As explained in the summary above, LinExpSat starts by guessing an ordering $\theta(x_0, \ldots, x_n)$ of the form $t_1 \geq t_2 \geq \cdots \geq t_n \geq 2^{x_0} = 1$, where $(t_1, \ldots, t_n)$ is a permutation of the terms $2^{x_1}, \ldots, 2^{x_n}$, and x_0 is a fresh variable used as a placeholder for 0. Note that if φ is satisfiable (over $\mathbb{N}$), then θ can be guessed so that $\varphi \wedge \theta$ is satisfiable; and conversely no such θ exists if φ is unsatisfiable. For the sake of convenience, we assume in this section that the ordering $\theta(x_0, \ldots, x_n)$ guessed by the procedure is $2^{x_n} \geq 2^{x_{n-1}} \geq \cdots \geq 2^{x_1} \geq 2^{x_0} = 1$.

Algorithm 2 LinExpSat: A procedure to decide linear-exponential systems over $\mathbb{N}$.

Input: $\varphi(x_1, \ldots, x_n)$: linear-exponential system (without divisibility constraints).
Output: True ($\top$) if φ has a solution over $\mathbb{N}$, and otherwise false ($\bot$).

1: **let** x_0 be a fresh variable ▷ *placeholder for* 0
2: **guess** $\theta \leftarrow$ ordering of the form $t_1 \geq t_2 \geq \cdots \geq t_n \geq 2^{x_0} = 1$, where $(t_1, \ldots, t_n)$ is a permutation of the terms $2^{x_1}, \ldots, 2^{x_n}$
3: **while** θ is not the ordering $(2^{x_0} = 1)$ **do**
4: $\quad 2^x \leftarrow$ leading exponential term of θ ▷ *in the i-th iteration, 2^x is t_i*
5: $\quad 2^y \leftarrow$ successor of 2^x in θ ▷ *and 2^y is t_{i+1}*
6: $\quad \varphi \leftarrow \varphi[w \,/\, (w \bmod 2^x) : w \text{ is a variable}]$
7: $\quad \boldsymbol{z} \leftarrow$ all variables z in φ such that z is x or z does not appear in θ
8: $\quad$ **foreach** z in $\boldsymbol{z}$ **do** ▷ *form a quotient system induced by θ*
9: $\quad\quad$ **let** x' and z' be two fresh variables
10: $\quad\quad \varphi \leftarrow \varphi \wedge (0 \leq z' < 2^y)$
11: $\quad\quad \varphi \leftarrow \varphi[z' \,/\, (z \bmod 2^y)]$
12: $\quad\quad \varphi \leftarrow \varphi[(z' \bmod 2^w) \,/\, (z \bmod 2^w) : w \text{ is such that } \theta \text{ implies } 2^w \leq 2^y]$
13: $\quad\quad \varphi \leftarrow \varphi[(x' \cdot 2^y + z') \,/\, z]$ ▷ *replaces only the linear occurrences of z*
14: $\quad\quad$ **if** z is x **then** $(x'_0, z'_0) \leftarrow (x', z')$ ▷ *for delayed substitution, see next line*
15: $\quad \varphi \leftarrow$ ElimMaxVar$(\theta, \varphi, [x'_0 \cdot 2^y + z'_0 \,/\, x])$
16: $\quad$ remove 2^x from θ
17: **return** $\varphi(\boldsymbol{0})$ ▷ *evaluates to $\top$ or $\bot$*

The **while** loop starting in line 3 manipulates φ and θ, non-deterministically obtaining at the end of the ith iteration a system $\varphi_i(\boldsymbol{x}, \boldsymbol{z})$ and an ordering $\theta_i(\boldsymbol{x})$, where $\boldsymbol{x} = (x_0, \ldots, x_{n-i})$ and $\boldsymbol{z}$ is a vector of i fresh variables. The non-deterministic guesses performed by LinExpSat are such that the following properties (I1)–(I3) are loop invariants across all branches, whereas (I4) is an invariant for at least one branch (below, $i \in [0, n]$ and $(\varphi_0, \theta_0) \coloneqq (\varphi, \theta)$):

I1. All variables that occur exponentiated in φ_i are among $x_0, \ldots, x_{n-i}$.
I2. θ_i is the ordering $2^{x_{n-i}} \geq 2^{x_{n-i-1}} \geq \cdots \geq 2^{x_1} \geq 2^{x_0} = 1$.
I3. All variables z in $\boldsymbol{z}$ are such that $z < 2^{x_{n-i}}$ is an inequality in φ_i.
I4. $\varphi_i \wedge \theta_i$ is equisatisfiable with $\varphi \wedge \theta$ over $\mathbb{N}$.

More precisely, writing $\bigvee_\beta \psi_\beta$ for the disjunction of all the formulae $\varphi_i \wedge \theta_i$ obtained across all non-deterministic branches, we have that $\bigvee_\beta \psi_\beta$ and $\varphi \wedge \theta$ are equisatisfiable. Therefore, whenever $\varphi \wedge \theta$ is satisfiable, (I4) holds for at least one branch. If $\varphi \wedge \theta$ is instead unsatisfiable, then (I4) holds instead for all branches.

The invariant above is clearly true for φ_0 and θ_0, with $\boldsymbol{z}$ being the empty set of variables. Item (I2) implies that, after n iterations, θ_n is $2^{x_0} = 1$, which causes the **while** loop to exit. Given θ_n, properties (I1) and (I3) force the values of x_0 and of all variables in $\boldsymbol{z}$ to be zero, thus making $\varphi \wedge \theta$ equisatisfiable with $\varphi_n(\boldsymbol{0})$ in at least one branch of the algorithm, by (I4). In summary, this will enable us to conclude that the procedure is correct.

Let us now look at the body of the **while** loop. Its objective is simple: manipulate the current system, say φ_i, so that it becomes a quotient system induced by θ_i, and then call Algorithm 3 (ElimMaxVar). For these systems, note that 2^x and 2^y in lines 4–5 correspond to $2^{x_{n-i}}$ and $2^{x_{n-i-1}}$, respectively. Behind the notion of quotient system there are two goals. One of them is to make sure that 2^x and 2^y are not involved in modulo operations. (We will discuss the second goal in Section 6.2.) The **while** loop achieves this goal as follows:

- Since 2^x is greater than every variable in φ_i, every $(w \bmod 2^x)$ can be replaced with w.
- For 2^y instead, we "divide" every variable z that might be larger than it. Observe that z is either x or from the vector $\boldsymbol{z}$ in (I3) of the invariant. The procedure replaces every linear occurrence of z with $x' \cdot 2^y + z'$, where x' and z' are fresh variables and z' is a residue modulo 2^y, that is, $0 \leq z' < 2^y$.

The above-mentioned replacement simplifies all modulo operators where z appears: $(z \bmod 2^y)$ becomes z', and every $(z \bmod 2^w)$ such that θ_i entails $2^w \leq 2^y$ becomes $(z' \bmod 2^w)$. We obtain in this way a quotient system induced by θ_i, and pass it to ElimMaxVar.

Whilst the goal we just discussed is successfully achieved, we have not in fact eliminated the variable x completely. Recall that, according to our definition of substitution, occurrences of 2^x in the system φ are unaffected by the application of $[x' \cdot 2^y + z' \,/\, x]$ in line 13 of LinExpSat. Because of this, the procedure keeps this substitution as a *delayed substitution* for future use, to be applied (by ElimMaxVar) when x will finally occur only linearly.

6.2 Algorithm 3: elimination of leading variable and quotient variables

Let $\varphi(\boldsymbol{x}, \boldsymbol{x}', \boldsymbol{z}')$ be a quotient system induced by an ordering $\theta(\boldsymbol{x})$, with $\boldsymbol{x}$ exponentiated, $\boldsymbol{x}'$ quotient and $\boldsymbol{z}'$ remainder variables, and consider a delayed substitution $[x' \cdot 2^y + z' \,/\, x]$. ElimMaxVar removes $\boldsymbol{x}'$ and x, obtaining a linear-exponential system ψ that adheres to the loop invariant of LinExpSat. This is done by following the three steps described in the summary of the procedure, which we now expand.

Step (i): lines 3–22. This step aims at calling Algorithm 1 (GaussQE) to eliminate all variables in $\boldsymbol{x}' \setminus x'$. There is, however, an obstacle: these variables are multiplied by 2^y. Here is where the second goal behind the notion of quotient system comes into play: making sure that least significant parts of quotient terms can be bounded in terms of 2^y. To see what we mean by this and why it is helpful, consider below an inequality $\tau \leq 0$ from φ, where $\tau = a \cdot 2^x + f(\boldsymbol{x}') \cdot 2^y + \rho(\boldsymbol{x} \setminus x, \boldsymbol{z}')$ and ρ is the least significant part of τ.

Since φ is a quotient system induced by θ, all variables and exponential terms 2^w appearing in ρ are bounded by 2^y, and thus every solution of $\varphi \wedge \theta$ must also satisfy $|\rho| \leq \|\rho\|_1 \cdot 2^y$. More precisely, the value of ρ must lie in the interval $[(r-1) \cdot 2^y + 1, r \cdot 2^y]$ for some $r \in [-\|\rho\|_1, \|\rho\|_1]$. The procedure guesses one such value r (line 9). The inequality $\tau \leq 0$ can be rewritten as

$$\big(a \cdot 2^x + f(\boldsymbol{x}') \cdot 2^y + r \cdot 2^y \leq 0\big) \;\wedge\; \big((r-1) \cdot 2^y < \rho \leq r \cdot 2^y\big). \tag{3}$$

Fundamentally, $\tau \leq 0$ has been split into a "left part" and a "right part", shown with big brackets around. The "right part" $(r-1) \cdot 2^y < \rho \leq r \cdot 2^y$ is made of two linear-exponential inequalities featuring none of the variables we want to eliminate ($\boldsymbol{x}'$ and x). Following the same principle, the procedure produces similar splits for all strict inequalities, equalities, and divisibility constraints of φ. In the pseudocode, the "left parts" of the system are stored in the formula γ, and the "right parts" are stored in the formula ψ.

Let us focus on a "left part" $a \cdot 2^x + f(\boldsymbol{x}') \cdot 2^y + r \cdot 2^y \leq 0$ in γ. Since θ implies $2^x \geq 2^y$, we can factor out 2^y from this constraint, obtaining the inequality $a \cdot 2^{x-y} + f(\boldsymbol{x}') + r \leq 0$. There we have it: the variables $\boldsymbol{x}' \setminus x'$ occur now linearly in γ and can be eliminated thanks to GaussQE. For performing this elimination, the presence of 2^{x-y} is unproblematic. In fact, the procedure uses a placeholder variable u for 2^{x-y} (line 1), so that γ is in fact a linear system with, e.g., inequalities $a \cdot u + f(\boldsymbol{x}') + r \leq 0$. Observe that inequalities $\boldsymbol{x}' \geq \boldsymbol{0}$ are added to γ in line 22, since GaussQE works over $\mathbb{Z}$ instead of $\mathbb{N}$. This concludes Step (i).

Algorithm 3 ElimMaxVar: Variable elimination for quotient systems.

Input: $\theta(\boldsymbol{x})$: ordering of exponentiated variables;
$\varphi(\boldsymbol{x}, \boldsymbol{x}', \boldsymbol{z}')$: quotient system induced by θ, with $\boldsymbol{x}$ exponentiated, $\boldsymbol{x}'$ quotient, and $\boldsymbol{z}'$ remainder variables;
$[x' \cdot 2^y + z'/x]$: delayed substitution for φ.

Output of each branch (β): $\psi_\beta(\boldsymbol{x} \setminus x, \boldsymbol{z}')$: linear-exponential system such that for every z in $\boldsymbol{z}'$, z does not occur in exponentials and $0 \le z < 2^y$ occurs in ψ_β.

Ensuring: $(\exists x\, \theta) \wedge \bigvee_\beta \psi_\beta$ is equivalent to $\exists x \exists \boldsymbol{x}' (\theta \wedge \varphi \wedge x = x' \cdot 2^y + z')$ over $\mathbb{N}$.

let u be a fresh variable ▷ *u is an alias for 2^{x-y}*
$\gamma \leftarrow \top$; $\psi \leftarrow \top$
Elimination of $\boldsymbol{x}' \setminus x'$:
$\Delta \leftarrow \varnothing$ ▷ *map from linear-exponential terms to $\mathbb{Z}$*
foreach $(\tau \sim 0)$ in φ, where $\sim \in \{=, <, \le, \equiv_d \colon d \ge 1\}$ **do**
  let τ be $(a \cdot 2^x + f(\boldsymbol{x}') \cdot 2^y + \rho)$, where ρ is the least significant part of τ
  if $a = 0$ and $f(\boldsymbol{x}')$ is an integer **then** $\psi \leftarrow \psi \wedge (\tau \sim 0)$
  else if the symbol $\sim$ belongs to $\{=, <, \le\}$ **then**
    if $\Delta(\rho)$ is undefined **then**
      guess $r \leftarrow$ integer in $[-\|\rho\|_1, \|\rho\|_1]$
      $\psi \leftarrow \psi \wedge ((r-1) \cdot 2^y < \rho) \wedge (\rho \le r \cdot 2^y)$
      update Δ : add the key–value pair (ρ, r)
    $r \leftarrow \Delta(\rho)$
    if the symbol $\sim$ is $<$ **then**
      $\sim \leftarrow \le$
      $r \leftarrow r + 1$ ▷ *$(v < w)$ is equivalent to $(v + 1 \le w)$*
    $\gamma \leftarrow \gamma \wedge (a \cdot u + f(\boldsymbol{x}') + r \sim 0)$
    if the symbol $\sim$ is $=$ **then** $\psi \leftarrow \psi \wedge (r \cdot 2^y = \rho)$
  else ▷ *$\sim$ is $\equiv_d$ for some $d \in \mathbb{N}$*
    guess $r \leftarrow$ integer in $[1, mod(\varphi)]$
    $\gamma \leftarrow \gamma \wedge (a \cdot u + f(\boldsymbol{x}') - r \sim 0)$
    $\psi \leftarrow \psi \wedge (r \cdot 2^y + \rho \sim 0)$
$\gamma \leftarrow$ GaussQE $(\boldsymbol{x}' \setminus x', \gamma \wedge \boldsymbol{x}' \ge \mathbf{0})$
$\gamma \leftarrow \gamma[2^u \,/\, u]$ ▷ *u now is an alias for $x - y$*
$(\chi, \gamma) \leftarrow$ SolvePrimitive(u, x', γ)
$\chi \leftarrow \chi[x - y \,/\, u][x' \cdot 2^y + z' \,/\, x]$ ▷ *apply delayed substitution: x is eliminated*
Elimination of x':
if χ is $(-x' \cdot 2^y - z' + y + c = 0)$ for some $c \in \mathbb{N}$ **then**
  guess $b \leftarrow$ integer in $[0, c]$
  $\gamma \leftarrow \gamma \wedge (x' = b)$
  $\psi \leftarrow \psi \wedge (b \cdot 2^y = -z' + y + c)$
else
  let χ be $(-x' \cdot 2^y - z' + y + c \le 0) \wedge (d \mid x' \cdot 2^y + z' - y - r)$, with $d, r \in \mathbb{N}$, $c \ge 3$
  guess $(b, g) \leftarrow$ pair of integers in $[0, c] \times [1, d]$
  $\gamma \leftarrow \gamma \wedge (x' \ge b) \wedge (d \mid x' - g)$
  $\psi \leftarrow \psi \wedge ((b-1) \cdot 2^y < -z' + y + c) \wedge (-z' + y + c \le b \cdot 2^y) \wedge (d \mid g \cdot 2^y + z' - y - r)$
assert(GaussQE(x', γ) is equivalent to $\top$) ▷ *upon failure, Algorithm 2 returns $\perp$*
return ψ

Before moving on to Step (ii), we justify the use of the map Δ from line 3. If the procedure were to apply Equation (3) and replace every inequality $\tau \leq 0$ with three inequalities, then multiple calls to ElimMaxVar would produce a system with exponentially many constraints. A solution to this problem is to guess $r \in [-\|\rho\|_1, \|\rho\|_1]$ only once, and use it in all the "left parts" stemming from inequalities in φ having ρ as their least significant part. The "right part" $(r-1)\cdot 2^y < \rho \leq r \cdot 2^y$ is added to ψ only once. The map Δ implements this memoisation, avoiding the aforementioned exponential blow-up. Indeed, the number of least significant parts grows very slowly throughout LinExpSat, as we will see in Section 7.

Step (ii): lines 23–25. The goal of this step is to eliminate all occurrences of the term 2^{x-y}. For convenience, the procedure first reassigns u to now be a placeholder for $x-y$ (line 23). Because of this reassignment, the system γ returned by GaussQE at the end of Step (i) is a (u, x')-primitive linear-exponential system.

The procedure calls Algorithm 4 (SolvePrimitive), which constructs from γ a pair of systems $(\chi_\beta(u), \gamma_\beta(x'))$, which is assigned to (χ, γ). Both are linear systems, and thus all occurrences of 2^{x-y} (rather, 2^u) have been removed. At last, all promised substitutions can be realised (line 25): u is replaced with $x-y$, and the delayed substitution replaces x with $x' \cdot 2^y + z'$. This eliminates x. The only variable that is yet to be removed is x' (Step (iii)).

It is useful to recall at this stage that SolvePrimitive is only correct under the assumption that $u \geq x' \geq 0$. This assumption is guaranteed by the definition of θ, the delayed substitution, and the fact that u is a placeholder for $x-y$ (and we are working over $\mathbb{N}$). Indeed, if $x' = 0$, then the inequality $2^x \geq 2^y$ in θ ensures $u = x - y \geq 0 = x'$. If $x' \geq 1$,

$$\begin{aligned} u = x - y &= x' \cdot 2^y + z' - y && \text{delayed substitution} \\ &\geq x' \cdot (y+1) + z' - y && 2^y \geq y+1, \text{ for every } y \in \mathbb{N} \\ &= y \cdot (x'-1) + x' + z' \geq x'. && \text{since } x' \geq 1. \end{aligned}$$

Step (iii): lines 26–35. This step deals with eliminating the variable x' from the formula $\gamma(x') \wedge \chi(x', z', y) \wedge \psi(\boldsymbol{x} \setminus x, \boldsymbol{z}')$, where ψ contains the "right parts" of φ computed during Step (i). The strategy to eliminate x' follows closely what was done to eliminate the other quotient variables from $\boldsymbol{x}'$ during Step (i): the algorithm first splits the formula $\chi(x', z', y)$ into a "left part", which is added to γ and features the variable x', and a "right part", which is added to ψ and features the variables z' and y. It then eliminates x' by calling GaussQE on γ. To perform the split into "left part" and "right part", observe that χ is a system of the form either $-x' \cdot 2^y - z' + y + c = 0$ or $(-x' \cdot 2^y - z' + y + c \leq 0) \wedge (d \mid x' \cdot 2^y + z' - y - r)$ (see the spec of SolvePrimitive). By arguments similar to the ones used for ρ in Step (i), $-z' + y + c$ can be bounded in terms of 2^y. (Notice, e.g., the similarities between the inequalities in line 34 and the ones in line 10.) After the elimination of x', if GaussQE does not yield an unsatisfiable formula, ElimMaxVar returns the system ψ to LinExpSat.

Before moving on to the description of SolvePrimitive, let us clarify the semantics of the **assert** statement occurring in line 35. It is a standard semantics from programming languages. If an assertion b evaluates to true at runtime, **assert**(b) does nothing. If b evaluates to false instead, the execution aborts and the main procedure (LinExpSat) returns $\perp$. This semantics allows for assertions to query NP problems, as done in line 35 (and in line 11 of SolvePrimitive), without undermining the membership in NP of LinExpSat.

Algorithm 4 SolvePrimitive: A procedure to decompose and linearise primitive systems.

Input: u, v : two varaibles; φ : (u,v)-primitive linear-exponential system.
Output of each branch (β): a pair of linear systems $(\chi_\beta(u), \gamma_\beta(v))$ such that $\chi_\beta(u)$ is either of the form $(u = a)$ or of the form $(u \geq b) \wedge (d \mid u - r)$, where $a, d, r \in \mathbb{N}$ and $b \geq 3$.
Ensuring: $(u \geq v \geq 0)$ entails that $\bigvee_\beta (\chi_\beta \wedge \gamma_\beta)$ is equivalent to φ.

1: **let** φ be $(\chi \wedge \psi)$, where χ is the conjunction of all (in)equalities from φ containing 2^u
2: $(d, n) \leftarrow$ pair of non-negative integers such that $mod(\varphi) = d \cdot 2^n$ and d is odd
3: $C \leftarrow \max\left\{n, 3 + 2 \cdot \left\lceil \log(\frac{|b|+|c|+1}{|a|}) \right\rceil : (a \cdot 2^u + b \cdot v + c \sim 0) \text{ in } \chi, \text{ where } \sim \in \{=, <, \leq\}\right\}$
4: **guess** $c \leftarrow$ element of $[0, C-1] \cup \{\star\}$ ▷ $\star$ *signals* $u \geq C$
5: **if** c is not $\star$ **then**
6: $\quad \chi \leftarrow (u = c)$
7: $\quad \gamma \leftarrow \varphi[2^c \,/\, 2^u]$
8: **else** ▷ *assuming* $u \geq C$, *(in)equalities in* χ *simplify to* $\top$ *or* $\bot$
9: $\quad$ **assert**(χ has no equality, and in all its inequalities 2^u has a negative coefficient)
10: $\quad$ **guess** $r \leftarrow$ integer in $[0, d-1]$ ▷ *remainder of* 2^{u-n} *modulo* d *when* $u \geq C \geq n$
11: $\quad$ **assert**($d \mid 2^u - 2^n \cdot r$ is satisfiable)
12: $\quad r' \leftarrow$ discrete logarithm of $2^n \cdot r$ base 2, modulo d
13: $\quad d' \leftarrow$ multiplicative order of 2 modulo d
14: $\quad \chi \leftarrow (u \geq C) \wedge (d' \mid u - r')$
15: $\quad \gamma \leftarrow \psi[2^n \cdot r / 2^u]$ ▷ $2^n \cdot r$ *is a remainder of* 2^u *modulo* $mod(\psi) = d \cdot 2^n$
16: **return** (χ, γ)

6.3 Algorithm 4: from primitive systems to linear systems

Consider an input (u,v)-primitive linear-exponential system φ, and further assume we are searching for solutions over $\mathbb{N}$ where $u \geq v$. The goal of SolvePrimitive is to decompose φ (in the sense of monadic decomposition [24, 16]) into two *linear* systems: a system χ only featuring the variable u, and a system γ only featuring v.

To decompose φ, the key parameter to understand is the threshold C for the variable u (line 3). This positive integer depends on two quantities, one for "linearising" the divisibility constraints, and one for "linearising" the equalities and inequalities of φ. Below we first discuss the latter quantity. Throughout the discussion, we assume $u \geq C$, as otherwise the procedure simply replaces u with a value in $[0, C-1]$ (see lines 6 and 7).

Consider an inequality $a \cdot 2^u + b \cdot v + c \leq 0$. Regardless of the values of u and v, as long as $|a \cdot 2^u| > |b \cdot v + c|$ holds, the truth of this inequality will solely depend on the sign of the coefficient a. Since we are assuming $u \geq v$ and $u \geq C \geq 1$, $|a \cdot 2^u| > |b \cdot v + c|$ is implied by $|a| \cdot 2^u > (|b| + |c|) \cdot u$. In turn, this inequality is implied by $u \geq C$, because both sides of the inequalities are monotone functions, $|a| \cdot 2^u$ grows faster than $(|b| + |c|) \cdot u$, and, given $C' \coloneqq 3 + 2 \cdot \left\lceil \log(\frac{|b|+|c|+1}{|a|}) \right\rceil$ (which is at most C), we have

$$|a| \cdot 2^{C'} \geq |a| \cdot 2^3 \cdot \left(\frac{|b| + |c| + 1}{|a|}\right)^2 > \big(|b| + |c|\big) \cdot 2^{\left\lceil \log(\frac{|b|+|c|+1}{|a|}) \right\rceil + 2} > \big(|b| + |c|\big) \cdot C',$$

where to prove the last inequalities one uses the fact that $2^{x+1} > 2 \cdot x + 1$ for every $x \geq 0$. Hence, when $u \geq C$, every inequality in φ simplifies to either $\top$ or $\bot$, and this is also true for strict inequalities. The Boolean value $\top$ arises when a is negative. The Boolean $\bot$ arises when a is positive, or when instead of an inequality we consider an equality.

It remains to handle the divisibility constraints, again under the assumption $u \geq C$. This is where the second part of the definition of C plays a role. Because $u \geq C \geq n$ (see the definition of (d, n) in line 2), we can guess $r \in [0, d-1]$ such that $mod(\varphi) \mid 2^u - 2^n \cdot r$ (line 10). This constraint is equivalent to $d \mid 2^{u-n} - r$ and, since 2^n and d are coprime, it is also equivalent to $d \mid 2^u - 2^n \cdot r$. It might be an unsatisfiable constraint: the procedure checks for this eventuality in line 11, by solving a discrete logarithm problem (which can be done in NP, see [18]). Suppose a solution is found, say r' (as in line 12). We can then represent the set of solutions of $d \mid 2^u - 2^n \cdot r$ as an arithmetic progression: it suffices to compute the multiplicative order of 2 modulo d, i.e., the smallest positive integer d' such that $d \mid 2^{d'} - 1$. This is again a discrete logarithm problem, but differently from the previous case d' always exists since d and 2 are coprime. The set of solutions of $d \mid 2^u - 2^n \cdot r$ is given by $\{r' + \lambda \cdot d' : \lambda \in \mathbb{Z}\}$, that is, $mod(\varphi) \mid 2^u - 2^n \cdot r$ is equivalent to $d' \mid u - r'$. The procedure then returns $\chi(u) \coloneqq (u \geq C \wedge d' \mid u - r')$ and $\gamma(v) \coloneqq \psi[2^n \cdot r \,/\, 2^u]$ (see lines 14 and 15), where ψ (defined in line 1) is the system obtained from φ by removing all equalities and inequalities featuring 2^u.

Elaborating the arguments sketched in this section, we can prove that Algorithms 2–4 comply with their specifications.

▶ **Proposition 4.** *Algorithm 2 (LinExpSat) is a correct procedure for deciding the satisfiability of linear-exponential systems over* $\mathbb{N}$.

7 Complexity analysis

We analyse the procedure introduced in Sections 5 and 6 and show that it runs in non-deterministic polynomial time. This establishes Theorem 1 restricted to $\mathbb{N}$.

▶ **Proposition 5.** *Algorithm 2 (LinExpSat) runs in non-deterministic polynomial time.*

To simplify the analysis required to establish Proposition 5, we assume that Algorithms 2–4 store the divisibility constraints $d \mid \tau$ of a system φ in a way such that the coefficients and the constant of τ are always reduced modulo $mod(\varphi)$. For example, if $mod(\varphi) = 5$, the divisibility $5 \mid (7 \cdot x + 6 \cdot 2^x - 1)$ is stored as $5 \mid (2 \cdot x + 2^x + 4)$. Any divisibility can be updated in polynomial time to satisfy this requirement, so there is no loss of generality. Observe that Algorithm 1 (GaussQE) is an exception to this rule, as the divisibility constraints it introduces in line 12 must respect some structural properties throughout its execution. Thus, line 23 of Algorithm 3 (ElimMaxVar) implicitly reduces the output of GaussQE modulo $m = mod(\varphi)$ as appropriate. Since GaussQE runs in non-deterministic polynomial time, the reduction takes polynomial time too.

As is often the case for arithmetic theories, the complexity analysis of our algorithms requires tracking several parameters of linear-exponential systems. Below, we assume an ordering $\theta(\boldsymbol{x}) = (2^{x_n} \geq \cdots \geq 2^{x_0} = 1)$ and let φ be either a linear-exponential system or a quotient system induced by θ. Here are the parameters we track:

- The least common multiple of all divisors $mod(\varphi)$, defined as in Section 3.
- The number of equalities, inequalities and divisibility constraints in φ, denoted by $\#\varphi$. (Similarly, given a set T, we write $\#T$ for its cardinality.)
- The 1-norm $\|\varphi\|_1 \coloneqq \max\{\|\tau\|_1 : \tau \text{ is a term appearing in an (in)equality of } \varphi\}$. For linear-exponential terms, $\|\tau\|_1$ is defined in Section 3. For quotient terms τ induced by θ, the 1-norm $\|\tau\|_1$ is defined as the sum of the absolute values of all the coefficients and constants appearing in τ. The definition of $\|\varphi\|_1$ excludes integers appearing in divisibility constraints since, as explained above, those are already bounded by $mod(\varphi)$.

- The *linear norm* $\|\varphi\|_{\mathfrak{L}} \coloneqq \max\{\|\tau\|_{\mathfrak{L}} : \tau \text{ is a term appearing in an (in)equality of } \varphi\}$. For a linear-exponential term $\tau = \sum_{i=1}^{n} \left(a_i \cdot x_i + b_i \cdot 2^{x_i} + \sum_{j=1}^{n} c_{i,j} \cdot (x_i \bmod 2^{x_j})\right) + d$, we define $\|\tau\|_{\mathfrak{L}} \coloneqq \max\{|a_i|, |c_{i,j}| : i, j \in [1,n]\}$, that is, the maximum of all coefficients of x_i and $(x_i \bmod 2^{x_j})$, in absolute value. For a quotient term induced by θ, of the form $\tau = a \cdot 2^{x_n} + (c_1 \cdot x'_1 + \cdots + c_m \cdot x'_m + d) \cdot 2^{x_{n-1}} + b \cdot x_{n-1} + \rho(x_0, \ldots, x_{n-2}, \boldsymbol{z}')$, we define $\|\tau\|_{\mathfrak{L}} \coloneqq \max\big(|b|, \|\rho\|_{\mathfrak{L}}, \max\{|c_i| : i \in [1,m]\}\big)$, thus also taking into account the coefficients of the quotient variables $x'_1, \ldots, x'_m$.
- The set of the least significant terms $lst(\varphi, \theta)$ defined as $\big\{ \pm\rho : \rho \text{ is the least significant part of a term } \tau \text{ appearing in an (in)equality } \tau \sim 0 \text{ of } \varphi, \text{ with respect to } \theta \big\}$. We have already defined the notion of the least significant part for a quotient term induced by θ in Section 5. For a (non-quotient) linear-exponential system φ, the least significant part of a term $a \cdot 2^{x_n} + b \cdot x_n + \tau'(x_1, \ldots, x_{n-1}, \boldsymbol{z})$ is the term $b \cdot x_n + \tau'$.

Two observations are in order. First, the bit size of a system $\varphi(x_1, \ldots, x_n)$ (i.e., the number of bits required to write down φ) is in $O(\#\varphi \cdot n^2 \cdot \log(\max(\|\varphi\|_1, mod(\varphi), 2)))$. Second, together with the number of variables in the input, our parameters are enough to bound all guesses in the procedure. For instance, the value of $c \neq \star$ guessed in line 4 of Algorithm 4 (SolvePrimitive) can be bounded as $O(\log(\max(mod(\gamma), \|\chi\|_1)))$.

The analysis of the whole procedure is rather involved. Perhaps a good overall picture of this analysis is given by the evolution of the parameters at each iteration of the main **while** loop of LinExpSat, described in Lemma 6 below. This loop iterates at most n times, with n being the number of variables in the input system. Below, Φ stands for Euler's totient function, arising naturally because of the computation of multiplicative orders in SolvePrimitive.

▶ **Lemma 6.** *Consider the execution of* LinExpSat *on an input $\varphi(x_1, \ldots, x_n)$, with $n \geq 1$. For $i \in [0,n]$, let (φ_i, θ_i) be the pair of a system and ordering obtained after the ith iteration of the **while** loop of line 3, where $\varphi_0 = \varphi$ and θ_0 is the ordering guessed in line 2. Then, for every $i \in [0, n-1]$, φ_{i+1} has at most $n+1$ variables, and for every $\ell, s, a, c, d \geq 1$,*

$$\textit{if} \quad \begin{cases} \#lst(\varphi_i, \theta_i) & \leq \ell \\ \#\varphi_i & \leq s \\ \|\varphi_i\|_{\mathfrak{L}} & \leq a \\ \|\varphi_i\|_1 & \leq c \\ mod(\varphi_i) & \mid d \end{cases} \quad \textit{then} \quad \begin{cases} \#lst(\varphi_{i+1}, \theta_{i+1}) & \leq \ell + 2(i+2) \\ \#\varphi_{i+1} & \leq s + 6(i+2) + 2 \cdot \ell \\ \|\varphi_{i+1}\|_{\mathfrak{L}} & \leq 3 \cdot a \\ \|\varphi_{i+1}\|_1 & \leq 2^5 (i+3)^2 (c+2) + 4 \cdot \log(d) \\ mod(\varphi_{i+1}) & \mid \operatorname{lcm}(d, \Phi(\alpha_i \cdot d)) \end{cases}$$

*for some $\alpha_i \in [1, (3 \cdot a + 2)^{(i+3)^2}]$. The $(i+1)$st iteration of the **while** loop of line 3 runs in non-deterministic polynomial time in the bit size of φ_i.*

We iterate the bounds in Lemma 6 to show that, for every $i \in [0,n]$, the bit size of φ_i is polynomial in the bit size of the initial system φ. A challenge is to bound $mod(\varphi_i)$, which requires studying iterations of the map $x \mapsto \operatorname{lcm}(x, \Phi(\alpha \cdot x))$, where α is some positive integer. We show the following lemma:

▶ **Lemma 7.** *Let $\alpha \geq 1$ be in $\mathbb{N}$. Consider the integer sequence $b_0, b_1, \ldots$ given by the recurrence $b_0 \coloneqq 1$ and $b_{i+1} \coloneqq \operatorname{lcm}(b_i, \Phi(\alpha \cdot b_i))$. For every $i \in \mathbb{N}$, $b_i \leq \alpha^{2 \cdot i^2}$.*

Given Lemma 6, one can show $\alpha_j \leq (\|\varphi\|_{\mathfrak{L}} + 2)^{O(j^3)}$ for every $j \in [0, n-1]$. Then, since $mod(\varphi_0) = 1$, for a given $i \in [0, n-1]$ we apply Lemma 7 with $\alpha = \operatorname{lcm}(\alpha_0, \ldots, \alpha_i)$ to derive $mod(\varphi_{i+1}) \leq (\|\varphi\|_{\mathfrak{L}} + 2)^{O(i^6)}$. Once a polynomial bound for the bit size of every φ_i is established, Proposition 5 follows immediately from the last statement of Lemma 6.

8 Proofs of Theorem 1 and Theorem 2

In this section, we discuss how to reduce the task of solving linear-exponential systems over $\mathbb{Z}$ to the non-negative case, thus establishing Theorem 1. We also prove Theorem 2.

Solving linear-exponential systems over $\mathbb{Z}$ (proof of Theorem 1). Let $\varphi(x_1, \ldots, x_n)$ be a linear-exponential system $\varphi(x_1, \ldots, x_n)$ (without divisibility constraints). We can non-deterministically guess which variables will, in an integer solution $\boldsymbol{u} \in \mathbb{Z}^n$ of φ, assume a non-positive value. Let $I \subseteq [1, n]$ be the set of indices corresponding to these variables. Given $i \in I$, all occurrences of $(x \bmod 2^{x_i})$ in φ can be replaced with 0, by definition of the modulo operator. We can then replace each linear and exponentiated occurrence of x_i with $-x_i$. Let $\chi(\boldsymbol{x})$ be the system obtained from φ after these replacements.

The absolute value of all entries of $\boldsymbol{u}$ is a solution for χ over $\mathbb{N}$. However, χ might feature terms of the form 2^{-x_i} for some $i \in I$ and thus not be a linear-exponential system. We show how to remove such terms. Consider an inequality of the form $\tau \leq \sigma$, where the term τ contains no 2^{-x} and $\sigma \coloneqq \sum_{i \in I} a_i \cdot 2^{-x_i}$ with some a_i non-zero. Since each x_i is a non-negative integer, we have $\left|\sum_{i \in I} a_i \cdot 2^{-x_i}\right| \leq \sum_{i \in I} |a_i| =: B$. Therefore, in order to satisfy $\tau \leq \sigma$, any solution $\boldsymbol{v}$ of χ must be such that $\tau(\boldsymbol{v}) \leq B$. We can then non-deterministically add to χ either $\tau < -B$ or $\tau = g$, for some $g \in [-B, B]$.

Case $\tau < -B$. The inequality $\tau \leq \sigma$ is entailed by $\tau < -B$ and can thus be eliminated.

Case $\tau = g$ for some $g \in [-B, B]$. We replace $\tau \leq \sigma$ with $g \leq \sigma$, and multiply both sides of this inequality by $2^{\sum_{i \in I} x_i}$. The resulting inequality is rewritten as $g \cdot 2^z \leq \sum_{i \in I} a_i \cdot 2^{z_i}$, where z and all z_i are fresh variables (over $\mathbb{N}$) that are subject to the equalities $z = \sum_{i \in I} x_i$ and $z_i = \sum_{j \in I \setminus \{i\}} x_j$. We add these equalities to χ.

In the above cases we have removed from χ the inequality $\tau \leq \sigma$ in favour of inequalities and equalities only featuring linear-exponential terms. Strict inequalities $\tau < \sigma$ can be handled analogously; and for equalities $\tau = \sigma$ one can separately consider $\tau \leq \sigma$ and $-\tau \leq -\sigma$. The fresh variables z and z_i can be introduced once and reused for all inequalities.

Repeating the process above for each equality and inequality yields (in non-deterministic polynomial time) a linear-exponential system ψ that is satisfiable over $\mathbb{N}$ if and only if the input system φ is satisfiable over $\mathbb{Z}$. The satisfiability of ψ is then checked by calling LinExpSat. Hence, correctness and NP membership follow by Propositions 4 and 5, respectively. ◀

Deciding existential Büchi–Semenov arithmetic (proof of Theorem 2). Let φ be a formula in the existential theory of the structure $(\mathbb{N}, 0, 1, +, 2^{(\cdot)}, V_2(\cdot,\cdot), \leq)$ (i.e., Büchi–Semenov arithmetic). By De Morgan's laws, we can bring φ to negation normal form. Negated literals can then be replaced by positive formulae: $\neg V_2(\tau, \sigma)$ becomes $V_2(\tau, z) \wedge \neg(z = \sigma)$ where z is a fresh variable, $\neg(\tau = \sigma)$ becomes $(\tau < \sigma) \vee (\sigma < \tau)$, and $\neg(\tau \leq \sigma)$ becomes $\sigma < \tau$. Next, occurrences of $V_2(\cdot,\cdot)$ and $2^{(\cdot)}$ featuring arguments other than variables can be "flattened" by introducing extra (non-negative integer) variables: e.g., an occurrence of 2^τ can be replaced with 2^z, where z is fresh, subject to conjoining to the formula φ the constraint $z = \tau$. Lastly, recall that $V_2(x, y)$ can be rephrased in terms of the modulo operator via a linear-exponential system $2 \cdot y = 2^v \wedge 2 \cdot (x \bmod 2^v) = 2^v$, where v is a fresh variable.

After the above transformation, we obtain a formula ψ of size polynomial with respect to the original one. This formula is a positive Boolean combination of linear-exponential systems. A non-deterministic polynomial-time algorithm deciding ψ first (non-deterministically) rewrites each disjunction $\varphi_1 \vee \varphi_2$ occurring in ψ into either φ_1 or φ_2. After this step, each non-deterministic branch contains a linear-exponential system. The algorithm then calls LinExpSat. Correctness and NP membership then follow by Propositions 4 and 5. ◀

9 Future directions

We have presented a quantifier elimination procedure that decides in non-deterministic polynomial time whether a linear-exponential system has a solution over $\mathbb{Z}$. As a by-product, this result shows that satisfiability for existential Büchi–Semenov arithmetic belongs to NP. We now discuss further directions that, in view of our result, may be worth pursuing.

As mentioned in Section 2, the $\exists^*\forall^*$-fragment of Büchi–Semenov arithmetic is undecidable. Between the existential and the $\exists^*\forall^*$-fragments lies, in a certain sense, the optimisation problem: minimising or maximising a variable subject to a formula. It would be interesting to study whether the natural optimisation problem for linear-exponential systems lies within an optimisation counterpart of the class NP.

With motivation from verification questions, problems involving integer exponentiation have recently been approached with satisfiability modulo theories (SMT) solvers [12]. The algorithms developed in our paper may be useful to further the research in this direction.

Our work considers exponentiation with a single base. In a recent paper [17], Hieronymi and Schulz prove the first–order theory of $(\mathbb{N}, 0, 1, +, 2^{\mathbb{N}}, 3^{\mathbb{N}}, \leq)$ undecidable, where $k^{\mathbb{N}}$ is the predicate for the powers of k. Therefore, the first-order theories of the structures $(\mathbb{N}, 0, 1, +, V_2, V_3, \leq)$ and $(\mathbb{N}, 0, 1, +, 2^{(\cdot)}, 3^{(\cdot)}, \leq)$, which capture $2^{\mathbb{N}}$ and $3^{\mathbb{N}}$, are undecidable. Decidability for the existential fragments of all the theories in this paragraph is open.

Lastly, it is unclear whether there are interesting relaxed versions of linear-exponential systems, i.e., over $\mathbb{R}$ instead of $\mathbb{Z}$. Observe that, in the existential theory of the structure $(\mathbb{R}, 0, 1, +, 2^{(\cdot)}, \leq)$, the formula $x = 2^{y'+z'} \wedge y = 2^{y'} \wedge z = 2^{z'}$ defines the graph of the multiplication function $x = y \cdot z$ for positive reals. This "relaxation" seems then only to be decidable subject to (a slightly weaker version of) Schanuel's conjecture [25]. To have an unconditional result one may consider systems where only one variable occurs exponentiated. These are, in a sense, a relaxed version of (u, v)-primitive systems. Under this restriction, unconditional decidability was previously proved by Weispfenning [40].

A Theorem 1 holds for any positive integer base given in binary

Algorithm 2 and Algorithm 3 are agnostic with regard to the choice of the base $k \geq 2$. They do not inspect k and see exponential terms k^x as purely syntactic objects. Their logic does not need to be updated to accommodate a different base. To add support for a base k given in input to these two algorithms, it suffices to replace in the pseudocode every 2 with k.

Algorithm 4 is different, as it uses properties of exponentiation. In that algorithm, line 2 must be updated as follows. The pair (d, n) is redefined to be such that d is the largest integer coprime with k dividing $mod(\gamma)$, and k^n is the smallest power of k divisible by $\frac{mod(\gamma)}{d}$. For example, in the case when $k = 6$ and $mod(\gamma) = 60$, we obtain $d = 5$ and $n = 2$, because 36 is the smallest power of 6 divisible by $\frac{60}{5} = 12$. It is clear that $n \leq \lceil \log(mod(\gamma)) \rceil$, and the pair (d, n) can be computed in deterministic polynomial time.

Apart from this update, it suffices to replace every occurrence of $2^n \cdot r$ with $\frac{mod(\varphi)}{d} \cdot r$, and every remaining occurrence of 2 with k (except for the constant 2 appearing in the expression $3 + 2 \cdot \lceil \log_k(\frac{|b|+|c|+1}{|a|}) \rceil$). This means that the discrete logarithm problems of lines 11–13 must be solved with respect to k instead of 2 (but this can still be done in non-deterministic polynomial time). No other change is necessary.

Finite-Memory Strategies for Almost-Sure Energy-MeanPayoff Objectives in MDPs

Mohan Dantam

Richard Mayr
School of Informatics, University of Edinburgh, UK

Abstract

We consider finite-state Markov decision processes with the combined Energy-MeanPayoff objective. The controller tries to avoid running out of energy while simultaneously attaining a strictly positive mean payoff in a second dimension.

We show that *finite memory* suffices for almost surely winning strategies for the Energy-MeanPayoff objective. This is in contrast to the closely related Energy-Parity objective, where almost surely winning strategies require infinite memory in general.

We show that exponential memory is sufficient (even for deterministic strategies) and necessary (even for randomized strategies) for almost surely winning Energy-MeanPayoff. The upper bound holds even if the strictly positive mean payoff part of the objective is generalized to multidimensional strictly positive mean payoff.

Finally, it is decidable in pseudo-polynomial time whether an almost surely winning strategy exists.

1 Introduction

Background. Markov decision processes (MDPs) are a standard model for dynamic systems that exhibit both stochastic and controlled behaviour [28]. MDPs play a prominent role in many domains, e.g., artificial intelligence and machine learning [32, 30], control theory [5, 1], operations research and finance [31, 23, 9, 29], and formal verification [2, 31, 20, 14, 3, 11].

An MDP is a directed graph where states are either controlled or random. If the current state is controlled then the controller can choose a distribution over all possible successor states. If the current state is random then the next state is chosen according to a fixed probability distribution. One assigns numeric rewards to transitions (and this can be generalized to multidimensional rewards). Moreover, priorities (aka colours), encoded by bounded non-negative numbers, are assigned to states. By fixing a strategy for the controller and an initial state, one obtains a probability space of runs of the MDP. The goal of the controller is to optimize the expected value of some objective function on the runs.

The *strategy complexity* of a given objective is the amount of memory (and randomization) needed for an optimal (resp. ε-optimal) strategy. Common cases include memoryless strategies, finite-memory strategies, Markov strategies (using a discrete clock, aka step counter), and general infinite-memory strategies.

Related work. The Parity, MeanPayoff and Energy objectives have been extensively studied in the formal verification community. A run satisfies the (min-even) *Parity objective* iff the minimal priority that appears infinitely often in the run is even. It subsumes all ω-regular objectives, and in particular safety, liveness, fairness, etc. The *MeanPayoff objective* requires that the limit average reward per transition along a run is positive (resp. non-negative in some settings). MeanPayoff objectives go back to a 1957 paper by Gillette [21] and have been widely studied, due to their relevance for efficient control. The *Energy objective* [10] requires that the accumulated reward at any time in a run stays above some finite threshold (typically 0). The intuition is that a controlled system has some finite initial energy level that must never become depleted.

Combinations of these objectives have also been studied, where the runs need to satisfy several of the above conditions simultaneously.

The existence of almost surely winning strategies for *MeanPayoff-Parity* in MDPs is decidable in polynomial time [12]. These strategies require only finite memory for MeanPayoff > 0 [22], but infinite memory for MeanPayoff ≥ 0 [13].

The existence of almost surely winning strategies for *Energy-Parity* in MDPs is decidable in $\mathsf{NP} \cap \mathsf{coNP}$ and in pseudo-polynomial time [25]. (The $\mathsf{NP} \cap \mathsf{coNP}$ upper bound holds even for turn-based stochastic games [26].) Almost surely winning strategies in MDPs require only finite memory in the special case of Energy-Büchi [12], but infinite memory for Energy-co-Büchi and thus for Energy-Parity [25]. However, ε-optimal strategies for Energy-Parity require only finite (at most doubly exponential) memory, and the value can be effectively approximated in doubly exponential time (even for turn-based stochastic games) [17].

The *Energy-MeanPayoff* objective is similar to Energy-Parity, but replaces the Parity part by a MeanPayoff objective for a second reward dimension. I.e., one considers an MDP with 2-dimensional transition rewards, where the Energy condition applies to the first dimension and the MeanPayoff condition applies to the second dimension. (It can be generalized to higher dimensions d, where the MeanPayoff condition applies to all dimensions $2, 3, \ldots, d$.) This might look like a direct generalization of the Energy-Parity objective, since Parity games are reducible to MeanPayoff games [27, 24]. However, this reduction does not work in the context of these combined objectives when one considers stochastic systems like MDPs; see below. Non-stochastic Energy-MeanPayoff games have been studied in [8].

A sightly different objective has been studied in [16] who consider MDPs with d-dimensional rewards, where $d = d_1 + d_2$. The objective requires a strictly positive MeanPayoff *surely* in the first d_1 dimensions, and *almost surely* in the remaining d_2 dimensions. This objective is strictly stronger than Energy-MeanPayoff. E.g., a MeanPayoff of zero in the first dimension may or may not satisfy the Energy objective, but it never satisfies the objective in [16].

The objective studied in [6] aims to maximize the expected MeanPayoff (rather than the probability of it being strictly positive) while satisfying the energy constraint. However, unlike in our work, the reward function has a single dimension (i.e., both criteria apply to the same value) and ε-optimal strategies can require infinite memory.

Our contribution. We consider the Energy-MeanPayoff objective in MDPs with d-dimensional rewards. The first dimension needs to satisfy the Energy condition (never drop below 0), while each other dimension needs to have a *strictly* positive MeanPayoff. We show that

almost surely winning strategies for Energy-MeanPayoff require only *finite* memory. [1] This is in contrast to the Energy-Parity objective where almost surely winning strategies require infinite memory in general [25, Page 4] (even for the simpler Energy-co-Büchi objectives). This also shows that Energy-Parity is not reducible to Energy-MeanPayoff in MDPs, unlike the reduction from Parity to MeanPayoff in [27, 24].

We show that almost surely winning strategies for Energy-MeanPayoff, if they exist, can be chosen as deterministic strategies with an exponential number of memory modes. The crucial property is that it suffices to remember the stored energy only up to some exponential upper bound. A small counterexample shows the corresponding exponential lower bound. Even for randomized strategies, an exponential number of memory modes is required, and this holds even for the case of small transition rewards in $\{-1, 0, +1\}$.

Although almost surely winning strategies are "exponentially large" in this sense, their existence is still decidable in pseudo-polynomial time; cf. Section 7.

2 Preliminaries

A *probability distribution* over a countable set S is a function $f\colon S \to [0,1]$ with $\sum_{s\in S} f(s) = 1$. $\mathsf{supp}(f) \stackrel{\text{def}}{=} \{s \mid f(s) > 0\}$ denotes the support of f and $\mathcal{D}(S)$ is the set of all probability distributions over S. Given an alphabet Σ, let Σ^ω and Σ^* (Σ^+) denote the set of infinite and finite (non-empty) sequences over Σ, respectively. Elements of Σ^ω or Σ^* are called words.

MDPs and Markov chains. A *Markov Decision Process* (MDP) is a controlled stochastic directed graph $\mathcal{M} \stackrel{\text{def}}{=} (S, S_\Box, S_\bigcirc, E, P, \boldsymbol{r})$ where the set of vertices S (also called states) is partitioned into the states $S_\Box$ of the player $\Box$ (*Maximizer*), and chance vertices (aka random states) $S_\bigcirc$. Let $E \subseteq S \times S$ be the transition relation. We write $s \longrightarrow s'$ if $(s, s') \in E$ and assume that $\mathsf{Succ}(s) \stackrel{\text{def}}{=} \{s' \mid sEs'\} \neq \emptyset$ for every state s. The *probability function* P assigns each random state $s \in S_\bigcirc$ a distribution over its successor states, i.e., $P(s) \in \mathcal{D}(\mathsf{Succ}(s))$. We extend the domain of P to $S^*S_\bigcirc$ by $P(\rho s) \stackrel{\text{def}}{=} P(s)$ for all $\rho s \in S^+S_\bigcirc$. A *Markov chain* is an MDP with only random states, i.e., $S_\Box = \emptyset$. In this paper we consider finite-state MDPs, i.e., the set of states S is finite.

Strategies. A *run* is an infinite sequence $s_0 s_1 \ldots \in S^\omega$ such that $s_i \longrightarrow s_{i+1}$ for all $i \geq 0$. A *path* is a finite prefix of a run. Let $\mathit{Runs}(\mathcal{M}) \stackrel{\text{def}}{=} \left\{\rho = (q_i)_{i\in\mathbb{N}} \mid q_i \longrightarrow q_{i+1}\right\}$ denote the set of all possible runs. A strategy of the player $\Box$ is a function $\sigma\colon S^*S_\Box \to \mathcal{D}(S)$ that assigns to every path $ws \in S^*S_\Box$ a probability distribution over the successors of s. If these distributions are always Dirac then the strategy is called *deterministic* (aka pure), otherwise it is called *randomized* (aka mixed). The set of all strategies of player $\Box$ in $\mathcal{M}$ is denoted by $\Sigma^{\mathcal{M}}$. A run/path $s_0 s_1 \ldots$ is compatible with a strategy σ if $s_{i+1} \in \mathsf{supp}(\sigma(s_0 \ldots s_i))$ whenever $s_i \in S_\Box$. Finite-memory strategies are a subclass of strategies using a finite set M of memory modes. A function $\mathsf{nxt} : \mathsf{M} \times S_\Box \mapsto \mathcal{D}(S)$ chooses a (distribution over) successor states based on the current memory mode and state and $\mathsf{upd} : \mathsf{M} \times E \mapsto \mathcal{D}(\mathsf{M})$ updates the memory mode upon observing a transition. Let $\sigma[\mathsf{m}]$ denote the finite-memory strategy σ starting in

[1] Our results do *not* carry over to Energy-MeanPayoff objectives with *non-strict* inequalities where one just requires a MeanPayoff ≥ 0 almost surely. This needs infinite memory even for the case of $d = 2$, i.e., one energy-dimension and one MeanPayoff-dimension. It suffices to modify the counterexample for Energy-co-Büchi from [25, Page 4] such that a visit to a state with unfavourable colour incurs a reward of -1 in the MeanPayoff-dimension.

memory mode m. The set of all finite-memory strategies in $\mathcal{M}$ is denoted by $\Sigma_f^{\mathcal{M}}$. Strategies with memory $|\mathsf{M}| = 1$ are called *memoryless*. Memoryless deterministic (resp. randomized) strategies are called MD (resp. MR). By fixing some finite-memory strategy σ from some initial state in a finite-state MDP $\mathcal{M}$, we obtain a finite-state Markov chain, denoted by $\mathcal{M}^\sigma$.

Measure. An MDP $\mathcal{M}$ with initial state s_0 and strategy σ yields a probability space $(s_0 S^\omega, \mathcal{F}_{s_0}, \mathcal{P}^{\mathcal{M}}_{\sigma,s_0})$ where $\mathcal{F}_{s_0}$ is the σ-algebra generated by the cylinder sets $s_0 s_1 \dots s_n S^\omega$ for $n \geq 0$. The probability measure $\mathcal{P}^{\mathcal{M}}_{\sigma,s_0}$ is first defined on the cylinder sets. For $\rho = s_0 \dots s_n$, let $\mathcal{P}^{\mathcal{M}}_{\sigma,s_0}(\rho) \stackrel{\text{def}}{=} 0$ if ρ is not compatible with σ and otherwise $\mathcal{P}^{\mathcal{M}}_{\sigma,s_0}(\rho S^\omega) \stackrel{\text{def}}{=} \prod_{i=0}^{n-1} \tau(s_0 \dots s_i)(s_{i+1})$ where τ is σ or P depending on whether $s_i \in S_\Box$ or $S_\bigcirc$, respectively. If $\mathcal{M}$ is a Markov chain then there is only a single strategy, and we simply write $\mathcal{P}^{\mathcal{M}}_{s_0}$. By Carathéodory's extension theorem [4], this defines a unique probability measure on the σ-algebra. Given some reward function $v : s_0 S^\omega \to \mathbb{R}$, we write $\mathcal{E}(.)$ for the expectation w.r.t. $\mathcal{P}$ and v.

Objectives. General objectives are defined by real-valued measurable functions. However, we mostly consider indicator functions of measurable sets. Hence, our objectives can be described by measurable subsets $\mathtt{O} \subseteq S^\omega$ of runs starting at a given initial state. By $\mathcal{P}^{\mathcal{M}}_{\sigma,s}(\mathtt{O})$ we denote the payoff under σ, i.e., the probability that runs from s belong to $\mathtt{O}$. The value of a state is defined as $\mathtt{val}^{\mathcal{M}}_{\mathtt{O}}(s) \stackrel{\text{def}}{=} \sup_{\sigma \in \Sigma^{\mathcal{M}}} \mathcal{P}^{\mathcal{M}}_{\sigma,s}(\mathtt{O})$. For $\varepsilon > 0$ and state s, a strategy $\sigma \in \Sigma^{\mathcal{M}}$ is ε-optimal iff $\mathcal{P}^{\mathcal{M}}_{\sigma,s}(\mathtt{O}) \geq \mathtt{val}^{\mathcal{M}}_{\mathtt{O}}(s) - \varepsilon$. A 0-optimal strategy is called *optimal*. An MD/MR strategy is called *uniformly* ε-optimal (resp. uniformly optimal) if it is so from every start state. An optimal strategy from s is called *almost surely winning* if $\mathtt{val}^{\mathcal{M}}_{\mathtt{O}}(s) = 1$. By $\mathtt{AS}(\mathtt{O})$ (resp. $\mathtt{AS}_f(\mathtt{O})$) we denote the set of states that have an almost surely winning strategy (resp. an almost surely winning finite-memory strategy) for objective $\mathtt{O}$. For ease of presentation, we drop subscripts and superscripts wherever possible if they are clear from the context.

We use the syntax and semantics of the LTL operators [15] F (eventually), G (always) and X (next) to specify some conditions on runs. A reachability objective is defined by a set of target states $T \subseteq S$. A run $\rho = s_0 s_1 \dots$ belongs to $\mathsf{F}\, T$ iff $\exists i \in \mathbb{N}\, s_i \in T$. Similarly, ρ belongs to $\mathsf{F}^{\leq n} T$ (resp. $\mathsf{F}^{\geq n} T$) iff $\exists i \leq n$ (resp. $i \geq n$) such that $s_i \in T$. Dually, the safety objective $\mathsf{G}\, T$ consists of all runs which never leave T. We have $\mathsf{G}\, T = \neg \mathsf{F} \neg T$.

Energy/Reward/Counter-based objectives. Let $r : E \to \{-R, \dots, 0, \dots, R\}$ be a bounded function that assigns rewards to transitions. Depending on context, the sum of these rewards in a path can be viewed as energy, cost/profit or a counter. If $s \longrightarrow s'$ and $r((s,s')) = c$, we write $s \xrightarrow{c} s'$. Let $\rho = s_0 \xrightarrow{c_0} s_1 \xrightarrow{c_1} \dots$ be a run. We say that ρ satisfies

1. the *k-energy* objective $\mathsf{EN}(k)$ iff $\left(k + \sum_{i=0}^{n-1} c_i\right) \geq 0$ for all $n \geq 0$.
2. the *l-storage condition* $\mathtt{Infix}(l)$ if $l + \sum_{i=m}^{n-1} c_i \geq 0$ holds for every infix $s_m \xrightarrow{c_m} s_{m+1} \dots s_n$ of the run. Let $\mathsf{ST}(k,l)$ denote the set of runs that satisfy both the k-energy and the l-storage condition. Let $\mathsf{ST}(k) \stackrel{\text{def}}{=} \bigcup_l \mathsf{ST}(k,l)$. Clearly, $\mathsf{ST}(k) \subseteq \mathsf{EN}(k)$.
3. *Mean payoff* $\mathtt{MP}(\rhd c)$ for some constant $c \in \mathbb{R}$ iff $\left(\liminf_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} c_i\right) \rhd\ c$ for $\rhd \in \{<, \leq, =, \geq, >\}$.

A different way to consider the energy objective is to encode the energy level (the sum of the transition weights so far) into the state space and then consider the obtained infinite-state game with a safety objective.

An objective $\mathtt{O}$ is called *shift-invariant* iff for all finite paths ρ and plays $\rho' \in S^\omega$, we have $\rho\rho' \in \mathtt{O} \iff \rho' \in \mathtt{O}$. Mean payoff objectives are shift-invariant, but energy and storage/infix objectives are not.

Multidimensional reward-based objectives. Let $\mathbb{N}, \mathbb{Q}, \mathbb{R}$ denote the set of positive integers, rationals and reals respectively. For a d-dimensional real vector $\boldsymbol{\mu}$, let μ_i denote the i^{th} component of $\boldsymbol{\mu}$ for $1 \leq i \leq d$. Given two vectors $\boldsymbol{\mu}, \boldsymbol{\nu} \in \mathbb{R}^d$, $\sim \in \{<, \leq, >, \geq, =\}$ we say $\boldsymbol{\mu} \sim \boldsymbol{\nu}$ if $\mu_i \sim \nu_i$ for every i. In particular, $\boldsymbol{\mu} > \mathbf{0}$ means that *every* component of $\boldsymbol{\mu}$ is strictly greater than 0. For a multidimensional reward function $\boldsymbol{r} : E \to [-R, R]^d$, we can consider any boolean combination of reward based objectives using any components of $\boldsymbol{r}$. For instance, $\mathtt{O}_1 = \mathtt{EN}_1(k) \cap \mathtt{MP}_2(> 0)$ denotes the objective that contains all runs that satisfy $\mathtt{EN}(k)$ in the 1^{st} dimension and $\mathtt{MP}(> 0)$ in the 2^{nd} one. We denote conjunctions of the same objective across different dimensions in vectorized form, with the dimension information in the subscript. Therefore, $\mathtt{EN}_{[a,b]}(\boldsymbol{k}) \cap \mathtt{MP}_{[c,d]}(\boldsymbol{> x})$ denotes the runs where the $\mathtt{EN}_i(k_i)$ objective is satisfied for each $i \in [a, b]$ and the $\mathtt{MP}_j(> x_j)$ objective is satisfied for each $j \in [c, d]$. Given an infinite run $\rho = s_0 \xrightarrow{\boldsymbol{c_0}} s_1 \xrightarrow{\boldsymbol{c_1}} \ldots$, let $X_n(\rho) \stackrel{\text{def}}{=} s_n$ denote the n-th state. Let $\boldsymbol{Y_n}$ be the sum of the rewards in the first n steps, i.e., $\boldsymbol{Y_n}(\rho) \stackrel{\text{def}}{=} \sum_{i=0}^{n-1} \boldsymbol{c_i}$. These become random variables once an initial distribution and a strategy are fixed.

Size of an instance. Given an MDP $\mathcal{M} = (S, S_\Box, S_\bigcirc, E, P, \boldsymbol{r})$ with reward function $\boldsymbol{r} : E \to [-R, R]^d$, its size $|\mathcal{M}|$ is the number of bits used to describe it. Similarly for $|P|$. Transition probabilities and rewards can thus be stored in binary. We call a size pseudo-polynomial in $|\mathcal{M}|$ if it is polynomial for the case where R is "small", i.e., if R is given in unary.

3 The Main Result

▶ **Theorem 1.** *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, E, P, \boldsymbol{r})$ be an MDP with d-dimensional rewards on the edges $\boldsymbol{r} : E \to [-R, R]^d$. For the multidimensional Energy-MeanPayoff objective $\mathtt{EN}_1(k) \cap \mathtt{MP}_{[2,d]}(\boldsymbol{> 0})$ the following properties hold.*

1. *The existence of an almost-surely winning strategy implies the existence of an almost-surely winning finite-memory strategy.*
2. *Moreover, a deterministic strategy with an exponential number of memory modes is sufficient.*
3. *An exponential (in $|P|$) number of memory modes is necessary in general, even for randomized strategies, even for $|S| = 5$, $d = 2$ and $R = 1$.*

In the following three sections we prove items 1.,2.,3. of Theorem 1, respectively.

Here we sketch the main idea for the upper bound. Except in a special corner case where the energy fluctuates only in a bounded region, almost-surely winning strategies for Energy-MeanPayoff can be chosen among some particular strategies that alternate between two modes, playing two different memoryless strategies. This alternation keeps the balance between the Energy-part and the MeanPayoff-part of the objective. This is similar to almost-surely winning strategies for the Energy-Parity objective in [25]. In one mode, one plays a randomized memoryless strategy that almost surely yields a positive mean payoff in all dimensions (in case of Energy-Parity, instead of mean payoff it satisfies Parity almost surely). This is called the *Gain* phase. Whenever the energy level (the cumulative reward in dimension 1) gets dangerously close to zero, one switches to the other mode and plays a different memoryless strategy that focuses exclusively on getting the energy level up again, while temporarily neglecting the other part of the objective (Parity or Mean payoff, respectively). This is called a *Bailout*. Once the energy level is sufficiently high, one switches back to the Gain phase again. The crucial property is that, except in a null set, only finitely many Bailouts are required, and thus the temporary neglect of the second part of the objective does not matter in the long run. Such a strategy uses infinite memory,

because it needs to remember the unbounded energy level. For Energy-Parity (and even Energy-co-Büchi) this cannot be avoided and finite-memory strategies do not work [25]. However, for Energy-MeanPayoff one can relax the requirements somewhat. Suppose that one records the stored energy only up to a certain bound b, i.e., one forgets about potential excess energy above b. In that case, one might have to do infinitely many Bailouts with high probability, most of which are unnecessary (but one does not know which ones). However, for a sufficiently large bound b, these superfluous Bailouts occur so infrequently that they do not compromise the MeanPayoff-part of the objective. The critical part of the proof is to show this property and an upper bound on b. Once this is established, one obtains a finite-memory strategy, because it suffices to record the energy level only in the range $[0, b]$ (plus one extra bit of memory to record the current phase, Gain or Bailout).

Note that the argument above is different from the one that justifies finite-memory ε-optimal strategies for *Energy-Parity* in [17]. These also record the energy only in a bounded region, but stop doing Bailouts after the upper bound has been visited. I.e., they do too few Bailouts, and thus incur an ε-chance of losing. In contrast, our almost-surely winning strategies for Energy-MeanPayoff rather do too many Bailouts, but sufficiently infrequently such that they don't compromise the objective.

4 Proof of Item 1

W.l.o.g, we assume that every state in $\mathcal{M}$ has an almost surely winning strategy for Energy-MeanPayoff for some initial energy level. (Otherwise, consider a suitably restricted sub-MDP.) For conciseness, we denote the objective by $\mathtt{O}(k) \stackrel{\text{def}}{=} \mathtt{EN}_1(k) \cap \mathtt{MP}_{[\mathbf{2},d]}(\mathbf{> 0})$. Let

$$\mathtt{Win}(s) \stackrel{\text{def}}{=} \{k \mid s \in \mathtt{AS}(\mathtt{O}(k))\}, \quad i_s \stackrel{\text{def}}{=} \min(\mathtt{Win}(s))$$

denote the possible initial energy levels and the minimum initial energy level such that one can win almost surely from state s. In particular, i_s is well defined by our assumption on $\mathcal{M}$.

Towards a contradiction, assume that not all configurations are winnable with a finite-memory strategy. I.e., let $\mathtt{Win}_f(s) \stackrel{\text{def}}{=} \{k \mid s \in \mathtt{AS}_f(\mathtt{O}(k))\}$ denote the energy levels from which one can win almost surely with a *finite-memory* strategy from s, and assume that there is a state $s^\dagger$ such that $i_{s^\dagger} \notin \mathtt{Win}_f(s^\dagger)$. We then construct a finite-memory winning strategy from $s^\dagger$ for $\mathtt{O}(i_{s^\dagger})$, leading to a contradiction. Similar to i_s, let f_s denote the minimal k such that $k \in \mathtt{Win}_f(s)$ and ∞ if there is no such k.

▶ **Definition 2.** *We construct a new MDP $\mathcal{M}^*$ which abstracts away all the $\mathtt{Win}_f$ configurations. At every state s, the player gets the option to enter a winning sink state if the energy level is sufficiently large to win with finite memory, i.e., if the current energy level is at least f_s. The states of the MDP $\mathcal{M}^*$ will have two copies of each state s of $\mathcal{M}$, namely s and s'. Moreover, we add a new state s_{win}. All states s' are controlled by $\Box$ and every step $s_1 \longrightarrow s$ in the original MDP $\mathcal{M}$ is now mapped to a step $s_1 \longrightarrow s'$ with the same reward (and the same probability if s_1 was a random state). In s', the player has two choices: he can either go to s with reward $\mathbf{0}$ or go to s_{win} with reward $(-f_s, \mathbf{0})$. The latter choice is only available if $f_s < \infty$. s_{win} is a winning sink where $s_{win} \longrightarrow s_{win}$ with reward $\mathbf{1}$, i.e., reward $+1$ in all dimensions.*

The following lemma shows that the existence of almost surely winning (finite-memory) strategies coincides in $\mathcal{M}^*$ and $\mathcal{M}$.

▶ **Lemma 3.** *Let $s \in S$ and $k \in \mathbb{N}$, and consider the objective $\mathtt{O}(k)$. There exists an almost surely winning strategy σ^* from s in $\mathcal{M}^*$ if and only if there exists an almost surely winning strategy σ from s in $\mathcal{M}$. Moreover, if σ^* is finite-memory then σ can be chosen as finite-memory, and vice-versa.*

Proof. Towards the "only if" direction, let σ^* be a strategy from s in $\mathcal{M}^*$ that is almost surely winning for $\mathtt{O}(k)$. We define a strategy σ from s in $\mathcal{M}$ that plays as follows. First σ imitates the moves of σ^* until (if ever) σ^* chooses a move $s'_1 \to s_{\text{win}}$ with non-zero probability at some state s'_1. This is possible, since any finite path in $\mathcal{M}^*$ that does not contain s_{win} can be bijectively mapped to a path in $\mathcal{M}$. The only difference is that paths in $\mathcal{M}^*$ contain extra steps via primed states, which are skipped in the paths in $\mathcal{M}$. Moreover, the transition probabilities at random states coincide in $\mathcal{M}^*$ and $\mathcal{M}$. If σ^* chooses a move $s'_1 \to s_{\text{win}}$ with non-zero probability at some state s'_1 then the current energy level must be $\geq f_{s_1}$, because σ^* satisfies the energy objective almost surely (and thus even surely). Thus, in $\mathcal{M}$, there exists an almost surely winning finite-memory strategy $\hat{\sigma}$ for $\mathtt{O}(f_{s_1})$ from s_1. In this situation σ continues by playing $\hat{\sigma}$ from s_1. Therefore, σ satisfies the energy objective surely. Moreover, by shift invariance and the properties of $\hat{\sigma}$, it also satisfies the Mean payoff objective almost surely. Thus, σ satisfies $\mathtt{O}(k)$ almost surely. Finally, if σ^* is finite-memory then so is σ, because $\hat{\sigma}$ is also finite-memory.

Towards the "if direction, let σ be a strategy from s in $\mathcal{M}$ that is almost surely winning for $\mathtt{O}(k)$. We define a strategy σ^* from s in $\mathcal{M}^*$ that imitates the moves of σ. Moreover, at primed states q' it always goes to q (and never to s_{win}). Since the probabilities at random states coincide in $\mathcal{M}^*$ and $\mathcal{M}$, also the probabilities of the induced paths coincide. The only difference is that the runs in $\mathcal{M}^*$ contain extra steps via primed states and these extra steps carry reward zero. Thus, the mean payoff of a run in $\mathcal{M}^*$ is $1/2$ the mean payoff of the corresponding run in $\mathcal{M}$. However, this does not affect the property that the mean payoff is > 0 almost surely in either MDP. Thus, σ^* satisfies $\mathtt{O}(k)$ almost surely. Finally, if σ is finite-memory then so is σ^*. ◀

The next lemma shows that, in $\mathcal{M}^*$, it is impossible to satisfy Energy-MeanPayoff from s with arbitrarily high probability, unless one also allows arbitrarily large fluctuations in the energy level, or $f_s = i_s$. (Recall that f_s, i_s are defined relative to $\mathcal{M}$.)

▶ **Lemma 4.** *For every state s with $f_s > i_s$ and every $\ell \in \mathbb{N}$, there exists a $\delta_\ell > 0$ such that* $\mathtt{val}^{\mathcal{M}^*}_{\mathtt{O}(i_s) \cap \mathtt{Infix}_1(\ell)}(s) \leq 1 - \delta_\ell$.

Proof. Towards a contradiction, assume that $\mathtt{val}^{\mathcal{M}^*}_{\mathtt{O}(i_s) \cap \mathtt{Infix}_1(\ell)}(s) = 1$ for some ℓ.

$\mathtt{O}(i_s) \cap \mathtt{Infix}_1(\ell) = \mathtt{EN}_1(i_s) \cap \mathtt{MP}_{[\mathbf{2},d]}(\mathbf{> 0}) \cap \mathtt{Infix}_1(\ell) = \mathtt{ST}_1(i_s, \ell) \cap \mathtt{MP}_{[\mathbf{2},d]}(\mathbf{> 0})$. Therefore, we have $\mathtt{val}^{\mathcal{M}^*}_s\big(\mathtt{ST}_1(i_s, \ell) \cap \mathtt{MP}_{[\mathbf{2},d]}(\mathbf{> 0})\big) = 1$. Below we prove that this objective has a finite-memory almost-surely winning strategy σ in $\mathcal{M}^*$. Consider a modified MDP $\mathcal{M}^*_1$ that encodes the energy level up to $i_s + \ell$ in the states. A step exceeding the upper energy bound $i_s + \ell$ results in a truncation to $i_s + \ell$, while a step leading to a negative energy leads to a losing sink. There exists a memoryless randomized (MR) strategy σ_1 in $\mathcal{M}^*_1$ from state (s, i_s) that wins $\mathtt{MP}_{[\mathbf{2},d]}(\mathbf{> 0})$ almost surely, by Lemma 6. We can then carry σ_1 back to $\mathcal{M}^*$ as a finite-memory strategy σ with $i_s + \ell + 1$ memory modes such that $\mathcal{P}^{\mathcal{M}^*}_{\sigma,s}\big(\mathtt{ST}_1(i_s, \ell) \cap \mathtt{MP}_{[\mathbf{2},d]}(\mathbf{> 0})\big) = 1$. By set inclusion, $\mathcal{P}^{\mathcal{M}^*}_{\sigma,s}(\mathtt{O}(i_s)) = 1$. By Lemma 3, there also exists a finite-memory strategy from s in $\mathcal{M}$ that is almost surely winning for $\mathtt{O}(i_s)$. This implies $f_s = i_s$, a contradiction to our assumption $f_s > i_s$. Hence, we obtain $\delta_\ell \overset{\text{def}}{=} 1 - \mathtt{val}^{\mathcal{M}^*}_{\mathtt{O}(i_s) \cap \mathtt{Infix}_1(\ell)}(s) > 0$. ◀

The following three lemmas show that almost surely winning strategies for Energy-MeanPayoff can be found by combining two different memoryless strategies for the simpler `Bailout` and `Gain` objectives.

First, we define the objective $\mathtt{Bailout}(k) \overset{\text{def}}{=} \mathtt{EN}_1(k) \cap \mathtt{MP}_1(> 0)$. Let $i_s^{\mathtt{Bailout}}$ denote the minimal energy value k with which one can almost surely satisfy $\mathtt{Bailout}(k)$ when starting from state s (or ∞ if it does not exist).

▶ **Lemma 5** ([6, Lemma 3]). *Let $\mathcal{M}$ be an MDP. If $s \in \mathtt{AS}(\mathtt{Bailout}(k))$ for some $k \in \mathbb{N}$ then $i_s^{\mathtt{Bailout}} \leq 3 \cdot |\mathcal{M}| \cdot R$. Moreover, there exists a uniform MD strategy $\sigma^*_{\mathtt{Bailout}}$ which is almost surely winning $\mathtt{Bailout}(k)$ from every state $s \in \mathtt{AS}(\mathtt{Bailout}(k))$.*

We define the `Gain` objective as $\mathtt{MP}_{[1,d]}(> 0)$. The following lemma shows that an almost surely winning strategy $\sigma^*_{\mathtt{Gain}}$ for this objective can be chosen as memoryless randomized.

▶ **Lemma 6** ([7, Proposition 5.1]). *There is a uniform MR strategy $\sigma^*_{\mathtt{Gain}}$ which is almost surely winning for `Gain` (or any subset of dimensions) from all states $s \in \mathtt{AS}(\mathtt{Gain})$.*

A difference between $\mathcal{M}^*$ and $\mathcal{M}$ is that if one can almost surely win Energy-MeanPayoff in $\mathcal{M}^*$ then one can also push the energy level arbitrarily high. This does not always hold in $\mathcal{M}$. (Consider, e.g., a single-state Markov chain with a single loop with reward 0 in the 1^{st} dimension and $+1$ in all other dimensions.) The difference comes from the loop at state s_{win} in $\mathcal{M}^*$ which has a strictly positive reward in all dimensions. Thus, the following lemma only holds for $\mathcal{M}^*$.

▶ **Lemma 7.** *In $\mathcal{M}^*$, there are two uniform memoryless strategies $\sigma^*_{\mathtt{Bailout}}$ and $\sigma^*_{\mathtt{Gain}}$ which, starting from any state $s \in \mathtt{AS}(\mathtt{0}(k))$, almost surely satisfy $\mathtt{Bailout}(k)$ and `Gain`, respectively.*

Proof. Let $s \in \mathtt{AS}(\mathtt{0}(k))$. We show that $s \in \mathtt{AS}(\mathtt{Bailout}(k))$ and $s \in \mathtt{AS}(\mathtt{Gain})$. The existence of the memoryless strategies $\sigma^*_{\mathtt{Bailout}}$ and $\sigma^*_{\mathtt{Gain}}$ then follows from Lemma 5 and Lemma 6, respectively.

We assumed that all states s in $\mathcal{M}$ admit an almost surely winning strategy for Energy-MeanPayoff. By Lemma 3, this also holds for all states q in $\mathcal{M}^*$. Let $\sigma^\sharp_q$ denote an almost surely winning strategy from q for $\mathtt{0}(i_q)$ in $\mathcal{M}^*$ (without restrictions on memory).

Recall from Section 2 that the random variable X_t denotes the state at time t, and Y_t denotes the (d-dimensional) sum of the rewards until time t.

▷ Claim 8. For every state $q \in \mathcal{M}^*$ there exists some number of steps $n_q \in \mathbb{N}$ and a probability $p_q > 0$ such that

$$\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_q, q}\left(\bigcup_{j=0}^{n_q} ((Y_j)_1 > i_{X_j} - i_q) \cup ((Y_j)_1 \geq f_{X_j} - i_q)\right) \geq p_q.$$

Proof. Towards a contradiction, assume that for all m

$$\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_q, q}\left(\bigcup_{j=0}^{m} ((Y_j)_1 > i_{X_j} - i_q) \cup ((Y_j)_1 \geq f_{X_j} - i_q)\right) = 0.$$

Due to the second part of the union, this implies that never $(Y_j)_1 + i_q \geq f_{X_j}$. Since $\sigma^\sharp_q$ satisfies $\mathtt{EN}_1(i_q)$ almost surely, it can never choose the step to s_{win}. This implies $\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_q, q}(\mathsf{F} s_{\text{win}}) = 0$, i.e., X_j is always different from s_{win}. (The values f_s were initially defined with respect to states s of the original MDP $\mathcal{M}$, but the definition is naturally extended to the MDP $\mathcal{M}^*$, by giving the primed states the same value, i.e., $f_{s'} = f_s$. The state s_{win} does not appear in $\mathcal{M}$, but only in $\mathcal{M}^*$. We can extend the definition by having $f_{s_{\text{win}}} = 0$. However, this is not strictly required. The f_{X_j} is already defined, since X_j is always different from s_{win}.)

Since $\sigma^\sharp_q$ satisfies $\mathtt{EN}_1(i_q)$ almost surely, all runs always satisfy $(Y_j)_1 \geq i_{X_j} - i_q$ for all j. On the other hand, our assumption yields $\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_q, q}\left(\bigcup_{j=0}^{m} (Y_j)_1 > i_{X_j} - i_q\right) = 0$. This implies that $(Y_j)_1 = i_{X_j} - i_q$ for all j. Hence, in all runs the energy fluctuates by at most $\ell \stackrel{\text{def}}{=} 2 \max_q i_q$.

Thus, $\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_q,q}(\mathtt{O}(i_q) \cap \mathtt{Infix}_1(\ell)) = 1$. Then Lemma 4 implies that $f_q = i_q$. Since $X_0 = q$ we have $f_{X_0} = f_q$ and thus $(Y_0)_1 \geq f_{X_0} - i_q = 0$. This contradicts our assumption, since the second part of the union is surely satisfied. ◁

For any state q, let n_q, p_q denote the values from Claim 8.

Now we show that $s \in \mathtt{AS}(\mathtt{Bailout}(k))$. Define a strategy $\sigma_{\mathtt{Bailout}}$ which plays in phases, separated by resets. It remembers the number of steps $t \geq 0$ since last reset, the (under-approximated) sum of rewards Q_t and the current state X_t. The first phase starts at state s and $\sigma_{\mathtt{Bailout}}$ plays like $\sigma^\sharp_s$ until one of the following events occur.

1. There is enough energy such that it is safe to move to s_{win}, i.e., $(Q_t \geq f_{X_t} - i_s)$, or
2. The current energy level is strictly greater than the minimal required energy level of the current state, i.e., $(Q_t > i_{X_t} - i_s)$, or
3. n_s steps have elapsed, i.e., $(t = n_s)$.

If at any point Item 1 happens, then the strategy simply goes to s_{win}. If it is the case that Item 2 occurs before $t = n_s$, let's say at some time t', then the phase ends at t'. The sum of the rewards in the phase, between the last reset (where $t = 0$) and the current time is $\geq i_{X_{t'}} - i_s + 1$. If neither Item 1 nor Item 2 occurs before $t = n_s$, then the phase ends and we let $t' \stackrel{\text{def}}{=} t = n_s$. The sum of the rewards in this phase is then exactly $i_{X_{t'}} - i_s$. At the end of the phase $\sigma_{\mathtt{Bailout}}$ resets the number of steps ($t = 0$), and Q_t to 0. In the following phase it moves according to $\sigma^\sharp_{X_{t'}}$ until the next reset.

$\sigma_{\mathtt{Bailout}}$ clearly satisfies $\mathtt{EN}_1(k)$ as it is a mix of energy safe strategies $\left(\sigma^\sharp_q\right)_{q \in S^*}$ and since we are starting from a safe energy level. By Claim 8, there is a positive probability (lower-bounded by $\min_q p_q > 0$) that either Item 1 or Item 2 happens in each phase.

Hence, unless event Item 1 occurs, Item 2 occurs infinitely often almost surely. Moreover, since the length of phases is upper bounded by $\max_q n_q$, it occurs frequently. We obtain $\mathcal{P}^{\mathcal{M}^*}_{\sigma_{\mathtt{Bailout}},s}\left(\mathtt{MP}_1 \geq \min_q\left(\frac{p_q}{n_q}\right) > 0 \,|\, \neg \mathsf{F} s_{\text{win}}\right) = 1$. On the other hand, if s_{win} is reached, then $\mathtt{MP}_1$ holds by shift invariance and the definition of the positive rewards in the loop at s_{win}. Therefore, $\mathcal{P}^{\mathcal{M}^*}_{\sigma_{\mathtt{Bailout}},s}(\mathtt{EN}_1(i_s) \cap \mathtt{MP}_1(> 0)) = 1$.

Now we show that $s \in \mathtt{AS}(\mathtt{Gain})$. We make use of the following strategies.

- $\sigma^\sharp_q$ which satisfies $\mathtt{EN}_1(k) \cap \mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}(\mathbf{> 0})$ almost surely from q for every $k \geq i_q$.
- a uniform MD strategy $\sigma^*_{\mathtt{MP}_1}$ which satisfies $\mathtt{MP}_1(> 0)$ almost surely from every state. It exists since $\mathtt{AS}(\mathtt{MP}_1(> 0)) = S^*$ (where S^* is the set of states of $\mathcal{M}^*$), because $\mathcal{P}^{\mathcal{M}^*}_{\sigma_{\mathtt{Bailout}},s}(\mathtt{EN}_1(i_s) \cap \mathtt{MP}_1(> 0)) = 1$.

From the former, we get probabilistic bounds on the achievable mean payoff in all the dimensions, i.e., for all states s, and $0 \leq \varepsilon < 1$, there is a $d-1$ dimensional vector $\boldsymbol{\nu_\varepsilon} > \mathbf{0}$ such that $\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_s,s}\left(\mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]} \geq \boldsymbol{\nu_\varepsilon}\right) \geq 1 - \frac{\varepsilon}{2}$. This follows from the fact that for any sequence of decreasing vectors $\boldsymbol{\nu_n} \to \mathbf{0}$ in $\mathbb{R}^{d-1}$, $\mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}(\mathbf{> 0}) = \bigcup_n \mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}(\mathbf{\geq \boldsymbol{\nu_n}})$ and continuity of measures. Furthermore, denoting by $\boldsymbol{Y_t}$ the sum of rewards in all dimensions until time t, there exists a sufficiently large bound $n_\varepsilon \in \mathbb{N}$ such that $\mathcal{P}^{\mathcal{M}^*}_{\sigma^\sharp_s,s}\left(\frac{(Y_t)_j}{t} \geq \frac{(\nu_\varepsilon)_j}{2}\right) \geq 1 - \varepsilon$ in each of the dimensions $j \in [2,d]$ for all $t \geq n_\varepsilon$ steps. This can be shown by observing that $\mathtt{MP}_j\left(\geq (\nu_\varepsilon)_j\right) = \bigcap_{k=1}^\infty \bigcup_{n=1}^\infty \bigcap_{t=n}^\infty \left(\frac{(Y_t)_j}{t} \geq (\nu_\varepsilon)_j \cdot \left(1 - \frac{1}{2^k}\right)\right)$ and using continuity of measures.

Similarly, there exists a bound $n^*_\varepsilon \in \mathbb{N}$ and value $\nu^*_\varepsilon > 0$ such that $\mathcal{P}_{\sigma^*_{\mathtt{MP}_1},s}\left(\frac{(Y_t)_1}{t} \geq \frac{\nu^*_\varepsilon}{2}\right) \geq 1 - \varepsilon$ after $t \geq n^*_\varepsilon$ steps for every state s.

Now consider the following strategy $\sigma_{\mathtt{Gain}}$, which switches between two phases.

Phase 1: If the current state is q, it moves according to $\sigma^\sharp_q$ for some number $\alpha > n_\varepsilon$ of steps. Then it switches to phase 2.

Phase 2: It moves according to $\sigma^*_{\mathtt{MP}_1}$ for some number $\beta > n^*_\varepsilon$ of steps, and then switches back to phase 1.

The strategy $\sigma_{\mathtt{Gain}}$ is a finite-memory strategy, since the lengths of the alternating phases are bounded by α and β, respectively. (Even if $\sigma^\sharp_q$ is an infinite-memory strategy, it can only use bounded memory in each phase.)

We fix $\sigma_{\mathtt{Gain}}$ from the start state s and obtain a finite-state Markov chain. In every BSCC of this Markov chain, the expected mean payoff in the 1^{st} dimension will be

$$\geq \frac{-i^\sharp + \beta \cdot (1-\varepsilon) \cdot \left(\frac{\nu^*_\varepsilon}{2}\right) - \beta \cdot \varepsilon \cdot R}{\alpha + \beta}.$$

where $i^\sharp = \max_s i_s$ denotes the maximum (over all states) minimal safe energy.

Similarly, in every BSCC, the expected mean payoff in the j^{th} dimension for $j \geq 2$ can be lower-bounded by

$$\geq \frac{\alpha \cdot \left((1-\varepsilon) \cdot \left(\frac{(\nu_\varepsilon)_j}{2}\right) - \varepsilon \cdot R\right) - \beta \cdot R}{\alpha + \beta}.$$

By choosing ε sufficiently small, β sufficiently large to make the first term positive and $\alpha \gg \beta$ sufficiently large to make the second term positive, we can get positive expected mean payoff in all dimensions. Since this holds in every BSCC of the induced finite Markov chain, the objective $\mathtt{Gain}$ is satisfied almost surely. ◀

The following lemma shows the converse of Lemma 7. In $\mathcal{M}^*$, it is always possible to win $\mathtt{O}(i_s)$ almost surely from s by playing a particular strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$ which combines the two uniform memoryless strategies $\sigma^*_{\mathtt{Bailout}}$ and $\sigma^*_{\mathtt{Gain}}$. Let Z_b denote the minimal universally safe energy level for $\mathtt{Bailout}$, i.e., $Z_b \stackrel{\text{def}}{=} \max_s \min\{k \mid s \in \mathtt{AS}(\mathtt{Bailout}(k))\}$. Moreover, let $Z_g > Z_b$ be a larger energy level at which our strategy switches from $\sigma^*_{\mathtt{Bailout}}$ to $\sigma^*_{\mathtt{Gain}}$.

Similarly to [25], we define an infinite-memory strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$ that always records the current energy level and operates by switching between two phases. It starts by playing $\sigma^*_{\mathtt{Gain}}$ (Gain-phase) if our starting energy level is sufficiently high ($\geq Z_b + R$), and otherwise starts by playing $\sigma^*_{\mathtt{Bailout}}$ (Bailout-phase). In the $\mathtt{Bailout}$-phase, the primary goal is to pump the energy level up until it is $\geq Z_g$, and then it switches to the $\mathtt{Gain}$-phase. It enters the $\mathtt{Bailout}$-phase again if the energy level drops below $Z_b + R$ (in which case it will still be $\geq Z_b$).

▶ **Lemma 9.** *There exists a $Z_g \in \mathbb{N}$ such that for every s in $\mathcal{M}^*$ the strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$ is almost surely winning for $\mathtt{O}(i_s)$ from s.*

Proof. The parameter Z_g is chosen sufficiently large such that there is a fixed non-zero probability that after every Bailout-phase one never needs another $\mathtt{Bailout}$. (Thus, except in a null set there are only finitely many Bailouts.) The existence of such a finite Z_g is guaranteed by the fact that $\lim_{k\to\infty} \mathcal{P}_{\sigma^*_{\mathtt{Gain}},s}(\mathtt{O}(k)) = 1$. ([18, Lemma 22]). Eventually, except in a null set, $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$ plays $\mathtt{Gain}$ forever, thus satisfying $\mathtt{O}(i_s)$ almost surely from s. ◀

Some combined objectives like Energy-Parity really require infinite memory for almost surely winning strategies [25]. However, we show that a sufficiently large *finite* memory is enough to win Energy-MeanPayoff almost surely. The idea is to modify the strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$ such that it remembers the current energy only in the interval $[0, b]$, for some sufficiently large $b > Z_g$, and ignores any possible excess energy above b. This modified strategy is denoted by $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$, and it has a finite set of memory modes $[0, b] \times \{0, 1\}$. The $\{0, 1\}$ part is used to remember the current phase ($\mathtt{Gain} = 0$ or $\mathtt{Bailout} = 1$). Then $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(u, x)]$ denotes the strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ with current memory mode $(u, x) \in [0, b] \times \{0, 1\}$.

The finite bound b on the remembered energy has the effect that $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ can no longer guarantee a fixed positive probability of not needing another Bailout after each Bailout-phase. Thus, one might have infinitely many Bailouts with positive probability. (Most of these are unnecessary, but one cannot be sure which ones). Unlike for Energy-Parity, where using infinitely many `Bailout` phases can compromise the objective, the nature of the $\mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}(\mathbf{> 0})$ objective allows us to use infinitely many Bailouts with non-zero probability, provided that they happen sufficiently infrequently.

By its construction, the strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(i_s, x)]$ is energy-safe from every state s, every initial energy $\geq i_s$ and $x \in \{0, 1\}$. It remains to show that it also satisfies $\mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}(\mathbf{> 0})$ almost surely. Since $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ is finite-memory, it suffices to consider the induced finite Markov chain $\mathcal{A}$ and show that the expected mean payoff is strictly positive in every BSCC. I.e., we prove that $\mathcal{E}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}},s}\big(\mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}\big) > \mathbf{0}$ for a sufficiently large b. To this end, we consider the finite Markov chains $\mathcal{A}^{\mathtt{Gain}}$ and $\mathcal{A}^{\mathtt{Bailout}}$ obtained by fixing the memoryless strategies $\sigma^*_{\mathtt{Gain}}$ and $\sigma^*_{\mathtt{Bailout}}$ in $\mathcal{M}^*$, respectively. The application of $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ can then be seen as alternating between these two Markov chains based on hitting certain energy levels.

Let $T^{\mathtt{Gain}}$ denote the random variable that measures the length of a Gain-phase, when starting at energy level Z_g and assuming that the energy it truncated at b. Similarly, $T^{\mathtt{Bailout}}$ is the random variable that measures the length of a Bailout-phase when starting at energy level Z_b. (Here it does not matter that the energy is truncated at b, since the Bailout-phase ends when the energy reaches $Z_g < b$.) Since R can be > 1, the Bailout-phase might actually start at a slightly higher energy level $u \in [Z_b, Z_b + R - 1]$, and thus $T^{\mathtt{Bailout}}$ over-approximates the actual length of the Bailout-phase, which is conservative for our analysis. Similarly, the Gain phase might start with an energy slightly higher than Z_g, and $T^{\mathtt{Gain}}$ under-approximates the length of the Gain-phase, which is again conservative. The random variables $(Y_{T^{\mathtt{Gain}}})_i$ and $(Y_{T^{\mathtt{Bailout}}})_i$ then measure the sum of the rewards the i^{th} dimension obtained during the Gain and Bailout phases, respectively.

The following lemma shows that the strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ can attain a strictly positive mean payoff in all dimensions $i \in [2, d]$, provided that the expected reward during the Gain-phase is sufficiently large (positive) and the expected reward during the Bailout-phase (though possibly negative) is not too small.

▶ **Lemma 10.** *If there are constants $v_i^1 > 0$ and v_i^2 such that, for all $i \in [2, d]$ and states q*

$$\mathcal{E}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(Z_g,0)],q}((Y_{T^{\mathtt{Gain}}})_i) \geq v_i^1$$
$$\mathcal{E}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(Z_b,1)],q}((Y_{T^{\mathtt{Bailout}}})_i) \geq v_i^2$$
$$v_i^1 + v_i^2 > 0$$

then $\mathcal{E}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[\mathsf{m}],s}(\mathtt{MP}_i) > 0$ for all s and $\mathsf{m} \in [i_s, b] \times \{0, 1\}$.

Proof. By fixing the finite-memory strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$, we obtain a finite Markov chain. Consider any BSCC in this Markov chain. In this BSCC, except for a null set of runs, either no Bailouts happen or infinitely many. In the former case, this BSCC behaves like playing $\sigma^*_{\mathtt{Gain}}$ forever, which attains a strictly positive mean payoff in all dimensions almost surely, and thus a strictly positive expected mean payoff in each dimension i. In the second case, almost surely there happen infinitely many Bailouts, each starting at an every level $\geq Z_b$. Then, by the finiteness of the BSCC, we obtain that $\mathcal{E}(T^{\mathtt{Gain}}) < \infty$. Moreover, by the definition of $\sigma^*_{\mathtt{Bailout}}$, the expected duration of the Bailout-phase is always finite, i.e., $\mathcal{E}(T^{\mathtt{Bailout}}) < \infty$. Thus, by linearity of expectations, $\mathcal{E}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}},s}(\mathtt{MP}_i) \geq (v_i^1 + v_i^2)/(\mathcal{E}(T^{\mathtt{Gain}}) + \mathcal{E}(T^{\mathtt{Bailout}})) > 0$. ◀

The following technical Lemma 11 (proof in [18, Appendix B]) shows that the constants v_i^1, v_i^2 from Lemma 10 exist. Recall that the finite Markov chains $\mathcal{A}^{\mathtt{Gain}}$ and $\mathcal{A}^{\mathtt{Bailout}}$ are obtained by fixing the memoryless strategies $\sigma^*_{\mathtt{Gain}}$ and $\sigma^*_{\mathtt{Bailout}}$ in $\mathcal{M}^*$, respectively. Let $x_{\min,1}$ and $x_{\min,2}$ denote the minimal occurring non-zero probabilities in these two Markov chains, respectively. (They come from solutions of linear programs and can be chosen as only exponentially small, i.e., described by a polynomial number of bits; cf. [18, Appendix B]). The proof works by applying general results about expected first passage times in truncated Markov chains to the induced Markov chains $\mathcal{A}^{\mathtt{Gain}}$ and $\mathcal{A}^{\mathtt{Bailout}}$. The general idea is that in the Gain-phase one has a general up drift in all dimensions, and in particular in the first (energy) dimension. It is thus unlikely to go down very far in the energy dimension, even if the energy is truncated at b. Thus, for a sufficiently large truncation point b (actually $b = Z_g + 1$ suffices), the expected time spent in the Gain-phase is very large relative to the expected time spent in the Bailout phase. More exactly, the former increases exponentially in b, while the latter is polynomial in b. For a sufficiently large b (exponential in $|\mathcal{M}^*|$), the condition $v_i^1 + v_i^2 > 0$ is met.

▶ **Lemma 11.** *Let $\mu_i > 0$ denote the lower bound on the mean payoff in dimensioni in any BSCC in the Markov chain $\mathcal{A}^{\mathtt{Gain}}$ with corresponding computable constants c_i, $g_{\mathtt{Gain}}$, $h_{\mathtt{Gain}}$, and let μ denote the lower bound on the mean payoff in the 1^{st} dimension in any BSCC of $\mathcal{A}^{\mathtt{Bailout}}$ with the corresponding constants $g_{\mathtt{Bailout}}, h_{\mathtt{Bailout}}$. All the above constants, except c_i, can be chosen as at most exponential in $|\mathcal{M}^*|$ and $1/(1-c_i) \in \mathcal{O}\big(\exp\big(\exp\big(|\mathcal{M}^*|^{\mathcal{O}(1)}\big)\big)\big)$.*

Then there are constants $0 < C_1 < 1$, $C_2 > 0$, $C_3 > 0$, $C_4 > 0$, $C_5 > 0$, all exponential in $|\mathcal{M}^*|$ and dependent only on $\mathcal{M}$, such that for $k \stackrel{def}{=} \frac{2\cdot|S^*|}{x_{\min,1}^{|S^*|}} \in \mathcal{O}\big(\exp\big(|\mathcal{M}^*|^{\mathcal{O}(1)}\big)\big)$, any $\delta \in (0,1)$ sufficiently small such that $(|S^*|+1)\cdot\big(\frac{1}{\delta}-1\big) + \lceil\big(\log_{c_i}(\delta\cdot(1-c_i))\big)\rceil \geq \frac{h_{\mathtt{Gain}}}{\mu_i}$ for all $2 \leq i \leq d$, one can choose
$Z_g \stackrel{def}{=} Z_b + R + k{\cdot}R + \max_i\big(R\cdot\lceil\log_{c_i}(\delta\cdot(1-c_i))\rceil - R + 1, h_{\mathtt{Gain}}\big) \in \mathcal{O}\Big(e^{|\mathcal{M}^*|^{\mathcal{O}(1)}}\cdot\log(1/\delta)\Big)$
and $b \stackrel{def}{=} Z_g + 1$ so that

$$\mathcal{E}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(Z_g,0)],q}\big((Y_{T^{\mathtt{Gain}}})_i\big) \geq C_1\cdot\frac{1}{\delta} - C_2\log_2\left(\frac{1}{\delta}\right) - C_3 \qquad \stackrel{def}{=} v_i^1$$

$$\mathcal{E}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(Z_b,1)],q}\big((Y_{T^{\mathtt{Bailout}}})_i\big) \geq -C_4\log_2\left(\frac{1}{\delta}\right) - C_5 \qquad \stackrel{def}{=} v_i^2$$

In particular, in order to satisfy the condition $v_i^1 + v_i^2 > 0$, it suffices to choose $1/\delta \in \mathcal{O}\big(\max(1/C_1, \max_{2\leq j\leq 5} C_j)^{\mathcal{O}(1)}\big)$. Since the constants C_j are exponential in $|\mathcal{M}^*|$, and by the conditions on the other constants above, the value Z_g, and hence the overall bound $b = Z_g + 1$, can be chosen such that $b \in \mathcal{O}\big(\exp\big(|\mathcal{M}^*|^{\mathcal{O}(1)}\big)\big)$.

Now we can prove the first item of our main result.

Proof of Theorem 1 (Item 1). Towards a contradiction, we assume that there exists a state $s^\dagger$ such that there is no finite-memory almost surely winning strategy from $s^\dagger$ for $\mathtt{O}(i_{s^\dagger})$ in the MDP $\mathcal{M}$.

First we consider the MDP $\mathcal{M}^*$. The finite-memory strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(i_{s^\dagger},1)]$ from $s^\dagger$ is energy-safe by construction and satisfies $\mathtt{EN}_1(i_{s^\dagger})$ surely. Now consider the finite Markov chain induced by fixing this finite-memory strategy in $\mathcal{M}^*$. By Lemma 10 and Lemma 11, for a sufficiently large (exponential) b it yields a strictly positive expected mean payoff $v_i^1 + v_i^2 > 0$ in every dimension $i \in [2,d]$ in every BSCC of this Markov chain. Since the Markov chain is finite, this implies that the mean payoff in every dimension $i \in [2,d]$ is strictly positive almost

surely. Hence, $\mathcal{P}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(i_{s^\dagger},1)],s^\dagger}\big(\mathtt{MP}_{[2,d]}(>0)\big) = 1$ and thus $\mathcal{P}^{\mathcal{M}^*}_{\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}[(i_{s^\dagger},1)],s^\dagger}(\mathtt{O}(i_{s^\dagger})) = 1$. So there exists an almost surely winning finite-memory strategy from $s^\dagger$ for $\mathtt{O}(i_{s^\dagger})$ in $\mathcal{M}^*$. However, Lemma 3 then implies that there also exists an almost surely winning finite-memory strategy from $s^\dagger$ for $\mathtt{O}(i_{s^\dagger})$ in $\mathcal{M}$. Contradiction. ◀

▶ Remark 12. If $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ satisfies $\mathtt{O}(i_s)$ almost surely from some state s then it also satisfies the stronger objective $\mathtt{O}(i_s) \cap \mathtt{Infix}(b)$ almost surely. Consider a winning run induced by $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$. While the true energy might sometimes be higher than b, the energy remembered by $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$ is always $\leq b$. Even with this conservative under-approximation of the energy, the run still satisfies the energy objective. Therefore, in any winning run induced by $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$, the energy can never *decrease* by more than b. Thus, also $\mathtt{Infix}(b)$ is satisfied almost surely.

5 Proof of Item 2

Given some state s, let $\sigma = (\mathsf{M}, \mathsf{m}_0, \mathsf{upd}, \mathsf{nxt})$ be a finite-memory strategy that is almost surely winning for $\mathtt{O}(i_s)$ (which exists by Item 1). We show there exists an almost surely winning strategy σ' for $\mathtt{O}(i_s)$ such that the energy fluctuations are bounded by some constant which is exponential in $|\mathcal{M}|$.

First, inside any BSCC B of $\mathcal{M}^\sigma$, we construct an almost surely winning strategy σ_B and upper bound the minimal safe energy levels and energy fluctuation while following σ_B. Using this, we upper bound the energy fluctuations in paths before reaching a BSCC. We use the fact that the set of states and transitions that occur in any BSCC of a Markov chain induced by fixing some finite-memory strategy in an MDP is an end component of this MDP ([19, Theorem 3.2]).

▶ **Lemma 13.** *Let B be a BSCC of $\mathcal{M}^\sigma$ and let $\mathcal{M}(B)$ be the corresponding end component in $\mathcal{M}$ with states S_B and transitions E_B. Then there is a strategy σ_B, a bound $b_B \in \mathcal{O}\big(\exp\big(|\mathcal{M}(B)|^{\mathcal{O}(1)}\big)\big)$ such that for any state $q \in S_B$, there is a minimal safe energy level $j_q \overset{def}{=} i_q^{\mathcal{M}(B)} \leq 3 \cdot |S_B| \cdot R$ such that $\mathcal{P}^{\mathcal{M}(B)}_{\sigma_B,q}(\mathtt{O}(j_q) \cap \mathtt{Infix}(b_B)) = 1$.*

Proof Sketch. (Full proof in [18, Appendix C].). The idea is that for $\mathcal{M}(B)$ there are two cases. In the first case it behaves similar to $\mathcal{M}^*$ from Section 4, in the sense that it is possible to win `Gain` and `Bailout` almost surely, and thus Energy-MeanPayoff can be won almost surely by switching between the two strategies for `Gain` and `Bailout` like in the strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$. Then one can invoke Lemma 11 and Remark 12 on $\mathcal{M}(B)$ to get an exponential bound b_B such that $\mathcal{P}^{\mathcal{M}(B)}_{\sigma_B,q}(\mathtt{O}(j_q) \cap \mathtt{Infix}(b_B)) = 1$.

If the first case does not hold then $\mathcal{M}(B)$ is very restrictive, and one can show that the energy level fluctuations are bounded by a constant in $\mathcal{O}(|S_B| \cdot R)$. ◀

Since the minimal safe energy levels inside these end components are not too large, one can then bound the energy fluctuations in paths before they reach any such end component $\mathcal{M}(B)$. The following lemma is shown in [18, Appendix C].

▶ **Lemma 14.** *Let T denote the union of all S_B of every BSCC B of $\mathcal{M}^\sigma$, as in Lemma 13. Then one can almost surely reach any state in T with the corresponding minimal safe energy level with energy fluctuations of at most $5 \cdot |S| \cdot R$.*

Proof of Theorem 1 (Item 2). By Lemmas 13 and 14, for each state s, one can choose a strategy σ and some constant $b \in \mathcal{O}\big(\exp\big(|\mathcal{M}|^{\mathcal{O}(1)}\big)\big)$ such that $\mathcal{P}^{\mathcal{M}}_{\sigma,s}(\mathtt{O}(i_s) \cap \mathtt{Infix}(b)) = 1$. This means if one encodes the energy levels between $[0, b]$ into the state space by discarding

any excess energy above b and redirecting all the transitions which result in a negative energy to a losing sink (for $\mathtt{MP}_{[2,d]}(>0)$) and constructs this larger MDP $\mathcal{M}[0,b]$, then there is a strategy σ' such that $\mathcal{P}^{\mathcal{M}[0,b]}_{\sigma',(s,k)}\big(\mathtt{MP}_{[2,d]}(>0)\big) = 1$ for every $k \in [i_s, b]$. Then, by Lemma 6, there also exists a memoryless (MR) strategy σ^* in $\mathcal{M}[0,b]$ which is almost surely winning $\mathtt{MP}_{[2,d]}(>0)$ from (s,k).

We can carry the memoryless strategy σ^* in $\mathcal{M}[0,b]$ back to $\mathcal{M}$ as a finite-memory strategy $\sigma^*_{\mathcal{M}}$ with memory $[0,b]$. It stores the encoded under-approximated energy level from $\mathcal{M}[0,b]$ in its finite memory instead. Thus, $\sigma^*_{\mathcal{M}}$ is a finite-memory strategy from s that satisfies $\mathtt{0}(i_s)$ almost surely, and the size of its memory is bounded by $b \in \mathcal{O}\big(\exp\big(|\mathcal{M}|^{\mathcal{O}(1)}\big)\big)$.

The strategy $\sigma^*_{\mathcal{M}}$ uses randomization, because σ^* from Lemma 6 is MR. However, the MR strategy σ^* for the mean payoff objective could be replaced by a deterministic strategy with an exponential number of memory modes. Hence, the overall number of memory modes in the obtained deterministic version of $\sigma^*_{\mathcal{M}}$ is still only exponential. ◀

6 The Lower Bound (Proof of Item 3)

In the previous sections we have shown that finite memory suffices for almost surely winning strategies for the Energy-MeanPayoff objective. However, the required memory depends on the given MDP. We show that no fixed finite amount of memory is sufficient for all MDPs. In fact, the required memory is exponential in the transition probabilities even for an otherwise fixed 5-state MDP with just one controlled state, $R = 1$ and $d = 2$.

▶ **Definition 15.** *Let $1 > \delta > 0$ and $\mathcal{M}_\delta = (S, S_\Box, S_\bigcirc, E, P, \boldsymbol{r})$ be an MDP with 2-dimensional rewards. It has just one controlled state s with transitions $s \to s_l$ and $s \to s_r$. From s_l there are two transitions $e_1 = (s_l \to s_l^1)$ and $e_2 = (s_l \to s_l^2)$. Let $\mathcal{P}(e_1) = (1+\delta)/2$ and $\mathcal{P}(e_2) = (1-\delta)/2$ and $\boldsymbol{r}(e_1) = (+1,+1)$ and $\boldsymbol{r}(e_2) = (-1,-1)$. s_l^1 and s_l^2 are random states which each have just one transition back to s with probability 1 and reward $\mathbf{0}$. From s_r there is only one transition e_3 back to s with probability 1 and $\boldsymbol{r}(e_3) = (+1,-1)$.*

The following lemma directly implies the exponential lower bound on the number of memory modes in Theorem 1(Item 3).

▶ **Lemma 16.** *Consider the Energy-MeanPayoff objective. For every finite bound $m \in \mathbb{N}$ on the number of memory modes there exists a $\delta \stackrel{def}{=} 1/(6m) > 0$ such that the finite MDP $\mathcal{M}_\delta = (S, S_\Box, S_\bigcirc, E, P, \boldsymbol{r})$ from Definition 15 satisfies the following properties.*

1. *$\exists \sigma'\ \mathcal{P}^{\mathcal{M}_\delta}_{\sigma',s}(\mathtt{EN}_1(0) \cap \mathtt{MP}_{\mathbf{2}}(>0)) = 1$, i.e., it is possible to win almost surely from s in $\mathcal{M}_\delta$, even with initial energy 0.*
2. *For every finite-memory strategy σ with $\leq m$ memory modes we have $\mathcal{P}^{\mathcal{M}_\delta}_{\sigma,s}(\mathtt{EN}_1(k) \cap \mathtt{MP}_{\mathbf{2}}(>0)) = 0$ for every $k \in \mathbb{N}$, i.e., σ attains nothing in $\mathcal{M}_\delta$, regardless of the initial energy k.*
3. *For $\mathcal{M}_\delta$ we have $|S| = 5$, $d = 1$ and $R = 1$. The number of memory modes required for an almost-surely winning strategy in $\mathcal{M}_\delta$ is exponential in $|P|$ (and in $|\mathcal{M}_\delta|$).*

Proof. Towards item 1, consider a strategy σ' that plays as follows. It keeps a counter that records the current energy, which is initially 0. Whenever the current energy is 0, it plays $s \to s_r$, otherwise it plays $s \to s_l$. Thus, σ' satisfies $\mathtt{EN}_1(0)$ surely from s. Since $\delta > 0$ it follows from the classic Gambler's ruin problem (with strictly positive expected gain, here in the first reward dimension) that σ' plays $s \to s_r$ only finitely often, except in a null set of the runs. Therefore, the expected mean payoff (in the second dimension) under σ' is $(1+\delta)/2 - (1-\delta)/2 = \delta > 0$. Hence, $\mathcal{P}^{\mathcal{M}_\delta}_{\sigma',s}(\mathtt{MP}_{\mathbf{2}}(>0)) = 1$. Since the energy objective is satisfied surely, we obtain $\mathcal{P}^{\mathcal{M}_\delta}_{\sigma',s}(\mathtt{EN}_1(0) \cap \mathtt{MP}_{\mathbf{2}}(>0)) = 1$.

Towards item 2, let $\delta \stackrel{\text{def}}{=} 1/(6m) > 0$ and let σ be a finite-memory strategy with $\leq m$ memory modes. Consider the finite-state Markov chain $\mathcal{C}$ that is induced by playing σ from s in $\mathcal{M}_\delta$. This Markov chain has $\leq 5m$ states, since $\mathcal{M}$ has 5 states and σ has $\leq m$ memory modes. Let B be any BSCC of $\mathcal{C}$ that is reachable from s and the initial memory mode of σ. In particular, $|B| \leq 5m$. In B there must not exist any loop that does not contain s_r, because otherwise the energy objective cannot be satisfied almost surely. Thus, every path in B of length $\geq 5m$ must contain s_r (and hence a reward $(+1, -1)$) at least once. Therefore, the expected mean payoff in B (in the second reward dimension) is $\leq 5m\delta - 1 = -1/6 < 0$. Since this holds in every reachable BSCC, we obtain $\mathcal{P}^{\mathcal{M}_\delta}_{\sigma,s}(\mathtt{MP}_{\mathbf{2}}(> 0)) = 0$ and thus $\mathcal{P}^{\mathcal{M}_\delta}_{\sigma,s}(\mathtt{EN}_1(k) \cap \mathtt{MP}_{\mathbf{2}}(> 0)) = 0$.

Towards item 3, the size of $\mathcal{M}_\delta$ follows from Definition 15. By items 1 and 2, the required number of memory modes m for an almost-surely winning strategy satisfies $m > 1/(6\delta)$. Since $|P| = \Theta(\log(1/\delta))$ and $|\mathcal{M}_\delta| = \Theta(|P|)$, we obtain $m = \Omega(\exp(|P|))$ and $m = \Omega(\exp(|\mathcal{M}_\delta|))$. ◀

The exponential lower bound on the required memory does not require probabilities encoded in binary like in Lemma 16. One can construct an equivalent example with polynomially many states where all transition probabilities are 1/2. This is because one can encode exponentially small probabilities 2^{-k} with a chain of k extra states and transition probabilities 1/2.

7 Computational Complexity

We have shown that the existence of an almost surely winning strategy for the Energy-MeanPayoff objective for a given state and initial energy level in an MDP implies the existence of a deterministic such strategy with exponentially many memory modes (unlike for Energy-Parity which requires infinite memory in general [25]).

A related problem is the decidability of the question whether a given state in an MDP and a given initial energy level admit an almost surely winning strategy for Energy-MeanPayoff. This problem is decidable in *pseudo-polynomial* time, using an algorithm very similar to the one for Energy-Parity presented in [25]. I.e., the time is polynomial, provided that the bound R on the rewards is given in unary. Transition probabilities in the MDP can still be represented in binary. The crucial point is that it suffices to witness the mere *existence* of an almost surely winning strategy, regardless of its memory. Basically, it suffices that the algorithm proves that the infinite-memory strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$ wins almost surely (plus a small extra argument about a corner case where the energy fluctuates only in a bounded region). The algorithm does not need to compute the bound b or to explicitly construct the finite-memory strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g},\mathtt{b}}$.

▶ **Proposition 17.** *Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, E, P, \boldsymbol{r})$ be an MDP with d-dimensional rewards on the edges $\boldsymbol{r} : E \to [-R, R]^d$. For any state s and $k \in \mathbb{N}$, the existence of an almost surely winning strategy from s for the multidimensional Energy-MeanPayoff objective $\mathtt{EN}_1(k) \cap \mathtt{MP}_{[\mathbf{2},\boldsymbol{d}]}(> \mathbf{0})$ is decidable in pseudo-polynomial time (i.e., polynomial for R in unary).*

Proof. The proof is similar to the one for Energy-Parity presented in [25]. We outline the differences below. First, in the corner case where it is impossible to pump the energy up arbitrarily high almost surely from some state q, the only possible way to win Energy-MeanPayoff (resp. Energy-Parity) almost surely (if at all) is by using a non-null set of runs where the energy only ever fluctuates in a bounded region. In that case, the size of the energy fluctuations in these runs can safely be restricted to a region that is polynomial in

$|S| \cdot R$, and thus pseudo-polynomial in $|\mathcal{M}|$ [25]. It thus suffices to win multi-dimensional $\mathtt{MP}_{[2,d]}(> 0)$ almost surely in a derived MDP $\mathcal{M}'$ where the bounded energy is encoded into the states. Deciding this requires time polynomial in $|\mathcal{M}'|$ [12, 22] and thus pseudo-polynomial in $|\mathcal{M}|$. The winning situations of the corner case can then be encoded into $\mathcal{M}$, yielding a derived MDP $\mathcal{M}'$ of pseudo-polynomial size, where Energy-MeanPayoff can be won almost surely if and only if it can be won almost surely by a combination of `Gain` and `Bailout` strategies, i.e., by strategy $\sigma^*_{\mathtt{alt},\mathtt{Z_b},\mathtt{Z_g}}$. Therefore, it suffices to compute the states (and minimal initial energy levels k) where `Gain` and $\mathtt{Bailout}(k)$ can be won almost surely. The objective $\mathtt{Bailout}(k) \stackrel{\text{def}}{=} \mathtt{EN}_1(k) \cap \mathtt{MP}_1(> 0)$ is exactly the same as the `Bailout` objective analysed in [25], and winning it almost surely is decidable in pseudo-polynomial time. Our objective $\mathtt{Gain} \stackrel{\text{def}}{=} \mathtt{MP}_{[1,d]}(> 0)$ differs from the `Gain` objective considered in [25] (which was $\mathtt{MP}_1(> 0) \cap \mathtt{Parity}$), but winning it almost surely is still decidable in polynomial time [12, 22] by solving a linear program. So overall the algorithm runs in pseudo-polynomial time. ◀

Functional Closure Properties of Finite $\mathbb{N}$-Weighted Automata

Julian Dörfler
Saarland Informatics Campus (SIC), Saarbrücken Graduate School of Computer Science, Saarland University, Germany

Christian Ikenmeyer
University of Warwick, Coventry, UK

Abstract

We determine all functional closure properties of finite $\mathbb{N}$-weighted automata, even all multivariate ones, and in particular all multivariate polynomials. We also determine all univariate closure properties in the promise setting, and all multivariate closure properties under certain assumptions on the promise, in particular we determine all multivariate closure properties where the output vector lies on a monotone algebraic graph variety.

1 Finite $\mathbb{N}$-weighted automata and functional closure properties

Let Σ be a finite set, for example $\Sigma = \{0, 1\}$. A finite $\mathbb{N}$-weighted automaton with all weights 1 is a nondeterministic finite automaton that on input $w \in \Sigma^\star$ outputs the number of accepting computation paths on input w, instead of just outputting whether or not an accepting computation path exists, see Def. 2.1 for the formal definition [1]. While every nondeterministic finite automaton determines a subset of $\Sigma^\star$, a finite $\mathbb{N}$-weighted automaton computes a function $\Sigma^\star \to \mathbb{N}$. A function $f : \Sigma^\star \to \mathbb{N}$ can be presented as the series $\sum_{w\in\Sigma^\star} f(w)w$, and the set of series is denoted by $\mathbb{N}\langle\langle\Sigma^\star\rangle\rangle$ in the automata literature, see e.g. [9][2]. The natural way of adding two functions $\Sigma^\star \to \mathbb{N}$ and adding two series in $\mathbb{N}\langle\langle\Sigma^\star\rangle\rangle$ coincides, but in both presentations we have a natural way of taking the product, and those do not coincide:

1. Pointwise product of functions $\Sigma^\star \to \mathbb{N}$. This is called the Hadamard product.
2. Convolution of series, called the Cauchy product.

A series f is called *recognizable* if there is a finite $\mathbb{N}$-weighted automaton that computes f. The set of recognizable series is denoted by $\mathbb{N}^{\mathrm{rec}}\langle\langle\Sigma^\star\rangle\rangle$ in [9], but we denote it by #FA, to emphasise that we undertake a study similar to #P in [11, Thm 3.13], [4, Thm 6], and recently [12], but instead of polynomial-time Turing machines we study finite automata.

[1] We use the equality of the number of accepting paths of an NFA and the output of the corresponding $\mathbb{N}$-weighted automaton, see [9, Exa. 2.2].

[2] A series with finite support is called a *polynomial*, but we will not be concerned with the support of series in this paper. Instead, we use the term *polynomial* as it is used in commutative algebra, and we mean multivariate polynomials with rational coefficients.

The Kleene-Schützenberger theorem states that #FA is the smallest set that contains all support 1 series and is closed under sums, Cauchy products, and Kleene-iterations (whenever well-defined, a Kleene-iteration is the sum of all Cauchy powers), see [9, §4], but we will not need this insight.

In this paper we study the functional closure properties[3] of #FA. A function $\varphi : \mathbb{N}^m \to \mathbb{N}$ is called a *functional closure property* of #FA if for all $f_1 \in \#\mathsf{FA}$, $f_2 \in \#\mathsf{FA}$, ..., $f_m \in \#\mathsf{FA}$ we have that $\varphi(f_1, \ldots, f_m) \in \#\mathsf{FA}$. By $\varphi(f_1, \ldots, f_m)$ we mean the function that on input $w \in \Sigma^\star$ outputs $\varphi(f_1(w), \ldots, f_m(w))$.

Classically, one of the simplest functional closure properties of #FA is $\varphi : \mathbb{N}^2 \to \mathbb{N}$, $\varphi(f_1, f_2) = f_1 + f_2$. This is a functional closure property of #FA, because given $f_1 \in \#\mathsf{FA}$ and $f_2 \in \#\mathsf{FA}$, we can show $\varphi(f_1, f_2) = f_1 + f_2 \in \#\mathsf{FA}$ by an easy construction: The new NFA consists of a copy of the NFA for f_1 and a copy of the NFA for f_2, and makes an initial nondeterministic choice as to which NFA to run, see Lemma 3.1 for the details.

Another classical simple functional closure property of #FA is $\varphi : \mathbb{N}^2 \to \mathbb{N}$, $\varphi(f_1, f_2) = f_1 \cdot f_2$. This corresponds to the Hadamard product. This is a functional closure property of #FA, because given $f_1 \in \#\mathsf{FA}$ and $f_2 \in \#\mathsf{FA}$, we can show $\varphi(f_1, f_2) = f_1 \cdot f_2 \in \#\mathsf{FA}$ by the following construction: The new NFA consists of the product NFA of the NFAs for f_1 and f_2, and the accepting states correspond to pairs of accepting states, see Lemma 3.2 for the details. This product construction corresponds to the Hadamard product.

The Cauchy product is also a product on the set #FA, but we explain now that the Cauchy product is not "functional", and hence it is out of scope for this type of studies. If $\varphi : \mathbb{N}^m \to \mathbb{N}$ is a functional closure property of #FA, then we can study the corresponding map $\widetilde{\varphi} : \underbrace{\#\mathsf{FA} \times \#\mathsf{FA} \times \cdots \times \#\mathsf{FA}}_{m \text{ times}} \to \#\mathsf{FA}$. Observe that if φ is a functional closure property of #FA, then by definition we have that for all pairs $(w, w') \in \Sigma^\star \times \Sigma^\star$:

if $(f_1(w), \ldots, f_m(w)) = (f_1(w'), \ldots, f_m(w'))$, then $\widetilde{\varphi}(f_1, \ldots, f_m)(w) = \widetilde{\varphi}(f_1, \ldots, f_m)(w')$.

Let $\zeta : \#\mathsf{FA} \to \#\mathsf{FA}$ denote the Cauchy square. We use the observation above to show that ζ is not equal to $\widetilde{\varphi}$ for any $\varphi : \mathbb{N} \to \mathbb{N}$. Let $m = 1$ and $f(w) = 1$ if $w = 1$, $f(w) = 0$ otherwise. Clearly, $f \in \#\mathsf{FA}$. Then $\zeta(f)(11) = 1$, and $\zeta(f)(w) = 0$ for all $w \neq 11$. In particular $\zeta(f)(0) \neq \zeta(f)(11)$, even though $f(0) = f(11)$. Hence, $\zeta \neq \widetilde{\varphi}$ for all $\varphi : \mathbb{N} \to \mathbb{N}$.

Numerous functional closure properties of #FA exist, for example the safe decrementation $\max\{0, f_1 - 1\}$, and the binomial coefficient $\binom{f_1}{2}$. But not all non-negative functions are functional closure properties of #FA, for example $(f_1 - f_2)^2$ is not, which can be shown using the Pumping Lemma. In this paper, we determine *all* functional closure properties of #FA, see §1.2 for the detailed statement.

1.1 Motivation

Functional closure properties can be studied for many different counting machine models (also for example with different types of oracle access) and different types of input sets. The first study of this type was done for nondeterministic polynomial-time Turing machines, i.e., the class #P, see [11], [4], and the recent [12]. Recall that the class #P is the class of functions $f : \Sigma^* \to \mathbb{N}$ for which a nondeterministic polynomial time Turing machine M exists such that for all $w \in \Sigma^*$ the number of accepting paths for the computation $M(w)$ is exactly $f(w)$. The papers mentioned above prove that the relativizing multivariate polynomial

[3] See [11, Sec. 1] for the naming *functional closure property*. A different reasonable name would be *pointwise closure property*.

closure properties are exactly those polynomials that have nonnegative integers in their expansion over the binomial basis, see [12]. A functional closure property $\varphi : \mathbb{N}^m \to \mathbb{N}$ of $\#\mathsf{P}$ is *relativizing* if φ is a closure property for all $\#\mathsf{P}^A$, where $A \subset \Sigma^*$ is some oracle. The hope is that for simpler models of computation no oracle access is required to determine the functional closure properties, and we show that this is true for $\#\mathsf{FA}$, see §1.2.

Functional closure properties can be used directly to construct combinatorial proofs of equalities and inequalities. For example, Fermat's little theorem states that p divides $a^p - a$. The quantity $\frac{1}{p}(a^p - a)$ has a combinatorial interpretation, which can be deduced from the fact that $\frac{1}{p}((f_1)^p - f_1)$ is a univariate functional closure property of $\#\mathsf{P}$, see [12, Prop. 7.3.1], which coincides with the original proof [18], see also [17, eq. (5)]). On the other hand, if a function is not a functional closure property, then this means in a very strong sense that there is no combinatorial interpretation for the quantity it describes. For example, the Hadamard inequality ([10, §2.13], [3, §2.11], [12, eq. (2)]) states that

$$\det \begin{pmatrix} a_{11} & \cdots & a_{1d} \\ \vdots & \ddots & \vdots \\ a_{d1} & \cdots & a_{dd} \end{pmatrix}^2 \leq \prod_{i=1}^{d} (a_{i1}^2 + \cdots + a_{id}^2).$$

One could try to prove this by finding a combinatorial interpretation of the difference $\mathcal{H} \geq 0$ of the right-hand side and the left-hand side, but even for $d = 3$ we have that

$$\varphi(f_1, \ldots, f_9) \;=\; (f_1^2 + f_2^2 + f_3^3) \cdot (f_4^2 + f_5^2 + f_6^3) \cdot (f_7^2 + f_8^2 + f_9^3) - \det \begin{pmatrix} f_1 & f_2 & f_3 \\ f_4 & f_5 & f_6 \\ f_7 & f_8 & f_9 \end{pmatrix}$$

is not a 9-variate relativizing functional closure property of $\#\mathsf{P}$, see [12, §7.2]. In particular, if the function is not a closure property of $\#\mathsf{P}$, then there are instantiations $f_1, \ldots, f_9 \in \#\mathsf{P}$ such that $\varphi(f_1, \ldots, f_9)$ is not in $\#\mathsf{P}$, whereas a combinatorial interpretation of $\mathcal{H}$ should yield $\varphi(f_1, \ldots, f_9) \in \#\mathsf{P}$. This does not rule out a more indirect combinatorial proof for the inequality: For example, for proving combinatorially that $(a-1)^2 \geq 0$ one could try to interpret the quantity $(a-1)^2$ combinatorially, but $(f_1 - 1)^2$ is not a relativizing closure property of $\#\mathsf{P}$. However, $f_1 \cdot (f_1 - 1)^2 = 6\binom{f_1}{3} + 2\binom{f_1}{2}$ is a relativizing closure property of $\#\mathsf{P}$ (see [12, §2.4]). There is an obvious combinatorial interpretation of $6\binom{a}{3} + 2\binom{a}{2}$ as counting size 2 and 3 subsets with multiplicity 6 and 2, respectively. Hence this gives an indirect combinatorial proof for the inequality $(a-1)^2 \geq 0$ by providing a combinatorial interpretation for $a(a-1)^2$.

Some inequalities are only true if the inputs satisfy certain constraints. For example, the *Ahlswede Daykin inequality*, see [1], [2], [12, §1.2(3)]: If $a_0b_0 \geq c_0d_0$ and $a_0b_1 \geq c_0d_1$ and $a_1b_0 \geq c_0d_1$ and $a_1b_1 \geq c_1d_1$, then $(c_0+c_1)(d_0+d_1) \geq (a_0+a_1)(b_0+b_1)$. If all quantities are in $\#\mathsf{P}$, including the differences $c_0d_0 - a_0b_0$, can we conclude that $(c_0 + c_1)(d_0 + d_1) - (a_0 + a_1)(b_0 + b_1)$ is in $\#\mathsf{P}$? This is an example of a promise problem: We are given twelve $\#\mathsf{P}$ functions $a_0, a_1, b_0, b_1, c_0, c_1, d_0, d_1, h_1, h_2, h_3, h_4$ with the guarantee that $a_0b_0 + h_1 = c_0d_0$, $a_0b_1 + h_2 = c_0d_1$, $a_1b_0 + h_3 = c_0d_1$, $a_1b_1 + h_4 = c_1d_1$. In other words, the 12-dimensional output vector that we get for every $w \in \Sigma^*$ lies on a codimension 4 algebraic subvariety in $\mathbb{Q}^{12}$. Recall that an algebraic subvariety is defined as the simultaneous zero set of a set of polynomials. Since the 4 variables $h_1, \ldots, h_4$ are determined by the other 8, this variety is a so-called *graph* or *graph variety*. Numerous questions about combinatorial proofs for inequalities from different areas of mathematics can be phrased in the language of graph varieties, see [12]. The idea is to collect the equations for a set S (the variety) into what is called the *vanishing ideal* I, i.e., $I = I(S) = \{\varphi \in \mathbb{Q}[f_1, \ldots, f_m] \mid \forall (f_1, \ldots, f_m) \in S : \varphi(f_1, \ldots, f_m) = 0\}$; and define the *coordinate ring* $\mathbb{Q}[S]$ as the quotient ring $\mathbb{Q}[f_1, \ldots, f_m]/I(S)$, see [7]. An element in the quotient ring is a coset with respect to the vanishing ideal. If there exists a representative

φ' in a coset $\varphi + I$ that is a functional closure property of #P, then every function in $\varphi + I$ is a promise closure property of #P on the variety S. It is desirable to also have the opposite direction, but this only holds under some reasonable restrictions on S, in particular it holds for all graph varieties. This is used in [12, Prop. 2.5.1] to show that $c_0d_0 - a_0b_0$ is not a relativizing promise closure property of #P on this graph variety. We prove the same strong dichotomy for monotone graph varieties for #FA instead of #P, see Theorem 4.9.

The systematic study of combinatorial interpretations and combinatorial proofs via definitions from computational complexity theory is a very recent research direction [15, 16, 12, 17, 13, 5, 6]. The goal is to determine whether or not certain quantities admit a combinatorial description or not. Famous open questions of this type in algebraic combinatorics have been listed by Stanley in [22], for example his problems 9, 10, and 12. As many combinatorialists do, Stanley has phrased his questions in an informal way without mentioning counting classes.

The class #P is the correct class for some purposes, but for others it is too large. For example, the determinant of a skew-symmetric matrix with entries from $\{-1, 0, 1\}$ is always non-negative, but this quantity is trivially in #P, because the determinant can be computed in polynomial time. This gives no satisfying insight into whether or not this quantity has a combinatorial interpretation. Smaller counting classes are required (see also the discussion in [15, §1]), and we provide the first study of functional closure properties for the subclass #FA $\subset$ #P. Unlike the classification for #P, our results do not rely on oracle separations, i.e., our classification is entirely unconditional.

1.2 Our results

Let $n \operatorname{rem} p \in \{0, \ldots, p-1\}$ denote the smallest nonnegative r such that $n \equiv_p r$. A function $\varphi : \mathbb{N} \to \mathbb{N}$ is called *ultimately PORC* (Polynomial On Residue Classes[4]) if $\exists p, N \in \mathbb{N}$ and there exist polynomials $\varphi_0, \ldots, \varphi_{p-1} : \mathbb{N} \to \mathbb{Q}$ such that for every $n \geq N$ we have $\varphi(n) = \varphi_{n \operatorname{rem} p}(n)$ [5].

We first classify the univariate functional closure properties of #FA:

- **Theorem** (see Theorem 3.22). *A function $\varphi : \mathbb{N} \to \mathbb{N}$ is a functional closure property of #FA if and only if φ is an ultimately PORC function.*

More generally, we classify the multivariate functional closure properties of #FA:

- **Theorem** (see Theorem 3.23). *A function $\varphi : \mathbb{N}^m \to \mathbb{N}$ is a functional closure property of #FA if and only if φ can be written as a finite sum of finite products of univariate ultimately PORC functions.*

We analyze the special case of multivariate polynomials:

- **Theorem** (see Lemma 3.26). *A multivariate polynomial $\varphi : \mathbb{N}^m \to \mathbb{N}$ with rational coefficients is a functional closure property of #FA iff for every ψ that can be formed from φ by replacing any subset of variables – including the empty set – by constants from $\mathbb{N}$, then all dominating terms of ψ in the binomial basis have positive coefficients.*

---

[4] PORC functions are also known as quasipolynomials or pseudopolynomials, but we want to avoid those names for the potential confusion to quasipolynomial growth and pseudopolynomial running times.

[5] Note that each φ in this paper is defined on the natural numbers and maps to the natural numbers, which is a subtle restriction. For example, a univariate polynomial $\varphi : \mathbb{Q} \to \mathbb{Q}$ maps integers to integers if and only if its coefficients in the binomial basis are integers, see Section 2. However, non-negativity is not an algebraic property. Also note that for the case of φ being just a univariate polynomial, the corresponding linear recursive sequence can have negative entries in the matrix.

We lift this result to monotone graph varieties (and to more general sets, see Theorem 4.6), where we get exactly the desirable classification given by the vanishing ideal:

- **Theorem** (see Theorem 4.9). *Let S be a monotone graph variety and let $I = I(S)$ be its vanishing ideal. A multivariate polynomial $\varphi : S \to \mathbb{N}$ is a functional promise closure property of #FA with regard to S if and only if there exists $\psi \in I$ such that $\varphi + \psi$ is a multivariate functional closure property of #FA.*

2 Notation

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$. For a finite set Σ let $\Sigma^\star$ denote the set of all finite length sequences with elements from Σ. The vector space of multivariate polynomials $\mathbb{Q}[f_1, \ldots, f_m]$ in variables $f_1, \ldots, f_m$ has a basis given by products of binomial coefficients: $\left\{ \prod_{i=1}^m \binom{f_i}{c_i} \right\}_{c_1,\ldots,c_m}$, where each $c_i \in \mathbb{N}$. Here we used $\binom{x}{c} = \frac{1}{c!} x \cdot (x-1) \cdot \ldots \cdot (x-c+1)$ as a polynomial. This is called the *binomial basis*. A multivariate polynomial φ is called *integer valued* if $\varphi(\mathbb{Z}^m) \subseteq \mathbb{Z}$, which is equivalent to $\varphi(\mathbb{N}^m) \subseteq \mathbb{Z}$, and which is also equivalent to all coefficients in the binomial basis being integers, see for example [12, Prop. 4.2.1] for a short proof of this classical fact.

We now recall (see [9, Def. 2.1]) our main model of computation, the finite $\mathbb{N}$-weighted automaton, which we just call non-deterministic finite automaton (NFA) for brevity.

▶ **Definition 2.1.** *An NFA M is a tuple $(Q, \Sigma, \mathrm{wt}, \mathrm{in}, \mathrm{out})$ where the set of states Q and the alphabet Σ are finite sets and $\mathrm{wt} : Q \times \Sigma \times Q \to \mathbb{N}$ is the weighted transition function, $\mathrm{in} : Q \to \mathbb{N}$ are the weighted initial states and $\mathrm{out} : Q \to \mathbb{N}$ are the weighted accepting states*[6]*. A* computation *P for a word $w = w_1 \ldots w_n \in \Sigma^\star$ of length n is a sequence $q_0 q_1 \ldots q_n$ in Q^{n+1}. It has* multiplicity *or* weight[7] *$\mathbf{w}(P) = \mathrm{in}(q_0) \cdot \prod_{i=1}^n \mathrm{wt}(q_{i-1}, w_i, q_i) \cdot \mathrm{out}(q_n)$ and* partial weight *$\underline{\mathbf{w}}(P) = \mathrm{in}(q_0) \cdot \prod_{i=1}^n \mathrm{wt}(q_{i-1}, w_i, q_i)$. We say that M* computes *$f : \Sigma^\star \to \mathbb{N}$ where $f(w)$ is the sum of the weights over all computations of M on w. The class #FA is defined as the set of all functions $f : \Sigma^\star \to \mathbb{N}$ that are computed by NFAs.*

If needed to distinguish these for different automata, we use a corresponding subscript, for example the weights of computations in M_f would be denoted by $\mathbf{w}_f$, etc.

▶ **Definition 2.2** (Simple NFA). *We say an NFA $M = (Q, \Sigma, \mathrm{wt}, \mathrm{in}, \mathrm{out})$ is* simple *if $\mathrm{im\,wt}, \mathrm{im\,in}, \mathrm{im\,out} \subseteq \{0, 1\}$.*

The notion of a simple NFA also motivates our use of the term NFA opposed to $\mathbb{N}$-weighted automaton: We simply count the number of accepting paths of M on a word w. This is in line with #P counting the number of accepting paths on a polynomial time non-deterministic Turing machine.

▶ **Lemma 2.3** (Folklore). *For every NFA M there exists a simple NFA M' computing the same function.*

[6] Note that in definitions by other authors one can find simpler versions of NFAs, in particular unweighted initial and accepting states and unweighted edges while also restricting to a single initial state. We will see soon that working with unweighted NFAs is not a restriction, but additionally restricting the model to have a single initial state is strictly weaker, since this model could not compute any function f with $f(\varepsilon) > 1$. To obtain the same expressiveness one would have to additionally allow for ε-transitions, while disallowing cycles of ε-transitions to prevent infinite values for f.

[7] We will use both of these terms interchangeably. For a weighted automaton, calling this weight is more natural, while when looking at the underlying graph as a multigraph, multiplicity of paths and walks is more natural.

A proof of this simple fact can be found in the appendix of the full version, for the sake of completeness. We denote by $a \equiv_p b$ that $a \in \mathbb{N}$ and $b \in \mathbb{N}$ are congruent modulo $p \in \mathbb{N} \setminus \{0\}$. The indicator function $\mathbb{1}_{n=c} : \mathbb{N} \to \mathbb{N}$ is defined as $n \mapsto \begin{cases} 1 & \text{if } n = c \\ 0 & \text{otherwise} \end{cases}$ and analogously for different conditions. By abuse of notation, if we have a function $f : \Sigma^\star \to \mathbb{N}$ and an expression $\varphi : \mathbb{N} \to \mathbb{N}$ in n, we replace n by f in the expression to denote $\varphi \circ f$. For example we use $\mathbb{1}_{f=c}$ to denote the function $w \mapsto \mathbb{1}_{f(w)=c}$, similarly $\binom{f}{2}$ denotes the function $w \mapsto \binom{f(w)}{2}$. Furthermore we use the notation $[n]$ to denote the set $\{1, \ldots, n\}$ for any $n \in \mathbb{N}$.

3 Functional closure properties

3.1 Univariate functional closure properties

We say a function $\varphi : \mathbb{N} \to \mathbb{N}$ is a functional closure property of #FA if $\varphi(\#\mathsf{FA}) \subseteq \#\mathsf{FA}$, i.e. if for every function $f \in \#\mathsf{FA}$ the function $\varphi \circ f$ is also in #FA. Our goal in this section is to classify all functional closure properties of #FA. They will be precisely the ultimately PORC functions.

We call a function $\varphi : \mathbb{N} \to \mathbb{N}$ an *ultimately almost PORC function* if there is a *quasiperiod* p, an *offset* $N \in \mathbb{N}$ and *constituents* $\varphi_0, \ldots, \varphi_{p-1} : \mathbb{N} \to \mathbb{Q}$, where each φ_i is either a polynomial with rational coefficients or a function in $2^{\Theta(n)}$, and for every $n \geq N$ we have $\varphi(n) = \varphi_{n \operatorname{rem} p}(n)$. If all the constituents are polynomials, we call φ an *ultimately PORC function*. The smallest representative of each constituent and of the finite cases before the periodic behaviour is captured by the *shifted remainder* operator $n \operatorname{srem}_p N$, defined via

$$n \operatorname{srem}_p N = \begin{cases} n & \text{if } n < N \\ \min\{k \geq N \mid k \equiv_p n\} & \text{if } n \geq N \end{cases}$$

The first half of the section is dedicated to proving that every ultimately PORC function is a functional closure property of #FA, see Lemma 3.18. In order to prove this we show that #FA is closed under

▶ **Lemma 3.1** (Addition). *If $f, g \in \#\mathsf{FA}$, then $f + g \in \#\mathsf{FA}$.*

▶ **Lemma 3.2** (Multiplication). *If $f, g \in \#\mathsf{FA}$, then $f \cdot g \in \#\mathsf{FA}$.*

▶ **Lemma 3.9** (Subtraction of constants). *If $f \in \#\mathsf{FA}$, then $\forall c \in \mathbb{N} : \max(f - c, 0) \in \#\mathsf{FA}$.*

▶ **Lemma 3.10** (Clamping). *If $f \in \#\mathsf{FA}$, then $\min(f, c) \in \#\mathsf{FA}$ for any constant $c \in \mathbb{N}$.*

▶ **Lemma 3.11** (Comparison with constants). *If $f \in \#\mathsf{FA}$, then the functions $\mathbb{1}_{f=c}$, $\mathbb{1}_{f \leq c}$, $\mathbb{1}_{f \geq c}$ are in #FA for any constant $c \in \mathbb{N}$.*

▶ **Lemma 3.13** (Division by constants). *If $f \in \#\mathsf{FA}$, then $\forall c \in \mathbb{N} \setminus \{0\} : \lfloor f/c \rfloor \in \#\mathsf{FA}$.*

▶ **Lemma 3.14** (Modular arithmetic). *If $f \in \#\mathsf{FA}$, then the function $\mathbb{1}_{f \equiv_c d}$ is in #FA for any constants $c \in \mathbb{N} \setminus \{0\}$ and $d \in \mathbb{Z}_c$.*

▶ **Lemma 3.15** (Binomial coefficients). *If $f \in \#\mathsf{FA}$, then $\binom{f}{c} \in \#\mathsf{FA}$ for any constant $c \in \mathbb{N}$.*

While addition and multiplication are technically bivariate functional closure properties, we list them here already since they are abundantly used throughout the proofs of the univariate functional closure properties. Proofs of those two classical results can be found in [8, Ch. 4.1 and 4.2.2] and in the appendix of the full version, for the sake of completeness.

With the exception of binomial coefficients all the other closure properties need to be able to "remove" some of the possible computations. For example, consider decrementation, the special case of truncated subtraction by one, and consider some simple NFA M computing some strictly positive function f. We now want to construct an NFA M' that computes $f-1$, i.e. an NFA that has exactly one non-zero computation less than M (assuming computations of weights zero or one). For this we want a procedure to single out one non-zero computation of M to then change its weight to zero. For stronger models of computation – like polynomial time non-deterministic Turing machines – this approach seems hopeless. Already deciding the existence of one such computation is NP-hard. However for NFAs, deciding the existence of a non-zero computation can be decided by a deterministic finite automaton, namely the powerset automaton. Adjusting the powerset construction to filter out a single non-zero computation, namely the lexicographically minimal one can then be used to show that decrementation is a closure property of #FA.

Generalizing this approach to more general properties about the computations gives us the framework of stepwise computation properties:

▶ **Definition 3.3** (Stepwise computation property). *Let $M = (Q, \Sigma, \mathrm{wt}, \mathrm{in}, \mathrm{out})$ be an NFA. A* stepwise computation property prop *is defined as* $\mathrm{prop} = (S, \mathrm{init}, \mathrm{step}, \mathrm{cond})$ *where S is a finite set and* $\mathrm{init} : Q \to S$, $\mathrm{step} : Q \times \Sigma \times Q \times S \to S$ *and* $\mathrm{cond} : S \to \{0,1\}$ *are functions. For $w = w_1 \dots w_n \in \Sigma^\star$ and a computation $P = q_0 \dots q_n$ of M on w we define a* step sequence $s_0 := \mathrm{init}(q_0)$ *and* $s_i := \mathrm{step}(q_{i-1}, w_i, q_i, s_{i-1})$ *for $i \in [n]$. We also write* $\mathrm{prop}(w, P) := \mathrm{cond}(s_n)$ *to be the evaluation of the property.*

These stepwise computation properties now enable us, given a simple NFA, to construct NFAs computing both of the following:

▶ **Lemma 3.4.** *Let M_f be a simple NFA computing a function f and let* prop *be a stepwise computation property. Then there is an NFA M computing $g(w) = \sum_P \mathbf{w}_f(P) \cdot \mathrm{prop}(w, P)$, where the sum is over all computations P of M_f on w.*

▶ **Lemma 3.5.** *Let M_f be a simple NFA computing a function f and let* prop *be a stepwise computation property. Then there is an NFA M computing $g(w) = \sum_P \mathrm{prop}(w, P)$, where the sum is over all computations P of M_f on w.*

Proof sketch. For both of these lemmas, we construct a sort of product automaton of M_f and prop (represented by the set S), the details can be found in the appendix of the full version. ◀

In other words, stepwise computation properties allow us to either "disable" specific computations of M_f or they allow us to directly extract information about the computations of M_f. Note that the restriction on the finiteness of S is necessary, as the elements of S are hard-coded into the state space of the NFA in Lemmas 3.4 and 3.5. In particular, these lemmas do not hold for even countably infinite S, which can be seen with the example $S = \mathbb{N}$ when we define the stepwise computation property in such a way that $\mathrm{prop}(w, P) = 1$ iff $|w|$ is prime, leading to an NFA recognizing the language of all words of prime length, a well known contradiction.

Further note that these two constructions do not incur exponential blowups themselves, however for most of our applications the set S will be of exponential size in the number of states of M_f.

Returning to our decrementation example, to use Lemma 3.4 we want to construct a stepwise computation property prop with $\text{prop}(w, P) = 0$ iff P is the lexicographically smallest non-zero weight computation on w. For this we can set $S = \mathcal{P}(Q)$ to be the set of all subsets of states Q, denoting the set of states that currently are the endpoints of lexicographically smaller partial computations of non-zero weight than the partial computation P we are on. We need to store all such potential states, since some current partial non-zero weight computations might not be possible to be completed to a full non-zero weight computation. Initially this set contains all states that are smaller than the start state of P, the step function then checks which lexicographically smaller partial computations can be extended and whether any new partial computations that agreed with P up to this state can be lexicographically smaller than P. Finally the cond function then checks whether there are any such lexicographically smaller partial computations left that can be completed to a non-zero weight computation, i.e. that end on a state $q \in Q$ with $\text{out}(q) = 1$.

We want to generalize this idea to be able to generally create stepwise computation properties that argue about the number of non-zero computations, either in total or lexicographically smaller than a given computation. However doing this in general would require choosing the set S as the set of functions $Q \to \mathbb{N}$, which is infinite. As a result we embed the number of computations into finite semirings first to then extract the relevant information. For this purpose we only consider semirings with both additive and multiplicative identities. Homomorphisms h from a semiring $\mathcal{R}$ into another semiring $\mathcal{R}'$ need to fulfill $h(a + b) = h(a) + h(b)$, $h(a \cdot b) = h(a) \cdot h(b)$, $h(1_{\mathcal{R}}) = 1_{\mathcal{R}'}$, $h(0_{\mathcal{R}}) = 0_{\mathcal{R}'}$. Since every element of $\mathbb{N}$ is either 0 or can be formed by repeated addition of 1, any homomorphism from $\mathbb{N}$ into any other semiring is uniquely defined.

We can then use $\mathcal{R}$ to construct stepwise computation properties (the full proofs can be found in the appendix of the full version). Combined with Lemmas 3.4 and 3.5 these use similar ideas to [14].

▶ **Lemma 3.6.** *Let $N = (Q, \Sigma, \text{wt}, \text{in}, \text{out})$ be a simple NFA and let $\mathcal{R}$ be a finite semiring and let $\tau : \mathbb{N} \to \mathcal{R}$ be the unique homomorphism from $\mathbb{N}$ to $\mathcal{R}$. For any function $\pi : \mathcal{R} \to \{0, 1\}$ there is a stepwise computation property* prop *with* $\text{prop}(w, P) = \pi(\tau(\sum_{P'} \mathbf{w}(P')))$*, where the sum is over all computations P' of N on w, independent of P.*

Proof sketch. Construct $\text{prop} = (S, \text{init}, \text{step}, \text{cond})$ via: $S = Q \to \mathcal{R}$, $\text{init}(q) = r \mapsto \tau(\text{in}(r))$, $\text{step}(q, \sigma, q', s) = r \mapsto \sum_{r' \in Q} s(r') \cdot \tau(\text{wt}(r', \sigma, r))$, and $\text{cond}(s) = \pi\big(\sum_{r \in Q} s(r) \cdot \tau(\text{out}(r))\big)$. Let $s_0, \ldots, s_n$ be the step sequence of any computation P of w. Since τ is a homomorphism, we can pull out τ. Thus $s_i(q) = \tau(\sum_{\tilde{P}} \underline{\mathbf{w}}(\tilde{P}))$, where the sum is over all computations $\tilde{P}$ of $w_1, \ldots w_i$ ending in the state q. The condition cond then completes this to $\text{prop}(w, P) = \pi(\tau(\sum_{P'} \mathbf{w}(P')))$, where the sum is over all computations P' of N on w. ◀

▶ **Lemma 3.7.** *Let $M = (Q, \Sigma, \text{wt}, \text{in}, \text{out})$ be a simple NFA with some ordering $<$ of Q, let $\mathcal{R}$ be a finite semiring and let $\tau : \mathbb{N} \to \mathcal{R}$ be the unique homomorphism from $\mathbb{N}$ to $\mathcal{R}$. For any function $\pi : \mathcal{R} \to \{0, 1\}$ there is a stepwise computation property* prop *with* $\text{prop}(w, P) = \pi(\tau(\sum_{P'} \mathbf{w}(P')))$ *for all non-zero computations P of N on w, where the sum is over all computations P' of N on w that are lexicographically smaller than P.*

Proof sketch. Construct $\text{prop} = (S, \text{init}, \text{step}, \text{cond})$ via: $S = Q \to \mathcal{R}$, $\text{init}(q) = r \mapsto \tau(\mathbb{1}_{r<q} \cdot \text{in}(r))$, $\text{step}(q, \sigma, q', s) = r \mapsto \sum_{r' \in Q} s(r') \cdot \tau(\text{wt}(r', \sigma, r)) + \tau(\mathbb{1}_{r<q'} \cdot \text{wt}(q, \sigma, r))$, $\text{cond}(s) = \pi(\sum_{r \in Q} \tau(\text{out}(r)) \cdot s(r))$. Let $s_0, \ldots, s_n$ be the step sequence of any computation $P = q_0 \ldots q_n$ of w. Inductively we can show that $s_i(r) = \sum_{P'} \tau(\underline{\mathbf{w}}(P'))$ for all $i \in \{0, \ldots, n\}$ and $r \in Q$, where the sum is over all computations $P' = q'_0 \ldots q'_i$ of N on $w_1 \ldots w_i$ with

$q'_i = r$ that are lexicographically smaller than $q_0 \dots q_i$. Initially the only computations $P' = q'_0$ that are lexicographically smaller than the computation q_0 are the ones with $q'_0 < q_0$. For $i > 0$ for a computation $P' = q'_0 \dots q'_i$ to be lexicographically smaller than $q_0 \dots q_i$ there are two possibilities. Either $q'_0 \dots q'_{i-1}$ is already lexicographically smaller than $q_0 \dots q_{i-1}$ or $q'_0 \dots q'_{i-1} = q_0 \dots q_{i-1}$ and $q'_i < q_i$. In the second case the weight of P' is precisely $w(q_{i-1}, w_i, q'_i)$ since P is a computation of non-zero weight and thus weight exactly 1. Combining all of this, we can finish the proof of the claim with a similar argument to Lemma 3.6. ◀

Note that the previous lemma makes no statement about the value of $\text{prop}(w, P)$ for any computations P of weight zero. However, this is enough for our uses, since we only combine it with Lemma 3.4, i.e., $\text{prop}(w, P)$ gets weighted by $\mathbf{w}(P)$.

Most commonly, as is the case for decrementation, we want to be able to exactly distinguish the number of non-zero computations if it is less than k and otherwise be able to tell that the number is at least k. This is achieved by using the following capped semiring:

▶ **Definition 3.8** (Capped semiring). *For $k \in \mathbb{N}$ we call the semiring $\mathcal{R}_k = \{0, \dots, k\}$ with the operations $a +_{\mathcal{R}} b := \min(a + b, k)$ and $a \cdot_{\mathcal{R}} b := \min(a \cdot b, k)$ the* capped *semiring.*

We can now show that decrementation is a functional closure property by simply using Lemma 3.7 using the capped semiring $\mathcal{R}_1$ and $\pi(a) = a$ to construct our wanted stepwise computation property computing $\text{prop}(w, P) = 0$ iff P is the lexicographically smallest non-zero weight computation on w.

Most of the remaining closure properties are now proven by using the capped semiring of a specific size and choosing the function π accordingly, we will show this in detail for the example of subtraction, the remaining proofs can be found in the appendix of the full version.

▶ **Lemma 3.9** (Subtraction of constants). *If $f \in \#\mathsf{FA}$, then $\forall c \in \mathbb{N} : \max(f - c, 0) \in \#\mathsf{FA}$.*

Proof. Let $M_f = (Q_f, \Sigma, \text{wt}_f, \text{in}_f, \text{out}_f)$ be a simple NFA computing f with an arbitrary ordering $<$ on Q_f. Lemma 3.7 on the capped semiring $\mathcal{R}_c$ with $\pi(a) = \mathbb{1}_{a \geq c}$ for all $a \in \mathcal{R}$ constructs a stepwise computation property prop with

$$\text{prop}(w, P) = \begin{cases} 1 & \text{if the number of non-zero computations } P' \text{ on } w \text{ that are lex. smaller than } P \text{ is at least } c \\ 0 & \text{otherwise} \end{cases}$$

for all computations P on w of non-zero weight, i.e., $\text{prop}(w, P) = 0$ iff P is one of the c lexicographically smallest computations on w with non-zero weight. It follows that the NFA M constructed by Lemma 3.4 computes $g(w) = \max(f(w) - c, 0)$. ◀

If instead of rejecting the c lexicographically smallest computations, we accept only those computations, we compute the minimum of f and c.

▶ **Lemma 3.10** (Clamping). *If $f \in \#\mathsf{FA}$, then $\min(f, c) \in \#\mathsf{FA}$ for any constant $c \in \mathbb{N}$.*

By using the capped semiring $\mathcal{R}_{c+1}$ with $\pi_=(a) = \mathbb{1}_{a=c}$, $\pi_\leq(a) = \mathbb{1}_{a \leq c}$ and $\pi_\geq(a) = \mathbb{1}_{a \geq c}$, we can compute the indicator functions $\mathbb{1}_{f=c}$, $\mathbb{1}_{f \leq c}$ and $\mathbb{1}_{f \geq c}$ respectively.

▶ **Lemma 3.11** (Comparison with constants). *If $f \in \#\mathsf{FA}$, then the functions $\mathbb{1}_{f=c}$, $\mathbb{1}_{f \leq c}$, $\mathbb{1}_{f \geq c}$ are in $\#\mathsf{FA}$ for any constant $c \in \mathbb{N}$.*

The previous lemma in particular also implies the following:

▶ **Lemma 3.12.** *If $\varphi : \mathbb{N} \to \mathbb{N}$ is a functional closure property of #FA and $\psi : \mathbb{N} \to \mathbb{N}$ is an arbitrary function with $\varphi(n) = \psi(n)$ for all but finitely many $n \in \mathbb{N}$, then ψ is also a functional closure property of #FA.*

Proof. Let $f \in \#\mathsf{FA}$ be arbitrary. Further let $N \in \mathbb{N}$ be such that $\varphi(n) = \psi(n)$ for all $n \geq N$. Then $(\psi \circ f)(w) = \sum_{i=0}^{N-1} \mathbb{1}_{f(w)=i}\psi(i) + \mathbb{1}_{f(w)\geq N}\varphi(f(w))$ for all $w \in \Sigma^\star$. In particular $\psi \circ f \in \#\mathsf{FA}$ since the $\psi(i)$ are constants and $\varphi \circ f \in \#\mathsf{FA}$. ◀

Division and modular arithmetic however use a different semiring: they use the finite cyclic semiring $\mathbb{Z}_c = \{0, \ldots, c-1\}$ with $\pi(a) = \mathbb{1}_{a=c-1}$ and $\pi(a) = \mathbb{1}_{a=d}$ respectively.

▶ **Lemma 3.13** (Division by constants)**.** *If $f \in \#\mathsf{FA}$, then $\forall c \in \mathbb{N} \setminus \{0\} : \lfloor f/c \rfloor \in \#\mathsf{FA}$.*

▶ **Lemma 3.14** (Modular arithmetic)**.** *If $f \in \#\mathsf{FA}$, then the function $\mathbb{1}_{f \equiv_c d}$ is in #FA for any constants $c \in \mathbb{N} \setminus \{0\}$ and $d \in \mathbb{Z}_c$.*

The previous closure properties turn out to already be sufficient to generate all functional closure properties, so in particular they are sufficient to generate binomial coefficients by using subtraction of constants, multiplication and division by constants by using the definition of binomial coefficients as a polynomial: $\binom{x}{c} = \frac{1}{c!}x \cdot (x-1) \cdot \ldots \cdot (x-c+1)$. Nonetheless, we give an additional proof for binomial coefficients as a different interesting application of the stepwise computation property framework.

▶ **Lemma 3.15** (Binomial coefficients)**.** *If $f \in \#\mathsf{FA}$, then $\binom{f}{c} \in \#\mathsf{FA}$ for any constant $c \in \mathbb{N}$.*

Proof. Let $M_f = (Q_f, \Sigma, \mathrm{wt}_f, \mathrm{in}_f, \mathrm{out}_f)$ be a simple NFA computing f and let $c \in \mathbb{N}$. For $c < 2$ the statement of this lemma is trivially true, so assume $c \geq 2$.

We construct the c-fold product automaton $M_f^c = (Q_f^c, \Sigma, \mathrm{wt}_f^c, \mathrm{in}_f^c, \mathrm{out}_f^c)$ with

$$\begin{aligned}
\mathrm{wt}_f^c((q_1, \ldots, q_c), \sigma, (q_1', \ldots, q_c')) &= \textstyle\prod_{i=1}^c \mathrm{wt}_f(q_i, \sigma, q_i') \\
\mathrm{in}_f^c((q_1, \ldots, q_c)) &= \textstyle\prod_{i=1}^c \mathrm{in}_f(q_i) \\
\mathrm{out}_f^c((q_1, \ldots, q_c)) &= \textstyle\prod_{i=1}^c \mathrm{out}_f(q_i)
\end{aligned}$$

M_f^c is a simple NFA and every computation on M_f^c is the cartesian product of c computations on M_f. Our aim is to now construct a stepwise computation property $\mathrm{prop} = (S, \mathrm{init}, \mathrm{step}, \mathrm{cond})$ such that $\mathrm{prop}(w, P) = 1$ iff P is composed of c pairwise distinct computations[8] on N_f.

For this let S be the set of all equivalence relations on the set $[c]$. We define $\mathrm{init}((q_0, \ldots, q_c))$ to be the equivalence relation R_0 with $(a, b) \in R_0$ iff $q_a = q_b$. Additionally we define $\mathrm{cond}(R) = 1$ iff R is the equivalence relation where every element is only equivalent to itself, i.e. a computation gets accepted iff all its constituent computations are pairwise distinct. Finally we define $\mathrm{step}((q_1, \ldots, q_c), \sigma, (q_1', \ldots, q_c'), R)$ to be the equivalence relation R' defined via $(a, b) \in R'$ iff $(a, b) \in R$ and $q_a' = q_b'$. With a simple induction we can prove that for a computation $P = P_1 \times \ldots \times P_c$ and the step sequence $R_0, \ldots, R_n$ we have $(a, b) \in R_i$ iff the computations P_a and P_b are identical for the first i steps. It follows that the NFA M constructed by Lemma 3.4 computes $g(w) = \binom{f(w)}{c} \cdot c!$. Now, $\binom{f}{c} \in \#\mathsf{FA}$ by Lemma 3.13. ◀

[8] We could also require them to be sorted in lexicographical order by having S be the set of all total preorders, but since we can divide by $c!$ we are going with the easier exposition.

While the combination of the previous lemmas can be used to show that any polynomial written in the binomial basis with non-negative integer coefficients is a functional closure property of #FA, we can do better by considering a shifted binomial basis. For example, consider the polynomial $\varphi(x) = \frac{x^2}{2} - \frac{3x}{2} + 1$. This polynomial is non-negative for all $x \in \mathbb{N}$. Writing φ in the binomial basis we get $\varphi(x) = \binom{x}{2} - \binom{x}{1} + 1$. If however we allow the upper indices of the binomial basis to be shifted, we can write φ without the use of negative coefficients as $\varphi(x) = \binom{x-1}{2}$. While $x - 1$ itself is not a functional closure property of #FA the function $\max(x-1, 0)$ is a functional closure property of #FA and is different from $x - 1$ for only finitely many $x \in \mathbb{N}$. In the same way we see that $\varphi'(x) := \binom{\max(x-1,0)}{2}$ only differs from φ for finitely many $x \in \mathbb{N}$, namely $x = 0$. Using Lemma 3.12 to change those finitely many values, we see that φ is indeed a functional closure property of #FA.

Generalizing this idea we will show with the next two lemmas that this is possible for any φ with integer coefficients in the binomial basis, with a small restriction: We don't show that φ itself is a functional closure property of #FA, but rather that $x \mapsto \max(\varphi(x), 0)$ is one. Note that this restriction is the best we can hope for, since no computation in an NFA can ever have negative weight.

▶ **Lemma 3.16.** *Let $\varphi(x) = \sum_{i=0}^{r} a_i \cdot \binom{x}{i}$ with $a_i \in \mathbb{Z}$ and $a_r > 0$. Then there are $b_0, \ldots, b_r \in \mathbb{N}$ and $c_0, \ldots, c_r \in \mathbb{N}$ with $\varphi(x) = \sum_{i=0}^{r} b_i \cdot \binom{x-c_i}{i}$.*

Proof sketch. We inductively prove this claim by using the Chu-Vandermonde identity [21] on the term of highest degree. It allows us to replace the highest degree binomial via $\binom{x-c_r}{r} = \sum_{i=0}^{r} (-1)^{r-i} \binom{r-i+c_r-1}{r-i} \binom{x}{i}$. For sufficiently large $c_r \in \mathbb{N}$ this implies that the leading term of $\varphi(x) - a_r \cdot \binom{x-c_r}{r}$ again is positive and of smaller degree. ◀

A full proof of the previous lemma can be found in the appendix of the full version.

▶ **Lemma 3.17** (Integer-valued polynomials)**.** *Let $f \in$ #FA and let $\varphi : \mathbb{Q} \to \mathbb{Q}$ be an integer-valued polynomial, then $\max(\varphi \circ f, 0) \in$ #FA.*

Proof. We can assume the leading coefficient of φ to be positive. Otherwise $\max(\varphi \circ f, 0)$ can be directly written as a finite sum $\sum_i c_i \cdot \mathbb{1}_{f=i}$ which is in #FA by Lemmas 3.1, 3.2 and 3.11. Write φ in the binomial basis as $\varphi(x) = a_0 \cdot \binom{x}{0} + \ldots + a_r \cdot \binom{x}{r}$ with $a_r > 0$. Since φ is integer-valued, all of the a_i are integers, see [12, Prop. 4.2.1]. Using Lemma 3.16 we get a representation $\varphi(x) = \sum_{i=0}^{r} b_i \cdot \binom{x-c_i}{i}$ with $b_0, \ldots, b_r \in \mathbb{N}$ and $c_0, \ldots, c_r \in \mathbb{N}$. For $x \geq \max\{c_i \mid 0 \leq i \leq r\} =: N$ we have that $\binom{x-c_i}{i} = \binom{\max(x-c_i,0)}{i}$ and thus $\psi(x) := \sum_{i=0}^{r} b_i \cdot \binom{\max(x-c_i,0)}{i}$ only differs from $x \mapsto \max(\varphi(x), 0)$ on finitely many inputs and is a functional closure property of #FA by Lemmas 3.1, 3.2, 3.9 and 3.15. Lemma 3.12 then finishes off the claim. ◀

We now have the tools available to show our claim that every ultimately PORC function is a functional closure property of #FA.

▶ **Lemma 3.18.** *Every ultimately PORC function is a functional closure property of* #FA*.*

Proof. Let $\varphi : \mathbb{N} \to \mathbb{N}$ be an ultimately PORC function with period p comprised of the polynomial constituents $\varphi_0, \ldots, \varphi_{p-1} : \mathbb{N} \to \mathbb{Q}$ and $N \in \mathbb{N}$, s.t. for all $n \geq N$ we have $\varphi(n) = \varphi_{n \operatorname{rem} p}(n)$. Additionally let $f \in$ #FA. We can write

$$\varphi \circ f = \sum_{i=0}^{N-1} \mathbb{1}_{f=i} \cdot \varphi(i) + \mathbb{1}_{f \geq N} \cdot \left(\sum_{i=0}^{p-1} \mathbb{1}_{f \equiv_p i} \cdot \lfloor \max(\varphi_i \circ f, 0) \rfloor \right).$$

Figure 1 NFAs computing the functions $1^n \mapsto n$ and $1^n \mapsto 2^n$ respectively. Edges with a multiplicity of 2 are denoted by listing the edge label twice.

Combining Lemmas 3.1, 3.2, 3.11 and 3.14 this shows $\varphi \circ f \in \#\mathsf{FA}$, if we can show $\lfloor \max(\varphi_i \circ f, 0) \rfloor \in \#\mathsf{FA}$ for all $i \in \{0, \dots, p-1\}$. To show this let α_i be the common denominator of the coefficients of φ_i. Then $\alpha_i \cdot \varphi_i$ is a polynomial with integer coefficients, so it in particular is an integer-valued polynomial and by Lemma 3.17 we have that $\max(\alpha_i \cdot \varphi_i \circ f, 0) \in \#\mathsf{FA}$. Combining this with Lemma 3.13 we get that $\left\lfloor \frac{\max(\alpha_i \cdot \varphi_i \circ f, 0)}{\alpha_i} \right\rfloor = \lfloor \max(\varphi_i \circ f, 0) \rfloor \in \#\mathsf{FA}$. ◀

The remainder of this section is dedicated to showing that no other functional closure properties of $\#\mathsf{FA}$ exist. This will make use of the following well known algebraic interpretation of NFAs:

▶ **Lemma 3.19** (see [19]). *If $M = (Q, \Sigma, \mathrm{wt}, \mathrm{in}, \mathrm{out})$ is an NFA, then there are matrices $A_\sigma \in \mathbb{N}^{|Q| \times |Q|}$ for each symbol $\sigma \in \Sigma$ and vectors $a, b \in \mathbb{N}^{|Q|}$, s.t. M computes $a^T \cdot \left(\prod_{j=1}^{|w|} A_{w_j} \right) \cdot b$ for all $w \in \Sigma^\star$.*

Proof. We index A_σ, a and b using states $q, q' \in Q$. Choose $(A_\sigma)_{q,q'} = \mathrm{wt}(q, \sigma, q')$, $a_q = \mathrm{in}(q)$ and $b_q = \mathrm{out}(q)$. It is now easy to see that M computes exactly $a^T \cdot \left(\prod_{j=1}^{|w|} A_{w_j} \right) \cdot b$. ◀

When restricting to a unary alphabet $\Sigma = \{\sigma\}$, this degenerates the computed function to $a^T \cdot A_\sigma^{|w|} \cdot b$. In order to analyze the behaviour of these functions we first analyze the behaviour of the matrix power as a function in $|w|$ in the next two lemmas. Their proofs can be found in the appendix of the full version.

▶ **Lemma 3.20.** *Let $A \in \mathbb{N}^{k \times k}$. Then any diagonal entry of A^n is a function $f : \mathbb{N} \to \mathbb{N}$ with one of the following properties:*

1. *$f(n) = 0$ for all $n \in \mathbb{N} \setminus \{0\}$ and $f(0) = 1$.*
2. *There is a $p \in \mathbb{N} \setminus \{0\}$, such that for all $n \in \mathbb{N}$ we have $f(n) = \mathbb{1}_{n \equiv_p 0}$.*
3. *There is a $p \in \mathbb{N} \setminus \{0\}$ and a function $g \in 2^{\Theta(n)}$, such that for all $n \in \mathbb{N}$ we have $f(n) = \mathbb{1}_{n \equiv_p 0} \cdot g(n)$.*

These naturally correspond to vertices v in the multigraph defined by the adjacency matrix A with

1. no paths from v to v.
2. exactly one path from v to v of length p.
3. multiple walks from v to v where the lengths of all the walks from v to v have gcd p.

We can then lift this result to all entries of A^n.

▶ **Lemma 3.21.** *If $A \in \mathbb{N}^{k \times k}$, then each entry of A^n is an ultimately almost PORC function.*

▶ **Theorem 3.22** (Classification of univariate functional closure properties of $\#\mathsf{FA}$). *A function $\varphi : \mathbb{N} \to \mathbb{N}$ is a functional closure property of $\#\mathsf{FA}$ iff φ is an ultimately PORC function. This even holds when $\#\mathsf{FA}$ is restricted to unary languages.*

Proof. Lemma 3.18 already shows that every ultimately PORC function is a closure property of $\#\mathsf{FA}$. It remains to show that all functional closure properties of $\#\mathsf{FA}$ are ultimately PORC functions. For this let $\varphi : \mathbb{N} \to \mathbb{N}$ be a functional closure property of $\#\mathsf{FA}$. The function

$f : \{1\}^\star \to \mathbb{N}$ defined by $f(1^n) = n$ is computed by the left NFA in Figure 1 and thus in #FA. Consequently $\varphi \circ f \in$ #FA. Let $M = (Q, \{1\}, \mathrm{wt}, \mathrm{in}, \mathrm{out})$ be an NFA computing $\varphi \circ f$. By Lemma 3.19 this NFA induces a transition matrix $A \in \mathbb{N}^{|Q|\times|Q|}$ and vectors $a, b \in \mathbb{N}^{|Q|}$, s.t. $a^T A^n b = \varphi(f(1^n)) = \varphi(n)$ for all $n \in \mathbb{N}$. Every entry of A^n is an ultimately almost PORC function by Lemma 3.21 and thus $a^T A^n b = \varphi(n)$ is one as well. Let p be the quasiperiod of φ and let φ_i be one of the constituents of φ corresponding to some residue class $i \in \{0, \dots, p-1\}$. Assume for the sake of contradiction that φ_i grows in $2^{\Theta(n)}$, i.e. there is a constant $\gamma \in \mathbb{R}^+$ and $N \in \mathbb{N}$, s.t. for every $n \geq N$ we have $\varphi_i(n) \geq 2^{\gamma n}$. Consider the function $f_{p,i} : \{1\}^\star \to \mathbb{N}$ defined by $f_{p,i}(1^n) = p \cdot (2^n + N) + i$. We claim $f_{p,i}$ is in #FA. The function $1^n \mapsto 2^n$ is computed by the right NFA in Figure 1 and thus in #FA. The remainder of the claim follows by Lemma 3.1 and Lemma 3.2. Note that $f_{p,i}(1^n) \equiv_p i$, so $\varphi \circ f_{p,i} = \varphi_i \circ f_{p,i}$ has to be in #FA as well. Furthermore $\varphi(f_{p,i}(1^n)) = \varphi_i(f_{p,i}(1^n)) = \varphi_i(p \cdot (2^n + N) + i) \geq 2^{\gamma p \cdot (2^n+N)+\gamma i}$ for all $n \in \mathbb{N}$ which is larger than any NFA can compute, since NFAs can only compute functions that are at most linearly exponential in the length of the input. We conclude that none of the constituents φ_i of φ can be exponential, so they are instead all polynomials, making φ an ultimately PORC function. ◀

3.2 Multivariate functional closure properties

▶ **Theorem 3.23** (Classification of multivariate functional closure properties of #FA)**.** *A function $\varphi : \mathbb{N}^m \to \mathbb{N}$ is a functional closure property of* #FA *iff φ can be written as a finite sum of finite products of univariate ultimately PORC functions.*

Proof. By Theorem 3.22 any univariate ultimately PORC function is a closure property of #FA. As such any finite sum or finite product of them is also a closure property of #FA by Lemmas 3.1 and 3.2.

It remains to show that all functional closure properties of #FA are of this form. For this let $\varphi : \mathbb{N}^m \to \mathbb{N}$ be a functional closure property of #FA. Define the alphabet $\Sigma = \{\sigma_1, \dots, \sigma_m\}$ and the functions $f_i : \Sigma^\star \to \mathbb{N}$ where $f_i(w) := \#_i(w)$ is defined as the number of occurences $\#_i(w)$ of the symbol σ_i in w. Applying the closure property to $f_1, \dots, f_m$ gives that $\varphi \circ (f_1, \dots, f_m) \in$ #FA and thus is computed by an NFA $M = (Q, \Sigma, \mathrm{wt}, \mathrm{in}, \mathrm{out})$. This induces transition matrices $A_\sigma \in \mathbb{N}^{|Q|\times|Q|}$ for each symbol $\sigma \in \Sigma$ and vectors $a, b \in \mathbb{N}^{|Q|}$, s.t. $a^T \prod_{j=1}^{|w|} A_{w_j} b = \varphi(f_1(w), \dots, f_m(w))$ for all $w \in \Sigma^\star$. Restricting to words of the form $w = \sigma_1^{n_1}\sigma_2^{n_2}\cdots\sigma_m^{n_m}$ for $n_1, \dots, n_m \in \mathbb{N}$ gives $a^T \left(\prod_{i=1}^m A_{\sigma_i}^{n_i}\right) b = \varphi(n_1, \dots, n_m)$. Using Lemma 3.21 on each of the $A_{\sigma_i}^{n_i}$ we see that every entry of $A_{\sigma_i}^{n_i}$ is an ultimately almost PORC function in n_i. Consequently, every entry of $\prod_{i=1}^m A_{\sigma_i}^{n_i}$ is a finite sum of products of different ultimately almost PORC functions and the same holds for $a^T \left(\prod_{i=1}^m A_{\sigma_i}^{n_i}\right) b = \varphi(n_1, \dots, n_m)$.

We now look at the individual summands of φ and prove that we can rewrite each one as a product of ultimately PORC functions by one-by-one rewriting the exponential constituents. For this let $\varphi^{(1)}(n_1)\cdots\varphi^{(m)}(n_m)$ be one of the summands of φ where $\varphi^{(1)}, \dots, \varphi^{(m)}$ are all ultimately almost PORC functions, with periods $p_1, \dots, p_m$, offsets $N_1, \dots, N_m$ and constituents $\varphi_0^{(i)}, \dots, \varphi_{p_i-1}^{(i)}$ for each $i \in [m]$. If none of the constituents are exponential we are done. Otherwise let $\varphi_j^{(i)}$ be one of the exponential constituents, let $\gamma \in \mathbb{R}^+$ and let $N \in \mathbb{N}$, s.t. $\varphi_j^{(i)}(n_i) \geq 2^{\gamma n_i}$ for $n_i \geq N$. We claim we can set $\varphi_j^{(i)}(n_i) = 0$ without changing the product $\varphi^{(1)}(n_1)\cdots\varphi^{(m)}(n_m)$ for any $n_1, \dots, n_m \in \mathbb{N}$. Call the resulting functions $\psi^{(i)}$ and $\psi_j^{(i)}$. Assume for the sake of contradiction, that there are some $c_1, \dots, c_m \in \mathbb{N}$ where $\varphi^{(1)}(c_1)\cdots\varphi^{(m)}(c_m) \neq \varphi^{(1)}(c_1)\cdots\varphi^{(i-1)}(c_{i-1})\cdot\psi^{(i)}(c_i)\cdot\varphi^{(i+1)}(c_{i+1})\cdots\varphi^{(m)}(c_m)$. This implies that $\varphi^{(1)}(c_1)\cdots\varphi^{(i-1)}(c_{i-1})\cdot\varphi^{(i+1)}(c_{i+1})\cdots\varphi^{(m)}(c_m) \neq 0$ and $c_i \geq N_i$ as we didn't change any other functions except $\varphi^{(i)}$ for $n_i \geq N_i$.

Constructing constant functions $f'_k(w) = c_k$ for $k \neq i$ and the function $f'_i(w) = p_i \cdot (2^{|x|} + \max(N_i, N)) + j$ which are all in #FA. We see that $\varphi \circ (f'_1, \ldots, f'_m) \in$ #FA. Note that for any $w \in \Sigma^\star$ we have $f'_i(w) \geq \max(N_i, N)$ and $f'_i(w) \equiv_{p_i} j$ and thus $\varphi^{(i)} \circ f'_i = \psi^{(i)}_j \circ f'_i$. Combining all of this we again reach a contradiction to the fact that NFAs can only compute at most linearly exponential functions via

$$\begin{aligned}\varphi(f'_1(w), \ldots, f'_m(w)) &\geq \varphi^{(1)}(c_1) \cdots \varphi^{(i-1)}(c_{i-1}) \cdot \varphi^{(i)}(f'_i(w)) \cdot \varphi^{(i+1)}(c_{i+1}) \cdots \varphi^{(m)}(c_m) \\ &\geq \varphi^{(i)}(f'_i(w)) \;=\; \varphi^{(i)}_j(f'_i(w)) \;=\; \varphi^{(i)}_j(p_i \cdot (2^{|w|} + \max(N_i, N)) + j) \\ &\geq 2^{\gamma p_i \cdot (2^{|w|} + \max(N_i, N)) + \gamma j}\,.\end{aligned}$$

Note that the first inequality holds due to all summands of φ being non-negative. ◀

Deciding whether a function φ has such a representation may not always be directly visible, however if φ is a multivariate polynomial we can be more explicit. Every integer-valued multivariate polynomial has integer coefficients when represented in the binomial basis (see [12, Prop. 4.2.1] for a proof of this fact). We say a term $a \cdot \binom{x_1}{d_1} \cdots \binom{x_m}{d_m}$ dominates another term $a' \cdot \binom{x_1}{d'_1} \cdots \binom{x_m}{d'_m}$ if $d_i \geq d'_i$ for all $i \in [m]$. A term is a dominating term of φ if it has non-zero coefficient and it is not dominated by any other term with non-zero coefficient. We can use a similar approach to Lemma 3.16 to rewrite φ as a positive integer linear combination of products of shifted binomials (details can be found in the appendix of the full version).

▶ **Lemma 3.24.** *Let $\varphi(x_1, \ldots, x_m) = \sum_{i=1}^{r} a_i \cdot \prod_{j=1}^{m} \binom{x_j}{d_{i,j}}$ with $a_i \in \mathbb{Z}$ and the coefficients of the dominating terms being positive. Then there are $a'_1, \ldots, a'_{r'} \in \mathbb{N}$ and $c_1, \ldots, c_{r'} \in \mathbb{N}$ with $\varphi(x_1, \ldots, x_m) = \sum_{i=1}^{r'} a'_i \cdot \prod_{j=1}^{m} \binom{x_j - c_i}{d_{i,j}}$.*

We can then use a generalization of Lemma 3.17 and replace subtractions $x_i - c'$ by $\max(x_i - c', 0)$. However special care has to be taken for $x_i < c'$, in which case x_i has to be replaced by the corresponding constants first. This adds the additional condition on φ.

▶ **Lemma 3.25.** *Let $\varphi : \mathbb{N}^m \to \mathbb{N}$ be a multivariate polynomial with rational coefficients, such that whenever ψ is formed from φ by replacing any set of variables – including the empty subset – by constants from $\mathbb{N}$, then all dominating terms of ψ have positive coefficients. Then φ is a functional closure property of* #FA.

▶ **Lemma 3.26.** *A multivariate polynomial $\varphi : \mathbb{N}^m \to \mathbb{N}$ with rational coefficients is a functional closure property of* #FA *iff for every ψ that can be formed from φ by replacing any subset of variables – including the empty set – by constants from $\mathbb{N}$, then all dominating terms of ψ have positive coefficients.*

Proof sketch. Lemma 3.25 already proves that all multivariate polynomials of this form are functional closure properties of #FA. Now let $\varphi : \mathbb{N}^m \to \mathbb{N}$ be a multivariate polynomial with rational coefficient and a functional closure property of #FA. By Theorem 3.23 φ can be written as a finite sum of finite products of ultimately PORC functions. Note that the leading coefficient of each constituent of these ultimately PORC functions is positive. By multivariate polynomial interpolation we can now show that φ is already a finite sum of finite products of these constituents. The dominating terms of φ are then formed by products of the leading coefficients of the constituents and thus are positive. ◀

4 Promise closure properties

▶ **Definition 4.1.** *Let $S \subseteq \mathbb{N}^m$ and let $\varphi : \mathbb{N}^m \to \mathbb{N}$ be a function. We call φ a* functional promise closure property *of #FA with regard to S if for every $f_1, \ldots, f_m \in$ #FA defined on some shared alphabet Σ there is a function $g \in$ #FA with $g(w) = \varphi(f_1(w), \ldots, f_m(w))$ for every $w \in \Sigma^\star$ for which $(f_1(w), \ldots, f_m(w)) \in S$.*

We now want to show that if S fulfils some property, namely admitting polynomial cluster sequences (we postpone the definition to Definition 4.5), then for every functional promise closure property with regard to S there is a functional closure property of #FA that agrees with it on all tuples in S. In other words we can interpolate the functional promise closure property φ on all values of S to obtain a functional closure property φ' for all of #FA. The proof for this follows along the following ideas: First, similar to Theorem 3.23, use the functional closure property φ on the unary counting functions to find an equivalent function φ' that is almost a functional closure property. However after this step some of the constituents of the ultimately almost PORC functions might still be exponential. Theorem 3.23 then proceeded by showing that we can replace all these exponential constituents by the constant zero function, as otherwise we were able to reach a contradiction by constructing functions $f'_1, \ldots, f'_m$ and an infinite sequence of inputs $w^{(i)}$, such that $\varphi(f'_1(w^{(i)}), \ldots, f'_m(w^{(i)}))$ grows doubly exponential in the length of the inputs. However when dealing with functional promise closure properties we have to be more careful when choosing $f'_1, \ldots, f'_m$ and the $w^{(i)}$, because we need $(f'_1(w^{(i)}), \ldots, f'_m(w^{(i)})) \in S$ to reach a contradiction. Additionally we don't replace the exponential constituents by the constant zero-function but rather a polynomial that behaves the same for small inputs. For this we need a special variant of univariate polynomial interpolation that yields integer-valued polynomials that are non-negative for all inputs from $\mathbb{N}$:

▶ **Lemma 4.2.** *Let $c_0, \ldots, c_N \in \mathbb{N}$. Then there is an integer-valued polynomial $q : \mathbb{Q} \to \mathbb{Q}$ with $q(n) = c_n$ for all $n \in \{0, \ldots, N\}$ and $q(n') \geq 0$ for all $n' \in \mathbb{N}$.*

To be able to hit all of S consistently we use independent binary encodings, that allow us to hit all of $\mathbb{N}^m$.

▶ **Lemma 4.3** (Folklore)**.** *The function $f : \{0,1\}^\star \to \mathbb{N}$ defined by being the value of $w \in \{0,1\}^\star$ interpreted as a binary number is in #FA. Additionally it is possible to extend the domain of f to any alphabet $\Sigma \supseteq \{0,1\}$ where the value of f is determined while ignoring any symbols not in $\{0,1\}$.*

For any $n \in \mathbb{N}$ we denote by $\mathrm{bin}(n)$ the unique binary representation of n without leading zeros. We first show the methodology in detail by proving the univariate case.

▶ **Theorem 4.4.** *Let $S \subseteq \mathbb{N}$. Then any function $\varphi : \mathbb{N} \to \mathbb{N}$ is a functional promise closure property of #FA with regard to S iff there is a functional closure property $\psi : \mathbb{N} \to \mathbb{N}$ of #FA with $\varphi_{|S} = \psi_{|S}$.*

Proof. If such a ψ exists, we directly see that φ is a functional promise closure property of #FA with respect to S. Indeed for any $f \in$ #FA we construct $g = \psi \circ f \in$ #FA and see $g(w) = \varphi(f(w))$ for every $w \in \Sigma^\star$ with $f(w) \in S$.

Now on the other hand let φ be any functional promise closure property of #FA with regard to S. Again define the alphabet $\Sigma = \{1\}$ and the function $f : \Sigma^\star \to \mathbb{N}$ with $f(1^n) := n$. Applying the closure property to f gives that there is some $g \in$ #FA with $g(1^n) = \varphi(f(1^n)) = \varphi(n)$ for all $n \in S$. Let $M = (Q, \Sigma, \mathrm{wt}, \mathrm{in}, \mathrm{out})$ be an NFA computing g.

This induces a transition matrix $A \in \mathbb{N}^{|Q|\times|Q|}$ and vectors $a, b \in \mathbb{N}^{|Q|}$, s.t. $a^T A^n b = g(1^n)$ for all $n \in \mathbb{N}$ by Lemma 3.19. We now define $\chi(n) := a^T A^n b$ and see $\chi_{|S} = \varphi_{|S}$. Using Lemma 3.21 on A^n we see that every entry of A^n is an ultimately almost PORC function in n and as such ψ is also an ultimately almost PORC function. Let p be the quasiperiod of χ and let $\chi_0, \ldots, \chi_{p-1}$ be the constituents of χ and let $N \in \mathbb{N}$ be the offset after which χ is defined by the constituents.

We claim that we can now replace every exponential constituent by a polynomial one without changing the value of χ for any $n \in S$. For each $i \in \{0, \ldots, p-1\}$ we distinguish two cases, depending on whether $S_i := S \cap (p\mathbb{Z}+i)$ is finite or it is infinite. If S_i is a finite set, we replace χ_i' with a polynomial that interpolates the same values as χ_i on S_i. Lemma 4.2 ensures that this polynomial is integer-valued and non-negative for all of $\mathbb{N}$. If S_i is an infinite set, we replace χ_i by the constant zero function. Call the resulting ultimately PORC function ψ with constituents ψ_i. Assume for the sake of contradiction there is an $c \in S$, s.t. $\chi(c) \neq \psi(c)$. Clearly such a c would have to be at least N. Now let i be, s.t. $c \in S_i$. It must hold that $\chi_i(c) \neq \psi_i(c)$. Hence S_i cannot be a finite set, since χ_i and ψ_i agree on S_i. Therefore S_i must be infinite. Since χ_i is exponential there is a $\gamma \in \mathbb{R}^+$ and $N' \in \mathbb{N}$, s.t. $\chi_i(n) \geq 2^{\gamma n}$ for all $n \geq N'$. Let $f' \in \#\mathsf{FA}$ be the function of binary evaluation from Lemma 4.3 over the alphabet $\Sigma' = \{0,1\}$. Then there is a $g' \in \#\mathsf{FA}$ with $g'(\mathrm{bin}(n)) = \varphi(f'(\mathrm{bin}(n))) = \chi(f'(\mathrm{bin}(n)))$ for all $n \in S$. Since S_i is infinite, in particular S_i must contain infinitely many values bigger than $\max(N, N')$. For $n \in S_i$ with $n \geq \max(N, N')$ we now have

$$g'(\mathrm{bin}(n)) = \chi(f'(\mathrm{bin}(n))) = \chi(n) = \chi_i(n) \geq 2^{\gamma n} \geq 2^{\gamma 2^{|\mathrm{bin}(n)|-1}},$$

which is a contradiction to NFAs only being able to only compute functions that are at most linearly exponential in the input length. In conclusion S_i cannot be infinite either and thus c itself cannot exist. ◀

▶ **Definition 4.5.** *A set $S \subseteq \mathbb{N}^m$ admits* polynomial cluster sequences *if for every $N_1, \ldots, N_m \in \mathbb{N}$, and $p_1, \ldots, p_m \in \mathbb{N}$ the projection $\tau : S \to \{0, \ldots, N_1 + p_1 - 1\} \times \ldots \times \{0, \ldots, N_m + p_m - 1\}$ defined by $\tau(n_1, \ldots n_m) = (n_1 \operatorname{srem}_{N_1} p_1, \ldots, n_m \operatorname{srem}_{N_m} p_m)$ has the following property: Any preimage T of a singleton set under τ for every $i \in [m]$ has either bounded i-th coordinate or there is a polynomial $q : \mathbb{N} \to \mathbb{N}$ and an infinite subset $T' \subseteq T$ with unbounded i-th coordinate*[9] *and with $\sum_{j=1}^{m} n_j \leq q(n_i)$ for all $(n_1, \ldots, n_m) \in T'$. We call such an infinite subset a* polynomial cluster sequence *with regards to dimension i.*

We call τ the shifted grid projection *of S with respect to offsets $N_1, \ldots, N_m$ and quasiperiods $p_1, \ldots, p_m$.*

Intuitively this definition requires that each dimension is either bounded or can grow reasonably quickly together with the other dimensions, even when restricted to inputs from specific shifted residue classes. For example $\{(n^2, n^3) \mid n \in \mathbb{N}\}$ admits polynomial cluster sequences, while $\{(n, 2^n) \mid n \in \mathbb{N}\}$ does not.

▶ **Theorem 4.6.** *Let $S \subseteq \mathbb{N}^m$ admit polynomial cluster sequences. Then any function $\varphi : \mathbb{N}^m \to \mathbb{N}$ is a functional promise closure property of $\#\mathsf{FA}$ with regard to S iff there is a functional closure property $\psi : \mathbb{N}^m \to \mathbb{N}$ of $\#\mathsf{FA}$ with $\varphi_{|S} = \psi_{|S}$.*

The technical proof of the theorem can be found in the appendix of the full version. There are multiple natural families for the set S such that S admits polynomial cluster sequences which we describe in the following.

[9] note that this property also follows directly from the polynomial bound on the other coordinates in the i-th coordinate, but we have it as part of the definition for clarity.

▶ **Lemma 4.7.** *Any finite set $S \subseteq \mathbb{N}^m$ admits polynomial cluster sequences.*

Proof. Independent of the offsets and quasiperiods and $i \in [m]$ any subset of S always is finite and thus bounded in every dimension. ◀

An affine variety is defined as the zero set of a finite number of multivariate polynomials. A special case of affine varieties are *graph varieties* (also just called *graphs*, see [20, §2.4, Exe. 12]). An affine variety S is a graph variety if there exist a finite number of j-variate polynomials $\mu_1, \ldots, \mu_k$ such that $S = \{(s_1, \ldots, s_j, \mu_1(s_1, \ldots, s_j), \ldots, \mu_k(s_1, \ldots, s_j)) \mid (s_1, \ldots, s_j) \in \mathbb{Q}^j\} \subseteq \mathbb{Q}^{j+k}$. We call $s_1, \ldots, s_j$ the *free* variables, and the remaining variables the *dependent* variables. We call S a monotone graph variety if $\mu_1, \ldots, \mu_k$ are all monotone.

▶ **Lemma 4.8.** *Let $S \subseteq \mathbb{Q}^m = \mathbb{Q}^{j+k}$ be a monotone graph variety. Then the set $S \cap \mathbb{N}^m$ admits polynomial cluster sequences.*

The proof of this lemma can be found in the appendix of the full version. All in all this combines to the following theorem which characterizes the special case of multivariate polynomial functional promise closure properties, the technical details can be found in the appendix of the full version.

▶ **Theorem 4.9.** *Let $S \subseteq \mathbb{Q}^m = \mathbb{Q}^{j+k}$ be a monotone graph variety and let $I = I(S)$ be its vanishing ideal. A multivariate polynomial $\varphi : S \to \mathbb{N}$ is a functional promise closure property of #FA with regard to S if and only if there exists a $\psi \in I$ such that $\varphi + \psi$ is a multivariate functional closure property of #FA.*

5 Conclusion

We characterized the functional closure properties of #FA to be precisely the ultimately PORC functions in the univariate case and combinations of ultimately PORC functions in the multivariate case. Additionally we characterize promise functional closure properties of #FA with regard to some natural families of sets S. Natural further directions of research are now whether we can characterize the promise functional closure properties of #FA for more sets S and whether our methods can be applied to characterize functional closure properties for more powerful models of computation.

Abstract

We provide a finite equational presentation of graphs of treewidth at most three, solving an instance of an open problem by Courcelle and Engelfriet.

We use a syntax generalising series-parallel expressions, denoting graphs with a small interface. We introduce appropriate notions of connectivity for such graphs (components, cutvertices, separation pairs). We use those concepts to analyse the structure of graphs of treewidth at most three, showing how they can be decomposed recursively, first canonically into connected parallel components, and then non-deterministically. The main difficulty consists in showing that all non-deterministic choices can be related using only finitely many equational axioms.

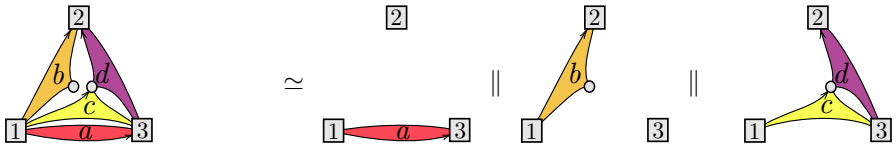
1 Introduction

Treewidth is a graph parameter measuring how close a graph is from a forest. It is frequently encountered in parameterised complexity: many NP-complete problems become polynomial or even linear once parameterised using treewidth [4]. This parameter admits many equivalent definitions. It was discovered at least by Bertelè and Brioschi [3], Halin [11], and Robertson and Seymour [13] via tree decompositions for their celebrated graph minor theorem. It was subsequently characterised using k-trees [2], k-elimination graphs [17, 16, 15], and chordal graphs [13].

One may also consider syntaxes, most often generalising series-parallel expressions [1, 8, 6]. There, the idea is to use terms to denote graphs, and an important problem is to understand when two terms denote the same graph. To this end, Courcelle and Engelfriet gave an



$$\mathrm{l}\mathrm{f}b \parallel \mathrm{f}\big((24)\mathrm{l}(c \parallel (23)\mathrm{l}a) \parallel (14)\mathrm{l}d\big) \equiv (23)\mathrm{l}a \parallel \mathrm{l}\mathrm{f}b \parallel \mathrm{f}\big((24)\mathrm{l}c \parallel (14)\mathrm{l}d\big)$$

Figure 1 Two parsings of a given graph.

equational axiomatisation for arbitrary graphs [7, p. 117]: a structured set of equations on terms from which it is possible to equate all terms denoting a given graph. Unfortunately, this axiomatisation is infinite. They note how finite fragments of the syntax make it possible to capture precisely the graphs up to a given treewidth, while finite restrictions of their axiomatisation seem to be incomplete.

This brings them to the following question [7, p. 118]: for a given bound k, is there a finite equational presentation of graphs of treewidth at most k? The case of $k = 1$ concerns forests and is relatively easy. The case of $k = 2$ has been given a solution a few years ago [5, 9]. Here we give a positive answer for $k = 3$: we provide a syntax of terms with an interpretation map g from terms to graphs whose image is exactly the set of graphs of treewidth at most three, and we give a finite list of equations whose equational theory ($\equiv$) characterises graph isomorphism ($\simeq$). In symbols, we prove that for all terms t, u,

$$g(t) \simeq g(u) \quad \text{if and only if} \quad t \equiv u$$

Like Arnborg, Courcelle, Proskurowski and Seese [1], we work with hypergraphs with a list of designated vertices, the *sources*, used as an interface to perform the following operations:

- *parallel composition* ($\parallel$): glue the graphs together along their sources.
- *permutation* (pG): given a permutation p, reorder the sources of G according to p.
- *lift* ($\mathrm{l}G$): add an isolated vertex to G and append it as last source.
- *forget* ($\mathrm{f}G$): remove the last source of G (keeping it as a mere vertex of the graph).

Consider the four graphs depicted in Figure 1, each with three sources denoted with numbered squares. The neighbours of each edge are ordered, which we indicate by drawing an arrow from the first to the second neighbour. The first graph on the left is the parallel composition of the three other ones. The second one can be obtained from a binary edge a (with interface its endpoints) by applying a lift to add a third isolated source and then swapping the last two sources: $(23)\mathrm{l}a$. The third one can be obtained from a ternary edge b (again with interface its endpoints), by forgetting the third source and adding a fresh one via a lift: $\mathrm{l}\mathrm{f}b$. The last one can be constructed as $\mathrm{f}\big((24)\mathrm{l}c \parallel (14)\mathrm{l}d\big)$: reasoning top-down, we promote the inner vertex as a fourth source, and then we put in parallel two graphs each with a single ternary edge connecting three out of the four sources – both being obtained as appropriate permutations of lifted edges.

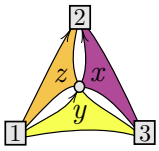
We call *parsings* the expressions we obtain when decomposing graphs as above.

The way we parsed the graph on the right generalises to all graphs: first promote all inner vertices as sources, and then build a large parallel composition of appropriately permuted and lifted edges. For instance, the first graph on the left also admits the following parsing:

$$\mathrm{f}\mathrm{f}\big((23)\mathrm{l}\mathrm{l}\mathrm{l}a \parallel (35)\mathrm{l}\mathrm{l}b \parallel (24)\mathrm{l}\mathrm{l}c \parallel (124)\mathrm{l}\mathrm{l}d\big)$$

While such a parsing exists for all graphs, it goes through an intermediate graph with a large interface. Instead, the graphs of treewidth at most k are exactly those for which we can find a parsing where all intermediate graphs have at most $k+1$ sources (Proposition 4.1, [1, Proposition 4.1]). This syntax for denoting precisely the graphs of treewidth at most k is the starting point for the present work.

A derived operation is of particular interest. Consider three graphs x, y, z each with three sources, and combine them as depicted on the right to obtain a new graph $\circ(x,y,z)$. This operation can be defined from the previous ones using the expression below.



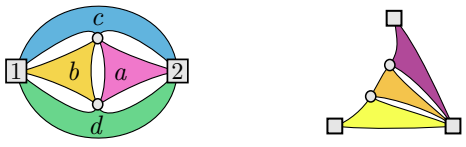
$$\circ(x,y,z) \triangleq \mathrm{f}\big((14)\mathrm{l}x \parallel (24)\mathrm{l}y \parallel (34)\mathrm{l}z\big)$$

It can be generalised into a n-ary operation on graphs with n sources, and when $n=2$ we recover the usual notion of *series composition* (with its arguments reversed).

Our goal is then to understand which laws are satisfied by the previous operations. Amongst the natural ones, we have that parallel composition is associative and commutative, that permutations commute over parallel compositions, and that applying two permutations in a row amounts to applying the composite permutation. There are more involved ones. For instance, we may also parse the first graph of Figure 1 by keeping edges a and c together as long as possible, resulting in the expression written below it. We thus have two rather different parsings for the same graph, which our axiomatisation should equate.

We proceed in two steps. First we use connectivity arguments in order to decompose any graph into a parallel composition of permuted lifts of *full prime graphs*: non-empty graphs which are connected through paths not using sources except possibly at their endpoints. Figure 1 actually provided an example of such a decomposition, which is always unique for a given graph. Using a few natural axioms, we show that every term can be rewritten under such a form (Proposition 5.1). This makes it possible to focus on full prime graphs in the second step, which is where the main difficulties arise.

A key property of full prime graphs of bounded treewidth is that either they are *atomic* (i.e., reduced to a permutation of an edge), or they have a *forget point*: at least one of their inner vertices can be promoted into a source without increasing the treewidth, thus making it possible to parse the graph as a forget operation. The difficulty is that forget points are not unique, resulting in several ways of parsing non-atomic full prime graphs. Consider for instance the following tetrahedron on the left, with only two vertices marked as sources.



Each of the two inner vertices is a forget point, so that modulo appropriate permutations of edges, we may parse this graph as $\mathrm{f}(\circ(a,b,c) \parallel d)$ or as $\mathrm{f}(\circ(a,b,d) \parallel c)$. In this case, the two forget points are relatively close, and one of our axioms makes it possible to jump directly from one parsing to the other. A similar situation arises with the graph given on the right.

The cornerstone of our completeness proof is the fact that two parsings of a non-atomic full prime graph can always be rewritten so as to agree on their forget point. This is Lemma 5.4, and most of the paper is devoted to proving it.

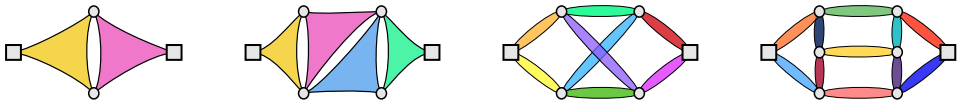


Figure 2 Separation pairs and graphs with several separation pairs.

To do so, we first delimit a class of vertices which we call *anchors*. Those can be thought of as a generalisation of cutvertices [8, Section 1.4]. When a full prime graph has an anchor, we show that we can use it as a universal agreement point (Lemma 7.1).

Unfortunately, there are graphs without anchors. We call them *hard*, they can be thought of as specific unseparable graphs [8, Section 1.4]. The rest of the proof consists in a structural analysis of hard graphs of treewidth at most three. We show that they admit *separation pairs*: every hard graph has the shape on the left of Figure 2, and every parsing can be rewritten as a double forget on some of these separation pairs (Lemma 8.5). However, as illustrated on the right, separation pairs are not unique. In order to finish the proof, we analyse how separation pairs relate to each other. There are easy cases like in the second graph of Figure 2 where the diagonal separation pair connects the two vertical ones, and previously encountered axioms make it possible to conclude. By analysing the shape of graphs excluding the triangle between their sources as a minor (Proposition 8.7 – note that cycles may still appear in such graphs), we show that all other situations reduce to one of the two graphs on the right of Figure 2. There, the two outer-vertical pairs of inner vertices are the only separation pairs, and they are disjoint. They correspond to distinct parsings of the same graph, and we must include the corresponding equations to complete our list of axioms.

For the sake of readability, some proofs and details are provided in the appendix of the full version [10].

2 Graphs, treewidth

A *ranked set* (or *signature*) is a set where every element has an associated natural number called its *arity*. Throughout the paper we fix a ranked set Σ of *letters*, which we call the *alphabet*. Given a set V, we denote by $\mathcal{L}(V)$ the ranked set of duplicate-free lists over V, where the arity of a list is its length.

We consider labelled and ordered hypergraphs with interfaces, defined as follows:

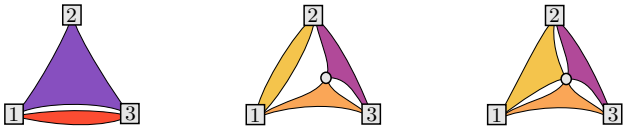
▶ **Definition 2.1.** *A* graph *is a tuple* $\langle V, E, n, l, i\rangle$ *where* V *is a finite set of* vertices*,* E *is a finite ranked set of* edges*,* $i \in \mathcal{L}(V)$ *is the* interface*, and* $n\colon E \to \mathcal{L}(V)$ *and* $l\colon E \to \Sigma$ *are arity-preserving functions respectively giving the* neighbours *and the* label *of each edge.*

The *elements* of a graph are its vertices and edges. The vertices appearing in the interface of a graph are its *sources*. Vertices (resp. elements) which are not sources are called *inner vertices (resp. elements)*. A vertex is *isolated* if it is not in the neighbourhood of any edge. The *size* of a graph G, written $|G|$, is its number of elements. The *arity* of a graph is that of its interface. Two graphs G, H are *isomorphic*, written $G \simeq H$, if their vertex and edge sets are related by structure-preserving bijections (cf. [10, Appendix A]). A graph is:

- *empty* if its only elements are its sources;
- *atomic* if its only inner element is an edge, whose neighbours comprise all the sources.

Our choice of considering ordered hypergraphs with interfaces comes from the need to be able to substitute graphs for edges. A *substitution* is an arity-preserving function from the alphabet to graphs. Given a graph G and a substitution σ, we write $G\sigma$ for the graph

obtained from G by replacing all its a-labelled edges by copies of the graph $\sigma(a)$, identifying pairwise the neighbours of the edges with the interfaces of the copies. We say that G *has shape* H when $G \simeq H\sigma$ for some substitution σ. For instance, the first graph of Figure 1 has the following shapes (amongst other ones):



(Note that the edge orientation is irrelevant in a graph used as a shape, as well as the labelling function – as long as it is injective, which will always be the case in the present paper.)

▶ **Proposition 2.2.** *For all graphs G, H and all substitutions σ, ρ, if $G \simeq H$ and $\sigma(a) \simeq \rho(a)$ for all letters a, then $G\sigma \simeq H\rho$.*

A graph in the sense of Definition 2.1 can be seen as a simple graph, its *skeleton*, by turning all its edges and its interface into cliques (removing duplicate edges if necessary). This operation makes it possible to use the standard notion of treewidth [8, Section 12.4]: the *treewidth* of a graph is that of its skeleton. Equivalently, we can define it as follows.

▶ **Definition 2.3.** *A* tree decomposition *of a graph is a tree whose nodes are labelled by sets of vertices, called* bags*, such that*

- *there is a bag containing all sources,*
- *for each edge there is a bag containing its neighbours,*
- *for each vertex, the bags containing it form a subtree.*

The width *of a tree decomposition is the size of its largest bag minus one. The* treewidth *of a graph is the minimal width of its possible tree decompositions.*

Observe that since the sources of a graph must be contained in a bag for all tree decompositions, the treewidth of a graph is at least its arity minus one. Therefore, at treewidth at most three, we only have graphs of arity up to four. The same constraint holds for the edge arities.

▶ **Proposition 2.4.** *If a graph G and the graphs in the image of a substitution σ all have treewidth at most k, then so does $G\sigma$.*

3 Graph operations

We can now define the operations discussed in the introduction.

▶ **Definition 3.1.** *Let G, H be graphs of arity k.*

- *The* parallel composition *of G and H, $G \parallel H$, is the graph of arity k obtained from the disjoint union of G and H by pairwise merging their sources.*
- *If $k \geq 1$, the* forget *of G, $\mathrm{f}G$, is the graph of arity $k-1$ obtained from G by removing the last vertex from its interface (keeping it in the vertex set).*
- *The* lift *of G, $\mathrm{l}G$, is the graph of arity $k+1$ obtained from G by adding a new isolated vertex, and appending it to its interface.*
- *For a permutation p of $[1, k]$, we denote by pG the graph obtained from G by permuting its interface according to p.*
- *We write $\emptyset_k$ for the empty graph of arity k, omitting k when it is clear from the context.*
- *For a letter $a \in \Sigma$, we also write a for the atomic graph whose edge is labelled a and has its neighbours appearing in the same order as in the interface.*

These operations all arise as substitutions of well chosen small graphs. By Proposition 2.4, this entails that they preserve treewidth (except of course for lifts, which may increase it when reaching the maximal arity). It remains to establish a few structural properties, in order to show that every graph of treewidth at most k can be constructed from the above operations up to arity $k+1$ (Proposition 4.1 below).

A *path* in a graph is a sequence of elements such that any two consecutive elements consist of an edge and one of its neighbours. An *inner path* is a path made only of inner elements, except possibly for the endpoints.

▶ **Definition 3.2.** *A graph is* prime *if it is not empty and all its inner elements are connected by inner paths; it is* full *if none of its sources are isolated.*

Observe that a graph is full prime iff all its elements are connected by inner paths. Amongst the graphs in Figure 1, the first one is full but not prime, the three other ones are prime, and only the last one is full prime.

▶ **Lemma 3.3.** *Every graph is isomorphic to a permutation of lifts of a full graph. This decomposition is unique up to permutation and isomorphism.*

▶ **Lemma 3.4.** *Every graph is isomorphic to a parallel composition of prime graphs. This decomposition is unique up to reindexing and isomorphism.*

We call *(prime) components of a graph* the prime graphs occurring in the latter decomposition. We call *reduced components of a graph* the full prime graphs obtained by removing isolated sources from its components.

We now give two key properties of full prime graphs of bounded treewidth. First, they are always atomic at maximal arity.

▶ **Proposition 3.5.** *Full prime graphs of treewidth at most k and arity $k+1$ are atomic.*

In the case of treewidth at most three, this means that when we decompose a graph of arity four into prime components, then except for a number of four-edges between the sources, we only get non-full components: drawing the graph as a tetrahedron between its sources, the non-atomic components are glued through the faces (or edges, or vertices, or nothing), and the interior of the tetrahedron remains empty. This corresponds to the characterisations of treewidth at most k graphs as partial k-trees [2] or as subgraphs of chordal graphs whose cliques are of size at most $k+1$ [13].

Second, non-atomic full prime graphs have *forget points*, which we define as follows.

▶ **Definition 3.6.** *When x is an inner vertex of a graph G, we write (G, x) for the graph obtained from G by appending x to its interface; if this graph has treewidth at most k then we say that x is a* k-forget point of G.

▶ **Proposition 3.7.** *Non-atomic full prime graphs of treewidth at most k have k-forget points.*

4 Terms and axioms

We finally provide a notion of *term* for denoting graphs. We use a multisorted syntax: the family $(\mathcal{T}_k)_{k\in\mathbb{N}}$ of sets of terms of a given arity is defined inductively by the following rules (where p ranges over permutations of $[1,k]$ and a over letters of arity k):

$$\frac{t,u\in\mathcal{T}_k}{t\parallel u\in\mathcal{T}_k}\qquad\frac{t\in\mathcal{T}_k}{\mathrm{l}t\in\mathcal{T}_{k+1}}\qquad\frac{t\in\mathcal{T}_{k+1}}{\mathrm{f}t\in\mathcal{T}_k}\qquad\frac{t\in\mathcal{T}_k}{pt\in\mathcal{T}_k}\qquad\frac{}{\emptyset\in\mathcal{T}_k}\qquad\frac{}{a\in\mathcal{T}_k}$$

This syntax matches the operations in Definition 3.1. Accordingly, we obtain a recursive arity-preserving function g from terms to graphs. We say that a term t *denotes* the graph G, or that t is a *parsing* of G, when $g(t) \simeq G$. For instance, the expressions below the graphs in Figure 1, seen as terms, are parsings of these graphs. Note that the number of inner vertices of a graph is the number of forgets appearing in any of its parsings.

We shall sometimes mention terms and refer implicitly to their graphs; for instance writing that a term is prime to mean that its graph is so.

The *width* of a term is the maximal arity of its subterms, minus one.

▶ **Proposition 4.1.** *A graph has treewidth at most k iff it has a parsing of width at most k.*

Proof. The backward implication is proven by induction on terms, using Proposition 2.4 and the observation that all operations arise as substitutions. For the direct implication, we proceed by lexicographic induction on the size of the graph followed by $k+1$ minus its arity (recall that the arity is always lower or equal to the treewidth plus one).

If the graph has isolated sources, we use Lemma 3.3 to write it as a permutation of lifts and proceed recursively. Otherwise it is full, and we decompose it into primes via Lemma 3.4:

- if there are no components then the graph is empty and has a trivial parsing;
- if there are at least two components then they are smaller, and we proceed recursively;
- otherwise the graph is (full) prime; either it is atomic and it admits a permutation of a letter as a parsing, or, by Proposition 3.7, it can be written as the forget of a graph of the same size but increased arity, which we may parse recursively. ◀

The previous proposition holds for all bounds k on the treewidth. Some of our results below also hold generically, and we will discuss these generalisations in Section 9. Still, from this point on we focus on treewidth at most three.

▶ **Convention 4.2.** *In the remainder, we only work with graphs of treewidth at most three. We simply call* terms *the terms of width at most three, and* forget points *the* 3*-forget points.*

A *(term) substitution* is an arity-preserving function from the alphabet to terms. Such a function σ extends uniquely to a homomorphism $\hat{\sigma}$ from terms to terms:

$$\hat{\sigma}(t \parallel u) \triangleq \hat{\sigma}(t) \parallel \hat{\sigma}(u) \qquad \hat{\sigma}(\mathrm{l}t) \triangleq \mathrm{l}\hat{\sigma}(t)$$
$$\hat{\sigma}(\emptyset) \triangleq \emptyset \qquad \hat{\sigma}(\mathrm{f}t) \triangleq \mathrm{f}\hat{\sigma}(t)$$
$$\hat{\sigma}(a) \triangleq \sigma(a) \qquad \hat{\sigma}(pt) \triangleq p\hat{\sigma}(t)$$

A *context of arity* $i \to o$ is a term of arity o with a single occurrence of a designated letter h of arity i, called the *hole*. Given such a context c and a term t of arity i, we write $c[t]$ for the term c where the hole is replaced by t. Note that $c[t] = \hat{\sigma}_t(c)$ for the substitution σ_t mapping h to t and fixing all other letters.

An *equational theory* is an equivalence relation R on terms, relating only terms of the same arity, and which is closed under contexts and substitutions:

- $(t,u) \in R$ entails $(c[t], c[u]) \in R$ for all contexts c of appropriate arity, and
- $(t,u) \in R$ entails $(\hat{\sigma}(t), \hat{\sigma}(u)) \in R$ for all substitutions σ.

Given two terms t, u, we write $t \cong u$ when $g(t) \simeq g(u)$. Thanks to Proposition 2.2, this relation ($\cong$) is an equational theory, and our goal is to provide a finite list of axioms that generates it.

We give such a list below; most axioms can be written explicitly, but three of them relate rather large terms, which are best presented by their graphs. This is why we rely on the following concept of forget axiom.

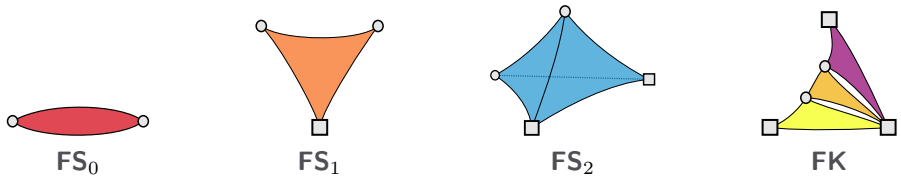


Figure 3 Forget axioms for anchors (swap and kite); x, y are the inner vertices.

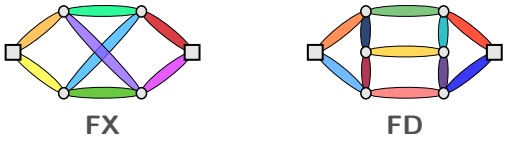

Figure 4 Forget axioms for hard graphs (cross and domino); x, y are the topmost inner vertices.

A *forget axiom* for a graph G with two forget points x, y is an equation of the shape $\mathrm{f}t \equiv \mathrm{f}u$ for some parsings t of (G, x) and u of (G, y).

▶ **Definition 4.3** (Finite axiomatisation). *We write $\equiv$ for the least equational theory containing the following axioms, for letters a, b, c of appropriate arities:*
A1. $a \parallel (b \parallel c) \equiv (a \parallel b) \parallel c$, $a \parallel b \equiv b \parallel a$, *and* $a \parallel \emptyset \equiv a$;
A2. $pqa \equiv (p \circ q)a$ *for all permutations* p, q, *and* $\mathrm{id}a \equiv a$ *where* id *is the identity permutation;*
A3. $p(a \parallel b) \equiv pa \parallel pb$ *and* $p\emptyset \equiv \emptyset$ *for all permutations* p;
A4. $\mathrm{l}(a \parallel b) \equiv \mathrm{l}a \parallel \mathrm{l}b$ *and* $\mathrm{l}\emptyset \equiv \emptyset$;
A5. $p\mathrm{f}a \equiv \mathrm{f}\dot{p}a$ *and* $\mathrm{l}pa \equiv \dot{p}\mathrm{l}a$ *where* $\dot{p}$ *is the extension of a permutation* p *of* $[1, k]$ *to* $[1, k+1]$;
A6. $\mathrm{l}\mathrm{f}a \equiv \mathrm{f}r\mathrm{l}a$ *and* $\mathrm{l}\mathrm{l}a \equiv r\mathrm{l}\mathrm{l}a$ *for the permutation* r *that swaps the last two elements;*
A7. $\mathrm{f}a \parallel b \equiv \mathrm{f}(a \parallel \mathrm{l}b)$;
FS. $\mathrm{f}\mathrm{f}a \equiv \mathrm{f}\mathrm{f}ra$ *for the permutation* r *that swaps the last two elements;*
as well as three forget axioms for the graphs with forget points **FK**, **FX** *and* **FD** *in Figures 3&4 (for some arbitrary choice of interface ordering, edge orientation, and injective edge labelling).*

The first eight items are universally quantified over all appropriate arities. For instance, associativity of parallel composition (in **A1**) is an axiom at each arity, and a, b and $\emptyset$ may have arity up to three in **A4**. Since we restrict globally to arities up to four, the list of axioms is nevertheless finite.

Also note that even though the axioms are expressed using letters, they yield laws which hold under all term substitutions since $\equiv$ is defined as an equational theory.

FS comprises three axioms depending on the arity of a (2, 3, or 4), which we shall sometimes refer to as $\mathbf{FS}_i$ (with $i = 0, 1$, or 2, respectively). These are forget axioms for the first three graphs in Figure 3, and we could have presented them as such. We cannot express $\mathbf{FS}_3$ as it would require an edge of arity five; **FK** intuitively is a weakened version of it, expressible at treewidth three.

We shall see at the end of Section 5 that the concrete choice of parsings for the forget axioms **FK**, **FX**, and **FD** is irrelevant thanks to **A1**-**7**. The interested reader may find concrete equations for them in [10, Appendix C].

▶ **Proposition 4.4** (Soundness). *If $t \equiv u$ then $t \cong u$.*

Proof. Since $\cong$ is an equational theory, it suffices to check that the two members of each axiom denote the same graph. This is by definition for the forget axioms, and a routine verification for the other ones. ◀

The axioms given textually in Definition 4.3 (**A1-7** and **FS**) intuitively correspond to those given for arbitrary graphs by Courcelle and Engelfriet [7, p.117], restricted to terms of width at most three. (Modulo some translation since our syntaxes and sets of operations differ.) This finite restriction is however incomplete for graphs of treewidth at most three: in their completeness proof, Courcelle and Engelfriet need axioms of the form $\mathbf{FS}_i$ for arbitrary large arity i, even when dealing with graphs of small treewidth. Somehow, we prove below that the forget axioms $\mathbf{FS}_0$, $\mathbf{FS}_1$, $\mathbf{FS}_2$, **FK**, **FX**, and **FD** suffice at treewidth at most three to fulfil the role played by this infinite family of axioms. Also observe that while **FK** easily generalises to deal with an arbitrary treewidth k (by replacing the source touching the three edges by $k-2$ sources), this is not the case for **FX** and **FD**.

5 Outline of the completeness proof

Using the first seven axioms, we easily obtain the following proposition. Together with Lemmas 3.3 and 3.4, it makes it possible to normalise terms and to focus on full prime ones.

▶ **Proposition 5.1.** *For all terms t, letters a, and graphs G, H, we have:*
1. *if $g(t) \simeq \emptyset$ then $t \equiv \emptyset$;*
2. *if $g(t) \simeq a$ then $t \equiv a$;*
3. *if $g(t) \simeq pG$ then there is a parsing u of G such that $t \equiv pu$;*
4. *if $g(t) \simeq \mathrm{l}G$ then there is a parsing u of G such that $t \equiv \mathrm{l}u$;*
5. *if $g(t) \simeq G \parallel H$ then there are parsings u of G and v of H such that $t \equiv u \parallel v$.*

Proof sketch. All items but the third are proven by induction on t. The first three items only need **A1-4**; the fourth one needs **A5-6**; the last one rests on the fourth one and **A7**. ◀

An item is patently missing from the previous proposition, for the forget operation. In fact, a statement similar to the third and fourth items does not hold for the forget operation: when t is a parsing of $\mathrm{f}G$, nothing guarantees that G has a parsing at all: its treewidth may be four; we need to restrict to those cases where the forgotten vertex is a forget point.

Given a term t denoting a graph G with an inner vertex x, we say that t *reaches* x if there is a parsing t' of (G, x) such that $t \equiv \mathrm{f}t'$. We can easily prove the following property.

▶ **Lemma 5.2.** *Every non-atomic full prime term reaches some forget point.*

Proof. By induction on t, using Proposition 5.1 until we find a forget operation. ◀

However, this property is not enough, because it gives no control on the forget point which is reached; instead, we would like to obtain:

▶ **Statement 5.3** (Reaching forget points)**.** *Full prime terms reach all their forget points.*

This statement holds, but we do not know how to prove it directly: we only get it *a posteriori*, from the completeness. We prove a variant of it in the next section (Lemma 7.1), for *anchors*.

Instead, the cornerstone of our proof is the following lemma: any two parsings of a non-atomic full prime graph may reach a common forget point.

▶ **Lemma 5.4** (Forget point agreement)**.** *For all parsings t, u of a non-atomic full prime graph, there is a forget point reached by both t and u.*

The rest of the paper is devoted to proving this lemma, with which we conclude as follows.

▶ **Theorem 5.5** (Completeness)**.** *For all parsings t, u of a given graph, we have $t \equiv u$.*

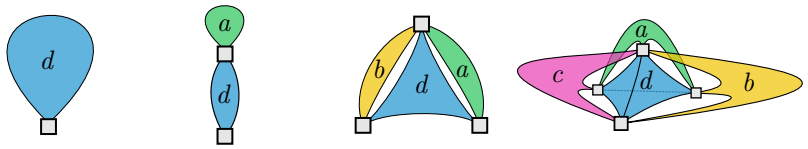

Figure 5 The series operations $\mathrm{s}(;d)$, $\mathrm{s}(a;d)$, $\mathrm{s}(a,b;d)$, and $\mathrm{s}(a,b,c;d)$.

Proof. We follow the same pattern as in the proof of the forward implication of Proposition 4.1: we proceed by lexicographic induction on the size of the graph followed by 4 minus its arity. If the graph has isolated sources, we use Lemma 3.3 and Proposition 5.1(3,4) to rewrite the parsings into permuted lifts and proceed recursively. Otherwise it is full, and we decompose it into primes via Lemma 3.4:

- if there are no components then both parsings are equivalent to $\emptyset$ by Proposition 5.1(1);
- if there are at least two components then we use Proposition 5.1(5) on both parsings and we proceed recursively.
- otherwise the graph must be (full) prime. Either it is atomic and we conclude by Proposition 5.1(2,3), or Lemma 5.4 gives us two terms t', u' such that $t \equiv \mathrm{f}(t')$, $t' \cong u'$, and $\mathrm{f}(u') \equiv u$, and we can conclude since $t' \equiv u'$ follows by induction hypothesis. ◀

We have only used Axioms **A1**-**7** up to this point. We prove below that those axioms are complete when there are few forget points. Say that a graph is *easy* if each of its non-atomic reduced components G has only one forget point x, and in turn (G, x) is easy. (This definition is well-founded by the same lexicographic ordering as we used in the above proof.)

▶ **Proposition 5.6.** *For all parsings t, u of an easy graph, we have $t \equiv u$.*

Proof. By adapting the previous completeness proof. Lemma 5.2 may replace Lemma 5.4 when we attain non-atomic full prime graphs: those are reduced components of the starting graph and since those have only one forget point, all their parsings reach that one. ◀

None of the graphs in Figures 3 and 4 are easy: they are all full prime, each with two forget points x, y (plus two symmetrical ones for **FX** and **FD**). Nevertheless, adding either x or y to their interface makes them easy (cf. [10, Lemma D.1]). This is why the precise choice of parsings does not matter when we use them as forget axioms in Definition 4.3.

6 Series decompositions

As explained in the introduction, there is a *series* operation on graphs which plays an important role. We slightly generalise it here, and we show how to use it to analyse graphs with a forget point.

Given k graphs $G_1, \dots, G_k$ of arity k and a graph H of arity $k+1$, we define the following graph of arity $k+1$, where p_i denotes the permutation which swaps i and $k+1$.

$$\mathrm{s}(G_1, \dots, G_k; H) \triangleq p_1 \mathrm{l} G_1 \parallel \cdots \parallel p_k \mathrm{l} G_k \parallel H$$

As is explicit from its definition, this operation on graphs is also a derived operation on terms. We illustrate its behaviour at each arity in Figure 5. We recover the operation from the introduction when the last argument is empty, and using a forget operation: we have $\circ(u, v, w) = \mathrm{fs}(u, v, w; \emptyset)$.

We use this operation in order to decompose full prime graphs along a given inner vertex.

▶ **Proposition 6.1** (Series decomposition). *For all full prime graphs G of arity k with an inner vertex x, there are graphs $G_1, \dots, G_k, H$ such that $(G, x) \simeq \mathrm{s}(G_1, \dots, G_k; H)$ and*
1. *all components of H are full, and*
2. *if the jth source of a component of G_i is isolated, then $i < j$.*

Such a decomposition is unique up to isomorphism.

We call G_i the *ith series argument*, and H the *series factor* of such a decomposition (at x).

Proof. We decompose (G, x) into prime components, which we classify according to their isolated sources. Since G is full prime, x is never isolated. Full components go into the series factor. Components where the first source is isolated go into the first series argument (under the permutation p_1, the first source gets swapped with x). Components where the second source is isolated but not the first one go into the second series argument. *Et caetera.* ◀

Also note that we can follow such decompositions at the term level, modulo **A1**-**7**:

▶ **Proposition 6.2.** *If a term t reaches the last source of a graph of the form $\mathrm{s}(G_1, \dots, G_k; H)$, then there are parsings $u_1, \dots, u_k, v$ of $G_1, \dots, G_k, H$ such that $t \equiv \mathrm{fs}(u_1, \dots, u_k; v)$.*

Proof. Consequence of Proposition 5.1. ◀

7 Anchors

In this section we define the concept of *anchors* – inner vertices with specific properties, and we prove the following variant of Statement 5.3:

▶ **Lemma 7.1** (Reaching anchors). *Full prime terms reach all their anchors.*

This lemma implies Lemma 5.4 when the considered graph has an anchor, by applying it to both parsings. Therefore, once Lemma 7.1 proved, it will only remain to prove Lemma 5.4 for anchor-free graphs (Section 8).

The definition of anchor is the following; we only consider them in full prime graphs.

▶ **Definition 7.2.** *An* anchor *in a (full prime) graph G is an inner vertex x such that either:*
1. *there are no full prime components in (G, x), or*
2. *there is an edge whose neighbours comprise at least x and all sources of G, or*
3. *there are two or more full prime components in (G, x).*

Using series decompositions, x is an anchor whenever the series factor at x is empty, or has only one edge, or has at least two components.

This last condition generalises the usual notion of cutvertex [8, Section 1.4]: such anchors at arity zero when there are only binary edges are exactly cutvertices as usual. Removing them disconnects the graph. The second branch in our definition may only arise with sources and/or hyperedges; it is convenient to have it for the present proof, but it would probably be more natural to disallow it in other contexts. Thanks to this alternative, all inner vertices in the graphs in Figure 3 are anchors. In contrast, the graphs in Figure 4 have no anchors.

We prove below that all forget points are anchors at arity three. The converse holds at all arities, but we only get it *a posteriori*, as a consequence of Lemma 7.1.

▶ **Proposition 7.3.** *At arity three, all forget points are anchors.*

Proof. If x is a forget point of a graph G of arity three, the full prime components of (G, x) must be atomic by Proposition 3.5. Thus x is an anchor, by either the first or the second condition in Definition 7.2. ◀

We also find anchors easily at arities zero and one.

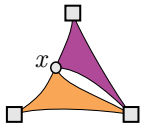
▶ **Proposition 7.4.** *Non-atomic full prime graphs of arity in* $\{0, 1, 3\}$ *have some anchor.*

Proof. Every inner vertex is an anchor at arity zero, either because it is isolated (anchor of the first kind), or because it belongs to some edge (anchor of the second kind). Every immediate neighbour of the only source is an anchor at arity one (of the second kind). At arity three we use Propositions 7.3 and 3.7. ◀

We first prove Lemma 7.1 for graphs of arity three, and then we show how to reduce the other cases to that one (Section 7.2).

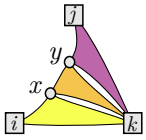
7.1 Parsing on anchors at arity three

A *checkpoint* between two vertices y, z of a graph G is an inner vertex x such that every inner path from y to z goes through x. When y, z are not mentioned explicitly, they are implicitly assumed to be sources. (This definition coincides with that from [5] at arity two.) Analysing the components of (G, x) by the sources they touch, we see that the checkpoints of a graph G of arity three are the inner vertices x for which G has the following shape:



This characterisation shows that checkpoints are anchors of the first kind in Definition 7.2. Another important property at arity three is that if there are two anchors, then they must be checkpoints for the same sources:

▶ **Proposition 7.5.** *At arity three, every full prime graph with two distinct anchors* x, y *has the following shape:*



Proof of Lemma 7.1 at arity three. We proceed by induction on the size of the graph.

Let t be a parsing of a full prime graph G of arity three, with an anchor x. By Lemma 5.2, t reaches some forget point y. If $x = y$ then we are done. Otherwise, y is a second anchor by Proposition 7.3, and G has the shape given by Proposition 7.5. Call A the graph between i,k,y, and B the one between j, k, y. Since t reaches y we have a parsing t' of (G, y) such that $t \equiv \mathrm{f}t'$. By analysing the full prime decomposition of (G, y), we can put t' under the form $(j4)\mathrm{l}u \parallel (i4)\mathrm{l}v$, where u is a parsing of A and v a parsing of B. Then we observe that x is a checkpoint in A, and thus an anchor, so that u reaches x by induction hypothesis. Therefore, $u \equiv \mathrm{f}u'$ for some parsing u' of (A, x). By analysing the full prime decomposition of (A, x) as before, we deduce that t reaches x using **FK**. ◀

7.2 Parsing on anchors at lower arities

We now finish the proof of Lemma 7.1 by showing how to reduce the other cases to that of arity three. We use for that the two following lemmas. The first one intuitively makes it possible to zoom on a specific inner vertex by going under a forget operation. The second one states that under some conditions, an anchor in $\mathrm{f}^i G$ is also an anchor in G, allowing to use the case of arity three.

▶ **Lemma 7.6.** *Let t be a term of arity up to two with an inner vertex x in a full prime component. There is a term u such that $t \equiv \mathrm{f}u$ and x is either the last source of u or an inner vertex of a full prime component of u.*

▶ **Lemma 7.7.** *For $i > 0$ let $\mathrm{f}^i G$ be a full prime graph of arity k and x, y two distinct inner vertices in a full prime component C of G. If x is an anchor of $\mathrm{f}^i G$ and is in one of the first k series arguments of the series decomposition of C at y, then x is a checkpoint in C.*

(Note that the only isolated sources of the components of the i last series arguments in the decomposition of C as above, are the i forgotten sources in $\mathrm{f}^i G$.)

Before we finish the proof of Lemma 7.1, also observe that **FS** implies $\mathrm{f}^j pu \equiv \mathrm{f}^j qu$ for all terms u of arity k and permutations p, q agreeing on the first $k - j$ elements.

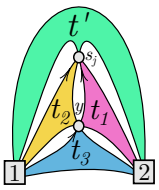
Proof of Lemma 7.1, at all arities. We prove the following generalisation, by induction on the lexicographic product of $|C|$ and $3 - k$:

> For all terms t of arity $k \leq 3$, for all $i \leq k$, if $\mathrm{f}^i t$ is full prime with an anchor x in a full prime component C of t, then $\mathrm{f}^i t$ reaches x.

If $k < 3$ then we use Lemma 7.6 to obtain u such that $\mathrm{f}^i t \equiv \mathrm{f}^{i+1} u$; if x is the last source of u then we are done, otherwise we conclude by induction, since x lies in a component of C.

We now assume $k = 3$, and we rewrite t as $t_C \parallel t'$, where t_C is the full prime component containing x. By Lemma 5.2, t_C reaches some forget point y. Take a series decomposition $t_C \equiv \mathrm{fs}(t_1, t_2, t_3; u)$ of t_C at y. The series factor u cannot contain x since all its components are atomic by Proposition 3.5. Thus x must be in a series argument.

If x is in one of the first $3 - i$ series arguments, then by Lemma 7.7 x must be a checkpoint, and thus an anchor of t_C. Using Lemma 7.1 at arity three (Section 7.1), we obtain that t_C reaches x. So does t by **A7**, and finally $\mathrm{f}^i t$ by **FS**. Otherwise, x is in one of the last i series arguments, say the jth one. The jth source s_j is the only source that is necessarily isolated in this argument. It is a source that is forgotten by the operations f^i (see the figure below for an illustration). Our goal is to "swap" this jth source for y in order to decrease the size of C. Indeed the new component containing x will then be contained in t_3, which is smaller in size than C.



Let S be the set of non-isolated sources in the component C' of $s(t_1, t_2, t_3; u)$ containing x. Using **FS** we get a term t'' such that $\mathrm{f}^i t \equiv \mathrm{f}^{|S|} t''$ and t'' denotes $g(t)$ with the inner vertices in S upgraded as sources. By definition of t'', C' is a full prime component of it. Furthermore, up to isolated sources, C' is the same component as the one of $s(t_1, t_2, t_3; u)$ containing x. This gives $|C'| < |C|$ and we conclude by induction on $\mathrm{f}^{|S|} t''$. ◀

At this point, we have used axioms **A1**-**7**, **FS**, and **FK**, but not **FX** and **FD**.

Figure 6 Separation pairs $(y \diamond x)$, and partial order on vertices $(y \prec x)$.

8 Separation pairs

We call *hard* the non-atomic anchor-free full prime graphs. Examples of such graphs were given in Figure 2. Hard graphs have arity two by Propositions 7.4 and 3.5, and it only remains to prove Lemma 5.4 for these graphs.

A *forget pair* in a graph G is a pair (x, y) of inner vertices such that (G, x, y) has treewidth at most three. A parsing t of a graph G *reaches a pair* (x, y) of inner vertices if there is some parsing t' of (G, x, y) such that $t \equiv \mathrm{fft}'$. By definition, a term may only reach forget pairs. By **FS**, a term reaches (x, y) iff it reaches (y, x); it follows that every term reaching (x, y) reaches both x and y.

Given two inner vertices x, y of a full prime graph of arity two, we write $y \diamond x$ when the graph has the shape on the left of Figure 6, and $y \prec x$ when the graph has the shape on the right (equivalently, when y is a checkpoint between x and some source). In the first case, we say that (x, y) is a *separation pair*. We prove a few properties about such inner vertices.

▶ **Lemma 8.1.** *If $y \prec x$ or $y \diamond x$ in a full prime graph G, then y is an anchor in (G, x), and every parsing of G reaching x also reaches (x, y).*

Proof. In both cases, there is no full prime component in (G, x, y), so that y is indeed an anchor in (G, x). Now if $t \equiv \mathrm{f}t'$ for some parsing t' of (G, x), then t' reaches y by Lemma 7.1: $t' \equiv \mathrm{f}t''$ for some parsing t'' of (G, x, y). Thus t reaches (x, y). ◀

It follows that a full prime term reaches a separation pair iff it reaches any of its constituents.

We write $S(x)$ for the series factor of a graph at some inner vertex x. When the graph is hard, x is not an anchor, so that $S(x)$ must be full prime and cannot contain just one edge.

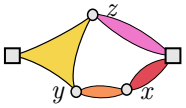
▶ **Proposition 8.2.** *For all hard graphs, $\prec$ is well-founded.*

Proof. Observe that if $y \prec x$ then $|S(y)| < |S(x)|$. ◀

▶ **Proposition 8.3.** *For all vertices x, y, z such that $y \prec x$ and $x \diamond z$, we have $y \diamond z$.*

Proof. Consider an inner path between the two sources; we have to show that it visits either y or z. It visits either x or z since (x, z) is a separation pair. If it visits x then it also visits y since y is a checkpoint between x and one of the two sources. ◀

When the graph is hard in the previous proposition, it must have the following shape:

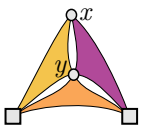


In such a case, we intuitively prefer the separation pair (y, z) to (x, z). This leads us to the notion of minimal separation pair. A vertex x is *minimal* if there is no vertex y such that $y \prec x$. A pair of vertices is minimal when its two elements are so.

The proposition below makes it possible to get separation pairs out of minimal vertices.

▶ **Proposition 8.4.** *Let x be a forget point in a hard graph. For all forget points y of $S(x)$, we have either $y \prec x$ or $y \diamond x$.*

Proof. Let us classify the components of (G, x, y) by their isolated sources. Full components cannot exist as by Proposition 3.5 they would be edges and both x and y would be anchors in G. So G must have the following shape:



If there is no inner path avoiding y between the sources in the bottom component, then $y \diamond x$. If there is no inner path avoiding y from x to one of the sources, then $y \prec x$. Otherwise there are at least two full prime components in (G, y), making y an anchor of G, which contradicts G being hard. ◀

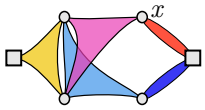
It follows easily that every hard graph has some separation pair – even a minimal one, which will be useful to reduce the number of cases to study. However, we need to be more precise and to keep track of terms.

▶ **Lemma 8.5.** *Every hard term reaches some minimal separation pair.*

Proof. Let t be a hard term. By Lemma 5.2 t reaches some forget point x, which we can choose minimal by Proposition 8.2 and Lemma 8.1. Accordingly, let t' be a parsing of (G, x) such that $t \equiv \mathrm{f}t'$. As $S(x)$ is full prime and non-atomic, it has a forget point y. Since x is minimal, (x, y) is a separation pair by Proposition 8.4. We can choose y to be minimal by Proposition 8.3, and t reaches (x, y) by Lemma 8.1. ◀

As before with forget points, separation pairs are not unique (even minimal ones), and we need to show how to move from one separation pair to another.

When studying the possible shapes of a hard graph H with distinct separation forget pairs, we end up with a few shapes S such as the following one:



In such situations, we know that (H, x) has treewidth at most three, but (S, x) has treewidth four. Therefore, for an appropriate notion of *minor*, (S, x) cannot be a minor of (H, x): the treewidth may not increase when taking minors. We use this information in order to refine the actual shape of H.

We use *sourced simple graphs* in order to define such a notion of minor. Those are triples (V, E, S) made of a set V of *vertices*, a set E of unordered binary *edges*, and a subset $S \subseteq V$ of *sources*. We write K_k for the clique over k sources. *Tree decompositions* and *treewidth* [8, Section 12.4] are adapted to sourced simple graphs by requiring the subset of sources to be contained in some bag. A *sourced minor of a (sourced simple) graph* is a (sourced simple) graph obtained from it by a sequence of the following operations: remove an edge, contract an edge, remove an isolated vertex. Those operations do not increase the treewidth.

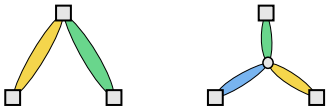
The *footprint* of a graph is the sourced simple graph obtained from it by replacing each edge by a clique over its neighbours, forgetting labels, and turning the interface into a mere set – note that we do not add a clique on the sources. A graph and its footprint have the same tree decompositions, and thus the same treewidth. A *sourced minor of a graph* is a sourced minor of its footprint.

Note that graphs excluding K_3 as a sourced minor need not be acyclic, as cycles may occur away from the sources. The point of using sourced minors is that they behave well with respect to substitutions, and thus shapes:

▶ **Proposition 8.6.** *Given a graph G and a substitution σ, if K_k is a sourced minor of $\sigma(a)$ for all letters a of arity k, then the footprint of G is a sourced minor of $G\sigma$.*

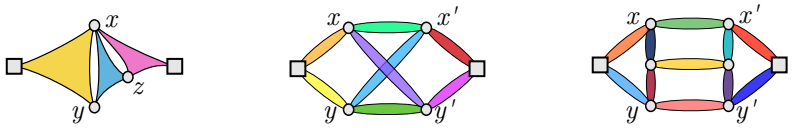
Now observe that full prime graphs of arity two admit the sourced edge K_2 as a sourced minor. At arity three, we have the following property instead.

▶ **Proposition 8.7.** *Every graph of arity three either has the sourced triangle K_3 as a sourced minor, or has one of the two following shapes:*



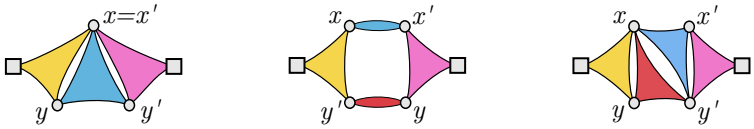
Let us continue our example and come back to the previous hard graph H. Assume that the binary edges in the given shape are instantiated by full prime graphs, and consider the three graphs instantiating the ternary edges. If those three graphs have the triangle as a sourced minor, then the footprint of (S, x) must be a sourced minor of (H, x), which is not possible. Therefore, at least one of them must have one of the shapes given by Proposition 8.7. By considering the different possibilities and continuing the same kind of reasoning, we end up proving that in this case, H must have shape **FX**. In the general case, we obtain the following classification.

▶ **Proposition 8.8.** *Let G be a hard graph with two minimal separation forget pairs (x, y) and (x', y'). Possibly up to swapping x and y, and/or x' and y', either (x, y') is a separation pair (**Case Z**), or G has one of the following shapes, where in the leftmost case, z is minimal and x', y' appear in the rightmost component:*



Case IH **Case X** **Case D**

The proof we provide in [10, Appendix F] actually establishes that in the case where (x, y') is a separation pair, then G has one of the following shapes:



Case Z1 **Case Z2** **Case Z3**

We finally deduce that hard terms reach all their minimal separation forget pairs.

▶ **Lemma 8.9.** *Let G be a hard graph with minimal separation forget pair (x', y'). All parsings t of G reaching a minimal separation pair (x, y) also reach (x', y').*

Proof. We fix G, x', y', we proceed by induction on the size of the component of (G, x, y) containing x', and we use Proposition 8.8. If (x, y') is a separation pair (**Case Z**), then we use Proposition 8.1 twice: t reaches x, thus (x, y'), thus y' in particular, thus (x', y'). In

Case IH we proceed by induction on (x, z), which is reached by t by similar reasoning, and for which the induction measure decreases. In **Case X** and **Case D**, we conclude directly by **FX** and **FD**, respectively. (In those latter two cases, we first need to rewrite t so that it agrees syntactically with the shape of the axiom we use. We use Lemma 7.1 for that, which requires showing that some of the inner vertices are anchors in appropriate subgraphs. To do so, we exploit the fact that G is hard, so that the subgraphs corresponding to the edges of the exhibited shape must be connected enough.) ◀

Together with Lemma 8.5, Lemma 5.4 follows, which concludes our completeness proof.

9 Conclusion and future work

We have provided a finite presentation of graphs of treewidth at most three. Our axiomatisation comprises axioms for dealing with full prime decompositions (**A1**-**7**), axioms for reaching anchors (**FS**, **FK**), and two axioms for hard graphs (**FX** and **FD**).

An obvious question for future work is whether the approach presented here generalises to the case of graphs of treewidth at most k.

It does so up to Section 7. The syntax we use readily characterises those graphs (Proposition 4.1), and the seven first axioms as well as the results in Section 5 are not specific to the case $k = 3$. Axioms for anchors (Figure 3) also generalise. Accordingly, our results about series decomposition and anchors (Lemma 7.1) extend easily. In particular, non-atomic full prime graphs of arity $0, 1$ and k would always have an anchor.

This means we also have finite presentations for bounds $k = 1, 2$. (For $k = 2$ this axiomatisation differs from the one previously proposed [5, 9], because the chosen syntax is different: there, graphs of arity three are not considered, and parallel composition may be applied to graphs of distinct arities.)

However, the results from Section 8 are specific to the case $k = 3$, and getting finite presentations for larger values of k seems difficult. Following the strategy presented here, we would need to prove the forget point agreement lemma (Lemma 5.4) for new hard graphs, which may have arities between 2 and $k - 1$.

Still, we would like to emphasise the utility of such a generalisation in the context of graph theory. Robertson and Seymour proved [14] that for all integers k there must be a finite list of excluded minors characterising the class of treewidth at most k graphs. Consider a minimal one amongst them, say H, along with a maximal clique over vertices $x_1, \ldots, x_i$. It is not difficult to prove that either H is K_{k+2}, or $(H, x_1, \ldots, x_i)$ is hard. Thus, studying hard graphs of treewidth $k + 1$ might lead to a better understanding of excluded minors for treewidth at most k.

Abstract

An F_d upper bound for the reachability problem in vector addition systems with states (VASS) in fixed dimension is given, where F_d is the d-th level of the Grzegorczyk hierarchy of complexity classes. The new algorithm combines the idea of the linear path scheme characterization of the reachability in the 2-dimension VASSes with the general decomposition algorithm by Mayr, Kosaraju and Lambert. The result improves the F_{d+4} upper bound due to Leroux and Schmitz (LICS 2019).

1 Introduction

Petri nets, or equivalently vector addition system with states (VASS), are a well studied model of concurrency. A VASS consists of a finite state control where each state transition has as its effect an integer-valued vector, and its configurations are pairs of a state and a vector with *natural number* components. A transition may lead from one configuration to another by adding its effect component-wise, conditioned on that the components of the resulting vector remain non-negative. The *reachability problem*, which asks whether from one configuration there is a path reaching another configuration, lies in the center of the algorithmic theory of Petri nets and has found a wide range of applications due to its generic nature. Since the problem was shown to be decidable by Mayr [17] in 1981, its computational complexity had been a long-standing open problem in the field. In 2015, Leroux and Schmitz [14] presented the first complexity upper bound, stating that the reachability problem is cubic-Ackermannian. This was later improved to an Ackermannian upper bound in 2019, again by Leroux and Schmitz [15]. Regarding the hardness, in 2021 seminal works by Czerwiński and Orlikowski [6], and independently by Leroux [13], provided matching Ackermannian lower bounds, settling the exact complexity of the problem.

[1] corresponding author

Concerning the parameterization by dimension, i.e. the reachability problem in d-dimensional VASSes where d is fixed, there is still a gap in the known complexity bounds. Currently, we only have exact complexity bounds for dimension one and two [7, 1]. For dimension $d \geq 3$, the result of Leroux and Schmitz [15] shows that the problem is in F_{d+4}, the $(d{+}4)$-th level of the Grzegorczyk hierarchy of complexity classes. Note that a recent work by Yang and Fu [22] points out that the problem for dimension 3 is in $\mathsf{F}_3 = \mathsf{TOWER}$. On the other hand, the best known lower bound by Czerwiński, Jecker, Lasota, Leroux and Orlikowski [5] states that reachability in $(2d{+}3)$-dimensional VASSes is F_d-hard. Motivated by this gap, our paper focuses on the computational complexity of reachability problem in the fixed-dimensional VASSes.

Our contribution

In this paper we show that the reachability problem in the d-dimensional VASS is in F_d for $d \geq 3$, improving the previous F_{d+4} upper bound by Leroux and Schmitz [15], and generalizing the tower upper bound for the reachability problem in 3-VASS [22]. The new upper bound is obtained with the help of two novel technical lemmas.

1. Our main technical tool (Theorem 3.4) is a generalization of the linear path scheme characterization for the reachability relation in the 2-dimensional VASSes [1]. By borrowing the key idea from the work of Yang and Fu [22], we show that as long as the "geometric dimension" of a VASS (that is, the dimension of the vector space spanned by the effects of cyclic paths) is bounded by 2, its reachability relation can be characterized by short linear path schemes. We then apply the lemma to simplify the KLMST algorithm so that (i) a VASS is replaced by a short linear path scheme whenever its geometric dimension is no more than 2 and (ii) the linear path schemes will not be decomposed further. It is then routine [15], using the tools from [21], to show that the reachability problem in the d-dimensional VASS is in F_{d+1} for all $d \geq 3$.
2. Our second lemma (Lemma 6.3) allows us to improve further the bound from F_{d+1} to F_d. This is done by a careful analysis of the properties of the fast-growing functions [21].

Due to space limitation the proofs of the two lemmas are placed in the appendices.

Organization

Section 2 fixes notation, defines the VASS model and its reachability problem. Section 3 generalizes the linear path scheme characterization [1] to VASSes whose geometric dimension are bounded by 2. Section 4 recalls the characterization system of linear inequalities for linear path schemes. Section 5 makes use of the results of Section 3 to give an improved version of the classic KLMST decomposition algorithm. Section 6 analyzes the complexity of our modified algorithm, proving the main result. Section 7 concludes. Proofs omitted from the main text can be found in the appendices.

2 Preliminaries

We use $\mathbb{N}, \mathbb{Z}, \mathbb{Q}$ to denote respectively the set of non-negative integers, integers, and rational numbers. Let $n \in \mathbb{N}$ be a number, we write $[n]$ for the range $\{1, 2, \ldots, n\}$. Let $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{X}^d$ be d-dimensional vectors where $\mathbb{X}$ can be any one of $\mathbb{N}, \mathbb{Z}, \mathbb{Q}$. We write $\boldsymbol{v}(i)$ for the i-th component of $\boldsymbol{v}$ where $i \in [d]$, so $\boldsymbol{v} = (\boldsymbol{v}(1), \ldots, \boldsymbol{v}(d))$. The *maximum norm* of $\boldsymbol{v}$ is defined to be $\|\boldsymbol{v}\| := \max_{i \in [d]} |\boldsymbol{v}(i)|$. We extend component-wise the order $\leq$ for vectors in $\mathbb{X}^d$, so $\boldsymbol{u} \leq \boldsymbol{v}$ if

and only if $\boldsymbol{u}(i) \leq \boldsymbol{v}(i)$ for all $i \in [d]$. Addition and subtraction of vectors are also component-wise, so $(\boldsymbol{u}+\boldsymbol{v})(i) = \boldsymbol{u}(i) + \boldsymbol{v}(i)$ for all $i \in [d]$. Define $\mathrm{supp}(\boldsymbol{v}) := \{i \in [d] : \boldsymbol{v}(i) \neq 0\}$ to be the set of indices of non-zero components of $\boldsymbol{v}$. This notation is extended to sets of vectors naturally, so $\mathrm{supp}(S) = \bigcup_{\boldsymbol{v}\in S} \mathrm{supp}(\boldsymbol{v})$ for any set $S \subseteq \mathbb{X}^d$.

For technical reasons we introduce the symbol ω that stands for the infinite element. Let $\mathbb{N}_\omega := \mathbb{N} \cup \{\omega\}$. We stipulate that $n < \omega$ for all $n \in \mathbb{N}$, and $x + \omega = \omega + x = \omega$ for all $x \in \mathbb{Z}$. Define the partial order $\sqsubseteq$ over $\mathbb{N}_\omega$ so that $x \sqsubseteq y$ if and only if $x = y$ or $y = \omega$ for all $x, y \in \mathbb{N}_\omega$. The relation $\sqsubseteq$ is also extended component-wise to vectors in $\mathbb{N}_\omega^d$.

Let Σ be a finite alphabet and $s, t \in \Sigma^*$ be two strings over Σ. We write st for the concatenation of s and t, and s^n for the concatenation of n copies of s where $n \in \mathbb{N}$. If $s = a_1 a_2 \dots a_\ell$ where $a_1, \dots, a_\ell \in \Sigma$, we write $|s| := \ell$ for the length of s, and $s[i \dots j] := a_i a_{i+1} \dots a_j$ for the substring of s between indices i and j where $1 \leq i \leq j \leq |s|$.

2.1 Vector Addition Systems with States

Let $d \geq 0$ be an integer. A *d-dimensional vector addition system with states (d-VASS)* is a pair $G = (Q, T)$ where Q is a finite set of *states* and $T \subseteq Q \times \mathbb{Z}^d \times Q$ is a finite set of *transitions*. Clearly a VASS can also be viewed as a directed graph with edges labelled by integer vectors. Given a word $\pi = (p_1, \boldsymbol{a}_1, q_1)(p_2, \boldsymbol{a}_2, q_2) \dots (p_n, \boldsymbol{a}_n, q_n) \in T^*$ over transitions, we say that π is a *path from p_1 to q_n* if $q_i = p_{i+1}$ for all $i = 1, \dots, n-1$. It is a *cycle* if we further have $p_1 = q_n$. The *effect* of π is defined to be $\Delta(\pi) := \sum_{i=1}^n \boldsymbol{a}_i$, and the *action word* of π is the word $[\![\pi]\!] := \boldsymbol{a}_1 \boldsymbol{a}_2 \dots \boldsymbol{a}_n$ over $\mathbb{Z}^d$. The *Parikh image* of π is the function $\phi \in \mathbb{N}^T$ mapping each transition to its number of occurrences in π. Given a function $\phi \in \mathbb{N}^T$ we also define $\Delta(\phi) := \sum_{t=(p,\boldsymbol{a},q)\in T} \phi(t) \cdot \boldsymbol{a}$. Note that $\Delta(\phi) = \Delta(\pi)$ if ϕ is the Parikh image of π. Let $L \subseteq T^*$ be a language (i.e. subset of words), we define its effect as $\Delta(L) := \{\Delta(\pi) : \pi \in L\}$.

The norm of a transition $t = (p, \boldsymbol{a}, q)$ is defined by $\|t\| := \|\boldsymbol{a}\|$. The norm of a path $\pi = t_1 t_2 \dots t_n$ is $\|\pi\| := \max_{i\in[n]} \|t_i\|$. For a d-VASS $G = (Q, T)$ we write $\|T\| := \max\{\|t\| : t \in T\}$. The *size* of G is defined by

$$|G| := |Q| + |T| + d \cdot |T| \cdot \|T\| \,. \tag{1}$$

Semantics of VASSes

Let $G = (Q, T)$ be a d-VASS. A *configuration* of G is a pair of a state $p \in Q$ and a vector $\boldsymbol{v} \in \mathbb{Z}^d$, written as $p(\boldsymbol{v})$. Let $\mathbb{D} \subseteq \mathbb{Z}^d$, we define the $\mathbb{D}$-semantics for G as follows. For each transition $t = (p, \boldsymbol{a}, q) \in T$, the one-step transition relation $\xrightarrow{t}_{\mathbb{D}}$ relates all pairs of configurations of the form $(p(\boldsymbol{u}), q(\boldsymbol{v}))$ where $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{D}$ and $\boldsymbol{v} = \boldsymbol{u} + \boldsymbol{a}$. Then for a word $\pi = t_1 t_2 \dots t_n \in T^*$, the relation $\xrightarrow{\pi}_{\mathbb{D}}$ is the composition $\xrightarrow{\pi}_{\mathbb{D}} := \xrightarrow{t_1}_{\mathbb{D}} \circ \cdots \circ \xrightarrow{t_n}_{\mathbb{D}}$. So $p(\boldsymbol{u}) \xrightarrow{\pi}_{\mathbb{D}} q(\boldsymbol{v})$ if and only if there are configurations $p_0(\boldsymbol{u}_0), \dots, p_n(\boldsymbol{u}_n) \in Q \times \mathbb{D}$ such that

$$p(\boldsymbol{u}) = p_0(\boldsymbol{u}_0) \xrightarrow{t_1}_{\mathbb{D}} p_1(\boldsymbol{u}_1) \xrightarrow{t_2}_{\mathbb{D}} \cdots \xrightarrow{t_n}_{\mathbb{D}} p_n(\boldsymbol{u}_n) = q(\boldsymbol{v}). \tag{2}$$

Also, when $\pi = \epsilon$ is the empty word, the relation $\xrightarrow{\epsilon}_{\mathbb{D}}$ is the identity relation over $Q \times \mathbb{D}$. Note that $\xrightarrow{\pi}_{\mathbb{D}}$ is non-empty only if π is a path. When $p(\boldsymbol{u}) \xrightarrow{\pi}_{\mathbb{D}} q(\boldsymbol{v})$ we also say that π induces (or is) a $\mathbb{D}$-*run* from $p(\boldsymbol{u})$ to $q(\boldsymbol{v})$. We emphasize that all configurations on this run lie in $\mathbb{D}$, and that they are uniquely determined by $p(\boldsymbol{u})$ and π. For a language $L \subseteq T^*$ we define $\xrightarrow{L}_{\mathbb{D}}$ as $\bigcup_{\pi\in L} \xrightarrow{\pi}_{\mathbb{D}}$. Finally, the $\mathbb{D}$-*reachability relation* of G is defined to be $\xrightarrow{*}_{\mathbb{D}} := \xrightarrow{T^*}_{\mathbb{D}}$.

For the above definitions, we shall often omit the subscript $\mathbb{D}$ when $\mathbb{D} = \mathbb{N}^d$.

We mention that in Section 5 we need to generalize the VASS semantics to configurations in $Q \times \mathbb{N}_\omega^d$, allowing ω components in vectors. The definitions of $\xrightarrow{t}_{\mathbb{N}_\omega^d}$, $\xrightarrow{\pi}_{\mathbb{N}_\omega^d}$, and $\xrightarrow{*}_{\mathbb{N}_\omega^d}$ are similar to the above.

Reachability problem

The reachability problem in vector addition systems with states is formulated as follows:

Reachability in d-Dimensional Vector Addition System with States
Input: A d-dimensional VASS $G = (Q, T)$, two configurations $p(\boldsymbol{u}), q(\boldsymbol{v}) \in Q \times \mathbb{N}^d$.
Question: Does $p(\boldsymbol{u}) \xrightarrow{*}_{\mathbb{N}^d} q(\boldsymbol{v})$ hold in G?

Note that we study the reachability problem for fixed-dimensional VASSes, where the dimension d is treated as a constant to allow more fine-grained analysis. So we shall use the big-O notation to hide constants that may depend on d. The general problem where the dimension can be part of the input was already shown to be Ackermann-complete [6, 13].

Cycle spaces and geometric dimensions

One of the key insights of [15] is a new termination argument for the KLMST decomposition algorithm based on the dimensions of vector spaces spanned by cycles in VASSes, which yielded the primitive recursive upper bound of VASS reachability problem in fixed dimensions. The vector spaces spanned by cycles also play an important role in our work.

▶ **Definition 2.1.** *Let G be a d-VASS. The* cycle space *of G is the vector space* $\mathrm{Cyc}(G) \subseteq \mathbb{Q}^d$ *spanned by the effects of all cycles in G, that is:*

$$\mathrm{Cyc}(G) := \mathrm{span}\{\Delta(\beta) : \beta \text{ is a cycle in } G\}. \tag{3}$$

The dimension of the cycle space of G is called the geometric dimension *of G. We say G is* geometrically k-dimensional *if* $\dim(\mathrm{Cyc}(G)) \leq k$.

3 Flattability of Geometrically 2-dimensional VASSes

A VASS is *flat* if each of its states lies on at most one cycle. Flat VASSes form an important subclass of VASSes due to its connection to Presburger arithmetic, and we refer the readers to [12] for a survey. In dimension 2, it was proved in [1] that 2-VASSes enjoy a stronger form of flat representation, known as the *linear path schemes*. A linear path scheme is a regular expression of the form $\alpha_0\beta_1^*\alpha_1 \dots \beta_k^*\alpha_k$ where $\alpha_0, \dots \alpha_k$ are paths and $\beta_1, \dots, \beta_k$ are cycles of the VASS, such that they form a path when joined together. The results of [1] show that the reachability relation of every 2-VASS can be captured by short linear path schemes.

Linear path schemes are extremely useful as they can be fully characterized by linear inequality systems so that standard tools for linear or integer programming can be applied. In this section, we generalize the results in [1] and show that the reachability relation of any d-VASS whose geometric dimension is bounded by 2 can also be captured by short linear path schemes.

Our proof follows closely to the lines of [1]. Given a geometrically 2-dimensional VASS G, we first cover $\mathbb{N}^d$ by the following two regions: one for the region far away from every axis:

$$\mathbb{O} := \{\boldsymbol{u} \in \mathbb{N}^d : \boldsymbol{u}(i) \geq D \text{ for all } i \in [d]\} \tag{4}$$

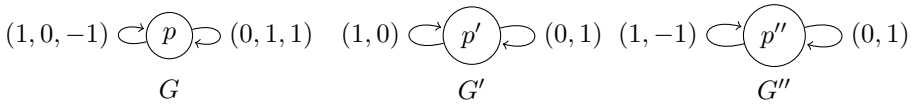

Figure 1 A geometrically 2-dimensional VASS G and two possible projections of it.

where D is some properly chosen threshold; the other one for the region close to some axis:

$$\mathbb{L} := \{\boldsymbol{u} \in \mathbb{N}^d : \boldsymbol{u}(i) \leq D' \text{ for some } i \in [d]\} \tag{5}$$

where D' is chosen slightly above D to create an overlap with $\mathbb{O}$. Let π be a run that we are going to capture by linear path schemes. We can extract its maximal prefix that lies completely in either $\mathbb{O}$ or $\mathbb{L}$, depending on where π starts. This prefix must end at a configuration that lies in $\mathbb{L} \cap \mathbb{O}$, if we haven't touched the end of π. From this configuration we then extract a maximal cycle that also ends in $\mathbb{L} \cap \mathbb{O}$. Continuing this fashion, we can break π into segments of runs that lie completely in $\mathbb{O}$ or $\mathbb{L}$, interleaved by cycles that start and end in $\mathbb{O}$ (actually in $\mathbb{L} \cap \mathbb{O}$). Note that the number of such cycles cannot exceed the number of states of G since they are maximal. Now we only need to capture the following three types of runs by short linear path schemes:

1. Runs that are cycles starting and ending in $\mathbb{O}$.
   This will be handled in Section A.4 in the appendix. Briefly speaking, since the geometric dimension of G is 2, the effect of such a cycle must belong to a plane in $\mathbb{Z}^d$. We will find a clever way to project this plane to a coordinate plane, and then project the d-VASS G onto this plane to get a 2-VASS. This is made possible by a novel technique called the "sign-reflecting projection" developed in Section A.3. Intuitively speaking, for any vector in a plane we are able to determine whether it belongs to a certain orthant by observing only 2 entries of this vector. The d-VASS can then be projected onto these 2 coordinates. (See Example 3.1 for a more concrete demonstration.) Now we apply the results of [1] to obtain a linear path scheme that captures the projected cyclic run. Combined with a lemma in [16], the projection guarantees that we can safely project it back to get a linear path scheme for the run in G.
2. Runs that lie completely in $\mathbb{O}$.
   This is just an easy corollary of the first type, and will also be handled in Section A.4. Just note that any run can be broken into a series of simple paths interleaved by cycles.
3. Runs that lie completely in $\mathbb{L}$.
   This will be handled in Section A.5, by a long and tedious case analysis. In principle, we are going to argue that any such run essentially corresponds to a run in some $(d-1)$-VASS, so that we can use induction.

▶ **Example 3.1.** Consider the geometrically 2-dimensional 3-VASS G as shown in Figure 1. It consists of a single state p and two transitions with effects $(1, 0, -1)$ and $(0, 1, 1)$. In order to apply the results of [1], one would like to derive a 2-VASS from G that reflects runs in G. A simple idea is to discard one coordinate of G. Two possibilities of this idea are shown in Figure 1 as G', which discards the third coordinate, and G'', which discards the second coordinate. However, not all of them are satisfactory. For example, the legal run $p(0,0) \xrightarrow{(1,0)} p(1,0)$ in G' reflects an illegal run $p(0,0,0) \xrightarrow{(1,0,-1)} p(1,0,-1)$ in G where the third coordinate goes negative. On the other hand, all runs in G'' can be safely projected back to a run in G. To see this, just observe that for any vector $\boldsymbol{v}$ in the linear span of $(1, 0, -1)$ and $(0, 1, 1)$, $\boldsymbol{v} \geq \mathbf{0}$ if and only if $\boldsymbol{v}(1) \geq 0$ and $\boldsymbol{v}(3) \geq 0$. Thus we can safely discard the second coordinate.

In general, the "sign-reflecting projection" developed in Section A.3 shows that any geometrically 2-dimensional VASS can be projected onto two coordinates so that the signs of these two coordinates reflects the signs of other coordinates.

In the rest of this section we just state formally our main technical results. The detailed proofs are placed in the appendix.

3.1 Linear Path Schemes

A *linear path scheme (LPS)* is a pair (G, Λ) where G is a VASS and Λ is a regular expression of the form $\Lambda = \alpha_0\beta_1^*\alpha_1 \dots \beta_k^*\alpha_k$ such that $\alpha_0, \dots, \alpha_k$ are paths in G and $\beta_1, \dots, \beta_k$ are cycles in G, and $\alpha_0\beta_1\alpha_1 \dots \beta_k\alpha_k$ is a path in G. We say an LPS (G, Λ) is *compatible to* a VASS G' if G' contains all states and transitions in Λ. Very often we shall omit the VASS G and say that Λ on its own is an LPS, with G understood as any VASS to which Λ is compatible. We write $|\Lambda| = |\alpha_0\beta_1\alpha_1 \dots \beta_k\alpha_k|$ for the length of Λ, $\|\Lambda\| = \|\alpha_0\beta_1\alpha_1 \dots \beta_k\alpha_k\|$ for its norm, and $|\Lambda|_* = k$ for the number of cycles in Λ.

We also treat Λ as the language defined by it, and thus for two configurations $p(\boldsymbol{u})$ and $q(\boldsymbol{v})$ we write $p(\boldsymbol{u}) \xrightarrow{\Lambda}_{\mathbb{D}} q(\boldsymbol{v})$ if and only if there exists $e_1, \dots, e_k \in \mathbb{N}$ such that

$$p(\boldsymbol{u}) \xrightarrow{\alpha_0\beta_1^{e_1}\alpha_1 \dots \beta_k^{e_k}\alpha_k}_{\mathbb{D}} q(\boldsymbol{v}). \tag{6}$$

Positive linear path schemes

A *positive LPS* is a regular expression of the form $\Lambda^+ = \alpha_0\beta_1^+\alpha_1 \dots \beta_k^+\alpha_k$ which is similar to a linear path scheme except that we require each cycle to be used at least once. We write $p(\boldsymbol{u}) \xrightarrow{\Lambda^+}_{\mathbb{D}} q(\boldsymbol{v})$ if and only if there are positive integers $e_1, \dots, e_k \in \mathbb{N}_{>0}$ such that

$$p(\boldsymbol{u}) \xrightarrow{\alpha_0\beta_1^{e_1}\alpha_1 \dots \beta_k^{e_k}\alpha_k}_{\mathbb{D}} q(\boldsymbol{v}). \tag{7}$$

A path π is said to be *admitted by* Λ^+ if $\pi = \alpha_0\beta_1^{e_1}\alpha_1 \dots \beta_k^{e_k}\alpha_k$ for some $e_1, \dots, e_k \in \mathbb{N}_{>0}$. We prefer positive LPSes as they can be easily characterized by linear inequality systems (see Section 4 for details). In fact, positive LPSes can be easily obtained from LPSes:

▶ **Lemma 3.2.** *For every linear path scheme Λ there exists a finite set S of positive linear path schemes compatible to the same VASSes with Λ, such that $\xrightarrow{\Lambda} \;= \bigcup_{\Lambda^+ \in S} \xrightarrow{\Lambda^+}$ and $|\Lambda^+| \le |\Lambda|$ for every $\Lambda^+ \in S$.*

Proof. Suppose $\Lambda = \alpha_0\beta_1^*\alpha_1 \dots \beta_k^*\alpha_k$. For each cycle component β_i^* in Λ we replace it by either β_i^+ or an empty word nondeterministically. Let S be the set of all resulting positive LPSes. It is obvious that S satisfies the desired properties. ◀

3.2 Main Results

The main results of this section is stated as follows.

▶ **Theorem 3.3.** *Let $G = (Q, T)$ be a geometrically 2-dimensional d-VASS. For every pair of configurations $p(\boldsymbol{u}), q(\boldsymbol{v}) \in Q \times \mathbb{N}^d$ with $p(\boldsymbol{u}) \xrightarrow{*} q(\boldsymbol{v})$ there exists a positive LPS Λ^+ compatible to G such that $p(\boldsymbol{u}) \xrightarrow{\Lambda^+} q(\boldsymbol{v})$ and $|\Lambda^+| \le |G|^{O(1)}$.*

We remark that the big-O term here and elsewhere in the paper hides constant that may depend on the dimension d, but does not depend on $G, \boldsymbol{u}, \boldsymbol{v}$ or anything else.

By Lemma 3.2 we know that positive LPSes can be obtained from LPSes. Thus theorem 3.3 follows easily from the following relaxed theorem, which will be proved in the appendix.

▶ **Theorem 3.4.** *Let $G = (Q, T)$ be a geometrically 2-dimensional d-VASS. For every pair of configurations $p(\boldsymbol{u}), q(\boldsymbol{v}) \in Q \times \mathbb{N}^d$ with $p(\boldsymbol{u}) \xrightarrow{*} q(\boldsymbol{v})$ there exists an LPS Λ compatible to G such that $p(\boldsymbol{u}) \xrightarrow{\Lambda} q(\boldsymbol{v})$ and $|\Lambda| \leq |G|^{O(1)}$.*

4 Characteristic Systems for Linear Path Schemes

The property that linear path schemes can be fully characterized by linear inequality systems is exploited in [2] to derive the PSPACE upper bound of the reachability problem in 2-VASSes. Here we recall this linear inequality system and its properties.

We mainly focus on positive linear path schemes. Fix $\Lambda = \alpha_0\beta_1^+\alpha_1 \dots \beta_k^+\alpha_k$ to be a positive LPS from state p to q that is compatible to some d-VASS $G = (Q, T)$, where $k = |\Lambda|_*$ is the number of cycles in Λ.

▶ **Definition 4.1** (cf. [2, Lem. 14])**.** *The* characteristic system $\mathcal{E}_{\mathrm{LPS}}(\Lambda)$ of the positive LPS Λ *is the system of linear inequalities such that a triple $\boldsymbol{h} = (\boldsymbol{u}, \boldsymbol{e}, \boldsymbol{v}) \in \mathbb{N}^d \times \mathbb{N}^k \times \mathbb{N}^d$ satisfies $\mathcal{E}_{\mathrm{LPS}}(\Lambda)$, written $\boldsymbol{h} \models \mathcal{E}_{\mathrm{LPS}}(\Lambda)$, if and only if the following conditions hold:*

1. *for every $i = 1, \dots, k$, $\boldsymbol{e}(i) \geq 1$;*
2. *for every $i = 0, \dots, k$ and every $j = 1, \dots, |\alpha_i|$,*

$$\boldsymbol{u} + \Delta(\alpha_0\beta_1^{\boldsymbol{e}(1)}\alpha_1 \dots \alpha_{i-1}\beta_i^{\boldsymbol{e}(i)}) + \Delta(\alpha_i[1 \dots j]) \geq \boldsymbol{0}; \tag{8}$$

3. *for every $i = 1, \dots, k$ and every $j = 1, \dots, |\beta_i|$,*

$$\boldsymbol{u} + \Delta(\alpha_0\beta_1^{\boldsymbol{e}(1)}\alpha_1 \dots \beta_{i-1}^{\boldsymbol{e}(i-1)}\alpha_{i-1}) \qquad + \Delta(\beta_i[1 \dots j]) \geq \boldsymbol{0}, \tag{9}$$

$$\boldsymbol{u} + \Delta(\alpha_0\beta_1^{\boldsymbol{e}(1)}\alpha_1 \dots \beta_{i-1}^{\boldsymbol{e}(i-1)}\alpha_{i-1}\beta_i^{\boldsymbol{e}(i)-1}) + \Delta(\beta_i[1 \dots j]) \geq \boldsymbol{0}; \tag{10}$$

4. *and finally, $\boldsymbol{u} + \Delta(\alpha_0\beta_1^{\boldsymbol{e}(1)}\alpha_1 \dots \beta_k^{\boldsymbol{e}(k)}\alpha_k) = \boldsymbol{v}$.*

The readers can easily verify that these constraints are indeed linear in terms of $\boldsymbol{u}, \boldsymbol{e}, \boldsymbol{v}$. The next lemma shows that $\mathcal{E}_{\mathrm{LPS}}(\Lambda)$ indeed captures all runs admitted by Λ.

▶ **Lemma 4.2.** *Let G be a d-VASS and $\Lambda = \alpha_0\beta_1^+\alpha_1 \dots \beta_k^+\alpha_k$ be a positive LPS from state p to q compatible to G. Then for every $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{N}^d$, $p(\boldsymbol{u}) \xrightarrow{\Lambda} q(\boldsymbol{v})$ if and only if there exists $\boldsymbol{e} \in \mathbb{N}^k$ such that $(\boldsymbol{u}, \boldsymbol{e}, \boldsymbol{v}) \models \mathcal{E}_{\mathrm{LPS}}(\Lambda)$. Moreover, for every $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{N}^d$ and every $\boldsymbol{e} \in \mathbb{N}^k$ such that $(\boldsymbol{u}, \boldsymbol{e}, \boldsymbol{v}) \models \mathcal{E}_{\mathrm{LPS}}(\Lambda)$, we have $p(\boldsymbol{u}) \xrightarrow{\alpha_0\beta_1^{\boldsymbol{e}(1)}\alpha_1 \dots \beta_k^{\boldsymbol{e}(k)}\alpha_k} q(\boldsymbol{v})$.*

We also need to introduce the homogeneous version of $\mathcal{E}_{\mathrm{LPS}}(\Lambda)$ for technical reasons.

▶ **Definition 4.3.** *The* homogeneous characteristic system $\mathcal{E}^0_{\mathrm{LPS}}(\Lambda)$ of Λ *is the system of linear inequalities such that a triple $\boldsymbol{h}_0 = (\boldsymbol{u}_0, \boldsymbol{e}_0, \boldsymbol{v}_0) \in \mathbb{N}^d \times \mathbb{N}^k \times \mathbb{N}^d$ satisfies $\mathcal{E}^0_{\mathrm{LPS}}(\Lambda)$, written $\boldsymbol{h}_0 \models \mathcal{E}^0_{\mathrm{LPS}}(\Lambda)$, if and only if the following conditions hold:*

1. *for every $i = 0, \dots, k$, $\boldsymbol{u}_0 + \Delta(\beta_1) \cdot \boldsymbol{e}_0(1) + \dots + \Delta(\beta_i) \cdot \boldsymbol{e}_0(i) \geq \boldsymbol{0}$;*
2. *$\boldsymbol{u}_0 + \Delta(\beta_1) \cdot \boldsymbol{e}_0(1) + \dots + \Delta(\beta_k) \cdot \boldsymbol{e}_0(k) = \boldsymbol{v}_0$.*

5 The Modified KLMST Decomposition Algorithm

In this section we apply our results of Section 3 to improve the notoriously hard KLMST decomposition algorithm for VASS reachability. Our narration will base on the work of Leroux and Schmitz [15]. For readers familiar with [15], the major modifications are listed below:

- The decomposition structure is now a sequence of generalized VASS reachability instances linked by (positive) linear path schemes rather than by single transitions.
- We introduce a new "cleaning" step that replaces all VASS instances which are geometrically 2-dimensional by polynomial-length linear path schemes compatible to them.
- We do not guarantee the exact preservation of action languages at each decomposition step. Instead, we only preserve a subset of action languages. This is a compromise since linear path schemes capture only the reachability relation but not every possible run. Nonetheless, it is enough for the reachability problem.

In this section we focus on the effectiveness and correctness of the modified KLMST decomposition algorithm. Its complexity will be analyzed in Section 6.

5.1 Linear KLM Sequences

The underlying decomposition structure in the KLMST algorithm was known as KLM sequences, named after Mayr[17], Kosaraju[10], and Lambert[11].

▶ **Definition 5.1.** *A* KLM tuple *of dimension d is a tuple $\langle p(\boldsymbol{x})Gq(\boldsymbol{y})\rangle$ where $G = (Q, T)$ is a d-VASS and $p(\boldsymbol{x}), q(\boldsymbol{y}) \in Q \times \mathbb{N}_\omega^d$ are two (generalized) configurations of G. A* KLM sequence *of dimension d is a sequence of KLM tuples interleaved by transitions of the form*

$$\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, t_1\, \langle p_1(\boldsymbol{x}_1)G_1q_1(\boldsymbol{y}_1)\rangle\, t_2 \dots t_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle\,, \tag{11}$$

where each tuple $\langle p_i(\boldsymbol{x}_i)G_iq_i(\boldsymbol{y}_i)\rangle$ is a KLM tuple of dimension d and each t_i is a transition of the form $(q_{i-1}, \boldsymbol{a}_i, p_i)$ from state q_{i-1} to p_i with effect $\boldsymbol{a}_i \in \mathbb{Z}^d$.

In this paper we generalize the definition of KLM sequences to allow (positive) linear path schemes to connect KLM tuples.

▶ **Definition 5.2.** *A* linear KLM sequence *of dimension d is a sequence*

$$\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, \Lambda_1\, \langle p_1(\boldsymbol{x}_1)G_1q_1(\boldsymbol{y}_1)\rangle\, \Lambda_2 \dots \Lambda_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle\,, \tag{12}$$

where each tuple $\langle p_i(\boldsymbol{x}_i)G_iq_i(\boldsymbol{y}_i)\rangle$ is a KLM tuple of dimension d and each Λ_i is a positive linear path scheme from state q_{i-1} to p_i.

One immediately sees that KLM sequences are just special cases of linear KLM sequences. Let ξ be a linear KLM sequence given as (12), we write $\xi_i := \langle p_i(\boldsymbol{x}_i)G_iq_i(\boldsymbol{y}_i)\rangle$ for the ith KLM tuple occurring in ξ.

Action languages

Let ξ be a linear KLM sequence given as (12). We say a path π from state p_0 to q_k is *admitted by* ξ, written $\xi \vdash \pi$, if π can be written as $\pi = \pi_0\rho_1\pi_1 \dots \rho_k\pi_k$ where π_i is a path from p_i to q_i in G_i for each $i = 0, \dots, k$, and ρ_i is a path admitted by Λ_i for each $i = 1, \dots, k$, such that there exist vectors $\boldsymbol{m}_0, \boldsymbol{n}_0, \dots, \boldsymbol{m}_k, \boldsymbol{n}_k \in \mathbb{N}^d$ such that

$$p_0(\boldsymbol{m}_0) \xrightarrow{\pi_0} q_0(\boldsymbol{n}_0) \xrightarrow{\rho_1} p_1(\boldsymbol{m}_1) \xrightarrow{\pi_1} q_1(\boldsymbol{n}_1) \xrightarrow{\rho_2} \cdots \xrightarrow{\rho_k} p_k(\boldsymbol{m}_k) \xrightarrow{\pi_k} q_k(\boldsymbol{n}_k) \tag{13}$$

and that $\boldsymbol{m}_i \sqsubseteq \boldsymbol{x}_i$, $\boldsymbol{n}_i \sqsubseteq \boldsymbol{y}_i$ for each $i = 0, \dots, k$.

The *action language* L_ξ of ξ is the language over $\mathbb{Z}^d$ defined by $L_\xi := \{[\![\pi]\!] : \xi \vdash \pi\}$, where we recall that $[\![\cdot]\!]$ is the word morphism mapping each transition to its effect.

We are more interested in the action languages because in some decomposition steps we have to modify the set of transitions, and only the action word of admitted runs can be preserved. Notice that action languages preserve not only the effects of admitted runs, but also their lengths.

Ranks and Sizes

Let t be a transition in a d-VASS G, we define $\mathrm{Cyc}(G/t)$ to be the vector space spanned by the effects of all cycles in G containing t. For the VASS G, let r_i be the number of transitions t in G such that $\dim(\mathrm{Cyc}(G/t)) = i$ for each $i = 0, \ldots, d$. Then the *rank* of G is defined as $\mathrm{rank}(G) = (r_d, \ldots, r_3) \in \mathbb{N}^{d-2}$. We also define the *full rank* of G as $\mathrm{rank}_{\mathrm{full}}(G) = (r_d, \ldots, r_0) \in \mathbb{N}^{d+1}$.

The following lemma was proved in [15], which shows that in a strongly connected VASS G, the space $\mathrm{Cyc}(G/t)$ corresponds to $\mathrm{Cyc}(G)$.

▶ **Lemma 5.3** ([15, Lem. 3.2]). *Let t be a transition of a strongly connected VASS G. Then* $\mathrm{Cyc}(G/t) = \mathrm{Cyc}(G)$.

The following corollary is immediate.

▶ **Corollary 5.4.** *Let G be a strongly connected d-VASS. Then* $\mathrm{rank}(G) = \mathbf{0}$ *if and only if G is geometrically 2-dimensional.*

Let ξ be a linear KLM sequence given as (12). We define the *rank* of ξ as $\mathrm{rank}(\xi) = \sum_{i=0}^{k} \mathrm{rank}(G_i)$, and the *full rank* of ξ as $\mathrm{rank}_{\mathrm{full}}(\xi) = \sum_{i=0}^{k} \mathrm{rank}_{\mathrm{full}}(G_i)$. We remark that the full rank corresponds to the rank defined in [15]. Ranks are ordered lexicographically: let $\boldsymbol{r} = (r_d, \ldots, r_0)$ and $\boldsymbol{r}' = (r'_d, \ldots, r'_0)$, we write $\boldsymbol{r} \leq_{\mathrm{lex}} \boldsymbol{r}'$ if $\boldsymbol{r} = \boldsymbol{r}'$ or the maximal i with $r_i \neq r'_i$ satisfies $r_i < r'_i$.

Recall that for a VASS G we write $|G|$ for its size as defined in (1). For a linear path scheme Λ, its length $|\Lambda|$ and norm $\|\Lambda\|$ are defined in Section 3.1. Let $\zeta = \langle p(\boldsymbol{x})Gq(\boldsymbol{y})\rangle$ be a KLM tuple of dimension d, its *size* is defined to be $|\zeta| = |G| + d \cdot (\|\boldsymbol{x}\| + \|\boldsymbol{y}\| + 1)$. Let ξ be a linear KLM sequence given as (12), we define its *size* as

$$|\xi| = \sum_{i=0}^{k} |\xi_i| + \sum_{i=1}^{k} d \cdot |\Lambda_i| \cdot (\|\Lambda_i\| + 1). \tag{14}$$

Note that the sizes defined in this paper reflect the sizes of unary encoding, thus have an exponential expansion in their binary encoding.

5.2 Characteristic Systems for Linear KLM Sequences

We define in this section the characteristic systems of linear KLM sequences, which are systems of linear inequalities that serve as an under-specification of admitted runs. Let $G = (Q, T)$ be a VASS, we first recall the *Kirchhoff system* $K_{G,p,q}$ of G with respect to states $p, q \in Q$, which is a system of linear equations such that a function $\phi \in \mathbb{N}^T$ is a model of $K_{G,p,q}$, written $\phi \models K_{G,p,q}$, if and only if

$$\mathbf{1}_q - \mathbf{1}_p = \sum_{t=(r,\boldsymbol{a},s)\in T} \phi(t) \cdot (\mathbf{1}_s - \mathbf{1}_r), \tag{15}$$

where $\mathbf{1}_p \in \{0,1\}^Q$ is the indicator function defined by $\mathbf{1}_p(q) = 1$ if $q = p$ and $\mathbf{1}_p(q) = 0$ otherwise. We also need the homogeneous version of $K_{G,p,q}$, denoted by $K^0_{G,p,q}$, where a function $\phi \in \mathbb{N}^T$ is a model of it, written $\phi \models K^0_{G,p,q}$, if and only if

$$\mathbf{0} = \sum_{t=(r,\boldsymbol{a},s)\in T} \phi(t) \cdot (\mathbf{1}_s - \mathbf{1}_r). \tag{16}$$

▶ **Definition 5.5.** *Let ξ be a linear KLM sequence given by*

$$\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, \Lambda_1\, \langle p_1(\boldsymbol{x}_1)G_1q_1(\boldsymbol{y}_1)\rangle\, \Lambda_2 \ldots \Lambda_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle \tag{17}$$

The characteristic system $\mathcal{E}(\xi)$ *is a set of linear (in)equalities such that a sequence*

$$\boldsymbol{h} = (\boldsymbol{m}_0, \phi_0, \boldsymbol{n}_0), \boldsymbol{e}_1, (\boldsymbol{m}_1, \phi_1, \boldsymbol{n}_1), \boldsymbol{e}_2, \ldots, \boldsymbol{e}_k, (\boldsymbol{m}_k, \phi_k, \boldsymbol{n}_k), \tag{18}$$

where each $(\boldsymbol{m}_i, \phi_i, \boldsymbol{n}_i) \in \mathbb{N}^d \times \mathbb{N}^{T_i} \times \mathbb{N}^d$ and each $\boldsymbol{e}_i \in \mathbb{N}^{|\Lambda_i|_*}$, is a model of $\mathcal{E}(\xi)$, written $\boldsymbol{h} \models \mathcal{E}(\xi)$, if and only if

1. *$\boldsymbol{m}_i \sqsubseteq \boldsymbol{x}_i$, $\phi_i \models K_{G,p,q}$, $\boldsymbol{n}_i \sqsubseteq \boldsymbol{y}_i$ and $\boldsymbol{n}_i = \boldsymbol{m}_i + \Delta(\phi_i)$ for every $i = 0, \ldots, k$;*
2. *$(\boldsymbol{n}_{i-1}, \boldsymbol{e}_i, \boldsymbol{m}_i) \models \mathcal{E}_{\mathrm{LPS}}(\Lambda_i)$ for every $i = 1, \ldots, k$.*

Similarly, the homogeneous characteristic system $\mathcal{E}^0(\xi)$ *is a set of linear (in)equalities such that a sequence $\boldsymbol{h}$ of the form (18) is a model of $\mathcal{E}^0(\xi)$, written $\boldsymbol{h} \models \mathcal{E}^0(\xi)$, if and only if*

1. *$\boldsymbol{m}_i(j) = 0$ whenever $\boldsymbol{x}_i(j) \neq \omega$, $\phi_i \models K^0_{G,p,q}$, $\boldsymbol{n}_i(j) = 0$ whenever $\boldsymbol{y}_i(j) \neq \omega$, and $\boldsymbol{n}_i = \boldsymbol{m}_i + \Delta(\phi_i)$ for every $i = 0, \ldots, k$;*
2. *$(\boldsymbol{n}_{i-1}, \boldsymbol{e}_i, \boldsymbol{m}_i) \models \mathcal{E}^0_{\mathrm{LPS}}(\Lambda_i)$ for every $i = 1, \ldots, k$.*

The sequence ξ is said to be satisfiable *if $\mathcal{E}(\xi)$ has a model, otherwise it's unsatisfiable.*

Let $\boldsymbol{h}$ be a model of $\mathcal{E}(\xi)$ (or $\mathcal{E}^0(\xi)$), we shall write $\boldsymbol{m}_i^{\boldsymbol{h}}, \phi_i^{\boldsymbol{h}}, \boldsymbol{n}_i^{\boldsymbol{h}}, \boldsymbol{e}_i^{\boldsymbol{h}}$ for the values of $\boldsymbol{m}_i, \phi_i, \boldsymbol{n}_i, \boldsymbol{e}_i$ assigned by $\boldsymbol{h}$, respectively. Recall that unsatisfiable linear KLM sequences have empty action languages.

▶ **Lemma 5.6** (cf. [15, Lem. 3.5])**.** *For any unsatisfiable linear KLM sequence ξ, $L_\xi = \emptyset$.*

5.2.1 Bounds on Bounded Values in $\mathcal{E}(\xi)$

We state here a lemma similar to [15, Lem. 3.7], which upper bounds the bounded values in the characteristic system $\mathcal{E}(\xi)$. Its proof can be found in the appendix, which is a straightforward application of tools in [3] and [18].

▶ **Lemma 5.7.** *Assume that $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, \Lambda_1 \cdots \Lambda_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ is satisfiable. Then for every $0 \leq i \leq k$ we have:*

- *For every $1 \leq j \leq d$, the set of values $\boldsymbol{m}_i^{\boldsymbol{h}}(j)$ where $\boldsymbol{h} \models \mathcal{E}(\xi)$ is unbounded if, and only if, there exists a model $\boldsymbol{h}_0$ of $\mathcal{E}^0(\xi)$ such that $\boldsymbol{m}_i^{\boldsymbol{h}_0}(j) > 0$.*
- *For every $t \in T_i$, the set of values $\phi_i^{\boldsymbol{h}}(t)$ where $\boldsymbol{h} \models \mathcal{E}(\xi)$ is unbounded if, and only if, there exists a model $\boldsymbol{h}_0$ of $\mathcal{E}^0(\xi)$ such that $\phi_i^{\boldsymbol{h}}(t) > 0$.*
- *For every $1 \leq j \leq d$, the set of values $\boldsymbol{n}_i^{\boldsymbol{h}}(j)$ where $\boldsymbol{h} \models \mathcal{E}(\xi)$ is unbounded if, and only if, there exists a model $\boldsymbol{h}_0$ of $\mathcal{E}^0(\xi)$ such that $\boldsymbol{n}_i^{\boldsymbol{h}_0}(j) > 0$.*

Moreover, every bounded value of $\mathcal{E}(\xi)$ is bounded by $(10|\xi|)^{12|\xi|}$.

5.3 Cleaning of Linear KLM Sequences

In this section we define three conditions that require a linear KLM sequence to be *strongly connected*, *pure*, and *saturated*. Together with the satisfiability condition, they make up the so-called "clean" condition of linear KLM sequences. Note that the purity condition is new compared to [15], which requires every geometrically 2-dimensional VASSes occur in a linear KLM sequence to be replaced by linear path schemes.

Strongly Connected Sequences

A linear KLM sequence $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\,\Lambda_1\cdots\Lambda_k\,\langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ is *strongly connected* if all the VASSes $G_0,\dots,G_k$ are strongly connected (as they are understood as directed graphs). One can easily obtain strongly connected sequences by expanding the strongly connected components of each VASS:

▶ **Lemma 5.8** ([15, Lem. 4.2]). *For any linear KLM sequence ξ which is not strongly connected, one can compute in time $\mathsf{exp}(|\xi|)$ a finite set Ξ of strongly connected linear KLM sequences such that $L_\xi = \bigcup_{\xi'\in\Xi} L_{\xi'}$ and that $\mathrm{rank}(\xi') \leq_{lex} \mathrm{rank}(\xi)$ and $|\xi'| \leq (2d+1)|\xi|$ for every $\xi' \in \Xi$.*

Pure Sequences

A KLM tuple $\langle p(\boldsymbol{x})Gq(\boldsymbol{y})\rangle$ is called *trivial* if $p(\boldsymbol{x}) = q(\boldsymbol{y})$ and G contains no transition and only a single state p. In this case we simply write $\langle p(\boldsymbol{x})\rangle$ for this tuple. Note that the action language of a trivial tuple contains exactly the empty word.

A linear KLM sequence $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\,\Lambda_1\cdots\Lambda_k\,\langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ is said to be *pure* if ξ is strongly connected and for every $i = 0,\dots,k$, $\mathrm{rank}(G_i) = \mathbf{0}$ implies that the tuple $\langle p_i(\boldsymbol{x}_i)G_iq_i(\boldsymbol{y}_i)\rangle$ is trivial. By Corollary 5.4, a rank-$\mathbf{0}$ strongly connected VASS is geometrically 2-dimensional, and thus can be replaced by linear path schemes in case it is not trivial.

▶ **Lemma 5.9.** *Let ξ be a strongly connected linear KLM sequence. Whether ξ is pure is in* PSPACE. *If ξ is not pure, one can compute in space $\mathsf{poly}(|\xi|)$ a finite set Ξ of pure linear KLM sequences such that $\bigcup_{\xi'\in\Xi} L_{\xi'} \subseteq L_\xi$ and $\bigcup_{\xi'\in\Xi} L_{\xi'} \neq \emptyset$ whenever $L_\xi \neq \emptyset$, and such that $\mathrm{rank}(\xi') = \mathrm{rank}(\xi)$ and $|\xi'| \leq |\xi|^{O(1)}$ for all $\xi' \in \Xi$.*

Saturated Sequences

Let $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\,\Lambda_1\cdots\Lambda_k\,\langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ be a linear KLM sequence. We say ξ is *saturated* if for every $0 \leq i \leq k$ and every $j \in [d]$, we have

- $\boldsymbol{x}_i(j) = \omega$ implies the set of values $\boldsymbol{m}_i^{\boldsymbol{h}}(j)$ where $\boldsymbol{h} \models \mathcal{E}(\xi)$ is unbounded; and
- $\boldsymbol{y}_i(j) = \omega$ implies the set of values $\boldsymbol{n}_i^{\boldsymbol{h}}(j)$ where $\boldsymbol{h} \models \mathcal{E}(\xi)$ is unbounded.

▶ **Lemma 5.10** ([15, Lem. 4.4]). *From any pure linear KLM sequence ξ, one can compute in time $\mathsf{exp}(|\xi|^{O(|\xi|)})$ a finite set Ξ of saturated pure linear KLM sequences such that $L_\xi = \bigcup_{\xi'\in\Xi} L_{\xi'}$, and such that $\mathrm{rank}(\xi') = \mathrm{rank}(\xi)$ and $|\xi'| \leq |\xi|^{O(|\xi|)}$ for every $\xi' \in \Xi$.*

Proof. By Lemma 5.7, if a variable $\boldsymbol{m}_i(j)$ or $\boldsymbol{n}_i(j)$ is bounded in $\mathcal{E}(\xi)$, we can replace the corresponding ω component in ξ by all possible values bounded by $(10|\xi|)^{12|\xi|} \leq |\xi|^{O(|\xi|)}$. ◀

The Cleaning Lemma

A linear KLM sequence ξ is called *clean* if it is satisfiable, strongly connected, pure and saturated. The lemmas 5.8 through 5.10 show how to make a linear KLM sequence clean.

▶ **Lemma 5.11.** *From any linear KLM sequence ξ, one can compute in time $\mathsf{exp}(g(|\xi|))$ a finite set $\mathrm{clean}(\xi)$ of clean linear KLM sequences such that $\bigcup_{\xi'\in\mathrm{clean}(\xi)} L_{\xi'} \subseteq L_\xi$ and $\bigcup_{\xi'\in\mathrm{clean}(\xi)} L_{\xi'} \neq \emptyset$ whenever $L_\xi \neq \emptyset$. Moreover, for every $\xi' \in \mathrm{clean}(\xi)$ we have $\mathrm{rank}(\xi') \leq_{lex} \mathrm{rank}(\xi)$ and $|\xi'| \leq g(|\xi|)$ where $g(x) = x^{x^{O(1)}}$.*

5.4 Decomposition of Linear KLM Sequences

In this section we recall three conditions that require a linear KLM sequence to be *unbounded*, *rigid*, and *pumpable*. If any one of them is violated, a decomposition into a set of linear KLM sequences with strictly smaller ranks can be performed. Essentially there is nothing new in this section compared to [15]. The decomposition operations in [15] can be directly applied here, since they operate on a single KLM tuple and produce KLM sequences that are just special cases of linear KLM sequences. The proofs in [15] can also be adapted easily, and we will omit the details here. Especially, the next lemma shows that the arguments of strict decrease in ranks are still valid even though we discard the lower three components of ranks.

▶ **Lemma 5.12.** *Let ξ' be a pure linear KLM sequence. For any linear KLM sequence ξ' with $\mathrm{rank}_{full}(\xi') <_{lex} \mathrm{rank}_{full}(\xi)$, we have $\mathrm{rank}(\xi') <_{lex} \mathrm{rank}(\xi)$.*

Unbounded Sequences

Let $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, \Lambda_1 \cdots \Lambda_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ be a linear KLM sequence. We say ξ is *unbounded* if for all $i = 0, \ldots, k$ and every transition $t \in T_i$ where T_i is the set of transitions of G_i, the set of values $\phi_i^{\boldsymbol{h}}(t)$ where $\boldsymbol{h} \models \mathcal{E}(\xi)$ is unbounded. Bounded transitions can be expanded exhaustively according to the bounds given by Lemma 5.7.

▶ **Lemma 5.13** ([15, Lem. 4.6])**.** *Whether a linear KLM sequence ξ is unbounded is decidable in* NP*. Moreover, if ξ is pure and bounded, one can compute in time $\mathsf{exp}(|\xi|^{O(|\xi|)})$ a finite set Ξ of linear KLM sequences such that $L_\xi = \bigcup_{\xi' \in \Xi} L_{\xi'}$ and such that $\mathrm{rank}(\xi') <_{lex} \mathrm{rank}(\xi)$ and $|\xi'| < |\xi|^{O(|\xi|)}$ for every $\xi' \in \Xi$.*

Rigid Sequences

A coordinate $j \in [d]$ is said to be *fixed* by a VASS $G = (Q, T)$ if there exists a function $f_j : Q \to \mathbb{N}$ such that $f_j(q) = f_j(p) + \boldsymbol{a}(j)$ for every transition $(p, \boldsymbol{a}, q) \in T$. We also say that f_j *fixes* G at coordinate j in this case.

A KLM tuple $\langle p(\boldsymbol{x})Gq(\boldsymbol{y})\rangle$ is said to be *rigid* if for every coordinate j fixed by $G = (Q, T)$, there exists a function $g_j : Q \to \mathbb{N}$ that fixes G at coordinate j and such that $g_j(p) \sqsubseteq \boldsymbol{x}(j)$ and $g_j(q) \sqsubseteq \boldsymbol{y}(j)$.

A linear KLM sequence $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, \Lambda_1 \cdots \Lambda_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ is said to be *rigid* if every tuple $\langle p_i(\boldsymbol{x}_i)G_iq_i(\boldsymbol{y}_i)\rangle$ in ξ is rigid.

▶ **Lemma 5.14** ([15, Lem. 4.9])**.** *From any pure linear KLM sequence ξ one can decide in polynomial time whether ξ is not rigid. Moreover, in that case one can compute in polynomial time a linear KLM sequence ξ' such that $L_\xi = L_{\xi'}$, $\mathrm{rank}(\xi') <_{lex} \mathrm{rank}(\xi)$, and $|\xi'| \leq |\xi|$.*

Pumpable Sequences

Given a KLM tuple $\langle p(\boldsymbol{x})Gq(\boldsymbol{y})\rangle$, recall the *forward and backward acceleration vectors* $\textsc{Facc}_{G,p}(\boldsymbol{x}), \textsc{Bacc}_{G,q}(\boldsymbol{y}) \in \mathbb{N}_\omega^d$ defined by

$$\textsc{Facc}_{G,p}(\boldsymbol{x})(j) = \begin{cases} \omega & \text{if } p(\boldsymbol{x}) \xrightarrow{*} p(\boldsymbol{x}') \text{ for some } \boldsymbol{x}' \text{ with } \boldsymbol{x}' \geq \boldsymbol{x}, \boldsymbol{x}'(j) > \boldsymbol{x}(j) \\ \boldsymbol{x}(j) & \text{otherwise} \end{cases} \tag{19}$$

$$\textsc{Bacc}_{G,q}(\boldsymbol{y})(j) = \begin{cases} \omega & \text{if } q(\boldsymbol{y}') \xrightarrow{*} q(\boldsymbol{y}) \text{ for some } \boldsymbol{y}' \text{ with } \boldsymbol{y}' \geq \boldsymbol{y}, \boldsymbol{y}'(j) > \boldsymbol{y}(j) \\ \boldsymbol{y}(j) & \text{otherwise} \end{cases} \tag{20}$$

A tuple $\langle p(\boldsymbol{x})Gq(\boldsymbol{y})\rangle$ is said to be *pumpable* if $\textsc{Facc}_{G,p}(\boldsymbol{x})(j) = \textsc{Bacc}_{G,q}(\boldsymbol{y})(j) = \omega$ for every coordinate j *not* fixed by G.

A linear KLM sequence given by $\xi = \langle p_0(\boldsymbol{x}_0)G_0q_0(\boldsymbol{y}_0)\rangle\, \Lambda_1 \cdots \Lambda_k\, \langle p_k(\boldsymbol{x}_k)G_kq_k(\boldsymbol{y}_k)\rangle$ is said to be *pumpable* if every tuple $\langle p_i(\boldsymbol{x}_i)G_iq_i(\boldsymbol{y}_i)\rangle$ in ξ is pumpable.

▶ **Lemma 5.15** ([15, Lem. 4.15]). *Whether a linear KLM sequence ξ is pumpable is decidable in* EXPSPACE. *Moreover, if ξ is pure and unpumpable, one can compute in time* $\mathsf{exp}(|\xi|^{O(1)})$ *a finite set Ξ of linear KLM sequences such that $L_\xi = \bigcup_{\xi'\in\Xi} L_{\xi'}$ and such that* $\mathrm{rank}(\xi') <_{lex} \mathrm{rank}(\xi)$ *and $|\xi'| < |\xi|^{O(1)}$ for every $\xi' \in \Xi$.*

Note that the $O(1)$ term here hides a constant depending on d, which essentially arises from a result on the coverability problem by Rackoff [19]. The $O(1)$ term also captures the difference between the sizes of linear KLM sequences defined here and that in [15].

The Decomposition Lemma

A linear KLM sequence is *normal* if it is clean, unbounded, rigid, and pumpable. The lemmas 5.13 through 5.15 show that when a clean linear KLM sequence is not normal, we are able to decompose it into a finite set of linear KLM sequences of strictly smaller ranks.

▶ **Lemma 5.16.** *From any clean linear KLM sequences ξ that is not normal, one can compute in time* $\mathsf{exp}(h(\xi))$ *a finite set* $\mathrm{dec}(\xi)$ *of clean linear KLM sequence such that $\bigcup_{\xi'\in\mathrm{dec}(\xi)} L_{\xi'} \subseteq L_\xi$ and $\bigcup_{\xi'\in\mathrm{dec}(\xi)} L_{\xi'} \neq \emptyset$ whenever $L_\xi \neq \emptyset$. Moreover, for every $\xi' \in \mathrm{dec}(\xi)$ we have* $\mathrm{rank}(\xi') <_{lex} \mathrm{rank}(\xi)$ *and $|\xi'| \leq h(\xi)$ where $h(x) = x^{x^{x^{O(1)}}}$.*

5.5 Normal Sequences

The following lemma shows that a normal linear KLM sequence is guaranteed to have non-empty action language, thus one can terminate the decomposition process once a normal sequence is produced.

▶ **Lemma 5.17.** *Let ξ be a normal linear KLM sequence, then there is a word $\sigma \in L_\xi$ whose length is bounded by $|\sigma| \leq \ell(|\xi|)$ where $\ell(x) \leq x^{O(x)}$.*

5.6 Putting All Together: The Modified KLMST Algorithm

Here we describe the modified KLMST decomposition algorithm for VASS reachability problem. Suppose we are given a d-VASS $G = (Q, T)$ and two configurations $p(\boldsymbol{m}), q(\boldsymbol{n}) \in Q \times \mathbb{N}^d$. To decide whether $p(\boldsymbol{m}) \xrightarrow{*} q(\boldsymbol{n})$ holds in G, it is enough to decide whether L_ξ is non-empty where $\xi = \langle p(\boldsymbol{m})Gq(\boldsymbol{n})\rangle$. To start with, we use Lemma 5.11 to clean the sequence ξ, and then choose $\xi^0 \in \mathrm{clean}(\xi)$ non-deterministically. If ξ^0 is normal then we are done by Lemma 5.17. Otherwise, we decompose ξ^0 using Lemma 5.16 and choose $\xi^1 \in \mathrm{dec}(\xi^0)$ non-deterministically. The procedure continues to produce a series of linear KLM sequences $\xi^0, \xi^1, \xi^2, \ldots$ where $\xi^{i+1} \in \mathrm{dec}(\xi^i)$, until either we finally obtain a normal sequence ξ^n, or at some point we have to abort because the decomposition of a linear KLM sequence is the empty set. The procedure terminates because $\mathrm{rank}(\xi^0) >_{\mathrm{lex}} \mathrm{rank}(\xi^1) >_{\mathrm{lex}} \mathrm{rank}(\xi^2) >_{\mathrm{lex}} \cdots$ form a decreasing chain of the well-order $(\mathbb{N}^{d-2}, <_{\mathrm{lex}})$, which must be finite. If $L_\xi = \emptyset$ then we cannot get a normal sequence since the action languages $L_\xi \supseteq L_{\xi^0} \supseteq L_{\xi^1} \supseteq \cdots$ are all empty. On the other hand, if $L_\xi \neq \emptyset$ then there are non-deterministic choices that always choose the linear KLM sequences with non-empty action languages, which finally lead to a normal sequence. This shows the correctness of the algorithm.

6 Complexity Upper Bound

The termination of the modified KLMST decomposition algorithm is guaranteed by a ranking function that decreases along a well-ordering. In order to analyze the length of this decreasing chain, we recall the so-called "length function theorems" by Schmitz [20] in Section 6.1. After that, we can locate the complexity upper bound of the algorithm in the fast-growing complexity hierarchy [21] which we recall in Section 6.2. Readers familiar with [15] may realize that the complexity upper bound for d-VASS can be improved to F_{d+1}, i.e. the $(d+1)$-th level in the fast-growing hierarchy, with our ranking function. In fact, by a careful analysis on a property of fast-growing functions, we further improve this bound to F_d.

In this section we assume some familiarity with ordinal numbers (see, e.g. [9]). We write ω here for the first infinite ordinal, not to be confused with the infinite element in previous sections.

6.1 Length of Sequences of Decreasing Ranks

Let ξ be a linear KLM sequence of dimension d with $\mathrm{rank}(\xi) = (r_d, \dots, r_3)$, we define the *ordinal rank* α_ξ of ξ as the ordinal number given by

$$\alpha_\xi := \omega^{d-3} \cdot r_d + \omega^{d-4} \cdot r_{d-1} + \cdots + \omega^0 \cdot r_3. \tag{21}$$

Note that $\mathrm{rank}(\xi) <_{\mathrm{lex}} \mathrm{rank}(\xi')$ if and only if $\alpha_\xi < \alpha_{\xi'}$. With this reformulation, we now focus on the decreasing chain of ordinal ranks.

Let $\alpha < \omega^\omega$ be an ordinal given in Cantor Normal Form as $\alpha = \omega^n \cdot c_n + \cdots + \omega^0 \cdot c_0$ where $n, c_0, \dots, c_n \in \mathbb{N}$, we define the *size* of α as $N\alpha := \max\{n, \max_{0 \le i \le n} c_i\}$. For the linear KLM sequence ξ with $\mathrm{rank}(\xi) = (r_d, \dots, r_3)$, we have $N\alpha_\xi = \max\{d-3, \max_{3 \le i \le d} r_i\} \le |\xi|$.

Given a number $n_0 \in \mathbb{N}$ and a function $h : \mathbb{N} \to \mathbb{N}$ that is monotone inflationary (that is, $x \le h(x)$ and $h(x) \le h(y)$ whenever $x \le y$), we say a sequence of ordinals $\alpha_0, \alpha_1, \dots$ is (n_0, h)-*controlled* if $N\alpha_i \le h^i(n_0)$ for all $i \in \mathbb{N}$, where $h^i(n_0)$ is the ith iteration of h on n_0.

Let $\xi^0, \xi^1, \dots$ be the linear KLM sequences produced in the modified KLMST algorithm, by Lemma 5.16 we know that the sequence of ordinal ranks

$$\alpha_{\xi^0} > \alpha_{\xi^1} > \cdots \tag{22}$$

is $(|\xi^0|, h)$-controlled where h is defined in Lemma 5.16. Recall that $\xi^0 \in \mathrm{clean}(\xi)$ where $\xi = \langle p(\boldsymbol{m}) G q(\boldsymbol{n}) \rangle$ corresponds to the input reachability instance. Then $|\xi^0| \le g(|\xi|)$ where g is defined in Lemma 5.11, and (22) is indeed $(g(n), h)$-controlled where $n := |\langle p(\boldsymbol{m}) G q(\boldsymbol{n}) \rangle|$.

Length function theorem

The length of the controlled sequence of ordinals (22) can be bounded in terms of the hierarchies of fast-growing functions of Hardy and Cichoń [4]. First recall that given a limit ordinal $\lambda \le \omega^\omega$, the standard *fundamental sequence* of λ is a sequence $(\lambda(x))_{x<\omega}$ defined inductively by

$$\omega^\omega(x) := \omega^{x+1}, \qquad (\beta + \omega^{k+1})(x) := \beta + \omega^k \cdot (x+1) \tag{23}$$

where $\beta + \omega^{k+1}$ is in Cantor Normal Form. Now given a function $h : \mathbb{N} \to \mathbb{N}$ that is monotone inflationary, we define the *Hardy hierarchy* $(h^\alpha)_{\alpha \le \omega^\omega}$ and the *Cichoń hierarchy* $(h_\alpha)_{\alpha \le \omega^\omega}$ as two families of functions $h^\alpha, h_\alpha : \mathbb{N} \to \mathbb{N}$ indexed by ordinals $\alpha \le \omega^\omega$ given inductively by

$$h^0(x) := x, \qquad h^{\alpha+1}(x) := h^\alpha(h(x)), \qquad h^\lambda(x) := h^{\lambda(x)}(x), \tag{24}$$

$$h_0(x) := 0, \qquad h_{\alpha+1}(x) := 1 + h_\alpha(h(x)), \qquad h_\lambda(x) := h_{\lambda(x)}(x). \tag{25}$$

Observe that Cichoń hierarchy counts the number of iterations of h in Hardy hierarchy, that is, $h^{h_\alpha(x)}(x) = h^\alpha(x)$. Also note that as h is monotone inflationary, by induction on α we have $h_\alpha(x) \leq h^\alpha(x)$. Now we give the length function theorem as follows.

▶ **Theorem 6.1** (Length function theorem, [20, Thm. 3.3]). *Let $n_0 \geq d-2$, then the maximal length of (n_0, h)-controlled decreasing sequences of ordinals in ω^{d-2} is $h_{\omega^{d-2}}(n_0)$.*

Small witness property

By Theorem 6.1 we can bound the length of (22), which then yields a bound on the minimal length of runs witnessing reachability.

▶ **Lemma 6.2** (Small witnesses). *Let $G = (Q, T)$ be a d-VASS where $d \geq 3$, let $p(\boldsymbol{m}), q(\boldsymbol{n}) \in Q \times \mathbb{N}^d$ be two configurations, and let $n := |\langle p(\boldsymbol{m}) G q(\boldsymbol{n})\rangle|$. If $p(\boldsymbol{m}) \xrightarrow{*} q(\boldsymbol{n})$ holds in G, then there is a path σ such that $p(\boldsymbol{m}) \xrightarrow{\sigma} q(\boldsymbol{n})$ and $|\sigma| \leq \ell(h^{\omega^{d-2}}(g(n)))$, where g, h, ℓ are defined in lemmas 5.11, 5.16, and 5.17.*

Proof. Suppose $p(\boldsymbol{m}) \xrightarrow{*} q(\boldsymbol{n})$, then there is a sequence of linear KLM sequence $\xi^0, \xi^1, \ldots, \xi^L$ produced in the modified KLMST algorithm, such that ξ^L is normal. We have discussed that the sequence of their ordinal ranks $\alpha_{\xi^0} > \alpha_{\xi^1} > \cdots > \alpha_{\xi^L}$ is $(g(n), h)$-controlled, so by Theorem 6.1 we have $L \leq h_{\omega^{d-2}}(g(n))$. From Lemma 5.16 and the fact that $h^{h_\alpha(x)} = h^\alpha(x)$, the size of ξ^L is bounded by

$$|\xi^L| \leq h^L(|\xi^0|) \leq h^{h_{\omega^{d-2}}(g(n))}(g(n)) = h^{\omega^{d-2}}(g(n)). \tag{26}$$

Now Lemma 5.17 bounds the length of the minimal witnesses by $\ell(h^{\omega^{d-2}}(g(n)))$. ◀

6.2 Fast-Growing Complexity Hierarchy

We recall the fast-growing hierarchy formally introduced by Schmitz [21] that captures the complexity class high above elementary. Define $H(x) := x + 1$, we shall use the Hardy hierarchy $(H^\alpha)_{\alpha<\omega^\omega}$, where for example $H^{\omega^2}(x) = 2^{x+1}(x+1)$ and $H^{\omega^3}(x)$ grows faster than the tower function. First we define the family $\mathcal{F}_\alpha := \bigcup_{\beta<\omega^\alpha} \mathsf{FDTIME}(H^\beta(n))$ which contains functions computable in deterministic time $O(H^\beta(n))$. Observe that, for example, $\mathcal{F}_3$ contains exactly the Kalmar elementary functions. Now we define

$$\mathsf{F}_\alpha := \bigcup_{p\in\mathcal{F}_\alpha} \mathsf{DTIME}(H^{\omega^\alpha}(p(n))) \tag{27}$$

which is the class of decision problems solvable in deterministic time $O(H^{\omega^\alpha}(p(n)))$. Note that non-deterministic time Turing machines can be made deterministic with an exponential overhead in $\mathcal{F}_3$, thus for $\alpha \geq 3$, we have equivalently that $\mathsf{F}_\alpha = \bigcup_{p\in\mathcal{F}_\alpha} \mathsf{NDTIME}(H^{\omega^\alpha}(p(n)))$. Observe that F_α is closed under reductions in $\mathcal{F}_\alpha$.

6.2.1 Relativized Fast-Growing Functions

In order to express the complexity of the modified KLMST algorithm in terms of the hierarchy $(\mathsf{F}_\alpha)_{\alpha<\omega}$, one needs to locate the function $h^{\omega^{d-2}}$ in the Hardy hierarchy $(H^\alpha)_{\alpha<\omega^\omega}$ where $h \in \mathcal{F}_3$ is the elementary function from Lemma 5.16. Previously we can upper bound $h^{\omega^{d-2}}$ by $H^{\omega^{d+1}}$ with the help of [21, Lem. 4.2]. Here we show a slightly better result, from which we can bound $h^{\omega^{d-2}}(x)$ by $H^{\omega^d}(O(x))$.

▶ **Lemma 6.3** (cf. [21, Lem. A.5]). *Let $h : \mathbb{N} \to \mathbb{N}$ be a monotone inflationary function, let $a, b, c \geq 1$ and $x_0 \geq 0$ be natural numbers. If for all $x \geq x_0$, $h(x) \leq H^{\omega^{b\cdot c}}(x)$, then $h^{\omega^a}(x) \leq H^{\omega^{b+a}}((c+1)x)$ for all $x \geq \max\{2c, x_0\}$.*

6.3 Upper Bounds for VASS Reachability

Now we analyze the time complexity of the modified KLMST algorithm. Given as input the d-VASS $G = (Q, T)$ and two configurations $p(\boldsymbol{m}), q(\boldsymbol{n})$, let $\xi := \langle p(\boldsymbol{m}) G q(\boldsymbol{n}) \rangle$ and $n := |\xi|$. The initial sequence $\xi^0 \in \mathrm{clean}(\xi)$ can be computed in (non-deterministic) time elementary in n by Lemma 5.11. Then the algorithm produces $\xi^0, \xi^1, \ldots, \xi^L$ with $L \leq h_{\omega^{d-2}}(g(n))$, where g, h are defined in lemmas 5.11, 5.16. Note that in each step, the sequence $\xi^{i+1} \in \mathrm{dec}(\xi^i)$ can be computed in time elementary in $|\xi^i|$ by Lemma 5.16, and the sizes $|\xi^i|$ are all bounded by $h^{\omega^{d-2}}(g(n))$ as we have discussed above in the proof of Lemma 6.2. To sum up, the entire algorithm finishes in non-deterministic time elementary in $h^{\omega^{d-2}}(g(n))$.

▶ **Lemma 6.4.** *On input a d-VASS $G = (Q, T)$ where $d \geq 3$ and $p(\boldsymbol{m}), q(\boldsymbol{n}) \in Q \times \mathbb{N}^d$, the modified KLMST algorithm finishes in non-deterministic time $e(h^{\omega^{d-2}}(g(n)))$ where $n = |\langle p(\boldsymbol{m}) G q(\boldsymbol{n}) \rangle|$, g, h are defined in lemmas 5.11, 5.16, and $e \in \mathcal{F}_3$ is some fixed function.*

Since h is an elementary function, there is a number $c \in \mathbb{N}$ such that h is eventually dominated by $H^{\omega^2 \cdot c}$. By Lemma 6.3 we can upper bound $h^{\omega^{d-2}}(x)$ by $H^{\omega^d}((c+1)x)$. Observe that the inner part $g(n)$ is elementary in the binary encoding size of the input $G, p(\boldsymbol{m}), q(\boldsymbol{n})$, thus can be captured by a function $p \in \mathcal{F}_3$. Finally, [21, Lem. 4.6] allows us to move the outermost function e to the innermost position. Hence we have the following upper bound.

▶ **Theorem 6.5.** *Reachability in d-dimensional VASS is in F_d for all $d \geq 3$.*

Also, by Lemma 6.2 there is a simple combinatorial algorithm for d-VASS reachability. We fist compute the bound $B := \ell(h^{\omega^{d-2}}(g(n)))$, which can be done in time elementary in B by [21, Thm. 5.1]. Then we can decide reachability by just enumerate all possible paths in G with length bounded by B.

7 Conclusion

We have shown that the reachability problem in d-dimensional vector addition system with states is in F_d, improving the previous F_{d+4} upper bound by Leroux and Schmitz [15]. By capturing reachability in geometrically 2-dimensional VASSes with linear path schemes, we are able to reduce significantly the number of decomposition steps in the KLMST decomposition algorithm. Combined with a careful analysis on fast-growing functions, we finally obtained the F_d upper bound. It should be noticed though, that our algorithm avoids computing the "full decomposition" [14] of KLM sequences, thus cannot improve the complexity of problems that essentially rely on the full decomposition, e.g., the VASS downward language inclusion problem [8, 23, 15].

It has been shown that the reachability problem in $(2d{+}3)$-VASS is F_d-hard [5]. In the case of 3-VASS, it is known that the reachability problem is PSPACE-hard. The gap between the lower bound and the upper bound $\mathsf{F}_3 = \mathsf{TOWER}$ [22] is huge. It is very unlikely that the problem is PSPACE-complete. Effort to uplift the lower bound is called for.

On Classes of Bounded Tree Rank, Their Interpretations, and Efficient Sparsification

Jakub Gajarský

Abstract

Graph classes of bounded tree rank were introduced recently in the context of the model checking problem for first-order logic of graphs. These graph classes are a common generalization of graph classes of bounded degree and bounded treedepth, and they are a special case of graph classes of bounded expansion. We introduce a notion of decomposition for these classes and show that these decompositions can be efficiently computed. Also, a natural extension of our decomposition leads to a new characterization and decomposition for graph classes of bounded expansion (and an efficient algorithm computing this decomposition).

We then focus on interpretations of graph classes of bounded tree rank. We give a characterization of graph classes interpretable in graph classes of tree rank 2. Importantly, our characterization leads to an efficient sparsification procedure: For any graph class $\mathcal{C}$ interpretable in a graph class of tree rank at most 2, there is a polynomial time algorithm that to any $G \in \mathcal{C}$ computes a (sparse) graph H from a fixed graph class of tree rank at most 2 such that $G = I(H)$ for a fixed interpretation I. To the best of our knowledge, this is the first efficient "interpretation reversal" result that generalizes the result of Gajarský et al. [LICS 2016], who showed an analogous result for graph classes interpretable in classes of graphs of bounded degree.

1 Introduction

The graph classes and problems studied in this paper are motivated by considering the first-order (FO) model checking problem for graphs. This problem asks, given a (finite) graph G and sentence φ as input, whether G is a model of φ. This problem is known to be PSPACE-hard, and so we do not expect to obtain a polynomial algorithm solving it. This has motivated the study of the FO model checking problem from the perspective of parameterized complexity, which has led to the discovery of many beautiful connections between structural and algorithmic graph theory and (finite) model theory.

In the parameterized setting (where we consider the size of the formula φ as the parameter), we can easily obtain a brute-force algorithm with runtime $n^{O(|\varphi|)}$, the so-called XP algorithm. However, we are interested in the existence of algorithms with runtime $f(|\varphi|) \cdot n^c$, where c

is some fixed constant (FPT algorithms). We do not expect to obtain such an algorithm if the input graphs come from the class of all graphs, since this problem is AW[$*$]-complete. However, for various structurally restricted graph classes we know that such an algorithm exists. Identifying these graph classes is the topic of a long line of research, and recently a lot of progress has been made towards understanding the boundaries of efficient tractability [2, 4, 5].

For graph classes that admit a model checking algorithm with runtime $f(|\varphi|) \cdot n^c$ one can ask what is the dependence of the runtime on the size of the formula φ. Unfortunately, for most graph classes this dependence is *non-elementary*, that is, $f(k)$ grows like a tower of twos whose height grows with k. By a result of Frick and Grohe [9], we know that this cannot be avoided even when $\mathcal{C}$ is the class of all trees. While this result may seem very limiting, it turns out that the landscape of graph classes that admit an elementary model checking algorithm is surprisingly rich. Classical examples of such graph classes include classes of graphs of bounded degree [9], bounded treedepth, and bounded shrubdepth [11]. (The last two results were obtained in the more general context of MSO model checking.) The interest in this problem was renewed recently when Lampis [15] established elementary model checking for graph classes of bounded pathwidth. After this, Gajarský, Pilipczuk, Sokołowski, Stamoulis and Toruńczyk [13] introduced graph classes of bounded tree rank and proved that these classes also admit (under certain restrictions, see the fourth bullet point below) an elementary FO model checking algorithm.

Classes of bounded tree rank, introduced in [13], can be defined as follows (in the definition, the *depth* of a tree T is the number of edges on a shortest leaf-to-root path in T).

▶ **Definition 1.** *A graph class $\mathcal{C}$ has* tree rank *at most d if for every $r \in \mathbb{N}$ there exists a tree T of depth d such that no $G \in \mathcal{C}$ contains T as an r-shallow topological minor*[1].

For example, one can easily see that graph classes of bounded degree have tree rank at most 1, that the class of all trees of height d has tree rank d, and that the class of all trees does not have bounded tree rank.

We briefly summarize some of the basic properties of graph classes of bounded tree rank established in [13]:

- They generalize graph classes of bounded degree, bounded treedepth, and bounded pathwidth.
- They are strictly less general than classes of graphs of bounded expansion.
- The tree rank of a graph class $\mathcal{C}$ is at most d if and only if Splitter has a winning strategy in the so-called "d-round batched Splitter game" for every $G \in \mathcal{C}$. This game is a natural variant of the Splitter game, which characterizes nowhere dense graph classes and was introduced by Grohe, Kreutzer, and Siebertz in their landmark paper [14].
- If $\mathcal{C}$ is a class of bounded tree rank and there exists an elementary function $f : \mathbb{N} \to \mathbb{N}$ such that the size of T in Definition 1 is bounded by $f(r)$, then there is an elementary FO model checking algorithm for $\mathcal{C}$.
- If $\mathcal{C}$ is a monotone graph class of unbounded tree rank, then $\mathcal{C}$ has no FO model checking algorithm with elementary dependence on the size of the formula unless FPT=AW[$*$].

We note that the concepts considered above (bounded degree, bounded treedepth, bounded tree rank, bounded expansion, and nowhere denseness) are all examples of classes of *sparse* graphs. Given how naturally the concept of bounded tree rank fits into the general theory of

[1] We note that this definition of tree rank is seemingly off by 1 from the original definition in [13]. However, we measure the depth of trees differently than in [13], and so the two definitions ultimately coincide.

sparse graphs introduced by Nešetřil and Ossona de Mendez [17], we suspect that it will play an important role in structural and algorithmic graph theory, and that further investigation of its structural and combinatorial properties is desirable.

Since classes of sparse graphs are mostly well-understood (one exception being classes of bounded tree rank), in recent years there has been a trend to study more general classes that can be obtained from classes of sparse graphs by means of *interpretations* or *transductions*, which are graph transformations based in logic. This point of view is also very relevant for classes of bounded tree rank, but we first discuss it in the general setting of sparse graphs. We focus on the simpler setting of interpretations. Essentially, an interpretation I is given by a formula $\psi(x, y)$ (we will actually use a slightly more complicated setting; see Section 2). When applied to a graph H, the result is a new graph $I(H)$ with the same vertex set as H and with edge set $\{uv \ : \ H \models \psi(u, v)\}$. This notion generalises easily to graph classes by setting $I(\mathcal{C}) = \{I(H) \ : \ H \in \mathcal{C}\}$. Finally, we say that a graph class $\mathcal{D}$ is *interpretable* in a graph class $\mathcal{C}$ if there exists an interpretation I such that $\mathcal{D} \subseteq I(\mathcal{C})$.

As mentioned above, the recent trend is to study graph classes interpretable in sparse (or nowhere dense) classes of graphs. In particular, the model checking problem has been considered extensively, and was recently fully solved for such graph classes.

▶ **Theorem 2** ([5]). *Let $\mathcal{C}$ be a graph class interpretable in a nowhere dense graph class. Then there exists an FPT model checking algorithm for $\mathcal{C}$.*

In the context of graph classes interpretable in classes of sparse graphs, it is also natural consider the following problem, which we refer to as the "efficient sparsification problem" or "interpretation reversal problem". This problem was considered in [12] in the context of graph classes interpretable in classes of graphs of bounded degree.

▶ **Problem 1.** *Let $\mathcal{C}$ be a graph class interpretable in a nowhere dense graph class. Show that there exists a nowhere dense graph class $\mathcal{D}$, an interpretation I, and a polynomial time algorithm that given $G \in \mathcal{C}$ as input computes a graph $H \in \mathcal{D}$ such that $G = I(H)$.*

It is well-known (and easy to argue, see for instance [12]) that solving Problem 1 would lead to an alternative proof of Theorem 2. Indeed, before the result of [5] was established, this was considered the main line of attack on the model checking problem on graph class interpretable in a nowhere dense graph class. However, Problem 1 turned out to be very challenging, and despite considerable effort essentially no success has been achieved in solving it. Instead, Theorem 2 was proved by adapting the techniques for classes of sparse graphs from [14] to the dense setting. Despite this, Problem 1 remains of considerable interest, and solving it would likely lead to many new insights on the structure of graph classes interpretable in classes of sparse graphs.

Coming back to classes of bounded tree rank, it is natural to try to obtain an elementary analogue of Theorem 2.

▶ **Problem 2.** *Let $\mathcal{C}$ be a graph class interpretable in a graph class of bounded tree rank. Show that there exists an elementary FPT model checking algorithm for $\mathcal{C}$.*

In light of the results of [13], it is possible that one needs to put some extra restriction on $\mathcal{C}$ – perhaps requiring that the size of trees avoided as r-shallow topological minors is bounded by an elementary function of r. However, it is currently unknown whether this is necessary, even for the original theorem from [13].

In relation to interpretations of graph classes of bounded tree rank, the authors of [13] introduced the more general graph classes of bounded *rank*, and conjectured that these are precisely the interpretations of colored graph classes of bounded tree rank. In order to attack this conjecture, or Problem 2, it is natural to consider the following variant of Problem 1.

▶ **Problem 3.** *Let $\mathcal{C}$ be a graph class interpretable in a graph class of bounded tree rank. Show that there exists a graph class $\mathcal{D}$ of bounded tree rank, an interpretation I, and a polynomial time algorithm that given $G \in \mathcal{C}$ as input computes a graph $H \in \mathcal{D}$ such that $G = I(H)$.*

Our contribution

For sparse graphs we introduce the notion of the (r, m)-*rank* of a vertex. Roughly speaking, the (r, m)-rank of a vertex $v \in V(G)$ is a positive integer that measures how complicated the r-neighborhood of v is with respect to the parameter m. We also allow the (r, m)-rank to be ∞ if the r-neighborhood of v is too complicated. Then the (r, m)-*ranking* of a graph G is the function $f : V(G) \to \mathbb{N} \cup \{\infty\}$ that assigns to each vertex of G its (r, m)-rank. This definition has the advantage of being much more localized than Definition 1 of tree rank. Yet we prove that it can also be used to define tree rank, as follows.

▶ **Theorem 3.** *For any $d \in \mathbb{N}$ and any graph class $\mathcal{C}$, the following are equivalent:*
- *The tree-rank of $\mathcal{C}$ is at most d.*
- *For every $r \in \mathbb{N}$ there exists $m \in \mathbb{N}$ such that every vertex of every graph in $\mathcal{C}$ has (r, m)-rank at most d.*

Vertex rankings provide a natural notion of decomposition for graph classes of bounded tree rank. We will show that this decomposition can be computed in elementary FPT runtime with respect to the parameters r and m (see Theorem 14). Moreover, the notion of (r, m)-ranking (and the FPT algorithm computing it) very naturally extends to graph classes of bounded expansion.

▶ **Theorem 4.** *The following are equivalent for any graph glass $\mathcal{C}$:*
- *The class $\mathcal{C}$ is of bounded expansion.*
- *For every $r \in \mathbb{N}$ there exists $m \in \mathbb{N}$ such that every vertex of every graph in $\mathcal{C}$ has finite (r, m)-rank, that is, has (r, m)-rank not equal to ∞.*

We note that the (r, m)-rank of a vertex is preserved under graph automorphisms. This fact that rankings are "canonical" is one of the key advantages of Theorem 4.

One of the main motivations for proving alternate characterizations of sparse graph classes (like Theorems 3 and 4) is the efficient sparsification problems discussed earlier (Problems 1 and 3). In particular, we hope that this definition of (r, m)-rank can be generalized to accommodate for interpretations of classes of bounded expansion. While we cannot yet take care of this more general case, we are able to use the insights obtained from (r, m)-rank to find the following structural characterization of interpretations of classes of tree rank 2.

▶ **Theorem 5.** *The following are equivalent for any graph glass $\mathcal{C}$:*
- *The class $\mathcal{C}$ is interpretable in a graph class of tree rank 2.*
- *The class $\mathcal{C}$ is a perturbation of a locally almost near-covered graph class.*

We defer the definition of locally almost near-covered graph classes to Section 5. Our characterization leads to the following algorithmic sparsification result. For technical reasons we restrict ourselves to classes of graphs interpretable in classes of tree rank 2 for which the bounds in the definition of tree rank can be efficiently computed. We call such classes *efficiently bounded* (see Section 5.1) for precise definition.

▶ **Theorem 6.** *Let $\mathcal{C}$ be a graph class interpretable in an efficiently bounded graph class of tree rank 2. Then there exists a graph class $\mathcal{D}$ of tree rank 2, an interpretation I, and a polynomial time algorithm that given $G \in \mathcal{C}$ as input computes a graph $H \in \mathcal{D}$ such that $G = I(H)$.*

We remark that the degree of the polynomial in Theorem 6 depends on the class $\mathcal{C}$.

While at first sight Theorem 6 might seem like a modest improvement on the analogous result of [12] for graph classes of bounded degree (or equivalently, classes of tree rank at most 1), this is the first progress on the challenging Problem 1 since its introduction that applies to graph classes of unbounded treewidth. (For graph classes of bounded treewidth such a result is given in [18].) Moreover, our proof introduces new techniques and ideas that may be useful for solving the sparsification problem (Problem 1) in greater generality.

In particular, as part of the proof of Theorem 5 we prove a lemma (Lemma 23) about the behaviour of the k-near-twin relation on graphs that do not contain a half-graph as a semi-induced subgraph. This lemma may be of independent interest in the context of (monadically) stable graph classes, which play a prominent role in recent developments establishing connections between (finite) model theory and algorithmic graph theory [4, 6].

Related work

In [13] it was shown that classes of tree rank at most d can be characterized using the *batched Splitter game* with d rounds. Roughly speaking, in this game two players take turns, one of them trying to simplify the graph, and the other trying to keep the graph as complicated as possible. The result of [13] states that the player trying to simplify the graph (this player is called Splitter) wins in at most d rounds.

While this characterization is very nice and useful, it is a characterization in terms of a dynamic process, and as such it does not directly provide us with a useful notion of decomposition (in the sense of giving us a concrete compact object on which one can design algorithms). One could of course consider using as a decomposition the game tree arising from a winning play by Splitter, but this tree has size of order n^d. It is known that this can be circumvented by combining the Splitter game with *sparse neighborhood covers* as introduced in [14], but working with the resulting object is technically demanding. Compared to this, vertex rankings give us a static decomposition on which one can use bottom-up inductive arguments and can design algorithms.

For graph classes of bounded expansion, vertex rankings of a graph (which certify that it has only vertices of finite rank) are closely related to strong coloring orders [23] and admissibility orders [7]. These are total orders on the vertex set of a graph that satisfy certain properties, and which have proven to be very useful for showing properties of graphs of bounded expansion. The main idea used in the definition of rankings, when one checks whether a removal of a small set of vertices can separate a vertex v from the set of previously processed vertices, has been used before (see Appendix A1 in [22]). This was again in the context of defining a suitable total order on the vertex set of a graph. Compared to total orders, our definition of rankings essentially leads to a pre-order on the vertex set of a graph, and therefore it can capture situations when two vertices are equally complicated (have the same rank).

Regarding the sparsification problem, in [12] it was shown that there is a polynomial time algorithm for sparsifying graphs from graph classes that are interpretable in classes of bounded degree. Another result related to efficient sparsification is [8], where the authors showed how to efficiently interpret the class of map graphs in a nowhere dense class of graphs. Finally, the already mentioned result [18] establishes a sparsification result for graph classes interpretable in graph classes of bounded treewidth, extending earlier results in [19].

Outline of our approach

We now briefly outline the approach used to prove Theorems 5 and 6. This approach builds on the ideas used in [12] to sparsify classes of graphs interpretable in graph classes of bounded degree. The key notion behind this result was that of *k-near-twin* vertices. We say that

two vertices u, v of G are k-near-twins if $|N^G(v)\Delta N^G(u)| \leq k$, i.e. if they have the same neighborhoods with at most k exceptions. The idea behind the proof given in [12] is that graphs from graph classes interpretable in classes of bounded degree have a simple structure – for such graphs we can find a small k such that the k-near-twin relation is an equivalence on $V(G)$ with a bounded number of classes. This is then easily used to find a bounded number of *flips* (edge complementations between two subsets of $V(G)$) to produce a sparse graph H from which G can be recovered by an interpretation.

In the case of classes of graphs interpretable in graph classes of tree rank 2, the structure of the k-near-twin relation is much more complicated. In what follows we will actually focus on analysing this relation on graphs from graph classes interpreted in classes of tree rank 2 by an *interpretation of bounded range*. This is an interpretation in which the formula $\psi(x, y)$ has the property that there is a number b such that for every G and $u, v \in V(G)$ we have that if $\mathrm{dist}_G(u, v) > b$, then $G \not\models \psi(u, v)$. In other words, such interpretation will never create edges between vertices that are far apart in G. The case of interpretations of bounded range forms the techincal core of our approach, since the reduction from the general case to the case of bounded range can be achieved by using existing tools (see Section 5.3). For the rest of this overview, let us fix a graph class $\mathcal{C}$ interpretable in a class of graphs of tree rank at most 2 by an interpretation of bounded range.

We now proceed with analysing the k-near-twin relation on a graph G from $\mathcal{C}$. It is useful to think of this relation in terms of the *k-near-twin graph* of G, denoted by $NT_k(G)$. This graph has the same vertex set as G, and two vertices are adjacent in $NT_k(G)$ if they are k-near-twins in G. In the case of interpretations of bounded degree, this graph was a collection of a small number of cliques. In our case of interpretations of classes of tree rank 2, the connected components of the graph $NT_k(G)$ are not cliques, and there can be arbitrarily many of them. Moreover, the connected components of $NT_k(G)$ can have arbitrarily large diameter – this is important because if we could find a bound d such that the diameter of all connected components of $NT_k(G)$ was at most d, then all vertices in any component C would be kd-near-twins, and this could be exploited for sparsification. In our proofs of Theorems 5 and 6 we overcome all these difficulties. The key insight (Lemma 23) is that even though the connected components of $NT_k(G)$ can have arbitrarily large diameter, we can nevertheless guarantee that any two vertices in the same connected component are k'-near-twins, for k' depending only on k and the order of largest half-graph in G. Using this, we sparsify G as follows: For a suitably chosen k, we consider $NT_k(G)$ and create a partition $\mathcal{F}$ of $V(G)$ by putting two vertices in the same part if they are in the same connected component of $NT_k(G)$. The aforementioned Lemma 23 then guarantees that the vertices in the same part A of $\mathcal{F}$ are pairwise k'-near-twins. We then create a sparse graph $\mathcal{S}(G)$ from G as follows: If A and B are two large parts of $\mathcal{F}$ such that there are almost all edges between A and B (see the proof of Lemma 33 for precise meaning of "large" and "almost all"), we complement the adjacency between them, create new vertices v_A and v_B adjacent to all vertices of A and B, respectively, and create and edge between v_A and v_B. The introduction of new vertices v_A, v_B guarantees that we can recover G from $\mathcal{S}(G)$ by a simple interpretation. The technical part of the proof is establishing that $\mathcal{S}(G)$ comes from a fixed class $\mathcal{D}$ of graphs of tree rank 2 which depends only on $\mathcal{C}$.

Organisation of the paper

After preliminaries in the next section, we introduce vertex rankings in Section 3, and then we relate them to graph classes of bounded tree rank and show how to compute them in FPT runtime. In Section 4 we prove a lemma about the behaviour of the k-near-twin relation in

graphs excluding arbitrarily large half-graphs; a crucial tool for the last section. In Section 5 we prove our main results – characterization and a sparsification algorithm for graph classes interpretable in classes of tree rank 2.

Due to space restrictions, the proofs of some statements could not be included in the conference version of the paper. Such statements are marked with [∗] and their proofs can be found in the full version of the paper.

2 Preliminaries

Graph theory. We use $[k]$ to denote the set $\{1, \dots, k\}$. We use mostly standard graph theoretic notation. Let G be a graph. We write $N_r^G(v)$ for the *closed* r-neighborhood of a vertex v, that is, $N_r^G(v)$ is set of all vertices that are reachable from v by a path with at most r edges, including v. The *distance* between vertices u and v, denoted by $dist_G(u, v)$, is the minimum number of edges in a path between u and v. The *radius* of a graph is smallest integer r so that there exists a vertex that has distance at most r from every other vertex. Given a graph G and a set $X \subseteq V(G)$, we write $G[X]$ for the subgraph of G induced on X, and $G - X$ for the subgraph of G induced on $V(G) \setminus X$.

By a *tree* we mean a connected acyclic graph with a specified root vertex. The *depth* (respectively, *height*) of a tree T is the maximum number of edges (respectively, vertices) on any leaf-to-root path in T.

Let G be a graph, and let A and B be subsets of $V(G)$ with $A \cap B = \emptyset$ or $A = B$. By *flipping the edges between A and B*, we mean removing all edges uv in G with $u \in A$ and $v \in B$, and adding all new edges of the form uv where $u \in A$, $v \in B$, $u \neq v$, and $uv \notin E(G)$. For $k \in \mathbb{N}$ and a graph G, a *k-flip* of G is any graph that can be obtained from G by considering a partition $\mathcal{F}$ of $V(G)$ with $|\mathcal{F}| \leq k$, and flipping the edges between some pairs of parts of $\mathcal{F}$ (that is, for each pair of parts A and B of $\mathcal{F}$, we may choose whether or not to flip the edges between A and B). We say that a graph class $\mathcal{C}$ is a *perturbation* of a graph class $\mathcal{D}$ if there exists k such that every $G \in \mathcal{C}$ is a k-flip of some $H \in \mathcal{D}$.

Let S be a set of vertices of a graph G. Let $\mathcal{F}_S$ be the partition of $V(G)$ such that each $v \in S$ is in its own part and all vertices in $V(G) \setminus S$ are partitioned according to their adjacency to S (so vertices with the same neighbors in S are in the same part). An *S-flip* of G is any graph G' obtained by flipping the edges between some pairs of parts of $\mathcal{F}_S$.

Shallow topological minors and bounded tree rank. Let H be a graph. An *$\leq r$-subdivision* of H is any graph that can be obtained from H by replacing each edge uv of H by a path with endpoints u and v and with at most r internal vertices (so that all of the paths are internally disjoint). We call the original vertices of H the *principal* vertices of the $\leq r$-subdivision. We say that H is an *r-shallow topological minor*[2] of a graph G if G contains a subgraph that is isomorphic to an $\leq r$-subdivision of H.

▶ **Definition 7.** *We define $T_{d,m}$ to be the tree of depth d in which every non-leaf vertex has exactly m children.*

It is easily seen that the definition of graph classes of bounded tree rank given in Definition 1 is equivalent to the following:

[2] We note that this definition differs slightly from the standard definition, which says that H is a r-shallow minor of G if there is a subgraph of G isomorphic to a graph obtained from H by subdividing its edges at most $2r$ times.

▶ **Definition 8.** *A graph class $\mathcal{C}$ has tree rank at most d if for every $r \in \mathbb{N}$ there exists $m \in \mathbb{N}$ such that no $G \in \mathcal{C}$ contains $T_{d,m}$ as an r-shallow topological minor.*

Strong coloring numbers, admissibility, and bounded expansion. Let G be a graph, and let $\leq$ be an order on its vertex set. Fix a number $r \in \mathbb{N}$. For two vertices v and w of G, we say that w is *strongly r-reachable*[3] from v (with respect to $\leq$) if $w \geq v$ and there is a path from v to w of length at most r in G such that all vertices on this path apart from v and w are smaller than v in $\leq$. The *strong r-coloring number* of G, denoted by $\mathrm{scol}_r(G)$, is the minimum over all orderings $\leq$ of $V(G)$, of the maximum number of vertices that are strongly r-reachable from a single vertex v of G.

Similarly as above, let G be a graph, and let $\leq$ be an order on its vertex set. Fix a number $r \in \mathbb{N}$. The *r-backconnectivity* of a vertex v of G is the maximum number of paths of length at most r in G that start in v, end at vertices $w \geq v$, and are vertex-disjoint except for their common endpoint v. The *r-admissibility* of G, denoted by $\mathrm{adm}_r(G)$, is the minimum over all orderings $\leq$ of $V(G)$, of the maximum r-backconnectivity of a vertex v of G.

Classes of graphs of *bounded expansion* were introduced by Nešetřil and Ossona de Mendez as one of the key notions of their general theory of sparsity [17]. We do not provide the original definition of bounded expansion; instead we use the following characterizations.

▶ **Theorem 9** ([23])**.** *A class $\mathcal{C}$ of graphs has* bounded expansion *if and only if there exists a function $f : \mathbb{N} \to \mathbb{N}$ such that for every $G \in \mathcal{C}$ and $r \in \mathbb{N}$, we have $\mathrm{scol}_r(G) \leq f(r)$.*

▶ **Theorem 10** ([7])**.** *A class $\mathcal{C}$ of graphs has* bounded expansion *if and only if there exists a function $f : \mathbb{N} \to \mathbb{N}$ such that for every $G \in \mathcal{C}$ and $r \in \mathbb{N}$, we have $\mathrm{adm}_r(G) \leq f(r)$.*

Logic, interpretations and locality. We assume familiarity with first-order logic and basic notions related to it, such as signatures, quantifier rank, and so on. We model graphs as a structure with one binary irreflexive symmetric relation E. We work with colored graphs, and we model colors as unary predicates.

Interpretations are logic-based transformations that allow us to create new structures from old ones. A (simple) *interpretation* $I = (\psi, \delta)$ consists of two formulas $\psi(x, y)$ and $\delta(x)$. When applied to a graph G, an interpretation defines a new graph $I(G)$ with $V(I(G)) = \{v \in V(G) \ : \ G \models \delta(v)\}$ and $E(I(G)) = \{uv \ : \ u, v \in V(I(G)), u \neq v, \text{ and } G \models \psi(u, v)\}$. (Here we assume that $\psi(x, y)$ is symmetric and irreflexive, that is, for all G and $u, v \in V(G)$ we have $G \models \psi(u, v)$ if and only if $G \models \psi(v, u)$, and also for each $v \in V(G)$ we have that $G \not\models \psi(v, v)$ so that the resulting graph is undirected and does not contain loops.)

For a less general version of interpretation that uses only one formula $\psi(x, y)$, we sometimes use the notation $\psi(G)$ to denote the graph on the same vertex set as G and with $E(\psi(G)) := \{uv \ : \ u \neq v \text{ and } G \models \psi(u, v)\}$. For a graph class $\mathcal{C}$, we say that $\mathcal{C}$ is *interpretable* in a graph class $\mathcal{D}$ if there exists an interpretation I such that $\mathcal{C} \subseteq I(\mathcal{D})$.

A crucial role in this paper will be played by interpretations of bounded range. We say that a formula $\psi(x, y)$ is of *range* b if for all graphs G and all $u, v \in V(G)$ we have that $dist_G(u, v) > b$ implies $G \not\models \psi(u, v)$. This means that if the formula ψ is used in an interpretation, it will not create edges between vertices that were at distance more than b in the original graph. We say that an interpretation $I = (\psi, \delta)$ is of *bounded range* if there exists b such that ψ is of range b.

[3] We remark that many authors use the order $\leq$ in the opposite direction in the definition of strong reachability, that is, they require $w \leq v$ and that the path from v to w goes through vertices larger than v in $\leq$. The definition we chose will be convenient later on.

When working with graphs, we often mark vertices of a graph G with (new) unary predicates and call the resulting graph $\widehat{G}$. Formally, this means that we are extending the signature of G, and that the formulas that we later evaluate on $\widehat{G}$ are assumed to be over this new signature. To make the exposition more streamlined, we always do this implicitly.

Locality-based methods are commonly used in relation with first-order logic; probably the most commonly used such result is Gaifman's locality theorem [10]. We do not need the full statement of Gaifman's theorem, only the following lemma, which is its simple corollary.

▶ **Lemma 11.** *For every formula $\psi(x,y)$, there exist an integer r and a formula ψ' with the following property: Every graph G can be equipped with two unary predicates to obtain $\widehat{G}$ such that for any $u,v \in V(G)$ and any $S \subseteq V(G)$ that contains $N_r^G(u) \cup N_r^G(v)$, we have $G \models \psi(u,v) \iff \widehat{G}[S] \models \psi'(u,v)$.*

For completeness we explain how Lemma 11 follows from Gaifman's theorem. This theorem tells us that for a given formula $\psi(x,y)$ there exists another formula $\alpha(x,y)$ and sentences $\tau_1,\dots,\tau_k$ such that $\psi(x,y)$ can be written as a boolean combination of $\alpha(x,y),\tau_1,\dots,\tau_k$. Importantly, the formula $\alpha(x,y)$ has the property that there exists r such that for any G and any $u,v \in V(G)$ we have $G \models \alpha(u,v)$ if and only if $G[N_r^G(u) \cup N_r^G(v)] \models \alpha(u,v)$. For any G we can evaluate all sentences $\tau_1,\dots,\tau_k$ on G, and then the boolean combination of $\alpha(x,y),\tau_1,\dots,\tau_k$ reduces to one of four possibilities on G – we have that $\psi(x,y)$ is equivalent one of the following: $\alpha(x,y)$, $\neg\alpha(x,y)$, $\top$ or $\bot$. We can encode these four options with two bits of information, and so we mark all vertices of G with two unary predicates (all vertices in the same way) accordingly. Finally, we define formula $\psi'(x,y)$ to be the formula which first checks the unary predicates on vertex x to determine which of the four possibilities $\varphi(x,y)$ is equivalent to on G, and based on this "outputs" the value of $\alpha(x,y)$, $\neg\alpha(x,y)$, $\top$ or $\bot$. To finish the argument, we argue that evaluating $\alpha(x,y)$ on $\widehat{G}[S]$ gives the same answer as evaluating $\alpha(x,y)$ on G for any u,v,S such that $N_r^G(u) \cup N_r^G(v) \subseteq S$. This follows from the properties of α (which hold for any graph, including $\widehat{G}[S]$) which guarantee that $\widehat{G}[S] \models \alpha(u,v) \iff G[N_r^G(u) \cup N_r^G(v)] \models \alpha(u,v) \iff G \models \alpha(u,v)$.

3 Vertex rankings in sparse graphs

In this section we introduce a way to assign, for given parameters r and m, to every vertex of a graph its (r,m)-*rank*. Intuitively, the (r,m)-rank of a vertex measures how complicated the r-neighborhood of v is. Our definition is algorithmic and is given in Section 3.1 together with the proof that the (r,m)–rank can be computed in FPT runtime with respect to the parameters r and m. Then we prove Theorems 3 and 4 relating graph classes for which suitable rankings of vertices exist to graph classes of bounded tree rank (Section 3.2) and bounded expansion (Section 3.3).

3.1 The ranking algorithm

We now describe the ranking algorithm that (based on the parameters r and m) for every graph G assigns to every vertex of G either a positive integer or ∞.

Let G be a graph and r,m be positive integers. The (r,m)-ranking algorithm works as follows. Initially, each vertex is assigned rank ∞. Then the algorithm proceeds in rounds for $i = 1,2,3,\dots$ as follows. In the i-th round, the algorithm considers all vertices of rank ∞ (these are the vertices that have not received a finite rank in rounds $1,\dots,i-1$), and for each such vertex v it checks (in parallel) the following condition: Does there exist a set $S \subseteq V(G) \setminus \{v\}$ of size at most m such that $N_r^{G-S}(v) \setminus \{v\}$ contains only vertices of finite

rank? If yes, then v receives rank i, otherwise it keeps rank ∞. (Notice that in the first round the algorithm assigns rank 1 to vertices of degree at most m.) The algorithm stops when all vertices obtain a finite rank or when in some round no new vertex receives a rank. Thus, in any case, the algorithm stops after at most $|V(G)|$ rounds.

▶ **Definition 12.** *Let G be a graph. The* (r,m)-rank *of a vertex $v \in V(G)$ is the element of $\mathbb{N} \cup \{\infty\}$ assigned to v by the ranking algorithm. The* (r,m)-rank *of G is the maximum (r,m)-rank of any vertex of G.*

We remark that the definition of (r,m)-ranking of vertices in a graph G can be phrased without any explicit mention of the ranking algorithm: All vertices of degree at most m are assigned rank 1, and for every vertex v of degree more than m we define the (r,m)-rank of v to be the minimum number k such that there exists a set S of vertices so that $N_r^{G-S}(v) \setminus \{v\}$ contains only vertices of smaller rank; or ∞ if such k does not exist. This is easily seen to be equivalent to the algorithmic definition given above, but we prefer to stick with the algorithmic perspective in what follows.

3.1.1 Algorithmic considerations

Notice that the straightforward implementation of the ranking algorithm runs in time $\mathcal{O}(n^{m+4})$: we have at most n rounds, in each round we consider at most n vertices, and for each vertex we can in time $\mathcal{O}(n^{m+2})$ try removing all sets S of size m in time $\mathcal{O}(n^m)$ and check whether $G - S$ satisfies the desired condition in time $\mathcal{O}(n^2)$. Thus, we trivially get an XP algorithm. However, we can replace the subroutine which checks whether there exists a set S with $|S| \leq m$ with desired properties by a simple branch-and-bound procedure with FPT runtime.

▶ **Lemma 13.** *There is an algorithm with runtime $\mathcal{O}(r^m \cdot n^2)$ which correctly decides the following problem: Given G, $v \in V(G)$, $A \subseteq V(G) \setminus \{v\}$ and $r, m \in \mathbb{N}$ as input, decide whether there exist a set of set $S \subseteq V(G) \setminus \{v\}$ with $|S| \leq m$ such that $N_r^{G-S}(v) \cap A = \emptyset$.*

Proof. The algorithm checks whether there is a path of length at most r from v to any vertex in A. If no such path exists, the algorithm outputs YES. If such a path P exists and $m = 0$, the algorithm outputs NO. If $m > 0$ then at least one of the vertices on the path P has to be in the solution S, and so we can branch on all vertices $u \in V(P) \setminus \{v\}$ (there are at most r of them) and call the algorithm with input $G - \{u\}, v, A \setminus \{u\}$, r, $m - 1$. Then the algorithm returns YES if for at least one such u the recursive call returned YES, and returns NO otherwise.

We thus get an algorithm with branching bounded by r and depth bounded by m, and finding the path from v to A takes time $\mathcal{O}(n^2)$, so the claimed runtime follows. ◀

As an immediate consequence of the lemma we get the following.

▶ **Theorem 14.** *The (r,m)-ranking of any graph G can be computed in time $\mathcal{O}(r^m \cdot n^4)$.*

3.2 Vertex rankings and bounded tree rank

In this section we prove Theorem 3. The proof is split into Lemmas 15 and 16, which correspond to the two directions of the theorem.

▶ **Lemma 15.** *Let G be a graph that contains $T_{d,m+1}$ as an r-shallow topological minor. Then G has (r,m)-rank more than d.*

Proof. Let T be a subgraph of G that corresponds to an $\leq r$-subdivision of $T_{d,m+1}$. We prove that the principal vertices of T of height i (where the height is measured in $T_{d,m+1}$, and we think of leaves as having height 0) have (r,m)-rank at least $i+1$ in G. For $i=0$, the leaves of T clearly have rank at least 1. For $i>1$, let v be a vertex of T corresponding to a vertex of height i in $T_{d,m+1}$. Then there are $m+1$ internally disjoint paths connecting v to the corresponding $m+1$ children that have rank at least i. Therefore we cannot disconnect v from all of these children by deleting m vertices other than v. Thus v has (r,m)-rank at least $i+1$, which completes the proof. ◀

▶ **Lemma 16.** *Fix any $d,r\in\mathbb{N}$. For every m there exists $m'=m'(d,r,m)$ such that every graph G with (r,m')-rank more than d contains $T_{d,m}$ as an r-shallow topological minor.*

Proof. We will prove the lemma by induction on d. Actually, we will prove a slightly stronger statement – that for a suitably defined m' we have that every vertex of (r,m')-rank more than d is the root of an $\leq r$-subdivision of $T_{d,m}$ in G.

For $d=1$ we can set $m'=m-1$. Then if there exists a vertex of (r,m')-rank more than 1 in G, this vertex has at least m neighbors, and thus is the root of a $T_{1,m}$ subgraph in G. For $d>1$ we proceed as follows. For a given m, we wish to define a suitable m'. First, let $W_{d,m,r}$ denote the number of vertices of the graph obtained from $T_{d-1,m}$ by subdividing each edge r times. For convenience, set $M=m\cdot W_{d,m,r}+r\cdot m+m$. Let m'' be the number obtained by the inductive assumption applied to $d-1$, r, and M. Then we define $m':=\max\{m'',r\cdot m\}$. Let v be a vertex of (r,m')-rank more than d in G. Then for every set $S\subseteq V(G)\setminus\{v\}$ of size at most m', the set $N_r^{G-S}(v)\setminus\{v\}$ contains at least one vertex of (r,m')-rank at least d.

We claim that there exist paths $P_1,P_2,\ldots,P_m$ of length at most r that are disjoint other than at v, and so that each path P_i joins v to a vertex $u_i\neq v$ that has (r,m')-rank at least d. We find the paths greedily by adding one path at a time. Suppose that so far we have found the paths $P_1,\ldots,P_j$ for some $j<m$. Let S be the set of all vertices $u\neq v$ that are in any of the paths $P_1,\ldots,P_j$. This set S contains at most r vertices from each of the paths, and thus S has size at most $r(m-1)\leq m'$. Thus the set $N_r^{G-S}(v)\setminus\{v\}$ contains at least one vertex of (r,m')-rank at least d, and we can add another path P_{j+1} to our collection. This proves the claim. We note that this argument amounts to a Menger-type result about short paths, and this type of result has previously appeared in [16].

Since $m'\geq m''$, the (r,m'')-rank of each vertex of G is at least its (r,m')-rank. So by the inductive assumption applied to $d-1$, r, and M, each vertex u_i is the root of an $\leq r$-subdivision of $T_{d-1,M}$. Let us call this $\leq r$-subdivision rooted at u_i by T_i.

We now greedily build up the desired r-shallow topological minor of $T_{d,m}$ rooted at v as follows. Suppose that for some $j<m$, we have found that $T_1,\ldots,T_j$ contain, respectively, subgraphs $T_1',\ldots,T_j'$ so that

- for every $i\in\{1,\ldots,j\}$, the subgraph T_i' of T_i is an $\leq r$-subdivision of $T_{d-1,m}$ that is rooted at u_i,
- the subgraphs $T_1',\ldots,T_j'$ are pairwise vertex-disjoint, and
- for every $i\in\{1,\ldots,j\}$, the vertex u_i is the only vertex that is in both T_i' and in any of the paths $P_1,\ldots,P_m$.

We begin this greedy process with $j=0$. Now suppose that it holds for some $j<m$. We will prove it for $j+1$. This will complete the proof of Lemma 16.

So, we need to find a subgraph T_{j+1}' of T_{j+1} so that T_{j+1}' is an $\leq r$-subdivision of $T_{d-1,m}$ that is rooted at u_{j+1}, and the only vertex in common between T_{j+1}' and any of $T_1',\ldots,T_j'$ or $P_1,\ldots,P_m$ is u_{j+1}. Notice that each of the trees $T_1',\ldots,T_j'$ has at most $W_{d,m,r}$ vertices by the definition of $W_{d,m,r}$. Moreover, each of the paths $P_1,\ldots,P_m$ contributes at most r

additional vertices. So, since $j < m$, the number of vertices in any of $T'_1, \ldots, T'_j$ or $P_1, \ldots, P_m$ is at most $m \cdot W_{d,m,r} + r \cdot m$. Recall from the definition that M is this quantity plus m. So we can just delete the branches of T_{j+1} in which any of the vertices of $T'_1, \ldots, T'_j$ or $P_1, \ldots, P_m$, other than u_{j+1}, occur. In this manner we arrive at the desired subgraph T'_{j+1}. ◀

3.3 Vertex rankings and bounded expansion

In this section we prove Theorem 4, characterizing classes of bounded expansion using vertex rankings. The theorem follows from the two lemmas below combined with Theorems 9 and 10.

▶ **Lemma 17.** *Let G be a graph with $\mathrm{scol}_r(G) = m$. Then G has finite $(r, m-1)$-rank.*

We stress that in Lemma 17 we are not bounding the maximum value of $(r, m-1)$-rank of any vertex of G, but merely claiming that the $(r, m-1)$-ranking algorithm will assign to each vertex of G a finite value. This value, however, can be arbitrarily large (and in particular it is not bounded in terms of r and m). This can be seen already on the class of trees – the class of all trees has bounded strong coloring numbers (one can set $m := r + 1$), but on the complete m-ary tree of depth d the $(r, m-1)$-ranking algorithm will need d rounds to finish.

Proof of Lemma 17. Assume for contradiction that there exists a vertex of G of $(r, m-1)$-rank ∞. Fix an order $\leq$ on $V(G)$ that certifies that $\mathrm{scol}_r(G) = m$. Let v be the smallest vertex of G with respect to $\leq$ that has $(r, m-1)$-rank ∞. Let A be the set of all vertices below v in $\leq$, and let i be the maximum $(r, m-1)$-rank of any vertex in A. We claim that in round $(i+1)$ of the ranking algorithm vertex v received rank (meaning it has rank $i+1$), which is a contradiction with our assumption on v. To see this, let S be the set of all vertices that are strongly r-reachable from v in G. Note that every path of length at most r from v to a vertex $w \geq v$ must contain a vertex in S. It follows that $N_r^{G-S}(v) \setminus \{v\}$ contains only vertices of finite rank, a contradiction. ◀

Lemma 17 guarantees that the ranking algorithm succeeds on graphs with bounded strong coloring numbers. The next lemma tells us that the ranking algorithm computes a good admissibility ordering for an input graph G.

▶ **Lemma 18.** *Let $r, m \in \mathbb{N}$ with $r \geq 1$. Let G be a graph with finite (r, m)-rank. Then $\mathrm{adm}_r(G) \leq m$.*

Proof. Let $\leq$ be an ordering of $V(G)$ so that if $v \leq w$, then the (r, m)-rank of v is at most the (r, m)-rank of w. Thus we are ordering vertices of G by their rank, breaking ties arbitrarily. We claim that this ordering certifies that $\mathrm{adm}_r(G) \leq m$. Let v be any vertex of G, and let i be its (r, m)-rank. Let S be the set of vertices certifying that the (r, m)-rank of v is i. That is, S is a subset of $V(G) \setminus \{v\}$ of size at most m so that $N_r^{G-S}(v) \setminus \{v\}$ contains only vertices of (r, m)-rank strictly less than i.

Since any vertex $w \geq v$ has (r, m)-rank at least i, any path from v that ends in a vertex larger than v with respect to the ordering must contain a vertex of S. Therefore, if we consider a collection $P_1, \ldots, P_\ell$ of paths that maximizes the r-backconnectivity of v, then each P_i has to intersect S. Since all of these paths are disjoint except for their common end v, we get that $\mathrm{adm}_r(G) \leq m$, as desired. ◀

4 A lemma about edge-stable graphs

In this section we state and prove a lemma (Lemma 23) about the behaviour of the so-called k-near-twin relation on graphs that do not contain large half-graphs. This lemma will be crucial in the next sections and may be of independent interest in the theory of (monadically) stable graphs [20, 21] (see also [4] for the latest important developments in this area).

First we need a few definitions. A crucial role will be played by the notion of k-near-twins.

▶ **Definition 19.** *Let G be a graph, and let $k \in \mathbb{N}$. We say that two vertices are* k-near-twins *if $|N^G(v) \Delta N^G(u)| \leq k$.*

▶ **Definition 20.** *Let G be a graph, and let $k \in \mathbb{N}$. The* k-near-twin graph of G, *denoted by $NT_k(G)$, is the graph with vertex set $V(G)$ in which there is an edge between two vertices u and v if they are k-near-twins in G.*

▶ **Definition 21.** *A* half-graph of order t *is a graph with vertex set $\{u_1, \ldots, u_t, w_1, \ldots, w_t\}$ such that there is an edge between u_i and w_j if and only if $i \leq j$.*

▶ **Definition 22.** *We say that a graph G contains a half-graph of order t as a* semi-induced subgraph *if there are distinct vertices $u_1, \ldots, u_t, w_1, \ldots, w_t$ in G such that there is an edge between u_i and w_j if and only if $i \leq j$.*

Note that in the definition we do not say anything about edges between the vertices within the set $\{w_1, \ldots, w_t\}$ or edges between the vertices within the set $\{u_1, \ldots, u_t\}$; the edges within these sets can be arbitrary.

Our main lemma in this section is the following.

▶ **Lemma 23** (∗). *There is a function $h : \mathbb{N}^2 \to \mathbb{N}$ so that for any $k, t \in \mathbb{N}$, if G is a graph with no half-graph of order t as a semi-induced subgraph, and u and v are vertices in the same component of the k-near-twin graph of G, then u and v are $h(k, t)$-near-twins in G.*

The technical proof of the lemma can be found in the full version of the paper.

5 Interpretations of graph classes of tree rank 2

In this section we prove Theorems 5 and 6. First we will establish some properties of classes of tree rank at most 2 (Section 5.1). After this, in Section 5.2, we give a characterization of graph classes interpretable in graph classes of tree rank at most 2 by interpretations of *bounded range*. This section contains the technical core of our results – the key result is Theorem 31, proof of which is split into Lemmas 32 and 33. The case of general interpretations (Theorem 5) is presented in Section 5.3; it will easily follow from results in Section 5.2. Finally, we prove our main algorithmic result, Theorem 6, in Section 5.4.

5.1 Classes of tree rank at most 2

We start with a characterization of graph classes of tree rank 2.

▶ **Definition 24.** *A class of graphs $\mathcal{C}$ has* locally almost[4] bounded degree *if there exist functions $f, d : \mathbb{N} \to \mathbb{N}$ such that for every $r \in \mathbb{N}$, every $G \in \mathcal{C}$, and every $v \in V(G)$, the set $N_r^G(v)$ contains at most $f(r)$ vertices with degree larger than $d(r)$ in G.*

[4] We remark that the adjective "almost" is sometimes used differently in context of structural graph parameters. For example, for a graph class $\mathcal{C}$, having almost bounded flipwidth (see [22]) means that for every ϵ there exists c such that every $G \in \mathcal{C}$ has flipwidth at most cn^ϵ. Our usage of the adjective "almost" is different – it refers to having a bounded number of exceptions.

▶ **Lemma 25.** *A class $\mathcal{C}$ of graphs has tree rank at most 2 if and only if has locally almost bounded degree.*

In the proof of the lemma we will use the following simple result from [13, Lemma 13].

▶ **Lemma 26.** *Let $r, t \in \mathbb{N}$, let H be a graph of radius at most r, and let $S \subseteq V(H)$. If $|S| \geq t^r + 1$, then there exists $u \in V(H)$ such that there are t vertices in S that are distinct from u and can be reached from u by internally vertex-disjoint paths of length at most r.*

Proof of Lemma 25. By Theorem 3, it suffices to prove that a class $\mathcal{C}$ is of locally almost bounded degree if and only if for every $r \in \mathbb{N}$ there exists $m \in \mathbb{N}$ such that every graph in $\mathcal{C}$ has (r, m)-rank at most 2.

First, assume that $\mathcal{C}$ is of locally almost bounded degree with respect to functions f and d. Let $r \in \mathbb{N}$, and set $m := \max\{f(r), d(r)\}$. We claim that the (r, m)-ranking algorithm will assign the number 1 or 2 to each $v \in V(G)$. In the first round, all vertices of degree at most $d(r) \leq m$ will get rank 1. In the second round, we know that each $N_r^G(v)$ contains at most $f(r)$ vertices of degree larger than $d(r)$. Thus we can delete a set $S \subseteq V(G) \setminus \{v\}$ of size at most $f(r)$ so that $N_r^{G-S}(v) \setminus \{v\}$ contains only vertices of rank 1. The result follows.

For the other direction, suppose that for every $r \in \mathbb{N}$ there exists $m \in \mathbb{N}$ such that every graph in $\mathcal{C}$ has (r, m)-rank at most 2. Let $r \in \mathbb{N}$, and set $f(r) := (m+1)^r$ and $d(r) := m$. Let $v \in V(G)$ be arbitrary, and let S be the set of vertices with (r, m)-rank exactly 2 in $N_r^G(v)$ (these are the vertices of degree more than m). Going for a contradiction, we may assume that $|S| > f(r)$, since otherwise we are done. Thus, by Lemma 26 applied to r, $t := m + 1$ and S in the subgraph H of G induced on $N_r^G(v)$, there exists a vertex $u \in N_r^G(v)$ such that there are $m+1$ vertices in S that are distinct from u and can be reached from u by internally vertex-disjoint paths of length at most r. As all of the vertices in S have (r, m)-rank 2, this shows that the (r, m)-rank of u is more than 2, which is a contradiction. Thus $\mathcal{C}$ is of locally almost bounded degree with functions f and d, as desired. ◀

Algorithmic considerations. For our algorithms we will need to assume that the functions which are used in the definitions of our graph classes are efficiently computable. In particular, we will need to be able to efficiently test whether a given graph G comes from a fixed graph class of locally almost bounded degree given by functions d and f. This can be done under fairly relaxed conditions on functions d and f, which we now describe. The key observation is that for any graph G we need to check the conditions imposed by functions f and d from Definition 24 only for values of r with $r \leq n$ (where $n = |V(G)|$), and that checking the conditions is trivial whenever $f(r) > n$ or $d(r) > n$.

With this in mind, we say that a function $h : \mathbb{N} \to \mathbb{N}$ is *nice* if there exists a an algorithm which inputs two numbers r and n represented in binary with $r \leq n$ and in time $poly(n)$ either correctly answers that $h(r) > n$ or outputs $h(r)$ (which is upper bounded by n).

Note that a function which is very fast growing and complicated to compute (with respect to its input which has length $\lceil \log(r) \rceil$) can still be nice. This is because it may be easy to check that $h(r) > n$, in which case no further computation is required, and if $h(r) \leq n$, we know that n is much larger than $\lceil \log(r) \rceil$, and then we have $poly(n)$ time at our disposal to compute $h(r)$. It is easy to verify that functions such as 2^r, $\mathrm{tow}_\ell(r)$ (tower of twos of height ℓ with r on top), $\mathrm{tow}_r(2)$ (tower of twos of height r) and also r^r are nice functions.

Coming back to graph classes of tree rank 2, we will use the following definition to specify graph classes for which we can prove Theorem 6.

▶ **Definition 27.** *We say that a class $\mathcal{C}$ of graphs of tree rank 2 is* efficiently bounded *if there exists a nice function $g : \mathbb{N} \to \mathbb{N}$ such that for every $r \in \mathbb{N}$ there exists $m \in \mathbb{N}$ such that no $G \in \mathcal{C}$ contains $T_{2,m}$ as an r-shallow topological minor.*

By inspecting the proof of Lemma 25 one easily checks that any efficiently bounded class $\mathcal{C}$ of tree rank 2 is a class of locally almost bounded degree for which the there exist functions f and d which ceritfy this. If we moreover assume that $\mathcal{C}$ is *maximum* class of locally bounded degree with respect to f and g (meaning it contains every G that satisfies conditions given by f and d for all $r \leq |V(G)|$), then we can efficiently test for any G whether $G \in \mathcal{C}$. This is easily achieved by testing the conditions from Definition 24 for all values r up to $|V(G)|$. Since the functions f and d are nice, these values are either too large (if $f(r) > n$ or $d(r) > n$ which can be efficiently checked), or efficiently computable. This yields the following lemma.

▶ **Lemma 28.** *Let $\mathcal{C}$ be a class of graphs with locally almost bounded degree given by nice functions $f, d : \mathbb{N} \to \mathbb{N}$. Assume that $\mathcal{C}$ is maximum such class with respect to f and d. Then there is a polynomial time algorithm that determines whether $G \in \mathcal{C}$.*

In subsequent sections, it would be desirable to show at various places that some function is nice (or at least can be upper bounded by some nice function). We will not spell out these arguments explicitly; we just note here that one can often combine two nice functions to obtain another nice function. In particular, one easily checks that if f and g are functions such that for all r we have $f(r) \geq r$ and $g(r) \geq r$, then also $h := g \circ f$ is nice with $h(r) \geq r$. This because for given r, n with $r \leq n$ we can check whether $f(r) > n$, and if yes then we know that $h(r) = g(f(n)) > n$. On the other hand if $f(r) \leq n$, then the input condition for function g is satisfied, and we can just check whether $g(f(r)) > n$ or compute the value of $g(f(r))$ efficiently.

5.2 The case of interpretations of bounded range

We now proceed by giving a characterization of graph classes that can be obtained from graph classes of tree rank at most 2 by an interpretation of bounded range (Theorem 31).

In what follows we will use the notions of k-near-twins and near-twin graphs introduced in Section 4.

▶ **Definition 29.** *We say that a graph G is* (k, m)-near-covered *if for every set $S \subseteq V(G)$ such that the elements of S are mutually not k-near-twins we have $|S| \leq m$.*

We remark that the definition of (k, m)-near-covered graphs introduced in [12] was slightly different – there it was required that there exists a set of at most m vertices such that every vertex v of G is a k-near-twin of some $w \in S$. One can easily check that the two definitions are functionally equivalent (i.e. up to changing k and m in one definition to k' and m' in the other definition). We use Definition 29 because it will be more convenient in our arguments.

▶ **Definition 30.** *A graph class $\mathcal{C}$ is* locally almost near-covered *if there exist functions $k, m : \mathbb{N} \to \mathbb{N}$ such that for every $r \in \mathbb{N}$, every $G \in C$, and every $v \in V(G)$, the subgraph of G induced on $N_r^G(v)$ is $(k(r), m(r))$-near-covered.*

▶ **Theorem 31.** *A class $\mathcal{C}$ is a interpretable from a class of locally almost bounded degree by a bounded range interpretation if and only if $\mathcal{C}$ is locally almost near-covered.*

The forward direction of Theorem 31 is handled by the following lemma, which can be proven by combining the locality-based Lemma 11 with the characterization of graph classes interpretable in graph classes of bounded degree in terms of near-covered graphs given in [12].

▶ **Lemma 32** (∗). *Let I be a bounded range interpretation, and let $\mathcal{C}$ be a class of locally almost bounded degree. Then $I(\mathcal{C})$ is locally almost near-covered.*

The rest of this section is dedicated to proving the backward direction of Theorem 31

▶ **Lemma 33.** *Let $\mathcal{C}$ be a locally almost near-covered graph class. Then $\mathcal{C}$ is interpretable in a class $\mathcal{D}$ of locally almost bounded degree by an interpretation I of bounded range.*

Moreover, there is a polynomial algorithm that to every graph G computes a graph $\mathcal{S}(G)$ so that if $G \in \mathcal{C}$, then $\mathcal{S}(G) \in \mathcal{D}$ and $G = I(\mathcal{S}(G))$.

We will need the following simple lemma showing that locally almost near-covered graph classes do not contain arbitrarily large half-graphs.

▶ **Lemma 34.** *Let $\mathcal{C}$ be a locally almost near-covered graph class with respect to functions k and m, and set $t := m(2) \cdot k(2) + m(2) + 1$. Then no graph in $\mathcal{C}$ contains a half-graph of order t as a semi-induced subgraph.*

Proof. Assume for contradiction that such a graph $G \in \mathcal{C}$ exists. Let $u_1, \ldots, u_t, w_1, \ldots, w_t$ be the vertices of a half-graph of order t that G contains as a semi-induced subgraph. Then all of these vertices $u_1, \ldots, u_t, w_1, \ldots, w_t$ are in $N_2^G(u_1)$. Also, for any $i, j \in \{1, 2, \ldots, t\}$ with $i - j > k(2)$, we know that u_i and u_j are not $k(2)$-near twins, since their adjacency differs in vertices $w_j, w_{j+1}, \ldots, w_{i-1}$. Therefore, the vertices $u_1, u_{k(2)+2}, u_{2k(2)+3}, \ldots u_{m(2)\cdot k(2)+m(2)+1}$ form a set of $m(2) + 1$ pairwise not $k(2)$-near-twins, a contradiction with $\mathcal{C}$ being locally almost near-covered. ◀

In the proof of Lemma 33 we will also use the following lemma taken from [12, Corollary 5.3]. We note that in that paper, an extra assumption was made that amounts to saying that no vertex in A is a k-near-twin of any vertex in B. However, that assumption was not used in the proof given in [12], and so same proof works to prove the following lemma.

▶ **Lemma 35.** *Let G be a graph and let A and B be two subsets of $V(G)$ that are either disjoint or have $A = B$ and such that $|A| \geq 5k + 1$, $|B| \geq 5k + 1$, all vertices in A are pairwise k-near-twins, and all vertices in B are pairwise k-near-twins. Then either*

1. *every vertex of A is adjacent to at most $2k$ vertices of B and every vertex of B is adjacent to at most $2k$ vertices of A, or*
2. *every vertex of A is adjacent to all but at most $2k$ vertices of B and every vertex of B is adjacent to all but at most $2k$ vertices of A*

We will also use the following immediate corollary of Lemma 35.

▶ **Corollary 36.** *Let G be a graph, and let A and B be two subsets of $V(G)$ that satisfy the assumptions of Lemma 35. If there exists a vertex $v \in A$ with $|N^G(v) \cap B| > 2k$, then in the graph G' obtained from G by flipping the edges between A and B, every vertex $u \in A$ has $|N^{G'}(u) \cap B| \leq 2k$.*

Finally, we will use the following Ramsey-type result, which is routine to prove.

▶ **Lemma 37.** *There exists functions $R, D : \mathbb{N}^3 \to \mathbb{N}$ so that for all $k, m, s \in \mathbb{N}$, the following holds for every graph G with no subgraph isomorphic to the complete bipartite graph $K_{s,s}$. If $X \subseteq V(G)$ is such that $|X| \geq R(k, m, s)$ and every vertex in X has degree at least $D(k, m, s)$, then there exists $Y \subseteq X$ such that $|Y| \geq m$ and every vertex $y \in Y$ has at least k neighbors in $V(G) \setminus Y$ that are not adjacent to any other $y' \in Y \setminus \{y\}$.*

Proof of Lemma 33. Let $\mathcal{C}$ be a locally almost near-covered graph class, and let k and m be the functions certifying this. We will describe a procedure $\mathcal{S}$ that to every $G \in \mathcal{C}$ assigns a graph $\mathcal{S}(G)$ such that $G = I(\mathcal{S}(G))$ for a fixed interpretation I of bounded range. This procedure will also return some graph $\mathcal{S}(G)$ even when G is not in $\mathcal{C}$, however in this case we make no guarantees about the graph $\mathcal{S}(G)$. We will then show that the graph class $\mathcal{D} := \{\mathcal{S}(G) \ : \ G \in \mathcal{C}\}$ is of locally almost bounded degree. Since by construction we will have $\mathcal{C} \subseteq I(\mathcal{D})$, this will finish the proof.

Let $G \in \mathcal{C}$ be arbitrary. Let $h := h(k(3), t)$, where h is the function from Lemma 23 and $t := m(2) \cdot k(2) + m(2) + 1$ is the integer from Lemma 34. Thus every pair of vertices in the same component of the $k(3)$-near-twin graph of G are h-near-twins in G. We define a partition $\mathcal{F}$ of $V(G)$ by putting two vertices into the same part if they are in the same connected component of the $k(3)$-near-twin graph of G (this creates a partition since being in the same connected component is an equivalence relation). We call parts $A, B \in \mathcal{F}$ (possibly with $A = B$) *mutually heavy* if $|A| \geq 5h + 1$, $|B| \geq 5h + 1$, and there exists a vertex $v \in B$ with $|N^G(v) \cap A| > 2h$. (Note that in this case, by Lemma 35, there also exists a vertex $u \in A$ with $|N^G(u) \cap B| > 2h$.) Similarly, we call a part $A \in \mathcal{F}$ *heavy* if it is mutually heavy with any part $B \in \mathcal{F}$ (possibly with $B = A$).

Creating the sparse graph $\mathcal{S}(G)$ from G. We can now describe the sparse graph $\mathcal{S}(G)$ associated to G. We start from G and proceed as follows:

1. For any heavy part $A \in \mathcal{F}$, we introduce a new vertex v_A, make it adjacent to all vertices in A, and mark it with a unary predicate R.
2. For any mutually heavy parts $A, B \in \mathcal{F}$, we flip between A and B. If $A = B$, then we mark v_A with a unary predicate F. If $A \neq B$, then we put an edge between v_A and v_B.

All other adjacencies that were not part of any flip remain as in G. Note that we can define this graph $\mathcal{S}(G)$ even when G is not in $\mathcal{C}$. Also note that by Corollary 36, for all mutually heavy parts $A, B \in \mathcal{F}$ and every vertex $v \in A$, we have that $|N^{\mathcal{S}(G)}(v) \cap B| \leq 2h$. We will use this important property later on.

Algorithmic considerations. It is easily seen that the construction of $\mathcal{S}(G)$ can be done in polynomial time from G.

Recovering G from $S(G)$ by an interpretation. We now show that there is an interpretation I such that $G = I(\mathcal{S}(G))$. Let u and v be two vertices from $V(G)$. In the construction of $\mathcal{S}(G)$, the adjacency between two vertices only changed in the second part of the construction. Thus, the formula $\psi(x, y)$ will complement the adjacency between distinct vertices x and y if

- x and y have the same (unique) neighbor w marked with the predicate R and this w is also marked with predicate F, or
- x and y each have a different neighbor marked with the predicate R and these neighbors are adjacent.

In all other cases we have $\psi(x, y) = E(x, y)$. The conditions above are easily expressed by a first-order formula. Note that $\psi(x, y)$ only keeps the existing edges or creates edges between vertices at distance at most 3 and therefore ψ is of range 3. To define the vertex set of G from the graph $\mathcal{S}(G)$, the formula $\delta(x)$ just keeps the vertices that are not marked with R (the original vertices of G).

Showing that the class $\mathcal{D} := \{\mathcal{S}(G) : G \in \mathcal{C}\}$ is of locally almost bounded degree. It remains to argue that $\mathcal{D}$ is of locally almost bounded degree. Due to space restrictions this argument is omitted from the conference version and can be found in the full version of the paper. ◀

5.3 The case of full interpretations

In this section we finish the proof of our main result, Theorem 5, which states that a class $\mathcal{C}$ of graphs is interpretable in a graph class of tree rank 2 if and only if $\mathcal{C}$ is a perturbation of a locally almost near-covered graph class.

For the forward direction, it is known (see for example [1, 3]) that every interpretation can decomposed into two steps in the following sense.

▶ **Lemma 38.** *For every interpretation I there exists an interpretation I' of bounded range and $k \in \mathbb{N}$ such that for every G we have that $I(G)$ is a k-flip of $I'(G)$.*

The forward direction of Theorem 5 then follows immediately from Lemmas 32 and 38. The backward direction follows from Lemma 33: If $\mathcal{C}$ is a perturbation of a locally almost near-covered graph class, then $\mathcal{C}$ is a perturbation of $I(\mathcal{D})$ for some graph class $\mathcal{D}$ of locally almost bounded degree. Since perturbations (k-flips) can be modelled by interpretations, add unary predicates to graphs from $\mathcal{D}$ and adjust I to I' such that $\mathcal{C} \subseteq I'(\mathcal{D})$.

5.4 Proof of Theorem 6

In this section we prove Theorem 6 by showing that for every graph class $\mathcal{C}$ interpretable in a graph class of tree rank 2, there is a polynomial time algorithm that to every $G \in \mathcal{C}$ computes $H \in \mathcal{D}$ such that $G = I(H)$, where I is a fixed interpretation and $\mathcal{D}$ is a fixed class of graphs of locally almost bounded degree (which is the same as tree rank 2 by Lemma 25).

We will rely on the following lemma which was proven in [1].

▶ **Lemma 39.** *Let $\mathcal{D}$ be an NIP class of graphs, and let I be an interpretation. Then there exist s, b, and a formula $\psi(x, y)$ of range b such that for every $G \in I(\mathcal{D})$ there exist $S \subseteq V(G)$ of size at most s, an S-flip G' of G, and a graph $H \in \mathcal{D}$ such that $G' = \psi(H)$.*

We do not define the notion of a graph class being NIP (see for example the relevant sections in [1]), but just note that this notion is very general and it is easily established that classes of tree rank 2 are NIP, so the lemma can be applied in our setting.

We now proceed with the proof Theorem 6. Since $\mathcal{C}$ is interpretable in a graph class of tree rank 2, there exist an interpretation I and a class $\mathcal{D}$ of tree rank at most 2 such that $\mathcal{C} \subseteq I(\mathcal{D})$. By applying Lemma 39 to $\mathcal{D}$ and I, we obtain numbers s and b and a formula ψ of range b. Since ψ is of bounded range, we know by Lemma 32 that the class $\psi(\mathcal{D})$ is locally almost near-covered. By Lemma 33 applied to $\psi(\mathcal{D})$, there exists a graph class $\mathcal{D}'$ of locally almost bounded degree, an interpretation I', and a polynomial time algorithm $\mathcal{A}$ that to any $G' \in \psi(\mathcal{D})$ computes a graph $\mathcal{S}(G') \in \mathcal{D}'$ such that $G' = I'(\mathcal{S}(G'))$. Moreover, by inspecting the proofs of Lemma 32 and Lemma 33 one can check that the functions f and d which certify that $\mathcal{D}'$ is a class of locally almost bounded degree are nice functions, and so we can use Lemma 28 to check membership in $\mathcal{D}'$.

We now consider the algorithm that for a graph $G \in \mathcal{C}$ does the following:

1. Go through all subsets S of $V(G)$ of size at most s.
2. For each such set S, go through all possible S-flips G' of G.
3. Apply the algorithm $\mathcal{A}$ from Lemma 33 to G' to obtain a graph $\mathcal{S}(G')$.
4. Check whether $G' = I'(\mathcal{S}(G'))$ and use Lemma 28 to check whether $\mathcal{S}(G') \in \mathcal{D}'$, if yes, then output $\mathcal{S}(G')$.

We now argue the correctness of the algorithm. By Lemma 39, at least one G' will be such that $G' = \psi(H)$ for some $H \in \mathcal{D}$. Then, since $G' \in \psi(\mathcal{D})$, we have (by Lemma 33) that the algorithm $\mathcal{A}$ returns a graph $\mathcal{S}(G')$ that is in $\mathcal{D}'$. Since for $\mathcal{S}(G')$ we have $G' = I'(\mathcal{S}(G'))$

and since from G' one can easily recover G by performing a bounded number of flips, we can adjust the interpretation I' to an interpretation I'' such that $G = I''(\mathcal{S}(G'))$, as desired. (We add unary predicates to $\mathcal{S}(G')$ in order to "mark" the sets that we flip between.)

The runtime of the algorithm is easily seen to be polynomial in $|V(G)|$: We have $|V(G)|^s$ possible sets of size s and consequently we have $|V(G)|^s$ iterations, where the number s depends only on the graph class $\mathcal{C}$. In each iteration we invoke the polynomial time algorithm $\mathcal{A}$ from Lemma 33.

6 Conclusions

We conclude with two open ended questions that may deserve further attention.

1. Is there a way of defining vertex rankings for dense graphs analogous to our rankings? Ideally, such rankings should be computable in FPT time.
2. While the proof of Lemma 33 is technical, our construction of the graph $\mathcal{S}(G)$ from the graph G is simple: First we determine which components of the k-near-twin graph of G to flip between, and then we use this information to construct $\mathcal{S}(G)$. It may be interesting to see under which conditions on G we can claim that the graph $\mathcal{S}(G)$ comes from a class of sparse graphs. Also, using our construction recursively may lead to interesting results: If $\mathcal{S}(G)$ is not a sparse graph, one may consider $\mathcal{S}(\mathcal{S}(G))$, and so on.

Abstract

We present a novel normal form for (total deterministic) macro tree transducers (mtts), called "depth proper normal form". If an mtt is in this normal form, then it is guaranteed that each parameter of each state appears at arbitrary depths in the output trees of that state. Intuitively, if some parameter only appears at certain bounded depths in the output trees of a state, then this parameter can be eliminated by in-lining the corresponding output paths at each call site of that state. We use regular look-ahead in order to determine which of the paths should be in-lined. As a consequence of changing the look-ahead, a parameter that was previously appearing at unbounded depths, may be appearing at bounded depths for some new look-ahead; for this reason, our construction has to be iterated to obtain an mtt in depth-normal form. Using the normal form, we can decide whether the translation of an mtt has linear height increase or has linear size-to-height increase.

1 Introduction

Tree transducers are fundamental devices in theoretical computer science. They generalize the finite state transductions from strings to (finite, ranked) trees and were invented in the 1970s in the context of compiler theory and mathematical linguistics. The most basic such transducers are the top-down tree transducer [24, 23] and the bottom-up tree transducer [25], see also [6]. These transducers traverse their input tree once, but may process subtrees in several copies. It is well known that these transducers have *linear height increase* ("LHI"), see e.g. [17].

In this paper we deal with a more powerful kind of tree transducer: the macro tree transducer [13] ("mtt"). Mtts can be seen as particularly simple functional programs on trees restricted to primitive recursion via (input) tree pattern matching. Alternatively, mtts can be seen as context-free tree grammars (introduced in [23] as "context-free dendrogrammars";

see also [15, 11, 12] and [19, Section 15]), the nonterminals of which are controlled by a top-down tree storage (in the spirit of [7]). It is an open problem, if it is decidable for a given mtt whether or not its translation can be realized by a top-down tree transducer (with "origin" semantics, this is decidable [14]). As mentioned above, it is a necessary condition for the mtt to have linear height increase ("LHI"). This raises the question, can we decide for a given mtt, whether or not its translation has LHI? Here we give an affirmative answer to this question. It is also an open problem, if it is decidable for a given mtt whether or not its translation can be realized by an attributed tree transducer [20, 21, 16] ("att"). It is well-known that atts have *linear size-to-height increase* ("LSHI"), see, e.g., [17]. This raises the question, can we decide for a given mtt, whether or not its translation is of LSHI? We give an affirmative answer. Note that it was conjectured in [10] that the methods of that paper could be adapted to give such an affirmative answer.

Let us now discuss our results in more detail. To decide both the LHI and LSHI properties, we introduce a new normal form called "depth proper". An mtt is depth proper if each parameter of every (reachable) state appears at infinitely many different depths (for different input trees). The idea of our construction is to eliminate parameters that only appear at bounded depths; we use regular look-ahead to determine which bounded paths to output at a given moment. Since in this way we may generate output "earlier" than the original transducer, new "helper states" need to be introduced which continue the translation at the correct input nodes. Both issues, the change of look-ahead and the introduction of new states may cause the newly constructed transducer *not* to be depth proper. For this reason our construction has to be iterated.

To understand the idea of the construction, let us examine a small example. We consider input and output trees over a binary symbol f and the nullary symbol a and an mtt with the following rules.

$$\begin{array}{llll} q_0(f(x_1,x_2)) & \to & f(q_1(x_2), q_2(x_2, q_{\mathrm{id}}(x_1))) & q_2(f(x_1,x_2),y_1) \to f(y_1, q_0(x_2)) \\ q_0(a) & \to & a & q_2(a,y_1) \to f(y_1,a) \\ q_1(f(x_1,x_2)) & \to & q_{\mathrm{id}}(x_1) & q_{\mathrm{id}}(f(x_1,x_2)) \to f(q_{\mathrm{id}}(x_1), q_{\mathrm{id}}(x_2)) \\ q_1(a) & \to & a & q_{\mathrm{id}}(a) \to a \end{array}$$

The transducer realizes the following translation:

$$f(t_1, f(t_2, \underbrace{f(t_3, f(t_4, \dots))}_{t})) \Rightarrow f(t_2, f(t_1, f(t_4, f(t_3, \dots))))$$

The following shows in detail how the rules of the mtt are applied to produce as output first the tree t_2 and then the tree t_1:

$$\begin{array}{rl} & q_0(f(t_1, f(t_2,t))) \\ \Rightarrow_{\text{first rule}} & f(q_1(f(t_2,t)), q_2(f(t_2,t), q_{\mathrm{id}}(t_1))) \\ \Rightarrow_{\text{second rule}} & f(q_{\mathrm{id}}(t_2), q_2(f(t_2,t), q_{\mathrm{id}}(t_1))) \\ \Rightarrow^*_{\text{last two rules}} & f(t_2, q_2(f(t_2,t), q_{\mathrm{id}}(t_1))) \\ \Rightarrow_{\text{third rule}} & f(t_2, f(q_{\mathrm{id}}(t_1), q_0(t))) \\ \Rightarrow^*_{\text{last two rules}} & f(t_2, f(t_1, q_0(t))) \end{array}$$

An mtt uses two different types of variables. The first argument of each state in the left-hand side of every rule of the mtt is always of type input tree and performs pattern matching on the current node of the input tree. For this pattern matching, *input variables* of the form x_1 and x_2 are used to denote the first and second subtree of the current input node, respectively. The (possible) next arguments of a state in the left-hand side of a rule are the (accumulating) *parameters* $y_1, y_2, \dots$ of that state. In our example, only the state q_2

has exactly one parameter y_1. Parameters are used to built up output trees in a bottom-up fashion. In the example, consider the application of the first rule, i.e., going from line one to line two in the previous display: here the first (and only) parameter y_1 of state q_2 is instantiated by the output tree that is produced by the call $q_{\mathrm{id}}(t_1)$.

Observe that state q_2 is *not* depth proper: each tree that it outputs is of the form $f(y_1, t)$ where t does not contain the parameter y_1. The idea of our construction is to replace each occurrence of state q_2 in the right-hand side of any rule by this tree "fragment", where at the position of t there will be the new "helper state" $[q_2, 2]$. The path "2" indicates that this state should produce the tree at the second child position of the output tree produced by q_2. We obtain the following (the rules of q_0, q_1 and input a are as before):

$$\begin{array}{lcl}
q_0(f(x_1,x_2)) & \to & f(q_1(x_2), f(q_{\mathrm{id}}(x_1), [q_2,2](x_2))) \\
q_1(f(x_1,x_2)) & \to & q_{\mathrm{id}}(x_1) \\
[q_2,2](f(x_1,x_2)) & \to & q_0(x_2) \\
[q_2,2](a) & \to & a \\
q_{\mathrm{id}}(f(x_1,x_2)) & \to & f(q_{\mathrm{id}}(x_1), q_{\mathrm{id}}(x_2)) \\
q_{\mathrm{id}}(a) & \to & a
\end{array}$$

It should be clear that the new transducer is equivalent to the original one. Moreover, the new transducer uses no parameters whatsoever, therefore it is depth proper. Given a depth proper mtt, we can decide the LSHI property as follows. We consider input trees which contain exactly one special marked input leaf (it will be marked by a state p of the look-ahead automaton, to act as a place-holder for any input tree for which the look-ahead automaton arrives in state p). For such input trees, the mtt produces output trees which only contain nested state calls to the special input leaf. The original transducer has LSHI if and only if the range of this transducer is finite (which is known to be decidable [5]). In a similar way we can decide LHI: here we consider input trees with multiple marked input leaves. To show that if such ranges are not finite, then the translation does not have LSHI (or LHI), is done via pumping arguments (which use depth properness); these pumping arguments are technically rather involved, but are (somewhat) similar to the ones used in [10] to show that it is decidable whether or not an mtt has *linear size increase* (LSI).

If we restrict the translations of mtts to LSI, then we obtain exactly the MSO definable tree translations [10]. Note that this class of translation has recently been characterized by new models of tree transducers, the *streaming tree transducer* [2] and even more recently the *register tree transducer* [3]. The LSI property is decidable for mtts (it can even be decided for compositions of mtts, and if so, then the translation is effectively MSO definable [8]). To decide LSI, the given mtt is first transformed into "proper" normal form. Properness guarantees that (1) each state (except possibly the initial state) produces infinitely many output trees and that (2) each parameter of a state is instantiated with infinitely many distinct argument trees. Note that input properness is a generalization of the proper form of [1]. Once in proper normal form, it suffices to check if the transducer is "finite copying". This means that (a) each node of each input tree is processed only a bounded number of times and that (b) each parameter of every state is copied only a bounded number of times.

2 Preliminaries

The set $\{0, 1, \dots\}$ of natural numbers is denoted by $\mathbb{N}$. For $k \in \mathbb{N}$ we denote by $[k]$ the set $\{1, \dots, k\}$; thus $[0] = \emptyset$. A ranked alphabet (set) consists of an alphabet (set) Σ together with a mapping $\mathrm{rank}_\Sigma : \Sigma \to \mathbb{N}$ that assigns to each symbol $\sigma \in \Sigma$ a natural number called its "rank". We write $\sigma^{(k)} \in \Sigma$ to denote that $\sigma \in \Sigma$ and $\mathrm{rank}_\Sigma(\sigma) = k$. By $\Sigma^{(k)}$ we denote the symbols of Σ that have rank k.

The set T_Σ of (finite, ranked, ordered) trees over Σ is the smallest set of strings S such that if $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in S$, then also $\sigma(s_1, \ldots, s_k) \in S$. We write σ instead of $\sigma()$. For a tree $s = \sigma(s_1, \ldots, s_k)$ with $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in T_\Sigma$, we define the set $V(s) \subseteq \mathbb{N}^*$ of nodes of s as $\{\varepsilon\} \cup \{iu \mid i \in [k], u \in V(s_i)\}$; thus, nodes are strings over positive integers, where ε denotes the root node of s, and for a node u, ui denotes the i-th child of u. For $u \in V(s)$ we denote by $s[u]$ the label of u in s and by s/u the subtree rooted at u. Formally, let $s = \sigma(s_1, \ldots, s_k)$ and define $s[\epsilon] = \sigma$, $s[iu] = s_i[u]$, $s/\varepsilon = s$, and $s/iu = s_i/u$ for $\sigma \in \Sigma^{(k)}$, $k \geq 0$, $s_1, \ldots, s_k \in T_\Sigma$, $i \geq 1$ and $u \in V(s_i)$ such that $iu \in V(s)$.

We fix two special sets of symbols: the set $X = \{x_1, x_2, \ldots\}$ of variables and the set $Y = \{y_1, y_2, \ldots\}$ of parameters. For $k \geq 1$ let $X_k = \{x_1, \ldots, x_k\}$ and $Y_k = \{y_1, \ldots, y_k\}$. Let A be a set that is disjoint from Σ. Then the set $T_\Sigma(A)$ of trees over Σ indexed by A is defined as $T_{\Sigma'}$ where $\Sigma' = \Sigma \cup A$ and $\mathrm{rank}_{\Sigma'}(a) = 0$ for $a \in A$ and $\mathrm{rank}_{\Sigma'}(\sigma) = \mathrm{rank}_\Sigma$ for $\sigma \in \Sigma$.

For a ranked alphabet Σ and a set A the ranked set $\langle \Sigma, A \rangle$ consists of all symbols $\langle \sigma, a \rangle$ with $\sigma \in \Sigma$ and $a \in A$; the rank of $\langle \sigma, a \rangle$ is defined as $\mathrm{rank}_\Sigma(\sigma)$.

2.1 Tree Substitution

Let Σ be a ranked alphabet and let $s, t \in T_\Sigma$. For $u \in V(s)$ we define the tree $s[u \leftarrow t]$ that is obtained from s by replacing the subtree rooted at node u by the tree t. Let $\sigma_1, \ldots, \sigma_n \in \Sigma^{(0)}$, $n \geq 1$ be pairwise distinct symbols and let $t_1, \ldots, t_n \in T_\Sigma$. Then $t[\sigma_i \leftarrow t_i \mid i \in [n]]$ is the tree obtained from t by replacing each occurrence of σ_i by the tree t_i. We have defined trees as particular strings, and this is just ordinary string substitution (because we only replace symbols of rank zero). We refer to this as "first-order tree substitution".

In "second-order tree substitution" it is possible to replace internal nodes u (of a tree s) by new trees. These new trees use parameters to indicate where the "dangling" subtrees s/ui of the node u are to be placed. Let $\sigma_1 \in \Sigma^{(k_1)}, \ldots, \sigma_n \in \Sigma^{(k_n)}$ be pairwise distinct symbols with $n \geq 1$, $k_1, \ldots, k_n \in \mathbb{N}$, and $t_i \in T_\Sigma(Y_{k_i})$ for $i \in [n]$. Let $s \in T_\Sigma$. Then $s[\![\sigma_i \leftarrow t_i \mid i \in [n]]\!]$ denotes the tree that is inductively defined as (abbreviating $[\![\sigma_i \leftarrow t_i \mid i \in [n]]\!]$ by $[\![\ldots]\!]$) follows: for $s = \sigma(s_1, \ldots, s_k)$, if $\sigma \notin \{\sigma_1, \ldots, \sigma_n\}$ then $s[\![\ldots]\!] = \sigma(s_1[\![\ldots]\!], \ldots, s_k[\![\ldots]\!])$ and if $\sigma = \sigma_j$ for some $j \in [n]$ then $s[\![\ldots]\!] = t_j[y_i \leftarrow s_i[\![\ldots]\!] \mid i \in [k]]$.

2.2 Macro Tree Transducers

A (deterministic bottom-up) *tree automaton* A is given by a tuple (P, Σ, h) where P is a finite set of states, Σ is a ranked alphabet, and h is a collection of mappings $h_\sigma : P^k \to P$ with $\sigma \in \Sigma^{(k)}$ and $k \geq 0$. The extension of h to a mapping $\hat{h} : T_\Sigma \to P$ is defined recursively as $\hat{h}(\sigma(s_1, \ldots, s_k)) = h_\sigma(\hat{h}(s_1), \ldots, \hat{h}(s_k))$ for every $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k$. For every $p \in P$ we define the subset L_p of trees in T_Σ as $\{s \in T_\Sigma \mid \hat{h}(s) = p\}$. We assume that $L_p \neq \emptyset$ for every $p \in P$.

A (total deterministic) *macro tree transducer with (regular) look-ahead* ("mttr") M is given by a tuple $(Q, P, \Sigma, \Delta, q_0, R, h)$, where

- Q is a ranked alphabet of *states*,
- Σ and Δ are ranked alphabet of *input* and *output symbols*,
- (P, Σ, h) is a tree automaton (called the *look-ahead automaton* of M),
- $q_0 \in Q^{(0)}$ is the *initial state*, and
- R is the *set of rules*, where for each $q \in Q^{(m)}$, $m \geq 0$, $\sigma \in \Sigma^{(k)}, k \geq 0$, and $p_1, \ldots, p_k \in P$ there is exactly one rule of the form

  $$\langle q, \sigma(x_1 : p_1, \ldots, x_k : p_k)\rangle(y_1, \ldots, y_m) \to t$$

  with $t \in T_{\Delta \cup \langle Q, X_k\rangle}(Y_m)$.
  The right-hand side t of such a rule is denoted by $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$

We use a notation that is slightly different from the one used in the Introduction: instead of, e.g., $q_2(x_2, q_{\mathrm{id}}(x_1))$ we write $\langle q_2, x_2\rangle(\langle q_{\mathrm{id}}, x_1\rangle)$. Thus, we use angular brackets $\langle\ldots\rangle$ to indicate a state call on an input subtree, and use round brackets (after the angular brackets), to indicate the parameter arguments of the particular state call.

The semantics of an mttr M (as above) is defined as follows. We define the derivation relation $\Rightarrow_M$ as follows. For two trees $\xi_1, \xi_2 \in T_{\Delta\cup\langle Q,T_\Sigma\rangle}(Y)$, $\xi_1 \Rightarrow_M \xi_2$ if there exists a node u in ξ_1 with $\xi_1/u = \langle q, s\rangle(t_1, \ldots, t_m)$, $q \in Q^{(m)}$, $m \geq 0$, $s = \sigma(s_1, \ldots, s_k)$, $\sigma \in \Sigma^{(k)}$, $k \geq 0$, $s_1, \ldots, s_k \in T_\Sigma$, $t_1, \ldots, t_m \in T_{\Delta\cup\langle Q,T_\Sigma\rangle}(Y)$, and $\xi_2 = \xi_1[u \leftarrow \xi]$ where ξ equals

$$\zeta[\![\langle q', x_i\rangle \leftarrow \langle q', s_i\rangle \mid q' \in Q, i \in [k]]\!][y_j \leftarrow t_j \mid j \in [m]]$$

and $\zeta = \mathrm{rhs}_M(q, \sigma, \langle \hat{h}(s_1), \ldots, \hat{h}(s_k)\rangle)$. Since M is total deterministic (i.e., for every state q, input symbol $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and look-ahead states $p_1, \ldots, p_k$, M contains exactly one corresponding rule) there is for every ξ_1 a unique tree $\xi' \in T_\Delta(Y)$ such that $\xi_1 \Rightarrow_M^* \xi'$. For every $q \in Q^{(m)}$, $m \geq 0$ and $s \in T_\Sigma$ we define the *q-translation of s*, denoted by $M_q(s)$, as the unique tree t in $T_\Delta(Y_m)$ such that $\langle q, s\rangle(y_1, \ldots, y_m) \Rightarrow_M^* t$. We denote the *translation realized by M* also by M, i.e., $M = M_{q_0}$ and for every $s \in T_\Sigma$, $M(s) = M_{q_0}(s)$ is the unique tree $t \in T_\Delta$ such that $\langle q_0, s\rangle \Rightarrow_M^* t$.

Let M be an mttr as before. We define *the extension $\widehat{M}$ of M* which can also process look-ahead states at leaves of input trees. Let $\widehat{M} = (Q, P, \hat{\Sigma}, \hat{\Delta}, q_0, R \cup \hat{R}, h \cup h')$ where $\hat{\Sigma} = \Sigma \cup \{p^{(0)} \mid p \in P\}$ and $\hat{\Delta} = \Delta \cup \{\langle q, p\rangle^{(m)} \mid q \in Q^{(m)}, p \in P, m \geq 0\}$. For every $q \in Q^{(m)}$, $m \geq 0$, and $p \in P$ we let $h(p) = p$ and we let the rule $\langle q, p\rangle(y_1, \ldots, y_m) \to \langle q, p\rangle(y_1, \ldots, y_m)$ be in $\hat{R}$; note that the $\langle q, p\rangle$ on the right-hand side of this rule is an output symbol. For the original transducer M we say that the pair (q, p) is *reachable (in M)* if there is an input tree $s \in T_{\hat{\Sigma}}$ such that $\langle q, p\rangle$ occurs in $\widehat{M}(s)$. Clearly it is decidable for a given pair (q, p), whether or not it is reachable; this is because (1) inverse translations of mttrs effectively preserve regularity [13, 22], (2) the set of all trees in $T_{\hat{\Delta}}$ that contain at least one occurrence of $\langle q, p\rangle$ is (effectively) regular, and (3) emptiness of regular tree languages is decidable [4].

We say that M is *nondeleting*, if for every state $q \in Q^{(m)}$, $\sigma \in \Sigma^{(k)}, k \geq 0$, $p_1, \ldots, p_k \in P$, and $j \in [m]$, there is at least one occurrence of y_j in $\mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$. The next proposition is proved in [9, Lemma 6.7] (for mttrs that do not copy parameters, but the proof works analogously for arbitrary mttrs).

▶ **Proposition 1.** *For every mttr, an equivalent nondeleting mttr M can be constructed. For every state q of a nondeleting mttr M of rank m and for every $j \in [m]$: $M_q(s)$ contains at least one occurrence of y_j, for every $s \in T_\Sigma$.*

It is well known that the finiteness of ranges of compositions of mttrs is decidable [5]. A (partial nondeterministic) top-down tree transducer with look-ahead ("topr" for short) is an mttr as before, where $Q = Q^{(0)}$ and R may contain none or several rules for each given q and σ.

▶ **Proposition 2.** *([5, Theorem 4.5]) For a given composition of mttrs and (partial nondeterministic) toprs it is decidable whether or not the range of the composition is finite. In the case of finiteness, the range can be constructed.*

3 Depth Proper Normal Form

The depth proper normal form requires that each parameter of each state q occurs at unbounded depth in the output trees of that state (for each given look-ahead state p such that (q, p) is reachable). Formally, let q be a state of rank $m \geq 1$, $j \in [m]$, and $p \in P$. If

(q,p) is reachable, then for every natural number n there must exist an input tree $s_n \in L_p$ such that y_j occurs at depth $> n$ in the tree $M_q(s_n)$. Conversely, we say that parameter y_j is *depth-bounded* for q and p if there exists an n for which no such input tree $s_n \in L_p$ exists; more generally, we say that $Z \subseteq Y_m$ is *depth-bounded* for q and p, if each $y \in Z$ is depth-bounded for q and p.

If Z is depth-bounded for q and p, then there are only finitely many output paths in the trees in $M_q(L_p)$ under which the parameters from Z occur. The *Z-skeleton* of an arbitrary tree t is obtained from t by replacing each top-most node u such that t/u does not contain any occurrence of a parameter from Z by some symbol. Clearly, Z is depth-bounded for q and p if and only if the Z-skeleta of all trees in $M_q(L_p)$ form a finite set.

Let Δ be an arbitrary ranked alphabet, $m \geq 1$, $t \in T_\Delta(Y_m)$, and $Z \subseteq Y_m$. Let us write $\mathsf{ps}(t) \subseteq Y_m$ for the set of parameters occurring in t. Let us now be more specific as to which symbols replace the top-most nodes u of t such that $\mathsf{ps}(t/u) \cap Z = \emptyset$. Since in our construction later we will want to obtain a transducer that is nondeleting, it will be helpful to know which parameters appear in a given deleted tree. Therefore we replace such nodes u by the set $\mathsf{ps}(t/u)$. We denote by $\lfloor t \rfloor_Z$ the Z-skeleton of t and define it inductively as follows (where $\delta \in \Delta$):

$$\lfloor t \rfloor_Z = \begin{cases} t & \text{if } t \in Z \\ \delta(\lfloor t_1 \rfloor_Z, \ldots, \lfloor t_n \rfloor_Z) & \text{if } \mathsf{ps}(t) \cap Z \neq \emptyset \text{ and } t = \delta(t_1, \ldots, t_n) \\ \mathsf{ps}(t) & \text{if } \mathsf{ps}(t) \cap Z = \emptyset. \end{cases}$$

The definition of $\lfloor t \rfloor_Z$ is extended to sets L of trees as $\lfloor L \rfloor_Z = \{\lfloor t \rfloor_Z \mid t \in L\}$. We call *$Y$-nodes* the nodes u in $V(\lfloor t \rfloor_Z)$ such that $\lfloor t \rfloor_Z / u = Z' \subseteq Y_m$. We denote by $\mathcal{U}(\lfloor t \rfloor_Z)$ the set of Y-nodes on $\lfloor t \rfloor_Z$. The notion of parameters in a tree naturally extends to Z-skeleta with, for a Y-node labeled Z': $\mathsf{ps}(Z') = Z'$. The proof of the next lemma is straightforward by induction on t (see full version of this paper: Lemma 3 in [18]).

▶ **Lemma 3.** *Let Δ be a ranked alphabet, $m \geq 1$, $Z \subseteq Y_m$, and $t \in T_\Delta(Y_m)$. (1) $t = \lfloor t \rfloor_Z [u \leftarrow t/u \mid u \in \mathcal{U}(\lfloor t \rfloor_Z)]$. (2) $\mathsf{ps}(\lfloor t \rfloor_Z) = \mathsf{ps}(t)$.*

Finally, we define depth properness for mtts with look-ahead.

▶ **Definition 4.** *The mttr $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ is in* depth proper normal form *(or, synonymously, M is* depth proper*) if for every $q \in Q^{(m)}$, $m \geq 1$, and $p \in P$ it holds that if (q,p) is reachable, then $\lfloor M_q(L_p) \rfloor_{\{y_j\}}$ is infinite for all $j \in [m]$.*

From now on we will want to make use of the following definitions:

$$\begin{aligned} F_p &= \{q \in Q^{(m)} \mid \exists j \in [m], \lfloor M_q(L_p) \rfloor_{\{y_j\}} \text{ is finite}\} \\ Y(q,p) &= \{y_j \mid j \in [\mathrm{rank}_Q(q)] \text{ such that } \lfloor M_q(L_p) \rfloor_{\{y_j\}} \text{ is finite}\} \end{aligned}$$

It should be clear that $\lfloor M_q(L_p) \rfloor_{Y(q,p)}$ is finite for every q and p, as stated in the next lemma (the proof is in the full version: Lemma 5 in [18]).

▶ **Lemma 5.** *Let M be an mtt, q a state of M, and p a look-ahead state of M. Then $\lfloor M_q(L_p) \rfloor_{Y(q,p)}$ is finite.*

3.1 Construction of the Normal Form and Examples

Let M be an mttr as before. We assume that M is nondeleting (which is justified by Proposition 1). The idea of the construction is as follows. First, we determine all reachable pairs (q,p) such that $Y(q,p) \neq \emptyset$. Let (q,p) be such a pair and let $Z = Y(q,p)$. An occurrence of $\langle q, x_i\rangle$ in a right-hand side $\mathrm{rhs}_M(q', \sigma, \langle p_1, \ldots, p_k\rangle)$ such that $p_i = p$ is called a (q,p)-*call*. Our aim is to replace each (q,p)-call by an appropriate tree from $\lfloor M_q(L_p)\rfloor_Z$. Just which tree is the appropriate one will be determined by regular look-ahead. Moreover, such trees should be modified not to contain leaf nodes labeled by subsets of Y: such nodes will be replaced by calls of new "helper states".

▶ **Definition 6.** *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be a nondeleting mttr that is not depth proper. We construct the new mttr $\pi(M) = (Q \cup H, P', \Sigma, \Delta, q_0, R', h')$. For every $q \in Q^{(m)}$ and $p \in P$ such that $Y(q,p) \neq \emptyset$, H contains the following set of helper states:*

$$\{[q,p,t,u]^{(|U|)} \mid t \in \lfloor M_q(L_p)\rfloor_{Y(q,p)}, u \in V(t), t/u = U \subseteq Y_m\}$$

and P' contains (p,φ) for any function φ that assigns to each $q \in F_p$ a tree in $\lfloor M_q(L_p)\rfloor_{Y(q,p)}$. Observe that H and P' are well defined, because $\lfloor M_q(L_p)\rfloor_{Y(q,p)}$ is finite by Lemma 5. Note that $|U| \leq |Y_m \setminus Y(q,p)|$; since $Y(q,p)$ is non-empty this implies that the rank of each helper state is at most $(r-1)$, where r is the maximal rank of the states in Q.

For every $q \in Q^{(m)}$, $m \geq 0$, $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $(p_1,\varphi_1), \ldots, (p_k,\varphi_k) \in P'$ we let the rule

$$\langle q, \sigma(x_1 : (p_1,\varphi_1), \ldots, x_k : (p_i,\varphi_i)\rangle(y_1, \ldots, y_m) \to rhs_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)[\![.]\!]$$

be in R', where the second-order tree substitution $[\![.]\!]$ is defined as follows.

$$[\![.]\!] = [\![\langle q', x_i\rangle \leftarrow \varphi_i(q')\big[u \leftarrow [q', p_i, \varphi_i(q'), u](y_{j_1}, \ldots, y_{j_n}) \mid \varphi_i(q')/u = \{y_{j_1}, \ldots, y_{j_n}\}, j_1 < \cdots < j_n\big] \mid q' \in F_{p_i}, i \in [k]]\!].$$

We define $h'_\sigma((p_1,\varphi_1), \ldots, (p_k,\varphi_k)) = (p,\varphi)$ where $p = h_\sigma(p_1, \ldots, p_k)$ and, using the special second-order substitution $[\![\ldots]\!]^{\$}$ from Definition 8, for every $q \in F_p$,

$$\varphi(q) = \Big\lfloor rhs_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)[\![\langle q', x_i\rangle \leftarrow \varphi_i(q') \mid q' \in F_{p_i}, i \in [k]]\!]^{\$}\Big\rfloor_{Y(q,p)}.$$

The special second-order substitution $[\![\ldots]\!]^{\$}$ is the same as the normal one except that the special first-order substitution is applied for each involved first-order substitution. The special first-order substitution is the same as the normal one except that it gives special treatment to Y-nodes which are replaced by Y-nodes containing all parameters occurring in trees to be substituted for the parameters in the original Y-nodes.

Note that, when $L_p \neq \emptyset$ for all $p \in P$, then $L_{(p,\phi)} \neq \emptyset$ for all $(p,\phi) \in P'$. For every helper state $[q,p,t,u] \in H^{(n)}$, $n \geq 0$, $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $(p_1,\varphi_1), \ldots, (p_k,\varphi_k) \in P'$ such that $h_\sigma(p_1, \ldots, p_k) = p$ we let the rule

$$\langle [q,p,t,u](\sigma(x_1 : (p_1,\varphi_1), \ldots, x_k : (p_k,\varphi_k))\rangle(y_1, \ldots, y_n) \to \xi/u[y_{j_\nu} \leftarrow y_\nu \mid \nu \in [n]]$$

be in R' where $t/u = \{y_{j_1}, \ldots, y_{j_n}\}$, $j_1 < \cdots < j_n$, $\xi = rhs_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)[\![.]\!]$, and $[\![.]\!]$ is the substitution from above.

We now show how the depth proper normal form is achieved using an example. An additional example (which makes more interesting use of helper states) can be found in the full version of this paper: at page 21 in [18]. Let $M = (Q, \{p\}, \Sigma, \Delta, q_0, R, h_0)$ with $Q = \{q_0^{(0)}, q_1^{(1)}, q_2^{(2)}\}$, $\Sigma = \{a^{(1)}, b^{(1)}, e^{(0)}\}$, and $\Delta = \{f^{(2)}, g^{(1)}, e^{(0)}\}$ be an mttr where $(\Sigma, \{p\}, h_0)$ with $L_p = T_\Sigma$ and R consists of these rules:

$$\begin{aligned}
\langle q_1, a(x)\rangle(y_1) &\to \langle q_2, x\rangle(y_1, \langle q_1, x\rangle(y_1)) & \langle q_2, a(x)\rangle(y_1, y_2) &\to f(y_1, \langle q_1, x\rangle(g(y_2)))\\
\langle q_1, b(x)\rangle(y_1) &\to y_1 & \langle q_2, b(x)\rangle(y_1, y_2) &\to f(y_2, y_1)\\
\langle q_1, e\rangle(y_1) &\to g(y_1) & \langle q_2, e\rangle(y_1, y_2) &\to f(y_2, y_1)
\end{aligned}$$

We suppose that the q_0-rules are defined so that all states are reachable. Now we have $F_p = \{q_2\}$, $Y(q_2, p) = \{y_1\}$, and $\lfloor M_{q_2}(L_p)\rfloor_{\{y_1\}} = \{t_1, t_2\}$ with $t_1 = f(y_1, \{y_2\})$ and $t_2 = f(\{y_2\}, y_1)$. As before, we can rewrite q_2-calls with the skeleta, but since there are two possibilities t_1 and t_2, we need to separate the rules according to the input using the look-ahead. In general, F_p contains several states each of which may have multiple skeleta, so each look-ahead contains a finite map from F_p to skeleta. Let $\varphi_1 = \{q_2 \mapsto t_1\}$ and $\varphi_2 = \{q_2 \mapsto t_2\}$ such that $L_{p,\varphi_1} = \{a(s) \mid s \in \mathcal{T}_\Sigma\}$ and $L_{p,\varphi_2} = \{b(s) \mid s \in \mathcal{T}_\Sigma\} \cup \{e\}$. The (q_1, a)-rule containing a q_2-call is separated as

$$\begin{aligned}
\langle q_1, a(x : (p, \varphi_1))\rangle(y_1) &\to f(y_1, \langle [q_2, p, t_1, 2], x\rangle(\langle q_1, x\rangle(y_1)))\\
\langle q_1, a(x : (p, \varphi_2))\rangle(y_1) &\to f(\langle [q_2, p, t_2, 1], x\rangle(\langle q_1, x\rangle(y_1)), y_1)
\end{aligned}$$

where $[q_2, p, t_1, 2]$ and $[q_2, p, t_2, 1]$ are helper states. Each helper state has rank 1 because the corresponding node in the skeleton is a Y-node of length 1. The arguments of the call are inherited from the arguments of the original q_2-call that occur in the sequence. For example, $\langle [q_2, p, t_1, 2], x\rangle$ is called with $\langle q_1, x\rangle(y_1)$ since t_1 has a Y-node $\{y_2\}$ and the original q_2-call has $\langle q_1, x\rangle(y_1)$ as the second argument. The rules of these helper states are constructed from the original q_2-rule with substitution (which causes nothing since no states in F_p are called) and extracting a subtree at the Y-node, that is,

$$\begin{aligned}
\langle [q_2, p, t_1, 2], a(x : (p, \varphi))\rangle(y_1) &\to \langle q_1, x\rangle(g(y_1))\\
\langle [q_2, p, t_2, 1], b(x : (p, \varphi))\rangle(y_1) &\to y_1\\
\langle [q_2, p, t_2, 1], e\rangle(y_1) &\to y_1
\end{aligned}$$

where $\varphi \in \{\varphi_1, \varphi_2\}$ and we had to rename the parameter y_2 into y_1 (because the helper states only refer to y_2). Note that rules for $([q_2, p, t_1, 2], b)$, $([q_2, p, t_1, 2], e)$ and $([q_2, p, t_2, 1], a)$ do not have to be considered. These rules are not referred because the states are never called with the input symbols due to their look-ahead. For example, the $[q_2, p, t_1, 2]$-call occurs only in the (q_1, a)-rule with $x \in L_{p,\varphi_1}$ in which the root symbol cannot be b.

Thereby we have been able to remove every call of states in F_p. However, new improper states may be generated by the separation of rules because of the look-ahead introduction. In fact, we have $F_{p,\varphi_2} = \{q_1, q_2, [q_2, p, t_2, 1]\}$ in the example above. Since every q_2-call has already been removed in the previous step, we have to apply the same technique again for the calls of q_1 and $[q_2, p, t_2, 1]$. We have $Y(q_1, (p, \varphi_2)) = \{y_1\}$ and $Y([q_2, p, t_2, 1], (p, \varphi_2)) = \{y_1\}$. Moreover $\left\lfloor M'_{q_1}(L_{p,\varphi_2})\right\rfloor_{\{y_1\}} = \{y_1, g(y_1)\}$ and $\left\lfloor M'_{[q_2,p,t_2,1]}(L_{p,\varphi_2})\right\rfloor_{\{y_1\}} = \{y_1\}$.

Look-ahead has to be introduced to determine which skeleton to output. Two maps over F_{p,φ_2}, except for q_2 whose call has already been removed, are defined: $\varphi_3 = \{q_1 \mapsto y_1, [q_2, p, t_2, 1] \mapsto y_1\}$ and $\varphi_4 = \{q_1 \mapsto g(y_1), [q_2, p, t_2, 1] \mapsto y_1\}$ such that $L_{p,\varphi_2,\varphi_3} = \{b(s) \in L_{p,\varphi_2} \mid s \in \mathcal{T}_\Sigma\}$ and $L_{p,\varphi_2,\varphi_3} = \{e\}$. The (q_1, a)- and $([q_2, p, t_1, 2], a)$-rules with look-ahead φ_2 which contains a q_2-call are separated as follows:

$$\begin{array}{lcl}
\langle q_1, a(x:(p,\varphi_2,\varphi_3))\rangle(y_1) & \to & f(y_1,y_1)\\
\langle [q_2,p,t_1,2], a(x:(p,\varphi_2,\varphi_3))\rangle(y_1) & \to & g(y_1)\\
\langle q_1, a(x:(p,\varphi_2,\varphi_4))\rangle(y_1) & \to & f(g(y_1),y_1)\\
\langle [q_2,p,t_1,2], a(x:(p,\varphi_2,\varphi_4))\rangle(y_1) & \to & g(g(y_1))
\end{array}$$

The resulting mttr is depth proper.

3.2 Correctness Proof and Termination of Iteration

Here we prove the correctness of transducer $\pi(M)$ that was defined in Definition 4. Lemma 7 establishes the correctness of the look-ahead, relates the states of $\pi(M)$ to those of M, and shows that the transducer $\pi(M)$ is nondeleting. The latter is needed, so that the construction of π can be carried out iteratively (recall from Definition 4 that M is required to be nondeleting in order to construct $\pi(M)$). To prove Point (2) we use a "special" kind of second-order tree substitution which replaces Y-nodes by new Y-nodes consisting of parameters in the output trees that would have been substituted for the parameters in the original Y-node (Definition 8).

▶ **Lemma 7.** *Let M be a nondeleting mttr and $N = \pi(M)$ be the mttr of Definition 6, both with the tuples as in that definition. Let $s \in T_\Sigma$ with $\hat{h}'(s) = (p,\varphi)$.*
(1) *$p = \hat{h}(s)$,*
(2) *$\forall q \in F_p$: $\varphi(q) = \lfloor M_q(s) \rfloor_{Y(q,p)}$,*
(3) *$\forall q \in Q$: $N_q(s) = M_q(s)$,*
(4) *$\forall q \in F_p$ and $u \in V(t)$ with $t = \varphi(q)$ and $t/u = \{y_{j_1}, \dots, y_{j_n}\}$ with $j_1 < \cdots < j_n$: $N_{[q,p,t,u]}(s) = M_q(s)/u[y_{j_\nu} \leftarrow y_\nu \mid \nu \in [n]]$, and*
(5) *the mttr N is nondeleting.*

We first need a small lemma showing that the skeleton of the output of an mttr M can be directly computed from given a input tree by modifying the rules of M. For this lemma we first need to define how to compute second-order substitutions of skeleta, which will be used for the modification of the right-hand sides of rules. We do so on a *nondeleting* mttr M, i.e. such that states always use all their parameters.

▶ **Definition 8.** *Let Γ be a ranked alphabet and let $t_1, \dots, t_n \in T_\Gamma(Y)$. Let $s \in T_\Gamma(Y_n \cup \mathcal{P}(Y_n))$. The* special first-order substitution $[y_i \leftarrow t_i \mid i \in [n]]^{\$}$ *(for short $[.]^{\$}$) applied to s is inductively defined as:*

$$s[.]^{\$} = \begin{cases} t_i & \text{if } s = y_i \text{ for } i \in [n] \\ \gamma(s_1[.]^{\$}, \dots, s_k[.]^{\$}) & \text{if } s = \gamma(s_1, \dots, s_k) \\ \bigcup_{i \in U} \mathsf{ps}(t_i) & \text{if } s = \{y_i \mid i \in U\} \subseteq Y_n \text{ for some } U \subseteq [n]. \end{cases}$$

Let $\gamma_1^{(k_1)}, \dots, \gamma_n^{(k_n)} \in \Gamma$, $n \geq 1$ be pairwise different symbols and assume now that $t_i \in T_\Gamma(Y_{k_i} \cup \mathcal{P}(Y_{k_i}))$ for $i \in [n]$ and that $s \in T_\Gamma(Y_n)$. The special second-order substitution $[\![\gamma_i \leftarrow t_i \mid i \in [n]]\!]$ *(for short $[\![.]\!]^{\$}$) applied to s is inductively defined as:*

$$s[\![.]\!]^{\$} = \begin{cases} t_i[y_j \leftarrow s_j[\![.]\!]^{\$} \mid j \in [k_i]]^{\$} & \text{if } s = \gamma_i(s_1, \dots, s_{k_i}) \text{ for } i \in [n] \\ \gamma(s_1[\![.]\!]^{\$}, \dots, s_k[\![.]\!]^{\$}) & \text{if } s = \gamma(s_1, \dots, s_k) \text{ with } \gamma \notin \{\gamma_1, \dots, \gamma_n\} \\ s & \text{if } s = y_j \text{ for } j \in [n]. \end{cases}$$

For all sets $Z \subseteq Y_m$ such that no Y-node in $t[\![.]\!]^{\$}$ intersects Z, we define the Z-skeleton $\lfloor t[\![.]\!]^{\$} \rfloor_Z$ of $t[\![.]\!]^{\$}$ inductively as before, with a special case for Y-nodes: for all Y-nodes S we have $\lfloor S \rfloor_Z = S \subseteq Y_m \setminus Z$.

▶ **Lemma 9.** *Let M be a nondeleting mttr as before. Let $q \in Q$, $\sigma \in \Sigma^{(k)}$, and $p_1, \ldots, p_k \in P$. Let $p = h(\sigma(p_1, \ldots, p_k))$ and $t = rhs_M(q, \sigma, \langle p_1, \ldots, p_k \rangle)$. Let $s_1 \in L_{p_1}, \ldots, s_k \in L_{p_k}$. By $[\![.]\!]^{\$}$ we denote the substitution $[\![\langle q', x_i \rangle \leftarrow \lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)} \mid q' \in Q, i \in [k]]\!]^{\$}$ and by $[\![M]\!]$ we denote $[\![\langle q', x_i \rangle \leftarrow M_{q'}(s_i) \mid q' \in Q, i \in [k]]\!]$.*

(1) If $y \in Y(q,p)$ and y occurs in t in the j-th argument of a node $\langle q', x_i \rangle$ for $q' \in Q$ and $i \in [k]$, then $y_j \in Y(q', p_i)$.

(2) No Y-node in $t[\![.]\!]^{\$}$ intersects $Y(q,p)$.

(3) $\lfloor t[\![.]\!]^{\$} \rfloor_{Y(q,p)} = \lfloor t[\![M]\!] \rfloor_{Y(q,p)}$

Proof. If some $y_j \notin Y(q', p_i)$ then $\lfloor M_{q'}(L_{p_i}) \rfloor_{y_j}$ is infinite and, if y occurs in t_j ($j \in [m]$), then $\lfloor M_q(L_p) \rfloor_y$ is also infinite and $y \notin Y(q,p)$. So (1) holds.

If $y \in Y(q,p)$ occurs in a Y-node of $t[\![.]\!]^{\$}$, then it occurs in t in the j-th argument of a node $\langle q', x_i \rangle$ with $y_j \notin Y(q', p_i)$, which contradicts (1). So (2) holds.

The statement (3) is proved by induction on t. The cases of $t = y_j$ and $t = \gamma(t_1, \ldots, t_n)$ are easy. In the case of $t = \langle q', x_i \rangle(t_1, \ldots, t_m)$, we have

$$\begin{aligned}
\left\lfloor t[\![.]\!]^{\$} \right\rfloor_{Y(q,p)} &= \left\lfloor \lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)} [y_j \leftarrow t_j[\![.]\!]^{\$} \mid j \in [m]]^{\$} \right\rfloor_{Y(q,p)} \\
&= \left\lfloor \lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)} [y_j \leftarrow t_j[\![M]\!] \mid j \in [m]]^{\$} \right\rfloor_{Y(q,p)} \\
&= \lfloor M_{q'}(s_i)[y_j \leftarrow t_j[\![M]\!] \mid j \in [m]] \rfloor_{Y(q,p)} \\
&= \lfloor t[\![M]\!] \rfloor_{Y(q,p)} .
\end{aligned}$$

◀

We can now prove Lemma 7:

Proof. All the statements are proven by induction on the structure of s. Let $s = \sigma(s_1, \ldots, s_k)$ with $\sigma \in \Sigma^{(k)}$, $k \geq 0$, and $s_1, \ldots, s_k \in T_\Sigma$. For $i \in [k]$ let $\hat{h}'(s_i) = (p_i, \varphi_i)$. By the definition of h', $p = h_\sigma(p_1, \ldots, p_k)$, which is equal to $\hat{h}(s)$. Thus, Statement (1) holds. For Statement (2) let $q \in F_p$: Then $\varphi(q)$ is defined as $\lfloor \zeta[\![\varphi_i]\!]^{\$} \rfloor_{Y(q,p)}$ where $\zeta = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k \rangle)$ and $[\![\varphi_i]\!]^{\$}$ denotes the special substitution $[\![\langle q', x_i \rangle \leftarrow \varphi_i(q') \mid q' \in F_{p_i}, i \in [k]]\!]^{\$}$. By induction, $\lfloor \zeta[\![\varphi_i]\!]^{\$} \rfloor_{Y(q,p)}$ equals $\left\lfloor \zeta[\![\langle q', x_i \rangle \leftarrow \lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)} \mid q' \in F_{p_i}, i \in [k]]\!]^{\$} \right\rfloor_{Y(q,p)}$. By Lemma 9(3) the latter equals $\lfloor \zeta[\![\langle q', x_i \rangle \leftarrow M_{q'}(s_i) \mid q' \in F_{p_i}, i \in [k]]\!] \rfloor_{Y(q,p)} = \lfloor M(s) \rfloor_{Y(q,p)}$.

We now prove Statement (3). Let $q \in Q$. Then $N_q(s) = \zeta[\![.]\!][\![N]\!]$, where $\zeta = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k \rangle)$, $[\![.]\!]$ is the substitution as in the construction, and $[\![N]\!] = [\![\langle r, x_i \rangle \leftarrow N_r(s_i) \mid r \in Q', i \in [k]]\!]$. By the induction hypothesis of Statement (2), we can replace $\varphi_i(q')$ by $\lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)}$ in the substitution $[\![.]\!]$. This gives

$$\begin{aligned}
\zeta[\![\langle q', x_i \rangle \leftarrow \lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)} [u' \leftarrow [q', p_i, \varphi_i(q'), u'](y_{j_1}, \ldots, y_{j_n}) \mid \\
\varphi_i(q')/u' = \{y_{j_1}, \ldots, y_{j_n}\}, j_1 < \cdots < j_n] \mid q' \in F_{p_i}, i \in [k]]\!][\![N]\!].
\end{aligned}$$

This can be written as $\zeta[\![.]\!][\![H]\!][\![Q]\!]$, where $[\![H]\!] = [\![\langle q', x_i \rangle \leftarrow N_{q'}(s_i) \mid q' \in H, i \in [k]]\!]$ and $[\![Q]\!] = [\![\langle q', x_i \rangle \leftarrow N_{q'}(s_i) \mid q' \in (Q \setminus F_{p_i}), i \in [k]]\!]$. By induction of Statement (4) the substitution $[\![H]\!]$ replaces the subtree $[q', p_i, \varphi_i(q'), u'](y_{j_1}, \ldots, y_{j_n})$ by the tree $M_{q'}(s_i)/u[y_{j_\nu} \leftarrow y_\nu \mid \nu \in [n]][y_\nu \leftarrow y_{j_\nu} \mid \nu \in [n]] = M_{q'}(s_i)/u$. Thus we obtain:

$$\begin{aligned}
\zeta[\![\langle q', x_i \rangle \leftarrow \lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)} [u' \leftarrow M_{q'}(s_i)/u' \mid u' \in \mathcal{U}(\lfloor M_{q'}(s_i) \rfloor_{Y(q',p_i)})] \\
\mid q' \in F_{p_i}, i \in [k]]\!][\![Q]\!]
\end{aligned}$$

By Lemma 3 (for $Z = Y(q', p_i)$ and $t = M_{q'}(s_i)$) the tree on the right of the arrow in the leftmost second-order substitution equals $M_{q'}(s_i)$. We have:

$$\zeta[\![\langle q', x_i\rangle \leftarrow M_{q'}(s_i) \mid q' \in F_{p_i}, i \in [k]]\!][\![\langle q', x_i\rangle \leftarrow N_{q'}(s_i) \mid q' \in Q \setminus F_{p_i}, i \in [k]]\!].$$

By induction of Statement (3), $N_{q'}(s_i) = M_{q'}(s_i)$ for $q \in Q \setminus F_{p_i}$. This gives us exactly $M_q(s)$, by the definition of the semantics of mttrs. Thus,

$$N_q(s) = \zeta[\![.]\!][\![N]\!] = M_q(s). \tag{1}$$

This concludes the proof of Statement (3).

We now prove Statement (4). Let $q \in F_p$ and $u \in V(t)$ with $t = \varphi(q)$ and $t/u \subseteq Y$. By the definition of the rules for the helper states, $N_{[q,p,t,u]}(s) = (\zeta[\![.]\!])/u[\![N]\!][y]$ where $t/u = \{y_{j_1}, \ldots, y_{j_n}\}$, $j_1 < \cdots < j_n$, and $[y] = [y_{j_\nu} \leftarrow y_\nu \mid \nu \in [n]]$. It follows from Lemma 9(1) that if $\langle q', x_i\rangle$ occurs in $\zeta = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $q \in F_p$, then $q' \notin Q \setminus F_{p_i}$. Hence, every proper ancestor v of u is labeled by a symbol in Δ, i.e., $(\zeta[\![.]\!][y])[v] \in \Delta$. This implies that we can move the "$/u$" operation of taking the subtree at node u to the right (after the application of the substitution $[\![N]\!]$) in the above displayed formula. We obtain $\zeta[\![.]\!][\![N]\!]/u[y]$. By the right equation in Formula 1, this equals $M_q(s)/u[y]$.

To prove Statement (5), let $q \in Q^{(m)}$, $m \geq 0$. Then

$$\zeta' = \mathrm{rhs}_N(q, \sigma, \langle (p_1, \varphi_1), \ldots, (p_k, \varphi_k)\rangle) = \zeta[\![.]\!],$$

where $\zeta = \mathrm{rhs}_M(q, \sigma, \langle p_1, \ldots, p_k\rangle)$ and $[\![.]\!]$ is as before. By Statement (2), $[\![.]\!]$ substitutes occurrences of $\langle q', x_i\rangle$ with $i \in [k]$ and $q' \in F_{p_i}$ by the tree $\lfloor M_{q'}(s_i)\rfloor_{Y(q',p_i)}$ in which leaves labeled by $Z \subseteq Y_m$ are replaced by $\langle q_H, x_i\rangle(y_{j_1}, \ldots, y_{j_n})$ with $Z = \{y_{j_1}, \ldots, y_{j_n}\}$. By Lemma 3(2) this implies that y_j occurs in ζ' for each $j \in [m]$. ◀

We show that the iteration of the construction $\pi(M)$ will terminate with a transducer that is depth proper. First, let us discuss what property a single iteration of π ensures. Let $p \in P$. Note that the set F_p is defined independently of reachability, i.e., F_p may contain states q such that (q, p) is *not* reachable. Let φ such that $(p, \varphi) \in P'$. Then $F_p \subseteq F_{(p,\varphi)}$. This inclusion follows from Lemma 7 as follows: let $s \in L_{(p,\varphi)}$ and let $q \in F_p$ be of rank m. The latter means that there exists a $j \in [m]$ and a number n such that every occurrence of y_j in $M_q(s')$ is at depth $\leq n$ for every $s' \in L_p$. By Lemma 7 (1), $s \in L_p$ and by Lemma 7 (3), $N_q(s) = M_q(s)$. Thus, every occurrence of y_j in $N_q(s)$ also occurs at depth $\leq n$. So $q \in F_{(p,\varphi)}$.

We now consider reachability. We say that a state q is *depth proper*, if for all $p \in P$ such that (q, p) is reachable, $q \notin F_p$. If $q \in F_p$, then for all φ such that $(p, \varphi) \in P'$ it holds that $(q, (p, \varphi))$ is not reachable. This property follows immediately from the definition of look-ahead and the rules of $\pi(M)$: the substitution $[\![.]\!]$ replaces each state call $\langle q', x_i\rangle$ with $q \in F_{p_i}$ by a tree that does not contain states of Q. So, if $(q, (p, \varphi))$ is reachable, then $q \notin F_p$; however, it may be that $q \in F_{(p,\varphi)}$, which means that q is not depth proper. It means that if $F_{(p,\varphi)} = F_p$ for all $(p, \varphi) \in P'$, then all states $q \in Q$ are depth proper. Let $Q_0 = Q$ and consider now the iterated application of π. Clearly, after some iterations of π, it will hold that $F_{(p,\varphi)} = F_p$ for all $(p, \varphi) \in P'$. To see this, consider the chain of inclusions

$$F_p \cap Q_0 \subseteq F_{(p,\varphi_1)} \cap Q_0 \subseteq \cdots \subseteq F_{(p,\varphi_1,\ldots,\varphi_k)} \cap Q_0 \subseteq \ldots$$

for any maps φ_i introduced in the look-ahead of $\pi^i(M)$. Since Q_0 is finite, the chain contains only finitely many strict inclusions. Hence there is a minimal n such that $F_{(p,\varphi_1,\ldots,\varphi_n)} \cap Q_0 = F_{(p,\varphi_1,\ldots,\varphi_{n'})} \cap Q_0$ for all $n' > n$.

Consider a tree with an artificial root node which contains all such chains, i.e., for each $p \in P$ there is exactly one child of the root node labeled F_p, and a node labeled F_p has children labeled $F_{(p,\varphi)}$ for each $(p,\varphi) \in P'$, etc. Moreover, a node labeled $F_{(p,\varphi_1,\ldots,\varphi_n)}$ as in the chain above is a leaf of this tree. Since each node of this tree is finitely branching (because P' is finite) and each path has finite length, we know by König's lemma that the tree is finite. Thus, if d is the depth of this tree, then for the mttr $M' = \pi^d(M)$, all states in Q_0 are depth proper.

Let m be the maximal rank of the states in Q_0. Since all helper states are of rank $< m$, we know that M' contains no improper states of rank $\geq m$. We now proceed in the same fashion and construct a transducer $M'' = \pi^{n'}(M')$ which contains no improper states of rank $\geq (m-1)$. In a similar way we eventually obtain an mttr for which *all states* are depth proper (and which is equivalent to M). Thus, even though we do not constructively derive a precise bound, we know that after *some* number of applications of π we are sure to obtain a depth proper mttr.

Before we state the main theorem of this section, we need the following lemma (the proof is a straightforward reduction to Proposition 2 and can be found in the full version of this paper: Lemma 8 in [18]).

▶ **Lemma 10.** *Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ be an mttr and let $q \in Q^{(m)}$, $m \in \mathbb{N}$, $j \in [m]$, and $p \in P$. It is decidable whether or not $\lfloor M_q(L_p) \rfloor_{\{y_j\}}$ is finite. In case of finiteness, $\lfloor M_q(L_p) \rfloor_{\{y_j\}}$ can be constructed.*

Since for a pair (q,p) it is decidable whether or not it is reachable (see Section 2.2), Lemma 10 implies that it is decidable whether or not a given mttr is depth proper.

▶ **Theorem 11.** *For every mttr M, we can construct an equivalent mttr M' such that M' is depth proper.*

Proof. There is a nondeleting mttr M_0 equivalent to M ([9] or Proposition 1). We repeatedly construct equivalent transducers $\pi(M)$, $\pi(\pi(M))$, etc. until a proper mttr is obtained (which is decidable by Lemma 10). The repetition terminates (first eliminating all reachable calls of improper states of the highest rank m, then those or rank $m-1$, etc.) as explained above. ◀

4 Linear Height and Linear Size-to-Height Increase

In this section we define the Linear Height and Linear Size-to-Height Increase properties. We then characterize and give decision algorithms for those properties by using the depth proper form.

Let Γ be a ranked alphabet and t be a tree over Γ. We define the size $|t|$ of a tree t as its number of nodes $|V(t)|$. The height $\mathsf{ht}(t)$ of t is defined as $\mathsf{ht}(t) = 0$ if $t \in \Gamma^{(0)}$ and $\mathsf{ht}(t) = 1 + \max\{\mathsf{ht}(t_i) \mid i \in [k]\}$ if $t = \gamma(t_1, \ldots, t_k)$ for $\gamma \in \Gamma^{(k)}$, $k \geq 1$, and $t_1, \ldots, t_k \in T_\Gamma$.

Let M be an mttr (with input ranked alphabet Σ). Then M has *linear size-to-height increase* (for short LSHI) if there exists a number c such that for every input tree $s \in T_\Sigma$: $\mathsf{ht}(M(s)) \leq c \cdot |s|$. The mttr M has *linear height increase* (for short LHI) if there exists a number c such that for every input tree $s \in T_\Sigma$: $\mathsf{ht}(M(s)) \leq c \cdot \mathsf{ht}(s)$.

We now introduce two additional properties for mttrs which will allow us to decide whether a given mttr has LSHI or LHI. Recall that $\widehat{M}$ denotes the extension of M: $\widehat{M}$ can translate input trees which may contain leaves that are labeled by elements from P (the set of look-ahead states of M). Whenever the state q of M, of rank m, encounters an input node u labeled by an element p of P, the transducer $\widehat{M}$ outputs $\langle q,p \rangle(y_1, \ldots, y_m)$. We call a tree in $s \in T_\Sigma(P)$ a Σ-*context* if it contains exactly one occurrence u of an element of P.

We say that the mttr M is *finite nesting* (for short fnest), if there exists a number c such that for every Σ-context s there are at most c-many occurrences of symbols $\langle q, p\rangle$ with $q \in Q$ on any path of the tree $\widehat{M}(s)$; in this case, we say that c is a *nesting bound* of M. We say that M is *finite yield nesting* (for short fynest), if there exists a number c such that for every input tree $s \in T_\Sigma(P)$ there are at most c-many occurrences of symbols from $\langle q, p\rangle$ with $q \in Q$ on any path of the tree $\widehat{M}(s)$; in this case, we say that c is a *yield nesting bound* of M. The proof of the next lemma is straightforward (by reduction to Proposition 2).

▶ **Lemma 12.** *Let M be an mttr. Then (1) it is decidable whether or not M is finite nesting and (2) it is decidable whether or not M is finite yield nesting.*

Proof. Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$. We use the extension $\widehat{M} = (\hat{Q}, P, \hat{\Sigma}, \hat{\Delta}, q_0, \hat{R}, h)$ of M with input trees in $s \in T_\Sigma(P)$ which contain (1) exactly one or (2) arbitrarily many occurrences of elements of P. We then use a nondeterministic top-down tree transducer N which chooses any path in the tree $\widehat{M}(s)$ and outputs only the elements from $\langle Q, P\rangle$ on that path, now seen as unary symbols. The resulting output language $N(\widehat{M}(T_\Sigma))$ is finite if and only if M is (1) fnest or (2) fynest.

Formally, $N = (\{q_1^{(0)}\}, \hat{\Delta}, \Gamma, q_1, R')$ where $\Gamma = \langle Q, P\rangle \cup \{e^{(0)}\}$. For every $\delta \in \Delta^{(k)}$, $k \geq 1$, and $i \in k$ we let the rule $\langle q_1, \delta(x_1, \ldots, x_k)\rangle \to \langle q_1, x_i\rangle$ be in R'. For every $\delta \in \Delta^{(0)}$ we let the rule $\langle q_1, \delta\rangle \to e$ be in R'. For every $\langle q, p\rangle \in \langle Q, P\rangle^{(m)}$, $m \geq 1$, and $i \in [m]$ we let the rule $\langle q_1, \langle q, p\rangle(x_1, \ldots, x_m)\rangle \to \langle q, p\rangle(\langle q_1, x_i\rangle)$ be in R'. For every $\langle q, p\rangle \in \langle Q, P\rangle^{(0)}$ we let the rule $\langle q_1, \langle q, p\rangle\rangle \to \langle q, p\rangle$ be in R'. It is straightforward to show (by induction on the structure of s), that $N(\widehat{M}(T_\Sigma(P)))$ is finite if and only if M is fynest. Let L be the set of trees in $T_\Sigma(P)$ which contain exactly one occurrence of an element of P. It is straightforward to show (by induction on the structure of s), that $N(\widehat{M}(L))$ is finite if and only if M is fnest. ◀

Informally the next lemma is easy to understand, e.g., for Statement (1), if M is finite nesting with bound c, then a single node of an input tree can only "contribute" at most $c \cdot \text{mhr}$ to the height of the output tree, where mhr denotes the maximum height of the right-hand side of any rule of the mttr.

▶ **Lemma 13.** *Let M be an mttr. (1) If M is finite nesting, then it is of linear size-to-height increase. (2) If M is finite yield nesting, then it is of linear height increase.*

Proof. Informally, we can understand this lemma by looking at a given path O in an output tree and, using origin semantics, at how many nodes along this path have their origin in different parts of the input tree.

For (1), the finite nesting property gives a bound c on the number of state calls to a single input node, nested along path O. Intuitively, noting mhr the maximum height of the right-hand side of a rule, $c \cdot \text{mhr}$ is a bound on the number of output nodes along path O with their origin in a single input node. This bound clearly implies that the height of the output (maximum number of nodes on a path) is linearly bounded by the size of the input.

For (2), instead of looking at a single input node, we look at all the input nodes at a given depth d in the input. The finite yield nesting property implies a bound c on the nesting (along a path O) of state calls to input nodes of depth d. Each such call may produce at most mhr nodes along path O with their origin in a node of depth d. So c.mhr is a bound for the number of nodes along path O with their origin in a node of depth d.

Formally, we apply $\widehat{M}$ to a tree $t \in T_\Sigma(P)$. We modify t by substituting nodes in P, and we bound the growth of the height of $\widehat{M}(t)$ for each substitution. We will conclude by stating that any input tree $s \in T_\Sigma$ can be built by successive substitutions, and so the height of the output is linearly bounded by the number of substitutions (which will be the size of s for (1), and the height of s for (2)). Let $M = (Q, P, \Sigma, \Delta, q_0, R, h)$ and let mhr be the maximum height of the right-hand side of any rule in R. Let s be a fixed tree in T_Σ.

To prove (1), consider an arbitrary set U of pairwise independent (i.e. not being descendants of each other) nodes of a fixed input tree $s \in T_\Sigma$. Let $s' = s[u \leftarrow h(s/u) \mid u \in U]$, let $u \in U$, and $\sigma = s[u] \in \Sigma^{(k)}$ with $k \geq 0$. Let c be a nesting bound for M, then, along any output path in $\widehat{M}(s')$, there are at most c state calls $\langle q, s'/u\rangle$ with origin u in s'. Then $\widehat{M}(s'[u \leftarrow \sigma(h(s/u1), \ldots, h(s/uk))])$ is obtained by replacing such state calls with the corresponding right-hand side of rules, which implies that: $\mathsf{ht}(\widehat{M}(s'[u \leftarrow \sigma(h(s/u1), \ldots, h(s/uk))])) \leq c \cdot \mathrm{mhr} + \mathsf{ht}(\widehat{M}(s'))$. The tree $s \in T_\Sigma$ can be obtained from the tree $h(s) \in T_\Sigma(P)$ by $|s|$ such substitutions. The height of $\widehat{M}(h(s)) = \langle q_0, h(s)\rangle$ is 0. So $\mathsf{ht}(M(s)) \leq c \cdot \mathrm{mhr} \cdot |s|$, so M of linear size-to-height increase.

To prove (2), for $i \in [\mathsf{ht}(s)]$, let U_i be the set of nodes at depth i in s, and let s_i be the tree obtained from s by replacing all nodes $u \in U_i$ by $h(s/u)$. Let c be a yield nesting bound for M, then, along any output path O in $\widehat{M}(s_i)$, there are at most c state calls $\langle q, s_i/u\rangle$ with $u \in U_i$. Then $\widehat{M}(s_{i+1}) = \widehat{M}(s_i[u \leftarrow \sigma_u(h(s/u1), \ldots, h(s/uk)) \mid u \in U_i])$ is obtained by replacing these state calls in $\widehat{M}(s_i)$ with the corresponding right-hand side of rules, so $\mathsf{ht}(\widehat{M}(s_{i+1})) \leq c \cdot \mathrm{mhr} + \mathsf{ht}(\widehat{M}(s_i))$. By applying this $\mathsf{ht}(s) + 1$ times, starting from s_0, we obtain that the height of $M(s)$ is $\leq c \cdot \mathrm{mhr} \cdot (\mathsf{ht}(s) + 1)$. So M is of linear-height-increase. ◀

The next lemma is a central piece of the paper. This is where we use the *depth proper property*.

▶ **Lemma 14.** *Let M be an mttr that is depth proper. (1) If M is not finite nesting, then M does not have linear size-to-height increase. (2) If M is not finite yield nesting, then M does not have linear height increase.*

Proof. Let M be given by a tuple as usual. To prove (1), assume that M is not fnest. We will use this and the *depth proper property* to show that M does not have LSHI. Since M is not fnest (and has only finitely many states) there must be some state $q \in Q^{(m)}$ with $m \geq 1$ that occurs arbitrarily often on paths of output trees of $\widehat{M}$. More precisely, there are infinite sequences of contexts $c_0, c_1, \ldots$ and numbers $n_0 < n_1 < \cdots$ such that q occurs $\geq n_0$ times on a path in $\widehat{M}(c_0)$ and q occurs $\geq n_1$ times on a path in $\widehat{M}(c_0[u_0 \leftarrow c_1])$ where u_0 is the path in c_0 to a node $p \in P$, etc. From this we can deduce (by considering sufficiently many numbers n_i), similarly to the proof of Lemma 6.5 of [10], that M is "(nested) input pumpable", i.e., there exist $q_1, q_2, j, s_0, s_1, u_0, u_1, p$ such that

1. $\langle q_1, p\rangle$ occurs in $\widehat{M}(s_0[u_0 \leftarrow p])$,
2. $\widehat{M}_{q_1}(s_1[u_1 \leftarrow p])$ has either: a subtree $\langle q_1, p\rangle(t_1, \ldots, t_m)$ such that some $t_{j'}$ contains a subtree $\langle q_2, p\rangle(\xi_1, \ldots, \xi_l)$ where ξ_j contains $y_{j'}$ for some $j' \in [m]$, or a subtree $\langle q_2, p\rangle(t_1, \ldots, t_l)$ such that t_j contains a subtree $\langle q_1, p\rangle(\xi_1, \ldots, \xi_m)$,
3. $\widehat{M}_{q_2}(s_1[u_1 \leftarrow p])$ has a subtree $\langle q_2, p\rangle(t_1, \ldots, t_l)$ such that t_j contains y_j, and
4. $p = h(s_1/u_1) = h(s_1[u_1 \leftarrow p])$.

By "pumping", i.e., considering $s_n = s_0[u_0 \leftarrow s_1[u_1 \leftarrow s_1[u_1 \leftarrow \ldots]]]$ with n replacements of the node u_1, we obtain that $\widehat{M}_{q_1}(s_n)$ contains a path with at least n nested occurrences of $\langle q_2, p\rangle$. Note that this proof is simpler than that of Lemma 6.5 of [10] because we only look here at the height of outputs instead of the size of outputs. This is simpler because, in a mttr, a state call can copy a parameter containing large outputs of other state calls, causing a size growth of the output that is difficult to track, but these copies cannot be copied vertically on top of each other, so the output height is easier to track.

This is where we use the *depth proper property*: we first assume by contradiction that M has LSHI, i.e., there exists a c such that for every input tree $s \in T_\Sigma$: $\mathsf{ht}(M(s)) \leq c \cdot |s|$. Since M is *depth proper*, we may choose $s \in L_p$ such that $M_{q_2}(s)$ contains an occurrence

of y_j at depth $\geq c \cdot c_1 + 1$, where $c_1 = |s_1[u_1 \leftarrow p]| - 1$. We know that $\widehat{M}_{q_1}(s_n)$ contains at least n nested occurrences of q_2 (where the j-th subtree of q_2 always contains further nested occurrences of q_2). Now let $t_n = s_0[u_0 \leftarrow s_n[u_1^n \leftarrow s]]$ and take $n > c(c_0 + c_2)$, where $c_0 = |s_0[u_0 \leftarrow p]| - 1$ and $c_2 = |s|$. Since $|t_n| = c_0 + nc_1 + c_2$, we obtain that $\mathsf{ht}(M(t_n)) > c \cdot |t_n|$ because $\mathsf{ht}(M(t_n)) \geq n(cc_1 + 1) > ncc_1 + c(c_0 + c_2) = c \cdot |t_n|$ by the choice of n. So *nested input pumpability* implies that M is not of LSHI.

We now prove that if M is not finite nesting, then it must be *nested input pumpable*. In order to do so, we first introduce a few notations and characterize *nested input pumpability* and the *finite nesting* property using these notations.

Let c be a Σ-context and $q \in Q$ be a state of M. To talk about the nesting of states in $\widehat{M}_q(c)$, we first give a notation for paths:

1. For any node u at depth n in $\widehat{M}_q(c)$, we note the path to node u as the sequence of pairs:

   $$(\ell_1, i_1)\,(\ell_2, i_2)\ldots(\ell_n, i_n)\,(\ell_{n+1}, \bot)$$

   where $i_1, \ldots, i_n$ are indexes such that $u = i_1\, i_2 \ldots i_n$ and, for all $j \leq n+1$, ℓ_j is the label of node $i_1 \ldots i_{j-1}$ or, if node $i_1 \ldots i_{j-1}$ is labeled by a state call $\langle q', p\rangle$, then $\ell_j = q'$,
2. Since we are only interested in the nesting of states, we remove from such paths all pairs (ℓ_j, i_j) where $\ell \in \Delta$. We obtain nesting sequences of the form:

   $$(q_1, k_1)\,(q_2, k_2)\ldots(q_n, k_n)\,(\ell_{n+1}, k_{n+1})$$

   where ℓ_{n+1} is either a state in Q or a parameter, $k_{n+1} \in \{\bot\} \cup \mathbb{N}$, and for all $j \leq n$, $k_j \in [m_j]$ where m_j is the arity of state q_j.
3. For each such sequence, if $\ell_{n+1} = q_{n+1} \in Q$ then we write:

   $$(q, \bot) \to_c (q_1, k_1)\,(q_2, k_2)\ldots(q_n, k_n)\,(\ell_{n+1}, k_{n+1})$$

   Otherwise $\ell_{n+1} = y_k$ is a parameter of q, $k_{n+1} = \bot$ and we write:

   $$(q, k) \to_c (q_1, k_1)\,(q_2, k_2)\ldots(q_n, k_n)$$

This defines a relation $\to_c \subseteq \Theta \times \Theta^*$ where $\Theta = \{(q, k) \mid q \in Q^{(m)}, k \in [m] \cup \{\bot\}\}$ and Θ^* denotes the set of (possibly empty) sequences of elements of Θ. Note that if $(q, \bot) \to_c w$, then in the nesting sequence $w \in \Theta^*$ only the last pair may contain $\bot$. A *nesting loop* is given by a Σ-context c with a leaf labeled p such that $h(c) = p$, and two pairs $(q_1, k_1), (q_2, k_2) \in \Theta$ such that:

- $(q_1, k_1) \to_c w_1\,(q_1, k_1)\,w_2\,(q_2, k_2)\,w_3$ or $(q_1, k_1) \to_c w_1\,(q_2, k_2)\,w_2\,(q_1, k_1)\,w_3$,
- $(q_2, k_2) \to_c w_4\,(q_2, k_2)\,w_5$,
- (q_1, p) is reachable, i.e., there exists Σ-context c_0 with a leaf labeled p such that $\langle q_1, p\rangle$ appears in $\widehat{M}(c_0)$,

for some nesting sequences $w_1, w_2, w_3, w_4, w_5 \in \Theta^*$. This allows us to rephrase the *nested input pumpability* property as the existence of a *nesting loop*. We want to prove that if M is not finite nesting then it has a nesting loop.

We extend the relation $\to_c$ to sequences of pairs on the left so that, for pairs (q_1, k_1), $(q_2, k_2) \in \Theta$ and sequences $w_1, w_2 \in \Theta^*$, if $(q_1, k_1) \to_c w_1$ and $(q_2, k_2) \to_c w_2$ then $(q_1, k_1)\,(q_2, k_2) \to_c w_1 w_2$. More generally, for all sequences $w_1, w_1', w_2, w_2' \in \Theta^*$, if $w_1 \to_c w_1'$ and $w_2 \to_c w_2'$ then $w_1\, w_2 \to_c w_1'\, w_2'$. We can now show the following claim:

▷ Claim 15. For all Σ-contexts c and c' with leafs labeled resp. p and p' such that $p = h(c')$, we can define the Σ-context $c \cdot c' = c[p \leftarrow c']$ and, for all sequences $w, w'' \in \Theta^*$, if $w \to_{c\cdot c'} w''$ then there exists a sequence $w' \in \Theta^*$ such that $w \to_c w' \to_{c'} w''$.

Proof. We only need to show this for $w = (q_0, k_0) \in \Theta$ because of the definition of $\to_c$ on sequences of pairs. Because $(q_0, k_0) \to_{c \cdot c'} w''$, there must be a path Π in $\widehat{M_{q_0}}(c \cdot c')$ reducing to w'' (by removing pairs in $\Delta \times \mathbb{N}$ and removing $(y_{k_0}, \bot)$ if $k_0 \neq \bot$). Because $\widehat{M_{q_0}}(c \cdot c') = \widehat{M_{q_0}}(c)[\langle q, p\rangle \leftarrow \widehat{M_q}(c')]$, path Π can be similarly obtained from a path Π' in $\widehat{M_{q_0}}(c)$ by substituting each (q, k) with a path in $\widehat{M_q}(c')$. More specifically, noting $(q_1, k_1), \ldots, (q_n, k_n)$ the pairs in path Π' that are in Θ (in order of apparition in Π'), we substitute in Π':

- each occurrence of a pair $(q_i, k_i) \in \Theta$ by a path Π'_i such that $\Pi'(y_{k_0,\bot})$ is a path in $\widehat{M_{q_i}}(c')$ (for $i \leq n$),
- each occurrence of a pair $(q_n, \bot)$ by a path Π'_n in $\widehat{M_{q_n}}(c')$.

We get: $\Pi = \Pi'[(q_i, k_i) \leftarrow \Pi'_i]$ and, by removing pairs in $(\Delta \times \mathbb{N}) \cup (Y^m \times \{\bot\})$:

$$w'' = w'_1 \, w'_2 \, \ldots \, w'_n$$

where for all $i \leq n$, w'_i is obtained from Π'_i by removing pairs in $(\Delta \times \mathbb{N}) \cup (Y^m \times \{\bot\})$. Then, for all $i \leq n$ and by definition of Π'_i, we have $(q_i, k_i) \to_{c'} w'_i$. So $(q_1, k_1) \ldots (q_n, k_n) \to_{c'} w'_1 \, w'_2 \, \ldots \, w'_n = w''$.

We note w' the sequence obtained from Π' by removing pairs in $(\Delta \times \mathbb{N}) \cup (Y^m \times \{\bot\})$. Then $w' = (q_1, k_1) \ldots (q_n, k_n)$ and so $(q_0, k_0) \to_c w' \to_{c'} w''$. ◁

We could also prove that $\to_{c \cdot c'} = \to_{c'} \circ \to_c$, but it is not necessary for this proof.

To prove that M has a nesting loop (i.e. M is nested input pumpable), we assume that M is not finite nesting. Then, for all $n \in \mathbb{N}$, there exists a Σ-context c_n such that: $(q_0, \bot) \to_{c_n} w$ for some $w \in \Theta^*$ with $|w| \geq n$. We can decompose any such c_n into a concatenation $c_{n,1} \cdot c_{n,2} \cdot \ldots c_{n,r}$ and use the claim to obtain:

$$(q_0, \bot) \to_{c_{n,1}} w_1 \to_{c_{n,2}} w_2 \cdots \to_{c_{n,r}} w_r$$

where $w_1, w_2, \ldots w_r \in \Theta^*$ and $|w_r| = |w| \geq n$. By choosing a large enough n, we will show how to find a *nesting loop*. To do that, we decompose c_n into several contexts and use the claim.

A Σ-context c is *atomic* if its leaf labeled in P is a child node of its root. Let $c = \sigma(t_1, \ldots, t_{i-1}, p_i, t_{i+1}, \ldots, t_k)$ be an atomic Σ-context and $q \in Q$ a state of M. Noting $p_j = h(t_j)$ for $j \neq i$, there is in M a rule $\langle q, \sigma(x_1 : p_1, \ldots, x_k : p_k)\rangle(y_1, \ldots, y_m) \to t$. Then $\widehat{M_q}(c) = t[\langle q', x_j\rangle \leftarrow M_{q'}(c/j) \mid j \neq i]$. Because $M_{q'}(c/j) \in T_\Delta$ for all $q' \in Q$ and $j \neq i$, the nesting of state calls in $\widehat{M_q}(c)$ is the nesting of state calls of the form $\langle q', x_i\rangle$ in t. So, for $(q, k) \in \Theta$, the length of nesting sequences w such that $(q, k) \to_c w$ is bounded by the height of t. There is a finite number of rules for M, so there is a finite number of such t and the length of sequences $w \in \Theta$ such that $(q, k) \to_c w$ has an upper bound B that does not depend on q, k or c. In other words, for all $(q, k) \in \Theta$, $w \in \Theta^*$ and atomic Σ-context c we have:

$$(q, k) \to_c w \quad \Rightarrow \quad |w| \leq B$$

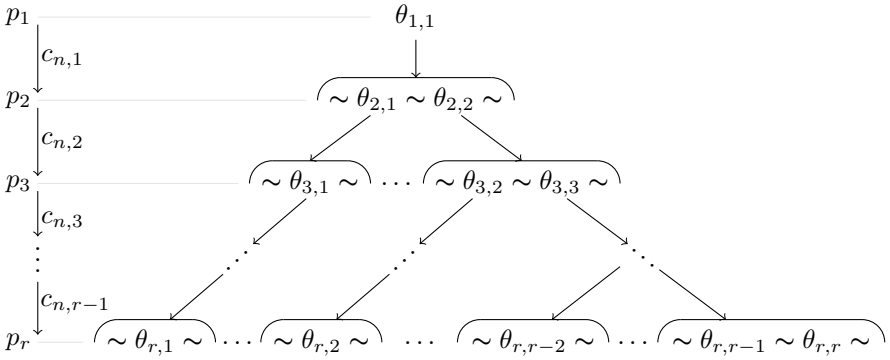
Moreover, for all $w_1, w_2 \in \Theta^*$: $w_1 \to_c w_2 \quad \Rightarrow \quad |w_2| \leq B\,|w_1|$.

We decompose the Σ-context c_n into atomic Σ-contexts $c_{n,1}, c_{n,2}, \ldots, c_{n,r}$. Since $(q_0, \bot) \to_{c_{n,1}} w_1 \to_{c_{n,2}} w_2 \cdots \to_{c_{n,r}} w_r$, we have $|w_r| \leq B^r$ and, since $|w_r| \geq n$: $n \leq B^r$. So, by choosing n large enough, we can also make r as big as we want. In order to find a nesting loop, we require more structure on the nesting sequences $c_{n,1}, \ldots, c_{n,r}$. The precise structure we need is described in the following claim:

▷ Claim 16. For all for all $r \in \mathbb{N}$, if there exists a Σ-context c, a pair $\theta \in \Theta$ and a sequence $w \in \Theta^*$ with $\theta \to_c w$ and $|w| \geq B^r$, then there exists Σ-contexts $c_1, \ldots, c_{r-1}$, look-ahead states $p_1, \ldots, p_r$ and pairs $\theta_{i,j} \in \Theta$ for all $i, j \in [r]$ with $j \leq i$ such that:

- for all $i \in [r-1]$, $h(c_i) = p_i$ and c_i has a leaf labeled p_{i+1},
- $\theta_{1,1} = \theta$,
- for all $i, j \in [r-1]$ with $j < i$, there exists $w_{i,j}, w'_{i,j} \in \Theta^*$ such that: $\theta_{i,j} \to_{c_i} w_{i,j}\, \theta_{i+1,j}\, w'_{i,j}$,
- for all $i \in [r-1]$, there exists $w_i, w'_i, w''_i \in \Theta^*$ such that either $\theta_{i,i} \to_{c_i} w_i\, \theta_{i+1,i}\, w'_i\, \theta_{i+1,i+1}\, w''_i$ or $\theta_{i,i} \to_{c_i} w_i\, \theta_{i+1,i+1}\, w'_i\, \theta_{i+1,i}\, w''_i$.

These conditions can be summed up graphically. To simplify the picture, we replace all sequences $w_{i,j}, w'_{i,j}, w_i, w'_i, w''_i$ for $i, j \in [r]$ with the symbol $\sim$.



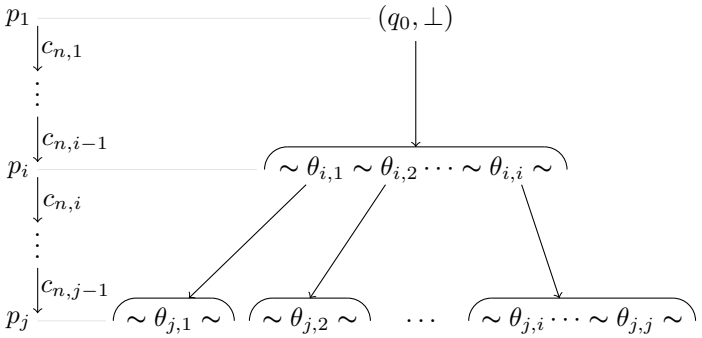
Note that, in this representation, we chose to represent $\theta_{i,i} \to_{c_i} w_i\, \theta_{i+1,i}\, w'_i\, \theta_{i+1,i+1}\, w''_i$ instead of $\theta_{i,i} \to_{c_i} w_i\, \theta_{i+1,i+1}\, w'_i\, \theta_{i+1,i}\, w''_i$ for all $i \in [r-1]$. But this distinction does not matter to the proof of the claim. From now on we use $\sim$ to denote arbitrary sequences in Θ^* which we will not use to find a nesting loop.

Proof. We prove this by induction on r. Let c be a Σ-context, θ a pair in Θ and w a sequence in Θ^* with $\theta \to_c w$ and $|w| \geq B^{r+1}$. We split c into atomic Σ-contexts $c'_1, \ldots, c'_n$, then we have sequences $w_1, \ldots, w_{n-1} \in \Theta^*$ such that $\theta \to_{c'_1} w_1 \cdots \to_{c'_{n-1}} w_{n-1} \to_{c'_n} w$. Let i be the largest i such that there is a pair θ' in the sequence w_i with $\theta' \to_{c'_{i+1} \cdots c'_n} w'$ and $|w'| \geq B^r$. If we had $|w'| \geq B^{r+1}$ then, because c'_{i+1} is atomic, we would have a θ'' in the sequence c'_{i+1} with $\theta'' \to_{c'_{i+2} \cdots c'_n} w''$ and $|w''| \geq B^r$. So $B^r \leq |w'| < B^{r+1} \leq |w|$. Therefore there is another pair $\theta_{2,1}$ in w_i (other than θ') with $\theta_{2,1} \to_{c'_{i+1} \cdots c'_n} w''$ and $|w''| \geq 1$.

Since $\theta' \to_{c'_{i+1} \cdots c'_n} w'$ and $|w'| \geq B^r$, we use the induction hypothesis on θ' and $c'_{i+1} \cdots c'_n$. In order to prove the induction for $r+1$, we rename the Σ-contexts $c_1, \ldots c_{r-1}$, look-ahead states $p_1, \ldots, p_r$ and pairs $\theta_{i,j}$ (for $j \leq i \leq r$) into Σ-contexts $c_2, \ldots c_r$, look-ahead states $p_2, \ldots, p_{r+1}$ and pairs $\theta_{i+1,j+1}$ (for $j \leq i \leq r$). Then $c'_{i+1} \cdots c'_n = c_2 \cdots c_r$.

Since $\theta_{2,1} \to_{c_2 \cdots c_r} w''$ with $|w''| \geq 1$, there are pairs $\theta_{3,1}, \ldots, \theta_{n,1}$ such that $\theta_{n,1}$ appears in the sequence w'' and, for all $i \in [r]$ with $i \geq 2$, $\theta_{i,1} \to_{c_i} w'_i\, \theta_{i+1,1}\, w''_i$ with $w'_i, w''_i \in \Theta^*$. To conclude, we choose $c_1 = c'_1 \ldots c'_i$, $p_1 = h(c_1)$ and $\theta_{1,1} = \theta$. ◁

In order to find a nesting loop, we need two indexes i and j with:



Formally, we require two indexes i, j with $i < j < r$ which share

- the same look-ahead state $h(c_{n,i}) = h(c_{n,j})$,
- the same pair $\theta_{i,i} = \theta_{j,j} \in \Theta$ and
- the same set of pairs $\{\theta_{i,\ell}\}_{0 \leq \ell \leq i} = \{\theta_{j,\ell}\}_{0 \leq \ell \leq j}$.

We ensure the existence of such i, j by choosing $r \geq |P|\,|Q|\,(m+1)\,2^{|Q|(m+1)} + 1$ where m is the maximum arity of states. We now show how to build the nesting loop from indexes i, j. We note $p = h(c_{n,i}) = h(c_{n,j})$, $(q_1, k_1) = \theta_{i,i} = \theta_{j,j}$ and $S = \{\theta_{i,\ell}\}_{0 \leq \ell \leq i} = \{\theta_{j,\ell}\}_{0 \leq \ell \leq j}$. We note $c' = c_{n,i}.c_{n,i+1}.\ldots.c_{n,j-1}$. Note that c' has a leaf labeled p and $h(c') = p$.

We need the sets $\{\theta_{i,\ell}\}_{0 \leq \ell \leq i}$ and $\{\theta_{j,\ell}\}_{0 \leq \ell \leq j}$ to be equal so that the pairs $\theta_{i,k}$ for $k \leq i$ loop on each other through the loop c'. Formally, noting $\theta'_0 = \theta_{j,i}$, for all $\theta'_k \in S$ for $k \in \mathbb{N}$, there exists $\theta'_{k+1} \in S$ such that $\theta'_k \to'_c \sim \theta'_{k+1} \sim$. Since $S \subseteq \Theta$ is finite, there must be $n, m \in \mathbb{N}$ such that $\theta'_n = \theta'_{n+m}$ (with $m \geq 1$), so $\theta'_n \to_{c'^m} \sim \theta'_n \sim$. Also $(q_1, k_1) \to_{c'} \sim \theta'_0 \sim (q_1, k_1) \sim$ and $\theta'_0 \to_{c'^n} x_n$, so $(q_1, k_1) \to_{c'^{n+1}} \sim \theta'_n \sim (q_1, k_1) \sim$ and, for all $m' \in \mathbb{N}$: $(q_1, k_1) \to_{c'^{m'}} \sim (q_1, k_1) \sim \to_{c'^{n+1}} \sim \theta'_n \sim (q_1, k_1) \sim$. Finally, for $c = c'^{m(n+1)}$, we have $(q_1, k_1) \to_c \sim \theta'_n \sim (q_1, k_1) \sim$ and $\theta'_n \to_c \theta'_n$. So we have a *nesting loop*.

In conclusion, if M is not finite nesting, then it is *nested input pumpable*, and so it does not have linear size-to-height increase.

The proof of Statement (2) can be given in a very similar way as for (1), here we only outline the changes to the notations which allow to adapt the proof of (1) to (2). We replace Σ-contexts with elements of the set $T_\Sigma(P)$ containing possibly several leafs labeled in P. The rest of the notational changes are consequences of this change. Given a $s \in T_\Sigma(P)$, we now consider the nesting of state calls called on distinct subtrees of s with potentially distinct look-ahead states. We augment pairs in Θ so as to include the look-ahead, so $\Theta = \{(q, k, p) \mid q \in Q^{(m)}, k \in [m] \cup \{\bot\}, p \in P\}$. The notation $(q, k, p) \to_s (q_1, k_1, p_1) \ldots (q_n, k_n, p_n)$ means that $h(s) = p$ and calls to states $q_1, \ldots, q_n$ on leafs of s labeled $p_1, \ldots, p_n$ resp. are nested on parameters $y_{k_1}, \ldots, y_{k_n}$ along a path in $\widehat{M}_q(s)$. This means that, when concatenating contexts, we write $s(s_1, \ldots, s_m)$ instead of $s \cdot s'$.

For (2), similarly to nesting loops for (1), we define a *yield nesting loop* as given by contexts $s_1, s_2 \in T_\Sigma(P)$, look-ahead states $p_1, p_2 \in P$ and triplets $(q_1, k_1, p_1), (q_2, k_2, p_2) \in \Theta$ such that:

- $h(s_1) = p_1$, $h(s_2) = p_2$, s_1 has two leafs labeled p_1 and p_2, s_2 has one leaf labeled p_2,
- $\langle q_1, p_1 \rangle$ is reachable,
- either $(q_1, k_1, p_1) \to_{s_1} \sim (q_2, k_2, p_2) \sim (q_1, k_1, p_1) \sim$
  or $(q_1, k_1, p_1) \to_{s_1} \sim (q_1, k_1, p_1) \sim (q_2, k_2, p_2) \sim$,
- $(q_2, k_2, p_2) \to_{s_2} \sim (q_2, k_2, p_2) \sim$.

We say that M is *yield nested input pumpable* when it has either a *yield nesting loop* or a *nesting loop*. Note that the existence of either of these loops contradicts the linear height increase property. To prove (2) we prove that infinite yield nesting implies the existence

of either a yield nesting loop or a nesting loop. That proof works similarly to (1): M is not fynest so we can find large enough nesting sequences (but with the new definition of $\rightarrow_s$), find a repeating triplet (q_1, k_1, p_1), pump the loop enough times that a triplet (q_2, k_2, p_2) loops onto itself. Note that if the nested calls to (q_1, k_1, p_1) and (q_2, k_2, p_2) in $(q_1, k_1, p_1) \rightarrow_{s_1} \sim (q_2, k_2, p_2) \sim (q_1, k_1, p_1) \sim$ are on the same leaf in s_1 (with $p_1 = p_2$), then we get a nesting loop (otherwise we get a yield nesting loop). ◀

From Theorem 11 and Lemmas 12, 13, and 14 we obtain our following main theorem.

▶ **Theorem 17.** *Let M be an mttr. Then (1) it is decidable whether or not M has linear size-to-height increase (2) it is decidable whether or not M is linear height-increase.*

5 Conclusions

We have proven that for a given macro tree transducer (with look-ahead) it is decidable whether or not it has linear height increase (LHI) and, whether or not it has linear size-to-height increase (LSHI). Both decision procedures rely on a novel normal form that is called "depth-proper" normal form. Roughly speaking the normal form requires that each parameter of every state of the transducer appears at arbitrary large depths in output trees generated by that state (and for a given look-ahead state).

One major open problem in the field is to prove a Conjecture of Joost Engelfriet (from around the year 2000), that the translation of an mttr can be defined by an attributed tree transducer (atts) if and only if the translation has "linear size to number of distinct output subtrees" increase. Note that deciding such property is out of reach (it is at least as difficult as deciding equivalence of atts). To prove this characterization, different loops need to be considered which produce unbounded numbers of states in (partial) output trees. We believe that the depth normal form will be instrumental in reducing the number of different such loops that must be considered and therefore will be of great help in proving the conjecture.

T-Rex: Termination of Recursive Functions Using Lexicographic Linear Combinations

Raphael Douglas Giles

Christine Rizkallah
The University of Melbourne, Australia

Abstract

We introduce a powerful termination algorithm for structurally recursive functions that improves on the core ideas behind lexicographic termination algorithms for functional programs. The algorithm generates linear-lexicographic combinations of primitive measure functions measuring the recursive structure of terms. We introduce a measure language that enables the simplification and comparison of measures and we prove meta-theoretic properties of our measure language. Moreover, we demonstrate our algorithm, on an untyped first-order functional language and prove its soundness and that it runs in polynomial time. We also provide a Haskell implementation. As part of this work, we also show how to solve the maximisation of negative vector-components as a linear program.

1 Introduction

To guarantee the *total correctness* of a program, it is essential to prove that the program terminates [10]. While the halting problem is undecidable for general recursive functions [8, 21], there has been a long line of work on creating termination algorithms that automatically determine whether certain classes of functions terminate [14, 22, 11, 7, 2, 1].

In the context of functional programming, a termination algorithm typically takes a recursive function f as input and attempts to find a function from terms in the language to some well-founded order; this function is called a measure function. When the measure is applied to the arguments of f, it strictly decreases at each recursive call site [22, 11]. Such a measure can be as simple as a single argument to the function that always decreases at each recursive call. Such a simple measure is sufficient for demonstrating the termination of primitive recursive functions [18]. For example, consider the following function defining the binomial coefficient:

$$\begin{aligned} \mathit{choose}\ \langle 0, k\rangle &= 1 \\ \mathit{choose}\ \langle n, 0\rangle &= 1 \\ \mathit{choose}\ \langle \mathbf{S}\, n, \mathbf{S}\, k\rangle &= \mathit{choose}\, \langle n, \mathbf{S}\, k\rangle + \mathit{choose}\, \langle n, k\rangle \end{aligned}$$

To prove that *choose* terminates, we observe that the first projection of the argument, labelled n, strictly decreases at each recursive call site. Since n is a natural number and the natural numbers are well-ordered, we can conclude that *choose* must eventually terminate. Thus

a decreasing measure of *choose* is $\mathbf{size} \circ \pi_1$. The measure of the argument to the *choose* function is the function $\mathbf{size} \circ \pi_1$, where the function π_1 projects the first argument out of the tuple and **size** returns the interpretation of object language number n in the underlying language or logic.

Of course, termination arguments are not always as simple as finding a single argument that decreases at every recursive call. Consider the following example:

$$\begin{array}{lcl} ex_1\,\langle 0, 0\rangle & = & 0 \\ ex_1\,\langle \mathbf{S}\,x, y\rangle & = & ex_1\ \langle x, \mathbf{S}\,y\rangle \\ ex_1\,\langle x, \mathbf{S}\,y\rangle & = & ex_1\ \langle x, y\rangle. \end{array}$$

In this example, no single part of the argument decreases at every recursive call. Hence, we cannot simply find a measure by considering each projection separately. However, this function terminates, and the argument for its termination can be generalised to determine the termination of a larger class of functions.

Note that the first projection of the argument never increases in any recursive call, and in the first recursive call, it strictly decreases. Hence the first recursive call can only be applied a finite number of times, bounded by the size of the first projection. With this fact, we may set the first recursive call aside. Observe that, considered alone, the second recursive call can also only be called a finite number of times, as the second projection of the argument always decreases. Thus, there can only be a finite number of recursive calls to this function overall. This idea is captured by the fact that the lexicographic order of the size of the first followed by that of the second argument decreases at each recursive call.

The Isabelle/HOL theorem prover [17] has a state-of-the-art termination algorithm that uses this idea for automatically detecting termination arguments [7, 2]. This more involved lexicographic order algorithm is quite powerful, covering termination arguments for various functions with non-trivial termination proofs, including the merge function on sorted lists and the Ackermann function [3]. However, it cannot handle the following function:

$$\begin{array}{lcl} ex_2\,\langle 0, 0\rangle & = & 0 \\ ex_2\,\langle \mathbf{S}\,(\mathbf{S}\,x), y\rangle & = & ex_2\ \langle x, \mathbf{S}\,y\rangle \\ ex_2\,\langle x, \mathbf{S}\,(\mathbf{S}\,y)\rangle & = & ex_2\ \langle \mathbf{S}\,x, y\rangle \end{array}$$

Though there is no lexicographic combination of generated measures that decreases at every recursive call, we know that this function must terminate because the sum of the arguments is always decreasing. More precisely, the measure $(\lambda t.\ (\mathbf{size} \circ \pi_1)\ t + (\mathbf{size} \circ \pi_2)\ t)$ decreases at every recursive call.

A termination algorithm that considers sums of the same generated measures as those of Isabelle/HOL would be successful in proving termination for ex_2. If we were to also consider linear combinations with coefficients in $\mathbb{N}$, it would also prove termination for ex_1, since we could take $(\lambda t.\ (2 \cdot ((\mathbf{size} \circ \pi_1)\ t)) + (\mathbf{size} \circ \pi_2)\ t)$.

The Isabelle/HOL algorithm can also not handle the following example, which converts from sparse lists to lists. Sparse lists provide a space-efficient representation of lists that contain many repeated elements. For example the list $[\mathtt{a}, \mathtt{a}, \mathtt{a}, \mathtt{h}, \mathtt{h}]$ would be represented as $[(\mathtt{a}, 3), (\mathtt{h}, 2)]$. We can more formally define the data type $\mathbf{SparseList}\ \alpha$ as inductively generated by elements $\mathbf{SNil}$ and $\mathbf{SCons}\ (x : \alpha)\ (n : \mathbb{N})\ (xs : \mathbf{SparseList}\ \alpha)$. The following function converts sparse lists to regular lists; defined through the usual **Nil** and **Cons** constructors:

$$\begin{array}{lcl} \mathit{toList}\ \mathbf{SNil} & = & \mathbf{Nil} \\ \mathit{toList}\ (\mathbf{SCons}\ x\ 0\ xs) & = & \mathit{toList}\ xs \\ \mathit{toList}\ (\mathbf{SCons}\ x\ (\mathbf{S}\,n)\ xs) & = & \mathbf{Cons}\ x\ (\mathit{toList}\ (\mathbf{SCons}\ x\ n\ xs)). \end{array}$$

$$
\begin{array}{lcl}
ack\,\langle 0, n\rangle & = & \mathbf{S}\,n \\
ack\,\langle \mathbf{S}\,m, 0\rangle & = & ack\,\langle m, \mathbf{S}\,0\rangle \\
ack\,\langle \mathbf{S}\,m, \mathbf{S}\,n\rangle & = & ack\,\langle m, ack\,\langle \mathbf{S}\,m, n\rangle\rangle
\end{array}
\qquad
\begin{array}{l}
\\
\text{call 1} \\
\text{call 2} \\
\text{call 3}
\end{array}
\begin{array}{c}
\mathbf{size} \circ \pi_1 \quad \mathbf{size} \circ \pi_2 \\
\left[\begin{array}{cc}
< & ? \\
< & ? \\
\leq & <
\end{array}\right]
\end{array}
$$

Figure 1 The Ackermann function is presented on the left and its difference matrix on the right.

This function terminates because either the number of **SCons** constructors decreases or it stays the same and the number n decreases. As this function has a lexicographic termination argument, we might expect the Isabelle/HOL termination algorithm to be able to handle it. The reason it cannot is that Isabelle/HOL only generates measures that consider the difference in the number of **SCons** constructors for each recursive function call – missing the fact that the number *inside* the **SCons** decreases.

We provide a novel algorithm, called T-Rex, that proves termination for a large class of functions including all the examples above. It first generates a set of measures based on structural size that is sufficiently detailed to handle examples such as *toList* where the decrease in structural size occurs within another data structure. It then determines whether there exists a lexicographic combination of these measures that decreases at every recursive call, or such an $\mathbb{N}$-linear combination, as well as complex measures combining the two (see ex_4). We demonstrate how to analyse the termination of functional programs by operating directly on and measuring the recursive structure of terms, without relying on the type structure or using higher-order logic and theories of term rewriting. This means that T-Rex can be used to analyse the termination of functional programs without relying on an underlying theorem prover, making it accessible to a wider community. We provide an implementation of our language and our T-Rex algorithm in Haskell.

2 Isabelle/HOL's Termination Algorithm

Isabelle/HOL's lexicographic termination algorithm [7] compares the measures of each argument to the function to that of each recursive call. For example, consider the Ackermann function (Figure 1). The Ackermann function has three recursive calls for which we need to show a decrease between the structural size of the initial and recursive arguments.

The size-change information for these calls is represented in a matrix, where each row corresponds to a recursive call and each column corresponds to a measure of part of the argument. The size-change comparison matrix for *ack* example (Figure 1) consists of the two columns that represent the size-change relation on the first and the second components of the argument tuple, respectively.

The entries record the change between the original and recursive arguments, recorded with the symbols $<$, $\leq$, and ?. The symbol $<$ means that there is a strict decrease in the size of the recursive call argument compared to the initial one, the symbol $\leq$ means that the size decreases or remains the same, and the symbol ? means that the size either increased or the relationship between the sizes is unknown.

From this point forward we omit the labels of the rows and columns of matrices, since these labels clutter the notation and as we wish to orient the reader slowly to thinking about these as matrices in the sense of linear algebra. This will ease introducing the ideas for our extension to the termination algorithm. Isabelle/HOL's lexicographic algorithm works by mimicking the informal argument given in the introduction. It attempts to find

arguments that always either decrease or stay the same size (i.e., that have $<$ and $\leq$ entries) and removes these recursive calls from consideration. Phrased in terms of the matrix, the algorithm repeatedly finds a column of the matrix with only $<$ and $\leq$ entries, and which must contain a $<$ entry, and removes every row of the matrix that has a $<$ entry in that column. If it eventually removes all the rows of the matrix, then the function must terminate.

To find the corresponding measure, it just keeps track of the measure associated with each column. Let m_1 be the measure associated with the first encountered column that only contains $<$ and $\leq$ entries, m_2 the measure associated with the second, and so on, up to the measure associated with the last such column m_n. The *lexicographic* measure, $[m_1, m_2, \ldots, m_n]_{\text{lex}}$, takes the measures m_1 to m_n, and combines their results into a lexicographically ordered tuple. Isabelle/HOL's lexicographic procedure produces a sequence of measures that, when combined lexicographically, decreases at every recursive call.

Returning to the Ackermann example, the sequence of row eliminations computed by the above algorithm is

$$\begin{bmatrix} < & ? \\ < & ? \\ \leq & < \end{bmatrix} \rightsquigarrow \begin{bmatrix} \leq & < \end{bmatrix} \rightsquigarrow \varnothing.$$

where $\varnothing$ stands for the empty matrix. The corresponding measure computed by this procedure, that decreases at every recursive call is $[\mathbf{size} \circ \pi_1, \mathbf{size} \circ \pi_2]_{\text{lex}}$.

Limitations of the Isabelle/HOL algorithm

As noted earlier the Isabelle/HOL algorithm, while very effective for many problems, fails to prove termination for examples such as *ex₂*. We can see this directly by generating the corresponding size-change matrix for *ex₂*:

$$\begin{bmatrix} < & ? \\ ? & < \end{bmatrix},$$

which cannot be reduced using the above procedure, since there is no column with only $<$ and $\leq$ entries. In order to extend this algorithm to prove the termination of such functions, we need more information in these matrices. The information we will use is the numeric increase or decrease of the measured size, when such a value is computable.

In this example, we can compute exactly how much each measure changes at each recursive call and we want to maintain a matrix with entries corresponding to those numeric size-changes, namely:

$$\begin{bmatrix} -2 & 1 \\ 1 & -2 \end{bmatrix}.$$

With this information, we can add the columns of this matrix, to produce a single column corresponding to the sum of these size changes, which in this case is negative in every entry, i.e. decreases at every recursive call, hence, proving termination.

This idea requires we solve three problems: how to generate such matrices, how to find such $\mathbb{N}$-linear combinations, and how to integrate this approach with the lexicographic algorithm. We first develop a language as well as a measure language in order to demonstrate how measure generation works. From there, the remainder of the paper is dedicated to solving these three problems.

Function names $f : N$ Variables $x, y, z : V$

$$\begin{array}{lll} \text{Terms } t \in T & ::= & \mathbf{var}\, x \mid \langle\rangle \mid \langle t, t\rangle \mid \mathbf{inl}\ t \mid \mathbf{inr}\ t \mid \mathbf{roll}\,\{t\} \mid \mathbf{app}\, f\, t \\ \text{Patterns } p \in P & ::= & \mathbf{var}\, x \mid \langle\rangle \mid \langle p, p\rangle \mid \mathbf{inl}\ p \mid \mathbf{inr}\ p \mid \mathbf{roll}\,\{p\} \end{array}$$

Function body $B = [(P \times T)]$ Program $\Gamma : [(N \times B)] ::= \overline{(f, b)}$

$0 = \mathbf{roll}\,\{\mathbf{inl}\,\langle\rangle\}$ $\mathbf{S}\, n = \mathbf{roll}\,\{\mathbf{inr}\ n\}$

Figure 2 Language Syntax.

3 Language

As our termination algorithm targets functional languages, we introduce a core calculus that supports common features of these languages, such as recursion, pattern matching, and standard algebraic data types. Standard ADTs can be encoded in our core language through the constructors that the language provides: recursive structures (roll), products, sums and unit. Our language is untyped, but would permit the addition of the standard type system for these constructs. Our language does not support lambda terms. The concrete syntax of our language is similar to Haskell function definitions. We provide examples in Sections 1, 2.

The syntax of our language is presented in Figure 2. A program is a sequence of function declarations, which are themselves a pair of a function name and function body. Each function body is a sequence of defining equations which are pairs of a pattern p and a term t. We will write the elements of a function body in the form $f\ p = t$, where f is the function name.

Each pattern has a corresponding term that it destructs on. Patterns contain binding variables $\mathbf{var}\, x, \mathbf{var}\, y, \mathbf{var}\, z$, written x, y, z for short, patterns for destructing sums $\mathbf{inl}\ p$ and $\mathbf{inr}\ p$, a pattern for destructing tuples $\langle p, p\rangle$, the pattern for destructing units $\langle\rangle$, and the pattern for destructing rolls $\mathbf{roll}\,\{p\}$. Terms include constructors for each of these as well as function application $\mathbf{app}\, f\, t$, written, $f\ t$ for short. When defining a function, terms describe how to build up the structure of the output using the variables bound by the input pattern.

4 Measure Language

We can prove that a function terminates by finding a measure of the size of the function's argument and showing that the argument's size decreases on every recursive call. This is called a *measure function*, and it is of type $T \to \mathcal{O}$ from the set of terms T to some well-ordered set $\mathcal{O}$. In particular, we use the set of natural numbers ($\mathbb{N}$) for primitive measures and linear combinations of primitive measures, and the set of lists of natural numbers ($[\mathbb{N}]$) under the lexicographic order for our overall lexicographic-linear measures.

There are five basic measures, **unroll**, **uninl**, **uninr**, π_1, and π_2. These deconstruct the basic datatypes, **roll**, **inl** , **inr** , and the left and right subterms of $\langle -, -\rangle$ respectively. The **unroll** destructor adds 1 to the return value, and **uninl** and **uninr** immediately terminate when passed the opposite constructors **inr** and **inl** respectively. In addition, there are two constant measures **case01** and **case10**, that attempts to match the input term as a sum, with **case01** returning 0 for **inl** and 1 for **inr** , and **case10** doing the opposite. There are two measure operators: $\triangleleft$ and **fix**. The measure operator $\triangleleft$ functionally composes two measures, and the **fix** measure operator repeatedly evaluates the given measure.

$$
\begin{array}{lrl}
\text{Measure destructor } m_{\mathrm{d}} & ::= & \mathbf{unroll} \mid \mathbf{uninl} \mid \mathbf{uninr} \mid \pi_1 \mid \pi_2 \\
\text{Recursive measure } m_{\mathrm{r}} & ::= & m_{\mathrm{d}} \mid m_{\mathrm{r}} \triangleleft m_{\mathrm{d}} \\
\text{Primitive measure } m & : & M \\
m & ::= & (\mathbf{fix}\, m_{\mathrm{r}}) \mid \mathbf{case01} \mid \mathbf{case10} \mid m \triangleleft m_{\mathrm{d}} \\
\text{Measure State } M_{st} & = & (M \times T \times \mathbb{N}) \uplus \mathbb{N}
\end{array}
$$

Measure Evaluation Semantics $(-)\Downarrow : (M \times T \times \mathbb{N}) \to M_{st}$

$$
\begin{array}{lcll}
((m \triangleleft \mathbf{unroll}), (\mathbf{roll}\, \{t\}), i)\Downarrow & = & (m, t, 1+i)\Downarrow & \\
((m \triangleleft \mathbf{uninl}), (\mathbf{inl}\ t), i)\Downarrow & = & (m, t, i)\Downarrow & \\
((m \triangleleft \mathbf{uninr}), (\mathbf{inr}\ t), i)\Downarrow & = & (m, t, i)\Downarrow & \\
((m \triangleleft \mathbf{uninr}), (\mathbf{inl}\ t), i)\Downarrow & = & i & \\
((m \triangleleft \mathbf{uninl}), (\mathbf{inr}\ t), i)\Downarrow & = & i & \\
((m \triangleleft \pi_1), \langle s, t\rangle, i)\Downarrow & = & (m, s, i)\Downarrow & \\
((m \triangleleft \pi_2), \langle s, t\rangle, i)\Downarrow & = & (m, t, i)\Downarrow & \\
(\mathbf{case01}, (\mathbf{inl}\ t), i)\Downarrow & = & i & \\
(\mathbf{case01}, (\mathbf{inr}\ t), i)\Downarrow & = & 1+i & \\
(\mathbf{case10}, (\mathbf{inl}\ t), i)\Downarrow & = & 1+i & \\
(\mathbf{case10}, (\mathbf{inr}\ t), i)\Downarrow & = & i & \\
((\mathbf{fix}\, m), t, i)\Downarrow & = & (((\mathbf{fix}\, m) \triangleleft m), t, i)\Downarrow & \\
(m, t, i)\Downarrow & = & (m, t, i) & \mathbf{otherwise}
\end{array}
$$

Measure Functional Semantics $[\![-]\!] : M \to (T \rightharpoonup \mathbb{N})$

$$[\![m]\!]\, t \quad = \quad (m, t, 0)\Downarrow$$

Note that this function is partial as the result of $\Downarrow$ is not always a natural number.

Figure 3 Measure language semantics.

Semantics

The big-step evaluation semantics of the measure language $(-)\Downarrow$, defined in Figure 3, takes as input a triple consisting of a term t in T, a measure m and a natural number. If the measure exhaustively destructures the term through the evaluation, the semantics returns a natural number, and if the evaluation is stuck, the semantics returns a triple of the same type as the input triple.

Note that the evaluation semantics is stuck when it encounters a term that is a variable, a function application, or the term and the measure have mismatched term constructors and measure destructors. The functional semantics abstracts from this case, only being defined for closed terms where the measure and term constructors match.

We will prove that our algorithm correctly demonstrates termination (when it succeeds in finding a measure) by showing that, for every initial argument a_{i} and every argument a_{r} to the recursive calls, $m\ a_{\mathrm{r}} < m\ a_{\mathrm{i}}$ [11]. Note that this method requires that a_{r} and a_{i} are *closed*, that is contain no variables or function calls. We will ensure this in our proofs by substituting variables for closed terms and functions for functions from closed terms to closed terms.

Bounded Difference

In general, we will not be able to determine the exact measure of a term statically, as measure execution can get stuck. Thus, we will need to approximate the difference between the partial evaluations of a measure. This approximation must be an upper bound on the difference between the measures (when applied to any substitution which results in a natural number).

Bounded difference $(\dot{-}) : M_{st} \to M_{st} \to \mathbb{Z} \uplus \{\omega\}$

$$
\begin{array}{rcll}
(m, s, i) & \dot{-} & (m, s, j) & = & i - j \\
i & \dot{-} & (m', t, j) & = & i - j \\
(m, s, i) & \dot{-} & j & = & \omega \\
(m, s, i) & \dot{-} & (m', t, j) & = & \omega \quad \textbf{otherwise}.
\end{array}
$$

Figure 4 Bounded difference.

The bounded difference (Figure 4), written $\dot{-}$, is a conservative estimate of the true difference between the size of a measure applied to two arguments. It has four cases, which depend on whether the measure fully executes and returns an integer, or whether the execution gets stuck, resulting in a measure-term-integer triple. In the first case, the value is exactly what the true subtraction would yield, as the s terms cancel. In the second case, we take the pessimistic assumption that t evaluates to a natural number which maximises the overall size of the difference; in this case, this occurs when t would evaluate to 0, so we may safely ignore the term. The third and fourth cases, we again assume the term s maximises the overall size. However, here s could evaluate to any natural number, and there is no finite bound. Thus in these cases, we return the error value ω, to denote that the subtraction is unboundedly large. We extend the order on integers to $\mathbb{Z} \uplus \{\omega\}$ by asserting that for all $n \in \mathbb{Z}$, $n \leq \omega$.

▶ **Lemma 1** (Difference is Bounded). *For all measures $m : M$, terms $t_1, t_2 : T$, and substitutions θ, where $[\![m]\!]\,\theta(t_1)$ and $[\![m]\!]\,\theta(t_2)$ are defined,*

$$[\![m]\!]\,\theta(t_1) - [\![m]\!]\,\theta(t_2) \;\leq\; (m, t_1, 0)\Downarrow \dot{-}\, (m, t_2, 0)\Downarrow.$$

5 Combining Measures

The termination of a function can be proven by finding a well-founded measure of the size of the arguments, such that the size of the arguments always decreases between the initial and recursive calls of the function.

Our termination algorithm builds measures from three components: *primitive measures*, *linear measures*, and *lexicographic measures*. Primitive measures are functions that transform a term into a natural number, representing a certain measure of the size of that term. We use "primitive measure" to refer both to the syntactic construct (M) and the corresponding mathematical functions ($T \to \mathbb{N}$).

A *linear combination of measures* is a weighted sum of measures. Given a vector of measures $\mathbf{m} : (\alpha \to \mathbb{N})^n$ and a vector of weights $\mathbf{w} : \mathbb{N}^n$ of the same length, we define

$$
\begin{array}{lcl}
(\cdot) & : & \mathbb{N}^n \to (\alpha \to \mathbb{N})^n \to (\alpha \to \mathbb{N}) \\
\mathbf{w} \cdot \mathbf{m} & = & (\lambda x.\ \sum_{i=1}^{m} \mathbf{w}_i \cdot \mathbf{m}_i(x)).
\end{array}
$$

In our termination algorithm, we will only take linear combinations of primitive measures, specialising the above to $\mathbb{N}^n \to (T \to \mathbb{N})^n \to (T \to \mathbb{N})$.

Since linear programming methods need to work in an ordered field, the tools we use will produce linear combinations of measures with positive *rational* coefficients. Finding such a linear combination is equivalent to finding a linear combination with natural coefficients, as the rational weights can be transformed to integers by multiplication of the least common multiple of the divisors of the weights. Note that the Haskell implementation of our algorithm uses fixed-point numbers, rather than exact arithmetic, which can lead to precision loss in this step.

6 Termination Algorithm

We want to show that our functions terminate, by showing that there is a measure of the arguments that decreases between every recursive call. We do this by combining primitive measures into linear combinations, and then making lexicographic combinations of these. Our termination algorithm is composed of three main phases:

1. Generating primitive measures of structural size for the sub-terms of the argument.
2. Generating the *primitive measure difference matrix*, that captures the size change between the initial and recursive arguments, as measured by the primitive measure functions.
3. Using the primitive measure difference matrix to find a lexicographic-linear combination of the primitive measure functions that decreases over every recursive call.

Finding lexicographic-linear combinations can be further broken down into two steps

i. Using the integer-only columns of the primitive measure difference matrix to find a linear combination of the primitive measure functions that decreases over the recursive calls that correspond to these columns.
ii. Using the linear combination procedure iteratively to determine a lexicographic combination of the linear measure functions that decreases over all recursive calls including those that do not have a simple integer difference.

To see how this algorithm works in the case of lexicographic termination, consider ex_3.

$$\begin{array}{lcl} ex_3\ \langle x, y, \mathbf{S}\, z\rangle & = & ex_3\ \langle x, y, z\rangle \\ ex_3\ \langle x, \mathbf{S}\, y, 0\rangle & = & ex_3\ \langle x, y, h\, y\rangle \\ ex_3\ \langle \mathbf{S}\, x, 0, 0\rangle & = & ex_3\ \langle x, h\, x, h\, x\rangle \end{array}$$

Note that, in this example h is some arbitrary function, and that we assume that any function called in a function definition (apart from the function being defined) terminates. That is, we show termination conditional on all called functions also terminating. However, when proving termination, we do not use any knowledge about the behaviour of called functions; so we have no bounds on the value that h will return. The primitive measures for ex_3 and the resulting difference matrix are

$$\begin{array}{l} m_1 = (\mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll})) \triangleleft \pi_1 \\ m_2 = (\mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll})) \triangleleft \pi_2 \\ m_3 = (\mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll})) \triangleleft \pi_3 \end{array} \qquad \begin{bmatrix} 0 & 0 & -1 \\ 0 & -1 & \omega \\ -1 & \omega & \omega \end{bmatrix}.$$

The value ω marks the worst-case value difference. The function h is assumed to terminate but may return a term of arbitrary size; thus the maximum bound of the change in value cannot be any integer. Note that ω prevents any column containing it from being used in a linear programming problem.

The ex_3 function has a lexicographic termination argument, as m_1 decreases or stays the same everywhere, m_2 decreases or stays the same when m_1 stays the same, and m_3 decreases when m_1 and m_2 stay the same. By the lexicographic elimination algorithm,

$$\begin{bmatrix} 0 & 0 & -1 \\ 0 & -1 & \omega \\ -1 & \omega & \omega \end{bmatrix} \rightsquigarrow \begin{bmatrix} 0 & -1 & \omega \\ -1 & \omega & \omega \end{bmatrix} \rightsquigarrow \begin{bmatrix} 0 & -1 & \omega \end{bmatrix} \rightsquigarrow \varnothing.$$

Linear and lexicographic termination arguments can be combined together to find a linear-lexicographic termination measure. To illustrate this, consider the function ex_4:

$$\begin{array}{lcl} ex_4\ \langle \mathbf{S}\, x, y, z, v, w\rangle & = & ex_4\ \langle x, h\, y, z, v, \mathbf{S}\, w\rangle \\ ex_4\ \langle x, \mathbf{S}\, y, \mathbf{S}\, z, v, w\rangle & = & ex_4\ \langle h\, x, y, z, \mathbf{S}\, v, \mathbf{S}\, w\rangle \\ ex_4\ \langle x, y, z, \mathbf{S}\,\mathbf{S}\,\mathbf{S}\, v, w\rangle & = & ex_4\ \langle x, h\, y, \mathbf{S}\, z, v, \mathbf{S}\, w\rangle \end{array}$$

where h represents an arbitrary function. The following is the difference matrix for ex_4:

$$\begin{bmatrix} -1 & \omega & 0 & 0 & 1 \\ \omega & -1 & -1 & 1 & 1 \\ 0 & \omega & 1 & -3 & 1 \end{bmatrix}.$$

Solving it requires both the linear and lexicographic aspects of our approach. This is again a situation where the pure lexicographic algorithm is not applicable. Moreover, in this case, one cannot find a positive rational linear combination of all the columns that results in a vector that is strictly less than 0 in all its entries. Using both ideas, we want to find some linear combination of the last three columns in the matrix, so as to eliminate some of the ω entries. Fortunately, it is not difficult to see that, labelling the columns of the matrix $c_1, c_2, \ldots, c_5$, one can take $2c_3 + c_4 + 0c_5 = (0 \ -1 \ -1)^\mathsf{T}$. (Where $(-)^\mathsf{T}$ is vector/matrix transposition.) This yields the following matrix

$$\begin{bmatrix} -1 & \omega & 0 \\ \omega & -1 & -1 \\ 0 & \omega & -1 \end{bmatrix}.$$

We now use the lexicographic algorithm to remove the last column and bottom-most two rows, resulting in the matrix $\begin{bmatrix} -1 & \omega \end{bmatrix}$, and then to reduce this matrix to $\varnothing$. Thus we have obtained a termination proof. The corresponding measure that decreases at every recursive call is $[(2 \cdot (\mathbf{size} \triangleleft \pi_3) + (\mathbf{size} \triangleleft \pi_4)), (\mathbf{size} \triangleleft \pi_1)]_{\text{lex}}$.

6.1 Primitive Measure Generation

Each term has several primitive measures, which are generated by observing how that term is destructured in the definition of the recursive function. These primitive measures are made of a composition of two parts: a function which descends through the non-recursive part of a term to extract the recursively constructed term, and a measure of that recursive term.

For example, take the two terms $\langle \mathbf{roll}\,\{\mathbf{inr}\ x\}, \langle\rangle\rangle$ and $\langle x, \langle\rangle\rangle$, and assume the former is the input argument to a function, and the second is the recursive argument. We can clearly see that the structural size of the left part of the tuple decreases from input to recursive call, due to the removal of the **roll**. We capture this intuition with the primitive measure function $(\mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll})) \triangleleft \pi_1$. The purpose of this measure is to extract the recursive part of the argument, i.e. to remove the $\langle -, \langle\rangle\rangle$ structure, and then to count the number of nestings of the structure $\mathbf{roll}\,\{\mathbf{inr}\ -\}$.

Primitive measure generation is composed of two parts: generating the recursive part of the measure and generating the function that extracts the recursive subterm. The function $primM_{\text{R}}$ generates the recursive parts of the primitive measures. It takes a variable name x, a partially constructed recursive measure m_r, and a term t. The measure is initialised with id for notational convenience where $m \triangleright \text{id} = m$; in our implementation we use lists of measure destructors.

The recursive measures are generated by the function

$$
\begin{array}{lcl}
primM_{\mathrm{R}}(x, m_r, \mathbf{var}\, y) & = & \begin{cases} \{\mathbf{fix}\, m_r\} & \mathbf{if}\ x = y \wedge m_r \neq \mathrm{id} \\ \emptyset & \mathbf{if}\ x \neq y \vee m_r = \mathrm{id} \end{cases} \\
primM_{\mathrm{R}}(x, m_r, \langle\rangle) & = & \emptyset \\
primM_{\mathrm{R}}(x, m_r, \langle t_1, t_2\rangle) & = & primM_{\mathrm{R}}(x, (\pi_1 \triangleleft m_r), t_1) \\
 & & \cup\, primM_{\mathrm{R}}(x, (\pi_2 \triangleleft m_r), t_2) \\
primM_{\mathrm{R}}(x, m_r, \mathbf{inl}\ t) & = & primM_{\mathrm{R}}(x, \mathbf{uninl} \triangleleft m_r, t) \\
primM_{\mathrm{R}}(x, m_r, \mathbf{inr}\ t) & = & primM_{\mathrm{R}}(x, \mathbf{uninr} \triangleleft m_r, t) \\
primM_{\mathrm{R}}(x, m_r, \mathbf{roll}\,\{t\}) & = & primM_{\mathrm{R}}(x, \mathbf{unroll} \triangleleft m_r, t) \\
primM_{\mathrm{R}}(x, m_r, \mathbf{app}\, f\, t) & = & \emptyset.
\end{array}
$$

Consider the example above comparing x and $\mathbf{roll}\,\{\mathbf{inl}\ x\}$. As expected, the generator produces the set $\{\mathbf{fix}\,(\mathbf{uninl} \triangleleft \mathbf{unroll})\}$. A more complex example is comparing x and $\mathbf{roll}\,\{\langle x, x\rangle\}$; the measure set generated is $\{\mathbf{fix}\,(\pi_1 \triangleleft \mathbf{unroll}), \mathbf{fix}\,(\pi_2 \triangleleft \mathbf{unroll})\}$ with a generated measure for each occurrence of x.

We can now generate a set of measures for recursive terms. However, we still need to generate the part of the measure that extracts the subterm where the recursion occurs. This part of the measure is appended to the recursive measures generated by calling $primM_{\mathrm{R}}$. It is constructed by recursion on both the initial and recursive arguments.

$$
\begin{array}{lcl}
primM(m, \mathbf{var}\, x, u) & = & \{r \triangleleft m \mid r \in primM_{\mathrm{R}}(x, \mathrm{id}, u)\} \\
primM(m, t, \mathbf{var}\, y) & = & \{r \triangleleft m \mid r \in primM_{\mathrm{R}}(y, \mathrm{id}, t)\} \\
primM(m, \langle\rangle, \langle\rangle) & = & \emptyset \\
primM(m, \langle t_1, t_2\rangle, \langle u_1, u_2\rangle) & = & primM(\pi_1 \triangleleft m, t_1, u_1) \\
 & & \cup\, primM(\pi_2 \triangleleft m, t_2, u_2) \\
primM(m, \mathbf{inl}\ t, \mathbf{inl}\ u) & = & primM(\mathbf{uninl} \triangleleft m, t, u) \\
 & & \cup\, \{\mathbf{case01} \triangleleft m, \mathbf{case10} \triangleleft m\} \\
primM(m, \mathbf{inr}\ t, \mathbf{inr}\ u) & = & primM(\mathbf{uninr} \triangleleft m, t, u) \\
 & & \cup\, \{\mathbf{case01} \triangleleft m, \mathbf{case10} \triangleleft m\} \\
primM(m, \mathbf{roll}\,\{t\}, \mathbf{roll}\,\{u\}) & = & primM(\mathbf{unroll} \triangleleft m, t, u) \\
primM(m, t, u) & = & \emptyset \qquad\qquad \mathbf{otherwise}
\end{array}
$$

Note that sums, in addition to the measures of recursive size-change of the components, also have measures to detect when a sum switches from left to right (or vice-versa). Due to these measures and the fact we are finding linear combinations of primitive measures, we do not need to generate quadratically many measures for the combinations of the left and right submeasures, as done by others [7].

To generate the primitive measures for a function f, we first apply *primM* to every initial and recursive argument pair in the equations defining f, initialising m with id. For each measure m generated through this process, if m is of the form $(\mathbf{fix}\ \ (m' \triangleleft \cdots \triangleleft m')) \triangleleft m''$, with the m' repeated, we simplify it to $(\mathbf{fix}\ \ m') \triangleleft m''$. This step is useful in cases where, for example, a function removes the same pattern multiple times; like ex_2, which removes multiple **S** constructors. This simplification step ensures the simplified measure function only removes one of these patterns at a time. The simplified measure returns the same size as $[\![m]\!]$ when $[\![m]\!]$ is defined, and it is defined for more terms; this property follows from the definition of the evaluation function.

With this method for primitive measure generation in hand, we return to the *toList* example from Section 1. To demonstrate how this measure generation works, we first need to unfold the SparseList and List constructors in *toList* according to Figure 5,

$$\begin{array}{llll} \mathbf{Nil} & = \mathbf{roll}\,\{\mathbf{inl}\,\langle\rangle\} & \mathbf{SNil} & = \mathbf{roll}\,\{\mathbf{inl}\,\langle\rangle\} \\ \mathbf{Cons}\ x\ xs & = \mathbf{roll}\,\{\mathbf{inr}\,\langle x, xs\rangle\} & \mathbf{SCons}\ x\ n\ xs & = \mathbf{roll}\,\{\mathbf{inr}\,\langle x, \langle n, xs\rangle\rangle\} \end{array}$$

Figure 5 Encodings of lists and sparse lists.

$$\begin{array}{lcl} \mathit{toList}\ (\mathbf{roll}\,\{\mathbf{inl}\,\langle\rangle\}) & = & \mathbf{roll}\,\{\mathbf{inl}\,\langle\rangle\} \\ \mathit{toList}\ (\mathbf{roll}\,\{\mathbf{inr}\,\langle x, \langle \mathbf{roll}\,\{\mathbf{inl}\,\langle\rangle\}, xs\rangle\rangle\}) & = & \mathit{toList}\ xs \\ \mathit{toList}\ (\mathbf{roll}\,\{\mathbf{inr}\,\langle x, \langle \mathbf{roll}\,\{\mathbf{inr}\ n\}, xs\rangle\rangle\}) & = & \mathbf{roll}\,\{\mathbf{inr}\,\langle x, \langle \mathit{toList}\ (\mathbf{roll}\,\{\mathbf{inr}\,\langle x, \langle n, xs\rangle\rangle\})\rangle\rangle\}. \end{array}$$

The primitive measure generation algorithm produces measures corresponding to the recursive uses of both n and xs. The two measures, along with their difference matrix, are

$$\begin{array}{ll} m_0 = \mathbf{fix}\,(\pi_2 \triangleleft \pi_2 \triangleleft \mathbf{uninr} \triangleleft \mathbf{unroll}) & \\ m_1 = \mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll}\,) \triangleleft (\pi_1 \triangleleft \pi_2 \triangleleft \mathbf{uninr} \triangleleft \mathbf{unroll}) & \begin{bmatrix} -1 & \omega \\ 0 & -1. \end{bmatrix} \end{array}$$

These can then be combined into an overall decreasing measure as $[m_0, m_1]_{\text{lex}}$.

6.2 Primitive Measure Difference Matrix

The fundamental data structure used in our termination-checking algorithm, T-Rex, is the *primitive measure difference matrix*, $D : (\mathbb{Z} \uplus \{\omega\})^{n \times k}$, or *difference matrix* for short. Rows in D represent argument-pairs and columns represent primitive measures. The elements are the conservative size change between the initial argument and the recursive argument. Formally, for any function definition (with n recursive calls), let the recursive call matrix of that function be $R : (T)^{n \times 2}$ where R_{i1} is the pattern of the i-th recursive call (lifted to a term) and R_{i2} is the recursive argument term of the i-th recursive call. We define the difference matrix D of a vector of k primitive measures, $\mathbf{m} : M^k$, as $D_{ij} = (\mathbf{m}_j, R_{i2}, 0)\Downarrow \mathbin{\dot{-}^\star} (\mathbf{m}_j, R_{i1}, 0)\Downarrow$ where $1 \le i \le n$ and $1 \le j \le k$. This matrix captures the size-change information of the measures $\mathbf{m}$ on every recursive call in the function. Note that it uses the upper bound difference, $(\mathbin{\dot{-}^\star})$, and so the estimated difference can be unbounded, i.e. ω.

Returning to the function ex_2, the entries of the difference matrix evaluate to

$$\begin{array}{llll} m_{\mathbf{S}}\ x & \mathbin{\dot{-}^\star} & (m_{\mathbf{S}}\ x + 2) & = -2 \\ (m_{\mathbf{S}}\ x + 1) & \mathbin{\dot{-}^\star} & m_{\mathbf{S}}\ x & = 1 \end{array} \quad \text{and} \quad \begin{array}{llll} m_{\mathbf{S}}\ y & \mathbin{\dot{-}^\star} & (m_{\mathbf{S}}\ y + 2) & = -2 \\ (m_{\mathbf{S}}\ y + 1) & \mathbin{\dot{-}^\star} & m_{\mathbf{S}}\ y & = 1 \end{array}$$

where $m_{\mathbf{S}} = \mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll})$,

This results in the following difference matrix:

$$\begin{bmatrix} -2 & 1 \\ 1 & -2 \end{bmatrix}.$$

In example ex_3, the arbitrary functions result in the measures becoming incomparable, resulting in ω. Consider the reduced differences that do not result in 0,

$$\begin{array}{llll} m_{\mathbf{S}}\ y & \mathbin{\dot{-}^\star} & (m_{\mathbf{S}}\ y + 1) & = -1 \\ m_{\mathbf{S}}\ (h\ y) & \mathbin{\dot{-}^\star} & 1 & = \omega \\ m_{\mathbf{S}}\ (h\ x) & \mathbin{\dot{-}^\star} & 1 & = \omega \end{array}$$

where $m_{\mathbf{S}} = \mathbf{fix}\,(\mathbf{uninr} \triangleleft \mathbf{unroll})$.

When the measure of the recursive argument, on the left-hand side, is not a concrete integer (e.g. $m_{\mathbf{S}}\ (h\ y)$), but the right hand side is, we can only pessimistically conclude that the value could be any large natural number. Thus we return ω, to mark that we cannot handle this case using linear arithmetic.

6.3 Finding Linear Measures

We wish to use our primitive measures to create better measures; that is, measures that decrease on more recursive calls. We will first consider *linear* combinations of measures. As we discussed in the last section, the difference matrix captures the size change information of the arguments as they change between recursive calls. This information helps determine weights that can be used to construct a linear combination of the primitive measures. Note that this phase only considers D matrices that contain no ω values. This enables applying standard linear solvers. The ω values are handled at a later phase.

To find suitable weights, first we will show that *any* vector of positive weights $\mathbf{w} : (\mathbb{Z}^+)^n$ that satisfies the equation $D\mathbf{w} \leq 0$ produces a non-increasing measure. Secondly, we will determine how to pick the *best* such vector: that is, the one that produces a measure that *strictly* decreases between the arguments of as many recursive calls as possible.

Decreasing linear combinations

The following lemma shows that any non-positive solution to $D\mathbf{w}$ can be used to construct a non-increasing measure.

▶ **Lemma 2** (Soundness of linear measure construction). *Given a vector of positive weights $\mathbf{w} : (\mathbb{Z}^+)^n$, a vector of measures $\mathbf{m} : M^n$, if there are no ω values in D and $(D\mathbf{w})_i \leq 0$ for row i, then for each initial-recursive argument pair R_i, and all substitutions θ where, for every j, $[\![\mathbf{m}_j]\!]\ \theta(R_{i1})$ and $[\![\mathbf{m}_j]\!]\ \theta(R_{i2})$ are defined, then $(\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i2}) - (\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i1}) \leq 0$. Similarly, if $(D\mathbf{w})_i < 0$, then $(\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{k2}) - (\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{k1}) < 0$. (Where $[\![-]\!]$ is lifted pointwise.)*

To give an example, we return to the function ex_2, which has the difference matrix

$$\begin{bmatrix} -2 & 1 \\ 1 & -2 \end{bmatrix}.$$

The weight vector $\mathbf{w} = (1\ 1)^\mathsf{T}$ produces the all-negative vector $D\mathbf{w} = (-1\ \ -1)^\mathsf{T}$. As such, we can conclude that the measure $(1\ 1)^\mathsf{T} \cdot (m_1\ m_2)^\mathsf{T}$ guarantees that ex_2 terminates.

The maximal negative entries problem

This problem is concerned with finding the best weights $\mathbf{w}$, that ensure that the maximum number of recursive calls decrease. To see why not just any weight will do, consider again the example ex_4. We showed that its matrix,

$$\begin{bmatrix} -1 & \omega & 0 & 0 & 1 \\ \omega & -1 & -1 & 1 & 1 \\ 0 & \omega & 1 & -3 & 1 \end{bmatrix}$$

was solvable using our proposed algorithm. However, had we chosen instead the linear combination $(1\ 1\ 0)^\mathsf{T}$, this would have resulted in the output vector $(0\ 0\ \ -2)^\mathsf{T}$, which only removes the final recursive call / row, resulting in the unsolvable subproblem:

$$\begin{bmatrix} -1 & \omega \\ \omega & -1 \end{bmatrix}.$$

Thus, we want to pick weights such that not only $D\mathbf{w} \leq 0$, but also that $D\mathbf{w}$ has as many negative entries as possible. We call this the *maximal negative entries* (MNE) problem.

▶ **Definition 3** (The Maximal Negative Entries Problem). *For a matrix A, find a vector $\mathbf{x}$ such that the vector $A\mathbf{x}$ has a maximal number of negative entries.*

Reducing the MNE problem to a linear program

We want to find a programmatic method to solve this problem. This problem can be reduced to solving a linear program. This is fortunate as linear programs are well-studied and they are solvable in polynomial time [5].

The MNE problem tells us to maximise the number of strictly negative entries of $A\mathbf{x}$, such that $\mathbf{x} \geq 0$ and $A\mathbf{x} \leq 0$. We can reframe this as finding some slack vector $\mathbf{c} \geq 0$, such that $A\mathbf{x} + \mathbf{c} = 0$ and $\mathbf{c}$ has a maximal number of *positive* entries (as $A\mathbf{x} = -\mathbf{c}$).

Secondly, note that solutions to this problem are linear, in the sense that if $(\mathbf{x}, \mathbf{c})$ is a solution to $A\mathbf{x} + \mathbf{c} = 0$ and $\mathbf{c}$ has maximal positive entries, then, for a positive scalar k, $A(k\mathbf{x}) + k\mathbf{c} = k(A\mathbf{x} + \mathbf{c}) = 0$, and so $(k\mathbf{x}, k\mathbf{c})$ is also a solution. The crucial thing to note here is that we can scale up or down the size of any such solution vector by any positive scaling factor. This means that a solution exists exactly when a solution exists that satisfies the additional condition that $\mathbf{c}$ has entries that are either exactly 0 or greater than or equal to 1. This allows us to take the final step in our transformation of this problem.

Break up $\mathbf{c}$ (with entries now guaranteed to be 0 or $\geq$1) into $\mathbf{b} + \mathbf{z}$, where b is bounded between 0 and 1 and $0 \leq z$, The optimisation goal "maximise the sum of $\mathbf{b}$" will produce a solution $(\mathbf{x}, \mathbf{b}, \mathbf{z})$ where $\mathbf{b}$ has entries that are either 0 or 1 (as $\mathbf{b} + \mathbf{z}$ is 0 or ≥ 1) and $\mathbf{z}$ is the slack necessary to make the sum cancel. Note that $\mathbf{b}_i$ is 1 exactly when $(A\mathbf{x})_i < 0$, thus the number of negative entries in $A\mathbf{x}$ is equal to the sum of $\mathbf{b}$. As the sum of b is maximised, the number of negative entries in $A\mathbf{x}$ is maximised.

Lastly, as $\mathbf{z}$ is only constrained to be ≥ 0, $\mathbf{z}$ is a slack vector of this new program. We may simplify the program by removing $\mathbf{z}$ and turning the equality constraints to inequality constraints. Thus, the maximal negative entries problem is equivalent to solving the linear programming problem specified in Algorithm 1. Note that the program *fails* to find a satisfactory solution for our purposes when it returns the all-zero vector.

Algorithm 1 LinMNE: A linear program for the MNE problem.

$$
\begin{array}{rcl}
\textbf{maximise} & \sum_{i=0}^{n-1} \mathbf{b}_i & \\
\textbf{subject to} & & \\
\mathbf{x}_i, \mathbf{b}_i & \in & \mathbb{Q} \\
A\mathbf{x} + \mathbf{b} & \leq & 0 \\
0 & \leq & \mathbf{x}_i \\
0 & \leq & \mathbf{b}_i \leq 1
\end{array}
$$

Uniqueness of the maximal negative entry set

Even though the above program will find a set with a maximal number of negative entries, we have not yet established that such a set is unique. If there are two solutions that identify a different set of rows that decrease, this may lead to a different order of row elimination in the lexicographic stage of our algorithm. Such a possibility threatens the complexity and completeness of our algorithm. However, there is, in fact, a *unique* maximal set of negative entries that solves the linear program. Note that this uniqueness is in the set of entries, not in the solution; there can be many solutions, but all of them will show the *same* set of recursive calls decrease.

▶ **Theorem 4** (Unique Maximal Negative Entries). *For every matrix $A \in \mathbb{Q}^{n \times m}$, if $\langle \mathbf{x}, \mathbf{b} \rangle$ and $\langle \mathbf{x}', \mathbf{b}' \rangle$ are solutions of the MNE problem for A, then $\mathbf{b} = \mathbf{b}'$.*

6.4 Finding Lexicographic Measures of Linear Combinations

The lexicographic phase of the algorithm solves the termination problem for a matrix of weights that may include ω; the value that marks that a finite bound on the size change could not be found. The algorithm finds a lexicographic combination of linear measures, such that whenever a linear measure was approximated to ω, there is a lexicographically larger linear measure that returns a natural number. This lexicographic algorithm follows the same structure as Isabelle/HOL's [7]. Our overall **T-Rex** algorithm proceeds as follows:

Algorithm 2 The T-Rex Termination Algorithm.

function T-Rex($m : [M], D :$ Matrix $(\mathbb{Z} \uplus \omega)) : [[\mathbb{N} \times M]] \uplus$ **fail**
  (Precondition: length$(m) =$ columnN(D).)
  $out \coloneqq []$
  repeat
    $N \coloneqq$ Extract the purely numeric ($\mathbb{Z}$) columns of D
    if $N = \varnothing$ **then return fail end if** ▷ (if there are no purely numeric columns, fail)
    $(x, b) \coloneqq$ LinMNE(N)
    $x \coloneqq$ select non-zero weights in x
    if $x = \varnothing$ **then return fail end if** ▷ (if no measures were selected, fail)
    $x \coloneqq x \cdot$ lcm(denoms(w)) ▷ (normalise the weights to natural numbers)
    $D \coloneqq D$ without rows where b is 1
    (Note: recall the linear program establishes that $(D\mathbf{x})_i$ is negative when $\mathbf{b}_i = 1$.)
    $wm \coloneqq$ weights in x paired with their corresponding measures in m
    $out \coloneqq out ::_{\mathrm{r}} wm$ ▷ ($::_{\mathrm{r}}$ is concatenate to end)
  until $M = \varnothing$
  return out
end function
(Note: we elide the tracking of column indices for clarity.)

Since linear program solving is polynomial time [5] and the number of loops performed is bounded by the number of rows in D, we can deduce that our algorithm also runs in polynomial time. But of course, we would like to know slightly more than just the correctness and complexity of our algorithm. Our algorithm is complete in the following sense. If a lexicographic-linear combination of primitive measures exists, our algorithm decides termination.

▶ **Lemma 5.** *Let f be a function and let A be a matrix whose columns correspond to some set of measures P whose elements we allow to be any $\mathbb{N}$-linear combination of the columns of the difference matrix of f. Then, there exists a lexicographic combination of the elements of P which decreases at every recursive call of f if and only if we can reduce A to $\emptyset$ by removing rows per the lexicographic algorithm.*

▶ **Theorem 6** (Decision Power of T-Rex)**.** *Given a function f with an associated set of primitive measures P, if there exists some lexicographic order of $\mathbb{N}$-linear combinations of elements of P which decreases at every recursive call of f, then **T-Rex** will succeed.*

7 Related Work

There is a relevant body of work in the context of analysing the termination of imperative programs called synthesis of ranking functions. This was initially introduced by Floyd [10], and later incorporated into Hoare logic to allow for proving the total correctness of imperative programs. Ranking functions are directly analogous to measures. In the context of imperative programs, ranking functions map variables that are updated in a loop body to a well-ordered set, and to prove termination they must decrease at each iteration. Typically in this context, the termination of a single loop with a single branch is studied, which broadly corresponds in our context to studying functions with a single recursive call.

A line of work on termination analysis is concerned with finding classes of programs (e.g. programs that operate on reals) with *linear loops* for which termination is decidable, by relating this problem to stability in control theory [20]. Part of the linear loops literature is concerned with synthesising ranking functions for linear-constraint loops [6, 19]. Here, we have a set of variables, a loop guard describing a linear constraint on these variables, and at each iteration, we have updated our vector of variables $\mathbf{x}$ by an affine transformation $A\mathbf{x} + \mathbf{b}$ [13]. (These affine transformations can always be converted to a linear transformation $A'\mathbf{x}$ by adding more variables.) The kind of ranking functions synthesised for these problems are similar to the lexicographic combinations of linear transformations that we see in our work [6]. One main distinction is that in our work, there is almost always more than one recursive call, and in their work, there is almost always some non-trivial condition on the loop guard, providing different challenges and resulting in different algorithms for handling termination within different programming language paradigms.

Linear and lexicographic termination techniques have also been explored in the context of probabilistic imperative programming. Similar algorithms to the measure combination step of the algorithm, utilising linear programming to combine size-change information, have been independently developed in this context [4]. However, a direct comparison between them presents a non-trivial challenge as this work operates on generalised transition systems generated from analysis of imperative code, while our work operates on primitive measures. Even given these similarities, our improved method of primitive measure generation handles cases that the Isabelle/HOL algorithm does not, even with the purely lexicographic solver.

Our work is directly inspired by and most closely related to Isabelle/HOL's lexicographic termination algorithm [2, 7]. It constructs termination matrices based on the comparison of arguments between the initial and recursive calls, as we do, but they do not compute a numeric difference. Since this approach ignores the numerical difference and conflates increase with uncertainty, it cannot be used to find linear combinations of measures. While our matrices carry more information, our lexicographic matrix elimination algorithm is structurally similar to Bulwahn et. al.'s lexicographic matrix elimination algorithm [7]. Note that we do not drop columns, as this can cause unsoundness if the final column is not wholly decreasing. Our algorithm also works without access to types or higher-order logic simplification theories. Hence, it is extensible to various functional languages and can be used without theorem-proving experience.

Another approach is the size-change termination method [16, 12], which is orthogonal to our method, as it tracks the size change of *data* (i.e. the constructors around variables) in function arguments, whereas we track the size change of the function arguments, disregarding the flow of variables. Types can be used to restrict functions to use terminating recursion [1], but this method requires user annotation, and cannot find complex linear termination measures.

Other approaches for functional termination checking involve using an external term-rewriting checker to show the termination of function programs [15]. This has the advantage of bringing well-developed termination checkers for term rewriting systems to functional termination checking, but requires that the semantics of the functional language be reflected in a term rewriting system. Further, any witness of termination must be translated backwards through this semantics. Our approach gives simple measure functions as witnesses.

8 Conclusion

We have developed T-Rex: a novel termination algorithm for recursive functions. It can prove the termination of functions by lexicographically ordering linear combinations of primitive measures that decrease at every recursive call. The primitive measures are computed directly

by examining the structure of the recursive program. We define a language for simplifying and comparing primitive measures that are used as part of our termination algorithm and prove meta-theoretic properties of our measure language. We prove that T-Rex is sound, that it runs in polynomial time and that it covers a large class of programs and demonstrate the algorithm on an untyped first-order functional language. We provide an implementation of the untyped language, measure language and of T-Rex in Haskell.

A Proofs

A.1 Proofs from Section 4

To prove Lemma 1, we need the following lemmas.

▶ **Lemma 7** (Measure Evaluation respects Substitution). *For all substitutions θ,*

1. *if $(m, t, i)\Downarrow = j$ then $(m, \theta(t), i)\Downarrow = j$; and*
2. *if $(m, t, i)\Downarrow = (m', t', j)$ then $(m, \theta(t), i)\Downarrow = (m', \theta(t'), j)\Downarrow$.*

Proof Sketch. By induction on $(m, t, i)\Downarrow$. We will only prove illustrative cases.

Stuck $(m, t, i)\Downarrow = (m, t, i)$: Note that t is a variable, function, or doesn't match m. If t is a variable or function, $\theta(t)$ could be a new term, but in this case $(m, \theta(t), i)\Downarrow = (m, \theta(t), i)\Downarrow$. If t is a non-matching term, then θ cannot change it, and $(m, \theta(t), i)\Downarrow = (m, \theta(t), i)$.

Uninr/Inl $(m \triangleleft \mathbf{uninr}, \mathbf{inl}\ t, i)\Downarrow = i$: as $\theta(\mathbf{inl}\ t) = \mathbf{inl}\ \theta(t)$, $(m \triangleleft \mathbf{uninr}, \theta(\mathbf{inl}\ t), i)\Downarrow = i$. The other base cases proceed similarly.

Unroll/Roll $((m \triangleleft \mathbf{unroll}), (\mathbf{roll}\ \{t\}), i)\Downarrow = (m, t, 1 + i)\Downarrow$:
As $\theta(\mathbf{roll}\ \{t\}) = \mathbf{roll}\ \{\theta(t)\}$,

$$(m \triangleleft \mathbf{unroll}, \theta(\mathbf{roll}\ \{t\}), i)\Downarrow = (m \triangleleft \mathbf{unroll}, \mathbf{roll}\ \{\theta(t)\}, i)\Downarrow = (m, \theta(t), i + 1)\Downarrow,$$

as required.

Fix $((\mathbf{fix}\, m), t, i)\Downarrow = (((\mathbf{fix}\, m) \triangleleft m), t, i)\Downarrow$:

$$((\mathbf{fix}\, m), \theta(t), i)\Downarrow = (((\mathbf{fix}\, m) \triangleleft m), \theta(t), i)\Downarrow,$$

as required.

The other inductive cases proceed similarly. ◀

▶ **Lemma 8** (Measure Evaluation Counter Export).
If $(m, \theta(t), i + j)\Downarrow = k$ iff $(m, \theta(t), i)\Downarrow = j + k$.

Proof Sketch. A simple proof by splitting the iff, then induction on $(-)\Downarrow$. ◀

With these lemmas in hand, we can prove Lemma 1.

Proof of Lemma 1. Recall that we are guaranteed that $(m, \theta(t_1), 0)\Downarrow$ and $(m, \theta(t_2), 0)\Downarrow$ are integers. We proceed by cases on $(m, t_1, 0)\Downarrow \mathbin{\dot{-}} (m, t_2, 0)\Downarrow$.

Case 1: $(m, t_1, 0)\Downarrow = (m', s, i)$ and $(m, t_2, 0)\Downarrow = (m', s, j)$. Then

$$\begin{aligned}
&(m, \theta(t_1), 0)\Downarrow - (m, \theta(t_2), 0)\Downarrow \\
&= (m', \theta(s), i)\Downarrow - (m', \theta(s), j)\Downarrow \quad \text{(Case assumptions \& Lemma 7)} \\
&= ((m', \theta(s), 0)\Downarrow + i) - ((m', \theta(s), 0)\Downarrow + j) \quad \text{(Lemma 8)} \\
&= i - j \\
&= (m', s, i) \mathbin{\dot{-}} (m', s, j) \\
&= (m, t_1, 0)\Downarrow \mathbin{\dot{-}} (m, t_2, 0)\Downarrow.
\end{aligned}$$

Case 2: $(m, t_1, 0)\Downarrow = i$ and $(m, t_2, 0)\Downarrow = (m', s, j)$. Then

$$\begin{aligned}
&(m, \theta(t_1), 0)\Downarrow - (m, \theta(t_2), 0)\Downarrow \\
&= i - (m', \theta(s), j)\Downarrow \quad \text{(Case assumptions \& Lemma 7)} \\
&= i - (m', \theta(s), j)\Downarrow \quad \text{(Lemma 8)} \\
&\leq i - j \\
&= i \mathbin{\dot{-}} (m', s, j) \\
&= (m, t_1, 0)\Downarrow \mathbin{\dot{-}} (m, t_2, 0)\Downarrow.
\end{aligned}$$

Case 3+4: $(m, t_1, 0)\Downarrow \mathbin{\dot{-}} (m, t_2, 0)\Downarrow$ evaluates to ω.

True as $(m, \theta(t_1), 0)\Downarrow - (m, \theta(t_2), 0)\Downarrow$ is an integer, and for all $k \in \mathbb{Z}$, $k \leq \omega$. ◀

A.2 Proofs from Section 6

For the following proof, we need to enrich ω with the properties that $\omega + k = k + \omega = \omega$ for all $k \in \mathbb{Z}$ and $n \cdot \omega = \omega$ for all $n \in \mathbb{Z}^+$.

Proof of Lemma 2. Recall the initial and recursive arguments are stored in R. Thus, for any recursive call in D, indexed by i, we have

$$\begin{aligned}
(D\mathbf{w})_i &= \sum_{j=0}^{k} \mathbf{w}_j \cdot R_{ij} \\
&= \sum_{j=0}^{k} \mathbf{w}_j \cdot ((\mathbf{m}_j, R_{i2}, 0)\Downarrow \mathbin{\dot{-}} (\mathbf{m}_j, R_{i1}, 0)\Downarrow) \\
&\geq \sum_{j=0}^{k} \mathbf{w}_j \cdot ((\mathbf{m}_j, \theta(R_{i2}), 0)\Downarrow - (\mathbf{m}_j, \theta(R_{i1}), 0)\Downarrow) \qquad \text{(Lemma 1)} \\
&= \sum_{j=0}^{k} \mathbf{w}_j \cdot ([\![\mathbf{m}_j]\!]\ \theta(R_{i2})) \ - \ \sum_{j=0}^{k} \mathbf{w}_j \cdot ([\![\mathbf{m}_j]\!]\ \theta(R_{i1})) \\
&= (\lambda x.\ \sum_{j=0}^{k} \mathbf{w}_j \cdot ([\![\mathbf{m}_j]\!]\ x))\ \theta(R_{i2}) \ - \ (\lambda x.\ \sum_{j=0}^{k} \mathbf{w}_j \cdot ([\![\mathbf{m}_j]\!]\ x))\ \theta(R_{i1}) \\
&= (\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i2}) \ - \ (\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i1}).
\end{aligned}$$

Thus $(D\mathbf{w})_i \leq 0$ implies $(\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i2}) - (\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i1}) \leq 0$, and $(D\mathbf{w})_i < 0$ implies $(\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i2}) - (\mathbf{w} \cdot [\![\mathbf{m}]\!])\ \theta(R_{i1}) < 0$. ◀

Proof of Theorem 4. Assume there are two solutions with a different set of negative entries $\langle \mathbf{x}, \mathbf{b} \rangle$ and $\langle \mathbf{x}', \mathbf{b}' \rangle$. Let $\mathbf{x}'' = \mathbf{x} + \mathbf{x}'$ and $\mathbf{b}''_j = \max(\mathbf{b}_j, \mathbf{b}'_j)$ for each $0 \leq j < n$. Then, the tuple $\langle \mathbf{x}'', \mathbf{b}'' \rangle$ is a more optimal solution.

Firstly, $\langle \mathbf{x}'', \mathbf{b}'' \rangle$ has a greater objective. As, by assumption, there is some component different between $\mathbf{b}$ and $\mathbf{b}'$, thus we have $\sum_{i=0}^{n-1} \mathbf{b}_i < \sum_{i=0}^{n-1} \mathbf{b}''_i$ and $\sum_{i=0}^{n-1} \mathbf{b}'_i < \sum_{i=0}^{n-1} \mathbf{b}''_i$. Thus the objective is larger.

Secondly, $\langle \mathbf{x}'', \mathbf{b}'' \rangle$ satisfies all constraints, as (i) by the fact we are taking a sum of non-negative values, $0 \leq \mathbf{x}''$, (ii) by the fact we are taking a maximum, $0 \leq \mathbf{b}'' \leq 1$, and (iii) $A\mathbf{x}'' + \mathbf{b}'' \leq 0$ as

$$\begin{aligned} A\mathbf{x}'' + \mathbf{b}'' \leq 0 &\iff A(\mathbf{x} + \mathbf{x}') + \max(\mathbf{b}, \mathbf{b}') \leq 0 \\ &\iff A\mathbf{x} + A\mathbf{x}' + \max(\mathbf{b}, \mathbf{b}') \leq 0 \\ &\impliedby A\mathbf{x} + A\mathbf{x}' + \mathbf{b} + \mathbf{b}' \leq 0 \\ &\impliedby A\mathbf{x} + \mathbf{b} \leq 0 \wedge A\mathbf{x}' + \mathbf{b}' \leq 0 \end{aligned}$$

Thus, our assumption was incorrect, and, by classical contradiction, the two solutions cannot have a different set of negative entries. ◀

To prove Lemma 5, we require the following auxiliary lemma establishing the soundness of lexicographic-linear combination:

▶ **Lemma 9** (Soundness of lexicographic-linear combination)**.** *Given a list of weighted measures* $\mathbf{wm} : [[\mathbb{N} \times M]]$ *returned by the algorithm (Algorithm 2), then for each initial-recursive argument pair* R_k*, and all substitutions* θ *where* $\mathbf{m}_{ij}\ \theta(R_{k1})$ *and* $\mathbf{m}_{ij}\ \theta(R_{k2})$ *are defined (for every* i *and* j*), then*

$$[\ldots, \mathbf{w}_i \cdot [\![\mathbf{m}_i]\!], \ldots]_{\text{lex}}\ \theta(R_{k2}) < [\ldots, \mathbf{w}_i \cdot [\![\mathbf{m}_i]\!], \ldots]_{\text{lex}}\ \theta(R_{k1}).$$

(Where $\mathbf{w}_i$ *and* $\mathbf{m}_i$ *are the unzipping of* $\mathbf{wm}_i$*, and* $(\cdot)$ *and* $[\![-]\!]$ *are lifted pointwise over lists.)*

Proof. By the construction of the output list and Lemma 2, there is a first $\mathbf{w}_i$, $\mathbf{m}_i$ such that $\mathbf{w}_i \cdot [\![\mathbf{m}_i]\!]\ \theta(R_{k2}) < \mathbf{w}_i \cdot [\![\mathbf{m}_i]\!]\ \theta(R_{k1})$ and for every $i' < i$, $\mathbf{w}_{i'} \cdot [\![\mathbf{m}_{i'}]\!]\ \theta(R_{k2}) = \mathbf{w}_{i'} \cdot [\![\mathbf{m}_{i'}]\!]\ \theta(R_{k1})$. This is the definition of a lexicographic decrease ◀

Proof of Lemma 5. Suppose there was some lexicographic combination of elements of P, which we will call $[m_1, m_2, \ldots m_n]_{\text{lex}}$, which decreases at every recursive call of f but which could not be found by removing rows from the associated matrix. At some point, by assumption, this sequence of measures $[m_1, m_2, \ldots m_n]_{\text{lex}}$ must not be reachable by removing rows from the matrix A, per the rule in the lexicographic algorithm. Call the first such measure m_i. Hence, by assumption once we remove all the rows corresponding to measures $m_1, \ldots, m_{i-1}$, we must not be able to proceed using the lexicographic algorithm. Hence, there can be no column in the corresponding matrix with all entries less than or equal to 0 with at least one negative entry, namely the column associated with the measure m_i cannot have this property. But this means that there exists a recursive call on which the measure $[m_1, m_2, \ldots m_i]_{\text{lex}}$ does not decrease, which is a contradiction. ◀

Proof of Theorem 6. Suppose this were not the case and there is a lexicographic order of linear combinations of the primitive measures that could not be found by our algorithm. By definition **T-Rex** can only fail if, at some stage of evaluation, it reaches a stage where there is no non-trivial solution to the MNE problem using the numeric columns of the matrix. But using Theorem 4, we know that each time we take a linear combination of numeric columns, we get a vector whose number of negative entries is maximal and where the location of these negative entries is unique. Hence, for any given numeric part of the matrix, there is a unique set of rows R that is removed by the lexicographic phase of the algorithm such that any other set of rows that could be removed by the process of taking linear combinations is a subset of R. ◀

The 2-Dimensional Constraint Loop Problem Is Decidable

Abstract

A linear constraint loop is specified by a system of linear inequalities that define the relation between the values of the program variables before and after a single execution of the loop body. In this paper we consider the problem of determining whether such a loop terminates, i.e., whether all maximal executions are finite, regardless of how the loop is initialised and how the non-determinism in the loop body is resolved. We focus on the variant of the termination problem in which the loop variables range over $\mathbb{R}$. Our main result is that the termination problem is decidable over the reals in dimension 2. A more abstract formulation of our main result is that it is decidable whether a binary relation on $\mathbb{R}^2$ that is given as a conjunction of linear constraints is well-founded.

1 Introduction

The problem of deciding loop termination is of fundamental importance in software verification. Deciding termination is already challenging for very simple classes of programs. One such class consists of *linear constraint loops*. These are single-path loops in which both the loop guard and the loop update are given by conjunctions of linear inequalities over the program variables. Such a loop can be written as follows, where A, B are matrices of rational numbers, $\boldsymbol{a}$, $\boldsymbol{b}$ are vectors of rational numbers, and $\boldsymbol{x}, \boldsymbol{x}'$ represent the respective values of the program variables before and after the loop update:

$$\mathsf{P} : \mathsf{while}\ (B\,\boldsymbol{x} \geq \boldsymbol{b})\ \mathsf{do}\ A\begin{pmatrix}\boldsymbol{x}\\ \boldsymbol{x}'\end{pmatrix} \geq \boldsymbol{a},$$

Such loops are inherently non-deterministic, since the effect of the loop body is described by a collection of constraints. Note in passing that the loop guard can be folded into the constraints that describe the loop body and so, without loss of generality, the guard can

be assumed to be trivial. Linear constraint loops naturally arise as abstractions of other programs. For example, linear constraints can be used to model size changes in program variables, data structures, or terms in a logic program (see, e.g. [9]).

A linear constraint loop is said to *terminate* if there is no initial value of the loop variables from which the loop has an infinite execution. The Termination Problem asks to decide whether a given loop terminates. As such, the Termination Problem depends on the numerical domain that the program variables range over: typically one considers either $\mathbb{Z}$, $\mathbb{Q}$, or $\mathbb{R}$.

One approach to proving termination of linear constraint loops involves synthesizing linear ranking functions [2]. However, it is well-known that there are terminating loops that admit no linear ranking function. In the special case of deterministic linear constraint loops (i.e., where the loop body applies an affine function to the program variables) decidability of termination over $\mathbb{R}$ was shown by Tiwari [10], decidability of termination over $\mathbb{Q}$ was shown by Braverman [5], and decidability of termination over $\mathbb{Z}$ was established in [7].[1] All three papers build on an analysis of the spectrum of the matrix that determines the update function in the loop body. To the best of our knowledge, decidability of termination of linear constraint loops over $\mathbb{R}$, $\mathbb{Q}$, and $\mathbb{Z}$ remains open. It is known however that termination for multi-path constraint loops is undecidable (i.e., where disjunctions are allowed in the linear constraints that define the update map). It is moreover known that termination of single-path constraint loops is undecidable if irrational constants are allowed in the constraints [3]. One of the few known positive results is the restricted case that all the constraints are octagonal, in which case termination is decidable over integers [4]. (Recall that a constraint is said to be *octagonal* if it is a conjunction of propositions of the form $\pm x_i \pm x_j \leq a$, for variables x_i, x_j and constant $a \in \mathbb{Z}$.)

In this paper we study the termination of linear constraint loops over the reals in dimension at most 2. We give a sufficient and necessary condition that such a loop be non-terminating in the form of a *witness of non-termination*. This is given in Definition 1. Here one should think of K as the transition relation of a linear constraint loop, while $\mathrm{rec}(K)$ is the *recession cone* of K, i.e., the set of vectors v such that $w + \lambda v \in K$ for all $w \in K$ and $\lambda \geq 0$. The witness of non-termination is essentially a finite representation of an infinite execution of the loop in the spirit of the geometric non-termination arguments of [8] and the recurrent sets of [1].

▶ **Definition 1.** *Let E be a Euclidean space. Let $K \subseteq E^2$ be a convex set. A witness $\mathcal{W}(K)$ consists of a linear map $M : E \to E$, a closed cone $C \subseteq E$, and $v, w \in E$, such that*

($\exists u1$) $MC \subseteq C$

($\exists u2$) $\forall x \in C \qquad (x, Mx) \in \mathrm{rec}(K)$

($\exists u3$) $(v, w) \in K$

($\exists u4$) $w - v \in C$.

If E has dimension at most 2 and K is a polyhedron, then the existence of such a witness can be expressed in the theory of real closed fields. (The restriction to dimension 2 entails that every cone is generated by a most 3 vectors, whereas there is no such upper bound in dimension 3.) Thus we obtain a polynomial-time reduction of the Termination Problem for constraint loops to the decision problem for the theory of real closed fields with a bounded number of quantifier, which is decidable in polynomial space.

[1] These works in fact consider loop guards that feature a mix of strict and non-strict inequalities, whereas in the present paper we consider only non-strict inequalities.

The following is our main result, which characterises non-termination in terms of the above notion of witness. We refer to Section 2.3 for the notion of MW-convex set, suffice to say here that this class includes all polyhedra and that the main property of MW-convex sets used in the proof is that for every linear projection π and MW-convex set K we have $\pi(\mathrm{rec}(K)) = \mathrm{rec}(\pi(K))$. Further background about convex sets is contained in Section 2.2.

▶ **Theorem 2.** *Let E be a Euclidean space of dimension at most 2. Let $K \subseteq E^2$ be MW-convex. There is a sequence $(u_n)_{n\in\mathbb{N}} \in E^{\mathbb{N}}$ such that $(u_n, u_{n+1}) \in K$ for all $n \in \mathbb{N}$ if and only if there exists a witness $\mathcal{W}(K)$.*

2 Preliminaries

2.1 Notation

A superscript $*$ removes 0 from a set. Namely, $\mathbb{R}^* = \mathbb{R} \setminus \{0\}$, $\mathbb{N}^* = \mathbb{N} \setminus \{0\}$ and so on. $\mathbb{R}_+$ stands for all non-negative real numbers and $\mathbb{R}_+^*$ for all the positive real numbers. Also, for $n, m \in \mathbb{N}$ such that $n \leq m$, we let $[\![n \,;\, m]\!]$ be the set of integers between n and m inclusive, namely $[\![n \,;\, m]\!] = \{n, n+1, \ldots, m\}$.

Landau Notations. We use the Landau notations. Let $d \in \mathbb{N}^*$. Let $\|\cdot\|$ be any norm over $\mathbb{R}^d$ (recall that all norms on $\mathbb{R}^d$ are equivalent). Let $u : \mathbb{N} \to \mathbb{R}^d$, $w : \mathbb{N} \to \mathbb{R}^d$ and $v : \mathbb{N} \to \mathbb{R}$ be sequences. We then have the following notations:

- $u_n = \underset{n\to+\infty}{\mathrm{o}}(v_n)$ when for all $\varepsilon \in \mathbb{R}_+^*$ there is some $N \in \mathbb{N}$ such that for all $n \geq N$, we have $\|u_n\| \leq \varepsilon |v_n|$.
- $u_n = \underset{n\to+\infty}{\mathrm{O}}(v_n)$ when there is some $M \in \mathbb{R}_+^*$ and some some $N \in \mathbb{N}$ such that for all $n \geq N$, we have $\|u_n\| \leq M|v_n|$.
- $u_n = \underset{n\to+\infty}{\Omega}(v_n)$ when there is some $M \in \mathbb{R}_+^*$ and some some $N \in \mathbb{N}$ such that for all $n \geq N$, we have $\|u_n\| \geq M|v_n|$.
- $u_n \underset{n\to+\infty}{\sim} w_n$ if $u_n - w_n = \underset{n\to+\infty}{\mathrm{o}}(\|w_n\|)$.
- $u_n = w_n + \underset{n\to+\infty}{\mathrm{o}}(v_n)$ if $u_n - w_n = \underset{n\to+\infty}{\mathrm{o}}(v_n)$.
- $u_n = w_n + \underset{n\to+\infty}{\mathrm{O}}(v_n)$ if $u_n - w_n = \underset{n\to+\infty}{\mathrm{O}}(v_n)$.

We keep the same notations if the sequences are undefined at a finite number of points in $\mathbb{N}$.

2.2 Convex Sets

Throughout this section E is an arbitrary Euclidean space.

These results are already known but for the sake of completeness, some proofs are written here anyway.

▶ **Definition 3.** *Let $S \subseteq E$. The **affine hull** of S, denoted* $\mathrm{AffHull}(S)$*, the **convex hull** of S, denoted* $\mathrm{ConvHull}(S)$*, and the **vector space spanned by** S, denoted* $\mathrm{Vect}(S)$*, are defined by*

$$\begin{aligned}
\mathrm{AffHull}(S) &= \left\{ \sum_{i=1}^{k} \alpha_i x_i \mid \alpha_i \in \mathbb{R}, x_i \in S, \sum_{i=1}^{k} \alpha_i = 1 \right\} \\
\mathrm{ConvHull}(S) &= \left\{ \sum_{i=1}^{k} \alpha_i x_i \mid \alpha_i \in [0;1], x_i \in S, \sum_{i=1}^{k} \alpha_i = 1 \right\} \\
\mathrm{Vect}(S) &= \left\{ \sum_{i=1}^{k} \alpha_i x_i \mid \alpha_i \in \mathbb{R}, x_i \in S \right\}
\end{aligned}$$

▶ **Definition 4.** *Let $K \subseteq E$ be a convex set. The **relative interior** of K, denoted* $\mathrm{ri}(K)$*, is defined by:*

$$\mathrm{ri}(K) = \{\, x \in K \mid \exists U \in \mathcal{O}(E), (x \in U) \wedge (U \cap \mathrm{AffHull}(K) \subseteq K) \}$$

where $\mathcal{O}(E)$ stands for the set of open subsets of E.

In other words, the relative interior of a convex set C is its interior with respect to the induced topology on the affine subspace spanned by C.

We have the following properties for the relative interior:

▶ **Proposition 5.** *Let $K \subseteq E$ be a non-empty convex set. Denoting as usual by $\overline{K}$ the smallest closed subset of E containing K, we have:*

(i) $\mathrm{ri}(K)$ *is a non-empty convex set*
(ii) $\mathrm{ri}(K) \subseteq K \subseteq \overline{K}$
(iii) $\mathrm{AffHull}(\mathrm{ri}(K)) = \mathrm{AffHull}(K)$
(iv) $\mathrm{ri}(K) = \mathrm{ri}(\overline{K})$
(v) $\overline{\mathrm{ri}(K)} = \overline{K}$

▶ **Proposition 6.** *Let K be a non-empty convex set and x, y such that $x \in \mathrm{ri}(K)$ and $y \in K \setminus \mathrm{ri}(K)$. Then for all $\lambda \in (\,0\,;1\,]$ we have $\lambda x + (1-\lambda)y \in \mathrm{ri}(K)$.*

▶ **Definition 7.** *Let $K \subseteq E$ be a non-empty convex set. The **recession cone** of K, denoted* $\mathrm{rec}(K)$*, is the set* $\mathrm{rec}(K) = \{\, z \in E \mid K + \mathbb{R}_+ z \subseteq K \}$.

Note that we always have $0 \in \mathrm{rec}(K)$. Also, the recession cone is indeed a cone, as it is stable under positive scalar multiplication by definition.

▶ **Lemma 8.** *Let $K \subseteq E$ be a convex set. Let $\pi : E \to E$ be a linear projection. Then $\pi(\mathrm{rec}(K)) \subseteq \mathrm{rec}(\pi(K))$.*

Proof. Let $x \in \pi\,(\mathrm{rec}(K))$. There is $y \in \mathrm{Ker}\,\pi$ such that $x + y \in \mathrm{rec}(K)$. Let $a \in \pi(K)$ and $b \in \mathrm{Ker}\,\pi$ such that $a + b \in K$. Then,

$$\begin{aligned}
& \forall \lambda \in \mathbb{R}_+ \qquad (a+b) + \lambda(x+y) \in K \\
\text{Hence,} \quad & \forall \lambda \in \mathbb{R}_+ \qquad a + \lambda x \in \pi(K) \\
\text{and} \quad & x \in \mathrm{rec}(\pi(K)).
\end{aligned}$$

◀

If K is closed, we even have an alternative characterization of the recession cone which requires a seemingly weaker property but that turns out to be equivalent.

▶ **Proposition 9.** *Let $K \subseteq E$ be a non-empty closed convex set. Then*

$$\mathrm{rec}(K) = \{\, z \in E \mid \exists x \in K \quad x + \mathbb{R}_+ z \subseteq K \}$$

Proof. We proceed by double inclusion.

(⊆) This direction is easy : if for all $x \in K$, $x + \mathbb{R}_+ z \subseteq K$, since $K \neq \varnothing$, there is at least one x such that $x + \mathbb{R}_+ z \subseteq K$.

(⊇) Let $z \in \mathbb{R}^d$ such that there is some $x \in K$ such that $x + \mathbb{R}_+ z \subseteq K$. Let $y \in K$. We have to show that for any $t_0 \in \mathbb{R}_+$, $y + t_0 z \in K$. Note that, by convexity, for all $\lambda \in [\,0\,;1\,]$, for all $t \in \mathbb{R}_+$ we have

$$(1-\lambda)y + \lambda(x + tz) \in K$$

$$\text{We then define the function} \qquad \lambda : \begin{cases} [\,t_0\,;+\infty\,) & \to & [\,0\,;1\,] \\ t & \mapsto & \dfrac{t_0}{t} \end{cases}$$

$$\text{hence} \qquad \forall t \geq t_0 \qquad (1-\lambda(t))\, y + \lambda(t) x + t_0 z \in K$$

$$\text{We also have} \qquad (1-\lambda(t))\, y + \lambda(t) x + t_0 z \underset{t \to +\infty}{\longrightarrow} y + t_0 z$$

Since K is closed, we then deduce that for all $y + t_0 z \in K$. Since this holds for any $y \in K$ and any $t_0 \in \mathbb{R}_+$ we end up with $z \in \mathrm{rec}(K)$. ◀

When considering a closed convex set, we can look at its relative interior to get the same recession cone.

▶ **Proposition 10.** *Let $K \subseteq E$ be a non-empty closed convex set. Then* $\mathrm{rec}(K) = \mathrm{rec}(\mathrm{ri}(K))$.

Proof. We proceed by double inclusion.

(⊆) Let $v \in \mathrm{rec}(K)$. Let $x \in \mathrm{ri}(K)$. In particular, $x \in K$. By definition, for any $\lambda \in \mathbb{R}_+$, $x + \lambda v \in K$. Let $S = \{\, \lambda \in \mathbb{R}_+ \mid x + \lambda v \in K \setminus \mathrm{ri}(K) \}$. We just have to show that $S = \varnothing$. Assume $S \neq \varnothing$ and consider $\mu \in S$. Let $\lambda > \mu$. Note that

$$x + \mu v = \left(1 - \frac{\mu}{\lambda}\right) x + \frac{\mu}{\lambda}\,(x + \lambda v)$$

We have two cases:

- $\underline{\lambda \in S}$, in this case, using Proposition 6, since $x \in \mathrm{ri}(K)$ and $x + \lambda v \in K \setminus \mathrm{ri}(K)$, we have $x + \mu v \in \mathrm{ri}\, K$, which is a contradiction.
- $\underline{\lambda \notin S}$, since, by Proposition 5, $\mathrm{ri}(K)$ is convex, $x \in \mathrm{ri}(K)$ and $x + \lambda v \in \mathrm{ri}(K)$, we again reach $x + \mu v \in \mathrm{ri}(K)$, a contradiction.

Both cases are impossible. Therefore, $S = \varnothing$.

(⊇) Let $v \in \mathrm{rec}(\mathrm{ri}(K))$. By Proposition 5, there is some $x \in \mathrm{ri}(K)$. Therefore, for all $\lambda \in \mathbb{R}_+$, $x + \lambda v \in \mathrm{ri}(K) \subseteq K$. By Proposition 9, we get that $v \in \mathrm{rec}(K)$. ◀

▶ Remark 11. Note that if K is not closed we have, thanks to Proposition 5, $\mathrm{rec}(\overline{K}) = \mathrm{rec}(\mathrm{ri}(K))$ but we may have $\mathrm{rec}(K) \neq \mathrm{rec}(\mathrm{ri}(K))$.

▶ **Lemma 12.** *Let C be a closed convex cone in E. Let $u : E \to E$ be linear. Then $u(C)$ is a closed convex cone.*

Proof. By definition of a cone,

$$C = \{0\} \cup \mathbb{R}_+ \{\, x \in C \mid \|x\| = 1 \}\,.$$

Since C is closed, $\{ x \in C \mid \|x\| = 1\}$ is bounded and closed in a vector space of finite dimension, hence it is compact. By linearity of u,

$$u(C) = \{0\} \cup \mathbb{R}_+ u(\{ x \in C \mid \|x\| = 1\}).$$

Since u is linear over a vector space of finite dimension, it is continuous. Thus, the set $u(\{ x \in C \mid \|x\| = 1\})$ is also compact, hence closed. The continuity of the norm ensures that $u(C)$ is closed. By linearity of u, we also get that $u(C)$ is a convex cone. ◀

▶ **Lemma 13.** *Let C be a non-trivial convex cone in E. Let $x \in \mathrm{ri}(C) \setminus \{0\}$ and $u \in \mathrm{Vect}(C)$. Then there is $\lambda \geq 0$ such that $u + \lambda x \in C$.*

Proof. If $x = u$ then $\lambda = 0$ works. We then assume $x \neq u$. Since $u \in \mathrm{Vect}(C)$, there is $\mu \in (\,0\,;1\,)$ $\mu u + (1-\mu)x \in \mathrm{ri}(C)$. Therefore, for any $\lambda \in \mathbb{R}_+$, $\lambda\,(\mu u + (1-\mu)x) \in \mathrm{ri}(C)$. In particular, for $\lambda = \dfrac{1}{\mu}$ (which exists since $\mu \neq 0$),

$$u + \frac{1-\mu}{\mu} x \in \mathrm{ri}(C)$$

and we indeed have $\dfrac{1-\mu}{\mu} \geq 0$. ◀

2.3 Minkowski-Weyl Convex Sets

▶ **Definition 14.** *A closed convex set K is said to be **MW-convex** if there is a compact convex set K' such that $K = K' + \mathrm{rec}(K)$.*

This property comes from the Minkowski-Weyl Theorem for polyhedra :

▶ **Theorem 15** (Minkowski-Weyl)**.** *Let $K \subseteq \mathbb{R}^d$. The following statements are equivalent:*

(i) *$K = \{x \in \mathbb{R}^d \mid Ax \leq b\}$ for some matrix $A \in \mathbb{R}^{n \times d}$ and $b \in \mathbb{R}^n$.*

(ii) *There are finitely many points $x_1, \dots x_k, \in P$ and finitely many directions $v_1, \dots, v_p$ such that*

$$K = \mathrm{ConvHull}(\{x_1, \dots, x_k\}) + \sum_{i=1}^{p} \mathbb{R}_+ v_i.$$

Needing this property, we will assume that the sets K we consider are MW-convex. Note that, among others, polyhedrons are MW-convex, and thus our results apply to a more general class of sets.

One of the main benefits of MW-convex sets is that they behave very nicely with linear projections. Unlike other convex sets, the projections "commute" with the operator rec, giving a reciprocal to Lemma 8.

▶ **Lemma 16.** *Let $K \subseteq \mathbb{R}^d$ be MW-convex. Let π be a linear projection over $\mathbb{R}^d$. We have $\mathrm{rec}(\pi(K)) \subseteq \pi(\mathrm{rec}(K))$.*

Proof. Let $x \in \mathrm{rec}(\pi(K))$. If $x = 0$ then we immediately have $x \in \pi(\mathrm{rec}(K))$. Therefore, we may assume $x \neq 0$. For $a \in \pi(K)$, we have $a + \mathbb{R}_+ x \subseteq \pi(K)$. Thus,

$$\forall \lambda \in \mathbb{R}_+ \quad \exists b(\lambda) \in \mathrm{Ker}\,\pi \qquad a + \lambda x + b(\lambda) \in K.$$

Let K' convex compact such that $K = K' + \mathrm{rec}(K)$. Therefore, for all $\lambda \in \mathbb{R}_+$ there are $a'(\lambda) \in \pi(K')$ and $x'(\lambda) \in \pi(\mathrm{rec}(K))$ such that

$$a + \lambda x = a'(\lambda) + x'(\lambda).$$

Since $a'(\lambda) \in \pi(K')$ and that $\pi(K')$ is compact (as the continuous image of a compact), there is $a' \in \pi(K')$ and an increasing sequence $(\lambda_n)_{n\in\mathbb{N}}$ that tends to infinity such that

$$a'(\lambda_n) \underset{n\to+\infty}{\longrightarrow} a'.$$

Thus

$$\lambda_n x - x'(\lambda_n) \underset{n\to+\infty}{\longrightarrow} a' - a.$$

We then get that

$$\frac{x'(\lambda_n)}{\lambda_n} = x + \frac{a - a'}{\lambda_n} + \underset{n\to+\infty}{\mathrm{o}}\left(\frac{1}{\lambda_n}\right) \qquad \text{and} \qquad \frac{x'(\lambda_n)}{\lambda_n} \underset{n\to+\infty}{\longrightarrow} x.$$

Also $\dfrac{x'(\lambda_n)}{\lambda_n} \in \pi(\mathrm{rec}(K))$. Moreover, using Lemma 12, $\pi(\mathrm{rec}(K))$ is closed. Hence, we have $x \in \pi(\mathrm{rec}(K))$ what concludes the proof. ◀

The converse inclusion is true for general convex sets (Lemma 8). Combining this to Lemma 16, we have:

▶ **Corollary 17.** *Let $K \subseteq \mathbb{R}^d$ be MW-convex. Let π be a linear projection over $\mathbb{R}^d$. We have* $\mathrm{rec}(\pi(K)) = \pi(\mathrm{rec}(K))$.

▶ **Corollary 18.** *Let $K \subseteq \mathbb{R}^d$ be MW-convex. Let $\pi : \mathbb{R}^d \to \mathbb{R}^d$ be a linear projection. Then $\pi(K)$ is MW-convex.*

Proof. We write $K = K' + \mathrm{rec}(K)$ where K' is a convex compact set. Hence, since π is continuous (linear in a finite dimensional space), $\pi(K')$ is also compact. Moreover, by linearity of π, we get that

$$\pi(K) = \pi(K') + \pi(\mathrm{rec}(K)).$$

By Lemma 12, $\pi(\mathrm{rec}(K))$ is a closed convex cone. Hence, $\pi(K)$ is closed convex as a sum of closed convex sets. By Corollary 17, we get

$$\pi(K) = \pi(K') + \mathrm{rec}(\pi(K)).$$ ◀

2.4 Accumulation Expansions

We consider an arbitrary Euclidean space E of dimension $d \in \mathbb{N}$. We denote $\langle \cdot, \cdot \rangle$ its scalar product and $\|\cdot\|$ the associated norm.

To study the sequences of the constraint loop problem, we need to identify the asymptotic directions these sequences are going towards, building a form of asymptotic expansion of those sequences. We thus introduce the concept of accumulation expansion. As sequences may point in several directions, we consider the expansion of a subsequence that has a single main direction.

▶ **Definition 19.** *Let $(u_n)_{n\in\mathbb{N}}$ be a sequence of E. An **accumulation expansion** of $(u_n)_{n\in\mathbb{N}}$ consists in an increasing function $\psi : \mathbb{N} \to \mathbb{N}$, an integer $p \in [\![0 \ ; \ d]\!]$, some vectors $z_1, \dots, z_{p+1} \in E$ and sequences $(\alpha_{k,n})_{n\in\mathbb{N}}$ for $k \in [\![1 \ ; \ p]\!]$ such that*

(AE1) $\forall k \in [\![1 \ ; \ p]\!] \qquad \|z_k\| = 1$

(AE2) $\forall k, k' \in [\![1 \ ; \ p]\!] \qquad \langle z_k, z_{k'} \rangle = \begin{cases} 1 & \text{if } k = k' \\ 0 & \text{if } k \neq k' \end{cases}$

(AE3) $\forall k \in [\![1 \ ; \ p]\!] \qquad \langle z_k, z_{p+1} \rangle = 0$

(AE4) $\forall k \in [\![1 \ ; \ p]\!] \qquad \forall n \in \mathbb{N} \qquad \alpha_{k,n} > 0$

(AE5) $\forall k \in [\![1 \ ; \ p]\!] \qquad \alpha_{k,n} \underset{n\to+\infty}{\longrightarrow} +\infty$

(AE6) $\forall m \in [\![1 \ ; \ p]\!] \qquad \alpha_{m,n} \underset{n\to+\infty}{\sim} \left\| u_{\psi(n)} - \sum_{k=1}^{m-1} \alpha_{k,n} z_k \right\|$

(AE7) $\forall k \in [\![1 \ ; \ p-1]\!] \qquad \alpha_{k+1,n} = \underset{n\to+\infty}{o}(\alpha_{k,n})$

(AE8) $\forall n \in \mathbb{N} \qquad \forall \ell \leq m \in [\![1 \ ; \ p]\!] \qquad \left\langle z_\ell, u_{\psi(n)} - \sum_{k=1}^{m} \alpha_{k,n} z_k \right\rangle = 0$

(AE9) $u_{\psi(n)} = \sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1} + \underset{n\to+\infty}{o}(1)$.

Abusing notations, we will say that $u_{\psi(n)} = \sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1} + \underset{n\to+\infty}{o}(1)$ is an accumulation expansion of $(u_n)_{n\in\mathbb{N}}$.

▶ **Definition 20.** *Let $u = (u_n)_{n\in\mathbb{N}}$ be a sequence of E. The set $\mathcal{D}_u$ of **principal directions** of u is defined by*

$$\mathcal{D}_u = \left\{ z \in E \;\middle|\; \begin{array}{c} u_{\psi(n)} = \sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1} + \underset{n\to+\infty}{o}(1) \text{ is an accumulation expansion} \\ p \geq 1 \qquad \text{and} \qquad z = z_1 \end{array} \right\}.$$

In other words, $\mathcal{D}_u$ is the set of directions that are in the dominant position of some accumulation expansion of u such that $p \geq 1$. It also corresponds to the dominant directions of an unbounded sequence.

For $x \in E \setminus \{0\}$ we denote $\widetilde{x} = \dfrac{x}{\|x\|}$ the associated normalized vector.

▶ **Lemma 21.** *Let $(u_n)_{n\in\mathbb{N}}$ be an unbounded sequence of E. There exist $z \in E$ a unit vector, an increasing function $\varphi : \mathbb{N} \to \mathbb{N}$ and a sequence $(\alpha_n)_{n\in\mathbb{N}}$ such that*

- $\forall n \in \mathbb{N} \qquad \alpha_n > 0$
- $\alpha_n \underset{n\to+\infty}{\longrightarrow} +\infty$
- $\alpha_n \underset{n\to+\infty}{\sim} \left\| u_{\varphi(n)} \right\|$
- $u_{\varphi(n)} = \alpha_n z + \underset{n\to+\infty}{o}(\alpha_n)$
- $\forall n \in \mathbb{N} \qquad u_{\varphi(n)} - \alpha_n z \in z^\perp$ *where $z^\perp$ means the vector subspace of E orthogonal to* $\mathrm{Vect}(\{z\})$

Proof. Since $(u_n)_{n\in\mathbb{N}}$ is unbounded, we can assume that we have an increasing function $\varphi : \mathbb{N} \to \mathbb{N}$ such that for all $n \in \mathbb{N}$, $u_{\varphi(n)} \neq 0$ and $\left\| u_{\varphi(n)} \right\| \underset{n\to+\infty}{\longrightarrow} +\infty$. Therefore the sequence $\left(\widetilde{u_{\varphi(n)}} \right)_{n\in\mathbb{N}}$ is well defined. Moreover, as it is bounded by definition, up to refining φ, we can assume that it converges to some $z \in E$. Let π be the orthogonal projection onto $\mathbb{R}z$. We define α_n to be the unique real number such that $\pi(u_{\varphi(n)}) = \alpha_n z$. As $\widetilde{u_{\varphi(n)}} \underset{n\to+\infty}{\longrightarrow} z$, we have that $\alpha_n \underset{n\to+\infty}{\sim} \left\| u_{\varphi(n)} \right\|$. Therefore, up to refining φ, we can assume that $\alpha_n \underset{n\to+\infty}{\longrightarrow} +\infty$ and $\alpha_n > 0$. Moreover, we have $u_{\varphi(n)} = \alpha_n z + \underset{n\to+\infty}{o}(\alpha_n)$. Finally, by definition of π, for all $n \in \mathbb{N}$, $u_{\varphi(n)} - \alpha_n z \in z^\perp$. ◀

▶ **Proposition 22.** *Any sequence $u = (u_n)_{n\in\mathbb{N}}$ of E admits accumulation expansions. Moreover, if u is unbounded, then $\mathcal{D}_u$ is not empty.*

Proof. If $(u_n)_{n\in\mathbb{N}}$ is bounded, then it has an accumulation point z_1. Hence, taking $p = 0$, all the points are trivially true except Point (AE9). Taking any ψ given by the definition of accumulation point lead to $u_{\psi(n)} = z_1 + \underset{n\to+\infty}{o}(1)$.

Assume now that $(u_n)_{n\in\mathbb{N}}$ is unbounded. We proceed by induction on $d = \dim E$.

- If $d = 1$, consider z_1 and $(\alpha_{1,n})_{n\in\mathbb{N}}$ and ψ given by Lemma 21. By definition, $\|z_1\| = 1$ and $u_{\psi(n)} - \alpha_{1,n}z_1 \in z_1^\perp = \{0\}$. Taking $p = 1$ and $z_2 = 0$ satisfies all the required properties. Moreover, $z_1 \in \mathcal{D}_u$.
- Assume the proposition holds for any Euclidean space of dimension $d-1$. Consider z_1, $\left(\alpha'_{1,n}\right)_{n\in\mathbb{N}}$ and φ given by Lemma 21. By definition $\|z_1\| = 1$ and $u_{\varphi(n)} - \alpha'_{1,n}z_1 \in z_1^\perp$. Since $z_1 \neq 0$, $\dim z_1^\perp = d-1$. We can thus apply the induction hypothesis on the sequence $\left(u_{\varphi(n)} - \alpha'_{1,n}z_1\right)_{n\in\mathbb{N}}$ in $z_1^\perp$. Let φ' be the function given by the induction hypothesis. Let $\psi = \varphi \circ \varphi'$ and $\alpha_{1,n} = \alpha'_{1,\varphi'(n)}$.
  Every point is immediately satisfied either by the induction hypothesis or the fact that z_1 is orthogonal to any point in $z_1^\perp$, except for Point (AE7): It remains to prove that if $p \geq 2$, then $\alpha_{2,n} = \underset{n\to+\infty}{o}(\alpha_{1,n})$. By induction hypothesis we know that

  $$\alpha_{2,n} \underset{n\to+\infty}{\sim} \left\|u_{\psi(n)} - \alpha_{1,n}z_1\right\|.$$

  Moreover, by Lemma 21

  $$\left\|u_{\varphi(n)} - \alpha'_{1,n}z_1\right\| = \underset{n\to+\infty}{o}\left(\alpha'_{1,n}\right).$$

  Since $(\alpha_{1,n})_{n\in\mathbb{N}}$ is a subsequence of $\left(\alpha'_{1,n}\right)_{n\in\mathbb{N}}$, we have

  $$\alpha_{2,n} \underset{n\to+\infty}{\sim} \left\|u_{\psi(n)} - \alpha_{1,n}z_1\right\| = \underset{n\to+\infty}{o}(\alpha_{1,n})$$

  as required. Moreover, $z_1 \in \mathcal{D}_u$. ◀

We now state a relation between the directions within the accumulation expansion and the set $\mathrm{rec}(K)$.

▶ **Proposition 23.** *Let E be an Euclidean space. Let $K \subseteq E$ be MW-convex. Let $u = (u_n)_{n\in\mathbb{N}}$ be an unbounded sequence in K. Let $u_{\varphi(n)} = \sum_{k=1}^{p} \alpha_{k,n}z_k + z_{p+1} + \underset{n\to+\infty}{o}(1)$ be an accumulation expansion of $(u_n)_{n\in\mathbb{N}}$. Then, there are some positive real numbers $(\beta_{k,\ell})_{1\leq\ell<k\leq p+1}$ such that*

$$\forall k \in [\![1\ ;\ p]\!] \qquad z_k + \sum_{\ell=1}^{k-1} \beta_{k,\ell}z_\ell \in \mathrm{rec}(K)$$

and $$z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell}z_\ell \in K.$$

Proof. For $k \in [\![1\ ;\ p]\!]$, we consider $\pi_k : E \to E$ the orthogonal projection onto the vector space $\mathrm{Vect}((z_1, \ldots, z_{k-1})^\perp)$. Let us first show that $z_k \in \pi_k(\mathrm{rec}(K))$. Let $\lambda \in \mathbb{R}_+$ and define

$$\lambda_{k,n} = \frac{\lambda}{\alpha_{k,n}}.$$

Note that for large enough n, $\lambda_{k,n} \in [\,0\,;1\,]$. Without loss of generality, we assume $\lambda_{k,n} \in [\,0\,;1\,]$. Then, by convexity,

$$\lambda_{k,n} u_{\varphi(n)} + (1-\lambda_{k,n}) u_0 \in K.$$

Moreover,

$$\begin{aligned}\pi_k\left(\lambda_{k,n} u_{\varphi(n)} + (1-\lambda_{k,n})u_0\right) &= \lambda z_k + \sum_{\ell=k+1}^{p} \lambda_{k,n}\alpha_{\ell,n} z_\ell \\ &\quad + \lambda_{k,n} z_{p+1} + (1-\lambda_{k,n})\pi_k(u_0) + \underset{n\to+\infty}{\mathrm{o}}(\lambda_{k,n}) \\ &\underset{n\to+\infty}{\longrightarrow} \lambda z_k + \pi_k(u_0).\end{aligned}$$

Also, thanks to Corollary 18, we have $\overline{\pi_k(K)} = \pi_k(K)$. Using now Proposition 9, we then conclude that $z_k \in \mathrm{rec}(\pi_k(K))$. Finally, using Corollary 17,

$$z_k \in \pi_k(\mathrm{rec}(K)).$$

We now prove the proposition by induction on k. For $k = 1$, our preliminary result gives in particular that $z_1 \in \mathrm{rec}(K)$.

Assume now that $(\beta_{q,\ell})_{1\le\ell<q<k}$ have been defined for some $k \in [\![\,1\;;\;p\,]\!]$. Since $z_k \in \pi_k(\mathrm{rec}(K))$ as proven earlier, there are some real numbers $(\gamma_{k,\ell})_{\ell\in[\![\,1\;;\;k-1\,]\!]}$ such that

$$z_k + \sum_{\ell=1}^{k-1} \gamma_{k,\ell} z_\ell \in \mathrm{rec}(K).$$

If all the $\gamma_{k,\ell}$ are positive then fixing $\beta_{k,\ell} = \gamma_{k,\ell}$ satisfies the proposition. Let $\ell \in [\![\,1\;;\;k-1\,]\!]$ maximum such that $\gamma_{k,\ell} \le 0$. Then, as by hypothesis we have that $z_\ell + \sum_{j=1}^{\ell-1} \beta_{\ell,j} z_j \in \mathrm{rec}(K)$, we can deduce that

$$z_k + \sum_{j=1}^{k-1} \gamma_{k,j} z_j + (1+|\gamma_{k,\ell}|)\left(z_\ell + \sum_{j=1}^{\ell-1} \beta_{\ell,j} z_j\right) \in \mathrm{rec}(K).$$

Considering $\gamma'_{k,j} = \begin{cases} \gamma_{k,j} & j > \ell \\ 1 & j = \ell, \\ \gamma_{k,j} + (1+|\gamma_{k,\ell}|)\beta_{\ell,j} & j < \ell \end{cases}$

we end up with $z_k + \sum_{\ell=1}^{k-1} \gamma'_{k,\ell} z_\ell \in \mathrm{rec}(K)$ with one less non-positive coefficient. Repeating this procedure until every coefficient is positive lead to a sum of the desired shape, thus establishing the induction hypothesis holds on k and therefore concluding the induction.

Let $\pi_{p+1} : E \to E$ the orthogonal projection on $\mathrm{Vect}((z_1,\dots,z_p)^\perp)$. We have

$$\pi_{p+1}\left(u_{\varphi(n)}\right) \underset{n\to+\infty}{\longrightarrow} z_{p+1}.$$

By Corollary 18,

$$z_{p+1} \in \overline{\pi_{p+1}(K)} = \pi_{p+1}(K).$$

Thus, there are some real numbers $(\gamma_{p+1,\ell})_{\ell\in[\![\,1\;;\;k\,]\!]}$ such that

$$z_{p+1} + \sum_{\ell=1}^{p} \gamma_{p+1,\ell} z_\ell \in K.$$

Doing the same work as above, we can add some elements of $\mathrm{rec}(K)$ so that we end up with some positive $(\beta_{p+1,\ell})_{\ell\in[\![1\ ;\ k]\!]}$ such that

$$z_{p+1}+\sum_{\ell=1}^{p}\gamma_{p+1,\ell}z_\ell\in K.$$ ◀

The two following corollaries specialise this result for some form of sequences.

▶ **Corollary 24.** *Let E an Euclidean space. Let $\pi : E \to E$ be a linear projection. Let $K \subseteq E$ be MW-convex. Let $u = (u_n)_{n\in\mathbb{N}}$ be an unbounded sequence in K and $x \in \mathcal{D}_{\pi(u)}$. Let*

$$f(\mathrm{id}-\pi)(u_{\varphi(n)})\left\|\pi(u_{\varphi(n)})\right\| = \sum_{k=1}^{p}\alpha_{k,n}z_k + z_{p+1} + \underset{n\to+\infty}{o}(1)$$

be an accumulation expansion of $\left(\dfrac{(\mathrm{id}-\pi)(u_n)}{\|\pi(u_n)\|}\right)_{n\in\mathbb{N}}$ *such that*

$$\widetilde{\pi(u_{\varphi(n)})} \underset{n\to+\infty}{\longrightarrow} x.$$

Then, there are some positive real numbers $(\beta_{k,\ell})_{1\le\ell<k\le p+1}$ such that

$$\forall k\in[\![1\ ;\ p+1]\!] \qquad z_k+\sum_{\ell=1}^{k-1}\beta_{k,\ell}z_\ell\in\mathrm{rec}(K) \qquad \text{and} \qquad x+z_{p+1}+\sum_{\ell=1}^{p}\beta_{p+1,\ell}z_\ell\in\mathrm{rec}(K)$$

Proof. We have

$$(\mathrm{id}-\pi)\left(u_{\varphi(n)}\right) = \sum_{k=1}^{p}\left\|\pi(u_{\varphi(n)})\right\|\alpha_{k,n}z_k + \left\|\pi(u_{\varphi(n)})\right\|z_{p+1} + \underset{n\to+\infty}{o}\left(\left\|\pi(u_{\varphi(n)})\right\|\right)$$

Also, provided $\widetilde{u_{\varphi(n)}} \underset{n\to+\infty}{\longrightarrow} x$, we have

$$\pi\left(u_{\varphi(n)}\right) = \left\|\pi(u_{\varphi(n)})\right\|x + \underset{n\to+\infty}{o}\left(\left\|\pi(u_{\varphi(n)})\right\|\right).$$

Therefore

$$u_{\varphi(n)} = \sum_{k=1}^{p}\left\|\pi(u_{\varphi(n)})\right\|\alpha_{k,n}z_k + \left\|\pi(u_{\varphi(n)})\right\|(x+z_{p+1}) + \underset{n\to+\infty}{o}\left(\left\|\pi(u_{\varphi(n)})\right\|\right).$$

The result is obtained by applying Proposition 23 to this accumulation expansion of $(u_n)_{n\in\mathbb{N}}$. Note that in this case we in fact have a truncated accumulation expansion so the case $p+1$ is not the last element of an actual accumulation expansion. That is why we get $\mathrm{rec}(K)$ instead of K even for $p+1$. ◀

▶ **Corollary 25.** *Let E an Euclidean space. Let $K \subseteq E^2$ be MW-convex. Let $\pi : E \to E$ be a linear projection. Let $u = (u_n)_{n\in\mathbb{N}}$ be an unbounded sequence in E such that*

$$\forall n\in\mathbb{N} \qquad (u_n,u_{n+1})\in K$$

and $x \in \mathcal{D}_u$. Let

$$\frac{u_{\varphi(n)+1}}{\left\|u_{\varphi(n)}\right\|} = \sum_{k=1}^{p}\alpha_{k,n}z_k + z_{p+1} + \underset{n\to+\infty}{o}(1)$$

be an accumulation expansion of $\left(\frac{u_{n+1}}{\|u_n\|}\right)_{n\in\mathbb{N}}$ *such that*

$\widetilde{u_{\varphi(n)}} \underset{n\to+\infty}{\longrightarrow} x$.

Then, there are some positive real numbers $(\beta_{k,\ell})_{1\leq\ell<k\leq p+1}$ *such that*

$$\forall k \in [\![1 \ ; \ p]\!] \qquad \left(0, z_k + \sum_{\ell=1}^{k-1} \beta_{k,\ell} z_\ell\right) \in \mathrm{rec}(K) \quad \textit{and} \quad \left(x, z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right) \in \mathrm{rec}(K)$$

and such that for sufficiently large n,

$$\left\langle \pi\left(z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right), \pi\left(z_{p+1} + \sum_{k=1}^{p} \alpha_{k,n} z_k\right)\right\rangle \geq 0.$$

Moreover, there is some $i \in [\![1 \ ; \ p+1]\!]$ *such that* $\pi(z_i) \notin \mathrm{Ker}(\pi)$*, this inequality can be taken to be strict.*

Proof. We first apply Corollary 24 to the sequence $((u_n, u_{n+1}))_{n\in\mathbb{N}}$ and the projection on the first component to get some positive real numbers $(\beta_{k,\ell})_{1\leq\ell<k\leq p+1}$ such that

$$\forall k \in [\![1 \ ; \ p]\!] \quad \left(0, z_k + \sum_{\ell=1}^{k-1} \beta_{k,\ell} z_\ell\right) \in \mathrm{rec}(K) \quad \text{and} \quad \left(x, z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right) \in \mathrm{rec}(K).$$

Let $k_0 \in [\![1 \ ; \ p+1]\!]$ minimum such that $z_k \notin \mathrm{Ker}\,\pi$.

- If there is no such k_0, then
$$\left\langle \pi\left(z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right), \pi\left(z_{p+1} + \sum_{k=1}^{p} \alpha_{k,n} z_k\right)\right\rangle = 0$$
and the proof is complete.
- If $k_0 = p+1$, then
$$\left\langle \pi\left(z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right), \pi\left(z_{p+1} + \sum_{k=1}^{p} \alpha_{k,n} z_k\right)\right\rangle = \langle \pi(z_{p+1}), \pi(z_{p+1})\rangle > 0.$$
- Otherwise, $k_0 \in [\![1 \ ; \ p]\!]$ and $\|\pi(z_{k_0})\| \neq 0$. Let
$$S_n(\lambda) = \left\langle \pi\left(z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right) + \lambda\pi\left(z_{k_0} + \sum_{\ell=1}^{k_0-1} \beta_{k_0,\ell} z_\ell\right), \pi\left(\sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1}\right)\right\rangle.$$
We have
$$\begin{aligned}
S_n(\lambda) &= \left\langle \pi(z_{p+1}) + \sum_{\ell=k_0}^{p} \beta_{p+1,\ell}\pi(z_\ell) + \lambda\pi\left(z_{k_0}\right), \sum_{k=k_0}^{p} \alpha_{k,n}\pi(z_k) + \pi(z_{p+1})\right\rangle \\
&= \left\langle \pi(z_{p+1}) + \sum_{\ell=k_0}^{p} \beta_{p+1,\ell}\pi(z_\ell) + \lambda\pi\left(z_{k_0}\right), \pi(z_{p+1})\right\rangle \\
&\quad + \sum_{k=k_0}^{p} \alpha_{k,n} \left\langle \pi(z_{p+1}) + \sum_{\ell=k_0}^{p} \beta_{p+1,\ell}\pi(z_\ell) + \lambda\pi\left(z_{k_0}\right), \pi(z_k)\right\rangle \\
&= \alpha_{k_0,n} \left\langle \pi(z_{p+1}) + \sum_{\ell=k_0}^{p} \beta_{p+1,\ell}\pi(z_\ell) + \lambda\pi\left(z_{k_0}\right), \pi(z_{k_0})\right\rangle + \underset{n\to+\infty}{\mathrm{o}}(\alpha_{k_0,n}) \\
&= \alpha_{k_0,n} \left(\lambda\|\pi(z_{k_0})\|^2 + \left\langle \pi(z_{p+1}) + \sum_{\ell=k_0}^{p} \beta_{p+1,\ell}\pi(z_\ell), \pi(z_{k_0})\right\rangle\right) + \underset{n\to+\infty}{\mathrm{o}}(\alpha_{k_0,n}).
\end{aligned}$$

Therefore, taking any $\lambda > 0$ such that

$$\lambda > -\frac{\left\langle \pi(z_{p+1}) + \sum_{\ell=k_0}^{p} \beta_{p+1,\ell}\pi(z_\ell), \pi(z_{k_0}) \right\rangle}{\|\pi(z_{k_0})\|^2}$$

we get $S_n(\lambda) \underset{n\to+\infty}{\longrightarrow} +\infty$. Thus, for sufficiently large n,

$$\left\langle \pi\left(z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right) + \lambda\pi\left(z_{k_0} + \sum_{\ell=1}^{k_0-1} \beta_{k_0,\ell} z_\ell\right), \pi\left(\sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1}\right) \right\rangle > 0.$$

Also,

$$\left(x, z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell + \lambda z_{k_0} + \lambda \sum_{\ell=1}^{k_0-1} \beta_{k_0,\ell} z_\ell\right) = \underbrace{\left(x, z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell\right)}_{\in \mathrm{rec}(K)} + \underbrace{\lambda}_{\geq 0} \underbrace{\left(0, z_{k_0} + \sum_{\ell=1}^{k_0-1} \beta_{k_0,\ell} z_\ell\right)}_{\in \mathrm{rec}(K)}$$

$$\left(x, z_{p+1} + \sum_{\ell=1}^{p} \beta_{p+1,\ell} z_\ell + \lambda z_{k_0} + \lambda \sum_{\ell=1}^{k_0-1} \beta_{k_0,\ell} z_\ell\right) \in \mathrm{rec}(K).$$

Thus, considering

$$\beta'_{p+1,\ell} = \begin{cases} \beta_{p+1,\ell} & \ell > k_0 \\ \beta_{p+1,\ell} + \lambda & \ell = k_0 \\ \beta_{p+1,\ell} + \lambda\beta_{k_0,\ell} & \ell < k_0 \end{cases}$$

instead of the $\beta_{k+1,\ell}$s, we get the desired result. ◀

3 Deciding the Constraint Loop Problem

The goal of this section is to establish Theorem 2. This will be done by showing equivalence between the existence of a witness of the form given by Definition 1 and the existence of an infinite run of a constraint loop. The easy direction in this argument – constructing an infinite execution from a witness – is the purpose of Proposition 27 in Subsection 3.2. In fact, there is an even easier case, namely certifying the existence of bounded infinite run, is dealt with in Section 3.1. It states that a bounded infinite run exists if an only if there is a fixed point. This proof holds in any dimension and relies on a simpler certificate. We will also reuse this result in the specific cases of dimension 1 and 2.

The main objective in this section is to construct a witness from an infinite execution. We provide the proof of sufficient condition in Subsection 3.2. This will help motivate the definition of witness. Subsection 3.3 deals with the simple 1-dimensional case, and Subsection 3.4 handles the dimension-2 case, which is more challenging. Because of the difficulty of this proof we only provide high level explanation here. For a complete proof, we refer to the full-version of this article [6].

3.1 Deciding the Existence of a Bounded Sequence

▶ **Proposition 26.** *Let E be a vector space of dimension $d \in \mathbb{N}$. Let $K \subseteq E^2$ be closed convex. Denoting $\Delta_E = \{(x,x) \mid x \in E\} \subseteq E^2$, we have that $K \cap \Delta_E \neq \varnothing$ if and only if there is a bounded sequence $u = (u_n)_{n\in\mathbb{N}}$ of E such that for all $n \in \mathbb{N}$, $(u_n, u_{n+1}) \in K$.*

Proof.
(⇒) Let $(x,x) \in K \cap \Delta_E$. The sequence constantly equal to x satisfy the proposition.
(⇐) Assume now that there exists a bounded sequence $(u_n)_{n\in\mathbb{N}}$ such that for all $n \in \mathbb{N}$, $(u_n, u_{n+1}) \in K$. Let $n \in \mathbb{N}^*$ and define $x_n = \frac{1}{n}\sum_{p=0}^{n}(u_p, u_p)$ and $y_n = \frac{1}{n}\sum_{p=0}^{n-1}(u_p, u_{p+1})$. We have

$$\|x_n - y_n\| = \frac{1}{n}\|(u_n, u_0)\|.$$

Since the sequence $(u_n)_{n\in\mathbb{N}}$ is bounded, there is a positive real number M such that

$$\forall n \in \mathbb{N}^* \qquad \|x_n - y_n\| \leq \frac{M}{n}.$$

In particular, both sequences $(x_n)_{n\in\mathbb{N}^*}$ and $(y_n)_{n\in\mathbb{N}^*}$ must have the same accumulation points. As these sequences are bounded (and since they are in a vector space of finite dimension), such a point exists. Let us denote it x. Notice that since K is closed and convex, for all positive integer n, $y_n \in K$ and thus $x \in K$. Moreover, by definition, for all positive integer n, $x_n \in \Delta_E$. This set is again closed, thus $x \in \Delta_E$. This proves that

$$x \in K \cap \Delta_E \neq \varnothing.$$ ◀

3.2 A Sufficient Condition for the Existence of a Sequence

▶ **Proposition 27.** *Let E be an Euclidean space of dimension d. Let $K \subseteq E^2$ be MW-convex. If there exists a witness $\mathcal{W}(K)$, then, there is a sequence $(u_n)_{n\in\mathbb{N}} \in E^{\mathbb{N}}$ such that*

$$\forall n \in \mathbb{N} \qquad (u_n, u_{n+1}) \in K.$$

Proof. Assume we have a witness $\mathcal{W}(K)$. We then take M, v, w, C as given by the witness and define the following sequence:

$$u_0 = v \qquad \text{and} \qquad u_1 = w$$
$$\forall n \in \mathbb{N} \qquad u_{n+2} - u_{n+1} = M\,(u_{n+1} - u_n)$$

Remark first that for all $n \in \mathbb{N}$, $u_{n+1} - u_n \in C$. This can be proven by induction, noting that the initialisation is given by Point ($\exists u4$) and the induction step comes from Point ($\exists u1$).

We now prove by induction that $\forall n \in \mathbb{N} \qquad (u_n, u_{n+1}) \in K$.

- By Point ($\exists u3$), $(u_0, u_1) \in K$.
- Assume that for some $n \in \mathbb{N}$, $(u_n, u_{n+1}) \in K$. As $u_{n+1} - u_n \in C$ as shown before, by Point ($\exists u2$)

$$(u_{n+1} - u_n, u_{n+2} - u_{n+1}) \in \mathrm{rec}(K).$$

Thus $(u_{n+1}, u_{n+2}) = (u_n, u_{n+1}) + (u_{n+1} - u_n, u_{n+2} - u_{n+1}) \in K + \mathrm{rec}(K) = K$.

By the induction principle we conclude that for all $n \in \mathbb{N}$, $(u_n, u_{n+1}) \in K$. ◀

3.3 Necessary Condition for the Existence of a 1-Dimensional Sequence

We establish the main result in the one dimensional case. Note that we prove a slightly stronger certificate here, which is not necessary in itself, but which we need for the 2 dimensional case.

▶ **Proposition 28.** *Let E be an Euclidean space of dimension 1. Let $K \subseteq E^2$ be MW-convex. Let a sequence $(u_n)_{n\in\mathbb{N}} \in E^{\mathbb{N}}$ such that $(u_n, u_{n+1}) \in K$ for all $n \in \mathbb{N}$. Let $\gamma \in \operatorname{cone}(\mathcal{D}_u)$ such that $(0,\gamma) \in \operatorname{rec}(K)$ (note that at least $\gamma = 0$ works). Then, there are $a \in \mathbb{R}^*$, a closed convex cone $C \subseteq E$ and $x, y \in E$ such that*

(i) $aC \subseteq C$
(ii) $\forall x \in C \qquad (x, ax) \in \operatorname{rec}(K)$
(iii) $(x, y) \in K$
(iv) $y - x \in C$
(v) $\gamma \in C$

Proof. Without loss of generality, as E is an Euclidean space of dimension 1, we assume $E = \mathbb{R}$. If $(u_n)_{n\in\mathbb{N}}$ is bounded, then, by Proposition 26 there exists $z \in \mathbb{R}$ such that $(z, z) \in K$. Then $\gamma = 0$ and we can select $y = x = z$, $C = \{0\}$ and $a \in \mathbb{R}^*$ arbitrary (e.g. 1) to produce the requested witness.

We now assume that $(u_n)_{n\in\mathbb{N}}$ is unbounded. By Proposition 22, it admits accumulation expansions and $\mathcal{D}_u \neq \varnothing$. The only two possible accumulation directions are 1 and -1. We consider three cases:

- If $\mathcal{D}_u = \{-1, 1\}$. Take φ_1 and φ_{-1} such that $\widetilde{u_{\varphi_1(n)}} \underset{n\to+\infty}{\longrightarrow} 1$ and $\widetilde{u_{\varphi_{-1}(n)}} \underset{n\to+\infty}{\longrightarrow} -1$. Up to extracting a subsequence, we have the accumulation expansions

$$\frac{u_{\varphi_1(n)+1}}{\left\|u_{\varphi_1(n)}\right\|} = \sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1} + \underset{n\to+\infty}{\mathrm{o}}(1)$$

and $$\frac{u_{\varphi_{-1}(n)+1}}{\left\|u_{\varphi_{-1}(n)}\right\|} = \sum_{k=1}^{p'} \alpha'_{k,n} z'_k + z'_{p'+1} + \underset{n\to+\infty}{\mathrm{o}}(1)\,.$$

  Then, by Corollary 25, there are $\alpha, \beta \in \mathbb{R}$ such that

$$(1, \alpha) \in \operatorname{rec}(K) \qquad \text{and} \qquad (-1, \beta) \in \operatorname{rec}(K).$$

  Let $\delta = \begin{cases} \gamma & \text{if } \gamma \neq 0 \\ \alpha + \beta & \text{if } \gamma = 0. \end{cases}$

  Therefore, either $(0, \delta) = (0, \gamma) \in \operatorname{rec}(K)$, or $(0, \delta) = (1, \alpha) + (-1, \beta)$ and $(0, \delta) \in \operatorname{rec}(K)$ by conic combinations.

  - If $\delta = 0$ then $\gamma = 0$ and $\alpha = -\beta$.
    - If $\alpha = 0$, then $\beta = 0$, $(u_1, u_1) = \underbrace{(u_0, u_1)}_{\in K} + \underbrace{(u_1 - u_0, 0)}_{\in \operatorname{rec}(K)} \in K$.

      We then choose for instance $a \in \mathbb{R}^*$, $C = \{0\}$ and $x = y = u_1$.
    - If $\alpha \neq 0$, then we just have to take $a = \alpha$, $C = \mathbb{R}$, $x = u_0$, $y = u_1$.

    Note that in both these cases we trivially have $\gamma \in C$.
  - If $\delta > 0$ then, for large enough n, $n\delta + \alpha > 0$. Moreover, as $\operatorname{rec}(K)$ is a cone,

$$(1, n\delta + \alpha) = \underbrace{n(0, \delta)}_{\in \operatorname{rec}(K)} + \underbrace{(1, \alpha)}_{\in \operatorname{rec}(K)} \in \operatorname{rec}(K).$$

We then take $a = n\delta + \alpha > 0$, $C = \mathbb{R}_+$, $x = u_k$, $y = u_{k+1}$, for some k such that $u_{k+1} - u_k + > 0$. This exists since $1 \in \mathcal{D}_u$ and hence $(u_n)_{n\in\mathbb{N}}$ is not bounded from above. Note also that since $\delta > 0$ then $\gamma \geq 0$. Thus $\gamma \in C$.

- If $\delta < 0$ then, for large enough n, $n\delta + \beta < 0$. Moreover, as $\mathrm{rec}(K)$ is a cone,

$$(-1, n\delta + \beta) = \underbrace{n(0,\delta)}_{\in \mathrm{rec}(K)} + \underbrace{(-1,\beta)}_{\in \mathrm{rec}(K)} \in \mathrm{rec}(K).$$

We then take $a = -n\delta - \beta > 0$, $C = \mathbb{R}_-$, $x = u_k$, $y = u_{k+1}$ for some k such that $u_{k+1} - u_k < 0$. This exists since $-1 \in \mathcal{D}_u$ and hence $(u_n)_{n\in\mathbb{N}}$ is not bounded from below. Note also that since $\delta < 0$ then $\gamma \leq 0$. Thus $\gamma \in C$.

- If $\mathcal{D}_u = \{1\}$, then, similarly to the first case, using Corollary 25, there is some $\alpha \in \mathbb{R}_+$ such that $(1, \alpha) \in \mathrm{rec}(K)$. Note also that $\gamma \geq 0$ and that $(1, \alpha + \gamma) \in \mathrm{rec}(K)$. Let k such that $u_{k+1} - u_k > 0$. This exists since $1 \in \mathcal{D}_u$ and hence $(u_n)_{n\in\mathbb{N}}$ is not bounded from above.
  - If $\alpha + \gamma = 0$, then, $\alpha = \gamma = 0$ and

$$(u_{k+1}, u_{k+1}) = \underbrace{(u_k, u_{k+1})}_{\in K} + \underbrace{(u_{k+1} - u_k, 0)}_{\in \mathrm{rec}(K)} \in K.$$

We then choose for instance $a \in \mathbb{R}^*$, $C = \{0\}$ and $x = y = u_{k+1}$.

  - If $\alpha + \gamma > 0$, then we just have to take $a = \alpha + \gamma$, $C = \mathbb{R}_+$, $x = u_k$ and $y = u_{k+1}$.

  Note that in both cases, $\gamma \in \mathbb{R}_+ = C$.
- The case $\mathcal{D}_u = \{-1\}$ can be made similarly to the previous point. ◀

We are now ready to prove the special case of Theorem 2 in which E has dimension 1 (see Section 1). Without loss of generality we just consider $E = \mathbb{R}$. The necessary condition is given by the application of Proposition 28 with $\gamma = 0$. The sufficient condition is given by Proposition 27.

3.4 Necessary Condition for the Existence of a 2-Dimensional Sequence

We now move to 2-dimensional Euclidean spaces and prove that the existence of a witness as given by Definition 1 is implied by the existence of an infinite sequence. This, combined with Proposition 27 will imply Theorem 2.

For the entire section, we thus fix E to be an Euclidean space of dimension 2, $K \subseteq E^2$ to be MW-convex and thus satisfying $K = K' + \mathrm{rec}(K)$ where K' is a compact convex set. We assume that there exists a sequence $(u_n)_{n\in\mathbb{N}} \in E^{\mathbb{N}}$ such that for all $n \in \mathbb{N}$, $(u_n, u_{n+1}) \in K$.

We start by two technical lemmas to lighten the proof of the proposition.

▶ **Lemma 29.** *Assume that $\mathcal{D}_u$ is not empty and for all $x \in \mathrm{cone}\,\mathcal{D}_u$, if $(0, x) \in \mathrm{rec}(K)$, then $x = 0$. Denoting $\mathcal{C}_u = \mathrm{cone}\,\mathcal{D}_u$, we have that for all $x \in \mathcal{C}_u$, there is $s(x) \in \mathcal{C}_u$ such that $(x, s(x)) \in \mathrm{rec}(K)$.*

Proof. Let $x \in \mathcal{C}_u$. By definition, we can consider $x_1, \ldots, x_m \in \mathcal{D}_u$ and $\lambda_1, \ldots, \lambda_m \in \mathbb{R}_+$ such that $x = \sum_{i=1}^{m} \lambda_i x_i$. By definition of $\mathcal{D}_u$, for $i \in [\![1 \ ; \ m]\!]$ there is an increasing function $\varphi_i : \mathbb{N} \to \mathbb{N}$ such that $\widetilde{u_{\varphi_i(n)}} \underset{n\to+\infty}{\longrightarrow} x_i$. Using Proposition 22, the sequence $\left(\left(u_{\varphi_i(n)}, u_{\varphi_i(n)+1}\right)\right)_{n\in\mathbb{N}}$ admits an accumulation expansion

$$\left(u_{\varphi_i\circ\psi_i(n)}, u_{\varphi_i\circ\psi_i(n)+1}\right) = \sum_{k=1}^{p_i} \alpha_{i,k,n}(z_{i,k,1}, z_{i,k,2}) + (z_{i,p+1,1}, z_{i,p+1,2}) + \underset{n\to+\infty}{\mathrm{o}}(1).$$

In particular, for $k \in [\![1 \,;\, p_i]\!]$ minimum such that $z_{i,k,1} \neq 0$, we have $z_{i,k,1} \in \mathbb{R}_+^* x_i$. Since the first component is not bounded, such a k exists. Let $\mu_i > 0$ such that $z_{i,k,1} = \mu_i x_i$. Now, applying Proposition 23, $(z_{i,1,1}, z_{i,1,2}) \in \mathrm{rec}(K)$ and $\|(z_{i,1,1}, z_{i,1,2})\| = 1$. Therefore, if $k > 1$, then $z_{i,1,1} = 0$ and $\|z_{i,1,2}\| = 1$. Hence $z_{i,1,2} \in \mathcal{D}_u$. This contradicts the hypothesis that for all $x \in \mathcal{C}_u$, if $(0, x) \in \mathrm{rec}(K)$, then $x = 0$. Thus, $k = 1$. Considering $s(x_i) = \dfrac{1}{\mu_i} z_{i,1,2}$ satisfies the claim for x_i. Thus, defining $s(x) = \sum_{i=1}^{m} \lambda_i s(x_i)$ establishes the lemma. ◀

▶ **Lemma 30.** *Assume that $\mathcal{D}_u$ is not empty, that for all $x \in \mathrm{cone}\, \mathcal{D}_u$, if $(0, x) \in \mathrm{rec}(K)$, then $x = 0$ and for all $x \in E$, $(x, x) \notin K$. Denoting $\mathcal{C}_u = \mathrm{cone}\, \mathcal{D}_u$, for all $x \in \mathcal{D}_u$, there are $\delta(x) \in E$ and $\lambda \in \mathbb{R}_+^*$ such that $(\delta(x), \lambda x + \delta(x)) \in K \cup \mathrm{rec}(K)$.*

Proof. Let $x \in \mathcal{D}_u$ and the accumulation expansion

$$u_{\varphi(n)} = \sum_{k=1}^{p} \alpha_{k,n} z_k + z_{p+1} + \underset{n \to +\infty}{\mathrm{o}}(1)$$

with $p > 0$ and $z_1 = x$. By convexity, we have

$$\forall n \in \mathbb{N} \qquad \frac{1}{\varphi(n)} \sum_{k=0}^{\varphi(n)-1} (u_k, u_{k+1}) \in K.$$

Up to refining φ, we can assume that we also have the accumulation expansion

$$\frac{1}{\varphi(n)} \sum_{k=0}^{\varphi(n)-1} (u_k, u_{k+1}) = \sum_{k=1}^{q} \beta_{k,n} (w_{k,1}, w_{k,2}) + (w_{q+1,1}, w_{q+1,2}) + \underset{n \to +\infty}{\mathrm{o}}(1)\,.$$

Therefore

$$\begin{aligned}
\sum_{k=1}^{q} \beta_{k,n} (w_{k,2} - w_{k,1}) + w_{q+1,2} - w_{q+1,1} &= \frac{1}{\varphi(n)} \sum_{k=0}^{\varphi(n)-1} (u_{k+1} - u_k) + \underset{n \to +\infty}{\mathrm{o}}(1) \\
&= \frac{u_{\varphi(n)} - u_0}{\varphi(n)} + \underset{n \to +\infty}{\mathrm{o}}(1) \\
&= \sum_{k=1}^{p} \frac{\alpha_{k,n}}{\varphi(n)} z_k + \underset{n \to +\infty}{\mathrm{o}}(1)\,.
\end{aligned}$$

If $\left(\dfrac{\alpha_{1,n}}{\varphi(n)} \right)_{n \in \mathbb{N}}$ has an accumulation point, say λ, up to refining φ, we assume that it converges to it. By definition of an accumulation expansion, we then have for all $k \in [\![1 \,;\, q]\!]$, $w_{k,1} = w_{k,2}$ Therefore, $w_{q+1,2} - w_{q+1,1} = \lambda x$.

By Proposition 23, there are some positive real numbers $\gamma_1, \ldots, \gamma_q$ such that

$$\sum_{k=1}^{q} \gamma_k (w_{k,1}, w_{k,2}) + (w_{q+1,1}, w_{q+1,2}) \in K.$$

The difference between the two coordinates of this vector is λx. Since λ is the limit of a positive sequence, $\lambda \geq 0$. Also, provided that there is no $a \in E$ such that $(a, a) \in K$ by hypothesis, we have $\lambda \neq 0$. Therefore, considering $\delta(x) = \sum_{k=1}^{q} \gamma_k w_{k,1} + w_{q+1,1}$ we get $(\delta(x), \lambda x + \delta(x)) \in K$.

Now suppose that $\left(\frac{\alpha_{1,n}}{\varphi(n)}\right)_{n\in\mathbb{N}}$ has no accumulation point. Since it is positive, we have

$$\frac{\alpha_{1,n}}{\varphi(n)} \underset{n\to+\infty}{\longrightarrow} +\infty.$$

Thus, there is $k \in [\![1 \ ; \ q]\!]$ minimum such that $w_{k,1} \neq w_{k,2}$ and for this k, we have

$$\beta_{k,n}(w_{k,2} - w_{k,1}) \underset{n\to+\infty}{\sim} \frac{\alpha_{1,n}}{\varphi(n)} x.$$

Therefore, there is $\lambda > 0$ such that $w_{k,2} - w_{k,1} = \lambda x$. By Proposition 23, there are some positive real numbers $\gamma_1, \ldots, \gamma_{k-1}$ such that

$$\sum_{\ell=1}^{k-1} \gamma_\ell (w_{\ell,1}, w_{\ell,2}) + (w_{k,1}, w_{k,2}) \in \mathrm{rec}(K).$$

The difference between the two coordinates of this vector is λx. Therefore, considering $\delta(x) = \sum_{\ell=1}^{k-1} \gamma_\ell w_{\ell,1} + w_{k,1}$ we have $(\delta(x), \lambda x + \delta(x)) \in \mathrm{rec}(K)$. ◀

▶ **Proposition 31.** *There exists a witness $\mathcal{W}(K)$.*

For the detailed proof we refer to the full version [6]. Here we just give an overview of the proof.

Proof sketch. The proof is divided into several cases under the structure described in Figure 1. Among all these cases, Case 6 is by far the most difficult, followed by Cases 2 and 5, then Case 4 (quite easy) and finally the almost trivial Cases 1 and 3. In this proof we denote $\mathcal{C}_u = \mathrm{cone}(\mathcal{D}_u)$.

- **Case 1:** There is a fixed point (x, x) in K. In this case we just need to take $v = w = x$, M arbitrary and $C = \{0\}$ to get a Witness. This just leads to a constant sequence.
- **Case 2:** No fixed point but there is $x \in \mathcal{C}_u \setminus \{0\}$ such that $(0, x) \in \mathrm{rec}(K)$. In this case we are going to try to make use of Proposition 28. Let $\pi : E \to E$ be the orthogonal projection onto $x^\perp$ and let $\widehat{\pi} : E^2 \to E^2$ be such that

  $$\forall e, f \in E, \widehat{\pi}(e, f) = (\pi(e), \pi(f)) .$$

  Assume that we have found some x' such that $(x, x') \in \mathrm{rec}(K)$. We then can write $x' = \gamma x + y$ for some y orthogonal to x and some $\gamma \in \mathbb{R}$. Then we have $\widehat{\pi}(x, x') = (0, y)$. Also $(0, y) \in \widehat{\pi}(\mathrm{rec}(K)) = \mathrm{rec}(\widehat{\pi}(K))$. Thus if we can build x' such that $y \in \mathrm{cone}(\mathcal{D}_{\pi(u)})$, we would be allowed to apply Proposition 28. This requires some work. The idea is to write $x = \sum_{i=1}^{n} a_i x_i$ with $x_i \in \mathcal{D}_u$ and $a_i \geq 0$ then apply Corollary 25 for all $i \in [\![1 \ ; \ n]\!]$ (see the full version [6] for details). Assume this is done. There are $a \in \mathbb{R}^*$, a closed convex cone $C \subseteq x^\perp$ and $v, w \in x^\perp$ such that
  - $aC \subseteq C$
  - $\forall c \in C \qquad (c, ac) \in \mathrm{rec}(\widehat{\pi}(K))$
  - $(v, w) \in \widehat{\pi}(K)$
  - $w - v \in C$
  - $y \in C$

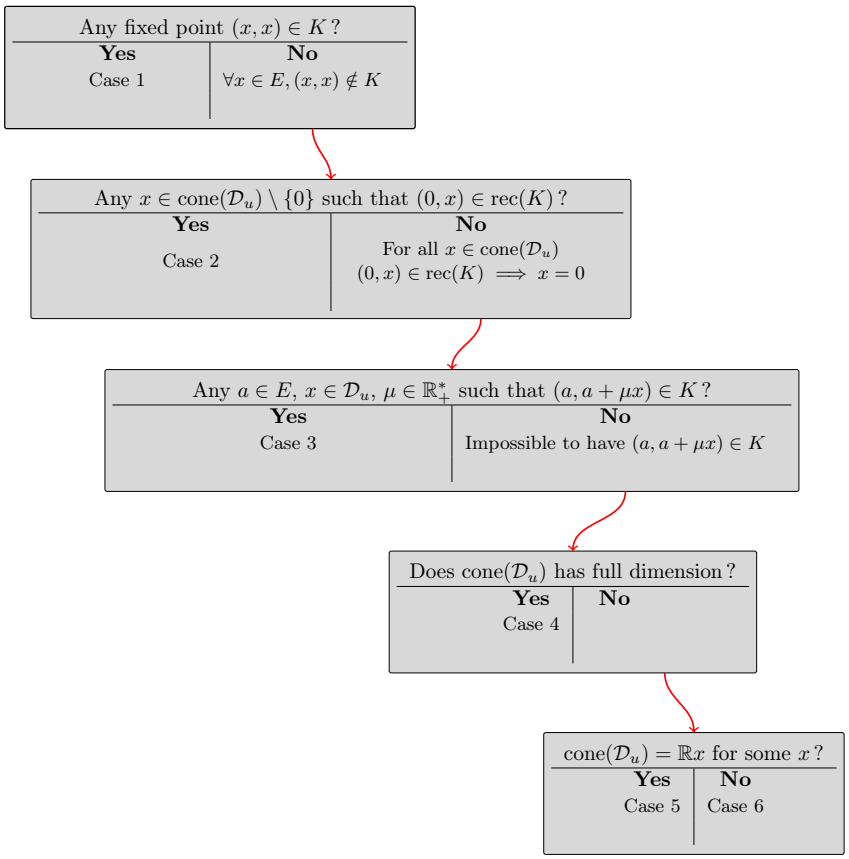

Figure 1 The case disjunction structure.

Again, since $\text{rec}(\widehat{\pi}K) = \widehat{\pi}(\text{rec}(K))$, for all $\xi \in C$, there are $b_\xi, c_\xi \in \mathbb{R}$ such that $(b_\xi x + \xi, c_\xi x + a\xi) \in \text{rec}(K)$. For all $\xi \in C$, we fix b_ξ and c_ξ such that $(|b_\xi|, |c_\xi|)$ is minimal for the lexicographic order and among all these possibilities, such that (b_ξ, c_ξ) is maximal for the lexicographic order. We denote

$$\gamma_0(\xi) = \max(1, \gamma, b_\xi) \qquad \text{and} \qquad \gamma_1(\xi) = \max(|a|, b_{a\xi}, c_\xi)$$

and for $n \geq 1$,

$$\gamma_{2n}(\xi) = \max\left(a^{2n}, a^{2n} b_\xi, a^{2(n-1)} c_{a\xi}\right)$$

$$\gamma_{2n+1}(\xi) = \max(|a|^{2n+1}, a^{2n} b_{a\xi}, a^{2n} c_\xi).$$

For $n \in \mathbb{N}$, let

$$\chi_n(\xi) = \gamma_n(\xi) x + a^n \xi \qquad \text{and} \qquad b'_{n,\xi} = \begin{cases} a^{2n} b_\xi & n \in 2\mathbb{N} \\ a^{2n} b_{a\xi} & n \in 2\mathbb{N} + 1. \end{cases}$$

We some algebraic manipulations and intensively using that $(0, x) \in \text{rec}(K)$ to add missing weight on x in the second component, we get

$$\forall n \in \mathbb{N} \qquad \left(\chi_n(\xi), \chi_{n+1}(\xi) + \left(\gamma_n(\xi) - b'_{n,\xi}\right) \chi_0(y)\right) \in \text{rec}(K).$$

Recalling that $w - v \in C$ we define $C' = \mathbb{R}_+ x + \sum_{n\in\mathbb{N}} (\mathbb{R}_+\chi_n(w-v) + \mathbb{R}_+\chi_n(y))$ This is the cone we want to use. It is finitely generated. We can also see that it cannot contain line. Since all such two-dimensional cones are generated by at most two vectors we can find such generating vectors. M will just be a matrix defined thanks to its behavior on these vectors and C' is defined to get stability. Finally, up to add some component on x again we can get our starting conditions thanks to v and w (See details in the full version [6]).

- **Case 3:** No fixed point or $x \in \mathcal{C}_u \setminus \{0\}$ such that $(0, x) \in \mathrm{rec}(K)$. However there are $a \in E$, $x \in \mathcal{D}_u$ and $\mu \in \mathbb{R}_+^*$ such that $(a, a+\mu x) \in K$. This means that their is a principle direction of u along which it is possible to take a first step. In this case, we select $C = \mathcal{C}_u$. C is a non empty closed convex cone of $\mathbb{R}^2$, thus, there are two vectors $x_1, x_2 \in C \setminus \{0\}$ such that either $C = \mathbb{R}x_1 + \mathbb{R}_+x_2$ or $C = \mathbb{R}_+x_1 + \mathbb{R}_+x_2$ or $C = \mathbb{R}x_1 + \mathbb{R}x_2$. Let $I \subseteq \{1, 2\}$, $I \neq \varnothing$ the largest set such that $(x_i)_{i\in I}$ is a free family. Using the function s defined by Lemma 29, we define M such that $Mx_i = s(x_i)$ for all $i \in I$. Noting that since, for $i \in I$, $-x_i \in C$, $(0, s(x_i) + s(-x_i)) \in \mathrm{rec}(K)$, we have that $s(-x_i) = -s(x_i)$, this choice of M satisfies Points ($\exists u1$) and ($\exists u2$). We now choose $v = a$ and $w = a + \mu x$. By assumption, $(v, w) \in K$. Also, $w - v = \mu x \in \mathcal{C}_u = C$. C, v and w thus satisfy Points ($\exists u3$) and ($\exists u4$).
- **Case 4:** No fixed point, $x \in \mathcal{C}_u \setminus \{0\}$ such that $(0, x) \in \mathrm{rec}(K)$ or $a \in E$, $x \in \mathcal{D}_u$, $\mu \in \mathbb{R}_+^*$ such that $(a, a + \mu x) \in K$. However $\mathcal{D}_u$ spans the entire space E. Given that, take $(a, b) \in K$. Using Lemma 13 there is $\lambda \geq 0$ such that $y := b - a + \lambda x \in \mathcal{C}_u$. Let $v = a + \lambda\delta(x)$ and $w = b + \lambda(x + \delta(x))$ with δ given by Lemma 30. We then have $(u, v) \in K$. Let $C = \overline{\mathrm{cone}\{\, s^k(y) \mid k \in \mathbb{N}\}}$ with s being the function defined in Lemma 29. C is a closed convex cone in a 2-dimensional vector space, therefore there are vectors $\zeta_1, \zeta_2 \in C \setminus \{0\}$ such that

  $$C \in \{\mathbb{R}_+\zeta_1 + \mathbb{R}_+\zeta_2, \mathbb{R}\zeta_1 + \mathbb{R}_+\zeta_2, \mathbb{R}_+\zeta_1 + \mathbb{R}\zeta_2, \mathbb{R}\zeta_1 + \mathbb{R}\zeta_2\}.$$

  Let $(\zeta_{i,n})_{n\in\mathbb{N}}$ be a sequence in $\mathrm{cone}\{\, s^k(y) \mid k \in \mathbb{N}\}$ such that

  $$\zeta_{i,n} \underset{n\to+\infty}{\longrightarrow} \zeta_i.$$

  If $(s(\zeta_{i,n}))_{n\in\mathbb{N}}$ is unbounded then Proposition 23 ensures that there is some $\zeta_i' \in \mathcal{D}_{(s(\zeta_{i,n}))_{n\in\mathbb{N}}}$ such that $(0, \zeta_i') \in \mathrm{rec}(K)$ and $\zeta_i' \in \mathcal{C}_u$. This is impossible by assumption on $\mathcal{C}_u$. Therefore, it is bounded and we have an accumulation point $\zeta_i' \in C$. Since $\mathrm{rec}(K)$ is closed, we also have $(\zeta_i, \zeta_i') \in \mathrm{rec}(K)$. Let $I \subseteq \{1, 2\}$ maximal such that $(\zeta_i)_{i\in I}$ is a free family. Let M be a matrix such that

  $$\forall i \in I \qquad M\zeta_i = \zeta_i'.$$

- **Case 5:** No fixed point, $x \in \mathcal{C}_u \setminus \{0\}$ such that $(0, x) \in \mathrm{rec}(K)$ or $a \in E$, $x \in \mathcal{D}_u$, $\mu \in \mathbb{R}_+^*$ such that $(a, a + \mu x) \in K$ and $\mathcal{C}_u$ is a line $\mathcal{C}_u = \mathbb{R}x$. This case uses the induction hypothesis (Proposition 28) and similar techniques as in Case 2. The main change here is that we use the function s defined by Lemma 29. Here $s(x)$ will have to be collinear with x. In stead of adding multiples of $(0, x)$, we have access to some $(x, \gamma x) \in \mathrm{rec}\, K$ and are allowed negative coefficients which makes the case relatively easy. See details in the full version [6].
- **Case 6:** No fixed point, $x \in \mathcal{C}_u \setminus \{0\}$ such that $(0, x) \in \mathrm{rec}(K)$ or $a \in E$, $x \in \mathcal{D}_u$, $\mu \in \mathbb{R}_+^*$ such that $(a, a + \mu x) \in K$ and $\mathcal{C}_u = \mathbb{R}_+x$ for some x. Let $y \in x^\perp$ such that $\|y\| = 1$. The main goal of this case is to find $a, b \geq 0$ and $c, d \in \mathbb{R}$ such that

  $$(x, ax) \in \mathrm{rec}(K) \qquad \text{and} \qquad (dx + y, cx + by) \in \mathrm{rec}(K) \qquad \text{and} \qquad c \geq db.$$

This can be achieved by a very careful look at the asymptotic behavior of the $(u_n)_{n\in\mathbb{N}}$ and more precisely its components along x and y. Namely, the component along x must blow up significantly faster than the one along y. This is where the difficulty of this case lies. We refer to the full version [6] for the details. This naturally leads to choose C and M such that:

$$C = \mathbb{R}_+x + \mathbb{R}_+(dx+y) \qquad \text{and} \qquad Mx = ax \qquad \text{and} \qquad M(dx+y) = cx + by$$

immediately satisfying $(\exists u1)$ and $(\exists u2)$. With the same technics we can show that there is some $n \in \mathbb{N}$ such that

$$\langle u_{n+1} - u_n, x\rangle \geq d\,\langle u_{n+1} - u_n, y\rangle\,.$$

Then considering $v = u_n$ and $w = u_{n+1}$.

$$\begin{aligned} w - v = u_{n+1} - u_n &= \langle u_{n+1} - u_n, x\rangle\, x + \langle u_{n+1} - u_n, y\rangle\, y \\ &= \left(\langle u_{n+1} - u_n, x\rangle - d\,\langle u_{n+1} - u_n, y\rangle\right) x + \langle u_{n+1} - u_n, y\rangle\,(dx+y) \in C. \end{aligned}$$

Hence, Points $(\exists u3)$ and $(\exists u4)$ are satisfied by C, v, w. ◀

Flattability of Priority Vector Addition Systems

Roland Guttenberg
Technical University of Munich, Germany

Abstract

Vector addition systems (VAS), also known as Petri nets, are a popular model of concurrent systems. Many problems from many areas reduce to the *reachability problem* for VAS, which consists of deciding whether a target configuration of a VAS is reachable from a given initial configuration. One of the main approaches to solve the problem on practical instances is called *flattening*, intuitively removing nested loops. This technique is known to terminate for semilinear VAS due to [22]. In this paper, we prove that also for VAS with nested zero tests, called Priority VAS, flattening does in fact terminate for all semilinear reachability relations. Furthermore, we prove that Priority VAS admit semilinear inductive invariants. Both of these results are obtained by defining a well-quasi-order on runs of Priority VAS which has good pumping properties.

1 Introduction

Vector addition systems (VAS), also known as Petri nets, are a popular model of concurrent systems. VAS have a very rich theory and have been intensely studied. In particular, the *reachability problem* for VAS, which consists of deciding whether a target configuration of a VAS is reachable from a given initial configuration, has been studied for over 50 years. It was proved decidable in the 1980s [28, 16, 17], but its complexity (Ackermann-complete) could only be determined recently [6, 7, 23].

In [19] and [22], Leroux proved two fundamental results about the reachability sets of VAS. In [19], he showed that every configuration outside the reachability set $\mathbf{R}$ of a VAS is separated from $\mathbf{R}$ by a semilinear inductive invariant (for basic facts on semilinear sets see e.g. [11]). This immediately led to a very simple algorithm for the reachability problem consisting of two semi-algorithms, one enumerating all possible paths to certify reachability, and one enumerating all semilinear sets and checking if they are separating inductive invariants.

In [22], he proved that if the reachability set of a VAS is semilinear, then it is *flattable*. Flattability states the existence of a finite sequence $\rho_1, \ldots, \rho_r$ of transition sequences such that every reachable vector can be reached via a sequence in $\rho_1^* \ldots \rho_r^*$, i.e., by means of a "flat" expression without nested loops. Flattability leads to an algorithm for deciding whether a semilinear set is included in or equal to the reachability set of a given VAS, i.e. whether a VAS has the set of desired behaviours. If it is not included, guess the violating configuration and check it is unreachable, otherwise guess a linear path scheme and verify it.

One major branch of ongoing research in the theory of VAS studies whether results like the above extend to more general systems [30, 3, 4, 31, 1, 25, 27, 13, 18, 8, 26, 2]. In particular, the reachability problem has been proved decidable for Priority VAS, an extension of VAS in which counters can be tested for zero, albeit in restricted manner: there is a total order on the counters such that whenever a counter is tested for 0, all smaller counters are simultaneously tested as well. In a famous but very technical paper, Reinhardt proved that the reachability problem remains decidable for Priority VAS [30]. In [3] and later in his thesis [4], Bonnet presented a more accessible proof which was obtained by extending the result of [19], separability by inductive semilinear sets.

In this paper we extend the result of [22] to arbitrary Priority VAS, and on the way obtain another proof that [19] extends. That is, we show that 1. Priority VAS admit semilinear inductive invariants, and 2. semilinear Priority VAS are flattable. Notice that 2. was not known even for the special case of one testable counter. Furthermore, as remarked in [26], while two-dimensional vector addition systems with a zero test and a reset are effectively semilinear [8], they are not flattable in general. Hence, our second result establishes a theoretical limit of flattability.

These results are obtained via two technical contributions of independent interest.

Regular expressions for Priority VAS. We give a new characterization of the reachability relations of Priority VAS. More precisely, we show that a relation is the reachability relation of a Priority VAS if and only if it can be represented as a regular expression over the reachability relations of standard VAS, with the restriction that the Kleene star operation can only be applied to monotone relations. For example in case of the Priority VASS in Figure 1 as $\mathcal{V}$, we would consider the VASS without the zero test transition as $\mathcal{V}_0$, and if we are interested in the reachability relation starting at q_s, ending at q_s and requiring counter x to start and end at 0, formally $\rightarrow^*_{\mathcal{V},q_s\rightarrow q_s} \cap\{x_{in} = x_{out} = 0\}$, then we would rewrite $\rightarrow^*_{\mathcal{V},q_s\rightarrow q_s} \cap\{x_{in} = x_{out} = 0\} = (\rightarrow^*_{\mathcal{V}_0,q_s\rightarrow q_t} \cap\{x_{in} = x_{out} = 0\})^*$. I.e., instead we consider the inner normal VASS starting at q_s, ending at q_t and fixing x to 0 at start and end, then taking the reflexive transitive closure of this relation. In general zero testing a coordinate will generate an expression of the form $\mathbf{E}^*$, where $\mathbf{E}$ fixes some coordinates to 0 at start and end. One important aspect of this characterization is that all intersections with linear relations (for example here with $x_{in} = x_{out} = 0$) can be pushed purely to the inner VASS level, where they were dealt with in [22]. Hence in our arguments we only have to consider how to deal with $\circ$ and $*$, not with intersections or projections.

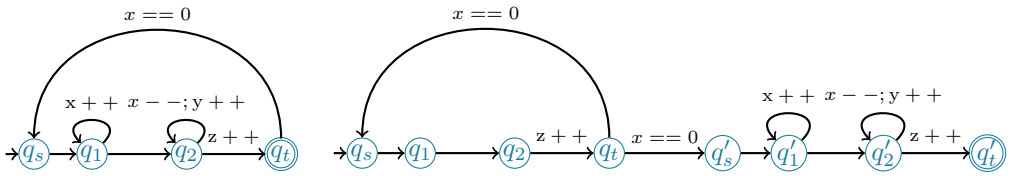

Figure 1 Example of a PVASS and an equivalent (for $x_{in} = 0$) flattened version.

Characterizations of complicated relations using RegEx over simpler relations have already proven useful in other contexts [29, 12].

A well-quasi-order (wqo) on the set of runs of Priority VAS. A wqo on a set is a partial order such that every subset has finitely many minimal elements. There exist wqos on many kinds of objects: vectors, sequences, trees, or graphs. A wqo on the set of runs of a PVAS

provides the following decomposition: Let $\mathrm{src}(\rho)$ denote the source of a run ρ, $\mathrm{tgt}(\rho)$ denote its target and $\mathrm{ends}(\rho) = (\mathrm{src}(\rho), \mathrm{tgt}(\rho))$ its *pair of ends*, i.e. source/target pair. Let Ω_{min} be the finite set of minimal runs. Then the reachability relation $\to^*_{\mathcal{V}}$ can be written as $\to^* = \bigcup_{\rho\in\Omega_{min}} \{\mathrm{ends}(\rho') \mid \rho' \geq \rho\}$, i.e. we observe that every pair of configurations $\mathbf{c}, \mathbf{c}'$ such that $\mathbf{c} \to^* \mathbf{c}'$ is witnessed by some run, and then we split runs into one group for every minimal run. Intuitively, this reduces the problem of proving flattability of a VAS to proving flattability in each of the groups determined by the minimal runs. The proof that semilinear VAS are flattable follows this scheme. More precisely, the proof, given in [22], takes the wqo on the runs of a VAS introduced by Jancar in [15], proves that it satisfies certain pumping properties, properties shown in [15, 20, 21] and new ones, and derives the result. We proceed in the same way, starting from a wqo on the set of runs of a Priority VAS[1].

Let us now cconsider the concrete case of pumping and flattening in the example in Figure 1. Consider the run $\rho : q_s \to q_1 \to q_2 \to q_t$ which does not use any of the self-loops. Intuitively, if we did not have the $x_{in} = x_{out} = 0$ restriction, both the x and y coordinates can be pumped arbitrarily along this run. In order to pump the x coordinate simply add one use of the self-loop on q_1, and to increase the y coordinate add both self-loops once. Observe that despite using a loop which is not non-negative in the second case, and hence could not be arbitrarily often repeated by itself, this loop only decreases a coordinate which was already pumped prior in the run, i.e. the sequence of loops can be pumped.

Using this basic image of pumping, we can now describe the idea of our proof. In the example, define $\mathbf{E} := \to^*_{\mathcal{V}_0, q_s\to q_t} \cap \{x_{in} = x_{out} = 0\}$, then the target is $\mathbf{E}^*$ as explained above. One first determines by induction hypothesis a decomposition of $\mathbf{E}$ into groups of runs. In this case there is one group, as the run above is the unique minimal run.

Now we proceed to describe runs of $\mathbf{E}^*$ as sequences of *which group of* $\mathbf{E}$ *was used*. I.e. we performed one important mental step here: A run of $\mathbf{E}^*$ is now viewed as a sequence $\mathbf{C}_0 \to_{\mathbf{E}} \mathbf{C}_1 \to_{\mathbf{E}} \cdots \to_{\mathbf{E}} \mathbf{C}_r$ of steps in $\mathbf{E}$, i.e. every step is now one application of the outer loop, and we *abstract away* the information of how precisely these steps look, in particular how often the inner self-loops were taken. This leads to pumping a vector into a run having two cases: Either add more outer loops/transitions, the same as for VASSs, or *increase one of the already existing loops*. For example for the run $q_s(0,0,0) \to_{\mathbf{E}} q_t(0,0,1)$ described above, with respect to $\mathbf{E}^*$, we can pump both the y and z coordinates arbitrarily. Pumping y is an instance of *increasing an existing loop*: Change the existing loop by taking the inner self-loops. On the other hand, pumping z is the other type: We simply add more instances of the outer loop. The resulting PVASS without any nested loops is depicted in the right of Figure 1. Observe in particular that for pumping those vectors it was not necessary to add arbitrarily many repetitions of the outer loop which take the inner loops arbitrarily often.

Structure of the paper. In Section 2 we define a few preliminaries. Section 3 introduces VAS and Priority VAS. Our first result, the characterization of the reachability relations of Priority VAS in terms of regular expressions, is proved in Section 4. In Section 5 we define well-quasi-orders, and in particular our novel wqo on runs of Priority VAS. Section 5.4 introduces geometric preliminaries and previous results about VAS needed to state and prove our results. Section 6 defines flattability, and proves our main result.

[1] The wqo for VAS does not respect the zero tests and hence does not work, a new ordering is necessary.

2 Preliminaries

We let $\mathbb{N}, \mathbb{Z}, \mathbb{Q}, \mathbb{Q}_{\geq 0}$ denote the sets of natural numbers containing 0, integers, and (non-negative) rational numbers. We use uppercase letters for sets/relations and boldface for vectors and sets/relations of vectors. For the i-th entry of a vector $\mathbf{x} \in \mathbb{Q}^d$ we write $\mathbf{x}(i)$.

Given sets $\mathbf{X}, \mathbf{Y} \subseteq \mathbb{Q}^d, Z \subseteq \mathbb{Q}$, we write $\mathbf{X} + \mathbf{Y} := \{\mathbf{x} + \mathbf{y} \mid \mathbf{x} \in \mathbf{X}, \mathbf{y} \in \mathbf{Y}\}$ for the Minkowski sum and $Z \cdot \mathbf{X} := \{\lambda \cdot \mathbf{x} \mid \lambda \in Z, \mathbf{x} \in \mathbf{X}\}$. By identifying elements $\mathbf{x} \in \mathbb{Q}^d$ with $\{\mathbf{x}\}$, we define $\mathbf{x} + \mathbf{X} := \{\mathbf{x}\} + \mathbf{X}$, and similarly $\lambda \cdot \mathbf{X} := \{\lambda\} \cdot \mathbf{X}$ for $\lambda \in \mathbb{Q}$.

A set $\mathbf{L} \subseteq \mathbb{N}^d$ is *linear* if $\mathbf{L} = \mathbf{b} + \mathbb{N}\mathbf{p}_1 + \cdots + \mathbb{N}\mathbf{p}_r$ with $\mathbf{b}, \mathbf{p}_1, \ldots, \mathbf{p}_r \in \mathbb{N}^d$. A relation $\mathbf{L} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ is linear if it is linear when viewed as a set. A set/relation $\mathbf{S}$ is *semilinear* if it is a finite union of linear sets/relations. The semilinear sets/relations coincide with the sets/relations definable via formulas $\varphi \in \mathrm{FO}(\mathbb{N}, +)$, also called Presburger Arithmetic.

Given relations $\mathbf{R}_1 \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d_{mid}}$ and $\mathbf{R}_2 \subseteq \mathbb{N}^{d_{mid}} \times \mathbb{N}^{d''}$, we write $\mathbf{R}_1 \circ \mathbf{R}_2 = \{(\mathbf{v}, \mathbf{w}) \in \mathbb{N}^{d'} \times \mathbb{N}^{d''} \mid \exists \mathbf{x} \in \mathbb{N}^{d_{mid}} : (\mathbf{v}, \mathbf{x}) \in \mathbf{R}_1, (\mathbf{x}, \mathbf{w}) \in \mathbf{R}_2\}$ for composition. Given $\mathbf{R} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d'}$, we write $\mathbf{R}^*$ for the reflexive and transitive closure (w.r.t. $\circ$).

Let $j, d', d'' \in \mathbb{N}$ with $j \leq d', d''$. A relation $\mathbf{R} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ is *monotone in the j-th last coordinate* if for every $(\mathbf{x}, \mathbf{y}) \in \mathbf{R}$ we also have $(\mathbf{x} + \mathbf{e}_{d'+1-j}, \mathbf{y} + \mathbf{e}_{d''+1-j}) \in \mathbf{R}$, where $\mathbf{e}_k$ is the k-th unit vector[2]. A relation $\mathbf{R} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ is *monotone* if $d' = d''$ and $\mathbf{R}$ is monotone in every coordinate.

3 Vector Addition Systems and Priority Vector Addition Systems

A *priority vector addition system with states* (PVASS) $\mathcal{V}$ of dimension $d \in \mathbb{N}$ is a finite directed multigraph (Q, E), whose edges e are labelled with a pair of a vector $f(e) \in \mathbb{Z}^d$ and a number $g(e) \in \{0, \ldots, d\}$. The set of configurations of $\mathcal{V}$ is $Q \times \mathbb{N}^d$. An edge $e = (p, p')$ with label $(f(e), g(e))$ induces a relation $\to_e$ on configurations via $\mathbf{c} = (q, \mathbf{x}) \to_e \mathbf{c}' = (q', \mathbf{x}')$ if and only if $q = p, q' = p'$, $\mathbf{x}(j) = 0$ for all $1 \leq j \leq g(e)$ and $\mathbf{x}' = \mathbf{x} + f(e)$. Intuitively, the edge can only be used in state p to move to state p' and adds the vector $f(e)$ to the current configuration. However, two conditions have to be fulfilled: We have to again arrive at a configuration $\mathbf{c}'$ (i.e. $\mathbf{x}'$ has to stay non-negative), and $\mathbf{x}$ must be 0 on the first $g(e)$ coordinates. We say that these coordinates are *tested for 0*. Observe that contrary to Minsky machines, if a counter i is tested for 0, also all smaller counters $j \leq i$ are tested for 0.

We write $\to_{\mathcal{V}} = \bigcup_{e \in E} \to_e$ and let $\to_{\mathcal{V}}^*$ denote its reflexive and transitive closure. A run of $\mathcal{V}$ is a finite sequence $\rho = (\mathbf{c}_0, \mathbf{c}_1, \ldots, \mathbf{c}_k)$ of configurations such that $\mathbf{c}_i \to_{\mathcal{V}} \mathbf{c}_{i+1}$ for all $0 \leq i \leq k-1$. The *source* of the run ρ is the configuration $\mathrm{src}(\rho) := \mathbf{c}_0$, and the *target* is $\mathrm{tgt}(\rho) := \mathbf{c}_k$. The *pair of ends* of ρ is $\mathrm{ends}(\rho) = (\mathrm{src}(\rho), \mathrm{tgt}(\rho))$. A configuration tgt is reachable from src in $\mathcal{V}$ if $\mathrm{src} \to_{\mathcal{V}}^* \mathrm{tgt}$, or equivalently if there exists a run ρ with $\mathrm{ends}(\rho) = (\mathrm{src}, \mathrm{tgt})$.

A *priority vector addition system* (PVAS) $\mathcal{V}$ is a PVASS with only one state, a *vector addition system with states* (VASS) is a PVASS where $g(e) = 0$ for every edge e, i.e. no counter is ever tested for 0. A VAS is a PVAS which is also a VASS.

Since the class of reachability relations of PVASS is lacking some important closure properties, and we do not want to distinguish between PVASS and PVAS all the time, we instead consider a larger class of sets (which coincides for the two models). Intuitively, not every run is accepting anymore, instead a run has to start in a given initial state p and end in a given final state q, and certain counters have to start and/or end with fixed values. The idea is to then view the relation as subset of $\mathbb{N}^{d'} \times \mathbb{N}^{d''}$ where d', d'' are the number of input and respectively output counters which are not fixed.

[2] The reason for starting to count coordinates from the end will be explained in the next section.

▶ **Definition 1** ([5]). *A relation* $\mathbf{X} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ *is a* (P)VASS section *if there exists a (P)VASS* $\mathcal{V}$ *of dimension* $d \geq d', d''$*, states* p, q *and vectors* $\mathbf{b}_s \in \mathbb{N}^{d-d'}, \mathbf{b}_t \in \mathbb{N}^{d-d''}$ *such that* $\mathbf{X} = \{(\mathbf{x}, \mathbf{y}) \in \mathbb{N}^{d'} \times \mathbb{N}^{d''} \mid (p, (\mathbf{b}_s, \mathbf{x})) \to_{\mathcal{V}}^* (q, (\mathbf{b}_t, \mathbf{y}))\}$.

This is the reason for defining monotonicity counting from the end: The same counter has different indices as unit vector because of fixing a different number of coordinates.

We write the section defined by the PVASS $\mathcal{V}$, the states p, q and the vectors $\mathbf{b}_s, \mathbf{b}_t$ as $\binom{\mathcal{V},p,q}{\mathbf{b}_s,\mathbf{b}_t}$. If $\mathcal{V}$ is a PVAS, then we leave away the unique states and only write $\binom{\mathcal{V}}{\mathbf{b}_s,\mathbf{b}_t}$. The reason for this notation is that PVASS sections should be viewed as an intersection of two relations: The reachability relation with fixed source state and target state, and the linear relation defined by the fixed coordinates. In the notation we like to split these parts.

We have three remarks on the definition of PVASS sections.

▶ Remark 2. We fix coordinates starting from the first, i.e. the most often zero tested coordinates are fixed first. This does not restrict the class of PVAS sections.

▶ Remark 3. At the cost of increasing the dimension by 3, states are a special case of fixed never-zero-tested coordinates [14], hence (P)VASS sections can equivalently be defined by (P)VAS. Furthermore, similar to how zero tests in Minsky machines can be assumed to only change the state, we will always require that $f(e)(j) = 0$ for all $j \leq g(e)$, i.e. any counter which is being zero tested is not updated. To obtain this assumption, simply move to an intermediate state from which you perform the additions afterwards.

▶ Remark 4. When using states, we can w.l.o.g. require $\mathbf{b}_s = 0^{d-d'}$ and $\mathbf{b}_t = 0^{d-d''}$, i.e. fixed coordinates are fixed to 0. However, since it is sometimes preferable to not use states, we allow general vectors $\mathbf{b}_s, \mathbf{b}_t$ for the fixed coordinates.

4 Equivalence of PVASS and Regular Expressions over VASS

Next we define the grammar which we will then prove to be equivalent to PVASS sections. Intuitively, one considers regular expressions where leaves/letters are VASS sections $\mathbf{Y}$. Intermediate relations might have different input and output dimensions, hence non-terminals depend on the dimensions, and composition requires matching dimensions.

▶ **Definition 5.** *Consider the following grammar with non-terminals* $\mathbf{E}_{d',d''}$ *for* $d', d'' \in \mathbb{N}$*:*

$$\mathbf{E}_{d',d''} = \mathbf{Y}_{d',d''} \mid \mathbf{E}_{d',d_{mid}} \circ \mathbf{E}_{d_{mid},d''} \mid \mathbf{E}_{d',d''} \cup \mathbf{E}_{d',d''}$$
$$\mathbf{E}_{d',d'} = \mathbf{Y}_{d',d'} \mid \mathbf{E}_{d',d_{mid}} \circ \mathbf{E}_{d_{mid},d'} \mid \mathbf{E}_{d',d'} \cup \mathbf{E}_{d',d'} \mid \mathbf{E}^*_{d',d'},$$

where the $\mathbf{Y}_{d',d''}$ *are VASS sections* $\subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$*. An expression* $\mathbf{E}_{d',d''}$ *defines in a natural way a relation* $\mathrm{Rel}(\mathbf{E}_{d',d''}) \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$*, by interpreting* $\circ$ *as composition of relations,* $\cup$ *as union and* $*$ *as reflexive transitive closure. We usually write* $\mathbf{E}$ *instead of* $\mathbf{E}_{d',d''}$ *when the dimensions* $in(\mathbf{E}) = d'$ *and* $out(\mathbf{E}) = d''$ *are clear.*

Before we state the main theorem of this section, there are two things to note about this definition of the semantics. 1) $*$ by definition adds reflexivity, however it only does so in the non-fixed counters. This was one goal of the definition allowing different dimensions of intermediate objects. 2) The semantics for composition however are not as intuitive as it might seem, see the following example.

▶ **Example 6.** Let $\mathcal{V}$ be the 1-dimensional VAS with two transitions, incrementing x and decrementing x. Then its reachability relation is $\to_{\mathcal{V}}^* = \mathbb{N} \times \mathbb{N}$. Consider $\mathrm{Rel}(\binom{\mathcal{V}}{\epsilon,0} \circ \binom{\mathcal{V}}{1,\epsilon}) \subseteq \mathbb{N} \times \mathbb{N}$. We have $\mathrm{Rel}(\binom{\mathcal{V}}{\epsilon,0}) = \mathbb{N} \times \{\epsilon\}$ and $\mathrm{Rel}(\binom{\mathcal{V}}{1,\epsilon}) = \{\epsilon\} \times \mathbb{N}$, where we write $\epsilon \in \mathbb{N}^0$ for the

unique empty product. Despite the fixed coordinates $0, 1 \in \mathbb{N}$ not matching up, we obtain $\mathrm{Rel}(\binom{\mathcal{V}}{\epsilon,0} \circ \binom{\mathcal{V}}{1,\epsilon}) = \mathbb{N} \times \mathbb{N}$ by definition. This is due to the composition being only defined on the remaining, i.e. non-fixed coordinates.

We can now state the main theorem of this section.

▶ **Theorem 7.** *A relation $\mathbf{X} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ is a PVASS section iff $\mathbf{X} = \mathrm{Rel}(\mathbf{E})$ for some $\mathbf{E}$.*

Proof. "⇒": Let $\mathbf{X} = \binom{\mathcal{V}}{\mathbf{b}_s,\mathbf{b}_t} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ for a d-dimensional PVAS $\mathcal{V}$ *without states*, since they produce the same class of sections as in Remark 3. We will prove by induction on $k := \max_{e \in E} g(e)$, i.e. the maximal zero-tested counter, that every PVAS section $\mathbf{X}_k \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ has an equivalent expression $\mathbf{E}_k$ in the grammar. In the base case $k = 0$, $\mathcal{V}$ is actually a VAS, and hence $\mathbf{Y} := \mathbf{X}_k$ is an equivalent expression in the grammar.

Induction step: $k-1 \to k$: For $j \in \{k-1, k\}$ let $E_j := \{e \in E \mid g(e) \leq j\}$, in particular $Z_k := E_k \setminus E_{k-1}$ are the edges with $g(e) = k$, i.e. testing counters $1, \dots, k$. Let $\mathcal{V}_j$ be the PVASS with edges E_j and the same labels $f(e)$ and $g(e)$ as $\mathcal{V}$. By induction, for $\mathcal{V}_{k-1}$ and any vectors $\mathbf{b}_s, \mathbf{b}_t$ there exists $\mathbf{E}_{k-1,\mathbf{b}_s,\mathbf{b}_t}$ with $\mathrm{Rel}(\mathbf{E}_{k-1,\mathbf{b}_s,\mathbf{b}_t}) = \binom{\mathcal{V}_{k-1}}{\mathbf{b}_s,\mathbf{b}_t}$.

Importantly, the semantics $\to_e$ of a single action $e \in E$, even if e performs a zero test, can be defined by a VASS. In particular for Z_k we define the following d-dimensional VASS $\mathcal{V}_{Z_k}$ with $|Z_k| + 2$ states $Q = \{q_{in}, q_{fin}\} \cup Z_k$ and $2|Z_k|$ actions: For every $e \in Z_k$, let $e' = (q_{in}, e)$ with label $f(e') = f(e)$ and $e'' = (e, q_{fin})$ with label $f(e'') = \mathbf{0}$. Intuitively, we non-deterministically choose an $e \in Z_k$ and execute its action, afterwards moving to q_{fin}. We do not perform the zero test, instead this will be done using the VASS section. Namely we define $\mathbf{E}_{Z_k} := \binom{\mathcal{V}_{Z_k},q_{in},q_{fin}}{0^k,0^k}$, i.e. we require the first k counters to be 0 at the start and end. That their values will still be 0^k also at the end follows by the assumption in Remark 3, that zero tests do not change the counters they are testing. Then we define

$\mathbf{E}_{k,\mathbf{b}_s,\mathbf{b}_t} := \mathbf{E}_{k-1,\mathbf{b}_s,\mathbf{b}_t} \cup \mathbf{E}_{k-1,\mathbf{b}_s,0^k} \circ \left(\mathbf{E}_{k-1,0^k,0^k} \cup \mathbf{E}_{Z_k}\right)^* \circ \mathbf{E}_{k-1,0^k,\mathbf{b}_t}$.

Intuitively, the expression says the following: Either the zero testing actions in Z_k are never used, or we move from $\mathbf{b}_s$ to a configuration with the first k counters fixed to 0, then repeatedly either move to another configuration with those counters 0 without using Z_k, or we can use Z_k. The computation ends using $\mathcal{V}_{k-1}$ and reaching the given target $\mathbf{b}_t$.

Well-definedness: We have to prove that in this expression $\mathbf{E}_k$ the operations $\circ, \cup, *$ are only used on matching dimensions. This follows since our specified targets and sources coincide. For example in the union $\mathbf{E}_{k-1,0^k,0^k} \cup \mathbf{E}_{Z_k}$, both parts fix $0^k, 0^k$ as required.

Correctness: It is clear that $\mathrm{Rel}(\mathbf{E}_{k,\mathbf{b}_s,\mathbf{b}_t}) \subseteq \binom{\mathcal{V}_k}{\mathbf{b}_s,\mathbf{b}_t}$, since the expression describes a special form of runs from $\mathbf{b}_s$ to $\mathbf{b}_t$. For the other direction, let $(\mathbf{c}_0, \dots, \mathbf{c}_r)$ be a run of $\mathcal{V}_k$ such that $\mathbf{c}_0 \in \{\mathbf{b}_s\} \times \mathbb{N}^{d-d'}$ and $\mathbf{c}_r \in \{\mathbf{b}_t\} \times \mathbb{N}^{d-d''}$. We have to show that $(\mathbf{c}_0, \mathbf{c}_r) \in \mathrm{Rel}(\mathbf{E}_{k,\mathbf{b}_s,\mathbf{b}_t})$. Case 1: The run does not use actions in Z_k. Then the run shows membership in $\binom{\mathcal{V}_{k-1}}{\mathbf{b}_s,\mathbf{b}_t} \subseteq \mathrm{Rel}(\mathbf{E}_{k-1,\mathbf{b}_s,\mathbf{b}_t}) \subseteq \mathrm{Rel}(\mathbf{E}_{k,\mathbf{b}_s,\mathbf{b}_t})$.

Case 2: The run does use Z_k. Let $\pi_k \colon \mathbb{N}^d \to \mathbb{N}^{d-k}$ be the projection to the last $d-k$ coordinates, i.e. it removes the anyways fixed coordinates. Let $i_1, \dots, i_s$ be the indices such that $\mathbf{c}_{i_j} \to \mathbf{c}_{i_j+1}$ uses an action $\mathbf{a}_j \in Z_k$, i.e. $(\pi_k(\mathbf{c}_{i_j}), \pi_k(\mathbf{c}_{i_j+1})) \in \mathrm{Rel}(\mathbf{E}_{Z_k})$. Then the part of the run $(\mathbf{c}_{i_j+1}, \dots, \mathbf{c}_{i_{j+1}})$ does not use any Z_k transitions. Hence $(\pi_k(\mathbf{c}_{i_j+1}), \pi_k(\mathbf{c}_{i_{j+1}})) \in \binom{\mathcal{V}_{k-1}}{0^k,0^k} \subseteq \mathrm{Rel}(\mathbf{E}_{k-1,0^k,0^k})$ for all $j \in \{1, \dots, s\}$. Hence we already obtain $(\pi_k(\mathbf{c}_{i_1}), \pi_k(\mathbf{c}_{i_s+1})) \in \mathrm{Rel}((\mathbf{E}_{k-1,0^k,0^k} \cup \mathbf{E}_{Z_k})^*)$. Now similar to π_k, let $\pi_{d-d'}, \pi_{d-d''}$ be the projections removing the first $d-d', d-d''$ coordinates. Since $(\mathbf{c}_0, \dots, \mathbf{c}_{i_1})$ does not use Z_k and $\mathbf{c}_0 \in \{\mathbf{b}_s\} \times \mathbb{N}^{d-d'}$, we obtain $(\pi_{d-d'}(\mathbf{c}_0), \pi_k(\mathbf{c}_{i_1})) \in \binom{\mathcal{V}_{k-1}}{\mathbf{b}_s,0^k} \subseteq \mathrm{Rel}(\mathbf{E}_{k-1,\mathbf{b}_s,0^k})$ and similarly $(\pi_k(\mathbf{c}_{i_s+1}), \pi_{d-d''}(\mathbf{c}_r)) \in \binom{\mathcal{V}_{k-1}}{0^k,\mathbf{b}_t} \subseteq \mathrm{Rel}(\mathbf{E}_{k-1,0^k,\mathbf{b}_t})$. Altogether we obtain $(\pi_{d-d'}(\mathbf{c}_0), \pi_{d-d''}(\mathbf{c}_r)) \in \mathrm{Rel}(\mathbf{E}_{k,\mathbf{b}_s,\mathbf{b}_t})$.

"⇐": This follows by structural induction. The construction follows the standard conversion RegEx to ε-NFA, while adding some obvious zero tests.

As our definition of Rel($\mathbf{Y}$) is representation independent, we choose to represent every Rel($\mathbf{Y}$) using VASS of the same dimension d, and with $\mathbf{b}_s = 0^k$ and $\mathbf{b}_t = 0^l$ for some $k, l \in \mathbb{N}$. That every VASS section has a representation with $\mathbf{b}_s = 0^k$ and $\mathbf{b}_t = 0^l$ follows since one can simply add a new initial and final state q_{in}, q_{fin}, and add $\mathbf{b}_s$ when leaving q_{in} respectively subtract $\mathbf{b}_t$ when entering q_{fin}. To guarantee that all VASS have the same dimension d, add unused counters. We will prove by induction that every subexpression $\mathbf{E}'$ of the given starting expression $\mathbf{E}$ has an equivalent PVASS section, where the PVASS has dimension d and $\mathbf{b}_s = 0^{d-in(\mathbf{E})}, \mathbf{b}_t = 0^{d-out(\mathbf{E})}$. In the base case $\mathbf{E} = \mathbf{Y}$ we have required this above.

$\mathbf{E} \cup \mathbf{E}'$: By induction hypothesis, we can write Rel($\mathbf{E}$) = $\binom{\mathcal{V},p,q}{0^{d'},0^{d''}}$ and Rel($\mathbf{E}'$) = $\binom{\mathcal{V}',p',q'}{0^{d'},0^{d''}}$ using d dimensional PVASS $\mathcal{V}, \mathcal{V}'$. That both sections use the same d' and d'' follows by the restriction on expressions. Our new PVASS simply has a new initial and final state, and performs a non-deterministic choice whether to move to p and simulate $\mathcal{V}$ or move to state p' and simulate $\mathcal{V}'$.

Formally, write $\mathcal{V} = (Q, E)$ and $\mathcal{V} = (Q', E')$. We define the new PVASS $\mathcal{V}''$ as $(Q \cup Q' \cup \{q_{in}, q_{out}\}, E \cup E' \cup \{(q_{in}, p), (q_{in}, p'), (q, q_{out}), (q', q_{out})\}$. All copied edges keep their labels, the four new edges get the label $g(e) = 0$, i.e. they do not zero test, and $f(e) = 0^d$, i.e. they do not change the counters. It is easy to see that Rel($\mathbf{E} \cup \mathbf{E}'$) = $\binom{\mathcal{V}'',q_{in},q_{out}}{0^{d'},0^{d''}}$.

$\mathbf{E} \circ \mathbf{E}'$: By induction hypothesis, we can write $\mathbf{E} = \binom{\mathcal{V},p,q}{0^{d-d'},0^{d-d_{mid}}}$ and $\mathbf{E}' = \binom{\mathcal{V}',p',q'}{0^{d-d_{mid}},0^{d-d''}}$ using d dimensional PVASS $\mathcal{V}, \mathcal{V}'$. Our new PVASS first simulates $\mathcal{V}$, then checks that the first d_{mid} counters are 0, before simulating $\mathcal{V}'$. Checking the intermediate configuration will be done using a zero test.

Formally, write $\mathcal{V} = (Q, E)$ and $\mathcal{V}' = (Q', E')$. We define the PVASS $\mathcal{V}''$ as $(Q \cup Q', E \cup E' \cup \{(q, p')\}$, where prior edges keep their labels, and $f(q, p') = 0^d$ and $g(q, p') = d - d_{mid}$, i.e. we zero test the first $d - d_{mid}$ counters. It is easy to see that Rel($\mathbf{E} \circ \mathbf{E}'$) = $\binom{\mathcal{V}'',p,q'}{0^{d-d'},0^{d-d''}}$.

$\mathbf{E}^*$: By induction hypothesis, we can write $\mathbf{E} = \binom{\mathcal{V},p,q}{0^{d-d'},0^{d-d'}}$, where both vectors have the same number of fixed coordinates by the restriction on the grammar. We now simply add a new initial state and an edge from q to this new initial state which performs zero tests on the first $d - d'$ coordinates.

Formally, write $\mathcal{V} = (Q, E)$ and define $\mathcal{V}' = (Q \cup \{q_{in}\}, E \cup \{(q_{in}, p), (q, q_{in})\})$, where edges $e \in E$ keep their labels, and $f(q_{in}, p) = f(q, q_{in}) = 0^d$, i.e. counters are not changed, and $g(q_{in}, p) = g(q, q_{in}) = d - d'$, i.e. the first $d - d'$ counters are zero tested. It is easy to see that Rel($\mathbf{E}^*$) = $\binom{\mathcal{V}',q_{in},p}{0^{d-d'},0^{d-d'}}$. ◀

The "⇒" direction breaks down for a Minsky machine. Namely for $k = 2$, one subexpression is $(\binom{\mathcal{V}_1}{0^2,0^2} \cup \mathbf{E}_{Z_2})^*$. The parts we take the union of do not have the same dimension, as the first coordinate should be free in $\mathbf{E}_{Z_2}$ for a Minsky machine.

In future sections we will require expressions where $*$ is only used on relations $\mathbf{X}$ which are monotone. Surprisingly, we can without loss of generality require this. Before we prove this, let us first provide an example of a valid expression in the grammar where this fails.

▶ **Example 8.** Let $\mathcal{V}$ be the PVAS of dimension 2 without any transitions. Consider the expression $(\binom{\mathcal{V}}{\epsilon,0^1} \circ \binom{\mathcal{V}}{0^1,\epsilon})^*$. The expression below the $*$ says that you start with any configuration, fix the first counter to 0 and end with any configuration. Since the PVASS $\mathcal{V}$ does not have any transitions, in order for the composition to be possible, you have to have already started with the first counter equal to 0, and also end with such a configuration.

Hence the better expression would be $(\binom{\mathcal{V}}{0^1,0^1} \circ \binom{\mathcal{V}}{0^1,0^1})^*$. This expression fulfills the property that if $\mathbf{E}'$ is a subexpression of $\mathbf{E}^*$, then $in(\mathbf{E}') \geq in(\mathbf{E})$ and $out(\mathbf{E}') \geq out(\mathbf{E})$, i.e. interior nodes have fewer fixed coordinates. This will suffice for monotonicity.

▶ **Lemma 9.** *Let $d' \in \mathbb{N}$ and $\mathbf{E}$ expression such that every subexpression $\mathbf{E}'$ fulfills $in(\mathbf{E}') \geq d'$ and $out(\mathbf{E}') \geq d'$. Then $\mathrm{Rel}(\mathbf{E})$ is monotone in the j-th last coordinate for all $j \leq d'$.*

Proof. By structural induction. In the base case, $\mathbf{Y} = \binom{\mathcal{V},p,q}{\mathbf{b}_s,\mathbf{b}_t}$ for a VASS $\mathcal{V}$. Since VAS reachability relations are monotone in every coordinate, when the last d' coordinates are neither fixed in the input nor output then $\mathbf{Y}$ is monotone in these coordinates.

$\mathbf{E} \cup \mathbf{E}'$: Relations monotone in the j-last coordinate are clearly stable under union.

$\mathbf{E} \circ \mathbf{E}'$: Let $j \leq d'$, $d_1 = in(\mathbf{E}), d_2 = out(\mathbf{E})$, $d_3 = out(\mathbf{E}')$. Since the subexpression $\mathbf{E}$ fulfills $in(\mathbf{E}) \geq d'$ and $out(\mathbf{E}) \geq d'$ by assumption, $\mathrm{Rel}(\mathbf{E})$ is by induction monotone in the j-th last coordinate. Same for $\mathrm{Rel}(\mathbf{E}')$. Let $(\mathbf{x}_1, \mathbf{x}_2) \in \mathrm{Rel}(\mathbf{E})$ and $(\mathbf{x}_2, \mathbf{x}_3) \in \mathrm{Rel}(\mathbf{E}')$. By monotonicity in the j-th last coordinate we obtain $(\mathbf{x}_1 + \mathbf{e}_{d_1+1-j}, \mathbf{x}_2 + \mathbf{e}_{d_2+1-j}) \in \mathrm{Rel}(\mathbf{E})$ and $(\mathbf{x}_2 + \mathbf{e}_{d_2+1-j}, \mathbf{x}_3 + \mathbf{e}_{d_3+1-j}) \in \mathrm{Rel}(\mathbf{E}')$. Hence $(\mathbf{x}_1 + \mathbf{e}_{d_1+1-j}, \mathbf{x}_3 + \mathbf{e}_{d_3+1-j}) \in \mathrm{Rel}(\mathbf{E} \circ \mathbf{E}')$.

$\mathbf{E}^*$: Let $j \leq d'$. By repeatedly applying the case of $\circ$, we obtain for all $n \in \mathbb{N}$ that $\mathbf{E}^n$ is monotone in the j-th last coordinate. Again by stability of such relations under union, the relation $\mathbf{E}^* = \bigcup_{n\in\mathbb{N}} \mathbf{E}^n$ is monotone in the j-th last coordinate. ◀

▶ **Corollary 10.** *For every expression $\mathbf{E}$, there is another expression $\mathbf{E}'$ with $\mathrm{Rel}(\mathbf{E}) = \mathrm{Rel}(\mathbf{E}')$, where $*$ is only applied on monotone relations.*

Proof. Let $\mathbf{E}$ be an expression. Apply first $\Leftarrow$ and then $\Rightarrow$ of Theorem 7. The constructed expression fulfills for every subexpression $\mathbf{E}^*$ and subsubexpression $\mathbf{E}'$ of $\mathbf{E}^*$ that $in(\mathbf{E}') \geq in(\mathbf{E})$ and $out(\mathbf{E}') \geq out(\mathbf{E})$. Then by Lemma 9, $\mathrm{Rel}(\mathbf{E})$ is monotone in every one of the last $in(\mathbf{E}) = out(\mathbf{E})$ coordinates, i.e. in every coordinate. Hence $\mathrm{Rel}(\mathbf{E})$ is monotone. ◀

5 A Well-Quasi-Order on Runs of Priority VAS

Starting from this section, we also use $*$ for repeated concatenation, not only transitive closure $*$ of repeated composition. To distinguish them, we write $*_{concat}$ for concatenation $*$.

A partial order $(\mathbf{X}, \leq)$ is a reflexive, transitive and antisymmetric relation $\leq \subseteq \mathbf{X} \times \mathbf{X}$. A set $\mathbf{U} \subseteq \mathbf{X}$ is upward-closed if for all $\mathbf{x} \in \mathbf{U}$ and all $\mathbf{x}' \geq \mathbf{x}$ we have $\mathbf{x}' \in \mathbf{U}$. Every subset $\mathbf{X}' \subseteq \mathbf{X}$ is contained in a unique minimal upward-closed set $\lceil \mathbf{X}' \rceil := \{\mathbf{x}' \in \mathbf{X} \mid \exists \mathbf{x} \in \mathbf{X}' \colon \mathbf{x} \leq \mathbf{x}'\}$. A basis of an upward-closed set $\mathbf{U}$ is a subset $\mathbf{F} \subseteq \mathbf{U}$ such that $\lceil \mathbf{F} \rceil = \mathbf{U}$.

A partial order is a well-quasi-order if every upward closed set $\mathbf{U} \subseteq \mathbf{X}$ has a finite basis $\mathbf{F}$. Or equivalently, for every infinite sequence $\mathbf{x}_1, \mathbf{x}_2, \cdots \subseteq \mathbf{X}$ there are indices $i < j$ with $\mathbf{x}_i \leq \mathbf{x}_j$, or equivalently there are indices $(i_m)_{m\in\mathbb{N}}$ such that $\mathbf{x}_{i_m} \leq \mathbf{x}_{i_k}$ for all $m \leq k$.

Most well-quasi-orders, in particular the ones we will need, are constructed from the following basic ordering by applying standard closure properties stated afterwards:

▶ **Example 11.** Let $\mathbf{F}$ be finite. Then the equality relation $=$ is a well-quasi-order on $\mathbf{F}$.

▶ **Lemma 12.** *Let $(\mathbf{X}_1, \leq_1), (\mathbf{X}_2, \leq_2)$ be wqo's. Then $((\mathbf{X}_1 \cup \mathbf{X}_2, \leq_1 \cup \leq_2)$ is a wqo.*

▶ **Lemma 13** (Dickson's Lemma)**.** *$(\mathbf{X}_1, \leq_1), (\mathbf{X}_2, \leq_2)$ wqo's $\Rightarrow$ $(\mathbf{X}_1 \times \mathbf{X}_2, \leq_1 \times \leq_2)$ wqo.*

▶ **Lemma 14** (Higman's Lemma)**.** *Let $(\mathbf{\Sigma}, \leq)$ be a well-quasi-order. Then $(\Sigma^{*concat}, \leq^{*concat})$ is a well-quasi-order, where $\leq^{*concat}$ is the scattered subword ordering defined via $w = (\mathbf{x}_1, \ldots, \mathbf{x}_r) \leq w' = (\mathbf{y}_1, \ldots, \mathbf{y}_s)$ $\iff$ there exists an injective order preserving function $f \colon \{1, \ldots, r\} \to \{1, \ldots, s\}$ such that $\mathbf{x}_i \leq \mathbf{y}_{f(i)}$ for all $i \in \{1, \ldots, r\}$.*

5.1 Well-Quasi-Order for VAS

In order to explain the wqo for expressions, we start by defining Jancar's wqo ordering for runs of a VAS $\mathcal{V}$. A run is no longer viewed as a sequence of configurations, but instead as element of $\Omega(\mathcal{V}) = \mathbb{N}^d \times (\mathbb{N}^d \times E)^{*_{concat}} \times \mathbb{N}^d$, where E is the set of edges of the VAS. The first part is $\mathrm{src}(\rho)$, the last part is $\mathrm{tgt}(\rho)$ and the middle parts are the steps of the run. One can extend this to states by replacing $\mathbb{N}^d$ by $Q \times \mathbb{N}^d$ everywhere and requiring states to coincide. $\Omega(\mathcal{V})$ is well-quasi-ordered by Lemma 13 and Lemma 14.

This wqo is carefully engineered to ensure that the relation $\{\mathrm{ends}(\rho') \mid \rho' \geq \rho\} =: \mathrm{ends}(\rho) + \mathbf{P}_\rho$ has good properties. $\mathbf{P}_\rho$ is called the *transformer relation* of the run. A vector $(\mathbf{v}, \mathbf{w})$ is *pumpable into* ρ if $(\mathbf{v}, \mathbf{w}) \in \mathbf{P}_\rho$. The minimal property we want $\mathbf{P}_\rho$ to fulfill is closure under addition, i.e. if a vector can be pumped once, then it can be pumped arbitrarily often. To understand why exactly the above expression ensures this, consider Figure 2.

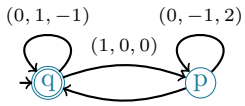

Figure 2 Typical example of a non-semilinear VAS [14]. Edges e are only labelled with their update $f(e)$, since this is a VASS, i.e. every edge fulfills $g(e) = 0$.

If we were to replace the middle part of the Jancar ordering with $(\mathbb{N}^d)^*$ instead, then the run $q(0,1,1) \to p(1,1,1)$ would be smaller than the run $q(0,1,1) \to q(0,2,0) \to p(1,2,0) \to p(1,1,2)$. Hence pumping properties would tell us that $p(1,1,n)$ should be reachable for every $n \geq 1$, which is obviously wrong. One might also consider the ordering without explicitly remembering the start and end configurations, but then some vectors with negative components might be claimed to be pumpable, since Higman might insert the smaller run in the middle. Pumping negative vectors is however trivially impossible.

Above we provided one way to define the transformer relation $\mathbf{P}_\rho$. As shown in [20, Lemma 7.5], there is an important equivalent characterization. Given a configuration $\mathbf{c}$, one defines the transformer relation $\mathbf{P}_\mathbf{c}$ for this configuration via $(\mathbf{x}, \mathbf{y}) \in \mathbf{P}_\mathbf{c} \iff \mathbf{c} + \mathbf{x} \to_\mathcal{V}^* \mathbf{c} + \mathbf{y}$. Intuitively, you utilize the existence of configuration $\mathbf{c}$ to *transform* $\mathbf{x}$ into $\mathbf{y}$. Another intuition is that $\mathbf{c}$ is a *capacity* which allows us to slightly enter the negative (up to $\mathbf{c}$). This relation is a generalization of "pumping possible via self-loop on a state". The equivalent characterization of $\mathbf{P}_\rho$ is: Write $\rho = (\mathbf{c}_0, \dots, \mathbf{c}_r)$, then $\mathbf{P}_\rho = \mathbf{P}_{\mathbf{c}_0} \circ \dots \circ \mathbf{P}_{\mathbf{c}_r}$.

Consider the example in Figure 1 in the introduction. At any configuration $\mathbf{c}_1$ in state q_1, we have $\mathbf{P}_{\mathbf{c}_1} = \{(x,y,z),(x',y,z) \mid x' \geq x\}$, i.e. one can "transform x into a larger number" and at a configuration $\mathbf{c}_2$ in state q_2, we have $\mathbf{P}_{\mathbf{c}_2} = \{(x,y,z),(x',y',z) \mid x+y = x'+y', x \geq x'\}$, i.e. one can "transform any number of x into the same number of y". This leads any run ρ through states $q_s \to q_1 \to q_2 \to q_t$ to be able to arbitrarily increase x and y, as mentioned in the introduction. Beware though that if a VASS has a complicated nested loop structure, then $\mathbf{P}_\mathbf{c}$ can be non-semilinear.

5.2 Well-Quasi-Order for Expressions

We will now define for every expression $\mathbf{E}$ a well-quasi-ordered set of runs $\Omega(\mathbf{E})$. We want the different segments of the runs to be labelled with which subexpression of $\mathbf{E}$ they belong to. Hence let Tag be a set containing unique start and end labels $\lambda_s(\mathbf{E}')$ and $\lambda_t(\mathbf{E}')$ for every node $\mathbf{E}'$ in the syntax tree of $\mathbf{E}$. The set $\Omega(\mathbf{E})$ will be modelled after the Jancar ordering, though configurations might now have different dimensions. It is important to

understand why $(\mathbb{N}^d \times E)^{*concat}$ has to be used for the Jancar ordering to lead to nice properties. The answer: It is equivalent to using $(\mathbb{N}^d \times E \times \mathbb{N}^d)^{*concat}$: When thinking of $\to_{\mathcal{V}}^*$ as $\{\to_{e_1} \cup \cdots \cup \to_{e_m}\}^*$, this means every letter is supposed to be a run of the expression $\mathbf{E}$ inside the $*$. For a VASS, this means $(\mathrm{src}, \mathrm{tgt}) \in \to_e$ tagged with the choice of e.

▶ **Definition 15.** *If $\mathbf{Y} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ is a VAS section represented by VAS $\mathcal{V}$, $\mathbf{b}_s, \mathbf{b}_t$, let π_{in}, π_{out} be the projections projecting away fixed coordinates of in- and output. Let $\Omega_{\mathbf{b}_s,\mathbf{b}_t}$ be the set of runs $\rho \in \Omega(\mathcal{V})$, whose source and target have the correct values on fixed coordinates. We define $\Omega(\mathbf{Y}) = \{(\pi_{in}(\mathrm{src}(\rho)), \lambda_s(\mathbf{Y})w\lambda_t(\mathbf{Y}), \pi_{out}(\mathrm{tgt}(\rho))) \mid \rho = (\mathrm{src}(\rho), w, \mathrm{tgt}(\rho)) \in \Omega_{\mathbf{b}_s,\mathbf{b}_t}(\mathcal{V})\}$. I.e. we consider runs of $\mathcal{V}$ with source and target adhering to the fixed coordinates, add markers in the word w, and instead of storing the full source and target, we only store the non-fixed coordinates. For $\rho \in \Omega(\mathbf{Y})$, we refer to the projected configurations as $\mathrm{src}(\rho)$ and $\mathrm{tgt}(\rho)$.*

We define $\Omega(\mathbf{E}_1 \cup \mathbf{E}_2) = \Omega(\mathbf{E}_1) \cup \Omega(\mathbf{E}_2)$, i.e. we simply take unions of the sets of runs.

We define $\Omega(\mathbf{E}_1 \circ \mathbf{E}_2) = \{\lambda_s(\mathbf{E}_1)\rho_1\lambda_t(\mathbf{E}_1)\lambda_s(\mathbf{E}_2)\rho_2\lambda_t(\mathbf{E}_2) \mid \mathrm{tgt}(\rho_1) = \mathrm{src}(\rho_2)\} \subseteq Tag \times \Omega(\mathbf{E}_1) \times Tag^2 \times \Omega(\mathbf{E}_2) \times Tag$. I.e. we concatenate the runs if possible and use markers.

We define $\Omega(\mathbf{E}^*) = \{\lambda_s(\mathbf{E})\rho_1\lambda_t(\mathbf{E}) \dots \lambda_s(\mathbf{E})\rho_n\lambda_t(\mathbf{E}) \mid n \in \mathbb{N}, \rho_1, \dots, \rho_n \in \Omega(\mathbf{E}), \mathrm{tgt}(\rho_i) = \mathrm{src}(\rho_{i+1})\} \subseteq \mathbb{N}^{in(\mathbf{E}^*)} \times (\Omega(\mathbf{E}) \cup Tag)^{*concat} \times \mathbb{N}^{out(\mathbf{E}^*)}$. I.e. we consider all concatenations of any length $n \in \mathbb{N}$ and add tags splitting the different parts ρ_i.

▶ **Definition 16.** *We define a wqo $\leq_{\Omega(\mathbf{E})}$ on $\Omega(\mathbf{E})$ recursively. For VAS sections $\mathbf{Y}$ we use the Jancar ordering, observing that fixed coordinates coincide for every run, and can hence be ignored. For the recursive definition we use Lemmas 12, 13 and 14.*

Whenever we concatenate runs, we do not write the tags, because they can be inferred. Their existence is however important, as we can see for example for $\mathbf{E}_1 \circ \mathbf{E}_2$: We have $\rho \leq_{\Omega(\mathbf{E}_1 \circ \mathbf{E}_2)} \rho'$ if and only if $\rho = \rho_1\rho_2, \rho' = \rho_1'\rho_2'$ with $\rho_1, \rho_1' \in \Omega(\mathbf{E}_1), \rho_2, \rho_2' \in \Omega(\mathbf{E}_2)$ such that $\rho_1 \leq_{\Omega(\mathbf{E}_1)} \rho_1'$ and $\rho_2 \leq_{\Omega(\mathbf{E}_2)} \rho_2'$. This is where the tags will become important: From the tags, we can infer how ρ is supposed to be split into ρ_1 and ρ_2, and similarly for ρ'. Let us give a different example for why we need the tags for every subexpression. Imagine we consider the expression $\mathbf{Y} \cup \mathbf{Y}'$, where $\mathrm{Rel}(\mathbf{Y}) = \mathbb{N} \cdot (2, 1)$ and $\mathrm{Rel}(\mathbf{Y}') = \mathbb{N} \cdot (1, 2)$. If we wrote the empty run ρ as $(0, \epsilon, 0)$, i.e. did not label it, it would not be clear whether it can pump $\mathbb{N} \cdot (2, 1)$ or $\mathbb{N} \cdot (1, 2)$, this depends on which subexpression it belongs to.

5.3 Comparison with other Well-Quasi-Orders

In prior literature, some wqos for Priority VAS [3, 4] and even for the more general model of Grammar VAS [24] were introduced. In this subsection we compare our wqo to theirs.

In a grammar VAS paths are restricted to a given context-free grammar G, and it is known that Priority VAS correspond to the subclass of Grammar VAS, where the grammar is thin/finite index. In a thin grammar, every non-terminal has a rank (called index) which can only decrease and for every production $X \to YZ$, either $\mathrm{rank}(Y) < \mathrm{rank}(X)$ or $\mathrm{rank}(Z) < \mathrm{rank}(X)$, i.e. only one of the produced non-terminals can have the same rank.

The equivalence of PVASS with these grammars can in fact be seen via our RegEx characterization: One can implement $\mathbf{E}^*$ via $S \to XS$, where X implements $\mathbf{E}$. Similarly composition $\mathbf{E} \circ \mathbf{E}'$ can be implemented via $S \to XX'$ where X implements $\mathbf{E}$, and X' implements $\mathbf{E}'$. In [24] a wqo on runs based on Kruskal's tree ordering on syntax trees is defined. It can be shown that their ordering for the grammar obtained from a RegEx coincides with our ordering. In fact this is another motivation for the markers we use for splitting runs: Syntax trees naturally distinguish between being in the left or right branch of the RegEx. In [24] however they did not manage to show some of the pumping properties of the well-quasi-order which we require, and will be able to prove using our RegEx.

Another example are Bonnet's works [3, 4]. His well-quasi-order is based on a repeated application of Higman's Lemma, similar to our ordering. The only difference is that in [4] the finest split of any run is chosen. In our terminology, if the expression is $\mathbf{E}^*$, where $\mathbf{E}$ requires the first coordinate to be 0, then a run $\rho = \rho_1\rho_2$ is always split as $\rho_1, \rho_2 \in \Omega(\mathbf{E})$ in [4], i.e. $\rho \in \Omega(\mathbf{E}^2)$. While in our case also $\rho \in \Omega(\mathbf{E})$ is possible, this is determined by the markers. When limitting ourselves to runs with the finest split the orderings coincide.

5.4 Geometric Preliminaries

In this section we repeat some definitions from the VASS literature, pertaining to the pumping properties the relations $\mathbf{P}_\rho$ fulfill. Readers familiar with the notions can skip this section. For a visual representation of the geometric definitions see e.g. [10]. We state definitions for sets, they apply to relations $\mathbf{R} \subseteq \mathbb{Q}^{d'} \times \mathbb{Q}^{d''}$ by viewing them as set $\mathbf{R} \subseteq \mathbb{Q}^{d'+d''}$.

Cones and periodic sets. A set $\mathbf{C} \subseteq \mathbb{Q}^{\mathrm{d}}$ is a *cone* if $\mathbf{0} \in \mathbf{C}$, $\mathbf{C} + \mathbf{C} \subseteq \mathbf{C}$ and $\mathbb{Q}_{>0}\mathbf{C} \subseteq \mathbf{C}$. Given a set $\mathbf{F} \subseteq \mathbb{Q}^{\mathrm{d}}$, the cone generated by $\mathbf{F}$ is the smallest cone containing $\mathbf{F}$.

A cone $\mathbf{C}$ is *definable* if it is definable in $\mathrm{FO}(\mathbb{Q}, +, \geq)$.

A set $\mathbf{P} \subseteq \mathbb{N}^{\mathrm{d}}$ is a *periodic set* if $\mathbf{P} + \mathbf{P} \subseteq \mathbf{P}$ and $\mathbf{0} \in \mathbf{P}$. For any set $\mathbf{F} \subseteq \mathbb{N}^{\mathrm{d}}$, the periodic set $\mathbf{F}^*$ generated by $\mathbf{F}$ is the smallest periodic set containing $\mathbf{F}$. A periodic set $\mathbf{P}$ is *finitely generated* if $\mathbf{P} = \mathbf{F}^*$ for some finite set $\mathbf{F}$.

Finitely generated periodic sets provide an equivalent way to define linear sets as sets of the form $\mathbf{b} + \mathbf{P}$, where $\mathbf{b} \in \mathbb{N}^{\mathrm{d}}$ and $\mathbf{P} \subseteq \mathbb{N}^d$ is a finitely generated periodic set.

Smooth Periodic Sets. The periodic relation $\mathbf{P}_\rho$ for a run ρ of a VASS is rarely finitely generated, but it is smooth, a class introduced by Leroux in [22]. In order to define smooth, we first reintroduce the set of directions of a periodic set.

▶ **Definition 17.** *[22, 10] Let $\mathbf{P}$ be a periodic set. A vector $\mathbf{v} \in \mathbb{Q}^{\mathrm{d}}$ is a* direction *of $\mathbf{P}$ if there exists $m \in \mathbb{N}_{>0}$ and a point $\mathbf{x}$ such that $\mathbf{x} + \mathbb{N} \cdot m\mathbf{v} \subseteq \mathbf{P}$, i.e. some line in direction $\mathbf{v}$ is fully contained in $\mathbf{P}$. The set of directions of $\mathbf{P}$ is denoted* $\mathrm{dir}(\mathbf{P})$.

We can now define smooth periodic sets.

▶ **Definition 18.** *[22, 10] Let $\mathbf{P}$ be a periodic set.*

- *$\mathbf{P}$ is* asymptotically definable *if $\mathrm{dir}(\mathbf{P})$ is a definable cone.*
- *$\mathbf{P}$ is* well-directed *if every sequence $(\mathbf{p}_m)_{m\in\mathbb{N}}$ of vectors $\mathbf{p}_m \in \mathbf{P}$ has an infinite subsequence $(\mathbf{p}_{m_k})_{k\in\mathbb{N}}$ such that $\mathbf{p}_{m_j} + \mathbb{N}(\mathbf{p}_{m_k} - \mathbf{p}_{m_j}) \subseteq \mathbf{P}$ for all $k \geq j$.*
- *$\mathbf{P}$ is* smooth *if it is asymptotically definable and well-directed.*

▶ **Example 19.** Examples of smooth periodic sets are $\mathbf{P}_1 = \{(0,0)\} \cup (1,1) + \mathbb{N}^2$ and $\mathbf{P}_2 = \{(x,y) \in \mathbb{N}^2 \mid y \leq x^2\}$. We have $\mathrm{dir}(\mathbf{P}_2) \setminus \{(0,0)\} = \{(x,y) \in \mathbb{Q}_{\geq 0} \mid x > 0\}$. I.e. except pure north, every vector in $\mathbb{Q}^2_{\geq 0}$ is a direction of $\mathbf{P}_2$. On the other hand $\mathrm{dir}(\mathbf{P}_1) = \mathbb{Q}^2_{\geq 0}$.

$\mathbf{P}_2$ is a very typical example: One idea with $\mathrm{dir}(\mathbf{P})$ is to store the asymptotic steepness of the upper function, and ignore whether it is exponential or quadratic if it is superlinear.

▶ **Example 20.** Examples of non-smooth sets are $\mathbf{P}'_1 = \{(x,y) \mid x \geq \sqrt{2}y\}$ and $\mathbf{P}'_2 = (\{(0,1)\} \cup \{(2^m, 1) \mid m \in \mathbb{N}\})^* = \{(x,n) \in \mathbb{N}^2 \mid x \text{ has at most } n \text{ bits set to 1 in binary.}\}$. $\mathbf{P}'_1$ is not asymptotically definable, because defining $\mathrm{dir}(\mathbf{P}'_1)$ requires irrationals, while $\mathbf{P}'_2$ is not well-directed (see observation 2 below).

We make a few observations:

1. The set $\mathrm{dir}(\mathbf{P})$ is a cone. It is by definition closed under non-negative scalar multiplication (due to the m in the definition). Furthermore, if two lines in different directions $\mathbf{v}$ and $\mathbf{v}'$ are contained in $\mathbf{P}$, then by periodicity $\mathbf{P}$ also contains a $\mathbf{v}, \mathbf{v}'$ plane, and so $\mathbf{P}$ contains a line in every direction between $\mathbf{v}$ and $\mathbf{v}'$. For more details see [22, Lemma V.7]. $\mathrm{dir}(\mathbf{P})$ should be viewed as a kind of "limit cone" containing $\mathbf{P}$, it is however only one possible definition for a "limit cone" of $\mathbf{P}$, other cones were considered in prior papers [20, 21].
2. The definition of well-directed is stated this way to relate to wqo's, but the most important case of definition 18 is when the $\mathbf{p}_m$ are all on the same infinite line $\mathbf{x} + \mathbf{v} \cdot \mathbb{N}$. Then the definition equivalently states that $\mathbf{v} \in \mathrm{dir}(\mathbf{P})$, i.e. some infinite line in direction $\mathbf{v}$ is contained in $\mathbf{P}$. This makes sets where points are "too scarce" non-smooth. For instance, the set $\mathbf{P}_2$ of Example 19 contains infinitely many points on a horizontal line, but no full horizontal line, which would correspond to an arithmetic progression.

Almost semilinear relations. We reintroduce almost-semilinear sets, introduced by Leroux in [20, 21, 22]. Intuitively, they generalize semilinear sets by replacing finitely generated periodic sets with smooth periodic sets.

▶ **Definition 21** ([21, 22]). *A set* $\mathbf{X}$ *is* almost linear *if* $\mathbf{X} = \mathbf{b} + \mathbf{P}$*, where* $\mathbf{b} \in \mathbb{N}^d$ *and* $\mathbf{P}$ *is a smooth periodic set, and* almost semilinear *if it is a finite union of almost linear sets.*

It was shown in [21, 22] that VAS reachability sets/relations are almost semilinear. However, it is easy to find almost semilinear sets that are not reachability sets of any VAS. One reason is that the definition of a smooth periodic set only restricts the "asymptotic behavior" of the set, which can be "simple" even if the set itself is very "complex".

▶ **Example 22.** Let $\mathbf{X} \subseteq \mathbb{N}_{>0}$ be any set, for example $\mathbf{X} := \{m \in \mathbb{N} \mid m \text{ is Gödel-number of non-halting TM}\}$. Then $\mathbf{P} := \{(0,0)\} \cup (\{1\} \times \mathbf{X}) \cup \mathbb{N}^2_{>1}$ is a smooth periodic set. Indeed, it contains a line in every direction, and is thus well-directed and asymptotically definable.

To eliminate these types of sets Leroux required that every intersection of the set with a semilinear set is still almost semilinear. For instance, the intersection of the set $\mathbf{X}$ in Example 22 and the linear set $(1,0) + (0,1) \cdot \mathbb{N}$ is not almost semilinear. This leads to the following main theorems of [22], which we want to extend to Priority VAS:

▶ **Theorem 23** ([22, Theorem IX.1]). *For every semilinear relation* $\mathbf{S}$ *and reachability relation* $\mathbf{R}$ *of a VAS,* $\mathbf{R} \cap \mathbf{S}$ *is a finite union of relations* $\mathbf{b} + \mathbf{P}$*, where* $\mathbf{P}$ *is smooth periodic and for every linear relation* $\mathbf{L} \subseteq \mathbf{b} + \mathbf{P}$ *there exists a* $\mathbf{p} \in \mathbf{P}$ *such that* $\mathbf{p} + \mathbf{L}$ *is flattable.*

Since projecting away fixed coordinates preserves almost semilinearity, namely the periodic sets are anyways 0 on fixed coordinates, this theorem also holds for VAS sections.

As mentioned in the introduction, the same paper proceeded to prove the following:

▶ **Theorem 24** ([22, Theorem XI.2]). *The reachability relation of a VAS is flattable if and only if it is semilinear.*

The hard part is of course to prove that semilinear implies flattable. Let us quickly recap how to obtain Theorem 24 from Theorem 23 as our main proof will not repeat this step, we will stop at obtaining Theorem 23 for Priority VAS.

Leroux in [22] defines a dimension $\dim(\mathbf{S}) \in \mathbb{N}$ of semilinear sets $\mathbf{S}$. The important aspect of the dimension is that for every linear set $\mathbf{L}$, we have $\dim(\mathbf{L} \setminus (\mathbf{p} + \mathbf{L})) < \dim(\mathbf{L})$. For example $\mathbb{N}^2 \setminus [(x, y) + \mathbb{N}^2]$ for any $x, y \in \mathbb{N}$ is a finite union of lines, and hence 1-dimensional. The proof then proceeds by induction on the dimension of $\mathbf{X} := \mathbf{R} \cap \mathbf{S}$.

Base $k = 0$: Since 0-dimensional implies finite, such sets are flattable.

Step $k \to k + 1$: Let $\mathbf{X} = \mathbf{R} \cap \mathbf{S}$ semilinear with $\dim(\mathbf{X}) = k + 1$. We have to show that $\mathbf{X}$ is flattable. Since flattable relations are closed under union, we can assume that $\mathbf{X}$ is not only semilinear but even linear. Using $\mathbf{X}$ as $\mathbf{L}$ in Theorem 23 (this requires combining almost linear components correctly, and hence some fiddling) there exists a vector $\mathbf{p}$ such that $\mathbf{p} + \mathbf{X}$ is flattable. Since $\dim(\mathbf{X} \setminus (\mathbf{p} + \mathbf{X})) < \dim(\mathbf{X})$, $\mathbf{X} \setminus (\mathbf{p} + \mathbf{X})$ is flattable by induction. Since flattable relations are closed under union, $\mathbf{X} = [\mathbf{X} \setminus (\mathbf{p} + \mathbf{X})] \cup [\mathbf{p} + \mathbf{X}]$ is flattable.

With a similar induction on the dimension, Leroux obtained the following:

▶ **Theorem 25** ([20, Theorem 9.2]). *Let $\mathbf{R}$ be reflexive, transitive and such that for every semilinear $\mathbf{S}$, $\mathbf{R} \cap \mathbf{S}$ is almost semilinear. Then $\mathbf{R}$ admits semilinear inductive invariants.*

As a corollary of Theorem 25 and the PVAS version of Theorem 23, namely Theorem 31 of the next section, we obtain the following.

▶ **Corollary 26.** *Let $\mathcal{V}$ be a PVASS, and $\mathbf{C}_s, \mathbf{C}_t$ two configurations such that $\mathbf{C}_s \not\to^* \mathbf{C}_t$. Then there exists a semilinear inductive invariant $\mathbf{S}$ such that $\mathbf{C}_s \in \mathbf{S}, \mathbf{C}_t \notin \mathbf{S}$.*

Proof. Let $\mathbf{R}$ be the reachability relation of $\mathcal{V}$. Clearly $\mathbf{R}$ is reflexive and transitive. By Theorem 31, every intersection $\mathbf{R} \cap \mathbf{S}$ with a semilinear $\mathbf{S}$ is a finite union of $\mathbf{b} + \mathbf{P}$, where $\mathbf{P}$ is smooth periodic, i.e. $\mathbf{R} \cap \mathbf{S}$ is almost semilinear. Hence $\mathbf{R}$ fulfills all assumptions of Theorem 25, whose conclusion is the existence of a separating inductive invariant $\mathbf{S}$ as claimed. ◀

6 Semilinear Priority VAS are Flattable

In this section we define flattability and prove that Theorem 23 holds also for PVAS. We work on expressions $\mathbf{E}$, and hence define flattability for expressions $\mathbf{E}$ by structural induction, instead of defining flattability on PVAS directly.

▶ **Definition 27.** *Base case: $\mathbf{R} \subseteq \mathrm{Rel}(\mathbf{Y})$ is flattable w.r.t. $\mathbf{Y}$ if and only if $\mathbf{R}$ is semilinear.*

For $\mathbf{E}_1 \cup \mathbf{E}_2$, a relation $\mathbf{R} \subseteq \mathrm{Rel}(\mathbf{E}_1 \cup \mathbf{E}_2)$ is flattable w.r.t. $\mathbf{E}_1 \cup \mathbf{E}_2$ if and only if there exist relations $\mathbf{R}_i \subseteq \mathrm{Rel}(\mathbf{E}_i)$ flattable w.r.t. $\mathbf{E}_i$ such that $\mathbf{R} \subseteq \mathbf{R}_1 \cup \mathbf{R}_2$.

For $\mathbf{E}_1 \circ \mathbf{E}_2$, a relation $\mathbf{R} \subseteq \mathrm{Rel}(\mathbf{E}_1 \circ \mathbf{E}_2)$ is flattable w.r.t. $\mathbf{E}_1 \circ \mathbf{E}_2$ if and only if there exist relations $\mathbf{R}_i \subseteq \mathrm{Rel}(\mathbf{E}_i)$ flattable w.r.t. $\mathbf{E}_i$ such that $\mathbf{R} \subseteq \mathbf{R}_1 \circ \mathbf{R}_2$.

For $\mathbf{E}^*$, remember that by Corollary 10 we can assume that $\mathrm{Rel}(\mathbf{E})$ is monotone. Let $in(\mathbf{E}) = d'$. We first make a preliminary definition: Given a vector $\mathbf{v} = (\mathrm{src}, \mathrm{tgt}) \in \mathrm{Rel}(\mathbf{E})$, its closure under monotonicity is $m(\mathbf{v}) = \{\mathbf{v}\} + \mathbb{N}(\mathbf{e}_1, \mathbf{e}_1) + \cdots + \mathbb{N}(\mathbf{e}_{d'}, \mathbf{e}_{d'})$, where $\mathbf{e}_i \in \mathbb{N}^{d'}$ is the i-th unit vector. We define the monotone transitive closure of $\mathbf{v}$ as $\mathrm{mtc}(\mathbf{v}) = m(\mathbf{v})^*$, i.e. it is the relation of source and target configurations, such that the target can be reached by repeatedly applying only $\mathbf{v}$, potentially at a larger configuration. A linear path scheme $\mathbf{S}$ is a relation which can be written as $\mathrm{mtc}(\mathrm{src}_1, \mathrm{tgt}_1) \circ \cdots \circ \mathrm{mtc}(\mathrm{src}_r, \mathrm{tgt}_r)$ with $(\mathrm{src}_i, \mathrm{tgt}_i) \in \mathrm{Rel}(\mathbf{E})$. This has to be defined using mtc *since for expressions we do not have a finite set E of "edges" anymore. But we want to express that the same edge sequences are taken.*

A relation $\mathbf{R} \subseteq \mathrm{Rel}(\mathbf{E}^*)$ is flattable w.r.t. $\mathbf{E}^*$ if and only if there exist finitely many relations $\mathbf{R}_1, \ldots, \mathbf{R}_k \subseteq \mathrm{Rel}(\mathbf{E})$ flattable w.r.t. $\mathbf{E}$ and linear path schemes $\mathbf{S}_0, \ldots, \mathbf{S}_k$ such that $\mathbf{R} \subseteq \mathbf{S}_0 \circ \mathbf{R}_1 \circ \mathbf{S}_1 \circ \mathbf{R}_2 \circ \cdots \circ \mathbf{R}_k \circ \mathbf{S}_k$. I.e., in terms of the ideas in the introduction, we have k loops where we are allowed to adapt the "inner" transitions, those are reflected by $\mathbf{R}_i$. In between those loops, we are allowed to use linear path schemes of the outer loop.

Let us mention some basic properties of this definition, proved in the full version [9]. In particular, we compare this definition with the transition word definition of flattable.

▶ **Definition 28.** *Let $\mathcal{V} = (Q, E)$ be a PVAS. For $w = (e_1, \dots, e_k) \in E^*$ define $\to_w := \to_{e_1} \circ \cdots \circ \to_{e_k}$. Let $\to_w^*$ denote the reflexive and transitive closure of $\to_w$.*

A relation $\mathbf{R}$ is transition word flattable w.r.t. $\mathcal{V}$ if there exist transition sequences $w_1, \dots, w_r \in E^*$ such that $\mathbf{R} \subseteq \to_{w_1}^* \circ \cdots \circ \to_{w_r}^*$.

▶ **Lemma 29.** *Let $\mathbf{E}$ be an expression.*

1. *If $\rho' \geq_{\Omega(\mathbf{E})} \rho$ are runs, then $\mathrm{dir}(\rho) + \mathbb{N}(\mathrm{dir}(\rho') - \mathrm{dir}(\rho))$ is flattable w.r.t. $\mathbf{E}$, and all the corresponding runs are $\geq_{\Omega(\mathbf{E})} \rho$.*
2. *If $\mathbf{R}, \mathbf{R}' \subseteq \mathrm{Rel}(\mathbf{E})$ are flattable w.r.t. $\mathbf{E}$, then also $\mathbf{R} \cup \mathbf{R}'$ is.*
3. *Let $\mathcal{V}$ be a PVAS such that $\mathbf{E}$ is its expression in Theorem 7. If a relation $\mathbf{R} \subseteq \mathrm{Rel}(\mathbf{E})$ is flattable in our sense, then $\mathbf{R} \subseteq \to_{\mathcal{V}}^*$ is transition word flattable.*

In our proofs we will need to distribute + over ∘.

▶ **Lemma 30.** *Let $(\mathbf{R}_i)_{i=1}^r \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d_{mid}}$ and $(\mathbf{R}'_i)_{i=1}^r \subseteq \mathbb{N}^{d_{mid}} \times \mathbb{N}^{d''}$ be relations. Then $\sum_{i=1}^r (\mathbf{R}_i \circ \mathbf{R}'_i) \subseteq (\sum_{i=1}^r \mathbf{R}_i) \circ (\sum_{i=1}^r \mathbf{R}'_i)$.*

6.1 Proof Outline for Theorem 31

In this subsection we provide a proof outline for Theorem 31. As remarked in Section 5.4, Theorem 31 suffices to obtain semilinear inductive invariants and flattability.

▶ **Theorem 31.** *For every semilinear relation $\mathbf{S}$ and reachability relation $\mathbf{R}$ of a PVAS, $\mathbf{R} \cap \mathbf{S}$ is a finite union of relations $\mathbf{b} + \mathbf{P}$, where $\mathbf{P}$ is smooth periodic and for every linear relation $\mathbf{L} \subseteq \mathbf{b} + \mathbf{P}$ there exists a $\mathbf{p} \in \mathbf{P}$ such that $\mathbf{p} + \mathbf{L}$ is flattable.*

The starting point is to extend the definition of the transformer relation to expressions. Let $\mathbf{E}$ be an expression, and $\rho \in \Omega(\mathbf{E})$ a run. Then we define the *transformer relation of ρ w.r.t. $\mathbf{E}$* via $\mathbf{P}_{\mathbf{E},\rho} := \{\mathrm{ends}(\rho') - \mathrm{ends}(\rho) \mid \rho' \geq \rho\}$, exactly as in the VAS case. The corresponding almost semilinear component is $\mathrm{Comp}(\mathbf{E}, \rho) = \mathrm{ends}(\rho) + \mathbf{P}_{\mathbf{E},\rho}$.

The outline now consists of two parts: First we reduce Theorem 31 to Theorem 32 and Lemma 33. The closure property of Lemma 33 is easy to see, we give a proof in the full version [9]. Hence afterwards the outline will focus on proving Theorem 32.

▶ **Theorem 32.** *Let $\mathbf{E}$ be an expression, $\rho \in \Omega(\mathbf{E})$. Then $\mathbf{P}_{\mathbf{E},\rho}$ is smooth, periodic and:*

1. *Let $\mathbf{R}_1, \mathbf{R}_2 \subseteq \mathrm{Comp}(\mathbf{E}, \rho)$ flattable. Then $\mathbf{R}_1 + \mathbf{R}_2 - \mathrm{ends}(\rho)$ is flattable.*
2. *Every direction of $\mathrm{Comp}(\mathbf{E}, \rho)$ is flattable, i.e. for every $(\mathbf{e}, \mathbf{f}) \in \mathrm{dir}(\mathbf{P}_{\mathbf{E},\rho})$ there exists $(\mathbf{a}, \mathbf{b}) \in \mathbf{P}_{\mathbf{E},\rho}$, $n \in \mathbb{N}$ such that $\mathrm{ends}(\rho) + (\mathbf{a}, \mathbf{b}) + \mathbb{N}n(\mathbf{e}, \mathbf{f})$ is flattable w.r.t. $\mathbf{E}$.*

Property 2. is rather self-explanatory, important is property 1. The statement of property 1. is that if two relations are flattable using the same minimal run ρ, then not just the sum is flattable, but even the sum *ignoring the base point* $\mathrm{ends}(\rho)$ is flattable.

▶ **Lemma 33.** *Let $\mathbf{S} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ be semilinear, and $\mathbf{X} \subseteq \mathbb{N}^{d'} \times \mathbb{N}^{d''}$ a PVAS section. Then $\mathbf{X} \cap \mathbf{S}$ is a PVAS section, and hence has an equivalent expression $\mathrm{Rel}(\mathbf{E})$ by Theorem 7.*

Proof of Theorem 31. Use Lemma 33 to obtain an expression $\mathbf{E}$ with $\mathrm{Rel}(\mathbf{E}) = \mathbf{R} \cap \mathbf{S}$. We write $\mathrm{Rel}(\mathbf{E}) = \bigcup_{\rho \in \Omega(\mathbf{E})_{min}} \mathrm{ends}(\rho) + \mathbf{P}_{\mathbf{E},\rho}$ as mentioned in the introduction. By Theorem 32, these periodic relations are smooth, hence only the flattability claim is left. Let $\mathbf{L} \subseteq \mathrm{ends}(\rho) + \mathbf{P}_{\mathbf{E},\rho}$ linear, i.e. $\mathbf{L} = \mathbf{b} + \mathbb{N}\mathbf{p}_1 + \cdots + \mathbb{N}\mathbf{p}_r$. By property 2. in Theorem 32, there exist

$n_i \in \mathbb{N}$ and $(\mathbf{a}_i, \mathbf{b}_i) \in \mathbf{P}_{\mathbf{E},\rho}$ such that $\mathbf{R}_i := \mathrm{ends}(\rho) + (\mathbf{a}_i, \mathbf{b}_i) + \mathbb{N} n_i \mathbf{p}_i$ is flattable for every i. We define the finite set $\mathbf{F} := \mathbf{b} + \{0, \dots, n_1\} \cdot \mathbf{p}_1 + \dots + \{0, \dots, n_r\} \cdot \mathbf{p}_r \subseteq \mathbf{L} \subseteq \mathrm{Comp}(\mathbf{E}, \rho)$. Since this set is finite, it is flattable. By property 1. in Theorem 32, the relation

$\sum_{i=1}^{r} \mathbf{R}_i + \mathbf{F} - r \cdot \mathrm{ends}(\rho) = \mathrm{ends}(\rho) + \sum_{i=1}^{r} [(\mathbf{a}_i, \mathbf{b}_i) + \mathbb{N} n_i \mathbf{p}_i] + (\mathbf{F} - \mathrm{ends}(\rho))$ is flattable. Defining $\mathbf{p} := \sum_{i=1}^{r} (\mathbf{a}_i, \mathbf{b}_i) + (\mathbf{b} - \mathrm{ends}(\rho)) \in \mathbf{P}_{\mathbf{E},\rho}$ by periodicity, the theorem is proven. ◀

Next we outline how to prove Theorem 32. The first step is an equivalent characterization of the transformer relation via "self-loop on $\mathbf{c}$" relations similar to $\mathcal{V}$. Let us start by defining these relations, which is similar to VAS.

Consider an expression $\mathbf{E}^*$ and a configuration $\mathbf{c} \in \mathbb{N}^{d'}$. We define the relation $\mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$ via $(\mathbf{x}, \mathbf{y}) \in \mathbf{P}_{\mathbf{E}^*,\mathbf{c}} \iff \exists \rho \in \Omega(\mathbf{E}^*) : \mathrm{ends}(\rho) = (\mathbf{x} + \mathbf{c}, \mathbf{y} + \mathbf{c})$.

The equivalent characterization of $\mathbf{P}_{\mathbf{E},\rho}$ via relations $\mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$ is as follows:

▶ **Lemma 34.** *Let $\mathbf{E}$ be an expression, and $\rho \in \Omega(\mathbf{E})$. Then there exist subexpressions $\mathbf{E}_i^*$ of $\mathbf{E}$ and configurations $\mathbf{c}_i$ occurring along ρ such that $\mathbf{P}_{\mathbf{E},\rho} = \mathbf{P}_{\mathbf{E}_1^*,\mathbf{c}_1} \circ \dots \circ \mathbf{P}_{\mathbf{E}_r^*,\mathbf{c}_r}$.*

This leaves us with three things to prove: Firstly, Lemma 34 itself. Secondly, that $\mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$ is smooth and properties 1. and 2. of Theorem 32 hold for $\mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$ (actually a slightly stronger version 2.' of property 2.). Thirdly, that composition preserves the properties of Theorem 32.

We dedicate one subsection to every step, with the second coming last. This is because steps 1 and 3 are new, while step 2 is based on [22]. Also, in order to understand why PVAS are flattable, Lemma 34 and step 3 contain the essence: Similar to VAS, pumping is a *sequence* of special self-loops, a very linear object. The fact that the different parts now use different expressions $\mathbf{E}_i^*$ is irrelevant for our composition proof.

6.2 Proving Lemma 34, Equivalent Definition of Transformer Relation

Proof by structural induction. For simplicity, we call a relation $\mathbf{P}_{\mathbf{E},\rho}$ decomposable if it has an equivalent description as in the lemma. The base case of VAS sections is clear.

$\mathbf{E}_1 \cup \mathbf{E}_2$: Let $\rho \in \Omega(\mathbf{E}_1 \cup \mathbf{E}_2)$. W.l.o.g. $\rho \in \Omega(\mathbf{E}_1)$. By definition of the wqo on runs in this case, we have $\mathbf{P}_{\mathbf{E}_1 \cup \mathbf{E}_2,\rho} = \mathbf{P}_{\mathbf{E}_1,\rho}$, which is decomposable by induction.

$\mathbf{E}_1 \circ \mathbf{E}_2$: Let $\rho \in \Omega(\mathbf{E}_1 \circ \mathbf{E}_2)$. Write $\rho = \rho_1 \rho_2$ with $\rho_1 \in \Omega(\mathbf{E}_1)$, $\rho_2 \in \Omega(\mathbf{E}_2)$, which is a unique split because of the tags on steps of the run. We claim that $\mathbf{P}_{\mathbf{E}_1 \circ \mathbf{E}_2,\rho} = \mathbf{P}_{\mathbf{E}_1,\rho_1} \circ \mathbf{P}_{\mathbf{E}_2,\rho_2}$.

Proof of claim: "$\subseteq$": Let $\rho' \geq \rho$. Then $\rho' = \rho_1' \rho_2'$ such that $\rho_1' \in \Omega(\mathbf{E}_1), \rho_2' \in \Omega(\mathbf{E}_2), \rho_1' \geq_{\mathbf{E}_1} \rho_1, \rho_2' \geq_{\mathbf{E}_2} \rho_2$. Then $\mathrm{ends}(\rho') - \mathrm{ends}(\rho) = (\mathrm{ends}(\rho_1') - \mathrm{ends}(\rho_1)) \circ (\mathrm{ends}(\rho_2') - \mathrm{ends}(\rho_2)) \in \mathbf{P}_{\mathbf{E}_1,\rho_1} \circ \mathbf{P}_{\mathbf{E}_2,\rho_2}$, where composition is possible since $\mathrm{tgt}(\rho_1') = \mathrm{src}(\rho_2'), \mathrm{tgt}(\rho_1) = \mathrm{src}(\rho_2)$.

The other direction "$\supseteq$" is clear, namely concatenate ρ_1' and ρ_2'.

Now simply use that both $\mathbf{P}_{\mathbf{E}_1,\rho_1}$ and $\mathbf{P}_{\mathbf{E}_2,\rho_2}$ are decomposable by induction.

This leaves the hardest case $\mathbf{E}^*$: For configurations $\mathbf{c}, \mathbf{c}' \in \mathbb{N}^{d'}$, we write $\mathbf{c} \to_{\mathbf{E}} \mathbf{c}'$ if there exists a run $\eta \in \Omega(\mathbf{E})$ such that $\mathrm{ends}(\eta) = (\mathbf{c}, \mathbf{c}')$, and call η a *generalized transition*. We want to emphasize the important fact that generalized transitions contain path information in $\Omega(\mathbf{E})$, and are not only an element of $\mathrm{Rel}(\mathbf{E})$. We let $\to_{\mathbf{E}}^*$ denote its reflexive and transitive closure. A first decomposition in this case contains relations $\mathbf{P}_{\mathbf{E},\eta_i}$, which correspond to "increasing existing transitions" as mentioned in the introduction. This leads to writing $\mathbf{P}_{\mathbf{E}^*,\rho}$ as a composition of alternating $\mathbf{P}_{\mathbf{E}^*,\mathbf{c}_i}$ and $\mathbf{P}_{\mathbf{E},\eta_i}$.

▶ **Lemma 35.** *Let $\rho = (\mathrm{src}(\rho), \eta_1 \dots \eta_r, \mathrm{tgt}(\rho)) \in \Omega(\mathbf{E}^*)$. The following equality holds: $\mathbf{P}_{\mathbf{E}^*,\rho} = \mathbf{P}_{\mathbf{E}^*,\mathrm{src}(\eta_1)} \circ \mathbf{P}_{\mathbf{E},\eta_1} \circ \mathbf{P}_{\mathbf{E}^*,\mathrm{src}(\eta_2)} \circ \dots \circ \mathbf{P}_{\mathbf{E},\eta_r} \circ \mathbf{P}_{\mathbf{E}^*,\mathrm{tgt}(\rho)}$.*

Proof. "$\Rightarrow$": Let $\rho' \geq_{\Omega(\mathbf{E}^*)} \rho$. We have to prove $\mathrm{ends}(\rho') - \mathrm{ends}(\rho) \in$ the claimed composition. Write $\rho' = \eta_1' \dots \eta_s'$ according to the tags. By definition of the wqo, there exists an order-preserving injective function $f\colon \{1, \dots, r\} \to \{1, \dots, s\}$ such that $\eta_i \leq_{\Omega(\mathbf{E})} \eta_{f(i)}'$. In particular,

$\text{ends}(\eta'_{f(i)}) \geq \text{ends}(\eta_i)$. We define the sequence of vectors $\mathbf{v}_i := \text{src}(\eta'_{f(i)}) - \text{src}(\eta_i)$ for $i \in \{1, \dots, r\}$, and $\mathbf{w}_i := \text{tgt}(\eta'_{f(i)}) - \text{tgt}(\eta_i)$ for $i \in \{1, \dots, r\}$. We also define $\mathbf{w}_0 := \text{src}(\rho') - \text{src}(\rho)$ and $\mathbf{v}_{r+1} := \text{tgt}(\rho') - \text{tgt}(\rho)$. For every $i \in \{1, \dots, r\}$, the run $\eta'_{f(i)}$ shows that $(\mathbf{v}_i, \mathbf{w}_i) \in \mathbf{P}_{\mathbf{E},\eta_i}$. The runs $\rho_i := \eta_{f(i)+1} \dots \eta_{f(i+1)-1}$ for $i \in \{1, \dots, r-1\}$ (these are possibly empty runs) prove that $\text{tgt}(\eta_i) + \mathbf{w}_i \to^*_{\mathbf{E}} \text{src}(\eta_{i+1}) + \mathbf{v}_{i+1}$. Since $\text{tgt}(\eta_i) = \text{src}(\eta_{i+1})$, we obtain $(\mathbf{w}_i, \mathbf{v}_{i+1}) \in \mathbf{P}_{\mathbf{E}^*,\text{tgt}(\eta_i)}$. A similar argument proves $(\mathbf{w}_0, \mathbf{v}_1) \in \mathbf{P}_{\mathbf{E}^*,\text{src}(\rho)}$ and $(\mathbf{w}_r, \mathbf{v}_{r+1}) \in \mathbf{P}_{\mathbf{E}^*,\text{tgt}(\rho)}$. Hence $\text{ends}(\rho') - \text{ends}(\rho) = (\mathbf{w}_0, \mathbf{v}_{r+1})$ is in the claimed composition.

"$\Leftarrow$": Let $(\mathbf{w}_i)_{i=0}^{r}$ and $(\mathbf{v}_i)_{i=1}^{r+1}$ such that $(\mathbf{w}_i, \mathbf{v}_{i+1}) \in \mathbf{P}_{\mathbf{E},\eta_i}$ for $i \in \{1, \dots, r\}$, $(\mathbf{v}_i, \mathbf{w}_i) \in \mathbf{P}_{\mathbf{E}^*,\text{tgt}(\eta_i)}$ for $i \in \{1, \dots, r-1\}$, $(\mathbf{w}_0, \mathbf{v}_1) \in \mathbf{P}_{\mathbf{E}^*,\text{src}(\rho)}$ and $(\mathbf{w}_r, \mathbf{v}_{r+1}) \in \mathbf{P}_{\mathbf{E}^*,\text{tgt}(\rho)}$. Let η'_i be generalized transitions witnessing $(\mathbf{w}_i, \mathbf{v}_{i+1}) \in \mathbf{P}_{\mathbf{E},\eta_i}$, let ρ_i for $i \in \{1, \dots, r-1\}$ be runs witnessing $(\mathbf{v}_i, \mathbf{w}_i) \in \mathbf{P}_{\mathbf{E}^*,\text{tgt}(\eta_i)}$, let ρ_0 witness $(\mathbf{w}_0, \mathbf{v}_1) \in \mathbf{P}_{\mathbf{E}^*,\text{src}(\rho)}$ and ρ_{r+1} witness $(\mathbf{w}_r, \mathbf{v}_{r+1}) \in \mathbf{P}_{\mathbf{E}^*,\text{tgt}(\rho)}$. Then $\rho' := \rho_0\eta'_1\rho_1 \dots \rho_{r-1}\eta'_r\rho_r$ fulfills $\rho' \in \Omega(\mathbf{E}^*)$ because sources and targets of the different parts coincide. In fact $\rho' \geq_{\Omega(\mathbf{E}^*)} \rho$, by choosing $f(i)$ to point at the index at which η'_i occurs in ρ'. ◀

This finishes proving Lemma 34 by observing that $\mathbf{P}_{\mathbf{E},\eta_i}$ are decomposable by induction.

We remark that the proof does obtain an explicit description of which $\mathbf{P}_{\mathbf{E}_i^*,\mathbf{c}_i}$ to use, but we stated Lemma 34 this way to stress that different $\mathbf{E}_i^*$ intertwine in the composition.

6.3 Preserving Smoothness and Flattability Under Composition

In this subsection we prove that if $\mathbf{P}_{\mathbf{E},\mathbf{c}}$ are smooth periodic relations fulfilling properties 1. and 2. of Theorem 32, then also their composition fulfills these conditions. While periodic relations are closed under composition (use e.g. Lemma 30), smooth periodic relations are not. We already slightly changed the definition of well-directed to accomplish this goal (compare with [22, 10]), but we still need to carefully choose the inductive statement. We choose to replace condition 2. by 2.' formulated as follows, which is similar to [22]:

2.': For every well-directed periodic $P \subseteq \mathbf{P}$ there exists a definable cone R such that $\text{dir}(P) \subseteq R$ and for every $(\mathbf{e}, \mathbf{f}) \in R$ there exist $(\mathbf{a}, \mathbf{b}) \in P, n \in \mathbb{N}$ such that $(\mathbf{a}, \mathbf{b}) + \mathbb{N}n(\mathbf{e}, \mathbf{f}) \subseteq \mathbf{P}$. In case of $\mathbf{P}_{\mathbf{E},\rho}$ we require $\text{ends}(\rho) + (\mathbf{a}, \mathbf{b}) + \mathbb{N}n(\mathbf{e}, \mathbf{f}) \subseteq \text{Comp}(\mathbf{E}, \rho)$ to be flattable.

The idea of property 2.' is to remove one basic difficulty of composition: Suddenly not all runs of $\mathbf{P}_1$ are useful anymore, only those which can be continued into $\mathbf{P}_2$. We will see in the proof how 2' takes care of this problem. Formally, property 2' says that even if $P \subseteq \mathbf{P}$ is non-smooth, we can find a definable R with $\text{dir}(P) \subseteq R \subseteq \text{dir}(\mathbf{P})$, and it only contains flattable directions. With the choice $P = \mathbf{P}$ this implies property 2. Important to notice is that the choice $R = \text{dir}(\mathbf{P})$ would always be best if not for the very crucial $\in P$ part, which we will use in the proof. Again, $\in P$ is easy to motivate. Imagine one is interested in the reachability set from a fixed point, i.e. in only pumping the target. Then choose $P := \{\mathbf{0}\} \times \mathbb{N}^d$. Property 2 would state existence of a line $(\mathbf{a}, \mathbf{b}) + \mathbb{N}(0, \mathbf{w}) \subseteq \mathbf{P}_{\mathbf{E},\rho}$. We actually want a line $(\mathbf{0}, \mathbf{b}) + \mathbb{N}(\mathbf{0}, \mathbf{w})$, i.e. with $(\mathbf{a}, \mathbf{b}) \in P$ as in property 2'.

▶ **Lemma 36.** *Let $\mathbf{P}_1, \mathbf{P}_2$ be smooth periodic relations fulfilling property 2.'. Then $\mathbf{P}_1 \circ \mathbf{P}_2$ is smooth periodic fulfilling property 2'. If $\mathbf{P}_1 = \mathbf{P}_{\mathbf{E}_1,\rho_1}$ and $\mathbf{P}_2 = \mathbf{P}_{\mathbf{E}_2,\rho_2}$ for $\rho = \rho_1\rho_2$, then in addition the flattability claims of property 1. and 2.' hold for $\mathbf{P}_{\mathbf{E}_1 \circ \mathbf{E}_2,\rho} = \mathbf{P}_{\mathbf{E}_1,\rho_1} \circ \mathbf{P}_{\mathbf{E}_2,\rho_2}$.*

Proof. Periodic: A composition of periodic relations is again periodic by Lemma 30.

Well-directed: Let $(\mathbf{v}_n, \mathbf{w}_n)_n \subseteq \mathbf{P}_1 \circ \mathbf{P}_2$ be a sequence. Then there exist intermediate values $\mathbf{x}_n$ such that $(\mathbf{v}_n, \mathbf{x}_n) \in \mathbf{P}_1, (\mathbf{x}_n, \mathbf{w}_n) \in \mathbf{P}_2$ for all n. Since $\mathbf{P}_1$ is well-directed, there exists a subsequence such that $(\mathbf{v}_{n_j}, \mathbf{x}_{n_j}) + \mathbb{N}(\mathbf{v}_{n_k} - \mathbf{v}_{n_j}, \mathbf{x}_{n_k} - \mathbf{x}_{n_j}) \subseteq \mathbf{P}_1$. Since $\mathbf{P}_2$ is well-directed we obtain additionally $(\mathbf{x}_{n_j}, \mathbf{w}_{n_j}) + \mathbb{N}(\mathbf{x}_{n_k} - \mathbf{x}_{n_j}, \mathbf{w}_{n_k} - \mathbf{w}_{n_j}) \subseteq \mathbf{P}_2$ for some subsubsequence. Together we have $(\mathbf{v}_{n_j}, \mathbf{w}_{n_j}) + \mathbb{N}(\mathbf{v}_{n_k} - \mathbf{v}_{n_j}, \mathbf{w}_{n_k} - \mathbf{w}_{n_j}) \subseteq \mathbf{P}_1 \circ \mathbf{P}_2$.

Property 2.': Let $P \subseteq \mathbf{P}_1 \circ \mathbf{P}_2$ be well-directed periodic. Define $P' := \{(\mathbf{v}, \mathbf{x}, \mathbf{w}) \mid (\mathbf{v}, \mathbf{w}) \in P, (\mathbf{v}, \mathbf{x}) \in \mathbf{P}_1, (\mathbf{x}, \mathbf{w}) \in \mathbf{P}_2\}$. P' is well-directed by an argument as above, but this time we even have to choose a subsubsubsequence. Consider the projections π_{12} and π_{23} to $(\mathbf{v}, \mathbf{x})$ and $(\mathbf{x}, \mathbf{w})$ respectively. $P_1 := \pi_{12}(P') \subseteq \mathbf{P}_1$ and $P_2 := \pi_{23}(P') \subseteq \mathbf{P}_2$ are projections of a well-directed periodic relation and therefore themselves well-directed periodic. Hence we can apply property 2.' for them to obtain definable cones R_1 and R_2 with $\mathrm{dir}(P_i) \subseteq R_i \subseteq \mathrm{dir}(\mathbf{P}_i)$. We claim property 2' holds with $R = R_1 \circ R_2$.

First we have to show that $\mathrm{dir}(P) \subseteq R_1 \circ R_2$. Let $(\mathbf{v}, \mathbf{w}) \in \mathrm{dir}(P)$. By definition of the set of directions, by potentially scaling with a positive integer, there exists $(\mathbf{v}_0, \mathbf{w}_0)$ such that $(\mathbf{v}_n, \mathbf{w}_n) := (\mathbf{v}_0, \mathbf{w}_0) + n(\mathbf{v}, \mathbf{w}) \in \mathbf{P}_1 \circ \mathbf{P}_2$ for every n. Therefore there exist intermediate values $\mathbf{x}_n$ such that $(\mathbf{v}_n, \mathbf{x}_n, \mathbf{w}_n) \in P'$ for all n. Since P' is well-directed, there exists a subsequence such that $(\mathbf{v}_{n_j}, \mathbf{x}_{n_j}, \mathbf{w}_{n_j}) + \mathbb{N}(\mathbf{v}_{n_k} - \mathbf{v}_{n_j}, \mathbf{x}_{n_k} - \mathbf{x}_{n_j}, \mathbf{w}_{n_k} - \mathbf{w}_{n_j}) \subseteq P'$. Hence $(\mathbf{v}_{n_k} - \mathbf{v}_{n_j}, \mathbf{x}_{n_k} - \mathbf{x}_{n_j}) \in \mathrm{dir}(P_1) \subseteq R_1$ and $(\mathbf{x}_{n_k} - \mathbf{x}_{n_j}, \mathbf{w}_{n_k} - \mathbf{w}_{n_j}) \in \mathrm{dir}(P_2) \subseteq R_2$. Therefore $(\mathbf{v}_{n_k} - \mathbf{v}_{n_j}, \mathbf{w}_{n_k} - \mathbf{w}_{n_j}) = (n_k - n_j)(\mathbf{v}, \mathbf{w}) \in R_1 \circ R_2$. This implies $(\mathbf{v}, \mathbf{w}) \in R_1 \circ R_2$.

Now let $(\mathbf{e}, \mathbf{g}) \in R$. Then there exists $\mathbf{f}$ such that $(\mathbf{e}, \mathbf{f}) \in R_1$ and $(\mathbf{f}, \mathbf{g}) \in R_2$. By definition of R_i, by potentially scaling, there exist $(\mathbf{a}_1, \mathbf{b}_1) \in P_1$ and $(\mathbf{b}_2, \mathbf{c}_2) \in P_2$ such that $(\mathbf{a}_1, \mathbf{b}_1) + \mathbb{N}(\mathbf{e}, \mathbf{f}) \subseteq \mathbf{P}_1$, and $(\mathbf{b}_2, \mathbf{c}_2) + \mathbb{N}(\mathbf{f}, \mathbf{g}) \subseteq \mathbf{P}_2$. Since P_1 and P_2 are projections of P', there exist $\mathbf{c}_1$ and $\mathbf{a}_2$ such that $(\mathbf{a}_i, \mathbf{b}_i, \mathbf{c}_i) \in P'$ for $i \in \{1, 2\}$. Hence $(\mathbf{a}_2, \mathbf{b}_2) \in P_1$ and $(\mathbf{b}_1, \mathbf{c}_1) \in P_2$. By periodicity of $\mathbf{P}_1$, we have $(\mathbf{a}_1 + \mathbf{a}_2, \mathbf{b}_1 + \mathbf{b}_2) + \mathbb{N}(\mathbf{e}, \mathbf{f}) \subseteq \mathbf{P}_1$ and similarly by periodicity of $\mathbf{P}_2$ we have $(\mathbf{b}_1 + \mathbf{b}_2, \mathbf{c}_1 + \mathbf{c}_2) + \mathbb{N}(\mathbf{f}, \mathbf{g}) \subseteq \mathbf{P}_2$. Altogether we have $(\mathbf{a}_1 + \mathbf{a}_2, \mathbf{c}_1 + \mathbf{c}_2) \in P$ and $(\mathbf{a}_1 + \mathbf{a}_2, \mathbf{c}_1 + \mathbf{c}_2) + \mathbb{N}(\mathbf{e}, \mathbf{g}) \subseteq \mathbf{P}_1 \circ \mathbf{P}_2$ as required. $(\mathbf{a}_1, \mathbf{b}_1) \in P_1$ was crucial here such that we could obtain a fitting $\mathbf{c}_1$, and accordingly for $(\mathbf{b}_2, \mathbf{c}_2) \in P_2$.

Asymptotically definable: Define $P := \mathbf{P}_1 \circ \mathbf{P}_2$. By property 2', we have $\mathrm{dir}(\mathbf{P}_1 \circ \mathbf{P}_2) = R_1 \circ R_2$, which as composition of definable cones is itself a definable cone.

Flattability claim in 2': We proved 2' and constructed the direction using well-directedness. By Lemma 29(1.), relations obtained this way from the wqo. on runs are flattable.

Property 1.: Let $\mathbf{R}, \mathbf{R}' \subseteq \mathrm{ends}(\rho) + \mathbf{P}_{\mathbf{E}_1 \circ \mathbf{E}_2, \rho}$ be flattable w.r.t. $\mathbf{E}_1 \circ \mathbf{E}_2$. We have to prove that $\mathbf{R} + \mathbf{R}' - \mathrm{ends}(\rho)$ is flattable w.r.t. $\mathbf{E}_1 \circ \mathbf{E}_2$. By definition of flattable, there exist relations $\mathbf{R}_1, \mathbf{R}_1'$ flattable w.r.t. $\mathbf{E}_1$ and $\mathbf{R}_2, \mathbf{R}_2'$ flattable w.r.t. $\mathbf{E}_2$ such that $\mathbf{R} \subseteq \mathbf{R}_1 \circ \mathbf{R}_2$ and $\mathbf{R}' \subseteq \mathbf{R}_1' \circ \mathbf{R}_2'$. Hence $\mathbf{R} + \mathbf{R}' - \mathrm{ends}(\rho) \subseteq (\mathbf{R}_1 \circ \mathbf{R}_2) + (\mathbf{R}_1' \circ \mathbf{R}_2') - (\mathrm{ends}(\rho_1) \circ \mathrm{ends}(\rho_2))$. By Lemma 30 we obtain $\mathbf{R} + \mathbf{R}' - \mathrm{ends}(\rho) \subseteq (\mathbf{R}_1 + \mathbf{R}_1' - \mathrm{ends}(\rho_1)) \circ (\mathbf{R}_2 + \mathbf{R}_2' - \mathrm{ends}(\rho_2))$. Applying property 1. for the subexpressions $\mathbf{E}_1$ and $\mathbf{E}_2$, we obtain the claim. ◀

6.4 Transformer Relations are Smooth with Flattable Directions

In this subsection we prove that the transformer relation $\mathbf{P}_{\mathbf{E}^*, \mathbf{c}}$ is a smooth periodic relation fulfilling properties 1 and 2' (see Section 6.3). We start with a reminder of the notation.

We write $\mathbf{x} \to_{\mathbf{E}} \mathbf{y}$ for $(\mathbf{x}, \mathbf{y}) \in \mathrm{Rel}(\mathbf{E})$ and denote its reflexive transitive closure as $\to_{\mathbf{E}}^*$. Remember that $(\mathbf{x}, \mathbf{y}) \in \mathbf{P}_{\mathbf{E}^*, \mathbf{c}} \iff \mathbf{c} + \mathbf{x} \to_{\mathbf{E}}^* \mathbf{c} + \mathbf{y}$. We first prove that $\mathbf{P}_{\mathbf{E}^*, \mathbf{c}}$ is periodic.

▶ **Lemma 37.** *Let* $\mathbf{c} + \mathbf{x}_1 \to_{\mathbf{E}}^* \mathbf{c} + \mathbf{y}_1$ *and* $\mathbf{c} + \mathbf{x}_2 \to_{\mathbf{E}}^* \mathbf{c} + \mathbf{y}_2$. *Then* $\mathbf{c} + \mathbf{x}_1 + \mathbf{x}_2 \to_{\mathbf{E}}^* \mathbf{c} + \mathbf{y}_1 + \mathbf{y}_2$.

Proof. Since $*$ in expressions is only used on monotone relations $\mathrm{Rel}(\mathbf{E})$, $\to_{\mathbf{E}}$ is monotone. Hence also $\to_{\mathbf{E}}^*$ is monotone. By monotonicity, $\mathbf{c} + \mathbf{x}_1 + \mathbf{x}_2 \to_{\mathbf{E}}^* \mathbf{c} + \mathbf{y}_1 + \mathbf{x}_2 \to_{\mathbf{E}}^* \mathbf{c} + \mathbf{y}_1 + \mathbf{y}_2$. ◀

That $\mathbf{P}_{\mathbf{E}^*, \mathbf{c}}$ is well-directed follows from Lemma 29 (1.).

The proof of Property 1. is similar to the above proof of Lemma 37. Indeed, the lemma did not duplicate $\mathbf{c}$, so in different notation $\mathbf{r}_1 \to_{\mathbf{E}}^* \mathbf{s}_1$ and $\mathbf{r}_2 \to_{\mathbf{E}}^* \mathbf{s}_2$ imply $\mathbf{r}_1 + \mathbf{r}_2 - \mathbf{c} \to_{\mathbf{E}}^* \mathbf{s}_1 + \mathbf{s}_2 - \mathbf{c}$. This leaves proving that $\mathbf{P}_{\mathbf{E}^*, \mathbf{c}}$ fulfills property 2.' and hence is asymptotically definable.

Since $(\mathbf{0},\mathbf{0}) \in \mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$, monotonicity implies that $\mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$ is reflexive. In [22, Section VIII] many lemmas were proven for reflexive periodic relations, we reuse many of them. This leads to a long sequence of restating lemmas, we prefer to end this part of the main text by sketching the idea, for the formal proof see the full version [9].

Let $P \subseteq \mathbf{P}_{\mathbf{E}^*,\mathbf{c}}$ periodic. In order to not confuse $\Omega(\mathbf{E})$ and $\Omega(\mathbf{E}^*)$, we write $\eta \in \Omega(\mathbf{E})$ and $\rho \in \Omega(\mathbf{E}^*)$. We call η a *generalized transition*. Write $\gamma = (\mathbf{E}^*, \mathbf{c}, P)$ and denote by Ω_γ the set of runs $\rho \in \Omega(\mathbf{E}^*)$ such that $\mathrm{ends}(\rho) \in (\mathbf{c},\mathbf{c}) + P$. The idea is to split counters into bounded and unbounded counters for Ω_γ. The bounded counters will all be stored in the states of a graph, and this leads to pumping corresponding to cycles in the graph. Namely any transition sequence will correspond to a path in the graph, and since bounded counters cannot be pumped, any pumping sequence has to restore all the bounded counters, i.e. be a cycle in the graph. The unbounded counters on the other hand will all be unbounded *simultaneously*, at which point the condition that counters have to stay non-negative will intuitively not influence possible behaviours anymore.

We hence define the graph of bounded counters. Let $Q_\gamma \subseteq \mathbb{N}^{d'}$ be the set of configurations occurring on some run $\rho \in \Omega_\gamma$. We denote by I_γ the set of indices such that $\{q(i) \mid q \in Q_\gamma\}$ is finite, i.e. the set of bounded counters. We consider the projection $\pi_\gamma \colon \mathbb{N}^{d'} \to \mathbb{N}^{I_\gamma}$ to the bounded counters. We now define a finite directed multigraph G_γ with vertices $S_\gamma := \pi_\gamma(Q_\gamma)$. For edges (s,t), first consider the set $\Omega_{s,t}$ of generalized transitions η with $\pi_\gamma(\mathrm{src}(\eta)) = s$ and $\pi_\gamma(\mathrm{tgt}(\eta)) = t$, which occur in some run $\rho \in \Omega_\gamma$. We add an edge (s,t) for every minimal (w.r.t. $\leq_{\Omega(\mathbf{E})}$) element of $\Omega_{s,t}$. We let $s_\gamma = \pi_\gamma(\mathbf{c})$ denote the "initial state" for this graph.

Clearly runs correspond to paths in G_γ, since the graph has projections of configurations as states, and generalized transitions as edges. Regarding unbounded counters, the proof that all of them are unbounded *simultaneously* is in the full version [9]. Finally, we then obtain a formula for a definable cone R overapproximating $\mathrm{dir}(P)$ by first considering the finitely many minimal cycles in G_γ. Every cycle $\eta_1 \dots \eta_m$ provides us with a smooth periodic relation $\mathbf{P}_{\mathbf{E},\eta_1} \circ \dots \circ \mathbf{P}_{\mathbf{E},\eta_m}$ of pumping possible along this cycle. These relations are smooth periodic by induction and Lemmas 34 and 36. We conclude using [22, Theorem VII.1], whose statement is essentially the following: If $\mathbf{P}_1, \dots, \mathbf{P}_m$ are *reflexive* asymptotically definable periodic relations, then $(\bigcup_{i=1}^m \mathbf{P}_i)^*$ is also asymptotically definable.

7 Conclusion

We have given a new characterization of PVAS sections as RegEx over VAS sections, and extended the abstract properties of almost semilinear sets to PVAS sections. We have concluded that therefore if the reachability relation of a PVAS is semilinear, then it is flattable, and moreover if a configuration is not reachable, then it is separated by a semilinear inductive invariant. This leaves two main unknowns for PVAS which are known for VAS: 1) The decidability of the semilinearity problem, that is, given a PVAS, decide if its reachability relation/set is semilinear. 2) The complexity of the reachability problem.

We leave these as future work. We believe that combining our characterization of PVAS sections and wqo on runs with ideas from [10] might allow for progress on these open problems.

Furthermore, this research can also be viewed as progress towards the open question whether the reachability problem for Pushdown/Grammar VASS is decidable, where Pushdown VASS have a stack in addition to the counters. Namely it is known [1] that Priority VASS are equivalent to a subclass of Pushdown VASS.

Abstract

All known quantifier elimination procedures for Presburger arithmetic require doubly exponential time for eliminating a single block of existentially quantified variables. It has even been claimed in the literature that this upper bound is tight. We observe that this claim is incorrect and develop, as the main result of this paper, a quantifier elimination procedure eliminating a block of existentially quantified variables in singly exponential time. As corollaries, we can establish the precise complexity of numerous problems. Examples include deciding (i) monadic decomposability for existential formulas, (ii) whether an existential formula defines a well-quasi ordering or, more generally, (iii) certain formulas of Presburger arithmetic with Ramsey quantifiers. Moreover, despite the exponential blowup, our procedure shows that under mild assumptions, even NP upper bounds for decision problems about quantifier-free formulas can be transferred to existential formulas. The technical basis of our results is a kind of small model property for parametric integer programming that generalizes the seminal results by von zur Gathen and Sieveking on small integer points in convex polytopes.

1 Introduction

Presburger arithmetic is the first-order theory of the integers with addition and order. This theory was shown decidable by Mojżesz Presburger in 1929 [25] by establishing a quantifier elimination procedure in the extended structure additionally consisting of infinitely many predicates $m \mid \cdot$ for all integers $m > 0$, asserting divisibility by a constant. Recall that a logical theory T admits quantifier elimination whenever for any formula $\Phi(y_1, \ldots, y_k) \equiv \exists x\, \varphi(x, y_1, \ldots, y_k)$ with φ being quantifier free there is a computable quantifier-free formula $\Psi(y_1, \ldots, y_k)$ such that $\Phi \leftrightarrow \Psi$ is a tautology in T. Presburger's quantifier elimination procedure has non-elementary running time. In the early 1970s, Cooper [6] developed an improved version of Presburger's procedure, which was later shown to run in triply exponential time [23]. Ever since, various other quantifier elimination procedures have been established and analyzed, especially for fragments of Presburger arithmetic with a fixed number of quantifier alternations, see e.g. [26, 32]. Weispfenning [33] analyzed lower bounds for quantifier-elimination procedures and showed that, assuming unary encoding of numbers, *any* quantifier elimination procedure requires triply exponential time. In the same paper, Weispfenning also claims that any algorithm eliminating a single block of existential quantifiers inherently requires *doubly* exponential time [33, p. 50].

The main contribution of this paper is to develop a quantifier elimination procedure for Presburger arithmetic that eliminates a block of existentially quantified variables in *singly* exponential time. This, of course, contradicts Weispfenning's claim, which actually turns out to be incorrect as we point out in detail in Appendix C. The key technical insight underlying our procedure is a kind of small model property for parametric integer programming. Given an integer matrix $A \in \mathbb{Z}^{\ell \times n}$ and $\boldsymbol{b} \in \mathbb{Z}^{\ell}$, recall that integer programming is to decide whether there is some $\boldsymbol{x} \in \mathbb{Z}^n$ such that $A\boldsymbol{x} \leq \boldsymbol{b}$. It is well-known by the work of von zur Gathen and Sieveking [31], and Borosh and Treybig [4], that if such an $\boldsymbol{x}$ exists then there is one whose bit length is polynomially bounded in the bit lengths of A and $\boldsymbol{b}$. In this paper, we refer to the situation in which $\boldsymbol{b}$ is not fixed and provided as a parameter as *parametric integer programming*. Our main technical result states that, in this setting, if $A\boldsymbol{x} \leq \boldsymbol{b}$ has a solution for a given $\boldsymbol{b} \in \mathbb{Z}^{\ell}$ then there are $D \in \mathbb{Q}^{n \times \ell}$ and $\boldsymbol{d} \in \mathbb{Q}^n$, both of bit length polynomial in the bit length of A, such that $\boldsymbol{x} = D\boldsymbol{b} + \boldsymbol{d}$ is integral and also a solution. Observe that there is only an exponential number (in the bit length of A) of possible choices for D and $\boldsymbol{d}$. Eliminating a block of variables $\boldsymbol{x}$ from a system of linear inequalities thus becomes easy: we have that $A\boldsymbol{x} \leq B\boldsymbol{y} + \boldsymbol{c}$ is equivalent to the disjunction of systems of the form $A(D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}) \leq B\boldsymbol{y} + \boldsymbol{c}$ for all D and $\boldsymbol{d}$ of bit length polynomial in A. Using standard arguments, this approach can then be turned into a quantifier elimination procedure that eliminates a block of existentially quantified variables in exponential time.

2 Preliminaries

Throughout this paper, all vectors $\boldsymbol{z}$ are treated as column vectors unless mentioned otherwise. For a vector $\boldsymbol{x} \in \mathbb{Q}^n$, let $\|\boldsymbol{x}\|_\infty$ be the maximal absolute value of all components of $\boldsymbol{x}$. Moreover, let $\|\boldsymbol{x}\|_{\mathsf{frac}}$ be the maximal absolute value of all *numerators* and *denominators* of components in $\boldsymbol{x}$. The latter is important for representations: Note that a vector $\boldsymbol{x} \in \mathbb{Q}^n$ with $\|\boldsymbol{x}\|_{\mathsf{frac}} \leq m$ can be represented using $O(n \log m)$ bits. We use analogous notations $\|A\|_\infty$ and $\|A\|_{\mathsf{frac}}$ for matrices A. We will sometimes refer to the *Hadamard inequality* [19], which implies that for a square matrix $A \in \mathbb{Z}^{n \times n}$, we have $|\det(A)| \leq n^{n/2} \cdot \|A\|_\infty^n$. In particular, the determinant of A is at most exponential in the maximal absolute value of entries of A.

Presburger arithmetic. *Presburger arithmetic* (PA) is the first-order theory of the structure $\langle \mathbb{Z}; +, <, 0, 1\rangle$. In order to enable quantifier elimination, we have to permit modulo constraints. Thus technically, we are working with the structure $\langle \mathbb{Z}; +, <, (\equiv_m)_{m\in\mathbb{Z}}, 0, 1\rangle$, where $a \equiv_m b$ stands for $a \equiv b \bmod m$. In our syntax, we allow atomic formulas of the forms $a_1x_1 + \cdots + a_nx_n \leq b$ (called *linear inequalities*) or $a_1x_1 + \cdots + a_nx_n \equiv b \bmod m$ (called *modulo* or *divisibility constraints*), where $x_1, \ldots, x_n$ are variables and $a_1, \ldots, a_n, b, m \in \mathbb{Z}$ are constants encoded in binary. A formula is *quantifier-free* if it contains no quantifiers or, equivalently, is a Boolean combination of atomic formulas. Notice that conjunctions of linear inequalities can be written as systems of linear inequalities $A\boldsymbol{x} \leq \boldsymbol{b}$.

The *size* of a PA Formula φ, denoted $|\varphi|$, is the number of letters used to write it down, where we assume all constants to be encoded in binary. (Sometimes, we say that a formula obeys a size bound even if constants are encoded in unary; but this will be stated explicitly).

Fixed quantifier alternation fragments. The Σ_k fragment of PA consists of formulas of the form $\exists \boldsymbol{u_1} \forall \boldsymbol{u_2} \ldots Q_k \boldsymbol{u_k} \colon \varphi(\boldsymbol{u_1}, \boldsymbol{u_2}, \ldots, \boldsymbol{u_k}, \boldsymbol{z})$ where $\boldsymbol{u_i}$ is a vector of quantified variables, $\boldsymbol{z}$ is a vector of free variables, $\varphi(\boldsymbol{u_1}, \boldsymbol{u_2}, \ldots, \boldsymbol{u_k}, \boldsymbol{z})$ is a quantifier free PA formula, and Q_k denotes $\forall$ or $\exists$ depending on whether k is even or odd respectively. Similarly, the Π_k fragment of PA consists of formulas of the form $\forall \boldsymbol{u_1} \exists \boldsymbol{u_2} \ldots Q_k \boldsymbol{u_k} \colon \varphi(\boldsymbol{u_1}, \boldsymbol{u_2}, \ldots, \boldsymbol{u_k}, \boldsymbol{z})$ where Q_k denotes $\forall$ or $\exists$ depending on whether k is odd or even respectively.

Bounded existential Presburger arithmetic. In addition to our quantifier elimination result, we shall prove a somewhat stronger version, which states that one can compute a compact representation of a quantifier-free formula in polynomial time. As compact representations, we introduce a syntactic variant of existential Presburger arithmetic, which we call *bounded existential Presburger arithmetic*, short $\exists^{\leq}$PA. Essentially, $\exists^{\leq}$PA requires all quantifiers to be restricted to bounded intervals, but also permits polynomials over the quantified variables. Using standard methods, one can translate every formula in $\exists^{\leq}$PA in polynomial time into an $\exists$PA formula. However, the converse is not obvious, and our main results states that this is possible. Syntactically, an $\exists^{\leq}$PA formula over free variables $y_1, \ldots, y_m$ is of the form

$$\exists^{\leq k_1} x_1 \cdots \exists^{\leq k_n} x_n \colon \varphi,$$

where $x_1, \ldots, x_n$ are variables, each $k_i \in \mathbb{N}$ is a number given in binary, and φ is a quantifier-free formula where every atom is of one of the forms:

$$\sum_{i=1}^{m} p_i y_i \leq q \quad \text{or} \quad \sum_{i=1}^{m} p_i y_i \equiv r \bmod q, \tag{1}$$

where $p_1, \ldots, p_m, q, r \in \mathbb{Z}[x_1, \ldots, x_n]$ are polynomials over the variables $x_1, \ldots, x_n$. Thus, where $\exists$PA allows constant integral coefficients, $\exists^{\leq}$PA allows polynomials from $\mathbb{Z}[x_1, \ldots, x_n]$. The quantifiers $\exists^{\leq k_i} x_i$ are interpreted as "there exists $x_i \in \mathbb{Z}$ with $|x_i| \leq k_i$".

▶ Remark 2.1. Now indeed, a $\exists^{\leq}$PA formula can be converted in polynomial time into an $\exists$PA formula: The bounded quantification is clearly expressible in $\exists$PA. The terms p_iy_i and q in (1) (recall p_i and q are polynomials are from $\mathbb{Z}[x_1, \ldots, x_n]$) are also expressible, because multiplication with exponentially bounded variables can be expressed using polynomial-size $\exists$PA formulas. This is because given a polynomial $p \in \mathbb{Z}[x_1, \ldots, x_n]$ and a variable y, we can construct a polynomial-size existential formula $\pi(x_1, \ldots, x_n, y, z)$ expressing $z = p(x_1, \ldots, x_n) \cdot y \wedge |x_1| \leq k_1 \wedge \cdots \wedge |x_n| \leq k_n$. This, in turn, follows from the fact that given ℓ in unary, we can construct an existential formula $\mu_\ell(x, y, z)$, of size linear in ℓ, expressing $z = x \cdot y \wedge |x| \leq 2^\ell$ (see [17, Sec. 3.1] or [18, p. 7]). Thus, we can construct π in $\exists$PA by introducing a variable for each subterm of p (which can clearly all be bounded exponentially).

Making $\exists^{\leq}$PA formulas quantifier-free. Moreover, a $\exists^{\leq}$PA formula can easily be converted (in exponential time) into an exponential-size quantifier-free formula: Just take an exponential disjunction over all assignments of the existentially bounded variables $x_1, \ldots, x_n$ and replace the variables by their values in all the atoms. Thus, $\exists^{\leq}$PA formulas can be regarded as compact representations of quantifier-free formulas.

3 Main results

Here, we state and discuss implications of the main result of this paper:

▶ **Theorem 3.1.** *Given a formula of* $\exists$PA*, we can construct in polynomial time an equivalent formula in* $\exists^{\leq}$PA*.*

From Theorem 3.1, we can deduce the following, since by the remark Remark 2.1 in Section 2, one can easily convert a $\exists^{\leq}$PA formula into an exponential-sized quantifier-free formula.

▶ **Corollary 3.2.** *Given a formula φ in existential Presburger arithmetic, we can compute in exponential time an equivalent quantifier-free formula ψ of size exponential in φ. Moreover, all constants in ψ are encoded in unary.*

In Section 6, we will see that an exponential blowup cannot be avoided when eliminating a block of existential quantifiers, even if we allow constants to be encoded in binary in the quantifier-free formula.

There are several applications of Theorem 3.1 and Corollary 3.2. The most obvious type of applications are those, where, for every problem[1] that is in NP (resp. coNP) for quantifier-free formulas, the same problem belongs to NEXP (resp. coNEXP) for existential formulas. Oftentimes, this yields optimal complexity. We mention some examples.

A direct consequence of Corollary 3.2 (and the NP membership of the quantifier free fragment of PA) is the following.

▶ **Corollary 3.3.** *The Σ_2-fragment of Presburger arithmetic belongs to* NEXP*.*

The NEXP upper bound is known and was shown by Haase [17, Thm. 1]. In fact, the Σ_2-fragment is known to be NEXP-complete: An NEXP lower bound was shown much earlier by Grädel [14], already for the $\exists\forall^*$-fragment.

Ramsey quantifiers. In fact, combining Corollary 3.2 with the results from [2], we can strengthen Corollary 3.3. The *Ramsey quantifier* $\exists^{\mathsf{ram}}$ states the existence of infinite (directed) cliques. More precisely, if $\varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ is a Presburger formula where $\boldsymbol{x}$ and $\boldsymbol{y}$ are vectors of n variables each, then $\exists^{\mathsf{ram}}(\boldsymbol{x}, \boldsymbol{y})\colon \varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ is satisfied for $\boldsymbol{z}$ if and only if there exists an infinite sequence $\boldsymbol{a}_1, \boldsymbol{a}_2, \ldots \in \mathbb{Z}^n$ of pairwise distinct vectors with $\varphi(\boldsymbol{a}_i, \boldsymbol{a}_j, \boldsymbol{z})$ for every $i < j$. As mentioned in [2], Ramsey quantifiers can be applied to deciding liveness properties, deciding monadic decomposability (see below), and deciding whether a formula defines a well-quasi-ordering (see below).

In [2, Thm. 5.1], it is shown that if $\varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ is an $\exists$PA formula, then one can compute in polynomial time an $\exists$PA formula $\varphi'(\boldsymbol{z})$ equivalent to $\exists^{\mathsf{ram}}(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})\colon \varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$.

[1] To be precise: Every *semantic* problem, meaning one that only depends on the set defined by the input formula.

▶ **Corollary 3.4.** *Given a Σ_2-formula $\varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, we can construct an exponential-size* ∃PA *formula equivalent to $\exists^{\mathsf{ram}}(\boldsymbol{x}, \boldsymbol{y})\colon \varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$. In particular, deciding the truth of $\exists^{\mathsf{ram}}(\boldsymbol{x}, \boldsymbol{y})\colon \psi$ for Σ_2-formulas $\psi(\boldsymbol{x}, \boldsymbol{y})$ is* NEXP*-complete.*

Indeed, Corollary 3.2 lets us convert $\varphi(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ into an exponential-size existential formula φ', so that we can apply the above result of [2] to the formula $\exists^{\mathsf{ram}}(\boldsymbol{x}, \boldsymbol{y})\colon \varphi'(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, which results in an equivalent exponential ∃PA formula. The NEXP lower bound in the second statement follows from NEXP-hardness of the Σ_2-fragment and the fact that for a given Σ_2-formula χ without free variables, the statement $\exists^{\mathsf{ram}}(\boldsymbol{x}, \boldsymbol{y})\colon \chi \wedge \boldsymbol{x} < \boldsymbol{y}$ is equivalent to χ.

Detecting WQOs. A *well-quasi-ordering* (WQO) is a reflexive and transitive ordering $(X, \leq)$ such that for every sequence $x_1, x_2, \ldots \in X$, there are $i < j$ with $x_i \leq x_j$. Well-quasi-orderings are of paramount importance in the widely applied theory of well-structured transition systems [7, 1, 10]. The problem of deciding whether a given Presburger formula $\varphi(\boldsymbol{x}, \boldsymbol{y})$ defines a WQO was recently raised by Finkel and Gupta [8], with the hope of establishing automatically that certain systems are well-structured. As observed in [9, Prop. 12], this problem reduces to evaluating Ramsey quantifiers, which is decidable by [28]. Based on an NP algorithm for Ramsey quantifiers, it is shown in [2, Sec. 8.3] that given a quantifier-free formula $\varphi(\boldsymbol{x}, \boldsymbol{y})$, where $\boldsymbol{x}$ and $\boldsymbol{y}$ are vectors of n variables each, it is coNP-complete whether the relation $R \subseteq \mathbb{Z}^n \times \mathbb{Z}^n$ defined by φ is a WQO. Our results allow us to settle the complexity for existential formulas:

▶ **Corollary 3.5.** *Given an* ∃PA *formula φ, it is* coNEXP*-complete to decide whether φ defines a WQO.*

The upper bound follows directly from Corollary 3.2 and the fact that it is coNP-complete to decide whether a given quantifier-free formula defines a well-quasi-ordering [2, Sec. 8.3]. This yields a coNEXP procedure overall. It should be noted that Corollary 3.5 can also be deduced from Corollary 3.4 (using the same idea as in [2, Sec. 8.3]). However, we find it instructive to demonstrate how quantifier elimination permits a direct transfer of the coNP algorithm as a black box. We show the coNEXP lower bound in Section 5.

Monadic decomposability. A Presburger formula is *monadic* if each of its atoms contains at most one variable. Moreover, we say that a Presburger formula φ is *monadically decomposable* if φ is equivalent to a monadic Presburger formula. Motivated by the role monadic formulas play in constraint databases [15, 21], Veanes, Bjørner, and Nachmanson, and Bereg recently raised the question of how to decide whether a given formula is monadically decomposable [30]. For Presburger arithmetic, decidability follows from [13, p. 1048] and for quantifier-free formulas, monadic decomposability was shown coNP-complete in [20, Thm. 1] (in [2, Cor. 8.1], the coNP upper bound is shown via Ramsey quantifiers). Corollary 3.2 allows us to settle the case of ∃PA formulas.

▶ **Corollary 3.6.** *Monadic decomposability of* ∃PA *formulas is* coNEXP*-complete.*

This is because given an ∃PA formula, we can compute an exponential-sized quantifier-free formula and apply the existing coNP procedure, yielding a coNEXP upper bound overall. Again, the coNEXP upper bound could also be deduced from Corollary 3.4 (but this proof shows again how to transfer algorithms using quantifier elimination). The coNEXP lower bound follows the same idea as the coNP lower bound in [2], see Section 5.

NP upper bounds. In addition to new NEXP and coNEXP upper bounds, Theorem 3.1 can also be used to obtain NP upper bounds. Suppose we have a predicate $\mathfrak{p}$ on sets of integral vectors. That is, for each $S \subseteq \mathbb{Z}^m$ for some $m \in \mathbb{N}$, either $\mathfrak{p}(S)$ is true or not. We call this predicate *admissible* if for any $m \in \mathbb{N}$, $S_1, S_2 \subseteq \mathbb{Z}^m$, we have that $\mathfrak{p}(S_1 \cup S_2)$ implies $\mathfrak{p}(S_1)$ or $\mathfrak{p}(S_2)$. Let us see some examples:

- **(i)** The predicate $\mathfrak{p}$ with $\mathfrak{p}(S)$ if and only if $S \neq \emptyset$.
- **(ii)** The predicate $\mathfrak{p}$ with $\mathfrak{p}(S)$ if and only if S is infinite.
- **(iii)** The predicate $\mathfrak{p}$ with $\mathfrak{p}(S)$ if and only if $S \subseteq \mathbb{Z}$ and S contains a power of 2.
- **(iv)** The predicate $\mathfrak{p}$ with $\mathfrak{p}(S)$ if and only if $S \subseteq \mathbb{Z}^{2k}$ and viewed as a relation $S \subseteq \mathbb{Z}^k \times \mathbb{Z}^k$, S has an infinite clique.
- **(v)** The predicate $\mathfrak{p}$ with $\mathfrak{p}(S)$ if and only if $S \subseteq \mathbb{Z}$ and S contains infinitely many primes.
- **(vi)** The predicate $\mathfrak{p}$ with $\mathfrak{p}(S)$ if and only if $S \subseteq \mathbb{Z}^2$ and S contains a pair $(x, 2^x)$.

For each such predicate, we consider the problem $\mathfrak{p}(\exists\text{PA})$:

Input An $\exists$PA formula φ with m free variables for some $m \in \mathbb{N}$.

Question Does $\mathfrak{p}(S)$ hold, where $S \subseteq \mathbb{Z}^m$ is the set defined by φ?

Moreover, $\mathfrak{p}(\text{QF})$ is the restriction of the problem where the input formula φ is quantifier-free.

For several of the examples above, it is known that $\mathfrak{p}(\exists\text{PA})$ is in NP: For (i) and (ii), these are standard facts, and for (iii), this follows from NP-completeness of existential Büchi arithmetic [16, Thm. 1]. For (iv), this follows from the fact that Ramsey quantifiers can be evaluated in NP [2, Thm 5.1]. Our results imply that for proving NP upper bounds, we may always assume a quantifier-free input formula. This is perhaps surprising, because one might expect that for non-linear predicates, it is difficult to bound the quantified variables.

▶ **Corollary 3.7.** *For every admissible predicate $\mathfrak{p}$, the problem $\mathfrak{p}(\exists\text{PA})$ is in NP if and only if $\mathfrak{p}(\text{QF})$ is in NP.*

Here, the "only if" direction is trivial, and the "if" direction follows from Theorem 3.1. This is because Theorem 3.1 allows us to assume that φ is given as a $\exists^{\leq}$PA formula $\exists^{\leq k_1} x_1 \cdots \exists^{\leq k_n} x_n \colon \psi(x_1, \ldots, x_n, y_1, \ldots, y_m)$. Moreover, admissibility of $\mathfrak{p}$ implies that $\mathfrak{p}$ is satisfied for φ if and only if there exists an assignment $(a_1, \ldots, a_n)$ for the bounded variables such that the quantifier-free formula $\psi(a_1, \ldots, a_n, y_1, \ldots, y_m)$ satisfies $\mathfrak{p}$. Thus, we can guess the assignment (which occupies polynomially many bits) and run the NP algorithm for quantifier-free formulas.

4 Quantifier elimination

In this section, we prove Theorem 3.1. The following is our main geometric ingredient.

▶ **Proposition 4.1.** *Let $A \in \mathbb{Z}^{\ell \times n}$ and $\boldsymbol{b} \in \mathbb{Z}^\ell$, and let Δ be an upper bound on all absolute values of the subdeterminants of A. If the system $A\boldsymbol{x} \leq \boldsymbol{b}$ has an integral solution, then it has an integral solution of the form $D\boldsymbol{b} + \boldsymbol{d}$, where $D \in \mathbb{Q}^{n \times \ell}$ and $\boldsymbol{d} \in \mathbb{Q}^n$ with $\|D\|_{\mathsf{frac}} \leq \Delta$ and $\|\boldsymbol{d}\|_{\mathsf{frac}} \leq n\Delta^2$.*

Before we prove Proposition 4.1, let us see how it implies Theorem 3.1 and Corollary 3.2.

Proof of Corollary 3.2. While Corollary 3.2 follows from Theorem 3.1, it follows very directly from Proposition 4.1 and the proof is a good warm-up for the proof of Theorem 3.1. Therefore, we first derive Corollary 3.2 from Proposition 4.1. Suppose we are given a Presburger formula $\exists \boldsymbol{x} \colon \varphi(\boldsymbol{x}, \boldsymbol{y})$, where $\boldsymbol{x} = (x_1, \ldots, x_n)$ and $\boldsymbol{y} = (y_1, \ldots, y_m)$ are variables and φ is quantifier-free.

It is well-known that divisibility constraints can be eliminated in favor of existentially quantified variables, since $a \equiv b \bmod m$ if and only if $\exists x\colon a - b = mx$. Thus, we may assume that φ contains no divisibility constraints. Then, by moving all negations inwards and using the standard equivalence $\neg(r \leq t) \iff t + 1 \leq r$, we may assume that φ is a positive Boolean combination of atoms $\boldsymbol{a}^\top \boldsymbol{x} \leq \boldsymbol{b}^\top \boldsymbol{y} + c$, where $\boldsymbol{a} \in \mathbb{Z}^n$, $\boldsymbol{b} \in \mathbb{Z}^m$, and $c \in \mathbb{Z}$.

By bringing φ into DNF, we can write it as a disjunction of exponentially many systems of inequalities of the form $A\boldsymbol{x} \leq B\boldsymbol{y} + \boldsymbol{c}$, where $A \in \mathbb{Z}^{\ell \times n}$, $B \in \mathbb{Z}^{\ell \times m}$, and $\boldsymbol{c} \in \mathbb{Z}^\ell$. Thus, it suffices to construct a quantifier-free formula for $\exists \boldsymbol{x}\colon A\boldsymbol{x} \leq B\boldsymbol{y} + \boldsymbol{c}$. Let Δ be an upper bound for all absolute values of subdeterminants of A. Since the transformation into DNF does not change the appearing constants, we have that $\Delta \leq n^{n/2}\|A\|_\infty^n$ is at most exponential in the size of the input formula.

According to Proposition 4.1, a vector $\boldsymbol{x}$ with $\varphi(\boldsymbol{x}, \boldsymbol{y})$ exists if and only if there exists a matrix $D \in \mathbb{Q}^{n \times \ell}$ and $\boldsymbol{d} \in \mathbb{Q}^n$ with $\|D\|_{\mathsf{frac}} \leq \Delta$ and $\|\boldsymbol{d}\|_{\mathsf{frac}} \leq n\Delta^2$ such that (i) substituting $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}$ for $\boldsymbol{x}$ satisfies $A\boldsymbol{x} \leq B\boldsymbol{y} + \boldsymbol{c}$ and also (ii) the vector $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}$ is integral. Therefore, the formula $\exists \boldsymbol{x}\colon A\boldsymbol{x} \leq B\boldsymbol{y} + \boldsymbol{c}$ is equivalent to

$$\bigvee_{(D,\boldsymbol{d}) \in P} A(D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}) \leq B\boldsymbol{y} + \boldsymbol{c} \ \wedge \ D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d} \in \mathbb{Z}^n$$

where P is the set of all pairs $(D, \boldsymbol{d})$ with $D \in \mathbb{Q}^{n \times \ell}$, $\boldsymbol{d} \in \mathbb{Q}^n$, $\|D\|_{\mathsf{frac}} \leq \Delta$, and $\|\boldsymbol{d}\|_{\mathsf{frac}} \leq n\Delta^2$. Clearly, P contains at most exponentially many elements. Moreover, note that the condition $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d} \in \mathbb{Z}^n$ is a set of n modulo constraints. ◀

Proof of Theorem 3.1. The proof of Theorem 3.1 is similar to the above construction – we just need to circumvent the exponential conversion into DNF. We proceed as follows.

As above, we are given a Presburger formula $\exists \boldsymbol{x}\colon \varphi(\boldsymbol{x}, \boldsymbol{y})$, where $\boldsymbol{x} = (x_1, \ldots, x_n)$ and $\boldsymbol{y} = (y_1, \ldots, y_m)$ are variables and φ is quantifier-free. Moreover, we may assume that φ contains no divisibility constraints and is a positive Boolean combination of atoms $\boldsymbol{a}^\top \boldsymbol{x} \leq \boldsymbol{b}^\top \boldsymbol{y} + c$, where $\boldsymbol{a} \in \mathbb{Z}^n$, $\boldsymbol{b} \in \mathbb{Z}^m$, and $c \in \mathbb{Z}$.

Let $\boldsymbol{a}_i^\top \boldsymbol{x} \leq \boldsymbol{b}_i^\top \boldsymbol{y} + c_i$ for $i = 1, \ldots, \ell$ be the set of all atoms occurring in φ and let $A \in \mathbb{Z}^{\ell \times n}$ be the matrix with rows $\boldsymbol{a}_i^\top$ and $B \in \mathbb{Z}^{\ell \times m}$ be the matrix of rows $\boldsymbol{b}_i^\top$, and let $\boldsymbol{c} \in \mathbb{Z}^\ell$ be the (column) vector with entries $c_1, \ldots, c_\ell$. Thus, our formula φ consists of ℓ atoms, each of which is a row in the system of linear inequalities $A\boldsymbol{x} \leq B\boldsymbol{y} + \boldsymbol{c}$. Let φ' be the formula obtained from φ by replacing the atom $\boldsymbol{a}_i^\top \boldsymbol{x} \leq \boldsymbol{b}_i^\top \boldsymbol{y} + c_i$ by $z_i = 1$, where z_i, $i \in \{1, \ldots, \ell\}$, is a fresh variable for each of the ℓ atoms. Now let Δ be an upper bound on all absolute values of the subdeterminants of A. Then $\Delta \leq n^{n/2}\|A\|_\infty^n$ is at most exponential in the size of the input formula. Consider the formula

$$\begin{aligned} &\exists z_1, \ldots, z_\ell \in \{0,1\}\colon \quad \exists D \in \mathbb{Q}^{n \times \ell}, \|D\|_{\mathsf{frac}} \leq \Delta\colon \\ &\qquad \exists \boldsymbol{d} \in \mathbb{Q}^n,\ \|\boldsymbol{d}\|_{\mathsf{frac}} \leq n\Delta^2\colon \quad \varphi' \ \wedge \ D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d} \in \mathbb{Z}^n \ \wedge \ \bigwedge_{i=1}^{\ell} (z_i = 1 \to \psi_i)\,, \end{aligned} \tag{2}$$

where ψ_i is the formula $\boldsymbol{a}_i^\top (D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}) \leq \boldsymbol{b}_i^\top \boldsymbol{y} + c_i$. Note that (2) is expressible in $\exists^{\leq}$PA: We introduce (i) one variable for each z_i, (ii) two variables for each entry of D (one for the numerator, and one for the denominator), and (iii) two variables for each entry of $\boldsymbol{d}$.

Each of the n divisibility constraints of $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d} \in \mathbb{Z}^n$ and each of the atoms ψ_i can be written in the forms (1). To see this, let $u_1, \ldots, u_k$ be the bounded variables used for the numerators or denominators in D and $\boldsymbol{d}$. Observe that the vector $B\boldsymbol{y}$ is a linear combination of $\boldsymbol{y}$ with integer coefficients. The matrix D and the vector $\boldsymbol{d}$ consist

of quotients of bounded variables, hence rational functions in $\mathbb{Z}[u_1, \ldots, u_k]$. Thus, the vector $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}$ has in each entry an expression $s + \sum_{i=1}^{m} r_i y_i$, where $r_1, \ldots, r_m, s \in \mathbb{Z}[u_1, \ldots, u_k]$. Hence, by multiplying with the product of all denominators, we can write each inequality $\boldsymbol{a}_i^\top (D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}) \leq \boldsymbol{b}_i^\top \boldsymbol{y} + c_i$ in the form of (1). Moreover, for the requirement $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d} \in \mathbb{Z}^n$, we can write each row of $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}$ as a quotient $\frac{1}{q}(r + \sum_{i=1}^{m} p_i y_i)$, where $q, r, p_1, \ldots, p_m \in \mathbb{Z}[u_1, \ldots, u_k]$, so that membership in $\mathbb{Z}$ is equivalent to $\sum_{i=1}^{m} p_i y_i \equiv -r \pmod{q}$.

Let us argue why (2) is equivalent to $\exists \boldsymbol{x} \colon \varphi(\boldsymbol{x}, \boldsymbol{y})$. Clearly, if (2) is satisfied, then $\boldsymbol{z} = (z_1, \ldots, z_\ell)$ yields a set of atoms that, if satisfied, makes φ true. Moreover, the vector $D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}$ is an integer vector that satisfies all the atoms specified by $\boldsymbol{z}$.

Conversely, suppose $\varphi(\boldsymbol{x}, \boldsymbol{y})$ holds for some $\boldsymbol{x} \in \mathbb{Z}^n$ and $\boldsymbol{y} \in \mathbb{Z}^m$. First, we set exactly those z_i to 1 for which the i-th atom in φ is satisfied by $\boldsymbol{x}, \boldsymbol{y}$. Recall that each row of A (and each row of B, and of $\boldsymbol{c}$) corresponds to an atom in φ. Let A' be the matrix obtained from A by selecting those rows that correspond to atoms that are satisfied by our $\boldsymbol{x}$ and $\boldsymbol{y}$. Define B' similarly from B, and $\boldsymbol{c}'$ from $\boldsymbol{c}$. Then we have $A'\boldsymbol{x} \leq B'\boldsymbol{y} + \boldsymbol{c}'$. Now Proposition 4.1 yields a matrix D' and a vector $\boldsymbol{d}$ (each with n rows) with $A'(D'(B'\boldsymbol{y} + \boldsymbol{c}') + \boldsymbol{d}) \leq B'\boldsymbol{y} + \boldsymbol{c}'$. Now the set of rows of $B'\boldsymbol{y} + \boldsymbol{c}'$ is a subset of the rows of $B\boldsymbol{y} + \boldsymbol{c}$, so by inserting zero-columns into D', we can construct a matrix D with $D(B\boldsymbol{y} + \boldsymbol{c}) = D'(B'\boldsymbol{y} + \boldsymbol{c}')$. Hence, we have $A'(D(B\boldsymbol{y} + \boldsymbol{c}) + \boldsymbol{d}) \leq B'\boldsymbol{y} + \boldsymbol{c}'$. The latter means exactly that ψ_i is satisfied for every i with $z_i = 1$. Thus, this choice of $z_1, \ldots, z_\ell$, D, and $\boldsymbol{d}$ satisfies (2). ◀

4.1 Constructing solutions as affine transformations

4.1.1 Convex geometry

Before we start with the proof of Proposition 4.1, we recall some standard definitions from convex geometry from Schrijver's book [29]. Below, we let $\mathbb{R}_+ = \{r \in \mathbb{R} \mid r \geq 0\}$. A *polyhedron* is a set $P = \{\boldsymbol{x} \in \mathbb{R}^n \mid A\boldsymbol{x} \leq \boldsymbol{b}\}$, where A is an $\ell \times n$ integer matrix and $\boldsymbol{b} \in \mathbb{Z}^\ell$. Let $C \subseteq \mathbb{R}^\ell$, then C is a *convex cone* if $\lambda\boldsymbol{x} + \mu\boldsymbol{y} \in C$ for all $\boldsymbol{x}, \boldsymbol{y} \in C$ and $\lambda, \mu \in \mathbb{R}_+$. Given a set $X \subseteq \mathbb{R}^\ell$,

$$\operatorname{cone}(X) = \{\lambda_1 \boldsymbol{x}_1 + \cdots + \lambda_t \boldsymbol{x}_t \mid t \geq 0,\ \boldsymbol{x}_1, \ldots, \boldsymbol{x}_t \in X,\ \lambda_1, \ldots, \lambda_t \in \mathbb{R}_+\}\,.$$

The *convex hull* of a set $X \subseteq \mathbb{R}^\ell$ is the smallest convex set containing that set, i.e.,

$$\text{conv. hull}(X) = \{\lambda_1 \boldsymbol{x}_1 + \cdots + \lambda_t \boldsymbol{x}_t \mid t \geq 1,\ \boldsymbol{x}_1, \boldsymbol{x}_2, \ldots \boldsymbol{x}_t \in X, \\ \lambda_1, \ldots, \lambda_t \in \mathbb{R}_+,\ \lambda_1 + \cdots + \lambda_t = 1\}\,.$$

Next, we recall some terminology concerning the structure of polyhedra. The *characteristic cone* of a polyhedron $P = \{\boldsymbol{x} \mid A\boldsymbol{x} \leq \boldsymbol{b}\} \subseteq \mathbb{R}^n$ is the set $\text{char. cone}(P) \coloneqq \{\boldsymbol{y} \in \mathbb{R}^n \mid A\boldsymbol{y} \leq 0\}$. The *lineality space* of polyhedron P is the set $\text{lin. space}(P) \coloneqq \{\boldsymbol{y} \in \mathbb{R}^n \mid A\boldsymbol{y} = 0\}$.

▶ **Definition 4.2** (Faces). *Given a polyhedron $P \subseteq \mathbb{R}^n$, $F \subseteq P$ is a* face *of P if and only if F is non-empty and*

$$F = \{\boldsymbol{x} \in P \mid A'\boldsymbol{x} = \boldsymbol{b}'\}$$

for some subsystem $A'\boldsymbol{x} \leq \boldsymbol{b}'$ of $A\boldsymbol{x} \leq \boldsymbol{b}$. We call $F \subseteq P$ a proper face *of P if $F \neq \emptyset$ and $F \neq P$.*

It follows that P has only finitely many faces. A *minimal face* of P is a face not containing any other face. We have the following characterization of minimal faces [29, Thm 8.4],

▶ **Proposition 4.3.** *A set F is a minimal face of a polyhedron $P \subseteq \mathbb{R}^n$ if and only if $\emptyset \neq F \subseteq P$ and*

$$F = \{\boldsymbol{x} \in \mathbb{R}^n \mid A'\boldsymbol{x} = \boldsymbol{b}'\}$$

for some subsystem $A'\boldsymbol{x} \leq \boldsymbol{b}'$ of $A\boldsymbol{x} \leq \boldsymbol{b}$, such that the matrix A' has the same rank as A.

The following is shown in [29, Sec. 8.8]:

▶ **Proposition 4.4.** *Let C be the cone $\{\boldsymbol{x} \in \mathbb{R}^n \mid A\boldsymbol{x} \leq \boldsymbol{0}\}$. There is a finite collection $G_1, G_2 \ldots, G_s$ of subsets, which are of the form $G_i = \{\boldsymbol{x} \in \mathbb{R}^n \mid \boldsymbol{a}_i^\top \boldsymbol{x} \leq 0,\ A'\boldsymbol{x} = \boldsymbol{0}\}$, where $\begin{bmatrix} A' \\ \boldsymbol{a}_i^\top \end{bmatrix}$ is a subset of the rows of A, such that the following holds. If we choose for each $i = 1, \ldots, s$ a vector $\boldsymbol{y}_i$ from $G_i \setminus \text{lin. space}(C)$ and choose $\boldsymbol{z}_0, \ldots, \boldsymbol{z}_t$ in $\text{lin. space}(C)$ such that $\text{lin. space}(C) = \text{cone}(\boldsymbol{z}_0, \ldots, \boldsymbol{z}_t)$, then*

$$C = \text{cone}(\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s, \boldsymbol{z}_0, \ldots, \boldsymbol{z}_t).$$

Here, the sets G_i are also called minimal proper faces (but Proposition 4.4 is not a characterization of those).

4.1.2 Proof of Proposition 4.1

We now prove Proposition 4.1. For the remainder of the section, let $A \in \mathbb{Z}^{\ell \times n}$ and $\boldsymbol{b} \in \mathbb{Z}^\ell$. Moreover, let Δ be an upper bound on all absolute values of the sub-determinants of A. Our first step is a simple application of standard facts about polyhedra.

▶ **Lemma 4.5.** *If the system $A\boldsymbol{x} \leq \boldsymbol{b}$ has a solution in $\mathbb{Q}^n$, then it has one of the form $\frac{1}{a}E\boldsymbol{b}$, where $E \in \mathbb{Z}^{n \times \ell}$, $a \in \mathbb{Z} \setminus \{0\}$, $|a| \leq \Delta$, and $\|E\|_\infty \leq \Delta$.*

Proof. It is well-known that if $A\boldsymbol{x} \leq \boldsymbol{b}$ has a rational solution, then there is a solution inside a minimal face of the polyhedron $P = \{\boldsymbol{x} \in \mathbb{R}^n \mid A\boldsymbol{x} \leq \boldsymbol{b}\}$ defined by the system of linear inequalities $A\boldsymbol{x} \leq \boldsymbol{b}$ [29, Thm. 8.5]. Recall that a *minimal face* is a non-empty subset $F \subseteq P$ of the form

$$F = \{\boldsymbol{x} \in \mathbb{R}^n \mid A'\boldsymbol{x} = \boldsymbol{b}'\}, \tag{3}$$

where $A'\boldsymbol{x} \leq \boldsymbol{b}'$ is a subset of the inequalities in $A\boldsymbol{x} \leq \boldsymbol{b}$ such that the matrix A' has the same rank as A (see Proposition 4.3 or [29, Thm. 8.4]). Suppose F is a non-empty minimal face and satisfies (3). Here, we may assume that the rows of A' are linearly independent (otherwise, we can remove redundant rows without changing F). This means, A' can be written as $A' = (B \quad C)$ such that B is invertible. Then the vector $\boldsymbol{x}^* := (B^{-1}\boldsymbol{b}' \quad \boldsymbol{0})^\top$ belongs to F. Since $F \subseteq P$, we know that $A\boldsymbol{x}^* \leq \boldsymbol{b}$. By Cramer's rule, the entry (j, i) of B^{-1} is $\frac{(-1)^{i+j}\det(B_{ij})}{\det(B)}$, where B_{ij} is the matrix obtained from B by removing the i-th row and j-th column. Note that $|\det(B_{ij})| \leq \Delta$ and $|\det(B)| \leq \Delta$. In particular, $\boldsymbol{x}^*$ can be written as $\frac{1}{a}E\boldsymbol{b}$, where $a = \det(B)$ and $\|E\|_\infty \leq \Delta$. ◀

We also employ the following well-known fact, which again uses standard arguments.

▶ **Lemma 4.6.** *There are integral vectors $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s$ with each component being at most Δ in absolute value, such that $\{\boldsymbol{x} \in \mathbb{R}^n \mid A\boldsymbol{x} \leq \boldsymbol{0}\} = \text{cone}(\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s)$.*

Proof. Let $C = \{\boldsymbol{x} \in \mathbb{R}^n \mid A\boldsymbol{x} \leq \boldsymbol{0}\}$. The lemma follows from Proposition 4.4. First, it is a consequence of Cramer's rule that we can choose $\boldsymbol{z}_0, \ldots, \boldsymbol{z}_t$ as a basis of $\text{lin. space}(C) = \{\boldsymbol{x} \in \mathbb{R}^n \mid A\boldsymbol{x} = \boldsymbol{0}\}$ so that all $\boldsymbol{z}_0, \ldots, \boldsymbol{z}_t$ are integral and have absolute values at most Δ in all components. For example, see [29, Cor. 3.1c]. It remains to pick from each set

$$G_i \setminus \text{lin. space}(C) = \{\boldsymbol{x} \in \mathbb{R}^n \mid \boldsymbol{a}_i^\top \boldsymbol{x} < 0,\ A'\boldsymbol{x} = \boldsymbol{0}\}$$

an integral vector with all components bounded by Δ. For this, we can proceed similarly to Lemma 4.5. As a subset of rows of A, the matrix $B = \begin{bmatrix} A' \\ \boldsymbol{a}_i^\top \end{bmatrix}$ has rank at most n, and we may assume $\boldsymbol{a}_i \neq \boldsymbol{0}$ (otherwise $G_i \setminus \text{lin. space}(C)$ would be empty). Moreover, we may assume that the rows of B are linearly independent, as otherwise we can remove rows from A' without changing G_i. We can thus write $B = (E \quad F)$, where E is invertible. By Cramer's rule (see, e.g. [29, Sec. 3.2]), the j-th component of the vector $\boldsymbol{y} = E^{-1}(0, \ldots, 0, -1)$ can be written as $\frac{1}{\det(E)} \det(\tilde{E})$, where $\tilde{E}$ is obtained from E by replacing the j-th column by $(0, \ldots, 0, -1)$. This means, the vector $|\det(E)| \cdot \boldsymbol{y}$ has only integer components and all of them have absolute value at most Δ. Now let $\boldsymbol{y}^*$ be the vector obtained from $|\det(E)| \cdot \boldsymbol{y}$ adding as many 0's as F has columns. Then we have $B\boldsymbol{y}^* = E(|\det(E)| \cdot \boldsymbol{y}) = (0, \ldots, 0, -|\det(E)|)$ and thus $\boldsymbol{y}^* \in G_i \setminus \text{lin. space}(C)$. ◀

We also rely on the well-known theorem of Carathéodory [29, Cor. 7.1(i)].

▶ **Theorem 4.7** (Carathéodory's theorem). *If $X \subseteq \mathbb{R}^n$ is some subset and $\boldsymbol{x} \in \text{cone}(X)$, then there are linearly independent $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_m \in X$ with $\boldsymbol{x} \in \text{cone}(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_m)$.*

The following lemma is the key ingredient for proving Proposition 4.1. Its proof closely follows the ideas of [29, Thm. 17.2], which Schrijver attributes to Cook, Gerards, Schrijver, and Tardos [5]. The latter shows that for every rational $\boldsymbol{x}$ that maximizes an expression $\boldsymbol{c}^\top \boldsymbol{x}$ among the solutions of $A\boldsymbol{x} \leq \boldsymbol{b}$, there is a close-by integral vector that maximizes this expression among all integral vectors.

▶ **Lemma 4.8.** *Suppose the system $A\boldsymbol{x} \leq \boldsymbol{b}$ has an integral solution, and let $\boldsymbol{r} \in \mathbb{Q}^n$ be a rational solution. Then there is an integral solution $\boldsymbol{z}^* \in \mathbb{Z}^n$ with $\|\boldsymbol{z}^* - \boldsymbol{r}\|_\infty \leq n\Delta$.*

Proof. An illustration of the proof is given in Figure 1. Let $\boldsymbol{z}$ be an integral solution to $A\boldsymbol{x} \leq \boldsymbol{b}$. Split the equations $A\boldsymbol{x} \leq \boldsymbol{b}$ into $A_1\boldsymbol{x} \leq \boldsymbol{b}_1$ and $A_2\boldsymbol{x} \leq \boldsymbol{b}_2$ such that $A_1\boldsymbol{r} \leq A_1\boldsymbol{z}$ and $A_2\boldsymbol{r} \geq A_2\boldsymbol{z}$. In other words, we split A, $\boldsymbol{b}$ into two sets of rows, depending on in which coordinates $\boldsymbol{r}$ resp. $\boldsymbol{z}$ is larger. Now consider the cone $C = \{\boldsymbol{x} \in \mathbb{R}^n \mid A_1\boldsymbol{x} \geq \boldsymbol{0},\ A_2\boldsymbol{x} \leq \boldsymbol{0}\}$. Then, by the choice of A_1 and A_2, we have $\boldsymbol{z} - \boldsymbol{r} \in C$ and therefore

$$\boldsymbol{z} - \boldsymbol{r} = \lambda_1\boldsymbol{y}_1 + \cdots + \lambda_t\boldsymbol{y}_t,$$

where $\lambda_1, \ldots, \lambda_t \geq 0$ are real numbers and $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_t$ are some linearly independent vectors chosen from the set of integer vectors $\{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s\}$ provided by Lemma 4.6 satisfying $C = \text{cone}(\boldsymbol{y}_1, \ldots, \boldsymbol{y}_s\}$. The choice of linearly independent vectors is possible due to Carathéodory's theorem. In particular, each $\boldsymbol{y}_i$ has maximal absolute value at most Δ and we have $t \leq n$.

Observe that for any $\mu_1, \ldots, \mu_t$ with $0 \leq \mu_i \leq \lambda_i$ for $i \in [1, t]$, the vector

$$\boldsymbol{r} + \mu_1\boldsymbol{y}_1 + \cdots + \mu_t\boldsymbol{y}_t$$

is still a solution to $A\boldsymbol{x} \leq \boldsymbol{b}$. Indeed, $A_1\boldsymbol{y}_i \geq \boldsymbol{0}$ and $A_2\boldsymbol{y}_i \leq \boldsymbol{0}$ implies

$$A_1(\boldsymbol{r} + \mu_1\boldsymbol{y}_1 + \cdots + \mu_t\boldsymbol{y}_t) \leq A_1\boldsymbol{z} \leq \boldsymbol{b}_1, \text{ and}$$
$$A_2(\boldsymbol{r} + \mu_1\boldsymbol{y}_1 + \cdots + \mu_t\boldsymbol{y}_t) \leq A_2\boldsymbol{r} \leq \boldsymbol{b}_2,$$

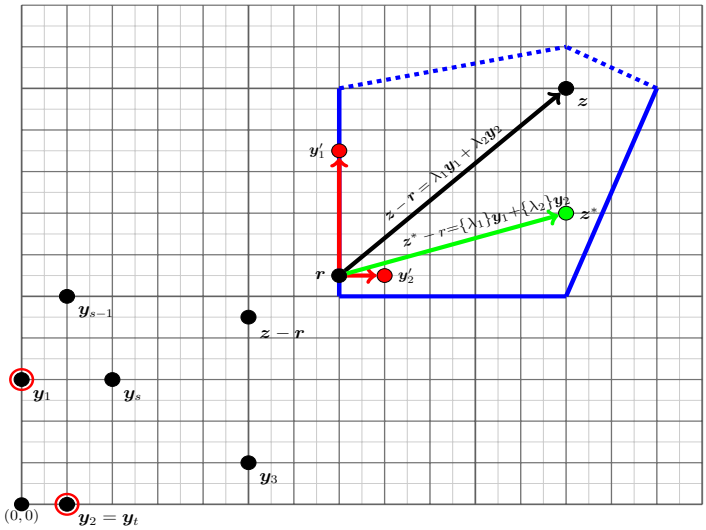

Figure 1 The main idea behind Lemma 4.8. The region enclosed by blue lines depicts the solution space of the given system of linear inequalities. As mentioned in the lemma, $\boldsymbol{r}$ and $\boldsymbol{z}$ are respectively the given rational and integral solutions. Due to Lemma 4.6, we know that C (containing $\boldsymbol{z} - \boldsymbol{r}$) can be obtained as a cone of integer vectors $\boldsymbol{y}_1, \dots \boldsymbol{y}_s$. Moreover, by Carathéodory's theorem, we know that there are t linearly independent ($t = 2$ in this case) vectors whose cone contains $\boldsymbol{z} - \boldsymbol{r}$. Intuitively, these vectors $(\boldsymbol{y}_1, \boldsymbol{y}_2)$ form a coordinate system for searching the required z^*. For $i \in \{1, 2\}$, $\boldsymbol{y}_i' = \boldsymbol{y}_i + \boldsymbol{r}$, $\{\lambda_i\} = \lambda_i - \lfloor \lambda_i \rfloor$.

and thus $A(\boldsymbol{r} + \mu_1 \boldsymbol{y}_1 + \cdots + \mu_t \boldsymbol{y}_t) \leq \boldsymbol{b}$. In particular, the vector

$$\boldsymbol{z}^* = \boldsymbol{r} + (\lambda_1 - \lfloor \lambda_1 \rfloor)\boldsymbol{y}_1 + \cdots + (\lambda_t - \lfloor \lambda_t \rfloor)\boldsymbol{y}_t$$

is a solution to $A\boldsymbol{x} \leq \boldsymbol{b}$. Moreover, $\boldsymbol{z}^*$ is obtained from $\boldsymbol{z}$ by subtracting integer multiples of the integer vectors $\boldsymbol{y}_1, \dots, \boldsymbol{y}_t$, and thus $\boldsymbol{z}^*$ is integral as well. Finally, we have

$$\|\boldsymbol{z}^* - \boldsymbol{r}\|_\infty = \|(\lambda_1 - \lfloor \lambda_1 \rfloor)\boldsymbol{y}_1 + \cdots + (\lambda_t - \lfloor \lambda_t \rfloor)\boldsymbol{y}_t\|_\infty \leq \sum_{i=1}^{t} \|\boldsymbol{y}_i\|_\infty \leq n\Delta. \qquad \blacktriangleleft$$

Proof of Proposition 4.1. According to Lemma 4.5, there is a rational solution $\frac{1}{a}E\boldsymbol{b}$ to $A\boldsymbol{x} \leq \boldsymbol{b}$, where $E \in \mathbb{Z}^{n \times \ell}$, $a \in \mathbb{Z} \setminus \{0\}$, $|a| \leq \Delta$, and $\|E\|_\infty \leq \Delta$. We set $D := \frac{1}{a}E$. Now since $A\boldsymbol{x} \leq \boldsymbol{b}$ has an integral solution, Lemma 4.8 yields an integral solution $\boldsymbol{z}^*$ close to $D\boldsymbol{b}$, meaning $\|\boldsymbol{z}^* - D\boldsymbol{b}\|_\infty \leq n\Delta$. We set $\boldsymbol{d} := \boldsymbol{z}^* - D\boldsymbol{b}$. Then of course $D\boldsymbol{b} + \boldsymbol{d} = \boldsymbol{z}^*$ is an integral solution to $A\boldsymbol{x} \leq \boldsymbol{b}$. Moreover, we clearly have $\|\boldsymbol{d}\|_\infty \leq n\Delta$. It remains to show that even $\|\boldsymbol{d}\|_{\mathsf{frac}} \leq n\Delta^2$. Indeed, since $\boldsymbol{z}^*$ is integral, $\boldsymbol{b}$ is integral, and $D = \frac{1}{a}E$ with integral E, we know that in $\boldsymbol{d} = \boldsymbol{z}^* - D\boldsymbol{b}$, every entry can be written with a as its denominator. As this fraction has absolute value at most $n\Delta$ and $|a| \leq \Delta$, both numerator and denominator have absolute value at most $n\Delta^2$. $\blacktriangleleft$

5 Matching complexity lower bounds

In this section we prove the lower bounds for Corollaries 3.5 and 3.6.

Detecting WQOs. We begin with the lower bound for Corollary 3.5. That is, we show that deciding whether an existential Presburger formula defines a WQO is coNEXP hard. The idea is essentially the same as the coNP lower bound for detecting WQOs for quantifier-free

formulas in [3, Sec. 8]. The proof follows from reducing the satisfiability problem for Π_2 sentences to WQO-definability of existential Presburger formulas. Given an instance γ of a Π_2 sentence, we synthesize an existential Presburger formula φ and show that φ defines a WQO iff γ is satisfiable. The coNEXP-completeness of Π_2 sentences follows from the NEXP-completeness of Σ_2 sentences [17].

Consider an instance of a Π_2 sentence

$$\gamma \coloneqq \forall \boldsymbol{y} \colon \exists \boldsymbol{x} \colon \psi(\boldsymbol{x}, \boldsymbol{y})$$

where ψ is quantifier-free, $\boldsymbol{x}$ ranges over $\mathbb{Z}^n$, and $\boldsymbol{y}$ ranges over $\mathbb{Z}^m$. The goal is to construct an existential PA formula φ such that φ defines a WQO iff γ is true. First we define the formula

$$\Gamma(\boldsymbol{y}) \coloneqq \exists \boldsymbol{x} \psi(\boldsymbol{x}, \boldsymbol{y})$$

Now, define the existential Presburger formula φ as follows.

$$\begin{aligned}\varphi((x, \boldsymbol{x}), (y, \boldsymbol{y})) \coloneqq &(x < 0 \wedge y < 0) \vee (x > 0 \wedge y > 0) \vee (x < 0 \wedge y = 0) \\ &\vee (x = 0 \wedge y > 0) \vee (x = 0 \wedge y = 0) \\ &\vee (x < 0 \wedge y > 0 \wedge \Gamma(\boldsymbol{y})).\end{aligned}$$

Here, both $\boldsymbol{x}$ and $\boldsymbol{y}$ range over $\mathbb{Z}^m$, hence φ defines a relation in $\mathbb{Z}^{1+m} \times \mathbb{Z}^{1+m}$. Since the existential quantifiers of Γ can be moved in front of φ, φ is an existential Presburger instance.

▶ **Lemma 5.1.** *φ defines a WQO if and only if γ is true i.e. $\Gamma(w)$ is true $\forall\, \boldsymbol{w} \in \mathbb{Z}^m$.*

Proof. ($\Rightarrow$) Let φ define a WQO. Assume for contradiction there exists $\boldsymbol{w} \in \mathbb{Z}^m$ such that $\Gamma(\boldsymbol{w})$ is false. Notice that, by definition, $\varphi((-1, \boldsymbol{w}), (0, \boldsymbol{w}))$ and $\varphi((0, \boldsymbol{w}), (1, \boldsymbol{w}))$ are true. By transitivity, we must have that $\varphi((-1, \boldsymbol{w}), (1, \boldsymbol{w}))$ is true. Therefore, $\Gamma(\boldsymbol{w})$ must be true. This is a contradiction.
($\Leftarrow$) Let $\Gamma(\boldsymbol{w})$ be true for all $\boldsymbol{w} \in \mathbb{Z}^m$. Let A, B and C be sets of all vectors over $\mathbb{Z}^{1+m}$ with negative, zero and positive first component, respectively. It is easy to see that φ relates all vectors within each of A, B and C. Further, $\varphi(\boldsymbol{u}, \boldsymbol{v})$ is true if

- $\boldsymbol{u} \in A$ and $\boldsymbol{v} \in B$, or
- $\boldsymbol{u} \in B$ and $\boldsymbol{v} \in C$, or
- $\boldsymbol{u} \in A$ and $\boldsymbol{v} \in C$.

This means that φ must be a transitive, reflexive relation. Hence, φ trivially defines a WQO: in any infinite sequence $\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots$ of vectors over $\mathbb{Z}^{1+m}$, we can always find $\boldsymbol{u}_i, \boldsymbol{u}_j$ with $i < j$ such that both $\boldsymbol{u}_i, \boldsymbol{u}_j$ belong to either A or B or C. Since φ relates all vectors within each of these, the lemma follows. ◀

Monadic decomposability. Let us now show the lower bound for Corollary 3.6, i.e., that monadic decomposability for ∃PA formulas is coNEXP-hard. The idea is the same as the coNP-hardness for quantifier-free formulas in [2][2]. We reduce from the Π_2-fragment of Presburger arithmetic, which is known to be coNEXP-complete (see the discussion around Corollary 3.3). Suppose we are given a Π_2-formula $\varphi = \forall \boldsymbol{x} \exists \boldsymbol{y} \colon \psi(\boldsymbol{x}, \boldsymbol{y})$, where $\boldsymbol{x}$ contains n variables, and $\boldsymbol{y}$ contains m variables. We claim that the existential formula $\kappa = \exists \boldsymbol{y} \colon \psi(\boldsymbol{x}, \boldsymbol{y}) \vee z_1 = z_2$ (which has free variables $\boldsymbol{x}$, z_1, z_2) is monadically decomposable if and only if φ holds (see Section 5), which would clearly complete the reduction.

[2] As Anthony W. Lin and Matthew Hague explained to us, it would also not be difficult to adapt the idea of the coNP lower bound in [20, Lem. 2].

Indeed, if φ holds, then κ is satisfied for every vector in $\mathbb{Z}^{n+2}$ and is thus clearly monadically decomposable. Conversely, if φ does not hold, then there is some $\boldsymbol{a} \in \mathbb{Z}^n$ so that $\exists \boldsymbol{y} \colon \psi(\boldsymbol{a}, \boldsymbol{y})$ fails to hold. If κ were monadically decomposable, then so would the formula $\kappa \wedge \boldsymbol{x} = \boldsymbol{a}$, but this is equivalent to $z_1 = z_2$, which is clearly not monadically decomposable. This establishes the claim and hence coNEXP-hardness.

6 An exponential lower bound for quantifier elimination

Our main results show that one can eliminate a block of existential quantifiers with only an exponential blow-up. Using an example from [17, Thm. 2], we will now prove an exponential lower bound, even if constants are encoded in binary.

In the presence of binary encoded constants, we cannot use Weispfenning's lower bound argument [33, Thm. 3.1] (even for a singly exponential lower bound), which compares norms of vectors in finite sets defined by ∃PA vs. quantifier-free formulas. Indeed, it is a simple consequence of Pottier's bounds on Hilbert bases [24] that finite sets defined by ∃PA formulas consist of at most exponentially large vectors. With binary encoded constants, one easily constructs quantifier-free formulas defining finite sets of exponentially large vectors.

Instead, we measure the periodicity of infinite sets. Recall that every Presburger formula with one free variable defines an *ultimately periodic* set $S \subseteq \mathbb{Z}$, meaning that there are $n_0, p \in \mathbb{N}$, $p \geq 1$, such that for every $n \in \mathbb{Z}$, $|n| \geq n_0$, we have $n + p \in S$ if and only if $n \in S$. Such a p is called a *period* of S. For a formula φ with one free variable, we denote by $|\varphi|_{\mathsf{p}}$ the *smallest* period of the set defined by φ. In [17, Thm. 2], Haase constructs[3] a sequence $(\Phi_n(x))_{n \geq 0}$ of ∃PA formulas of size $O(n^2)$ such that $|\Phi_n|_{\mathsf{p}}$ is at least $2^{2^{\Omega(n)}}$. The following will imply that the formulas Φ_n require exponential-sized quantifier-free equivalents:

▶ **Lemma 6.1.** *Let φ be quantifier-free with one free variable. Then $|\varphi|_{\mathsf{p}} \leq 2^{|\varphi|}$.*

Proof. We prove this by structural induction. If φ is an atom $ax \leq b$, then $|\varphi|_{\mathsf{p}} = 1$. If φ is an atom $ax \equiv b \bmod c$ with constants a, b, c written in binary, then $|\varphi|_{\mathsf{p}} \leq |c| \leq 2^{|\varphi|}$. Moreover, $|\neg\varphi|_{\mathsf{p}} = |\varphi|_{\mathsf{p}}$. Now observe that if $S_1, S_2 \subseteq \mathbb{Z}$ are ultimately periodic sets, then we have $|S_1 \cup S_2|_{\mathsf{p}} \leq |S_1|_{\mathsf{p}} \cdot |S_2|_{\mathsf{p}}$ and $|S_1 \cap S_2|_{\mathsf{p}} \leq |S_1|_{\mathsf{p}} \cdot |S_2|_{\mathsf{p}}$. This implies $|\varphi_1 \vee \varphi_2|_{\mathsf{p}} \leq |\varphi_1|_{\mathsf{p}} \cdot |\varphi_2|_{\mathsf{p}} \leq 2^{|\varphi_1|+|\varphi_2|} \leq 2^{|\varphi|}$ and similarly $|\varphi_1 \wedge \varphi_2|_{\mathsf{p}} \leq |\varphi_1|_{\mathsf{p}} \cdot |\varphi_2|_{\mathsf{p}} \leq 2^{|\varphi_1|+|\varphi_2|} \leq 2^{|\varphi|}$. ◀

Now indeed, if $(\varphi_n)_{n \geq 0}$ is a sequence of quantifier-free equivalents of $(\Phi_n)_{n \geq 0}$, then for some constant $c > 0$ and large n, we have $2^{|\varphi_n|} \geq |\varphi_n|_{\mathsf{p}} = |\Phi_n|_{\mathsf{p}} \geq 2^{2^{cn}}$ and hence $|\varphi_n| \geq 2^{cn}$.

A More Details for Lemma 4.6

We recall Cramer's rule which has been used in the proof.

▶ **Proposition A.1** (Cramer's rule). *Let a system of n linear equations for n unknowns be represented as*

$$Ax = b\,,$$

where A is an invertible $(n \times n)$ matrix. This system has as unique solution given by $x = (x_1, x_2, \ldots, x_n)$ where,

$$x_i = \frac{\det(A_i)}{\det(A)}$$

A_i is the matrix formed by replacing the ith column of A by b.

B Sets with large periods

The formula Φ_n constructed by Haase in [17, Thm. 2] defines the set

$$S_n = \{a \in \mathbb{N} \mid \exists b\colon 1 < b < 2^n,\ b \text{ divides } a\}.$$

and Haase argues that the smallest period of S_n is $2^{2^{\Omega(n)}}$. While the latter is true, the argument in [17] does not quite show this. The proof of [17, Thm. 2] argues that the smallest period of S_n is the least common multiple of the numbers $\{1, \ldots, 2^n - 1\}$, which is lower bounded by $2^{2^{\Omega(n)}}$ according to Nair [22]. However, as we will see, the smallest period of S_n is in fact a slightly smaller number. It is still lower bounded $2^{2^{\Omega(n)}}$, but this requires a different argument. We present a correction.

An easy fix for the result would be to instead define the set

$$\begin{aligned} S'_n &= \{a \in \mathbb{N} \mid \exists b\colon 1 < b < 2^n,\ b \text{ does not divide } a\} \\ &= \{a \in \mathbb{N} \mid \exists b, c\colon 1 < b < 2^n,\ 1 \le c < 2^n,\ b \text{ divides } a + c\}, \end{aligned}$$

for which a simple modification of the formulas Φ_n in [17] yields a polynomial-sized $\exists$PA formula Φ'_n. Moreover, the smallest period of S'_n is indeed the least common multiple of $\{1, \ldots, 2^n - 1\}$, and so Nair's bound would apply.

However, one can show that the smallest period of S_n is indeed lower bounded by $2^{2^{\Omega(n)}}$, just not by the least common multiple of $\{1, \ldots, 2^n - 1\}$. For any natural $n \in \mathbb{N}$, define the *primorial* of n, in symbols $n\#$, as the product of all primes $\leq n$. Thus, if $p_1, p_2, \ldots$ is the sequence of all primes in ascending order and $\pi(n)$ is the number of all prime numbers $\leq n$, then

$$n\# = \prod_{i=1}^{\pi(n)} p_i.$$

▷ Claim B.1. The smallest period of S_n is $2^n\#$.

Proof. Clearly, $2^n\#$ is a period of S_n: S_n is the set of all numbers that have a prime divisor among $\{2, \ldots, 2^n - 1\}$, and adding or subtracting the product of all these primes does not change that.

It remains to show that $2^n\#$ is the smallest period of S_n. Suppose k is a period of S_n. We will show that every prime p with $1 < p < 2^n$ is a divisor of k, which will clearly establish the claim. Let $\{p_1, \ldots, p_\ell\}$ be the primes in $\{2, \ldots, 2^n - 1\}$. Towards a contradiction, suppose there is a prime p_j, $1 \leq j \leq \ell$, that does not divide k. By the Chinese Remainder Theorem, the system of congruences

$$\begin{aligned} x &\equiv 1 \pmod{p_i} && \text{for each } i \in \{1, \ldots, \ell\},\ i \neq j, \\ x &\equiv -k \pmod{p_j} \end{aligned}$$

has infinitely many solutions $a \in \mathbb{N}$. For each such a, we have $a \notin S_n$, because a is not divisible by any p_i, $1 \leq i \leq \ell$. However, $a + k$ is divisible by p_j, and thus $a + k \in S_n$. Therefore, k cannot be a period of S_n. ◁

Using Claim B.1, we can now obtain the $2^{2^{\Omega(n)}}$ lower bound for the smallest period of S_n. This is because equation (3.14) of [27] implies that for every $m \geq 563$, we have $m\# \geq 2^{m-1}$. In particular, for $n \geq 10$, we have $2^n\# \geq 2^{2^n - 1}$. This proves that $|\Phi_n|_{\mathsf{p}}$ is lower bounded by $2^{2^{\Omega(n)}}$.

C Incorrect lower bounds on eliminating a block of existential quantifiers

We elaborate on a flaw in Weispfenning's paper [33] which is a consequence of misinterpreting results from the literature, from which he incorrectly concludes that the elimination of a block of existential quantifiers from a formula of Presburger arithmetic results in an inherent doubly exponential blow-up.

The main result of Section 3 of [33] is Theorem 3.1, which states that performing quantifier elimination on *arbitrary* formulas of Presburger arithmetic results in an inherent triply exponential blow-up, assuming unary encoding of numbers. To this end, Weispfenning invokes a result by Fischer and Rabin [11] who showed that there exists a function $g\colon \mathbb{N} \to \mathbb{N}$ such that for almost all n,

$$g(n) \geq 2^{2^{2^{n+1}}},$$

and who gave a family of formulas $\Phi_n(x, y, z)$ of Presburger arithmetic of size linear in n such that $\Phi_n(x, y, z)$ holds if and only if $0 \leq x, y, z < g(n)$ and $x \cdot y = z$. He then goes on concluding that the smallest quantifier-free formula defining the set $\{z \in \mathbb{Z} \mid \Phi_n(1, z, z)\}$ requires a formula of size at least $g(n)$, assuming unary encoding of numbers.

Weispfenning then continues sketching how to adapt this approach in the presence of a bounded number of quantifier alternations. To this end, he appeals to a result by Fürer [12], which states that for some constant $r > 0$, one can define multiplication up to

$$2^{2^{(n/a)^{ra}}} \tag{4}$$

using a formula of length n and a quantifier alternations. Adapting his line of reasoning from the general case, Weispfenning applies this to $a = 1$ and concludes that eliminating a block of existential quantifiers yields an inherent doubly exponential blow up. Fürer does indeed claim the existence of such a family in the third paragraph in [12, p. 108]. However, a close inspection of Fürer's proof reveals that these formulas are not constructed *for every a and n*, but only *for infinitely many a and n*. More specifically, Fürer supposes some given $k, m \in \mathbb{N}$ and constructs a formula of length $c(mk \log k + 1)$ and $2m + d$ quantifier alternations (see the seventh paragraph in [12, p. 108]). Here, c and d appear to be unspecified constants. By choosing $a = 2m + d$ and $n = c(mk \log k + 1)$, Fürer's claims then yield multiplication up to (4) for a suitable $r > 0$. In particular, Fürer's construction does not yield the existence of such formulas for *every* $a \in \mathbb{N}$.

Of course, from the fact that existential Presburger arithmetic allows for defining ultimately periodic sets with a doubly exponential period, cf. Appendix B, it is not unreasonable to believe that this could somehow be turned into a lower bound similar to the one claimed by Weispfenning. However, such large periods can already be produced by an exponential intersection of divisibility constraints and thus do not imply a doubly exponential lower bound on the formula size after eliminating a block of existentially quantified variables.

Forcing, Transition Algebras, and Calculi

Abstract

We bring forward a logical system of *transition algebras* that enhances many-sorted first-order logic using features from dynamic logics. The sentences we consider include compositions, unions, and transitive closures of transition relations, which are treated similarly to the actions used in dynamic logics in order to define necessity and possibility operators. This leads to a higher degree of expressivity than that of many-sorted first-order logic. For example, one can finitely axiomatize both the finiteness and the reachability of models, neither of which are ordinarily possible in many-sorted first-order logic. We introduce syntactic entailment and study basic properties such as compactness and completeness, showing that the latter does not hold when standard finitary proof rules are used. Consequently, we define proof rules having both finite and countably infinite premises, and we provide conditions under which completeness can be proved. To that end, we generalize the forcing method introduced in model theory by Robinson from a single signature to a category of signatures, and we apply it to obtain a completeness result for signatures that are at most countable.

1 Introduction

Algebraic specification is one of the main approaches to formal methods that supports both the formal specification of software and hardware systems and the formal verification of their requirements. The underlying logic of an algebraic specification language is often presented as an institution [16], a category-theoretic formalization of the intuitive notion of logic that includes its syntax, semantics and the satisfaction relation between them. A lot of theoretical computer science has been developed within institution theory [9, 31, 10] based on the principle that formal specification should be based rigorously upon a concrete institution. Two notable specification languages have been designed by following this principle: CafeOBJ in Japan [11] and CASL in Europe [1]. However, there also is an exception given by the Maude system [3], which was originally developed at SRI International in the United States. The underlying logic of Maude, called rewriting logic [25], is not given as an institution, which has led to a series of developments that diverged from mainstream institution-theoretic approaches to topics such as modularization and heterogeneity [4].

Motivation. The main goal of the present study is to apply a body of methods and principles developed within institutional model theory for defining a denotational semantics of algebraic specification languages that are executable by term rewriting such that:

1. it enjoys the modular properties of the logic underlying CafeOBJ such as the *satisfaction condition* for signature morphisms, and therefore it can be formalized as an *institution*;
2. it has the rich expressivity of rewriting logic, in the sense that it can provide a semantics for the Maude language, in general, and for its strategy language [12], in particular.

In algebraic specification languages executable by rewriting such as Maude and CafeOBJ, systems are specified using two kinds of atomic statements: (*a*) *equations*, which define an algebraic structure on system states, with constructors and derived operations, for example; and (*b*) *transition rules*, which capture the behaviour of a system by telling us how the states may change as a result of certain actions. In the present contribution, we propose a logic of *transition algebras* where the models consist of many-sorted algebras equipped with binary relations that give semantics to the transition rules. From transition rules one can construct *actions* by applying composition, union, and the Kleene star (i.e., the reflexive and transitive closure of a relation). For the sake of simplicity, we omit the subsorting relation [14].

Many-sorted logical systems. Many-sorted logics are widely acknowledged as being suitable for applications in computer science. However, in pure mathematical logic, they tend to be classified as "inessential variations" [28] of their unsorted forms. This might be true w.r.t. some classical aspects such as compactness or axiomatizability. However, in general, moving from the unsorted to the many-sorted case is a far from trivial task. Allowing for multiple sorts, and thus for multiple carriers in models, some of which may be empty, alters the properties of the logics and significantly increases the complexity of proofs.

An important example of logical property that does not have a straightforward many-sorted generalization is Craig interpolation [7]. This property generally holds in unsorted first-order logic, but fails to hold in the many-sorted variant of the logic; a counterexample can be found, for example, in [2]. Finding the most general criteria for Craig interpolation property was an open problem originally stated in [33]. A solution based on techniques advanced in institutional model theory was provided in [22] after nearly two decades.

Moreover, as noticed in [13], if we admit models with potentially empty carrier sets, then proof rules for unsorted (or single-sorted) first-order logic may be unsound for its many-sorted counterpart. This already suggests that generalizations to other variants of many-sorted first-order logic may pose difficulties. The completeness results proved in an institutional setting, such as [29, 21, 18] are applicable to logical systems where models interpret sorts as non-empty sets. In fact, we are not aware of any completeness result for many-sorted first-order logic in which models interpret sorts as possibly empty sets.

Forcing. In the present contribution, we prove the completeness of the many-sorted logic of transition algebras by applying *forcing*. This technique was originally introduced by Paul Cohen [5, 6] in set theory to show the independence of the continuum hypothesis from the other axioms of Zermelo-Fraenkel set theory. Robinson [30] developed an analogous theory of forcing in model theory. In our setting, forcing is a technique used for constructing expanded models of consistent sets of sentences. More specifically, it allows one to expand a set of sentences while preserving satisfiability even if compactness does not hold in the underlying logical system. Transition algebra is not compact for the same reason classical dynamic propositional logic is not compact. Therefore, the classical Henkin method for proving completeness, which relies on compactness, is not applicable to transition algebra. Another

issue arises when proving completeness from the fact that we work with models with empty carriers, because the addition of constants does not necessarily preserve the consistency of theories. Therefore, we generalize the forcing method from a single signature to a category of signatures using ideas from institutional model theory such that the so-called Henkin constants can be added when needed in a way that preserves consistency.

An extended version of this work, which includes all proofs, is available on arXiv [23].

2 Transition algebra

In this section, we define *the logic of many-sorted transition algebras*, or *transition algebra* (TA), for short. We present, in order: signatures, models, sentences, and the TA satisfaction relation.

Signatures. The signatures we consider are ordinary algebraic signatures endowed with polymorphic transition labels and monotonic function symbols. We denote them by tuples of the form $(S, F \supseteq M, L)$, where:

- (S, F) is a many-sorted algebraic signature consisting of a set S of *sorts* and a family $F = \{F_{w,s} \mid w \in S^*, s \in S\}$ of sets of *function symbols*;
- M is a family of subsets $M_{w,s} \subseteq F_{w,s}$ of *monotonic* function symbols; and
- L is a set whose elements we call *transition labels*.

We often write $\sigma\colon w \to s \in F$ to indicate that $\sigma \in F_{w,s}$, and we refer to $w \in S^*$ and $s \in S$ as the *arity* and *sort*, respectively, of the symbol σ. Under this notation, F can also be regarded as an ordinary set consisting of *function declarations* of the form $\sigma\colon w \to s$. When w is the empty arity, we may speak of $\sigma\colon \to s$ as a *constant* (symbol) of sort s.

Throughout the paper, we let Σ, Σ', and Σ_i range over arbitrary signatures of the form $(S, F \supseteq M, L)$, $(S', F' \supseteq M', L')$, and $(S_i, F_i \supseteq M_i, L_i)$, respectively.

As usual in institution theory [9, 31], important constructions such as signature extensions with constants as well as open formulae and quantifiers are realized in a multi-signature setting, so moving between signatures is common. A *signature morphism* $\chi\colon \Sigma \to \Sigma'$ consists of an ordinary algebraic signature morphism $\chi\colon (S, F) \to (S', F')$ such that $\chi(M) \subseteq M'$ together with a function $L \to L'$, which we typically denote using the same symbol, χ.

▶ Remark 1. Signature morphisms compose componentwise. Their composition has identities and is associative, thus leading to a category Sig of signatures.

Models. Given a signature Σ, a Σ-*model* $\mathfrak{A}$ is an (S, F)-algebra $\mathfrak{A}$ that interprets every label $\lambda \in L$ as a *many-sorted transition relation* $\lambda^{\mathfrak{A}} \subseteq \mathfrak{A} \times \mathfrak{A}$ (that is, $\lambda^{\mathfrak{A}} = \{\lambda^{\mathfrak{A}}_s \mid s \in S\}$ and $\lambda^{\mathfrak{A}}_s \subseteq \mathfrak{A}_s \times \mathfrak{A}_s$ for all sorts $s \in S$) that respects monotonic function symbols (that is, for all function symbols $\sigma\colon s_1 \cdots s_n \to s$ in M, all tuples $(a_1, \ldots, a_n) \in \mathfrak{A}_{s_1} \times \cdots \times \mathfrak{A}_{s_n}$, all indices $k \in \{1, \ldots, n\}$, and all elements $b \in \mathfrak{A}_{s_k}$, if $\langle a_k, b\rangle \in \lambda^{\mathfrak{A}}_{s_k}$ then $\langle \sigma^{\mathfrak{A}}(a_1 \ldots, a_k, \ldots, a_n), \sigma^{\mathfrak{A}}(a_1 \ldots, b, \ldots, a_n)\rangle \in \lambda^{\mathfrak{A}}_s$).

A *homomorphism* $h : \mathfrak{A} \to \mathfrak{B}$ over a signature Σ is an algebraic (S, F)-homomorphism that preserves transitions: $h(\lambda^{\mathfrak{A}}) \subseteq \lambda^{\mathfrak{B}}$ for all $\lambda \in L$. It is easy to see that Σ-homomorphisms form a category, which we denote by $\mathsf{Mod}(\Sigma)$, under their obvious componentwise composition.

▶ Remark 2. Every signature morphism $\chi\colon \Sigma \to \Sigma$ determines a *model-reduct functor* $\_{\restriction_\chi}\colon \mathsf{Mod}(\Sigma') \to \mathsf{Mod}(\Sigma)$ such that:

- for every Σ'-model $\mathfrak{A}'$, $(\mathfrak{A}'{\restriction_\chi})_s = \mathfrak{A}'_{\chi(s)}$ for each sort $s \in S$, $\sigma^{\mathfrak{A}'{\restriction_\chi}} = \chi(\sigma)^{\mathfrak{A}'}$ for each symbol $\sigma \in F$, and $\lambda^{\mathfrak{A}'{\restriction_\chi}} = \chi(\lambda)^{\mathfrak{A}'}$ for each label $\lambda \in L$; and
- for every Σ'-homomorphism $h'\colon \mathfrak{A}' \to \mathfrak{B}'$, $(h'{\restriction_\chi})_s = h'_{\chi(s)}$ for each $s \in S$.

Moreover, the mapping $\chi \mapsto \_{\restriction_\chi}$ is functorial.

For any signature morphism $\chi : \Sigma \to \Sigma'$, any Σ-model $\mathfrak{A}$ and any Σ'-model $\mathfrak{A}'$ if $\mathfrak{A} = \mathfrak{A}'|_\chi$, we say that $\mathfrak{A}$ is the *χ-reduct* of $\mathfrak{A}'$, and that $\mathfrak{A}'$ is a *χ-expansion* of $\mathfrak{A}$. For example, for any many-sorted set X (say, of variables) that is disjoint from the set of constant-function symbols in Σ, consider the inclusion morphism $\iota_X : \Sigma \hookrightarrow \Sigma[X]$, where $\Sigma[X] = (S, F[X] \supseteq M, L)$ is the signature obtained from $\Sigma = (S, F \supseteq M, L)$ by adding the elements of X to F as new constant-operation symbols of appropriate sort. Then an expansion of a Σ-model $\mathfrak{A}$ along ι_X can be seen as a pair $\langle \mathfrak{A}, g : X \to \mathfrak{A} \rangle$, where g is a valuation of X in $\mathfrak{A}$.

As in many-sorted algebra, there is a special, initial model in $\mathsf{Mod}(\Sigma)$, which we denote by T_Σ, whose elements are ground terms built from function symbols, and whose transition relations are all empty. The Σ-model $T_\Sigma(X)$ of terms with variables from X is defined as the ι_X-reduct of $T_{\Sigma[X]}$; i.e., $T_\Sigma(X) = T_{\Sigma[X]}|_{\iota_X}$. The following property is an immediate consequence of the initiality of T_Σ.

▶ Remark 3. Any signature morphism $\chi\colon \Sigma \to \Sigma'$ determines uniquely a Σ-homomorphism $T_\Sigma \to T_{\Sigma'}|_\chi$. In order to simplify notations later on, we denote that homomorphism by $\chi\colon T_\Sigma \to T_{\Sigma'}|_\chi$; therefore, for any Σ-term $\sigma(t_1, t_2, \ldots, t_n)$, we have $\chi(\sigma(t_1, t_2, \ldots, t_n)) = \chi(\sigma)(\chi(t_1), \chi(t_2), \ldots, \chi(t_n))$.

Sentences. The *actions* over a signature Σ are defined by the following grammar:

$$\mathfrak{a} ::= \lambda \mid \mathfrak{a} \fatsemi \mathfrak{a} \mid \mathfrak{a} \cup \mathfrak{a} \mid \mathfrak{a}^*$$

where λ is a transition label of Σ. We let A denote the set of all actions obtained from transition labels declared in a signature Σ, and we extend the notational convention that we use for the components of signatures to their corresponding sets of actions; that is, we usually denote by A' the set of actions over a signature Σ', by A_i the set of actions over a signature Σ_i, and so on. Moreover, through a slight abuse of notation, we also denote by $\chi\colon A \to A'$ the canonical map determined by a signature morphism $\chi\colon \Sigma \to \Sigma'$.

To define sentences, we assume a countably infinite set of *variable names* $\{v_i \mid i < \omega\}$. A *variable* for a signature Σ is a triple $\langle v_i, s, \Sigma \rangle$, where v_i is a variable name and s is a sort in Σ – the third component is used only to ensure that variables are distinct from the constant-operation symbols declared in Σ, which is essential when dealing with quantifiers. The set $\mathsf{Sen}(\Sigma)$ of *sentences* over Σ is given by the following grammar:

$$\phi ::= t_1 = t_2 \mid t_1 \overset{\mathfrak{a}}{\Rightarrow} t_2 \mid \neg\phi \mid \bigvee \Phi \mid \exists X \cdot \phi'$$

where (a) t_1 and t_2 are (S, F)-terms of the same sort; (b) $\mathfrak{a} \in A$ is an action; (c) Φ is a finite set of Σ-sentences; and (d) X is a finite set of variables for Σ and ϕ' is a $\Sigma[X]$-sentence.

When $\Phi = \{\phi_1, \phi_2, \ldots, \phi_n\}$, we may write $\phi_1 \vee \phi_2 \vee \cdots \vee \phi_n$ instead of $\bigvee \Phi$. Besides the above core connectives, we also make use of the following convenient (and standard) abbreviations: $\bigwedge \Phi := \neg \bigvee \{\neg\phi \mid \phi \in \Phi\}$ for finite conjunctions; $\bot := \bigvee \emptyset$ for falsity; $\top := \bigwedge \emptyset = \neg\bot$ for truth; $\phi_1 \to \phi_2 := \neg\phi_1 \vee \phi_2$ for implications; and $\forall X \cdot \phi' := \neg\exists X \cdot \neg\phi'$ for universally quantified sentences.

▶ Remark 4. Any signature morphism $\chi\colon \Sigma \to \Sigma'$ can be canonically extended to a *sentence-translation function* $\chi\colon \mathsf{Sen}(\Sigma) \to \mathsf{Sen}(\Sigma')$ given by:

- $\chi(t_1 = t_2) = (\chi(t_1) = \chi(t_2))$;
- $\chi(t_1 \overset{\mathfrak{a}}{\Rightarrow} t_2) = \chi(t_1) \overset{\chi(\mathfrak{a})}{\Longrightarrow} \chi(t_2)$;
- $\chi(\neg\phi) = \neg\chi(\phi)$;
- $\chi(\bigvee \Phi) = \bigvee \chi(\Phi)$; and
- $\chi(\exists X \cdot \phi') = \exists X' \cdot \chi'(\phi')$, where $X' = \{\langle x, \chi(s), \Sigma' \rangle \mid \langle x, s, \Sigma \rangle \in X\}$ and $\chi' : \Sigma[X] \to \Sigma'[X']$ is the extension of χ mapping each variable $\langle x, s, \Sigma \rangle \in X$ to $\langle x, \chi(s), \Sigma' \rangle \in X'$.

Moreover, this sentence-translation mapping is functorial in χ.

For the sake of simplicity, we identify variables only by their name and sort, provided that there is no danger of confusion. Using this convention, each inclusion morphism $\iota\colon \Sigma \hookrightarrow \Sigma'$ determines an inclusion function $\iota\colon \mathsf{Sen}(\Sigma) \hookrightarrow \mathsf{Sen}(\Sigma')$, which corresponds to the approach of classical model theory. This simplifies the presentation greatly. A situation when we cannot apply this convention arises when translating a Σ-sentence $\exists X \cdot \phi$ along the inclusion $\iota_X : \Sigma \hookrightarrow \Sigma[X]$.

Satisfaction relation. Actions are interpreted as binary transition relations in models. Given a model $\mathfrak{A}$ over a signature Σ, and actions $\mathfrak{a}, \mathfrak{a}_1, \mathfrak{a}_2 \in A$, we have:

- $(\mathfrak{a}_1 \fatsemi \mathfrak{a}_2)^{\mathfrak{A}} = \mathfrak{a}_1^{\mathfrak{A}} \fatsemi \mathfrak{a}_2^{\mathfrak{A}}$ (i.e., diagrammatic composition of binary relations);
- $(\mathfrak{a}_1 \cup \mathfrak{a}_2)^{\mathfrak{A}} = \mathfrak{a}_1^{\mathfrak{A}} \cup \mathfrak{a}_2^{\mathfrak{A}}$ (the union of binary relations); and
- $(\mathfrak{a}^*)^{\mathfrak{A}} = (\mathfrak{a}^{\mathfrak{A}})^*$ (the reflexive and transitive closure of binary relations).

We define the *satisfaction relation* between models and sentences as follows:

- $\mathfrak{A} \models t_1 = t_2$ iff $t_1^{\mathfrak{A}} = t_2^{\mathfrak{A}}$;
- $\mathfrak{A} \models t_1 \overset{\mathfrak{a}}{\Rightarrow} t_2$ iff $(t_1^{\mathfrak{A}}, t_2^{\mathfrak{A}}) \in \mathfrak{a}^{\mathfrak{A}}$;
- $\mathfrak{A} \models \neg\phi$ iff $\mathfrak{A} \not\models \phi$,
- $\mathfrak{A} \models \bigvee \Phi$ iff $\mathfrak{A} \models \phi$ for some sentence $\phi \in \Phi$, and
- $\mathfrak{A} \models \exists X \cdot \phi'$ iff $\mathfrak{A}' \models \phi'$ for some expansion $\mathfrak{A}'$ of $\mathfrak{A}$ to the signature $\Sigma[X]$.

For the sake of simplicity, we write $d_1 \overset{\mathfrak{a}}{\Longrightarrow} d_2$ if $\langle d_1, d_2 \rangle \in \mathfrak{a}^{\mathfrak{A}}$.

Let ϕ, ϕ' be sets of Σ-sentences, $\mathfrak{A}$ a Σ-model. We also use the following notations:

- $\mathfrak{A} \models \Phi$ iff $\mathfrak{A} \models \phi$ for all sentences $\phi \in \Phi$;
- $\Gamma \models \Phi$ iff $\mathfrak{A} \models \Gamma$ implies $\mathfrak{A} \models \Phi$ for all Σ-models $\mathfrak{A}$.

In particular, we write $\Gamma \models \phi$ instead of $\Gamma \models \{\phi\}$ for any set of sentences Γ and any single sentence ϕ.

▶ **Proposition 5.** *For all signature morphisms $\chi : \Sigma \to \Sigma'$, all Σ'-models $\mathfrak{A}$ and all sentences $\phi \in \mathsf{Sen}(\Sigma)$ we have: $\mathfrak{A}{\restriction_\chi} \models \phi$ iff $\mathfrak{A} \models \chi(\phi)$.*

▶ **Example 6** (CCS)**.** To illustrate the expressivity of transition algebra, we refer to Robin Milner's *calculus of communicating systems* (CCS) [26, 27], which is emblematic of a broad family of formal languages used for modelling and reasoning about concurrency. In a nutshell, CCS is a process calculus that enables syntactic descriptions of concurrent systems to be written, and subsequently manipulated and analysed, based on two kinds of atomic entities – process identifiers and channel names – and a handful of composition operators.

To start, we assume two sets: *PI* of *process identifiers*, and *CN* of so-called *channel names*, which capture the interaction capabilities of processes. Take, for instance, the following famous quote by Alfréd Rényi: "A mathematician is a machine for turning coffee into theorems" [32]. This can be modelled in CCS as an interaction between two processes, a mathematician and a coffee vending machine, that trade coffee (in exchange, perhaps, of coins or some other form of payment) in order to jointly produce theorems. Hence, we can consider theorems, coffee, and coins as types of interactions between the two processes.

For each channel name $c \in CN$, we let $\overline{c}$ be a new symbol, distinct from all channel names, called the *co-name* of c. We also let $\overline{CN} = \{\overline{c} \mid c \in CN\}$ be the set of all co-names, and $L = CN \cup \overline{CN}$ be the set of *labels*. Intuitively, we may regard the symbols in CN as inputs of some process, and the symbols in $\overline{CN}$ as outputs. Besides labels, we also consider an additional *silent-action* symbol, denoted τ, that indicates an internal, unobservable behaviour of the system under consideration. Altogether, we refer to the symbols in $A = L \cup \{\tau\}$ as CCS *actions*.[1] *Processes* over CN and PI are defined according to the following grammar:

[1] Although they share the name "action", CCS actions are conceptually very different from the actions we have defined for transition algebra. To distinguish the two, we always prefix the former by CCS.

$$P \ ::= \ 0 \mid \pi \mid a \,.\, P \mid P + P \mid P \text{ `|' } P \mid P \setminus k$$

where (a) 0 denotes a special terminal, inactive process; (b) $\pi \in PI$ is a process identifier; (c) $a \in A$ is a CCS action, which can be used to prefix a process P in order to form a new process, $a \,.\, P$, that intuitively performs a then continues as P; (d) '+' denotes the non-deterministic choice between two processes; (e) '|' denotes the parallel composition of two processes; and (f) $k \in CN$ is a channel name, which can be used in expressions like $P \setminus k$ to form a new, restricted process with the same interaction capabilities as P except for the labels k and $\overline{k}$. To simplify the presentation, we omit the relabelling operator because it plays no role in the examples we consider in this paper and it could be added with ease if needed. For a comprehensive account of CCS, see for example [27].

A CCS *context*, or *program*, is a set of *declarations* of the form $\pi ::= P$, where $\pi \in PI$ is a process identifier and P is a process conforming to the grammar introduced above, such that any two distinct declarations have distinct left-hand sides; in other words, we do not admit multiple declarations of the same process identifier within a given context.

Using this syntax, the interaction between mathematicians and coffee vending machines announced in Alfréd Rényi's quote can be formalized as a parallel composition of processes over $PI = \{\texttt{Mathematician}, \texttt{CoffeeVM}\}$ and $CN = \{\texttt{coin}, \texttt{coffee}, \texttt{theorem}\}$, which we write as $\texttt{Mathematician} \mid \texttt{CoffeeVM}$, where `Mathematician` and `CoffeeVM` are process identifiers "defined" recursively according to the following context:

- $\texttt{Mathematician} ::= \overline{\texttt{coin}} \,.\, \texttt{coffee} \,.\, \overline{\texttt{theorem}} \,.\, \texttt{Mathematician}$,
- $\texttt{CoffeeVM} ::= \texttt{coin} \,.\, \overline{\texttt{coffee}} \,.\, \texttt{CoffeeVM}$.

Thanks to the expressivity of transition algebra, we can easily capture both the syntax and the operational semantics of CCS. For the syntax of processes, it suffices to consider a many-sorted TA signature with $S = \{\texttt{Channel}, \texttt{Action}, \texttt{Process}\}$ and with F given by the following function symbols (which employ OBJ's [15] and Maude's [3] mixfix notation):

- $0\colon \to \texttt{Process}$,
- $\pi\colon \to \texttt{Process}$ for each process identifier $\pi \in PI$,
- $a\colon \to \texttt{Action}$ for each CCS action $a \in A$,
- $\_\,.\,\_\colon \texttt{Action Process} \to \texttt{Process}$,
- $\_ + \_\,,\ \_ \mid \_\colon \texttt{Process Process} \to \texttt{Process}$,
- $k\colon \to \texttt{Channel}$ for each channel name $k \in CN$,[2]
- $\_ \setminus \_\colon \texttt{Process Channel} \to \texttt{Process}$.

The parallel-composition operator is the only monotonic function symbol of this example. For convenience, we also declare the parallel-composition operator and the non-deterministic choice as associative, commutative, and with identity 0. These properties can be presented – as usual in algebraic specification – using plain equations. To capture and reason about the behaviour of processes, we regard each CCS action as an atomic action (i.e., a transition label) in transition algebra – and those are the only TA labels that we consider here.

The transitional semantics of a CCS program *Pgm* is given by the following collection of axioms. The transition-algebra sentences below are all universally quantified over variables P, P', Q, Q' of sort `Process` and k of sort `Channel`; however, we drop the quantifiers in order to simplify the notation. We also use names for the axioms (at the beginning of each line) that are indicative of the transition rules defined in [27].

[2] To avoid subsorting, we overload channel names, which can be seen either as constants of sort `Channel` or as constants of sort `Action` depending on the context in which they are used.

- (Act) $a \,.\, P \overset{a}{\Rightarrow} P$ for all $a \in A$,
- (Sum) $P \overset{a}{\Rightarrow} P' \to P + Q \overset{a}{\Rightarrow} P'$ for all $a \in A$,
- (Com) $P \overset{c}{\Rightarrow} P' \wedge Q \overset{\overline{c}}{\Rightarrow} Q' \to P \mid Q \overset{\tau}{\Rightarrow} P' \mid Q'$ for all $c \in CN$,
- (Res) $P \overset{a}{\Rightarrow} P' \wedge a \neq k \wedge \overline{a} \neq k \to P \setminus k \overset{a}{\Rightarrow} P' \setminus k$ for all $a \in A$,[3]
- (Con) $P \overset{a}{\Rightarrow} P' \to \pi \overset{a}{\Rightarrow} P'$ for all $\pi ::= P \in Pgm$.

To simplify some of the notations used later on in the paper, for any process P and any non-empty and finite sequence $K = (k_i \mid 1 \leq i \leq n)$ of channel names, we also write $P \setminus K$ in place of $P \setminus k_1 \setminus \cdots \setminus k_n$ and we consider the following derived form of the axiom (Res):

- (Res^*) $P \overset{a}{\Rightarrow} P' \wedge \bigwedge\{a \neq k_i \wedge \overline{a} \neq k_i \mid 1 \leq i \leq n\} \to P \setminus K \overset{a}{\Rightarrow} P' \setminus K$ for all $a \in A$.

Similar encodings of CCS in languages that support transitions can be found in the rewriting-logic literature, notably in [24, 34, 8]. But the encodings presented therein rely on a notion of *derivative* of a process instead of reasoning about plain processes, which is usually because labelled transitions cannot be used in the conditions of Horn clauses such as *Sum* and *Com*. That is, the axiomatization is done in terms of pairs $\langle \alpha, P \rangle$, where P is a process and α is a CCS action or a sequence of CCS actions leading to P. In TA, this additional step can be avoided because the use of labelled transitions is unrestricted, which allows our axioms to be nearly to-the-letter transcriptions of Robin Milner's rules for CCS.

3 Entailment relations

In this section, we define the proof-theoretic properties necessary for proving our results such as entailment relation, soundness and completeness. Before we proceed, let us recall an example from [13], which shows that classical rules of first-order deduction are not sound.

▶ **Example 7.** Let $\Sigma = (S, F)$ be an algebraic signature consisting of:

- two sorts, that is, $S = \{Elt, Bool\}$, and
- five function symbols $F = \{true :\to Bool, false :\to Bool, \sim\_ : Bool \to Bool, \_\&\_ : Bool\ Bool \to Bool, \_ + \_ : Bool\ Bool \to Bool, foo : Elt \to Bool\}$.

Let Γ be a set of sentences over Σ which consists of the following sentences:

- $\sim true = false$ and $\sim false = true$,
- $\forall y \cdot y \ \& \sim y = false$ and $\forall y \cdot y \ \& \ y = y$,
- $\forall y \cdot y + \sim y = true$ and $\forall y \cdot y \ + \ y = y$, and
- $\forall x \cdot \ \sim foo(x) = foo(x)$.

Using the ordinary rules of first-order deduction, we can show that

$$\begin{aligned} true &= foo(x) + \sim foo(x) \\ &= foo(x) + foo(x) \\ &= foo(x) \\ &= foo(x) \ \& \ foo(x) \\ &= foo(x) \ \& \sim foo(x) \\ &= false \end{aligned} \tag{1}$$

As a result, one would expect $true = false$ to hold in all algebras satisfying Γ. But that is not the case. To see why, suppose $\mathfrak{A}$ is the algebra obtained from T_Σ through a factorization under the congruence relation $\equiv_\Gamma$ generated by Γ, that is:

[3] As usual in CCS, we extend the over-line notation employed for channel co-names to a bijection $\overline{\cdot} : A \to A$ given by $\overline{\overline{c}} = c$ for all channel names c and by $\overline{\tau} = \tau$ for the silent action.

- $\mathfrak{A}_{Bool} = \{true/_{\equiv_\Gamma}, false/_{\equiv_\Gamma}\}$ and $\mathfrak{A}_{Elt} = \emptyset$,
- $\sim$ is interpreted as the negation, & as the conjunction and + as the disjunction, and
- $foo^{\mathfrak{A}}$ is the empty function.

Clearly, the algebra $\mathfrak{A}$ satisfies the sentences in Γ referring to the negation, conjunction, and disjunction of booleans. Moreover, since there is no function from $\{x\}$ to $\mathfrak{A}_{Elt} = \emptyset$, we have $\mathfrak{A} \models_\Sigma \forall x \cdot \sim foo(x) = foo(x)$. It follows that $\mathfrak{A} \models_\Sigma \Gamma$ but $\mathfrak{A} \not\models_\Sigma true = false$.

This shows that moving from the unsorted to the many-sorted case is not as straightforward as one might expect. Since a model may have some empty domains, one needs to design proof rules that take into account changes of signatures.

▶ **Definition 8** (Entailment relation). *An entailment relation* $\vdash = \{\vdash_\Sigma\}_{\Sigma \in |\mathsf{Sig}^{\mathsf{TA}}|}$ *is a family of binary relations between sets of sentences indexed by signatures, that is,* $\vdash_\Sigma \subseteq \mathcal{P}(\mathsf{Sen}(\Sigma)) \times \mathcal{P}(\mathsf{Sen}(\Sigma))$ *for all first-order signatures* Σ*, such that the following properties are satisfied:*

$$(Monotonicity)\ \frac{\Gamma \supseteq \Phi}{\Gamma \vdash_\Sigma \Phi} \qquad (Transitivity)\ \frac{\Gamma \vdash_\Sigma \Phi \qquad \Phi \vdash_\Sigma \Psi}{\Gamma \vdash_\Sigma \Psi}$$

$$(Union)\ \frac{\Gamma \vdash_\Sigma \phi \text{ for all } \phi \in \Phi}{\Gamma \vdash_\Sigma \Phi} \qquad (Translation)\ \frac{\Gamma \vdash_\Sigma \Phi}{\chi(\Gamma) \vdash_{\Sigma'} \chi(\Phi)} \text{ where } \chi : \Sigma \to \Sigma'$$

For the sake of simplicity, we write $\Gamma \vdash_\Sigma \phi$ rather than $\Gamma \vdash_\Sigma \{\phi\}$. Also, we omit the subscript Σ from the notation $\vdash_\Sigma$ when it is clear from the context. An example of entailment relation is $\models$. It is straightforward to prove that $\models$ satisfies $(Monotonicity)$, $(Transitivity)$, $(Union)$ and $(Translation)$.

▶ **Definition 9** (Entailment properties). *An entailment relation* $\vdash$ *is* sound (complete) *if* $\vdash \subseteq \models$ ($\models \subseteq \vdash$)*. An entailment relation* $\vdash$ *is* α-compact*, where* α *is an infinite cardinal, if*

$$\Gamma \vdash_\Sigma \phi \text{ implies } \Gamma_\alpha \vdash_\Sigma \phi \text{ for some subset } \Gamma_\alpha \subseteq \Gamma \text{ of cardinality } \mathsf{card}(\Gamma_\alpha) < \alpha,$$

for all signatures Σ*, all sets of* Σ*-sentences* Γ *and all* Σ*-sentences* ϕ*. If* $\alpha = \omega$*, we say, simply, that* $\vdash$ *is compact.*

The dynamic entailment relation is defined in two steps. Firstly, we define an entailment relation to reason about the logical consequences of atomic sentences, given as equations or relations. Secondly, we define the dynamic entailment relation by adding proof rules to deal with actions, Boolean connectives and quantifiers.

3.1 Basic entailment relation

The fragment obtained from TA by restricting the sentences to atoms is studied in this section.

▶ **Definition 10** (Basic entailment relation). The basic entailment relation $\vdash^b$ *is the least entailment relation closed under the following basic proof rules:*

$$(R)\ \frac{}{\Gamma \vdash_\Sigma t = t} \qquad (S)\ \frac{\Gamma \vdash_\Sigma t_1 = t_2}{\Gamma \vdash_\Sigma t_2 = t_1} \qquad (T)\ \frac{\Gamma \vdash_\Sigma t_1 = t_2 \qquad \Gamma \vdash_\Sigma t_2 = t_3}{\Gamma \vdash_\Sigma t_1 = t_3}$$

$$(F)\ \frac{\Gamma \vdash_\Sigma t_i = t_i' \quad \text{for } 1 \leq i \leq n}{\Gamma \vdash_\Sigma \sigma(t_1, \ldots, t_n) = \sigma(t_1', \ldots, t_n')} \qquad (P)\ \frac{\Gamma \vdash_\Sigma t_1 = t_1' \quad \Gamma \vdash_\Sigma t_2 = t_2' \quad \Gamma \vdash_\Sigma t_1 \overset{\lambda}{\Longrightarrow} t_2}{\Gamma \vdash_\Sigma t_1' \overset{\lambda}{\Longrightarrow} t_2'}$$

$$(M)\ \frac{\Gamma \vdash_\Sigma t_j \overset{\lambda}{\Longrightarrow} u_j}{\Gamma \vdash_\Sigma f(t_1, \ldots, t_j, \ldots, t_n) \overset{\lambda}{\Longrightarrow} f(t_1, \ldots, u_j, \ldots, t_n)} \quad \text{where } f \in M$$

▶ **Lemma 11** (Basic compactness). *The basic entailment relation is compact.*

Any set of atomic sentences E defined over a signature Σ determines a congruence $\equiv^E := \{t_1 \equiv^E t_2 \mid E \vdash_\Sigma t_1 = t_2\}$ on T_Σ. One can construct a model $\mathfrak{A}^E$ from the initial model of terms T_Σ factorized by the congruence $\equiv^E$ interpreting each transition label λ in Σ as the set $\{(t_1, t_2) \mid t_1, t_2 \in T_{\Sigma,s} \text{ and } E \vdash_\Sigma t_1 \overset{\lambda}{\Longrightarrow} t_2\}$.

▶ **Lemma 12.** *Let E be a set of atomic sentences defined over a signature Σ. For all Σ-models $\mathfrak{A}$, we have $\mathfrak{A} \models E$ iff there exists a unique homomorphism $\mathfrak{A}^E \to \mathfrak{A}$.*

Lemma 12 says that the satisfaction of E by a model $\mathfrak{A}$ is equivalent with the existence of a unique homomorphism from $\mathfrak{A}^E$ to $\mathfrak{A}$. In particular, $\mathfrak{A}^E$ is the initial model of E. See [9] for a proof of Lemma 12.

▶ **Proposition 13** (Basic completeness). *For any set of atomic sentences E and any atomic sentence φ defined over a signature Σ, the following are equivalent:*

$$(a)\ E \models \varphi, \qquad (b)\ \mathfrak{A}^E \models \varphi, \qquad \text{and} \qquad (c)\ E \vdash^b \varphi.$$

3.2 Dynamic entailment relation

The dynamic entailment relation is built on top of basic entailment relation by adding the proof rules to reason about actions, Boolean connectives, and first-order quantifiers.

▶ **Definition 14** (Dynamic entailment relation). The dynamic entailment relation $\vdash$ *is the least entailment relation closed under the basic proof rules presented in Definition 10 and the following proof rules:*

Proof rules for actions

$$(Comp_I)\ \frac{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}_1}{\Longrightarrow} t \qquad \Gamma \vdash_\Sigma t \overset{\mathfrak{a}_2}{\Longrightarrow} t_2}{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}_1 ; \mathfrak{a}_2}{\Longrightarrow} t_2}$$

$$(Comp_E)\ \frac{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}_1 ; \mathfrak{a}_2}{\Longrightarrow} t_2 \quad \Gamma \cup \{t_1 \overset{\mathfrak{a}_1}{\Longrightarrow} x, x \overset{\mathfrak{a}_2}{\Longrightarrow} t_2\} \vdash_{\Sigma[x]} \phi}{\Gamma \vdash_\Sigma \phi}$$

$$(Union_I)\ \frac{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}_i}{\Longrightarrow} t_2}{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}_1 \cup \mathfrak{a}_2}{\Longrightarrow} t_2} \qquad (Union_E)\ \frac{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}_1 \cup \mathfrak{a}_2}{\Longrightarrow} t_2 \quad \Gamma \cup \{t_1 \overset{\mathfrak{a}_i}{\Longrightarrow} t_2\} \vdash_\Sigma \phi \text{ for all } i \in \{1,2\}}{\Gamma \vdash_\Sigma \phi}$$

$$(Star_I)\ \frac{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}^n}{\Longrightarrow} t_2}{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}^*}{\Longrightarrow} t_2} \qquad (Star_E)\ \frac{\Gamma \vdash_\Sigma t_1 \overset{\mathfrak{a}^*}{\Longrightarrow} t_2 \quad \Gamma \cup \{t_1 \overset{\mathfrak{a}^n}{\Longrightarrow} t_2\} \vdash_\Sigma \phi \text{ for all } n \in \omega}{\Gamma \vdash_\Sigma \phi}$$

Proof rules for Boolean connectives

$$(Neg_D)\ \frac{\Gamma \vdash_\Sigma \neg\neg\phi}{\Gamma \vdash_\Sigma \phi} \qquad (False)\ \frac{\Gamma \vdash_\Sigma \bot}{\Gamma \vdash_\Sigma \phi}$$

$$(Neg_I)\ \frac{\Gamma \cup \{\phi\} \vdash_\Sigma \bot}{\Gamma \vdash_\Sigma \neg\phi} \qquad (Neg_E)\ \frac{\Gamma \vdash_\Sigma \neg\phi}{\Gamma \cup \{\phi\} \vdash_\Sigma \bot}$$

$$(Disj_I)\ \frac{\Gamma \vdash_\Sigma \phi}{\Gamma \vdash_\Sigma \vee\Phi} \text{ where } \phi \in \Phi \qquad (Disj_E)\ \frac{\Gamma \vdash_\Sigma \vee\Phi \quad \Gamma \cup \{\phi\} \vdash_\Sigma \gamma \text{ for all } \phi \in \Phi}{\Gamma \vdash_\Sigma \gamma}$$

Proof rules for first-order quantifiers

$$(Quant_I)\ \frac{\Gamma \cup \{\phi\} \vdash_{\Sigma[X]} \gamma}{\Gamma \cup \{\exists X \cdot \phi\} \vdash_\Sigma \gamma} \qquad (Quant_E)\ \frac{\Gamma \cup \{\exists X \cdot \phi\} \vdash_\Sigma \gamma}{\Gamma \cup \{\phi\} \vdash_{\Sigma[X]} \gamma}$$

$$(Subst)\ \frac{\Gamma \vdash_\Sigma \theta(\phi)}{\Gamma \vdash_\Sigma \exists X \cdot \phi} \qquad \text{where } \theta : X \to T_\Sigma \text{ is a substitution}$$

▶ **Proposition 15** (ω_1-compactness). *We have that*

1. *the dynamic entailment relation $\vdash$ is ω_1-compact, and*
2. *the satisfaction relation $\models$ is not ω_1-compact.*

The first statement holds because the dynamic entailment relation is generated by proof rules with an at most countable number of premises. For uncountable signatures Σ, the satisfaction relation $\models_\Sigma$ is not ω_1-compact. It follows that the dynamic logic proposed in this contribution, TA, is not complete. However, the restriction of TA to countable signatures, TA^c, is complete. Since TA^c is not compact, the Henkin method for proving completeness is not applicable.

▶ **Example 16** (Analysis of CCS programs). Recall the CCS description of the interaction between mathematicians and coffee vending machines discussed in Section 2, and let `Institute` be an abbreviation for the following process:

$(\texttt{Mathematician} \mid \texttt{CoffeeVM}) \setminus (\texttt{coin}, \texttt{coffee})$.

In this context, can we check, as an example, that the process `Institute` is able to continuously output theorems? The property can be formalized in TA as a transition

$$\texttt{Institute} \xRightarrow{\tau^* \,;\, \overline{\texttt{theorem}} \,;\, \tau^*} \texttt{Institute}$$

whose τ-components correspond to internal communications between sub-processes of the institute – i.e., mathematicians and vending machines. Therefore, we need to check an entailment of the form $\Gamma \vdash_\Sigma \phi$, where (a) Σ is the TA-signature that consists of the process identifiers `Mathematician` and `CoffeeVM` together with the CCS process-building operators for action prefixing, non-deterministic choice, parallel composition, etc., discussed in Section 2; (b) Γ is the set of Σ-sentences given by the axiom schemas *Act*, *Sum*, *Com*, *Res**, and *Con* listed on page 7 together with equations pertaining to the axiomatization of CCS actions (e.g., $\overline{\texttt{theorem}} \neq \texttt{coffee}$), as well as equations that capture elementary properties of processes such as the associativity, commutativity, and identity element of the non-deterministic-choice and parallel-composition operators; and (c) ϕ is the transition written above.

The proof mimics the following chain of CCS transitions:

$$\begin{aligned}\texttt{Institute} &\xRightarrow{\tau} (\texttt{coffee} \,.\, \overline{\texttt{theorem}} \,.\, \texttt{Mathematician} \mid \overline{\texttt{coffee}} \,.\, \texttt{CoffeeVM}) \setminus (\texttt{coin}, \texttt{coffee}) \\ &\xRightarrow{\tau} (\overline{\texttt{theorem}} \,.\, \texttt{Mathematician} \mid \texttt{CoffeeVM}) \setminus (\texttt{coin}, \texttt{coffee}) \\ &\xRightarrow{\overline{\texttt{theorem}}} (\texttt{Mathematician} \mid \texttt{CofeeVM}) \setminus (\texttt{coin}, \texttt{coffee}) = \texttt{Institute}\end{aligned}$$

To shorten the presentation of the proof, we use the following derived proof rule:

$$(GMP)\ \frac{\Gamma \vdash_\Sigma \forall X \cdot \bigwedge \Phi \to \gamma \quad \Gamma \vdash_\Sigma \theta(\Phi)}{\Gamma \vdash_\Sigma \theta(\gamma)} \qquad \text{where } \theta : X \to T_\Sigma \text{ is a substitution.}$$

In addition, we simplify the notations by writing down only the conclusions of entailments and by abbreviating `Mathematician` as `M`, `CoffeeVM` as `CVM`, and the sequence of channel names $(\texttt{coin}, \texttt{coffee})$ as K. This leads us to the (sketch of) proof tree depicted in Figure 1.

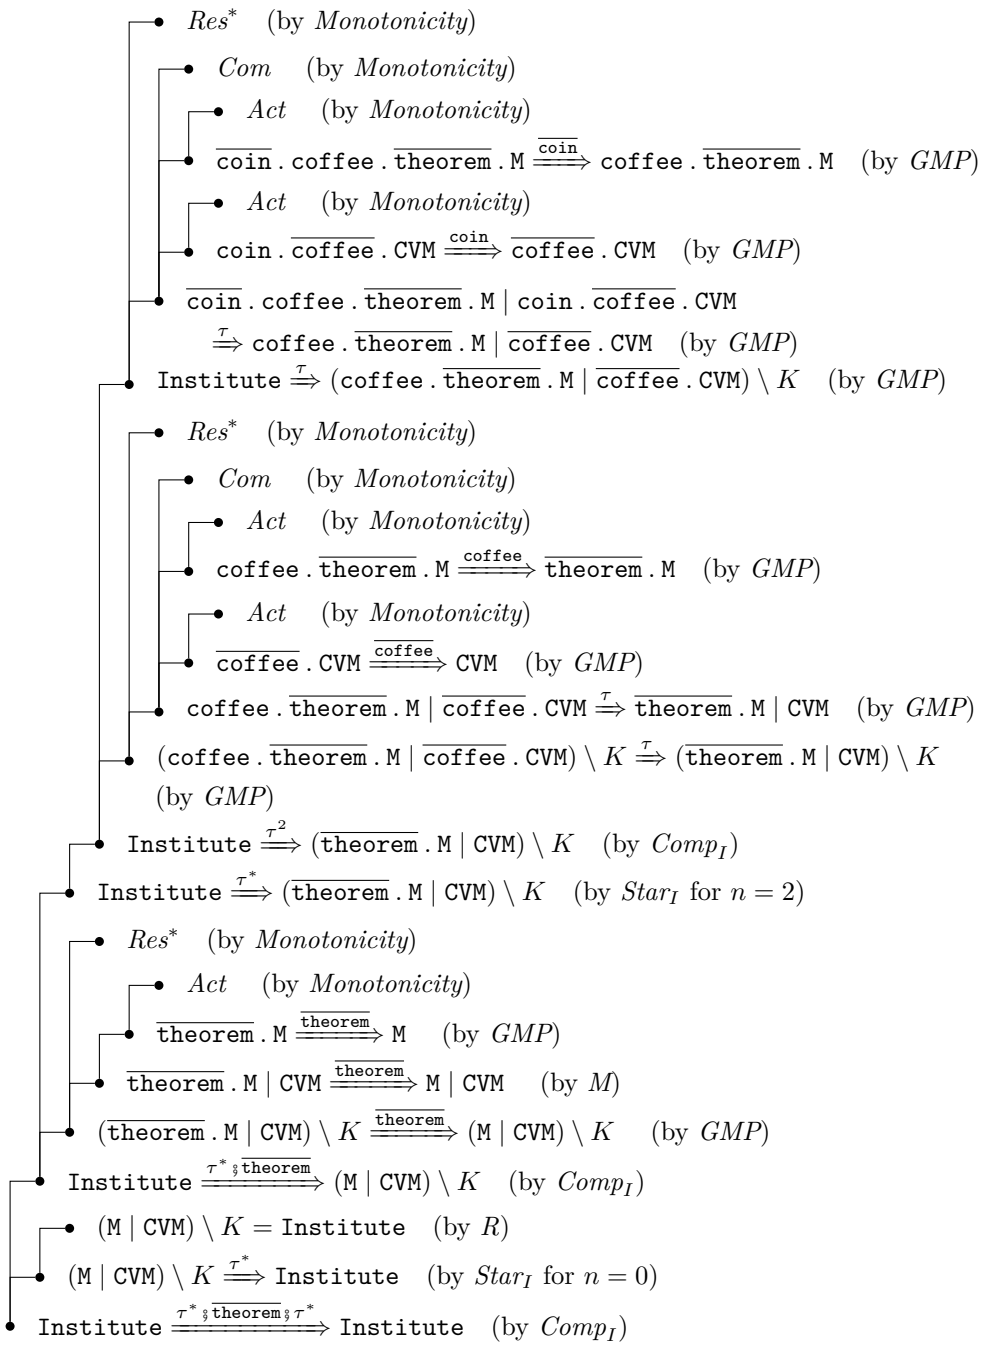

Figure 1 Proof tree for the continuous output of theorems by the process `Institute`.

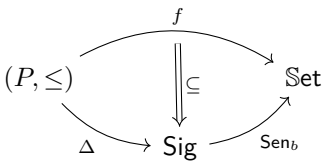
4 Forcing

In this section, we develop a forcing technique for proving completeness which extends in a non-straightforward way the classical forcing from one signature to a category of signatures.

▶ **Definition 17** (Forcing property). *A forcing property is a tuple $\mathbb{P} = (P, \leq, \Delta, f)$, where:*



1. *$(P, \leq)$ is a partially ordered set with a least element 0.*
   The elements of P are traditionally called conditions.
2. *$\Delta : (P, \leq) \to \mathsf{Sig}$ is a functor, which maps each arrow $(p \leq q) \in (P, \leq)$ to an inclusion $\Delta_p \subseteq \Delta_q$.*
3. *$f : (P, \leq) \to \mathbb{S}\mathsf{et}$ is a functor from the small category $(P, \leq)$ to the category of sets $\mathbb{S}\mathsf{et}$ such that $f \subseteq \Delta; \mathsf{Sen}_b$ is a natural transformation, that is: (a) $f(p) \subseteq \mathsf{Sen}_b(\Delta_p)$ for all conditions $p \in P$, and (b) $f(p) \subseteq f(q)$ for all arrows $(p \leq q) \in (P, \leq)$.*
4. *If $f(p) \models \phi$ then $\phi \in f(q)$ for some $q \geq p$, for all atoms $\phi \in \mathsf{Sen}_b(\Delta_p)$.*

A classical forcing property is a particular case of forcing property such that $\Delta_p = \Delta_q$ for all conditions $p, q \in P$.

▶ **Example 18** (Syntactic forcing). Let Σ be a base signature and C an S-sorted set of new constants such that $\mathsf{card}(C_s) = \omega$ for all $s \in S$. Let $\mathbb{P} = (P, \leq, \Delta, f)$ be a forcing property defined as follows:

- P is the set of presentations of the form $p = (\Delta_p, \Gamma_p)$, where (a) Δ_p is obtained from Σ by adding a finite set C_p of constants from C, and (b) $\Gamma_p \subseteq \mathsf{Sen}(\Delta_p)$ is consistent, that is, $\Gamma_p \nvdash_{\Delta_p} \bot$.
- $p \leq q$ iff $\Delta_p \subseteq \Delta_q$ and $\Gamma_p \subseteq \Gamma_q$, for all conditions $p, q \in P$.
- Δ is the forgetful functor which maps each condition $p \in P$ to Δ_p.
- $f(p) = \Gamma_p \cap \mathsf{Sen}_b(\Delta_p)$, for all conditions $p \in P$.

The syntactic forcing described in the example above is used to prove completeness. The constants from C are traditionally called Henkin constants and are used as witnesses for existentially quantified sentences obtained by extending an initial theory to a maximally consistent set of sentences.

As usual, forcing properties determine suitable relations between conditions and sentences.

▶ **Definition 19** (Forcing relation). *Let $\mathbb{P} = \langle P, \leq, \Delta, f \rangle$ be a forcing property.* The forcing relation $\Vdash$ *between conditions $p \in P$ and sentences from $\mathsf{Sen}(\Delta_p)$ is defined by induction on the structure of sentences, as follows:*

- *$p \Vdash \varphi$ if $\varphi \in f(p)$, for all atomic sentences $\varphi \in \mathsf{Sen}_b(\Delta_p)$.*
- *$p \Vdash t_1 \overset{\mathfrak{a}_1 ; \mathfrak{a}_2}{\Longrightarrow} t_2$ if $p \Vdash t_1 \overset{\mathfrak{a}_1}{\Longrightarrow} t$ and $p \Vdash t \overset{\mathfrak{a}_2}{\Longrightarrow} t_2$ for some $t \in T_{\Delta_p}$.*
- *$p \Vdash t_1 \overset{\mathfrak{a}_1 \cup \mathfrak{a}_2}{\Longrightarrow} t_2$ if $p \Vdash t_1 \overset{\mathfrak{a}_1}{\Longrightarrow} t_2$ or $p \Vdash t_1 \overset{\mathfrak{a}_2}{\Longrightarrow} t_2$.*
- *$p \Vdash t_1 \overset{\mathfrak{a}^*}{\Longrightarrow} t_2$ if $p \Vdash t_1 \overset{\mathfrak{a}^n}{\Longrightarrow} t_2$ for some natural number $n \in \omega$.*
- *$p \Vdash \neg\phi$ if there is no $q \geq p$ such that $q \Vdash \phi$.*
- *$p \Vdash \vee\Phi$ if $p \Vdash \phi$ for some $\phi \in \Phi$.*
- *$p \Vdash \exists X \cdot \phi$ if $p \Vdash \theta(\phi)$ for some substitution $\theta : X \to T_{\Delta_p}$.*

The relation $p \Vdash \phi$ in $\mathbb{P}$, is read as p forces ϕ. We say that p weakly forces ϕ, in symbols, $p \Vdash^w \phi$, if $p \Vdash \neg\neg\phi$.

A few basic properties of forcing are presented below.

▶ **Lemma 20** (Forcing properties). *Let $\mathbb{P} = (P, \leq, \Delta, f)$ be a forcing property. For all conditions $p \in P$ and all sentences $\phi \in \mathsf{Sen}(\Delta_p)$ we have:*

1. *$p \Vdash \neg\neg\phi$ iff for each $q \geq p$ there is a condition $r \geq q$ such that $r \Vdash \phi$.*
2. *If $p \leq q$ and $p \Vdash \phi$ then $q \Vdash \phi$.*
3. *If $p \Vdash \phi$ then $p \Vdash \neg\neg\phi$.*
4. *We can not have both $p \Vdash \phi$ and $p \Vdash \neg\phi$.*

The second property stated in the above lemma shows that the forcing relation is preserved along inclusions of conditions. The fourth property shows that the forcing relation is consistent, that is, a condition cannot force all sentences. The remaining conditions are about negation.

▶ **Definition 21** (Generic set). *Let $\mathbb{P} = (P, \leq, \Delta, f)$ be a forcing property. A subset of conditions $G \subseteq P$ is generic if*

1. *G is an ideal, that is: (a) for all $p \in G$ and all $q \leq p$ we have $q \in G$, and (b) for all $p, q \in G$ there exists $r \in G$ such that $p \leq r$ and $q \leq r$; and*
2. *for all conditions $p \in G$ and all sentences $\phi \in \mathsf{Sen}(\Delta_p)$ there exists a condition $q \in G$ such that $q \geq p$ and either $q \Vdash \phi$ or $q \Vdash \neg\phi$ holds.*

We write $G \Vdash \phi$ if $p \Vdash \phi$ for some $p \in G$.

A generic set G describes a reachable model which satisfies all sentences forced by the conditions in G.

▶ **Lemma 22** (Existence). *Let $\mathbb{P} = (P, \leq, \Delta, f)$ be a forcing property. If any signature in $\{\Delta_p\}_{p \in P}$ is countable then every $p \in P$ belongs to a generic set.*

Proof sketch. Let $\text{pair} : \omega \times \omega \to \omega$ be a bijective function defined by $\text{pair}(i, j) := \big((i + j)(i + j + 1) + 2j\big)/2$ for all $i, j \in \omega$. For all conditions $p \in P$, let $\psi_p : \omega \to \mathsf{Sen}(\Delta_p)$ be a bijective mapping, which gives an enumeration of $\mathsf{Sen}(\Delta_p)$. We define an increasing chain of conditions $p_0 \leq p_1 \leq \ldots$ in P recursively. Let $p = p_0$. For the induction step, we assume that we have defined p_n and we define p_{n+1}. Notice that there are unique natural numbers $i, j \in \omega$ such that $n = \text{pair}(i, j)$ and $i, j \leq n$.

- If there is $q \geq p_n$ such that $q \Vdash \psi_{p_i}(j)$, then let $p_{n+1} := q$.
- Otherwise, $p_{n+1} := p_n$, which means that $p_{n+1} \Vdash \neg\psi_{p_i}(j)$.

Then $G := \{q \in P \mid q \leq p_n \text{ for some } n \in \omega\}$ is generic and contains p. ◀

Lemma 22 is the key for a modular approach to forcing and it is the equivalent of the Lindenbaum's lemma from Henkin's method for proving completeness.

▶ Remark 23. Since $\Delta : (G, \leq) \to \mathsf{Sig}$ is a directed diagram of signature inclusions, one can construct a co-limit $\mu : \Delta \Rightarrow \Delta_G$ of the functor $\Delta : (G, \leq) \to \mathsf{Sig}$ such that $\mu_p : \Delta_p \to \Delta_G$ is an inclusion for all $p \in G$.

The results which leads to completeness are developed over the signature Δ_G. If $\mathbb{P}$ is the syntactic forcing described in Example 18, then Δ_G is obtain from the base signature Σ by adding all Henkin constants from $\{\Delta_p\}_{p \in G}$. In general, Δ_G does not contain all Henkin constants from C, which is one of the major differences between the classical approach and the present developments.

▶ **Definition 24** (Generic model). *Let $\mathbb{P} = (P, \leq, \Delta, f)$ be a forcing property and $G \subseteq P$ a generic set. A model $\mathfrak{A}$ defined over Δ_G is a* generic model *for G iff for every sentence $\phi \in \bigcup_{p \in G} \mathsf{Sen}(\Delta_p)$, we have $\mathfrak{A} \models \phi$ iff $G \Vdash \phi$.*

The notion of generic model is the semantic counterpart of the definition of generic set. The following result shows that every generic set has a generic model.

▶ **Theorem 25** (Generic Model Theorem). *Let $\mathbb{P} = (P, \leq, \Delta, f)$ be a forcing property and $G \subseteq P$ a generic set. Then there is a generic model $\mathfrak{A}$ for G which is countable and reachable.*

Proof sketch. We define the set of all atomic sentences $B \coloneqq \{\phi \in \mathsf{Sen}_b(\Delta_G) \mid G \Vdash \phi\}$ forced by the generic set G. The basic model $\mathfrak{A}^B$ given by Lemma 12 is the generic model for G. ◀

5 Completeness

The logical framework in which the results are developed in this section is the fragment TA^c obtained from TA by restricting the syntax to at most countable signatures. The syntactic forcing property defined in Example 18 is the starting point for proving completeness. Therefore, throughout this section, we let $\mathbb{P} = (P, \leq, \Delta, f)$ be a syntactic forcing property in TA^c as described in Example 18. In particular, all signatures in $\{\Delta\}_{p \in P}$ are at most countable. For the sake of simplicity, we write $p \vdash \phi$ iff $\Gamma_p \vdash_{\Delta_p} \phi$, for all conditions $p = (\Delta_p, \Gamma_p)$ in P.

▶ **Theorem 26.** *For all $p \in P$ and all $\phi \in \mathsf{Sen}(\Delta_p)$, we have $p \Vdash^w \phi$ iff $p \vdash \phi$.*

The above theorem says that a sentence is entailed by a condition if and only if it is weakly forced by that condition. In other words, the entailment relation is the weak forcing relation. Now, we can interpret Lemma 22 in the present context given by the syntactic forcing property $\mathbb{P}$ set above. The following result is a direct consequence of Theorem 26 and Lemma 22.

▶ **Corollary 27** (Lindenbaum's lemma). *Assume the following:*
- *a condition $p^\circ = (\Delta_{p^\circ}, \Gamma_{p^\circ})$ from P, and*
- *a generic set G which contains p° (by Lemma 22).*

Let Δ_G be the vertex of the co-limit $\mu : \Delta \to \Delta_G$ of the functor $\Delta : (G, \leq) \to \mathsf{Sig}$ defined in Remark 23. Then $\Gamma_G = \bigcup_{p \in G} \Gamma_p$ is a maximally consistent set which includes Γ_{p°.

The following example shows that Δ_G does not contain all Henkin constants defined for the base signature.

▶ **Example 28.** Let Σ be the signature defined by: $S \coloneqq \{s_i \mid i \in \omega\}$, $F \coloneqq \{c :\to s_0, d :\to s_0\}$, $M \coloneqq \emptyset$, and $P \coloneqq \{\lambda\}$. Let Γ be the set of sentences over Σ which consists of: (a) $c \overset{\lambda^*}{\Longrightarrow} d$, and (b) $(\exists x_n \cdot \top) \to \neg(c \overset{\lambda^n}{\Longrightarrow} d)$ for all $n \in \omega$, where x_n is a variable of sort s_n.

The first sentence says that there is a transition from c to d in a finite number of steps. For each natural number n, the sentence $(\exists x_n \cdot \top) \to \neg(c \overset{\lambda^n}{\Longrightarrow} d)$ says that if the sort s_n is not empty then there is no transition from c to d in exactly n steps. Recall that $C = \{C_{s_n}\}_{n \in \omega}$ is the set of all Henkin constants, and $\mathsf{card}(C_{s_n}) = \omega$ for all natural numbers n. Notice that $p^\circ = (\Sigma, \Gamma)$ is consistent, but $q = (\Sigma[C], \Gamma)$ is not consistent. By Corollary 27, one can extend Γ to a maximally consistent set of sentences Γ_G. Unlike in classical first-order logic, Γ_G does not contain all Henkin constants from C.

▶ **Theorem 29** (Downwards Löwenheim-Skolem Theorem). *For any consistent set of sentences Γ defined over a countable signature Σ, there exists a countable Σ-model $\mathfrak{A}$ that satisfies Γ.*

Proof. Let $\mathbb{P} = (P, \leq, \Delta, f)$ be the forcing property described in Definition 17. Notice that $p := (\Sigma, \Gamma)$ is a condition from P. Since all signatures are countable, by Lemma 22, p belongs to a generic set G. By Theorem 25, G has a generic model $\mathfrak{B}$ which is countable and reachable. In particular, $\mathfrak{B} \models_{\Delta_G} \Gamma$. Let $\mathfrak{A} := \mathfrak{B}\restriction_{\Sigma}$, and by the satisfaction condition, $\mathfrak{A} \models_{\Sigma} \Gamma$. ◀

▶ **Theorem 30** (Completeness). *For all sets of sentences Γ and all sentences ϕ defined over a countable signature Σ, we have: $\Gamma \vdash_{\Sigma} \phi$ iff $\Gamma \models_{\Sigma} \phi$.*

Proof. The forward implication holds because all proof rules are sound. For the backwards implication assume $\Gamma \nvdash_{\Sigma} \phi$. We have $\Gamma \cup \{\neg\phi\} \nvdash_{\Sigma} \bot$. By Theorem 29, there is a countable Σ-model $\mathfrak{A}$ such that $\mathfrak{A} \models_{\Sigma} \Gamma \cup \{\neg\phi\}$. Therefore, $\Gamma \not\models_{\Sigma} \phi$. ◀

6 Conclusions

In this study, we have defined an extension of many-sorted first-order logic, called transition algebra, that offers explicit support for state transitions; furthermore, we have investigated its logical properties in order to apply the institutional model theory approach to new algebraic specification languages based on this logic, and with a greater expressivity than Maude and CafeOBJ. Transition algebra satisfies desirable properties such as truth invariance under change of signature, and has an expressive power that goes beyond that of ordinary first-order logic, which is important for formal-verification purposes. Our efforts have focused on two main aspects of transition algebra: first, on its formal-specification capabilities, i.e., to show that it forms a proper extension of first-order equational logic; and second, on support for formal verification, for which we have studied a number of model-theoretic properties, syntactic entailment and, most importantly, soundness and completeness results.

Concerning its formal-specification capabilities, transition algebra blends features of dynamic logic with features of many-sorted first-order logic. From the former, it borrows the idea of expressing the dynamics of a system by means of actions, which are built from atomic transitions using composition, iteration, and so on. The iteration of an action is a key feature because it allows us to express reachability, which is not possible in ordinary first-order logic. From the latter, our logic borrows term-building operators and quantifiers. This allows us to capture system states as terms, and hence to reason about the structure of states more freely and in a more complex manner than it is possible in dynamic logic.

For verification purposes, our contribution is twofold: on one hand, we have introduced a sound proof system for transition algebra; and on the other hand, we have developed a new general method for proving completeness based on forcing. The latter is highly important, because it has enabled us to circumvent the lack of compactness of transition algebra, which prevents the use of readily available methods for proving completeness. Moreover, it also overcomes a significant limitation of existing forcing techniques, namely their reliance on models with non-empty carriers, which is another basic property (like compactness) that does not hold for transition algebra. We have demonstrated the use of this extended forcing technique to show that the proof system for transition algebra is complete. We aim to further develop and apply this technique to extensions of transition algebra that take into account, for example, subsorting – to which we have already alluded in this paper. Furthermore, future research includes applying forcing to prove omitting types theorem for logical systems that interpret sorts as sets, possibly empty, thus upgrading the results from [17, 20]. Subsequently, the application of omitting types theorem to Robinson consistency property and interpolation, as demonstrated in [19], remains a feasible avenue for exploration.

Abstract

We consider numbers of the form $S_\beta(\boldsymbol{u}) := \sum_{n=0}^{\infty} \frac{u_n}{\beta^n}$, where $\boldsymbol{u} = \langle u_n \rangle_{n=0}^{\infty}$ is an infinite word over a finite alphabet and $\beta \in \mathbb{C}$ satisfies $|\beta| > 1$. Our main contribution is to present a combinatorial criterion on $\boldsymbol{u}$, called echoing, that implies that $S_\beta(\boldsymbol{u})$ is transcendental whenever β is algebraic. We show that every Sturmian word is echoing, as is the Tribonacci word, a leading example of an Arnoux-Rauzy word. We furthermore characterise $\overline{\mathbb{Q}}$-linear independence of sets of the form $\{1, S_\beta(\boldsymbol{u}_1), \ldots, S_\beta(\boldsymbol{u}_k)\}$, where $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_k$ are Sturmian words having the same slope. Finally, we give an application of the above linear independence criterion to the theory of dynamical systems, showing that for a contracted rotation on the unit circle with algebraic slope, its limit set is either finite or consists exclusively of transcendental elements other than its endpoints 0 and 1. This confirms a conjecture of Bugeaud, Kim, Laurent, and Nogueira.

1 Introduction

A well-known conjecture of Hartmanis and Stearns asserts that for an integer $b \geq 2$ and a sequence $\boldsymbol{u} \in \{0, \ldots, b-1\}^\omega$ that is computable by linear-time Turing machine (in the sense that given input n in unary, the machine outputs the first n elements of $\boldsymbol{u}$ in time $O(n)$), the number $S_b(\boldsymbol{u}) := \sum_{n=0}^{\infty} \frac{u_n}{b^n}$ is either rational or transcendental. This conjecture remains open and is considered to be very difficult [4]. Among many other consequences, the conjecture implies that integer multiplication cannot be done in linear time [7].

A weaker version of the Hartmanis-Stearns conjecture was formulated in 1968 by Cobham, who conjectured that every irrational automatic number is transcendental [9]. In other words, if $b \geq 2$ is an integer and $\boldsymbol{u}$ is an automatic word, then the number $S_b(\boldsymbol{u})$ is either rational

or transcendental. Note that every automatic word is morphic, and that morphic words are precisely those that can be generated by so-called tag machines, a restricted class of linear-time Turing machines [4]. The transcendence of irrational automatic numbers over an integer base was proven in 2004 by Adamczewski, Bugeaud, and Luca [3]. It is noted in [1] that extending this result from the class of automatic words to the more general class of morphic words (specifically, for those generated by morphisms with polynomial growth) encompasses recognised open problems in transcendence theory. In another direction, Adamczewski and Faverjon [5] proved a generalisation of Cobham's conjecture to algebraic number bases. Their result entails that for an algebraic number β, with $|\beta| > 1$ and automatic sequence $\boldsymbol{u}$ over a finite alphabet $\{0, 1, \ldots, k-1\}$, the number $S_\beta(\boldsymbol{u})$ either lies in the field $\mathbb{Q}(\beta)$ or is transcendental.

Closely connected with the class of morphic words, one has Sturmian words and, more generally, Arnoux-Rauzy words [6]. A Sturmian word is an infinite word over the alphabet $\{0, 1\}$ that has $n + 1$ factors of length n for all $n \in \mathbb{N}$. In terms of factor complexity, Sturmian words are thereby the simplest non-periodic infinite words. Arnoux-Rauzy words are a generalisation of Sturmian words to the alphabet $\{0, 1, \ldots, k-1\}$ for arbitrary k. Among other properties, an Arnoux-Rauzy word on a k-letter alphabet has factor complexity $(k-1)n+1$. We refer to [6, Definition 3.3] for the precise definition. Perhaps the best-known example of a Sturmian word is the Fibonacci word, while the best-known example of an Arnoux-Rauzy word that is not Sturmian is the Tribonacci word. It so happens that both these words are morphic, although not automatic. The Fibonacci word is the fixed point of the morphism $0 \mapsto 01, 1 \mapsto 0$, while the Tribonacci word is the fixed point of the morphism $0 \mapsto 01, 1 \mapsto 02, 2 \mapsto 0$. More generally, Arnoux-Rauzy words can be generated by iterating a finite set of morphisms via so-called S-adic generation. Sturmian and Arnoux-Rauzy words are also intimately connected with dynamical systems. In their pioneering work [20, 21], Morse and Hedlund showed that every Sturmian word arises as the coding of a translation of the one-dimensional torus and, following the work of Rauzy [23], a subclass of Arnoux-Rauzy words can be realised as natural codings of toral translations in higher dimension [6].

There is an extensive literature on transcendence of Sturmian and Arnoux-Rauzy words over an integer base $b \geq 2$. Danilov [10] proved the transcendence of $S_b(\boldsymbol{u})$ for $\boldsymbol{u}$ the Fibonacci word. This result was significantly strengthened by Ferenczi and Mauduit [11], who proved the transcendence of $S_b(\boldsymbol{u})$, for $\boldsymbol{u}$ either a Sturmian word or an Arnoux-Rauzy word on alphabet $\{0, 1, 2\}$. This result was extended to Arnoux-Rauzy words over alphabet $\{0, 1, \ldots, k-1\}$ for any k in [24]. Meanwhile, Bugeaud *et al.* [8] showed the $\overline{\mathbb{Q}}$-linear independence of sets of the form $\{1, S_b(\boldsymbol{u}_1), S_b(\boldsymbol{u}_2)\}$, where $\boldsymbol{u}_1, \boldsymbol{u}_2$ are Sturmian words having the same slope (where the slope of a Sturmian word is the limiting frequency of 1's, which always exists).

Our interest in this paper is in proving transcendence results for Sturmian and Arnoux-Rauzy words over an algebraic-number base β, with $|\beta| > 1$. Here the picture is less complete compared to the case that β is an integer. Laurent and Nogueira [14] observe that if $\boldsymbol{u}$ is a *characteristic* Sturmian word (cf. Section 3.3), then the transcendence of $S_\beta(\boldsymbol{u})$ follows from a classical result of Loxton and Van der Poorten [17, Theorem 7] concerning transcendence of Hecke-Mahler series. For $\boldsymbol{u}$ having linear subword complexity (which includes all Arnoux-Rauzy words), it follows from [2, Theorem 1] that $S_\beta(\boldsymbol{u})$ is either transcendental or lies in the field $\mathbb{Q}(\beta)$, subject to a non-trivial inequality between the height of β and a combinatorial parameter of $\boldsymbol{u}$ called the *Diophantine exponent*. Most closely related to the present work, recently [18], introduced a criterion that can be used to show transcendence of $S_\beta(\boldsymbol{u})$ for a Sturmian word $\boldsymbol{u}$ and any β.

The main contribution of the present paper is to give a new combinatorial criterion on an infinite word $\boldsymbol{u}$, called *echoing*, that implies that $S_\beta(\boldsymbol{u}) := \sum_{n=0}^{\infty} \frac{u_n}{\beta^n}$ is transcendental for any algebraic number β. The echoing condition is an evolution of the above-mentioned criterion of [18] that allows both handling certain Arnoux-Rauzy words over non-binary alphabets as well as giving a considerably simplified treatment of Sturmian words. To illustrate the utility of the echoing notion, we show that every Sturmian word is echoing, as is the Tribonacci word, a leading example of an Arnoux-Rauzy word. We anticipate that the notion will find further applications among Arnoux-Rauzy words, and note that the thesis [13] contains further examples of such that are echoing. We also employ the echoing condition to give sufficient and necessary conditions for the $\overline{\mathbb{Q}}$-linear independence of a set of Sturmian numbers $\{1, S_\beta(\boldsymbol{u}_1), \ldots, S_\beta(\boldsymbol{u}_k)\}$, where $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_k$, are Sturmian words that have the same slope.

In Section 7 we give an application of our results to the theory of dynamical systems. We consider the set C of limit points of a contracted rotation f on the unit interval, where f is assumed to have an algebraic contraction factor. The set C is finite if f has a periodic orbit and is otherwise a Cantor set, that is, it is homeomorphic to the Cantor ternary set (equivalently, it is compact, nowhere dense, and has no isolated points). In the latter case we show that all elements of C except its endpoints 0 and 1 are transcendental. Our result confirms a conjecture of Bugeaud, Kim, Laurent, and Nogueira, who proved a special case of this result in [8]. We remark that it is a longstanding open question whether the actual Cantor ternary set contains any irrational algebraic elements.

2 Preliminaries

This section contains some number-theoretic preliminaries that will be used in Section 6.

For functions f and g, we use the Vinogradov notation $f \ll g$ to mean $f = O(g)$.

Let K be a number field of degree d and let $M(K)$ be the set of *places* of K. We divide $M(K)$ into the collection of *infinite places*, which are determined either by an embedding of K in $\mathbb{R}$ or a complex-conjugate pair of embeddings of K in $\mathbb{C}$, and the set of *finite places*, which are determined by prime ideals in the ring $\mathcal{O}_K$ of integers of K.

For $x \in K$ and $v \in M(K)$, define the absolute value $|x|_v$ as follows: $|x|_v := |\sigma(x)|^{1/d}$ in case v corresponds to a real embedding $\sigma : K \to \mathbb{R}$; $|x|_v := |\sigma(x)|^{2/d}$ in case v corresponds to a complex-conjugate pair of embeddings $\sigma, \overline{\sigma} : K \to \mathbb{C}$; finally, $|x|_v := N(\mathfrak{p})^{-\mathrm{ord}_\mathfrak{p}(x)/d}$ if v corresponds to a prime ideal $\mathfrak{p}$ in $\mathcal{O}$ and $\mathrm{ord}_\mathfrak{p}(x)$ is the order of $\mathfrak{p}$ as a divisor of the ideal $x\mathcal{O}$. With the above definitions we have the *product formula*: $\prod_{v \in M(K)} |x|_v = 1$ for all $x \in K^*$. Given a set of places $S \subseteq M(K)$, the ring $\mathcal{O}_S$ of *S-integers* is the subring comprising all $x \in K$ such $|x|_v \leq 1$ for all finite places $v \in S$.

For $m \geq 2$ the *absolute Weil height* of $\boldsymbol{x} = (x_1, \ldots, x_m) \in K^m$ is defined to be

$$H(\boldsymbol{x}) := \prod_{v \in M(K)} \max(|x_1|_v, \ldots, |x_m|_v)\,.$$

This definition is independent of the choice of field K containing $x_1, \ldots, x_m$. Note the restriction $m \geq 2$ in the above definition. For $x \in K$ we define its height $H(x)$ to be $H(1, x)$. For a non-zero polynomial $f = \sum_{i=0}^{s} a_i X^i \in K[X]$, where $s \geq 1$, we define its height $H(f)$ to be the height of its coefficient vector $(a_0, \ldots, a_s)$.

The following special case of the p-adic Subspace Theorem of Schlickewei is one of the main ingredients of our approach.

▶ **Theorem 1.** *Let $S \subseteq M(K)$ be a finite set of places of K that contains all infinite places. Let $v_0 \in S$ be a distinguished place. Given $m \geq 2$, let $L(x_1, \ldots, x_m)$ be a linear form with algebraic coefficients and let $i_0 \in \{1, \ldots, m\}$. Then for any $\varepsilon > 0$ the set of solutions $\boldsymbol{a} = (a_1, \ldots, a_m) \in (\mathcal{O}_S)^m$ of the inequality*

$$|L(\boldsymbol{a})|_{v_0} \cdot \left(\prod_{\substack{(i,v) \in \{1,\ldots,m\} \times S \\ (i,v) \neq (i_0,v_0)}} |a_i|_v \right) \leq H(\boldsymbol{a})^{-\varepsilon}$$

is contained in a finite union of proper linear subspaces of K^m.

We will also need the following additional proposition about roots of univariate polynomials.

▶ **Proposition 2** ([15, Proposition 2.3])**.** *Let $f \in K[X]$ be a polynomial with at most $k+1$ terms. Assume that f can be written as the sum of two polynomials g and h, where every monomial of g has degree at most d_0 and every monomial of h has degree at least d_1. Let β be a root of f that is not a root of unity. If $d_1 - d_0 > \frac{\log(k\,H(f))}{\log H(\beta)}$ then β is a common root of g and h.*

3 Echoing Words

In this section we present the main definition of the paper, the notion of echoing word. Before we present this, by way of motivation we present an informal analysis of the periodicity properties of the Fibonacci and Tribonacci words.

3.1 The Fibonacci Word

Let $\Sigma = \{0, 1\}$ and consider the morphism $\sigma : \Sigma^* \to \Sigma^*$ given by $\sigma(0) = 01$ and $\sigma(1) = 0$. The *Fibonacci word* $F_\infty \in \Sigma^\omega$ is the morphic word

$$F_\infty := \lim_{n \to \infty} \sigma^n(0) = 01001010010010100 \ldots .$$

In more detail, the Fibonacci word F_∞ is the limit of the sequence of finite words $(F_n)_{n=0}^\infty$ given by $F_n = \sigma^n(0)$ for all n (observe that F_n is a prefix of F_{n+1} for all n, so the limit is well defined). Note that the sequence $(F_n)_{n=0}^\infty$ satisfies the recurrence

$$F_n = F_{n-1}F_{n-2} \quad (n \geq 2)$$

analogous to that satisfied by the sequence of Fibonacci numbers.

The Fibonacci word is not periodic and hence F_∞ is not equal to any its tails $\mathrm{tl}^n(F_\infty)$ for $n > 0$. However, if the shift n is judiciously chosen then, intuitively speaking, the mismatches between F_∞ and $\mathrm{tl}^n(F_\infty)$ are *few and far between*. This intuition will be formalised in the definition of echoing word. It turns out that a particularly good choice of shifts is to take them from the sequence $\langle 1, 2, 3, 5, 8 \ldots \rangle$ of Fibonacci numbers: for example, juxtaposing F_∞ and $\mathrm{tl}^5(F_\infty)$ and writing mismatches in bold we see:

$$\begin{aligned} F_\infty &:= 0100101\mathbf{10}0100101001010\mathbf{10}0100101\mathbf{10}0100101001 \ldots \\ \mathrm{tl}^5(F_\infty) &:= 0100101\mathbf{01}0100101001010\mathbf{01}0100101\mathbf{01}0100101001 \ldots \end{aligned}$$

Here, we see that each mismatch involves a factor 10 of F_∞ for which the corresponding factor in $\mathrm{tl}^5(F_\infty)$ is the reverse, 01. In fact, we see the same phenomenon for all shifts of F_∞ by an element of the Fibonacci sequence. Furthermore, it turns out that for each successive such shift, the distance between the mismatching factors increases. This is formalised below as the *expanding gaps property*. We will show that the preceding observations about the Fibonacci word generalise to arbitrary Sturmian words.

3.2 The Tribonacci Word

Recall that Sturmian words have factor complexity $p(n) = n + 1$ and thus can be considered as the simplest non-periodic infinite words. A natural candidate for the next simplest such class is the set of Arnoux-Rauzy words. Over a ternary alphabet such words have factor complexity $p(n) = 2n+1$. A prototypical example of an Arnoux-Rauzy word is the Tribonacci word, which we introduce next.

Let $\Sigma = \{0, 1, 2\}$ and consider the morphism $\sigma : \Sigma^* \to \Sigma^*$ given by $\sigma(0) = 01$, $\sigma(1) = 02$, and $\sigma(2) = 0$. The *Tribonacci word* $W_\infty \in \Sigma^\omega$ is the morphic word

$$W_\infty := \sigma^\omega(0) = 0102010010201\ldots .$$

In more detail, the Tribonacci word W_∞ is the limit of the sequence of finite words $(W_n)_{n=0}^\infty$ given by $W_n = \sigma^n(0)$ for all n (again we have that W_n is a prefix of W_{n+1} for all n, so the limit is well defined). Observe that the sequence of words $(W_n)_{n=0}^\infty$ satisfies recurrence

$$W_n = W_{n-1}W_{n-2}W_{n-3} \quad (n \geq 3)\,.$$

Associated with the Tribonacci word we have the sequence $\langle t_n\rangle_{n=0}^\infty$ of Tribonacci numbers, defined by the recurrence $t_n = t_{n-1} + t_{n-2} + t_{n-3}$ and initial conditions $t_0 = 1, t_1 = 2, t_2 = 4$. Clearly the word W_n has length t_n for all $n \in \mathbb{N}$.

In the spirit of our analysis of the Fibonacci word, we match the Tribonacci word against shifts of itself by elements of the Tribonacci sequence $\langle 1, 2, 4, 7, 13, \ldots\rangle$. By way of example, below we compare W_∞ and $\mathrm{tl}^{13}(W_\infty)$:.

$$\begin{aligned} T_\infty &:= 0102010010201\mathbf{02}\mathbf{01}\mathbf{00}\mathbf{102}0102010010201\mathbf{02}\mathbf{01}\mathbf{0}0102010010201\mathbf{02}\ldots \\ \mathrm{tl}^{13}(T_\infty) &:= 0102010010201\mathbf{02}\mathbf{01}\mathbf{0}\mathbf{02}\mathbf{01}0102010010201\mathbf{0}\mathbf{02}\mathbf{01}0102010010201\mathbf{02}\ldots \end{aligned}$$

Similar to the example of the Fibonacci word, the mismatches above appear as a fixed set of factors (either 10,20, or 102) in T_∞ that get reversed in $\mathrm{tl}^{13}(T_\infty)$. Unlike with the Fibonacci word, this time the factors may appear close to each other. Nevertheless, by suitably grouping these factors, we recover a form of the expanding gaps property and we are moreover able to show that the mismatches between T_∞ and its shifts are relatively sparse.

3.3 Definition of Echoing Words

Inspired by the respective examples of the Fibonacci and Tribonacci words, we give in this section the formal definition of echoing word.

Given two non-empty intervals $I, J \subseteq \mathbb{N}$, write $I < J$ if $a < b$ for all $a \in I$ and $b \in J$, and define the distance of I and J to be $d(I, J) := \min\{|a - b| : a \in I, b \in J\}$.

▶ **Definition 3.** *Let $\Sigma \subseteq \overline{\mathbb{Q}}$ be a finite alphabet. An infinite word $\boldsymbol{u} = u_0u_1u_2\ldots \in \Sigma^\omega$ is said to be* echoing *if for all $c, \varepsilon_1 > 0$, there exists $d \geq 2$ and for all $n \in \mathbb{N}$ there exist positive integers r_n, s_n and intervals $\{0\} < I_{1,n} < \cdots < I_{d,n} < \{s_n + 1\}$ of total length ℓ_n, such that:*

1. *the sequence $\langle r_n\rangle_{n=0}^\infty$ is unbounded and $s_n \geq cr_n$ for all n;*
2. *for all n it holds that $\{i \in \{0, \ldots, s_n\} : u_i \neq u_{i+r_n}\} \subseteq \bigcup_{j=1}^d I_{j,n}$ and $\ell_n \leq \varepsilon_1 s_n$;*
3. *as $n \to \infty$ we have $d(\{0\}, I_{1,n}) = \omega(\log(r_n + \ell_n))$ and $d(I_{j,n}, I_{j+1,n}) = \omega(\log \ell_n)$ for $1 \leq j \leq d - 1$;*
4. *for all $\beta \in \overline{\mathbb{Q}}$ such that $|\beta| > 1$ and all $n \in \mathbb{N}$ there exist at least two $j \in \{1, \ldots, d\}$ such that $\sum_{i \in I_{j,n}} (u_i - u_{i+r_n})\beta^{-i} \neq 0$.*

Properties 1–4 concern the factors $\langle u_0, \ldots, u_{s_n}\rangle$ and $\langle u_{r_n}, \ldots, u_{r_n+s_n}\rangle$ of $\boldsymbol{u}$. The inequality in Property 1 allows us to take the prefix length s_n to be an arbitrarily large multiple of the shift r_n. We call this the *Long-Overlap Property.* Informally speaking, Property 2 says that mismatches between the above two factors can be grouped into a fixed number d of intervals whose total length ℓ_n is small in proportion to s_n. We call this the *Short-Intervals Property.* Property 3 gives lower bounds on the length of the gaps between the above-mentioned intervals. We call this the *Expanding-Gaps Property.* Property 4 will be used to show, in case β is algebraic, that the words $\langle u_0, \ldots, u_{s_n}\rangle$ and $\langle u_{r_n}, \ldots, u_{r_n+s_n}\rangle$ denote different numbers base β for infinitely many n. We call this the *Non-Vanishing Property.*

The Fibonacci and Tribonacci words are both echoing. The formal proofs will be given respectively in Section 4 and Section 5. As suggested by the examples above, in the case of the Fibonacci word a suitable choice for the sequence $\langle r_n\rangle_{n=0}^{\infty}$ of shifts will be the Fibonacci sequence, while in the case of the Tribonacci word it will be the Tribonacci sequence. In the case of the Fibonacci word (and other Sturmian words) all of the intervals $I_{j,n}$ will be doubletons, whereas in the case of the Tribonacci word their total length ℓ_n grows linearly with s_n.

We conclude this section with some remarks about related work. The notion of a echoing word is reminiscent of the transcendence conditions of [1, 8, 11] in that it concerns periodicity in an infinite word. The ability to choose the parameter c to be arbitrarily large (the Long-Overlap property) is key to our being able to prove transcendence results over an arbitrary algebraic base β. In compensation, we allow for a small number of mismatches, as detailed in the Short-Interval property. This should be contrasted with the notion of stammering word in [1, 3, Section 4], where there is no allowance for such discrepancies and in which the quantity corresponding to c is determined in advance by the word (cf. the notion of the *Diophantine exponent* of a word in [2]).

4 Sturmian Words are Echoing

In this section we show that Sturmian words are echoing and, more generally, that a pointwise linear combination of a collection of Sturmian words having the same slope is echoing.

We will work with a characterisation of Sturmian words in terms of dynamical systems. Write $I := [0, 1)$ for the unit interval and given $x \in \mathbb{R}$ denote the integer part of x by $\lfloor x\rfloor$ and the fractional part of x by $\{x\} := x - \lfloor x\rfloor \in I$. Let $0 < \theta < 1$ be an irrational number and define the *rotation map* $R = R_\theta : I \to I$ by $R(y) = \{y + \theta\}$. Given $x \in I$, the *θ-coding of x* is the infinite word $\boldsymbol{u} = u_1u_2u_3\ldots$ defined by $u_n := 1$ if $R^n(x) \in [0, \theta)$ and $u_n := 0$ otherwise. As shown by Morse and Hedlund, $\boldsymbol{u}$ is a Sturmian word and, up to changing at most two letters, all Sturmian words over a binary alphabet arise as codings of the above type for some choice of θ and x. In particular, for the purposes of establishing our transcendence results we may work exclusively with codings as defined above. The number θ is equal to the slope of the Sturmian word, as defined in Section 1. The θ-coding of 0 is in particular called the *characteristic (or standard)* Sturmian word of slope θ.

The main result of this section is as follows:

▶ **Theorem 4.** *Let $\theta \in (0, 1)$ be irrational. Given a positive integer k, let $c_0, \ldots, c_k \in \mathbb{C}$ and $x_1, \ldots, x_k \in I$ with $c_1, \ldots, c_k$ non-zero. Suppose that $x_i - x_j \notin \mathbb{Z}\theta + \mathbb{Z}$ for all $i \neq j$. Writing $\langle u_n^{(i)}\rangle_{n=0}^{\infty}$ for the θ-coding of x_i, for $i = 1, \ldots, k$, define $u_n := c_0 + \sum_{i=1}^{k} c_i u_n^{(i)}$ for all $n \in \mathbb{N}$. Then $\boldsymbol{u} = \langle u_n\rangle_{n=0}^{\infty}$ is echoing.*

Proof. We start by recalling some basic notions concerning continued fractions (see [12, Chapter 10] for details). Let

$$\theta = \cfrac{1}{a_0 + \cfrac{1}{a_1 + \cfrac{1}{a_2 + \ddots}}}$$

be the simple continued-fraction expansion of θ. Given $n \in \mathbb{N}$, we write $\frac{p_n}{q_n}$ for the n-th convergent of the above continued fraction, which is obtained by truncating it at a_n. Then $\langle q_n \rangle_{n=0}^{\infty}$ is a strictly increasing sequence of positive integers such that $\|q_n\theta\| = |q_n\theta - p_n|$, where $\|\alpha\|$ denotes the distance of $\alpha \in \mathbb{R}$ to the nearest integer. We moreover have that $q_n\theta - p_n$ and $q_{n+1}\theta - p_{n+1}$ have opposite signs for all n. Finally we have the *law of best approximation*: $q \in \mathbb{N}$ occurs as one of the q_n just in case $\|q\theta\| < \|q'\theta\|$ for all q' with $0 < q' < q$.

To establish that $\boldsymbol{u}$ is echoing, given $c > 0$ we define $\langle r_n \rangle_{n=0}^{\infty}$ to be the subsequence of $\langle q_n \rangle_{n=0}^{\infty}$ comprising all terms q_n such that $\|q_n\theta\| = q_n\theta - p_n > 0$. We thereby have that either $r_n = q_{2n}$ for all n or $r_n = q_{2n+1}$ for all n, so $\langle r_n \rangle_{n=0}^{\infty}$ is an infinite sequence that diverges to infinity. Next, define $d := (k+1)c$ and for all $n \in \mathbb{N}$ define s_n to be the greatest number such that the words $u_0 \dots u_{s_n}$ and $u_{r_n} \cdots u_{r_n+s_n}$ have Hamming distance $2d$. Since $\boldsymbol{u}$ is not ultimately periodic, s_n is well-defined.

Short-Intervals Property. Given $n \in \mathbb{N}$, denote the set of positions at which $u_0 \dots u_{s_n}$ and $u_{r_n} \dots u_{s_n+r_n}$ differ by

$$\Delta_n := \left\{ m \in \{0, \dots, s_n\} : u_m \neq u_{m+r_n} \right\}. \tag{1}$$

We claim that for n sufficiently large, $m \in \Delta_n$ if and only if there exists $\ell \in \{1, \dots, k\}$ such that one of the following two conditions holds:

- **(i)** $R^m(x_\ell) \in [1 - \|r_n\theta\|, 1)$,
- **(ii)** $R^m(x_\ell) \in [\theta - \|r_n\theta\|, \theta)$.

We moreover claim that for all m there is at most one ℓ such that Condition (i) or (ii) holds.

Assuming the claim, since $R^m(x_\ell) \in [1 - \|r_n\theta\|, 1)$ if and only if $R^{m+1}(x_\ell) \in [\theta - \|r_n\theta\|, \theta)$, it follows that the elements of Δ_n come in consecutive pairs, i.e., we can write

$$\Delta_n = \bigcup_{j=1}^{d} \{i_{j,n}, i_{j,n} + 1\},$$

where $i_{1,n} < \cdots < i_{d,n}$ are the elements $m \in \Delta_n$ that satisfy Condition (i) above for some ℓ, while $i_{1,n} + 1 < \cdots < i_{d,n} + 1$ are those that satisfy Condition (ii). Defining $I_{j,n} := \{i_{j,n}, i_{j,n} + 1\}$ for $j \in \{1, \dots, d\}$, we have that Item 2 of Defintion 3 is satisfied. Indeed, since the intervals $I_{1,n}, \dots, I_{d,n}$ have total length $\ell_n = 2d$, for any choice of $\varepsilon_1 > 0$ we have $\ell_n \leq \varepsilon_1 s_n$ for n sufficiently large.

It remains to prove the claim. To this end note that for a fixed $\ell \in \{1, \dots, k\}$, for all m we have that $u_m^{(\ell)} \neq u_{m+r_n}^{(\ell)}$ iff exactly one of $R^m(x_\ell)$ and $R^{m+r_n}(x_\ell)$ lies in the interval $[0, \theta)$ iff one of Condition (i) or Condition (ii), above, holds. Moreover, since $x_\ell - x_{\ell'} \neq \theta \pmod 1$ for $\ell \neq \ell'$, we see that for n sufficiently large there is at most one $\ell \in \{1, \dots, k\}$ such that $u_m^{(\ell)} \neq u_{m+r_n}^{(\ell)}$. We deduce that $u_m \neq u_{m+r_n}$ if and only if $u_m^{(\ell)} \neq u_{m+r_n}^{(\ell)}$ for some $\ell \in \{1, \dots, k\}$. This concludes the proof of the claim.

Long-Overlap Property. Our objective is to show that $s_n \geq cr_n$ for all $n \in \mathbb{N}$. We have already established that there are $d = (k+1)c$ distinct $m \in \Delta_n$ that satisfy Condition (i), above, for some $\ell \in \{1, \ldots, k\}$. Thus there exists $\ell_0 \in \{1, \ldots, k\}$ and $\Delta'_n \subseteq \Delta_n$ such that $|\Delta'_n| \geq c$ and all $m \in \Delta'_n$ satisfy Condition (i) for $\ell = \ell_0$. In this case we have $\|(m_1 - m_2)\theta\| < \|r_n\theta\|$ for all $m_1, m_2 \in \Delta'_n$. By the law of best approximation it follows that every two distinct elements of Δ'_n have difference strictly greater than r_n. But this contradicts $|\Delta'_n| = c$, given that $\Delta'_n \subseteq \{0, 1, \ldots, cr_n\}$.

Expanding-Gaps Property. By definition of $i_{1,n}, \ldots, i_{d,n}$, for all $1 \leq j_1 < j_2 \leq d$ there exists $\ell_1, \ell_2 \in \{1, \ldots, k\}$ with $R^{i_{j_1,n}}(x_{\ell_1}), R^{i_{j_2,n}}(x_{\ell_2}) \in [1 - \|r_n\theta\|, 1)$. We deduce that

$$\|(i_{j_2,n} - i_{j_1,n})\theta + x_{\ell_1} - x_{\ell_2}\| \leq \|r_n\theta\| \,. \tag{2}$$

We claim that the left-hand side of (2) is non-zero. Indeed, the claim holds if $\ell_1 = \ell_2$ because θ is irrational, while the claim also holds in case $\ell_1 \neq \ell_2$ since in this case we have $x_{\ell_1} - x_{\ell_2} \notin \mathbb{Z}\theta + \mathbb{Z}$ by assumption. Since moreover the right-hand side of (2) tends to zero as n tends to infinity, we have that $i_{j_2,n} - i_{j_1,n} = \omega(1)$ as $n \to \infty$. Since $\ell_n = 2d$ is constant, independent of n, we have $i_{j_2,n} - i_{j_1,n} = \omega(\ell_n)$. Finally, we have $i_{1,n} > r_n$ by the requirement that $||R^{i_{n,1}}(x_{\ell_{n,1}})|| < ||r_n\theta||$ and the best-approximation property of r_n. Clearly this entails that $i_{1,n} = \omega(\log(r_n + \ell_n))$. This completes the verification of Item 3 of Definition 3(3).

Non-Vanishing Property. Consider $m \in \Delta_n$ satisfying Condition (i) above, i.e., such that $R^m(x_\ell) \in [1 - \|r_n\theta\|, 1)$ for some $\ell \in \{1, \ldots, k\}$. Then we have

$$u_m^{(\ell)} = 0,\ u_{m+1}^{(\ell)} = 1 \quad \text{and} \quad u_{m+r_n}^{(\ell)} = 1,\ u_{m+r_n+1}^{(\ell)} = 0 \,. \tag{3}$$

Moreover for all $\ell' \neq \ell$ and n sufficiently large we have

$$u_m^{(\ell')} = u_{m+r_n}^{(\ell')} \quad \text{and} \quad u_{m+1}^{(\ell')} = u_{m+r_n+1}^{(\ell')} \,. \tag{4}$$

From Equations (3) and (4) we deduce that $u_m \neq u_{m+r_n}$, $u_{m+1} \neq u_{m+1+r_n}$, and $u_m + u_{m+1} = u_{m+r_m} + u_{m+r_n+1}$. But this implies that $\beta u_m + u_{m+1} \neq \beta u_{m+r_n} + u_{m+r_n+1}$ for all $\beta \neq 1$. This establishes Item 4 of Definition 3. ◀

5 The Tribonacci Word is Echoing

5.1 The Matching Morphism

In this section we define a morphism in order to understand how the Tribonacci word aligns with shifts of itself. This is an instance of a construction that is used elsewhere to show that for certain morphisms, the associated shift dynamical system has pure discrete spectrum (see the notion of *balanced pairs* in [16] and [22, Definition 6.8]).

Recall that the Tribonacci word W_∞ is defined over the alphabet $\Sigma = \{0, 1, 2\}$ as a fixed point of the morphism $\sigma(0) = 01, \sigma(1) = 02, \sigma(2) = 0$. We define an alphabet $\Delta = \{a_0, \ldots, a_{10}\}$ whose elements are certain ordered pairs of words in Σ^+ having the same Parikh image. For intuition we represent the elements of Δ as tiles as follows:

$$a_0 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \quad a_1 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad a_2 = \begin{bmatrix} 0 & 2 \\ 2 & 0 \end{bmatrix} \quad a_3 = \begin{bmatrix} 2 & 0 \\ 0 & 2 \end{bmatrix} \quad a_4 = \begin{bmatrix} 1 & 0 & 2 \\ 2 & 0 & 1 \end{bmatrix} \quad a_5 = \begin{bmatrix} 2 & 0 & 1 \\ 1 & 0 & 2 \end{bmatrix}$$

$$a_6 = \begin{bmatrix} 0 & 1 & 0 & 2 \\ 2 & 0 & 1 & 0 \end{bmatrix} \quad a_7 = \begin{bmatrix} 2 & 0 & 1 & 0 \\ 0 & 1 & 0 & 2 \end{bmatrix} \quad a_8 = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad a_9 = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \quad a_{10} = \begin{bmatrix} 2 \\ 2 \end{bmatrix}$$

We partition Δ into a set $\Delta_0 := \{a_0, \ldots, a_7\}$ of *mismatches* and a set $\Delta_1 := \{a_8, a_9, a_{10}\}$ of *matches*.

Define morphisms $\mathrm{top}, \mathrm{bot} : \Delta^* \to \Sigma^*$ such that top extracts the word on the top of each tile and bottom extracts the word on the bottom, e.g.,

$$\mathrm{top}\left(\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\right) = 01 \quad \text{and} \quad \mathrm{bot}\left(\begin{bmatrix}1 & 0 & 2\\ 2 & 0 & 1\end{bmatrix}\right) = 201\,.$$

Below we define the *matching morphism* $\mu : \Delta^* \to \Delta^*$, which is characterised by the following properties:

$$\mathrm{top} \circ \mu = \sigma \circ \mathrm{top} \qquad \text{and} \qquad \mathrm{bot} \circ \mu = \sigma \circ \mathrm{bot}\,. \tag{5}$$

Specifically we have

$$\mu\left(\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}1 & 0 & 2\\ 2 & 0 & 1\end{bmatrix} \qquad \mu\left(\begin{bmatrix}1 & 0 & 2\\ 2 & 0 & 1\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}2 & 0 & 1 & 0\\ 0 & 1 & 0 & 2\end{bmatrix}$$

$$\mu\left(\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}2 & 0 & 1\\ 1 & 0 & 2\end{bmatrix} \qquad \mu\left(\begin{bmatrix}2 & 0 & 1\\ 1 & 0 & 2\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}0 & 1 & 0 & 2\\ 2 & 0 & 1 & 0\end{bmatrix}$$

$$\mu\left(\begin{bmatrix}0 & 2\\ 2 & 0\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix} \qquad \mu\left(\begin{bmatrix}2 & 0 & 1 & 0\\ 0 & 1 & 0 & 2\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}\begin{bmatrix}0 & 2\\ 2 & 0\end{bmatrix}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}$$

$$\mu\left(\begin{bmatrix}2 & 0\\ 0 & 2\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix} \qquad \mu\left(\begin{bmatrix}0 & 1 & 0 & 2\\ 2 & 0 & 1 & 0\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}\begin{bmatrix}2 & 0\\ 0 & 2\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix}$$

and

$$\mu\left(\begin{bmatrix}0\\ 0\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}1\\ 1\end{bmatrix} \qquad \mu\left(\begin{bmatrix}1\\ 1\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}\begin{bmatrix}2\\ 2\end{bmatrix} \qquad \mu\left(\begin{bmatrix}2\\ 2\end{bmatrix}\right) := \begin{bmatrix}0\\ 0\end{bmatrix}.$$

For later use we remark that the morphism $\iota : \Sigma^* \to \Delta^*$, defined by $\iota(0) = a_0, \iota(1) = a_2, \iota(2) = a_8$ satisfies $\mathrm{top} \circ \iota = \sigma$, while $\mathrm{bot} \circ \iota$ and $\mathrm{tl} \circ \sigma$ agree on Σ^ω. It follows that

$$\mathrm{top}(\iota(W_\infty)) = W_\infty \quad \text{and} \quad \mathrm{bot}(\iota(W_\infty)) = \mathrm{tl}(W_\infty)\,. \tag{6}$$

Associated with the morphism μ we have its *incidence matrix* $M(\mu) \in \mathbb{N}^{11\times 11}$, where $M(\mu)_{i,j} := |\mu(a_i)|_j$ is the number of occurrences of a_j in $\mu(a_i)$ for all $i, j \in \{0, \ldots, 10\}$. It is straightforward that $M(\mu)^n_{i,j} = |\mu^n(a_i)|_j$ for all n and all $i, j \in \{0, \ldots, 10\}$. Matrix $M(\mu)$ admits a block decomposition

$$M(\mu) = \begin{pmatrix} B_1 & B_2 \\ 0 & B_3 \end{pmatrix},$$

where B_1 is the restriction of $M(\mu)$ to the set of mismatch symbols Δ_0 and B_3 is the restriction to the set of match symbols Δ_1. By direct calculation one see that both B_1 and B_3 are primitive and have respective spectral radii $\rho' \approx 1.395$ and $\rho \approx 1.839$. [1]

We hence have that for all $n \in \mathbb{N}$ and $i \in \{0, \ldots, 7\}$,

$$\frac{\sum_{j=0}^{7} |\mu^n(a_i)|_j}{|\mu^n(a_i)|} = \frac{\sum_{j=0}^{7} M(\mu)^n_{i,j}}{\sum_{j=0}^{10} M(\mu)^n_{i,j}} \leq \frac{\sum_{j=0}^{7} (B_1^n)_{i,j}}{\sum_{j=0}^{2}\sum_{k=0}^{n-1} (B_1^k B_2 B_3^{n-k})_{i,j}} \ll \left(\frac{\rho'}{\rho}\right)^n. \tag{7}$$

We deduce that the frequency of mismatch symbols in $\mu^n(a_0)$ converges to 0 as n tends to infinity. The above reasoning shows, *inter alia* that for all $a \in \Delta$ the sequence $|\mu^n(a)| = \Theta(\rho^n)$ and hence there exists a constant κ such that $|\mu^n(a)| \leq \kappa |\mu^n(b)|$ for all $a, b \in \Delta$ and all n sufficiently large.

[1] The inequality $\rho' < \rho$ implies that the Tribonacci morphism has pure discrete spectrum (see [22, Section 6.3] and the references therein).

5.2 Matching Polynomials

Define eval : $\Sigma^* \to \mathbb{Z}[x]$ by $\mathrm{eval}(u_0 \dots u_n) := \sum_{i=0}^{n} u_i x^i$. For all $i \in \{0, \dots, 7\}$ and $n \in \mathbb{N}$ define the *matching polynomial* $P_{i,n}(x) \in \mathbb{Z}[x]$ by

$$P_{i,n} := \mathrm{eval}(\mathrm{top}(\mu^n(a_i))) - \mathrm{eval}(\mathrm{bot}(\mu^n(a_i)))\,. \tag{8}$$

By inspection, the only common root of $P_{i,0}(x)$ for $i \in \{0, \dots, 7\}$ is $x = 1$.

Observe that for all $n \in \mathbb{N}$ and $i \in \{0, 1, 2, 3\}$ we have

$$\mathrm{top}(\mu^n(a_{2i})) = \mathrm{bot}(\mu^n(a_{2i+1})) \quad \text{and} \quad \mathrm{bot}(\mu^n(a_{2i})) = \mathrm{top}(\mu^n(a_{2i+1}))\,,$$

and hence $P_{2i,n}(x) = -P_{2i+1,n}(x)$. As a consequence we can focus our attention on the even-index polynomials $P_{0,n}$, $P_{2,n}$, $P_{4,n}$, and $P_{6,n}$. Indeed, writing $\boldsymbol{P}_n := (P_{0,n}, P_{2,n}, P_{4,n}, P_{6,n}) \in \mathbb{Z}[x]^4$ and

$$M_n := (-1) \cdot \begin{pmatrix} 0 & 0 & -x^{t_n} & 0 \\ x^{t_n} & 0 & 0 & 0 \\ 0 & 0 & 0 & x^{t_n} \\ x^{t_n} + x^{t_{n+1}} & x^{t_n + t_{n+1}} & 0 & 0 \end{pmatrix},$$

then we have $\boldsymbol{P}_{n+1} = M_n \boldsymbol{P}_n$ for all $n \in \mathbb{N}$. But now, since $\boldsymbol{P}_0(\beta) \neq \boldsymbol{0}$ for all $\beta \neq 1$ and $\det(M_n) = -x^{t_{n+1}+4t_n}$, it follows that $\boldsymbol{P}_n(\beta) \neq \boldsymbol{0}$ for all $\beta \in \mathbb{C} \setminus \{0, 1\}$.

5.3 Putting Things Together

▶ **Theorem 5.** *The Tribonacci word $\boldsymbol{u} := W_\infty$ is echoing.*

Proof. We refer to Definition 3. Let $c, \varepsilon_1 > 0$ be given and write $\boldsymbol{w} := \iota(u_0 u_1 \dots u_{c-1}) \in \Delta^*$. It follows from (6) that $\mathrm{top}(\boldsymbol{w})$ is a prefix of $\boldsymbol{u}$ and $\mathrm{bot}(\boldsymbol{w})$ is a prefix of $\mathrm{tl}(\boldsymbol{u})$. Given $n_0 \in \mathbb{N}$, write

$$\mu^{n_0}(\boldsymbol{w}) = \boldsymbol{w}_0 a_{i_1} \boldsymbol{w}_1 \cdots \boldsymbol{w}_{d-1} a_{i_d} \boldsymbol{w}_d\,, \tag{9}$$

where $\boldsymbol{w}_0, \dots, \boldsymbol{w}_d \in \Delta_1^*$ are sequences of match symbols and $a_{i_1}, \dots, a_{i_d} \in \Delta_0$ are mismatch symbols. For $n_0 \in \mathbb{N}$ sufficiently large it holds that $\mu^{n_0}(\boldsymbol{w})$ contains at least two occurrences of every mismatch symbol and the proportion of mismatch symbols in $\mu^{n_0}(\boldsymbol{w})$ is at most ε_1/κ, for κ as in Section 5.1.

For all $n \in \mathbb{N}$, referring to Equation (9), we have

$$\mu^{n+n_0}(\boldsymbol{w}) = \mu^n(\boldsymbol{w}_0) \underbrace{\mu^n(a_{i_1})}_{I_{1,n}} \mu^n(\boldsymbol{w}_1) \cdots \mu^n(\boldsymbol{w}_{d-1}) \underbrace{\mu^n(a_{i_d})}_{I_{d,n}} \mu^n(\boldsymbol{w}_d)\,. \tag{10}$$

The data to show the echoing property are as follows. For all $n \in \mathbb{N}$ define $r_n := |\sigma^n(0)| = t_{n+n_0}$, $s_n := |\mathrm{top}(\mu^{n+n_0}(\boldsymbol{w}))|$, and we take d as in (9). For all $j \in \{1, \dots, d\}$ we define $I_{j,n} \subseteq \mathbb{N}$ to be the interval of positions in $\mu^{n+n_0}(a_0)$ corresponding to the shortest suffix of $\mu^n(a_{i_j})$ that contains all mismatch symbols that occur therein (see (10)).

From Equation (5) we have $\mathrm{top}(\mu^{n+n_0}(\boldsymbol{w})) = \langle u_0, \dots, u_{s_n} \rangle$ and $\mathrm{bot}(\mu^{n+n_0}(\boldsymbol{w})) = \langle u_{r_n}, \dots, u_{s_n+r_n} \rangle$. Since $\mathrm{top}(\boldsymbol{w})$ contains at least c occurrences of the letter 0, we get that $s_n \geq c r_n$, establishing the Long-Overlap Property.

By construction, the intervals $I_{1,n}, \dots, I_{d,n}$ contain all indices where the above two strings differ and they have total length at most $\varepsilon_1 s_n$, establishing the Short-Intervals Property.

By definition of the matching polynomials, it holds that $P_{i_j,n}(\beta^{-1})$ is the product of $\sum_{i\in I_{j,n}}(u_i - u_{i+r_n})\beta^{-1}$ and a power of β for all $j \in \{1,\dots,d\}$. We have shown in Section 5.2 that the vector $(P_{0,n}(\beta^{-1}),\dots,P_{7,n}(\beta^{-1}))$ is non-zero for all n. Since all mismatch symbols occur at least twice among $a_{i_1},\dots,a_{i_d}$, we have that $P_{i_j,n}(\beta^{-1})$ is non-zero for at least two different choices of $j \in \{1,\dots,d\}$. It follows that $\sum_{i\in I_{j,n}}(u_i - u_{i+r_n})\beta^{-1}$ is non-zero for at least two different values of j, establishing the Non-Vanishing Property.

Finally, note that there is at least one letter between each pair of intervals $I_{j,n}$ in (10). Hence the inequality $|\mu(a^n)| \le \kappa|\mu^n(b)|$ for $a,b \in \Delta$ implies that $d(\{0\},I_{1,n}) \gg s_n$ and $d(I_{j,n},I_{j+1,n}) \gg s_n$ for all $j \in \{0,\dots,d-1\}$, which implies the Expanding-Gaps Property. ◀

6 Transcendence Results

6.1 Transcendence for Echoing Words

▶ **Theorem 6.** *Let Σ be a finite set of algebraic numbers and let $\boldsymbol{u} \in \Sigma^\omega$ be an echoing word. Then for any algebraic number β such that $|\beta| > 1$, the sum $\alpha := \sum_{n=0}^{\infty} \frac{u_n}{\beta^n}$ is transcendental.*

Proof. Suppose for a contradiction that α is algebraic. By scaling, we can assume without loss of generality that Σ consists solely of algebraic integers. Let K be the field generated over $\mathbb{Q}$ by $\{\beta\} \cup \Sigma$ and write $S \subseteq M(K)$ for the set comprising all infinite places of K and those finite places of K arising from prime-ideal divisors of elements of $\{\beta\} \cup \Sigma$. Let $v_0 \in S$ be the place corresponding to the inclusion of K in $\mathbb{C}$. Recall that $|a|_{v_0} = |a|^{1/[K:\mathbb{Q}]}$, where $|a|$ denotes the usual absolute value on $\mathbb{C}$.

Applying the definition of echoing sequence (as given in Definition 3) for values of c and ε_1 to be specified later, we obtain $d \ge 2$ such that for all $n \in \mathbb{N}$ there are $r_n, s_n \in \mathbb{N}$ and intervals $\{0\} < I_{1,n} < \cdots < I_{d,n} < \{s_n + 1\}$, of total length ℓ_n, satisfying Items 1–4 of Definition 3.

For $n \in \mathbb{N}$, define $\boldsymbol{a}_n = (a_{1,n},\dots,a_{d+3,n}) \in (\mathcal{O}_S)^{d+3}$ by

$$a_{1,n} := \beta^{r_n},\ a_{2,n} := \sum_{i=0}^{r_n} u_i \beta^{r_n - i},\ a_{3,n} := 1,\ a_{j+3,n} := \sum_{i\in I_{n,j}} (u_{i+r_n} - u_i)\beta^{-i}\ (j = 1,\dots,d)$$

The Non-Vanishing Property (Definition 3(4)) implies that for all $n \in \mathbb{N}$ we have $a_{j+3,n} \neq 0$ for at least two elements $j \in \{1,\dots,d\}$. By passing to a subsequence we henceforth assume without loss of generality that there exists $J \subseteq \{1,\dots,d\}$, of cardinality at least two, such that for all j and n, $a_{j+3,n} \neq 0$ if and only if $j \in J$.

▷ Claim 7. If $F(x_1,\dots,x_{d+3}) = \sum_{i\in\{1,2,3\}\cup J} \alpha_i x_i$ is a linear form with coefficients in K such that $F(\boldsymbol{a}_n) = 0$ for infinitely many n, then $\alpha_j = 0$ for all $j \in J$.

The proof of the claim is as follows. For all $n \in \mathbb{N}$ we have $F(\boldsymbol{a}_n) = P_n(\beta)$ for the polynomial $P_n(x) := P_{0,n}(x) + \sum_{j\in J} P_{j,n}(x)$, where

$$P_{0,n}(x) := \alpha_1 x^{r_n} + \alpha_2 \sum_{i=0}^{r_n} u_i x^{r_n - i} + \alpha_3 \quad \text{and} \quad P_{j,n}(x) := \alpha_j \sum_{i\in I_{j,n}} (u_i - u_{i+r_n})x^{-i}\,.$$

Polynomial P_n has at most $r_n + \ell_n$ monomials. From Proposition 2 and the property $d(\{0\},I_{1,n}) = \omega(\log(r_n + \ell_n))$ (see Definition 3(3)), we deduce that $\sum_{j\in J} P_{j,n}(\beta) = 0$ for infinitely many n. Now $\sum_{j\in J} P_{j,n}(x)$ comprises at most ℓ_n monomials. Thus Proposition 2

and the assumption that $d(I_{j,n}, I_{j+1,n}) = \omega(\log \ell_n)$ for all $j \in \{1, \dots, d-1\}$, entail that for infinitely many n we have $P_{j,n}(\beta) = 0$ for all $j \in J$. But $P_{j,n}(\beta) = \alpha_j a_{j,n}$ and so, since $a_{j,n} \neq 0$ for all $j \in J$, we have $\alpha_j = 0$ for all $j \in J$. This concludes the proof of the claim.

Consider the linear form $L_0(x_1, \dots, x_{d+3}) := \alpha x_1 - x_2 - \alpha x_3 - \sum_{j\in J} x_{j+3}$. Then there exists $c_1 > 1$ such that for all n,

$$\begin{array}{rcl} 0 < |L_0(\boldsymbol{a}_n)| & = & \left|\beta^{r_n}\alpha - \sum_{i=0}^{r_n} u_i \beta^{r_n - i} + \alpha + \sum_{j\in J}\sum_{i\in I_{j,n}} (u_i - u_{i+r_n})\beta^i\right| \\ & = & \left|\sum_{i=s_n+1}^{\infty} (u_i - u_{i+r_n})\beta^{-i}\right| < c_1|\beta|^{-s_n}, \end{array} \tag{11}$$

where the left-hand inequality follows from an application of Claim 7 to L_0. Consider a linear form $L(x_1, \dots, x_{d+3})$ with the following properties: (i) L has coefficients in K; (ii) L has support $\{x_i : i \in I \cup J\}$ for some $I \subseteq \{1, 2, 3\}$; (iii) $0 < |L(\boldsymbol{a}_n)| < c_1|\beta|^{-s_n}$ for all $n \in \mathbb{N}$; (iv) the set I is minimal with respect to set inclusion among linear forms satisfying (i)–(iii). We have just exhibited a form, namely L_0, that satisfies Conditions (i)–(iii), so L is well-defined.

Let $c_2 \geq 2$ be an upper bound of the set of numbers $\{|\gamma|_v : \gamma \in \{\beta\} \cup A \cup A - A,\ v \in S\}$. Then for $v \in S$, by the assumption that $s_n \geq cr_n$ we have

$$|a_{2,n}|_v \leq \sum_{i=0}^{r_n} c_2^{i+1} \leq c_2^{r_n+2} \leq c_2^{(c^{-1}s_n+2)}. \tag{12}$$

We moreover have

$$\prod_{j\in J}\prod_{v\in S} |a_{j+3,n}|_v \leq \prod_{j\in J}\prod_{v\in S}\sum_{i=0}^{|I_{j,n}|} c_2^{i+1} \leq \prod_{j\in J} c_2^{|S|(2+|I_{j,n}|)} \leq c_2^{|S|(2d+\varepsilon_1 s_n)}, \tag{13}$$

where we use the assumption that the intervals $I_{1,n}, \dots, I_{d,n}$ have total length $\ell_n \leq \varepsilon_1 s_n$. We also have $\prod_{v\in S} |a_{1,n}|_v = \prod_{v\in S} |\beta^{r_n}|_v = 1$ by the product formula and, obviously, $\prod_{v\in S} |a_{3,n}|_v = 1$.

Pick $i_0 \in I \cup J$. Then, combining (12) and (13) and the bound $|L(\boldsymbol{a}_n)| < c_1|\beta|^{-s_n}$, we have

$$|L(\boldsymbol{a}_n)|_{v_0} \cdot \prod_{\substack{(i,v)\in(I\cup J)\times S \\ (i,v)\neq(i_0,v_0)}} |a_{i,n}|_v \leq c_2^{\left(s_n(\varepsilon_1+c^{-1})+2d+2\right)|S|} \cdot (c_1|\beta|^{-s_n})^{1/[K:\mathbb{Q}]}. \tag{14}$$

For c sufficiently large, ε_1 sufficiently small, and all but finitely many n, the right-hand side of (14) is less than $|\beta|^{-s_n/2[K:\mathbb{Q}]}$. On the other hand, there exists a constant $c_3 > 0$ such that the height of $\boldsymbol{a}_n$ satisfies the bound $H(\boldsymbol{a}_n) \leq |\beta|^{c_3 s_n}$ for all n. Thus there exists $\varepsilon > 0$ such that the right-hand side of (14) is at most $H(\boldsymbol{a}_n)^{-\varepsilon}$ for infinitely many n.

Given (14), we can apply Theorem 1 to obtain a non-zero linear form $L'(x_1, \dots, x_{3+d})$ that has coefficients in K and support in $\{x_i : i \in I \cup J\}$, such that for infinitely many $n \in \mathbb{N}$ we have both $0 < |L(\boldsymbol{a}_n)| < c_1|\beta|^{-s_n}$ and $L'(\boldsymbol{a}_n) = 0$. By Claim 7, the support of L' is in fact contained in I. Hence, by subtracting a suitable multiple of L' from L we obtain a linear form $L''(x_1, \dots, x_{3+d})$ with strictly fewer coefficients than L such that $0 < |L''(\boldsymbol{a}_n)| < c_1|\beta|^{-s_n}$ for infinitely many $n \in \mathbb{N}$. But this contradicts the minimality of the support of L. ◀

6.2 Transcendence for Sturmian Words and the Tribonacci Word

Combining the transcendence result for echoing words (Theorem 6) with the fact that Sturmian words and the Tribonacci word are echoing (Theorem 4 and Theorem 5), we obtain:

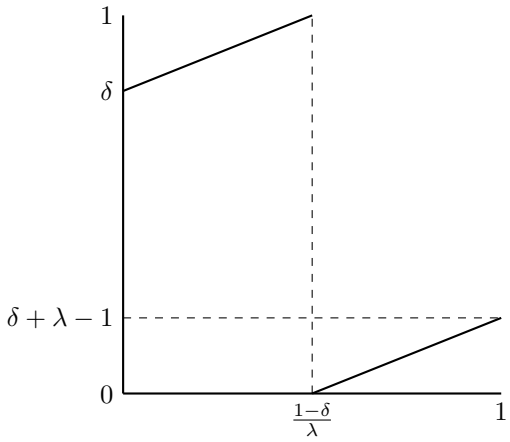

Figure 1 A plot of $f_{\lambda,\delta} : I \to I$.

▶ **Theorem 8.** *Let β be an algebraic number with $|\beta| > 1$.*

1. *Let $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_k$ be Sturmian words with the same slope such that $\boldsymbol{u}_i$ is not a suffix of $\boldsymbol{u}_j$ for all $i \neq j$. Then $\{1, S_\beta(\boldsymbol{u}_1), \ldots, S_\beta(\boldsymbol{u}_k)\}$ is linearly independent over $\overline{\mathbb{Q}}$.*
2. *Let $\boldsymbol{u}$ be the Tribonacci word. Then $S_\beta(\boldsymbol{u})$ is transcendental.*

7 Application to Limit Sets of Contracted Rotations

Let $0 < \lambda, \delta < 1$ be real numbers such that $\lambda + \delta > 1$. We call the map $f = f_{\lambda,\delta} : I \to I$ given by $f(x) := \{\lambda x + \delta\}$ a *contracted rotation* with slope λ and *offset* δ. Associated with f we have the map $F = F_{\lambda,\delta} : \mathbb{R} \to \mathbb{R}$, given by $F(x) = \lambda\{x\} + \delta + \lfloor x \rfloor$. We call F a *lifting* of f: it is characterised by the properties that $F(x+1) = F(x) + 1$ and $\{F(x)\} = f(\{x\})$ for all $x \in \mathbb{R}$. The *rotation number* $\theta = \theta_{\lambda,\delta}$ of f is defined by

$$\theta := \lim_{n\to\infty} \frac{F^n(x_0)}{n},$$

where the limit exists and is independent of the initial point $x_0 \in \mathbb{R}$.

If the rotation number θ is irrational then the restriction of f to the *limit set* $\bigcap_{n\geq 0} f^n(I)$ is topologically conjugated to the rotation map $R = R_\theta : I \to I$ with $R(y) = \{y + \theta\}$. The closure of the limit set is a Cantor set $C = C_{\lambda,\delta}$, that is, C is compact, nowhere dense, and has no isolated points. On the other hand, if θ is rational then the limit set C is the unique periodic orbit of f. For each choice of slope $0 < \lambda < 1$ and irrational rotation number $0 < \theta < 1$, there exists a unique offset δ such that $\delta + \lambda > 1$ and the map f has rotation number θ. It is known that such δ must be transcendental if λ is algebraic [14].

The main result of this section is as follows:

▶ **Theorem 9.** *Let $0 < \lambda, \theta < 1$ be such that λ is algebraic and θ is irrational. Let δ be the unique offset such that the contracted rotation $f_{\lambda,\delta}$ has rotation number θ. Then every element of the Cantor set $C_{\lambda,\delta}$ other than 0 and 1 is transcendental.*

A special case of Theorem 9, in which λ is assumed to be the reciprocal of an integer, was proven in [8, Theorem 1.2]. In their discussion of the latter result the authors conjecture the truth of Theorem 9, i.e., the more general case in which λ may be algebraic. As noted in [8], while $C_{\lambda,\delta}$ is homeomorphic to the Cantor ternary set, it is a longstanding open problem, formulated by Mahler [19], whether the Cantor ternary set contains irrational algebraic elements.

Proof of Theorem 9. For a real number $0 < x < 1$ define

$$\begin{aligned} \xi_x &:= \sum_{n\geq 1} \left(\lceil x+(n+1)\theta\rceil - \lceil x+n\theta\rceil\right)\lambda^n \\ \xi'_x &:= \sum_{n\geq 1} \left(\lfloor x+(n+1)\theta\rfloor - \lfloor x+n\theta\rfloor\right)\lambda^n . \end{aligned}$$

Note that for all x the binary sequence $\langle \lceil x+(n+1)\theta\rceil - \lceil x+n\theta\rceil : n\in\mathbb{N}\rangle$ is the coding of $-x-\theta$ by $1-\theta$ (as defined in Section 4) and hence is Sturmian of slope $1-\theta$. Similarly, the binary sequence $\langle \lfloor x+(n+1)\theta\rfloor - \lfloor x+n\theta\rfloor : n\in\mathbb{N}\rangle$ is the coding of $x+\theta$ by θ and hence is Sturmian of slope θ. Thus for all x, both ξ_x and ξ'_x are Sturmian numbers.

It is shown in [8, Lemma 4.2][2] that for every element of $y \in C_{\lambda,\delta}\setminus\{0,1\}$, either there exists $z\in\mathbb{Z}$ and $0<x<1$ with $x\notin\mathbb{Z}\theta+\mathbb{Z}$ such that

$$y = z + \xi_0 - \xi_{-x}$$

or else there exists a strictly positive integer m and $\gamma\in\mathbb{Q}(\beta)$ such that

$$y = \gamma + (1-\beta^{-m})\,\xi'_0 .$$

In either case, transcendence of y follows from Theorem 8. ◀

The Threshold Problem for Hypergeometric Sequences with Quadratic Parameters

George Kenison
School of Computer Science and Mathematics, Liverpool John Moores University, UK

Abstract

Hypergeometric sequences are rational-valued sequences that satisfy first-order linear recurrence relations with polynomial coefficients; that is, $\langle u_n \rangle_{n=0}^{\infty}$ is hypergeometric if it satisfies a first-order linear recurrence of the form $p(n)u_{n+1} = q(n)u_n$ with polynomial coefficients $p, q \in \mathbb{Z}[x]$ and $u_0 \in \mathbb{Q}$.

In this paper, we consider the Threshold Problem for hypergeometric sequences: given a hypergeometric sequence $\langle u_n \rangle_{n=0}^{\infty}$ and a threshold $t \in \mathbb{Q}$, determine whether $u_n \geq t$ for each $n \in \mathbb{N}_0$. We establish decidability for the Threshold Problem under the assumption that the coefficients p and q are monic polynomials whose roots lie in an imaginary quadratic extension of $\mathbb{Q}$. We also establish conditional decidability results; for example, under the assumption that the coefficients p and q are monic polynomials whose roots lie in any number of quadratic extensions of $\mathbb{Q}$, the Threshold Problem is decidable subject to the truth of Schanuel's conjecture. Finally, we show how our approach both recovers and extends some of the recent decidability results on the Membership Problem for hypergeometric sequences with quadratic parameters.

1 Introduction

Background

The *Threshold Problem* is a fundamental open decision problem in automated verification that asks to determine whether every term in a recursively defined sequence is bounded from below by a given value (commonly, the *threshold*). The Threshold Problem appears under many guises across the computational and mathematical sciences with applications in fields as diverse as software verification, probabilistic model checking, combinatorics, and formal languages (we refer the interested reader to the discussion in [26] and the references therein).

The inputs for the Threshold Problem are a recursively defined sequence $\langle u_n \rangle_{n=0}^{\infty} \subseteq \mathbb{Q}$ and a threshold $t \in \mathbb{Q}$. (Hereafter, we shall use tuple notation $(\langle u_n \rangle_{n=0}^{\infty}, t)$ as shorthand for a given problem instance.) Threshold then asks to determine whether $u_n \geq t$ for each $n \in \mathbb{N}_0$. Arguably, the variant of the Threshold Problem that has received the most attention in automated verification is the Positivity Problem for *C-finite sequences* (those sequences that obey a linear recurrence relation with constant coefficients). Therein, Positivity sets as a threshold $t = 0$ and so asks whether every term in a C-finite sequence is non-negative.

Herein we consider the hypergeometric subclass of *P-finite sequences* (those sequences that satisfy a linear recurrence relation with polynomial coefficients) [11]. Recall that a *hypergeometric sequence* is a rational-valued first-order linear recurrence sequence with polynomial coefficients; that is to say, a sequence $\langle u_n \rangle_{n=0}^{\infty} \subseteq \mathbb{Q}$ that satisfies a relation of the form

$$p(n)u_{n+1} = q(n)u_n \tag{1}$$

where $p, q \in \mathbb{Z}[x]$ and $p(x)$ has no non-negative integer zeros. By the latter assumption on $p(x)$, the recurrence relation (1) uniquely defines an infinite sequence of rational numbers once the initial value $u_0 \in \mathbb{Q}$ is specified. For a hypergeometric sequence $\langle u_n \rangle_{n=0}^{\infty}$ satisfying (1), we call the roots of the polynomial pq the sequence's *parameters*. Hypergeometric sequences and their associated generating functions, the hypergeometric series, are commonplace in fields such as numerical analysis and analytic combinatorics [8, 11].

In this paper, we consider the Threshold Problem for hypergeometric sequences. Naïvely, we might construe that decidability of the Threshold Problem in this setting is easily settled. Consider an instance of the Threshold Problem $(\langle u_n \rangle_{n=0}^{\infty}, t)$. Without loss of generality, we can assume that $\langle u_n \rangle_{n=0}^{\infty}$ either diverges to infinity or converges to a non-zero limit (further explanation behind this assumption is given in the Preliminaries). Suppose that $\langle u_n \rangle_{n=0}^{\infty}$ converges to a limit not equal to t. From the form of the recurrence relation in (1), we can compute a bound B such that if $n > B$ then $u_n > t$ or $u_n < t$. Similar deductions handle the case that $\langle u_n \rangle_{n=0}^{\infty}$ diverges to infinity. In the case that the limit of $\langle u_n \rangle_{n=0}^{\infty}$ is the threshold t, we can compute a similar bound based on the fact that the convergence to t is eventually monotonic. It follows that, in each case, the Threshold Problem reduces to exhaustively checking whether $u_n \geq t$ for each $n \in \{0, 1, \ldots, B\}$. Unfortunately this reasoning does not suffice to decide the Threshold Problem. Indeed, we do not know how to decide whether a generic hypergeometric sequence converges to a given rational limit. Further, such convergence questions are intricately linked to open problems concerning algebraic relations for the gamma function (we give further details below).

Contributions

Our primary contributions are:

(a) The Threshold Problem for hypergeometric sequences whose polynomial coefficients are monic and split over an imaginary quadratic field are decidable (Theorem 15).

(b) The Threshold Problem for hypergeometric sequences whose polynomial coefficients are monic and each irreducible factor of pq is either linear or quadratic is decidable subject to the truth of Schanuel's conjecture (Corollary 18).

We delay a formal statement of Schanuel's conjecture to the Preliminaries. For our conditional decidability results, we note that only termination is conditional on Schanuel's conjecture and that correctness of our procedure is unconditional (Remark 24). Corollary 18 follows from the more general result:

(c) The Threshold Problem for hypergeometric sequences whose monic polynomial coefficients possess Property S is decidable subject to the truth of Schanuel's conjecture (Theorem 17 in Subsection 4.1).

Polynomials with Property S (Subsection 4.1) lead to classes of hypergeometric sequences with unnested radical and cyclotomic parameters.

Our secondary contribution concerns the *Membership Problem* for hypergeometric sequences. Given a hypergeometric sequence $\langle u_n \rangle_{n=0}^{\infty}$ and target $t \in \mathbb{Q}$, Membership asks to determine whether there is an $n \in \mathbb{N}_0$ for which $u_n = t$.

(d) For classes of hypergeometric sequences where we establish (un)conditional decidability of the Threshold Problem, we also obtain (un)conditional decidability of the Membership Problem. This contribution is a straightforward corollary of the following observation: for hypergeometric sequences, decidability of the Membership Problem reduces to that of the Threshold Problem (Proposition 7).

We note this secondary contribution both recovers and extends some of the recent results in work by Kenison et al. [15]. For the avoidance of doubt, we break new ground for the Membership Problem. For example, we have conditional decidability of the Membership Problem for hypergeometric sequences with unnested radical and cyclotomic parameters (both classes fall outside of the remit of the previous works). A concrete subclass is given by those hypergeometric sequences whose polynomial coefficients are of the form $(x^2 - \ell_1)(x^2 - \ell_2) \cdots (x^2 - \ell_d)$ where $\ell_1, \ldots, \ell_d \in \mathbb{Z}$.

Approach

As previously mentioned, an obstacle that prevents us from settling decidability of the Threshold Problem for hypergeometric sequences is determining whether a given hypergeometric sequence converges to some rational limit.

To each hypergeometric sequence $\langle u_n \rangle_{n=0}^{\infty}$ satisfying (1), we associate the *shift quotient* $r(x) := q(x)/p(x) \in \mathbb{Q}(x)$. It is clear that the terms of $\langle u_n \rangle_{n=0}^{\infty}$ are given by a sequence of partial products such that the nth term is given thus: $u_n = u_0 \cdot \prod_{k=0}^{n} r(k)$. Without loss of generality, we can a normalise a sequence with $u_0 \neq 0$ by assuming that $u_0 = 1$. (We note that the Threshold Problem is trivial to decide when $u_0 = 0$.) Thus our consideration of the Threshold Problem reduces to analysing the sequence of partial products $\langle \prod_{k=0}^{n} r(k) \rangle_{n=0}^{\infty}$. In all problem instances where the Threshold Problem is not trivial to determine, we employ a classical theorem in analysis (Theorem 5) that permits us to write the limit of the sequence $\langle \prod_{k=0}^{n} r(k) \rangle_{n=0}^{\infty}$ as a quotient of two finite products involving the gamma function. Thus the Threshold Problem for hypergeometric sequences reduces to testing an equality between gamma products. Our novel approach leverages algebraic and transcendental properties to settle such equality tests. For example, we frequently employ the algebraic independence of transcendental constants π and e^{π} (a celebrated consequence of Nesterenko's work on modular functions [20]).

There is a large corpus of research connecting hypergeometric sequences and the gamma function (often under the guise of infinite product identities [1, 5, 7]). This is particularly relevant for our approach (as described above) and sets us apart from previous papers on the Membership Problem in this setting [15, 22]. As a nod to the wider appeal of our approach, let us consider two examples from the literature on numeric and symbolic computation.

▶ **Example 1** (Numerical evaluation of the Kepler–Bouwkamp constant [5, Section 4])**.** This example closely follows work by Chamberland and Straub [5]. Those authors demonstrate the use of hypergeometric sequences to efficiently approximate certain numerical constants given by infinite products. One such example is the Kepler–Bouwkamp constant $\prod_{k=3}^{\infty} \cos(\pi/k)$. The convergence of this infinite product is notoriously slow: the error bound between the approximation $\prod_{k=3}^{10^4} \cos(\pi/k)$ and the Kepler–Bouwkamp constant is 10^{-4}.

Let us consider a Padé approximation that uses hypergeometric sequences with quadratic parameters. We recall that the $[2,2]$-*Padé approximant* of a function $f(x)$ is the rational function $q(x)/p(x)$ where $p, q \in \mathbb{Z}[x]$ are quadratic polynomials for which the Maclaurin series of $q(x)/p(x)$ agrees with that of $f(x)$ up to order 4. For example, the $[2,2]$-Padé approximant of $\cos(x)$ is

$$r_2(x) := \frac{12 - 5x^2}{12 + x^2} = \cos(x) + O(x^6).$$

Now consider

$$\prod_{k=3}^{\infty} r_2(\pi/k) = \prod_{k=3}^{\infty} \frac{12k^2 - 5\pi^2}{12k^2 + \pi^2} = \frac{\Gamma(3 - \frac{\mathrm{i}}{6}\sqrt{3}\pi)\Gamma(3 + \frac{\mathrm{i}}{6}\sqrt{3}\pi)}{\Gamma(3 - \frac{1}{6}\sqrt{15}\pi)\Gamma(3 + \frac{1}{6}\sqrt{15}\pi)}.$$

Here the evaluation as a quotient of two gamma products follows from Theorem 5. We pass this evaluation to any modern computer algebra system and determine that the error between $\prod_{k=3}^{\infty} r_2(\pi/k)$ and the Kepler–Bouwkamp constant is bounded by 10^{-3}.

Loosely speaking, the $[2, 2]$-Padé approximant leverages a hypergeometric sequence with quadratic parameters.[1] Higher-order approximants will give a closer numerical estimate via hypergeometric sequences with higher-degree parameters.

▶ **Example 2** (Evaluation of a gamma product with cyclotomic parameters)**.** Here we include a simple (yet concrete) example [4, pages 4–6] of the difficulty in determining whether a hypergeometric sequence converges to a rational limit. Consider

$$\prod_{k=2}^{\infty} \frac{k^5 - 1}{k^5 + 1} = \frac{2 \cdot \Gamma(-\omega_{10})\Gamma(\omega_{10}^2)\Gamma(-\omega_{10}^3)\Gamma(\omega_{10}^4)}{5 \cdot \Gamma(\omega_{10})\Gamma(-\omega_{10}^2)\Gamma(\omega_{10}^3)\Gamma(-\omega_{10}^4)} \tag{2}$$

where $\omega_{10} = \mathrm{e}^{2\pi\mathrm{i}/10}$ and, once again, the right-hand side is derived from Theorem 5. As noted by the authors of [4], it is not known whether the limit in (2) is even algebraic.

Whilst the state of the art cannot generally handle the evaluation of expressions given by gamma products, many works in the literature have established identities for restricted classes of products (a non-exhaustive list includes [5, 18, 21, 27, 34, 35]). Our connection to such interests stems from our approach herein: our reduction-step leaves us to determine whether the ratio of two gamma products (as above) is rational.

Related Work

Membership for Hypergeometric Sequences. Two recent works consider the Membership Problem for hypergeometric sequences [15, 22]. In both of these works, the authors use p-adic techniques and divisibility arguments (in stark contrast to the approach herein). It is worth noting that such techniques seem appropriate only for the Membership Problem and not the Threshold Problem.

The authors of [22] establish decidability of the Membership Problem for the class of hypergeometric sequences with rational parameters. Closer to our setting, the authors of [15] establish decidability of the Membership Problem for the class of hypergeometric sequences whose polynomial coefficients (as in (1)) are both monic and split over a quadratic field. By comparison to [15], we establish decidability of not only the Membership Problem, but also the Threshold Problem (Theorem 15) for hypergeometric sequences whose monic polynomial coefficients split over an imaginary quadratic field. We note our result for the Membership Problem is weaker for sequences whose monic polynomial coefficients split over a real quadratic field: in this setting we are limited to conditional decidability (Proposition 7 and Corollary 18).

[1] The quadratics $12k^2 - 5\pi^2$ and $12k^2 + \pi^2$ do not have rational coefficients, but in Appendix B we demonstrate how our approach handles decidability of the Threshold Problem in this example.

Positivity for P-finite sequences. Identities for P-finite sequences are frequent in the literature; however, as noted by Kauers and Pillwein, "in contrast,... almost no algorithms are available for inequalities" in this setting [12]. Determining whether the terms of a P-finite sequence are non-negative has garnered much attention in recent works (see, for example, [10, 12, 13, 28]). On the one hand, these works handle higher-order P-finite sequences than the hypergeometric sequences we consider. On the other hand, the algorithms described in the above studies are restricted in their applicability (placing syntactic restrictions on the polynomial coefficients) and termination is not guaranteed for all initial values. Indeed, genericity of initial conditions (in the sense that, the growth rate of a recurrence sequence is determined by a positive dominant eigenvalue) is required for the algorithms in [10, 12]. Additionally, determining whether the initial conditions of a given sequence are generic is an open problem (even at low orders) [13].

Positivity for C-finite sequences. It is easily seen that the Threshold Problem for C-finite sequences reduces to the Positivity Problem for C-finite sequences. Recall that *Positivity* asks to determine whether all terms in a sequence lie above the threshold zero (so the variant of the Threshold Problem where $t = 0$). This reduction is straightforward: to determine whether $u_n \geq t$ for each $n \in \mathbb{N}_0$ we can equivalently ask whether $v_n := u_n - t \geq 0$ for each $n \in \mathbb{N}_0$. Observe that $\langle v_n \rangle_{n=0}^{\infty}$ is C-finite since it is given by the difference of two C-finite sequences $\langle u_n \rangle_{n=0}^{\infty}$ and $\langle t \rangle_{n=0}^{\infty}$ and we are done.

Decidability of the Positivity Problem for C-finite sequences is considered a challenging open problem. Further, Positivity and its variants have garnered much research interest in recent works [9, 14, 23, 24, 25, 26]. Akin to our focus on restricted classes of hypergeometric sequences herein, the authors of [14] and [23] consider restricted classes of C-finite sequences: both of those works place restrictions on the algebraic properties of the associated recurrence relations.

Structure and Outline

This paper is structured as follows. In the next section we gather together relevant preliminary material. In Sections 3 and 4, we establish (un)conditional decidability of the Threshold Problem for classes of hypergeometric sequences. In one sense, Section 3 gives an overview of our approach in the setting of hypergeometric sequences with quadratic parameters. In Section 4, we introduce the class of polynomials with Property S (Subsection 4.1) and then show that the Threshold Problem for hypergeometric sequences whose monic polynomial coefficients possess Property S is decidable subject to the truth of Schanuel's conjecture (Theorem 17 in Subsection 4.2). We make suggestions for future avenues of research in the conclusion (Section 5). Proofs omitted from the main text are given in Appendix A. Appendix B contains a worked example related to the Kepler–Bouwkamp (Example 1) and demonstrates an application of Schanuel's conjecture.

2 Preliminaries

The Gamma Function. The approach herein relies on transcendence theory for the gamma function Γ where

$$\Gamma(z) = \int_0^{\infty} x^{z-1} \mathrm{e}^{-x}\, dx \quad \text{for } z \in \mathbb{C} \text{ with } \mathrm{Re}(z) > 0.$$

It is possible to analytically extend the domain of Γ to the whole complex plane minus the non-positive integers where the function has simple poles. We briefly recall standard results for the gamma function. Further details and historical accounts are given in a number of sources (cf. [2, 37]).

The standard relations for the gamma function give the functional identities: the *recurrence* (or *translation*) *property* $\Gamma(z+1) = z\Gamma(z)$ for $z \notin \mathbb{Z}$ and the *reflection property* $\Gamma(z)\Gamma(1-z) = \pi/\sin(\pi z)$ for $z \notin \mathbb{Z}$. In the domain of the gamma function, repeated application of the translation property leads to the following "rising factorial" identity. For $n \in \{1, 2, \ldots\}$, we have

$$\frac{\Gamma(z+n)}{\Gamma(z)} = z(z+1)\cdots(z+n-1).$$

Similarly, the "falling factorial" identity is given by

$$\frac{\Gamma(z+1)}{\Gamma(z-n+1)} = z(z-1)\cdots(z-n+1).$$

The next technical lemma is derived from the aforementioned properties of the gamma function. We employ the notation $\frac{1}{2}\mathbb{Z}$ for the set of integers and half-integers.

▶ **Lemma 3.** *Let $\rho \in \frac{1}{2}\mathbb{Z}$. Suppose that $w \in \mathbb{C}$ is an algebraic number such that both $\rho + w$ and $\rho - w$ lie in the domain of the gamma function and $w \notin \frac{1}{2}\mathbb{Z}$. Up to multiplication by an algebraic number, we have the following equalities:*

$$\Gamma(\rho+w)\Gamma(\rho-w) = \begin{cases} \dfrac{2\pi \mathrm{i} e^{\pi w \mathrm{i}}}{w(1-e^{2\pi w \mathrm{i}})} & \text{if } \rho \text{ is an integer, or} \\ \dfrac{2\pi e^{\pi w \mathrm{i}}}{e^{2\pi w \mathrm{i}}+1} & \text{if } \rho \text{ is a half-integer.} \end{cases}$$

Proof. Let us apply the rising and falling factorial identities (as appropriate to the sign of ρ). Then, up to multiplication by an algebraic number, we have the following equalities:

$$\Gamma(\rho+w)\Gamma(\rho-w) = \begin{cases} \Gamma(w)\Gamma(-w) & \text{if } \rho \text{ is an integer, or} \\ \Gamma(1/2+w)\Gamma(1/2-w) & \text{if } \rho \text{ is a half-integer.} \end{cases}$$

Consider the first of the two cases above. The reflection and recurrence formulas lead to

$$\Gamma(w)\Gamma(-w) = \frac{\Gamma(w)\Gamma(1-w)}{-w} = \frac{\pi}{-w\sin(\pi w)} = -\frac{2\pi \mathrm{i}}{w(e^{\pi w \mathrm{i}} - e^{-\pi w \mathrm{i}})}.$$

For the second case, we employ the cosine variant of Euler's reflection formula to obtain

$$\Gamma(1/2+w)\Gamma(1/2-w) = \frac{\pi}{\cos(\pi w)} = \frac{2\pi}{e^{\pi w \mathrm{i}} + e^{-\pi w \mathrm{i}}}.$$

The equalities in the statement of the lemma quickly follow. ◀

Decidability and Reduction Results. Recall that a rational-valued sequence $\langle u_n \rangle_{n=0}^{\infty}$ is *hypergeometric* if it satisfies a first-order recurrence relation of the form (1) with polynomial coefficients $p, q \in \mathbb{Z}[x]$. Due to space restrictions, we omit the proofs of Lemma 4, Proposition 6, and Proposition 7 from the main text. Each proof is included in Appendix A.

The following straightforward lemma appears in previous works [13, 22].

▶ **Lemma 4.** *Consider the class of hypergeometric sequences $\langle u_n \rangle_n$ whose shift quotients $r(n)$ either diverge to $\pm\infty$ or converge to a limit ℓ with $|\ell| \neq 1$. For this class, the Membership and Threshold Problems are both decidable.*

Thus to decide the Membership and Threshold Problems for hypergeometric sequences, we need only consider the sequences whose shift quotients $r(n)$ converge to ± 1 as $n \to \infty$. We say an infinite product $\prod_{k=0}^{\infty} r(k)$ *converges* if the sequence of partial products converges to a finite non-zero limit (otherwise the product is said to diverge). Recall the following classical theorem ([37, §12] and [5]).

▶ **Theorem 5.** *Consider the rational function*

$$r(k) := \frac{c(k+\alpha_1)\cdots(k+\alpha_m)}{(k+\beta_1)\cdots(k+\beta_{m'})}$$

where we suppose that each $\alpha_1, \ldots, \alpha_m, \beta_1, \ldots, \beta_{m'}$ is a complex number that is neither zero nor a negative integer. The infinite product $\prod_{k=0}^{\infty} r(k)$ converges to a finite non-zero limit only if $c = 1$, $m = m'$, and $\sum_j \alpha_j = \sum_j \beta_j$. Further, the value of the limit is given by

$$\prod_{k=0}^{\infty} r(k) = \prod_{j=1}^{m} \frac{\Gamma(\beta_j)}{\Gamma(\alpha_j)}.$$

With Theorem 5 in mind, it is useful to introduce the following terminology for shift quotients. We call a rational function $r(k)$ (as above) *harmonious* if $r(k)$ satisfies the assumptions $c = 1$, $m = m'$, and $\sum_j \alpha_j = \sum_j \beta_j$. From Theorem 5, it is immediately apparent that a hypergeometric sequence $\langle u_n \rangle_n$ with shift quotient r converges to a finite non-zero limit only if r is harmonious.

Related to the assumptions in Theorem 5 (and Proposition 6 below), when considering Membership and Threshold we can assume without loss of generality that the roots $\alpha_1, \ldots, \alpha_m$ of the coefficient q (as in (1)) are neither zero nor negative integers. For otherwise, a hypergeometric sequence eventually hits zero and is identically zero thereafter. In [22], Nosan et al. establish Propositions 6 and 7 for rational parameters. The proof of Proposition 6 given in Appendix A is all but identical to the proof of Proposition 2 in [22].

▶ **Proposition 6.** *Let $\langle u_n \rangle_n$ be a hypergeometric sequence whose shift quotient is given by a ratio of two polynomials with real coefficients. For such sequences, the Membership and Threshold Problems are both Turing-reducible to the following decision problem. Given $d \in \mathbb{N}$, $\alpha_1, \ldots, \alpha_d \in \mathbb{C} \setminus \mathbb{Z}_{<0}$ (the roots of some $P(x) \in \mathbb{R}[x]$), and $\beta_1, \ldots, \beta_d \in \mathbb{C} \setminus \mathbb{Z}_{<0}$ (the roots of some $Q(x) \in \mathbb{R}[x]$), determine whether*

$$\frac{\Gamma(\beta_1)\cdots\Gamma(\beta_d)}{\Gamma(\alpha_1)\cdots\Gamma(\alpha_d)} = t$$

for $t \in \mathbb{Q} \setminus 0$.

To be absolutely clear, the fact that $t \in \mathbb{Q}$ is non-zero in Proposition 6 follows directly from the infinite product in Theorem 5 converging to a non-zero limit.

Our (un)conditional decidability results for the Membership Problem follow from the next proposition. This proposition can be deduced from the work in [22] (a straightforward proof is given in Appendix A).

▶ **Proposition 7.** *For hypergeometric sequences, decidability of the Membership Problem Turing-reduces to that of the Threshold Problem.*

Number Fields. We recall standard results for quadratic fields below (cf. [33, Chapter 3]). A number field K is *quadratic* if $[K : \mathbb{Q}] = 2$. A field K is quadratic if and only if there is a square-free integer d such that $K = \mathbb{Q}(\sqrt{d})$. Further, a quadratic field $\mathbb{Q}(\sqrt{d})$ is *imaginary* if $d < 0$.

▶ **Theorem 8.** *Suppose that $d \in \mathbb{Z}$ is square-free. Then the algebraic integers of $\mathbb{Q}(\sqrt{d})$ are given by $\mathbb{Z}[\sqrt{d}]$ if $d \not\equiv 1 \pmod 4$ or $\mathbb{Z}[1/2 + \sqrt{d}/2]$ if $d \equiv 1 \pmod 4$.*

We include the following straightforward lemma for ease of reference.

▶ **Lemma 9.** *Let $\mathbb{L}/\mathbb{Q}$ be a finite Galois extension. Suppose that $\mathcal{P} \in \mathbb{L}(X_1, \ldots, X_m)$ is a polynomial such that $\mathcal{P}(s_1, \ldots, s_m) = 0$ with $(s_1, \ldots, s_m) \in \mathbb{C}^m$. Then there is a polynomial $\mathcal{Q} \in \mathbb{Q}(X_1, \ldots, X_m)$ such that $\mathcal{Q}(s_1, \ldots, s_m) = 0$.*

Proof. Let $\mathcal{P} = \sum_{(t_1,\ldots,t_m)} c_{(t_1,\ldots,t_m)} X_1^{t_1} X_2^{t_2} \cdots X_m^{t_m}$ and for each $\sigma \in G$ (the Galois group of $\mathbb{L}/\mathbb{Q}$) let

$$\sigma(\mathcal{P}) = \sum_{(t_1,\ldots,t_m)} \sigma(c_{(t_1,\ldots,t_m)}) X_1^{t_1} X_2^{t_2} \cdots X_m^{t_m}.$$

Let $\mathcal{Q} = \mathrm{N}_{\mathbb{L}/\mathbb{Q}}(\mathcal{P}) := \prod_{\sigma \in G} \sigma(\mathcal{P})$. It is clear that each of the coefficients of the polynomial $\mathcal{Q}$ is rational since the coefficients are invariant under the action of the group G. Further,

$$\mathcal{Q}(s_1, \ldots, s_m) = \mathcal{P}(s_1, \ldots, s_m) \prod_{\sigma \in G \setminus e_G} \sigma(\mathcal{P})(s_1, \ldots, s_m) = 0,$$

as desired. ◀

Transcendental Number Theory. The transcendence degree of a field extension is a measure of the size of the extension. In fact, for finitely generated extensions of $\mathbb{L}/\mathbb{Q}$ (such as those that we consider), the transcendence degree indicates the largest cardinality of an algebraically independent subset of $\mathbb{L}$ over $\mathbb{Q}$. For a field extension $\mathbb{L}/\mathbb{Q}$, a subset $\{\xi_1, \ldots, \xi_n\} \subset \mathbb{L}$ is *algebraically independent* over $\mathbb{Q}$ if for each polynomial $P(X_1, \ldots, X_n) \in \mathbb{Q}[X_1, \ldots, X_n]$ we have that $P(\xi_1, \ldots, \xi_n) = 0$ only if P is identically zero.

It is useful to recall the Gelfond–Schneider Theorem that establishes the transcendentality of α^β for algebraic numbers α and β except for the cases where $\alpha = 0, 1$ or β is rational.

Schanuel's conjecture is a unifying prediction in transcendental number theory. If Schanuel's conjecture is true, then it generalises several of the principal results in transcendental number theory such as: the Gelfond–Schneider Theorem, the Lindemann–Weierstrass Theorem, and Baker's theorem (cf. [16, 3, 36]). The conjecture makes the following prediction: for $\xi_1, \ldots, \xi_n$ rationally linearly independent complex numbers, there is a subset of $\{\xi_1, \ldots, \xi_n, \mathrm{e}^{\xi_1}, \ldots, \mathrm{e}^{\xi_n}\}$ of size at least n that is algebraically independent over $\mathbb{Q}$.

▶ **Conjecture 10** (Schanuel). *Suppose that $\xi_1, \ldots, \xi_n \in \mathbb{C}$ are linearly independent over the rationals $\mathbb{Q}$. Then the transcendence degree of the field extension $\mathbb{Q}(\xi_1, \ldots, \xi_n, \mathrm{e}^{\xi_1}, \ldots, \mathrm{e}^{\xi_n})$ over $\mathbb{Q}$ is at least n.*

3 Hypergeometric Sequences with Quadratic Parameters

As an appetiser to the proofs of Theorems 15 and 17, we introduce our approach by first establishing decidability of the Threshold Problem for hypergeometric sequences with Gaussian integer parameters (Proposition 11 below). We also include a worked example in Example 12. Recall that the *Gaussian integers* $\mathbb{Z}[\mathrm{i}]$ are those complex numbers of the form $a + b\mathrm{i}$ for which $a, b \in \mathbb{Z}$.

▶ **Proposition 11.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients are monic and split over* $\mathbb{Q}(\mathrm{i})$ *are decidable.*

Proof. By Theorem 5 and Proposition 6, we need only consider hypergeometric sequences with harmonious shift quotients. Since the polynomial coefficients $p, q \in \mathbb{Z}[x]$ are monic, the roots and poles of the shift quotient are integers in $\mathbb{Q}(i)$; that is to say, they lie in $\mathbb{Z}[i]$. It follows from Lemma 3 that each such instance $(\langle u_n \rangle_n, t)$ of the Threshold Problem reduces to testing an equality of the form

$$\theta \pi^{\ell} \prod_m (\mathrm{e}^{b_m \pi} - \mathrm{e}^{-b_m \pi})^{\varepsilon_m} = t. \tag{3}$$

Here θ is rational and non-zero, $\ell \in \mathbb{Z}$, each pair $\Gamma(a_m + b_m \mathrm{i})\Gamma(a_m - b_m \mathrm{i})$ from Proposition 6 contributes a term $(\mathrm{e}^{b_m \pi} - \mathrm{e}^{-b_m \pi})^{\varepsilon_m}$ in the finite product, and $\varepsilon_m = \pm 1$.

We break the remainder of the proof into several subcases. Without loss of generality, we can assume that not all the roots and poles of r are rational integers, for otherwise testing (3) reduces to the decidable task of testing equality between two rational numbers.

We continue under the assumption that not all the roots and poles of r are rational integers. Let us now consider the product in (3). Up to multiplication by a rational, we can write the left-hand side of (3) in the form

$$\theta \pi^{\ell} \prod_m (\mathrm{e}^{b_m \pi} - \mathrm{e}^{-b_m \pi})^{\varepsilon_m} = \theta \pi^{\ell} \frac{f(\mathrm{e}^{\pi})}{g(\mathrm{e}^{\pi})}$$

where $f, g \in \mathbb{Q}[X]$ are non-trivial polynomials. Observe that $\mathrm{e}^{\pi} = (\mathrm{e}^{\pi \mathrm{i}})^{-\mathrm{i}} = (-1)^{-\mathrm{i}}$; thus, by the Gelfond–Schneider theorem, e^{π} is transcendental. We break the remainder of the proof into two cases depending on the rationality of $f(\mathrm{e}^{\pi})/g(\mathrm{e}^{\pi})$.

Suppose that $f(\mathrm{e}^{\pi})/g(\mathrm{e}^{\pi}) \in \mathbb{Q}$. There are two further subcases to consider: if $\ell = 0$, then, once again, the equality test (3) reduces to deciding whether two rationals are equal; and if $\ell \neq 0$, then the equality test (3) reduces to testing whether π^{ℓ} is equal to a given rational number, which cannot hold for then π is necessarily algebraic.

All that remains is to consider the case where $f(\mathrm{e}^{\pi})/g(\mathrm{e}^{\pi}) \notin \mathbb{Q}$, which we again split into two subcases. If $\ell = 0$, then it is trivial to see that (3) cannot hold as the right-hand side is rational. If $\ell \neq 0$ and we assume, for a contradiction, that (3) holds, then a simple rearrangement of (3) shows that there is a non-trivial polynomial $\mathcal{P} \in \mathbb{Q}[X, Y]$ such that $\mathcal{P}(\pi, \mathrm{e}^{\pi}) = 0$. This contradicts Nesterenko's theorem [20] that π and e^{π} are algebraically independent. We have dispatched each of the subcases and conclude the desired result. ◀

▶ **Example 12.** Suppose that $\langle u_n \rangle_{n=0}^{\infty}$ is the hypergeometric sequence defined by

$$u_n = \frac{n^2 - 4n + 5}{n^2 - 4n + 13} u_{n-1} \text{ with } u_0 = 1.$$

For the Threshold Problem, let us consider the problem instance $(\langle u_n \rangle_n, t)$ with $t \in \mathbb{Q}$. First, we evaluate the associated infinite product:

$$\prod_{k=0}^{\infty} \frac{k^2 - 4k + 5}{k^2 - 4k + 13} = \frac{\Gamma(-2 - 3\mathrm{i})\Gamma(-2 + 3\mathrm{i})}{\Gamma(-2 - \mathrm{i})\Gamma(-2 + \mathrm{i})} = \frac{\sinh(\pi)}{39 \sinh(3\pi)} = \frac{\mathrm{e}^{3\pi}(\mathrm{e}^{2\pi} - 1)}{39\mathrm{e}^{\pi}(\mathrm{e}^{6\pi} - 1)}.$$

Second, as directed by the proof of Proposition 11, decidability of the Threshold Problem in this instance reduces to determining whether the following equality holds:

$$\frac{\mathrm{e}^{3\pi}(\mathrm{e}^{2\pi} - 1)}{39\mathrm{e}^{\pi}(\mathrm{e}^{6\pi} - 1)} = t.$$

A simple rearrangement shows that if the above equality holds, then there is a non-trivial polynomial $p \in \mathbb{Q}[X]$ such that $p(\mathrm{e}^\pi) = 0$, from which we deduce that e^π is algebraic. However, by the Gelfond–Schneider theorem, e^π is transcendental. We have reached a contradiction and deduce that the aforementioned equality cannot hold.

Finally, as described in Proposition 6, the Threshold Problem reduces to an exhaustive search of a computable number of initial terms in the sequence $\langle u_n \rangle_n$. As an aside, by Proposition 7, we also obtain decidability of the Membership Problem for problem instances $(\langle u_n \rangle_n, t)$.

▶ Remark 13. Subject to appropriate changes and by employing Lemma 9, we can extend the result in Proposition 11 from instances of the Membership and Threshold Problems $(\langle u_n \rangle_n, t)$ with $u_0, t \in \mathbb{Q}$ to problem instances with $u_0, t \in \mathbb{L}(\pi, \mathrm{e}^\pi)$ where $\mathbb{L}$ is any finite Galois extension of $\mathbb{Q}$. This extension similarly holds for Theorem 15 (below).

▶ Remark 14. Analogous decision procedures to the proof of Proposition 11 also hold for other famous rings of integers: the Eisenstein, Kummer, and Kleinian integers. Recall that the *Eisenstein integers* are the elements of $\mathbb{Z}[\zeta_3] = \{a + b\zeta_3 : a, b \in \mathbb{Z}\}$ where $\zeta_3 := \mathrm{e}^{2\pi \mathrm{i}/3}$. Similarly, the *Kummer integers* are the elements of $\mathbb{Z}[\sqrt{-5}] = \{a + b\sqrt{-5} : a, b \in \mathbb{Z}\}$. Finally, the *Kleinian integers* are the elements of $\mathbb{Z}[\mu] = \{a + b\mu : a, b \in \mathbb{Z}\}$ where $\mu = -1/2 + \sqrt{-7}/2$.

The claims for decidability in Remark 14, follow from the next theorem. We establish decidability of the Threshold Problem for hypergeometric sequences whose parameters are drawn from the ring of integers of an imaginary quadratic number field.

▶ **Theorem 15.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients are monic and split over an imaginary quadratic number field is decidable.*

Proof. Mutatis mutandis, the proof of Theorem 15 follows the approach in Proposition 11. For the sake of brevity, we shall indicate only the major changes to Proposition 11 here. Consider the ring of integers of an imaginary quadratic field $\mathbb{Q}(\sqrt{d})$ where $-d \in \mathbb{N}$ is square-free. By Theorem 8, there are two cases to consider: first, when $d \not\equiv 1 \pmod 4$ and second, when $d \equiv 1 \pmod 4$.

We concentrate on the changes to the proof of Proposition 11 when $d \not\equiv 1 \pmod 4$. Like before, we can use the recurrence formula to write $\Gamma(a + b\sqrt{d}) = \theta\Gamma(b\sqrt{d})$ where $\theta \in \mathbb{N}$. Thus all that remains is to evaluate products $\Gamma(b\sqrt{d})\Gamma(-b\sqrt{d})$ of conjugate elements. By the reflection formula, we have

$$\Gamma(b\sqrt{d})\Gamma(-b\sqrt{d}) = -\frac{\pi}{b\sqrt{d}\sin(b\pi\sqrt{d})} = \frac{2\pi}{b\sqrt{-d}(\mathrm{e}^{\pi b\sqrt{-d}} - \mathrm{e}^{-\pi b\sqrt{-d}})}.$$

The important update is the product in (3). In our new setting, the product takes the form

$$\prod_m (\mathrm{e}^{\pi b\sqrt{-d}} - \mathrm{e}^{-\pi b\sqrt{-d}})^{\varepsilon_m}.$$

Observe that $\mathrm{e}^{\pi\sqrt{-d}}$ is transcendental (once again by Gelfond–Schneider) and that for each $-d \in \mathbb{N}$ the numbers π and $\mathrm{e}^{\pi\sqrt{-d}}$ are algebraically independent over $\mathbb{Q}$ [20, Corollary 6]. The rest of the proof in this case follows as before.

In the second case where $d \equiv 1 \pmod 4$ we must additionally deal with contributions of the form $\Gamma(b/2 + b\sqrt{d}/2)\Gamma(b/2 - b\sqrt{d}/2)$. This setting introduces cases where $2 \nmid b$, which we resolve by repeated application of the recurrence formula and the cosine variant of Euler's reflection formula. Indeed, we have

$$\Gamma(1/2 + b\sqrt{d}/2)\Gamma(1/2 - b\sqrt{d}/2) = \frac{\pi}{\cos(\pi b\sqrt{d}/2)} = \frac{2\pi}{\mathrm{e}^{\pi b\sqrt{-d}/2} + \mathrm{e}^{-\pi b\sqrt{-d}/2}},$$

and so we can construct an updated version of the product in (3). This update and analogous arguments for the transcendental properties of $e^{\pi\sqrt{-d}/2}$ let us conclude decidability in this case too. ◀

4 Conditional Decidability Subject to Schanuel's conjecture

In this section we shall give a generalisation (Theorem 17) of the decidability results in Section 3. The result applies to a strictly larger class of hypergeometric sequences; however, we sacrifice unconditional decidability. Briefly, termination of the decidability procedure in Theorem 17 is dependent on the truth of Schanuel's conjecture (further details are given in Remark 24). The motivation for studying reachability problems for this larger class arises from interest in the literature for limits of hypergeometric sequences with unnested radical and cyclotomic parameters (see Subsection 4.2).

Let us first describe the class of hypergeometric sequences for which we establish conditional decidability of the Membership and Threshold Problems. This will require us to introduce some notations and Property S below.

Consider $\mathcal{R}_f$ the multiset of roots of a given monic polynomial $f \in \mathbb{Z}[x]$ and $\mathcal{V}_f$ the multiset of irrational roots of f. We define the graph $\mathcal{G}_f := (\mathcal{V}_f, \mathcal{E}_f)$ with vertex set $\mathcal{V}_f$ and edge set $\mathcal{E}_f$. Here $\mathcal{E}_f$ is encoded using an adjacency matrix A (whose rows and columns are indexed by $\mathcal{V}_f$) as follows. For distinct $u, v \in \mathcal{V}_f$, let $A(u,v) = 1$ if $u = \rho + w$ and $v = \rho - w$ for some $\rho \in \frac{1}{2}\mathbb{Z}$ and w an algebraic number not in $\frac{1}{2}\mathbb{Z}$. Otherwise, let $A(u,v) = 0$.

▶ **Property S.** *We say that f has Property S if $\mathcal{G}_f$ admits a perfect matching.*

The motivation for introducing Property S is as follows: in combination with Lemma 3 and subject to the truth of Schanuel's conjecture, we can circumvent certain hard problems concerning the evaluation of gamma products if the input parameters possess certain symmetries. The main result of this section is a conditional decidability result for the class of hypergeometric sequences whose polynomial coefficients are monic and possess Property S.

▶ **Theorem 17.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients (as in* (1)*) are both monic and have Property S is decidable subject to the truth of Schanuel's conjecture.*

The remainder of this section is structured as follows. In Subsection 4.1 we list classes of polynomials with Property S and highlight straightforward corollaries (Corollaries 18, 22, and 23) of Theorem 17. In Subsection 4.2 we prove Theorem 17.

4.1 Polynomials with Property S

Even Polynomials. It is immediate that even polynomials with at least one irrational root possess Property S. Suppose that $f \in \mathbb{Z}[x]$ is a monic even polynomial. Then $f(-x) = f(x)$ and so $\mathcal{G}_f$ admits a perfect matching, as desired. More generally, we note that a horizontal translation of such a polynomial, say $\tilde{f}$, for which $\tilde{f}(\rho - x) = \tilde{f}(\rho + x)$ where $\rho \in \frac{1}{2}\mathbb{Z}$, also has Property S.

Quadratic Polynomials. Every irreducible monic quadratic polynomial in $\mathbb{Z}[x]$ possesses Property S. This observation is straightforward: consider an irreducible monic quadratic polynomial $x^2 + bx + c \in \mathbb{Z}[x]$. The roots of said quadratic satisfy $-\frac{b}{2} \pm \frac{\sqrt{b^2-4c}}{2}$. We note that $-\frac{b}{2} \in \frac{1}{2}\mathbb{Z}$ and $b^2 - 4c \neq 0$.

The following corollary is a straightforward consequence of Theorem 17: we have conditional decidability of the Threshold Problem for hypergeometric sequences whose parameters are drawn from the rings of integers of quadratic number fields.

▶ **Corollary 18.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients are monic with irreducible factors that are either linear or quadratic is decidable subject to the truth of Schanuel's conjecture.*

We note that the assumption in Corollary 18 permits us to draw sequence parameters from the integers of any number of quadratic fields in order to establish conditional decidability of both the Threshold and Membership Problems. This is in stark contrast to the work in [15] that establishes decidability of Membership for hypergeometric sequences whose parameters are drawn from the integers of a single quadratic field.

Algebraic Numbers with Rational Real Part. Consider the class $\mathcal{C}$ of monic irreducible polynomials in $\mathbb{Q}[x]$ that possess a root with rational real part. Trivially, a linear polynomial with rational coefficients is always a member of $\mathcal{C}$ since the single root of the polynomial is rational. It is straightforward to see that an irreducible quadratic polynomial $x^2+bx+c \in \mathbb{Q}[x]$ is in $\mathcal{C}$ if and only if $b^2-4c<0$. Dilcher, Noble, and Smyth [6] achieve a complete classification of the class $\mathcal{C}$ with the following result.

▶ **Theorem 19** ([6, Theorem 1])**.** *Let f be a polynomial of degree at least three. Then $f \in \mathcal{C}$ if and only if $f(x) = g((x-\rho)^2)$ for some $\rho \in \mathbb{Q}$ and monic irreducible $g \in \mathbb{Q}[X]$ that has a negative real root. In this case, f has a root with a rational real part ρ.*

The following corollary is key to understanding the connection to Property S and demonstrates the 2-fold rotational symmetry of the set of roots of a polynomial in $\mathcal{C}$.

▶ **Corollary 20** ([6, Corollary 2])**.** *Suppose that $f \in \mathcal{C}$ has degree at least three. The roots of f that have rational real part have the same real part ρ. Further, we have $f(\rho-x) = f(\rho+x)$.*

The trivial lemma below shows that if an algebraic integer has rational real part, then said real part lies in $\frac{1}{2}\mathbb{Z}$.

▶ **Lemma 21.** *Let α be an algebraic integer with $\mathrm{Re}(\alpha) \in \mathbb{Q}$. Then $\mathrm{Re}(\alpha) \in \frac{1}{2}\mathbb{Z}$.*

Proof. Since $\mathrm{Re}(\alpha) = \frac{1}{2}(\alpha+\overline{\alpha})$, we deduce that $\alpha+\overline{\alpha} \in \mathbb{Q}$. Observe that both α and $\overline{\alpha}$ are algebraic integers and so $\alpha+\overline{\alpha}$ is too due to the closure of the ring of algebraic integers. We deduce that $\alpha+\overline{\alpha} \in \mathbb{Z}$, from which the desired result follows. ◀

When we combine the result in Theorem 17 with the observations in Corollary 20 and Lemma 21 we obtain the following corollary.

▶ **Corollary 22.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients are monic with irreducible factors in $\mathcal{C}$ is decidable subject to the truth of Schanuel's conjecture.*

Unnested Radicals and Cyclotomic Polynomials. We now highlight the class of hypergeometric sequences with parameters determined by unnested radicals and cyclotomic polynomials. The limits of such sequences are considered in both [29, pp. 753–757] and [7]. In the sequel we use Φ_d to denote the dth cyclotomic polynomial. We state and prove the following corollary of Theorem 17.

▶ **Corollary 23.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients have irreducible factors of the form $x^d - a$ with $d \in 2\mathbb{Z}$, or Φ_d with $d \in 4\mathbb{Z}$ is decidable subject to the truth of Schanuel's conjecture.*

Proof. In light of Theorem 17, it is sufficient to prove that non-linear polynomials of the form $x^d - a$ with $d \in 2\mathbb{Z}$, or Φ_d with $d \in 4\mathbb{Z}$ have Property S.

We first consider irreducible factors of the form $x^d - a \in \mathbb{Z}[x]$. The roots of $x^d - a$ are unnested radicals of the form $\sqrt[n]{a}\omega_m^j$ for $j \in \{0, \ldots, m-1\}$ where $\omega_d := \mathrm{e}^{2\pi \mathrm{i}/d}$. Recall that $x^d - a \in \mathbb{Z}[x]$ is irreducible if a is not the Nth power of an element of $\mathbb{Q}$ for some $N > 1$ with $N \mid d$ (cf. [19]). When d is even, it follows that $x^d - a$ is even and so possesses Property S.

The cyclotomic polynomial Φ_d is irreducible and its roots are the primitive dth roots of unity. Under the assumption that d is a multiple of four, it is straightforward to show that Φ_d is even. It follows that for such d, Φ_d has Property S. ◀

We note with our approach we cannot lift the additional assumption that $d \in 4\mathbb{Z}$ for cyclotomic factors: the set of primitive 18th roots of unity $\{\omega_{18}, \omega_{18}^5, \omega_{18}^7, \omega_{18}^{11}, \omega_{18}^{13}, \omega_{18}^{17}\}$ show that Φ_{18} does not have Property S.

4.2 Proof of Theorem 17

We now prove our main result. A worked example, demonstrating our approach, is given in Appendix B.

▶ **Theorem 17.** *The Threshold Problem for hypergeometric sequences whose polynomial coefficients (as in* (1)*) are both monic and have Property S is decidable subject to the truth of Schanuel's conjecture.*

Proof. Let $\langle u_n \rangle_{n=0}^{\infty}$ be a hypergeometric sequence whose polynomial coefficients are both monic and satisfy Property S. We assume without loss of generality that the associated shift quotient $r(x) := q(x)/p(x)$ is harmonious. As previously noted, each instance of the Threshold Problem $(\langle u_n \rangle_n, t)$ with $t \in \mathbb{Q}$ reduces to checking an equality of the form

$$\Gamma(\beta_1) \cdots \Gamma(\beta_d) = t\Gamma(\alpha_1) \cdots \Gamma(\alpha_d) \tag{4}$$

where $\{\alpha_1, \ldots, \alpha_d\} =: \mathcal{R}_p$ and $\{\beta_1, \ldots, \beta_d\} =: \mathcal{R}_q$ are the multisets of the roots of the respective polynomial coefficients p and q. The proof is split into two parts: a reduction to an equality testing problem and a proof of decidability subject to the truth of Schanuel's conjecture.

Reduction to Equality Testing. Since pq is a monic polynomial, the rational elements of the multisets $\mathcal{R}_p$ and $\mathcal{R}_q$ are rational integers (so we can assume their contributions are absorbed into the rational parameter t in (4)). Further, under Property S there are perfect matchings on both of the graphs $\mathcal{G}_p$ and $\mathcal{G}_q$, which we denote by $\mathcal{M}_p$ and $\mathcal{M}_q$ respectively. Indeed, we recall that in $\mathcal{G}_p$ the edges in $\mathcal{M}_p$ are of the form $e(\alpha_-, \alpha_+)$ such that $\alpha_\pm = \rho_e \pm w_e$ where $\rho_e \in \frac{1}{2}\mathbb{Z}$ and w_e is an algebraic number not in $\frac{1}{2}\mathbb{Z}$ (and similarly for $\mathcal{G}_q$ and $\mathcal{M}_q$). In this setting, we repeatedly apply the recurrence formula and absorb the resulting algebraic factors into a single term θ in order to rewrite (4) as

$$\prod_{i \in \mathcal{M}_q} \Gamma(w_i)\Gamma(-w_i) = \theta \prod_{j \in \mathcal{M}_p} \Gamma(w_j)\Gamma(-w_j). \tag{5}$$

Consider the set of algebraic numbers $\{w_1, \ldots, w_M\}$ determined by the parameters in (5). We denote by $S' := \{s'_1, \ldots, s'_m\}$ a maximal subset of $\{w_1, \ldots, w_M\}$ for which the elements of $\{\pi, \pi\mathrm{i}\} \cup \pi S'$ are $\mathbb{Q}$-linearly independent (here $\pi S' := \{\pi s'_1, \ldots, \pi s'_m\}$). Then for each $k \in \{1, \ldots, M\}$, write w_k as a $\mathbb{Q}$-linear sum of elements in $\{s'_1, \ldots, s'_m\}$ so that

$$w_k = \frac{x_{k1}}{y_{k1}} s'_1 + \cdots + \frac{x_{km}}{y_{km}} s'_m.$$

We define $s_j := s'_j / \operatorname{lcm}(y_{1j}, y_{2j}, \ldots, y_{Mj})$ for each $j \in \{1, \ldots, m\}$. Now we can write each $w_k \in \{w_1, \ldots, w_M\}$ as a $\mathbb{Z}$-linear sum of elements in the normalised set $S := \{s_1, \ldots, s_m\}$.

We apply Lemma 3 to (5) and, by the preceding paragraph, determine that the problem of testing the equality in (5) reduces to that of determining whether a certain non-trivial polynomial with coefficients in $\mathbb{Q}(\theta)$ vanishes at a given point (this is analogous to the process in Proposition 11 and Example 12). More specifically, we want to test whether a given non-trivial polynomial $P \in \mathbb{Q}(\theta)[X_1, \ldots, X_{4m+4}]$ satisfies

$$P\big(\pi, \pi\mathrm{i}, \pi S, \pi S\mathrm{i}, \mathrm{e}^{\pi}, \mathrm{e}^{\pi\mathrm{i}}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}\big) = 0. \tag{6}$$

Here $\pi S\mathrm{i} := \{\pi s_1\mathrm{i}, \ldots, \pi s_m\mathrm{i}\}$, $\mathrm{e}^{\pi S} := \{\mathrm{e}^{\pi s_1}, \ldots, \mathrm{e}^{\pi s_m}\}$, and likewise for $\mathrm{e}^{\pi S\mathrm{i}}$. Note that we need only consider a polynomial in $4m + 4$ variables as the parameters $\{w_1, \ldots, w_M\}$ of our problem instance are given by $\mathbb{Z}$-linear combinations of the elements of $S \cup S\mathrm{i}$. We claim that the equality in (6) cannot hold if Schanuel's conjecture is true. We prove this claim below.

Conditional Decidability Subject to Schanuel's conjecture. Consider the set

$$\mathfrak{S} := \big\{\pi, \pi\mathrm{i}, \pi S, \pi S\mathrm{i}, \mathrm{e}^{\pi}, \mathrm{e}^{\pi\mathrm{i}}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}\big\}$$

with cardinality $4m + 4$. We observe that the elements in the subset $\{\pi, \pi\mathrm{i}, \pi S, \pi S\mathrm{i}\} \subset \mathfrak{S}$ are $\mathbb{Q}$-linearly independent. It follows that if Schanuel's conjecture is true, then $\mathfrak{S}$ possesses a subset of cardinality at least $2m + 2$ whose elements are algebraically independent. By construction, this algebraically independent subset is necessarily $\{\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}\}$ since the $2m + 2$ elements of $\{\pi, \pi\mathrm{i}, \pi S, \pi S\mathrm{i}\}$ are pairwise algebraically dependent and $\mathrm{e}^{\pi\mathrm{i}} = -1$.

We now rewrite the equality in (6) in terms of the (obvious) polynomial $\hat{P}$ that absorbs the algebraically dependent parameters of $S \cup S\mathrm{i}$ into the coefficients. That is to say, we employ a polynomial $\hat{P} \in \mathbb{L}(X_1, \ldots, X_{2m+2})$ where $\mathbb{L}$ is the Galois closure of the number field $\mathbb{Q}(\theta)(S, S\mathrm{i})$ and evaluate $\hat{P}$ on the algebraically independent subset $\{\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}\}$ of $\mathfrak{S}$. It follows that the equality in (6) holds only if

$$\hat{P}(\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}) = 0. \tag{7}$$

By Lemma 9, the equality in (7) holds only if there exists a non-trivial polynomial $Q \in \mathbb{Q}[X_1, \ldots, X_{2m+2}]$ such that $Q(\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}) = 0$. Recall that if Schanuel's conjecture is true, then the elements of the set $\{\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}\}$ are algebraically independent over $\mathbb{Q}$, from which we deduce that the preceding equality cannot hold.

Subject to the truth of Schanuel's conjecture, we can determine equality tests of the above form. Thus we have conditional decidability of the Threshold Problem for the desired class of hypergeometric sequences. ◀

▶ Remark 24. We note that the equality test $\mathcal{Q}(\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S\mathrm{i}}) = 0$ can be realised as a proposition in the first-order theory of the reals with exponentiation. Macintyre and Wilkie [17] established decidability of said theory subject to the truth of Schanuel's conjecture. As noted in previous works, careful inspection of Macintyre and Wilkie's algorithm reveals

that correctness is independent of the truth of Schanuel's conjecture. Indeed, Schanuel's conjecture is only used to prove termination. Thus if we apply Macintyre and Wilkie's algorithm to determine whether the equality $\mathcal{Q}(\pi, \mathrm{e}^{\pi}, \mathrm{e}^{\pi S}, \mathrm{e}^{\pi S \mathrm{i}}) = 0$ holds and find the procedure terminates, then the output is certainly correct.

We note that Macintyre and Wilkie's algorithm terminates unless the inputs constitute a counterexample to Schanuel's conjecture. Thus, the process underlying the proof of Theorem 17 presents an interesting prospect in the sense described by Richardson in [31] (see also [32]) "A failure of the [process] to terminate would be even more interesting than [its] success."

▶ Remark 25. Recall Remark 13 where we extended our class of problem instances to include setups with $u_0, t \in \mathbb{L}(\pi, \mathrm{e}^{\pi})$. Under the assumption that Schanuel's conjecture is true we can include a broader range of setups. Notice, for instance, that the algebraic independence of π and e is currently unknown; however, if Schanuel's conjecture is true, then it follows that π and e are algebraically independent. Thus, subject to the truth of Schanuel's conjecture, we can extend our results in Proposition 11, Theorem 15, and Theorem 17 to instances where $u_0, t \in \mathbb{L}(\pi, \mathrm{e})$. In fact, we can go further in this direction since the truth of Schanuel's conjecture implies the algebraic independence of the numbers e, e^{π}, e^{e}, π, π^{π}, π^{e}, 2^{π}, 2^{e}, $\log \pi$, $\log 2$, $\log 3$, $\log \log 2$, $(\log 2)^{\log 3}$, $2^{\sqrt{2}}$, and many more (cf. [30, Conjecture S_7]).

5 Conclusion

Summary. In this paper we establish (un)conditional decidability results for the Threshold Problem for hypergeometric sequences and, as a side-effect, (un)conditional decidability results for the Membership Problem for hypergeometric sequences. Previous works have considered the Membership Problem for hypergeometric sequences [13, 22]; however, the approach in those works cannot handle instances of the Threshold Problem. The novelty of our approach is the combination of a classical convergence result (Theorem 5) with results on the algebraic independence of common mathematical constants.

Obstacles. Let us illustrate an immediate obstacle to the methods herein. We cannot handle parameters drawn from biquadratic fields because the monic polynomials that split over such fields are not necessarily amenable to our approach. Recall that biquadratic fields are a particularly well-behaved class of quartic fields (such as $\mathbb{Q}(\sqrt{5}, \sqrt{13})$ and $\mathbb{Q}(\sqrt{21}, \sqrt{33})$). For example the minimal polynomial $x^4 - 5x^3 - 71x^2 + 120x + 1044$ of $(5 + 3\sqrt{5} + \sqrt{13} + 3\sqrt{65})/4 \in \mathbb{Q}(\sqrt{5}, \sqrt{13})$ does not have Property S. Similarly, the minimal polynomial $x^4 - x^3 - 16x^2 + 37x - 17$ of $(1 + \sqrt{21} + \sqrt{33} - \sqrt{77})/4 \in \mathbb{Q}(\sqrt{21}, \sqrt{33})$ does not have Property S. Both of these examples are taken from [38].

We also note that the class of sequences we can handle does not permit standard operations on the parameters such as addition. Consider, for example, that $\sqrt{2}$ and $\sqrt[4]{2}$ are both unnested radicals whose minimal polynomials satisfy Property S; however, the minimal polynomial $x^4 - 4x^2 - 8x + 2$ of $\sqrt{2} + \sqrt[4]{2}$ does not possess Property S.

It is not clear how to extend our approach to hypergeometric sequences with larger classes of parameters. For example, the parameters herein are all algebraic integers. Even in the restricted setting of hypergeometric sequences with rational parameters (as in the work of Nosan et al. [22]) it is beyond the state of the art to evaluate equalities between associated gamma products. Indeed, for $s \in \{1/6, 1/4, 1/3, 2/3, 3/4\}$ and $n \in \mathbb{N}$, it is known that $\Gamma(n + s)$ is a transcendental number and algebraically independent of π (cf. [36]). However, transcendence of the gamma function at other rational points is not known. It is notable that

for rational parameters determining equality between gamma products is decidable subject to the truth of the Rohrlich–Lang conjecture (which itself concerns multiplicative relations for the gamma function [16, 36]).

Directions for Future Work. We give one class of hypergeometric sequences whose parameters link the related works. Consider the class of hypergeometric sequences whose parameters lie in $\mathbb{Q}(\mathrm{i})$. For such sequences, decidability of both the Membership and Threshold Problems is open.

The sequences in this class generalise the setting discussed here (and in work by Kenison et al. [15]) by removing the condition that the polynomial coefficients of the defining recurrence relation are both monic. Further, results in this direction would extend the discussion of the Membership Problem for hypergeometric sequences with rational parameters in work by Nosan et al. [22] as well as those sequences whose polynomial coefficients have irreducible factors in $\mathcal{C}$ (i.e., each irreducible factor has a root with rational real part) discussed herein.

A Appendixed Proofs

▶ **Lemma 4.** *Consider the class of hypergeometric sequences $\langle u_n \rangle_n$ whose shift quotients $r(n)$ either diverge to $\pm\infty$ or converge to a limit ℓ with $|\ell| \neq 1$. For this class, the Membership and Threshold Problems are both decidable.*

Proof. When $r(n) \equiv 0$ decidability of both problems is trivial. So we assume that this is not the case for the remainder of the proof. Write the shift quotient $r(n) = c\frac{q(n)}{p(n)}$ where $p, q \in \mathbb{Q}[x]$ are monic polynomials and $c \in \mathbb{Q}$. Without loss of generality, we can assume that $c > 0$; for otherwise, sequence $\langle u_n \rangle_{n=0}^{\infty}$ is given by the interlacing of two hypergeometric sequences with this property. Let us assume that $r(n)$ diverges to $+\infty$. In this case it is easily seen that, for each $t \in \mathbb{Q}$, there exists a computable $N_0 \in \mathbb{N}$ such that if $n \geq N_0$ then $|u_n| = |u_0 \cdot \prod_{k=0}^{n} r(k)| > |t|$. Thus to determine the Threshold Problem in this instance, we need only determine the ultimate sign of $\langle u_n \rangle_{n=0}^{\infty}$ (which is straightforward). Moreover, we can compute a bound N_1 after which the sign of $\langle u_n \rangle_{n=0}^{\infty}$ is constant. Thus the Threshold Problem in such instances reduces to an exhaustive search that asks whether $u_n \geq t$ for each $n \in \{0, 1, \ldots, \max\{N_0, N_1\}\}$. Mutatis mutandis, decidability is similarly established for instances of the Threshold Problem where $r(n)$ converges to a limit ℓ with $|\ell| \neq 1$.

The argument for the Membership Problem is similar and given in full in [22]. ◀

▶ **Proposition 6.** *Let $\langle u_n \rangle_n$ be a hypergeometric sequence whose shift quotient is given by a ratio of two polynomials with real coefficients. For such sequences, the Membership and Threshold Problems are both Turing-reducible to the following decision problem. Given $d \in \mathbb{N}$, $\alpha_1, \ldots, \alpha_d \in \mathbb{C} \setminus \mathbb{Z}_{<0}$ (the roots of some $P(x) \in \mathbb{R}[x]$), and $\beta_1, \ldots, \beta_d \in \mathbb{C} \setminus \mathbb{Z}_{<0}$ (the roots of some $Q(x) \in \mathbb{R}[x]$), determine whether*

$$\frac{\Gamma(\beta_1) \cdots \Gamma(\beta_d)}{\Gamma(\alpha_1) \cdots \Gamma(\alpha_d)} = t$$

for $t \in \mathbb{Q} \setminus 0$.

Proof. From Lemma 4, we need only consider cases where the associated shift quotient $r(k)$ converges to ± 1 and, by Theorem 5, we can assume without loss of generality that $r(k)$ is harmonious. We treat the case that the sequence of partial products $\langle \prod_{k=0}^{n} r(k) \rangle_n$ is eventually strictly increasing. The case where the sequence of partial products is eventually strictly decreasing follows *mutatis mutandis*.

Consider an instance $(\langle u_n\rangle_n, t)$ of the Threshold Problem with $r(k)$ as above and recall our running assumption that $u_0 = 1$. Let $\tau := \prod_{k=0}^{\infty} r(k)$. We assume that the sequence $\langle u_n\rangle_n$, whose terms $u_n = \prod_{k=0}^{n} r(k)$ are given by partial products, is eventually strictly increasing. Then there exists a computable $N \in \mathbb{N}$ such that $u_n < \tau$ for each $n \geq N$. There are two subcases to consider. First, if $\tau \leq t$ then it is clear that $u_n < t$ for each $n \geq N$ and so we return the answer `no` to the Threshold Problem. Second, if $\tau > t$ then there exists an $N_1 \in \mathbb{N}$ such that $u_n > t$ for each $n \geq N_1$. So decidability of Threshold in this instance reduces to an exhaustive check that asks whether $u_n \geq t$ for each $n \in \{0, 1, \ldots, N-1\}$.

All that remains is to decide whether $\tau \leq t$. It is clear that, by computing τ to sufficient precision, the problem of determining whether $\tau < t$ or $\tau > t$ is recursively enumerable. Thus we need only test whether the equality $\tau = t$ holds. By Theorem 5, we know that $\tau = \prod_{j=1}^{m} \Gamma(\beta_j)/\Gamma(\alpha_j)$, from which we deduce the desired result.

For the sake of brevity, we omit the argument for the reduction from the Membership Problem, which is near identical to the reasoning displayed above. ◀

▶ **Proposition 7.** *For hypergeometric sequences, decidability of the Membership Problem Turing-reduces to that of the Threshold Problem.*

Proof. By Theorem 5 and Proposition 6, we need only consider hypergeometric sequences with harmonious shift quotients. Thus, we continue under this assumption.

Let $(\langle u_n\rangle_n, t)$ be an instance of the Membership Problem as above and, in addition, assume that $\langle u_n\rangle_n$ is eventually decreasing. We note there is a computable bound $N_0 \in \mathbb{N}$ such that $u_{n+1} \leq u_n$ for all $n \geq N_0$. Now let τ be the limit of the the sequence $\langle u_n\rangle_n$. Either we have that $\tau = t$ or $\tau \neq t$. We note that the Membership Problem is decidable when $\tau \neq t$ and so it remains to test cases when $\tau = t$.

- Suppose that an oracle for the Threshold Problem returns the answer `yes` to the problem instance $(\langle u_n\rangle_{n=N_0}^{\infty}, \tau)$. Since $u_{n+1} < u_n$ for all $n \geq N_0$, we deduce that τ is not a member of the sequence $\langle u_n\rangle_{n=N_0}^{\infty}$. Thus all that remains is to test whether $\tau \in \{u_0, u_1, \ldots, u_{N_0-1}\}$.
- Suppose that an oracle for the Threshold Problem returns the answer `no` to the problem instance $(\langle u_n\rangle_{n=N_0}^{\infty}, \tau)$. Then there is a computable bound N_1 such that $u_n < \tau$ for all $n \geq N_1$. Thus we can decide the Membership Problem by testing whether $\tau \in \{u_0, u_1, \ldots, u_{N_1-1}\}$.

We note a similar argument to that given above holds for testing the Membership Problem for hypergeometric sequences that are eventually increasing. Thus we deduce the desired result: that decidability of the Membership Problem for hypergeometric sequences Turing-reduces to that of the Threshold Problem for hypergeometric sequences. ◀

B Threshold for the Kepler–Bouwkamp Constant Approximation

In this section we demonstrate that we can conditionally determine the Threshold Problem for instances $(\langle v_n\rangle_{n=3}^{\infty}, t)$ where sequence $\langle v_n\rangle_{n=3}^{\infty}$ is the recurrence sequence associated with the approximation of the Kepler–Bouwkamp Constant (Example 1) by the $[2,2]$-Padé approximant of $\cos(\,\cdot\,)$.

Let us begin. Recall that the sequence $\langle v_n\rangle_{n=3}^{\infty}$ has terms given by $v_n := \prod_{k=3}^{n} \frac{12k^2-5\pi^2}{12k^2+\pi^2}$. By Proposition 6, decidability of problem instance $(\langle v_n\rangle_{n=3}^{\infty}, t)$ reduces to determining whether

$$\prod_{k=3}^{\infty} \frac{12k^2-5\pi^2}{12k^2+\pi^2} = \frac{\Gamma(3-\frac{\mathrm{i}}{6}\sqrt{3}\pi)\Gamma(3+\frac{\mathrm{i}}{6}\sqrt{3}\pi)}{\Gamma(3-\frac{1}{6}\sqrt{15}\pi)\Gamma(3+\frac{1}{6}\sqrt{15}\pi)} \tag{8}$$

is equal to t. (We note that the formulation as a gamma product is given to us by Theorem 5.)

We consider the numerator and denominator in turn. First, we use the translation and reflection properties of the gamma function to write the numerator of (8) as

$$\begin{aligned}\Gamma\left(3-\frac{\sqrt{3}\pi\mathrm{i}}{6}\right)\Gamma\left(3+\frac{\sqrt{3}\pi\mathrm{i}}{6}\right) &= \Gamma\left(-\frac{\sqrt{3}\pi\mathrm{i}}{6}\right)\Gamma\left(\frac{\sqrt{3}\pi\mathrm{i}}{6}\right)\prod_{k=0}^{2}\left(k^2+\frac{\pi^2}{12}\right)\\ &= \frac{4\sqrt{3}}{\mathrm{e}^{\frac{\pi^2}{2\sqrt{3}}}-\mathrm{e}^{-\frac{\pi^2}{2\sqrt{3}}}}\prod_{k=0}^{2}\left(k^2+\frac{\pi^2}{12}\right)\\ &= \frac{4\sqrt{3}\mathrm{e}^{\frac{\pi^2}{2\sqrt{3}}}}{\mathrm{e}^{\frac{\pi^2}{\sqrt{3}}}-1}\prod_{k=0}^{2}\left(k^2+\frac{\pi^2}{12}\right). \qquad (9)\end{aligned}$$

Second, we likewise write the denominator of (8) as

$$\begin{aligned}\Gamma\left(3-\frac{\sqrt{15}\pi}{6}\right)\Gamma\left(3+\frac{\sqrt{15}\pi}{6}\right) &= \Gamma\left(-\frac{\sqrt{15}\pi}{6}\right)\Gamma\left(\frac{\sqrt{15}\pi}{6}\right)\prod_{k=0}^{2}\left(k^2-\frac{5\pi^2}{12}\right)\\ &= -\frac{12\mathrm{i}}{\sqrt{15}\left(\mathrm{e}^{\frac{\sqrt{15}\pi^2\mathrm{i}}{6}}-\mathrm{e}^{-\frac{\sqrt{15}\pi^2\mathrm{i}}{6}}\right)}\prod_{k=0}^{2}\left(k^2-\frac{5\pi^2}{12}\right)\\ &= -\frac{12\mathrm{i}\mathrm{e}^{\frac{\pi^2\sqrt{15}\mathrm{i}}{6}}}{\sqrt{15}\left(\mathrm{e}^{\frac{\pi^2\sqrt{15}\mathrm{i}}{3}}-1\right)}\prod_{k=0}^{2}\left(k^2-\frac{5\pi^2}{12}\right). \qquad (10)\end{aligned}$$

Let us consider the decision problem at hand. Taken together, we are tasked to determine whether the ratio of (9) and (10) is equal to t. For this equality to hold, a simple rearrangement argument leads us to the following: there is a non-trivial polynomial $\mathcal{Q} \in \mathbb{Q}[x,y,z] = 0$ such that $\mathcal{Q}\big(\pi^2, \mathrm{e}^{\frac{\pi^2}{\sqrt{3}}}, \mathrm{e}^{\frac{\sqrt{15}\pi^2\mathrm{i}}{3}}\big) = 0$ (the fact that such a polynomial with rational coefficients exists is guaranteed by Lemma 9). However, we claim that no such polynomial $\mathcal{Q}$ exists if Schanuel's conjecture is true.

Let us prove the above claim. Consider the set

$$\mathfrak{S} := \left\{\frac{\pi^2}{\sqrt{3}}, \frac{\sqrt{15}\pi^2\mathrm{i}}{3}, \pi\mathrm{i}, \mathrm{e}^{\frac{\pi^2}{\sqrt{3}}}, \mathrm{e}^{\frac{\sqrt{15}\pi^2\mathrm{i}}{3}}, \mathrm{e}^{\pi\mathrm{i}}\right\}.$$

We note that the elements of $\left\{\frac{\pi^2}{\sqrt{3}}, \frac{\sqrt{15}\pi^2\mathrm{i}}{3}, \pi\mathrm{i}\right\}$ are $\mathbb{Q}$-linearly independent. Thus, Schanuel's conjecture predicts that there is a subset of $\mathfrak{S}$ of size at least 3 whose elements are algebraically independent. Since $\frac{\pi^2}{\sqrt{3}}$ and $\frac{\sqrt{15}\pi^2\mathrm{i}}{3}$ are algebraically dependent and $\mathrm{e}^{\pi\mathrm{i}} = -1$, we deduce that, subject to the truth of Schanuel's conjecture, the elements of $\left\{\pi^2, \mathrm{e}^{\frac{\pi^2}{\sqrt{3}}}, \mathrm{e}^{\frac{\sqrt{15}\pi^2\mathrm{i}}{3}}\right\}$ are algebraically independent. From the preceding work, we deduce that there is no non-trivial polynomial $\mathcal{Q}$ for which $\mathcal{Q}\big(\pi^2, \mathrm{e}^{\frac{\pi^2}{\sqrt{3}}}, \mathrm{e}^{\frac{\sqrt{15}\pi^2\mathrm{i}}{3}}\big) = 0$. It follows that the desired equality cannot hold. Thus we can conditionally decide the Threshold Problem for instances $(\langle v_n\rangle_{n=0}^{\infty}, t)$ with $t \in \mathbb{Q}$.

Solving Promise Equations over Monoids and Groups

Alberto Larrauri
Department of Computer Science, University of Oxford, UK

Stanislav Živný
Department of Computer Science, University of Oxford, UK

Abstract

We give a complete complexity classification for the problem of finding a solution to a given system of equations over a fixed finite monoid, given that a solution over a more restricted monoid exists. As a corollary, we obtain a complexity classification for the same problem over groups.

1 Introduction

Constraint satisfaction problems (CSPs) form a large class of fundamental computational problems studied in artificial intelligence, database theory, logic, graph theory, and computational complexity. Since CSPs (with infinite domains) capture, up to polynomial-time Turing reductions, *all* computational problems [11], some restrictions need to be imposed on CSPs in order to have a chance to obtain complexity classifications. One line of work, pioneered in the database theory [36], restricts the interactions of the constraints in the instance [30, 41].

Another line of work, pioneered in [34, 26], restricts the types of relations used in the instance; these CSPs are known as nonuniform CSPs, or as having a fixed template/constraint language. Such CSPs with infinite domains capture graph acyclicity, systems of linear equations over the rationals, and many other problems [10]. Already fixed-template CSPs with finite domains form a large class of fundamental problems, including graph colourings [32], variants of the Boolean satisfiability problem, and, more generally, systems of equations over different types of finite algebraic structures. Even then, the class of finite-domain CSPs avoided a complete complexity classification for two decades despite a sustained effort.

In 2017, Bulatov [20] and, independently, Zhuk [47] classified all finite-domain CSPs as either solvable in polynomial time or NP-hard, thus answering in the affirmative the Feder-Vardi dichotomy conjecture [26]. In the effort to answer the Feder-Vardi conjecture, many complexity dichotomies were established in restricted fragments of CSPs. This included conservative CSPs [19], or equations over finite algebraic structures such as semigroups, groups, and monoids [29, 35]. In particular, while systems of equations[1] over Abelian groups are solvable in polynomial time, they are NP-hard over non-Abelian groups [29].

[1] Some papers use the term a *linear* equation.

One of the recent research directions in constraint satisfaction that has attracted a lot of attention is the area of *promise* CSPs (PCSPs) [3, 13, 5]. The idea is that each constraint has two versions, a strong version and a weak version. Given an instance, one is promised that a solution satisfying all strict constraints exists and the goal is to find a solution satisfying all weak constraints, which may be an easier task. The prototypical example is the approximate graph colouring problem [28]: Given a 3-colourable graph, can one find a 6-colouring? The complexity of this problem is open (but believed to be NP-hard). Despite a flurry of papers on PCSPs, e.g., [27, 1, 4, 17, 43, 44, 6, 2, 21, 14, 15, 24, 22], the PCSP complexity landscape is widely open and unexplored. It is not even clear whether a dichotomy should be expected. Even the case of Boolean PCSPs remain open, the state-of-the-art being a dichotomy for Boolean *symmetric* PCSPs [27]. This should be compared with Boolean (non-promise) CSPs, which were classified by Schaefer in 1978 [45]. Schaefer's tractable cases include the classic and well-known examples of CSPs: equations and graph colouring. Both have been studied on non-Boolean domains and their complexity is well understood. However, the complexity of the promise variant of these fundamental problems is open. The first problem, graph colouring, leads to the already mentioned approximate graph colouring problem, which is a notorious open problem, despite recent progress [5, 38]. In this paper, we look at the second problem, and study PCSPs capturing systems of equations.

Contributions

The precise statements of all our main results are presented in Section 3.

As our most important contribution, in Section 5 we establish a complexity dichotomy for PCSPs capturing *promise* systems of equations over finite monoids, and over finite groups as a special case. Perhaps unsurprisingly, the tractability boundary is linked to the notion of Abelianness, just like in the non-promise setting, but the result is non-trivial and requires some care. Our main tool is the "the algebraic approach to PCSPs" [5]. The influential paper [5] identified *minions* as an important concept. Minions generalise the notion of "a family of functions that is closed under permuting arguments, identifying arguments, and adding dummy arguments". A crucial example is the polymorphism minion of a PCSP template. Polymorphisms can be seen as high-dimensional symmetries of a PCSP template and capture the complexity of the underlying computational problem [13, 5]. Following the algebraic approach [5], hardness of a PCSP is established by showing that the associated polymorphism minion is, in some sense, limited. Conversely, if this minion is rich enough then the PCSP can be shown to be solvable via some efficient algorithm [5, 16, 22, 15].

To prove our main result, we study a class of minions that arise naturally from monoids, which we call monoidal minions. In Section 4 we show a complexity dichotomy for PCSPs whose polymorphism minions are homomorphically equivalent to some monoidal minion. This is our second contribution, which may be of independent interest. In particular, the concept of monoidal minions captures studied minions, cf. Remark 14 in Section 3.

All our tractability results use solvability via the BLP + AIP algorithm [16]. In fact, tractable PCSPs corresponding to promise systems of equations over monoids are finitely tractable in the sense of [13, 1]. In the special case of promise systems of equations over groups, the affine integer programming (AIP) algorithm [13, 5] suffices, rather than BLP + AIP. However, AIP is provably not enough to solve promise equations over general monoids.

As our final contribution, in Section 6 we show that our dichotomy for systems of equations over monoids cannot be easily extended to semigroups, as this would imply a dichotomy for all PCSPs. We do so by showing that every PCSP is polynomial-time equivalent to a PCSP capturing systems of equations over semigroups, a phenomenon observed for CSPs in [35].

Related work

PCSPs are a qualitative approximation of CSPs; the goal is still to satisfy all constraints, but in a weaker form. A recent related line of work includes the series [7, 8, 9]. A traditional approach to approximation is quantitative: maximising the number of satisfied constraints. Regarding approximation of equations, Håstad showed that, for any Abelian group G and any $\varepsilon > 0$, it is NP-hard to find a solution satisfying $1/|G| + \varepsilon$ constraints [31] even if $1 - \varepsilon$ constraints can be satisfied. Hence, the random assignment, which satisfies $1/|G|$ constraints, is optimal! Håstad's result has been extended to non-Abelian groups in [25, 7]. Systems of equations have been studied, e.g., over semigroups in [46], over monoids and semigroups in [35], and over arbitrary finite algebras in [39, 37, 12, 42].

The full version of this paper [40] contains all details and proofs.

2 Preliminaries

We denote by $[k]$ the set $\{1, 2, \dots, k\}$. We write id_X for the identity map on a set X. We use the lowercase boldface font for tuples; e.g., we write $\boldsymbol{b}$ for a tuple $(b_1, \dots, b_n)$. We say that a function f *extends* another function g if $\mathrm{dom}(g) \subseteq \mathrm{dom}(f)$, and $f|_{\mathrm{dom}(g)} = g$.

Algebraic structures

A *semigroup* S is a set equipped with an associative binary operation, for which we use multiplicative notation. Two elements $a, b \in S$ commute if $ab = ba$. An *Abelian* semigroup is a semigroup in which every two elements commute. A *semigroup homomorphism* from a semigroup S_1 to a semigroup S_2 is a map $\varphi : S_1 \to S_2$ satisfying $\varphi(s \cdot_{S_1} t) = \varphi(s) \cdot_{S_2} \varphi(t)$.[2] Given two elements $s, t \in S$ we write $s \sqsubseteq t$ if s can be expressed as a product of elements in S including t. Note that $\sqsubseteq$ constitutes a preorder over any semigroup. We define the equivalence relation $\sim$ by $s \sim t$ whenever $s \sqsubseteq t$ and $t \sqsubseteq s$.

A *monoid* is a semigroup containing an identity element for its binary operation, denoted by e. A *monoid homomorphism* from a monoid M_1 to a monoid M_2 is a map $\varphi : M_1 \to M_2$ satisfying $\varphi(x \cdot_{M_1} y) = \varphi(x) \cdot_{M_2} \varphi(y)$ and $\varphi(e_{M_1}) = e_{M_2}$. We say that φ is *Abelian* if its image $\mathrm{Im}(\varphi)$ is an Abelian monoid. A *group* is a monoid in which each element has an inverse. A *group homomorphism* from a group G_1 to a group G_2 is a map $\varphi : G_1 \to G_2$ satisfying $\varphi(x \cdot_{G_1} y) = \varphi(x) \cdot_{G_2} \varphi(y)$ (which implies that also the inverses and the identity element are preserved).

Given a semigroup S, a subset $G \subseteq S$ is called a *subgroup* if G equipped with S's binary operation is a group, meaning that there is a distinguished element $e_G \in G$ satisfying that (1) $e_G \cdot_M g = g \cdot_M e_G = g$ for each $g \in G$, and (2) for each element $g \in G$ there exists $h \in G$ satisfying $g \cdot_M h = h \cdot_M g = e_G$. We say that S is a *union of subgroups* if every element $s \in S$ belongs to a subgroup of S. We call an element s of S *regular* if $s^2 t = s$ and $ts = st$ for some t in S.[3] Intuitively, t acts as some type of inverse of s. It is known that s belongs to a subgroup of S if and only if s is regular [33, Theorem 2.2.5].

We use the standard product (and also the power) of a semigroup (monoid, group), where the operation is defined componentwise. We use the symbol $\preceq$ for a substructure; e.g., if S is a semigroup then we write $T \preceq S$ to indicate that T is a subsemigroup of S (and similarly for monoids and groups).

Unless stated explicitly otherwise, all semigroups, monoids, and groups in this paper are finite.

[2] I.e., the multiplication on the LHS is in S_1, whereas the multiplication on the RHS is in S_2.
[3] The usual definition of a regular element in a semigroup just requires that $sts = s$ for some t [33].

Relational structures

A *relational signature* σ consists of a finite set of relation symbols R, each with a finite arity $\mathrm{ar}(R) \in \mathbb{N}$. A *relational structure* $\boldsymbol{A}$ over the signature σ, or a σ-structure, consists of a finite set A and a relation $R^{\boldsymbol{A}} \subseteq A^k$ of arity $k = \mathrm{ar}(R)$ for every $R \in \sigma$. Let $\boldsymbol{A}$ and $\boldsymbol{B}$ be two σ-structures. A map $h : A \to B$ is called a *homomorphism* from $\boldsymbol{A}$ to $\boldsymbol{B}$ if h preserves all relations in $\boldsymbol{A}$; i.e., if, for every $R \in \sigma$, $h(\mathbf{x}) \in R^{\boldsymbol{B}}$ whenever $\mathbf{x} \in R^{\boldsymbol{A}}$, where h is applied componentwise. We denote the existence of a homomorphism from $\boldsymbol{A}$ to $\boldsymbol{B}$ by writing $\boldsymbol{A} \to \boldsymbol{B}$. A *template* is a pair $(\boldsymbol{A}, \boldsymbol{B})$ of relational structures such that $\boldsymbol{A} \to \boldsymbol{B}$.

A k-ary *polymorphism* of a template $(\boldsymbol{A}, \boldsymbol{B})$ over signature σ is a map $p : A^k \to B$ that preserves all relations $R^{\boldsymbol{A}}$ from $\boldsymbol{A}$ in the following sense: For any $\mathrm{ar}(R) \times k$ matrix whose columns belong to $R^{\boldsymbol{A}}$, applying p row-wise results in a tuple that belongs to $R^{\boldsymbol{B}}$. We denote by $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ the set of all polymorphisms of $(\boldsymbol{A}, \boldsymbol{B})$.[4]

Minions

A *minion* $\mathcal{M}$ consists of a set $\mathcal{M}(n)$ for each positive number n, and a map $\pi^{\mathcal{M}} : \mathcal{M}(n) \to \mathcal{M}(m)$ for each map $\pi : n \to m$ satisfying (1) $\mathrm{id}_{[n]}^{\mathcal{M}} = \mathrm{id}_{\mathcal{M}(n)}$ for every $n > 0$, and (2) $\pi^{\mathcal{M}} \circ \tau^{\mathcal{M}} = (\pi \circ \tau)^{\mathcal{M}}$ for every pair of suitable maps π, τ. When the minion is clear from the context, we write $p^{(\pi)}$ for $\pi^{\mathcal{M}}(p)$. Elements $p \in \mathcal{M}(n)$ are called n-ary, and whenever $p^{(\pi)} = q$ we say that q is a *minor* of p. A *minion homomorphism* $\xi : \mathcal{M} \to \mathcal{N}$ is a map from a minion $\mathcal{M}$ to another minion $\mathcal{N}$ that preserves arities and minor operations. I.e., $\xi(p^{(\pi)}) = (\xi(p))^{(\pi)}$ for every minor $p^{(\pi)}$.

Given a template $(\boldsymbol{A}, \boldsymbol{B})$, its set of polymorphisms $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ can be equipped with a minion structure in a natural way. That is, n-ary elements of $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ are just n-ary polymorphisms $p : A^n \to B$. Additionally, given some n-ary polymorphism p, and some map $\pi : [n] \to [m]$, the minor $p^{(\pi)}$ is the polymorphism $q : A^m \to B$ given by $(a_1, \ldots, a_m) \mapsto p(b_1, \ldots, b_n)$, where $b_i = a_{\pi(i)}$ for each $i \in [n]$.

Given a minion $\mathcal{M}$, we define two special types of elements. An element $p \in \mathcal{M}(2k+1)$ is called *alternating* if $p^{(\pi)} = p$ for any permutation $\pi : [2m+1] \to [2m+1]$ that preserves parity, and $p^{(\pi_1)} = p^{(\pi_2)}$, where for each $i = 1, 2$ the map π_i is given by $1 \mapsto i$, $2 \mapsto i$ and $j \mapsto j$ for all $j > 2$. An element $p \in \mathcal{M}(2k+1)$ is called 2-*block-symmetric* if the set $[2k+1]$ can be partitioned into two blocks of size $k+1$ and k in such a way that $p^{(\pi)} = p$ for any map $\pi : [2m+1] \to [2m+1]$ that preserves each block.

Constraint satisfaction

Let $(\boldsymbol{A}, \boldsymbol{B})$ be a template with common signature σ. The *promise constraint satisfaction problem* (PCSP) with template $(\boldsymbol{A}, \boldsymbol{B})$ is the following computational problem, denoted by $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$. Given a σ-structure $\boldsymbol{X}$, output YES if $\boldsymbol{X} \to \boldsymbol{A}$ and output NO if $\boldsymbol{X} \not\to \boldsymbol{B}$. This is the decision version. In the search version, one is given a σ-structure $\boldsymbol{X}$ with the promise that $\boldsymbol{X} \to \boldsymbol{A}$; the goal is to find a homomorphism from $\boldsymbol{X}$ to $\boldsymbol{B}$ (which necessarily exists, as $\boldsymbol{X} \to \boldsymbol{A}$ and $\boldsymbol{A} \to \boldsymbol{B}$, and homomorphisms compose). It is known that the decision version polynomial-time reduces to the search version (but it is not known whether the two variants are polynomial-time equivalent) [5]. In our results, the positive (tractability) results are for the search version, whereas the hardness (intractability) results are for the decision version. We denote by $\mathrm{CSP}(\boldsymbol{A})$ the problem $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{A})$; this is the standard (non-promise) constraint satisfaction problem (CSP). For CSPs, the decision version and the search version are polynomial-time equivalent [18].

[4] Equivalently, p is a polymorphism of $(\boldsymbol{A}, \boldsymbol{B})$ if p is a homomorphism from the k-th power of $\boldsymbol{A}$ to $\boldsymbol{B}$.

We need two existing algorithms for PCSPs, namely the AIP algorithm [5] and the strictly more powerful BLP + AIP algorithm [16]. Their power is captured by the following results.

▶ **Theorem 1** ([5]). *Let* $(\boldsymbol{A}, \boldsymbol{B})$ *be a template. Then* $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ *is solved by AIP if and only if* $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ *contains alternating maps of all odd arities.*

▶ **Theorem 2** ([16]). *Let* $(\boldsymbol{A}, \boldsymbol{B})$ *be a template. Then* $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ *is solved by BLP + AIP if and only if* $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ *contains 2-block-symmetric maps of all odd arities.*

3 Overview of Results

Promise equations over monoids and groups

Our first and main result is a dichotomy theorem for solving promise equations over finite monoids and thus also, as a special case, over finite groups. We first define equations in the standard, non-promise setting as it is useful for mentioning previous work and for our own proofs.

An *equation* over a semigroup S is an expression of the form $x_1 \dots x_n = y_1 \dots y_m$, where each x_i, y_i is either a variable or some element from S, referred to as a *constant*. A *system of equations* over S is just a set of equations. A solution to such a system is an assignment of elements of S to the variables of the system that makes all equations hold. Equations and systems of equations are defined similarly for monoids and groups. The only difference is that for groups we allow "inverted variables" x^{-1} in the equations, which are interpreted as inverses of the elements assigned to x.

In the context of CSPs, it is common to consider only restricted "types" of equations that can then express all other equations. The following definition captures systems of equations where each equation is either of the form $x_1 x_2 = x_3$, for three variables, or $x = c$, fixing a variable to a constant. It is well known that restricting to systems of equations of this kind is without loss of generality [40].

▶ **Definition 3.** *Let* S *be a semigroup and* $T \preceq S$ *a subsemigroup. The relational structure* $\mathrm{Eqn}(S, T)$ *has universe* S*, and the following relations:*

- *A ternary relation* $R_\times = \{(s_1, s_2, s_3) \in S^3 \mid s_1 s_2 = s_3\}$*, and*
- *a singleton unary relation* $R_t = \{t\}$ *for each* $t \in T$*.*

This template captures systems of equations of the kind described above when we allow only constants in a subsemigroup T of the ambient semigroup S. Similarly, we define the templates $\mathrm{Eqn}(M, N)$, $\mathrm{Eqn}(G, H)$ in the same way when M is a monoid and $N \preceq M$ a submonoid, and when G is a group and $H \preceq G$ is a subgroup. Observe that the definition of subgroup is more restrictive than the one of submonoid and this in turn is more restrictive than the notion of subsemigroup. We abuse the notation and write $\mathrm{Eqn}(S, T)$ for $\mathrm{CSP}(\mathrm{Eqn}(S, T))$.

Previous works focused on problems $\mathrm{Eqn}(G, G)$ and $\mathrm{Eqn}(M, M)$. Given a group G, it is known that $\mathrm{Eqn}(G, G)$ is solvable in polynomial time (by AIP) if G is Abelian, and NP-hard otherwise [29]. Similarly, when M is a monoid, $\mathrm{Eqn}(M, M)$ is solvable in polynomial time if M is Abelian and it is the union of its subgroups, and NP-hard otherwise [35].

We now define promise equations.

▶ **Definition 4.** *Let* S_1, S_2 *be semigroups, and let* φ *be a semigroup homomorphism with* $\mathrm{dom}(\varphi) \preceq S_1$ *and* $\mathrm{Im}(\varphi) \preceq S_2$*. The* promise system of equations over semigroups *problem* $\mathrm{PEqn}(S_1, S_2, \varphi)$ *is the* $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$*, where* $A = S_1$*,* $B = S_2$*, and the relations are defined as follows:*

- *A ternary relation* $R_\times^{\boldsymbol{A}} = \{(s_1, s_2, s_3) \in S_1^3 \mid s_1 s_2 = s_3\}$*, and* $R_\times^{\boldsymbol{B}} = \{(s_1, s_2, s_3) \in S_2^3 \mid s_1 s_2 = s_3\}$.
- *For each* $t \in \mathrm{dom}(\varphi)$*, a unary relation given by* $R_t^{\boldsymbol{A}} = \{t\}$*, and* $R_t^{\boldsymbol{B}} = \{\varphi(t)\}$.

For this template to be well defined there should be a homomorphism from $\boldsymbol{A}$ *to* $\boldsymbol{B}$*, which is equivalent to the existence of a semigroup homomorphism* $\psi : S_1 \to S_2$ *that extends* φ.

Analogously, we also define the *promise system of equations over monoids* problem and the *promise system of equations over groups* problem by replacing semigroup-related notions with monoid-related notions and group-related notions respectively. Observe that the problem $\mathrm{Eqn}(S, T)$ described before corresponds precisely to $\mathrm{PEqn}(S, S, \mathrm{id}_T)$.

We can now state our main result.

▶ **Theorem 5** (Main). $\mathrm{PEqn}(M_1, M_2, \varphi)$ *is solvable in polynomial time by BLP + AIP if there is an Abelian homomorphism* $\psi : M_1 \to M_2$ *extending* φ *and* $\mathrm{Im}(\psi)$ *is a union of subgroups. Otherwise,* $\mathrm{PEqn}(M_1, M_2, \varphi)$ *is* NP*-hard.*

For the special case of groups, we get a simpler tractability criterion and a simpler algorithm.

▶ **Corollary 6.** $\mathrm{PEqn}(G_1, G_2, \varphi)$ *is solvable in polynomial time via AIP if there is an Abelian homomorphism* $\psi : G_1 \to G_2$ *extending* φ*. Otherwise,* $\mathrm{PEqn}(G_1, G_2, \varphi)$ *is* NP*-hard.*

As easy corollaries, Theorem 5 applies in the special case of non-promise setting.

▶ **Corollary 7.** *Given two monoids* $N \preceq M$*,* $\mathrm{Eqn}(M, N)$ *is solvable in polynomial time by BLP + AIP if there is an Abelian endomorphism of* M *extending* id_N *whose image is a union of subgroups, and is* NP*-hard otherwise.*

▶ **Corollary 8.** *Given two groups* $H \preceq G$*,* $\mathrm{Eqn}(G, H)$ *is solvable in polynomial time by AIP if there is an Abelian endomorphism of* G *that extends* id_H*, and is* NP*-hard otherwise.*

▶ **Example 9.** Let G be the dihedral group on four elements, and H be the symmetric group on four elements. Observe that G can be seen as a subgroup of H in a natural way: H consists of all permutations on four elements, while G contains only those that are symmetries of the square. The group G is generated by the right 90-degree rotation r and an arbitrary reflection f that leaves no element fixed. We consider two group homomorphisms φ_1, φ_2 with $\mathrm{dom}(\varphi_i) \preceq G$ and $\mathrm{Im}(\varphi_i) \preceq H$. The domain of both homomorphism is the subgroup $\{e, r, r^2, r^3\} \preceq G$. Then, φ_1 is given by $r \mapsto r^2$, and φ_2 is given by $r \mapsto r$. The following hold:

- $\mathrm{PEqn}(G, H, \varphi_1)$ is tractable, and solvable via AIP. However both $\mathrm{Eqn}(G, \mathrm{dom}(\varphi_1))$ and $\mathrm{Eqn}(H, \mathrm{Im}(\varphi_1))$ are NP-hard.
- $\mathrm{PEqn}(G, H, \varphi_2)$ is NP-hard.

To see the first item, observe that the group homomorphism $\psi : G \to H$ given by $r \mapsto r^2$ and $f \mapsto f$ is Abelian (its image is isomorphic to the direct product $Z_2 \times Z_2$) and extends φ_1. Hardness of $\mathrm{Eqn}(G, \mathrm{dom}(\varphi_1))$ is a consequence of the fact that the commutator subgroup of G is $\{e, r, r^2, r^3\} \succeq \mathrm{dom}(\varphi_1)$, so $\mathrm{dom}(\varphi_1)$ is included in the kernel of any Abelian endomorphism of G. Similarly, hardness of $\mathrm{Eqn}(H, \mathrm{Im}(\varphi_1))$ follows from the fact that the commutator subgroup of H is the alternating group on four elements, and has $\mathrm{Im}(\varphi_1)$ as a subgroup.

The second item can be proved by observing that the only normal subgroup of G that does not intersect $\mathrm{dom}(\varphi_2)$ is the trivial subgroup, so any homomorphism $\psi : G \to H$ that extends φ_2 needs to be injective, and thus non-Abelian.

We say that $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ is *finitely tractable* if there is $\boldsymbol{C}$ such that $\boldsymbol{A} \to \boldsymbol{C} \to \boldsymbol{B}$ and $\mathrm{CSP}(\boldsymbol{C})$ is solvable in polynomial time. The tractable cases in Theorem 5 are in fact finitely tractable; for details, cf. [40].

The power of BLP + AIP is necessary in Theorem 5 in the sense that AIP does not suffice for all monoids, even for (non-promise) CSPs, unlike in the case of groups. Indeed, adding a fresh element to a group that serves as the monoid identity fools AIP; for details, cf. [40].

Promise equations over semigroups

As our next result, we prove that every PCSP is polynomial-time equivalent to a problem of the form $\mathrm{PEqn}(S_1, S_2, \varphi)$ over some semigroups S_1, S_2. Hence, extending our classification of promise equations beyond monoids is difficult in the sense that understanding the computational complexity of promise equations over semigroups is as hard as classifying all PCSPs. This result is analogous to the one known in the non-promise setting obtained in [35], whose proof we closely follow. One difficulty in lifting the result from [35] is the lack of constants in the promise setting. The details can be found in Section 6.

▶ **Theorem 10.** *Let $(\boldsymbol{A}, \boldsymbol{B})$ be a template. Then there are semigroups S_1, S_2 and a semigroup homomorphism φ with $\mathrm{dom}(\varphi) \preceq S_1$ and $\mathrm{Im}(\varphi) \preceq S_2$ such that $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ is polynomial-time equivalent to $\mathrm{PEqn}(S_1, S_2, \varphi)$.*

Monoidal minions

As our third result, we investigate minions based on monoids. For PCSPs whose polymorphism minions are homomorphically equivalent to such minions, we establish a dichotomy. This is a building block in the proof of our main result, but may be interesting in its own right. In this direction, we show that for each monoidal minion $\mathcal{M}$, there are PCSP templates whose polymorphism minions are isomorphic to $\mathcal{M}$. For a finite set $[n]$, a tuple $(a_i)_{i\in[n]} \in M^n$ is called commutative if each pair of its elements commute.

▶ **Definition 11.** *Given an element $a \in M$ the* monoidal minion $\mathcal{M}_{M,a}$ *is the one where for each $n \in \mathbb{N}$ the elements $\boldsymbol{b} \in \mathcal{M}_{M,a}(n)$ are commutative tuples $\boldsymbol{b} \in M^n$ with $\prod_{i\in[n]} b_i = a$, and where for each $m > 0$ and each $\pi : [n] \to [m]$ the minor $\boldsymbol{b}^{(\pi)}$ is the tuple $\boldsymbol{c} \in M^m$ given by $c_j = \prod_{i\in\pi^{-1}(j)} b_i$, and the empty product equals the identity element e.*

▶ **Theorem 12.** *Let M be a finite monoid and let $a \in M$. Consider a template $(\boldsymbol{A}, \boldsymbol{B})$ with $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ homomorphically equivalent to $\mathcal{M}_{M,a}$. If a is regular in M then $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ is solvable in polynomial time by BLP + AIP. Otherwise, $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ is* NP*-complete.*

Next, we show that there are templates whose polymorphism minions are of the considered type (up to isomorphism).

▶ **Theorem 13.** *Let M be a monoid, and $a \in M$ an arbitrary element. Then the template $(\boldsymbol{A}, \boldsymbol{B})$ described below satisfies that $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B}) \simeq \mathcal{M}_{M,a}$.[5] The signature σ of $\boldsymbol{A}$ and $\boldsymbol{B}$ contains three relation symbols: a ternary symbol R, and two unary ones C_0, C_1. We define $A = \{0, 1\}$, $R^{\boldsymbol{A}} = \{(1,0,0), (0,1,0), (0,0,1)\}$, $C_0^{\boldsymbol{A}} = \{0\}$ and $C_1^{\boldsymbol{A}} = \{1\}$. The universe B of $\boldsymbol{B}$ is $\mathcal{M}_{M,a}(2)$. We define $R^{\boldsymbol{B}}$ as the set of triples in $(\mathcal{M}_{M,a}(2))^3$ of the form $((c_1, c_2c_3), (c_2, c_1c_3), (c_3, c_1c_2))$, where $c_1, c_2, c_3 \in M$ commute pairwise, and $c_1c_2c_3 = a$. Finally, the unary relations $C_0^{\boldsymbol{B}}$ and $C_1^{\boldsymbol{B}}$ are the singleton sets containing the tuples (e, a) and (a, e) respectively.*[6]

[5] We use $\simeq$ to denote the isomorphism relation, i.e., the existence of a bijection between the minions that preserves arities and minor operations.

[6] The map $f : A \to B$ given by $0 \mapsto (e, a)$ and $1 \mapsto (a, e)$ is a homomorphism from $\boldsymbol{A}$ to $\boldsymbol{B}$. The structure $\boldsymbol{A}$ corresponds to the "1-in-3" template, where both constants are added, and $\boldsymbol{B}$ is the so-called "free structure" [5] of $\mathcal{M}_{M,a}$ generated by $\boldsymbol{A}$.

Finally, we remark that monoidal minions are natural objects of study, as they include other relevant previously studied minions.

▶ Remark 14. Consider the Abelian monoid $M = \{0, 1, \epsilon\}$, whose multiplicative identity is 0, and where $1 \cdot 1 = 1 \cdot \epsilon = \epsilon \cdot \epsilon = \epsilon$. The elements of $\mathcal{M}_{M,1}$ are tuples with all zero entries except for a single 1 entry. Hence $\mathcal{M}_{M,1}$, corresponds to the so-called trivial minion $\mathcal{T}$ consisting of all projections (also known as dictators) on a two-element set. This minion represents the hardness boundary for CSPs, in the sense that a CSP is NP-hard if and only if its polymorphism minion maps homomorphically to $\mathcal{T}$ [18, 47].

Another example of a monoidal minion is the one capturing the power of arc consistency from [24]. In fact, every *linear* minion (in the sense of [23]) is a union of monoidal minions.[7]

If we allow infinite monoids to be considered, then monoidal minions include important minions that capture solvability via relevant algorithms. Consider the monoid $M = \{(r, z) \in \mathbb{Q} \times \mathbb{Z} \mid r \in [0, 1], \text{ and } r = 0 \text{ implies } z = 0\}$, where the binary operation is given by coordinate-wise addition, and the identity is $(0, 0)$. Then $\mathcal{M}_{M,(1,1)}$ is precisely the minion $\mathcal{M}_{\mathrm{BLP+AIP}}$ described in [16], which expresses the power of BLP + AIP. Similarly, the minions described in [5] to capture the power of BLP and AIP are monoidal minions as well.

4 Monoidal Minions: Proof of Theorem 12

Tractability. We use the characterisation of the power of BLP + AIP from Theorem 2 for the tractability part of Theorem 12. Observe that if there is a minion homomorphism $\xi : \mathcal{M}_{M,a} \to \mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$ and $p \in \mathcal{M}_{M,a}$ is a $(2k+1)$-ary 2-block-symmetric element, then so is $\xi(p)$. Hence, showing that $\mathcal{M}_{M,a}$ has 2-block-symmetric elements of all arities proves that $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ is solvable in polynomial time via BLP + AIP. Let $b \in M$ witness that a is regular. For each $k > 0$ consider the $(2k+1)$-ary element of $\mathcal{M}_{M,a}$ consisting of $k+1$ consecutive a's followed by k consecutive b's. To see that this this is indeed an element of $\mathcal{M}_{M,a}$ we need to check that $a^{k+1}b^k = a$. This follows from the assumption that b witnesses that a is regular and using $a^{k+1}b^k = a(ba)^k$. This tuple is 2-block-symmetric, with the blocks corresponding to a and b (of sizes k and $k+1$, respectively).

Intractability. We prove the intractability part of Theorem 12 (as well as other hardness results later in this paper) using the following result.

▶ **Theorem 15** ([5]). *Let $\mathcal{M} = \mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$, and let $K, L > 0$ be any fixed integers. Suppose that M satisfies the following condition:*

$\mathcal{M} = \bigcup_{\ell \in [L]} \mathcal{M}_\ell$, and for each $\ell \in [L]$ there is a map $p \mapsto \mathcal{I}_\ell(p)$ that sends each $p \in \mathcal{M}_\ell$ to a set of its coordinates $\mathcal{I}_\ell(p)$ of size at most K. Furthermore, suppose that for each $\ell \in [L]$ and for each minor $p^{(\pi)} = q$ where $p, q \in \mathcal{M}_\ell$ it holds that $\pi(\mathcal{I}_\ell(p)) \bigcap \mathcal{I}_\ell(q) \neq \varnothing$.

Then $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$ is NP-complete.

Given a template $(\boldsymbol{A}, \boldsymbol{B})$, if there is a minion homomorphism $\xi : \mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B}) \to \mathcal{M}_{M,a}$ and $\mathcal{M}_{M,a}$ satisfies the condition in the previous theorem, so does $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B})$. Indeed, if $\mathcal{M}_{M,a} = \bigcup_{\ell \in [L]} \mathcal{M}_\ell$, then we can write $\mathrm{Pol}(\boldsymbol{A}, \boldsymbol{B}) = \bigcup_{\ell \in [L]} \xi^{-1}(\mathcal{M}_\ell)$. Additionally, if the map $\mathcal{I}_\ell$ witnesses the condition in the theorem for $\mathcal{M}_\ell$, then the map $\mathcal{I}'_\ell$ given by $p \mapsto \mathcal{I}_\ell(\xi(p))$ witnesses the same condition for $\xi^{-1}(\mathcal{M}_\ell)$. Hence, we show the hardness part of Theorem 12 by proving that $\mathcal{M}_{M,a}$ satisfies the assumptions in Theorem 15 when $a \in M$ is not regular.

[7] We thank Lorenzo Ciardo for this observation.

For a monoid M, we define a refinement $\sqsubseteq^{\mathrm{A}}$ of the preorder $\sqsubseteq$ introduced in Section 2. In detail, we write $a \sqsubseteq^{\mathrm{A}} b$ for $a, b \in M$ if there is a third element $c \in M$ that commutes with b such that $bc = a$. We put $a \sim^{\mathrm{A}} b$ when both $a \sqsubseteq^{\mathrm{A}} b$ and $b \sqsubseteq^{\mathrm{A}} a$ hold, and $a \sqsubsetneq^{\mathrm{A}} b$ when $a \sqsubseteq^{\mathrm{A}} b$ holds but $b \sqsubseteq^{\mathrm{A}} a$ does not. We use the following simple observation.

▶ **Observation 16.** *Let M be a monoid and $a, b, c \in M$ be three elements that commute pairwise. Suppose that $abc \sqsubsetneq^{\mathrm{A}} ab$. Then $ac \sqsubsetneq^{\mathrm{A}} a$.*

Proof. We prove the contrapositive. Suppose that $a \sqsubseteq^{\mathrm{A}} ac$. That is, there is some $d \in M$ that commutes with ac and satisfies $acd = a$. We have $dabc = (dac)b = (acd)b = ab$ $abcd = c(abd) = ca = ac$, and thus $dabc = abcd = ab$, proving that $abc \sqsupseteq^{\mathrm{A}} ab$. ◀

Assume that a is not regular. That is, that $a^2 b \neq a$ for every $b \in M$ that commutes with a. Let $\boldsymbol{b} \in \mathcal{M}_{M,a}(n)$ for some number $n > 0$. A coordinate $j \in [n]$ is called *relevant* in $\boldsymbol{b}$ if $\prod_{i \in [m] \setminus j} b_i \sqsupsetneq^{\mathrm{A}} \prod_{i \in [n]} b_i$. Consider the map $\mathcal{I}$ that assigns to each $\boldsymbol{b} \in \mathcal{M}_{M,a}$ its set of relevant coordinates. Claims 1 through 3 proved below establish the required assumptions in Theorem 15 with $L = 1$ and $K = |m|$, thus showing NP-hardness of $\mathrm{PCSP}(\boldsymbol{A}, \boldsymbol{B})$.

Claim 1: b has at most $|M|$ relevant coordinates. Let $\{i_1, \ldots, i_h\} \subseteq [n]$ be the set of relevant coordinates of $\boldsymbol{b}$. Given $k \in [h]$ we define

$$c_k = \prod_{j \in [k-1]} b_{i_j}, \quad \text{and} \quad d_k = \prod_{j \in [n] \setminus \{i_1, \ldots, i_k\}} b_j.$$

The following hold: (1) $a = d_k c_k b_{i_k}$, (2) b_{i_k}, c_k and d_k commute pairwise, and (3) as i_k is a relevant coordinate, it holds that $d_k c_k b_{i_k} \sqsubsetneq^{\mathrm{A}} d_k c_k$. Applying Observation 16, we obtain that $c_k b_{i_k} \sqsubsetneq^{\mathrm{A}} c_k$. Expanding the definition of c_k this means that

$$\prod_{j \in [k]} b_{i_j} \sqsubsetneq^{\mathrm{A}} \prod_{j \in [k-1]} b_{i_j}.$$

This holds for all $k \in [h]$, so in particular the products $\prod_{j \in [k]} b_{i_j}$ must be pairwise different and the number h of relevant coordinates is at most $|M|$, proving the claim.

Claim 2: Minors preserve relevant coordinates. Let $\boldsymbol{c} = \boldsymbol{b}^{(\pi)}$, where $\pi : [n] \to [m]$ is a map and let $i \in [n]$ be a relevant coordinate of $\boldsymbol{b}$. We want to show that $j = \pi(i)$ is a relevant coordinate of $\boldsymbol{c}$. Indeed, if that was not the case we would have that

$$\prod_{k \in [n] \setminus \pi^{-1}(j)} b_k \sqsubseteq^{\mathrm{A}} a.$$

However, $i \in \pi^{-1}(j)$, so we know that $\prod_{k \in [n] \setminus \{i\}} b_k \sqsubseteq^{\mathrm{A}} \prod_{k \in [n] \setminus \pi^{-1}(j)} b_k$. Putting this together with the previous identity shows that

$$\prod_{k \in [n] \setminus \pi^{-1}(j)} b_k \sqsubseteq^{\mathrm{A}} a,$$

contradicting the fact that i was a relevant coordinate of $\boldsymbol{b}$.

Claim 3: b has at least one relevant coordinate. Suppose otherwise for the sake of contradiction. Then for each $i \in [n]$ there is an element $c_i \in M$ that commutes with a such that $ac_i = \prod_{i \in [n] \setminus \{j\}} b_i$. Let $c = \prod_{i \in [n]} c_i$. Observe that c itself commutes with a. However, one can check that that $a^2 c = a$, contradicting our assumption that a was not regular. Indeed,

$$
\begin{aligned}
a^2c &= \left(\prod_{i=1}^{n} b_i\right)(ac_1)\left(\prod_{i=2}^{n} c_i\right) = \left(\prod_{i=1}^{n} b_i\right)\left(\prod_{i\in[n]\setminus\{1\}} b_i\right)\left(\prod_{i=2}^{n} c_i\right) \\
&= \left(\prod_{i=2}^{n} b_i\right)(ac_2)\left(\prod_{i=3}^{n} c_i\right) = \left(\prod_{i=2}^{n} b_i\right)\left(\prod_{i\in[n]\setminus\{2\}} b_i\right)\left(\prod_{i=3}^{n} c_i\right) \\
&= \left(\prod_{i=3}^{n} b_i\right)(ac_3)\left(\prod_{i=4}^{n} c_i\right) = \left(\prod_{i=3}^{n} b_i\right)\left(\prod_{i\in[n]\setminus\{3\}} b_i\right)\left(\prod_{i=4}^{n} c_i\right) \\
&= \cdots = \left(\prod_{i=n}^{n} b_i\right)\left(\prod_{i\in[n]\setminus\{n\}} b_i\right) = a.
\end{aligned}
$$

5 Equations Over Monoids and Groups: Proofs of Theorem 5 and Corollary 6

We need a simple characterisation of the polymorphisms of promise equation templates, and various characterisations of regularity; both are proved in [40].

▶ **Lemma 17.** *Consider a template* $\mathrm{PEqn}(Z_1, Z_2, \varphi)$ *of promise equations over semigroups/-monoids/groups. A map* $p : Z_1^n \to Z_2$ *is a polymorphism of* $\mathrm{PEqn}(Z_1, Z_2, \varphi)$ *if and only if* p *is a semigroup/monoid/group homomorphism and* $p(s, s, \ldots, s) = \varphi(s)$ *for all* $s \in \mathrm{dom}(\varphi)$.

▶ **Lemma 18.** *Let* M *be a monoid and* $s \in M$. *Then the following are equivalent:*

1. s *is regular,*
2. $s^k = s$ *for some* $k > 1$,
3. s *belongs to a subgroup of* M,
4. $s \sqsubseteq s^2$.

With these two lemmas, we can now prove our main result.

▶ **Theorem 5** (Main). $\mathrm{PEqn}(M_1, M_2, \varphi)$ *is solvable in polynomial time by BLP + AIP if there is an Abelian homomorphism* $\psi : M_1 \to M_2$ *extending* φ *and* $\mathrm{Im}(\psi)$ *is a union of subgroups. Otherwise,* $\mathrm{PEqn}(M_1, M_2, \varphi)$ *is* NP*-hard.*

Proof. We prove both implications. Suppose that such homomorphism ψ exists. As $\mathrm{Im}(\psi)$ is a union of subgroups, by Lemma 18 there is some number $k > 1$ such that $s^k = s$ for all $s \in \mathrm{Im}(\psi)$. Let $n > 0$ be arbitrary. Consider the map $p : M_1^{2n+1} \to M_2$ given by

$$
(s_i)_{i\in[2n+1]} \mapsto \left(\prod_{i\in[n+1]} \psi(s_i)\right)\left(\prod_{i\in[n]} \psi(s_{i+n+1})^{k-2}\right),
$$

where the convention is that the zero-th power of an element equals the identity of the monoid. We claim that p is a 2-block-symmetric polymorphism of $\mathrm{PEqn}(M_1, M_2, \varphi)$ with the first block consisting of the first $n+1$ coordinates, and the second block consisting of the rest. The fact that p is a 2-block-symmetric map with the blocks as claimed follows from the fact that ψ is Abelian. To complete the argument, we show that p is a polymorphism of $\mathrm{PEqn}(M_1, M_2, \varphi)$ using the characterisation from Lemma 17. First, observe that the fact that ψ is Abelian implies that p is a monoid homomorphism. Indeed,

$$\begin{aligned} &p(s_1,\dots,s_{2n+1})p(t_1,\dots,t_{2n+1}) \\ &\qquad = \left(\prod_{i\in[n+1]} \psi(s_i)\psi(t_i)\right)\left(\prod_{i\in[n]} \psi(s_{i+n+1})^{k-1}\psi(t_{i+n+1})^{k-1}\right) \\ &\qquad = p(s_1t_1,\dots,s_{2n+1}t_{2n+1}), \end{aligned}$$

so p preserves products. Now we only need to prove that $p(s,\dots,s) = \varphi(s)$ for all $s \in \mathrm{dom}(\varphi)$ in order to show that p is a polymorphism. To see that this holds, observe that

$$p(s,\dots,s) = \psi(s)^{n(k-1)+1} = \psi(s) = \varphi(s),$$

where the last equality uses the fact that ψ extends φ. This completes the proof of the first implication via Theorem 2.

In the other direction, we show that $\mathrm{PEqn}(M_1, M_2, \varphi)$ is NP-hard assuming there is no Abelian homomorphism $\psi : M_1 \to M_2$ extending φ whose image is a union of subgroups. Let $\mathcal{M}$ be the polymorphism minion of $\mathrm{PEqn}(M_1, M_2, \varphi)$. Given a polymorphism $p \in \mathcal{M}$, we define $\mathcal{N}(p)$ as the submonoid $\{p(s,\dots,s) \mid s \in M_1\} \preceq M_2$. Observe that by assumption, for a given polymorphism p it holds that the monoid $\mathcal{N}(p)$ is non-Abelian or that $\mathcal{N}(p)$ is not a union of subgroups. Define Ω as the set of monoid homomorphisms $\psi : M_1 \to M_2$ for which $\mathrm{Im}(\psi)$ is not a union of subgroups. By Lemma 18, this happens precisely when $\mathrm{Im}(\psi)$ contains some non-regular element $a \in M_2$. Let $L = |\Omega| + 1$, and let $K = \max(|M_2|, |\{N \preceq M_2 \mid N \text{ is non-Abelian }\}|$. We use Theorem 15 with the constants L, K to show NP-hardness. We define the following subminions of $\mathcal{M}$.

$$\mathcal{M}_{\mathrm{A}} = \{p \in \mathcal{M}, \mid \mathcal{N}(p) \text{ is not Abelian}\},$$

and given any monoid homomorphism $\psi \in \Omega$ we set

$$\mathcal{M}_{\psi} = \{p \in \mathcal{M}, \mid p(s,\dots,s) = \psi(s) \text{ for all } s \in M_1\}.$$

By the previous observation it holds that

$$\mathcal{M} = \mathcal{M}_{\mathrm{A}} \bigcup_{\psi\in\Omega} \mathcal{M}_{\psi}.$$

We give selection functions $\mathcal{I}$ for each of these sub-minions satisfying the assumptions of Theorem 15. Suppose that $\mathcal{M}_{\mathrm{A}}$ is not empty. Otherwise we are done defining $\mathcal{I}_{\mathrm{A}}$. Let p be any n-ary polymorphism in $\mathcal{M}_{\mathrm{A}}$. Given $i \in [n]$ we define $\mathcal{N}(p,i) \preceq M_2$ as the submonoid

$$\{p(s_1,\dots,s_n) \mid s_i \in M_1, \text{ and } s_j = e \text{ when } j \neq i\}.$$

We give some facts about these submonoids.

Fact 1: The map $\phi : \prod_{i\in[n]} \mathcal{N}(p,i) \to M_2$ given by $(s_1,\dots s_n) \mapsto \prod_{i\in[n]} s_i$ is a monoid homomorphism. In particular, given $1 \leqslant i < j \leqslant n$, any two elements $t_1 \in \mathcal{N}(p,i)$, $t_2 \in \mathcal{N}(p,j)$ commute.

Fact 2: If $\mathcal{N}(p,i) = \mathcal{N}(p,j)$ for some $i \neq j \in [n]$ then $\mathcal{N}(p,i)$ is Abelian.

Fact 3: The submonoid $\mathcal{N}(p)$ is contained in $\mathrm{Im}(\phi)$, where ϕ is as defined in Fact 1. In particular, given that $\mathcal{N}(p)$ is not Abelian, some $\mathcal{N}(p,i)$ must be non-Abelian.

Given an n-ary polymorphism $p \in \mathcal{M}_{\mathrm{A}}$, we define $\mathcal{I}_{\mathrm{A}}(p) \subseteq [n]$ as the set of coordinates i for which $\mathcal{N}(p,i)$ is non-Abelian. We claim that $\mathcal{I}_{\mathrm{A}}$ satisfies the assumptions of Theorem 15. Indeed, given some n-ary p:

- $\mathcal{I}_{\mathrm{A}}(p)$ is non empty by Fact 3.
- $|\mathcal{I}_{\mathrm{A}}(p)| \leqslant K$. Otherwise it would be that $\mathcal{N}(p,i) = \mathcal{N}(p,j)$ for some different $i, j \in \mathcal{I}_{\mathrm{A}}(p)$, contradicting the fact that $\mathcal{N}(p,i)$ is non-Abelian (by Fact 2).
- Suppose that $p = q^{(\pi)}$ for some m-ary q and some $\pi : [m] \to [n]$. Let $i \in \mathcal{I}_{\mathrm{A}}(p)$, then

$$\mathcal{N}(p,i) \subseteq \left\{ \prod_{j \in \pi^{-1}(i)} s_j \mid s_j \in \mathcal{N}(s,j) \text{ for all } j \in \pi^{-1}(i) \right\}.$$

  As $\mathcal{N}(p,i)$ is non-Abelian, some submonoid $\mathcal{N}(q,j)$ with $j \in \pi^{-1}(i)$ must be non-Abelian as well. This means that $\mathcal{I}_{\mathrm{A}}(p) \subseteq \pi(\mathcal{I}_{\mathrm{A}}(q))$.

Now consider an arbitrary homomorphism $\psi \in \Omega$ for which $\mathcal{M}_\psi$ is non-empty. We define a selection function $\mathcal{I}_\psi$ satisfying the assumptions of Theorem 15. Let $t \in \mathrm{Im}(\psi)$ be a non-regular element, and let $s \in M_1$ be such that $\psi(s) = t$. Let $\mathcal{M}_{M_2,t}$ be the monoidal minion defined in Definition 11. Consider the map $\xi : \mathcal{M}_\psi \to \mathcal{M}_{M_2,a}$ that sends any n-ary polymorphism $p \in \mathcal{M}_\psi$ to the tuple $(r_1, \dots, r_n) \in \mathcal{M}_{M_2,a}(n)$ where for each $i \in [n]$

$$r_i = p(s_1, \dots, s_n), \quad \text{where } s_i = s, \text{ and } s_j = e \text{ for all } j \neq i \ .$$

Observe that this is a well-defined minion homomorphism from $\mathcal{M}_\psi$ to $\mathcal{M}_{M_2,t}$. Indeed, first observe that $(r_1, \dots, r_n)$ belongs to the second minion. This holds because $r_1 r_2 \dots r_n = p(s, \dots, s) = \psi(s) = t$, and for each $i \in [n]$ the element r_i belongs to $\mathcal{N}(p,i)$, so the r_i's commute pairwise by Fact 1 above. One can also check that ξ preserves minors.

From the proof of Theorem 12 there is some selection function $\mathcal{I}$ on $\mathcal{M}_{M_2,t}$ satisfying the hypotheses of Theorem 15 for some constant $K' = |M_2| \leqslant K$ and $L = 1$. Thus, we can define $\mathcal{I}_\psi$ on $\mathcal{M}_\psi$ simply by setting $\mathcal{I}_\psi(p) = \mathcal{I}(\xi(p))$ for each polymorphism $p \in \mathcal{M}_\psi$.

Hence, have defined selection functions $\mathcal{I}_{\mathrm{A}}$ and $\mathcal{I}_\psi$ for each $\psi \in \Omega$ that satisfy the requirements of Theorem 15, showing that $\mathrm{PEqn}(M_1, M_2, \varphi)$ is NP-hard. ◀

▶ **Corollary 6.** $\mathrm{PEqn}(G_1, G_2, \varphi)$ *is solvable in polynomial time via AIP if there is an Abelian homomorphism* $\psi : G_1 \to G_2$ *extending* φ*. Otherwise,* $\mathrm{PEqn}(G_1, G_2, \varphi)$ *is* NP*-hard.*

Proof. We prove both directions. The hardness case follows from Theorem 5. Indeed, $\mathrm{PEqn}(G_1, G_2, \varphi)$ is a template of promise equations over monoids (where the monoids just happen to be groups). Suppose that there is no Abelian group homomorphism $\psi : G_1 \to G_2$ that extends φ. Observe that a monoid homomorphism between two groups must also be a group homomorphism, so there is no Abelian monoid homomorphism $\psi : G_1 \to G_2$ that extends φ. Thus, by Theorem 5, $\mathrm{PEqn}(G_1, G_2, \varphi)$ is NP-hard.

In the other direction, suppose that such a ψ exists. We show that $\mathrm{PEqn}(G_1, G_2, \varphi)$ is solved by AIP using Theorem 1. Let n be any odd arity and let $p : G_1^n \to G_2$ be the map given by $p(g_1, \dots, g_n) \mapsto \prod_{i \in [n]} t_i$, where $t_i = \psi(g_i)$ for every odd i, and $t_i = \psi(g_i)^{-1}$ for every even i. Then p is an alternating polymorphism of $\mathrm{PEqn}(G_1, G_2, \varphi)$. ◀

6 Equations over Semigroups: Proof of Theorem 10

A *digraph* $\boldsymbol{D}$ is a relational structure whose signature consists of a single binary relation $E^{\boldsymbol{D}}$.

We follow closely the ideas from [35, Theorem 7]. That result states that every CSP is polynomial-time equivalent to a problem of the form $\mathrm{Eqn}(S, S)$ for some semigroup S. Their proof uses the fact that every CSP is polynomial-time equivalent to another CSP whose template is a digraph $\boldsymbol{D}$ with all singleton unary relations [26]. The fact that they consider these unary relations on $\boldsymbol{D}$ yields equations in $\mathrm{Eqn}(S, S)$ where all constants are allowed. For PCSPs, however, this is our starting point.

▶ **Theorem 19** ([13]). *For every template* $(\boldsymbol{A}_1, \boldsymbol{A}_2)$ *there is a template* $(\boldsymbol{D}_1, \boldsymbol{D}_2)$ *of digraphs such that* $\mathrm{PCSP}(\boldsymbol{A}_1, \boldsymbol{A}_2)$ *is polynomial-time equivalent to* $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$.

The fact that we lack singleton unary relations in the templates $(\boldsymbol{D}_1, \boldsymbol{D}_2)$ is the main obstacle for applying the techniques from [35]. We overcome this by extending our digraphs with an additional edge joining two fresh distinguished vertices. The relational signature σ^+ contains one binary relation symbol E, and two unary relation symbols P, Q. Given a digraph $\boldsymbol{D}$, we write $\boldsymbol{D}^+$ for the σ^+ structure defined by $D^+ = D \cup \{p, q\}$, where p and q are fresh vertices, $E^{\boldsymbol{D}^+} = E^{\boldsymbol{D}} \cup \{(p, q)\}$, $P^{\boldsymbol{D}^+} = \{p\}$, and $Q^{\boldsymbol{D}^+} = \{q\}$.

▶ **Lemma 20.** *Let* $(\boldsymbol{D}_1, \boldsymbol{D}_2)$ *be a template of digraphs. Then* $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$ *is polynomial-time equivalent to* $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$.

Proof. We give polynomial-time Turing reductions in both directions. First, we reduce from $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$ to $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$. We consider two cases. Suppose that $E^{\boldsymbol{D}_2}$ is empty. Then $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$ amounts to deciding whether a given instance $\boldsymbol{I}$ has an edge or not, which takes polynomial time. Otherwise, assume that $E^{\boldsymbol{D}_2}$ is non-empty. Then our reduction takes any instance $\boldsymbol{I}$ of $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$ and considers it as an instance of $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$. Clearly, if $\boldsymbol{I}$ maps homomorphically to $\boldsymbol{D}_1$ then it also maps homomorphically to $\boldsymbol{D}_1^+$ using the same homomorphism. Otherwise, if $\boldsymbol{I}$ does not map homomorphically to $\boldsymbol{D}_2$ then it cannot map homomorphically to $\boldsymbol{D}_2^+$. Indeed, to see this observe that the digraph resulting from of $\boldsymbol{D}_2^+$ (by forgetting about the P, Q relations) maps homomorphically to $\boldsymbol{D}_2$: it suffices to send the edge (p, q) to an arbitrary edge in $E^{\boldsymbol{D}_2}$, which is non-empty by assumption.

Now we describe a polynomial-time reduction from $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$ to $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$. The reduction considers an instance $\boldsymbol{I}$ of $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$ and checks in polynomial time whether every connected component of $\boldsymbol{I}$ that intersects $P^{\boldsymbol{I}}$ or $Q^{\boldsymbol{I}}$ maps homomorphically to the edge structure $\boldsymbol{W}$ with $W = \{p, q\}$, $E^{\boldsymbol{W}} = \{(p, q)\}$, $P^{\boldsymbol{W}} = \{p\}$, and $Q^{\boldsymbol{W}} = \{q\}$. If this is not the case, $\boldsymbol{I}$ is rejected. Otherwise, we remove from $\boldsymbol{I}$ the components that intersect $P^{\boldsymbol{I}}$ or $Q^{\boldsymbol{I}}$. Next, we check in polynomial time whether each remaining component of $\boldsymbol{I}$ can be mapped homomorphically to $\boldsymbol{W}$, and removes the ones that do. If the resulting structure $\boldsymbol{I}'$ is empty, then our reduction accepts $\boldsymbol{I}$. Otherwise, observe that the resulting instance $\boldsymbol{I}'$ is equivalent to the original $\boldsymbol{I}$, in the sense that $\boldsymbol{I}$ maps to $\boldsymbol{D}_i^+$ if and only if $\boldsymbol{I}'$ does so as well. Furthermore, observe that a homomorphism from $\boldsymbol{I}'$ to $\boldsymbol{D}_i^+$ cannot include p and q in its image, as there are no components in $\boldsymbol{I}'$ that map homomorphically to $\boldsymbol{W}$. This means that $\boldsymbol{I}'$ maps to $\boldsymbol{D}_i^+$ if and only if it maps to $\boldsymbol{D}_i$. Hence, as the last step in our reduction we simply use $\boldsymbol{I}'$ as an instance of $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$. ◀

A semigroup S is a *right-normal band* if $ss = s$ for all $s \in S$ and $rst = srt$ for all $r, s, t \in S$. Recall that we write $s \sim r$ if $s \sqsubseteq r$ and $r \sqsubseteq s$ hold. It is easy to see that the quotient $\widehat{S} = S/\sim$ inherits the semigroup structure from S. Moreover, $\widehat{S}$ is a *semilattice*, meaning that it is an Abelian semigroup where every element is idempotent. Given an instance $\boldsymbol{I}$ of $\mathrm{Eqn}(S, S)$ we denote by $\widehat{\boldsymbol{I}}$ the corresponding instance over $\widehat{S}$, where every constant s is substituted by its $\sim$ class $\hat{s}$.

We need two lemmas from [35] and a simple observation.

▶ **Lemma 21** ([35]). *Let* S *be a semilattice. Then* $\mathrm{Eqn}(S, S)$ *can be solved in polynomial time. Moreover, if an instance* $\boldsymbol{I}$ *has a solution, it also has a unique minimal one (with respect to the* $\sqsubseteq$ *preorder) that can be obtained in polynomial time.*

▶ **Lemma 22** ([35]). *Let* S *be a right-normal band. Then an instance* $\boldsymbol{I}$ *of* $\mathrm{Eqn}(S, S)$ *is solvable if it has a solution satisfying* $f(x) \in \hat{s}_x$*, for all* $x \in I$*, where the map* $x \mapsto \hat{s}_x$ *is the minimal solution of* $\widehat{\boldsymbol{I}}$ *in* $\mathrm{Eqn}(\widehat{S}, \widehat{S})$.

▶ **Observation 23.** *Let S be a right-normal band, and let $s, s', t \in S$ be three arbitrary elements with $s \sim s'$. Then $st = s't$.*

Proof. As $s \sim s'$ and S is right-normal, it must hold that $s = s'r'$ and $s' = sr$ for some $r, r' \in S$. Thus, $st = s'r't = srr't$, and $s't = srt = s'r'rt = srr'rt = srr't$, where the last equality holds since S is a right-normal band. ◀

Let $\boldsymbol{D}$ be a digraph. We define a semigroup S_D related to $\boldsymbol{D}$ in a similar fashion as [35]. The main difference is that we need to "plant" a special subsemigroup S_W inside S_D that is used later as the set of constants in our promise equations. The semigroup $S = S_D$ is a right-normal band. It has the following $\sim$-classes: $V^{\mathrm{L}}, V^{\mathrm{R}}, V^{\mathrm{LC}}, V^{\mathrm{LR}}, V^{\mathrm{CR}}, E^{\mathrm{C}}, 0$, described as follows. Given $\square \in \{\mathrm{L}, \mathrm{R}, \mathrm{LC}, \mathrm{LR}, \mathrm{CR}\}$ the class $V^{\square}$ is a copy of $D \cup \{p, q\}$. That is, $V^{\square} = \{v^{\square} \mid v \in D\} \cup \{p^{\square}, q^{\square}\}$. The class E^{C} is a copy of $E^D \cup \{(p, q)\}$, meaning that $E^{\mathrm{C}} = \{(u, v)^{\mathrm{C}} \mid (u, v) \in E^D\} \cup \{(p, q)^{\mathrm{C}}\}$. Finally, the class 0 contains a single element 0. By Observation 23, in a right-normal band T it must hold that $st = s't$ for all $s, s', t \in T$ with $s \sim s'$. Hence, given a $\sim$-class $C \subseteq T$ and an element t we abuse the notation and write Ct to denote the product of an arbitrary element from C with t. The product operation in S is given by the following rules:

$$\begin{aligned} V^{\mathrm{R}}v^{\mathrm{L}} = V^{\mathrm{L}}v^{\mathrm{R}} = V^{\mathrm{LR}}v^{\mathrm{R}} = V^{\mathrm{LR}}v^{\mathrm{L}} = V^{\mathrm{L}}v^{\mathrm{LR}} = V^{\mathrm{R}}v^{\mathrm{LR}} = v^{\mathrm{LR}} \\ V^{\mathrm{L}}v^{\mathrm{LC}} = V^{\mathrm{LC}}v^{\mathrm{L}} = E^{\mathrm{C}}v^{\mathrm{L}} = E^{\mathrm{C}}v^{\mathrm{LC}} = v^{\mathrm{LC}} \\ V^{\mathrm{R}}v^{\mathrm{CR}} = V^{\mathrm{CR}}v^{\mathrm{R}} = E^{\mathrm{C}}v^{\mathrm{R}} = E^{\mathrm{C}}v^{\mathrm{CR}} = v^{\mathrm{CR}}, \end{aligned}$$

where v is an arbitrary element in $D \cup \{p, q\}$. Additionally,

$$V^{\mathrm{L}}(u, v)^{\mathrm{C}} = V^{\mathrm{LC}}(u, v)^{\mathrm{C}} = u^{\mathrm{LC}}, \quad \text{and} \quad V^{\mathrm{R}}(u, v)^{\mathrm{C}} = V^{\mathrm{CR}}(u, v)^{\mathrm{C}} = v^{\mathrm{CR}},$$

where (u, v) belongs to $E^D \cup \{(p, q)\}$. Finally, all other products not described above have 0 as their result.

We define the subsemigroup $S_W \preceq S_D$ as the one containing the elements $0, (p, q)^{\mathrm{C}}, p^{\square}, q^{\square}$ for $\square \in \{\mathrm{L}, \mathrm{R}, \mathrm{LC}, \mathrm{LR}, \mathrm{CR}\}$. Observe that for any digraph D, the quotient $\widehat{S_D} = S_D/\sim$ is isomorphic to $\widehat{S_W} = S_W/\sim$.

▶ **Lemma 24.** *There is a polynomial-time algorithm Φ that takes as an input a σ^+-structure $\boldsymbol{I}$ and outputs a system of equations $\Phi(\boldsymbol{I})$ with constants in S_W satisfying that for any digraph $\boldsymbol{D}$, $\boldsymbol{I}$ maps into $\boldsymbol{D}^+$ if and only if $\Phi(\boldsymbol{I})$ has a solution over S_D.*

Proof. This follows the first reduction in [35, Theorem 7] while making sure that all constants remain in S_W. We construct the system $\Phi(\boldsymbol{I})$. For every vertex $v \in I$ we include variables $v^{\mathrm{L}}, v^{\mathrm{R}}, v^{\mathrm{LR}}$. For each $\square \in \{\mathrm{L}, \mathrm{R}, \mathrm{LR}\}$ we include the constraint $v^{\square} \in V^{\square}$, which is a shorthand for the equations $p^{\square}v^{\square} = v^{\square}$ and $v^{\square}p^{\square} = p^{\square}$. We also include the equations $p^{\mathrm{LR}}v^{\mathrm{L}} = v^{\mathrm{LR}}$ and $p^{\mathrm{LR}}v^{\mathrm{R}} = v^{\mathrm{LR}}$. If $v \in P^{\boldsymbol{I}}$ we include all constraints $v^{\square} = p^{\square}$ for $\square \in \{\mathrm{L}, \mathrm{R}, \mathrm{LR}\}$. Similarly, if $v \in Q^{\boldsymbol{I}}$, then we include the constraints of the form $v^{\square} = q^{\square}$. For each edge $(u, v) \in E^{\boldsymbol{I}}$ we include a variable $(u, v)^{\mathrm{C}}$ in $\Phi(\boldsymbol{I})$, together with the constraint $(u, v)^{\mathrm{C}} \in E^{\mathrm{C}}$, which is a shorthand for the equations $(u, v)^{\mathrm{C}}(p, q)^{\mathrm{C}} = (p, q)^{\mathrm{C}}$ and $(p, q)^{\mathrm{C}}(u, v)^{\mathrm{C}} = (u, v)^{\mathrm{C}}$. Finally, we also add the equations $p^{\mathrm{LC}}(u, v)^{\mathrm{C}} = p^{\mathrm{LC}}u^{\mathrm{L}}$ and $p^{\mathrm{CR}}(u, v)^{\mathrm{C}} = p^{\mathrm{CR}}v^{\mathrm{R}}$. The resulting system $\Phi(\boldsymbol{I})$ satisfies the statement of the theorem. ◀

▶ **Lemma 25.** *There is a polynomial-time algorithm Ψ that takes as an input a system of equations $\boldsymbol{X}$ with constants in S_W and produces one of the following outcomes:*

- **(I)** *It outputs a σ^+-structure $\Psi(\boldsymbol{X})$ that maps into $\boldsymbol{D}^+$ for any digraph $\boldsymbol{D}$ if and only if $\boldsymbol{X}$ has a solution over S_D, or*
- **(II)** *it rejects $\boldsymbol{X}$ and $\boldsymbol{X}$ has no solution over S_D for any digraph $\boldsymbol{D}$.*

Proof. We describe the algorithm Ψ. This algorithm is meant to transform the system $\boldsymbol{X}$ into a system of the form $\Phi(\boldsymbol{I})$, for the algorithm Φ given in Lemma 24 and some σ^+-structure $\boldsymbol{I}$. This time we follow the second reduction in [35, Theorem 7] while making sure that all constants in $\boldsymbol{X}$ remain in S_W throughout all the transformations.

Without loss of generality, we may assume that every equation in $\boldsymbol{X}$ is initially of the form $x_1x_2 = x_3$, for some variables x_1, x_2, x_3, or of the form $x = s$, for some variable x and some element $s \in S_W$. Consider the system $\widehat{\boldsymbol{X}}$ with constants in $\widehat{S_W} = S_W/\sim$. By Lemma 21 we can find a minimal solution of $\widehat{\boldsymbol{X}}$ in polynomial time. If such a solution does not exist, then the system $\boldsymbol{X}$ is not satisfiable over S_D for any digraph $\boldsymbol{D}$, and the algorithm Ψ just rejects it. Otherwise, suppose that the system $\widehat{\boldsymbol{X}}$ has some minimal solution. This solution maps each variable $x \in X$ to a $\sim$-class C_x of S_W. Consider an arbitrary digraph $\boldsymbol{D}$. Using the observation that $\widehat{S_W} \simeq \widehat{S_D}$ and Lemma 22, we deduce that $\boldsymbol{X}$ has a solution over S_D if and only if it has a solution where the value of each variable $x \in X$ belongs to the class C_x. Given a class C_x, we define the constant $c_x \in S_W$ as

- $p^\square$ if C_x is the class $V^\square$ for $\square \in \{\mathrm{L}, \mathrm{R}, \mathrm{LC}, \mathrm{LR}, \mathrm{CR}\}$,
- $(p, q)^{\mathrm{C}}$ if $C_x = E^{\mathrm{C}}$, or
- 0 if $C_x = 0$.

For each variable $x \in X$ we add the equations $c_x x = x$ and $xc_x = c_x$. These equations are equivalent to the constraint that $x \in C_x$ (and we use $x \in C_x$ as a shorthand for those equations), so the resulting system is satisfiable over a semigroup S_D if and only if the original one was. Additionally, once every variable x is constrained to take values inside C_x, we can replace every equation of the form $x_1x_2 = x_3$ in $\boldsymbol{X}$ with the equation $c_{x_3}x_2 = c_{x_3}x_3$ to yield an equivalent system. Indeed, it must hold that $c_{x_i}x_i = x_i$, so the equation $x_1x_2 = x_3$ is equivalent to $c_{x_1}x_1c_{x_2}x_2 = c_{x_3}x_3$. Not only that, but S_D is a normal band and $x_1c_{x_1} = c_{x_1}$, so last equation is equivalent to $c_{x_1}c_{x_2}x_2 = c_{x_3}x_3$. Finally, the classes $C_{x_1}, C_{x_2}, C_{x_3}$ were part of a solution to $\widehat{\boldsymbol{X}}$, so it must be that $c_{x_1}c_{x_2} \sim c_{x_3}$, and by Observation 23 it holds that $c_{x_1}c_{x_2}x_1 = c_{x_3}x_1$.

Every resulting equation of the form $0x_1 = 0x_2$ is trivially satisfied and can be discarded. Consider a variable $x \in X$ whose corresponding class C_x is 0. As we have removed every equation of the form $0x_1 = 0x_2$, x can only appear in constraints of the form $x \in 0$, and $x = 0$. These are trivially satisfiable by any assignment that maps x to 0, so we can remove the variable x and all equations containing it.

We are left with a system $\boldsymbol{X}$ where each variable is bound to a class $V^\square$ for $\square \in \{\mathrm{L}, \mathrm{R}, \mathrm{LC}, \mathrm{LR}, \mathrm{CR}\}$ or E^{C}. Consider a variable $x \in X$ bound to the class V^{LC}. Suppose this variable appears in some equation of the form $c_1x = c_1y$, and consider the class C of c_1. By construction, it must be that $C \supseteq V^{\mathrm{LC}}$ in $\widehat{S_W}$. However, we have removed all equations containing 0, so the only possibility left is that $C = V^{\mathrm{LC}}$. Suppose that we replace the requirement $x \in V^{\mathrm{LC}}$ with $x \in V^{\mathrm{L}}$ and every equation of the form $x = v^{\mathrm{LC}}$, where $v^{\mathrm{LC}} \in S_W$ is a constant, with $x = v^{\mathrm{L}}$. We claim the system $\boldsymbol{X}$ remains equivalent after these changes. Indeed, this results from the observation that $V^{\mathrm{LC}}v^{\mathrm{L}} = V^{\mathrm{LC}}v^{\mathrm{LC}}$ in any semigroup S_D for any vertex $v \in D^+$. By the same logic we can also replace any requirement of the kind $x \in V^{\mathrm{LR}}$ or $x \in V^{\mathrm{CR}}$ with $x \in V^{\mathrm{CR}}$.

Consider any equation of the form $x = (u, v)^{\mathrm{C}}$ for a constant $(u, v)^{\mathrm{C}}$. This equation is equivalent to the constraints $p^{\mathrm{LC}}x = p^{\mathrm{LC}}y$, $p^{\mathrm{CR}}x = p^{\mathrm{CR}}z$, $y = u^{\mathrm{L}}$ and $z = v^{\mathrm{R}}$, where y and z are fresh variables.

Consider an equation of the form $cx = cy$, where both x, y are constrained to be in c's $\sim$-class. $(p, q)^{\mathrm{C}}x = (p, q)^{\mathrm{C}}y$, both This equation holds if and only if $x = y$. Hence, we may remove this equation and identify both variables x, y together.

This far we have obtained a system $\boldsymbol{X}$ where each variable is bound to either $V^{\mathrm{L}}, V^{\mathrm{R}}$ or E^{C}, and the only constants are among $p^{\mathrm{L}}, p^{\mathrm{R}}, q^{\mathrm{L}}, q^{\mathrm{R}}$. Identifying variables and adding dummy variables if necessary we can assume the following hold:

- For each variable $x \in X$ constrained by $x \in E^{\mathrm{C}}$ there is exactly one variable x_{L} constrained by $x_{\mathrm{L}} \in V^{\mathrm{L}}$ in an equation of the form $p^{\mathrm{LC}}x = p^{\mathrm{LC}}x_{\mathrm{L}}$, and exactly one variable x_{R} constrained by $x_{\mathrm{R}} \in V^{\mathrm{R}}$ that appears in an equation of the form $p^{\mathrm{CR}}x = p^{\mathrm{CR}}x_{\mathrm{R}}$.
- There are no two variables $x, y \in X$ constrained by $x, y \in E^{\mathrm{C}}$ with $x_{\mathrm{L}} = y_{\mathrm{L}}$ and $x_{\mathrm{R}} = y_{\mathrm{L}}$.
- Not considering equations that are part of the constraints $x \in C$ for some $\sim$-class C, each equation is of the form (i) $p^{\mathrm{LR}}x = p^{\mathrm{LR}}y$ with $x \in V^{\mathrm{L}}$ and $y \in V^{\mathrm{R}}$, (ii) $p^{\mathrm{LC}}x = p^{\mathrm{LC}}x_{\mathrm{L}}$ or $p^{\mathrm{CR}}x = p^{\mathrm{CR}}x_{\mathrm{R}}$ for some $x \in E^{\mathrm{C}}$, or (iii) $x = p^{\square}$ or $x = q^{\square}$ for $\square \in \{\mathrm{L}, \mathrm{R}\}$.

One can see that such a system corresponds to $\Phi(\boldsymbol{I})$ for some σ^+-structure $\boldsymbol{I}$ that can be built in polynomial time. Then Ψ returns $\boldsymbol{I}$, which satisfies our requirements by Lemma 24. ◀

▶ **Corollary 26.** *Let $(\boldsymbol{D}_1, \boldsymbol{D}_2)$ be a template of digraphs. Then $\mathrm{PCSP}(\boldsymbol{D}_1, \boldsymbol{D}_2)$ is polynomial-time equivalent to $\mathrm{PEqn}(S_{D_1}, S_{D_2}, \varphi)$, where $\varphi = \mathrm{id}_{S_W}$.*

Proof. We show that $\mathrm{PEqn}(S_{D_1}, S_{D_2}, \varphi)$ is polynomial-time equivalent to $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$, which suffices by Lemma 20. Observe that algorithm Φ given in Lemma 25 is a polynomial-time Turing reduction from $\mathrm{PCSP}(\boldsymbol{D}_1^+, \boldsymbol{D}_2^+)$ to $\mathrm{PEqn}(S_{D_1}, S_{D_2}, \varphi)$, and algorithm Ψ, given in Lemma 24 is a polynomial-time Turing reduction in the other direction. ◀

Corollary 26 and Theorem 19 establish Theorem 10.

Smoothed Analysis of Deterministic Discounted and Mean-Payoff Games

Bruno Loff

Abstract

We devise a policy-iteration algorithm for deterministic two-player discounted and mean-payoff games, that runs in polynomial time with high probability, on any input where each payoff is chosen independently from a sufficiently random distribution and the underlying graph of the game is ergodic.

This includes the case where an arbitrary set of payoffs has been perturbed by a Gaussian, showing for the first time that deterministic two-player games can be solved efficiently, in the sense of smoothed analysis.

More generally, we devise a *condition number* for deterministic discounted and mean-payoff games played on ergodic graphs, and show that our algorithm runs in time polynomial in this condition number.

Our result confirms a previous conjecture of Boros et al., which was claimed as a theorem [18] and later retracted [19]. It stands in contrast with a recent counter-example by Christ and Yannakakis [24], showing that Howard's policy-iteration algorithm does *not* run in smoothed polynomial time on *stochastic* single-player mean-payoff games.

Our approach is inspired by the analysis of random optimal assignment instances by Frieze and Sorkin [39], and the analysis of bias-induced policies for mean-payoff games by Akian, Gaubert and Hochart [6].

1 Extended Abstract

1.1 A history of discounted and mean-payoff games

John von Neumann proved his minimax theorem in 1928, founding game theory by showing the existence of optimal strategies in zero-sum matrix games. In 1953, Lloyd Shapley [75] considered what happened if two players repeatedly played a zero-sum matrix game. The overall game proceeds as follows. We have n states, and to each state $i \in [n]$ corresponds

a zero-sum matrix game G_i. At each round, the two players are in some state $i \in [n]$ and play the corresponding game G_i, with each player simultaneously choosing an action out of a finite set of possible actions. The two players' choice of actions determines not just the payoff, but also the state at the next round. This is repeated ad-infinitum.

In these games, randomness is possible in two different ways. First, the state at the next round can be chosen stochastically, or deterministically, based on the current state and on the players' chosen actions. This gives us two variants: *stochastic* games, and *deterministic* games, with the latter being a special case of the former. Second, the players' choice of action can itself be *pure* (a single action), or *mixed* (a distribution over the possible actions).

In an infinite game such as this there are two natural ways of determining the winning player. In the *discounted* variant, payoffs received at round t are multiplied by a *discount factor* of γ^t (for some $0 \leqslant \gamma < 1$), and we wish to know the total discounted payoff in the limit as the number of rounds goes to infinity. This is equivalent to saying that the game is forced to stop after every round with probability $1 - \gamma$, and asking for the expected payoff at the limit. In the *mean-payoff* variant, we measure the liminf or limsup, as the number of rounds goes to infinity, of the average payoff received so far (i.e. total payoff divided by the number of rounds). Shapley [75] proved the existence of a value and optimal (mixed) strategies for the stochastic, discounted variant.

Concurrently to Shapley's work, Bellman [16] studied a class of problems which he termed *Markov Decision Processes* (MDPs). MDPs model decision making when the result of one's actions can be partly random, and they can be seen as *single-player* variant of stochastic games. At each round, the player finds himself in a given state out of a finite number of states, and chooses an action. Depending on his choice he receives a payoff, and transitions to a different state. This transition can be either deterministic or stochastic. The player's goal is to maximize the discounted payoff or mean payoff at the limit, as the number of rounds goes to infinity. Bellman provided a method to find an optimal pure strategy in the discounted variant.

In both MDPs and in discounted games the optimal strategies can be made *memoryless*, in that the choice of what to do only depends on the current state i, and not on the past history. In the general case of discounted stochastic games where the players play simultaneously, the optimal memoryless strategies must be mixed. In the case of MDPs, the optimal memoryless strategy can further be made *pure*.

As for the mean-payoff variant, Gillette [42] gave an example of a mean-payoff two-player game, where the players play simultaneously at each round, whose optimal strategies cannot be memoryless.[1] With this in mind, Gillette introduced a *turn-based* variant of Shapley's infinite game, where two players play in turns. At each round, the game is in some state i, and one of the players (depending on i) chooses an action, which determines the next state (stochastically or deterministically) and a resulting payoff. One player is trying to maximize the payoff at the limit, and the other tries to minimize it. Gillette claimed that turn-based two-player games have a value and that optimal strategies exist for both players which are both memoryless and pure. Gillette's proof was actually wrong, but it was later corrected by Liggett and Lippman [60], so the statement *is* true. It also implies the corresponding statement for the mean-payoff variant of MDPs, as a special case.

[1] In fact, it was only in the 1980s [63] that simultanous-move mean-payoff games were proven to have a value. For every $\varepsilon > 0$, optimal (not memoryless) strategies exist for each player ensuring that the payoff is ε-close to the value.

A pure, memoryless strategy for such games is called a *policy*, and it is a finite object: one can represent it as a finite function $\sigma : \mathsf{States} \to \mathsf{Actions}$ specifying the chosen action at each state. In this paper, we will not concern ourselves with simultaneous two-player games, and only consider single-player games and turn-based two-player games. We will use the informal nomenclature "deterministic/stochastic single-player/two-player discounted/mean-payoff game" to denote each of the eight variants of (non-simultaneous) games just mentioned. Let us also use the term "discounted and mean-payoff games" to refer to these games as whole.

1.2 Algorithms

The above results show that all eight variants have a value, and that optimal strategies are policies, hence finite objects. It then makes sense to consider the algorithmic problem of *solving* such a game: given as input a specification of the game with rational weights (and with rational discount factor, if applicable), compute the value of the game, and optimal policies for the players.[2] The study of discounted and mean-payoff games has always been accompanied by the development of algorithms for solving them. Most algorithms for solving discounted and mean-payoff games can be broadly classified into three families: value-iteration algorithms[3], algorithms for MDPs that use linear programming[4], and, of particular importance to us, policy iteration algorithms.

Policy iteration algorithms have been invented for solving all variants of games described above. These algorithms maintain a policy in memory, and proceed by repeatedly modifying the policy, so that its quality improves monotonically according to some measure, until it can no longer be improved, at which point the measure must guarantee that we have found an optimal strategy for both players.

The first policy iteration algorithm was invented by Howard [52], and finds an optimal strategy for deterministic (and some stochastic) Markov Decision Processes. This was later extended by Denardo and Fox [30] to work on all stochastic MDPs. The method was first extended to two-player mean-payoff games by Hoffman and Karp [50], and two-player discounted games by Denardo [29], with later developments by many other authors [70, 67, 25, 40, 69, 26]. A good historical overview with more technical details appears in [3], where a policy iteration algorithm first appeared that can handle all the variants of mean-payoff games. In the case of discounted games, an optimal strategy can be found in time polynomial in $\frac{1}{1-\gamma}$ [78, 47]. Otherwise, for mean-payoff games, or for discount factors γ exponentially close to 1, no upper-bound is known on the number of iterations, significantly better than the number of policies, which is exponential in the number n of states. More precisely, the best upper-bound on the number of iterations is $2^{\tilde{O}(\sqrt{n})}$ [46, 48].

1.3 Policy iteration versus the simplex method

When one first studies policy iteration algorithms, one gets a sense of familiarity, as if policy iteration algorithms are analogous to the simplex method for linear programming. The intuitive sense is that the choice of policy plays the same role as the choice of basic feasible solution in the simplex method, with a change in policy being analogous to a pivot operation.

[2] It can be shown that the value of such a game with rational weights (and discount factor) is a rational number of comparable size.

[3] The first algorithm ever invented was a value iteration algorithm [16]. For a modern value-iteration algorithm for single-player games, see [76], which contains a historical overview in Section 2. For two players see, e.g., [79, 54, 23, 13, 8].

[4] See, e.g., Chapter 2 of [37], or various sections of [68].

In fact, in some cases, this analogy can be formally established. It is possible to express a MDP by a particular linear program, and in this particular case the connection is perfect: a simplex pivoting rule gives us a policy iteration algorithms for MDPs, and any policy iteration algorithm that switches a single node at a time gives us a pivoting rule for applying simplex on this particular program.

As a result, many known counter-examples for the simplex method, showing that certain pivoting rules require an exponential number of pivots, were devised by first finding examples of MDPs for which certain policy-iteration algorithms need an exponential number of iterations, and then *translating* the counter-example to work for the simplex algorithm, by the above connection [38, 33].

More broadly, it turns out that deterministic two-player mean-payoff games are exactly equivalent to tropical linear programming, i.e., solving systems of "linear" inequalities over the tropical $(\min, +)$ semiring. This was first explicitly shown by Akian, Gaubert, and Guterman [4], strengthening earlier connections between these problems that were made in the literature on tropical algebra (such as [40, 32, 58]) and in works on scheduling problems [64].[5]

Furthermore, tropical linear programs can be reduced to linear programs over the non-Archimedean field of convergent generalized power series [31, 11].[6] This characterization has been exploited to show that, if there exists a strongly-polynomial-time pivoting rule for the simplex algorithm, where the choice of basis element to pivot is semialgebraic in a certain technical sense (and this is the case for many pivoting rules), then the entire algorithm can be tropicalized, to get a polynomial-time algorithm for deterministic two-player mean-payoff games [10].

The analogy between policy iteration and the simplex method is also seen in practice. The aforementioned counter-examples show that policy-iteration algorithms run in exponential time in the worst-case. And yet, various benchmarks have shown that policy-iteration algorithms are very efficient at solving real-world instances, both for single-player [41, 27, 59] and two-player games [32, 21]. This difference between worst-case and real-life performance is also what happens with the simplex method. And in both cases it begs the question: *why?*

1.4 Smoothed analysis

In the case of the simplex method, the generally accepted explanation was proposed by Spielman and Teng [77]. They have shown that, if one takes any linear programming instance $\max\{c \cdot x \mid A \cdot x \geqslant b\}$ of dimension n, and perturbs each entry of A, b and c by a Gaussian with mean 0 and standard deviation $\frac{1}{\phi}$, then the simplex method, with a particular choice of pivoting rule, will solve the resulting perturbed system in time $\text{poly}(\phi \cdot n)$ [77, 28]. It is then reasonable to expect the simplex method to work efficiently on real-world instances, since they incorporate real-world data which is prone to such perturbations. It was this result of Spielman and Teng that founded the area of *smoothed analysis*, where one studies the efficiency of algorithms on such perturbed inputs.

---

[5] Stochastic two-player mean-payoff games, on the other hand, are equivalent to tropical semidefinite programming [14].

[6] A linear program over such a field can be thought of as a parametric family of linear programs over $\mathbb{R}$. It follows from the above reduction that deterministic mean-payoff games can be encoded as linear programs with coefficients of exponential bit-length. Such an encoding was first derived by Schewe [73], without reference to non-Archimedean fields.

The question then naturally follows: are policy-iteration algorithms efficient in the sense of smoothed analysis?

Recent evidence seems to indicate that no, they are not. The first policy-iteration algorithm for single-player games (MDPs), by Howard [52], determines for the current policy $\sigma : \mathsf{States} \to \mathsf{Actions}$, and for each state i of the game, if a local improvement is possible: *would a different choice of action at i improve the value of the game when starting at i, if the game were to be played according to σ at every other state?* The algorithm then changes the action $\sigma(i)$ at every state i where such a local improvement is possible, to the best possible local improvement. This is sometimes called *Howard's policy iteration*, or the *greedy all-switches* rule.

Last year, Christ and Yannakakis [24] showed a remarkable lower bound. They showed that $2^{\Omega(n^c)}$ iterations are necessary on a certain family of stochastic MDPs (single-player games), even when the payoffs are perturbed. In fact, the lower bound holds not only probabilistically, where each payoff is independently perturbed by a Gaussian with standard deviation $\frac{1}{\mathrm{poly}(n)}$, but even adversarially, where each payoff is perturbed by any value within $\pm\frac{1}{\mathrm{poly}(n)}$.

It is surprising that such a bound can be proven at all. However, their result only holds for *stochastic* games, and does not necessarily apply to deterministic games, where it has been previously conjectured that Howard's rule is efficient [49]. Also, this result shows that a particular way of improving the policy, the greedy all-switches rule, does not give us an efficient algorithm (in the sense of smoothed analysis). This is analogous to saying that a particular pivoting rule in the simplex algorithm is not efficient, and does not exclude the possibility that other ways of improving the policy might work.

Exploiting any one of these caveats could in principle allow for a smoothed analysis for policy iteration. Our main result exploits both: we show that for *deterministic* two-player games, a *slightly different* policy-improvement method will be efficient, in the sense of smoothed analysis.

▶ **Theorem 1** (our main theorem). *There exists a policy-iteration algorithm for solving n-state deterministic two-player (discounted or mean-payoff) games played on ergodic graphs, which runs in time* $\mathrm{poly}(\phi \cdot n)$ *with high probability, on an input where normalized payoffs in* $[-1, 1]$ *have been independently perturbed by a Gaussian with mean* 0 *and standard deviation* $\frac{1}{\phi}$.

It should be emphasized that the lower bound of Christ and Yannakakis holds even for the single-player case, and our result could be contrasted with theirs, even if we only had proved it for the single-player case. However, our policy-iteration algorithm (our upper-bound) works even for two-player games, which are much harder. Our policy-improvement rule is similar to the greedy all-switches rule, except that the choice of switches is allowed to depend on an additional parameter (a discount factor) which evolves over time.

1.5 Computational complexity

Our result should also be contrasted with the case of the simplex algorithm for linear programming. Recall that we *do* know polynomial-time algorithms for linear programming, it is only the simplex algorithm which fails to run efficiently in the worst case. However, it should be emphasized that we do *not* know any polynomial-time algorithms for solving two-player discounted or mean-payoff games.

Indeed, solving one-player discounted and mean-payoff games reduces to linear programming, so we have polynomial-time algorithms. But the complexity of solving *two-player* discounted and mean-payoff games is one of the great unsolved problems in computational

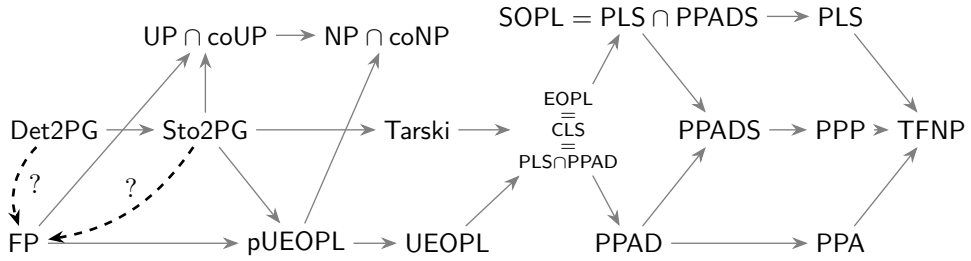

Figure 1 A hierarchy of NP search problems. Det2PG and Sto2PG refer to deterministic, respectively stochastic, two-player games. Arrows denote inclusion or containment. By inclusion of a search problem in the classes UP ∩ coUP and NP ∩ coUP of decision problems, we mean that the problem of deciding each bit of the unique answer can be computed in these classes.

complexity, first posed by Gurvich, Karzanov, and Khachiyan [44]. For any of the two-player variants, the respective decision problem (what is the i-th bit of the value) is in UP∩coUP [56], and the search problem (find an optimal strategy) is in the computational complexity class UEOPL (*Unique End-of-Potential-Line*) [53, 35]. In fact it is in the promise version of this class, which we denote pUEOPL. Even within the class pUEOPL, the problem of solving two-player discounted and mean-payoff games seems to be only a special, simple case: the sought optimal policies can be obtained from the unique fixed point of a simple monotone operator. This places the search problem in the class Tarski. The two complexity classes pUEOPL and Tarski sit at the bottom of a large hierarchy of complexity classes [34, 43]. This hierarchy stratifies the broad class TFNP of NP *search problems* [55, 62, 66]. See Figure 1.

In this sense, the problem of solving two-player discounted and mean-payoff games is the simplest known problem in NP, which is not yet known to be solvable in polynomial time (or even in time $2^{n^{o(1)}}$). For any problem which is not known to be in P, one may ask the question: *is the problem still hard on a random instance?* Many hard problems have been conjectured to have this property, of being hard to solve even for a random instance. This is the case for SAT [74, 36] and subset sum [72], but also for other, not necessarily NP-hard, problems in NP, such as lattice problems [2]. There is a broad belief that natural problems which are hard, remain hard on random inputs.[7] In contrast, our main theorem generalizes to show that solving deterministic two-player games is easy, for any sufficiently random input distribution.

▶ **Theorem 2** (generalization). *Consider distributions on n-state deterministic two-player discounted or mean-payoff games played on an ergodic graph, where each payoff is chosen independently according to a (not necessarily identical) distribution with mean in $[-1, 1]$ and standard deviation $\leqslant \frac{1}{\phi}$ and with probability density functions satisfying $f(y) \leqslant \phi$ for all $y \in \mathbb{R}$. (This includes, for example, payoffs perturbed by a Gaussian, or payoffs sampled from a uniform interval of length $\geqslant \frac{1}{\phi}$.)*

There exists a policy-iteration algorithm which runs in time $\mathrm{poly}(n, \phi)$*, with high probability, on games sampled according to any such distribution.*

[7] The distributions which are considered hard must be chosen carefully to avoid trivial cases, e.g. CNF formulas with too many or too few clauses, but there are often simple and natural distributions.

1.6 A previous approach and our approach

A first, naive attempt at proving Theorem 1 could proceed along the same lines as the Mulmuley, Vazirani and Vazirani's isolation lemma [65]. We think of what happens to the game when all of the payoffs of all the actions are fixed, except for one, which is sampled independently according to some distribution as above. Let us suppose that the free payoff is for an action of some state i. As it turns out, when every other payoff is fixed, the value of the game at state i is a piecewise linear function of the free payoff, and one can then hope that it has few break points. If this were indeed the case, that there were only $\text{poly}(n)$ break points, one could then argue similarly to the MVV isolation lemma, to show that approximating the random payoffs using $O(\log(n))$ bits of precision is enough to isolate the linear piece (in the piecewise linear function). From this it would follow that optimal policies for the truncated payoffs are also optimal for the untruncated payoffs. One could then invoke a pseudo-polynomial-time value-iteration algorithm [79] on the truncated payoffs, and this would run in polynomial time.

The conference version of the paper of Boros, Elbassioni, Fouz, Gurvich, Makino and Manthey [18] outlines a similar proof strategy. Among other results, a result similar to our Theorem 1 was claimed [18, Theorem 4.6]. Their proof works for the one-player case, and the authors claimed, without a careful proof, that the two-player case also follows. This claim was later retracted in the journal version [19].[8] Indeed, it turns out that the two-player case is significantly more subtle.

In the one-player case it can be shown that for every action there exist at most n break points, and hence an isolation lemma can be proven. One can then conjecture, for the two-player case, a $\text{poly}(n)$ upper-bound on the number of break points. As it turns out, this conjecture is wrong. An exponential example can be created using the construction of [17] that was also used in [12] to prove that interior point methods for linear programming are not strongly polynomial. This construction gives us a deterministic two-player game with n states such that, leaving the payoffs of all but one of actions fixed, as the free payoff varies between -1 and 1, the value of the game is a piecewise-linear function with $2^{\Omega(n)}$ break points.

So what do we do instead? One natural thing to try is to show that the number of break points *is* $\text{poly}(n)$, with very high probability, for randomly-chosen payoffs. This could well be true, and an argument in the style of the MVV isolation lemma would then follow. But we were unable to show it.

Instead, our results depend on a deeper analysis of deterministic two-player games. We also prove an isolation lemma, but using an approach different to MVV. Instead of attempting to isolate an optimal policy among all possible policies, we show that sufficiently random payoffs, with high probability, isolate a Blackwell-optimal policy. Blackwell-optimal policies are policies that arise in discounted games with discount factor γ close to 1. Blackwell-optimal policies are part of a family of policies which are induced by an object called a *bias*. Not all optimal policies are Blackwell-optimal, or even bias-induced. Nonetheless, every two-player discounted game has a Blackwell-optimal policy [60]. Furthermore, there exist policy-iteration algorithms for finding a Blackwell-optimal policy [57, 51] (that are inefficient in the worst case).

[8] In their paper, the breakpoints are chosen so that between any two breakpoints the value of the optimal strategy and the value of the second-best strategy are sufficiently far apart. This works for the single player-case, but the argument we just presented, where we only keep track of the number of break points in the value function, is simpler and also works.

We are then able to show that, if the payoffs are sufficiently random, then with high probability it will happen that there is a unique bias-induced policy, which must then be the Blackwell-optimal policy. Furthermore, from the proof of this theorem we devise a *condition number* $\Delta(r)$, associating a number in $[0, +\infty]$ to any given choice r of payoffs. The uniqueness proof generalizes to show that a deterministic two-player game with sufficiently random payoffs will have a small condition number ($\Delta(r) \leqslant \text{poly}(n)$) with high probability.

This is a condition number in the same sense as the known condition numbers that govern the complexity of algorithms for solving linear equations, semidefinite feasibility, *etc*, and broadly measure the *inverse-distance to ill-posedness* (see [20]). Although, strictly speaking, our condition number does not measure inverse-distance to some set, it does have the property that $\Delta(r)$ is finite if and only if the game with payoffs r has a unique bias-induced policy, and that every payoff $\tilde{r} \in B_\infty(r, \delta)$, within a ball of size $\delta \leqslant \frac{1}{\text{poly}(\Delta(r))}$ around r, will also have a unique bias-induced policy. So, at least intuitively, we can think of $\Delta(r)$ as an inverse-distance between r and the set of games with multiple bias-induced policies.

Finally, it can be shown that, taking a discount rate $\gamma \geqslant 1 - \frac{1}{\text{poly}(n,\Delta)}$ (i.e., sufficiently close to 1), the only optimal policy is the Blackwell-optimal policy. We can then use the results of [78, 47] to obtain a policy iteration algorithm for finding the Blackwell optimal policy in time $\text{poly}(n, \Delta)$. This algorithm runs in polynomial smoothed time, because, as mentioned above, sufficiently random payoffs have small condition number. This includes any fixed choice of payoffs that has been randomly perturbed by a Gaussian.

1.7 Related work

There is not a lot of work on the complexity of discounted and mean-payoff games with random payoffs. Besides the papers of Boros et al. [18, 19] and Christ and Yannakakis [24], which we mentioned above, we only know of a paper by Mathieu and Wilson [61]. They do not provide an algorithm, but they analyze the distribution of the value of a deterministic single-player mean-payoff game (deterministic MDP) played on a complete graph with i.i.d. exponentially distributed payoffs. Our algorithm will also work on such a payoff distribution.

A paper of Allamigeon, Benchimol, and Gaubert [9] analyzes efficiency in a different random model. The shadow vertex rule is known to be efficient on average under any distribution over linear feasibility problems, which is symmetric up to changing of the sign in each linear inequality [1]. Allamigeon et al. tropicalize this result, to show that a certain tropical analogue of the shadow vertex rule will solve deterministic two-player mean-payoff games in a bipartite graph in expected polynomial time, if the distribution over the payoff matrix is invariant under transposition (this is the tropical analogue of the above symmetry). In particular, if the payoffs of some given fixed input obey the same symmetry, their algorithm runs in polynomial time. Of course, in general, perturbed payoffs need not be symmetric in this way.

It was a paper of Frieze and Sorkin [39] that gave us the first idea of how to approach the problem. Frieze and Sorkin analyse the gap between optimal and second-optimal assignment in the assignment problem, using a bound on the reduced costs of the associated linear program at the optimum solution [39, Theorem 3]. In the simplex algorithm, the reduced cost works as a gradient, telling us the improvement in the objective function obtained by changing the current basic solution in a given direction. Frieze and Sorkin show that, at an optimum basic solution of a random assignment problem, every reduced cost is large, which implies that there is a large difference between the optimum and second-best solution. This large difference implies that the optimum solution is stable under perturbations. In the case of deterministic two-player games, biases will play the role of dual variables, which

allows us define an analogous notion of reduced costs at the optimal solution. We then show, analogously, that, with high probability for a random instance, every reduced cost is large at the optimum policy, which also implies stability. Our condition number is the (normalized) inverse of the smallest reduced cost.

Our analysis of discounted and mean-payoff games is based on the operator approach to study these games. Using this approach, Akian, Gaubert, and Hochart [6] have previously shown that a generic two-player mean-payoff game has a unique bias (which must then equal the Blackwell bias). More precisely, they show that for any stochastic or deterministic two-player mean-payoff game, the set of payoffs where the bias is not unique has measure zero. We give a more precise version of this result, for deterministic two-player mean-payoff games, by showing that the policies induced by the unique bias are also unique. This further allows us the measure "how far from having multiple bias-induced policies" is a given choice of payoffs.

The operator approach was also used by Allamigeon, Gaubert, Katz and Skomra [13], who define a condition number for the value iteration algorithm. Computer experiments indicate that value iteration converges quickly for random games [14], which strongly suggests that the condition number of [13] is small for random games, but there is currently no formal proof of this claim. Even though our condition number and the one from [13] are based on the bias vector, it is not clear how these two conditions numbers compare to each other. In particular, we do not know if the value iteration algorithm has polynomial smoothed complexity and we leave this problem as an open question.

2 Technical summary

For the sake of simplicity, we restrict our attention to deterministic mean-payoff games played on an *ergodic* weighted directed graph $\vec{\mathcal{G}} = ([n], E, r)$, where $|E| = m$ and $[n]$ is split into vertices controlled by players Max and Min, $[n] = V_{\text{Max}} \uplus V_{\text{Min}}$. The ergodicity is taken in the sense of [45, 5, 7]: a graph is called ergodic if the value of any mean-payoff game played on this graph is independent of the initial state of the game.[9] A typical example of such a graph is a complete bipartite graph, in which the bipartition is formed by $V_{\text{Max}}, V_{\text{Min}}$. Ergodic graphs are representative for the difficulty of mean-payoff games, because solving games on general graphs reduces to solving games on complete bipartite graphs [22]. We note however that it is not clear if this reduction can be done in the smoothed analysis setting. We leave the problem of extending our results to non-ergodic graphs as a question for future research.

The weights r_{ij} of the edges in our model are chosen randomly: we suppose that (r_{ij}) are independent absolutely continuous variables with densities f_{ij}. We further suppose that weights are normalized – $\mathbb{E}(r_{ij}) \in [-1, 1]$ – and that there exists a number $\phi > 0$ such that $f_{ij}(y) \leqslant \phi$ for all i, j, y and $\text{Var}(r_{ij}) \leqslant 1/\phi^2$. As an example, if the weights r are taken by perturbing some fixed weights $\bar{r}_{ij} \in [-1, 1]$ by Gaussian noise, so that $r_{ij} \sim \mathcal{N}(\bar{r}_{ij}, \rho^2)$, then we can take $\phi := 1/\rho$.

Under the ergodicity assumption, it is known [44, 7] that the following *ergodic equation* has a solution $(\lambda, u) \in \mathbb{R}^{n+1}$ for all choices of weights:

$$\begin{cases} \forall i \in V_{\text{Max}},\ \lambda + u_i = \max_{(i,j)\in E}\{r_{ij} + u_j\}\,, \\ \forall i \in V_{\text{Min}},\ \lambda + u_i = \min_{(i,j)\in E}\{r_{ij} + u_j\}\,. \end{cases}$$

[9] This is a notion similar to strong connectivity, but for two-player games. Intuitively, a graph is ergodic if no player can play in such a way as to force the game to get stuck on a sub-graph.

Furthermore, the number λ is unique and it is the value of the game (which does not depend on the initial state because of ergodicity)[10]. The vector $u \in \mathbb{R}^n$, called a *bias*, is never unique because the set of solutions contains at least one line: we can always add a constant to all coordinates of u. In general, the set of biases may consist of more than one line. We say that a pair of policies $\sigma\colon V_{\mathrm{Max}} \to V$ (of Max) and $\tau\colon V_{\mathrm{Min}} \to V$ (of Min) is *bias-induced* if there is a bias u such that the edges used by σ, τ achieve the maxima and minima in the ergodic equation. Bias-induced policies are optimal [44], but not every optimal policy is bias-induced. To study the behavior of random games, we introduce the sets

$$\mathcal{P}^{\sigma,\tau} \coloneqq \{r \in \mathbb{R}^m\colon (\sigma,\tau) \text{ is the only pair of bias-induced policies in the MPG with weights } r\},$$

for any pair (σ, τ) such that the resulting graph $\vec{\mathcal{G}}^{\sigma,\tau}$ has a single directed cycle. We denote by Ξ the set of all such pairs of policies. We also put $\mathcal{U} \coloneqq \cup\mathcal{P}^{\sigma,\tau}$. Using the techniques from [6] we are then able to show the following proposition. This proposition strengthens [6, Theorem 3.2] for deterministic games by showing that each maximum and minimum in the ergodic equation is generically achieved by a single edge.

▶ **Proposition 3** (cf. [6, Theorem 3.2])**.** *The sets $\mathcal{P}^{\sigma,\tau}$ are open polyhedral cones. Moreover, these cones are disjoint and $\mathbb{R}^m \setminus \mathcal{U}$ is included in a finite union of hyperplanes. In particular, this set has Lebesgue measure zero. Furthermore, if $r \in \mathcal{U}$, then the ergodic equation has a single solution (up to adding a constant to the bias), and each maximum and minimum in the ergodic equation is achieved by a single edge.*

This motivates the introduction of the following *condition number* Δ, which measures the difference between the edge that achieves a maximum or minimum in the ergodic equation and the "second best" edge, relatively to the spread of the weights around the value:

▶ **Definition 4.** *Given $r \in \mathcal{U}$, we put*

$$\Delta(r) \coloneqq \frac{\max\{|r_{ij} - \lambda|\colon (i,j) \in E\}}{\min\{|r_{ij} - \lambda + u_j - u_i|\colon (i,j) \in E, r_{ij} - \lambda + u_j - u_i \neq 0\}}\,.$$

When defined in such a way, the condition number does not change when the weights are multiplied by a positive constant, or when the same constant is added to all the weights.

To analyze the behavior of random games, we introduce the following random variables. If i is a vertex controlled by Min, then for any edge $(i,j) \in E$ we put

$$Z_{ij} = \inf\{x \in \mathbb{R}\colon (x, r_{-ij}) \in \mathcal{U} \text{ and the MPG with weights } (x, r_{-ij}) \text{ has a pair of bias-induced policies } (\sigma,\tau) \in \Xi \text{ such that } \tau(i) \neq j\}\,.$$

Here, (x, r_{-ij}) is the vector obtained from r by replacing the ijth coordinate with x. We analogously define the variables Z_{ij} for vertices controlled by Max, changing inf to sup. Since the variable Z_{ij} does not depend on r_{ij}, we get the estimate

▶ **Lemma 5.** *For any $\alpha > 0$, $\mathbb{P}(\exists ij, |r_{ij} - Z_{ij}| \leqslant \alpha) \leqslant 2\alpha m\phi$.*

[10] This is a fundamental result which appeared already in [44]: in the paper's only theorem, $p(v)$ is the value and $c'_{ij} = r_{ij} + u_j - u_i$ are the payoffs modified by u. In the reference [7], the existence of λ and u is line (iii) of the much more general Theorem 2.1, which applies to additive eigenvectors of additively homogeneous monotone operators.

Furthermore, the variables Z_{ij} are related to the ergodic equation in the following way.

▶ **Lemma 6.** *Suppose that $r \in \mathcal{P}^{\sigma,\tau}$ for some $(\sigma,\tau) \in \Xi$. Then, for every $(i,j) \in E$ that is not used in (σ,τ) we have $Z_{ij} = \lambda + u_i - u_j$.*

The two lemmas above improve the conclusion of Proposition 3: not only each maximum and minimum in the ergodic equation is achieved by a single edge, but with high probability the difference between the best edge and the second best edge is large. In particular, this shows that bias-induced policies do not change when the random weights are truncated, and it gives an estimate of the condition number.

▶ **Theorem 7.** *Let $\delta := 1/(4n(2n+1)m\phi)$. Then, with probability at least $1-1/n$, the whole ℓ_∞ ball $B_\infty(r,\delta)$ is included in a single polyhedron $\mathcal{P}^{\sigma,\tau}$.*

▶ **Theorem 8.** *Random mean payoff games are well conditioned with high probability. More formally, for every $\varepsilon > 0$ we have $\mathbb{P}\big(\Delta \geqslant \frac{8m}{\varepsilon}(\phi + \sqrt{\frac{2m}{\varepsilon}})\big) \leqslant \varepsilon$.*

To propose an algorithm that exploits the condition number, we use the fact that every mean-payoff game has a pair of *Blackwell-optimal* policies, i.e., policies that are optimal for all discount factors γ close to 1. Such policies are induced by the *Blackwell bias*, which is defined as $u^* := \lim_{\gamma\to 1}(\lambda^{(\gamma)} - \lambda)/(1-\gamma)$, where $\lambda^{(\gamma)}$ is the value of the discounted game with discount factor γ. We then show that, for well-conditioned games, the Blackwell-optimal policies can be already found when the discount factor is low.

▶ **Theorem 9.** *Suppose that $r \in \mathcal{P}^{\sigma,\tau}$ and fix $1 > \gamma > 1 - \frac{1}{6n^2\Delta(r)}$. Then, (σ,τ) is the unique pair of optimal policies in the discounted game with discount factor γ.*

Combining Theorems 8 and 9 with the results of [78, 47] showing that policy iteration has polynomial complexity for discount factor $\gamma < 1 - \frac{1}{\mathrm{poly}(n)}$, we get our final result.[11]

▶ **Theorem 10.** *The greedy-all switches policy iteration rule combined with increasing discount factor solves random instances of deterministic discounted or mean-payoff games in polynomial smoothed complexity.*

In the theorem above, "polynomial smoothed complexity" is defined as in [15, 71]: there exists a polynomial $\mathrm{poly}(x_1,x_2,x_3,x_4)$ such that for all $\varepsilon \in]0,1]$ the probability that the number of iterations of our algorithm exceeds $\mathrm{poly}(n,m,\phi,\frac{1}{\varepsilon})$ is at most ε.

3 Conclusion and future work

We gave an analysis of two-player discounted and mean-payoff games, that led to a condition number, and a policy-iteration algorithm which is efficient on well-conditioned inputs. We showed that random inputs are well-conditioned with high probability. A few remarks are in order.

1. Our techniques work for two-player games played on ergodic graphs. In non-ergodic graphs, the value λ_i is not necessarily the same at each vertex i. A folklore reduction, appearing for example in [22], shows that computing the value vector of a non-ergodic

[11] To wit: since the pair of optimal policies is unique, we can find them using an algorithm for discount factor $\gamma < 1 - \frac{1}{\mathrm{poly}(n,\phi)}$, and the same policies will be optimal for any higher γ and also for the mean-payoff game.

game reduces to computing the value of an ergodic game. So one can ask if our algorithms can be used on non-ergodic games. The answer is not obvious. The reduction proceeds in rounds, where in the first round one finds, say, the largest coordinate λ_i of the value vector, and then discards the node i (which requires some care) and repeats. Now, if one takes a non-ergodic game $\vec{\mathcal{G}}$ with sufficiently random payoffs, and applies this reduction, the resulting game is sufficiently random at the first round, but it is not clear what happens in the succeeding rounds. So, as far as we can tell, the question remains open: *Do deterministic two-player discounted and mean-payoff games have polynomial smoothed complexity, when played on non-ergodic graphs?* A possible way of answering this question is by doing an analysis of Blackwell-optimal policies in the non-ergodic case, similar to what we have done here for the ergodic case.

2. Allamigeon, Gaubert, Katz and Skomra [13] show that a certain value-iteration algorithm runs efficiently on all ergodic instances with value λ bounded away from zero. They use $\frac{\max_i u_i - \min_i u_i}{|\lambda|}$ as a condition number. Can we use their result to show that value iteration has polynomial smoothed complexity? I.e., is a sufficiently-random instance well-conditioned as per their condition number? This was the central question left unanswered in their paper, and we tried to solve it, or provide a counter-example, but have so far failed to do so.
3. Our policy-iteration rule is not one of the standard rules (Howard, lexicographic, RandomFacet, *etc*). Do these standard rules also have polynomial smoothed complexity on deterministic two-player games? How about other "combinatorial" algorithms?
4. Can we extend our results to *stochastic* two-player games? The counter-example of Christ and Yannakakis shows that the Howard all-switches rule does not have polynomial smoothed complexity on stochastic two-player games. This seems to indicate that the stochastic setting is more delicate. On the other hand, our policy iteration rule is different to Howard's. So one could tentatively ask: is there a smoothed counter-example to the Howard rule also in the deterministic (say, two-player) setting? This would show that our policy-iteration rule cannot be replaced by the Howard rule.
5. How about other problems in UEOPL? Some of these problems are combinatorial, and do not seem to be amenable to smoothed analysis. But one can consider, for example, the P-Matrix Linear Complementarity Problem (P-LCP, see [35, Section 4.3]), and ask: *does it have polynomial smoothed complexity?* More broadly speaking, one can make the conjecture that *every problem in* UEOPL *becomes easy under a suitable notion of perturbation*. This conjecture is broad and imprecise, but it might be an interesting starting point for further research.

Abstract

We consider the problem of satisfiability of sets of constraints in a given set of finite uniform hypergraphs. While the problem under consideration is similar in nature to the problem of satisfiability of constraints in graphs, the classical complexity reduction to finite-domain CSPs that was used in the proof of the complexity dichotomy for such problems cannot be used as a black box in our case. We therefore introduce an algorithmic technique inspired by classical notions from the theory of finite-domain CSPs, and prove its correctness based on symmetries that depend on a linear order that is external to the structures under consideration. Our second main result is a P/NP-complete complexity dichotomy for such problems over many sets of uniform hypergraphs. The proof is based on the translation of the problem into the framework of constraint satisfaction problems (CSPs) over infinite uniform hypergraphs. Our result confirms in particular the Bodirsky-Pinsker conjecture for CSPs of first-order reducts of some homogeneous hypergraphs. This forms a vast generalization of previous work by Bodirsky-Pinsker (STOC'11) and Bodirsky-Martin-Pinsker-Pongrácz (ICALP'16) on graph satisfiability.

1 Introduction

In [15], Bodirsky and the third author introduced the computational problem Graph-SAT as a generalization of systematic restrictions of the Boolean satisfiability problem studied by Schaefer [36]. A *graph formula* is a formula formed from the atomic formulas $E(x, y)$ and $x = y$ using negation, conjunction and disjunction, where E is interpreted as the edge

relation of a simple undirected graph. Given a finite set Ψ of graph formulas, the *graph satisfiability problem* Graph-SAT(Ψ) gets as an input a finite set $\mathcal{V}$ of variables and a graph formula $\Phi = \phi_1 \wedge \cdots \wedge \phi_n$, where every ϕ_i is obtained from a formula $\psi \in \Psi$ by substituting the variables of ψ by variables from $\mathcal{V}$; the goal is to decide the existence of a graph satisfying Φ. Any instance of a Boolean satisfiability problem can indeed easily be reduced to a problem of this form, roughly by replacing Boolean variables by pairs of variables which are to be assigned vertices in a graph, and by translating the potential Boolean values 0 and 1 into the non-existence or existence of an edge between these two variables. The main result of [15] states that this computational problem is either solvable in polynomial time or is NP-complete. This can be put in contrast with the theorem of Ladner [28] stating that if P $\neq$ NP, then there exist computational problems that are neither solvable in polynomial-time nor NP-complete. Similar *dichotomy theorems* have been established for related problems concerning the satisfaction of constraints by linear orders [8], partially ordered sets [26], tournaments [30], or phylogenetic trees [6]. It is conjectured that such dichotomies defying Ladner's theorem are common; we refer to Section 1.2 and Conjecture 4 for a precise statement.

In order to develop our understanding of such natural generalizations of the classical Boolean satisfiability problem, we consider in this article the complexity of Graph-SAT where graph formulas are replaced by *ℓ-hypergraph formulas* for some fixed $\ell \geq 2$. More precisely, we consider formulas where E is an ℓ-ary symbol denoting the edge relation of an ℓ-uniform undirected hypergraph; in the following, since all our hypergraphs are uniform and undirected, we simply write *ℓ-hypergraph*. The problem ℓ-Hypergraph-SAT is then defined in the same way as the problem Graph-SAT above. We also study the complexity of the natural variant of the ℓ-Hypergraph-SAT problem, investigated in [12] for the special case of graphs, where we ask for the existence of a satisfying hypergraph that belongs to a prescribed set $\mathcal{K}$ of finite ℓ-hypergraphs. This corresponds to imposing structural restrictions on the possible satisfying hypergraph solutions. For example, it is natural to ask for the existence of a solution in the class $\mathcal{K}_r^\ell$ of all finite ℓ-hypergraphs omitting a generalized clique on r vertices. We use the notation ℓ-Hypergraph-SAT($\Psi, \mathcal{K}$) to denote this problem.

Surprisingly, it turns out that ℓ-hypergraph problems behave very differently from the corresponding graph problems, requiring in particular genuinely novel algorithmic methods to handle them. A natural attempt to solve hypergraph satisfiability in polynomial time is to use a generic reduction to constraint satisfaction problems (CSPs) whose domain consists of the hypergraphs with at most ℓ elements [13]. While this reduction always works in the (graph) case of $\ell = 2$ [30], it can happen for $\ell > 2$ that the resulting finite-domain CSP is an NP-complete problem, although the original hypergraph satisfiability problem is solvable in polynomial time. Our main result, Theorem 8, is an algorithm running in polynomial time and solving the ℓ-Hypergraph-SAT($\Psi, \mathcal{K}$) problem under some general algebraic assumptions.

The next example illustrates that in this setting our algorithm is strictly more powerful than the reduction of [13].

▶ **Example 1.** Let $\ell = 3$, let ψ be a formula with 4 free variables that holds precisely for the hypergraphs in Figure 1, and let Ψ be the set consisting of ψ. This is an example where the reduction to the finite from [13] cannot be applied to prove the tractability of ℓ-Hypergraph-SAT(Ψ). However, the problem is solvable in polynomial time, as it can be solved by the algorithm introduced in Section 3.

Building on Theorem 8, our second contribution is a full complexity dichotomy for the problems ℓ-Hypergraph-SAT($\Psi, \mathcal{K}$) where $\mathcal{K}$ is the class $\mathcal{K}_{\text{all}}^\ell$ of all finite ℓ-hypergraphs, or $\mathcal{K}_r^\ell$.

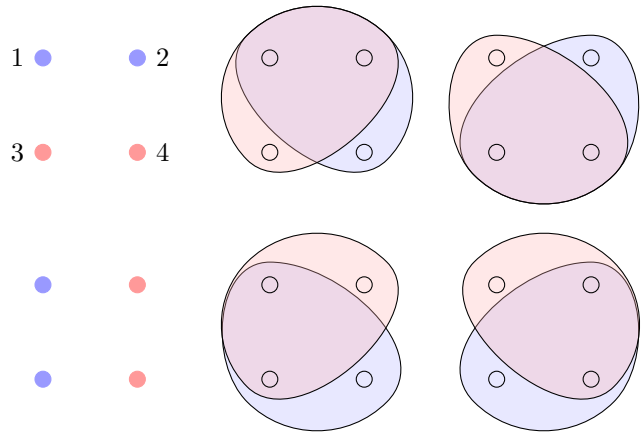

Figure 1 Hypergraphs on at most 4 elements satisfying ψ in Example 1. The vertices are labeled to represent each of the four free variables of ψ (only shown on one of the hypergraphs for readability). The two 3-hypergraphs on the left have 2 vertices, and the color coding denotes vertices that are equal. The other four 3-hypergraphs have four vertices each and precisely two hyperedges.

▶ **Theorem 2.** *Let $\ell \geq 3$, let $\mathcal{K}$ be either the class $\mathcal{K}^{\ell}_{\text{all}}$ of all finite ℓ-hypergraphs or the class $\mathcal{K}^{\ell}_{r}$ for some $r > \ell$, and let Ψ be a set of ℓ-hypergraph formulas. Then ℓ-Hypergraph-SAT$(\Psi, \mathcal{K})$ is either in P, or it is NP-complete. Moreover, given Ψ, one can algorithmically decide which of the cases holds.*

In fact, our polynomial-time algorithm in Theorem 8 solves the hypergraph satisfiability problem for all classes $\mathcal{K}$ of hypergraphs satisfying certain assumptions that we introduce in Section 3. Likewise, our results imply a dichotomy result as in Theorem 2 for every class $\mathcal{K}$ satisfying certain structural assumptions. For more details, see the full version of the article [29].

1.1 Connection to Constraint Satisfaction Problems

The *constraint satisfaction problem* with template $\mathbb{A} = (A; R_1, \dots, R_n)$ is the computational problem CSP($\mathbb{A}$) of deciding, given an instance with variables $\mathcal{V}$ and constraints $\phi(x_{i_1}, \dots, x_{i_r})$ with $\phi \in \{R_1, \dots, R_n\}$ and $x_{i_1}, \dots, x_{i_r} \in \mathcal{V}$, whether there exists an assignment $f\colon \mathcal{V} \to A$ that satisfies all the constraints.

Note how the problem ℓ-Hypergraph-SAT(Ψ) is similar in nature to a constraint satisfaction problem, where the difference lies in the fact that we are not asking for a labelling of variables to elements of a structure $\mathbb{A}$, but rather for a consistent labelling of ℓ-tuples of variables to a finite set describing all the possible ℓ-hypergraphs on at most ℓ elements. For example, in the case of $\ell = 2$, this set contains 3 elements (for the graph on a single vertex, and the two undirected graphs on 2 vertices), while for $\ell = 3$ this set contains 6 elements (there is one labeled 3-hypergraph on a single element, three on 2 elements, and two on 3 elements).

It was already noticed in [15] that it is possible to design a structure $\mathbb{A}$ (which is necessarily infinite) such that Graph-SAT(Ψ) is equivalent to CSP($\mathbb{A}$), and this observation also carries out to the hypergraph setting as follows.

Fix $\ell \geq 3$ and a class $\mathcal{K}$ of finite ℓ-hypergraphs. Let us assume that $\mathcal{K}$ is an *amalgamation class*: an isomorphism-closed class that is closed under induced sub-hypergraphs and with the property that for any two hypergraphs $\mathbb{H}_1, \mathbb{H}_2 \in \mathcal{K}$ having a common hypergraph $\mathbb{H}$ as

intersection, there exists $\mathbb{H}' \in \mathcal{K}$ and embeddings of $\mathbb{H}_1, \mathbb{H}_2$ into $\mathbb{H}'$ which agree on $\mathbb{H}$. A classical result of Fraïssé [22] yields that there exists an infinite limit hypergraph $\mathbb{H}_\mathcal{K}$, called the *Fraïssé limit of* $\mathcal{K}$, with the property that the finite induced sub-hypergraphs of $\mathbb{H}_\mathcal{K}$ are precisely the hypergraphs in $\mathcal{K}$. Moreover, this limit can be taken to be *homogeneous*, i.e., highly symmetric in a certain precise sense – see Section 2 for precise definitions of these concepts. If Ψ is a set of ℓ-hypergraph formulas, then it defines in $\mathbb{H}_\mathcal{K}$ a set of relations that one can view as a CSP template $\mathbb{A}_{\mathcal{K},\Psi}$. It follows that the problem ℓ-Hypergraph-SAT$(\mathcal{K}, \Psi)$ is precisely the same as CSP$(\mathbb{A}_{\mathcal{K},\Psi})$. The assumption that $\mathcal{K}$ is an amalgamation class is rather mild and is for example fulfilled by the classes of interest for Theorem 2, namely by the class $\mathcal{K}^\ell_{\text{all}}$ of all finite ℓ-hypergraphs, or for any $\ell < r$ by the class $\mathcal{K}^\ell_r$. We refer to [1] for a discussion of amalgamation classes of 3-hypergraphs; importantly, while in the case of $\ell = 2$ all such classes are known [27], it seems very difficult to obtain a similar classification in general since there are uncountably-many such classes already for $\ell = 3$. The latter fact obliges us to build on and refine abstract methods rather than relying on the comfort of a classification in our general dichotomy result, which contrasts with the approach for graphs in [12].

Using the reformulation of ℓ-hypergraph problems as constraint satisfaction problems, we show that the border between tractability and NP-hardness in Theorem 2 can be described algebraically by properties of the *polymorphisms* of the structures $\mathbb{A}_{\mathcal{K},\Psi}$, i.e., by the functions preserving all relations of $\mathbb{A}_{\mathcal{K},\Psi}$. This implies, in particular, the above-mentioned decidability of this border. Roughly speaking, the tractable case corresponds to the CSP template enjoying some non-trivial algebraic invariants in the form of polymorphisms, whereas the hard case is characterized precisely by the absence of such invariants.

▶ **Theorem 3.** *Let $\ell \geq 3$, let $\mathcal{K}$ be either the class $\mathcal{K}^\ell_{\text{all}}$ of all finite ℓ-hypergraphs or the class $\mathcal{K}^\ell_r$ for some $r > \ell$, and let Ψ be a set of ℓ-hypergraph formulas. Then precisely one of the following applies.*

1. *The clone of polymorphisms of $\mathbb{A}_{\mathcal{K},\Psi}$ has no uniformly continuous minion homomorphism to the clone of projections $\mathscr{P}$, and* CSP$(\mathbb{A}_{\mathcal{K},\Psi})$ *is in* P.
2. *The clone of polymorphisms of $\mathbb{A}_{\mathcal{K},\Psi}$ has a uniformly continuous minion homomorphism to the clone of projections $\mathscr{P}$, and* CSP$(\mathbb{A}_{\mathcal{K},\Psi})$ *is* NP*-complete.*

The algebraic assumptions in the second item of the theorem correspond to the clone of polymorphisms being trivial in a certain sense (i.e., containing only polymorphisms that imitate the behaviour of projections when restricted to a certain set). For the precise definitions, see [5].

1.2 Related work on constraint satisfaction problems

In the framework of CSPs, it is natural to consider not only classes of finite ℓ-hypergraphs but also classes of different finite structures in a fixed relational signature. If such a class $\mathcal{K}$ is an amalgamation class, then there exists a countably infinite homogeneous structure $\mathbb{B}_\mathcal{K}$ whose finite substructures are precisely the structures in $\mathcal{K}$. However, CSP$(\mathbb{B}_\mathcal{K})$ is not guaranteed to be contained in the complexity class NP since the class $\mathcal{K}$ does not have to be algorithmically enumerable (as mentioned above, there are uncountably many amalgamation classes of 3-hypergraphs; hence there exists such a $\mathcal{K}$ such that CSP$(\mathbb{B}_\mathcal{K})$ is undecidable). A natural way of achieving the algorithmical enumerability of $\mathcal{K}$ is to require that there exists a natural number $b_\mathcal{K}$ such that a structure is contained in $\mathcal{K}$ if, and only if, all its substructures of size at most $b_\mathcal{K}$ are in $\mathcal{K}$. In this case, we say that $\mathcal{K}$ (or its Fraïssé limit $\mathbb{B}_\mathcal{K}$) is *finitely bounded*. For every set Ψ of formulas in the language of the structures at hand, one then

gets as in the previous section a structure $\mathbb{A}_{\mathcal{K},\Psi}$ whose domain is the same as $\mathbb{B}_{\mathcal{K}}$ and whose relations are definable in first-order logic from the relations of $\mathbb{B}_{\mathcal{K}}$ – we say that $\mathbb{A}_{\mathcal{K},\Psi}$ is a *first-order reduct* of $\mathbb{B}_{\mathcal{K}}$.

Thus, for every set Ψ of formulas and every finitely bounded amalgamation class $\mathcal{K}$, the generalized satisfiability problem parameterized by Ψ and $\mathcal{K}$ is the CSP of a first-order reduct $\mathbb{A}_{\mathcal{K},\Psi}$ of a finitely bounded homogeneous structure. It is known that the complexity of the CSP over any such template depends solely on the polymorphisms of $\mathbb{A}_{\mathcal{K},\Psi}$ [16]. This motivates the following conjecture generalizing the dichotomy for Graph-SAT which was formulated by Bodirsky and Pinsker in 2011 (see [17]). The modern formulation of the conjecture based on recent progress [2, 3, 5] is the following:

▶ **Conjecture 4.** *Let $\mathbb{A}$ be a CSP template which is a first-order reduct of a finitely bounded homogeneous structure. Then one of the following applies.*

1. *The clone of polymorphisms of $\mathbb{A}$ has no uniformly continuous minion homomorphism to the clone of projections $\mathscr{P}$, and* CSP($\mathbb{A}$) *is in* P.
2. *The clone of polymorphisms of $\mathbb{A}$ has a uniformly continuous minion homomorphism to the clone of projections $\mathscr{P}$, and* CSP($\mathbb{A}$) *is* NP*-complete.*

It follows that Theorem 3 is a special case of Conjecture 4. It is known that if the clone of polymorphisms of any CSP template within the range of Conjecture 4 has a uniformly continuous minion homomorphism to $\mathscr{P}$, then the CSP of such template is NP-hard [5]. Already before Conjecture 4 was introduced, a similar conjecture was formulated by Feder and Vardi [23] for CSPs over templates with finite domains and it was confirmed independently by Bulatov and Zhuk [19, 39, 40] recently. Conjecture 4 itself has been confirmed for many subclasses: for example for CSPs of all structures first-order definable in finitely bounded homogeneous graphs [15, 12], in $(\mathbb{Q};<)$ [8], in any unary structure [14], in the random poset [26], in the random tournament [30], or in the homogeneous branching C-relation [6], in ω-categorical monadically stable structures [18], as well as for all CSPs in the class MMSNP [11], and for CSPs of representations of some relational algebras [9, 10].

1.3 Novelty of the methods and significance of the results

We prove that under the algebraic assumption in item (1) of Theorem 3, $\mathbb{A}_{\mathcal{K},\Psi}$ admits non-trivial symmetries that can be seen as operations acting on the set of *linearly ordered* ℓ-hypergraphs with at most ℓ elements. We moreover know from [34] that the introduction of a linear order "out of nowhere" is unavoidable, in the sense that the symmetries of $\mathbb{A}_{\mathcal{K},\Psi}$ acting on unordered ℓ-hypergraphs can be trivial even if CSP($\mathbb{A}_{\mathcal{K},\Psi}$) is solvable in polynomial time. This is rather surprising (in model-theoretic terms, hypergraphs form a class having the *non-strict order property*, and thus have no ability to encode linear orders) and is to date the only example of such a phenomenon. As a consequence, the aforementioned "reduction to the finite" introduced in [13], which is enough to prove the tractability part of most of the complexity dichotomies mentioned in the previous section, cannot be used in the hypergraph satisfiability setting. In order to prove the tractability part of Theorem 3, we thus introduce new algorithmic techniques inspired by results in the theory of constraint satisfaction problems with *finite* domains, in particular by absorption theory [4] and Zhuk's theory [39, 40]. More precisely, let $\mathcal{I}$ be an instance of CSP($\mathbb{A}_{\mathcal{K},\Psi}$). Our algorithm transforms $\mathcal{I}$ into an equi-satisfiable instance $\mathcal{I}'$ that is sufficiently locally consistent, such that the solution set of a certain relaxation of $\mathcal{I}'$ does not imply any restrictions on the solution set of the whole instance, and that satisfies an additional condition resembling Zhuk's notion of irreducibility [39, 40]. We then prove that any non-trivial instance satisfying those

properties has an injective solution. This step is to be compared with the case of *absorbing reductions* in Zhuk's algorithm. The existence of an injective solution can then be checked by the aforementioned reduction to the finite from [13, 14]. In this way, we resolve the trouble with hitherto standard methods pointed out in [34]. A positive resolution of the general Conjecture 4 will likely have to proceed in a similar spirit, albeit at a yet higher level of sophistication. In the case of graphs, the above described algorithm is not necessary since every instance can be immediately reduced to a finite-domain CSP by the black box reduction.

We use the recently developed theory of smooth approximations [30] to prove the dichotomy, i.e., that $\mathbb{A}_{\mathcal{K},\Psi}$ satisfies one of the two items of Theorem 3, for all Ψ. The classification of the complexity of graph-satisfiability problems from [15] used a demanding case distinction over the possible automorphisms groups of the structures $\mathbb{A}_{\mathcal{K},\Psi}$ (where Ψ is a set of graph formulas, and $\mathcal{K}$ is the class of all finite simple undirected graphs) – it was known previously that there are exactly 5 such groups [37]. Our result relies neither on such a classification of the automorphism groups of the structures under consideration, nor on the classification of the hypergraphs of which they are first-order reducts; as mentioned above, no such classification is available. While Thomas [38] obtained a classification of the mentioned automorphism groups for every fixed ℓ and for $\mathcal{K}$ consisting of all finite ℓ-hypergraphs, this number grows with ℓ and makes an exhaustive case distinction impossible. To overcome the absence of such classifications, we rely on the scalability of the theory of smooth approximations, i.e., on the fact that the main results of the theory can be used without knowing the base structures under consideration. This was claimed to be one of the main contributions of this theory; Theorem 3 and its generalization [29, Theorem 21] are the first complexity classification using smooth approximations that truly exemplifies this promise.

1.4 Bonus track: local consistency

Our structural analysis of ℓ-hypergraph problems allows us to obtain as an easy consequence a description of the hypergraph satisfiability problems ℓ-Hypergraph-SAT$(\Psi, \mathcal{K})$ that are solvable by local consistency methods, assuming that Ψ contains the atomic formula E. Similar classifications, and general results on the amount of local consistency needed in those cases, had previously obtained for various other problems (including Graph-SAT problems) which can be modeled as CSPs of first-order reducts of finitely bounded homogeneous structures [31, 30].

▶ **Theorem 5.** *Let $r > \ell \geq 3$, let $\mathcal{K}$ be either the class $\mathcal{K}^{\ell}_{\text{all}}$ of all finite ℓ-hypergraphs or the class $\mathcal{K}^{\ell}_{r}$, and let Ψ be a set of ℓ-hypergraph formulas containing $E(x_1, \dots, x_\ell)$. Then precisely one of the following applies.*

1. *The clone* $\text{Pol}(\mathbb{A})$ *has no uniformly continuous minion homomorphism to the clone of affine maps over a finite module, and* $\text{CSP}(\mathbb{A})$ *has relational width* $(2\ell, \max(3\ell, r))$.
2. *The clone* $\text{Pol}(\mathbb{A})$ *has a uniformly continuous minion homomorphism to the clone of affine maps over a finite module.*

1.5 Future work

This work is concerned with the complexity of the decision version of constraint satisfaction problems whose study is motivated by Conjecture 4. A natural variant of such problems is the optimisation version, where one is interested in finding a solution to an instance of the CSP that minimizes the number of unsatisfied constraints. The complexity of such problems (called MinCSPs) has mostly been investigated for finite templates, but recently also in the

case of infinite templates falling within the scope of Conjecture 4 from the point of view of exact optimisation and approximation [21, 20, 24], as well as from the point of view of parameterized complexity [33].

Our complexity classification for the decision CSP (Theorem 3) can be seen as a foundation for a systematic structural study of optimisation problems over hypergraphs.

1.6 Organisation of the present article

After introducing a few notions needed for the formulation of the main algorithm in Section 2, we introduce the algorithm and prove its correctness in Section 3. For lack of space, we only present the proof of one of the main correctness arguments (Theorem 13) for the algorithmic part of Theorem 3 and otherwise illustrate the main concepts that we introduce using examples. In Section 4, we give an outline of the proof of Theorem 3. The rest of the proofs can be found in the appendix.

2 Preliminaries

For any $k \geq 1$, we write $[k]$ to denote the set $\{1, \dots, k\}$. A tuple is called *injective* if its entries are pairwise distinct. In the entire article, we consider only relational structures in a finite signature.

A *primitive-positive* (pp-)formula is a first-order formula built only from atomic formulas, existential quantification, and conjunction. A relation $R \subseteq A^n$ is *pp-definable* in a relational structure $\mathbb{A}$ if there exists a pp-formula $\phi(x_1, \dots, x_n)$ such that the tuples in R are precisely the tuples satisfying ϕ.

Let $\ell \geq 2$. A structure $\mathbb{H} = (H; E)$ is an *ℓ-hypergraph* if the relation E is of arity ℓ, contains only injective tuples (called *hyperedges*), and is *fully symmetric*, i.e., every tuple obtained by permuting the components of a hyperedge is a hyperedge as well. Given any ℓ-hypergraph $\mathbb{H} = (H; E)$, we write N for the set of all injective ℓ-tuples in H that are not hyperedges, and we call this set the *non-hyperedge* relation.

2.1 CSPs and Relational Width

A *CSP instance* over a set A is a pair $\mathcal{I} = (\mathcal{V}, \mathcal{C})$, where $\mathcal{V}$ is a non-empty finite set of variables, and $\mathcal{C}$ is a set of *constraints*; each constraint $C \in \mathcal{C}$ is a subset of A^U for some non-empty $U \subseteq \mathcal{V}$ (U is called the *scope* of C). For a relational structure $\mathbb{A}$, we say that $\mathcal{I}$ is an *instance of* $\mathrm{CSP}(\mathbb{A})$ if for every $C \in \mathcal{C}$ with scope U, there exists an enumeration $u_1, \dots, u_k$ of the elements of U and a k-ary relation R of $\mathbb{A}$ such that for all $f \colon U \to A$ we have $f \in C \Leftrightarrow (f(u_1), \dots, f(u_k)) \in R$. A mapping $s \colon \mathcal{V} \to A$ is a *solution* of the instance $\mathcal{I}$ if we have $s|_U \in C$ for every $C \in \mathcal{C}$ with scope U. Given a constraint $C \subseteq A^U$ and a tuple $\mathbf{v} \in U^k$ for some $k \geq 1$, the *projection of C onto* $\mathbf{v}$ is defined by $\mathrm{proj}_{\mathbf{v}}(C) := \{f(\mathbf{v}) \colon f \in C\}$. Let $U \subseteq \mathcal{V}$. We define the *restriction* of $\mathcal{I}$ to U to be an instance $\mathcal{I}|_U = (U, \mathcal{C}|_U)$ where the set of constraints $\mathcal{C}|_U$ contains for every $C \in \mathcal{C}$ the constraint $C|_U = \{g|_U \mid g \in C\}$.

We denote by $\mathrm{CSP}_{\mathrm{Inj}}(\mathbb{A})$ the restriction of $\mathrm{CSP}(\mathbb{A})$ to those instances of $\mathrm{CSP}(\mathbb{A})$ where for every constraint C and for every pair of distinct variables u, v in its scope, $\mathrm{proj}_{(u,v)}(C) \subseteq \{(a, b) \in A^2 \mid a \neq b\}$.

▶ **Definition 6.** *Let $1 \leq m \leq n$. We say that an instance $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ is* (m, n)-minimal *if both of the following hold:*

- *every non-empty subset of at most n variables in $\mathcal{V}$ is contained in the scope of some constraint in $\mathcal{I}$;*
- *for every at most m-element tuple of variables $\mathbf{v}$ and any two constraints $C_1, C_2 \in \mathcal{C}$ whose scopes contain all variables of $\mathbf{v}$, the projections of C_1 and C_2 onto $\mathbf{v}$ coincide.*

For $m \geq 1$, we say that an instance is *m-minimal* if it is (m, m)-minimal. We say that an instance $\mathcal{I}$ of the CSP is *non-trivial* if it does not contain any empty constraint. Otherwise, $\mathcal{I}$ is *trivial*.

For all $1 \leq m \leq n$ and for every instance $\mathcal{I}$ of a CSP($\mathbb{A}$) for some finite-domain structure $\mathbb{A}$, an (m, n)-minimal instance with the same solution set as $\mathcal{I}$ can be computed from $\mathcal{I}$ in polynomial time. The same holds for any ω-categorical structure $\mathbb{A}$ (see Section 2.2 for the definition of ω-categoricity, and see e.g., Section 2.3 in [32] for a description of the (m, n)-minimality algorithm in this setting). The resulting instance $\mathcal{I}'$ is called the *(m, n)-minimal instance equivalent to $\mathcal{I}$* and the algorithm that computes this instance is called the *(m, n)-minimality algorithm*. Note that the instance $\mathcal{I}'$ is not necessarily an instance of CSP($\mathbb{A}$). However, $\mathcal{I}'$ is an instance of CSP($\mathbb{A}'$) where $\mathbb{A}'$ is the expansion of $\mathbb{A}$ by all at most n-ary relations pp-definable in $\mathbb{A}$. Moreover, CSP($\mathbb{A}'$) has the same complexity as CSP($\mathbb{A}$).

If $\mathcal{I}$ is m-minimal and $\mathbf{v}$ is a tuple of variables of length at most m, then by definition there exists a constraint of $\mathcal{I}$ whose scope contains all variables in $\mathbf{v}$, and all the constraints who do have the same projection on $\mathbf{v}$. We write $\mathrm{proj}_{\mathbf{v}}(\mathcal{I})$ for this projection, and call it the *projection of $\mathcal{I}$ onto $\mathbf{v}$*.

▶ **Definition 7.** *Let $1 \leq m \leq n$, and let $\mathbb{A}$ be a relational structure. We say that* CSP($\mathbb{A}$) *has relational width (m, n) if every non-trivial (m, n)-minimal instance equivalent to an instance of* CSP($\mathbb{A}$) *has a solution.* CSP($\mathbb{A}$) *has* bounded width *if it has relational width (m, n) for some natural numbers $m \leq n$.*

2.2 Basic model-theoretic definitions

Let $\mathbb{B}$ and $\mathbb{C}$ be relational structures in the same signature. A *homomorphism* from $\mathbb{B}$ to $\mathbb{C}$ is a mapping $f\colon B \to C$ with the property that for every relational symbol R from the signature of $\mathbb{B}$ and for every $\mathbf{b} \in R^{\mathbb{B}}$, it holds that $f(\mathbf{b}) \in R^{\mathbb{C}}$. An embedding of $\mathbb{B}$ into $\mathbb{C}$ is an injective homomorphism $f\colon \mathbb{B} \to \mathbb{C}$ such that f^{-1} is a homomorphism from the structure induced by the image of f in $\mathbb{C}$ to $\mathbb{B}$, and an *isomorphism* from $\mathbb{B}$ to $\mathbb{C}$ is a bijective embedding of $\mathbb{B}$ into $\mathbb{C}$. An endomorphism of $\mathbb{B}$ is a homomorphism from $\mathbb{B}$ to $\mathbb{B}$, an *automorphism* of $\mathbb{B}$ is an isomorphism from $\mathbb{B}$ to $\mathbb{B}$. We denote the set of endomorphisms of $\mathbb{B}$ by End($\mathbb{B}$) and the set of its automorphisms by Aut($\mathbb{B}$).

Let $\ell \geq 2$, and let $\mathcal{K}$ be an isomorphism-closed class of finite ℓ-hypergraphs. We say that $\mathcal{K}$ is an *amalgamation class* if the following two conditions are satisfied: It is closed under induced substructures, and for any ℓ-hypergraphs $\mathbb{H}, \mathbb{H}_1, \mathbb{H}_2 \in \mathcal{K}$ and for any embeddings f_i of $\mathbb{H}$ into $\mathbb{H}_i$ ($i \in \{1, 2\}$), there exists an ℓ-hypergraph $\mathbb{H}'$ and embeddings g_i of $\mathbb{H}_i$ into $\mathbb{H}'$ ($i \in \{1, 2\}$) such that $g_1 \circ f_1 = g_2 \circ f_2$. We write $\overrightarrow{\mathcal{K}}$ for the class which contains for every ℓ-hypergraph $\mathbb{H}$ from $\mathcal{K}$ all ordered ℓ-hypergraphs obtained by linearly ordering $\mathbb{H}$.

A relational structure $\mathbb{B}$ is *homogeneous* if every isomorphism between finite induced substructures of $\mathbb{B}$ extends to an automorphism of $\mathbb{B}$. The class of finite substructures of a homogeneous structure $\mathbb{B}$ is an amalgamation class; and conversely, for every amalgamation class $\mathcal{K}$ there exists a homogeneous structure $\mathbb{B}_{\mathcal{K}}$ whose finite induced substructures are exactly the structures in $\mathcal{K}$ (see e.g. [25] for this as well as the other claims in this section). The structure $\mathbb{B}_{\mathcal{K}}$ is called the Fraïssé limit of $\mathcal{K}$. The *universal homogeneous ℓ-hypergraph* is the Fraïssé limit of $\mathcal{K}^{\ell}_{\mathrm{all}}$.

A *first-order reduct* of a structure $\mathbb{B}$ is a structure $\mathbb{A}$ on the same domain whose relations are definable over $\mathbb{B}$ by first-order formulas without parameters. Recall that for any amalgamation class $\mathcal{K}$ and for any set Ψ of ℓ-hypergraph formulas, $\mathbb{A}_{\mathcal{K},\Psi}$ denotes the first-order reduct of

the Fraïssé limit $\mathbb{H}_{\mathcal{K}}$ of $\mathcal{K}$ whose relations are defined by the formulas in Ψ. We remark that if $\mathbb{B}$ is the Fraïssé limit of a finitely bounded class, then every first-order formula is equivalent to one without quantifiers.

A countable relational structure is *ω-categorical* if its automorphism group has finitely many orbits in its componentwise action on n-tuples of elements for all $n \geq 1$. This is equivalent to saying that there are only finitely many relations of any fixed arity $n \geq 1$ that are first-order definable from $\mathbb{A}$. Every first-order reduct of a finitely bounded homogeneous structure is ω-categorical.

2.3 Polymorphisms

A *polymorphism* of a relational structure $\mathbb{A}$ is a function from A^n to A for some $n \geq 1$ which *preserves* all relations of $\mathbb{A}$, i.e., for every such relation R of arity m and for all tuples $(a_1^1, \dots, a_m^1), \dots, (a_1^n, \dots, a_m^n) \in R$, it holds that $(f(a_1^1, \dots, a_1^n), \dots, f(a_m^1, \dots, a_m^n)) \in R$. We also say that a polymorphism of $\mathbb{A}$ preserves a constraint $C \subseteq A^U$ if for all $g_1, \dots, g_n \in C$, it holds that $f \circ (g_1, \dots, g_n) \in C$. The set of all polymorphisms of a structure $\mathbb{A}$, denoted by $\mathrm{Pol}(\mathbb{A})$, is a *function clone*, i.e., a set of finitary operations on a fixed set which contains all projections and which is closed under arbitrary compositions. Every relation that is pp-definable in a relational structure $\mathbb{A}$ is preserved by all polymorphisms of $\mathbb{A}$.

Let $S \subseteq R \subseteq A^n$ be relations pp-definable in a structure $\mathbb{A}$. We say that S *is a binary absorbing subuniverse of R in* $\mathbb{A}$ if there exists a binary operation $f \in \mathrm{Pol}(\mathbb{A})$ such that for every $\mathbf{s} \in S, \mathbf{r} \in R$, we have that $f(\mathbf{s}, \mathbf{r}), f(\mathbf{r}, \mathbf{s}) \in S$. In this case, we write $S \trianglelefteq_{\mathbb{A}} R$, and we say that f *witnesses* the binary absorption.

Let $\mathbb{A}$ be a relational structure, and let $\mathscr{G} = \mathrm{Aut}(\mathbb{A})$ be the group of its automorphisms. For $n \geq 1$, a k-ary operation f defined on the domain of $\mathbb{A}$ is *n-canonical* with respect to $\mathbb{A}$ if for all $\mathbf{a}_1, \dots, \mathbf{a}_k \in A^n$ and all $\alpha_1, \dots, \alpha_k \in \mathscr{G}$, there exists $\beta \in \mathscr{G}$ such that $f(\mathbf{a}_1, \dots, \mathbf{a}_k) = \beta \circ f(\alpha_1(\mathbf{a}_1), \dots, \alpha_k(\mathbf{a}_k))$. A function f that is n-canonical with respect to $\mathbb{A}$ for all $n \geq 1$ is called *canonical* with respect to $\mathbb{A}$. In particular, f induces an operation on the set $A^n/\mathscr{G}$ of orbits of n-tuples under $\mathscr{G}$ for every $n \geq 1$. In our setting, we are interested in operations that are canonical with respect to a homogeneous ℓ-hypergraph $\mathbb{H}$ or to a homogeneous linearly ordered ℓ-hypergraph $(\mathbb{H}, <)$. In this case, an operation canonical with respect to $\mathbb{H}$ can simply be seen as an operation on labeled ℓ-hypergraphs with at most n elements, while an operation canonical with respect to $(\mathbb{H}, <)$ can be seen as an operation on labeled ℓ-hypergraphs with at most n elements which carry a weak linear order.

3 Polynomial-Time Algorithms From Symmetries

In this section, we fix $\ell \geq 3$ and a finitely bounded class $\mathcal{K}$ of ℓ-hypergraphs such that $\overrightarrow{\mathcal{K}}$ is an amalgamation class. We write $(\mathbb{H}, <)$ for the Fraïssé limit of $\overrightarrow{\mathcal{K}}$, I_n for the set of injective n-tuples of elements from H for any $n \geq 1$, I for I_ℓ, and $b_{\mathbb{H}}$ for an integer witnessing that $\mathcal{K}$ is finitely bounded. We also fix a first-order reduct $\mathbb{A}$ of $\mathbb{H}$. We say that $\mathbb{A}$ *admits an injective linear symmetry* if it has a ternary injective polymorphism m which is canonical with respect to $(\mathbb{H}, <)$, and which has the property that for any $\mathbf{a}, \mathbf{b} \in I$, the orbits under $\mathrm{Aut}(\mathbb{H})$ of $m(\mathbf{a}, \mathbf{a}, \mathbf{b}), m(\mathbf{a}, \mathbf{b}, \mathbf{a}), m(\mathbf{b}, \mathbf{a}, \mathbf{a})$ and $\mathbf{b}$ agree. Note that in this case, m induces an operation on the set $\{E, N\}$ of orbits of injective ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$. We say that m *acts as a minority operation on* $\{E, N\}$ since the second condition on m can be equivalently written as $m(X, X, Y) = m(X, Y, X) = m(Y, X, X) = Y$ for all $X, Y \in \{E, N\}$.

We prove the following.

▶ **Theorem 8.** *Let $\ell \geq 3$, let $\mathcal{K}$ be a finitely bounded class of ℓ-hypergraphs such that $\overrightarrow{\mathcal{K}}$ is an amalgamation class. Let $\mathbb{A}$ be a first-order reduct of the Fraïssé limit $\mathbb{H}$ of $\mathcal{K}$. Suppose that $I \trianglelefteq_{\mathbb{A}} H^\ell$, and that $\mathbb{A}$ admits an injective linear symmetry or is such that $\mathrm{CSP}_{\mathrm{Inj}}(\mathbb{A})$ has bounded width. Then $\mathrm{CSP}(\mathbb{A})$ is solvable in polynomial time.*

If $\mathrm{CSP}_{\mathrm{Inj}}(\mathbb{A})$ has bounded width, $\mathrm{CSP}(\mathbb{A})$ has bounded width as well by general principles, and is therefore in particular solvable in polynomial time (see [29, Section 3.2]). In the rest of this section, we will therefore focus on the case when $\mathbb{A}$ admits an injective linear symmetry.

Let $\mathbb{A}$ be a first-order reduct of $\mathbb{H}$ admitting an injective linear symmetry. Set $p_1(x, y) := m(x, y, y)$. It follows that p_1 is canonical with respect to $(\mathbb{H}, <)$ and that it acts as the first projection on $\{E, N\}$, i.e., it satisfies for any $\mathbf{a}, \mathbf{b} \in I$ that the orbit of $p_1(\mathbf{a}, \mathbf{b})$ under $\mathrm{Aut}(\mathbb{H})$ is equal to the orbit of $\mathbf{a}$. Moreover, by composing p_1 with a suitable endomorphism of $\mathbb{H}$, we can assume that $p_1(y, x)$ acts lexicographically on the order, i.e., $p_1(x, y) < p_1(x', y')$ if $y < y'$ or $y = y'$ and $x < x'$ (for more details, see [29, Section 5.2]).

In the remainder of this section, we present an algorithm solving $\mathrm{CSP}(\mathbb{A})$ in polynomial time, given that $\mathbb{A}$ has among its polymorphisms operations p_1 and m with the properties derived above. Before giving the technical details, we give here an overview of the methods we employ. Let $\mathcal{I}$ be an instance of $\mathrm{CSP}(\mathbb{A})$. Our algorithm transforms $\mathcal{I}$ into an equi-satisfiable instance $\mathcal{I}'$ that is sufficiently minimal, such that the solution set of a certain relaxation of $\mathcal{I}'$ is subdirect on all projections to an ℓ-tuple $\mathbf{v}$ of pairwise distinct variables (i.e., for every tuple $\mathbf{a}$ in this projection, this relaxation of $\mathcal{I}'$ has a solution where the variables from $\mathbf{v}$ are assigned values from $\mathbf{a}$), and that additionally satisfies a condition which we call *inj-irreducibility*, inspired by Zhuk's notion of irreducibility [39, 40]. We then prove that any non-trivial instance satisfying those properties has an injective solution. This step is to be compared with the case of *absorbing reductions* in Zhuk's algorithm, and in particular with Theorem 5.5 in [40], in which it is proved that any sufficiently minimal and irreducible instance that has a solution also has a solution where an arbitrary variable is constrained to belong to an absorbing subuniverse. Since in our setting I is an absorbing subuniverse of H^ℓ in $\mathbb{A}$, this fully establishes a parallel between the present work and [40]. The algorithm that we are going to introduce will work with infinite sets which are however always unions of orbits of ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$. $\mathrm{Aut}(\mathbb{H})$ is oligomorphic, i.e., it has only finitely many orbits in its action on H^k for every $k \geq 1$; in particular, there are only finitely many orbits of ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$, whence we can represent every union of such orbits by listing all orbits included in this union.

We now show that the structure defined by the formula from Example 1 has polymorphisms satisfying our assumptions on p_1 and on m, and hence it falls into the scope of this section.

▶ **Example 1** (continued)**.** Let $R \subseteq H^4$ be the relation defined by ψ, and let $\mathbb{A} := (H; R)$. We define the canonical behaviour of a binary injection (i.e., a binary injective function) p_1 with respect to $(\mathbb{H}, <)$ as follows. We require that p_1 acts as the first projection on $\{E, N\}$, if O is a non-injective orbit of triples under $\mathrm{Aut}(\mathbb{H})$, and P is an injective orbit, then we require that $p_1(O, P) = p_1(P, O) = P$. Finally, for two non-injective orbits O_1, O_2 of triples under $\mathrm{Aut}(\mathbb{H}, <)$ such that $p_1(O_1, O_2)$ needs to be injective, we require that $p_1(O_1, O_2) = E$ if the minimum of any triple in O_1 appears only once in this triple, and $p_1(O_1, O_2) = N$ otherwise. Now, we take a ternary injection m' canonical with respect to $(\mathbb{H}, <)$ which behaves like a minority on $\{E, N\}$, and we define $m := m'(p_1(x, p_1(y, z)), p_1(y, p_1(z, x)), p_1(z, p_1(x, y)))$. It is easy to see that p_1 and m preserve R, hence $\mathbb{A}$ satisfies the assumptions from Theorem 8.

Let $\sim$ denote the 6-ary relation containing the tuples $(\mathbf{a}, \mathbf{b})$ where $\mathbf{a}, \mathbf{b}$ are triples that are in the same orbit under $\mathrm{Aut}(\mathbb{H})$. Note that the relation T defined by

$$(x_1, x_2, x_3, x_4) \in T :\Longleftrightarrow R(x_1, x_2, x_3, x_4) \wedge (x_1, x_3, x_2) \sim (x_4, x_2, x_3)$$

is preserved by all polymorphisms of $\mathbb{A}$ that are canonical with respect to $\mathbb{H}$ and that it contains precisely those tuples of the form (a,a,b,b) and (a,b,a,b) for arbitrary $a \neq b$. It can be seen (e.g., from [7]) that $\mathrm{Pol}(H;T)$ only contains *essentially unary* operations, of the form $(x_1,\dots,x_n) \mapsto \alpha(x_i)$ for arbitrary permutations α of H, and therefore the polymorphisms of $\mathbb{A}$ that are canonical with respect to $\mathbb{H}$ are also essentially unary. It follows that the finite-domain CSP used in the reduction from [13] is NP-complete.

3.1 Finitisation of instances

Let $\mathbb{A}$ be a first-order reduct of $\mathbb{H}$. Let $\mathcal{I} = (\mathcal{V},\mathcal{C})$ be an instance of $\mathrm{CSP}(\mathbb{A})$. In this section, we always assume that the variable set $\mathcal{V}$ is equipped with an arbitrary linear order; this assumption is however inessential and only used to formulate the statements and proofs in a more concise way. We denote by $[\mathcal{V}]^\ell$ the set of injective increasing ℓ-tuples of variables from $\mathcal{V}$. Given any instance $\mathcal{I}$ of $\mathrm{CSP}(\mathbb{A})$, consider the following CSP instance $\mathcal{I}_{\mathrm{fin}}$ over the set $\mathcal{O}$ of orbits of ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$, called the *finitisation of* $\mathcal{I}$:

- The variable set of $\mathcal{I}_{\mathrm{fin}}$ is the set $[\mathcal{V}]^\ell$.
- For every constraint $C \subseteq A^U$ in $\mathcal{I}$, $\mathcal{I}_{\mathrm{fin}}$ contains the constraint C' containing the maps $g\colon [U]^\ell \to \mathcal{O}$ such that there exists $f \in C$ satisfying $f(\mathbf{v}) \in g(\mathbf{v})$ for every $\mathbf{v} \in [U]^\ell$.

This instance corresponds to the instance $\mathcal{I}_{\mathrm{Aut}(\mathbb{H}),\ell}$ from [32, Definition 3.1], with the difference that there the ℓ-element subsets of $\mathcal{V}$ were used as variables, and the domain consisted of orbits of maps. However, the translation between the two definitions is straightforward. Note that if a mapping $f\colon \mathcal{V} \to A$ is a solution of $\mathcal{I}$, then the mapping $h\colon [\mathcal{V}]^\ell \to \mathcal{O}$, where $h(\mathbf{v})$ is the orbit of $f(\mathbf{v})$ under $\mathrm{Aut}(\mathbb{H})$ for every $\mathbf{v} \in [\mathcal{V}]^\ell$ is a solution of $\mathcal{I}_{\mathrm{fin}}$.

Let $\mathcal{J} = (S,\mathcal{C})$ be an instance over the set $\mathcal{O}$ of orbits of ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$, e.g., $\mathcal{J} = \mathcal{I}_{\mathrm{fin}}$ for some $\mathcal{I}$. The *injectivisation* of $\mathcal{J}$, denoted by $\mathcal{J}^{(\mathrm{inj})}$, is the instance obtained by removing from all constraints all maps taking some value outside the two injective orbits E and N.

Let $\mathcal{I} = (\mathcal{V},\mathcal{C})$ be an instance of $\mathrm{CSP}(\mathbb{A})$; the *injective finitisation of* $\mathcal{I}$ is the instance $(\mathcal{I}_{\mathrm{fin}})^{(\mathrm{inj})}$. Let $S \subseteq [\mathcal{V}]^\ell$. The *injective finitisation of* $\mathcal{I}$ *on* S is the restriction of the injective finitisation of $\mathcal{I}$ to S. For any constraint $C \in \mathcal{C}$, the corresponding constraint in the injective finitisation of $\mathcal{I}$ is called the injective finitisation of C. Note that if $\mathbb{A}$ admits an injective linear symmetry, then for any instance $\mathcal{I} = (\mathcal{V},\mathcal{C})$ of $\mathrm{CSP}(\mathbb{A})$ and for any $S \subseteq [\mathcal{V}]^\ell$, the injective finitisation of $\mathcal{I}$ on S is solvable in polynomial time. This follows from Lemma 3.4 in [32] and from the dichotomy theorem for finite-domain CSPs [39, 40, 19].

Let $\mathbb{A}$ be a first-order reduct of $\mathbb{H}$ preserved by m and by p_1. We can assume that $\mathbb{A}$ has among its relations all unions of orbits of ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$ that are preserved by p_1 and by the ternary injection m. Otherwise, we expand $\mathbb{A}$ by these finitely many relations and we prove that the CSP of this expanded structure is solvable in polynomial time. Note that in particular, every orbit of ℓ-tuples under $\mathrm{Aut}(\mathbb{H})$ is a relation of $\mathbb{A}$. Moreover, we suppose that $\mathbb{A}$ has the property that for every instance $\mathcal{I}$ of $\mathrm{CSP}(\mathbb{A})$, the $(2\ell, \max(3\ell, b_{\mathbb{H}}))$-minimal instance equivalent to $\mathcal{I}$ is again an instance of $\mathrm{CSP}(\mathbb{A})$. This can be achieved without loss of generality since it is enough to expand $\mathbb{A}$ by finitely many pp-definable relations, which are also preserved by m and p_1. Note that if $\mathcal{I}$ is a $(2\ell, \max(3\ell, b_{\mathbb{H}}))$-minimal instance of $\mathrm{CSP}(\mathbb{A})$, then its injective finitisation $\mathcal{I}_{\mathrm{fin}}$ is $(2,3)$-minimal by [32, Lemma 3.2]; in particular, $\mathcal{I}_{\mathrm{fin}}$ is *cycle consistent*, i.e., it satisfies one of the basic consistency notions used in Zhuk's algorithm [39]. Moreover, if $\mathcal{I}_{\mathrm{fin}}$ is $(2,3)$-minimal, then for any solution $h\colon [\mathcal{V}]^\ell \to \mathcal{O}$ of $\mathcal{I}_{\mathrm{fin}}$, any mapping $f\colon \mathcal{V} \to A$ with $f(\mathbf{v}) \in h(\mathbf{v})$ for every $\mathbf{v} \in [\mathcal{V}]^\ell$ is a solution of $\mathcal{I}$ by [32, Lemma 3.3].

Let $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ be an instance of CSP($\mathbb{A}$), and let $C \in \mathcal{C}$. Since $\mathbb{A}$ is preserved by m, there exists a set of linear equations over $\mathbb{Z}_2$ associated with the injective finitisation of C. By abuse of notation, we write every linear equation as $\sum_{\mathbf{v} \in S} X_{\mathbf{v}} = P$, where $P \in \{E, N\}$ and $S \subseteq [\mathcal{V}]^\ell$ is a set of injective ℓ-tuples of variables from the scope of C. In these linear equations, we identify E with 1 and N with 0, so that e.g. $E + E = N$ and $N + E = E$. Using this notation, the canonical behaviour of the function m on $\{E, N\}$ can be written as $m(X, Y, Z) = X + Y + Z$ which justifies the notion of $\mathbb{A}$ admitting linear symmetries.

For an instance $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ of CSP($\mathbb{A}$), we define an instance $\mathcal{I}_{\text{eq}} = (\mathcal{V}, \mathcal{C}_{\text{eq}})$ of the equality-CSP (i.e., CSP over structures first-order definable over $(H; =)$) over the same base set H corresponding to the closure of the constraints under the full symmetric group on H. Formally, for every constraint $C \in \mathcal{C}$, the corresponding constraint $C_{\text{eq}} \in \mathcal{C}_{\text{eq}}$ contains all functions αh for all $h \in C$ and $\alpha \in \text{Sym}(H)$. Since $\mathbb{A}$ is preserved by a binary injection, the constraints of $\mathcal{I}_{\text{eq}}$ are preserved by the same or indeed any binary injection and hence, its CSP has relational width $(2, 3)$ by the classification of equality CSPs [7].

Let $\mathcal{I}$ be an ℓ-minimal instance of CSP($\mathbb{A}$), let $\mathbf{v} \in [\mathcal{V}]^\ell$, and let $R \subseteq \text{proj}_{\mathbf{v}}(\mathcal{I})$ be an ℓ-ary relation from the signature of $\mathbb{A}$. Let $\mathcal{I}^{\mathbf{v} \in R}$ be the instance obtained from $\mathcal{I}$ by replacing every constraint C containing all variables from $\mathbf{v}$ by $\{g \in C \mid g(\mathbf{v}) \in R\}$.

We call an ℓ-minimal instance of CSP($\mathbb{A}$) *eq-subdirect* if for every $\mathbf{v} \in [\mathcal{V}]^\ell$ and for every non-injective orbit $O \subseteq \text{proj}_{\mathbf{v}}(\mathcal{I})$ under Aut($\mathbb{H}$), the instance $(\mathcal{I}^{\mathbf{v} \in O})_{\text{eq}}$ has a solution. Note that by ℓ-minimality and since all constraints of the instance are preserved by a binary injection, the instance $(\mathcal{I}^{\mathbf{v} \in O})_{\text{eq}}$ has a solution for every injective orbit $O \subseteq \text{proj}_{\mathbf{v}}(\mathcal{I})$ under Aut($\mathbb{H}$). Indeed, any injective mapping from $\mathcal{V}$ to H is a solution of $(\mathcal{I}^{\mathbf{v} \in O})_{\text{eq}}$.

▶ **Example 9.** Let $\mathbb{H}$ be the universal homogeneous ℓ-hypergraph. Let $\mathbf{u} = (u_1, \ldots, u_\ell), \mathbf{v} = (v_1, \ldots, v_\ell)$ be disjoint ℓ-tuples of variables, and let $\mathcal{V}$ be the set of all variables contained in these tuples. We define a CSP instance $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ over the set H as follows. Let $\mathbf{u}' = (u_2, \ldots, u_\ell, u_1)$. We set $\mathcal{C}$ to contain two constraints C, C' such that C contains all mappings $f \colon \mathcal{V} \to H$ such that $f(\mathbf{u})$ and $f(\mathbf{v})$ belong to the same orbit under Aut($\mathbb{H}$), and C' contains all mappings $f \colon \mathcal{V} \to H$ such that $f(\mathbf{u}')$ and $f(\mathbf{v})$ belong to the same orbit. Note that the constraints C, C' are preserved by any function which is canonical with respect to $\mathbb{H}$. It is easy to see that $\mathcal{I}$ is non-trivial and ℓ-minimal, but it is not eq-subdirect. Indeed, for any non-injective and non-constant mapping g from the set of variables of $\mathbf{u}$ to H, it holds that $g(\mathbf{u})$ and $g(\mathbf{u}')$ are contained in different orbits under Aut($\mathbb{H}$).

We can obtain an eq-subdirect instance out of an ℓ-minimal instance in polynomial time by the algorithm introduced in [29, Section 3.1]. The algorithm successively shrinks for every $\mathbf{v} \in [\mathcal{V}]^\ell$ the projection $\text{proj}_{\mathbf{v}}(\mathcal{I})$ to the union of those orbits $O \subseteq \text{proj}_{\mathbf{v}}(\mathcal{I})$ under Aut($\mathbb{H}$) for which the instance $(\mathcal{I}^{\mathbf{v} \in O})_{\text{eq}}$ has a solution; it stops when no more orbits can be removed from $\text{proj}_{\mathbf{v}}(\mathcal{I})$ for any $\mathbf{v} \in [\mathcal{V}]^\ell$.

Note that for any $1 \leq m \leq n$ and any instance $\mathcal{I}$ of CSP($\mathbb{A}$), we can compute an instance that is both eq-subdirect and (m, n)-minimal and that has the same solution set as $\mathcal{I}$ in polynomial time. Indeed, it is enough to repeat the above-mentioned algorithm and the (m, n)-minimality algorithm until no orbits under Aut($\mathbb{H}$) are removed from any constraint.

3.2 Inj-irreducibility

For any $\mathbf{a} \in H^\ell$, we write $O(\mathbf{a})$ for the orbit of $\mathbf{a}$ under Aut($\mathbb{H}$) and $O_<(\mathbf{a})$ for the orbit of $\mathbf{a}$ under Aut($\mathbb{H}, <$). Recall that being canonical with respect to $(\mathbb{H}, <)$, the function p_1 acts naturally on orbits under Aut($\mathbb{H}, <$); we can therefore abuse the notation and write $p_1(O, P)$ for orbits O, P under Aut($\mathbb{H}, <$). We will say that a non-injective orbit O of ℓ-tuples under Aut($\mathbb{H}$) is:

- *deterministic* if for every $\mathbf{a} \in O$, there exists $\alpha \in \mathrm{Aut}(\mathbb{H})$ such that $p_1(O_<(\alpha(\mathbf{a})), O_<(\mathbf{e})) = p_1(O_<(\alpha(\mathbf{a})), O_<(\mathbf{n}))$, where $\mathbf{e}, \mathbf{n}$ are arbitrary strictly increasing ℓ-tuples of elements of $\mathbb{H}$ with $\mathbf{e} \in E$, $\mathbf{n} \in N$,
- *non-deterministic* otherwise.

For a tuple $\mathbf{a}$ contained in a deterministic orbit O, we call any $\alpha \in \mathrm{Aut}(\mathbb{H})$ with the property that $p_1(O_<(\alpha(\mathbf{a})), E) = p_1(O_<(\alpha(\mathbf{a})), N)$ for the strictly increasing ordering in the second coordinate *deterministic for* $\mathbf{a}$. Note that for any $\beta \in \mathrm{Aut}(\mathbb{H}, <)$, $\beta\alpha \in \mathrm{Aut}(\mathbb{H})$ is deterministic for $\mathbf{a}$ as well since p_1 is canonical with respect to $(\mathbb{H}, <)$.

Let $\mathcal{J} = (\mathcal{V}, \mathcal{C})$ be a CSP instance over a set B. A sequence $v_1, C_1, v_2, \ldots, C_k, v_{k+1}$, where $k \geq 1$, $v_i \in \mathcal{V}$ for every $i \in [k+1]$, $C_i \in \mathcal{C}$ for every $i \in [k]$, and v_i, v_{i+1} are contained in the scope of C_i for every $i \in [k]$, is called a *path* in $\mathcal{J}$. We say that two elements $a, b \in B$ are *connected* by a path $v_1, C_1, v_2, \ldots, C_k, v_{k+1}$ if there exists a tuple $(c_1, \ldots, c_{k+1}) \in B^{k+1}$ such that $c_1 = a, c_{k+1} = b$, and such that $(c_i, c_{i+1}) \in \mathrm{proj}_{(v_i, v_{i+1})}(C_i)$ for every $i \in [k]$. Suppose that $\mathcal{J}$ is 1-minimal. The *linkedness congruence* on $\mathrm{proj}_v(\mathcal{J})$ is the equivalence relation λ on $\mathrm{proj}_v(\mathcal{J})$ defined by $(a, b) \in \lambda$ if there exists a path $v_1, C_1, v_2, \ldots, C_k, v_{k+1}$ from a to b in $\mathcal{J}$ such that $v_1 = v_{k+1} = v$. Note that for a finite relational structure $\mathbb{B}$, for a $(2,3)$-minimal instance $\mathcal{J} = (\mathcal{V}, \mathcal{C})$ of $\mathrm{CSP}(\mathbb{B})$, and for any $v \in \mathcal{V}$, the linkedness congruence λ on $\mathrm{proj}_v(\mathcal{J})$ is a relation pp-definable in $\mathbb{B}$. Indeed, it is easy to see that the binary relation containing precisely the pairs $(a, b) \in B^2$ that are connected by a particular path in $\mathcal{I}$ is pp-definable in $\mathbb{B}$. If we concatenate all paths that connect two elements $(a, b) \in \lambda$, the resulting path connects every pair $(a, b) \in \lambda$ since by the $(2,3)$-minimality of $\mathcal{J}$, every path from v to v connects c to c for every $c \in \mathrm{proj}_v(\mathcal{J})$. It follows that λ is pp-definable.

▶ **Definition 10.** *Let $\mathbb{A}$ be a first-order reduct of $\mathbb{H}$, and let $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ be a non-trivial ℓ-minimal instance of* $\mathrm{CSP}(\mathbb{A})$*. We call $\mathcal{I}$* inj-irreducible *if for every set $S \subseteq [\mathcal{V}]^\ell$, one of the following holds for the instance $\mathcal{J} = \mathcal{I}_{fin}|_S$:*

- *$\mathcal{J}^{(\mathrm{inj})}$ has a solution,*
- *for some $\mathbf{v} \in S$, $\mathrm{proj}_{\mathbf{v}}(\mathcal{J})$ contains the two injective orbits and the linkedness congruence on $\mathrm{proj}_{\mathbf{v}}(\mathcal{J})$ does not connect them,*
- *for some $\mathbf{v} \in S$, the linkedness congruence on $\mathrm{proj}_{\mathbf{v}}(\mathcal{J})$ links an injective orbit to a non-deterministic orbit.*

▶ **Example 11.** We illustrate the concept of inj-irreducibility on the following instance. Let $\ell = 3$, and let $\mathbb{H}$ be the universal homogeneous ℓ-hypergraph. Let $a \neq b \in H$ be arbitrary; we call the orbits $O(a,a,b), O(a,b,a), O(b,a,a)$ under $\mathrm{Aut}(\mathbb{H})$ *half-injective*. Let us define an instance $\mathcal{I} = (\mathcal{V}, \mathcal{C})$ over the set H as follows. Above, we identified E with 1 and N with 0 in the linear equations associated to injective finitisations of constraints. In this example, we identify also all half-injective orbits under $\mathrm{Aut}(\mathbb{H})$ with 1. Hence, we can write, e.g., $E + O(a,a,b) = 0$.

Let $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3$ be increasing triples of pairwise disjoint variables, and set $\mathcal{V}$ to be the union of all variables of these tuples. We define $\mathcal{C}$ to be a set consisting of two constraints, C_0 and C_1, defined as follows. For $i \in \{0, 1\}$, we set C_i to contain all mappings $f \in H^{\mathcal{V}}$ such that both of the following hold:

- either $O(f(\mathbf{v}_1)) + O(f(\mathbf{v}_2)) + O(f(\mathbf{v}_3)) = i$, or $O(f(\mathbf{v}_1)) = O(f(\mathbf{v}_2)) = O(f(\mathbf{v}_3)) = \{(a,a,a) \mid a \in H\}$,
- $f(x) \neq f(y)$ for all $x, y \in \mathcal{V}$ belonging to different triples from $\{\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3\}$.

We show that the constraints C_0, C_1 are preserved by a binary injection p_1 and a ternary injection m that are both canonical with respect to $\mathbb{H}$. To this end, we define the canonical behaviours of p_1 and m on the orbits of triples under $\mathrm{Aut}(\mathbb{H})$ as follows. We set p_1 to act

as the first projection on the numbers associated to the respective orbits, and to satisfy $p_1(O(a,a,a),P) = p_1(P,O(a,a,a)) = P$ for an arbitrary $a \in H$ and for an arbitrary orbit P. Note that these assumptions together with the requirement that p_1 is an injection uniquely determine the behaviour of p_1 – e.g., $p_1(P,N) = E$ for an arbitrary half-injective orbit P. We set m to act as an idempotent minority on the numbers associated to the orbits, and to act as $p_1(x,p_1(y,z))$ on the orbits where the action is not determined by the previous condition. It is easy to verify that the constraints C_0 and C_1 are preserved by both p_1 and m, and hence $\mathcal{I}$ is an instance of CSP($\mathbb{A}$) for some first-order reduct $\mathbb{A}$ of $\mathbb{H}$ which falls into the scope of this section.

It immediately follows that all the half-injective orbits under Aut($\mathbb{H}$) are deterministic since $p_1(O_<(\mathbf{c}),E) = p_1(O_<(\mathbf{c}),N) = E$ for any $\mathbf{c} \in H^3$ contained in a half-injective orbit; the orbit P of the constant tuples is non-deterministic since $p_1(P,E) = E$, and $p_1(P,N) = N$. It is also easy to see that $\mathcal{I}$ is non-trivial and $(6,9)$-minimal. Moreover, $\mathcal{I}$ is not inj-irreducible. Indeed, setting $S := \{\mathbf{v}_1,\mathbf{v}_2,\mathbf{v}_3\}$, the linkedness congruence on $\mathrm{proj}_{\mathbf{v}_1}(\mathcal{I}_{\mathrm{fin}}|_S)$ connects precisely all injective and half-injective orbits, and the injective finitisation of $\mathcal{I}$ on S does not have a solution.

Note that if $\mathbb{A}$ is the structure from Example 11, its CSP can be solved by the reduction to the finite from [13]. For simplicity, we choose to illustrate the concepts that we have just introduced on this example rather than on an example where the canonical behaviour of the functions p_1 and m depends on the linear order. However, Example 1 provides us with a structure admitting linear symmetries where the canonical behaviour of any polymorphism satisfying the assumptions on m or on p_1 depends on the additional linear order.

▶ **Lemma 12.** *Let C be a constraint of an instance of* CSP($\mathbb{A}$) *which contains an injective mapping, and let S be a set of variables appearing together in an unsplittable linear equation associated with the injective finitisation of C. Then for every $g \in C$, either $g(\mathbf{v})$ is in an injective or deterministic orbit for all $\mathbf{v} \in S$, or $g(\mathbf{v})$ is in a non-deterministic orbit for all $\mathbf{v} \in S$.*

▶ **Theorem 13.** *Let $\mathbb{A}$ be a first-order reduct of $\mathbb{H}$ that admits linear symmetries. Let $\mathcal{I}$ be a $(2\ell, \max(3\ell, b_{\mathbb{H}}))$-minimal, inj-irreducible instance of* CSP($\mathbb{A}$) *with variables $\mathcal{V}$ such that for every distinct $u,v \in \mathcal{V}$, $\mathrm{proj}_{(u,v)}(\mathcal{I}) \cap I_2 \neq \emptyset$. Then $\mathcal{I}$ has an injective solution.*

Proof. Note that if $\mathcal{I}$ has fewer than ℓ variables, it has an injective solution by the assumption on binary projections of $\mathcal{I}$ and since all constraints of $\mathcal{I}$ are preserved by the binary injection p_1. Let us therefore suppose that $\mathcal{I}$ has at least ℓ variables. Let us assume for the sake of contradiction that $\mathcal{I}$ does not have an injective solution. Let $\mathcal{J}$ be $\mathcal{I}_{\mathrm{fin}}$, and let $\mathcal{C}$ be the set of its constraints. By assumption, $\mathcal{J}^{(\mathrm{inj})}$ does not have a solution. Note that $\mathcal{J}^{(\mathrm{inj})}$ corresponds to a system of linear equations over $\mathbb{Z}_2$, which is therefore unsatisfiable. In case this system can be written as a diagonal block matrix, there exists a set $S \subseteq [\mathcal{V}]^\ell$ of variables such that the system of equations associated with the injectivisation of $\mathcal{L} := \mathcal{J}|_S = (S,\mathcal{C}')$ corresponds to a minimal unsatisfiable block. By definition, this means that $\mathcal{L}^{(\mathrm{inj})}$ is unsatisfiable. The instance $\mathcal{L}$ has the property that for every non-trivial partition of S into parts S_1, S_2, there exists an unsplittable equation associated with the injectivisation of a constraint $C \in \mathcal{C}'$ which contains variables from both S_1 and S_2.

Since $\mathcal{I}$ is inj-irreducible, there exists $\mathbf{v} \in S$ such that the two injective orbits are elements of $\mathrm{proj}_{\mathbf{v}}(\mathcal{L})$ and are not linked, or some injective orbit in $\mathrm{proj}_{\mathbf{v}}(\mathcal{L})$ is linked to a non-deterministic orbit in $\mathrm{proj}_{\mathbf{v}}(\mathcal{L})$.

In the first case, we note that for *all* $\mathbf{w} \in S$ such that $\mathrm{proj}_{\mathbf{w}}(\mathcal{L})$ contains the two injective orbits, the two injective orbits are not linked. Indeed, suppose that there exists $\mathbf{w} \in S$ such that $E, N \in \mathrm{proj}_{\mathbf{w}}(\mathcal{L})$ are linked, i.e., there exists a path $\mathbf{v}_1 = \mathbf{w}, C_1, \dots, C_k, \mathbf{v}_{k+1} = \mathbf{w}$ in $\mathcal{L}$ connecting E and N. Since $\mathcal{I}$ is $(2\ell, \max(3\ell, b_{\mathbb{H}}))$-minimal, Lemma 3.2 in [32] yields that $\mathcal{J}$ and hence also $\mathcal{L}$ is $(2,3)$-minimal. In particular, there exists $C \in \mathcal{C}'$ containing in its scope both $\mathbf{v}$ and $\mathbf{w}$. Let $O_1, O_2 \in \{E, N\}$ be disjoint such that there exist $g_1, g_2 \in C$ with $g_1(\mathbf{v}) = O_1, g_1(\mathbf{w}) = E, g_2(\mathbf{v}) = O_2, g_2(\mathbf{w}) = N$. It follows that the path $\mathbf{v}, C, \mathbf{w} = \mathbf{v}_1, C_1, \dots, C_k, \mathbf{v}_{k+1} = \mathbf{w}, C, \mathbf{v}$ connects O_1 with O_2 in $\mathrm{proj}_{\mathbf{v}}(\mathcal{J})$, a contradiction. Let $g\colon S \to \{E, N\}$ be defined as follows. For a fixed $\mathbf{v} \in S$, let $g(\mathbf{v})$ be an arbitrary element of $\mathrm{proj}_{\mathbf{v}}(\mathcal{L}^{(\mathrm{inj})})$. Next, for $\mathbf{w} \in S$, define $g(\mathbf{w})$ to be the unique injective orbit O such that there exists a constraint $C \in \mathcal{C}'$ containing both $\mathbf{v}$ and $\mathbf{w}$ in its scope and such that there exists $g' \in C$ with $g'(\mathbf{v}) = g(\mathbf{v})$ and $g'(\mathbf{w}) = O$. This g is a solution of $\mathcal{L}^{(\mathrm{inj})}$, a contradiction.

Thus, it must be that a non-deterministic orbit in $\mathrm{proj}_{\mathbf{v}}(\mathcal{L})$ is linked to an injective orbit in $\mathrm{proj}_{\mathbf{v}}(\mathcal{L})$. Hence, there exists a path in $\mathcal{L}$ from $\mathbf{v}$ to $\mathbf{v}$ and connecting an injective orbit to a non-deterministic one. Moreover, up to composing this path with additional constraints, one can assume that this path goes through all the variables in S. This follows by the $(2,3)$-minimality of $\mathcal{J}$. Define a partition of S where $\mathbf{w} \in S_1$ if the first time that $\mathbf{w}$ appears in the path, the element associated with $\mathbf{w}$ is in an injective orbit, and $\mathbf{w} \in S_2$ otherwise. Since the system of unsplittable equations associated with $\mathcal{L}^{(\mathrm{inj})}$ cannot be decomposed as a diagonal block matrix, some constraint $C \in \mathcal{C}'$ gives an equation in that system containing $\mathbf{u}_1 \in S_1$ and $\mathbf{u}_2 \in S_2$. Thus, there exists $g \in C$ with $g(\mathbf{u}_1)$ injective, and $g(\mathbf{u}_2)$ non-deterministic. This contradicts Lemma 12. ◀

3.3 Establishing inj-irreducibility

We introduce a polynomial-time algorithm which produces, given an instance $\mathcal{I}$ of $\mathrm{CSP}(\mathbb{A})$, an instance $\mathcal{I}'$ of $\mathrm{CSP}(\mathbb{A})$ that is either inj-irreducible or trivial and that has a solution if, and only if, $\mathcal{I}$ has a solution. It uses the fact that the injective finitisation of an instance $\mathcal{I}$ of $\mathrm{CSP}(\mathbb{A})$ on S is solvable in polynomial time for any set $S \subseteq [\mathcal{V}]^{\ell}$. This follows from the fact that the constraints of the injective finitisation of $\mathcal{I}$ are preserved by a ternary minority by Lemma 3.4 from [32].

We give a brief description of the algorithm. It gradually ensures that the instance is $(2\ell, \max(3\ell, b_{\mathbb{H}}))$-minimal, eq-subdirect, and so that for no distinct variables $u, v \in \mathcal{V}$, it holds that $\mathrm{proj}_{(u,v)}(\mathcal{I}) = \{(a,a) \mid a \in H\}$. If the instance satisfies these assumptions, we consider for every $\mathbf{u} \in [\mathcal{V}]^{\ell}$ every partition $\{E^1_{\mathbf{u}}, \dots, E^s_{\mathbf{u}}\}$ on $\mathrm{proj}_{\mathbf{u}}(\mathcal{I})$ with pp-definable classes satisfying that $E^1_{\mathbf{u}}$ contains no non-deterministic orbit. We find a subset $S \subseteq [\mathcal{V}]^{\ell}$ such that for every $\mathbf{w} \in S$, the set $\{E^1_{\mathbf{w}}, \dots, E^s_{\mathbf{w}}\}$ defined by $E^i_{\mathbf{w}} := \{\mathbf{a} \in H^{\ell} \mid \exists \mathbf{b} \in H^{\ell}\colon (\mathbf{b}, \mathbf{a}) \in \mathrm{proj}_{(\mathbf{u},\mathbf{w})}(\mathcal{I})\}$ for every $i \in [s]$ forms a partition on $\mathrm{proj}_{\mathbf{w}}(\mathcal{I})$ with the property that $E^1_{\mathbf{w}}$ contains no non-deterministic orbit, and such that this partition cannot be extended to any other tuple in $[\mathcal{V}]^{\ell}$. For every such partition, the algorithm checks if the injective finitisation of $\mathcal{I}$ on S has a solution; if not, we constrain every $\mathbf{w} \in S$ to not take any value from $E^1_{\mathbf{w}}$. It is *a priori* unclear that adding these constraints on the one hand yields an instance of $\mathrm{CSP}(\mathbb{A})$, and on the other hand that we do not transform a satisfiable instance into an unsatisfiable one in this way. The following technical result is that, in fact, this does not happen.

▶ **Theorem 14.** *The instance $\mathcal{I}'$ produced by the procedure* InjIrreducibility *in [29, Section 3.1] is an instance of* $\mathrm{CSP}(\mathbb{A})$ *and it has a solution if, and only if, the original instance has a solution. Moreover, $\mathcal{I}'$ is either trivial or inj-irreducible.*

4 Final Arguments for the Complexity Dichotomy

Finally, we briefly sketch the proof of Theorem 3. If the algebraic assumptions in the second item are met, it is known that CSP($\mathbb{A}$) is NP-complete [5]. On the other hand, if I is a binary absorbing subuniverse of H^ℓ and $\mathbb{A}$ either admits an injective linear symmetry or is such that $\mathrm{CSP}_{\mathrm{Inj}}(\mathbb{A})$ has bounded width, then CSP($\mathbb{A}$) is polynomial-time solvable by Theorem 8. It therefore remains to prove that the assumptions in the first item of Theorem 3 (i.e., the clone of polymorphisms of $\mathbb{A}$ being non-trivial) imply that $\mathbb{A}$ falls into the scope of Theorem 8.

By [35], if some polymorphism of $\mathbb{A}$ acts on $\{E, N\}$ in a non-trivial way, then $\mathbb{A}$ either admits an injective linear symmetry or is such that $\mathrm{CSP}_{\mathrm{Inj}}(\mathbb{A})$ has bounded width. Moreover, by results from [30, Proposition 25], the polymorphisms of $\mathbb{A}$ being non-trivial imply that $\mathbb{A}$ contains a binary injection witnessing that I is a binary absorbing subuniverse of H^ℓ. On the other hand, if the action of the polymorphisms of $\mathbb{A}$ on $\{E, N\}$ is trivial, then we can use the theory of smooth approximations [30] to show that the polymorphisms of $\mathbb{A}$ are trivial and $\mathbb{A}$ thus falls into the scope of the second item of Theorem 3.

A Complete Quantitative Axiomatisation of Behavioural Distance of Regular Expressions

Wojciech Różowski
Department of Computer Science, University College London, UK

Abstract

Deterministic automata have been traditionally studied through the point of view of language equivalence, but another perspective is given by the canonical notion of *shortest-distinguishing-word* distance quantifying the of states. Intuitively, the longer the word needed to observe a difference between two states, then the closer their behaviour is. In this paper, we give a sound and complete axiomatisation of *shortest-distinguishing-word* distance between regular languages. Our axiomatisation relies on a recently developed quantitative analogue of equational logic, allowing to manipulate rational-indexed judgements of the form $e \equiv_\varepsilon f$ meaning *term e is approximately equivalent to term f within the error margin of ε*. The technical core of the paper is dedicated to the completeness argument that draws techniques from order theory and Banach spaces to simplify the calculation of the behavioural distance to the point it can be then mimicked by axiomatic reasoning.

1 Introduction

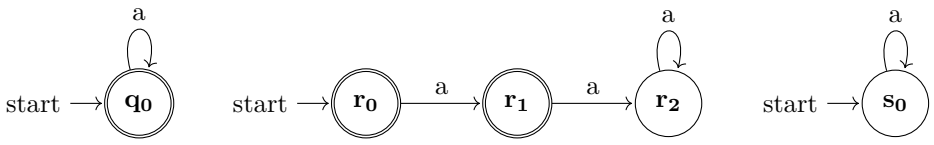
Transition systems have been widely employed to model computational phenomena. In theoretical computer science, it is customary to model computations as transition systems and subsequently reason about their equivalence or similarity. Classical examples include checking language equivalence of deterministic finite automata using Hopcroft and Karp's algorithm [18] or constructing bisimulations between labelled transition systems [25]. Throughout the years, especially in the concurrency theory community, researchers have studied a plethora of different notions of behavioural equivalences and preorders one could impose on a transition system [41]. However, in many practical applications, especially when dealing with probabilistic or quantitative transition systems, asking about such classical notions of equivalence (or similarity) could be too strict, and it might be more reasonable to ask quantitative questions about how far apart the behaviour of the two states is.

A growing line of work on *behavioural distances* [38, 5, 39, 40, 13] answers this problem by equipping state-spaces of transition systems with (pseudo)metric structures quantifying the dissimilarity of states. In such a setting, states at distance zero are not necessarily the same, but rather equivalent with respect to some classical notion of behavioural equivalence. In a nutshell, equipping transition systems with such a notion of distance crucially relies on the possibility of *lifting* the distance between the states to the distance on the observable

behaviour of the transition system. Behavioural distances were originally studied in the context of probabilistic transition systems [16, 39], where observable behaviour is in the form of probability distribution among possible transitions. In such a case, the necessary lifting of distances between states to distances between probability distributions of possible outcomes relies on the famous Kantorovich/Wasserstein liftings, studied traditionally in transportation theory [42]. In general, transition systems can be viewed more abstractly through a well-established category-theoretic framework of coalgebras for an endofunctor [27]. Recent work [5] generalised the Kantorovich/Wassertstein lifting to lifting endofunctors (modelling one-step behaviour of transition systems) from the category of sets and functions to the category of (pseudo)metric spaces and nonexpansive functions, thus allowing equipping a multitude of different kinds of transition systems with a sensible notion of behavioural distance.

Traditionally, besides looking at behavioural equivalence/similarity purely from the algorithmic point of view, one can look at those problems axiomatically, by describing behaviours of transition systems as expressions and by providing formal systems based on (in)equational logic for reasoning about equivalence/similarity of the transition systems described by the expressions. Classic examples include reasoning about language equivalence of Kleene's regular expressions representing deterministic finite automata using inference systems of Salomaa [30] or Kozen [19], or reasoning about bisimilarity of finite-state labelled transition systems through Milner's calculus of finite-state behaviours [24].

In this paper, we are interested in a similar axiomatic point of view, but in the case of behavioural distances. Unfortunately, the classical (in)equational logic cannot be applied here, as it has no way of talking about approximate equivalence. Instead, we rely on the quantitative analogue of equational logic [22], which deals with the statements of the form $e \equiv_\varepsilon f$, intuitively meaning *term e is within the distance of at most $\varepsilon \in \mathbb{Q}^+$ from the term f*. While the existing work [4, 2, 1] looked at quantitative axiomatisations of behavioural distance for probabilistic transition systems calculated through the Kantorovich/Wasserstein lifting, which can be thought of as a special case of the abstract coalgebraic framework relying on lifting endofunctors to the category of pseudometric spaces, the notions of behavioural distance for other kinds of transition systems have not been axiomatised before. It turns out that the approach to completeness used in [2] relies on properties which are not unique to distances obtained through the Kantorovich/Wasserstein lifting and can be employed to give complete axiomatisations of behavioural distances for other kinds of transition systems obtained through the coalgebraic framework [5]. In this paper, as a starting point, we look at one of the simplest instantiations of that abstract framework in the case of deterministic automata, yielding *shortest-distinguishing-word* distance. To illustrate that notion of distance, consider the following three deterministic finite automata:



Neither of the above automata are language equivalent. Their languages are respectively $\{\epsilon, a, aa, aaa, \dots\}$, $\{\epsilon, a\}$ and $\emptyset$. However, one could argue that the behaviour of the middle automaton is closer to the one on the left rather than the one on the right. In particular, languages of the left and middle automaton agree on all of the words of length less than two, while the left and right one disagree on all words. One can make this idea precise, by providing 1-bounded metric $d_{\mathcal{L}} : \mathcal{P}(A^*) \times \mathcal{P}(A^*) \to [0, 1]$ on the set of all formal languages over some fixed alphabet A given by the following formula, where $\lambda \in]0, 1[$ and $L, M \subseteq A^*$:

$$d_{\mathcal{L}}(L,M) = \begin{cases} \lambda^{|w|} & w \text{ is the shortest word that belongs to only one of } L \text{ and } M \\ 0 & \text{if } L = M \end{cases} \tag{1}$$

If we set $\lambda = \frac{1}{2}$, then $d_{\mathcal{L}}(\{\epsilon, a, aa, aaa, \dots\}, \{\epsilon, a\}) = \frac{1}{4}$ and $d_{\mathcal{L}}(\{\epsilon, a, aa, aaa, \dots\}, \emptyset) = 1$, which allows to formally state that the behaviour of the middle automaton is a better approximation of the left one, rather than the right one. Observe, that we excluded $\lambda = 0$ and $\lambda = 1$, as in both cases $d_{\mathcal{L}}$ would become a pseudometric setting all languages to be at distance zero or one. Automata in the example above correspond to the regular expressions a^*, $a + 1$ and 0 respectively. In order to determine the distance between arbitrary regular expressions e and f one would have to construct corresponding deterministic finite automata and calculate (or approximate) the distance between their languages. Instead, as a main contribution of this paper, we present a sound and complete quantitative inference system for reasoning about the shortest-distinguishing-word distance of languages denoted by regular expressions in question. Formally speaking, if $[\![-]\!] : \mathsf{Exp} \to \mathcal{P}(A^*)$ is a function taking regular expressions to their languages, then our inference system satisfies the following:

$$\vdash e \equiv_\varepsilon f \iff d_{\mathcal{L}}([\![e]\!], [\![f]\!]) \leq \varepsilon$$

Although much of our development is grounded in category theory and coalgebra, we spell out all the definitions and results concretely, without the need for specialised language. We organise the paper as follows:

1. In Section 2 we review basic definitions from automata theory and recall the semantics of regular expressions through Brzozowski derivatives [10]. Then, in order to talk about distances, we state basic definitions and properties surrounding (pseudo)metric spaces.
2. In Section 3 we instantiate the framework of coalgebraic behavioural metrics [5] to the concrete case of deterministic automata. We recall the abstract results from [5] in simple automata-theoretic terms.
3. In Section 4 we start by recalling the definitions surrounding the quantitative equational theories [22] from the literature. We then present the axioms of our inference system for the shortest-distinguishing-word distance of regular expressions, give soundness result and provide a discussion about the axioms. The interesting insight is that when relying on quantitative equational theories which contain an infinitary rule capturing the notion of convergence, there is no need for any fixpoint introduction rule. We illustrate this by axiomatically deriving Salomaa's fixpoint rule for regular expressions [30].
4. The key result of our paper is contained in Section 5, where we prove completeness of our inference system. The heart of the argument relies on showing that the behavioural distance of regular expressions can be approximated from above using Kleene's fixpoint theorem, which can be then mimicked through the means of axiomatic reasoning. This part of the paper makes heavy use of the order-theoretic and Banach space structures carried by the sets of pseudometrics over a given set.
5. We conclude in Section 6, review related literature, and sketch directions for future work.

Omitted proofs appear in the full version [28].

2 Preliminaries

We start by recalling basic definitions surrounding deterministic automata, regular expressions and (pseudo)metric spaces from the literature.

Deterministic automata. A deterministic automaton $\mathcal{M}$ with inputs in a finite alphabet A is a pair $(M, \langle o_M, t_M \rangle)$ consisting of a set of states M and a pair of functions $\langle o_M, t_M \rangle$, where $o_M : M \to \{0,1\}$ is the *output* function which determines whether a state m is final ($o_M(m) = 1$) or not ($o_M(m) = 0$), and $t : M \to M^A$ is the *transition* function, which, given an input letter a determines the next state. If the set M of states is finite, then we call an automaton $\mathcal{M}$ a deterministic finite automaton (DFA). We will frequently write m_a to denote $t_M(m)(a)$ and refer to m_a as the derivative of m for the input a. Definition of derivatives can be inductively extended to words $w \in A^*$, by setting $m_\varepsilon = m$ and $m_{aw'} = (m_a)_{w'}$. Note that our definition of deterministic automaton slightly differs from the most common one in the literature, by not explicitly including the initial state. Instead of talking about the language of the automaton, we will talk about the languages of particular states of the automaton. Given a state $m \in M$, we write $L_{\mathcal{M}}(m) \subseteq A^*$ for its language, which is formally defined by $L_{\mathcal{M}}(m) = \{w \in A^* \mid o(m_w) = 1\}$. Given two deterministic automata $(M, \langle o_M, t_M \rangle)$ and $(N, \langle o_N, t_N \rangle)$, a function $h : M \to N$ is a homomorphism if it preserves outputs and input derivatives, that is $o_N(h(m)) = o_M(m)$ and $h(m)_a = h(m_a)$. The set of all languages $\mathcal{P}(A^*)$ over an alphabet A can be made into a deterministic automaton $(\mathcal{P}(A^*), \langle o_L, t_L \rangle)$, where for $l \in \mathcal{P}(A^*)$ the output function is given by $o_L(l) = [\epsilon \in l]$ and for all $a \in A$ the input derivative is defined to be $l_a = \{w \mid aw \in l\}$. This automaton is *final*, that is for any other automaton $\mathcal{M} = (M, \langle o_M, t_M \rangle)$ there exists a unique homomorphism from M to $\mathcal{P}(A^*)$, which is precisely given by the map $L_{\mathcal{M}} : M \to \mathcal{P}(A^*)$ taking each state $m \in S$ to its language. Given a set of states $M' \subseteq M$, we write $\langle M' \rangle_{\mathcal{M}} \subseteq M$ for the smallest set of states reachable from M' through the transition function of the automaton $\mathcal{M}$. Clearly, $(\langle M' \rangle_{\mathcal{M}}, \langle o_M, t_M \rangle)$ is a deterministic automaton. We will abuse the notation and write $\langle M' \rangle_{\mathcal{M}}$ for $(\langle M' \rangle_{\mathcal{M}}, \langle o_M, t_M \rangle)$. The canonical inclusion map $\iota : \langle M' \rangle_{\mathcal{M}} \hookrightarrow M$ given by $\iota(m) = m$ for all $m \in \langle M' \rangle_{\mathcal{M}}$ is a homomorphism from $\langle M' \rangle_{\mathcal{M}}$ to $\mathcal{M}$. In the case of singleton and two-element sets of states, we will simplify the notation and write $\langle m \rangle_{\mathcal{M}}$ and $\langle m, m' \rangle_{\mathcal{M}}$.

Regular expressions. We let e, f range over *regular expressions over* A generated by the following grammar:

$$e, f \in \mathsf{Exp} ::= 0 \mid 1 \mid a \in A \mid e + f \mid e\,;f \mid e^*$$

The standard interpretation of regular expressions $[\![-]\!] : \mathsf{Exp} \to \mathcal{P}(A^*)$ is inductively defined by the following:

$$[\![0]\!] = \emptyset \quad [\![1]\!] = \{\epsilon\} \quad [\![a]\!] = \{a\} \quad [\![e + f]\!] = [\![e]\!] \cup [\![f]\!] \quad [\![e\,;f]\!] = [\![e]\!] \diamond [\![f]\!] \quad [\![e^*]\!] = [\![e]\!]^*$$

We write ϵ for the empty word. Given $L, M \subseteq A^*$, we define $L \diamond M = \{lm \mid l \in L, m \in M\}$, where mere juxtaposition denotes concatenation of words. L^* denotes the *asterate* of the language L defined as $L^* = \bigcup_{i \in \mathbb{N}} L^i$ with $L^0 = \{\epsilon\}$ and $L^{n+1} = L \diamond L^n$.

Brzozowski derivatives. The famous Kleene's theorem states that the formal languages accepted by DFA are in one-to-one correspondence with formal languages definable by regular expressions. One direction of this theorem involves constructing a DFA for an arbitrary regular expression. The most common way is via Thompson construction, ϵ-transition removal and determinisation. Instead, we recall a direct construction due to Brzozowski [10], in which the set Exp of regular expressions is equipped with a structure of deterministic automaton $\mathcal{R} = (\mathsf{Exp}, \langle o_{\mathcal{R}}, t_{\mathcal{R}} \rangle)$ through so-called Brzozowski derivatives [10]. The output derivative $o_{\mathcal{R}} : \mathsf{Exp} \to \{0,1\}$ is defined inductively by the following for $a \in A$ and $e, f \in \mathsf{Exp}$:

$$o_{\mathcal{R}}(0) = 0 \quad o_{\mathcal{R}}(1) = 1 \quad o_{\mathcal{R}}(a) = 0$$
$$o_{\mathcal{R}}(e + f) = o_{\mathcal{R}}(e) \vee o_{\mathcal{R}}(f) \quad o_{\mathcal{R}}(e\,;f) = o_{\mathcal{R}}(e) \wedge o_{\mathcal{R}}(f) \quad o_{\mathcal{R}}(e^*) = 1$$

Similarly, the transition derivative $t_{\mathcal{R}} \in \mathsf{Exp} \to A \to \mathsf{Exp}$ denoted $t_{\mathcal{R}}(e)(a) = (e)_a$ is defined by the following:

$$(0)_a = 0 \quad (1)_a = 0 \quad (a')_a = \begin{cases} 1 & a = a' \\ 0 & a \neq a' \end{cases}$$
$$(e + f)_a = (e)_a + (f)_a \quad (e\,;f)_a = (e_a)\,;f + o_{\mathcal{R}}(e)\,;f \quad (e^*) = (e)_a\,;e^*$$

The canonical language-assigning homomorphism from $\mathcal{R}$ to $\mathcal{L}$, happens to coincide with the semantics map $[\![-]\!]$ assigning a language to each regular expression.

▶ **Lemma 1** ([33, Theorem 3.1.4]). *For all $e \in \mathsf{Exp}$, $[\![e]\!] = L_{\mathcal{R}}(e)$*

Instead of looking at infinite-state automaton defined on the state-space of all regular expressions, we can restrict ourselves to the subautomaton $\langle e \rangle_{\mathcal{R}}$ of $\mathcal{R}$ while obtaining the semantics of e.

▶ **Lemma 2.** *For all $e \in \mathsf{Exp}$, $[\![e]\!] = L_{\langle e \rangle_{\mathcal{R}}}(e)$*

Unfortunately, for an arbitrary regular expression $e \in \mathsf{Exp}$, the automaton $\langle e \rangle_{\mathcal{R}}$ is not guaranteed to have a finite set of states. However, simplifying the transition derivatives by removing duplicates in the expressions in the form $e_1 + \cdots + e_n$, guarantees a finite number of reachable states from any expression. Formally speaking, let $\doteqdot \subseteq \mathsf{Exp} \times \mathsf{Exp}$ be the least congruence relation closed under $(e + f) + g \doteqdot e + (f + g)$ (Associativity), $e + f \doteqdot f + e$ (Commutativity) and $e \doteqdot e + e$ (Idempotence) for all $e, f, g \in \mathsf{Exp}$. We will write $\mathsf{Exp}/\doteqdot$ for the quotient of Exp by the relation $\doteqdot$ and $[-]_{\doteqdot} : \mathsf{Exp} \to \mathsf{Exp}/\doteqdot$ for the canonical map taking each expression $e \in \mathsf{Exp}$ into its equivalence class $[e]_{\doteqdot}$ modulo $\doteqdot$. Because of [27, Proposition 5.8], $\mathsf{Exp}/\doteqdot$ can be equipped with a structure of deterministic automaton $\mathcal{Q} = (\mathsf{Exp}/\doteqdot, \langle o_{\mathcal{Q}}, t_{\mathcal{Q}} \rangle)$, where for all $e \in \mathsf{Exp}, a \in A$, $o_{\mathcal{Q}}([e]_{\doteqdot}) = o_{\mathcal{R}}(e)$ and $([e]_{\doteqdot})_a = [e_a]_{\doteqdot}$, which makes the quotient map $[-]_{\doteqdot} : \mathsf{Exp} \to \mathsf{Exp}/\doteqdot$ into an automaton homomorphism from the Brzozowski automaton $\mathcal{R}$ into $\mathcal{Q}$. This automaton enjoys the following property:

▶ **Lemma 3** ([10, Theorem 4.3]). *For any $e \in \mathsf{Exp}$, the set $\langle e \rangle_{\mathcal{Q}} \subseteq \mathsf{Exp}/\doteqdot$ is finite.*

Through an identical line of reasoning as before (Lemma 2), we can show that:

▶ **Lemma 4.** *For all $e \in \mathsf{Exp}$, $L_{\langle [e]_{\doteqdot} \rangle_{\mathcal{Q}}}([e]_{\doteqdot}) = [\![e]\!]$*

(Pseudo)metric spaces. Let $\top \in]0, \infty]$ be a fixed maximal element. A $\top$-bounded *pseudometric* on a set X (equivalently $\top$-*pseudometric* or even just a *pseudometric* if $\top$ is clear from the context) is a function $d : X \times X \to [0, \top]$ satisfying $d(x, x) = 0$ (*reflexivity*), $d(x, y) = d(y, x)$ (*symmetry*) and $d(x, z) \leq d(x, y) + d(y, z)$ (*triangle inequality*) for all $x, y, z \in X$. If additionally $d(x, y) = 0$ implies $x = y$, d is called a $\top$-*metric*. A *(pseudo)metric* space is a pair (X, d) where X is a set and d is a (pseudo)metric on X. Given pseudometric spaces (X, d_X) and (Y, d_Y), we call a map $f : X \to Y$ *nonexpansive*, if for all $x, x' \in X$, $d_Y(f(x), f(x')) \leq d_X(x, x')$ and an *isometry* if $d_Y(f(x), f(x')) = d_X(x, x')$. A simple example of a pseudometric is the discrete metric which can be defined on any set X as $d_X(x, x) = 0$ for all $x \in X$ and $d(x, y)_X = \top$ for $x, y \in X$ such that $x \neq y$. The set D_X of (pseudo)metrics over some fixed set X can be equipped with a partial order structure given by the pointwise order, i.e. $d \sqsubseteq d' \iff \forall x, x' \in X. d(x, y) \leq d'(x, y)$.

▶ **Lemma 5** ([5, Lemma 3.2]). *$(D_X, \sqsubseteq)$ is a complete lattice. The join of an arbitrary set of pseudometrics $D \subseteq D_X$ is taken pointwise, ie.* $(\sup D)(x,y) = \sup\{d(x,y) \mid d \in D\}$ *for $x, y \in X$. The meet of D is defined to be* $\inf D = \sup\{d \mid d \in D_X, \forall d' \in D, d \sqsubseteq d'\}$.

Crucially for our completeness proof, if we are dealing with descending chains, that is sequences $\{d_i\}_{i\in\mathbb{N}}$, such that $d_i \sqsupseteq d_{i+1}$ for all $i \in \mathbb{N}$, then we can also calculate infima in the pointwise way[1].

▶ **Lemma 6.** *Let $\{d_i\}_{i\in\mathbb{N}}$ be an infinite descending chain in the lattice $(D_X, \sqsubseteq)$ of pseudometrics over some fixed set X. Then* $(\inf\{d_i \mid i \in \mathbb{N}\})(x,y) = \inf\{d_i(x,y) \mid i \in \mathbb{N}\}$ *for any $x, y \in X$.*

Proof. It suffices to argue that $d(x,y) = \inf\{d_i(x,y) \mid i \in \mathbb{N}\}$ is a pseudometric. For reflexivity, observe that $d(x,x) = \inf\{d_i(x,x) \mid i \in \mathbb{N}\} = \inf\{0\} = 0$ for all $x \in X$. For symmetry, we have that $d(x,y) = \inf\{d_i(x,y) \mid i \in \mathbb{N}\} = \inf\{d_i(y,x) \mid i \in \mathbb{N}\} = d(y,x)$ for any $x, y \in X$. The only difficult case is triangle inequality. First, let $i, j \in \mathbb{N}$ and define $k = \max(i,j)$. Since $d_k \sqsubseteq d_i$ and $d_k \sqsubseteq d_j$, we have that $d_k(x,y)+d_k(y,z) \leq d_i(x,y)+d_j(y,z)$. Therefore $\inf\{d_l(x,y) + d_l(y,z) \mid l \in \mathbb{N}\}$ is a lower bound of $d_i(x,y) + d_j(y,z)$ for any $i, j \in \mathbb{N}$ and hence it is below the greatest lower bound, that is $\inf\{d_l(x,y) + d_l(y,z) \mid l \in \mathbb{N}\} \leq \inf\{d_i(x,y) + d_j(y,z) \mid i, j \in \mathbb{N}\}$. We can use that property to show the following $d(x,y) = \inf\{d_i(z,y) \mid i \in \mathbb{N}\} \leq \inf\{d_i(x,y) + d_i(y,z) \mid i \in \mathbb{N}\} \leq \inf\{d_i(x,y) + d_j(y,z) \mid i, j \in \mathbb{N}\} = \inf\{d_i(x,y) \mid i \in \mathbb{N}\} + \inf\{d_j(y,z) \mid j \in \mathbb{N}\} = d(x,y) + d(y,z)$, which completes the proof. ◀

Additionally, the set of pseudometrics can be equipped with a norm. We write $\overline{\mathbb{R}} = [-\infty, \infty]$ for the set of extended reals. For any set X, the set of functions $\overline{\mathbb{R}}^{X\times X}$, which is a superset of D_X, can be seen as a Banach space [26] (complete normed vector space) by means of the sup-norm $\|d\| = \sup_{x,y\in X} |d(x,y)|$. This structure will implicitly underly some of the claims used as intermediate steps in the proof of completeness.

3 Behavioural distance

We now instantiate the abstract coalgebraic framework [5] to the case of deterministic automata relying on the lifting described in [5, Example 5.33]. We concretise the generic results from that paper and spell them in simple automata-theoretic terms.

Lifting pseudometrics. Let $\mathcal{M} = (M, \langle o_M, t_M\rangle)$ be a deterministic automaton. Its one-step observable behaviour (after applying the output and transition derivatives) can be seen as pairs of the type $\{0,1\} \times M^A$, where the first component determines whether the given state is accepting or not and the second one gives successor state for each letter from the input alphabet. Let's say we have two such observations $\langle o_1, f_1\rangle, \langle o_2, f_2\rangle \in \{0,1\} \times M^A$. If we had had some notion of a distance defined on the state-space of our automaton, or speaking more formally a 1-pseudometric $d : M \times M \to [0,1]$, then we can *lift* this notion of distance, to a distance on observations, given by the following:

$$d_{\{0,1\}\times M^A}(\langle o_1, f_1\rangle, \langle o_2, f_2\rangle) = \max\{d_2(o_1,o_2), \lambda \cdot \max_{a\in A} d(f_1(a), f_2(a))\} \qquad \lambda \in]0,1[$$

[1] Lemma 6 is one of the intermediate results used in the proof of [2, Lemma 5.6] that was communicated to us by the authors of [2]. As this result was excluded in the mentioned paper, we incorporated it along with its proof for the sake of completeness.

The definition above involves d_2, the discrete metric on the set $\{0,1\}$. One can observe that $d_{\{0,1\}\times M^A}$ is again a 1-pseudometric, but this time defined on the set $\{0,1\}\times M^A$ instead. We now move on to showing how one could use this lifting in order to equip a state-space of automaton $\mathcal{M}$ with a sensible notion of behavioural pseudometric.

Behavioural pseudometric. If one gave us a 1-metric $d : M \times M \to [0,1]$ on the state-space of the automaton, we could use our lifting to produce a new pseudometric $\Phi_{\mathcal{M}}(d) : M \times M \to [0,1]$ on the same set, which would calculate a distance between an arbitrary pair of states by first applying the output and transition derivatives to obtain a pair of observations and then by calculating the distance between them using the aforementioned lifting of pseudometric d to the pseudometric defined on the set $\{0,1\}\times M^A$. Formally speaking, define a map $\Phi_{\mathcal{M}} : D_M \to D_M$ on the lattice of 1-pseudometrics on M given by the following:

$$\Phi_{\mathcal{M}}(d)(m,m') = \max\{d_2(o_M(m), o_M(m')), \lambda \cdot \max_{a\in A} d(m_a, m'_a)\} \qquad \lambda \in]0,1[$$

The construction above only tells us how to construct new pseudometrics on the state-space of the automaton out of existing ones, but does not give one to start with. It turns out, that the map $\Phi_{\mathcal{M}}$ is a monotone mapping on the lattice of 1-psuedometrics on the set M [5, Lemma 6.1]. Because of that, one can use the Knaster-Tarski fixpoint theorem [36] and construct its least fixed point, explicitly given by $d_{\mathcal{M}} = \inf\{d \mid d \in D_M \wedge \Phi_{\mathcal{M}}(d) \sqsubseteq d\}$. Pseudometrics, which are fixpoints of $\Phi_{\mathcal{M}}$ intuitively interact well with the automaton structure, as they satisfy the property that the distance between two states is the same as the distance between their observable behaviour calculated using the lifting. Taking the least such pseudometric satisfies several desirable properties [5] and thus we will call $d_{\mathcal{M}}$ a behavioural pseudometric on the automaton $\mathcal{M}$. First of all, preserving automaton transitions also preserves behavioural distances.

▶ **Proposition 7.** *Let $\mathcal{M} = (M, \langle o_M, t_M\rangle)$ and $\mathcal{N} = (N, \langle o_N, t_N\rangle)$ be deterministic automata. If $h : M \to N$ is a homomorphism, then it is also an isometric mapping between pseudometric spaces $(M, d_{\mathcal{M}})$ and $(N, d_{\mathcal{N}})$.*

If we look at the final automaton on the set of all formal languages over a fixed finite alphabet A, then one can easily verify that the behavioural distance given by the least fixpoint construction precisely corresponds to the Equation (1) defining the shortest-distinguishing-word distance we stated in Section 1. In general, states of an arbitrary deterministic automaton characterised by the behavioural pseudometric to be in distance zero are language equivalent. When we look at $d_{\mathcal{L}}$ defined on the states of the final automaton, whose state-space consists of formal languages, then the language equivalence corresponds to the equality of states. In other words $d_{\mathcal{L}}$ becomes a metric space.

▶ **Lemma 8.** *Let $\mathcal{M} = (M, \langle o_M, t_M\rangle)$ be an arbitrary deterministic automaton and let $\mathcal{L} = (\mathcal{P}(A^*), \langle o_L, t_L\rangle)$ be a deterministic automaton structure on the set of all languages over an alphabet A.*

1. *$(\mathcal{P}(A^*), d_{\mathcal{L}})$ is a metric space.*
2. *For any $m, m' \in M$, $d_{\mathcal{M}}(m,m') = 0 \iff L_{\mathcal{M}}(m) = L_{\mathcal{M}}(m')$.*

4 Quantitative Axiomatisation

In order to provide a quantitative inference system for reasoning about the behavioural distance of languages denoted by regular expressions, we first recall the definition of quantitative equational theories from the existing literature [22, 2] following the notational conventions

from [2]. We then present our axiomatisation and demonstrate its soundness. The interesting thing about our axiomatisation is the lack of any fixpoint introduction rule. We show that in the case of quantitative analogue of equational logic [22] containing the infinitary rule capturing the notion of convergence, we can use our axioms to derive Salomaa's fixpoint rule from his axiomatisation of language equivalence of regular expressions [30].

Quantitative equational theories. Let Σ be an algebraic signature (in the sense of universal algebra [11]) consisting of operation symbols $f_n \in \Sigma$ of arity $n \in \mathbb{N}$. If we write X for the countable set of *metavariables*, then $\mathbb{T}(\Sigma, X)$ denotes a set of freely generated terms over X built from the signature Σ. As a notational convention, we will use letters $t, s, u, \ldots \in \mathbb{T}(\Sigma, X)$ to denote terms. By a *substitution* we mean a function of the type $\sigma\colon X \to \mathbb{T}(\Sigma, X)$ allowing to replace metavariables with terms. Each substitution can be inductively extended to terms in a unique way by setting $\sigma(f(t_1, \ldots, t_n)) = f(\sigma(t_1), \ldots, \sigma(t_n))$ for each operation symbol $f_n \in \Sigma$ from the signature. We will write $\mathcal{S}(\Sigma)$ for the set of all substitutions. Given two terms $t, s \in \mathbb{T}(\Sigma, X)$ and a nonnegative rational number $\varepsilon \in \mathbb{Q}^+$ denoting the distance between the terms, we call $t \equiv_\varepsilon s$ a *quantitative equation (of type Σ)*. Notation-wise, we will write $\mathcal{E}(\Sigma)$ to denote the set of all quantitative equations (of type Σ) and we will use the capital Greek letters $\Gamma, \Theta, \ldots \subseteq \mathcal{E}(\Sigma)$ to denote the subsets of $\mathcal{E}(\Sigma)$. By a *deducibility relation* we mean a binary relation denoted $\vdash \subseteq \mathcal{P}(\mathcal{E}(\Sigma)) \times \mathcal{E}(\Sigma)$. Similarly, to the classical equational logic, we will use the following notational shorthands $\Gamma \vdash t \equiv_\varepsilon s \iff (\Gamma, t \equiv_\varepsilon s) \in \vdash$ and $\vdash t \equiv_\varepsilon s \iff \emptyset \vdash t \equiv_\varepsilon s$. Furthermore, following the usual notational conventions, we will write $\Gamma \vdash \Theta$ as a shorthand for the situation when $\Gamma \vdash t \equiv_\varepsilon s$ holds for all $t \equiv_\varepsilon s \in \Theta$. To call $\vdash$ a *quantitative deduction system (of type Σ)* it needs to satisfy the following rules of inference:

(Refl) $\vdash t \equiv_0 t$,

(Symm) $\{t \equiv_\varepsilon s\} \vdash s \equiv_\varepsilon t$,

(Triang) $\{t \equiv_\varepsilon u, u \equiv_{\varepsilon'} s\} \vdash t \equiv_{\varepsilon+\varepsilon'} s$,

(Max) $\{t \equiv_\varepsilon s\} \vdash t \equiv_{\varepsilon+\varepsilon'} s$, for all $\varepsilon' > 0$,

(Cont) $\{t \equiv_{\varepsilon'} s \mid \varepsilon' > \varepsilon\} \vdash t \equiv_\varepsilon s$,

(NExp) $\{t_1 \equiv_\varepsilon s_1, \ldots, t_n \equiv_\varepsilon s_n\} \vdash f(t_1, \ldots, t_n) \equiv_\varepsilon f(s_1, \ldots, s_n)$, for all $f_n \in \Sigma$,

(Subst) If $\Gamma \vdash t \equiv_\varepsilon s$, then $\sigma(\Gamma) \vdash \sigma(t) \equiv_\varepsilon \sigma(s)$, for all $\sigma \in \mathcal{S}(\Sigma)$,

(Cut) If $\Gamma \vdash \Theta$ and $\Theta \vdash t \equiv_\varepsilon s$, then $\Gamma \vdash t \equiv_\varepsilon s$,

(Assum) If $t \equiv_\varepsilon s \in \Gamma$, then $\Gamma \vdash t \equiv_\varepsilon s$.

where $\sigma(\Gamma) = \{\sigma(t) \equiv_\varepsilon \sigma(s) \mid t \equiv_\varepsilon s \in \Gamma\}$. Finally, by a *quantitative equational theory* we mean a set $\mathcal{U}$ of universally quantified *quantitative inferences* $\{t_1 \equiv_{\varepsilon_1} s_1, \ldots, t_n \equiv_{\varepsilon_n} s_n\} \vdash t \equiv_\varepsilon s$, with *finitely many premises*, closed under $\vdash$-derivability.

Quantitative algebras. Quantitative equational theories lie on the syntactic part of the picture. On the semantic side, we have their models called *quantitative algebras*, defined as follows.

▶ **Definition 9** ([22, Definition 3.1])**.** *A quantitative algebra is a tuple $\mathcal{A} = (A, \Sigma^{\mathcal{A}}, d^{\mathcal{A}})$, such that $(A, \Sigma^{\mathcal{A}})$ is an algebra for the signature Σ and $(A, d^{\mathcal{A}})$ is an ∞-pseudometric such that for all operation symbols $f_n \in \Sigma$, for all $1 \leq i \leq n$, $a_i, b_i \in A$, $d^{\mathcal{A}}(a_i, b_i) \leq \varepsilon$ implies $d^{\mathcal{A}}(f^{\mathcal{A}}(a_1, \ldots, a_n), f^{\mathcal{A}}(b_1, \ldots, b_n)) \leq \varepsilon$.*

Consider a quantitative algebra $\mathcal{A} = (A, \Sigma^{\mathcal{A}}, d^{\mathcal{A}})$. Given an assignment $\iota\colon X \to A$ of meta-variables from X to elements of carrier A, one can inductively extend it to Σ-terms $t \in \mathbb{T}(\Sigma, X)$ in a unique way. We will abuse the notation and just write $\iota(t)$ for the interpretation of the term t in quantitative algebra $\mathcal{A}$. We will say that $\mathcal{A}$ *satisfies* the quantitative inference $\Gamma \vdash t \equiv_\varepsilon s$, written $\Gamma \models_{\mathcal{A}} t \equiv_\varepsilon s$, if for any assignment of the meta-variables $\iota\colon X \to A$ it is the case that for all $t' \equiv_{\varepsilon'} s' \in \Gamma$ we have that $d^{\mathcal{A}}(\iota(t'), \iota(s')) \leq \varepsilon'$ implies $d^{\mathcal{A}}(\iota(t), \iota(s)) \leq \varepsilon$. Finally, we say that a quantitative algebra $\mathcal{A}$ *satisfies* (or is a *model* of) the quantitative theory $\mathcal{U}$, if whenever $\Gamma \vdash t \equiv_\varepsilon s \in \mathcal{U}$, then $\Gamma \models_{\mathcal{A}} t \equiv_\varepsilon s$.

Quantitative algebra of regular expressions. From now on, let's focus on the signature $\Sigma = \{0_0, 1_0, +_2, ;_2, (-)^*{}_1\} \cup \{a_0 \mid a \in A\}$, where A is a finite alphabet. This signature consists of all operations of regular expressions. We can easily interpret all those operations in the set Exp of all regular expressions, using trivial interpretation functions eg. $+^{\mathcal{B}}(e, f) = e + f$, which interpret the operations by simply constructing the appropriate terms. Formally speaking, we can do this because the set Exp is the carrier of initial algebra [11] (free algebra over the empty set of generators) for the signature Σ.

To make this algebra into a quantitative algebra, we first equip the set Exp with a ∞-pseudometric, given by $d^{\mathcal{B}}(e, f) = d_{\mathcal{L}}([\![e]\!], [\![f]\!])$ for all $e, f \in \mathsf{Exp}$. Recall that $d_{\mathcal{L}}$ used in the definition above is a behavioural pseudometric on the final deterministic automaton carried by the set $\mathcal{P}(A^*)$ of all formal languages over an alphabet A. In other words, we define the distance between arbitrary expressions e and f to be the distance between formal languages $[\![e]\!]$ and $[\![f]\!]$ calculated through the shortest-distinguishing-word metric. It turns out, that in such a situation all the interpretation functions of Σ-algebra structure on Exp are non-expansive with respect to to the pseudometric defined above. In other words, we have that:

▶ **Lemma 10.** *$\mathcal{B} = (\mathsf{Exp}, \Sigma^{\mathcal{B}}, d^{\mathcal{B}})$ is a quantitative algebra.*

Axiomatisation. In order to talk about the quantitative algebra $\mathcal{B}$ of the behavioural distance of regular expressions in an axiomatic way, we introduce the quantitative equational theory REG (Figure 1). The first group of axioms capture properties of the nondeterministic

	Nondeterministic choice		**Sequential composition**
(SL1)	$\vdash e + e \equiv_0 e$,	(1S)	$\vdash 1\,;e \equiv_0 e$,
(SL2)	$\vdash e + f \equiv_0 f + e$,	(S)	$\vdash e\,;(f\,;g) \equiv_0 (e\,;f)\,;g$,
(SL3)	$\vdash (e + f) + g \equiv_0 e + (f + g)$,	(S1)	$\vdash e\,;1 \equiv_0 e$,
(SL4)	$\vdash e + 0 \equiv_0 e$,	(0S)	$\vdash 0\,;e \equiv_0 0$,
(SL5)	$\{e \equiv_\varepsilon g, f \equiv_{\varepsilon'} h\}$	(S0)	$\vdash e\,;0 \equiv_0 0$,
	$\vdash e + f \equiv_{\max(\varepsilon,\varepsilon')} g + h$,	(D1)	$\vdash e\,;(f + g) \equiv_0 e\,;f + e\,;g$,
		(D2)	$\vdash (e + f)\,;g \equiv_0 e\,;g + f\,;g$,
	Loops		**Behavioural pseudometric**
(Unroll)	$\vdash e^* \equiv_0 e\,;e^* + 1$,	(Top)	$\vdash e \equiv_1 f$,
(Tight)	$\vdash (e + 1)^* \equiv_0 e^*$,	(λ-Pref)	$\{e \equiv_\varepsilon f\} \vdash a\,;e \equiv_{\varepsilon'} a\,;f$, for $\varepsilon' \geq \lambda \cdot \varepsilon$

Figure 1 Axioms of the quantitative equational theory REG for $e, f, g \in \mathsf{Exp}$ and $a \in A$.

choice operator $+$ (SL1-SL5). The first four axioms (SL1-SL4) are the usual laws of semilattices with bottom element 0. (SL5) is a quantitative axiom allowing one to reason about distances between sums of expressions in terms of distances between expressions being summed. Moreover, (SL1-SL5) are axioms of so-called *Quantitative Semilattices with zero*, which

have been shown to axiomatise the Hausdorff metric [22]. The sequencing axioms (1S), (S1), (S) state that the set Exp of regular expressions has the structure of a monoid (with neutral element 1) with absorbent element 0 (0S), (S0). Additionally, (D1-D2) talk about interaction of the nondeterministic choice operator + with sequential composition. The loop axioms (Unroll) and (Tight) are directly inherited from Salomaa's axiomatisation of language equivalence of regular expressions [30]. (Unroll) axiom associates loops with their intuitive behaviour of choosing, at each step, between successful termination and executing the loop body once. (Tight) states that the loop whose body might instantly terminate, causing the next loop iteration to be executed immediately is provably equivalent to a different loop, whose body does not contain immediate termination. The last remaining group are behavioural pseudometric axioms. (Top) states that any two expressions are at most in distance one from each other. Finally, (λ-Pref) captures the fact that prepending the same letter to arbitrary expressions shrinks the distance between them by the factor of $\lambda \in]0,1[$ (used in the definition of $d^{\mathcal{B}}$). This axiom is adapted from the axiomatisation of discounted probabilistic bisimilarity distance [2].

Through a simple induction on the length of derivation, one can verify that indeed $\mathcal{B}$ is a model of the quantitative theory REG.

▶ **Theorem 11.** *(Soundness) The quantitative algebra $\mathcal{B} = (\mathsf{Exp}, \Sigma^{\mathcal{B}}, d^{\mathcal{B}})$ is a model of the quantitative theory* REG. *In other words, for any $e, f \in \mathsf{Exp}$ and $\varepsilon \in \mathbb{Q}^+$, if $\Gamma \vdash e \equiv_\varepsilon f \in \mathsf{REG}$, then $\Gamma \models_{\mathcal{B}} e \equiv_\varepsilon f$*

Proof. By the structural induction on the judgement $\Gamma \vdash e \equiv_\varepsilon f \in \mathsf{REG}$. (Subst), (Cut) and (Assum) deduction rules from classical logic hold immediately. The soundness of (Refl), (Symm), (Triang), (Cont) and (Max) follows from the fact that $d^{\mathcal{B}}$ is a pseudometric. (NExp) follows from the fact that interpretations of symbols from the algebraic signature are nonexpansive (Lemma 10). Recall that $d^{\mathcal{B}} = d_{\mathcal{L}} \circ (\llbracket - \rrbracket \times \llbracket - \rrbracket)$. The soundness of (Top) follows from the fact that $d_{\mathcal{L}}$ is a 1-pseudometric. Additionally, for all axioms in the form $\vdash e \equiv_0 f$ it suffices to show that $\llbracket e \rrbracket = \llbracket f \rrbracket$. (SL1), (SL2), (SL3), (SL4), (1S), (S), (S1), (0S), (S0), (D1), (D2), (Unroll) and (Tight) are taken from Salomaa's axiomatisation of language equivalence of regular expressions [30] and thus both sides of those equations denote the same formal languages [43, Theorem 5.2]. For (λ-Pref) assume that the premise is satisfied in the model, that is $d_{\mathcal{L}}(\llbracket e \rrbracket, \llbracket f \rrbracket) \leq \varepsilon$. Let $\varepsilon' \geq \lambda \cdot \varepsilon$. We show the following:

$$
\begin{aligned}
d^{\mathcal{B}}(a\,;e, a\,;f) &= d_{\mathcal{L}}(\llbracket a\,;e \rrbracket, \llbracket a\,;f \rrbracket) && \text{(Def. of } d^{\mathcal{B}}\text{)} \\
&= \Phi_{\mathcal{L}}(d_L)(\llbracket a\,;e \rrbracket, \llbracket a\,;f \rrbracket) && \text{(d_L is a fixpoint of } \Phi_{\mathcal{L}}\text{)} \\
&= \max\{d_2(o_{\mathcal{L}}(a\,;e), o_{\mathcal{L}}(a\,;f)), \lambda \cdot \max_{a' \in A} d_{\mathcal{L}}(\llbracket a\,;e \rrbracket_{a'}, \llbracket a\,;f \rrbracket_{a'})\} \\
&= \lambda \cdot d_{\mathcal{L}}(\llbracket e \rrbracket, \llbracket f \rrbracket) && \text{(Def. of final automaton)} \\
&\leq \lambda \cdot \epsilon \leq \varepsilon' && \text{(Assumptions)}
\end{aligned}
$$

Finally, (SL5) is derivable from other axioms[2]. If $\varepsilon = \max(\varepsilon, \varepsilon')$ then $\{e \equiv_\epsilon g\} \vdash e \equiv_{\max(\varepsilon,\varepsilon')} g$ holds by (Assum). If $\epsilon < \max(\varepsilon, \varepsilon')$, then we can derive the quantitative judgement above using (Max). By a similar line of reasoning, we can show that $\{f \equiv_{\epsilon'} h\} \vdash f \equiv_{\max(\varepsilon,\varepsilon')} h$. Finally, using (Cut) and (NExp), we can show that $\{e \equiv_\varepsilon g, f \equiv_{\varepsilon'} h\} \vdash e + f \equiv_{\max(\varepsilon,\varepsilon')} g + h$ as desired. ◀

[2] We included (SL5) as an axiom to highlight the similarity of our inference system with axiomatisations of language equivalence of regular expressions [30, 19] containing the axioms of semilattices with bottom. In the previous work [22], (SL1 – SL5) are precisely the axioms of *Quantitative Semilattices with zero* axiomatising the Hausdorff distance.

We now revisit the example from Section 1. Recall that states marked as initial of the left and middle automata can be respectively represented as a^* and $a+1$. The shortest word distinguishing languages representing those expressions is aa. If we fix $\lambda = \frac{1}{2}$, then $d_{\mathcal{L}}([\![a^*]\!], [\![a+1]\!]) = \frac{1}{4} = \left(\frac{1}{2}\right)^{|aa|}$. We can derive this distance through the means of axiomatic reasoning using the quantitative equational theory REG in the following way:

▶ **Example 12.**

$$\begin{aligned}
\vdash a^* &\equiv_1 0 && \text{(Top)}\\
\vdash a\,;a^* &\equiv_{\frac{1}{2}} a\,;0 && (\lambda\text{-Pref})\\
\vdash a\,;a^*+1 &\equiv_{\frac{1}{2}} a\,;0+1 && (\vdash 1 \equiv_0 1 \text{ and SL5})\\
\vdash a^* &\equiv_{\frac{1}{2}} 1 && \text{(Triang, Unroll, S0 and SL4)}\\
\vdash a\,;a^* &\equiv_{\frac{1}{4}} a\,;1 && (\lambda\text{-Pref})\\
\vdash a\,;a^*+1 &\equiv_{\frac{1}{4}} a\,;1+1 && (\vdash 1 \equiv_0 1 \text{ and SL5})\\
\vdash a^* &\equiv_{\frac{1}{4}} a+1 && \text{(Triang, Unroll and S1)}
\end{aligned}$$

(The lack of) the fixpoint axiom. Traditionally, completeness of inference systems for behavioural equivalence of languages of expressions featuring recursive constructs such as Kleene star or μ-recursion [24] rely crucially on fixpoint introduction rules. Those allow showing that an expression is provably equivalent to a looping construct if it exhibits some form of self-similarity, typically subject to productivity constraints. As an illustration, Salomaa's axiomatisation of language equivalence of regular expressions incorporates the following inference rule:

$$\frac{g \equiv e\,;g+f \qquad \epsilon \notin [\![e]\!]}{g \equiv e^*\,;f} \tag{2}$$

The side condition on the right states that the loop body is *productive*, that is a deterministic automaton corresponding to an expression e cannot immediately reach acceptance without performing any transitions. This is simply equivalent to the language $[\![e]\!]$ not containing the empty word. It would be reasonable for one to expect REG to contain a similar rule to be complete, especially since it should be able to prove language equivalence of regular expressions (by proving that they are in distance zero from each other). Furthermore, all axioms of Salomaa except Equation (2) are contained in REG as rules for distance zero.

It turns out that in the presence of the infinitary continuity (Cont) rule of quantitative deduction systems and the (λ-Pref) axiom of REG, the Salomaa's inference rule (Equation (2)) becomes a derivable fact for distance zero. First of all, one can show that (λ-Pref) can be generalised from prepending single letters to prepending any regular expression satisfying the side condition from Equation (2).

▶ **Lemma 13.** *Let $e, f, g \in \mathsf{Exp}$, such that $\epsilon \notin [\![e]\!]$. Then, $\{f \equiv_\varepsilon g\} \vdash e\,;f \equiv_{\varepsilon'} e\,;g$ is derivable using the axioms of REG for all $\varepsilon' \geq \lambda \cdot \varepsilon$.*

With the above lemma in hand, one can inductively show that if $g \equiv_0 e\,;g+f$ and $\epsilon \notin [\![e]\!]$, then g gets arbitrarily close to $e^*\,;f$. Intuitively, the more we unroll the loop in $e^*\,;f$ using (Unroll) and the more we unroll the definition of g, then the closer both expressions become.

▶ **Lemma 14.** *Let $e, f, g \in \mathsf{Exp}$, such that $\epsilon \notin [\![e]\!]$ and let $n \in \mathbb{N}$. Then, $\{g \equiv_0 e\,;\, g + f\} \vdash g \equiv_\varepsilon e^*\,;\, f$ is derivable using the axioms of* REG *for all $\varepsilon \geq \lambda^n$.*

Having the result above, we can now use the infinitary (Cont) rule capturing the limiting property of decreasing chain of overapproximations to the distance and show the derivability of Salomaa's inference rule.

▶ **Lemma 15.** *Let $e, f, g \in \mathsf{Exp}$, such that $\epsilon \notin [\![e]\!]$. Then, $\{g \equiv_0 e\,;\, g + f\} \vdash g \equiv_0 e^*\,;\, f$ is derivable using the axioms of REG.*

Proof. To deduce that $\vdash g \equiv_0 e^*\,;\, f$ using (Cont) it suffices to show that $\vdash g \equiv_\varepsilon e^*\,;\, f$ for all $\varepsilon > 0$. To do so, pick an arbitrary $\varepsilon > 0$ and let $N = \lceil \log_\lambda \varepsilon \rceil$. Observe that $\lambda^N = \lambda^{\lceil \log_\lambda \varepsilon \rceil} \leq \lambda^{\log_\lambda \varepsilon} = \varepsilon$. Because of Lemma 14 we have that $\vdash g \equiv_\varepsilon e^*\,;\, f$, which completes the proof. ◀

5 Completeness

We now move on to the central result of this paper, which is the completeness of REG with respect to the shortest-distinguishing-word metric on languages denoting regular expressions. We use the strategy from the proof of completeness of quantitative axiomatisation of probabilistic bisimilarity distance [2]. It turns out that the results from [2] rely on properties that are not unique to the Kantorovich/Wassertstein lifting and can be also established for instances of the abstract coalgebraic framework [5].

The heart of our argument relies on the fact that the distance between languages denoting regular expressions can be calculated in a simpler way than applying the Knaster-Tarski fixpoint theorem while looking at the infinite-state final automaton of all formal languages over some fixed alphabet. In particular, regular expressions denote the behaviour of finite-state deterministic automata. Since automata homomorphisms are non-expansive mappings, the distance between languages $[\![e]\!]$ and $[\![f]\!]$ of some arbitrary regular expressions $e, f \in \mathsf{Exp}$ is the same as the distance between states in some DFA whose languages corresponds to $[\![e]\!]$ and $[\![f]\!]$. To be precise, we will look at the finite subautomaton $\langle [e]_{\doteq}, [f]_{\doteq} \rangle_{\mathcal{Q}}$ of the $\doteq$ quotient of the Brzozowski automaton. The reason we care about deterministic finite automata is that it turns out that one can calculate the behavioural distance between two states through iterative approximation from above, which can be also derived axiomatically using the (Cont) rule of quantitative deduction systems. We start by showing how this simplification works and then we move on to establishing completeness.

Behavioural distance on finite-state automata. Consider a deterministic automaton $\mathcal{M} = (M, \langle o_M, t_M \rangle)$. The least fixpoint of a monotone endomap $\Phi_{\mathcal{M}} : D_M \to D_M$ on the complete lattice of 1-pseudometrics on the set M results in $d_{\mathcal{M}}$, which is a behavioural pseudometric on the states of the automaton $\mathcal{M}$. It is noteworthy that $\Phi_{\mathcal{M}}$ exhibits two generic properties. Firstly, $\Phi_{\mathcal{M}}$ behaves well within the Banach space structure defined by the supremum norm.

▶ **Lemma 16.** *$\Phi_{\mathcal{M}} : D_M \to D_M$ is nonexpansive with respect to the supremum norm. In other words, for all $d, d' \in D_M$ we have that $\|\Phi_{\mathcal{M}}(d') - \Phi_{\mathcal{M}}(d)\| \leq \|d' - d\|$.*

Proof. We can safely assume that $d \sqsubseteq d'$, as other case will be symmetric. It sufices to show that for all $m, m' \in M$, $\Phi_{\mathcal{M}}(d')(m, m') - \Phi_{\mathcal{M}}(d)(m, m') \leq \|d' - d\|$. First, let's consider the case when $o_M(m) \neq o_M(m')$ and hence $d_2(m, m') = 1$. In such a scenario, it holds that $\Phi_{\mathcal{M}}(d')(m, m') - \Phi_{\mathcal{M}}(d)(m, m') = 0 \leq \|d' - d\|$. From now on, we will assume that $o_M(m) = o_M(m)$ and hence $d_2(m, m') = 0$. We have the following

$$\begin{aligned}
\Phi_{\mathcal{M}}(d')(m,m') - \Phi_{\mathcal{M}}(d)(m,m') &= \lambda \cdot \max_{a\in A} d'(m_a,m'_a) - \lambda \cdot \max_{a\in A} d(m_a,m'_a) \\
&= \lambda \cdot \left(\max_{a\in A} d'(m_a,m'_a) - \max_{a\in A} d(m_a,m'_a) \right) \\
&\leq \lambda \cdot \left(\max_{a\in A} \{d'(m_a,m'_a) - d(m_a,m'_a)\} \right) \\
&\leq \lambda \cdot \sup_{n,n'\in M} \{d'(n,n') - d(n,n')\} \\
&= \lambda \cdot \|d' - d\| \leq \|d' - d\|
\end{aligned}$$ ◀

Secondly, it turns out that $\Phi_{\mathcal{M}}$ has only one fixpoint. This means that if we want to calculate $d_{\mathcal{M}}$ it suffices to look at any fixpoint of $\Phi_{\mathcal{M}}$. This will enable a simpler characterisation, than the one given by the Knaster-Tarski fixpoint theorem.

▶ **Lemma 17.** *$\Phi_{\mathcal{M}}$ has a unique fixed point.*

Proof. Let $d, d' \in D_M$ be two fixed points of $\Phi_{\mathcal{M}}$, that is $\Phi_{\mathcal{M}}(d) = d$ and $\Phi_{\mathcal{M}}(d') = d'$. We can safely assume that $d \sqsubseteq d'$, as the other case is symmetric. We wish to show that $d = d'$ and to do so we will use proof by contradiction.

Assume that $d \neq d'$, and hence there exist $m, m' \in M$, such that $d(m,m') < d'(m,m')$ and $\|d' - d\| = d'(m,m') - d(m,m') \neq 0$. First, consider the case when $o_M(m) \neq o_M(m')$. In such a case both $d(m,m')$ and $d(m,m')$ are equal to 1 and hence $\|d' - d\| = 0$, which leads to contradiction. From now, we can safely assume that $o_M(m) = o_M(m')$. Through an identical line of reasoning to the proof of Lemma 16, we can show that $\|\Phi_{\mathcal{M}}(d') - \Phi_{\mathcal{M}}(d)\| \leq \lambda \cdot \|d' - d\|$. Since both d and d' are fixed points, this would mean that $\|d' - d\| \leq \lambda \cdot \|d' - d\|$. Since $\lambda \in]0,1[$, this would imply that $\|d' - d\| = 0$ leading again to contradiction. ◀

In particular, we will rely on the characterisation given by the Kleene fixpoint theorem [31, Theorem 2.8.5], which allows to obtain the greatest fixpoint of an endofunction on the lattice as the infimum of the decreasing sequence of finer approximations obtained by repeatedly applying the function to the top element of the lattice.

▶ **Theorem 18** (Kleene fixpoint theorem)**.** *Let $(X, \sqsubseteq)$ be a complete lattice with a top element $\top$ and $f : X \to X$ an endofunction that is ω-cocontinuous or in other words for any decreasing chain $\{x_i\}_{i\in\mathbb{N}}$ it holds that $\inf_{i\in\mathbb{N}}\{f(x_i)\} = f\left(\inf_{i\in\mathbb{N}} x_i\right)$. Then, f possesses a greatest fixpoint, given by $\mathrm{gfp}(f) = \inf_{i\in\mathbb{N}}\{f^{(i)}(\top)\}$ where $f^{(n)}$ denotes n-fold self-composition of f given inductively by $f^{(0)}(x) = x$ and $f^{(n+1)}(x) = f^{(n+1)}(f(x))$ for all $x \in X$.*

The theorem above requires the endomap to be ω-cocontinuous. Luckily, it is the case for $\Phi_{\mathcal{M}}$ if we restrict our attention to DFA. To show that, we directly follow the line of reasoning from [2, Lemma 5.6] generalising the similar line of reasoning for ω-continuity from [37, Theorem 1]. First, using Lemma 6 we show that decreasing chains of pseudometrics over a finite set converge to their infimum. That result is a minor re-adaptation of [37, Theorem 1] implicitly used in [2, Lemma 5.6].

▶ **Lemma 19.** *Let $\{d_i\}_{i\in\mathbb{N}}$ be an infinite descending chain in the lattice $(D_X, \sqsubseteq)$, where X is a finite set. The sequence $\{d_i\}_{i\in\mathbb{N}}$ converges (in the sense of convergence in the Banach space) to $d(x,y) = \inf_{i\in\mathbb{N}} d_i(x,y)$.*

Proof. Let $\varepsilon > 0$ and let $x, y \in X$. Since $d(x,y) = \inf_{i\in\mathbb{N}} d_i(x,y)$ there exists an index $m_{x,y} \in \mathbb{N}$ such that for all $n \geq m_{x,y}$, $|d_n(x,y) - d(x,y)| < \varepsilon$. Now, let $N = \max\{m_{x,y} \mid x, y \in X\}$. This is well-defined because X is finite. Therefore, for all $n \geq N$ and $x, y \in X$, $|d_n(x,y) - d(x,y)| < \varepsilon$ and hence $\|d_n - d\| < \varepsilon$. ◀

We can now use the above to show the desired property, by re-adapting [37, Theorem 1].

▶ **Lemma 20.** *If $\mathcal{M}$ is a deterministic finite automaton, then $\Phi_{\mathcal{M}}$ is ω-cocontinuous.*

Proof. By Lemma 19, the chain $\{d_i\}_{i\in\mathbb{N}}$ converges to $\inf_{i\in\mathbb{N}} d_i$. Since $\Phi_{\mathcal{M}}$ is nonexpansive (Lemma 16) it is also continuous (in the sense of the Banach space continuity) and therefore $\{\Phi_{\mathcal{M}}(d_i)\}_{i\in\mathbb{N}}$ converges to $\Phi_{\mathcal{M}}(\inf_{i\in\mathbb{N}} d_i)$. Recall that $\Phi_{\mathcal{M}}$ is monotone, which makes $\{\Phi_{\mathcal{M}}(d_i)\}_{i\in\mathbb{N}}$ into a chain, which by Lemma 6 and Lemma 19 converges to $\inf_{i\in\mathbb{N}}\{\Phi_{\mathcal{M}}(d_i)\}$. Since limit points are unique, $\inf_{i\in\mathbb{N}}\{\Phi_{\mathcal{M}}(d_i)\} = \Phi_{\mathcal{M}}(\inf_{i\in\mathbb{N}} d_i)$. ◀

We can combine the preceding results and provide a straightforward characterisation of the distance between languages represented by arbitrary regular expressions, denoted as $e, f \in \mathsf{Exp}$. Utilising a simple argument based on Proposition 7, which asserts that automata homomorphisms are nonexpansive, one can demonstrate that the distance between $[\![e]\!]$ and $[\![f]\!]$ in the final automaton is equivalent to the distance between $[e]_{\doteq}$ and $[f]_{\doteq}$ in $\langle [e]_{\doteq}, [f]_{\doteq}\rangle_{\mathcal{Q}}$. This is the least subautomaton of $\mathcal{Q}$ that contains the derivatives (modulo $\doteq$) reachable from $[e]_{\doteq}$ and $[f]_{\doteq}$. Importantly, this automaton is finite (Lemma 3), allowing us to apply the Kleene fixpoint theorem to calculate the distance.

Let $\Psi^{(0)}_{e,f}$ denote the discrete metric on the set $\langle [e]_{\doteq}, [f]_{\doteq}\rangle_{\mathcal{Q}}$ (the top element of the lattice of pseudometrics over that set). Define $\Psi^{(n+1)}_{e,f} = \Phi_{\langle [e]_{\doteq},[f]_{\doteq}\rangle_{\mathcal{Q}}}(\Psi^{(n)}_{e,f})$. Additionally, leveraging the fact that infima of decreasing chains are calculated pointwise (Lemma 6), we can conclude with the following:

▶ **Lemma 21.** *For all $e, f \in \mathsf{Exp}$, the underlying pseudometric of the quantitative algebra $\mathcal{B}$ can be given by $d^{\mathcal{B}}(e,f) = \inf_{i\in\mathbb{N}} \left\{ \Psi^{(i)}_{e,f}([e]_{\doteq}, [f]_{\doteq}) \right\}$*

In simpler terms, we have demonstrated that the behavioural distance between a pair of arbitrary regular expressions can be calculated as the infimum of decreasing approximations of the actual distance from above. Alternatively, one could calculate the same distance as the supremum of increasing approximations from below using the Kleene fixpoint theorem for the least fixpoint. We chose the former approach because our proof of completeness relies on the (Cont) rule of quantitative deduction systems. This rule essentially states that to prove two terms are at a specific distance, we should be able to prove that for all approximations of that distance from above. This allows us to replicate the fixpoint calculation through axiomatic reasoning.

Completeness result. We start by recalling that regular expressions satisfy a certain decomposition property, stating that each expression can be reconstructed from its small-step semantics, up to $\equiv_0$. This property, often referred to as the fundamental theorem of Kleene Algebra/regular expressions (in analogy with the fundamental theorem of calculus and following the terminology of Rutten [27] and Silva [33]) is useful in further steps of the proof of completeness.

▶ **Theorem 22** (Fundamental Theorem). *For any $e \in \mathsf{Exp}$, $\vdash e_i \equiv_0 \sum_{a\in A} a\,;(e_i)_a + o_{\mathcal{R}}(e_i)$ is derivable using the axioms of REG.*

The theorem above makes use of the n-ary generalised sum operator, which is well defined because of (SL1-SL4) axioms of REG. Let's now say that we are interested in the distance between some expressions $e, f \in \mathsf{Exp}$. As mentioned before, we will rely on $\langle [e]_{\doteq}, [f]_{\doteq} \rangle_{\mathcal{Q}}$, the least subautomaton of the $\doteq$ quotient of the Brzozowski automaton containing states reachable from $[e]_{\doteq}$ and $[f]_{\doteq}$. Recall that by Lemma 3 its state space is finite. It turns out that the approximations from above (from Lemma 21) to the distance between any pair of states in that automaton can be derived through the means of axiomatic reasoning.

▶ **Lemma 23.** *Let $e, f \in \mathsf{Exp}$ be arbitrary regular expressions and let $[g]_{\doteq}, [h]_{\doteq} \in \langle [e]_{\doteq}, [f]_{\doteq} \rangle_{\mathcal{Q}}$. For all $i \in \mathbb{N}$, and $\varepsilon \geq \Psi^{(i)}_{e,f}([g]_{\doteq}, [h]_{\doteq})$, one can derive $\vdash g \equiv_{\varepsilon} h$ using the axioms of* REG.

Proof. We proceed by induction on i. For the base case, observe that $\Psi^{(0)}_{e,f}$ is the discrete 1-pseudometric on the set $\langle [e]_{\doteq}, [f]_{\doteq} \rangle_{\mathcal{Q}}$ such that $\Psi^{(0)}_{e,f}([g]_{\doteq}, [h]_{\doteq}) = 0$ if and only if $g \doteq h$, or otherwise $\Psi^{(0)}_{e,f}([g]_{\doteq}, [h]_{\doteq}) = 1$. In the first case, we immediately have that $g \equiv_0 h$, because $\doteq$ is contained in distance zero axioms of REG. In the latter case, we can just use (Top), to show that $g \equiv_1 h$. Then, in both cases, we can apply (Max) to obtain $\vdash g \equiv_{\varepsilon} h$, since $\varepsilon \geq \Psi^{(0)}_{e,f}([g]_{\doteq}, [h]_{\doteq})$. For the induction step, let $i = j + 1$ and derive the following:

$$\begin{aligned}
&\varepsilon \geq \Psi^{(j+1)}_{e,f}([g]_{\doteq}, [h]_{\doteq}) \iff \varepsilon \geq \Phi_{\langle [e]_{\doteq}, [f]_{\doteq} \rangle_{\mathcal{Q}}} \left(\Psi^{(j)}_{e,f} \right) ([g]_{\doteq}, [h]_{\doteq}) && \text{(Def. of } \Psi^{j+1}_{e,f}\text{)} \\
&\iff \varepsilon \geq \max \left\{ d_2(o_{\mathcal{Q}}([g]_{\doteq}), o_{\mathcal{Q}}([h]_{\doteq})), \lambda \cdot \max_{a \in A} \left\{ \Psi^{(j)}_{e,f}([g]_{\doteq a}, [h]_{\doteq a}) \right\} \right\} && \text{(Def. of } \Phi\text{)} \\
&\iff \varepsilon \geq \max \left\{ d_2\left(o_{\mathcal{R}}(g), o_{\mathcal{R}}(h)\right), \lambda \cdot \max_{a \in A} \left\{ \Phi^{(j)}_{\langle [e]_{\doteq}, [f]_{\doteq} \rangle_{\mathcal{Q}}}([(g)_a]_{\doteq}, [(h)_a]_{\doteq}) \right\} \right\} \\
& && \text{(Def. of } \mathcal{Q}\text{)} \\
&\iff \varepsilon \geq d_2(o_{\mathcal{R}}(g), o_{\mathcal{R}}(h)) \text{ and for all } a \in A,\ \varepsilon \cdot \lambda^{-1} \geq \Psi^{(j)}_{e,f}([(g)_a]_{\doteq}, [(h)_a]_{\doteq})
\end{aligned}$$

Firstly, since d_2 is the discrete 1-pseudometric on the set $\{0, 1\}$, we can use (Refl) or (Top) depending on whether $o_{\mathcal{R}}(g) = o_{\mathcal{R}}(h)$ and then apply (Max) to derive $\vdash o_{\mathcal{R}}(g) \equiv_{\varepsilon} o_{\mathcal{R}}(h)$.

Let $a \in A$. We will show that $\vdash a\,;(g)_a \equiv_{\varepsilon} a\,;(h)_a$. Since $\varepsilon \cdot \lambda^{-1}$ is not guaranteed to be rational, we cannot immediately apply the induction hypothesis. Instead, we rely on (Cont) rule. First, pick an arbitrary rational ε' strictly greater than ε and fix $\{r_n\}_{n \in \mathbb{N}}$ to be any decreasing sequence of rationals that converges to λ^{-1}. Let r_N be an element of that sequence such that $\varepsilon' \geq \lambda \cdot \varepsilon \cdot r_N$. It is always possible to pick such element because $\{\lambda \cdot r_n\}_{n \in \mathbb{N}}$ is a decreasing sequence that converges to 1 and $\varepsilon' > \varepsilon$. Since $\epsilon \cdot r_N \geq \epsilon \cdot \lambda^{-1}$ and $\varepsilon \cdot r_N \in \mathbb{Q}^+$, we can use the induction hypothesis and derive $\vdash (g)_a \equiv_{\epsilon \cdot r_N} (h_a)$. Then, by ($\lambda$-Pref) axiom we have that $\vdash a\,;(g)_a \equiv_{\varepsilon'} a\,;(h)_a$. Since we have shown it for arbitrary $\varepsilon' > \varepsilon$, by (Cont) rule we have that $\vdash a\,;(g)_a \equiv_{\varepsilon} a\,;(h)_a$. Using (SL5), we can combine all subexpressions involving the output and transition derivatives into the following:

$$\vdash \sum_{a \in A} a\,;(g)_a + o_{\mathcal{R}}(g) \equiv_{\varepsilon} \sum_{a \in A} a\,;(h)_a + o_{\mathcal{R}}(h)$$

Since both sides are normal forms of g and h existing because of Theorem 22, we can apply (Triang) on both sides and obtain $\vdash g \equiv_{\varepsilon} h$ thus completing the proof. ◀

At this point, we have done all the hard work, and establishing completeness involves a straightforward argument that utilises the (Cont) rule and the lemma above.

▶ **Theorem 24** (Completeness). *For any $e, f \in \mathsf{Exp}$ and $\varepsilon \in \mathbb{Q}^+$, if $\models_{\mathcal{B}} e \equiv_{\varepsilon} f$, then $\vdash e \equiv_{\varepsilon} f \in$ REG*

Proof. Assume that $\models_{\mathcal{B}} e \equiv_\varepsilon f$, which by the definition of $\models_{\mathcal{B}}$ is equivalent to $d^{\mathcal{B}}(e,f) \leq \varepsilon$. In order to use (Cont) axiom to derive $\vdash e \equiv_\varepsilon f$, we need to be able to show $\vdash e \equiv_{\varepsilon'} f$ for all $\varepsilon' > \varepsilon$. Because of iterative characterisation of $d^{\mathcal{B}}$ from Lemma 21, we have that $\inf_{i\in I}\{\Psi^{(i)}_{e,f}([e]_{\doteq},[f]_{\doteq})\} < \varepsilon'$. Since ε' is strictly above the infimum of the descending chain of approximants, there exists a point $i \in \mathbb{N}$, such that $\varepsilon' > \Psi^{(i)}_{e,f}([e]_{\doteq},[f]_{\doteq})$. We can show this by contradiction.

Assume that for all $i \in \mathbb{N}$, $\varepsilon' \leq \Psi^{(i)}_{e,f}([e]_{\doteq},[f]_{\doteq})$. This would make ε' into the lower bound of the chain $\left\{\Psi^{(i)}_{e,f}([e]_{\doteq},[f]_{\doteq})\right\}_{i\in\mathbb{N}}$ and in such a case ε' would be less than or equal to the infimum of that chain, which by assumption is less than or equal to ε. By transitivity, we could obtain $\varepsilon' \leq \varepsilon$. Since $\varepsilon' > \varepsilon$, by antisymmetry we could derive that $\varepsilon' = \varepsilon$, which would lead to the contradiction.

Using the fact shown above, we can use Lemma 23 to obtain $\vdash e \equiv_{\varepsilon'} f \in \mathsf{REG}$ for any $\varepsilon' > \varepsilon$, which completes the proof. ◀

In simpler terms, the (Cont) rule enables us to demonstrate that two terms are at a specific distance by examining all strict overapproximations of that distance. Due to the iterative nature outlined in Lemma 21, this implies that we only need to consider finite approximants used in the Kleene fixpoint theorem. Each of those finite approximants can be axiomatically derived using Lemma 23.

6 Discussion

We have presented a sound and complete axiomatisation of the shortest-distinguishing word distance between languages representing regular expressions through a quantitative analogue of equational logic [22]. Before our paper, only axiomatised behavioural distances of probabilistic/weighted transition systems existed, through (variants of) the Kantorovich/Wasserstein lifting [21, 12, 4, 2, 1], while we looked at a behavioural distance obtained through a more general coalgebraic framework [5]. Outside of the coalgebra community, the shortest-distinguishing word distance and its variants also appear in the model checking [20] and in the automata learning [14] literature.

We have followed the strategy for proving completeness from [2]. The interesting insight about that strategy is that it relies on properties that are not exclusive to distances obtained through the Kantorovich/Wasserstein lifting and can be established for notions of behavioural distance for other kinds of transition systems stemming from the coalgebraic framework. In particular, one needs to show that the monotone map on the lattice of pseudometrics used in defining the distance of finite-state systems is nonexpansive with respect to the sup norm (and hence ω-cocontinuous) and has a unique fixpoint, thus allowing to characterise the behavioural distance as the greatest fixpoint obtained through the Kleene fixpoint theorem. This point of view allows one to reconstruct the fixpoint calculation in terms of axiomatic manipulation involving the (Cont) rule, eventually leading to completeness.

We have additionally observed that in the presence of the infinitary (Cont) rule and the (λ-Pref) axiom, there is no need for a fixpoint rule, which is common place in all axiomatisations of regular expressions but also in other work on distances. In particular, the previous work on axiomatising a discounted probabilistic bisimilarity distance from [2] includes both (λ-Pref) and the fixpoint introduction rule, but its proof of completeness [2, Theorem 6.4] does not involve the fixpoint introduction rule at any point. We are highly confident that in the case of that axiomatisation, the fixpoint introduction rule could be derived from other axioms in a similar fashion to the way we derived Salomaa's rule for introducing the Kleene star [30]. Additionally, we are interested in how much this argument relates to the recent study of fixpoints in quantitative equational theories [23].

Moreover, the axiomatisations from [1, 2] rely on a slight modification of quantitative equational theories, which drop the requirement of all operations from the signature to be nonexpansive. This is dictated by the fact that the interpretation of μ-recursion in Stark and Smolka's probabilistic process algebra [35] can increase the behavioural distances in the case of unguarded recursion, while in regular expressions recursive behaviour is introduced through Kleene's star, whose interpretation is non-expansive with respect to the shortest-distinguishing-word distance. This allowed us to fit instantly into the original framework of quantitative equational theories. The earlier work [4] focusing on Markov processes [8] also relies on quantitative equational theories, but its syntax does not involve any recursive primitives. Instead, the recursive behaviour is introduced through Cauchy completion of a pseudometric induced by the axioms. The earliest works on axiomatising behavioural distances of weighted [21] and probabilistic [12] transition systems, studied before the introduction of quantitative equational theories, rely on ad-hoc inference systems that cannot be easily generalised.

The pioneering works [13, 39, 37, 40, 38, 3] laid foundations for behavioural (pseudo)metrics of various flavours of probabilistic transition systems. The coalgebraic point of view [5] allowed to generalise these ideas to a wide range of transition systems by moving from the Kantorovich/Wasserstein lifting to the abstract setting of lifting endofunctors from the category of sets to the category of pseudometric spaces. Building upon this theory, further lines of work were dedicated to asymmetric distances (called hemimetrics) through the theory of quasi-lax liftings [44], fuzzy analogues of Hennessy-Milner logic characterising behavioural distance [17, 6], fibrational generalisations involving quantale-enriched categories [7], up-to techniques allowing for efficient approximation of behavioural distances [9] and quantitative analogues of van Glabbek's linear-time branching-time spectrum [15].

In this paper, we have focused on the simplest and most intuitive instantiation of the coalgebraic framework in the case of deterministic automata, but the natural next step would be to generalise our results to a wider class of transition systems. A good starting point could be to consider coalgebras for *polynomial* endofunctors, in the fashion of the framework of *Kleene Coalgebra* [33]. Alternatively, it would be interesting to look at recent work on a family of process algebras parametric on an equational theory representing the branching constructs [32] and study its generalisations to quantitative equational theories. A related and interesting avenue for future work are equational axiomatisations of behavioural equivalence of Guarded Kleene Algebra with Tests (GKAT) [34, 32] and its probabilistic extension (ProbGKAT) [29], whose completeness results rely on a powerful uniqueness of solutions axiom (UA). The soundness of UA in both cases is shown through an involved argument relying on equipping the transition systems giving the operational semantics with a form of behavioural distance and showing that recursive specifications describing finite-state systems correspond to certain contractive mappings. It may be more sensible, particularly for ProbGKAT to consider quantitative axiomatisations in the first place and give the proofs of completeness through the pattern explored in this paper.

Homogeneity and Homogenizability: Hard Problems for the Logic SNP

Jakub Rydval
Technische Universität Wien, Austria

Abstract

The infinite-domain CSP dichotomy conjecture extends the finite-domain CSP dichotomy theorem to reducts of finitely bounded homogeneous structures. Every countable finitely bounded homogeneous structure is uniquely described by a universal first-order sentence up to isomorphism, and every reduct of such a structure by a sentence of the logic SNP. By Fraïssé's Theorem, testing the existence of a finitely bounded homogeneous structure for a given universal first-order sentence is equivalent to testing the amalgamation property for the class of its finite models. The present paper motivates a complexity-theoretic view on the classification problem for finitely bounded homogeneous structures. We show that this meta-problem is EXPSPACE-hard or PSPACE-hard, depending on whether the input is specified by a universal sentence or a set of forbidden substructures. By relaxing the input to SNP sentences and the question to the existence of a structure with a finitely bounded homogeneous expansion, we obtain a different meta-problem, closely related to the question of homogenizability. We show that this second meta-problem is already undecidable, even if the input SNP sentence comes from the Datalog fragment and uses at most binary relation symbols. As a byproduct of our proof, we also get the undecidability of some other properties for Datalog programs, e.g., whether they can be rewritten in the logic MMSNP, whether they solve some finite-domain CSP, or whether they define a structure with a homogeneous Ramsey expansion in a finite relational signature.

1 Introduction

Strict NP (SNP) is an expressive fragment of existential second-order logic and thus, by Fagin's Theorem, of the complexity class NP. If one only considers structures over a finite relational signature, then SNP can be obtained from the universal fragment of first-order logic simply by allowing existential quantification over relation symbols at the beginning of the quantifier prefix. In particular, universal first-order formulas themselves are SNP formulas. Despite the name, SNP already has the full power of NP, in the sense that every problem in NP is equivalent to a problem in SNP under polynomial-time reductions [30]. In addition, this logic class has many connections to *Constraint Satisfaction Problems* (CSPs), which we use as the primary source of motivation for the present article. The CSP of a

relational structure $\mathfrak{B}$, denoted by CSP($\mathfrak{B}$), is (the membership problem for) the class of all finite structures which homomorphically map to $\mathfrak{B}$. Every computational decision problem is polynomial-time equivalent to a CSP [12]. Many practically relevant problems like Boolean satisfiability or graph colorability can even be formulated as a *finite-domain* CSP, i.e., where the *template* $\mathfrak{B}$ can be chosen finite. The basic link from SNP to CSP is that every sentence of the monotone fragment of this logic defines a finite disjoint union of CSPs of (possibly infinite) relational structures [8]. There are, however, some more nuanced connections, such as the one that led to the formulation of the *Feder-Vardi conjecture*, now known as the finite-domain CSP dichotomy theorem [52]. In their seminal work [30], Feder and Vardi showed that the *Monotone Monadic* fragment of SNP (MMSNP) exhibits a dichotomy between P and NP-completeness if and only if the seemingly less complicated class of all finite-domain CSPs exhibits such a dichotomy,[1] they also conjectured the latter to be true. The logic class MMSNP contains all finite-domain CSPs, and many other interesting combinatorial problems, e.g., the problem of deciding whether the vertices of a given graph can be 2-coloured without obtaining any monochromatic triangle [42]. The Feder-Vardi conjecture was confirmed in 2017 independently by Bulatov and Zhuk [23, 51].

There is a yet unconfirmed generalization of the Feder-Vardi conjecture, to CSPs of *reducts of finitely bounded homogeneous structures*, formulated by Bodirsky and Pinsker in 2011 [18]. Here we refer to it as the *Bodirsky-Pinsker conjecture*. A structure is *finitely bounded* if it has a finite relational signature and the class of all finite structures embeddable into it is definable by a universal first-order sentence, and *homogeneous* if every isomorphism between two of its finite substructures extends to an automorphism. *Reducts* of such structures are obtained simply by removing some of the original relations. A prototypical example of a structure that satisfies both finite boundedness and homogeneity is $(\mathbb{Q}; <)$, the set of rational numbers equipped with the usual countable dense linear order without endpoints. It is a folklore fact that the class of reducts of finitely bounded homogeneous structures is closed under taking expansions of structures by first-order definable relations [8]. Roughly said, the condition imposed on the structures within the scope of the Bodirsky-Pinsker conjecture ensures that the CSP is in NP and that its template enjoys some of the universal-algebraic properties that have played an essential role in the proofs of the Feder-Vardi conjecture [6]. At the same time, it covers CSP-reformulations of many natural problems in qualitative reasoning, as well as all problems definable in MMSNP.

Every countable finitely bounded homogeneous structure is uniquely described by a universal first-order sentence up to isomorphism, and every reduct of such a structure by a sentence of the logic SNP. The CSPs of both kinds of structures are always definable in the monotone fragment of SNP. By Fraïssé's theorem, asking whether a given universal first-order sentence describes a finitely bounded homogeneous structure is equivalent to asking whether the class of its finite models has the *Amalgamation Property* (AP). This question has been considered many times in the context of the Lachlan-Cherlin classification programme for homogeneous structures [3, 36, 26], and is known to be decidable in the case of binary signatures [38, 15]. It also appears as an open problem in Bodirsky's book on infinite-domain constraint satisfaction [8]. Whether a given SNP sentence describes a reduct of a finitely bounded homogeneous structure is a different question, closely related to *homogenizability* [2, 4, 28, 35]. To the best of our knowledge, neither of the two questions is known to be decidable in general. Hence, it is unclear which CSPs actually fall within

[1] The correspondence between MMSNP and finite-domain CSP was initially only achieved up to randomized reductions, but it was later derandomized by Kun [37].

the scope of the Bodirsky-Pinsker conjecture. Besides CSPs, they are also relevant to other areas of theoretical computer science such as verification of database-driven systems [21] or description logics with concrete domains [39, 5]. Below, we state the two questions explicitly.

1. **The amalgamation meta-problem.** Given a universal sentence Φ over a finite relational signature, does there exist a finitely bounded homogeneous structure $\mathfrak{B}$ such that the finite models of Φ are precisely the finite substructures of $\mathfrak{B}$ up to isomorphism?
2. **The homogenizability meta-problem.** Given an SNP sentence Φ over a finite relational signature, does there exist a reduct $\mathfrak{B}$ of a finitely bounded homogeneous structure such that the finite models of Φ are precisely the finite substructures of $\mathfrak{B}$ up to isomorphism?

Contributions. In the present paper, we prove the intractability of the two meta-problems. More specifically, we show that the amalgamation meta-problem is EXPSPACE-hard (Theorem 6) or PSPACE-hard (Theorem 7), depending on the encoding of the input, and that the homogenizability meta-problem is undecidable (Theorem 13). Theorem 6 and Theorem 7 are proved in Section 3.1 by taking a proof-theoretic perspective on the AP for classes defined by universal Horn sentences. We show that, for some of these classes, the failures of the AP are in a 1:1 correspondence with the rejecting runs of certain Datalog programs verifying instances of the rectangle tiling problem. Here, by Datalog we mean the monotone Horn fragment of SNP. Theorem 13 is proved in Section 4, by analyzing model-theoretic properties of a very natural encoding of context-free grammars into Datalog sentences. As a byproduct of the proof, we also get the undecidability of some other properties for Datalog programs, e.g., whether they can be rewritten in the logic MMSNP, whether they solve some finite-domain CSP, or whether they define a structure with a homogeneous Ramsey expansion in a finite relational signature.

It is known that, from every finite structure $\mathfrak{A}$ over a finite relational signature one can construct in polynomial time a finite structure $\mathfrak{B}$ over a finite binary relational signature such that CSP($\mathfrak{A}$) and CSP($\mathfrak{B}$) are polynomial-time equivalent [24, 30]. By our results, such a reduction is unlikely to exist for universal sentences representing finitely bounded homogeneous structures, unless it avoids the amalgamation meta-problem. The reason is that, for binary relational signatures, the amalgamation meta-problem can be decided in coNEXPTIME (Proposition 3). Our results provide evidence for the need for a fundamentally new language-independent approach to the Bodirsky-Pinsker conjecture. First steps in this direction were taken in the recent works of Mottet and Pinsker [44] and Bodirsky and Bodor [9], but they do not fully address the issues stemming from the two meta-problems. We elaborate on this claim below. To keep our results as general as possible, we formulate them for some reasonable promise relaxations of the two meta-problems, i.e., where a subclass and a superclass of the positive instances are being separated from each other with the promise that the input never belongs to the complement of the subclass within the superclass.

The subtleties of the Bodirsky-Pinsker conjecture. In 2016, Bodirsky and Mottet presented an elegant tool for lifting tractability from finite-domain constraint satisfaction to the infinite [17], hereby establishing the first general link between the Feder-Vardi and the Bodirsky-Pinsker conjecture. Since then, their method has been used numerous times to prove new or reprove old complexity classification results for infinite-domain CSPs. One prominent such example is the universal-algebraic proof of the complexity dichotomy for MMSNP [16]. Conveniently enough, every MMSNP sentence defines a finite union of CSPs of structures within the scope of the Bodirky-Pinsker conjecture, so the two meta-problems were not relevant in this context. There is a prospect that the methods from [17] will also

prove useful in proving a dichotomy for the even more general logic class *Guarded Monotone* SNP (GMSNP) introduced in [7]. Also GMSNP enjoys the above mentioned property of MMSNP [15], and hence avoids the two meta-problems.

However, outside of GMSNP there exists a regime where the methods from [17] definitely fall short, and where the two meta-problems become relevant. Consider for instance the dichotomy for *temporal CSPs*, i.e., for CSPs of structures with domain $\mathbb{Q}$ and whose relations are definable by a Boolean combination of formulas of the form $(x = y)$ or $(x < y)$, obtained by Bodirsky and Kára in 2010 [14]. At the present time, these problems are already very well understood; tractable temporal CSPs can always be solved by an algorithm that repeatedly searches for a set of potential minimal elements among the input variables, where each instance of the search is performed using an oracle for a tractable finite-domain CSP. The latter is generally determined by the shape of the Boolean combinations. E.g., in the case of $\mathrm{CSP}(\mathbb{Q}; \{(x, y, z) \in \mathbb{Q}^3 \mid (x = y < z) \vee (y = z < x) \vee (z = x < y)\})$, solving the finite-domain CSP in question amounts to solving linear equations modulo 2 [14, 19]. It is known that the tractability results from [14] cannot be obtained using the reduction from [17].

In 2022, Mottet and Pinsker introduced the machinery of *smooth approximations* [44], which vastly generalizes the methods in [17]. The last section of their paper is devoted to temporal CSPs, and the authors manage to reprove a significant part of the dichotomy on just a few pages. They achieve this by applying some of their general results to first-order expansions of $(\mathbb{Q}; <)$ and obtaining either NP-hardness for the CSP, or one of the two types of symmetry that played a fundamental role in the original proof from [14]. This symmetry can then be used to prove correctness of the reduction to a finite-domain CSP described above, but only under an explicit usage of the homogeneity of $(\mathbb{Q}; <)$ (see Proposition 3.1 in [19] and the last section of [44]). In contrast to the methods in [17] which only use homogeneity as a blackbox, this approach can be described as *language-dependent*.

A similar situation occurs in the case of phylogeny CSPs [13], which capture decision problems concerning the existence of a binary tree satisfying certain constraints imposed on its leaves. Tractable phylogeny CSPs are strikingly similar to tractable temporal CSPs; they can always be solved by an algorithm that repeatedly searches for a subdivision of the input variables into two parts, representing the two different branches below the root of a binary tree, where each instance of this search is performed using an oracle for a tractable finite-domain CSP. However, for tractable phylogeny CSPs, already the homogeneity of the infinite-domain CSP template is both sufficient and necessary for proving the correctness of the reduction to the finite-domain CSP (Theorem 6.13 and Lemma 6.12 in [13]). We can therefore speak of a case of extreme language-dependency. Temporal and phylogeny CSPs are special cases of CSPs of structures obtainable from the universal homogeneous binary tree [10] by specifying relations using first-order formulas. Achieving a complexity dichotomy in this context will require a non-trivial combination of the methods from [14] and [13].

An optimal way of approaching the conjecture would be gaining a very good understanding of the class of reducts of finitely bounded homogeneous structures, e.g., through some sort of a classification. However, it is unclear how realistic this prospect is as model-theoretic properties often tend to be undecidable [25]. We remark that homogeneity is a vital part of the Bodirsky-Pinsker conjecture; this assumption can be weakened or strengthened but not dropped entirely, as otherwise we get a class that provably does not have a dichotomy [30, 8].

2 Preliminaries

Relational structures. The set $\{1, \ldots, n\}$ is denoted by $[n]$, and we use the bar notation $\bar{t}$ for tuples. A (*relational*) *signature* τ is a set of *relation symbols*, each $R \in \tau$ with an associated natural number called *arity*. We say that τ is *binary* if it consists of symbols of

arity ≤ 2. A (*relational*) τ*-structure* $\mathfrak{A}$ consists of a set A (the *domain*) together with the relations $R^{\mathfrak{A}} \subseteq A^k$ for each $R \in \tau$ with arity k. An *expansion* of $\mathfrak{A}$ is a σ-structure $\mathfrak{B}$ with $A = B$ such that $\tau \subseteq \sigma$, $R^{\mathfrak{B}} = R^{\mathfrak{A}}$ for each relation symbol $R \in \tau$. Conversely, we call $\mathfrak{A}$ a *reduct* of $\mathfrak{B}$. The *union* of two τ-structures $\mathfrak{A}$ and $\mathfrak{B}$ is the τ-structure $\mathfrak{A} \cup \mathfrak{B}$ with domain $A \cup B$ and relations of the form $R^{\mathfrak{A}\cup\mathfrak{B}} := R^{\mathfrak{A}} \cup R^{\mathfrak{B}}$ for every $R \in \tau$.

A *homomorphism* $h\colon \mathfrak{A} \to \mathfrak{B}$ for τ-structures $\mathfrak{A}, \mathfrak{B}$ is a mapping $h\colon A \to B$ that *preserves* each relation of $\mathfrak{A}$, i.e., if $\bar{t} \in R^{\mathfrak{A}}$ for some k-ary relation symbol $R \in \tau$, then $h(\bar{t}) \in R^{\mathfrak{B}}$. We write $\mathfrak{A} \to \mathfrak{B}$ if $\mathfrak{A}$ maps homomorphically to $\mathfrak{B}$. The *Constraint Satisfaction Problem* (CSP) of $\mathfrak{A}$, denoted by $\mathrm{CSP}(\mathfrak{A})$, is defined as the class of all finite structures which homomorphically map to $\mathfrak{A}$. An *embedding* is a homomorphism $h\colon \mathfrak{A} \to \mathfrak{B}$ that additionally satisfies the following condition: for every k-ary relation symbol $R \in \tau$ and $\bar{t} \in A^k$ we have $h(\bar{t}) \in R^{\mathfrak{B}}$ only if $\bar{t} \in R^{\mathfrak{A}}$. We write $\mathfrak{A} \hookrightarrow \mathfrak{B}$ if $\mathfrak{A}$ embeds to $\mathfrak{B}$. The *age* of $\mathfrak{A}$, denoted by $\mathrm{age}(\mathfrak{A})$, is the class of all finite structures which embed to $\mathfrak{A}$. A *substructure* of $\mathfrak{A}$ is a structure $\mathfrak{B}$ over $B \subseteq A$ such that the inclusion map $i\colon B \to A$ is an embedding. An *isomorphism* is a surjective embedding. Two structures $\mathfrak{A}$ and $\mathfrak{B}$ are *isomorphic* if there exists an isomorphism from $\mathfrak{A}$ to $\mathfrak{B}$. An *automorphism* is an isomorphism from $\mathfrak{A}$ to $\mathfrak{A}$. The *orbit* of a tuple $\bar{t} \in A^k$ in $\mathfrak{A}$ is the set $\{g(\bar{t}) \mid g \text{ is an automorphism of } \mathfrak{A}\}$. A countable structure $\mathfrak{A}$ is ω*-categorical* if, for every $k \geq 1$, there are only finitely many orbits of k-tuples in $\mathfrak{A}$.

First-order logic. We assume that the reader is familiar with classical *first-order* logic as well as with basic preservation properties of first-order formulas, e.g., that every first-order formula ϕ is preserved by isomorphisms; by embeddings if ϕ is existential, and by homomorphisms if ϕ is existential positive. For a first-order sentence Φ, we denote the class of all its finite models by $\mathrm{fm}(\Phi)$. We say that a first-order formula is k*-ary* if it has k free variables. For a first-order formula ϕ, we use the notation $\phi(\bar{x})$ to indicate that the free variables of ϕ are among $\bar{x}$. This does not mean that the truth value of ϕ depends on each entry in $\bar{x}$. We assume that equality $=$ as well as the nullary predicate symbol $\bot$ for falsity are always available when building first-order formulas. Thus, *atomic* τ*-formulas*, or τ*-atoms* for short, over a relational signature τ are of the form $\bot$, $(x = y)$, and $R(\bar{x})$ for some $R \in \tau$. We say that a formula is *equality-free* if it does not contain any occurrence of the default equality predicate. If ϕ is a disjunction of possibly negated τ-atoms, then we define the *Gaifman graph* of ϕ as the undirected graph whose vertex set consists of all free variables of ϕ and where two distinct variables x, y form an edge if and only if they appear jointly in a negative atom of ϕ. Let Φ be a universal τ-sentence in prenex normal form whose quantifier-free part ϕ is in CNF. We call Φ *Horn* if every clause of ϕ is Horn, i.e., contains at most one positive disjunct. We call Φ *complete* if the Gaifman graph of each clause of ϕ is complete. It is a folklore fact that, if Φ is complete, then $\mathrm{fm}(\Phi)$ is preserved by unions.

SNP and its fragments. An *SNP* τ*-sentence* is a second-order sentence Φ of the form $\exists X_1, \ldots, X_n \forall \bar{x}.\, \phi$ where ϕ is a quantifier-free formula in CNF over $\tau \cup \{X_1, \ldots, X_n\}$. We call Φ *monadic* if X_i is unary for every $i \in [n]$; *monotone* if ϕ does not contain any positive τ-atoms (in particular no positive equality atoms); and *guarded* if, for every positive atom β there exists a negative atom α containing all variables of β. Note that all notions from the previous paragraph easily transfer to SNP sentences viewed as universal sentences in an extended signature. The monadic monotone and the guarded monotone fragments of SNP are denoted by MMSNP and GMSNP, respectively. The monotone Horn fragment of SNP is commonly known as the logic programming language *Datalog*. When we say that a Datalog program Φ *solves* the CSP of a structure $\mathfrak{B}$, we simply mean that $\mathrm{fm}(\Phi) = \mathrm{CSP}(\mathfrak{B})$.

Homogeneity, homogenizability, and finite boundedness. A countable structure $\mathfrak{S}$ is *homogeneous* if every isomorphism between two finite substructures of $\mathfrak{S}$ extends to an automorphism of $\mathfrak{S}$. Clearly, every homogeneous structure in a finite relational signature is ω-categorical, and so are the reducts of such structures. Homogeneous structures arise as limit objects of well-behaved classes of finite structures in the sense of Theorem 1.

Let $\mathcal{K}$ be a class of finite structures in a finite relational signature τ closed under isomorphisms and substructures. We say that $\mathcal{K}$ has the *amalgamation property* (AP) if, for all $\mathfrak{B}_1, \mathfrak{B}_2 \in \mathcal{K}$ whose substructures on $B_1 \cap B_2$ are identical, there exists $\mathfrak{C} \in \mathcal{K}$ together with embeddings $f_1 \colon \mathfrak{B}_1 \hookrightarrow \mathfrak{C}$ and $f_2 \colon \mathfrak{B}_2 \hookrightarrow \mathfrak{C}$ such that $f_1|_{B_1 \cap B_2} = f_2|_{B_1 \cap B_2}$. We refer to $\mathfrak{C}$ as an *amalgam* of $\mathfrak{B}_1$ and $\mathfrak{B}_2$ in $\mathcal{K}$. Note that, for a class closed under isomorphisms and substructures, the AP is implied by the property of being closed under unions $\mathfrak{B}_1 \cup \mathfrak{B}_2$, also called *free amalgams*.

▶ **Theorem 1** (Fraïssé). *For a class $\mathcal{K}$ of finite structures in a finite relational signature τ, the following are equivalent:*

- *$\mathcal{K}$ is the age of an up to isomorphism unique countable homogeneous τ-structure;*
- *$\mathcal{K}$ is closed under isomorphisms, substructures, and has the AP.*

As already mentioned in the introduction, the structure $(\mathbb{Q}; <)$ is homogeneous because every local isomorphism can be extended to an automorphism using a piecewise affine transformation. Its age is the class of all finite strict linear orders.

A countable structure $\mathfrak{S}$ is *homogenizable* if it is a reduct of a homogeneous structure $\mathfrak{H}$ over a finite relational signature such that $\mathfrak{S}$ and $\mathfrak{H}$ have the same sets of automorphisms [28]. Whenever this happens, by the theorem of Ryll-Nardzewski, all relations of $\mathfrak{H}$ are first-order definable in $\mathfrak{S}$ [33]. One might say that $\mathfrak{S}$ already has all the relations necessary for homogeneity but they perhaps do not all have names. A prototypical example of this phenomenon is the universal "homogeneous" binary tree, which is homogenizable but not homogeneous, see, e.g., Proposition 3.2 in [10]. We call a class $\mathcal{K}$ of finite structures in a finite relational signature τ *homogenizable* if it forms the age of a homogenizable structure.

For a class $\mathcal{N}$ of finite structures in a finite relational signature τ, the class $\mathrm{Forb}_e(\mathcal{N})$ consists of all finite τ-structures which do not embed any member of $\mathcal{N}$. Following the terminology in [40], we say that a class $\mathcal{K}$ of finite structures in a finite relational signature is *finitely bounded* if there exists a finite $\mathcal{N}$ such that $\mathcal{K} = \mathrm{Forb}_e(\mathcal{N})$. We refer to $\mathcal{N}$ as a set of *bounds* for $\mathcal{K}$, and define the *size* of $\mathcal{N}$ as the sum of the cardinalities of the domain and the relations of all structures in $\mathcal{N}$. A structure $\mathfrak{S}$ is *finitely bounded* if its age is finitely bounded. We say that a class $\mathcal{K}$ is *finitely bounded homogenizable* if it forms the age of a reduct $\mathfrak{R}$ of a finitely bounded homogeneous structure $\mathfrak{H}$ such that $\mathfrak{R}$ and $\mathfrak{H}$ have the same sets of automorphisms. Sufficient conditions for finitely bounded homogenizability were provided by Hubička and Nešetřil [34], generalizing previous work of Cherlin, Shelah, and Shi [27].

3 The Amalgamation Meta-Problem

By Theorem 1, every homogeneous structure is uniquely described by its age (up to isomorphism). Consequently, every finitely bounded homogeneous structure is uniquely described by a finite set of bounds. It is known that the question whether $\mathrm{Forb}_e(\mathcal{N})$ has the AP for a given finite set of bounds $\mathcal{N}$ can be tested algorithmically in the case where the signature is binary [38]. This decidability result is based on the following observation. A *one-point amalgamation diagram* is an input $\mathfrak{B}_1, \mathfrak{B}_2$ to the AP where $|B_1 \setminus B_2| = |B_2 \setminus B_1| = 1$.

▶ **Proposition 2** ([38]). *A class of finite relational τ-structures that is closed under isomorphisms and substructures has the AP if and only if it has the AP restricted to one-point amalgamation diagrams.*

As a consequence of Proposition 2, if τ is binary and $\mathrm{Forb}_e(\mathcal{N})$ does not have the AP, then the size of a smallest counterexample to the AP is polynomial in the size of $\mathcal{N}$ [15]. Such a counterexample can be non-deterministically guessed and verified using a coNP-oracle, which places the problem at the second level of the polynomial hierarchy (Theorem 15 in [5]).

There is a second, arguably more practical, equivalent definition of finite boundedness. Namely, a class $\mathcal{K}$ of finite structures in a finite relational signature is finitely bounded if and only if there exists a universal sentence Φ such that $\mathcal{K} = \mathrm{fm}(\Phi)$. Using this definition, it is easy to see that $(\mathbb{Q}; <)$ is finitely bounded because its age, the class of all finite strict linear orders, admits a finite universal axiomatization (irreflexivity, transitivity, and totality). From a complexity-theoretical perspective, the two definitions are equivalent only up to a single-exponential blow-up in one direction. Given a finite set of bounds $\mathcal{N}$, we can obtain a universal sentence Φ of size polynomial in the size of $\mathcal{N}$ satisfying $\mathrm{fm}(\Phi) = \mathrm{Forb}_e(\mathcal{N})$ by describing each structure in $\mathcal{N}$ up to isomorphism using a quantifier-free formula. However, given a universal sentence Φ, it can be the case that a smallest $\mathcal{N}$ satisfying $\mathrm{fm}(\Phi) = \mathrm{Forb}_e(\mathcal{N})$ is of size single-exponential in the size of Φ. The reason is that obtaining $\mathcal{N}$ from Φ is comparable to rewriting Φ in DNF. Consequently, the algorithm from [15] only gives us a relatively weak upper bound for the case where the inputs are specified by universal sentences.

▶ **Proposition 3.** *Let Φ be a universal sentence over a finite binary relational signature τ. If $\mathrm{fm}(\Phi)$ does not have the AP, then the size of a smallest counterexample to the AP is at most single-exponential in the size of Φ. Consequently, the question whether $\mathrm{fm}(\Phi)$ has the AP is decidable in* coNEXPTIME.

The upper bound provided by Proposition 3 is not unreasonable since a smallest counterexample to the AP might be of size exponential in the size of the input sentence even if the signature is binary. This is demonstrated in Example 4.

▶ **Example 4.** Let τ be the signature consisting of the unary symbols $\{L, R\} \cup \{X_i \mid i \in [n]\}$ and the binary symbols $\{E\} \cup \{Y_i \mid i \in [n]\}$ for some $n \in \mathbb{N}$. Consider the universal sentence

$$\Phi \coloneqq \forall x, y_1, y_2 \Big(L(y_1) \wedge R(y_2) \wedge E(x, y_1) \wedge E(x, y_2) \wedge \big(\textstyle\bigwedge_{i \in [n]} Y_i(y_1, y_2) \Leftrightarrow X_i(x) \big) \Rightarrow \bot \Big).$$

Our first claim is that $\mathrm{fm}(\Phi)$ does not have the AP. We define the one-point amalgamation diagram $\mathfrak{B}_1, \mathfrak{B}_2 \in \mathrm{fm}(\Phi)$ as follows. The domains are $B_i \coloneqq \{b_i\} \cup \{b_S \mid S \subseteq [n]\}$, $i \in \{1, 2\}$, and the relations are given by the following conjunction of atomic formulas:

$$L(b_1) \wedge R(b_2) \wedge \textstyle\bigwedge_{S \subseteq [n]} E(b_S, b_1) \wedge E(b_S, b_2) \wedge \bigwedge_{i \in S} X_i(b_S).$$

We have that $\mathfrak{B}_1$ and $\mathfrak{B}_2$ satisfy Φ because $R^{\mathfrak{B}_1} = \emptyset$ and $L^{\mathfrak{B}_2} = \emptyset$. Clearly, no amalgam for $\mathfrak{B}_1$ and $\mathfrak{B}_2$ can be obtained by identifying b_1 and b_2 because $L^{\mathfrak{B}_1} = \{b_1\}$ and $R^{\mathfrak{B}_2} = \{b_2\}$. The free amalgam $\mathfrak{B}_1 \cup \mathfrak{B}_2$ does not satisfy Φ because of the assignment $y_1 \coloneqq b_1$, $y_2 \coloneqq b_2$, and $x \coloneqq b_\emptyset$. But since we can assign $x \coloneqq b_S$ for any $S \subseteq [n]$, also no amalgam satisfying Φ can be obtained by adding the pair (b_1, b_2) to any subset of the relations $Y_1^{\mathfrak{B}_1 \cup \mathfrak{B}_2}, \ldots, Y_n^{\mathfrak{B}_1 \cup \mathfrak{B}_2}$ of the free amalgam. We conclude that $\mathrm{fm}(\Phi)$ does not have the AP.

Our second claim is that every one-point amalgamation diagram $\mathfrak{B}_1, \mathfrak{B}_2 \in \mathrm{fm}(\Phi)$ satisfying $|B_1 \cap B_2| < 2^n$ has an amalgam in $\mathrm{fm}(\Phi)$. Let b_1 and b_2 be the unique elements contained in $B_1 \setminus B_2$ and $B_2 \setminus B_1$, respectively. If $\mathfrak{B}_1 \cup \mathfrak{B}_2 \models \Phi$, then we are done because $\mathfrak{B}_1 \cup \mathfrak{B}_2$ is

an amalgam for $\mathfrak{B}_1$ and $\mathfrak{B}_2$. So suppose that $\mathfrak{B}_1 \cup \mathfrak{B}_2 \not\models \Phi$. Consider any evaluation of the quantifier-free part of Φ witnessing the fact that $\mathfrak{B}_1 \cup \mathfrak{B}_2 \not\models \Phi$. Since b_1 and b_2 do not appear together in any relation of $\mathfrak{B}_1 \cup \mathfrak{B}_2$ and $\mathfrak{B}_1, \mathfrak{B}_2 \models \Phi$, by the shape of Φ, it must be the case that x is assigned some element $b \in B_1 \cap B_2$, y_1 is assigned b_1, and y_2 is assigned b_2 (or vice versa). Since $|B_1 \cap B_2| < 2^n$, there must exist $S \subseteq [n]$ such that, for every $b \in B_1 \cap B_2$, it is not the case that $b \in X_i^{\mathfrak{B}_1 \cup \mathfrak{B}_2}$ if and only if $i \in S$. Consequently, we can obtain an amalgam $\mathfrak{C} \in \mathrm{fm}(\Phi)$ for $\mathfrak{B}_1$ and $\mathfrak{B}_2$ by adding the pairs (b_1, b_2) and (b_2, b_1) to $Y_i^{\mathfrak{B}_1 \cup \mathfrak{B}_2}$ for every $i \in S$. We conclude that a smallest counterexample to the AP for $\mathrm{fm}(\Phi)$ is of size $> 2^n$.

Very little progress has been done on signatures containing symbols of arities larger than 2. In particular, it is not even known whether the AP is decidable for finitely bounded classes in general. The scenario where this is not the case is not unrealistic since the closely related *joint embedding property* (JEP) is undecidable already for finitely bounded classes of graphs [22]. The JEP determines whether a finitely bounded class forms the age of any structure, without the requirement of homogeneity [33]. Note that the undecidability of the JEP does not necessarily have any consequences for the Bodirsky-Pinsker conjecture, similarly as it did not have any for the Feder-Vardi conjecture.

If the AP turns out to be undecidable as well (for finitely bounded classes), then the Bodirsky-Pinsker conjecture addresses a class of structures with an undecidable membership problem, at least under the currently best known input to the meta-problem. It seems that, to some extent, the decidability issue can be ignored by only using homogeneity as a blackbox. This was demonstrated in the recent work [45] on the complexity of CSPs of homogeneous uniform hypergraphs, whose classification remains an open problem [3]. We remark that the complexity of the amalgamation meta-problem is already open in the following case, where we can only prove PSPACE-hardness.

▶ **Theorem 5.** *Given a universal Horn sentence Φ over a finite relational signature that is binary except for one ternary symbol, the question whether* $\mathrm{fm}(\Phi)$ *has the AP is* PSPACE*-hard.*

The next theorem states that testing the AP becomes properly harder than in the binary case if we do not impose any restrictions on the input (unless coNEXPTIME = EXPSPACE). The fact that this is also true for the strong version of the AP might be of independent interest to model-theorists. The *strong* version of the AP is when $\mathfrak{C} \in \mathcal{K}$ and $f_i \colon \mathfrak{B}_i \hookrightarrow \mathfrak{C}$ for $i \in \{1, 2\}$ can always be chosen so that $f_1(B_1) \cap f_2(B_2) = f_1(B_1 \cap B_2)$. Note that the theorem is formulated as a statement of the form "the question whether X or not even Y is hard." This is a compact way for writing that both X and Y (and every property in between) are hard, the formulation tacitly assumes that the inputs never satisfy "Y and not X."

▶ **Theorem 6.** *Given a universal sentence Φ over a finite signature, the question whether* $\mathrm{fm}(\Phi)$ *has the strong AP or not even the AP is* EXPSPACE*-hard.*

Theorem 7 is a variant of Theorem 6 in the setting where the input is specified by a set of bounds instead of a universal sentence. This setting can be compared to the situation where, in Theorem 6, the quantifier-free part of Φ is required to be in DNF. As a consequence, we cannot profit from succinctness of general universal sentences, which leads to a weaker PSPACE lower bound on the complexity. On the other hand, it turns out that PSPACE-hardness is witnessed even by instances whose domain size remains constant.

▶ **Theorem 7.** *Given a finite set $\mathcal{N}$ of finite structures over a finite signature, the question whether* $\mathrm{Forb}_e(\mathcal{N})$ *has the strong AP or not even the AP is* PSPACE*-hard. The statement is true even when the domain size for the structures in $\mathcal{N}$ is bounded by a constant.*

3.1 Proofs of Theorem 6 and Theorem 7

Our proofs of Theorem 6 and Theorem 7 are based on the fact that, if Φ is a universal Horn sentence such that $\mathrm{fm}(\Phi)$ does not have the AP, then every counterexample to the AP has the form of a particular Horn clause which can be derived from Φ in a syntactical manner. By padding each Horn clause in Φ with auxiliary negative atoms and hereby increasing its "degree of completeness," we gain some control over the form of the counterexamples to the AP. When this is performed in a careful and systematic way, the counterexamples to the AP can be brought into a 1:1 correspondence with the rejecting runs of certain Datalog programs. In our case, such programs verify the validity of tilings w.r.t. given input parameters to a bounded tiling problem. This is the main technical contribution of the present article.

▶ **Definition 8.** *Let Φ be an equality-free universal Horn sentence over a relational signature τ. Additionally, let $\phi(\bar{x})$ and $\psi(\bar{x},\bar{y})$ be equality-free conjunctions of atomic τ-formulas. We write $\psi(\bar{x},\bar{y}) \leq_\Phi \phi(\bar{x})$ if, for every atomic τ-formula $\chi(\bar{x})$ other than equality,*

$$\Phi \models \forall \bar{x},\bar{y}\big(\psi(\bar{x},\bar{y}) \Rightarrow \chi(\bar{x})\big) \quad \textit{implies} \quad \Phi \models \forall \bar{x}\big(\phi(\bar{x}) \Rightarrow \chi(\bar{x})\big).$$

In the next lemma, we reformulate the (strong) AP using Definition 8.

▶ **Lemma 9.** *Let Φ be an equality-free universal Horn sentence over a relational signature τ. Then the following are equivalent:*

1. $\mathrm{fm}(\Phi)$ *has the strong AP.*
2. $\mathrm{fm}(\Phi)$ *has the AP.*
3. *If $\phi(\bar{x})$, $\phi_1(\bar{x},y_1)$, and $\phi_2(\bar{x},y_2)$ are equality-free conjunctions of atomic formulas, where y_1 and y_2 are distinct variables not contained in $\bar{x}$, such that, for both $i \in \{1,2\}$, every atom in $\phi_i(\bar{x},y_i)$ contains the variable y_i and $\phi(\bar{x}) \wedge \phi_i(\bar{x},y_i) \leq_\Phi \phi(\bar{x})$, then*

$$\phi(\bar{x}) \wedge \phi_1(\bar{x},y_1) \wedge \phi_2(\bar{x},y_2) \leq_\Phi \phi(\bar{x}) \wedge \phi_1(\bar{x},y_1).$$

Let Φ be an equality-free universal Horn sentence and ψ a Horn clause over a relational signature τ. An *SLD-derivation of ψ from Φ* is a finite sequence of Horn clauses $\psi_0,\dots,\psi_s = \psi$ such that ψ_0 is a conjunct in Φ and, for every $i \in [s]$, there exists a Horn clause ϕ_i which is, up to renaming of variables, a conjunct in Φ, and such that ψ_i is obtained from ψ_{i-1} by replacing a negative atom of ψ_{i-1} that appears positively in ϕ_i with all negative atoms of ϕ_i. We say that ψ_i is a *resolvent* of ψ_{i-1} and ϕ_i. We call ψ a *weakening* of a clause ψ' if ψ' can be obtained from ψ by removing any amount of atoms. In particular, ψ is a weakening of itself. There exists an *SLD-deduction* of ψ from Φ, written as $\Phi \vdash \psi$, if ψ is a tautology or a weakening of a Horn clause ψ' that has an SLD-derivation from Φ. The following theorem presents a fundamental property of equality-free universal Horn sentences.

▶ **Theorem 10** (Theorem 7.10 in [46]). *Let Φ be an equality-free universal Horn sentence and ψ an equality-free Horn clause, both in a fixed signature τ. Then $\Phi \models \psi$ if and only if $\Phi \vdash \psi$.*

Our hardness proofs are by polynomial-time reductions from the complements of two well-known bounded versions of the tiling problem. Consider the signature σ consisting of the two binary symbols P_h, P_v, as well as the four unary symbols P_ℓ, P_r, P_t, P_b. For natural numbers $m,n \geq 1$, the σ-structure $\mathfrak{R}_{m,n}$ has the domain $[m] \times [n]$ and the relations

$$P_h^{\mathfrak{R}_{m,n}} := \{((i,j),(i+1,j)) \mid i \in [n-1], j \in [m]\},$$
$$P_v^{\mathfrak{R}_{m,n}} := \{((i,j),(i,j+1)) \mid i \in [n], j \in [m-1]\},$$
$$P_\ell^{\mathfrak{R}_{m,n}} := [m] \times \{1\},\ P_r^{\mathfrak{R}_{m,n}} := [m] \times \{n\},$$
$$P_b^{\mathfrak{R}_{m,n}} := \{1\} \times [n],\ P_t^{\mathfrak{R}_{m,n}} := \{m\} \times [n].$$

The *rectangle tiling problem* asks whether, given a natural number n and a finite σ-structure $\mathfrak{T}$, there exists a natural number m such that $\mathfrak{R}_{m,n} \to \mathfrak{T}$. Note that this is just a reformulation of the usual statement using the language of homomorphisms.[2] In contrast to the better-known NP-complete square tiling problem, one dimension of the tiling grid is not part of the input and is existentially quantified instead. As a result, the problem becomes PSPACE-complete [50].[3] One can further increase the complexity by allowing a succinct encoding of the space bound. The input remains the same but now we ask for a a rectangle tiling with 2^n columns. Analogously to the natural complete problems based on Turing machines, this yields a decision problem that is complete for the complexity class EXPSPACE [48].

Inputs specified by universal sentences. Theorem 6 is proved by polynomial-time reduction from the complement of the exponential rectangle tiling problem. From every input, we construct a universal sentence Φ of polynomial size such that $\mathrm{fm}(\Phi)$ has the AP if and only if there exists no exponential rectangle tiling satisfying the given parameters. The sentence Φ is almost Horn but disjunctions of non-negated atoms are used in premises of implications to represent exponentially many Horn clauses in a universal sentence of polynomial size. In the text that follows, we allow ourselves to still call such sentences Horn. Our encoding is very compact; each row, i.e., an ordered sequence of 2^n-many tiles, is represented using a constant amount of variables. This is achieved by storing the information about each individual row in binary using $(n+1)$-ary atoms whose entries always contain at most three variables. We refer to the variables representing rows of the tiling as *path* nodes. In order to check the tiling from bottom to top, i.e., parse a chain of path nodes, we require each pair of subsequent path nodes to be verified by a set of 2^n-many *verifier* nodes. This process ensures the vertical consistency of the tiling as well as the presence of 2^n-many tiles in every row. The precise number of verifier nodes is achieved using combinations of n pairs of unary atoms.

To control the occurrence of amalgamation failures, we first introduce a binary symbol E and two unary symbols L, R. Atoms with these symbols serve no other purpose than to ensure that *almost* each conjunct in Φ is complete, i.e., defines a class of structures that is preserved by taking unions and hence has the AP. More concretely, the premise of almost every Horn clause in Φ has a subformula of the form

$$L(y_1) \wedge R(y_2) \wedge \bigwedge\nolimits_{i\in[k]} E(y_1, x_i) \wedge E(y_2, x_i) \wedge \bigwedge\nolimits_{j\in[k]} E(x_i, x_j)$$

making the Horn clause almost complete, with the exception of one potentially missing edge in the Gaifman graph between y_1 and y_2. Our intention is to make this missing edge the only place at which potential faulty one-point amalgamation diagrams can be built (see Figure 1). The sentence Φ is defined as $\Phi_1 \wedge \Phi_2$, where the two parts are described below.

The first part Φ_1 does not yet explain how our reduction works, but ensures that it does not fall apart, e.g., due to ill-behaved identifications of variables. For every $\alpha \in T$, the signature τ contains an $(n+1)$-ary symbol T_α. The first n arguments in a T_α-atom serve as binary counters, and the last argument carries a given path node p. Suppose that the variables $\mathtt{0}$ and $\mathtt{1}$ represent the bits 0 and 1, respectively. Then each atomic formula $T_\alpha(c_1, \dots, c_n, p)$ with $c_1, \dots, c_n \in \{\mathtt{0}, \mathtt{1}\}$ represents the situation in which a tile α is present in the p-th row and in the $\big(1 + \sum_{k\in[n]} (c_k = \mathtt{1}) \cdot 2^{n-k}\big)$-th column. First, we want to ensure the horizontal consistency of the tiling. To this end, for every pair $(\alpha, \beta) \in T^2 \setminus P_h^{\mathfrak{T}}$, we

[2] For comparison, see, e.g., Section 4 in [32].
[3] In [50], the rectangle tiling problem is called the corridor tiling problem.

include in Φ_1 a complete Horn sentence without positive atoms ensuring that two horizontally adjacent positions in the p-th row cannot be tiled with α and β. Here, we encode the successor relation w.r.t. binary addition using a combination of equalities: $(c_{n+1}, \dots, c_{2n})$ is the successor of $(c_1, \dots, c_n)$ if and only if there exists $j \in [n]$ such that $c_i = c_{i+n} \in \{0, 1\}$ for every $i \in [j-1]$, $c_j = 0$ and $c_{n+j} = 1$, and $c_i = 1$ and $c_{i+n} = 0$ for every $i \in [n] \setminus [j]$. This encoding only makes sense if 0 and 1 truly represent the bits 0 and 1, so we introduce a simple mechanism (in terms of a Horn sentence) for distinguishing between the variables 0 and 1. Next, we want to ensure that every position in the p-th row is occupied by at most one tile. To this end, for every $(\alpha, \beta) \in T^2$ with $\alpha \neq \beta$, we include

$$\forall p, 0, 1, c_1, \dots, c_n \big(T_\alpha(c_1, \dots, c_n, p) \wedge T_\beta(c_1, \dots, c_n, p) \wedge \bigwedge\nolimits_{i \in [n]} (c_i = 0 \vee c_i = 1) \Rightarrow \bot \big)$$

as a conjunct in Φ_1. Finally, we want to ensure that each verifier node v represents at most one number from $[2^n]$. For every $i \in [n]$, τ contains two unary symbols $\mathbf{0}_i$ and $\mathbf{1}_i$ which will be used to encode numbers in binary. We include $\forall v \big(\bigvee_{i \in [n]} \mathbf{0}_i(v) \wedge \mathbf{1}_i(v) \Rightarrow \bot \big)$ as the last conjunct in Φ_1. Now the idea is that the combinations of atomic formulas $\mathbf{0}_i(v)$ and $\mathbf{1}_i(v)$ at a verifier node v will be compared with the combinations of 0 and 1 in atomic formulas $T_\alpha(c_1, \dots, c_n, p)$. The Horn sentences in the second part of Φ will be formulated so that verifying the presence of all 2^n atoms of the form $T_\alpha(c_1, \dots, c_n, p_1)$ at a path node p_1 using verifier nodes $v_1, \dots, v_{2^n}$ is the only possible way to progress to a next path node p_2. Consequently, we do not need to add an explicit requirement for rows, represented by path nodes, to be completely tiled from left to right. For the same reason, we also do not need to add an explicit requirement for verifier nodes to represent at least one number from $[2^n]$.

We now proceed with the sentence Φ_2, which explains how the parsing of a tiling actually works. The parsing of a tiling starts from a path node p representing a row whose leftmost position contains a tile that can be present in the bottom left corner of a tiling grid. This must be confirmed by a verifier node, in which case a 6-ary Q_b-atom is derived, representing the fact that the leftmost column of the p-th row has been checked. To this end, we include in Φ_2 suitable Horn sentences for every $\alpha \in P_\ell^{\mathfrak{T}} \cap P_b^{\mathfrak{T}}$. These sentences form *the* non-complete part of Φ; we intentionally leave a missing edge between y_1 and y_2 in the Gaifman graph to enable the formation of potential AP-counterexamples. Moreover, the variables y_1 and y_2 appear in the 1st and the 2nd entry of the derived atom, respectively, and this invariant is maintained throughout the whole construction of Φ_2.

Using 2^n-many verifier nodes and propagation of Q_b-atoms, the whole bottom row is checked for the presence of tiles. Their horizontal consistency already follows from the conditions imposed on path nodes by Φ_2 and needs not to be checked during this step. To this end, we include in Φ_2 suitable Horn sentences for every $\alpha \in P_b^{\mathfrak{T}}$. After the p-th row has been checked by a 2^n-th verifier node, we mark p with a Q-atom indicating that the parsing can progress to a successor path node. To this end, we include in Φ_2 suitable Horn sentences for every $\alpha \in P_b^{\mathfrak{T}} \cap P_r^{\mathfrak{T}}$. The successor relation for path nodes is represented by the binary symbol S, and the certificate of vertical verification for pairs (p_1, p_2) of successive path nodes is represented by the 7-ary symbol Q_v. For every $(\alpha, \beta) \in P_v^{\mathfrak{T}} \cap (P_\ell^{\mathfrak{T}})^2$, we include in Φ_2 a Horn sentence verifying the vertical consistency of the leftmost positions in the rows p_1 and p_2 and deriving the first Q_v-atom containing p_1 and p_2, but only if there is a Q-atom containing p_1. Next, for every $(\alpha, \beta) \in P_v^{\mathfrak{T}}$, we include in Φ_2 a Horn sentence verifying the vertical consistency for the intermediate positions by deriving further Q_v-atoms containing p_1 and p_2. And finally, for every $(\alpha, \beta) \in P_v^{\mathfrak{T}} \cap (P_r^{\mathfrak{T}})^2$, we include in Φ_2 a Horn sentence verifying the vertical consistency of the leftmost positions in the rows p_1 and p_2 and deriving the first Q-atom containing p_2 only. The top row is verified using a 6-ary symbol Q_t similarly as the bottom row; however, the verification of the rightmost position in the top row results in the derivation of $\bot$.

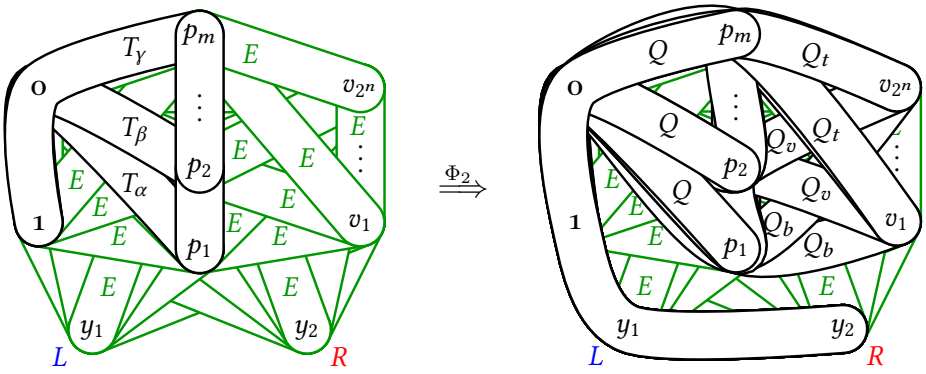

Figure 1 An illustration of an AP-counterexample representing a verification of a valid tiling of an exponential rectangle with m rows and 2^n columns.

Proof of Theorem 6. We first argue that Φ is equivalent to a particular Horn sentence, to which we can apply Lemma 9. By construction, the quantifier-free part of each conjunct in Φ has the form of an implication where the premise possibly also contains instances of disjunction, which are not allowed in Horn clauses, but no instances of negation. Therefore, it can be rewritten as a conjunction of Horn clauses by converting the premise into positive DNF and then considering each disjunct as a separate premise. As a result, the size of the sentence increases exponentially, but this does not matter for the purpose of the proof. Subsequently, all equality atoms can be eliminated by replacing each variable c_i with either o or $\mathrm{1}$. We denote the resulting Horn sentence by $\overline{\Phi}$ and the two parts stemming from Φ_1 and Φ_2 by $\overline{\Phi}_1$ and $\overline{\Phi}_2$, respectively.

"$\Rightarrow$" Suppose that there exists a tiling $f\colon \mathfrak{R}_{m,2^n} \to \mathfrak{T}$. Guided by f, we define a one-point amalgamation diagram $\mathfrak{B}_1, \mathfrak{B}_2 \in \mathrm{fm}(\overline{\Phi})$ which has no amalgam in $\mathrm{fm}(\overline{\Phi})$ (see Figure 1). The domains are $B_i \coloneqq \{y_i, p_1, \dots, p_m, v_1, \dots, v_{2^n}, \mathrm{o}, \mathrm{1}\}$ for $i \in \{1, 2\}$, and the relations are given by the following conjunctions of atomic formulas. We require $T_\alpha(c_1, \dots, c_n, p_j)$ for $c_1, \dots, c_n \in \{\mathrm{o}, \mathrm{1}\}$ if and only if $f(1 + \sum_{k\in[n]}(c_k = \mathrm{1}) \cdot 2^{n-k}, j) = i$. Next, we require all of the L, R, and E-atoms necessary for enabling the Horn clauses in $\mathfrak{B}_1 \cup \mathfrak{B}_2$. Finally, we require $\bigwedge_{i\in[m-1]} S(p_i, p_{i+1})$ to define a successor chain through path nodes, and $\mathrm{O}_i(v_j)$ or $\mathrm{1}_i(v_j)$ if and only if $j = 1 + \sum_{k\in[n]} \lambda_k \cdot 2^{n-k}$ for $\lambda_1, \dots, \lambda_n \in \{0, 1\}$ and $\lambda_i = 0$ or $\lambda_i = 1$, respectively. Clearly, the tiling atoms are placed correctly and the verifier nodes correctly represent values in $[2^n]$. Since $R^{\mathfrak{B}_1} = \emptyset$ and $L^{\mathfrak{B}_2} = \emptyset$, we have $\mathfrak{B}_1, \mathfrak{B}_2 \models \overline{\Phi}_2$. Since f is horizontally consistent, we have $\mathfrak{B}_1, \mathfrak{B}_2 \models \overline{\Phi}_1$, i.e., $\mathfrak{B}_1, \mathfrak{B}_2 \in \mathrm{fm}(\overline{\Phi})$. But since f is also vertically consistent and $\overline{\Phi}_2$ is a universal Horn sentence, we have $\mathfrak{C} \not\models \overline{\Phi}_2$ for every τ-structure $\mathfrak{C}$ with a homomorphism from $\mathfrak{B}_1 \cup \mathfrak{B}_2$. Hence, $\mathrm{fm}(\overline{\Phi})$ does not have the AP.

"$\Leftarrow$" Suppose that $\mathrm{fm}(\overline{\Phi})$ does not have the AP. Then there exists a counterexample to item (3) in Lemma 9, i.e., there exists a Horn clause ψ of the form $\phi(\bar{x}) \wedge \phi_1(\bar{x}, y_1) \wedge \phi_2(\bar{x}, y_2) \Rightarrow \chi$, where ϕ, ϕ_1, and ϕ_2 satisfy the prerequisites of item (3) in Lemma 9 and $\chi(\bar{x}, y_1)$ is an atomic τ-formula other than equality, such that

$$\overline{\Phi} \models \forall \bar{x}, y_1, y_2 \big(\phi \wedge \phi_1 \wedge \phi_2 \Rightarrow \chi\big), \tag{1}$$

$$\overline{\Phi} \not\models \forall \bar{x}, y_1 \big(\phi \wedge \phi_1 \Rightarrow \chi\big). \tag{2}$$

We choose ψ minimal with respect to the number of its atomic subformulas. By Theorem 10, ψ has an SLD-deduction from $\overline{\Phi}$. Note that, by (2), $\chi(\bar{x}, y_1)$ cannot be a subformula of $\phi(\bar{x}) \wedge \phi_1(\bar{x}, y_1)$. Also, $\chi(\bar{x}, y_1)$ cannot be a subformula of $\phi_2(\bar{x}, y_2)$ because every atom in

$\phi_2(\bar{x}, y_2)$ contains the variable y_2 which does not appear in $\chi(\bar{x}, y_1)$. Hence, $\chi(\bar{x}, y_1)$ is not a subformula of $\phi(\bar{x}) \wedge \phi_1(\bar{x}, y_1) \wedge \phi_2(\bar{x}, y_2)$, i.e., ψ is not a tautology. Consequently, ψ is a weakening of a Horn clause ψ' which has an SLD-derivation $\psi'_0, \dots, \psi'_s = \psi'$ from $\overline{\Phi}$. Recall that every atom from ψ' appears in ψ.

▷ Claim 11. $\overline{\Phi}_2 \vdash \psi'$.

Proof. We start by showing that ψ'_0 is a conjunct of $\overline{\Phi}_2$. Suppose, on the contrary, that ψ'_0 is a conjunct of $\overline{\Phi}_1$. Then ψ' does not contain any positive atom because, by construction, Horn sentences in $\overline{\Phi}_1$ do not contain any positive atoms. By construction, in $\overline{\Phi}$ there is no Horn clause containing a positive atom that occurs negatively in a Horn clause from $\overline{\Phi}_1$, i.e., it is impossible to take resolvents of ψ'_0 and Horn clauses from $\overline{\Phi}$. It follows that $s = 0$. Also, every Horn clause from $\overline{\Phi}_1$ is complete. Since there is no edge between y_1 and y_2 in the Gaifman graph of ψ, and, for $i \in \{1, 2\}$, each atom in ϕ_i contains the variable y_i, either ϕ_1 or ϕ_2 must be empty. Since ψ' does not contain any positive atom and $\phi(\bar{x}) \wedge \phi_i(\bar{x}, y_i) \leq_{\overline{\Phi}} \phi(\bar{x})$ for both $i \in \{1, 2\}$, we get a contradiction to (2). Thus, ψ'_0 must be a conjunct of $\overline{\Phi}_2$. Since no Horn clause in $\overline{\Phi}_1$ contains a positive atom, no Horn clause from $\overline{\Phi}_1$ can be used as a resolvent. We conclude that ψ' has an SLD-derivation from $\overline{\Phi}_2$. ◁

▷ Claim 12. ψ' contains no positive atoms, and no atoms with a symbol from $\{Q_b, Q_v, Q_t, Q\}$.

Proof. By the construction of $\overline{\Phi}_2$, for every $i \in [s]$, if ψ'_{i-1} contains variables z_1, z_2 such that

$$\begin{array}{l}\text{every atomic subformula with a symbol from } \{Q_b, Q_v, Q_t, Q\} \\ \text{contains } z_1 \text{ in its 1st and } z_2 \text{ in its 2nd argument, respectively,}\end{array} \tag{3}$$

then this is also the case for ψ'_i, for the same variables z_1, z_2 up to renaming. Since every possible choice of ψ'_0 from $\overline{\Phi}_2$ initially satisfies (3), it follows via induction that (3) holds for $\psi' = \psi'_s$ for some variables z_1, z_2. Next, we show that $\{z_1, z_2\} = \{y_1, y_2\}$ holds for the pair z_1, z_2 satisfying (3) for ψ'. Suppose, on the contrary, that both z_1 and z_2 are among $\bar{x}, y_1$ or $\bar{x}, y_2$. By construction, the only Horn clauses in $\overline{\Phi}_2$ that are not complete have the property that the incompleteness is only due to one missing edge in the Gaifman graph between two distinguished variables satisfying (3). Therefore, for every $i \in [s]$, ψ'_i is a resolvent of ψ'_{i-1} and a Horn clause from $\overline{\Phi}_2$ which is almost complete except possibly for one missing edge in the Gaifman graph between a pair of variables which must be substituted for the pair (z_1, z_2) satisfying (3) for ψ'_{i-1}. Since the variables y_1 and y_2 do not appear together in any atom in ψ' and $\{z_1, z_2\} \neq \{y_1, y_2\}$, they also do not appear together in any atom during the SLD-derivation. Then it follows from the fact that ϕ, ϕ_1, and ϕ_2 satisfy the prerequisites of item (3) in Lemma 9 that we already have $\overline{\Phi}_2 \vdash \forall \bar{x}, y_1 \big(\phi \wedge \phi_1 \Rightarrow \chi\big)$, a contradiction to (2). Since $\{z_1, z_2\} = \{y_1, y_2\}$ holds for the pair z_1, z_2 satisfying (3) for ψ', ψ' cannot contain any negative atoms with a symbol from $\{Q_b, Q_v, Q_t, Q\}$. Suppose that the conclusion of ψ'_0 is not $\bot$. Then, by construction, ψ' contains a positive atom with a symbol from $\{Q_b, Q_v, Q_t, Q\}$. But then, since z_1, z_2 with $\{z_1, z_2\} = \{y_1, y_2\}$ satisfy (3) for ψ', the said positive atom in ψ' contains both variables y_1 and y_2. This leads to a contradiction to (1) where we assume that the positive atom in ψ may may only contain variables from $\bar{x}, y_1$. Thus the conclusion of ψ'_0 is $\bot$, which means that χ equals $\bot$ due to the minimality assumption. ◁

It remains to show that the existence of such ψ' implies the existence of a tiling $f \colon \mathfrak{R}_{m,2^n} \to \mathfrak{T}$. By the first and the second claim, the conclusion of ψ'_0 is $\bot$. Since ψ' does not contain any atoms with a symbol from $\{Q_b, Q_v, Q_t, Q\}$, the last such atom must have been eliminated from ψ'_{s-1} by taking a resolvent with one of the incomplete Horn clauses in $\overline{\Phi}_2$. By the

construction of $\overline{\Phi}_2$, to obtain ψ' through an SLD-derivation $\psi'_0, \ldots, \psi'_s = \psi'$ from $\overline{\Phi}_2$, all Horn clauses introduced in the definition of $\overline{\Phi}_2$ must have been used in the intended order. Recall that we have replaced each variable c_i in Φ_2 with either 0 or 1 while rewriting Φ_2 as an Horn sentence. Every Horn clause from $\overline{\Phi}_2$ has the property that every positive atomic subformula has a symbol from $\{Q_b, Q_v, Q_t, Q\}$ and contains all variables that appear in a negative atomic subformula, with the following two exceptions. First, verifier nodes are not carried over in any atoms because their only contribution is the encoding of a unique number. Second, after a pair of successive rows has been checked by deriving a Q_v-atom containing a 2^n-th verifier node, the variable representing the lower row is not carried over in any atom because it is no longer needed. Since ϕ, ϕ_1, and ϕ_2 satisfy the prerequisites of item (3) in Lemma 9, no ill-behaved variable identifications might have occurred during the SLD-derivation above as otherwise, we would have $\overline{\Phi}_1 \models \forall \bar{x}, y_1\big(\phi \wedge \phi_1 \Rightarrow \chi\big)$, a contradiction to (2). Consequently, the SLD-derivation must have the full intended length $(2^n + 1) \cdot m$ for some $m \geq 1$, because every intermediate stage starts and ends with verifier nodes encoding the numbers 2^n and 1, respectively, and one can only progress in steps which decrement the encoded number by one. Clearly, the SLD-derivation witnesses the existence of $f\colon \mathfrak{R}_{m,2^n} \to \mathfrak{T}$. ◀

Inputs specified by sets of bounds. We continue with the proof of Theorem 7. This time, we reduce from the complement of the basic rectangle tiling problem. The proof strategy is similar. In particular, we include in τ the two auxiliary unary symbols L, R and the binary auxiliary symbol E. However, the encoding of the tiles is different. We include in τ a symbol I of arity $\lceil \log_2 |T| \cdot n \rceil + 1$. The first $\lceil \log_2 |T| \cdot n \rceil$ entries serve as binary counters to represent the pairs $(i, \alpha) \in [n] \times T$ in binary, and the last entry carries a path node representing a row of the tiling grid. Each pair $(i, \alpha) \in [n] \times T$ is to be interpreted as the fact that the i-th column in the row represented by a particular path node contains the tile α. The reason for this choice of encoding is that we aim to construct a universal sentence Φ which is equivalent to a set of forbidden substructures $\mathcal{N}$ of size polynomial in $|T| \cdot n$. To achieve this, we use a constant number of symbols whose arity is logarithmic in the size of the input.

Suppose that 0 and 1 are two variables representing the bits 0 and 1, respectively. For each pair $(i, \alpha) \in [n] \times T$, the ternary formula $\mathrm{TILE}_{i,\alpha}(0, 1, p)$ is the I-atom whose last entry contains the variable p and the first $\lceil \log_2 |T| \cdot n \rceil$ entries contain the variables 0 and 1 in the unique way that represents the number $i \cdot \alpha$ in binary when read from left to right. Note that the number of such formulas is polynomial in the size of the input to the tiling problem. In contrast to the proof of Theorem 6, it is not necessary to introduce any verifier nodes as the number of columns in the tiling grid is polynomial in the size of the input. The sentence Φ is defined similarly as in the proof of Theorem 6, so we only provide a general overview and highlight the main differences. We want each row to be horizontally consistent. For all $i \in [n-1]$ and $(\alpha, \beta) \in T^2 \setminus P_h^{\mathfrak{T}}$, we include the following sentence as a conjunct in Φ_1:

$$\forall p, 0, 1\big(\psi(0, 1) \wedge \mathrm{TILE}_{i,\alpha}(0, 1, p) \wedge \mathrm{TILE}_{i+1,\beta}(0, 1, p) \Rightarrow \bot\big),$$

where $\psi(0, 1)$ represents a simple mechanism for distinguishing between 0 and 1. We also want each position in a given row to be occupied by at most one tile. For all $i \in [n], \alpha, \beta \in T$, we include the following sentence as a conjunct in Φ_1:

$$\forall p, 0, 1\big(\mathrm{TILE}_{i,\alpha}(0, 1, p) \wedge \mathrm{TILE}_{i,\beta}(0, 1, p) \Rightarrow \bot\big).$$

As in the proof of Theorem 7, we do *not* need to include an explicit condition stating that each row must be completely tiled from left to right. For the purpose of verifying the validity

of a tiling, we include in τ a 5-ary symbol Q, a $(\lceil \log_2 |T| \cdot n \rceil + 4)$-ary symbol Q_v, and two $(\lceil \log_2 |T| \cdot n \rceil + 3)$-ary symbols Q_b, Q_t. For each pair $(i, \alpha) \in [n] \times T$, the formulas

$$\mathrm{BOT}_{i,\alpha}(0, 1, p, y_1, y_2), \quad \mathrm{TOP}_{i,\alpha}(0, 1, p, y_1, y_2), \quad \text{and} \quad \mathrm{VERT}_{i,\alpha}(0, 1, p_1, p_2, y_1, y_2)$$

are defined analogously to $\mathrm{TILE}_{i,\alpha}(0, 1, p)$ but using the Q_b, Q_t and Q_v-atoms instead. We use them to verify the bottom row, top row, and the vertical consistency of a given tiling. In contrast to $\mathrm{TILE}_{i,\alpha}$, the parameter α is not important in $\mathrm{BOT}_{i,\alpha}$, $\mathrm{TOP}_{i,\alpha}$, and $\mathrm{VERT}_{i,\alpha}$.

We now explain how to convert Φ into a set of forbidden substructures. Let $\mathcal{N}$ be the class of all τ-structures with the domain $[i]$ for some $i \in [6]$ that do not satisfy Φ. Since Φ only uses six variables, we have $\mathrm{fm}(\Phi) = \mathrm{Forb}_e(\mathcal{N})$. It remains to show that there exists a polynomial that bounds the size of $\mathcal{N}$. Since there is a constant number of domains of structures in $\mathcal{N}$ and their sizes are also constant, it is enough to show that there exists a polynomial that bounds the number of structures in $\mathcal{N}$. The only non-constant parameters in the construction are the four symbols I, Q_b, Q_t, and Q_v whose arity grows logarithmically with $|T| \cdot n$. Thus, there exists a constant c such that the number of structures in $\mathcal{N}$ is bounded by $c \cdot \left(2^{\lceil \log_2 |T| \cdot n \rceil}\right)^4 \leq c \cdot (2 \cdot |T| \cdot n)^4$. The rest is analogous to the proof of Theorem 6.

4 The Homogenizability Meta-Problem

Every reduct $\mathfrak{R}$ of a finitely bounded homogeneous structure $\mathfrak{H}$ is uniquely described by an SNP sentence, which can be obtained from a universal sentence for $\mathrm{age}(\mathfrak{H})$ by existentially quantifying all the surplus predicates upfront. This is (arguably) the most natural representation for such structures. The homogenizability meta-problem asks whether a given SNP τ-sentence Φ is logically equivalent to an SNP τ-sentence $\Psi = \exists Y_1, \ldots, Y_m \forall \bar{y}. \psi$ such that $\mathrm{fm}(\forall \bar{y}. \psi)$ has the AP in the signature $\tau \cup \{Y_1, \ldots, Y_m\}$. We are additionally interested in the refinement of the question where we require the homogeneous structure from Theorem 1 associated to $\mathrm{fm}(\forall \bar{y}. \psi)$ to have the same set of automorphisms as its reduct to the original signature τ. This amounts to asking whether $\mathrm{fm}(\Phi)$ is finitely bounded homogenizable.

MMSNP was presented in [30] as a large subclass of SNP which has a dichotomy between P and NP-completeness if and only if the class of all finite-domain CSPs has one. The latter has been confirmed, and the dichotomy for MMSNP has received a new universal-algebraic proof within the programme attacking the Bodirsky-Pinsker conjecture [16]. The new proof relies on the observation that every MMSNP sentence Φ is equivalent to a finite disjunction $\Phi_1 \vee \cdots \vee \Phi_n$ of MMSNP sentences such that, for every $i \in [n]$, there exists a reduct $\mathfrak{R}_i$ of a finitely bounded homogeneous structure $\mathfrak{H}_i$ such that $\mathrm{fm}(\Phi_i) = \mathrm{CSP}(\mathfrak{R}_i)$.[4] Moreover, the structure $\mathfrak{H}$ can be chosen so that its age has the *Ramsey property*, which plays an essential role in an argument in [16] showing that the authors correctly identified all of the tractable cases. The exact definition of this property is not essential to the present article and is therefore omitted. GMSNP was first introduced in [41] in its seemingly weaker form MMSNP_2, as a generalization of MMSNP where "monadic" second-order variables may also range over atomic formulas. It was later shown that relaxing the above requirement for monotone SNP to guardedness does not result in a more expressive logic [7]. There is a prospect that GMSNP will also have dichotomy between P and NP-completeness since it enjoys similar model-theoretic properties as MMSNP [15].

Theorem 13 is the most general version of our undecidability result. It applies not only to the original formulation of the homogenizability meta-problem, but also to its generalization to ω-categorical structures. The second item of the theorem might give the impression that

[4] This observation was first made in the the proof of Theorem 7 in [11].

one cannot effectively distinguish between CSPs of reducts of finitely bounded structures and CSPs of reducts of finitely bounded homogeneous structures. Recall that the former class does not have a dichotomy [30, 8]. However, as indicated by the formulation of the second item, all CSPs of reducts of finitely bounded homogeneous structures in the proof of Theorem 13 are in fact finite-domain CSPs, for which there is a dichotomy. Therefore, Theorem 13 merely shows that SNP sentences are an exceptionally bad choice of an input to the question, albeit one that is often used [4, 43].

▶ **Theorem 13.** *For a given a Datalog sentence Φ using at most binary relation symbols, it is undecidable whether:*

1. *Φ is logically equivalent to a monadic Datalog sentence,*
   or Φ is not even logically equivalent to any GMSNP sentence;
2. *Φ simultaneously satisfies the following three conditions:*
   - *$\mathrm{fm}(\Phi)$ is the CSP of a finite structure,*
   - *$\mathrm{fm}(\Phi)$ is a finitely bounded homogenizable class,*
   - *$\mathrm{fm}(\Phi)$ is the age of a reduct of a finitely bounded homogeneous Ramsey structure,*

   or $\mathrm{fm}(\Phi)$ is not even the CSP or the age of any ω-categorical structure.

The following corollary extracts the statement originally announced in the introduction.

▶ **Corollary 14.** *It is undecidable whether a given SNP sentence defines the age of a reduct of a finitely bounded homogeneous structure. The statement is true even if the SNP sentence comes from the Datalog fragment and uses at most binary relation symbols.*

4.1 A proof of Theorem 13

As usual, the *Kleene plus* and the *Kleene star* of a finite set of symbols Σ, denoted by Σ^+ and Σ^*, are the sets of all finite words over Σ of lengths ≥ 1 and ≥ 0, respectively.

A *context-free grammar* (CFG) is a 4-tuple $\mathcal{G} = (N, \Sigma, P, S)$ where N is a finite set of *non-terminal symbols*, Σ is a finite set of *terminal symbols*, P is a finite set of *production rules* of the form $A \to w$ where $A \in N$ and $w \in (N \cup \Sigma)^+$, $S \in N$ is the *start symbol*. For $u, v \in (N \cup \Sigma)^+$ we write $u \to_G v$ if there are $x, y \in (N \cup \Sigma)^+$ and $(A \to w) \in P$ such that $u = xAy$ and $v = xwy$. The *language of* $\mathcal{G}$ is $L(\mathcal{G}) \coloneqq \{w \in \Sigma^+ \mid S \to^*_{\mathcal{G}} w\}$, where $\to^*_{\mathcal{G}}$ denotes the transitive closure of $\to_{\mathcal{G}}$. Note that with this definition the *empty word* ϵ can never be an element of $L(\mathcal{G})$; some authors use a modified definition that also allows rules that derive ϵ, but for our purposes the difference is not essential. A context-free grammar is called *(left-)regular* if its production rules are always of the form $A \to a$ or $A \to Ba$ for non-terminal symbols A, B and a terminal symbol a. For a finite set Σ, we call a set $L \subseteq \Sigma^+$ *regular* if it is the language of a regular grammar with terminal symbols Σ.

▶ **Example 15.** Consider the CFG $\mathcal{G}$ with a single terminal symbol a, non-terminal symbols S, A, B, C, and production rules $S \to a$, $S \to aa$, $S \to aaa$, $S \to Aa$, $A \to Ba$, $B \to Ca$, $C \to Ca$, and $C \to a$. Clearly, $\mathcal{G}$ is not regular. However, $L(\mathcal{G}) = \{a\}^+$ is regular.

Let $\mathcal{G} = (N, \Sigma, P, S)$ be a CFG. The signature τ_Σ consists of the unary symbols I, T and the binary symbols R_a for every $a \in \Sigma$, and the signature τ_N consists of a binary symbol R_a for every element $a \in N$. For $a_1 \dots a_n \in \Sigma^+$, we set $\phi_{a_1 \dots a_n}(x_1, \dots, x_{n+1}) \coloneqq \bigwedge_{i \in [n]} R_{a_i}(x_i, x_{i+1})$. Let $\overline{\Phi}_{\mathcal{G}}$ be the universal Horn sentence over the signature $\tau_\Sigma \cup \tau_N$ whose quantifier-free part contains, for every $(A, w) \in P$, the Horn clause $\phi_w(x_1, \dots, x_{|w|+1}) \Rightarrow R_A(x_1, x_{|w|+1})$, and additionally the Horn clause $I(x_1) \wedge R_S(x_1, x_2) \wedge T(x_2) \Rightarrow \bot$. Then $\Phi_{\mathcal{G}}$ is the Datalog sentence obtained from $\overline{\Phi}_{\mathcal{G}}$ by existentially quantifying all symbols from τ_N

upfront. This encoding of CFGs into Datalog programs is standard (Exercise 12.26 in [1]), and the correspondence provided by the next lemma can be shown via a straightforward induction. For a proof, we refer the reader to [20].

▶ **Lemma 16.** *For a τ_Σ-structure $\mathfrak{A}$, we have $\mathfrak{A} \models \Phi_{\mathcal{G}}$ if and only if, for every $w \in L(\mathcal{G})$,*

$$\mathfrak{A} \models \forall x_1, \dots, x_{|w|+1} \big(I(x_1) \wedge \phi_w(x_1, \dots, x_{|w|+1}) \wedge T(x_{|w|+1}) \Rightarrow \bot \big).$$

The following lemma is proved by establishing a connection between the well-known Myhill-Nerode correspondence and ω-categoricity, under the addition of several auxiliary results from [29, 15].

▶ **Lemma 17.** *Let $\mathcal{G}$ be a context-free grammar. Then the following are equivalent:*

1. *$L(\mathcal{G})$ is regular.*
2. *$\Phi_{\mathcal{G}}$ is equivalent to a monadic Datalog sentence.*
3. *$\Phi_{\mathcal{G}}$ is equivalent to a GMSNP sentence.*
4. *$\mathrm{fm}(\Phi_{\mathcal{G}})$ is the CSP of a finite structure.*
5. *$\mathrm{fm}(\Phi_{\mathcal{G}})$ is the CSP of an ω-categorical structure.*
6. *$\mathrm{fm}(\Phi_{\mathcal{G}})$ is the age of a reduct of a finitely bounded homogeneous Ramsey structure.*
7. *$\mathrm{fm}(\Phi_{\mathcal{G}})$ is the age of an ω-categorical structure.*
8. *$\mathrm{fm}(\Phi_{\mathcal{G}})$ is finitely bounded homogenizable.*

Proof of Theorem 13. It is well-known that the questions whether $L(\mathcal{G})$ is regular for a given context-free grammar $\mathcal{G}$ is undecidable, see, e.g., Theorem 6.6.6 in [49]. Hence, all eight equivalent conditions in Lemma 17 are undecidable for $\mathcal{G}$. ◀

5 Open Questions

We proved the EXPSPACE-hardness of the amalgamation meta-problem. However, our methods rely heavily on the following three facts. First, symbols of arity > 2 allow us to simulate a restricted form of Datalog computation within one-point amalgamation diagrams. Second, Boolean combinations of atoms enable succinct representations of the Datalog rules. And third, symbols of unbounded arity enable storing exponential amount of information on a constant number of variables. We do not know how to extend our hardness result beyond EXPSPACE. In particular, it does not seem to be possible to reduce from any of the standard undecidable problems, which can be done for the closely related joint embedding property [22, 20]. Intuitively, the reason is that every representation of a run of a Turing machine in a finitely bounded class requires some sort of a successor predicate (see, e.g., [31]), and the successor predicate is never definable in any ω-categorical structure [8].

Open question: Is the amalgamation meta-problem decidable in EXPSPACE?

Identifying Tractable Quantified Temporal Constraints Within Ord-Horn

Abstract

The constraint satisfaction problem, parameterized by a relational structure, provides a general framework for expressing computational decision problems. Already the restriction to the class of all finite structures forms an interesting microcosm on its own, but to express decision problems in temporal reasoning one has to take a step beyond the finite-domain realm. An important class of templates used in this context are temporal structures, i.e., structures over $\mathbb{Q}$ whose relations are first-order definable using the usual countable dense linear order without endpoints.

In the standard setting, which allows only existential quantification over input variables, the complexity of finite and temporal constraints has been fully classified. In the quantified setting, i.e., when one also allows universal quantifiers, there is only a handful of partial classification results and many concrete cases of unknown complexity. This paper presents a significant progress towards understanding the complexity of the quantified constraint satisfaction problem for temporal structures. We provide a complexity dichotomy for quantified constraints over the Ord-Horn fragment, which played an important role in understanding the complexity of constraints both over temporal structures and in Allen's interval algebra. We show that all problems under consideration are in P or coNP-hard. In particular, we determine the complexity of the quantified constraint satisfaction problem for $(\mathbb{Q}; x = y \Rightarrow x \geq z)$, hereby settling a question open for more than ten years.

1 Introduction

The constraint satisfaction problem (CSP) of a structure $\mathfrak{B}$ in a finite relational signature τ, denoted by CSP($\mathfrak{B}$), is the problem of deciding whether a given primitive positive τ-sentence holds in $\mathfrak{B}$. The class of all *finite-domain* CSPs, i.e., where $\mathfrak{B}$ can be chosen finite, famously constitutes a large fragment of NP that admits a dichotomy between P and NP-completeness [19]. Quantified constraint satisfaction problems (QCSPs) generalize CSPs by allowing both existential *and* universal quantification over input variables. The complexity of such problems is much less understood already for finite structures, the state of the art being a complexity classification for QCSPs of finite structures with all unary relations and three-element structures with all singleton unary relations [21]. For infinite structures, the investigations essentially follow the CSP programme, which was initiated by the study of the CSPs of structures over $\mathbb{N}$ (or $\mathbb{Q}$) whose relations are definable by Boolean combinations of equalities and disequalities, the so-called *equality structures* [6]. The full complexity classification for quantified equality constraints was completed quite recently [22], by resolving the long-standing question of determining the complexity of QCSP($\mathbb{Q}$; D), where

$$\mathrm{D} \coloneqq \{(x, y, z) \in \mathbb{Q}^3 \mid x = y \Rightarrow x = z\}.$$

This question was left open in [3], where all the remaining results have been provided. The next in line are *temporal structures*, which are structures with domain $\mathbb{Q}$ whose relations are first-order definable over $\{<\}$, where $<$ interprets as the usual unbounded dense linear order. The relations of such structures are called *temporal*.

By definition, temporal structures form a richer class than equality structures. While the complexity of temporal CSPs has been classified more than a decade ago [7], there is only a handful of partial classification results regarding the complexity of temporal QCSPs [4, 10, 11, 12, 18]. Yet, already from this limited amount of available data it is apparent that the majority of the pathological cases is concentrated in the *Ord-Horn* (OH) fragment, we elaborate on this below. The OH fragment comprises all temporal structures whose relations are definable by an OH formula, i.e., a conjunction of clauses of the form

$$(x_1 \neq y_1 \vee \cdots \vee x_k \neq y_k \vee x_{k+1} \geq y_{k+1}) \tag{1}$$

for $k \geq 0$, where the last disjunct is optional and some variables might be identified [2].

1.1 Ord-Horn

OH was first introduced and used by Nebel and Bürckert to describe a maximally tractable constraint language containing all basic relations on Allen's interval algebra [16]. For a full classification of maximally tractable subalgebras of Allen, see [15]. In the context of CSPs over temporal structures, OH is not even a maximally tractable language as it is properly contained in two of the nine maximally tractable fragments characterized by the eight binary operations *min*, *max*, *mx*, *dual mx*, *mi*, *dual mi*, $\ell\ell$, *dual* $\ell\ell$, and a constant operation [7]. The *dual* of an operation f on $\mathbb{Q}$ is the operation $(x_1, \ldots, x_n) \mapsto -f(-x_1, \ldots, -x_n)$, e.g., *max* is the dual of *min*. The description of maximally tractable languages by operations is typical for the so-called algebraic approach to constraint satisfaction problems. For the sake of the reader unfamiliar with this approach, we simply refer to a maximally tractable temporal language characterized by an operation *op* as the *op* fragment and refrain from defining the operations. For example, we write "the *min* fragment" or "the *max* fragment." The question which of the nine fragments are also maximal w.r.t. tractability of the QCSP

was investigated in [4], and answered positively in the first four cases. The answer is negative in the last three cases [22], and the question remains open for *mi* and *dual mi* fragments. In the intersections of $\ell\ell$, *mi* and *dual mi* fragments lie the OH structures $(\mathbb{Q}; \mathrm{M}^+)$ and $(\mathbb{Q}; \mathrm{M}^-)$, respectively, where

$$\mathrm{M}^+ \coloneqq \{(x,y,z) \in \mathbb{Q}^3 \mid x = y \Rightarrow x \geq z\} \quad \text{and} \quad \mathrm{M}^- \coloneqq \{(x,y,z) \in \mathbb{Q}^3 \mid x = y \Rightarrow x \leq z\}.$$

Determining the complexity of $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ was posed as an open question in [4]; it could have been anywhere between PTIME and PSPACE. Note that its counterpart $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^-)$ is essentially the same problem with the order reversed.

Apart from temporal structures preserved by a constant operation, OH captures precisely those temporal structures whose CSP is solvable by local consistency checking [8]. This well-known generic preprocessing algorithm can be formulated for any CSP satisfying some reasonable structural assumptions [5], and thus OH constraints are fairly well understood from the CSP perspective. However, the analysis of OH constraints in the quantified setting requires a surprisingly large amount of creativity. As a simple example, already $\mathrm{QCSP}(\mathbb{Q}; R)$ for the OH relation R defined by $(x_1 \neq x_2 \vee x_3 \geq x_4) \wedge \phi$ is in PTIME if ϕ equals $(x_3 \geq x_1) \wedge (x_1 \geq x_3) \wedge (x_3 \neq x_4)$ [12], coNP-complete if ϕ equals $(\bigwedge_{i,j \in \{1,2\}} x_i \neq x_{j+2})$ [20], and PSPACE-complete if ϕ is the empty conjunction [22].

The class of *Guarded Ord-Horn* (GOH) formulas [12] is defined inductively. In the base case we are allowed to take OH formulas of the form $(x \leq y)$, $(x_1 \neq y_1 \vee \cdots \vee x_k \neq y_k)$, or $(x \neq x_1 \vee \cdots \vee x \neq x_k) \vee (x < y) \vee (y \neq y_1 \vee \cdots \vee y \neq y_\ell)$. In the induction step we can form formulas of the form $\psi_1 \wedge \psi_2$ or $(x_1 \leq y_1 \vee \cdots \vee x_k \leq y_k) \wedge (x_1 \neq y_1 \vee \cdots \vee x_k \neq y_k \vee \psi)$, where ψ, ψ_1, ψ_2 are GOH formulas. Thus, newly added disequalities are guarded by atomic $\{\leq\}$-formulas. A GOH structure may only contain temporal relations definable by GOH formulas. Observe that the tractable template from the previous paragraph is GOH.

▶ **Theorem 1** ([12]). *Let $\mathfrak{B}$ be a GOH structure. Then* $\mathrm{QCSP}(\mathfrak{B})$ *is in* PTIME.

The tractability result from [12] is conceptually simple and based on pebble games generalizing local consistency methods. At the same time, all quantified OH constraints outside of GOH are coNP-hard or admit a LOGSPACE reduction from $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$.

▶ **Theorem 2** ([18]). *Let $\mathfrak{B}$ be an OH structure. Then one of the following holds.*

- *$\mathfrak{B}$ is GOH.*
- $\mathrm{QCSP}(\mathfrak{B})$ *is* coNP*-hard.*
- *$\mathfrak{B}$ primitively positively defines* M^+ *or* M^-.

There was a prospect that $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ would be PSPACE-hard, because the PSPACE-hardness proof from [22] for $\mathrm{QCSP}(\mathbb{Q}; \mathrm{D})$, when adjusted appropriately, almost yields a proof of PSPACE-hardness for this QCSP. In that case, Theorems 1 and 2 would immediately yield a dichotomy between P and coNP-hardness for quantified OH constraints. However, it turns out that the situation is more complicated, as we explain below.

1.2 Contributions

On the one hand, we prove tractability for $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$, and thereby provide a positive answer to an open question from [4]. This is the main technical contribution of the present paper, and the proof stretches over the entirety of Section 3.

In a certain sense, the presented algorithm generalizes local consistency methods. We iteratively expand a given instance Φ of $\mathrm{QCSP}(\mathfrak{B})$ by constraints associated to relations whose arity is bounded by the size of Φ and which have short primitive positive definitions

in $\mathfrak{B}$, until a fixed-point is reached. The condition for the expansion by these constraints is tested using an oracle for $\mathrm{CSP}(\mathfrak{B}, <)$. The algorithm is thus not very far from the well-known framework of Datalog with existential rules [1, 9].

▶ **Theorem 3.** $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ *is in* PTIME.

Our tractability result naturally extends to the QCSPs of those OH structures which can be expressed in $(\mathbb{Q}; \mathrm{M}^+, \neq)$ using primitive positive definitions (see Proposition 6). We show that the set of these structures coincides with the intersection of the OH fragment with the $\pi\pi$ fragment. Here by $\pi\pi$ [1] we refer to the "*projection-projection*" operation from [7], which played an important role in identifying the maximally tractable temporal CSP languages covered by *min*, *mi* and *mx*. In the present paper, we introduce the $\pi\pi$ fragment using the syntactic description obtained in [4]. For a definition of the operation $\pi\pi$, see [7]. The $\pi\pi$ fragment consists of all temporal relations definable by a conjunction of clauses of the form

$$(x \neq y_1 \vee \cdots \vee x \neq y_k \vee x \geq z_1 \vee \cdots \vee x \geq z_\ell) \tag{2}$$

for $k, l \geq 0$. The *dual* $\pi\pi$ fragment is obtained by replacing every instance of $\geq$ in (2) by $\leq$.

▶ **Corollary 4.** $\mathrm{QCSP}(\mathfrak{B})$ *is in* PTIME *if* $\mathfrak{B}$ *is an OH structure in which every relation is definable by a conjunction of clauses of the form*

$$(x \neq y_1 \vee \cdots \vee x \neq y_k \vee x \geq z) \tag{3}$$

for $k \geq 0$ *and where the last disjunct* $(x \geq z)$ *may be omitted. The above condition is satisfied if and only if* $\mathfrak{B}$ *is contained in the intersection of the OH fragment and the* $\pi\pi$ *fragment.*

On the other hand, we confirm that $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ indeed walks a very fine line between tractability and hardness. We show that, if M^+ is combined with any OH relation R that is not contained in the $\pi\pi$ fragment, then the resulting QCSP becomes coNP-hard, even if $\mathrm{QCSP}(\mathbb{Q}; R)$ is tractable. Intuitively, either $(\mathbb{Q}; \mathrm{M}^+, R)$ already primitively positively defines D and we use the PSPACE-hardnees proof from [22] directly, or we replace each constraint of the form $\mathrm{D}(x, y, z)$ in the proof by $\mathrm{M}^+(x, y, z) \wedge \mathrm{M}^+(z, z, x)$. The latter, however, is not entirely conditional, and certain issues arise due to the transitivity of $\leq$. These issues can be partially (but not entirely) resolved using constraints associated to

$$\check{\mathrm{Z}} \coloneqq \{(x_1, y_1, x_2, y_2) \in \mathbb{Q}^4 \mid (x_1 \neq y_1 \vee x_2 \neq y_2) \wedge (y_1 < y_2)\},$$

which is quantified primitively positively definable in $(\mathbb{Q}; \mathrm{M}^+, R)$, ultimately leaving us with a proof of coNP-hardness.

By a careful combination of syntactic pruning arguments, Theorem 2, and a new coNP-hardness proof inspired by the PSPACE-hardness proof from [22], we prove coNP-hardness in all cases for which tractability does not follow from Theorem 1, Corollary 4 or its analogue for *dual* $\pi\pi$, i.e., where $\geq$ is replaced with $\leq$ in (3). This leads to the following dichotomy for quantified OH constraints.

▶ **Theorem 5.** *Let* $\mathfrak{B}$ *be an OH structure. Then* $\mathrm{QCSP}(\mathfrak{B})$ *is solvable in polynomial time if* $\mathfrak{B}$ *is GOH, contained in the* $\pi\pi$ *fragment, or in the dual* $\pi\pi$ *fragment. Otherwise,* $\mathrm{QCSP}(\mathfrak{B})$ *is* coNP*-hard.*

[1] In contrast to previous literature on temporal CSPs, we deviate from the notation pp from [7] that clashes with the shortcut for "primitive positive" and use $\pi\pi$ instead.

We believe that the methods used in this paper will also prove useful in identifying the complexity of quantified temporal constraints outside of OH, e.g., in the case of *mi* or $\pi\pi$. Omitted proofs can be found in the long version of the article available on arXiv [17], where we also provide more details on the algebraic approach and relevant operations on $\mathbb{Q}$.

2 Preliminaries

2.1 First-order structures

The set $\{1, \dots, n\}$ is denoted by $[n]$. In the present paper, we consider structures $\mathfrak{A} = (A; R_1, \dots, R_k)$ over a finite relational signature τ. For the sake of simplicity, we often use the same symbol R for both the relation $R^{\mathfrak{A}}$ and the relational symbol R. An *expansion* of $\mathfrak{A}$ is a σ-structure $\mathfrak{B}$ with $A = B$ such that $\tau \subseteq \sigma$ and $R^{\mathfrak{B}} = R^{\mathfrak{A}}$ for each $R \in \tau$. We write $(\mathfrak{A}, R)$ for the expansion of $\mathfrak{A}$ by the relation R over A.

We assume that the reader is familiar with classical first-order logic; we allow the first-order formulas $x = y$ and $\bot$ (the nullary falsity predicate). Let T be a set of first-order τ-sentences over a common signature τ and ϕ, ψ τ-formulas whose free variables are among $\bar{x}$. We say that ϕ *entails* ψ w.r.t. T if $\mathfrak{A} \models \forall \bar{x}(\phi \Rightarrow \psi)$ holds for all models $\mathfrak{A}$ of T. We do not explicitly mention T if it is clear from the context, e.g., the theory of linear orders. A first-order τ-formula ϕ is *primitive positive* (pp) if it is of the form $\exists x_1, \dots, x_m(\phi_1 \wedge \dots \wedge \phi_n)$, where each ϕ_i is *atomic*, i.e., of the form $\bot$, $(x_i = x_j)$, or $R(x_{i_1}, \dots, x_{i_\ell})$ for some $R \in \tau$. *Quantified primitive positive* (qpp) formulas generalize pp-formulas by allowing both existential *and* universal quantification. If ϕ and ψ are (q)pp-formulas, then $\phi \wedge \psi$ can be rewritten into an equivalent (q)pp-formula, so we treat such formulas as (q)pp-formulas as well.

The *(quantified) constraint satisfaction problem* for a structure $\mathfrak{B}$, denoted by (Q)CSP($\mathfrak{B}$), is the computational problem of deciding whether a given (q)pp τ-sentence holds in $\mathfrak{B}$. By *constraints*, we refer to the conjuncts in the quantifier-free part of a given (Q)CSP instance of (Q)CSP($\mathfrak{B}$). In the QCSP framework, we usually think of an instance as a game between two players: an *existential player* (EP) and a *universal player* (UP) who assign values to the existentially and universally quantified variables, respectively. To every moment of the game we associate a partial function $[\![\cdot]\!]$ from the variables into the domain of the parametrizing structure describing values assigned to the variables by either of the players. The instance is true if and only if the EP has a winning strategy in this game, i.e., can respond to all moves of the UP while keeping all constraints satisfied. Otherwise, the instance is false and the UP has a winning strategy, i.e., can violate a constraint regardless of the moves of the EP.

If $\mathfrak{A}$ is a τ-structure and $\phi(x_1, \dots, x_n)$ is a τ-formula with free variables $x_1, \dots, x_n$, then the relation $\{(a_1, \dots, a_n) \in A^n \mid \mathfrak{A} \models \phi(a_1 \dots, a_n)\}$ is the *relation defined by* ϕ *in* $\mathfrak{A}$, and denoted by $\phi^{\mathfrak{A}}$. Let S be a set of τ-formulas. We say that a relation R has a *S-definition* in $\mathfrak{A}$, or that $\mathfrak{A}$ *S-defines* R, if R equals $\phi^{\mathfrak{A}}$ for some $\phi \in S$. For instance, S can be the set of all quantifier-free or primitive positive formulas over τ. We might also say that a relation R S-defines another relation R' if the structure $(A; R)$ S-defines R'. The next proposition is folklore in the constraint satisfaction literature.

▶ **Proposition 6** ([2, 3]). *Let $\mathfrak{A}, \mathfrak{B}$ be structures with the same domain. If every relation of $\mathfrak{B}$ is (q)pp-definable in $\mathfrak{A}$, then* (Q)CSP($\mathfrak{B}$) *reduces to* (Q)CSP($\mathfrak{A}$) *in* LOGSPACE.

2.2 Temporal structures

Since $(\mathbb{Q}; <)$ has quantifier-elimination [13], every temporal relation is in fact quantifier-free-definable in $(\mathbb{Q}; <)$. We may further assume that every quantifier-free definition is in *conjunctive normal form* (CNF). We might sometimes refer to temporal relations directly

using their CNF-definitions. Also, it will sometimes be convenient to work with formulas over the structure $(\mathbb{Q};\leq,\neq)$ instead of the structure $(\mathbb{Q};<)$, e.g., in the definitions of OH or $\pi\pi$ from the introduction. The following lemma is folklore.

▶ **Lemma 7** ([2]). *The OH and the (dual) $\pi\pi$ fragments are closed under expansions by pp-definable relations.*

From the syntactic descriptions (1) and (2) it is apparent that the fragments OH and $\pi\pi$ are incomparable. Their intersection consists of all temporal relations definable by a conjunction of clauses of the form (3). This can be shown using the following lemma.

▶ **Lemma 8.** *Let R be an OH relation defined by a quantifier-free formula ϕ in CNF over the signature $\{\leq,\neq\}$ containing a clause $\psi_1\vee\psi_2$, where ψ_1 is equivalent to $(x\geq z_1\vee\cdots\vee x\geq z_\ell)$ for some variables x and $z_1,\dots,z_\ell$. Then we may replace ψ_1 in ϕ by $(x\geq z_i)$ for some $i\in[\ell]$ so that the resulting formula still defines R.*

In the present article, the intersection of OH and the (*dual*) $\pi\pi$ fragment is the sole source of all newly identified tractable QCSPs. It is convenient to work with a finite relational basis. Recall the relations M^+ and M^- from the introduction. By Lemma 8 and Lemma 9 below, a temporal relation is OH and contained in the $\pi\pi$ fragment if and only if it is pp-definable in $(\mathbb{Q};\mathrm{M}^+,\neq)$. An analogous statement holds for *dual* $\pi\pi$ and $(\mathbb{Q};\mathrm{M}^-,\neq)$.

▶ **Lemma 9.** *The $(k+2)$-ary temporal relation defined by (3) has the pp-definition*

$$\exists h_1,\dots,h_{k+1}\Big((x=h_1)\wedge\big(\textstyle\bigwedge_{i\in[k]}\mathrm{M}^+(h_i,h_i,x)\wedge\mathrm{M}^+(h_i,y_i,h_{i+1})\big)\wedge(h_{k+1}=z)\Big).$$

Note that the length of the above pp-definition is linear in k, this will be relevant later in the proof of Theorem 3.

3 QCSP$(\mathbb{Q};\mathrm{M}^+)$ is in PTIME

In this section, we prove that QCSP$(\mathbb{Q};\mathrm{M}^+)$ can be solved in polynomial time using Algorithm 1. In the formulation of the algorithm, we view instances of QCSP$(\mathbb{Q};\mathrm{M}^+)$ as sentences over $\{\geq,\neq\}$ in prenex normal form whose quantifier-free part is in CNF.

We first need to fix some terminology. For the remainder of Section 3, Φ always denotes an arbitrary or explicitly specified instance of QCSP$(\mathbb{Q};\mathrm{M}^+)$, ϕ its quantifier-free part, and V the set if its variables. Furthermore, we denote the universal variables by $\mathrm{V}_\forall$ and the existential variables by $\mathrm{V}_\exists$. Let $\prec$ be the linear order on all variables of Φ in which they appear in the quantifier prefix of Φ. When we write $A\prec B$ for $A,B\subseteq V$, we mean $x\prec y$ for all $x\in A,y\in B$. In particular, this condition is trivially true if one of the two sets is empty.

▶ **Definition 10.** *For $x,z\in\mathrm{V}$, we define*
- *$x\equiv z$ if and only if x,z refer to the same variable,*
- *$x\preceq z$ if and only if $x\equiv z$ or $x\prec z$,*
- *$x\preceq_\forall z$ if and only if $x\equiv z$, or $x\prec z$ and $z\in\mathrm{V}_\forall$.*

For $u\in V$ and $A\subseteq V$, we define
- *$\uparrow_u\coloneqq\{y\in\mathrm{V}_\forall\mid u\preceq y\}$,*
- *$\uparrow_A\coloneqq\bigcup_{u\in A}\uparrow_u$ (recall that the empty union is empty).*

Note that the three binary relations in Definition 10 are transitive.

▶ **Definition 11.** *For every pair $x,z\in\mathrm{V}$, we define x-z-cut $\coloneqq\{u\in\mathrm{V}_\forall\mid\mathrm{V}_\exists\cap\{x,z\}\prec u\}\setminus\{z\}$.*

Observe that the definition of the x-z-cut depends on how x and z are quantified. The idea is that x-z-cut represents the universal variables that the UP can always make equal to x to trigger the condition $(x \geq z)$ via an entailed constraint of the form $\big((\bigwedge_{v \in A} x = v) \Rightarrow x \geq z\big)$. Since the UP has full control over the values of these variables with respect to x and z, they can be removed from the clauses added in the second last line in Algorithm 1.

Note that, by Lemma 9, the constraints added by Algorithm 1 correspond to relations which have pp-definitions in $(\mathbb{Q}; \mathrm{M}^+)$ of length linear in their arity. This means that satisfiability in Algorithm 1 can be tested using an oracle for $\mathrm{CSP}(\mathbb{Q}; \mathrm{M}^+, <)$, because we can simply replace each constraint by its pp-definition in $\mathrm{CSP}(\mathbb{Q}; \mathrm{M}^+)$ while only changing the size of Φ by a polynomial factor.

Algorithm 1 An algorithm for $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$.

Input: An instance Φ of $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ with the quantifier-free part ϕ
Output: *true* or *false*
while ϕ *changes* **do**
  for $x, z, u \in \mathrm{V}$ **do**
    if ϕ *contains the clause* $(x \geq z)$ *or* $(z \geq x)$*, where* $x \prec z$ *and* $z \in \mathrm{V}_\forall$ **then**
      return *false*;
    if $\phi \wedge (\bigwedge_{v \in \uparrow_u \setminus \{x,z\}} x = v) \wedge (x < z)$ *is unsatisfiable* **then**
      expand ϕ by the clause $\big((\bigwedge_{v \in \uparrow_u \setminus (\{x,z\} \cup x\text{-}z\text{-cut})} x = v) \Rightarrow x \geq z\big)$;
return *true*;

▶ **Example 12.** Consider the instance Φ of $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ defined by

$$\exists x_1 \forall x_2 \exists x_3 \forall x_4 \exists x_5 \big((x_1 = x_2 \Rightarrow x_1 \geq x_5) \wedge (x_3 = x_2 \Rightarrow x_3 \geq x_4) \\ \wedge\ (x_5 = x_4 \Rightarrow x_5 \geq x_3) \wedge (x_3 \geq x_1) \wedge (x_5 \geq x_1)\big).$$

We claim that Algorithm 1 derives $(x_1 \geq x_4)$, and thereby rejects on Φ. We first observe that the formula $\phi \wedge (\bigwedge_{v \in \uparrow_u \setminus \{x_1, x_4\}} x_1 = v) \wedge (x_1 < x_4)$ is satisfiable for every $u \in \{x_1, \ldots, x_5\}$. Since $x_3, x_5 \in \mathrm{V}_\exists$, it is enough to show that $\phi \wedge (x_1 = x_2) \wedge (x_1 < x_4)$ is satisfiable, which is witnessed by any assignment satisfying $(x_5 = x_1 = x_2 < x_3 < x_4)$. On the other hand, $\phi \wedge (\bigwedge_{v \in \uparrow_{x_2} \setminus \{x_1, x_3\}} x_1 = v) \wedge (x_1 < x_3)$ is not satisfiable. Therefore, the algorithm expands ϕ by $(x_1 = x_2 \Rightarrow x_1 \geq x_3)$, because $x_4 \in x_1$-x_3-cut. But now $\phi \wedge (\bigwedge_{v \in \uparrow_{x_2} \setminus \{x_1, x_4\}} x_1 = v) \wedge (x_1 < x_4)$ is not satisfiable anymore. Since $x_2 \in x_1$-x_4-cut, the algorithm expands ϕ by $(x_1 \geq x_4)$.

As mentioned below Definition 11, Algorithm 1 rejects correctly because all constraints added during the run of the algorithm are entailed by Φ, see Lemma 13.

▶ **Lemma 13.** *Suppose that Algorithm 1 derives from Φ a constraint ψ. Then Φ is true if and only if Φ expanded by ψ is true.*

Proof. Denote by Ψ and Ψ' the sentences obtained from Φ by replacing ϕ with $\phi \wedge \psi$ and $\phi \wedge \psi'$, respectively, where

$$\psi \coloneqq \Big(\bigvee\nolimits_{v \in \uparrow_u \setminus (\{x,z\} \cup x\text{-}z\text{-cut})} x \neq v\Big) \vee (x \geq z) \quad \text{and} \quad \psi' \coloneqq \Big(\bigvee\nolimits_{v \in \uparrow_u \setminus \{x,z\}} x \neq v\Big) \vee (x \geq z).$$

Since $\phi \wedge \neg\psi'$ is unsatisfiable, we have that ϕ entails ψ'. It follows that Φ is true iff Ψ' is true. To complete the proof, we have to show that if Ψ' is true, then Ψ is true. We prove the contraposition and assume that the UP has a winning strategy on Ψ. If the UP wins

on Ψ by falsifying any clause different from ψ, then the very same choices lead the UP to falsifying the same clause in Ψ'. Otherwise, the UP falsifies ψ while playing on Ψ. Then the UP can play in the same way on Ψ' when it comes to the variables that occur both in ψ and ψ' and set all variables in x-z-cut to the same value as x. Note that this is possible since either x is universal or x precedes all variables in x-z-cut. It remains to show that ψ' is falsified. Clearly, all $\{\neq\}$-disjuncts are falsified. Since z is either universal or precedes all variables in x-z-cut, the disjunct $(x \geq z)$ is falsified as well, because it is falsified in ψ. ◀

Example 14 showcases how a winning strategy of the UP, obtainable implicitly from Lemma 13, might in fact be uniquely determined.

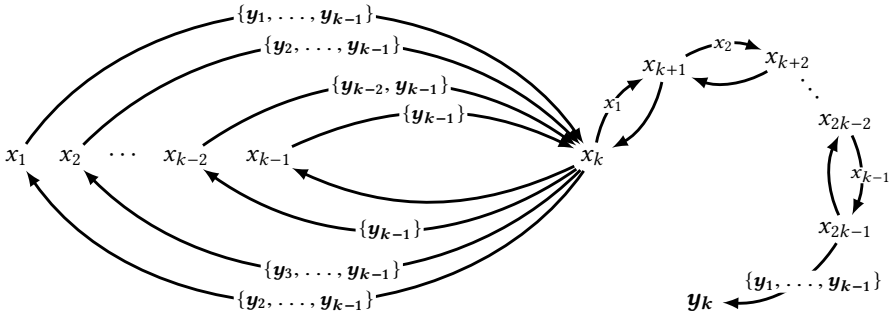

Figure 1 The quantifier-free part of Φ from Example 14.

▶ **Example 14.** Consider the instance $\Phi := \exists x_1 \forall y_1 \exists x_2 \forall y_2 \cdots \exists x_k \forall y_k \exists x_{k+1} \ldots \exists x_{2k-1}\ \phi$ with ϕ described by Figure 1, where an edge from x to z labeled with y stands for $\mathrm{M}^+(x, y, z)$. An edge from x to z labeled with some subset A of the universal variables stands for a constraint of the form $\big((\bigwedge_{v \in A} x = v) \Rightarrow x \geq z\big)$ already derived by Algorithm 1. Using Lemma 9, these edges can be appropriately replaced with pp-definitions, and thus Φ is well-defined.

We claim that the UP has the unique winning strategy on Φ of playing $[\![y_i]\!]$ equal to an arbitrary number $> [\![x_i]\!]$ if $i = k$ and $[\![x_1]\!] = \cdots = [\![x_k]\!]$, and equal to $min\{[\![x_1]\!], \ldots, [\![x_i]\!]\}$ otherwise. We start by showing that this is a winning strategy.

Suppose, on the contrary, that there exists an assignment $[\![\cdot]\!] \colon \mathrm{V} \to \mathbb{Q}$ of values to the variables witnessing that the EP has a counter-strategy to the strategy of the UP from above. First, consider the case where $[\![x_1]\!], \ldots, [\![x_k]\!]$ are not all equal. Suppose that $[\![x_k]\!] = min\{[\![x_1]\!], \ldots, [\![x_k]\!]\}$ and let $j \in [k]$ be the largest index such that $[\![x_j]\!] > [\![x_k]\!]$. Recall that the algorithm already derived the constraint $\psi_1 := \big((\bigwedge_{v \in \{y_{j+1}, \ldots, y_{k-1}\}} x_k = v) \Rightarrow x_k \geq x_j\big)$ on Φ. By the strategy of the UP, we have $[\![y_{j+1}]\!] = \cdots = [\![y_{k-1}]\!] = [\![x_{j+1}]\!] = [\![x_k]\!]$. But then ψ_1 is clearly not satisfied by $[\![\cdot]\!]$, a contradiction. Suppose now that $[\![x_k]\!] > min\{[\![x_1]\!], \ldots, [\![x_k]\!]\}$. Let $j \in [k]$ be the largest index such that $[\![x_j]\!] = min\{[\![x_1]\!], \ldots, [\![x_k]\!]\}$. Recall that the algorithm already derived the constraint $\psi_2 := \big((\bigwedge_{v \in \{y_j, \ldots, y_{k-1}\}} x_j = v) \Rightarrow x_j \geq x_k\big)$. By the strategy of the UP, we have $[\![y_j]\!] = \cdots = [\![y_{k-1}]\!] = [\![x_j]\!] < [\![x_k]\!]$. But then ψ_2 is clearly not satisfied by $[\![\cdot]\!]$, a contradiction. We conclude that $[\![x_1]\!] = \cdots = [\![x_k]\!]$. In this case, the UP played $[\![y_k]\!] > [\![x_k]\!]$. Since $[\![\cdot]\!]$ is a satisfying assignment, we must have $[\![x_k]\!] = [\![x_{k+1}]\!] = \cdots = [\![x_{2k-1}]\!]$. But then $[\![\cdot]\!]$ does not satisfy $\big((\bigwedge_{v \in \{y_1, \ldots, y_{k-1}\}} x_{2k-1} = v) \Rightarrow x_{2k-1} \geq y_k\big)$ because $[\![y_k]\!] > [\![x_k]\!] = [\![x_{2k-1}]\!] = [\![y_1]\!] = \cdots = [\![y_{k-1}]\!]$, a contradiction. We conclude that the strategy of the UP from above is a winning strategy.

The strategy of the UP is unique in the sense that, no matter what values the EP played for $x_1, \ldots, x_i$, if the UP deviates from his strategy at y_i, then the EP wins by playing $[\![x_{i+1}]\!] = \cdots = [\![x_{2k-1}]\!]$ equal to an arbitrary number $> max([\![x_i]\!], [\![y_i]\!])$ if $[\![x_i]\!] \neq [\![y_i]\!]$ and equal to $min\{[\![x_1]\!], \ldots, [\![x_i]\!]\}$ otherwise.

Table 1 The inference rules of the proof system $\mathcal{P}$. Here I stands for "initialize," S for "simplify," T for "transitivity," R for "reject," A for "alternative transitivity," and C for "constraint".

§I	$\mathcal{P}(x,x;\emptyset) :- x \in V$
§S	$\mathcal{P}(x,z;A \setminus x\text{-}z\text{-cut}) :- \mathcal{P}(x,z;A)$
§T	$\mathcal{P}(x,z;A) :- \mathcal{P}(x,y;A) \wedge \mathcal{P}(y,z;\emptyset)$
§R	$\bot :-$ 1. $\mathcal{P}(x,z;\emptyset)$; 2. $x \prec z$ and $z \in \mathrm{V}_\forall$, or $z \prec x$ and $x \in \mathrm{V}_\forall$
§A	$\mathcal{P}(x_i,z;A \cup B \cup (\{x_1,x_2\} \setminus \{x_i\})) :-$ 1. $\mathcal{P}(x_1,y;A) \wedge \mathcal{P}(y,x_2;\emptyset) \wedge \mathcal{P}(y,z;B)$; 2. $(\{x_1,x_2\} \setminus \{x_i\}) \subseteq \mathrm{V}_\forall$ $(i \in \{1,2\})$
§C	$\mathcal{P}(x_i,z;A \cup B \cup (\{x_1,x_2,x_3,x_4\} \setminus \{x_i\})) :-$ 1. $\mathcal{P}(x_1,u;A) \wedge \mathcal{P}(u,x_2;\emptyset)$; 2. $\mathcal{P}(x_3,v;B) \wedge \mathcal{P}(v,x_4;\emptyset)$; 3. $(\{x_1,x_2,x_3,x_4\} \setminus \{x_i\}) \subseteq \mathrm{V}_\forall$ $(i \in \{1,2,3,4\})$; 4. $(u{=}v \Rightarrow u \geq z)$ or $(v{=}u \Rightarrow v \geq z)$ in ϕ

Finally, we show that the algorithm derives *false*. In the first run of the main loop, we get $(x_{i+1} \geq x_i)$ for all $i \in \{1,\dots,k-2\}$. Assuming previously derived constraints, we get $(x_k \geq x_i)$ for all $i \in \{1,\dots,k-1\}$ (purely by transitivity). Now it is possible to derive $(x_i = y_i \Rightarrow x_i \geq x_{i+1})$ for all $i \in \{1,\dots,k-1\}$. In the final step, we get $(x_1 \geq y_k)$, again, simply by invoking an oracle for $\mathrm{CSP}(\mathbb{Q}; \mathrm{M}^+, <)$, which makes the algorithm reject.

3.1 False instances

The goal of this subsection is to reformulate the condition for rejection by Algorithm 1 within a certain proof system $\mathcal{P}$ operating on Φ, whose rules are given in Table 1 using a Datalog-style syntax. The proof system syntactically derives predicates of the form $\mathcal{P}(x, y; A)$ with $x, y \in V$ and $A \subseteq \mathrm{V}_\forall$ (on the left hand side of $:-$) from other predicates of this form derived earlier and the information encoded in Φ (on the right hand side of $:-$).

We shall now provide some intuition behind the formulation of the proof system. The idea is that an expression $\mathcal{P}(x, z; A)$ should capture a constraint $\left((\bigwedge_{v \in A} x = v) \Rightarrow x \geq z\right)$ entailed by Φ, where A only consists of universal variables. Assuming the adopted semantics, §T and §A just describe natural properties of such expressions, and §S and §R witness consequences of the quantification over the variables. The combination of §I and §C captures precisely the situations where the UP can indirectly enforce the identification of two (potentially existential) variables within a constraint in ϕ. In particular, it can be used to introduce $\mathcal{P}(u, z; \{v\})$ for conjuncts $(u = v \Rightarrow v \geq z)$ in ϕ with v universally quantified as follows. The proof system first derives $\mathcal{P}(u, u; \emptyset)$ and $\mathcal{P}(v, v; \emptyset)$ using §I. Then it uses §C to derive $\mathcal{P}(u, z; \{v\})$ by identifying x_1, x_2 with u and x_3, x_4 with v.

The reader might naturally ask why we cannot obtain a polynomial-time algorithm by just closing Φ under the rules of the proof system with a suitable form of fixed-point semantics. The reason is that, already under the least fixed-point semantics, the proof system might derive exponentially many expressions of the form $\mathcal{P}(x, z; A)$. Such a situation occurs, e.g., in Example 18 and in the case of the constraint paths in ϕ as defined in the proof of Lemma 25.

The precise connection between the proof system and Algorithm 1 is captured by Lemma 15. Note that Lemma 15 in particular implies that Algorithm 1 rejects whenever the proof system derives $\bot$. When combined with Lemma 13 and Lemma 19 (proved later in Section 3.2), we get that this is in fact the only situation in which Algorithm 1 rejects. Lemma 15 can be proved by a straightforward induction on the length of the derivation sequences within $\mathcal{P}$.

▶ **Lemma 15.** *Suppose that $\mathcal{P}(x, z; A)$ is derived by the proof system and $z \notin A$. Then Algorithm 1 expands ϕ by the clause*

$$\Big(\big(\bigwedge\nolimits_{v \in \uparrow_A \setminus (\{x,z\} \cup x\text{-}z\text{-}cut)} x = v\big) \Rightarrow x \geq z\Big).$$

In particular, it expands ϕ by the clause $(x \geq z)$ for every derived $\mathcal{P}(x, z; \emptyset)$.

In the proof of Lemma 15, we use the following simple observation.

▷ Claim 16. For every pair $(x, z) \in V^2$, and every $A \subseteq \mathrm{V}_\forall$, there exists $u \in V$ such that $A \subseteq \uparrow_u$ and $\uparrow_A \setminus (\{x, z\} \cup x\text{-}z\text{-cut}) = \uparrow_u \setminus (\{x, z\} \cup x\text{-}z\text{-cut})$.

Proof. It is easy to see that if $A \neq \emptyset$, then we may choose u to be the variable in A that satisfies $u \preceq y$ for all $y \in A$.

If $A = \emptyset$, then we choose u as the last variable in the quantifier-prefix of Φ. Indeed, if u is existential, then we are done. Otherwise, u is universal. If $u \in \{x, z\}$, then this variable is removed from $\uparrow_A$ and we are done. If $u \notin \{x, z\}$, then $u \in x\text{-}z\text{-cut}$. This completes the proof of the observation. ◁

Proof sketch (Lemma 15). We assume that ϕ is expanded by all derived clauses from the run of Algorithm 1, and show that $\big((\bigwedge_{v \in \uparrow_A \setminus (\{x,z\} \cup x\text{-}z\text{-cut})} x = v) \Rightarrow x \geq z\big)$ is among these clauses.

We prove the lemma by induction on the length of the derivation of $\mathcal{P}(x, z; A)$. Observe that it is enough to show that, if $\mathcal{P}(x, z; A)$ is derived, where $z \notin A$, then $\phi \wedge (\bigwedge_{v \in A} x = v) \wedge (x < z)$ is not satisfiable. Then indeed, by Claim 16, we may choose $u \in V$ such that $A \subseteq \uparrow_u$ and $\uparrow_A \setminus (\{x, z\} \cup x\text{-}z\text{-cut}) = \uparrow_u \setminus (\{x, z\} \cup x\text{-}z\text{-cut})$. Since $z \notin A$ and $(x = x)$ is always satisfied, if $\phi \wedge (\bigwedge_{v \in A} x = v) \wedge (x < z)$ is not satisfiable, then neither is $\phi \wedge (\bigwedge_{v \in \uparrow_u \setminus \{x,z\}} x = v) \wedge (x < z)$, and therefore the algorithm expands ϕ by the desired clause. The rest of the proof consists of a straightforward verification of the base case for §I and the induction step for the remaining rules of $\mathcal{P}$. ◀

We conclude this subsection with two examples, the first one showcasing how the run of Algorithm 1 can be represented within the proof system, and the second one demonstrating that, in general, the proof system cannot be used to verify true instances in polynomial time.

▶ **Example 17.** Consider the instance Φ from Example 12. We show that the proof system derives $\bot$. First, we can derive $\mathcal{P}(x_i, x_i; \emptyset)$ for every $i \in [5]$ using §I. With §C (and suitable identifications of variables), we get $\mathcal{P}(x_3, x_1; \emptyset), \mathcal{P}(x_5, x_1; \emptyset)$, $\mathcal{P}(x_1, x_5; \{x_2\})$, $\mathcal{P}(x_3, x_4; \{x_2\})$, and $\mathcal{P}(x_5, x_3; \{x_4\})$. Next, a single application of §A yields $\mathcal{P}(x_1, x_3; \{x_2, x_4\})$. We can use §S to simplify the latter to $\mathcal{P}(x_1, x_3; \{x_2\})$. Using §A again, we get $\mathcal{P}(x_1, x_4; \{x_2\})$, and finally, §S simplifies the latter to $\mathcal{P}(x_1, x_4; \emptyset)$. Now an application of §R yields $\bot$.

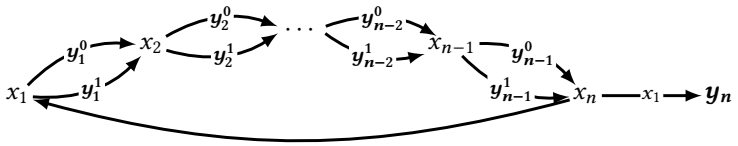

Figure 2 The quantifier-free part of Φ from Example 18.

▶ **Example 18.** Consider $\Phi \coloneqq \exists x_1 \forall y_1^0 \forall y_1^1 \exists x_2 \forall y_2^0 \forall y_2^1 \cdots \exists x_{n-1} \forall y_{n-1}^0 \forall y_{n-1}^1 \exists x_n \forall y_n\ \phi$ with ϕ described by Figure 2, where an edge from x to z labeled with y stands for $\mathrm{M}^+(x, y, z)$. Note that the proof system derives $\mathcal{P}(x_1, x_n; \{y_1^{i_1}, \ldots, y_{n-1}^{i_{n-1}}\})$ for all $i_1, \ldots, i_{n-1} \in \{0, 1\}$. Indeed, this is because it can follow the shortest derivation sequences, of which there are exponentially many. In contrast, Algorithm 1 derives the constraints $(x_{n-1} \geq x_1), \ldots, (x_2 \geq x_1), (x_1 \geq y_n)$ in this order, which leads to rejection. Interestingly enough, constraint paths as in Figure 2 were previously used in [22] to prove PSPACE-hardness of QCSP($\mathbb{Q}$; D).

3.2 True instances

In this subsection we prove Lemma 19, which states that the refutation condition §R from Table 1 is not only sufficient, but also necessary.

▶ **Lemma 19.** *If the proof system does not derive $\bot$ from Φ, then Φ is true.*

Proof. Suppose that the proof system cannot derive $\bot$ from Φ. Consider the following strategy for the EP. Let $x \in \mathrm{V}_\exists$ be such that $[\![x]\!]$ is not yet defined, but $[\![z]\!]$ is defined for every $z \prec x$. Then the EP selects any value for x such that, for every $z \prec x$:

- $[\![x]\!] \geq [\![z]\!]$ *if and only if* there exists $y \prec x$ with $[\![y]\!] \geq [\![z]\!]$ and $\mathcal{P}(x, y; \emptyset)$;
- $[\![x]\!] = [\![z]\!]$ *if and only if* there exist $y_1, y_2 \prec x$ and $y_2 \prec A \prec x$ such that

$$\mathcal{P}(x, y_1; \emptyset) \wedge \mathcal{P}(y_2, x; A) \quad \text{and} \quad [\![z]\!] = [\![y_1]\!] = [\![y_2]\!] = [\![A]\!].$$

We remark that some naïve simplifications of the above strategy fail already on small instances. For example, it is not enough for the EP to set $[\![x]\!] \geq [\![z]\!]$ if and only if $\mathcal{P}(x, z; \emptyset)$. To see this, consider $\Phi = \exists y \forall z \exists x\, \mathrm{M}^+(x, x, y)$. If the UP sets $[\![z]\!] = [\![y]\!]$, then the EP has to respect $(x \geq z)$ even though $\mathcal{P}(x, z; \emptyset)$ is not derived.

▷ Claim 20. The strategy of the EP is well-defined.

Proof. Suppose, on the contrary, that it is not. Let $x \in \mathrm{V}_\exists$ be the smallest variable w.r.t. $\prec$ for which the strategy of the EP is not well-defined. Then it must be the case that there exist $y, y_1, y_2 \prec x$ and $y_2 \prec A \prec x$ such that

$$\mathcal{P}(x, y; \emptyset) \wedge \mathcal{P}(x, y_1; \emptyset) \wedge \mathcal{P}(y_2, x; A) \quad \text{and} \quad [\![y]\!] > [\![y_1]\!] = [\![y_2]\!] = [\![A]\!]. \tag{4}$$

In particular, $y \notin A$. We choose the smallest possible y w.r.t. $\prec$ witnessing a condition of the form (4). By §T, we have $\mathcal{P}(y_2, y; A)$.

Case 1: $y \prec y_2$. Then, by §S, we have $\mathcal{P}(y_2, y; \emptyset)$.

Case 1.1: $y_2 \in \mathrm{V}_\forall$. Then $\bot$ can be derived using §R, a contradiction.

Case 1.2: $y_2 \in \mathrm{V}_\exists$. Then the EP did not follow his strategy because $[\![y]\!] > [\![y_2]\!]$ and we have $\mathcal{P}(y_2, y; \emptyset)$, a contradiction.

Case 2: $y_2 \prec y$.

Case 2.1: $y \in \mathrm{V}_\forall$. Then, by §S, we have $\mathcal{P}(y_2, y; \emptyset)$. But then $\bot$ can be derived using §R, a contradiction.

Case 2.2: $y \in \mathrm{V}_\exists$. Then, by §S, we have $\mathcal{P}(y_2, y; A \setminus y_2\text{-}y\text{-cut})$. Since $[\![y]\!] \geq [\![y_2]\!]$, by the strategy of the EP, there exists a variable $y' \prec y$ such that $[\![y']\!] \geq [\![y_2]\!]$ and $\mathcal{P}(y, y'; \emptyset)$. If $[\![y']\!] = [\![y_2]\!]$, then the EP did not follow his strategy, because he played $[\![y]\!] > [\![y']\!]$ while $y' \prec y$, $y_2 \prec A \setminus y_2\text{-}y\text{-cut} \prec y$, $\mathcal{P}(y, y'; \emptyset) \wedge \mathcal{P}(y_2, y; A \setminus y_2\text{-}y\text{-cut})$, and $[\![y']\!] = [\![y_2]\!] = [\![A \setminus y_2\text{-}y\text{-cut}]\!]$. a contradiction. So it must be the case that $[\![y']\!] > [\![y_2]\!]$. By §T, we have $\mathcal{P}(y_2, y'; A)$. But now y' can assume the role of y in (4), a contradiction to the minimality of y w.r.t. $\prec$. ◁

The next claim characterizes the equality of values for pairs of variables under $[\![\cdot]\!]$ in terms of properties of previously quantified variables, assuming that the EP has followed the strategy above. In particular, we show that if $[\![x]\!] = [\![z]\!]$ if and only if there exists a variable $y \preceq \{x, z\}$ so that $[\![x]\!] = [\![y]\!]$ and $[\![y]\!] = [\![z]\!]$ are enforced by the identifications of values of universal variables with y by the UP. Recall the comparison relations $\preceq$ and $\preceq_\forall$ from Definition 10.

▷ Claim 21. Suppose that the EP follows the strategy above. Then, for all $x, z \in \mathrm{V}$, we have $[\![x]\!] = [\![z]\!]$ if and only if there exist $x_1, x_2, z_1, z_2 \in V$ and $A_{x_2,x}, A_{z_2,z} \subseteq \mathrm{V}_\forall$ such that

1. $\{x_1, x_2\} \preceq x$ and $\{z_1, z_2\} \preceq z$
2. $x_2 \prec A_{x_2,x} \preceq x$ and $z_2 \prec A_{z_2,z} \preceq z$,
3. $y \preceq_\forall \{x_1, x_2, z_1, z_2\}$ for some $y \in \{x_2, z_2\}$,
4. $\mathcal{P}(x_2, x; A_{x_2,x}) \wedge \mathcal{P}(x, x_1; \emptyset) \wedge \mathcal{P}(z_2, z; A_{z_2,z}) \wedge \mathcal{P}(z, z_1; \emptyset)$,
5. $[\![A_{x_2,x}]\!] = [\![x_1]\!] = [\![x_2]\!] = [\![z_1]\!] = [\![z_2]\!] = [\![A_{z_2,z}]\!]$.

Whenever the right-hand side of the equivalence holds, we also have $[\![x]\!] = [\![x_2]\!]$ and $[\![z]\!] = [\![z_2]\!]$.

Proof sketch (Claim 21). "⇐" We show that $[\![x]\!] = [\![x_2]\!]$ and $[\![z]\!] = [\![z_2]\!]$. If $x \equiv x_2$, then clearly $[\![x]\!] = [\![x_2]\!]$. So, w.l.o.g., $x_2 \prec x$. If $x \in \mathrm{V}_\forall$, then §S yields $\mathcal{P}(x_2, x; \emptyset)$ and hence §R produces $\bot$, a contradiction. So we must have $x \in \mathrm{V}_\exists$. Then either $x_1 \equiv x$ or $x_1 \prec x$, and it follows from the strategy of the EP that $[\![x]\!] = [\![x_2]\!]$. Analogously we obtain that $[\![z]\!] = [\![z_2]\!]$. The rest follows by the transitivity of the equality.

"⇒" Whenever the right-hand side of the equivalence in Claim 21 is satisfied, we call $(x, x_1, x_2; A_{x_2,x})$ and $(z, z_1, z_2; A_{z_2,z})$ *witnessing quadruples* for $[\![x]\!] = [\![z]\!]$. If $x \equiv z$, then the statement trivially follows using §I, the witnessing quadruples are $(x, x, x; \emptyset)$ and $(z, z, z; \emptyset)$. So, w.l.o.g., $z \prec x$. If $x \in \mathrm{V}_\forall$, then the claim follows using §I, the witnessing quadruples are again $(x, x, x; \emptyset)$ and $(z, z, z; \emptyset)$. So suppose that $x \in \mathrm{V}_\exists$ and that the claim holds for all pairs of variables preceding x. Since $[\![x]\!] = [\![z]\!]$, by the strategy of the EP, there exist $x_1, x_2 \prec x$ and $x_2 \prec A \prec x$ such that $\mathcal{P}(x, x_1; \emptyset) \wedge \mathcal{P}(x_2, x; A)$ and $[\![z]\!] = [\![x_1]\!] = [\![x_2]\!] = [\![A]\!]$.

Since $[\![x_2]\!] = [\![z]\!]$ and $x_2, z \prec x$, we can apply the induction hypothesis for the pair x_2, z to obtain the witnessing quadruples $(x_2, x_{2_1}, x_{2_2}; A_{x_{2_2},x_2})$ and $(z, z_1, z_2; A_{z_2,z})$. By assumption, there exists $y \in \{z_2, x_{2_2}\}$ such that $y \preceq_\forall \{z_1, z_2, x_{2_1}, x_{2_2}\}$. Note that $[\![y]\!] = [\![x_1]\!]$. Thus, we can apply the induction hypothesis for the pair x_1, y to obtain the witnessing quadruples $(x_1, x_{1_1}, x_{1_2}; A_{x_{1_2},x_1})$ and $(y, y_1, y_2; A_{y_2,y})$. By assumption, there exists $y' \in \{y_2, x_{1_2}\}$ such that $y' \preceq_\forall \{y_1, y_2, x_{1_1}, x_{1_2}\}$. The two cases $y \equiv z_2$ and $y \equiv x_{2_2}$ are illustrated in Figure 3.

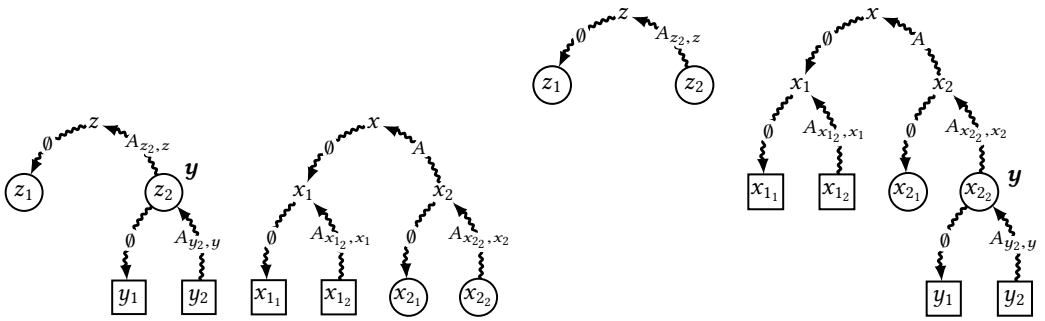

Figure 3 Cases $y \equiv z_2$ and $y \equiv x_{2_2}$ in the proof of Claim 21. The squiggly arrows represent inferences of $\mathcal{P}$.

Our goal is to find witnesses x'_1, x'_2, z'_1, z'_2 for the main statement of the claim, i.e., the witnessing quadruples will be of the form $(x, x'_1, x'_2; A_{x'_2,x})$ and $(z, z'_1, z'_2; A_{z'_2,z})$. The idea is that we want to choose x'_1, x'_2, z'_1, z'_2 from the variables introduced above, which all evaluate

to the value $[\![x]\!] = [\![z]\!]$ in $[\![\cdot]\!]$. To obtain the property in item 3, we want to choose variables that are small enough with respect to the order $\prec$, so that one of them can be compared to the others with respect to $\preceq_\forall$, assuming the properties of y and y' from above.

One suitable choice of witnesses is as follows. First, we choose $x'_1 \coloneqq x_{1_1}$. As visible in Figure 3, we can apply §T to $\mathcal{P}(x, x_1; \emptyset) \wedge \mathcal{P}(x_1, x_{1_1}; \emptyset)$ to derive $\mathcal{P}(x, x_{1_1}; \emptyset)$. Second, we choose $z'_1 \coloneqq z_1$ if $y \not\equiv z_1$ and $z'_1 \coloneqq y_1$ otherwise. Note that we have $\mathcal{P}(z, z_1; \emptyset)$ by assumption and, if $y \equiv z_1$, then we can use §T to derive $\mathcal{P}(z, y_1; \emptyset)$ from $\mathcal{P}(z, z_1; \emptyset) \wedge \mathcal{P}(y, y_1; \emptyset)$. Next, we choose $x'_2 \coloneqq x_{2_2}$ if $y \not\equiv x_{2_2}$, and $x'_2 \coloneqq y_2$ otherwise. A short argument shows that $x_{2_2} \preceq_\forall x_{2_1}$, which allows us to apply §A to $\mathcal{P}(x_{2_2}, x_2; A_{x_{2_2}, x_2}) \wedge \mathcal{P}(x_2, x_{2_1}; \emptyset) \wedge \mathcal{P}(x_2, x; A)$ to obtain an expression of the form $\mathcal{P}(x_{2_2}, x; A_{x_{2_2}, x})$. If $y \equiv x_{2_2}$, then it is necessary to apply §A a second time to obtain the expression of the form $\mathcal{P}(y_2, x; A_{y_2, x})$. Finally, the choice for z'_2 that we need will be $z'_2 \coloneqq z_2$ if $y \not\equiv z_2$ or $z'_2 \coloneqq y_2$ otherwise.

With the above witnessing quadruples, one can verify that items 1, 2, 4, and 5 will be satisfied. Thanks to choosing "small enough candidates" with respect to $\prec$ for each of x'_1, x'_2, z'_1, z'_2, item 3 can be verified as well. A full proof of Claim 21 with a verification of these properties can be found in Appendix A. ◁

▷ Claim 22. The strategy of the EP is a winning strategy.

Proof. Suppose, on the contrary, that this is not the case. Then there has to be a violated constraint of the form $(x = z \Rightarrow x \geq w)$, i.e., $[\![x]\!] = [\![z]\!] < [\![w]\!]$. Since $[\![x]\!] = [\![z]\!]$, by Claim 21, there exist $x_1, x_2, z_1, z_2 \in V$ and $A_{x_2,x}, A_{z_2,z} \subseteq \mathrm{V}_\forall$ such that

- $\{x_1, x_2\} \preceq x$ and $\{z_1, z_2\} \preceq z$
- $x_2 \prec A_{x_2,x} \preceq x$ and $z_2 \prec A_{z_2,z} \preceq z$,
- $y \preceq_\forall \{x_1, x_2, z_1, z_2\}$ for some $y \in \{x_2, z_2\}$,
- $\mathcal{P}(x_2, x; A_{x_2,x}) \wedge \mathcal{P}(x, x_1; \emptyset) \wedge \mathcal{P}(z_2, z; A_{z_2,z}) \wedge \mathcal{P}(z, z_1; \emptyset)$,
- $[\![A_{x_2,x}]\!] = [\![x_1]\!] = [\![x_2]\!] = [\![z_1]\!] = [\![z_2]\!] = [\![A_{z_2,z}]\!]$.

Moreover, we have $[\![x]\!] = [\![y]\!] = [\![z]\!]$. Let $A \coloneqq A_{x_2,x} \cup A_{z_2,z} \cup (\{x_1, x_2, z_1, z_2\} \setminus \{y\})$. By a single application of §C, we get $\mathcal{P}(y, w; A)$. Since $[\![z]\!] < [\![w]\!]$, clearly w is different from all variables which share the value with z. We choose the smallest possible w w.r.t. $\prec$ for which $\mathcal{P}(y, w; A)$ can be derived and such that $[\![z]\!] < [\![w]\!]$. Since $[\![w]\!] \neq [\![z]\!]$, we have $w \notin A$. Now we consider the following cases.

Case 1: $w \prec y$. By §S, we have $\mathcal{P}(y, w; \emptyset)$.

Case 1.1: $y \in \mathrm{V}_\forall$. In this case $\bot$ can be derived using §R, a contradiction.

Case 1.2: $y \in \mathrm{V}_\exists$. Then the EP was supposed to set $[\![y]\!] \geq [\![w]\!]$, however, we have $[\![y]\!] < [\![w]\!]$. Hence, the EP did not follow his strategy, a contradiction.

Case 2: $y \prec w$.

Case 2.1: $w \in \mathrm{V}_\forall$. By §S, we get $\mathcal{P}(y, w; \emptyset)$. But then $\bot$ can be derived using §R, a contradiction.

Case 2.2: $w \in \mathrm{V}_\exists$. Since $[\![w]\!] > [\![y]\!]$, by the strategy of the EP, there must exist $w' \prec w$ with $[\![w']\!] \geq [\![y]\!]$ such that $\mathcal{P}(w, w'; \emptyset)$. By §S, we have $\mathcal{P}(y, w; A \setminus y\text{-}w\text{-cut})$. If $[\![w']\!] = [\![y]\!]$, then the EP did not follow his strategy because he played $[\![w]\!] > [\![w']\!]$ while $y, w' \prec w$ and $y \prec A \setminus y\text{-}w\text{-cut} \prec w$, $[\![w']\!] = [\![y]\!] = [\![A \setminus y\text{-}w\text{-cut}]\!]$, and $\mathcal{P}(y, w; A \setminus y\text{-}w\text{-cut}) \wedge \mathcal{P}(w, w'; \emptyset)$, a contradiction. So it must be the case that $[\![w']\!] > [\![y]\!]$. By an application of §T to $\mathcal{P}(y, w; A) \wedge \mathcal{P}(w, w'; \emptyset)$, we have $\mathcal{P}(y, w'; A)$. But note that now w' can assume the role of w, a contradiction to the minimality of w w.r.t. $\prec$. ◁

This concludes the proof of Lemma 19. ◀

3.3 Putting everything together

Proof (Theorem 3). We show that Algorithm 1 solves $\mathrm{QCSP}(\mathbb{Q}; \mathrm{M}^+)$ in polynomial time. Observe that Algorithm 1 runs in polynomial time with respect to the length of Φ. Indeed, it expands Φ by at most V^3-many constraints, all of which have pp-definitions in $(\mathbb{Q}; \mathrm{M}^+, <)$ of linear length due to Lemma 9, and $\mathrm{CSP}(\mathbb{Q}; \mathrm{M}^+, <)$ is solvable in polynomial time [8]. Note that, if Φ contains a clause $(x \geq z)$ or $(z \geq x)$ such that $x \prec z$ and $z \in \mathrm{V}_\forall$, then Φ is false. Therefore, by Lemma 13, Φ is false whenever the algorithm rejects. Suppose that the algorithm accepts an instance Φ. By Lemma 15, $\bot$ cannot be derived from Φ using the proof system and hence, by Lemma 19, Φ is true. This completes the proof. ◀

4 The Complexity Dichotomy

This section is devoted to the proof of Theorem 5. We start by explaining how coNP-hardness is obtained in the cases that are not covered by Theorem 1, Corollary 4, or its analogue for *dual* $\pi\pi$. Recall Theorem 2 that can be used as a black box.

First, we use a syntactical argument to reduce the arity of the relations that need to considered to 4.

▶ **Lemma 23.** *Let $\mathfrak{B}$ be an OH structure that is not contained in the $\pi\pi$ fragment. Then $\mathfrak{B}$ pp-defines a relation of arity at most 4 that is not contained in the $\pi\pi$ fragment.*

Second, we perform an "educated brute-force" search through all relations of arity at most 4 that are not contained in the $\pi\pi$ fragment in order to classify them. Recall the relations D and $\check{\mathrm{Z}}$ defined in the introduction.

▶ **Lemma 24.** *Let $\mathfrak{B}$ be an OH structure that is not contained in the $\pi\pi$ fragment. Then $\mathfrak{B}$ pp-defines* D *or* $(\mathfrak{B}; \mathrm{M}^+)$ *qpp-defines* $\check{\mathrm{Z}}$.

Third, we show coNP-hardness of the QCSP for said relations combined with M^+.

▶ **Lemma 25.** *Let $\mathfrak{B}$ be an OH structure that is not contained in the $\pi\pi$ fragment and pp-defines M^+. Then $\mathrm{QCSP}(\mathfrak{B})$ is coNP-hard.*

The proof of Lemma 25 below relies almost entirely on constraint paths built using M^+. In Figure 4, edges relate to constraints over M^+, e.g. the two leftmost arrows in the lower chain represent $\mathrm{M}^+(f, y_1^i, z) \wedge \mathrm{M}^+(z, z, f)$ for $i \in \{1, 2\}$ where z corresponds to an unlabelled vertex. These constraint paths are used to generate exponentially many incomparable expressions within the proof system $\mathcal{P}$, but M^+ itself has no mechanism for turning them into a working gadget. This is why such constraint paths can be handled by Algorithm 1. The situation changes already when we add a single constraint associated to the relation $\check{\mathrm{Z}}$.

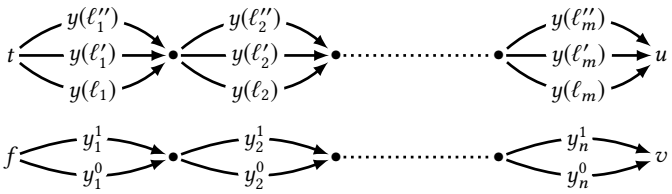

Figure 4 A gadget for the proof of Lemma 25.

Proof (Lemma 25). In the case where $\mathfrak{B}$ pp-defines D, we have that QCSP($\mathfrak{B}$) is PSPACE-hard by Corollary 6 in [22] and Proposition 6. So suppose that $\mathfrak{B}$ does not pp-define D. By Lemma 24, we have that $\mathfrak{B}$ qpp-defines $\check{\mathrm{Z}}$.

We reduce from the complement of the satisfiability problem for propositional 3-CNF. Consider an arbitrary propositional 3-CNF formula ψ, i.e., a conjunction of clauses of the form $\ell_i \vee \ell'_i \vee \ell''_i$ for $i \in [m]$, where $\ell_i, \ell'_i, \ell''_i$ are potentially negated propositional variables from $\{x_1, \dots, x_n\}$. We set $\Phi \coloneqq \exists t \exists f \forall y_1^0 \forall y_1^1 \dots \forall y_n^0 \forall y_n^1 \exists \dots \exists u \exists v\ \phi \wedge \check{\mathrm{Z}}(v, f, u, t)$, where $\exists \dots$ are additional unlabelled existentially quantified variables, and ϕ is defined as in Figure 4. Here $y(x_i) \coloneqq y_i^1$, $y(\neg x_i) \coloneqq y_i^0$, a directed edge from x to z labeled with y stands for $\mathrm{M}^+(x, y, z) \wedge \mathrm{M}^+(z, z, x)$,[2] and unlabelled dots correspond to unlabelled existential variables.

"$\Rightarrow$" Suppose that ψ is not satisfiable. We show that the EP has a winning strategy on Φ. First, the EP chooses $[\![f]\!] < [\![t]\!]$. If there exists $i \in [n]$, such that the UP chose $[\![y_i^0]\!] \neq [\![f]\!]$ and $[\![y_i^1]\!] \neq [\![f]\!]$, then the EP chooses the values for the remaining existential variables as follows: equal $[\![f]\!]$ if they appear in the lower chain in Figure 4 before y_i^0 and y_i^1, and equal $[\![t]\!]$ otherwise. Since $[\![f]\!] < [\![t]\!]$, this choice satisfies $\phi \wedge (v \neq f)$. We may therefore assume that $[\![f]\!] \in \{[\![y_i^0]\!], [\![y_i^1]\!]\}$ for every $i \in [n]$.

We claim that there exists $j \in [m]$ such that $[\![t]\!] \notin \{[\![y(\ell_j)]\!], [\![y(\ell'_j)]\!], [\![y(\ell''_j)]\!]\}$. Suppose, on the contrary, that this is not the case. Let $[\![\cdot]\!]'$ be any map from $\{x_1, \dots, x_n\}$ to $\{0, 1\}$ such that, for every $i \in [n]$, $[\![x_i]\!]' = 0$ if $[\![y_i^0]\!] = t$ and $[\![x_i]\!]' = 1$ if $[\![y_i^1]\!] = t$. Recall that $[\![f]\!] \in \{[\![y_i^0]\!], [\![y_i^1]\!]\}$ for every $i \in [n]$ and thus $[\![\cdot]\!]'$ is well-defined. Observe that $[\![\cdot]\!]'$ is a satisfying assignment to ψ, contradicting our assumption. Hence the claim holds.

The EP can choose the values for the remaining existential variables as follows: equal $[\![t]\!]$ if they appear in the upper chain in Figure 4 before the j-th column, equal to an arbitrary number $q > [\![t]\!]$ if they appear in the upper chain after the j-th column, and equal $[\![f]\!]$ otherwise. Such assignment satisfies $\phi \wedge (t \neq u)$.

"$\Leftarrow$" Suppose that there exists a satisfying assignment $[\![\cdot]\!]'$ to ψ. We show that then the UP has a winning strategy on Φ. If the EP chooses $[\![f]\!] \geq [\![t]\!]$, the UP wins on Φ, suppose therefore that $[\![f]\!] < [\![t]\!]$. If $[\![x_i]\!]' = 0$, the UP plays $[\![y_i^0]\!] = t$ and $[\![y_i^1]\!] = f$, and if $[\![x_i]\!]' = 1$, the UP plays $[\![y_i^0]\!] = f$ and $[\![y_i^1]\!] = t$. It follows from the lower chain in Figure 4 that the EP loses unless $[\![v]\!] = [\![f]\!]$. Moreover, since $[\![\cdot]\!]'$ is a satisfying assignment to ψ, it follows from the upper chain that the EP loses unless $[\![u]\!] = [\![t]\!]$. But then $[\![\cdot]\!]$ violates $(v \neq f \vee u \neq t)$ and the UP wins again. ◀

We are now ready to prove Theorem 5. As an intermediate step, we prove Corollary 4, which extends the tractability result for M^+ to the whole $\pi\pi$ fragment.

Proof (Corollary 4). By Lemma 9, every relation definable by a clause of the form (3) is pp-definable in $(\mathbb{Q}; \mathrm{M}^+)$. For clauses of the form (3) where the last disjunct $(x \geq z)$ is not present, we may use the pp-definition from Lemma 9 and universally quantify over z, which yields a qpp-definition. Hence, if $\mathfrak{B}$ is as in Corollary 4, then every relation of $\mathfrak{B}$ is qpp-definable in $(\mathbb{Q}; \mathrm{M}^+)$. In this case, QCSP($\mathfrak{B}$) reduces in LOGSPACE to QCSP($\mathbb{Q}; \mathrm{M}^+$) due to Proposition 6 and, by Theorem 3, is in PTIME.

For the second part, note that the forward direction immediately follows from the definition of the OH and $\pi\pi$ fragment, since the syntactic form in (3) is a special case of both (2) and (1). For the backward direction, suppose that $\mathfrak{B}$ is an OH structure contained in the $\pi\pi$ fragment. Then every relation has a CNF-definition ϕ over $\{\neq, \geq\}$ where each conjunct is of the form (2) for $k, \ell \geq 0$. By Lemma 8, we can choose ϕ so that every conjunct is of the form (3), possibly with the last disjunct omitted. ◀

[2] Note the difference from the previous interpretation of labeled directed edges, e.g., in Examples 14 and 18. The current interpretation entails $D(x, y, z)$.

Proof (Theorem 5). If $\mathfrak{B}$ is GOH, then QCSP($\mathfrak{B}$) is in PTIME by Theorem 3. If $\mathfrak{B}$ is contained in the $\pi\pi$ fragment, then QCSP($\mathfrak{B}$) is in PTIME by Corollary 4. If $\mathfrak{B}$ is contained in the *dual* $\pi\pi$ fragment, then we reach the same conclusion as in the previous case using the dual version of Corollary 4, which can be obtained by reversing the order in each individual statement used in its proof. Finally, suppose that $\mathfrak{B}$ is not GOH, and also not contained in the $\pi\pi$ or *dual* $\pi\pi$ fragment. Then it either follows directly from Theorem 2 that QCSP($\mathfrak{B}$) is coNP-hard, in which case we are done, or $\mathfrak{B}$ pp-defines M^+ or M^-. If $\mathfrak{B}$ pp-defines M^+, then QCSP($\mathfrak{B}$) is coNP-hard by Lemma 25, because $\mathfrak{B}$ is not contained in the $\pi\pi$ fragment. Otherwise $\mathfrak{B}$ pp-defines M^-. Then we reach the same conclusion as in the previous case using the dual version of Lemma 25, which can again be obtained by reversing the order. ◀

5 The Meta-Problem

For a classification as the one in Theorem 5, one is often interested in the complexity of the following meta-problem: "Does a given structure satisfy the condition for tractability provided by the classification?" In the present section, we give a nondeterministic single-exponential upper bound on the complexity of this meta-problem for Theorem 5.

▶ **Theorem 26.** *The question whether* QCSP($\mathfrak{B}$) *is tractable for a given OH structure* $\mathfrak{B}$ *is decidable in* NEXPTIME.

The most natural way to finitely represent a temporal relation R of arity k is by the set of all weak linear orderings on k variables that are witnessed by the tuples in R. Since the first-order theory of $(\mathbb{Q};<)$ has quantifier-elimination [13], every temporal relation has such a representation. To see this, note that the atomic formula $R(x_1,\dots,x_k)$ has a quantifier-free definition ψ over $\{<\}$, then it is enough to list all weak linear orderings that are compatible with ψ. For instance, the temporal relation defined by $(x_1 \neq x_2 \vee x_1 < x_3) \wedge (x_1 \leq x_2) \wedge (x_2 \leq x_3)$ admits the following three weak linear orderings:

$$(x_1 = x_2 < x_3), \quad (x_1 < x_2 < x_3), \quad \text{and} \quad (x_1 < x_2 = x_3).$$

Proof (Theorem 26). For every relation R of $\mathfrak{B}$, let ϕ_R be the first-order formula over $\{<\}$ defining R that is provided as an input to the meta-problem. Let ψ_R be the disjunction of all k-ary formulas specifying a weak linear order compatible with R. We claim that ψ_R can be computed from ϕ_R in exponential time. Indeed, to test whether a k-ary formula θ specifying a weak linear ordering is compatible with R, we must only test whether $(\mathbb{Q};<) \models \forall\bar{x}\big(\theta(\bar{x}) \Rightarrow \phi_R(\bar{x})\big)$. This can be done in PSPACE (Theorem 21.2 in [14]). Clearly, ψ_R defines R. Now, to test whether R is contained in the (*dual*) $\pi\pi$ fragment, we simply guess a conjunction ϕ of clauses of the form (2) that defines R. Note that ϕ might be of size exponential in the size of the input. To verify whether ϕ defines R, we test whether $(\mathbb{Q};<) \models \forall\bar{x}\big(\phi(\bar{x}) \Leftrightarrow \psi_R(\bar{x})\big)$. This can be done in NEXPTIME because the satisfiability of quantifier-free formulas over $(\mathbb{Q};<)$, such as $\neg(\phi(\bar{x}) \Leftrightarrow \psi_R(\bar{x}))$, can be decided in NP. Whether R is contained in the GOH fragment can be tested similarly. ◀

6 Open Questions

For quantified OH constraints, we leave the following question open:

Question 1: Do OH QCSPs exhibit a dichotomy between coNP and PSPACE-hardness?

We also ask the following questions regarding open cases outside of OH:

Question 2: Is QCSP($\mathfrak{B}$) in P whenever $\mathfrak{B}$ is a temporal structure contained in the *mi* fragment [7]? It is enough to consider QCSP($\mathbb{Q}; x \neq y \vee x \geq z \vee x > w$) [2].

Question 3: Is QCSP($\mathfrak{B}$) in NP whenever $\mathfrak{B}$ is a temporal structure contained in the $\pi\pi$ fragment? It is enough to consider QCSP($\mathbb{Q}; x \neq y \vee x \geq z_1 \vee x \geq z_2$) [2].

A A Full Proof of Claim 21

▷ Claim 21. Suppose that the EP follows the strategy above. Then, for all $x, z \in \mathrm{V}$, we have $[\![x]\!] = [\![z]\!]$ if and only if there exist $x_1, x_2, z_1, z_2 \in V$ and $A_{x_2,x}, A_{z_2,z} \subseteq \mathrm{V}_\forall$ such that

1. $\{x_1, x_2\} \preceq x$ and $\{z_1, z_2\} \preceq z$
2. $x_2 \prec A_{x_2,x} \preceq x$ and $z_2 \prec A_{z_2,z} \preceq z$,
3. $y \preceq_\forall \{x_1, x_2, z_1, z_2\}$ for some $y \in \{x_2, z_2\}$,
4. $\mathcal{P}(x_2, x; A_{x_2,x}) \wedge \mathcal{P}(x, x_1; \emptyset) \wedge \mathcal{P}(z_2, z; A_{z_2,z}) \wedge \mathcal{P}(z, z_1; \emptyset)$,
5. $[\![A_{x_2,x}]\!] = [\![x_1]\!] = [\![x_2]\!] = [\![z_1]\!] = [\![z_2]\!] = [\![A_{z_2,z}]\!]$.

Whenever the right-hand side of the equivalence holds, we also have $[\![x]\!] = [\![x_2]\!]$ and $[\![z]\!] = [\![z_2]\!]$.

Proof. "⇐" We show that $[\![x]\!] = [\![x_2]\!]$ and $[\![z]\!] = [\![z_2]\!]$. If $x \equiv x_2$, then clearly $[\![x]\!] = [\![x_2]\!]$. So, w.l.o.g., $x_2 \prec x$. If $x \in \mathrm{V}_\forall$, then §S yields $\mathcal{P}(x_2, x; \emptyset)$ and hence §R produces $\bot$, a contradiction. So we must have $x \in \mathrm{V}_\exists$. Then either $x_1 \equiv x$ or $x_1 \prec x$, and it follows from the strategy of the EP that $[\![x]\!] = [\![x_2]\!]$. Analogously we obtain that $[\![z]\!] = [\![z_2]\!]$. The rest follows by the transitivity of the equality.

"⇒" Whenever the right-hand side of the equivalence in Claim 21 is satisfied, we call $(x, x_1, x_2; A_{x_2,x})$ and $(z, z_1, z_2; A_{z_2,z})$ *witnessing quadruples* for $[\![x]\!] = [\![z]\!]$. If $x \equiv z$, then the statement trivially follows using §I, the witnessing quadruples are $(x, x, x; \emptyset)$ and $(z, z, z; \emptyset)$. So, w.l.o.g., $z \prec x$. If $x \in \mathrm{V}_\forall$, then the claim follows using §I, the witnessing quadruples are again $(x, x, x; \emptyset)$ and $(z, z, z; \emptyset)$. So suppose that $x \in \mathrm{V}_\exists$ and that the claim holds for all pairs of variables preceding x. Since $[\![x]\!] = [\![z]\!]$, by the strategy of the EP, there exist $x_1, x_2 \prec x$ and $x_2 \prec A \prec x$ such that $\mathcal{P}(x, x_1; \emptyset) \wedge \mathcal{P}(x_2, x; A)$ and $[\![z]\!] = [\![x_1]\!] = [\![x_2]\!] = [\![A]\!]$.

Since $[\![x_2]\!] = [\![z]\!]$ and $x_2, z \prec x$, we can apply the induction hypothesis for the pair x_2, z to obtain the witnessing quadruples $(x_2, x_{2_1}, x_{2_2}; A_{x_{2_2},x_2})$ and $(z, z_1, z_2; A_{z_2,z})$. By assumption, there exists $y \in \{z_2, x_{2_2}\}$ such that $y \preceq_\forall \{z_1, z_2, x_{2_1}, x_{2_2}\}$. Note that $[\![y]\!] = [\![x_1]\!]$. Thus, we can apply the induction hypothesis for the pair x_1, y to obtain the witnessing quadruples

$(x_1, x_{1_1}, x_{1_2}; A_{x_{1_2},x_1})$ and $(y, y_1, y_2; A_{y_2,y})$. By assumption, there exists $y' \in \{y_2, x_{1_2}\}$ such that $y' \preceq_\forall \{y_1, y_2, x_{1_1}, x_{1_2}\}$. The two cases w.r.t. the variable y that can occur are illustrated in Figure 3, see Case 1 and Case 2 below.

Our goal is to find witnesses x'_1, x'_2, z'_1, z'_2 for the main statement of the claim, i.e., the witnessing quadruples will be of the form $(x, x'_1, x'_2; A_{x'_2,x})$ and $(z, z'_1, z'_2; A_{z'_2,z})$. For the sake of brevity, we will not explicitly write down the precise definitions of $A_{x'_2,x}$ and $A_{z'_2,z}$ as they will be clear from the context. We set $x'_1 \coloneqq x_{1_1}$, and:

$$z'_1 \coloneqq \begin{cases} y_1 & \text{if } y \equiv z_1, \\ z_1 & \text{otherwise,} \end{cases} \qquad z'_2 \coloneqq \begin{cases} y_2 & \text{if } y \equiv z_2, \\ z_2 & \text{otherwise,} \end{cases} \qquad x'_2 \coloneqq \begin{cases} y_2 & \text{if } y \equiv x_{2_2}, \\ x_{2_2} & \text{otherwise.} \end{cases}$$

By the induction hypothesis and the transitivity of $\prec$, x'_1, x'_2, z'_1, z'_2 clearly satisfy item 1. It will also be clear that our implicit choice of $A_{x'_2,x}$ and $A_{z'_2,z}$ leads to satisfaction of item 5. The remaining three items are proved in the case distinction below. In both Cases 1 and 2, we initially start proving items 2 and 4, and then proceed with item 3 in the finer subdivision into Cases 1.1, 1.2, 2.1, and 2.2. For the sake of conciseness, when applying rules of $\mathcal{P}$ to derive new expressions, we often do not state all necessary expressions for the inference, as long as they are clear from the rule and the resulting expression.

To justify the applications of the rule §A that follow, we observe that $y_2 \preceq_\forall y_1$. Indeed, suppose that $y_1 \not\equiv y_2$. By §T, we have $\mathcal{P}(y_2, y_1, A_{y_2,y})$. If $y_1 \in \mathrm{V}_\exists$ or $y_1 \prec y_2$, then $y' \preceq_\forall \{y_1, y_2\}$ implies $y_1 \prec y_2$ and $y_2 \in \mathrm{V}_\forall$. By §S, we obtain $\mathcal{P}(y_2, y_1, \emptyset)$, and then using §R we get $\bot$, a contradiction. By an analogous argument, we have $x_{2_2} \preceq_\forall x_{2_1}$. Now it immediately follows that, by §A, we have

$$\mathcal{P}(x_{2_2}, x; A \cup A_{x_{2_2},x_2} \cup (\{x_{2_1}\} \setminus \{x_{2_2}\}). \tag{5}$$

A subsequent double application of §T yields

$$\mathcal{P}(x_{2_2}, x_{1_1}; A \cup A_{x_{2_2},x_2} \cup (\{x_{2_1}\} \setminus \{x_{2_2}\})). \tag{6}$$

Case 1: $y \equiv z_2$. Then $z_2 \preceq_\forall \{z_1, x_{2_1}, x_{2_2}\}$. We now establish item 4 with a suitable choice of sets $A_{x'_2,x}$ and $A_{z'_2,z}$. It is easy to verify that item 2 is satisfied as well.

- If $y \equiv z_1$, then, by §T, we have $\mathcal{P}(z, z'_1; \emptyset)$ because $z'_1 \equiv y_1$. Otherwise $z_1 \in \mathrm{V}_\forall$ and $y \prec z_1$; we have $\mathcal{P}(z, z'_1; \emptyset)$, because $z'_1 \equiv z_1$.
- Recall that $y_2 \preceq_\forall y_1$. Thus, by §A, we have

  $$\mathcal{P}(z'_2, z; A_{z_2,z} \cup A_{y_2,y} \cup (\{y_1\} \setminus \{y_2\})), \tag{7}$$

  because $z'_2 \equiv y_2$.
- By §T, we have $\mathcal{P}(x, x'_1; \emptyset)$, because $x'_1 = x_{1_1}$.
- By assumption, we have $y \preceq_\forall x_{2_2}$. Recall that we have (5). If $y \equiv x_{2_2}$, then an application of §A yields

  $$\mathcal{P}(x'_2, x; A \cup A_{x_{2_2},x_2} \cup (\{x_{2_1}\} \setminus \{x_{2_2}\}) \cup A_{y_2,y} \cup (\{y_1\} \setminus \{y_2\})), \tag{8}$$

  because $x'_2 \equiv y_2$. Otherwise $y \prec x_{2_2}$ and $x_{2_2} \in \mathrm{V}_\forall$. Then $\mathcal{P}(x'_2, x; A \cup A_{x_{2_2},x_2} \cup (\{x_{2_1}\} \setminus \{x_{2_2}\}))$ follows directly from (5) because $x'_2 \equiv x_{2_2}$.

In the case distinction below, we verify item 3 for x'_1, x'_2, z'_1, z'_2.

Case 1.1: $y' \equiv y_2$. By the choice of y', we have $y_2 \equiv y' \preceq \{y_1, y_2, x_{1_1}\}$. Recall that $y_2 \preceq y \preceq_\forall \{z_1, z_2, x_{2_2}\}$. Hence, if $y \prec z_1$, then $y_2 \preceq_\forall z_1$. Similar applies to z_2 and x_{2_2}. It follows that, for all choices of x'_1, x'_2, z'_1, z'_2 above, we get $z'_2 \equiv y_2 \preceq_\forall \{z'_1, x'_1, x'_2\}$.

Case 1.2: $y' \equiv x_{1_2}$. We show that, as above, $z'_2 \equiv y_2 \preceq_\forall \{z'_1, x'_1, x'_2\}$, starting with x'_2. If $y \equiv z_2 \prec x_{2_2}$ and $x_{2_2} \in \mathrm{V}_\forall$, then we have $z'_2 \equiv y_2 \preceq_\forall x_{2_2} \equiv x'_2$. Otherwise $x_{2_2} \equiv z_2 \equiv y$ and by our choice of x'_2 and z'_2, we have $z'_2 \equiv y_2$ and $x'_2 \equiv y_2$. In particular, $z'_2 \preceq_\forall x'_2$. Next comes z'_1. If $y \prec z_1$ and $z_1 \in \mathrm{V}_\forall$, then $y_2 \preceq_\forall z_1$ because $y_2 \preceq y$. Consequently, $z'_2 \equiv y_2 \preceq_\forall z_1 \equiv z'_1$. Otherwise $y \equiv z_1$ and $z'_1 \equiv y_1$. Recall that we always have $y_2 \preceq_\forall y_1$ and hence $z'_2 \equiv y_2 \preceq_\forall y_1 \equiv z'_1$.

Finally x'_1. Recall that we have $y \equiv z_2 \preceq_\forall x_{2_2} \preceq_\forall x_{2_1}$ (the second $\preceq_\forall$ was derived above equation (5)). We consider the following two cases. First, suppose that $z_2 \prec x_{2_2}$ and $x_{2_2} \in \mathrm{V}_\forall$. Since $x_{2_2} \in \mathrm{V}_\forall$, it cannot be the case that $x_{1_1} \prec x_{2_2}$, otherwise §S applied on (6) yields $\mathcal{P}(x_{2_2}, x_{1_1}; \emptyset)$. Using §R, we obtain $\bot$, a contradiction. Hence $x_{2_2} \preceq x_{1_1}$. Now it follows that $y_2 \preceq z_2 \prec x_{2_2} \preceq x_{1_1}$. Since $y' \preceq_\forall \{y_2, x_{1_1}\}$, we even have $z'_2 \equiv y_2 \preceq_\forall x_{1_1} \equiv x'_1$. Second, suppose that $x_{2_2} \equiv z_2 \equiv y$. Recall that $y_2 \preceq_\forall y_1$ (derived above (5)) and $\mathcal{P}(y_2, y; A_{y_2,y})$. Combining this with (6) and applying §A, we get

$$\mathcal{P}(y_2, x_{1_1}; A \cup A_{x_{2_2},x_2} \cup (\{x_{2_1}\} \setminus \{x_{2_2}\}) \cup A_{y_2,y} \cup (\{y_1\} \setminus \{y_2\})). \tag{9}$$

We cannot have $x_{1_1} \prec y_2$, otherwise $y_2 \in \mathrm{V}_\forall$ in which case §S yields $\mathcal{P}(y_2, x_{1_1}; \emptyset)$ and then §R yields $\bot$, a contradiction. Hence, $y_2 \preceq x_{1_1}$. Since $y' \preceq_\forall \{y_2, x_{1_1}\}$, we get $z'_2 \equiv y_2 \preceq_\forall x_{1_1} \equiv x'_1$.

Case 2: $y \equiv x_{2_2}$. Then $x_{2_2} \preceq_\forall \{z_1, z_2, x_{2_1}\}$. We now show that item 4 holds true with a suitable choice of sets $A_{x'_2,x}$ and $A_{z'_2,z}$; it will be clear that item 2 is satisfied as well.

- If $y \equiv z_1$, then, by §T, we get $\mathcal{P}(z, z'_1; \emptyset)$, because $z'_1 \equiv y_1$. Otherwise $z_1 \in \mathrm{V}_\forall$ and $y \prec z_1$; we have $\mathcal{P}(z, z'_1; \emptyset)$ because $z'_1 \equiv z_1$.
- First, suppose that $y \equiv z_2$. Recall that we have $y_2 \preceq_\forall y_1$. By §A, we have (7) because $z'_2 \equiv y_2$. Second, suppose that $y \prec z_2$ and $z_2 \in \mathrm{V}_\forall$. Then we have $\mathcal{P}(z'_2, z; A_{z_2,z})$ because $z'_2 \equiv z_2$.
- By §T, we have $\mathcal{P}(x, x'_1; \emptyset)$ because $x'_1 \equiv x_{1_1}$.
- Recall that we have (5) and $y_2 \preceq_\forall y_1$. By §A, we have (8) because $x'_2 \equiv y_2$.

Finally, we verify item 3 of the claim.

Case 2.1: $y' \equiv y_2$. By the choice of y', we have $y_2 \equiv y' \preceq \{y_1, y_2, x_{1_1}\}$. Recall that $y_2 \preceq y \preceq_\forall \{z_1, z_2, x_{2_2}\}$. Hence, if $y \prec z_1$, then $y_2 \preceq_\forall z_1$. Similar applies to z_2 and x_{2_2}. It follows that, for all choices of x'_1, x'_2, z'_1, z'_2 above, we get $x'_2 \equiv y_2 \preceq_\forall \{z'_1, z'_2, x'_1\}$.

Case 2.2: $y' \equiv x_{1_2}$. By a double application of §T on (8), we get (9). It cannot be that $x_{1_1} \prec y_2$, as this implies $y_2 \in \mathrm{V}_\forall$, in which case §S yields $\mathcal{P}(y_2, x_{1_1}; \emptyset)$ and then §R yields $\bot$, a contradiction as in Case 1.2. Hence $x'_2 \equiv y_2 \preceq_\forall x_{1_1} \equiv x'_1$. Recall that $y_2 \preceq_\forall y_1$. Either $x_{2_2} \prec z_1$ and $z_1 \in \mathrm{V}_\forall$, in which case $x'_2 \equiv y_2 \preceq_\forall z_1 \equiv z'_1$, or $x_{2_2} \equiv z_1$ in which case $x'_2 \equiv y_2 \preceq_\forall y_1 \equiv z'_1$. Also either $x_{2_2} \prec z_2$ and $z_2 \in \mathrm{V}_\forall$, in which case $x'_2 \equiv y_2 \preceq_\forall z_2 \equiv z'_2$, or $x_{2_2} \equiv z_2$ in which case $x'_2 \equiv y_2 \preceq_\forall y_2 \equiv z'_2$. Hence, $x'_2 \preceq_\forall \{z'_1, z'_2, x'_1\}$. ◁

On Homomorphism Indistinguishability and Hypertree Depth

Benjamin Scheidt
Humboldt-Universität zu Berlin, Germany

Abstract

GC^k is a logic introduced by Scheidt and Schweikardt (2023) to express properties of hypergraphs. It is similar to first-order logic with counting quantifiers (C) adapted to the hypergraph setting. It has distinct sets of variables for vertices and for hyperedges and requires vertex variables to be guarded by hyperedge variables on every quantification.

We prove that two hypergraphs G, H satisfy the same sentences in the logic GC^k with *guard depth* at most k if, and only if, they are homomorphism indistinguishable over the class of hypergraphs of strict hypertree depth at most k. This lifts the analogous result for tree depth $\leq k$ and sentences of first-order logic with counting quantifiers of quantifier rank at most k due to Grohe (2020) from graphs to hypergraphs. The guard depth of a formula is the quantifier rank with respect to hyperedge variables, and strict hypertree depth is a restriction of hypertree depth as defined by Adler, Gavenčiak and Klimošová (2012). To justify this restriction, we show that for every H, the strict hypertree depth of H is at most 1 larger than its hypertree depth, and we give additional evidence that strict hypertree depth can be viewed as a reasonable generalisation of tree depth for hypergraphs.

1 Introduction

The (k-dimensional) Weisfeiler-Leman algorithm describes a technique to classify the vertices (or k-tuples) of a graph, by iteratively computing a colouring (i.e., a classification) of the vertices (or k-tuples), which gets refined each iteration until it stabilises. While it can be used as a way to (imperfectly) test graphs for isomorphism, it has found many other – seemingly very different – uses, e.g. reducing the cost of solving linear programs [14], as graph kernels [29] or even as an architecture for graph neural networks [30, 22, 13, 12]. For a more in-depth overview on the expressive power of the Weisfeiler-Leman algorithm itself, consult [17] as a starting point. The success of the Weisfeiler-Leman algorithm can in part be explained by its simplicity, but also by the fact that it appears to capture the structure of a graph really well. This can be explained by its connection to first-order logic with counting quantifiers and to homomorphism counts over graphs of bounded tree width. A classical result due to Cai, Fürer and Immerman [5] and Immerman and Lander [16] says that two graphs are indistinguishable by the k-dimensional Weisfeiler-Leman algorithm if, and only if, they satisfy the same sentences of first-order logic with counting quantifiers (C) and k+1 variables (C^{k+1}).

Dvořák [9] and Dell, Grohe, Rattan [8] related the Weisfeiler-Leman algorithm to homomorphism counts over graphs of bounded tree width (this was subsequently generalised to relational structures of bounded tree width by Butti and Dalmau [3]). They showed that two graphs are homomorphism indistinguishable over the class TW_k of graphs of tree width at most k if, and only if, they are indistinguishable by the k-dimensional Weisfeiler-Leman algorithm. Here, two graphs G and H are *homomorphism indistinguishable* over a class $\mathfrak{C}$ of graphs, if the number of homomorphisms from F into G equals the number of homomorphisms from F into H for all $F \in \mathfrak{C}$. Dvořák used the previously mentioned connection to C^{k+1} and an inductive characterisation of the graphs of bounded tree width to prove this result, while Dell et al. used elaborate algebraic techniques on vectors containing homomorphism counts.

In recent years, a whole theory has emerged around homomorphism indistinguishability. There are characterisations of homomorphism indistinguishability for classes of graphs other than TW_k (cf. [7, 10, 21, 25]), among which we would like to emphasise the following: A classical result by Lovász [18], stating that two graphs are isomorphic if, and only if, they are homomorphism indistinguishable over all graphs; a well-received result by Mančinska and Roberson [20], stating that two graphs are homomorphism indistinguishable over the class of planar graphs if, and only if, they are quantum isomorphic; and, of importance for this paper, Grohe [11] showed that two graphs are homomorphism indistinguishable over the graphs of tree depth at most m if, and only if, they satisfy the same sentences of C with quantifier rank at most m (C_m). There is also work concerned with a more fundamental analysis of homomorphism counting from restricted classes (cf. [2, 15, 23, 24, 28]).

Some real-world problems can be represented by hypergraphs in a much more natural way than by graphs. The great track record of the Weisfeiler-Leman method poses the question, whether a similar algorithm exists that works on *hypergraphs*. A direct application of the Weisfeiler-Leman algorithm on the incidence structure of a hypergraph is sometimes used. But Böker noted in [4], that this approach does not capture the hypergraph structure well, since the algorithm will mix up hyperedges and vertices. Thus, a proper variant of the Weisfeiler-Leman algorithm that works on hypergraphs is, to the best of our knowledge, still missing. We believe that establishing results analogous to the ones mentioned so far can give valuable insight on how the algorithm should operate on hypergraphs. A first step from this angle is a result by Scheidt and Schweikardt [27], who lift Dvořák's result to hypergraphs by proving the following: two hypergraphs G, H are homomorphism indistinguishable over the class GHW_k of hypergraphs of generalised hypertree width at most k if, and only if, they satisfy the same sentences of the logic GC^k. GC^k is a novel logic introduced in [27]. It has distinct variables for vertices and for hyperedges and counting quantifiers for both variable types. The main feature of GC^k is that it bounds the number of variables for hyperedges by k, and it requires that vertex variables are "guarded by" (i.e., contained in) hyperedge variables on every quantification.

Contributions. As the main contribution of this work, we show that two hypergraphs satisfy the same sentences of the logic GC^k with guard depth at most k if, and only if, they are homomorphism indistinguishable over the class of hypergraphs of strict hypertree depth at most k (Theorem 6.1). The guard depth is the quantifier depth of the hyperedge variables. This theorem follows from an inductive characterisation of the class of hypergraphs of strict hypertree depth $\leq k$, combined with the main technical lemmas of Scheidt and Schweikardt [27]. We believe that this inductive characterisation is interesting on its own, since the same technique combined with the core lemmata in Dvořák's work [9] can be used to give a concise proof of the analogous result on graphs due to Grohe [11], which was

independently recognised and shown by Fluck et al. [10] recently. Strict hypertree depth is a mild restriction of hypertree depth as defined by Adler, Gavenčiak and Klimošová [1]. This (as it turns out only slight) deviation from hypertree depth is surprising at first. Because of the properties and relations between strict hypertree depth and hypertree depth we acquire in this paper, we claim that strict hypertree depth can be viewed as a reasonable generalisation of tree depth for hypergraphs too. In particular, we show that the strict hypertree depth of a hypergraph is at most 1 larger than its hypertree depth (Theorem 2.5). Moreover, we show that the distinguishing power of homomorphism counts from hypergraphs of hypertree depth at most k is different from the distinguishing power of homomorphism counts from their respective incidence graphs (Theorem 2.9). Compared to other hypergraph parameters, this is very unexpected.

Organisation. The remainder of the paper is organised as follows. Section 2 is dedicated to the introduction of the necessary notation and definitions. In particular, we introduce incidence graphs as representations of hypergraphs that will be used throughout the paper, following Böker [4] and Scheidt and Schweikardt [27]. The notions of (strict) hypertree depth are introduced in Section 2.1, followed by Section 2.2 where we handle the differences between homomorphisms between hypergraphs and homomorphisms between incidence graphs. In Section 3 we introduce k-labeled incidence graphs that were the principle tool used in [27] to achieve their result. We utilise them in Section 4 to give an inductive characterisation of the hypergraphs of strict hypertree depth at most k (Theorem 4.1). Section 5 is devoted to the logic GC^k. In Section 6 we combine the results from Section 4 and Section 2.2 with the results from [27] to obtain Theorem 6.1. Section 7 concludes the paper with a summary of the results obtained in this paper, as well as an outlook on further research directions.

2 Preliminaries

Since we heavily rely on the work by Scheidt and Schweikardt [27], we will keep our notation close to theirs. We denote the set of natural numbers *including* 0 by $\mathbb{N}$, the set of *positive* natural numbers by $\mathbb{N}_{\geq 1}$, and we write $[n]$ to denote the set $\{1, 2, \ldots, n\}$. To denote isomorphism of two objects, we use $\cong$. A tuple is denoted using a bar, e.g. $\overline{a}$. For a given ℓ-tuple $\overline{a}$, we use a_i to denote the i-th element of $\overline{a}$, i.e., $\overline{a} = (a_1, a_2, \ldots, a_\ell)$. For any set S, let $\mathcal{P}(S)$ be the set of subsets of S and let $\mathcal{P}_k(S)$ be the subsets of cardinality exactly k. If S is a set of sets, let $\bigcup S = \bigcup_{s \in S} s$.

For a finite set S of cardinality $\ell \in \mathbb{N}$, a total order $<$ on S and any number $d \in \mathbb{N}$, we say that $\langle i_{d+1}, i_{d+2} \ldots, i_{d+\ell} \rangle$ is the *$<$-enumeration of S*, if $i_{d+1} < i_{d+2} < \cdots < i_{d+\ell}$ and $\{i_{d+1}, \ldots, i_{d+\ell}\} = S$. If the order $<$ is clear from the context, we simply say that $\langle i_{d+1}, i_{d+2} \ldots, i_{d+\ell} \rangle$ is the enumeration of S. Note that we usually let $d = 0$, i.e., we usually write $\langle i_1, \ldots, i_\ell \rangle$. Furthermore, the enumeration $\langle i_{d+1}, i_{d+2} \ldots, i_{d+\ell} \rangle$ of S is empty if, and only if, S is empty.

We denote a partial function f from A to B by $f \colon A \rightharpoonup B$, and we let $\mathrm{dom}(f) \coloneqq \{a \in A : f(a) \text{ is defined}\}$ and $\mathrm{img}(f) \coloneqq \{b \in B : \text{ex. } a \in A \text{ s.t. } f(a) = b\}$. We say that two functions f and g are *compatible*, if $f(x) = g(x)$ for all $x \in \mathrm{dom}(f) \cap \mathrm{dom}(g)$. We identify a (partial) function f with the set $\{(x, f(x)) : x \in \mathrm{dom}(f)\}$ whenever we are using set notation on functions. For example, we write $f \subseteq g$ to indicate $\mathrm{dom}(f) \subseteq \mathrm{dom}(g)$ and $f(x) = g(x)$ for all $x \in \mathrm{dom}(f)$. In particular, by $f \cup g$ we denote the function h with $\mathrm{dom}(h) = \mathrm{dom}(f) \cup \mathrm{dom}(g)$ and $h(x) = f(x)$ for all $x \in \mathrm{dom}(f)$ and $h(x) = g(x)$ for all $x \in \mathrm{dom}(g) \setminus \mathrm{dom}(f)$. Note that f has *precedence* over g, but this only matters if f and g are not compatible. For a

(partial) function f and a set $S \subseteq \mathrm{dom}(f)$ we write $f(S)$ to denote $\{f(x) : x \in S\}$, and we call the function $g \subseteq f$ with $\mathrm{dom}(g) \coloneqq S$ the *restriction of f to S*. Finally, we define partial functions inline like this: $\{a \to 3, b \to 2, c \to 5\}$. In particular, the empty set $\varnothing$ denotes a partial function with empty domain.

Graphs, Trees and Forests. An (undirected) graph is a tuple $G = (V(G), E(G))$, where $V(G)$ is a finite set and $E(G) \subseteq \mathcal{P}_2(V(G))$. For a set $S \subseteq V(G)$, $G[S]$ denotes the subgraph induced by S, i.e., $V(G[S]) \coloneqq S$ and $E(G[S]) \coloneqq E(G) \cap \mathcal{P}_2(S)$. A connected component of a graph is a maximal induced subgraph that is connected. A tree is a connected acyclic graph and a forest is a graph were each connected component is a tree. A rooted tree T is a tree with some distinguished node that we call its *root*, which we denote by ω_T. A rooted forest F is the disjoint union of a collection of rooted trees. It therefore has a set of roots denoted by Ω_F. We may omit the index if it is clear from the context. Note that a rooted tree is also a rooted forest and that every node n in a rooted forest is contained in a unique connected component which is a tree that we call the *tree for n* and whose root is the *root for n*.

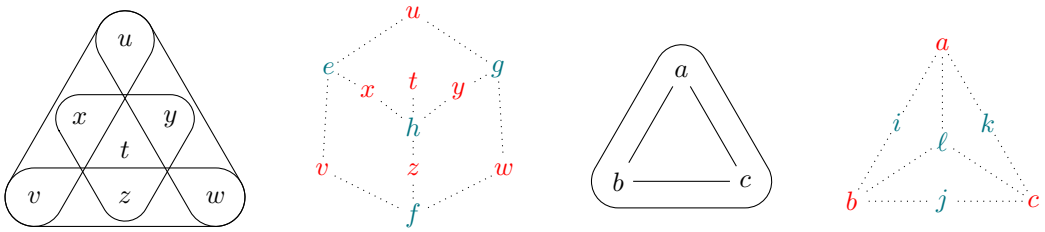
For a rooted forest F we let $\leq_F$ be the induced partial order on the nodes, i.e., the roots are the minimal elements and $s \leq_F t$ if s is on the unique path from t to its root in Ω. By $\mathrm{P}(s,t)$ we denote the set of nodes on the path from s to t (including s and t). In particular, if no path from s to t exists, $\mathrm{P}(s,t) = \varnothing$. By $\mathrm{P}(s)$ we denote the set of nodes on the path from s to the root for s and by $\wedge(s,t)$ we denote the unique element, if it exists, where the paths $\mathrm{P}(s)$, $\mathrm{P}(t)$ join, i.e., $\wedge(s,t) \coloneqq \max_{\leq_F}(\mathrm{P}(s) \cap \mathrm{P}(t))$. Notice that $\wedge(s,t)$ is undefined iff s and t are not in the same tree, and that $\wedge(s,t) = s$, iff $s \leq_F t$ (and conversely, $\wedge(s,t) = t$ iff $t \leq_F s$).

The subtree T_t induced by $t \in V(F)$ is the tree $F[V]$ with root t and $V \coloneqq \{s \in V(T) : t \leq_F s\}$. The *level* of a node $s \in V(F)$ is defined as the number of elements on the path from s to its root, i.e., $\mathrm{level}(s) \coloneqq |\mathrm{P}(s)|$. The *height* of a rooted tree T is the maximal level, i.e., $\mathrm{height}(T) \coloneqq \max\{\mathrm{level}(t) : t \in V(T)\}$ and the height of a node $t \in V(T)$ is the height of its induced subtree T_t, i.e., $\mathrm{height}(t) \coloneqq \mathrm{height}(T_t)$.

Hyper- and Incidence Graphs. A *hypergraph* is a tuple $\mathcal{H} = (V, E, \beta)$, where V and E are disjoint finite sets and β is a total function from E to $\mathcal{P}(V)$ with $V = \bigcup_{e \in E} \beta(e)$. We call the elements of V *vertices* and the elements of E *hyperedges* and for every $e \in E$, we call $\beta(e)$ its *contents*. We denote V by $V(\mathcal{H})$, E by $E(\mathcal{H})$ and β by $\beta_{\mathcal{H}}$, though we may omit the index if there is no ambiguity. Notice that, in general, multiple hyperedges with the same content and hyperedges without content are allowed. We call $\mathcal{H}$ *simple* if β is injective.

An *incidence graph* is a tuple $I = (R, B, E)$ consisting of two disjoint finite sets R and B of *red* and *blue* vertices and a relation $E \subseteq B \times R$. We denote R by $\mathcal{R}(I)$, B by $\mathcal{B}(I)$ and E by $E(I)$. For every $e \in \mathcal{B}(I)$, we let $\beta(e) \coloneqq \{v \in \mathcal{R}(I) : (e,v) \in E(I)\}$. Notice that β is equivalent in its function to the map β for a hypergraph, hence we denote them similarly. We only consider incidence graphs where for every $v \in \mathcal{R}(I)$ there is an $e \in \mathcal{B}(I)$ such that $(e,v) \in E(I)$. It is easy to see that we can assign an incidence graph to every hypergraph and the other way around: For every hypergraph $\mathcal{H}$ we let $I_{\mathcal{H}} \coloneqq (V(\mathcal{H}), E(\mathcal{H}), E)$ where $E \coloneqq \{(e,v) : e \in E(\mathcal{H}), v \in \beta(e)\}$. Conversely, for every incidence graph I we let $\mathcal{H}_I \coloneqq (\mathcal{R}(I), \mathcal{B}(I), \beta)$ where $\beta(e) \coloneqq \{v \in \mathcal{R}(I) : (e,v) \in E(I)\}$ for all $e \in \mathcal{B}(I)$.

For every set $S \subseteq E(\mathcal{H})$ we define the *induced subhypergraph* $\mathcal{H}[S]$ as $(V', S, \beta'_{\mathcal{H}})$ where $V' \coloneqq \bigcup_{e \in S} \beta(e)$ and $\beta'_{\mathcal{H}}$ is the restriction of $\beta_{\mathcal{H}}$ to S. We say that a hypergraph is connected if its incidence graph is connected. An induced subhypergraph is a connected component, if its corresponding incidence graph is a connected component.



(a) The hypergraph $\mathcal{H}$. **(b)** The IG $I_{\mathcal{H}}$ for $\mathcal{H}$. **(c)** The hypergraph $\mathcal{G}$. **(d)** The IG $I_{\mathcal{G}}$ for $\mathcal{G}$.

Figure 1 Examples for hypergraphs and their corresponding incidence graphs.

By $\mathcal{P}_n$ we denote the path of n hyperedges, where each hyperedge contains 2 vertices. I.e., we let $V(\mathcal{P}_n) = [n+1]$, $E(\mathcal{P}_n) = \{e_i : i \in [n]\}$ and $\beta(e_i) = \{i, i+1\}$ for all $i \in [n]$. We may use different names for the vertices if it is convenient.

▶ **Example 2.1.** The hypergraph $\mathcal{H}$ illustrated in Figure 1a is defined as $V(\mathcal{H}) = \{u, v, w, x, y, z, t\}$, $E(\mathcal{H}) = \{e, f, g, h\}$ and $\beta_{\mathcal{H}} = \{e \to \{u, v, x\}, f \to \{v, w, z\}, g \to \{u, w, y\}, h \to \{t, x, y, z\}\}$. Its incidence graph $I_{\mathcal{H}}$, depicted in Figure 1b, is defined by $\mathcal{R}(I_{\mathcal{H}}) = V(\mathcal{H})$, $\mathcal{B}(I_{\mathcal{H}}) = E(\mathcal{H})$ and $E(I_{\mathcal{H}}) = \{(e,u), (e,v), (e,x), (f,v), (f,w), (f,z), (g,u), (g,w), (g,y), (h,t), (h,x), (h,y), (h,z)\}$.

The hypergraph $\mathcal{G}$ depicted in Figure 1c is defined as $V(\mathcal{G}) = \{a, b, c\}$, $E(\mathcal{G}) = \{i, j, k, \ell\}$ and $\beta_{\mathcal{G}} \coloneqq \{i \to \{a, b\}, j \to \{b, c\}, k \to \{a, c\}, \ell \to \{a, b, c\}\}$. Its incidence graph $I_{\mathcal{G}}$, depicted in Figure 1d, is defined as $\mathcal{R}(I_{\mathcal{G}}) = V(\mathcal{G})$, $\mathcal{B}(I_{\mathcal{G}}) = E(\mathcal{G})$ and $E(I_{\mathcal{G}}) = \{(i,a), (i,b), (j,b), (j,c), (k,a), (k,c), (\ell,a), (\ell,b), (\ell,c)\}$.

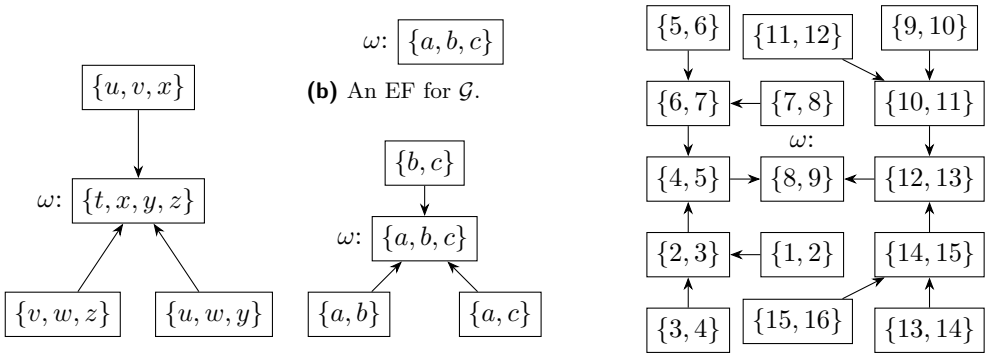
2.1 Hypertree Depth

The following definition of *elimination forest* and *hypertree depth* is due to Adler, Gavenčiak and Klimošová [1], though they refer to elimination forests as "decomposition forests". We call them elimination forests, since this reflects their conceptual similarity to elimination forests for graphs and avoids confusion with hypertree decompositions. Further, we define this notion in terms of incidence graphs, because we mainly work on those. Do notice however, that this definition easily translates to hypergraphs and that it is equivalent to the one given by Adler, Gavenčiak and Klimošová.

▶ **Definition 2.2** (Hypertree Depth and Elimination Forests, [1])**.** Let I be an incidence graph. An *elimination forest* (F, Γ) for I consists of a forest F and a mapping $\Gamma\colon V(F) \to \mathcal{B}(I)$ such that conditions 1–3 hold. We write $\widehat{\Gamma}(t)$ as shorthand for $\beta(\Gamma(t))$.

1. *Completeness for vertices*: For every red vertex $v \in \mathcal{R}(I)$, there is a $t \in V(F)$ such that $v \in \widehat{\Gamma}(t)$.
2. *Hyperedge-Containment*: For every blue vertex $e \in \mathcal{B}(I)$ there are nodes $s, t \in V(F)$ such that $s \leq_F t$ and $\beta(e) \subseteq \bigcup \widehat{\Gamma}(\mathrm{P}(s,t))$.
3. *Shared heritage*: For all $s, t \in V(F)$, if $\widehat{\Gamma}(s) \cap \widehat{\Gamma}(t) \neq \varnothing$, then $\wedge(s,t)$ is defined and $\widehat{\Gamma}(s) \cap \widehat{\Gamma}(t) \subseteq \bigcup \widehat{\Gamma}(\mathrm{P}(\wedge(s,t)))$.

The intuition behind condition 3 is that hyperedges can only share the vertices contained in their common ancestors in the elimination forest. The height of an elimination forest (F, Γ) is simply the height of F. The *hypertree depth of* I is defined as the minimal height over all elimination forests for I, and we denote it by $\mathrm{hd}(I)$. Analogously, we let $\mathrm{hd}(\mathcal{H}) \coloneqq \mathrm{hd}(I_{\mathcal{H}})$ for all hypergraphs. We write IHD_k to denote the class of incidence graphs of hypertree depth at most k and HD_k to denote the corresponding class of hypergraphs. ⌟



(a) A (strict) EF for $\mathcal{H}$. **(b)** An EF for $\mathcal{G}$. **(c)** A strict EF for $\mathcal{G}$. **(d)** A (strict) elimination forest for $\mathcal{P}_{15}$.

Figure 2 Elimination forests for various (hyper)graphs.

We call an elimination forest (F, Γ) *strict* if Γ is bijective. It is easy to see that the first and second condition are trivially satisfied when Γ is bijective, thus we can redefine the notion of strict elimination forest in a more succinct manner.

▶ **Definition 2.3** (Strict Elimination Forest)**.** Let I be an incidence graph. A *strict elimination forest* (F, Γ) for I consists of a forest F and a *bijective* function $\Gamma \colon V(F) \to \mathcal{B}(I)$ satisfying condition 3 of Definition 2.2. The *strict hypertree depth of* I, denoted by $\mathrm{shd}(I)$, is defined as the minimal height over all strict elimination forests for I. Again, we let $\mathrm{shd}(\mathcal{H}) \coloneqq \mathrm{shd}(I_{\mathcal{H}})$ for every hypergraph $\mathcal{H}$. We write ISHD_k to denote the class of incidence graphs of strict hypertree depth at most k and SHD_k to denote the corresponding class of hypergraphs. ⌟

▶ **Example 2.4.** Consider the hypergraphs $\mathcal{G}$ and $\mathcal{H}$ as well as their incidence graphs $I_{\mathcal{G}}$, $I_{\mathcal{H}}$ from Example 2.1 (see Figure 1). Let (F_1, Γ_1) be defined as follows. F_1 is a tree defined by $V(F_1) = \{t_1, t_2, t_3, t_4\}$ and $E(F_2) \coloneqq \{\{t_1, t_2\}, \{t_1, t_3\}, \{t_1, t_4\}\}$ with root t_1. Γ_1 is a map defined as $\{t_1 \to h, t_2 \to e, t_3 \to f, t_4 \to g\}$. (F_1, Γ_1) is an elimination forest of height 2 for $I_{\mathcal{H}}$. It is depicted in Figure 2a, where we labeled the node t_i with $\widehat{\Gamma}_1(t_i)$. Notice, that (F_1, Γ_1) is strict.

Analogously, we depicted two elimination forests for $I_{\mathcal{G}}$ of height 1 and 2 in Figures 2b and 2c. Notice how the elimination forest depicted in Figure 2b, witnessing $\mathrm{hd}(\mathcal{G}) = 1$, is not strict. It is easy to see that $\mathrm{shd}(\mathcal{G}) \geq 2$ since a bijective map implies that there are as many nodes in the forest as there are edges. Thus, Figure 2c witnesses that $\mathrm{shd}(\mathcal{G}) = 2$.

Finally, Figure 2d depicts a (strict) elimination forest for $\mathcal{P}_{15}$ witnessing $\mathrm{shd}(\mathcal{P}_{15}) \leq 4$. Recall that $\mathcal{P}_{15}$ is defined by $V(\mathcal{P}_{15}) = [16]$ and $E(\mathcal{P}_{15}) = \{\{i, i{+}1\} : i \in [15]\}$. ⌟

One can show that the strict hypertree depth of a hypergraph is at most its hypertree depth increased by one. The main idea is that we can turn every elimination forest into a strict one, if we add a leaf for every hyperedge that is currently not being mapped to below the path that contains it according to condition 2 in Definition 2.2. The proof can be found in the full version.

▶ **Theorem 2.5.** *For all hypergraphs* $\mathcal{H}$, $\mathrm{hd}(\mathcal{H}) \leq \mathrm{shd}(\mathcal{H}) \leq \mathrm{hd}(\mathcal{H}){+}1$.

Finally, it is easy to see that, due to condition 3 (shared heritage), every elimination forest of a connected incidence graph is also an *elimination tree*.

▶ **Lemma 2.6.** *Let* I *be a connected incidence graph. For every elimination forest* (F, Γ) *of* I*,* F *is a tree.*

2.2 Homomorphisms

While hypergraphs and incidence graphs are conceptually close, their "natural" notions of homomorphisms are not the same. Since our interest lies in hypergraphs, but we are mainly working on incidence graphs in this paper, we have to relate these notions. Following Scheidt and Schweikardt, we use the same definitions as Böker [4].

A homomorphism from a hypergraph $\mathcal{H}$ into another hypergraph $\mathcal{G}$ is a pair of functions $(h_V\colon V(\mathcal{H}) \to V(\mathcal{G}), h_E\colon E(\mathcal{H}) \to E(\mathcal{G}))$ such that for every $e \in E(\mathcal{H})$ the equality $h_V(\beta(e)) = \beta(h_E(e))$ holds.

A homomorphism from an incidence graph I into another incidence graph J is a pair of mappings $(h_V\colon \mathcal{R}(I) \to \mathcal{R}(J), h_E\colon \mathcal{B}(I) \to \mathcal{B}(J))$ such that $(h_E(e), h_V(v)) \in E(J)$ holds for every edge $(e, v) \in E(I)$. This is equivalent to the requirement $h_V(\beta(e)) \subseteq \beta(h_E(e))$. Thus, the equality that we require for a hypergraph homomorphism is relaxed to an inclusion for incidence graphs.

Let A, B and $\mathfrak{C}$ be two hypergraphs and a class of hypergraphs or two incidence graphs and a class of incidence graphs. We denote the number of homomorphisms from A to B by $\hom(A, B)$, and we let $\mathrm{Hom}(\mathfrak{C}, A)$ be the "vector" that has a row for every $F \in \mathfrak{C}$ containing $\hom(F, A)$. We say that A and B are *homomorphism indistinguishable* over $\mathfrak{C}$ ($A \equiv_{\mathfrak{C}} B$), if $\mathrm{Hom}(\mathfrak{C}, A) = \mathrm{Hom}(\mathfrak{C}, B)$, i.e., if $\hom(F, A) = \hom(F, B)$ for all $F \in \mathfrak{C}$.

The following crucial theorem relates homomorphism indistinguishability over a class of hypergraphs to homomorphism indistinguishability over the corresponding class $\mathfrak{C}_{\mathsf{I}}$ of incidence graphs. As noted in [27], this theorem is implicit in [4], consult Appendix A of the full version of [27] for details.

▶ **Theorem 2.7** ([4, 27]). *Let $\mathfrak{C}$ be a class of hypergraphs and let $\mathfrak{C}_{\mathsf{I}}$ be its corresponding class of incidence graphs. If $\mathfrak{C}$ is closed under* pumping *and* local merging*, then $\mathrm{Hom}(\mathfrak{C}, \mathcal{G}) = \mathrm{Hom}(\mathfrak{C}, \mathcal{H})$ if, and only if, $\mathrm{Hom}(\mathfrak{C}_{\mathsf{I}}, I_{\mathcal{G}}) = \mathrm{Hom}(\mathfrak{C}_{\mathsf{I}}, I_{\mathcal{H}})$ for all hypergraphs $\mathcal{G}$ and $\mathcal{H}$.*

$\mathfrak{C}$ is closed under pumping, if $H' \in \mathfrak{C}$ for every $H \in \mathfrak{C}$, where H' is created from H by inserting a new vertex into *one* arbitrary hyperedge of H; and closed under local merging, if $H' \in \mathfrak{C}$ for every $H \in \mathfrak{C}$, where H' is created from H by choosing an arbitrary hyperedge e and then merging two vertices u, v that are both contained in e.

It is easy to see that SHD_k is closed under both pumping and local merging, whereas HD_k is only closed under local merging.

▶ **Proposition 2.8.** *Let $k \in \mathbb{N}_{\geq 1}$. The class SHD_k is closed under pumping and local merging, the class HD_k is closed under local merging but* ***not*** *under pumping.*

The following theorem shows that homomorphism indistinguishability over HD_k is not equal to homomorphism indistinguishability over SHD_k. Because $\mathsf{SHD}_k \subseteq \mathsf{HD}_k$, counting homomorphisms from HD_k is more powerful in the sense that it distinguishes more hypergraphs. But we also show that it is unequal to homomorphism indistinguishability over IHD_k, which is unexpected. Since this prohibits us from relating HD_k to any fragment of GC, it is conceivable that this could pose a problem in other scenarios too. Thus, we argue that the notion of strict hypertree depth can be viewed as a reasonable generalisation of tree depth, especially when we recall that $\mathsf{HD}_{k-1} \subseteq \mathsf{SHD}_k \subseteq \mathsf{HD}_k$.

▶ **Theorem 2.9.** *For every $k \in \mathbb{N}_{\geq 1}$ there exist pairs of hypergraphs $(\mathcal{G}_k, \mathcal{H}_k)$ and $(\mathcal{G}'_k, \mathcal{H}'_k)$, such that:*

1. $\mathrm{Hom}(\mathsf{SHD}_k, \mathcal{G}_k) = \mathrm{Hom}(\mathsf{SHD}_k, \mathcal{H}_k)$, *but* $\mathrm{Hom}(\mathsf{HD}_k, \mathcal{G}_k) \neq \mathrm{Hom}(\mathsf{HD}_k, \mathcal{H}_k)$;
2. $\mathrm{Hom}(\mathsf{HD}_k, \mathcal{G}'_k) = \mathrm{Hom}(\mathsf{HD}_k, \mathcal{H}'_k)$, *but* $\mathrm{Hom}(\mathsf{IHD}_k, I_{\mathcal{G}'_k}) \neq \mathrm{Hom}(\mathsf{IHD}_k, I_{\mathcal{H}'_k})$.

(a) $\mathcal{G}_1$. **(b)** $\mathcal{H}_1$. **(c)** $\mathcal{G}'_1$. **(d)** $\mathcal{H}'_1$.

Figure 3 $(\mathcal{G}_1, \mathcal{H}_1)$, $(\mathcal{G}'_1, \mathcal{H}'_1)$ witness Theorem 2.9 for $k = 1$. Circles denote singleton hyperedges.

For $k = 1$ this is easy to see: A connected hypergraph has strict hypertree depth 1 iff it consists of a single hyperedge, whereas a connected hypergraph has hypertree depth 1 if one hyperedge contains all vertices. It is therefore not hard to see that the statement of the theorem holds for $k = 1$ using the hypergraphs depicted in Figure 3. For $k \geq 2$ a similar idea for the construction of $(\mathcal{G}_k, \mathcal{H}_k)$ and $(\mathcal{G}'_k, \mathcal{H}'_k)$ works, but we had to defer the details to the full version due to space constraints.

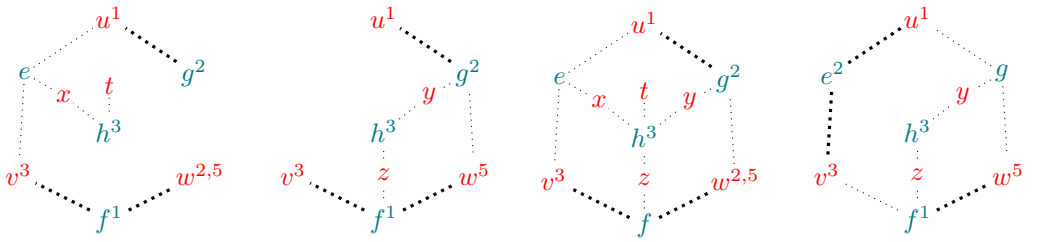
3 k-Labeled Incidence Graphs

Our goal is to give an inductive characterisation of the incidence graphs of strict hypertree depth at most k (and thus also of hypergraphs of strict hypertree depth at most k). The concepts presented in this section were first defined in [27], and we adopt their notation and phrasing for the most part. Note that the k-labeled incidence graphs defined here are inspired by the concept of k-labeled graphs as they are used in [6, 9, 10, 19] and elsewhere. In particular, k-labeled graphs are the main tool used by Dvořák [9] to prove his result. In principle, a *k-labeled incidence graph* is an incidence graphs that has *labels* attached to some of its red and blue vertices. We have an unbounded number of red labels that can be attached to red vertices (though the number of labels actually used must always be finite), but we only have k labels that we can attach to blue vertices. We are allowed to attach multiple labels to the same vertex, but we are not required to use all of them. Every red label has an assigned "guard", which is a blue vertex with a label on it. In practice, we will require every red labeled vertex to be a neighbour of its guard (i.e., we want it to have a *real* guard, as defined in the next paragraph), though it makes the proofs easier if we do not enforce this in the definition itself. This idea is formalised as follows.

A k-labeled incidence graph is a tuple $L = (I, r, b, g)$, where I is an incidence graph, $r\colon \mathbb{N}_{\geq 1} \rightharpoonup \mathcal{R}(I)$, $b\colon [k] \rightharpoonup \mathcal{B}(I)$ and $g\colon \mathbb{N}_{\geq 1} \rightharpoonup [k]$ are partial mappings such that $\mathrm{dom}(r)$ is finite and $\mathrm{dom}(g) = \mathrm{dom}(r)$. We use I_L, r_L, ... to denote the components of L. But to keep the indices from getting overly complicated, we may write $I', r', \ldots$ and $I_i, r_i, \ldots$ instead of $I_{L'}, r_{L'}$ and $I_{L_i}, r_{L_i}, \ldots$, respectively. If it is clear from the context, we may omit the index altogether and simply write I, r, b, g.

We say that L *has real guards (w.r.t. g)*, if for every $i \in \mathrm{dom}(r)$ we have $g(i) \in \mathrm{dom}(b)$ and $(b(g(i)), r(i)) \in E(I)$. A k-labeled incidence graph L is *label-free* if $r_L = b_L = g_L = \varnothing$. We call I the *skeleton* of L. Next, we define some operations on k-labeled incidence graphs.

For any set $X_r \subseteq \mathbb{N}_{\geq 1}$ of finite size ℓ and any tuple $\overline{v} = (v_1, v_2, \ldots, v_\ell) \in \mathcal{R}(I_L)^n$ we write $L[X_r \to \overline{v}]$ to denote a copy of L where we modified r such that $r(i_j) = v_j$ for all j in the enumeration $\langle i_1, \ldots, i_\ell \rangle$ of X_r, i.e., we introduce, and change the placement of, some red labels. Similarly, for any $X_b = \{i_1, \ldots, i_\ell\} \subseteq [k]$ and any $\overline{e} = (e_1, e_2, \ldots, e_\ell) \in \mathcal{B}(I_L)^\ell$ we write $L\langle X_b \to \overline{e} \rangle$ to denote a copy of L where we modified b accordingly. We write $L[X_r \to \bullet]$ ($L\langle X_b \to \bullet \rangle$) to denote a copy of L where we *removed* the red (blue) labels in X_r (X_b). Note, that we remove *just* the labels and *not* the vertices that carry them.



(a) The 3-labeled incidence graph L_1.

(b) The 3-labeled incidence graph L_2.

(c) An example of glueing: $(L_1 \cdot L_2)$.

(d) An example of applying a transition: $L_1[\rightsquigarrow f]$.

Figure 4 3-labeled incidence graphs and operations on them. Labels are encoded as exponents and the guard function is encoded using thicker edges between the red vertex and its guard.

Intuitively, the "product" $(L_1 \cdot L_2)$ or *glueing* of two k-labeled incidence graphs L_1, L_2 is the k-labeled incidence graph L that is created by first taking the disjoint union of L_1 and L_2, followed by repeatedly merging pairs of red (blue) vertices, that carry a shared red (blue) label. By merging we mean that we replace these vertices by a single fresh vertex, which inherits their neighbourhoods and labels. We apply this procedure until there are no more such pairs. The guard function of $(L_1 \cdot L_2)$ is simply $g_{L_1} \cup g_{L_2}$, i.e., in theory, g_{L_1} has precedence over g_{L_2}. In practice, we will require that g_{L_1} and g_{L_2} are compatible, which means the precedence of g_{L_1} will be irrelevant. Note that the order in which we merge vertices does not matter, and that if a vertex carries two or more labels, all vertices carrying any one of these labels will be replaced by a single fresh vertex that carries *all* those labels and inherits *all* neighbourhoods. Finally, for $i \in [2]$ we define mappings $\mathrm{succ}^R_{L_i} \colon \mathcal{R}(I_{L_i}) \to \mathcal{R}(I_L)$ and $\mathrm{succ}^B_{L_i} \colon \mathcal{B}(I_{L_i}) \to \mathcal{B}(I_L)$ such that $\mathrm{succ}^R_{L_i}(v)$ is the red vertex of I_L that corresponds to $v \in \mathcal{R}(I_i)$, and $\mathrm{succ}^B_{L_i}(e)$ is the blue vertex of I_L that corresponds to $e \in \mathcal{B}(I_i)$.

▶ **Example 3.1.** Consider the k-labeled incidence graphs L_1, L_2 according to Figures 4a and 4b. In particular, we have

i	1	2	3	5
$r_1(i)$	u	w	v	w
$r_2(i)$	u	–	v	w

i	1	2	3
$b_1(i)$	f	g	h
$b_2(i)$	f	g	h

and

i	1	2	3	5
$g_1(i)$	2	1	1	1
$g_2(i)$	2	–	1	1

.

The product $(L_1 \cdot L_2)$ is depicted in Figure 4c.

So far, we should not be allowed to remove a blue label from a vertex, if it serves as the guard of a red label. But sometimes we want to *transition* from one (real) guard assignment to another (real) guard assignment. I.e., we want to remove blue labels even if they still guard some red labels, because we guarantee that we introduce new guards for these labels right away. We formalise this operation as a special partial function, that assigns new guards to existing red labels: We call $f \colon \mathbb{N}_{\geq 1} \rightharpoonup [k]$ a *transition for L (for g)*, if $\varnothing \neq \mathrm{dom}(f) \subseteq \mathrm{dom}(g)$ and for all $i \in \mathrm{dom}(g)$ we have that if $g(i) \in \mathrm{img}(f)$, then $i \in \mathrm{dom}(f)$. This means that if f reassigns the blue label guarding the red label i, then f provides a new guard for i. Applying a transition, denoted by $L[\rightsquigarrow f]$, means modifying a copy of L as follows: we want to insert fresh vertices with these blue labels, thus we must first remove all blue labels, that are currently in use, i.e., we must first remove the labels in the set $X_b \coloneqq \mathrm{img}(f) \cap \mathrm{dom}(b_L) \cap \mathrm{img}(g_L)$ from b. Notice that we have to intersect with $\mathrm{dom}(b_L)$ since we do not require L to have real guards. After removing the labels in X_b, we insert $|X_b|$ new blue vertices into I_L, each carrying one of the blue labels in X_b, and introduce an edge between $b(f(i))$ and $r(i)$ for all

$i \in \mathrm{dom}(f)$. Finally, we redefine the guard function as $f \cup g_L$. Note that this procedure can be easily expressed as the product $(M_f \cdot L\langle X_b \to \bullet\rangle)$ for a suitably defined k-labeled incidence graph M_f.

▶ **Example 3.2.** Consider the k-labeled incidence graph L_1 from Example 3.1 and Figure 4a. The partial function $f = \{1 \to 2, 3 \to 2\}$ is a transition for L_1. The result $L_1[\rightsquigarrow f]$ of the application of f on L_1 is depicted in Figure 4d.

We define the class GLI_k^i of k-labeled incidence graphs that can be constructed in a way that at most i blue labels are removed "in series".

▶ **Definition 3.3.** For $k \in \mathbb{N}_{\geq 1}$ and $i \in \mathbb{N}$ we define the set GLI_k^i inductively as follows.

Base case. $L \in \mathsf{GLI}_k^0$ for all k-labeled incidence graphs L with $\mathrm{dom}(r) = \mathcal{R}(I)$, $\mathrm{dom}(b) = \mathcal{B}(I)$ and real guards.
For all $i \in \mathbb{N}$, if $L \in \mathsf{GLI}_k^i$, then $L \in \mathsf{GLI}_k^{i+1}$.

Glueing. Let $L_1 \in \mathsf{GLI}_k^{i_1}$, $L_2 \in \mathsf{GLI}_k^{i_2}$ have compatible guard functions and $L = (L_1 \cdot L_2)$.
Then, $L \in \mathsf{GLI}_k^i$ where $i := \max\{i_1, i_2\}$.

Transitioning. Let $L \in \mathsf{GLI}_k^i$, let f be a transition for L and $L' = L_1[\rightsquigarrow f]$.
Then, $L' \in \mathsf{GLI}_k^{i'}$ where $i' := i + |\,\mathrm{img}(f) \cap \mathrm{img}(b_L) \cap \mathrm{img}(g_L)|$.

Label-Removal. Let $L \in \mathsf{GLI}_k^i$.

(a) For $X_r \subseteq \mathrm{dom}(r)$, $L[X_r \to \bullet] \in \mathsf{GLI}_k^i$.

(b) For $X_b \subseteq \mathrm{dom}(b) \setminus \mathrm{img}(g)$, $L\langle X_b \to \bullet\rangle \in \mathsf{GLI}_k^{i'}$ where $i' := i + |X_b|$.

Finally, we let $\mathsf{GLI}^k := \mathsf{GLI}_k^k$ for every $k \in \mathbb{N}$. ⌟

4 Characterising Hypergraphs of Strict Hypertree Depth at most k

In this section we prove that the inductively defined class GLI^k corresponds precisely to the class ISHD_k.

▶ **Theorem 4.1.** *An incidence graph J has strict hypertree depth at most k if, and only if, there exists a label-free $L \in \mathsf{GLI}^k$ such that $I_L \cong J$.*

In the following, we first show how to construct an incidence graph of strict hypertree depth at most k as the skeleton of a label-free k-labeled incidence graph in GLI^k (Lemma 4.2). Then we show that every label-free $L \in \mathsf{GLI}^k$ has strict hypertree depth at most k (Lemma 4.3). Theorem 4.1 follows directly from the combination of these two Lemmata.

For the rest of this section, let $J \in \mathsf{ISHD}_k$ and let (T, Γ) be a strict elimination forest of height $\leq k$ for J. We can w.l.o.g. assume that J is connected and that T is a tree (Lemma 2.6). Let $\mathcal{R}(J) = \{v_1, v_2, \ldots, v_m\}$ where $m \geq 1$.

(T, Γ) will help us decide when to remove (i.e., eliminate) which label from which blue vertex in the following sense. The core idea is to start with a trivial k-labeled incidence graph for every path from a leaf to the root in the elimination tree. Then we walk bottom-up along these paths and whenever several paths join in a node, we apply red and blue vertex removals in a suitable way on their k-labeled incidence graphs, such that afterwards we can glue them together and receive a k-labeled incidence graph that is isomorphic to the incidence graph induced by the union of said paths.

For this we need the following notions: For a node n in a tree T, the *subtree with stem induced by* n is the tree $\dot{T}_n$ induced on T by the set $\mathrm{P}(n) \cup \{t \in V(T) : n \leq_T t\}$. Recall that $\mathrm{P}(n)$ is the set of nodes on the path from n to the root ω (including n and ω), and

notice that the subtree with stem induced by the root is T, i.e., $T_\omega = T$, and for every leaf n it is the path from the root ω to n. For every node $n \in V(T)$ we define the set $\text{labels}(n) \coloneqq \{i \in [m] : v_i \in \widehat{\Gamma}(n)\}$. To avoid an overload of notation, we will write $\text{labels}(N)$ to denote the set $\bigcup_{n\in N} \text{labels}(n)$ and write $J[\dot{T}_n]$ to abbreviate $J[\widehat{\Gamma}(V(\dot{T}_n))]$. With these notions, we can prove the following lemma via induction.

▶ **Lemma 4.2.** *For every $n \in V(T)$ of level d where $\langle t_1, \dots, t_d\rangle$ is a $\leq_T$-enumeration of $\mathrm{P}(n)$ (i.e., in particular $t_1 = \omega$, $t_d = n$), there exists an $L_n \in \mathsf{GLI}_k^{k-d}$ of the form (I, r, b, g) such that*

(A) $\text{dom}(b) = [d]$ *and* $\text{dom}(r) = \text{labels}(\mathrm{P}(n))$*;*

(B) $g(i) \coloneqq \min\{j \in [d] : v_i \in \widehat{\Gamma}(t_j)\}$ *for every* $i \in \text{dom}(g)$*;*

(C) *There exists an isomorphism (π_R, π_B) between I and $J[\dot{T}_n]$ such that*

- **(i)** $\pi_R(r(i)) = v_i$ *for all* $i \in \text{dom}(r)$*, and*
- **(ii)** $\pi_B(b(j)) = \Gamma(t_j)$ *for all* $j \in \text{dom}(b)$*.*

Notice that, in particular, this lemma states $J \cong I_{L_\omega}$ for the root ω of T. But L_ω is not label-free, since $\text{dom}(b_{L_\omega}) = \{1\}$ and $\text{dom}(r_{L_\omega}) = \text{labels}(\mathrm{P}(\omega)) = \text{labels}(\omega)$. But, the lemma also states that $L_\omega \in \mathsf{GLI}_k^{k-1}$, since $\text{level}(\omega) = 1$. Thus, $J \cong I_{L'}$ for $L' = L_\omega[\text{labels}(\omega)\to\bullet]\langle\{1\}\to\bullet\rangle$, and in particular, $L' \in \mathsf{GLI}_k^k$ is label-free. Thus, this lemma shows the forward direction of Theorem 4.1.

The following lemma can be shown by induction. On a high level, the idea of the proof is to only modify the elimination forest, if blue labels are removed. At that point, we prepend a chain of new nodes to the root(s) of the elimination forest. If we take the product of two k-labeled incidence graphs, we take the union of the forests, and if we remove red labels, we do not alter the forest at all.

▶ **Lemma 4.3.** *For every $L \in \mathsf{GLI}_k^d$ of the form (I, r, b, g) there is a tuple (F, Γ), where F is a forest of height $\leq d$ and Γ is a bijective function from $V(F)$ to $\mathcal{B}(I) \setminus \text{img}(b)$ satisfying condition A. We write $\widehat{\Gamma}(t)$ as a shorthand for $\beta(\Gamma(t))$ and $\widetilde{\Gamma}(t)$ as a shorthand for $\widehat{\Gamma}(t) \setminus \text{img}(r)$.*

(A) *For all $s, t \in V(F)$, and all $v \in \widetilde{\Gamma}(s) \cap \widetilde{\Gamma}(t) \neq \varnothing$ it holds that:*
$v \in \beta(b(j))$ for a $j \in \text{dom}(b)$ or $\wedge(s,t)$ is defined and $v \in \bigcup \widetilde{\Gamma}(\mathrm{P}(\wedge(s,t)))$.

Notice that, if $L \in \mathsf{GLI}_k^d$ is label-free, this guarantees a strict elimination forest (F, Γ) of height d for I_L. This shows the backward direction of Theorem 4.1.

5 The Logic GC^k

This section introduces the logic GC^k as defined in [27] and its restricted fragment GC_k, consisting of all formulas of guard depth at most k. Let k be a positive natural number, that is fixed for this section.

Variables. GC^k uses two different kinds of variables: $\mathsf{VAR}_\mathsf{v} \coloneqq \{\mathsf{v}_1, \mathsf{v}_2, \mathsf{v}_3 \dots\}$ to address vertices and $\mathsf{VAR}_\mathsf{e} \coloneqq \{\mathsf{e}_1, \mathsf{e}_2, \dots, \mathsf{e}_k\}$ to address hyperedges. Notice that the number of variables for hyperedges is bounded by k, but unbounded for vertices. We say that a tuple of the form $\overline{\mathsf{v}} = (\mathsf{v}_{i_1}, \dots, \mathsf{v}_{i_\ell}) \in \mathsf{VAR}_\mathsf{v}^\ell$ or $\overline{\mathsf{e}} = (\mathsf{e}_{i_1}, \dots, \mathsf{e}_{i_\ell}) \in \mathsf{VAR}_\mathsf{e}^\ell$ is a v- *or* e-*tuple*, if $i_1 < i_2 < \dots < i_\ell$. We let $\text{vars}(\overline{\mathsf{v}}) \coloneqq \{\mathsf{v}_{i_1}, \dots, \mathsf{v}_{i_\ell}\}$ and $\text{vars}(\overline{\mathsf{e}}) \coloneqq \{\mathsf{e}_{i_1}, \dots, \mathsf{e}_{i_\ell}\}$ respectively. We call $\{i_1, \dots, i_\ell\}$ the *index set* of $\overline{v}$ and $\overline{e}$, respectively.

Logical Guards. The key idea behind GC^k is that on quantification, vertex variables must be *guarded* by hyperedge variables. This is formalised by a partial function $g\colon \mathbb{N}_{\geq 1} \rightharpoonup [k]$ with finite domain (similar to the guard function of a k-labeled incidence graph, cf. Section 3) and its corresponding *logical guard* $\Delta_g \coloneqq \bigwedge_{i \in \mathrm{dom}(g)} E(\mathsf{e}_{g(i)}, \mathsf{v}_i)$. For the special partial function g with empty domain, we let $\Delta_g \coloneqq \top$, which is a special formula that always evaluates to true.

▶ **Definition 5.1.** The logic GC^k is inductively defined along with the *free vertex variables*, the *free hyperedge variables* and the *guard depth*, as formalised by the functions

$$\mathrm{free}_{\mathsf{v}}\colon \mathsf{GC}^k \to \mathcal{P}(\mathsf{VAR}_{\mathsf{v}}), \quad \mathrm{free}_{\mathsf{e}}\colon \mathsf{GC}^k \to \mathcal{P}(\mathsf{VAR}_{\mathsf{e}}), \quad \text{and} \quad \mathrm{gd}\colon \mathsf{GC}^k \to \mathbb{N}.$$

Atomic Formulas. For all $i, i' \in \mathbb{N}_{\geq 1}$ and all $j, j' \in [k]$ the following formulas are in GC^k:

- $\varphi = \mathsf{v}_i = \mathsf{v}_{i'}$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \{\mathsf{v}_i, \mathsf{v}_{i'}\}$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \varnothing$;
- $\varphi = \mathsf{e}_j = \mathsf{e}_{j'}$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \varnothing$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \{\mathsf{e}_j, \mathsf{e}_{j'}\}$;
- $\varphi = E(\mathsf{e}_j, \mathsf{v}_i)$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \{\mathsf{v}_i\}$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \{\mathsf{e}_j\}$.

In all the above cases, $\mathrm{gd}(\varphi) \coloneqq 0$.

Inductive Rules. Let χ, ψ be formulas of GC^k. The following formulas are in GC^k.

- $\varphi = \neg\chi$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{v}}(\chi)$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{e}}(\chi)$, and $\mathrm{gd}(\varphi) \coloneqq \mathrm{gd}(\chi)$;
- $\varphi = (\chi \wedge \psi)$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{v}}(\chi) \cup \mathrm{free}_{\mathsf{v}}(\psi)$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{e}}(\chi) \cup \mathrm{free}_{\mathsf{e}}(\psi)$, and $\mathrm{gd}(\varphi) \coloneqq \max\{\mathrm{gd}(\chi), \mathrm{gd}(\psi)\}$.

Note that by the rules defined so far, $\mathrm{gd}(\Delta_g) = 0$ for all logical guards Δ_g.

We say that $g\colon \mathbb{N}_{\geq 1} \rightharpoonup [k]$ *is a guard function for* φ if $\mathrm{dom}(g) = \{i : \mathsf{v}_i \in \mathrm{free}_{\mathsf{v}}(\varphi)\}$.

Let $n \in \mathbb{N}_{\geq 1}$, let g be a guard function for ψ and $\chi = (\Delta_g \wedge \psi)$. The following formulas are in GC^k for every v-tuple $\overline{\mathsf{v}}$ with $\mathrm{vars}(\overline{\mathsf{v}}) \subseteq \mathrm{free}_{\mathsf{v}}(\chi)$ and every e-tuple $\overline{\mathsf{e}}$ with $\mathrm{vars}(\overline{\mathsf{e}}) \subseteq \mathrm{free}_{\mathsf{e}}(\chi)$:

- $\varphi = \exists^{\geq n} \overline{\mathsf{v}}\,.\,\chi$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{v}}(\chi) \setminus \mathrm{vars}(\overline{\mathsf{v}})$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{e}}(\chi)$, and $\mathrm{gd}(\varphi) \coloneqq \mathrm{gd}(\chi)$;
- $\varphi = \exists^{\geq n} \overline{\mathsf{e}}\,.\,\chi$ with $\mathrm{free}_{\mathsf{v}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{v}}(\chi)$ and $\mathrm{free}_{\mathsf{e}}(\varphi) \coloneqq \mathrm{free}_{\mathsf{e}}(\chi) \setminus \mathrm{vars}(\overline{\mathsf{e}})$, and $\mathrm{gd}(\varphi) \coloneqq \mathrm{gd}(\chi) + |\mathrm{vars}(\overline{\mathsf{e}})|$. ⌟

For convenience, we let $\mathrm{free}(\varphi) \coloneqq \mathrm{free}_{\mathsf{v}}(\varphi) \cup \mathrm{free}_{\mathsf{e}}(\varphi)$ for all $\varphi \in \mathsf{GC}^k$. Formulas of GC^k are evaluated over a hypergraph $\mathcal{H}$ via interpretations $\mathcal{I} = (I_{\mathcal{H}}, \nu_{\mathsf{v}}, \nu_{\mathsf{e}})$ that consist of $\mathcal{H}$'s incidence graph $I_{\mathcal{H}}$ and assignments $\nu_{\mathsf{v}}\colon \mathsf{VAR}_{\mathsf{v}} \to \mathcal{R}(I_{\mathcal{H}})$ and $\nu_{\mathsf{e}}\colon \mathsf{VAR}_{\mathsf{e}} \to \mathcal{B}(I_{\mathcal{H}})$. The semantics of GC^k are as expected and a definition can be found in Section 6 of the full version of [27], thus we do not give one here. A *sentence* is a formula $\varphi \in \mathsf{GC}^k$ that has neither free vertex, nor free hyperedge variables, i.e., $\mathrm{free}(\varphi) = \varnothing$. By GC^k_d we denote the fragment $\{\varphi \in \mathsf{GC}^k : \mathrm{gd}(\varphi) \leq d\}$, and we let $\mathsf{GC}_k \coloneqq \mathsf{GC}^k_k$. We write $\mathcal{G} \equiv_{\mathsf{L}} \mathcal{H}$ to denote that $\mathcal{G}$ and $\mathcal{H}$ satisfy the same sentences in the fragment $\mathsf{L} \subseteq \mathsf{GC}^k$.

For simplicity, we omit logical guards if they are empty or equal to the formula they are guarding. I.e., we may abbreviate subformulas of the form $(\top \wedge \varphi)$ or $(\varphi \wedge \varphi)$ as φ. We may also omit parentheses in the usual way. We write $\exists^{=n}(\overline{\mathsf{x}})\,.\,(\Delta \wedge \varphi)$ as shorthand for $\exists^{\geq n}(\overline{\mathsf{x}})\,.\,(\Delta \wedge \varphi) \wedge \neg\exists^{\geq n+1}(\overline{\mathsf{x}})\,.\,(\Delta \wedge \varphi)$. Clearly, these shorthands change neither the semantics, nor the free variables, nor the guard depth of a formula.

▶ **Example 5.2.** The sentence $\varphi_{\mathcal{G}} \coloneqq \psi_1 \wedge \psi_2 \wedge \psi_3$ describes $\mathcal{G}$ from Example 2.1 up to isomorphism, where

$$\chi_n \coloneqq \bigwedge_{1\leq i<j\leq n} \neg \mathtt{v}_i = \mathtt{v}_j \ \wedge\ \neg\exists^{\geq 1}(\mathtt{v}_{n+1}) \,.\, \Big(E(\mathtt{e},\mathtt{v}_{n+1}) \ \wedge\ \bigwedge_{i\in[n]} \neg \mathtt{v}_{n+1} = \mathtt{v}_i\Big)\,,$$
$$\psi_1 \coloneqq \exists^{=4}(\mathtt{e}) \,.\, \mathtt{e}=\mathtt{e}\,,$$
$$\psi_2 \coloneqq \exists^{=1}(\mathtt{e}) \,.\, \exists^{\geq 1}(\mathtt{v}_1,\mathtt{v}_2,\mathtt{v}_3) \,.\, \Big(\bigwedge_{i\in[3]} E(\mathtt{e},\mathtt{v}_i) \ \wedge\ \chi_3 \ \wedge\ \bigwedge_{i\in[3]} \exists^{=3}(\mathtt{e}) \,.\, E(\mathtt{e},v_i)\Big)\,,$$
$$\psi_3 \coloneqq \exists^{=3}(\mathtt{e}) \,.\, \exists^{\geq 1}(\mathtt{v}_1,\mathtt{v}_2) \,.\, \Big(\bigwedge_{i\in[2]} E(\mathtt{e},\mathtt{v}_i) \ \wedge\ \chi_2 \ \wedge\ \bigwedge_{i\in[3]} \exists^{=3}(\mathtt{e}) \,.\, E(\mathtt{e},v_i)\Big)\,.$$

It is easily verified that $\varphi_{\mathcal{G}} \in \mathsf{GC}^1_2$. χ_n is a helper formula, describing that there are precisely n vertices $\mathtt{v}_1,\dots,\mathtt{v}_n$ in the hyperedge $\mathtt{e}$. ψ_1 describes that there are precisely four hyperedges, ψ_2 describes that precisely one hyperedge contains precisely three vertices, each being contained in precisely 3 hyperedges. Finally, ψ_3 describes that there are exactly 3 hyperedges containing precisely 2 vertices, each being contained in precisely 3 hyperedges. It is not hard to see that, in total, this describes $\mathcal{G}$ up to isomorphism.

Scheidt and Schweikardt [27] prove their result only for the following restricted variant of GC^k, called RGC^k. They mention in the conclusion, that RGC^k and GC^k are equivalent and show in the full version of the paper (Theorem 7.2) how a formula in GC^k can be translated into one in RGC^k. We still need RGC^k since it is used in the formulation and the proof of the two core lemmata of [27] that we want to borrow.

▶ **Definition 5.3** ([27])**.** The restriction RGC^k is inductively defined as follows:

Atomic Formulas. $(\Delta_g \wedge \varphi)$ is in RGC^k for all atomic formulas $\varphi \in \mathsf{GC}^k$ and all guard functions for φ, i.e., all $g\colon \mathbb{N}_{\geq 1} \rightharpoonup [k]$ with $\mathrm{dom}(g) = \{i : \mathtt{v}_i \in \mathrm{free}_{\mathtt{v}}(\varphi)\}$.

Inductive Rules.

- For every formula $(\Delta_g \wedge \varphi) \in \mathsf{RGC}^k$, the formula $(\Delta_g \wedge \neg\varphi)$ is also in RGC^k.
- For $i \in [2]$ and formulas $(\Delta_{g_i} \wedge \psi_i) \in \mathsf{RGC}^k$, the formula $(\Delta_{(g_1 \cup g_2)} \wedge (\psi_1 \wedge \psi_2))$ is in RGC^k, if g_1 and g_2 are compatible.

Let $n \in \mathbb{N}_{\geq 1}$, $(\Delta_g \wedge \varphi) \in \mathsf{RGC}^k$.

- For every $\mathtt{v}$-tuple $\overline{\mathtt{v}}$ with $\mathrm{vars}(\overline{\mathtt{v}}) \subseteq \mathrm{free}_{\mathtt{v}}(\varphi)$ and index set S, the formula $(\Delta_{\tilde{g}} \wedge \chi)$ is in RGC^k, where

  $$\chi \coloneqq \exists^{\geq n}\overline{\mathtt{v}} \,.\, (\Delta_g \wedge \varphi) \quad \text{and } \tilde{g} \text{ is the restriction of } g \text{ to } \mathrm{dom}(g) \setminus S.$$

- For every $\mathtt{e}$-tuple $\overline{\mathtt{e}}$ with $\mathrm{vars}(\overline{\mathtt{e}}) \subseteq \mathrm{free}_{\mathtt{e}}(\Delta_g \wedge \varphi)$ and index set S, the formula

  $$(\Delta_{\tilde{g}} \wedge \exists^{\geq n}\overline{\mathtt{e}} \,.\, (\Delta_g \wedge \varphi))$$

  is in RGC^k, if $\mathrm{dom}(\tilde{g}) = \mathrm{dom}(g)$ and all $i \in \mathrm{dom}(g)$ satisfy

  $$\tilde{g}(i) = g(i) \quad \text{or} \quad \tilde{g}(i) \in S \quad \text{or} \quad \tilde{g}(i) \notin \mathrm{img}(g). \tag{1}$$

Intuitively, formulas in RGC^k always carry the information, which hyperedge variable currently guards which vertex variable and the logical guards are in a certain sense "consistent" (1) along the syntax tree. ⌟

A simple inspection of the inductive proof for Theorem 7.2 in the full version of [27] shows that the guard depth is unaffected by the translation, thus it gives us the following refined result.

▶ **Lemma 5.4.** *For every formula $\varphi \in \mathsf{GC}^k$ and every guard function g for φ, there exists a formula $(\Delta_g \wedge \varphi_g) \in \mathsf{RGC}^k$ such that*

1. $(\Delta_g \wedge \varphi) \equiv (\Delta_g \wedge \varphi_g)$,
2. $\mathrm{free}(\varphi) = \mathrm{free}(\varphi_g)$, *and* $\mathrm{gd}(\varphi) = \mathrm{gd}(\varphi_g)$.

6 Main Result

We are now ready to plug everything together, which yields our main result.

▶ **Theorem 6.1.** *Let $\mathcal{G}$ and $\mathcal{H}$ be hypergraphs and let $k \in \mathbb{N}_{\geq 1}$.*

$$\begin{aligned} \mathcal{G} \equiv_{\mathsf{GC}_k} \mathcal{H} &\iff \mathrm{Hom}(\mathsf{ISHD}_k, I_{\mathcal{G}}) = \mathrm{Hom}(\mathsf{ISHD}_k, I_{\mathcal{H}}) \\ &\iff \mathrm{Hom}(\mathsf{SHD}_k, \mathcal{G}) = \mathrm{Hom}(\mathsf{SHD}_k, \mathcal{H}). \end{aligned}$$

We use the fact that the proofs for the core Lemmata 8.1 and 8.2 in the work by Scheidt and Schweikardt [27] actually give us the following refined results. This is easy to see on inspection of the original proofs (consult Appendix E in the full version of [27]), since there is a one-to-one correspondence between the blue label i and the hyperedge variable e_i in the proofs for both lemmas: whenever a blue label i is removed, the corresponding variable e_i is quantified and vice-versa.

For a k-labeled incidence graph L of the form (I, r, b, g), we let $\mathcal{I}_L := (I, \nu_{\mathsf{v}}, \nu_{\mathsf{e}})$ be defined by $\nu_{\mathsf{v}}(\mathsf{v}_i) := r(i)$ for all $i \in \mathrm{dom}(r)$ and $\nu_{\mathsf{e}}(\mathsf{e}_j) := b(j)$ for all $j \in \mathrm{dom}(b)$.

▶ **Lemma 6.2** (implicit in [27])**.** *Let $L = (I, r, b, g) \in \mathsf{GLI}_k^i$. For every $m \in \mathbb{N}$ there is a formula $\varphi_{L,m}$ with $(\Delta_g \wedge \varphi_{L,m}) \in \mathit{RGC}^k$, $\mathrm{free}_{\mathsf{v}}(\Delta_g \wedge \varphi_{L,m}) = \{\mathsf{v}_i : i \in \mathrm{dom}(r)\}$, $\mathrm{free}_{\mathsf{e}}(\Delta_g \wedge \varphi_{L,m}) = \{\mathsf{e}_j : j \in \mathrm{dom}(b)\}$, and $\mathrm{gd}(\varphi_{L,m}) \leq i$, such that for every k-labeled incidence graph L' with $\mathrm{dom}(b_{L'}) \supseteq \mathrm{dom}(b)$, $\mathrm{dom}(r_{L'}) \supseteq \mathrm{dom}(r)$, and with real guards w.r.t. g we have: $\mathcal{I}_{L'} \models \Delta_g$, and $\mathrm{hom}(L, L') = m \iff \mathcal{I}_{L'} \models \varphi_{L,m}$.*

▶ **Lemma 6.3** (implicit in [27])**.** *Let $\chi := (\Delta_g \wedge \psi) \in \mathit{RGC}^k$ with $\mathrm{gd}(\chi) = \ell$ and let $m, d \in \mathbb{N}$ with $m \geq 1$. There exists a linear combination $Q := \sum_{i \in [q]} \alpha_i L_i$, and sets $\mathrm{dr}_Q = \{i : \mathsf{v}_i \in \mathrm{free}_{\mathsf{v}}(\chi)\}$ and $\mathrm{db}_Q = \{i : \mathsf{e}_i \in \mathrm{free}_{\mathsf{e}}(\chi)\}$, where for all $i \in [q]$:*

$$\alpha_i \in \mathbb{R}, \quad L_i \in \mathsf{GLI}_k^{\ell}, \quad g_i = g, \quad \mathrm{dom}(b_i) = \mathrm{db}_Q, \quad \text{and} \quad \mathrm{dom}(r_i) = \mathrm{dr}_Q;$$

such that for all k-labeled incidence graphs L' with $|\mathcal{B}(I')| = m$, $\max\{|\,\beta(e)| : e \in \mathcal{B}(I')\} \leq d$ and $\mathrm{dom}(b') \supseteq \mathrm{db}_Q$, $\mathrm{dom}(r') \supseteq \mathrm{dr}_Q$, $g' \supseteq g$, and with real guards w.r.t. g we have: $\mathcal{I}_{L'} \models \Delta_g$, and

$$\sum_{i \in [q]} \alpha_i \cdot \mathrm{hom}(L_i, L') = \begin{cases} 1, & \text{if } \mathcal{I}_{L'} \models \chi \\ 0, & \text{if } \mathcal{I}_{L'} \not\models \chi. \end{cases}$$

The proof of Theorem 6.1 works the same way as the one for Theorem 6.1 in [27, Section 8]: the second biimplication is provided by Theorem 2.7 and Proposition 2.8. The first biimplication is shown via contraposition, where the contraposition of the forward direction uses Lemma 6.2 and the one for the backward direction uses Lemma 6.3.

Proof of Theorem 6.1. Let $I = I_{\mathcal{G}}$ and $J = I_{\mathcal{H}}$. If $|\mathcal{B}(I)| \neq |\mathcal{B}(J)|$ then $\mathrm{hom}(I', I) \neq \mathrm{hom}(I', J)$ for the incidence graph $I' \in \mathsf{ISHD}_1$ that consists of a single blue vertex and no red vertices. Similarly, I and J are distinguished by a suitable GC_1-sentence of the form $\exists^{\geq n} \mathsf{e}\,.\,(\mathsf{e} = \mathsf{e})$. If $|\mathcal{B}(I)| = |\mathcal{B}(J)|$, consider their corresponding label-free k-labeled incidence graphs $L_I = (I, \varnothing, \varnothing, \varnothing)$ and $L_J = (J, \varnothing, \varnothing, \varnothing)$.

Assume there is an $I' \in \mathsf{ISHD}_k$ such that $\mathrm{hom}(I', I) = m_1 \neq m_2 = \mathrm{hom}(I', J)$. According to Theorem 4.1, there is a label-free $L \in \mathsf{GLI}^k$ such that $I' \cong I_L$, which means $\mathrm{hom}(L, L_I) = m_1 \neq m_2 = \mathrm{hom}(L, L_J)$. By Lemma 6.2 there exists a formula $(\top \wedge \varphi_{L,m_1}) \in \mathsf{RGC}^k$ with $\mathrm{gd}(\varphi_{L,m_1}) \leq k$ such that $\mathcal{I}_{L_I} \models (\top \wedge \varphi_{L,m_1})$ and $\mathcal{I}_{L_J} \not\models (\top \wedge \varphi_{L,m_1})$. Hence, $\mathcal{I}_{L_I} \models \varphi_{L,m_1}$ and $\mathcal{I}_{L_J} \not\models \varphi_{L,m_1}$, and since $\varphi_{L,m_1} \in \mathsf{GC}_k$, $\mathcal{G} \not\equiv_{\mathsf{GC}_k} \mathcal{H}$.

Assume there is a sentence $\varphi \in \mathsf{GC}^k$ with $\mathrm{gd}(\varphi) = k$ such that $\mathcal{I}_{L_I} \models \varphi$ and $\mathcal{I}_{L_J} \not\models \varphi$. By Lemma 5.4 there exists a formula $(\top \wedge \psi) \in \mathsf{RGC}^k$ with $\mathrm{gd}(\psi) = k$ such that $\mathcal{I}_{L_I} \models (\top \wedge \psi)$ and $\mathcal{I}_{L_J} \not\models (\top \wedge \psi)$. Let $m := |\mathcal{B}(I)| = |\mathcal{B}(J)|$ be the number of hyperedges and let $n \in \mathbb{N}$ such that $|\,\beta(e)| \leq n$ for all $e \in \mathcal{B}(I)$ and all $e \in \mathcal{B}(J)$. According to Lemma 6.3 there exists a linear combination $Q = \sum_{i\in[q]} \alpha_i L_i$ such that $\sum_{i\in[q]} \alpha_i \cdot \hom(L_i, L_I) = 1$ and $\sum_{i\in[q]} \alpha_i \cdot \hom(L_i, L_J) = 0$ and $L_i \in \mathsf{GLI}_k^k$ for all $i \in [q]$. This means there must be an $i \in [q]$ such that $\alpha_i \cdot \hom(L_i, L_I) \neq \alpha_i \cdot \hom(L_i, L_J)$, which means $\hom(L_i, L_I) \neq \hom(L_i, L_J)$. Since $\mathrm{dr}_Q = \mathrm{db}_Q = \varnothing$, L_i is label-free. According to Theorem 4.1, there exists an $I' \in \mathsf{ISHD}_k$ such that $I' \cong I_{L_i}$. Thus, $\hom(I', I) \neq \hom(I', J)$, i.e., $\mathrm{Hom}(\mathsf{ISHD}_k, I) \neq \mathrm{Hom}(\mathsf{ISHD}_k, J)$.

This finishes the proof for the first "iff". The second is provided by the combination of Theorem 2.7 and Proposition 2.8. ◀

7 Final Remarks

This paper solves one of the open questions of Scheidt and Schweikardt [27], who lift a result by Dvořák [9] from graphs to hypergraphs. Dvořák shows that homomorphism indistinguishability over the graphs of tree width at most k is equivalent to indistinguishability over first-order logic with counting quantifiers (C) and $k{+}1$ variables (C^{k+1}). Scheidt and Schweikardt show that homomorphism indistinguishability over the class GHW_k of hypergraphs of generalised hypertree width at most k is equivalent to indistinguishability over the logic GC with k guards (GC^k). Grohe [11] gave a result complementing Dvořák's: C with quantifier depth at most m (C_m) matches homomorphism indistinguishability over graphs of tree depth at most m. An obvious expectation was that the distinguishing power of GC_m would match homomorphism indistinguishability over the class HD_m of hypergraphs of hypertree depth at most m as it is defined by Adler et al. [1]. However, this expectation did not manifest in this exact way. Instead, we proved that the distinguishing power of GC_m matches homomorphism indistinguishability over hypergraphs of *strict* hypertree depth at most m, which is a (mild) restriction of hypertree depth. Combining Theorem 6.1 with the main result of [27] yields the following combined result.

▶ **Theorem 7.1.** *For all hypergraphs $\mathcal{G}$ and $\mathcal{H}$, the following equivalences hold:*

$$\mathcal{G} \equiv_{\mathsf{GC}_k} \mathcal{H} \iff \mathcal{G} \equiv_{\mathsf{SHD}_k} \mathcal{H} \iff I_{\mathcal{G}} \equiv_{\mathsf{ISHD}_k} I_{\mathcal{H}} \quad \text{and}$$
$$\mathcal{G} \equiv_{\mathsf{GC}^k} \mathcal{H} \iff \mathcal{G} \equiv_{\mathsf{GHW}_k} \mathcal{H} \iff I_{\mathcal{G}} \equiv_{\mathsf{IGHW}_k} I_{\mathcal{H}}.$$

We took this unexpected mismatch between GC_k and HD_k as an opportunity to investigate the relationship between HD_k and SHD_k. In Theorem 2.5 we showed that the strict hypertree depth of a hypergraph is at most 1 larger than its hypertree depth.

▶ **Theorem 2.5.** *For all hypergraphs $\mathcal{H}$,* $\mathrm{hd}(\mathcal{H}) \leq \mathrm{shd}(\mathcal{H}) \leq \mathrm{hd}(\mathcal{H})+1$.

To show that homomorphism counts from the class SHD_k are just as expressive as homomorphism counts from the class ISHD_k, which was necessary to prove Theorem 6.1, we used an implicit result by Böker [4], who gives a sufficient set of properties for a class $\mathfrak{C}$ of hypergraphs, such that homomorphism indistinguishability over $\mathfrak{C}$ is the same as homomorphism indistinguishability over the corresponding class $\mathfrak{C}_{\mathsf{I}}$ of incidence graphs. Since HD_k does not have these properties, Böker's result cannot be applied with respect to HD_k and IHD_k. In fact, we showed in Theorem 2.9 that homomorphism indistinguishability over HD_k is *not* the same as homomorphism indistinguishability over IHD_k and furthermore, that it is also not the same as homomorphism indistinguishability over SHD_k.

▶ **Theorem 2.9.** *For every $k \in \mathbb{N}_{\geq 1}$ there exist pairs of hypergraphs $(\mathcal{G}_k, \mathcal{H}_k)$ and $(\mathcal{G}'_k, \mathcal{H}'_k)$, such that:*

1. $\mathrm{Hom}(\mathsf{SHD}_k, \mathcal{G}_k) = \mathrm{Hom}(\mathsf{SHD}_k, \mathcal{H}_k)$, *but* $\mathrm{Hom}(\mathsf{HD}_k, \mathcal{G}_k) \neq \mathrm{Hom}(\mathsf{HD}_k, \mathcal{H}_k)$;
2. $\mathrm{Hom}(\mathsf{HD}_k, \mathcal{G}'_k) = \mathrm{Hom}(\mathsf{HD}_k, \mathcal{H}'_k)$, *but* $\mathrm{Hom}(\mathsf{IHD}_k, I_{\mathcal{G}'_k}) \neq \mathrm{Hom}(\mathsf{IHD}_k, I_{\mathcal{H}'_k})$.

Further Research. It would be very interesting to see if the result by Böker (Theorem 2.7) is tight in the sense that closure under pumping and local merging are sufficient *and required* properties. I.e., whether for every class $\mathfrak{C}$ that misses one of these properties, homomorphism counts over $\mathfrak{C}$ differ from homomorphism counts over the corresponding class $\mathfrak{C}_{\mathsf{I}}$ of incidence graphs in their distinguishing power.

As mentioned in the introduction, this work can be seen as one more step in the search of a "proper" lifting of the k-dimensional Weisfeiler-Leman algorithm to hypergraphs. Given the relationship between Weisfeiler-Leman, C and homomorphism indistinguishability on graphs [5, 7, 8, 9, 10, 11], we believe that the proper lifting should admit a similar relationship to the corresponding hypergraph parameters. Hence, we believe that the distinguishing power of such an algorithm should match homomorphism indistinguishability over the class GHW_k of hypergraphs of generalised hypertree width at most k and thus also indistinguishability by the logic GC^k. Since we believe that GC^k is the natural lifting of C^k in this setting, this paper adds to this picture: The k-dimensional Weisfeiler-Leman algorithm restricted to m iterations should have the same distinguishing power as the intersection of the classes $\mathsf{GHW}_k \cap \mathsf{SHD}_m$. Hence, the mismatch we uncovered in this work might propagate to the Weisfeiler-Leman algorithm.

On the Length of Strongly Monotone Descending Chains over $\mathbb{N}^d$

Sylvain Schmitz
Université Paris Cité, CNRS, IRIF, Paris, France

Lia Schütze
Max Planck Institute for Software Systems (MPI-SWS), Kaiserslautern, Germany

Abstract

A recent breakthrough by Künnemann, Mazowiecki, Schütze, Sinclair-Banks, and Węgrzycki (ICALP 2023) bounds the running time for the coverability problem in d-dimensional vector addition systems under unary encoding to $n^{2^{O(d)}}$, improving on Rackoff's $n^{2^{O(d \lg d)}}$ upper bound (*Theor. Comput. Sci.* 1978), and provides conditional matching lower bounds.

In this paper, we revisit Lazić and Schmitz' "ideal view" of the backward coverability algorithm (*Inform. Comput.* 2021) in the light of this breakthrough. We show that the controlled strongly monotone descending chains of downwards-closed sets over $\mathbb{N}^d$ that arise from the dual backward coverability algorithm of Lazić and Schmitz on d-dimensional unary vector addition systems also enjoy this tight $n^{2^{O(d)}}$ upper bound on their length, and that this also translates into the same bound on the running time of the backward coverability algorithm.

Furthermore, our analysis takes place in a more general setting than that of Lazić and Schmitz, which allows to show the same results and improve on the 2EXPSPACE upper bound derived by Benedikt, Duff, Sharad, and Worrell (LICS 2017) for the coverability problem in invertible affine nets.

1 Introduction

Well-Quasi-Orders (wqo for short) are a notion from order theory [29, 41] that has proven very effective in many areas of mathematics, logic, combinatorics, and computer science in order to establish finiteness statements. For instance, in the field of formal verification, they provide the termination arguments for the generic algorithms for *well structured transition systems* [1, 23], notably the *backward coverability algorithm* for deciding safety properties [3, 1, 23].

In full generality, one cannot extract complexity bounds from wqo-powered termination proofs. Nevertheless, in an algorithmic setting, one can "instrument" wqos by considering so-called *controlled sequences* [41, 39], and new tight complexity upper bounds for wqo-based algorithms now appear on a regular basis [40, 4, 6, 5, 26, for a few recent examples].

Those complexity upper bounds are however astronomically high, and sometimes actually way too high for the problem at hand. An emblematic illustration of this phenomenon is the backward coverability algorithm for vector addition systems (VAS), which was shown to run in double exponential time by Bozzelli and Ganty [13] based on an original analysis due to Rackoff [37]: the corresponding bounds over the wqo $\mathbb{N}^d$ are Ackermannian [20].

Descending Chains. One way pioneered by Lazić and Schmitz [32] to close such complexity gaps while retaining some of the wide applicability of wqos and well structured transition systems is to focus on the descending chains of downwards closed sets over the wqo at hand. Indeed, one of the equivalent characterisations of wqos is the *descending chain condition* [29, 41], which guarantees that those descending chains are finite.

In themselves, descending chains are no silver bullet: e.g., the controlled descending chains over $\mathbb{N}^d$ are also of Ackermannian length [32, Thm. 3.10]. Nevertheless, these chains sometimes exhibit a form of "monotonicity," which yields vastly improved upper bounds. When applied to a *dual* version of the backward coverability algorithm in well structured transition systems, this allows to recover the same double exponential time upper bound as in [13, 37] for the VAS coverability problem, along with tight upper bounds for coverability in several VAS extensions. The same framework was also the key to establishing tight bounds for coverability in ν-Petri nets [31]. As a further testimony to the versatility of the approach, Benedikt, Duff, Sharad, and Worrell use it in [7] to derive original upper bounds for problems on invertible polynomial automata and invertible affine nets, in a setting that is not strictly speaking one of well structured transition systems.

Fine-grained Bounds for VAS Coverability. The coverability problem in VAS is well-known to be EXPSPACE-complete, thanks to Rackoffs's 1978 upper bound [37] matching a 1976 lower bound by Lipton [34]. The main parameter driving this complexity is the dimension of the system: the problem is in pseudo-polynomial time in fixed dimension d; more precisely, Rackoff's analysis yields a $n^{2^{O(d \lg d)}}$ deterministic time upper bound for d-dimensional VAS encoded in unary [38], by proving the same bound on the length of a covering execution of minimal length. Here, there is a discrepancy with the $n^{2^{\Omega(d)}}$ lower bound on the length of that execution in Lipton's construction – a discrepancy that was already highlighted as an open problem in the early 1980's by Mayr and Meyer [35], and settled in the specific case of reversible systems by Koppenhagen and Mayr [28]. The upper bounds of both Bozzelli and Ganty [13] and Lazić and Schmitz [32] on the complexity of the backward coverability algorithm inherit from Rackoff's $n^{2^{O(d \lg d)}}$ bound and suffer from the same discrepancy.

This was the situation until Künnemann, Mazowiecki, Schütze, Sinclair-Banks, and Węgrzycki [30] showed an $n^{2^{O(d)}}$ upper bound on the length of minimal covering executions of unary encoded d-dimensional VAS, matching Lipton's lower bound [30, Thm. 3.3]. This directly translates into a deterministic algorithm with the same upper bound on the running time [30, Cor. 3.4]. Furthermore, assuming the exponential time hypothesis, Künnemann et al. also show that there does not exist a deterministic $n^{o(2^d)}$ time algorithm deciding coverability in unary encoded d-dimensional VAS [30, Thm. 4.2].

Thinness. The improved upper bound relies on the notion of a *thin* vector in $\mathbb{N}^d$ [30, Def. 3.6] (somewhat reminiscent of the "extractors" of Leroux [33]). The proof of [30, Thm. 3.3] works by induction on the dimension d. By splitting a covering execution of minimal length at the first non-thin configuration, Künnemann et al. obtain a prefix made of distinct thin configurations (which must then be of bounded length), and a suffix starting from a configuration with some components high enough to be disregarded, hence that can be treated as an execution in a VAS of lower dimension, on which the induction hypothesis applies.

Contributions. In this paper, we show that the improved $n^{2^{O(d)}}$ upper bound of Künnemann et al. [30] also applies to the number of iterations of the backward coverability algorithm for d-dimensional VAS encoded in unary (see Theorem 4.2). In order to do so, one could

reuse the approach of Bozzelli and Ganty [13] to lift the improved bound from the length of minimal covering executions to the running time of the backward coverability algorithm, but here we aim for the generality of the framework of [32].

Our main contribution is thus to show in Section 3 that the upper bounds on the length of strongly monotone controlled descending chains of downwards closed sets over $\mathbb{N}^d$ – which include those constructed during the running of the backward coverability algorithm for VAS – can be improved similarly (see Theorem 3.6) when focusing on a suitably generalised notion of thinness. As a byproduct, we observe that thinness is an inherent property of such chains (see Corollary 3.7), rather than an *a priori* condition that – almost magically – yields the improved bound.

We apply our results to the coverability problem in vector addition systems in Section 4.2 – thus providing as promised an alternative to applying Bozzelli and Ganty's approach to Künnemann et al.'s results – and show that the backward coverability algorithm runs in time $n^{2^{O(d)}}$ (see Corollary 4.5) and is therefore conditionally optimal by [30, Thm. 4.2].

As a further demonstration of the versatility of our results, we show in Section 4.3 how to apply them to invertible affine nets, a generalisation of vector addition systems introduced by Benedikt et al. [7], and a good showcase for our techniques. We obtain the same bounds for their coverability problem as in the case of vector addition systems (see Theorem 4.11 and Corollary 4.12), and thereby improve on the 2EXPSPACE upper bound of [7] by showing that the problem is actually EXPSPACE-complete (see Corollary 4.13). Along the way, we will see that the improved upper bounds also apply for other VAS extensions, for which Rackoff's proof scheme had been successfully adapted (see Remarks 4.4 and 4.15), namely strictly increasing affine nets [11], branching VAS [16], and alternating VAS [15].

2 Well-Quasi-Orders and Ideals

We start by introducing the necessary background on well-quasi-orders, descending chains, and order ideals.

Well-Quasi-Orders. A *quasi-order* $(X, \leq)$ comprises a set X and a transitive reflexive relation $\leq \subseteq X \times X$. For a subset $S \subseteq X$, its *downward closure* is the set of elements smaller or equal to some element in S, i.e., $\downarrow S \stackrel{\text{def}}{=} \{x \in X \mid \exists y \in S \,.\, x \leq y\}$. When $S = \{y\}$ is a singleton, we note $\downarrow y$ for this set. A subset $S \subseteq X$ is *downwards-closed* if $S = \downarrow S$. A *well-quasi-order* is a quasi-order $(X, \leq)$ such that all the *descending chains*

$$D_0 \supsetneq D_1 \supsetneq D_2 \supsetneq \cdots \tag{1}$$

of downwards-closed subsets $D_k \subseteq X$ are finite [29, 41].

Conversely, the *upward closure* of a subset $S \subseteq X$ is $\uparrow S \stackrel{\text{def}}{=} \{x \in X \mid \exists y \in S \,.\, y \leq x\}$, and S is *upwards-closed* if $S = \uparrow S$. The complement $X \setminus D$ of a downwards-closed set D is upwards-closed (and conversely), hence wqos have the *ascending chain condition* for chains $U_0 \subsetneq U_1 \subsetneq \cdots$ of upwards-closed sets: they are necessarily finite. Furthermore, any upwards-closed set U over a wqo has a *finite basis* B such that $U = \uparrow B$ [29, 41]; without loss of generality, we can take the elements of B to be minimal and mutually incomparable in U.

A well-studied wqo is $(\mathbb{N}^d, \sqsubseteq)$ the set of d-dimensional vectors of natural numbers along with the component-wise (aka product) ordering [17]; see Figure 1 for an illustration of a descending chain over $\mathbb{N}^2$, which happens to be produced by the backward coverability algorithm for a vector addition system [32, Ex. 3.6].

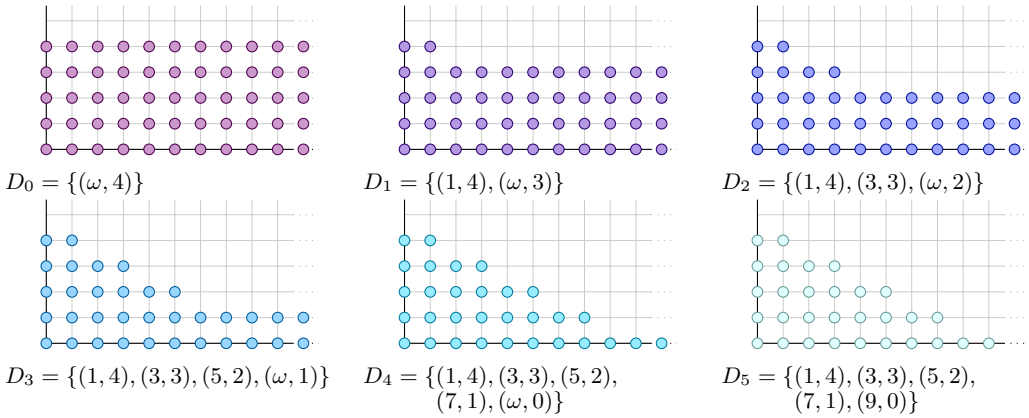

Figure 1 A descending chain $D_0 \supsetneq D_1 \supsetneq \cdots \supsetneq D_5$ over $\mathbb{N}^2$ [32, Ex. 3.6].

Order Ideals. An *order ideal* of X is a downwards-closed subset $I \subseteq X$, which is *directed*: it is non-empty, and if x, x' are two elements of I, then there exists y in I with $x \leq y$ and $x' \leq y$. Alternatively, order ideals are characterised as the *irreducible* non-empty downwards-closed sets of X: an order ideal is a non-empty downwards-closed set I with the property that, if $I \subseteq D_1 \cup D_2$ for two downwards-closed sets D_1 and D_2, then $I \subseteq D_1$ or $I \subseteq D_2$.

Over a wqo $(X, \leq)$, any downwards-closed set $D \subseteq X$ has a canonical decomposition as a finite union of order ideals $D = I_1 \cup \cdots \cup I_n$, where the I_j's are mutually incomparable for inclusion [12, 25]. We write $I \in D$ if I is an order ideal appearing in the canonical decomposition of D, i.e., if it is a maximal order ideal included in D. Then $D \subseteq D'$ if and only if, for all $I \in D$, there exists $I' \in D'$ such that $I \subseteq I'$.

Effective Representations over $\mathbb{N}^d$. Over the wqo $(\mathbb{N}^d, \sqsubseteq)$, the order ideals are exactly the sets of the form $\downarrow \boldsymbol{v} \cap \mathbb{N}^d$ where $\boldsymbol{v}$ ranges over $\mathbb{N}_\omega^d \stackrel{\text{def}}{=} (\mathbb{N} \uplus \{\omega\})^d$, where ω is a new top element [25]. From here on, we will abuse notations and identify an order ideal I of $\mathbb{N}^d$ with the vector $\boldsymbol{v}$ in $\mathbb{N}_\omega^d$ such that $I = \downarrow \boldsymbol{v} \cap \mathbb{N}^d$. See for instance the decompositions in Figure 1.

Let us introduce some notations for the sets of *infinite* and *finite components* of I, namely

$$\omega(I) \stackrel{\text{def}}{=} \{1 \leq i \leq d \mid I(i) = \omega\}\,, \qquad \text{fin}(I) \stackrel{\text{def}}{=} \{1 \leq i \leq d \mid I(i) < \omega\}\,, \tag{2}$$

along with its *dimension* and *finite dimension*, respectively defined as

$$\dim I \stackrel{\text{def}}{=} |\omega(I)|\,, \qquad \text{fdim}\, I \stackrel{\text{def}}{=} |\text{fin}(I)|\,. \tag{3}$$

Note that $\text{fin}(I) = \{1, \ldots, d\} \setminus \omega(I)$ and $\text{fdim}\, I = d - \dim I$. For instance, the order ideal $I = (\omega, 4)$ in the decomposition of D_0 in Figure 1 satisfies $\omega(I) = \{1\}$ and $\dim I = 1$.

The order ideals of $\mathbb{N}^d$, when represented as vectors in $\mathbb{N}_\omega^d$, are rather easy to manipulate [25] – and thus so are the downwards-closed subsets of $\mathbb{N}^d$ when represented as finite sets of vectors in $\mathbb{N}_\omega^d$. For instance,

- $I \subseteq I'$ (as subsets of $\mathbb{N}^d$) if and only if $I \sqsubseteq I'$ (as vectors in $\mathbb{N}_\omega^d$) – which incidentally entails $\omega(I) \subseteq \omega(I')$ and therefore $\dim I \leq \dim I'$; also note that, if $I \subseteq I'$ and $\dim I = \dim I'$, then $\omega(I) = \omega(I')$;
- the intersection of two order ideals is again an order ideal, represented by the vector $I \wedge I'$ defined by $(I \wedge I')(i) \stackrel{\text{def}}{=} \min(I(i), I'(i))$ for all $1 \leq i \leq d$;
- the complement of an order ideal I is the upwards-closed set $\bigcup_{i \in \text{fin}(I)} \uparrow\big((I(i)+1) \cdot \boldsymbol{e}_i\big)$, where $\boldsymbol{e}_i$ denotes the unit vector with "1" in coordinate i and "0" everywhere else.

Proper Ideals and Monotonicity. If $D \supsetneq D'$, then there must be an order ideal $I \in D$ such that $I \notin D'$. Coming back to a descending chain $D_0 \supsetneq D_1 \supsetneq \cdots \supsetneq D_\ell$, we then say that an order ideal I is *proper* at step k, for $0 \leq k < \ell$, if $I \in D_k$ but $I \notin D_{k+1}$; at each step $0 \leq k < \ell$, there must be at least one proper order ideal. In Figure 1, $(\omega, 4)$ is proper at step 0, and more generally $(\omega, 4-k)$ is the only proper order ideal at step $0 \leq k < 5$.

It turns out that the descending chains arising from some algorithmic procedures, including the backward coverability algorithm for VAS, enjoy additional relationships between their proper order ideals. Over $(\mathbb{N}^d, \sqsubseteq)$, we say that a descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ is

- *strongly monotone* [36, 7] if, whenever an ideal I_{k+1} is proper at some step $k+1$, then there exists I_k proper at step k such that $\dim I_{k+1} \leq \dim I_k$, and
- in particular *ω-monotone* [32] if, whenever an ideal I_{k+1} is proper at some step $k+1$, then there exists I_k proper at step k such that $\omega(I_{k+1}) \subseteq \omega(I_k)$.

The descending chain depicted in Figure 1 is ω-monotone – and thus strongly monotone – with $\omega((\omega, 4-(k+1))) \subseteq \omega((\omega, 4-k))$ for all $4 > k \geq 0$.

Controlled Sequences. While guaranteed to be finite, descending chains over a wqo can have arbitrary length. Nevertheless, their length can be bounded under additional assumptions. We define the *size* of a downwards-closed subset of $\mathbb{N}^d$ and of an order ideal of $\mathbb{N}^d$ as

$$\|D\| \stackrel{\text{def}}{=} \max_{I \in D} \|I\| \,, \qquad\qquad \|I\| \stackrel{\text{def}}{=} \max_{i \in \text{fin}(I)} I(i) \,. \tag{4}$$

In Figure 1, $\|D_0\| = \|D_1\| = \|D_2\| = 4$, $\|D_3\| = 5$, $\|D_4\| = 7$, and $\|D_5\| = 9$.

Given a *control* function $g \colon \mathbb{N} \to \mathbb{N}$, which will always be monotone (i.e., $\forall x \leq y . g(x) \leq g(y)$) and expansive (i.e., $\forall x . x \leq g(x)$) along with an *initial size* $n_0 \in \mathbb{N}$, we say that a descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ over $\mathbb{N}^d$ is (g, n_0)-*controlled* if, for all $k \geq 0$,

$$\|D_k\| \leq g^k(n_0) \tag{5}$$

where $g^k(n_0)$ is the kth iterate of g applied to n_0 [39]. In particular, $\|D_0\| \leq n_0$ initially. In Figure 1, the descending chain is $(g, 4)$-controlled for $g(x) \stackrel{\text{def}}{=} x + 1$.

3 Main Result

In this section, we establish a new bound on the length of controlled strongly monotone descending sequences. This relies on a generalisation of the notion of *thinness* from Künnemann et al. [30, Def. 3.6] (see Section 3.1), before we can apply thinness in the setting of strongly monotone descending chains and prove our main result in Section 3.2.

3.1 Thinness

Fix a control function g, an initial size n_0, and a dimension $d \geq 0$. Define inductively the bounds on sizes $(N_i)_{0 \leq i \leq d}$ and lengths $(L_i)_{0 \leq i \leq d}$ as follows

$$N_0 \stackrel{\text{def}}{=} n_0 \,, \qquad\qquad N_{i+1} \stackrel{\text{def}}{=} g^{L_i+1}(n_0) \,, \tag{6}$$

$$L_0 \stackrel{\text{def}}{=} 0 \,, \qquad\qquad L_{i+1} \stackrel{\text{def}}{=} L_i + \prod_{1 \leq j \leq i+1} (d - j + 1)(N_j + 1) \,. \tag{7}$$

Beware the abuse of notation, as the bounds above depend on (g, n_0) and d, but those will always be clear from the context.

▶ Remark 3.1 (Monotonicity of $(N_i)_{0\leq i\leq d}$ and $(L_i)_{0\leq i\leq d}$). By definition, for all $0 \leq i < j \leq d$, $0 \leq L_i < L_j$, and because g is assumed monotone expansive, $n_0 \leq N_i \leq N_j$. ⌟

The following definition generalises [30, Def. 3.6] to handle order ideals and an arbitrary control function and initial size.

▶ **Definition 3.2** (Thin order ideal). *Let (g, n_0) be a control function and initial size and $d > 0$ a dimension. An order ideal I of $\mathbb{N}^d$ is* thin *if there exists a bijection $\sigma\colon \mathrm{fin}(I) \to \{1, \ldots, \mathrm{fdim}\, I\}$ such that, for all $i \in \mathrm{fin}(I)$, $I(i) \leq N_{\sigma(i)}$.*

Observe that that, if I' is thin, $I \subseteq I'$, and $\dim I = \dim I'$, then I is thin.

▶ Remark 3.3 (Number of thin order ideals). There cannot be more than $\binom{d}{i} \cdot i! \cdot \prod_{1\leq j\leq i}(N_j+1) = \prod_{1\leq j\leq i}(d-j+1)(N_j+1)$ distinct thin order ideals of finite dimension i. As will become apparent in the proofs, this is what motivates the definition in (7). ⌟

3.2 Thinness Lemma

The crux of our result is the following lemma.

▶ **Lemma 3.4** (Thinness). *Consider a (g, n_0)-controlled strongly monotone descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ of downwards-closed subsets of $\mathbb{N}^d$. If I_ℓ is a proper order ideal at some step ℓ, then I_ℓ is thin and $\ell \leq L_{\mathrm{fdim}\, I_\ell}$.*

The proof of Lemma 3.4 proceeds by induction over the finite dimension $\mathrm{fdim}\, I_\ell = d - \dim I_\ell$. For the base case where I_ℓ has full dimension $\dim I_\ell = d$, then $I_\ell = (\omega, \ldots, \omega)$ is thin and $D_\ell = \mathbb{N}^d$ is the full space, which can only occur at step $\ell = 0 = L_0$. For the induction step, we first establish thinness with the following claim; note that, as just argued, an order ideal of dimension d is necessarily thin. We then follow with the bound on ℓ to complete the proof of Lemma 3.4.

▷ Claim 3.5. Let $0 \leq d' < d$ and assume that Lemma 3.4 holds for all proper order ideals I' of dimension $\dim I' > d'$. If I is any (not necessarily proper) order ideal of dimension $\dim I = d'$ appearing as a maximal ideal in the descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$, then I is thin.

Proof of Claim 3.5. Let k be a step where I appears in the descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$, i.e., $I \in D_k$, and let us write $I_k \stackrel{\text{def}}{=} I$. If $k > 0$, since $D_k \subseteq D_{k-1}$, there exists an order ideal $I_{k-1} \in D_{k-1}$ such that $I_k \subseteq I_{k-1}$. If $k = 0$, or by repeating this argument if $k > 0$, we obtain a chain of order ideals (with decreasing indices)

$$I_k \subseteq I_{k-1} \subseteq \cdots \subseteq I_0 \tag{8}$$

where $I_m \in D_m$ for all $k \geq m \geq 0$. Every order ideal in that chain must have dimension at least $\dim I_k = d'$ since they all contain I_k. Two cases arise.

1. If every order ideal in the chain (8) has dimension $\dim I_k$, then because the descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ is (g, n_0)-controlled, we have $\|I_0\| \leq n_0 = N_0$ and we know by Remark 3.1 that I_0 is thin. Since $I_k \subseteq I_0$ and $\dim I_k = \dim I_0$, I_k is also thin.
2. Otherwise there exists a first index K along the chain (8) where the dimension increases, i.e., such that $\dim I_k < \dim I_K$ and $\dim I_m = \dim I_k$ for all $k \geq m > K$. Then I_K is proper, as otherwise D_{K+1} would contain two distinct but comparable order ideals in its canonical decomposition, namely I_K and I_{K+1}: indeed, $I_{K+1} \subseteq I_K$ and $\dim I_{K+1} = \dim I_k < \dim I_K$ imply $I_{K+1} \subsetneq I_K$. By assumption, Lemma 3.4 can be applied to I_K of dimension $\dim I_K > \dim I_k = d'$, thus I_K is thin and $K \leq L_{\mathrm{fdim}\, I_K}$.

Let us now show that I_{K+1} is thin, which will also yield that I_k is thin since $I_k \subseteq I_{K+1}$ and $\dim I_k = \dim I_{K+1}$.
Since $\dim I_{K+1} < \dim I_K$, we let $f \stackrel{\text{def}}{=} \dim I_K - \dim I_{K+1} = \operatorname{fdim} I_{K+1} - \operatorname{fdim} I_K > 0$. As furthermore $I_{K+1} \subseteq I_K$, $\omega(I_{K+1}) \subsetneq \omega(I_K)$ and we let $\{i_1, \dots, i_f\} \stackrel{\text{def}}{=} \omega(I_K) \setminus \omega(I_{K+1}) = \operatorname{fin}(I_{K+1}) \setminus \operatorname{fin}(I_K)$.
Since I_K is thin, there exists a bijection $\sigma\colon \operatorname{fin}(I_K) \to \{1, \dots, \operatorname{fdim}(I_K)\}$ such that $I_K(i) \leq N_{\sigma(i)}$ for all $i \in \operatorname{fin}(I_K)$. We extend σ to a bijection $\sigma'\colon \operatorname{fin}(I_K) \uplus \{i_1, \dots, i_f\} \to \{1, \dots, \operatorname{fdim} I_K + f\}$: we let $\sigma'(i) \stackrel{\text{def}}{=} \sigma(i)$ for all $i \in \operatorname{fin}(I_K)$, and $\sigma'(i_j) \stackrel{\text{def}}{=} \operatorname{fdim} I_K + j$ for all $1 \leq j \leq f$. Let us check that σ' witnesses the thinness of I_{K+1}.

- Because $I_{K+1} \subseteq I_K$, for all those $i \in \operatorname{fin}(I_K)$, $I_{K+1}(i) \leq I_K(i) \leq N_{\sigma(i)} = N_{\sigma'(i)}$.
- Since $K + 1 \leq L_{\operatorname{fdim} I_K} + 1$ and since the descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ is (g, n_0)-controlled, we have a bound of $g^{L_{\operatorname{fdim} I_K}+1}(n_0) = N_{\operatorname{fdim} I_K + 1}$ on all the finite components of I_{K+1}, and in particular $I_{K+1}(i_j) \leq N_{\operatorname{fdim} I_K + 1}$ for all $1 \leq j \leq f$. By Remark 3.1, we conclude that $I_{K+1}(i_j) \leq N_{\operatorname{fdim} I_K + j} = N_{\sigma'(i_j)}$ for all $1 \leq j \leq f$. ◁

Proof of Lemma 3.4. We have already argued for the base case, so let us turn to the inductive step where $\dim I_\ell < d$. If $\ell > 0$ and since our descending chain is strongly monotone, we can find an order ideal $I_{\ell-1}$ proper at step $\ell - 1$ such that $\dim I_\ell \leq \dim I_{\ell-1}$. Both if $\ell = 0$ or by repeating this argument, we obtain a sequence of order ideals (with decreasing indices)

$$I_\ell, I_{\ell-1}, \dots, I_0 \tag{9}$$

where, for each $\ell > k \geq 0$, I_k is proper at step k, and $\dim I_{k+1} \leq \dim I_k$.

Let us decompose our sequence (9) by identifying the first step L where $\dim I_{L+1} < \dim I_L$; let $L \stackrel{\text{def}}{=} -1$ if this never occurs. After this step, for all $L \geq k \geq 0$, $\dim I_k > \dim I_\ell$. Within the initial segment, for $\ell \geq k > L$, the dimension $\dim I_k$ remains constant equal to $\dim I_\ell$, and the induction hypothesis allows to apply Claim 3.5 and infer that every order ideal I_k in this initial segment, and in particular I_ℓ among them, is thin.

It remains to provide a bound on ℓ. The $\ell - L$ order ideals in the initial segment are thin, and distinct since they are proper, hence by Remark 3.3,

$$\ell \leq L + \prod_{1 \leq i \leq \operatorname{fdim} I_\ell} (d - i + 1)(N_i + 1)\,. \tag{10}$$

If $L \geq 0$ we can apply the induction hypothesis to the proper order ideal I_L of finite dimension $\operatorname{fdim} I_L < \operatorname{fdim} I_\ell$ along with Remark 3.1 to yield $L \leq L_{\operatorname{fdim} I_L} \leq L_{\operatorname{fdim} I_\ell - 1}$ and therefore

$$\ell \leq L_{\operatorname{fdim} I_\ell - 1} + \prod_{1 \leq i \leq \operatorname{fdim} I_\ell} (d - i + 1)(N_i + 1) = L_{\operatorname{fdim} I_\ell}\,. \tag{11}$$

If $L = -1$ then (11) also holds since $L_{\operatorname{fdim} I_\ell - 1} \geq 0 > L$ in (10). ◀

We deduce a general combinatorial statement on the length of controlled strongly monotone descending chains, that generalises and refines [32, Thm. 4.4] thanks to thinness.

▶ **Theorem 3.6** (Length function for strongly monotone descending chains). *Consider a (g, n_0)-controlled strongly monotone descending chain $D_0 \supsetneq \cdots \supsetneq D_\ell$ of downwards-closed subsets of $\mathbb{N}^d$. Then $\ell \leq L_d + 1$.*

Proof. In such a descending chain, either $\ell = 0 \leq L_d + 1$, or $\ell > 0$ and there must be an order ideal I proper at step $\ell - 1$, and I has finite dimension at most d. By Lemma 3.4 and Remark 3.1, $\ell - 1 \leq L_{\operatorname{fdim} I} \leq L_d$ in that case. ◀

3.3 Thin Order Ideals and Filters

Let us conclude this section with some consequences of Lemma 3.4 and Claim 3.5. Whereas thinness was posited *a priori* in the proof of Künnemann et al. [30, Thm. 3.3] and then shown to indeed allow a suitable decomposition of minimal covering executions and to eventually prove their result, here in the descending chain setting it is an inherent property of all the order ideals appearing in the chain, thereby providing a "natural" explanation for thinness.

▶ **Corollary 3.7.** *Consider a (g, n_0)-controlled strongly monotone descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ of downwards-closed subsets of $\mathbb{N}^d$. Then every order ideal appearing in the chain is thin.*

Corollary 3.7 also entails a form of thinness of the minimal configurations in the complement of the downwards-closed sets D_k. Recall that such a complement is the upward-closure of a finite basis $B_k \stackrel{\text{def}}{=} \min_{\sqsubseteq} \mathbb{N}^d \setminus D_k$. Each element $\boldsymbol{v} \in B_k$ is a vector defining a so-called *(principal) order filter* $\uparrow\boldsymbol{v}$ of $\mathbb{N}^d$. Let us call a vector $\boldsymbol{v} \in \mathbb{N}^d$ *nearly thin* if there exists a permutation $\sigma\colon \{1, \ldots, d\} \to \{1, \ldots, d\}$ such that, for all $1 \leq i \leq d$, $\boldsymbol{v}(i) \leq N_{\sigma(i)} + 1$. We can relate thin order ideals with nearly thin order filters, which by Corollary 3.7 applies to every vector $\boldsymbol{v} \in \bigcup_k B_k$ (see the full version for a proof).

▶ **Proposition 3.8.** *If every order ideal in the canonical decomposition of a downwards-closed set $D \subseteq \mathbb{N}^d$ is thin, then each $\boldsymbol{v} \in \min_{\sqsubseteq} \mathbb{N}^d \setminus D$ is nearly thin.*

4 Applications

We describe two applications of Theorem 3.6 in this section. The first application in Section 4.2 is to the coverability problem in vector addition systems, and relies on the analysis of the backward coverability algorithm done in [32]. Thus we can indeed recover the improved upper bound of Künnemann et al. [30] for the coverability problem in the more general setting of descending chains, and show that the backward coverability algorithm achieves this $n^{2^{O(d)}}$ upper bound (see Corollary 4.5).

The second application in Section 4.3 focuses on the coverability problem in invertible affine nets, a class introduced by Benedikt et al. [7], who analysed the complexity of the problem through a reduction to zeroness in invertible polynomial automata. We give a direct analysis of the complexity of the backward coverability algorithm, which follows the same lines as in the VAS case, and allows to improve on the 2EXPSPACE upper bound shown in [7] for the problem, by showing that it is actually EXPSPACE-complete (see Corollary 4.13). This application additionally illustrates the usefulness of considering strongly monotone descending chains rather than the ω-monotone ones, as the descending chains constructed by the backward algorithm for invertible affine nets are in general not ω-monotone.

As both applications take place in the framework of well-structured transition systems [1, 23], we start with a quick refresher on this framework, the backward coverability algorithm, and its dual view using downwards-closed sets [32] in the upcoming Section 4.1.

4.1 Coverability in Well-Structured Transition Systems

Well-structured transition systems (WSTS) form an abstract family of computational models where the set of configurations is equipped with a well-quasi-ordering "compatible" with the computation steps. This wqo ensures the termination of generic algorithms checking some important behavioural properties like coverability and termination. While the idea can be traced back to the 1980's [21], this framework has been especially popularised through two landmark surveys [1, 23] that emphasised its wide applicability, and new WSTS models keep being invented in multiple areas to this day.

4.1.1 Well-Structured Transition Systems

A *well-structured transition system* (WSTS) [1, 23] is a triple $(X, \to, \leq)$ where X is a set of configurations, $\to \subseteq X \times X$ is a transition relation, and $(X, \leq)$ is a wqo with the following *compatibility* condition: if $x \leq x'$ and $x \to y$, then there exists $y' \geq y$ with $x' \to y'$.

The coverability problem below corresponds to the verification of safety properties, i.e., to checking that no bad configuration can ever be reached from a given initial configuration $s \in X$. Here we are given an error configuration $t \in X$, and we assume that any configuration larger than t is also an error.

▶ **Problem** (Coverability in well-structured transition systems).
input a well-structured transition system $(X, \to, \leq)$ and two configurations s and t in X
question does s *cover* t, i.e., does there exist $t' \in X$ such that $s \to^* t' \geq t$?

4.1.2 The Backward Coverability Algorithm

The first published version of this algorithm seems to date back to [3], where it was used to show the decidability of coverability in vector addition systems extended with reset capabilities, before it was rediscovered and generalised to well-structured transition systems [1].

The Algorithm. Given an instance of the coverability problem, the *backward coverability algorithm* [3, 1, 23] computes (a finite basis for) the upwards-closed set

$$U_* \stackrel{\text{def}}{=} \{x \in X \mid \exists t' \geq t \,.\, x \to^* t'\} \tag{12}$$

of all the configurations that cover t, and then checks whether $s \in U_*$.

The set U_* itself is computed by letting

$$U_0 \stackrel{\text{def}}{=} \uparrow t \,, \qquad\qquad U_{k+1} \stackrel{\text{def}}{=} U_k \cup \mathrm{Pre}_\exists(U_k) \,, \tag{13}$$

where, for a set $S \subseteq X$, $\mathrm{Pre}_\exists(S) \stackrel{\text{def}}{=} \{x \in X \mid \exists y \in S \,.\, x \to y\}$. Then $U_k = \{x \in X \mid \exists t' \geq t \,.\, x \to^{\leq k} t'\}$ is the set of configurations that can cover t in at most k steps. Equation (13) defines a chain $U_0 \subseteq U_1 \subseteq \cdots$ of upwards-closed subsets of X. Furthermore, if $U_\ell = U_{\ell+1}$ at some step, then we have reached stabilisation: $U_\ell = U_{\ell+k} = U_*$ for all k. Thus we focus in this algorithm on ascending chains $U_0 \subsetneq U_1 \subsetneq \cdots$, which are finite thanks to the ascending chain condition of the wqo $(X, \leq)$. In order to turn (13) into an actual algorithm, one needs to make some effectiveness assumptions on $(X, \to, \leq)$, typically that $\leq$ is decidable and a finite basis for $\mathrm{Pre}_\exists(\uparrow x)$ can be computed for all $x \in X$ [23, Prop. 3.5].

A Dual View. Lazić and Schmitz [32] take a dual view of the algorithm and define from (13) a descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ of the same length where

$$D_k \stackrel{\text{def}}{=} X \setminus U_k \tag{14}$$

for each k; this stops with $D_* = X \setminus U_*$ the set of configurations that do *not* cover t. The entire computation in (13) can be recast in this dual view, by setting

$$D_0 \stackrel{\text{def}}{=} X \setminus \uparrow t \,, \qquad\qquad D_{k+1} \stackrel{\text{def}}{=} D_k \cap \mathrm{Pre}_\forall(D_k) \,, \tag{15}$$

where, for a set $S \subseteq X$, $\mathrm{Pre}_\forall(S) \stackrel{\text{def}}{=} \{x \in X \mid \forall y \in X.(x \to y \implies y \in S)\} = X \setminus (\mathrm{Pre}_\exists(X \setminus S))$. Under some effectiveness assumptions, in particular for manipulating ideal representations over X, this can be turned into an actual algorithm [32, Sec. 3.1].

4.2 Coverability in Vector Addition Systems

Vector addition systems are a well-established model for simple concurrent processes [27] equivalent to Petri nets, with far-reaching connections to many topics in theoretical computer science. In particular, their coverability problem, which essentially captures safety checking, has been thoroughly investigated from both a theoretical [27, 34, 37, 13, 32, 30] and a more practical [19, 8, 24, 10] standpoint.

4.2.1 Vector Addition Systems

A d-dimensional *vector addition system* (VAS) [27] is a finite set $\boldsymbol{A}$ of vectors in $\mathbb{Z}^d$. It defines a well-structured transition system $(\mathbb{N}^d, \to_{\boldsymbol{A}}, \sqsubseteq)$ with $\mathbb{N}^d$ as set of configurations and transitions $\boldsymbol{u} \to_{\boldsymbol{A}} \boldsymbol{u}+\boldsymbol{a}$ for all $\boldsymbol{u}$ in $\mathbb{N}^d$ and $\boldsymbol{a}$ in $\boldsymbol{A}$ such that $\boldsymbol{u}+\boldsymbol{a}$ is in $\mathbb{N}^d$. We work with a unary encoding, and let $\|\boldsymbol{u}\| \stackrel{\text{def}}{=} \max_{1\le i\le d} |\boldsymbol{u}(i)|$ and $\|\boldsymbol{A}\| \stackrel{\text{def}}{=} \max_{\boldsymbol{a}\in\boldsymbol{A}} \|\boldsymbol{a}\|$ for all $\boldsymbol{u} \in \mathbb{Z}^d$ and $\boldsymbol{A} \subseteq \mathbb{Z}^d$ finite.

The coverability problem in vector addition systems was first shown decidable in 1969 by Karp and Miller [27], before being proven EXPSPACE-complete when d is part of the input by Lipton [34] and Rackoff [37]. Note that the problem parameterised by d is trivial for $d = 1$ (a target $\boldsymbol{t}$ is coverable if and only if $\boldsymbol{s} \ge \boldsymbol{t}$ or there exists $\boldsymbol{a} \in \boldsymbol{A}$ with $\boldsymbol{a} > 0$), hence we will assume $d \ge 2$.

4.2.2 Complexity Upper Bounds

The dual backward coverability algorithm of Section 4.1.2 is straightforward to instantiate in the case of a vector addition system. Figure 1 displays the computed descending chain for the 2-dimensional VAS $\boldsymbol{A}_{\div 2} \stackrel{\text{def}}{=} \{(-2, 1)\}$ and target configuration $\boldsymbol{t} \stackrel{\text{def}}{=} (0, 5)$ [32, Ex. 3.6].

▶ **Fact 4.1** ([32, claims 3.9 and 4.3])**.** The descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ defined by equations (13–15) for a d-dimensional VAS $\boldsymbol{A}$ and a target vector $\boldsymbol{t}$ is (g, n_0)-controlled for $g(x) \stackrel{\text{def}}{=} x + \|\boldsymbol{A}\|$ and $n_0 \stackrel{\text{def}}{=} \|\boldsymbol{t}\|$, and is ω-monotone.

The length of the descending chain defined by equations (13–15) is the main source of complexity for the whole backward coverability algorithm, and we can apply our own Theorem 3.6 instead of [32, Thm. 4.4] in order to prove the following bound on this length, where the combinatorics are somewhat similar to those of [30, Lem. 3.5].

▶ **Theorem 4.2.** *The backward coverability algorithm terminates after at most $n^{2^{O(d)}}$ iterations on a d-dimensional VAS encoded in unary.*

Proof. Let n be the size of the input to the coverability problem; we assume in the following that $n, d \ge 2$. By Fact 4.1 and due to the unary encoding, the descending chain $D_0 \supsetneq D_1 \supsetneq \cdots \supsetneq D_\ell = D_*$ is (g, n_0)-controlled for $g(x) \stackrel{\text{def}}{=} x + n$ and $n_0 \stackrel{\text{def}}{=} n$, and is ω-monotone and thus strongly monotone. By Theorem 3.6, $\ell \le L_d + 1$. Let us bound this value.

▷ Claim 4.3. Let $g(x) \stackrel{\text{def}}{=} x + n$ and $n_0 \stackrel{\text{def}}{=} n$. Then, for all $i \le d$,

$$N_{i+1} = n \cdot (L_i + 2)\,, \qquad\qquad L_i + 4 \le n^{3^i \cdot (\lg d + 1)}\,.$$

Proof of Claim 4.3. In the case of N_{i+1}, by the definition of N_{i+1} in (6), $N_{i+1} = g^{L_i+1}(n_0) = n + (L_i + 1) \cdot n = n \cdot (L_i + 2)$ as desired.

Regarding L_i, we proceed by induction over i. For the base case $i = 0$, $L_0 + 4 = 4 \leq n^{3^0 \cdot (\lg d + 1)}$ since we assumed $n, d \geq 2$. For the induction step, by the definition of L_{i+1} in (7)

$$\begin{aligned} L_{i+1} + 4 &= L_i + 4 + \prod_{0 \leq j \leq i} (d - j)(N_{j+1} + 1) \\ &\leq L_i + 4 + \prod_{0 \leq j \leq i} (d - j) \cdot n \cdot (L_j + 3) \\ &\leq 2 \cdot (dn)^{i+1} \cdot \prod_{0 \leq j \leq i} (L_j + 3) \,. \end{aligned}$$

Here, since $n \geq 2$,

$$2 \cdot (dn)^{i+1} \leq n^{(i+1)(\lg d + 1) + 1}$$

and by induction hypothesis for $j \leq i$

$$\prod_{0 \leq j \leq i} (L_j + 3) \leq n^{\sum_{0 \leq j \leq i} 3^j (\lg d + 1)} \,.$$

Thus, it only remains to see that, since $i > 0$,

$$\begin{aligned} 3^{i+1} \cdot (\lg d + 1) &= (1 + 2 \cdot \sum_{0 \leq j \leq i} 3^j) \cdot (\lg d + 1) \\ &\geq (1 + 3^0 + 3^i) \cdot (\lg d + 1) + \sum_{0 \leq j \leq i} 3^j \cdot (\lg d + 1) \\ &\geq (i + 1) \cdot (\lg d + 1) + 1 + \sum_{0 \leq j \leq i} 3^j \cdot (\lg d + 1) \,. \end{aligned}$$

◁

Thus $L_d + 1 \leq n^{3^d \cdot (\lg d + 1)}$ by Claim 4.3, and this is in $n^{2^{O(d)}}$. ◀

▶ Remark 4.4 (Branching or alternating vector addition systems). The improved upper bound parameterised by the dimension d in Theorem 4.2 also applies to some extensions of vector addition systems, for which Lazić and Schmitz [32] have shown that the backward coverability algorithm was constructing an ω-monotone descending chain controlled as in Fact 4.1, namely

- in [32, claims 6.7 and 6.8] for bottom-up coverability in branching vector addition systems (BVAS) – which is 2EXP-complete [16] – , and
- in [32, claims 5.4 and 5.5] for top-down coverability in alternating vector addition systems (AVAS) – which is 2EXP-complete as well [15]. ⌟

Recall that U_ℓ is the set of configurations that can cover the target $\boldsymbol{t}$ in at most ℓ steps, hence Theorem 4.2 provides an alternative proof for [30, Thm. 3.3]: if there exists a covering execution, then there is one of length in $n^{2^{O(d)}}$, from which an algorithm in $n^{2^{O(d)}}$ follows by [30, Thm. 3.2]. Regarding the optimality of Theorem 4.2, recall that Lipton [34] shows an $n^{2^{\Omega(d)}}$ lower bound on the length of a minimal covering execution, which translates into the same lower bound on the number ℓ of iterations of the backward coverability algorithm [13, Cor. 2]. Finally, this also yields an improved upper bound on the complexity of the (original) backward coverability algorithm. Here, we can rely on the analysis performed by Bozzelli and Ganty [13, Sec. 3] and simply replace Rackoff's $n^{2^{O(d \lg d)}}$ bound on the length of minimal covering executions by the bound from Theorem 4.2.

▶ **Corollary 4.5.** *The backward coverability algorithm runs in time $n^{2^{O(d)}}$ on d-dimensional VAS encoded in unary.*

Proof. Let n be the size of the input to the coverability problem and $U_0 \subsetneq U_1 \subsetneq \cdots \subsetneq U_\ell = U_*$ be the ascending chain constructed by the backward coverability according to (13). By Theorem 4.2, ℓ is in $n^{2^{O(d)}}$.

Let $B_k \stackrel{\text{def}}{=} \min_{\sqsubseteq} U_k$ be the minimal basis at each step k. The algorithm computes B_{k+1} from B_k as per (13) by computing $\min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{v})$ for each $\boldsymbol{v} \in B_k$, adding the elements of B_k, and removing any non-minimal vector. Thus each step can be performed in time polynomial in n, d, and the number of vectors in B_k. Here, Bozzelli and Ganty's analysis in [13, Sec. 3] shows that $\|\boldsymbol{v}'\| \leq g(\|\boldsymbol{v}\|)$ for all $\boldsymbol{v}' \in \min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{v})$, yielding a bound of $|B_k| \leq (g^k(n)+1)^d \leq ((\ell+1)\cdot n + 1)^d$, which is still in $n^{2^{O(d)}}$.

We can do slightly better. By Corollary 3.7, all the ideals in the canonical decomposition of $D_k \stackrel{\text{def}}{=} \mathbb{N}^d \setminus U_k$ are thin, and in turn Proposition 3.8 shows that all the vectors in B_k are nearly thin. Accordingly, let us denote by $\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)$ the set of order filters $\uparrow \boldsymbol{v}$ such that $\boldsymbol{v}$ is nearly thin. Then $|B_k| \leq |\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)|$, and the latter is in $n^{2^{O(d)}}$:

$$
\begin{aligned}
|\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)| &\leq d! \cdot \prod_{1 \leq i \leq d} (N_i + 2) \\
&\leq d! \cdot n^d \cdot \prod_{0 \leq i \leq d-1} (L_i + 4) && \text{(by Claim 4.3 on } N_i\text{)} \\
&\leq n^{2d + \sum_{0 \leq i \leq d-1} 3^i \cdot (\lg d + 1)} && \text{(because } d \leq n \text{ and by Claim 4.3 on } L_i\text{)} \\
&\leq n^{3^d \cdot (\lg d + 1)} \,. && (16)
\end{aligned}
$$

Therefore, the overall complexity of the backward coverability algorithm is polynomial in ℓ, $\max_{0 \leq k \leq \ell} |B_k|$, n, and d, which is in $n^{2^{O(d)}}$. ◀

The bounds in $n^{2^{O(d)}}$ for $\|\boldsymbol{v}\| \leq N_d + 1$ for all $\boldsymbol{v} \in \min_{\sqsubseteq} U_k$ and for $|\min_{\sqsubseteq} U_k| \leq |\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)|$ in the previous proof also improve on the corresponding bounds in [44, Thm. 9] and [13, Thm. 2]. Recall that Künnemann et al. [30, Thm. 4.2] show that, assuming the exponential time hypothesis, there does not exist a deterministic $n^{o(2^d)}$ time algorithm deciding coverability in unary encoded d-dimensional VAS, hence the backward coverability algorithm is conditionally optimal.

4.3 Coverability in Affine Nets

Affine nets [22], also known as affine vector addition systems, are a broad generalisation of VAS and Petri nets encompassing multiple extended VAS operations designed for greater modelling power.

4.3.1 Affine Nets

A d-dimensional (well-structured) *affine net* [22] is a finite set $\mathcal{N}$ of triples $(\boldsymbol{a}, A, \boldsymbol{b}) \in \mathbb{N}^d \times \mathbb{N}^{d \times d} \times \mathbb{N}^d$. It defines a well-structured transition system $(\mathbb{N}^d, \to_{\mathcal{N}}, \sqsubseteq)$ with $\mathbb{N}^d$ as set of configurations and transitions $\boldsymbol{u} \to_{\mathcal{N}} A \cdot (\boldsymbol{u} - \boldsymbol{a}) + \boldsymbol{b}$ for all $\boldsymbol{u}$ in $\mathbb{N}^d$ and $(\boldsymbol{a}, A, \boldsymbol{b})$ in $\mathcal{N}$ such that $\boldsymbol{u} - \boldsymbol{a}$ is in $\mathbb{N}^d$. This model encompasses notably

- VAS and Petri nets when (each such) A is the identity matrix I_d,
- *reset nets* [2, 3] when A is component-wise smaller or equal to I_d,
- *transfer nets* [14] when the sum of values in every column of A is one,
- *post self-modifying nets* [43] – also known as *strongly increasing affine nets* [22, 11] – when A is component-wise larger or equal to I_d, and
- *invertible* affine nets [7] when A is invertible over the rationals, i.e., $A \in \mathsf{GL}_d(\mathbb{Q})$.

As in the case of VAS, we will work with a unary encoding, and we let $\|\mathcal{N}\| \stackrel{\text{def}}{=} \max\{\|\boldsymbol{a}\| \mid (\boldsymbol{a}, A, \boldsymbol{b}) \in \mathcal{N}\}$; note that the entries from $\boldsymbol{b}$ and A are not taken into account.

▶ **Example 4.6.** Consider the affine nets

$$\mathcal{N}_1 \stackrel{\text{def}}{=} \left\{\begin{bmatrix}2\\0\end{bmatrix}, \begin{bmatrix}1&0\\0&1\end{bmatrix}, \begin{bmatrix}0\\1\end{bmatrix}\right\} \quad \mathcal{N}_2 \stackrel{\text{def}}{=} \left\{\begin{bmatrix}0\\0\end{bmatrix}, \begin{bmatrix}1&1\\0&0\end{bmatrix}, \begin{bmatrix}0\\0\end{bmatrix}\right\} \quad \mathcal{N}_3 \stackrel{\text{def}}{=} \left\{\begin{bmatrix}0\\0\end{bmatrix}, \begin{bmatrix}1&1\\2&0\end{bmatrix}, \begin{bmatrix}0\\0\end{bmatrix}\right\}.$$

Then $\mathcal{N}_1$ defines the same WSTS as the 2-dimensional VAS $\boldsymbol{A}_{\div 2} = \{(-2, 1)\}$. Focusing on the effects of their transition matrices, $\mathcal{N}_2$ performs a transfer from its second component into its first component, while $\mathcal{N}_3$ sums the values of its first two components into the first one, and puts the double of its first component into its second one. ⌟

The coverability problem for reset VAS was first shown decidable in 1978 by Arnold and Latteux [3] using the backward coverability algorithm, and the same algorithm applies to all affine nets [18, 22]. Its complexity is considerable: their coverability problem has already an Ackermannian complexity in the reset or transfer cases [42, 20, 40]. In the strongly increasing case, Bonnet, Finkel, and Praveen [11, Lem. 11 and Thm. 13] show how to adapt Rackoff's original argument to derive an upper bound in $n^{2^{O(d \lg d)}}$ on the length of minimal coverability witnesses, with an EXPSPACE upper bound for the problem when d is part of the input, while in the invertible case, Benedikt et al. [7, Thm. 6] show a 2EXPSPACE upper bound.

Control. Before we turn to the case of invertible affine nets, let us show that the descending chains defined by the backward coverability algorithm for affine nets are controlled, with a control very similar to the VAS case (c.f. Fact 4.1).

▶ **Proposition 4.7.** *The descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ defined by equations (13–15) for a d-dimensional affine net $\mathcal{N}$ and a target vector $\boldsymbol{t}$ is (g, n_0)-controlled for $g(x) \stackrel{\text{def}}{=} x + \|\mathcal{N}\|$ and $n_0 \stackrel{\text{def}}{=} \|\boldsymbol{t}\|$.*

Proof. Rather than handling $\mathrm{Pre}_\forall$ computations directly, we use the fact that $\mathrm{Pre}_\forall(S) = \mathbb{N}^d \setminus (\mathrm{Pre}_\exists(\mathbb{N}^d \setminus S))$ for all $S \subseteq \mathbb{N}^d$ and the following statement on $\mathrm{Pre}_\exists$ computations.

▷ Claim 4.8. If $\boldsymbol{u}' \in \min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{u})$, then $\|\boldsymbol{u}'\| \leq \|\boldsymbol{u}\| + \|\mathcal{N}\|$.

Proof of Claim 4.8. In such a situation, there exists a triple $(\boldsymbol{a}, A, \boldsymbol{b}) \in \mathcal{N}$ such that $\boldsymbol{u}' \sqsupseteq \boldsymbol{a}$ and $A \cdot (\boldsymbol{u}' - \boldsymbol{a}) \sqsupseteq \boldsymbol{u} - \boldsymbol{b}$. Let $\boldsymbol{y}$ be defined by $\boldsymbol{y}(i) \stackrel{\text{def}}{=} \max(\boldsymbol{u}(i), \boldsymbol{b}(i)) - \boldsymbol{b}(i)$ for all $1 \leq i \leq d$, thus of size $\|\boldsymbol{y}\| \leq \|\boldsymbol{u}\|$. Then $\boldsymbol{u}' = \boldsymbol{x} + \boldsymbol{a}$ where $\boldsymbol{x}$ is a $\sqsubseteq$-minimal solution of the system of inequalities $A\boldsymbol{x} \sqsupseteq \boldsymbol{y}$.

We are going to show that if $\boldsymbol{x}$ is an $\sqsubseteq$-minimal solution, then $\|\boldsymbol{x}\| \leq \|\boldsymbol{y}\|$. This will yield the result, as then $\|\boldsymbol{u}'\| \leq \|\boldsymbol{y}\| + \|\boldsymbol{a}\| \leq \|\boldsymbol{u}\| + \|\mathcal{N}\|$. Assume by contradiction that $\boldsymbol{x}$ is a $\sqsubseteq$-minimal solution with $\boldsymbol{x}(j) > \|\boldsymbol{y}\|$ for some $1 \leq j \leq d$. Consider $\boldsymbol{x}'$ defined by $\boldsymbol{x}'(j) \stackrel{\text{def}}{=} \|\boldsymbol{y}\|$ and $\boldsymbol{x}'(i) \stackrel{\text{def}}{=} \boldsymbol{x}(i)$ for all $i \neq j$; note that $\boldsymbol{x}' \sqsubsetneq \boldsymbol{x}$. Let us show that $\boldsymbol{x}'$ is also a solution, i.e., that $A\boldsymbol{x}' \sqsupseteq \boldsymbol{y}$: for all $1 \leq i \leq d$,

- if $A(i, j) > 0$ then $\sum_{1 \leq k \leq d} A(i, k) \cdot \boldsymbol{x}'(k) \geq \boldsymbol{x}'(j) \geq \|\boldsymbol{y}\| \geq \boldsymbol{y}(i)$, and
- otherwise $\sum_{1 \leq k \leq d} A(i, k) \cdot \boldsymbol{x}'(k) = \sum_{1 \leq k \leq d} A(i, k) \cdot \boldsymbol{x}(k) \geq \boldsymbol{y}(i)$ since $\boldsymbol{x}$ is a solution.

Thus $\boldsymbol{x}'$ is a solution, contradicting the $\sqsubseteq$-minimality of $\boldsymbol{x}$. ◁

Now, since $D_0 = \mathbb{N}^d \setminus \uparrow \boldsymbol{t}$, $\|D_0\| \leq \|\boldsymbol{t}\| - 1$ by [32, Lem. 3.8]. Regarding the control function, $D_{k+1} = D_k \cap \mathrm{Pre}_\forall(D_k)$ is such that $\|D_{k+1}\| \leq \max(\|D_k\|, \|\mathrm{Pre}_\forall(D_k)\|)$ also by [32, Lem. 3.8]. In turn, regarding $\mathrm{Pre}_\forall(D_k) = \mathbb{N}^d \setminus \mathrm{Pre}_\exists(U_k)$, the minimal elements $\boldsymbol{u}$ of $U_k = \mathbb{N}^d \setminus D_k$ have size $\|\boldsymbol{u}\| \leq \|D_k\| + 1$ still by [32, Lem. 3.8], thus the minimal elements $\boldsymbol{u}'$ of $\mathrm{Pre}_\exists(U_k)$ have size $\|\boldsymbol{u}'\| \leq \|D_k\| + 1 + \|\mathcal{N}\|$ by Claim 4.8, hence $\|\mathrm{Pre}_\forall(D_k)\| \leq \|D_k\| + \|\mathcal{N}\|$ by a last application of [32, Lem. 3.8]. ◀

4.3.2 Invertible Affine Nets

The restriction to invertible affine nets [7] is somehow orthogonal to the usual restrictions to reset/transfer/post self-modifying/... nets. For instance, in Example 4.6, the identity matrix in $\mathcal{N}_1$ is clearly invertible, and the transfer matrix in $\mathcal{N}_2$ is not. More generally, reset nets are never invertible (when they perform resets), and transfer nets are invertible exactly when their matrices are permutation matrices. Nevertheless, some more involved affine nets are invertible, like $\mathcal{N}_3$ in Example 4.6, whose matrix is invertible with inverse $\left[\begin{smallmatrix} 0 & 1/2 \\ 1 & -1/2 \end{smallmatrix}\right]$.

Strong Monotonicity. When dealing with a descending sequence of downwards-closed sets produced by the dual backward coverability algorithm for WSTS, a key observation made in [32] allows to sometimes derive monotonocity. For this, in a WSTS $(X, \to, \leq)$, define $\mathrm{Post}_\exists(S) \stackrel{\text{def}}{=} \{y \in X \mid \exists x \in S \,.\, x \to y\}$. Following [9], for two order ideals I and I', write $I \rightsquigarrow I'$ if I' appears in the canonical decomposition of $\downarrow\mathrm{Post}_\exists(I)$.

▶ **Fact 4.9** ([32, Claim 4.2]). Let $D_0 \supsetneq D_1 \supsetneq \cdots$ be a descending chain of downwards-closed sets defined by equations (13–15). If I_{k+1} is an order ideal proper at step $k+1$, then there exists an order ideal I and an order ideal I_k proper at step k such that $I_{k+1} \rightsquigarrow I \subseteq I_k$.

In the case of affine nets, and identifying order ideals I with vectors in $\mathbb{N}_\omega^d$ with $\omega + n = \omega - n = \omega \cdot n = \omega$ for all n in $\mathbb{N}$, $\downarrow\mathrm{Post}_\exists(I) = \downarrow\{A \cdot (I - \boldsymbol{a}) + \boldsymbol{b} \mid (\boldsymbol{a}, A, \boldsymbol{b}) \in \mathcal{N}, I \sqsupseteq \boldsymbol{a}\}$.

▶ **Proposition 4.10.** *The descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ defined by equations (13–15) for a d-dimensional invertible affine net $\mathcal{N}$ and a target vector $\boldsymbol{t}$ is strongly monotone.*

Proof. Let I_{k+1} be proper at step $k+1$. By Fact 4.9, there exists an order ideal I and an order ideal I_k proper at step k such that $I_{k+1} \rightsquigarrow_{\mathcal{N}} I \subseteq I_k$. Let us show that $\dim I_{k+1} \leq \dim I$; as $\dim I \leq \dim I_k$ because $I \subseteq I_k$, this will yield the result.

Since $I_{k+1} \rightsquigarrow_{\mathcal{N}} I$, there exists $(\boldsymbol{a}, A, \boldsymbol{b})$ in $\mathcal{N}$ such that $I - \boldsymbol{b} = A \cdot (I_{k+1} - \boldsymbol{a})$. For this to hold, note that for all $i \in \mathrm{fin}(I)$, the ith row of A must be such that $A(i,j) = 0$ for all $j \in \omega(I_{k+1})$. As A is invertible, those $(\mathrm{fdim}\, I)$-many rows must be linearly independent. As just argued, the jth column for each of these rows is made of zeroes whenever $j \in \omega(I_{k+1})$. Thus the remaining $(\mathrm{fdim}\, I_{k+1})$-many columns must make those $\mathrm{fdim}\, I$ rows linearly independent, hence necessarily $\mathrm{fdim}\, I_{k+1} \geq \mathrm{fdim}\, I$, i.e., $\dim I_{k+1} \leq \dim I$. ◀

Observe that the proof of Proposition 4.10 does not work for the transfer net $\mathcal{N}_2$ of Example 4.6: $\left[\begin{smallmatrix} \omega \\ \omega \end{smallmatrix}\right] \rightsquigarrow_{\mathcal{N}_2} \left[\begin{smallmatrix} \omega \\ 0 \end{smallmatrix}\right]$; this is exactly the kind of non-monotone behaviour invertibility was designed to prevent. Also observe that $\left[\begin{smallmatrix} 2 \\ \omega \end{smallmatrix}\right] \rightsquigarrow_{\mathcal{N}_3} \left[\begin{smallmatrix} \omega \\ 4 \end{smallmatrix}\right]$ in the invertible affine net $\mathcal{N}_3$, which is not an ω-monotone behaviour: this illustrates the usefulness of capturing strongly monotone descending chains, as [32, Thm. 4.4 and Cor. 4.6] do not apply.

Complexity Upper Bounds. We are now equipped to analyse the complexity of the backward coverability algorithm in invertible affine nets. Regarding the length ℓ of the chain constructed by the algorithm, by Propositions 4.7 and 4.10 we are in the same situation as in Theorem 4.2 and we can simply repeat the arguments from its proof.

▶ **Theorem 4.11.** *The backward coverability algorithm terminates after at most $n^{2^{O(d)}}$ iterations on d-dimensional invertible affine nets encoded in unary when $d \geq 2$.*

We deduce two corollaries from Theorem 4.11: one pertaining to the complexity of the backward coverability algorithm in dimension d, which mirrors Corollary 4.5, and one for the coverability problem when d is part of the input. Let us start with the backward coverability algorithm.

▶ **Corollary 4.12.** *The backward coverability algorithm runs in time $n^{2^{O(d)}}$ on d-dimensional invertible affine nets encoded in unary when $d \geq 2$.*

Proof. Theorem 4.11 shows that the length ℓ of the ascending chain $U_0 \subsetneq U_1 \subsetneq \cdots \subsetneq U_\ell = U_*$ constructed by the backward coverability algorithm is at most $L_d + 1$, which is in $n^{2^{O(d)}}$.

Let $B_k \stackrel{\text{def}}{=} \min_{\sqsubseteq} U_k$ denote the minimal basis at step k. In order to compute B_{k+1} as per (13), thanks to Claim 4.8, we could essentially argue as in the proof of Corollary 4.5, with the caveat that computing bluntly $\min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{v})$ for each $\boldsymbol{v} \in B_k$ is dangerously similar to a linear integer programming question and will incur an additional cost.

Alternatively, recall from equation (16) that $\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)$, the set of order filters $\uparrow \boldsymbol{v}$ such that $\boldsymbol{v}$ is nearly thin, has at most $n^{2^{O(d)}}$ elements, and that $|B_k| \leq |\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)|$ by Corollary 3.7 and Proposition 3.8. Thus in order to compute B_{k+1} one can enumerate the nearly thin vectors $\boldsymbol{v}' \in \mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)$ and check for each $(\boldsymbol{a}, A, \boldsymbol{b}) \in \mathcal{N}$ such that $\boldsymbol{v}' \sqsupseteq \boldsymbol{a}$ whether there exists $\boldsymbol{v} \in B_k$ such that $A \cdot (\boldsymbol{v}' - \boldsymbol{a}) + \boldsymbol{b} \sqsupseteq \boldsymbol{v}$. Each such check can be performed in time polynomial in $\|\boldsymbol{v}'\| \leq N_d + 1 = n \cdot (L_{d-1} + 2) + 1$, n, d, and $|B_k| \leq |\mathrm{Fil}^{\mathsf{thin}+1}(\mathbb{N}^d)|$. Thus the entire computation can be carried out in $n^{2^{O(d)}}$. ◀

As VAS are a particular case of invertible affine nets, the upper bounds in Corollary 4.12 are optimal assuming the exponential time hypothesis by [30, Thm. 4.2].

Our last result concerns the complexity of coverability in invertible affine nets when d is part of the input. Note that the arguments leading to an algorithm working in space $O(d \lg(n \cdot \ell))$ in the VAS case [30, Thm. 3.2] – which are essentially the same as those used to derive a 2EXPSPACE upper bound for invertible affine nets in [7, Thm. 6] – do not work here, as the configurations along an execution of an affine net can grow exponentially with ℓ.

▶ **Corollary 4.13.** *The coverability problem for invertible affine nets is* EXPSPACE*-complete.*

Proof. The hardness for EXPSPACE follows from the hardness of the coverability problem for VAS [34]. Regarding the upper bound, consider the execution of the classical backward coverability algorithm as defined in equation (13) on an invertible affine net $\mathcal{N}$ with target configuration $\boldsymbol{t}$: this is an ascending chain $U_0 \subsetneq U_1 \subsetneq \cdots \subsetneq U_\ell$ where $U_\ell = U_{\ell+1} = U_*$. The following characterisation of coverability actually holds more generally in WSTS.

▷ Claim 4.14. In an affine net $\mathcal{N}$, $\boldsymbol{s}$ covers $\boldsymbol{t}$ if and only if there exists $\ell' \leq \ell$ and a sequence of configurations $\boldsymbol{t}_0, \ldots, \boldsymbol{t}_{\ell'}$, called a *coverability pseudo-witness*, satisfying

$$\boldsymbol{t}_0 \stackrel{\text{def}}{=} \boldsymbol{t}\,, \qquad \boldsymbol{t}_{k+1} \in \min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{t}_k)\,, \qquad \boldsymbol{t}_{\ell'} \sqsubseteq \boldsymbol{s}\,. \tag{17}$$

Proof of Claim 4.14. If a coverability pseudo-witness exists, then we claim that for all $\ell' \geq k \geq 0$ there exists $\boldsymbol{s}_k \sqsupseteq \boldsymbol{t}_k$ such that $\boldsymbol{s} = \boldsymbol{s}_{\ell'} \to_{\mathcal{N}} \boldsymbol{s}_{\ell'-1} \to_{\mathcal{N}} \cdots \to_{\mathcal{N}} \boldsymbol{s}_k$, and thus in particular $\boldsymbol{s} \to^*_{\mathcal{N}} \boldsymbol{s}_0 \geq \boldsymbol{t}_0$ for $k = 0$. We can check this by induction over k. For the base case $k = \ell'$, define $\boldsymbol{s}_{\ell'} \stackrel{\text{def}}{=} \boldsymbol{s}$. For the induction step k, since $\boldsymbol{t}_{k+1} \in \mathrm{Pre}_\exists(\uparrow \boldsymbol{t}_k)$ there exists $\boldsymbol{s}'_k \sqsupseteq \boldsymbol{t}_k$ such that $\boldsymbol{t}_{k+1} \to_{\mathcal{N}} \boldsymbol{s}'_k$; by WSTS compatibility and since $\boldsymbol{s}_{k+1} \sqsupseteq \boldsymbol{t}_{k+1}$, there exists $\boldsymbol{s}_k \sqsupseteq \boldsymbol{s}'_k$ such that $\boldsymbol{s}_{k+1} \to_{\mathcal{N}} \boldsymbol{s}_k$.

Conversely, assume that $\boldsymbol{s}$ covers $\boldsymbol{t}$ in $\mathcal{N}$. Then $\boldsymbol{s} \in U_\ell$, and let $\ell' \leq \ell$ be the least index such that $\boldsymbol{s} \in U_{\ell'}$. Then either $\ell' = 0$, i.e., $\boldsymbol{s} \sqsupseteq \boldsymbol{t} = \boldsymbol{t}_0$ and we are done, or $\ell' > 0$. Because $\boldsymbol{s} \in U_{\ell'}$ there must be some $\boldsymbol{t}_{\ell'} \in \min_{\sqsubseteq} U_{\ell'}$ with $\boldsymbol{s} \sqsupseteq \boldsymbol{t}_{\ell'}$, and $\boldsymbol{t}_{\ell'} \notin U_{\ell'-1}$ as otherwise $\boldsymbol{s}$ would be in $U_{\ell'-1}$, contradicting the minimality of ℓ'. In general, if we have found a sequence $(\boldsymbol{t}_j)_{\ell' \geq j \geq k > 0}$ satisfying (17) until rank $k+1$ included and know that $\boldsymbol{t}_k \in (\min_{\sqsubseteq} U_k) \setminus U_{k-1}$, then either $k = 1$ and $\boldsymbol{t}_1 \in \min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{t}_0)$ by definition of U_0 and U_1 in (13), or $k > 1$

and because $\boldsymbol{t}_k \notin U_{k-1}$, there exists $\boldsymbol{t}_{k-1} \in \min_{\sqsubseteq} U_{k-1}$ such that $\boldsymbol{t}_k \in \min_{\sqsubseteq} \mathrm{Pre}_\exists(\uparrow \boldsymbol{t}_{k-1})$, and $\boldsymbol{t}_{k-1} \notin U_{k-2}$ as otherwise we would have $\boldsymbol{t}_k$ in U_{k-1}. Repeating this process yields a coverability pseudo-witness. ◁

By Claim 4.14, a non-deterministic algorithm for coverability can guess and check the existence of a coverability pseudo-witness. By Theorem 4.11, such a pseudo-witness has a length $\ell' \leq \ell$ in $n^{2^{O(d)}}$. Furthermore, by Claim 4.8 the components in each $\boldsymbol{t}_k$ in such a pseudo-witness are bounded by $\|\boldsymbol{t}\| + \|\mathcal{N}\| \cdot k \leq (\ell+1) \cdot n$, which is still in $n^{2^{O(d)}}$. Thus exponential space suffices. Note that this also holds when we assume the invertible affine net to be encoded in binary, by substituting 2^n for n in the bound $n^{2^{O(d)}}$. ◀

▶ Remark 4.15 (Strictly increasing affine nets). Strictly increasing affine nets [43, 22, 11] are intuitively the affine nets devoid of any form of reset or transfer; in Example 4.6, only $\mathcal{N}_1$ is strictly increasing. All the results we have proven for invertible affine nets in this section – namely in Theorem 4.11 and Corollaries 4.12 and 4.13 – also hold for strictly increasing affine nets, because the descending chains of downwards-closed sets they generate when running the backward coverability algorithm are ω-monotone.

▷ Claim 4.16. The descending chain $D_0 \supsetneq D_1 \supsetneq \cdots$ defined by equations (13–15) for a d-dimensional strictly increasing affine net $\mathcal{N}$ and a target vector $\boldsymbol{t}$ is ω-monotone.

Proof of Claim 4.16. Let I_{k+1} be proper at step $k+1$. By Fact 4.9, there exists an order ideal I and an order ideal I_k proper at step k such that $I_{k+1} \rightsquigarrow_{\mathcal{N}} I \subseteq I_k$. Let us show that $\omega(I_{k+1}) \subseteq \omega(I)$; as $\omega(I) \subseteq \omega(I_k)$ because $I \subseteq I_k$, this will yield the result.

Since $I_{k+1} \rightsquigarrow_{\mathcal{N}} I$, there exists $(\boldsymbol{a}, A, \boldsymbol{b})$ in $\mathcal{N}$ such that $I_{k+1} \sqsupseteq \boldsymbol{a}$ and $I = A \cdot (I_{k+1} - \boldsymbol{a}) + \boldsymbol{b}$. Because $\mathcal{N}$ is strictly increasing, $A = I_d + A'$ for some matrix $A' \in \mathbb{N}^{d \times d}$, hence $I = I_{k+1} - \boldsymbol{a} + A' \cdot (I_{k+1} - \boldsymbol{a}) + \boldsymbol{b}$. Thus $I \sqsupseteq (I_{k+1} - \boldsymbol{a})$ and therefore $\omega(I) \supseteq \omega(I_{k+1})$. ◁

An EXPSPACE upper bound was already shown by Bonnet et al. [11] for the coverability problem, but the $n^{2^{O(d)}}$ bound for the problem parameterised by d is an improvement over the $n^{2^{O(d \lg d)}}$ bounds of [11, Lem. 11 and Thm. 13], and the bounds for the backward coverability algorithm are new. ⌟

FO Logic on Cellular Automata Orbits Equals MSO Logic

Guillaume Theyssier
I2M, CNRS, Université Aix-Marseille, France

Abstract

We introduce an extension of classical cellular automata (CA) to arbitrary labeled graphs, and show that FO logic on CA orbits is equivalent to MSO logic. We deduce various results from that equivalence, including a characterization of finitely generated groups on which FO model checking for CA orbits is undecidable, and undecidability of satisfiability of a fixed FO property for CA over finite graphs. We also show concrete examples of FO formulas for CA orbits whose model checking problem is equivalent to the domino problem, or its seeded or recurring variants respectively, on any finitely generated group. For the recurring domino problem, we use an extension of the FO signature by a relation found in the well-known Garden of Eden theorem, but we also show a concrete FO formula without the extension and with one quantifier alternation whose model checking problem does not belong to the arithmetical hierarchy on group $\mathbb{Z}^2$.

1 Introduction

Symbolic dynamics was historically introduced as the study of one-dimensional infinite words representing discretized orbits of smooth dynamical systems through a finite partition of space [35, 34]. It has since then been largely extended to higher dimensions and arbitrary Cayley graphs of finitely generated groups, and seen rich developments going way beyond the initial motivations. The field of symbolic dynamics would now be better described as the study of sets of configurations (*i.e.* coloring of a graph) which can be defined by local uniform constraints (subshift of finite type, sofic subshift, etc) and maps on configurations acting by a uniform and local update rule (cellular automata, and morphisms between subshifts, which are the continuous maps commuting with translations [26, 12]). A fascinating aspects of these objects is that they are very simple to define, yet can produce very complex behaviors which make them challenging to analyze. They can be considered as a reasonable modeling tool [13], but more importantly, they constitute a natural model of computation for which undecidablity and computational hardness can arise in the most simple and seemingly unrelated questions in a spectacular way [28, 30, 25, 9, 29].

In symbolic dynamics, a major trend is to relate the properties of the considered objects (cellular automata or subshifts) to the structure of the underlying graph they are defined on (usually Cayley graphs of finitely generated groups). An emblematic example is the domino problem: since the breakthrough undecidability result of Berger [9], a lot of works

have focused on the characterization of Cayley graphs of groups for which the domino problem is undecidable [4, 5, 8, 7] or other graphs with less symmetries [20, 27]. Concerning cellular automata (CA), properties of the global map that can be expressed in first-order (FO) logic (or, said differently, FO properties of their orbit graph) are already challenging. For instance, injectivity and surjectivity problems were shown decidable on $\mathbb{Z}$ [1] and on context-free graphs [36], but undecidable on $\mathbb{Z}^2$ [29]. Other FO properties of CA were studied in relation to the graph structure: the Gotschalk conjecture [12, 23] asks whether the property "injectivity implies surjectivity" is true for all CA on all group. Besides, the garden of Eden theorem [12] characterizes amenability among finitely generated groups by the fact that another simple FO property[1] is true for all CA on this group.

It turns out that many central problems considered in symbolic dynamics can actually be rephrased in *monadic second order logic* (MSO). It was for instance noticed in [36] for injectivity and surjectivity of CA. MSO is a logical language that has received enormous interest, probably for its balance between expressivity and decidability in many cases. More precisely, for graph properties, algorithmic metatheorems [36, 15, 17] and reciprocals [32, 33] relates the complexity of the MSO model checking problem to the structure of considered graph or graph family. The key parameter at play here is treewidth [39] which is related to the non-existence of arbitrarily large grid minors [40]: bounded treewidth provides positive algorithmic results, while arbitrarily large grid minors often allows lower bounds or undecidability results. For instance, on a Cayley graph of a finitely generated group, the MSO model checking problem is decidable if and only if the group is virtually free (meaning having a free group as finite index subgroup) [33].

Of course, positive algorithmic results for MSO apply to the particular problems studied in symbolic dynamics, but lower bounds or undecidability results for MSO are not directly transferable. For instance, on the graph $\mathbb{Z}^2$, undecidability of MSO model checking follows from a straightforward encoding of Turing machines, while undecidability of the domino problem [9] or of injectivity problem of CA [29] requires detailed and non-straightforward constructions that involves ideas and tools of independent interest (aperiodic tile sets and space filling curves for instance). Moreover, it is still open to our knowledge whether both problems are undecidable on any Cayley graph of group which is not virtually free. More generally, much work remains to close the gap between the global understanding of MSO logic on arbitrary graphs and the particular MSO fragments at sake in symbolic dynamics that are mostly understood on Cayley graphs of some group families.

Contributions of the paper. In this paper we explore properties of CA on arbitrary labeled graphs (finite or infinite). To do this, we introduce a definition of local rules of CA that doesn't use any explicit reference to the local structure of the graph as it is classically done, but instead just relies on the notion of bounded labeled walks and multiset of possible states read at the end of these walks. In particular, we don't require the graph to be uniform nor to have bounded degree, but our notion exactly corresponds to the classical one on Cayley graphs of finitely generated groups. Moreover, a fixed CA local rule provides a well-defined CA global map on any graph with same label sets. We can thus explore the influence of the graph separately from the local rule. For instance, we can specify a graph property by a CA local rule f and a FO property ϕ of CA orbits: the set of graphs on which the local rule f induces a global map that satisfies ϕ. Our main result (theorems 8, 9 and 12) is then an equivalence between this approach and MSO logic, on arbitrary labeled graphs. Precisely, for every class $\mathcal{C}$ of graphs, the following two conditions are equivalent:

[1] As detailed in Section 5, it uses an additional relation in the FO signature which doesn't break the main point of our approach, an equivalence with MSO.

- there exists an MSO formula Ψ, such that $G \in \mathcal{C} \iff G \models \Psi$,
- there exists a pair (ϕ, f), where ϕ is a FO formula and f is a CA local rule, such that $G \in \mathcal{C}$ if and only if the global map induced by f on G satisfies ϕ.

Moreover, the pair (ϕ, f) can be effectively constructed from Ψ, and conversely.

Said differently, (FO,CA) pairs and MSO formulas define exactly the same graph languages, and the corresponding model checking problems are many-one equivalent on any fixed graph. We believe that this new characterization of MSO is particularly relevant in the context of symbolic dynamics.

First, FO properties of orbits of CA are a conjugacy invariant and were much studied as mentioned above. We obtain a characterization of the decidability of FO model checking for CA orbits on Cayley graphs (Corollary 14) and we show that undecidability can be obtained with a fixed FO formula (Corollary 16) exactly on non virtually free f.g. groups, which should be put in perspective with the Ballier-Stein conjecture [6]. We also obtain undecidability of a satisfiability problem for CA on finite graphs for a fixed FO formula (Corollary 17).

Besides, when fixing an arbitrary FO formula and letting the CA vary, we get fragments of MSO that make sense beyond the examples directly motivated by CA theory. In particular, we show in Section 5 that on Cayley graphs of finitely generated groups, such fragments do not depend on the choice of generators, and that the domino problem and its variants (seeded and recurring) are equivalent to the model checking problem of some simple fixed FO formula (Theorem 19). For this we use an additional relation in the case of the recurring domino problem that remains MSO-expressible (Lemma 18). Finally we obtain a FO formula with just one quantifier alternation whose model checking problem does not belong to the arithmetical hierarchy when fixing the graph $\mathbb{Z}^2$ (Theorem 20).

Warm-up examples. To fix ideas and give some intuition on how FO logic on CA orbits can be used to express graph properties, let us consider two well-known MSO properties and give an informal translation into a pair made of a FO formula and a CA local rule.

▶ **Example 1** (k-Colorable graphs)**.** Fix k and consider an undirected graph $G = (V, E)$. Consider the CA local rule with state set $S = \{0, \dots, k-1\}$ such that a vertex in state i changes its state to $i + 1 \bmod k$ if it has a neighbor in state i and remains in state i otherwise. It can be checked that the CA induced on G by this local rule has a fixed-point if and only if G admits a proper vertex coloring with k colors (*i.e.* a coloring where no two neighboring vertices have the same color).

▶ **Example 2** (Connected graphs)**.** Consider an undirected graph $G = (V, E)$. Consider the state set $S = \{0, 1, a_0, a_1, a_2\}$ and the CA local rule such that a vertex in state $i \in \{0, 1\}$ becomes $1 - i$, a vertex in state a_i becomes 0 if it has a neighbor in $\{0, 1\}$ and $a_{i+1 \bmod 3}$ otherwise. We claim that G is connected if and only if the CA induced on G by this local rule has no periodic orbit of minimal period 6, which is obviously an FO property of orbits.

Comparison with another characterization of MSO by automata. Several previous works established equivalence results between logic formalism and automata theory in the context of MSO languages of graphs. As mentioned above, [36] already noticed that some cellular automata properties can be translated into MSO. Following this, [44] and [42] introduced tiling and automata recognizers that are equivalent to (small) fragments of MSO. In [37], alternating distributed graph automata are introduced that recognize exactly the languages of graphs definable in MSO logic. These distributed automata are close to CA in the sense that they run on configurations (coloring of the input graph by states) and use finite local

memory and local communication between neighboring vertices. However, they are highly non-deterministic (alternating) and their accepting mechanism uses both initialization of the run to a particular configuration, and a global knowledge of the final configuration reached (precisely the set of states present in this configuration). Restrictions of this model to deterministic or non-deterministic automata (instead of alternating) gives strictly weaker fragments.

Our goal here is not to define a single automata model equivalent to MSO. Instead our approach motivated by symbolic dynamics uses deterministic CA on one hand and quantifier alternations in a separated FO formula which plays also the role of the accepting condition on the other hand. A key aspect is that we thus get natural fragments of MSO by fixing the FO formula and letting the CA rule vary. This also makes a strong difference with distributed alternating automata in the accepting mechanism since the FO formula does not offer any direct means of initializing some computation on a particular configuration, nor to detect presence of some particular states in a final configuration.

2 Formal definitions

Graphs. A (Σ, Δ)-labeled graph is a graph $G = (V, (E_\delta)_{\delta\in\Delta}, L)$, which can be finite or infinite, where $L : V \to \Sigma$ is the vertex labeling and $E_\delta \subseteq V \times V$ are the edges labeled by δ. In such a graph, given some finite word $w = w_1 \cdots w_k \in \Delta^*$, a path labeled by w is a sequence of vertices $v_1, \ldots, v_{k+1}$ such that, for any $1 \leq i \leq k$, $(v_i, v_{i+1}) \in E_{w_i}$. All graphs considered in this paper are simple, meaning that there is at most one edge of a given label between two given vertices[2]. Such a graph is said to be *connected* if it is connected as an undirected and unlabeled graph, *i.e.* if $G = (V, E)$ is connected where $(v, v') \in E$ if either $(v, v') \in E_\delta$ or $(v', v) \in E_\delta$ for some $\delta \in \Delta$. The set of connected graphs is denoted by $\mathcal{C}$. Σ will in some case be a singleton and can therefore be silently omitted: we speak about Δ-labeled graph in this case. An important class of graphs studied in symbolic dynamics is that of Cayley graphs of finitely generated (f.g.) groups. Given a f.g. group $(\Gamma, \cdot)$ and a (finite) set of generators Δ (including their inverses), the associated Cayley graph is the Δ-labeled graph where $(\gamma, \gamma') \in E_\delta$ if and only if $\gamma' = \gamma \cdot \delta$. An undirected graph G_1 is a minor of another undirected graph G_2 if it can be obtained from G_2 by deleting edges and vertices, and by contracting edges (*i.e.* identifying the vertices incident to the edge without creating multiple edges).

Cellular automata. Given a finite set of states S and a set of vertices V, a configuration is an element of S^V. It can be seen as a coloring of vertices by S. A CA is a map from configurations to configurations, that is induced by a uniform local rule. It is generally studied as a dynamical system through its set of orbits, which are sequences of configurations obtained by iterating the map from an initial configuration.

CA are usually defined over a fixed Cayley graph of a (f.g.) group [12]. Following this classical approach, the local rule defining a CA is formally a lookup table and is bound to a particular graph as it relies on local patterns defined over bounded balls of the graph. It also requires the graph to be uniform and of bounded degree. More general definitions were proposed that don't stick to a particular graph [3, 2], but they still rely on the hypothesis of bounded degree and use a particular labeling by port numbers.

[2] The hypothesis that our graphs are simple will be used in sections 4 and 5. We choose to adopt this hypothesis across the entire paper for simplicity and clarity, however the main results from Section 3 should also hold without this hypothesis.

We introduce in this section a simple definition of CA on arbitrary labeled graphs. The key advantage of our formalism is that a given local rule actually defines a CA on *any* labeled graph for fixed label sets. We can therefore fix a local rule and asks on which graphs the corresponding CA has a given property (as sketched in Section 1): a pair made of a local rule and a property of CA dynamics actually defines a property of graphs. Moreover, on Cayley graphs of f.g. groups our formalism is equivalent to the classical one. The CA local rules we consider can intuitively be seen as finite memory and finite distance exploring machines working as follows in parallel from each vertex v: they walk from v following all possible Δ-labeled walks up to some length r, and harvest states seen at the end of these walks and count their occurrences up to some constant k, then they decide from this information (a multiset) the new state at vertex v. From this point of view, the edge labeling by Δ acts as local directions that give more information on the position in the graph given a labeled walk, while vertex labeling σ gives some level of non-uniformity as in non-uniform cellular automata [18].

Let us now formalize this definition. Given $v \in V$ and a word $w \in \Delta^*$, we denote by $\mathcal{R}^w(v)$ the set of vertices reachable from v by a path labeled by w. If $w = \epsilon$ (empty word), then $\mathcal{R}^w(v) = \{v\}$ by definition. If G is the Cayley graph of a f.g. group, then $\mathcal{R}^w(v)$ is always a singleton, however there are generally several paths reaching the same vertex.

The k-capped multisets over set X are the multisets where no cardinality is greater than k, and are denoted $\text{MS}^k(X) = \{0, \dots, k\}^X$. Given a multiset $m \in \mathbb{N}^X$, we denote by $\mathsf{cap}^k(m)$ the k-capped multiset such that $\mathsf{cap}^k(m)(x) = \max(m(x), k)$. We denote by $A^{\leq r}$ the words of length at most r over alphabet A including the empty word ϵ. Given a set of states S and a configuration $c \in S^V$ and $v \in V$, the k-capped pattern of radius r at v in c is the k-capped multiset $P(c, v, r, k) \in \text{MS}^k\big(\Delta^{\leq r} \times S\big)$ defined by:

$$P(c, v, r, k) = \mathsf{cap}^k\big((w, s) \mapsto \#\{v' \in \mathcal{R}^w(v) : c_{v'} = s\}\big).$$

▶ **Definition 3** (CA local rules and global maps). *A CA local rule for (Σ, Δ)-labeled graphs of state set S, radius r and using k-capped multisets ($k \geq 1$) is a map*

$$f : \Sigma \times \text{MS}^k\big(\Delta^{\leq r} \times S\big) \to S.$$

For any (Σ, Δ)-labeled graph with vertices V, the global CA map $F_{G,f} : S^V \to S^V$ associated to the local map f and graph G is then defined by $F_{G,f}(c)_v = f(\sigma(c_v), P(c, v, r, k))$ for any configuration $c \in S^V$ and any vertex $v \in V$.

In the sequel, when considering a local map f, it always implicitly comes with a specified state set S and values of r and k defining its domain and image sets. We are mainly interested in the case where Σ is a singleton (uniform CA), but incorporating Σ in our definition allows non-uniformity in the local rule as in non-uniform CA [18].

▶ Remark 4. On a Cayley graph of f.g. group, $P(x, v, r, k)$ gives all the information about configuration x restricted to the ball in the graph centered in v and with radius r: indeed, in this case, $P(x, v, r, k)(q, w) = 1$ if and only if the unique vertex $v' \in \mathcal{R}^w(v)$ is such that $x_{v'} = q$, and $\mathcal{R}^w(v)$ describes the entire ball when w enumerates $\Delta^{\leq r}$. From this observation it follows that in the case of Cayley graphs and when Σ is a singleton, the global CA maps from Definition 3 are exactly the classical global CA maps (see for instance [12]).

Definition 3 explains how a given CA local rule f induces a CA global map $F_{G,f}$ on a given graph. $F_{G,f}$ is the main object of study in CA theory, as it represents a dynamical system.

▶ **Example 5** (Two definitions of Game of Life)**.** Consider the famous Game of Life CA $F : \{0,1\}^{\mathbb{Z}^2} \to \{0,1\}^{\mathbb{Z}^2}$ [10, 22]. In this example Σ is a singleton and thus ignored to simplify notations. First, let G_1 be the Cayley graph of $\mathbb{Z}^2$ with generators $n = (0,1)$, $e = (1,0)$ and their inverses. Let M be the following set of words in $\Delta^{\leq 2}$: n, n^{-1}, e, e^{-1}, ne, ne^{-1}, $n^{-1}e$, $n^{-1}e^{-1}$. Now define the local rule f_1 of radius 2 and using 4-capped multiset by

$$f_1(\mu) = \begin{cases} 1 & \text{if } \mu(1,\epsilon) = 0 \text{ and } \sum_{w\in M} \mu(1,w) = 3 \\ 1 & \text{if } \mu(1,\epsilon) = 1 \text{ and } 2 \leq \sum_{w\in M} \mu(1,w) \leq 3 \\ 0 & \text{otherwise.} \end{cases}$$

One can check that $F_{G_1,f_1} = F$. Now consider the undirected and unlabeled graph $G_2 = (\mathbb{Z}^2, E)$ with $((i,j),(i',j')) \in E$ if $|i-i'| \leq 1$ and $|j-j'| \leq 1$ and $(i,j) \neq (i',j')$. Here we denote $\Delta = \{u\}$. We then define another local rule f_2 of radius 1 and using 4-capped multiset as follows:

$$f_2(\mu) = \begin{cases} 1 & \text{if } \mu(1,\epsilon) = 0 \text{ and } \mu(1,u) = 3 \\ 1 & \text{if } \mu(1,\epsilon) = 1 \text{ and } 2 \leq \mu(1,u) \leq 3 \\ 0 & \text{otherwise.} \end{cases}$$

One can again check that $F_{G_2,f_2} = F$.

Logics. To make the exposition more concise, we suppose some familiarity with standard concepts of formal logic (variables, assignments, quantification, free variables, etc). MSO logic uses first-order variables (usually denoted by lower-case letters) representing vertices and second-order variables (usually denoted by upper-case letters) representing sets of vertices. To help reading, relations in formulas will use infix notation ($x\,R\,y$) while relation in the meta-language will use the set notation ($(x,y) \in R$).

▶ **Definition 6** (MSO formulas and their semantics)**.** *The set MSO formulas over label sets (Σ,Δ) is the set of atomic formulas:*

- *$x\,L\,\sigma$ for x a first-order variable and $\sigma \in \Sigma$ (meaning x has label σ),*
- *$x\,E_\delta\,x'$ for x and x' first-order variables and $\delta \in \Delta$ (meaning that there is an edge labeled δ from x to x'),*
- *$x = x'$ for first-order variables x and x' (meaning that x is equal to x'),*
- *$x \in X$ for first-order variable x and second-order variable X (meaning that x belongs to set X),*

closed by the usual logic connectives ($\vee$, $\wedge$, $\neg$) and quantifiers ($\forall$, $\exists$). Given an MSO formula Ψ, a (Σ,Δ)-labeled graph G and an assignment α of free variables of Ψ we define the semantics in the standard way starting from the obvious meaning of atomic formula above (see [17] for an in-depth introduction). We write $(G,\alpha) \models \Psi$ when Ψ is true on G with assignment α. If Ψ has no free variable, we simply write $G \models \Psi$ when Ψ is true on G.

We will sometimes use substitution of relations with formulas defining them. For instance we can write $\Psi(X, \Psi_R(x_1,x_2))$, where Ψ is a formula using an additional relation symbol R, to denote the MSO formula obtained by substituting Ψ_R for R in Ψ (with the usual precaution of renaming variables if necessary, see [17]).

We now define FO logic over orbits of CA: they are just formulas allowing quantifications over configurations and using two relations, equality and application of one step of the CA global rule.

▶ **Definition 7** (FO formulas and their semantics). *The set of FO formulas is made of atomic formulas:*

- $y = y'$ *(meaning that configuration y is equal to configuration y'),*
- $y \to y'$ *(meaning that the global CA map leads to y' in one step starting from y),*

and closed under the usual logic connectives and quantifiers. Given a FO formula ϕ, a CA global map $F : S^V \to S^V$ and an assignment β of free variables of ϕ to configurations from S^V, we write $(F, \beta) \models \phi$ to denote that F satisfies ϕ with assignment β following the obvious semantics of formulas starting from the relations above. When ϕ has no free variable, we just write $F \models \phi$.

For a CA global map $F : S^V \to S^V$ and a FO formula ϕ with free variables $(y^1, \dots, y^n)$, we use the shortcut $F \models \phi(c^1, \dots, c^n)$ for configurations $c^1, \dots, c^n \in S^V$ to express that $(F, \beta) \models \phi$ where β is the assignment given by $y^i \mapsto c^i$ for $1 \leq i \leq n$. We will also use the FO shortcut $y^0 \to^k_{\neq} y^k$ to represent the FO formula expressing that y^0 leads to y^k in k steps and the $k+1$ configurations involved in this partial orbit are pairwise different:

$$y^0 \to^k_{\neq} y^k \stackrel{\text{def}}{=} \exists y^1, \dots, \exists y^k : \bigwedge_{0 \leq i < k} y^i \to y^{i+1} \wedge \bigwedge_{i \neq j} y^i \neq y^j.$$

Notation convention: we will always use letter Ψ for MSO formulas, x or X for MSO variables, α for MSO assignments, ϕ for FO formulas, y for FO variables, G for graphs, f for CA local rules, F for CA global maps and c for configurations. We use notation c_v to denote state of configuration at vertex v, that's why we prefer the exponent notation $c^1, c^2, \dots$ to denote several configurations.

Combining graphs, CA and logics. The above definitions suggest various definitions of sets of objects (or languages): the graph language $\mathcal{G}(\Psi) = \{G : G \models \Psi\}$, the graph language $\mathcal{G}(\phi, f) = \{G : F_{G,f} \models \phi\}$, the set of CA local rules $\mathcal{CA}(\phi, G) = \{f : F_{G,f} \models \phi\}$, where we use the notation convention above, and where Σ and Δ are fixed so graphs are actually (Σ, Δ)-graphs and CA local rules are rules for such graphs. Moreover, $\mathcal{CA}(\phi, G)$ can be seen as decision problems where inputs are given as local maps of CA (model checking problem of ϕ on G).

3 Translation results

3.1 From FO/CA pairs to MSO

Whatever the state set, a CA configuration can be represented as a tuple of vertex sets: we can code the state at a vertex by the number of sets it belongs to among the tuple. This way, FO variables can easily be translated into tuples of second-order MSO variables undergoing the same quantification and we get an onto map from possible assignments of the tuple of second-order MSO variables onto possible assignments of the corresponding FO variable.

Under that coding, equality of configurations translates into a simple MSO formula with just one universal first-order quantifier. It remains to show that the other relation in the signature of FO, relation $\to$ which represents the application of one step of the CA global map, can also be translated into MSO: this boils down to checking that at each vertex the local rule is correctly applied, which itself boils down to counting up to some constant occurrences of states that can be reached by a labeled walk of bounded length.

▶ **Theorem 8.** *There is a recursive translation τ from pairs (ϕ, f) made of a FO formula ϕ and a CA local rule f to MSO formulas such that the following equivalence holds for any graph G: $F_{f,G} \models \phi \iff G \models \tau(\phi, f)$.*

3.2 From MSO to FO/CA pairs

This converse translation is less straightforward. Let us first give a simplified overview by considering an MSO formula Ψ in prenex normal form, and describing its translation into a CA local rule f together with a FO formula ϕ.

We will use binary configurations (*i.e.* elements of $\{0,1\}^V$) to code either second-order variable assignments (a set coded by its indicator function) or first-order variable assignments (a singleton coded by its indicator function). More generally, we can code several variable assignments in a configuration made of several binary components, *i.e.* configurations over a product alphabet $S = \{0,1\} \times \cdots \times \{0,1\}$. Given a configuration made of a product of binary components coding an assignment of several variables, the truth of an atomic formula using these variables over this assignment can be checked by a CA local rule in a distributed manner. With slightly more work and using a particular FO property of orbits, we can actually test any quantifier free formula in a distributed manner.

The CA local rule together with the FO formula we are going to construct will essentially enforce an erasing process that starts from a configuration made of a product of binary components (to code an assignment of all MSO variables at once) and then removes components of the product one by one at successive steps until reaching a fixed point: on one hand having all information about variables assignment at the start allows to check the truth of the quantifier-free matrix of the MSO formula as hinted before, and, on the other hand, having components to disappear individually in successive steps allows to make a FO quantification over configurations following exactly the MSO quantification over variables.

For instance, taking MSO formula $\Psi = \forall X_1, \exists x_2, \forall X_3, R(X_1, x_2, X_3)$, we construct a FO formula that is essentially of the form:

$$\forall y_1, \exists y_2, \forall y_3 : y_3 \to y_2 \to \ y_1 \circlearrowright$$

and a CA local rule that will ensure that $y_1 \approx a_1$, $y_2 \approx (a_1, a_2)$ and $y_3 \approx (a_1, a_2, a_3)$ where a_1 is an assignment for X_1, a_2 is an assignment for x_2 and a_3 is an assignment for X_3. It will also ensure, when in configuration y_3, that the assignments (a_1, a_2, a_3) satisfy $R(X_1, x_2, X_3)$. It is important to note that successive choices of assignments of variables y_1, y_2 and y_3 corresponds, up to a simple product encoding, to successive choices of assignments for variables X_1, x_2 and X_3. Non-deterministic choices of successive assignments are possible in this construction because they correspond to going backward in time in the canonical orbit enforced by the FO formula above: there is no contradiction with the determinism of cellular automata.

To turn this overview into a concrete construction, several technical points have to be addressed:

- the simplified behavior described above only works on some well-formed configuration; as usual in CA constructions, we will use local error detection and special error states to mark orbits of bad configurations and distinguish them from good ones: here we use two error states that oscillate with period two in order to ensure that any orbit reaching a fixed point has successfully passed all error detection mechanisms.
- to code first-order variables, binary configurations need to have exactly one vertex in state 1 and the local nature of CA prevents from verifying this (it cannot a priori distinguish a configuration with a single 1 from a configuration with two 1s arbitrarily far away, not to mention the case of non-connected graphs). Our construction handles this through the FO formula to be satisfied using a sibling configurations counting trick combined with a particular behavior of the CA which uses additional layers of states.

  The erasing process of the CA mentioned above will therefore take several steps for first-order variables, and only one step for second-order variables.

- checking a quantifier-free formula given an assignment of its variables encoded in a configuration is generally not doable in one step by a CA, especially on non-connected graphs that prevent the CA from communicating between components (think of the example: $x \in X \vee y \in X$) ; to solve this problem our construction will once again rely on a combination of FO logic over several steps and a particular behavior of the CA.

We first give a solution to these technical problems that works when we restrict to connected graphs. This construction is a little simpler than the general case that we address later, and it has the benefit to induce a better controlled dependence of the FO formula on the MSO formula (an aspect that will turn out to be useful in Section 4).

If Ψ is an MSO formula in prenex normal form with quantifier prefix $Q_1, \dots, Q_n$, its prefix signature is the word describing the alternations of quantifiers taking into account both the type of quantification and the order of quantified variables. More precisely, it is the word over alphabet $\{\forall, \exists\} \times \{1, 2\}$ obtained as follows: first map each quantifier to the alphabet according to the actual type and order, then remove any repetition of consecutive identical letters.

▶ **Theorem 9.** *There are two recursive transformations τ_{FO} from MSO formulas to FO formulas and τ_{CA} from MSO formulas to CA local rules such that, for any MSO formula Ψ, the pair made of $\phi = \tau_{FO}(\Psi)$ and $f = \tau_{CA}(\Psi)$ verifies:*

1. *for any connected graph G the following equivalence holds: $G \models \Psi \iff F_{G,f} \models \phi$,*
2. *if Ψ is prenex then ϕ depends only on its prefix signature.*

Let $\Psi = \mathbf{Q}_1 x_1^1, \dots, \mathbf{Q}_1 x_1^{k_1}, \mathbf{Q}_2 x_2^1, \dots, \mathbf{Q}_2 x_2^{k_2}, \dots, \mathbf{Q}_n x_n^1, \dots, \mathbf{Q}_n x_n^{k_n}, R(x_1^1, \dots, x_n^{k_n})$ be any MSO formula in prenex normal form where $\mathbf{Q}_1, \dots, \mathbf{Q}_n$ are the n quantifiers types (either $\forall$ or $\exists$ and either first or second-order) forming the prefix signature, variables $x_i^1, \dots, x_i^{k_i}$ are bound by quantifier of type $\mathbf{Q}_i$ and $R(x_1^1, \dots, x_n^{k_n})$ is the matrix of the prenex normal form (i.e. a quantifier free formula). We use this numbering of variables grouped by quantifiers type to obtain a more compact FO formula that only depends on the prefix signature of Ψ. Let's write $R(x_1^1, \dots, x_n^{k_n})$ in disjunctive normal form:

$$R(x_1^1, \dots, x_n^{k_n}) = \bigvee_{1 \le j \le d} C_j(x_1^1, \dots, x_n^{k_n})$$

where each clause C_j is a conjunction of terms which are atomic formula or negation thereof using variables $x_1^1, \dots, x_n^{k_n}$. Let $\mathcal{O}$ be the set of i such that $\mathbf{Q}_i$ is a first-order quantifier.

Structure of configurations. For each $1 \le i \le n$, let $\omega(i) = \left|\mathcal{O} \cap \{1, \dots, i\}\right|$ and define $\lambda(i) = i + 2 \cdot \omega(i)$. As it will become clear below, $\lambda(n)$ denotes the length of an orbit along which n particular configurations will be identified. Configurations along this orbit will use distinct state sets, and $\lambda(i)$ will also denotes the number of layers of the i-th configuration. We first introduce sets S_l for $1 \le l \le \lambda(n)$ that will be used to hold variable assignments and translate MSO quantification over variables of first or second-order into FO quantification over configurations. S_l is a product of l *layers* each of the form $\{0,1\}^{k_i}$ (*variable* layer) or $\{1, \dots, k_i\}$ (*choice* layer) for some i, or $\{0, 1\}$ (*control* layer). Intuitively, variable layers will hold MSO variables assignments, and choice and control layers are used only for first-order variables as a control mechanism. Sets S_l are precisely defined as follows:

- $S_1 = \{0,1\}^{k_1}$ and if $1 \in \mathcal{O}$ then $S_2 = S_1 \times \{1, \dots, k_1\}$ and $S_3 = S_2 \times \{0, 1\}$,
- for $1 \le i < n$, $S_{\lambda(i)+1} = S_{\lambda(i)} \times \{0,1\}^{k_{i+1}}$ and if $i + 1 \in \mathcal{O}$ then $S_{\lambda(i)+2} = S_{\lambda(i)+1} \times \{1, \dots, k_{i+1}\}$ and $S_{\lambda(i)+3} = S_{\lambda(i)+2} \times \{0, 1\}$.

If $j = \lambda(i) \leq l$ with $i \notin \mathcal{O}$ or $j = \lambda(i) - 2 \leq l$ with $i \in \mathcal{O}$ then the j-th layer of S_l is a *variable* layer, denoted as $V_i(S_l)$, and intuitively represents an assignment for the tuple of variables $x_i^1, \ldots, x_i^{k_i}$. For $1 \leq j \leq k_i$, we denote by $V_i^j(S_l)$ the j-th binary component of $V_i(S_l)$ which intuitively represents an assignment for variable x_i^j. For $i \in \mathcal{O}$ and $j = \lambda(i) - 1 \leq l$, the jth layer of S_l is a choice layer, denoted $\chi_i(S_l)$. Other layers, precisely j-th layers with $j = \lambda(i)$ with $i \in \mathcal{O}$, are *control* layers and denoted $K_i(S_l)$. Choice layer χ_i together with control layer K_i are used to ensure that the corresponding variable layer V_i correctly encodes a k_i-tuple of assignments of first-order variables, *i.e.* is a k_i-tuple of binary configurations each having exactly one position in state 1.

We denote by π the natural projection from S_l onto S_{l-1} (for any $2 \leq l \leq \lambda(n)$) which removes the last (l-th) layer of elements of S_l.

A well-formed configuration where all vertices are in a state from $S_{\lambda(n)}$ intuitively contains an assignment for all variables involved in formula Ψ (provided the control mechanism for first-order variables to be detailed below has been successful). We need to implement a distributed check of the truth of quantifier-free formula R on such an assignment. The key is to ensure that some clause C_j from the disjunctive normal form of R is chosen uniformly on the entire graph and to check everywhere that each terms of C_j is locally correct given the assignment. For $1 \leq j \leq d$, let $T_j = S_{\lambda(n)} \times \{j\}$ (recall that d is the number of clauses in the disjunctive normal form of $R(x_1^1, \ldots, x_n^{k_n})$). We again use notation π to denote the natural projection from T_j onto $S_{\lambda(n)}$, which removes the last component of states. T_j sates will be used to check clause C_j.

We can now define the state set of the CA $\tau_{CA}(\Psi)$ as

$$S = \{e_0, e_1\} \cup \bigcup_{1 \leq l \leq \lambda(n)} S_l \cup \bigcup_{1 \leq j \leq d} T_j$$

where e_1 and e_2 are distinct elements from the rest of S. We say that the *type* of an element of S is l if it belongs to S_l, *error* if it is e_0 or e_1 and *j-truth-check* if it belongs to T_j. We also naturally extend the notation V_i, χ_i and K_i for any state $s \in T_j$ by $V_i(s) = V_i(\pi(s))$, $\chi_i(s) = \chi_i(\pi(s))$ and $K_i(s) = K_i(\pi(s))$.

A configuration $c \in S^V$ is *valid* if the following conditions hold:

- states of all pairs of neighboring vertices of G are of the same type, and not of error type;
- choice layer χ_i of all pairs of neighboring vertices of G are equal;
- at each vertex v the control layers have zeros where the corresponding variable layers indicated by the choice layers have, precisely: $K_i(c_v) \leq V_i^{\chi_i(c_v)}(c_v)$ for all i such that $K_i(c_v)$ is defined (intuitively, a 1 in a control layer is authorized only if their is a 1 in the 'chosen' component of the corresponding variable layer);

Note that this definition of validity is purely local. For μ a capped multiset (second argument of the local rule of a CA), we write $\texttt{valid}(\mu)$ to express the local validity conditions above on μ: the first two item are checked on each pair of states (s, s') such that $\mu(s, \epsilon) \geq 1$ and $\mu(s', \delta) \geq 1$ for some $\delta \in \Delta$; the third item is checked on state s such that $\mu(s, \epsilon) \geq 1$.

CA local rule. The behavior of the CA local rule $f = \tau_{CA}(\Psi)$ can intuitively be described as follows:

- check the local validity of the configuration and if not generate states of error type that alternate with period 2 (between e_0 and e_1),
- apply projection π on states of type l with $l \geq 2$ and let states of type 1 unchanged,
- on states of type j-truth-check, verify that the assignment of variables $x_1^1, \ldots, x_n^{k_n}$ coded in variable layers V_i^j are such that $C_j(x_1^1, \ldots, x_n^{k_n})$ holds, and apply π if it is the case, or generate an error state otherwise.

Of course, the behavior on states of type j-truth-check above has to be understood locally since we are defining a CA. The implementation of this distributed truth check is as follows: each term $t(x_a^b, x_p^q)$ appearing in clause C_j (an atomic formula or its negation), where x_a^b is a first-order variable, is checked only at any vertex having a V_a^b component at 1, otherwise it is considered true by default. More precisely, for a pair (σ, μ) made of a vertex label and a capped multiset (arguments of the local rule f), we write $(\sigma, \mu) \models_{loc} C_j$ (clause C_j is locally valid) if the local state (unique s such that $\mu(s, \epsilon)$) is of type j-truth-check and the neighboring states also, and if all terms of C_j are locally true according to the previous rule. It turns out that $(\sigma, \mu) \models_{loc} C_j$ can be checked by a local rule of CA of radius 1 and using 1-capped multisets (*i.e.* sets). Precisely, all possible terms of clause C_j are treated as follows (denoting again s the unique state such that $\mu(s, \epsilon) \geq 1$):

- $x_a^b \, L \, \sigma'$ (resp. its negation) is true if and only if $V_a^b(s) = 0$ or if $\sigma = \sigma'$ (resp. $\sigma \neq \sigma'$),
- $x_a^b \, E_\delta \, x_p^q$ (resp. its negation) is true if and only if $V_a^b(s) = 0$ or if $1 \in \{V_p^q(q') : \mu(q', \delta) \geq 1\}$ (resp. 1 does not belong to this set),
- $x_a^b = x_p^q$ (resp. its negation) is true if and only if $V_a^b(s) = 0$ or $V_p^q(s) = 1$ (resp. $V_p^q(s) = 0$),
- $x_a^b \in x_p^q$ (resp. its negation) is true if and only if $V_a^b(s) = 0$ or $V_p^q(s) = 1$ (resp. $V_p^q(s) = 0$).

For t a term, we write $(\sigma, \mu) \models_{loc} t$ if t is locally true according to the above definition. Recall that x_a^b is a first order variable and the rest of the construction will ensure that, on configurations that matter, there will always exist a node at which $V_a^b(s) = 1$ so these tests will actually check that the assignments of variables encoded in the configuration do satisfy the term as desired.

The CA local rule f is then defined as follows (denoting again s the unique state such that $\mu(s, \epsilon) \geq 1$):

$$f(\sigma, \mu) = \begin{cases} e_{1-i} & \text{if } s = e_i \\ e_0 & \text{otherwise, and if } \neg \texttt{valid}(\mu), \\ e_0 & \text{otherwise, and if } s \text{ has type } j\text{-truth-check and } (\sigma, \mu) \not\models_{loc} C_j, \\ s & \text{otherwise, and if } s \text{ is of type 1}, \\ \pi(s) & \text{otherwise.} \end{cases}$$

FO formula. Most of the task of the FO formula is to check that n configurations are well-positioned in an orbit leading to a fixed-point. However, along this orbit, we also have to make checks to ensure that layers corresponding to first-order variables are well formed. For $i \in \mathcal{O}$, the CA behavior already ensures (by generating error states if not) that choice layers χ_i are uniform and that control layers K_i are upper-bounded by the chosen corresponding variable layer V_i^j. In this context, the check is done as follows (intuitively, variable y^i represents a configuration of type $\lambda(i)$ at each vertex, for some $i \in \mathcal{O}$):

$$\texttt{goodFOVAR}(y^i) \stackrel{\text{def}}{=} \forall y, \forall y', (y^i \to^2_{\neq} y' \wedge y \to^2_{\neq} y') \Rightarrow \texttt{\#siblings}(y) = 1,$$

where the formula $\texttt{\#siblings}(y) = 1$ expresses that there is exactly 1 configuration other than y with same image as y and can be written explicitly in FO as follows:

$$\exists y_s, \exists y_+, y_s \to y_+ \wedge y \to y_+ \wedge y_s \neq y \wedge (\forall y' : y' \to y_+ \Rightarrow (y' = y \vee y' = y_s)).$$

The idea is that a variable layer V_i is good if, for any choice j made in choice layer χ_i, there are only 2 possible ways to correctly complete the control layer K_i, because there is exactly one vertex v at which V_i^j is 1 and therefore at which K_i can be freely chosen to be 0 or 1.

Let us now define formulas to deal with the global structure of the orbit leading to a fixed point:

$$\texttt{seq}_1(y) \stackrel{\text{def}}{=} \begin{cases} y \to y & \text{if } 1 \notin \mathcal{O}, \\ \exists y^0, y \to^2_{\neq} y^0 \wedge y^0 \to y^0 \wedge \texttt{goodFOVAR}(y) & \text{if } 1 \in \mathcal{O}, \end{cases}$$

and for any $2 \leq i \leq n$

$$\texttt{seq}_i(y, y^+) \stackrel{\text{def}}{=} \begin{cases} y^+ \to y & \text{if } i \notin \mathcal{O} \\ y^+ \to^3_{\neq} y \wedge \texttt{goodFOVAR}(y^+) & \text{if } i \in \mathcal{O} \end{cases}.$$

Then, denote by $\texttt{good}_i(y^1, \ldots, y^i)$ for each $1 \leq i \leq n$ the formula:

$$\texttt{good}_i(y^1, \ldots, y^i) \stackrel{\text{def}}{=} \texttt{seq}_1(y^1) \wedge \bigwedge_{2 \leq k \leq i} \texttt{seq}_k(y^{k-1}, y^k).$$

The truth check for R has to make a non-deterministic choice of clause C_j to then use the distributed truth check implemented in the CA, we therefore define the following formula to be used in ϕ: $\texttt{truth}(y) \stackrel{\text{def}}{=} \exists y' \to y$ which make sense when y represents a configuration everywhere of type $\lambda(n)$.

As we show later, formula $\texttt{good}_i(y^1, \ldots, y^i)$ paired with CA F ensures that the configuration assigned to y^i is a well-formed configuration of type $\lambda(i)$ that holds an assignment for variables $(x_i^1, \ldots, x_i^{k_i})$ through its variable components $V_i^1, \ldots, V_i^{k_i}$. We use these formulas in ϕ to make restricted domain FO quantifications that exactly correspond to well-formed configurations that hold assignments of the corresponding MSO variables.

To make the formula ϕ more readable, we use the following syntactic sugar to express restricted domain quantification. If ϕ_D and ϕ are formulas containing y as free variable, then:

- $\exists y \in \phi_D, \phi$ stands for $\exists y, \phi_D \wedge \phi$,
- $\forall y \in \phi_D, \phi$ stands for $\forall y, \phi_D \Rightarrow \phi$.

We can finally define FO formula $\phi = \tau_{FO}(\Psi)$:

$$\phi \stackrel{\text{def}}{=} \mathbf{Q}'_1 y^1 \in \texttt{good}_1(y^1), \mathbf{Q}'_2 y^2 \in \texttt{good}_2(y^1, y^2), \ldots, \mathbf{Q}'_n y^n \in \texttt{good}_n(y^1, \ldots, y^n), \texttt{truth}(y^n)$$

where the FO quantifier $\mathbf{Q}'_i$ is $\exists$ if the MSO quantifier $\mathbf{Q}_i$ is existential, and $\forall$ if $\mathbf{Q}_i$ is universal.

Correctness of the construction. First, it can be checked that ϕ only depends on the prefix of Ψ and not on R. Second, the construction of f and ϕ are clearly computable from Ψ. The proof of Theorem 9 then relies on two lemmas. The first one ensures that $\texttt{good}_i(\ldots)$ predicates correctly translate assignments of FO variables quantified in ϕ into assignments of MSO variables quantified in Ψ and conversely.

▶ **Lemma 10.** *Let G be a (Σ, Δ)-labeled graph which is connected. Consider configurations $c^1, \ldots, c^i$ with $1 \leq i \leq n$ such that $F_{G,f} \models \texttt{good}_i(c^1, \ldots, c^i)$, then the following holds:*

1. *c^k is of type $\lambda(k)$ at each vertex, for $1 \leq k \leq i$;*
2. *for $1 \leq l \leq i$ and $1 \leq j \leq k_l$, variable component $V_l^j(c^k)$ is the same for all k with $l \leq k \leq i$, and it is such that exactly one vertex is in state 1 when $l \in \mathcal{O}$;*

3. *if $i < n$, for any assignment α of variables $(x_{i+1}^1, \dots, x_{i+1}^{k_{i+1}})$ there exists c^{i+1} such that*

$$F_{G,f} \models \texttt{good}_{i+1}(c^1, \dots, c^{i+1})$$

and $V_{i+1}^j(c^{i+1}) = \alpha(x_{i+1}^j)$ for all $1 \leq j \leq k_{i+1}$.

From the above lemma, if $F_{G,f} \models \texttt{good}_i(c^1, \dots, c^i)$ then c^i codes an assignment for all MSO variables x_l^j for $1 \leq l \leq i$ and $1 \leq j \leq k_l$ through components V_l^j of c^i. Precisely, when $l \in \mathcal{O}$ variable x_l^j is assigned to the unique vertex v such that $V_l^j(c_v^i) = 1$, and when $l \notin \mathcal{O}$ variable x_l^j is assigned to the set of vertices $\{v : V_l^j(c_v^i) = 1\}$. We denote this assignment by α_{c^i}. Moreover, α_{c^i} is an extension of assignment α_{c^j} for any $1 \leq j < i$.

Next lemma ensures that $\texttt{truth}(\dots)$ predicate correctly codes truth of formula $R(\dots)$ (matrix of Ψ) through the previous assignment translation.

▶ **Lemma 11.** *Under the hypothesis of Lemma 10, it holds that $F_{G,f} \models \texttt{truth}(c^n)$ if and only if $(G, \alpha_{c^n}) \models R(x_1^1, \dots, x_n^{k_n})$.*

The proof of Theorem 9 then consists in applying inductively the definition of truth by assignments of variables simultaneously in Ψ and ϕ, use Lemma 11 as base case and Lemma 10 for the induction step to translate assignments between MSO variables and FO variables.

Generalizing to arbitrary graphs. In the previous construction, we use the fact that considered graphs are connected in two places: to ensure uniformity of choice layers χ_i and to ensure a uniform choice of j for testing clause C_j with states of type j-truth-check. When generalized to possibly disconnected graphs, such uniformity conditions cannot be checked by the CA alone, simply because the CA has no possibility to communicate between connected components. We can compensate this impossibility by slightly changing the behavior of F and adding new FO constraints in the definition of ϕ. The price to pay is that the new definition of ϕ will depend on all parts of Ψ, not only its prefix signature.

First, the case of choice layers χ_i can be solved easily by de-grouping variables x_i^1 to $x_i^{k_i}$, *i.e.* renumbering variables in the prefix of Ψ by letting $k_i = 1$ and taking $\sum_{1 \leq i \leq n} k_i$ as the new value of n. Then, choice layers become trivial (they contain just one state) and are therefore always uniform by definition.

To solve the case of truth check, we introduce a general pre-image counting trick to ensure that a configuration c is uniform by a FO property. First, each state s of the alphabet S used by c is associated to a distinct prime number p_s, and there is a probing mechanism that selects a set of vertices and allows exactly p_s predecessors at selected vertices which are in state s, and only 1 at vertices which are not selected. The trick to check that c is s-uniform then consists in counting the number of pre-images up to $\max_{s' \in S} p_{s'}$: whatever the set of selected vertices, it should always be a power of p_s.

▶ **Theorem 12.** *There are two recursive transformations τ_{FO} from MSO formulas to FO formulas and τ_{CA} from MSO formulas to CA local rules such that for any MSO formula Ψ, and any graph G the following equivalence holds: $G \models \Psi$ if and only if $F_{G,\tau_{CA}(\Psi)} \models \tau_{FO}(\Psi)$.*

Using notations from the construction of Theorem 9, let us now describe precisely the modifications required to generalize to arbitrary graphs. As explained above, we assume $k_i = 1$ for all $1 \leq i \leq n$, so choice layers χ_i are always trivial and uniform. States of type l for $1 \leq l \leq \lambda(n)$ are identical as in the construction of Theorem 9. However, we need additional states to implement the truth check for the matrix R of formula Ψ, and it will spread over 3 time steps of the CA. The key is to ensure that some clause C_j from the disjunctive normal form of R is chosen uniformly on the entire graph and to check everywhere

that each terms of C_j is locally correct given the assignment. Let $2 = p_1 < p_2 < \cdots < p_d$ be the first d prime numbers. For $1 \leq j \leq d$, let $T_j^0 = S_{\lambda(n)} \times \{j\}$ and $T_j^1 = T_j^0 \times \{0,1\}$ and $T_j^2 = T_j^1 \times \{1, \ldots, p_j\}$. T_j^1 is used to *mark* vertices, while T_j^2 is used to alter the number of pre-images depending on j and the mark. We use the notation π to denote at the same time the natural projection from T_j^0 onto $S_{\lambda(n)}$, or from T_j^1 onto T_j^0 or from T_j^2 onto T_j^1, which removes the rightmost component of states. T_j^0 sates will be used to check clause C_j, while states from T_j^1 and T_j^2 will be used to guarantee through a pre-image counting trick that the same choice of j is made on the entire graph, thus ensuring correctness of the truth check of formula R.

We can now define the state set of the CA local rule $\tau_{CA}(\Psi)$ as

$$S = \{e_0, e_1\} \cup \bigcup_{1 \leq l \leq \lambda(n)} S_l \cup \bigcup_{1 \leq j \leq d} T_j^0 \cup T_j^1 \cup T_j^2.$$

We say that the *type* of an element of S is l if it belongs to S_l, *error* if it is e_0 or e_1 and (j,m)-*truth-check* if it belongs to T_j^m for $1 \leq j \leq d$ and $m = 0, 1$ or 2.

A configuration $c \in S^V$ is *valid* if the following conditions hold:

- states of all pairs of neighboring vertices of G are of the same type, and not of error type;
- at each vertex v the control layers have zeros where the corresponding variable layers indicated by the choice layers have, precisely: $K_i(c_v) \leq V_i^{\chi_i(c_v)}(c_v)$ for all i such that $K_i(c_v)$ is defined (intuitively, a 1 in a control layer is authorized only if their is a 1 in the 'chosen' component of the corresponding variable layer);
- for a state $(s, m, w) \in T_j^2$ where $s \in T_j^0$, $m \in \{0,1\}$ and $w \in \{1, \ldots, p_j\}$, it must be the case that $w = 1$ whenever $m = 0$ (this condition expresses intuitively, that only marked vertices can generate pre-images and it will allow through a pre-image counting trick in the FO formula to ensure that the choice to check truth of clause j is coherent on the entire graph).

We write $\texttt{valid}(\mu)$ when the capped multiset μ represents a locally valid neighborhood according to the above conditions.

The modified CA local rule f is almost identical as the one from Theorem 9 and defined as follows (denoting again s the unique state such that $\mu(s, \epsilon) \geq 1$):

$$f(\sigma, \mu) = \begin{cases} e_{1-i} & \text{if } s = e_i \\ e_0 & \text{otherwise, and if } \neg\texttt{valid}(\mu), \\ e_0 & \text{otherwise, and if } s \text{ has type } (j,0)\text{-truth-check and } (\sigma,\mu) \not\models_{loc} C_j, \\ s & \text{otherwise, and if } s \text{ is of type 1,} \\ \pi(s) & \text{otherwise.} \end{cases}$$

The key aspect of this new construction is that the correctness of the distributed truth check implemented in the CA above by states of type (j,m)-truth check rely on a modification of the considered FO formula. Let $\texttt{preimg}_j(y)$ be a FO formula expressing that the number of pre-images of y is either $> p_d$ or a multiple of p_j. We use the following modified definition of formula $\texttt{truth}(y)$:

$$\texttt{truth}(y) \stackrel{\text{def}}{=} \bigvee_{1 \leq j \leq d} \exists y^j : y^j \to y \wedge \left(\forall y' : y' \to y^j \Rightarrow \texttt{preimg}_j(y')\right)$$

which intuitively makes sense when y represents a configuration everywhere of type $\lambda(n)$, so y^j represents of configuration of type $(j,0)$-truth check everywhere. We this new definition of $\texttt{truth}(y)$, we introduce a strong dependence of the FO-formula on the matrix part of Ψ (by the presence of d for instance), which was not the case in Theorem 9.

The final FO formula ϕ is defined exactly as in Theorem 9 but using this modified version of $\texttt{truth}(y)$:

$$\phi \stackrel{\text{def}}{=} \mathbf{Q}'_1 y^1 \in \texttt{good}_1(y^1), \mathbf{Q}'_2 y^2 \in \texttt{good}_2(y^1, y^2), \ldots, \mathbf{Q}'_n y^n \in \texttt{good}_n(y^1, \ldots, y^n) : \texttt{truth}(y^n)$$

where the FO quantifier $\mathbf{Q}'_i$ is $\exists$ if the MSO quantifier $\mathbf{Q}_i$ is existential, and $\forall$ if $\mathbf{Q}_i$ is universal.

The proof of Theorem 12 is based on two lemmas adapted from Lemma 10 and 11, and can be copied word for word from the proof of Theorem 9, but simply removing the connectedness hypothesis.

4 Consequences on FO model checking for CA

A set of (Σ, Δ)-labeled graphs, or graph language, is *MSO-definable* if it is of the form $\mathcal{G}(\Psi)$ for some MSO formula Ψ. It is *FOCA-definable* if it is of the form $\mathcal{G}(\phi, f)$ for some FO formula ϕ and some CA local rule f. From Theorem 12, we get the following immediate corollary.

▶ **Corollary 13.** *MSO-definable and FOCA-definable graph languages are the same.*

Since the translations given in Section 3 are effective, we also obtain equivalence of model checking problems. Using [33], this gives a characterization of decidability of FO model checking for CA orbits on f.g. groups.

▶ **Corollary 14.** *On any fixed graph, FO model checking for CA is many-one equivalent to MSO model checking. In particular, FO-model checking for CA on a f.g. group Γ is decidable if and only if Γ is virtually free.*

We can get a more precise result on graphs of bounded degree, but we need an additional lemma in order to apply Theorem 9. It is well-known that undecidability in MSO can be obtained using the MSO-definability of grids and encoding Turing-computations on it [17]. Moreover, MSO on bounded degree graphs actually allows to code quantification on edge sets and not only vertex sets [16], so that we can express the grid minor relation (and not only the fact that a fixed graph is a minor). The following lemma doesn't use any new idea, but it ensures the fact that all this encoding process can be done within a fixed prefix signature. It also gives a variant of the construction for Σ^1_1-hardness (see [41]) using infinite grids and the recurring domino problem [25].

A $n \times n$-grid (or simply a grid when n is not specified), is the directed finite graph with vertices $\{(i, j) : 1 \leq i, j \leq n\}$ and edges the set of pairs $\big((i, j), (i + 1, j)\big)$ (the east edges) for $1 \leq j \leq n$ and $1 \leq i < n$, and pairs $\big((i, j), (i, j + 1)\big)$ (the north edges) for $1 \leq j < n$ and $1 \leq i \leq n$. A ∞-grid is the infinite directed graph with vertices $\mathbb{N} \times \mathbb{N}$ and same north/east adjacency relation.

▶ **Lemma 15.** *Fix some D. There exists a fixed quantifier prefix signature ρ for MSO such that, for any graph G of degree at most D that contains arbitrarily large grid as minors, deciding whether a given MSO formula in prenex form with prefix signature ρ is satisfied on G is undecidable. There also exists a fixed quantifier prefix signature ρ' for MSO such that, for any graph G of degree at most D that contains a ∞-grid as minor, deciding whether a given MSO formula in prenex form with prefix signature ρ' is satisfied on G is Σ^1_1-hard.*

This lemma together with Theorem 9 gives undecidability of model checking for a fixed FO formula expressed in the following corollary. For the first part of the corollary, we use the grid minor theorem [40] to translate the statement of the lemma in terms of treewidth [39],

and for the second part, it is known that the Cayley graph of a f.g. group which is not virtually free has a thick end (see [6]), hence it contains a ∞-grid as a minor by Halin's grid theorem [24]. The decidable part of the Corollary comes from [14, 36].

▶ **Corollary 16.** *Fix some D. There is a fixed FO formula ϕ such that for any connected graph G of degree at most D, the set $\mathcal{CA}(G, \phi)$ is computable if and only if G has finite treewidth. Moreover, there is a FO formula ϕ' such that for any Cayley graph G of a f.g. group with at most D generators, the set $\mathcal{CA}(G, \phi)$ is:*

- *computable if the group is virtually free,*
- *Σ^1_1-hard otherwise.*

In the context of modeling, it makes sense to consider distributed dynamical systems over arbitrary finite graphs. For instance automata networks (which are non-uniform CA on arbitrary finite graphs) are a well-established model for its use in the study of gene regulation networks [43, 31]. The theory of automata networks has largely grown around FO properties of orbits (typically fixed points) and their crucial dependence on the graph [38]. However, although many results deal with computational complexity in automata networks [11, 21], no natural undecidability result appeared so far to our knowledge. By our translation result from MSO, we can import Trakhtenbrot's theorem [19] to obtain an undecidability result for FO properties of CA orbits on finite graphs. It can intuitively be formulated as follows in the context of modeling: it is undecidable to know whether there is some finite interaction graph on which a given local interaction law (CA) induces a given dynamical property (FO). By the way, this corollary doesn't need Trakhtenbrot's theorem since we have all the expressive power of MSO (not only FO logic on graphs), and we can obtain it for a fixed FO formula. For instance, it follows directly from Theorem 9 and the techniques of Lemma 15 (see also [17, Theorem 5.6]).

▶ **Corollary 17.** *There exists a FO formula ϕ such that the following problem is undecidable: given some input CA local rule f, decide whether there exists a finite graph G with $F_{G,f} \models \phi$.*

5 Cayley graphs and domino problems

The case of Cayley graphs of f.g. groups is particular for our approach in two relevant ways. First, we can express in MSO that a set of vertices is infinite.

▶ **Lemma 18.** *For any $D \geq 1$, there is an MSO formula $\Psi(X)$ such that, on any Cayley graph G of some f.g. group with D generators and any assignment α, it holds that $(G, \alpha) \models \Psi(X)$ if and only if $\alpha(X)$ is infinite.*

From this lemma, it makes sense to extend the signature of FO logic with the addition of new relation $\overset{\infty}{=}$ on configurations which is at the heart of the 'Garden of Eden' theorem [12]: we write $c \overset{\infty}{=} c'$ whenever $\{v : c_v \neq c'_v\}$ is finite. We denote by FO($\overset{\infty}{=}$) the extension of FO signature by adding relation $\overset{\infty}{=}$. By Lemma 18, this extension remains within MSO. Precisely, in any fixed Cayley graph of a f.g. group and by a straightforward extension of Theorem 8, we can compute from any formula in FO($\overset{\infty}{=}$) and CA local rule, an equivalent MSO formula. We deduce that FO($\overset{\infty}{=}$) model checking for CA is decidable on some f.g. group exactly when MSO model checking is, and exactly when FO model checking for CA is.

Besides, if Γ is a f.g. group and G_1 and G_2 two Cayley graphs of Γ with two different sets of generators Δ_1 and Δ_2, then the definable CA global maps $F : S^\Gamma \to S^\Gamma$ are the same on G_1 and G_2. More precisely, there is a computable translation τ on CA local maps such that for any local map f for G_1, it holds: $F_{G_1,f} = F_{G_2,\tau(f)}$. This simply comes from the fact that we can translate Δ_1-walks into equivalent Δ_2-walks.

Therefore, if ϕ is a FO formula, we have that the sets $\mathcal{CA}(\phi, G_1)$ and $\mathcal{CA}(\phi, G_2)$ are actually Turing-equivalent. Said differently, by Theorem 8, any FO formula (actually any FO($\overset{\infty}{=}$) formula) defines a fragment of MSO logic whose model checking problem's Turing degree is independent of the choice of generators on a f.g. group Γ. It turns out that such fragments naturally capture the domino problem and its classical variants.

Given some finite set S, a domino specification $\mathcal{D}$ is a set of pairs $D_\delta \subseteq S^2$ for each $\delta \in \Delta$. A configuration $c \in S^V$ is said $\mathcal{D}$-valid for some graph if for any $v, v' \in V$ it holds: $(v, v') \in E_\delta$ implies $(c_v, c_{v'}) \in R_\delta$. The domino problem on a fixed graph, consists in deciding given $\mathcal{D}$ whether there exists a $\mathcal{D}$-valid configuration. The seeded domino problem consists in deciding given $\mathcal{D}$ and $s_0 \in S$ whether there exists a $\mathcal{D}$-valid configuration where s_0 occurs at some vertex. Finally, the recurring domino problem consists in deciding given $\mathcal{D}$ and $s_0 \in S$ whether there exists a $\mathcal{D}$-valid configuration where s_0 occurs infinitely often.

▶ **Theorem 19.** *Fix any Cayley graph G of any f.g. group, then:*

- *domino problem $\equiv_T \exists x, x \to x$,*
- *seeded domino problem $\equiv_T \exists x, \exists y, x \to x \wedge y \to x \wedge x \neq y$,*
- *recurring domino problem $\equiv_T \exists x, \exists y, x \to x \wedge y \to x \wedge \neg(x \overset{\infty}{=} y)$,*

where '$\equiv_T \phi$' means Turing-equivalent to the set $\mathcal{CA}(\phi, G)$ (model checking of ϕ for CAs on G).

The recurring domino problem is Σ^1_1-hard on $\mathbb{Z}^2$ [25], as well as the model checking of the corresponding FO($\overset{\infty}{=}$) formula from Theorem 19. It is just an existential formula, but it crucially uses relation $\overset{\infty}{=}$. We can actually also obtain Σ^1_1-hardness on $\mathbb{Z}^2$ with a pure FO formula with just one quantifier alternation, using pre-image counting trickery to check finiteness of a set and a reduction from the recurring domino problem.

▶ **Theorem 20.** *The problem $\mathcal{CA}(\phi, \mathbb{Z}^2)$ is Σ^1_1-hard where ϕ is the following formula:*

$$\phi \overset{def}{=} \exists y, y \to y \wedge \forall y', \forall y_1, \forall y_2, \forall y_3, (y' \neq y \wedge y' \to y \wedge \bigwedge_i y_i \to y') \Rightarrow \bigvee_{i \neq j} y_i = y_j.$$

6 Perspectives

We see several interesting research directions inspired by the approach taken in this work.

First, we believe that the dependence of ϕ on the degree or the number of generators in Corollary 16 is an artifact that can be removed with more work in the proof of Lemma 15. The same proof techniques should also provide hardness result at any level of the analytical hierarchy.

Then, this corollary should be put into perspective with the Ballier-Stein conjecture [6] saying that the domino problem on a f.g. group is decidable if and only if the group is virtually free. On one hand, it seems natural to ask whether the recurring domino problem (or its equivalent FO formula from Theorem 19) can play the role of formula ϕ' in Corollary 16. On the other hand, N. Pytheas Fogg pointed us simple examples of 4-regular graphs having an ∞-grid as subgraph on which the domino problem is decidable. So formula ϕ in Corollary 16 cannot be the FO formula expressing the existence of a fixed point (Turing-equivalent to the domino problem), and we wonder how simple such formula ϕ can be. Actually, we can ask a similar question for Corollary 17.

In general, we believe that the Turing degrees of FO-model checking problems for various concrete formulas is worth being investigated. As mentioned above, the Turing degree of all such model checking problems for a fixed FO formula is independent of the choice of

generators on f.g. groups, and we wonder how they change when changing the group among non virtually free groups. Injectivity of CA is a natural candidate that received little attention to our knowledge since the seminal result on $\mathbb{Z}^2$ [29].

Finally, we believe that there exists a fixed CA rule f for which the FO-model checking problem is undecidable on graph $\mathbb{Z}^2$ (the rule is fixed, the formula is given as input). While we see the proof ingredient to obtain this specifically for $\mathbb{Z}^2$, we have no idea of whether it is always the case that undecidability of FO model checking for CA orbits can be obtained for a fixed CA rule on any f.g. which is not virtually free.

Regular Expressions with Backreferences and Lookaheads Capture NLOG

Yuya Uezato
CyberAgent, Inc., Tokyo, Japan
National Institute of Informatics, Tokyo, Japan

Abstract

Backreferences and lookaheads are vital features to make classical regular expressions (REGEX) practical. Although these features have been widely used, understanding of the unrestricted combination of them has been limited. Practically, most likely, no implementation fully supports them. Theoretically, while some studies have addressed these features separately, few have dared to combine them. Those few studies showed that the amalgamation of these features significantly enhances the expressiveness of REGEX. However, no acceptable expressivity bound for REWBLk – REGEX with backreferences and lookaheads – has been established. We elucidate this by establishing that REWBLk coincides with **NLOG**, the class of languages accepted by log-space nondeterministic Turing machines (NTMs). In translating REWBLk to log-space NTMs, negative lookaheads are the most challenging part since it essentially requires complementing log-space NTMs in nondeterministic log-space. To address this problem, we revisit Immerman–Szelepcsényi theorem. In addition, we employ log-space nested-oracles NTMs to naturally handle nested lookaheads of REWBLk. Utilizing such oracle machines, we also present the new result that the membership problem of REWBLk is **PSPACE**-complete.

1 Introduction

Backreferences and lookaheads are practical extensions for classical regular expressions (REGEX). REGEX with backreferences – *REWB* – can represent the non context-free language $L = \{w\#w : w \in \{a,b\}^*\}$ with the REWB expression $E = ((a+b)^*)_x \ \# \ \backslash x$. Roughly telling about this expression, we save a substring matched with $(a+b)^*$ into the variable x, and later, we refer back to the matched string using $\backslash x$; therefore, E represents L. REWB is a classical calculus [2], and there are some results:

1. Schmid showed that **REWB**, the class of languages accepted by REWB, is contained in **NLOG**, the class of languages accepted by log-space nondeterministic Turing machines (NTMs) [23, Lemma 18].
2. Recently, Nogami and Terauchi showed that **REWB** is contained in the class of indexed languages, **IL** (an extension of context-free languages [1]) [20].
3. The membership problem of REWB – for an input REWB expression E and an input word w, deciding if E accepts w – is **NP**-complete [2].

On REGEX with lookaheads, there are two kinds of lookaheads. A *positive* lookahead $?(E)$ checks if the rest of the input can be matched by E *without* consuming the input. A *negative* lookahead $!(E)$ checks if the rest of the input *cannot* be matched by E without consuming the input. For example, the expression $?(E)F + !(E)G$ runs an expression F if E goes well with the rest of the input and runs an expression G otherwise. Thus, it can be read as `if` E `then` F `else` G and is helpful in writing practical applications. Although lookaheads are useful, they do not alter the REGEX expressiveness. This fact immediately follows from the result of alternating Turing machines that the language class of alternating finite automata corresponds to that of usual finite automata [6].

Now, it is a natural question: *How expressive are REWB with lookaheads?*

The class REWB with lookaheads – REWBLk – was studied by Chida and Terauchi [7, 8]. They have shown (a) **REWBLk**, the class of languages accepted by REWBLk, is closed under intersection and complement (it is immediately shown using lookaheads); (b) REWB is a proper subclass of REWB(+) – REWB with positive lookaheads – and REWB(−) – REWB with negative lookaheads; (c) the language emptiness problem of REWB(−) is undecidable. They also developed a new class of automata called *positive lookaheads memory automata (PLMFA)* and proved that REWB(+) equals PLMFA.

However, the following two key questions remain unresolved:

1. Which known language classes are related to **REWBLk**?
2. What is the computational complexity of the membership problem of REWBLk– a problem deciding if E accepts w for an input expression E and an input string w?

We solve these questions by presenting the following tight results:

(I) **REWBLk** = **NLOG**. Besides, **REWB** already contains an **NLOG**-complete language.

(II) The membership problem of REWBLk is **PSPACE**-complete.

Together with existing results, our results are summarized in the following table:

	Language Class	Membership Problem
REGEX + lookaheads	= **Regular** [6]	**P**-c [18]
REWB	$\subseteq$ **IL** [20], incomparable to **CFL** [4, 5], $\subseteq$ **NLOG** [23], $\ni$ **NLOG**-c language (I)	**NP**-c [2]
REWBLk	= **NLOG** (I)	**PSPACE**-c (II)

where **NLOG**-c is short for **NLOG**-complete, and the same applies to the others.

1.1 Difficulty in Translating REWBLk to Log-space NTMs

To investigate a hard part of translation from REWBLk to log-space NTMs, let us consider the following language, which is a well-known **NLOG**-complete language:

$$L_{\text{reach}} = \{s\,\#\,x_1 \to y_1 \# \cdots \# x_n \to y_n \#\, t : s, t, x_i, y_i \in V^*, \text{and there is a path from } s \text{ to } t\}$$

where the part $\#x_1 \to y_1 \# \cdots \# x_n \to y_n \#$ means the directed graph with direct edges $x_1 \to y_1$, $x_2 \to y_2$, and so on. The following REWBLk expression E_{reach} recognizes L_{reach}:

$$E_{\text{reach}} = (V^*)_{\text{Cur}}\,\#\,\left(?(\Sigma^*\,\#\,\backslash\text{Cur} \to (V^*)_{\text{Cur}}\,\#)\right)^*\,\Sigma^*\,\#\,\backslash\text{Cur}$$

where $\Sigma = V \cup \{\#, \to\}$. It first captures s into the variable Cur and walks on graphs while repeatedly evaluating the part $?(\cdots)$. Each evaluation makes a nondeterministic one-step move on the graph. The part $\Sigma^*\,\#\,\backslash\text{Cur}$ checks if we reach the goal t.

It is not difficult to structurally translate E_{reach} to a log-space NTM M such that $L(M) = L(E_{\mathrm{reach}})$. Now, using M, let us translate the if-then-else expression $?(E_{\mathrm{reach}})F + !(E_{\mathrm{reach}})G$ for some expressions F and G to a log-space NTM N. Let w be an input word $s\#edges\#t$. For the part $?(E_{\mathrm{reach}})F$, we run M in N; if M accepts w, we proceed to simulate F.

However, for the other part $!(E_{\mathrm{reach}})G$, we encounter problems:

(A) We need to check if all possible walks of M starting from s do not reach t.

(B) Walking paths starting from s and aiming for t become infinitely long, and thus there are infinitely many walks (branching) to be checked.

Therefore, we cannot run M directly in N to handle the negative lookahead $!(E_{\mathrm{reach}})$.

Our Idea: Immerman–Szelepcsényi Theorem & Log-space Nested-Oracles NTMs

To address the above problems, we leverage Immerman–Szelepcsényi theorem [16, 27]. This theorem states that the class **NLOG** is closed under complement; i.e., there exists a log-space NTM $\overline{M}$ such that $L(\overline{M}) = \Sigma^* \setminus L(M)$. Therefore, in our machine N, we run $\overline{M}$ for the part $!(E_{\mathrm{reach}})G$: If $\overline{M}$ eventually accepts w, then we proceed to simulate G.

On the other hand, REWBLk permits nested lookaheads, such as $?(\cdots!(\cdots?(\cdots)\cdots)\cdots)$. To handle them naturally, we employ log-space NTMs with *nested oracles* [16, 25, 19]. These machines can easily simulate REWBLk and are translated to log-space NTMs by Immerman–Szelepcsényi theorem; thus, **REWBLk** = **NLOG** holds. Moreover, oracle machines are crucial to showing that the membership problem of REWBLk is **PSPACE**-complete. To this end, we also give the new result that the membership problem of such machines is in **PSPACE**.

Structure of Paper

The rest of the paper is structured as follows. Section 2 discusses related work. Section 3 reviews REWBLk and demonstrates that **REWB** already contains an **NLOG**-complete language. Section 4 illustrates the expressiveness of REWBLk: (1) **NLOG** $\subseteq$ **REWBLk**; (2) the membership problem of REWBLk is **PSPACE**-hard; (3) REWB(+) and REWB(−) represent languages $\notin$ **IL**; and (4) the emptiness problems of REWB(+) and REWB(−) are undecidable even if $\Sigma = \{a\}$. Section 5 reviews log-space nested-oracles NTMs and their language class (= **NLOG**), and shows our new result: their membership problem is in **PSPACE**. Section 6 establishes **REWBLk** $\subseteq$ **NLOG** and that the membership problem of REWBLk is in **PSPACE**. Section 7 concludes this paper by giving open problems.

2 Related Work

As discussed in the Introduction, Chida and Terauchi have formalized REWBLk and its semantics [7, 8]. To our knowledge, their study is the first theoretical exploration into the simultaneous treatment of backreferences and lookaheads. Surprisingly, there has been no prior theoretical research on the topic despite their longstanding and widespread use. They introduced PLMFA (positive lookahead MFA) by expanding MFA (memory finite automata), which Schmid presented for studying REWB in [24]. One of their main results is the equivalence of PLMFA to REWB(+), established through translations between PLMFA and REWBLk. Nevertheless, they did not address: (i) a relationship between REWBLk and existing known language classes; (ii) the complexity of the membership problem of REWBLk. In contrast, we show that REWBLk captures **NLOG** and the membership problem of REWBLk is **PSPACE**-complete.

As highlighted in the Introduction, for REWB, Schmid showed **REWB** $\subseteq$ **NLOG** [23], and Nogami and Terauchi showed **REWB** $\subseteq$ **IL** [20]. Schmid also introduced MFA and showed that MFA corresponds to REWB [24]. About the relationship between **NLOG** and **IL**, it is worth noting that:

- **NLOG** $\not\subseteq$ **IL**. It is shown as follows. The language $L_{2^{2^n}} = \{a^{2^{2^n}} : n \in \mathbb{N}\}$ clearly belongs to **NLOG**. However, $L_{2^{2^n}} \notin$ **IL** by pumping lemmas for indexed languages [14, 11].
- **IL** $\not\subseteq$ **NLOG** unless **NLOG** = **NP**. It is shown as follows. **IL** can represent the language $L_{3\mathrm{SAT}}$, whose words are true 3-CNF formulas [22]. However, $L_{3\mathrm{SAT}} \notin$ **NLOG** unless **NLOG** = **NP**.

In the present paper, we take their result further and show that **REWBLk** = **NLOG** and that **REWB** already contains an **NLOG**-complete language.

We also refer to modern REGEX engines that (partially) support both backreferences and lookaheads. Several programming languages (for example, Perl, Python, PHP, Ruby, and JavaScript) and .NET framework support these features. However, their support is limited in both syntax and semantics. First, expressions like $(\backslash x \backslash x)_x$ and $(\backslash x + \backslash x)_x$ are rejected by most implementations because the variable x appears more than once in single captures. Next, in most implementations, the expression $F = (?((\backslash x a)_x))^* \backslash x$, which represents $\{\epsilon, a, a^2, \ldots\}$, does not match with a^2 and a^3, so on. It is due to conservative loop-detecting semantics. Such a semantics is standardized in ECMAScript [9]. This semantics works for F as follows. First, it unfolds the Kleene-* of $(?((\backslash x a)_x))^*$ as $(\epsilon + \underline{?((\backslash x a)_x)}(?((\backslash x a)_x))^*)$. Next, it enters the underline part and updates the variable x without consuming any input characters. Then, it tries to evaluate $(?((\backslash x a)_x))^*$ *again* at the same input position. At this point, many REGEX engines think that we enter an infinite loop and so stop unfolding the Kleene-*. Consequently, F only matches with ϵ (without loop unfolding) and a (with a single loop unfolding).

We can rephrase this situation as follows: (1) the amalgamation of lookaheads with variables induces side effects without consuming any characters; (2) however, the loop-detecting semantics overlooks such side effects and changes behaviors from the naive semantics. On the other hand, such conservative semantics work well for REGEX, REGEX with lookaheads, and REWB since they do not induce such side effects.

This paper presents a translation between REWBLks and log-space NTMs, enabling the development of REGEX engines that fully support backreferences and lookaheads. Notably, such engines run in *polynomial time* (for a fixed expression) since **NLOG** $\subseteq$ **P**.

3 Preliminaries: REWBLk

We review the syntax and semantics of REWBLk [7, 8] step-by-step below.

3.1 Regular Expressions with Backreferences and Lookaheads

We first give the syntax of REWBLk over an alphabet Σ and variables $\mathcal{V}$:

$$E ::= \sigma \mid \epsilon \mid E + E \mid E\,E \mid E^* \mid \underbrace{(E)_v}_{\text{capture}} \mid \underbrace{\backslash v}_{\text{backreference}} \mid \underbrace{?(E)}_{\text{positive lookahead}} \mid \underbrace{!(E)}_{\text{negative lookahead}}$$

where $\sigma \in \Sigma$ and $v \in \mathcal{V}$ is a variable. The first line defines classical regular expressions, REGEX. We consider the following subclasses in this paper: *REWB* (REGEX with captures and backreferences), *REWB(+)* (REWB with positive lookaheads $?(E)$), *REWB(−)* (REWB with negative lookaheads $!(E)$).

Semantics of REGEX

We first give a semantics for REGEX. To accommodate variables and lookaheads, configurations for REGEX are 4-tuples $\langle E, w, p, \Lambda\rangle$ where

- E is an expression to be executed;
- w is an input string and will not change throughout computation;
- p is a 0-origin position on w ($0 \leq p \leq |w|$). We write $w[p]$ for the symbol on the position p. It should be noted that $p = |w|$ is allowed to represent that we consume all the input.
- $\Lambda : \mathcal{V} \to \Sigma^*$ is an assignment from variables $\mathcal{V}$ to substrings of w.

We write $\mathcal{C}$ for the set of configurations. To denote all the results obtained by computing, we use a semantic function $[\![\cdot]\!] : \mathcal{C} \to \mathcal{P}(\mathbb{N} \times (\mathcal{V} \to \Sigma^*))$ where $\mathcal{P}(X)$ is the power set of X. On $[\![\langle E, w, p, \Lambda\rangle]\!] = \{\langle p_1, \Lambda_1\rangle, \ldots, \langle p_n, \Lambda_n\rangle\}$, each pair $\langle p_i, \Lambda_i\rangle$ means that, after executing E on w from p under Λ, we move to the position p_i and obtain an assignment Λ_i. On the basis of this idea, we define a semantics for each rule of the REGEX part:

$$[\![\langle \sigma, w, p, \Lambda\rangle]\!] = \begin{cases} \{\langle p+1, \Lambda\rangle\} & \text{if } p < |w| \text{ and } w[p] = \sigma, \\ \emptyset & \text{otherwise,} \end{cases} \qquad [\![\langle \epsilon, w, p, \Lambda\rangle]\!] = \{\langle p, \Lambda\rangle\},$$

$$\begin{aligned} [\![\langle E_1 + E_2, w, p, \Lambda\rangle]\!] &= [\![\langle E_1, w, p, \Lambda\rangle]\!] \cup [\![\langle E_2, w, p, \Lambda\rangle]\!], \\ [\![\langle E_1 E_2, w, p, \Lambda\rangle]\!] &= \bigcup_{\langle p', \Lambda'\rangle \in [\![\langle E_1, w, p, \Lambda\rangle]\!]} [\![\langle E_2, w, p', \Lambda'\rangle]\!], \\ [\![\langle E^*, w, p, \Lambda\rangle]\!] &= \bigcup_{i=0}^{\infty} [\![\langle E^i, w, p, \Lambda\rangle]\!] \quad \text{where } E^0 = \epsilon,\ E^i = \overbrace{EE\cdots E}^{i}. \end{aligned}$$

We note that our semantic function $[\![\langle E, w, p, \Lambda\rangle]\!]$ is inductively defined on the lexicographic ordering over the star height of E and the expression size of E. The start height and expression size of REWBLK is defined in the usual way.

We also note that each $[\![\langle E, w, p, \Lambda\rangle]\!]$ forms a finite set because the value of each variable x must be a substring of w, and also p is bounded as $0 \leq p \leq |w|$.

Semantics of REWB

A capture expression $(E)_x$ attempts to match the input string with E. If it succeeds, the matched substring is stored in the variable x.

$$[\![\langle\, (E)_x, w, p, \Lambda\,\rangle]\!] = \left\{\left\langle\ p', \Lambda'\left[\, x \mapsto w[p..p')\,\right]\ \right\rangle : \langle p', \Lambda'\rangle \in [\![\langle E, w, p, \Lambda\rangle]\!]\right\}$$

where $w[p..q)$ is the string $w[p]\, w[p+1] \cdots w[q-1]$.

A backreference $\backslash x$ refers to the substring stored previously by evaluating some $(E)_x$.

$$[\![\langle \backslash x, w, p, \Lambda\rangle]\!] = [\![\langle \Lambda(x), w, p, \Lambda\rangle]\!].$$

Semantics of Lookaheads

Positive lookaheads $?(E)$ run E from the current input without consuming any input. Although the change in head position is undone after running E, the modification to variables in E is not. So, we can also call it destructive lookahead.

$$[\![\langle ?(E), w, p, \Lambda\rangle]\!] = \left\{\langle p, \Lambda'\rangle : \langle p', \Lambda'\rangle \in [\![\langle E, w, p, \Lambda\rangle]\!]\right\}.$$

Negative lookaheads $!(E)$ also run E without consuming any input. If E does not match anything, we invoke a continuation. Compared with positive lookaheads $?(E)$, both the previous head position and the previous values of variables are recovered.

$$[\![\langle !(E), w, p, \Lambda\rangle]\!] = \begin{cases} \{\langle p, \Lambda\rangle\} & \text{if } [\![\langle E, w, p, \Lambda\rangle]\!] = \emptyset, \\ \emptyset & \text{otherwise.} \end{cases}$$

Readers may wonder why positive lookaheads modify variables while negative ones do not. This asymmetry arises because, in negative lookaheads, all computations uniformly fail, leaving no suitable configuration for altering variables. On the other hand, using the non-destructive property of the negative lookaheads, we can also define non-destructive positive lookaheads by $!(!(E))$. This expression executes E from the current position without any variable modifications.

Remark: Special character \$. Using a negative lookahead, we define $\$ = !(\Sigma)$ to check the end of the input. \$ is one of the most important applications of negative lookaheads.

▶ **Definition 1.** *The language of a REWBLk E, $L(E)$, is defined as follows:*

$$L(E) = \left\{ w \in \Sigma^* : \langle p, \Lambda\rangle \in [\![\langle E, w, 0, \iota\rangle]\!],\ p = |w| \right\} \quad \textit{where } \forall x \in \mathcal{V}.\, \iota(x) = \epsilon.$$

We can also consider another definition using $\gamma(x) = \bot$ instead of ι, where γ indicates that all variables are initially undefined. Although some real-world regular expression engines adopt that definition, we adopt the above ι-definition since it is tedious to initialize all variables x using $(\epsilon)_x$. The results discussed in this paper will not change regardless of which one is used. There is another formalization that excludes labels that appear multiple times in a single group, for instance $(\backslash x \backslash x)_x$. We discuss such a restriction, which we call reference restriction, in the immediately following section.

3.2 Reference Restriction and Normalization

Our formalization of REWBLk allows that variable references appear inside their definitions; for example, we allow expressions like $(\backslash x \backslash x)_x$. On the other hand, many studies on REWB do not allow them; i.e., expressions like $(\backslash x \backslash x)_x$ are prohibited [5, 23, 10, 20].

To the best of the author's knowledge, it remains unclear whether the restriction alters the expressive power of REWB. However, on REWBLk, the restriction does not change the language class of REWBLk. Here, we formalize the restriction and then present our normalization, which converts REWBLk expressions to language-equivalent restricted forms.

We use the function Var that receives an expressions E and returns the set of all the backreference variables inside E. For example,

$$\textsc{Var}(\ \backslash x \backslash x\ ) = \{x\},\ \textsc{Var}(\ (\backslash x \backslash y)_z\ ) = \{x, y\},\ \textsc{Var}(\ a\, b\, c\, ?(\ (\backslash w (\backslash x)_z)_y\ )\ ) = \{w, x\}.$$

It can be easily defined inductively on the expression size of E.

We also define a restriction, *reference restriction*. An REWBLk expression E satisfies the reference restriction condition if, for all the capture subexpressions $(F)_x$ of E, $x \notin \textsc{Var}(F)$ holds. For example, the expression $a\, b\, c\, ?((\backslash w (\backslash x)_z)_y)$ satisfies the condition. On the other hand, the expressions $(\backslash x \backslash x)_x$ and $a\, b\, c\, ?((\backslash w (\backslash y)_z)_y)$ do not.

▶ **Theorem 2.** *For any REWBLk expression E, there is an expression E' that satisfies the reference restriction condition and $L(E) = L(E')$.*

Proof. It suffices to perform variable renaming like alpha-conversion in lambda calculus to remove patterns $(\cdots x \cdots)_x$. Formally, we apply the following renaming function $\mathcal{R}$ from the innermost of E to the outermost:

$$\mathcal{R}(F) = \begin{cases} ?((F')_y)(\backslash y)_x & \text{where } y \text{ is a fresh variable} \quad \text{if } F = (F')_x, \\ F & \text{otherwise.} \end{cases}$$

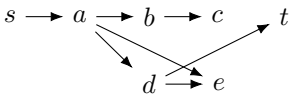
The expression $?((F')_y)(\backslash y)_x$ is equivalent to $(F')_x$ because it first stores the result of running F' to a fresh variable y and then puts it to the original variable x. Thus, the innermost-to-outermost applying $\mathcal{R}$ changes expressions to ones, which satisfy the restriction condition, without change their languages.

For example, an expression $(aa)_x(\backslash x \backslash x)_x$ is translated to $(aa)_x?((\backslash x \backslash x)_y)(\backslash y)_x$ by introducing a variable y. Another expression $(a)_x(b)_y(?[(\backslash x \backslash x)_x]aa\backslash y)_x$ is first translated to $(a)_x(b)_y(?[?((\backslash x \backslash x)_\alpha)(\backslash \alpha)_x]aa\backslash y)_x$ by introducing α. Then, introducing β, it is translated to $(a)_x(b)_y?((?[?((\backslash x \backslash x)_\alpha)(\backslash \alpha)_x]aa\backslash y)_\beta)(\backslash \beta)_x$. ◀

We will use this theorem in Section 6 to translate REWBLk to nested-oracles machines.

3.3 NLOG-Complete Language Accepted by REWB

Hartmanis and Mahaney proposed a decision problem called *TAGAP*, which is the topological sorted version of the reachability problem of directed *acyclic* graphs (DAG) [13]. Let us consider a word $w = \ulcorner x_1 \to y_1 \urcorner \ulcorner x_2 \to y_2 \urcorner \cdots \ulcorner x_n \to y_n \urcorner$, which represents a DAG. We call w *topologically sorted* if: for all pairs of $a \to b$ and $b \to c$ of w, $a \to b$ appears before $b \to c$ in w. The following example represents a DAG and one of its topologically sorted representation:



, $\ulcorner s \to a \urcorner \ulcorner a \to d \urcorner \ulcorner a \to e \urcorner \ulcorner d \to t \urcorner \ulcorner a \to b \urcorner \ulcorner d \to e \urcorner \ulcorner b \to c \urcorner$.

We define the language for TAGAP as follows:

$$L_{\text{TAGAP}} = \{s \# R \# t : R \text{ is a topologically sorted repr. of } G,\ t \text{ is reachable from } s \text{ in } G\}.$$

Hartmanis and Mahaney showed that this language is **NLOG**-complete [13, Theorem 3]. Since we only consider the topologically sorted representation, there is no longer a need to explore the entire input many times. In the above example, we can reach t from s by nondeterministically finding edges $s \to a$, $a \to d$, and $d \to t$ in this order by one-way scanning. Indeed, we can show the following theorem.

▶ **Theorem 3.** *$L_{TAGAP} \in$ **REWB**.*

Proof. The following expression E_{TAGAP} clearly recognizes L_{TAGAP}:

$$E_{\text{TAGAP}} = (V^*)_{\text{Cur}} \# \left(\Sigma^* \ulcorner \backslash\text{Cur} \to (V^*)_{\text{Cur}} \urcorner\right)^* \Sigma^* \# \backslash\text{Cur},$$

where V is an alphabet for vertices. ◀

4 Expressiveness of REWBLk

In this section, we present some theorems about the expressiveness of REWBLk.

4.1 Unary Non-Indexed Language

We consider the single exponential numerical language $L_{1exp} = \{a^{2^k} : k \in \mathbb{N}\}$ over the unary alphabet $\Sigma = \{a\}$. The language L_{1exp} is represented by the REWB(+) expression $E_{1exp} = ?(a)_x\,(?(\backslash x \backslash x)_x)^*\,\backslash x$. The part $?(a)_x$ initializes $x = a$ (i.e., $x = a^0$), and the Kleene-$*$ part iteratively doubles x.

Furthermore, we can represent the doubly exponential language $L_{2exp} = \{a^{2^{2^k}} : k \in \mathbb{N}\}$ by the following REWBLK expression E_{2exp}:

$$\begin{aligned} E(\alpha,\beta) &= \big(?[(\backslash\alpha\, a)_\alpha]\ ?[(\backslash\beta\backslash\beta)_\beta]\big)^*, \qquad \text{(it adds } a \text{ to } \alpha \text{ and doubles } \beta) \\ E_{2exp} &= ?((a)_m)\ E(n,m)\ ?((a)_x)\ E(y,x)\ ?(a^*\,?(\backslash m\$)\,?(\backslash y\$))\ \backslash x. \end{aligned}$$

It searches the numbers n, m, x, y that satisfy $2^n = m$, $2^y = x$, and $m = y$; so, $x = 2^{2^n}$. While unfolding the Kleene-* of $E(n,m)$ and $E(y,x)$, $2^n = m$ and $2^y = x$ hold. The part $?(a^*\,?(\backslash m\$)\,?(\backslash y\$))$ checks if $m =_?\ y$ by utilizing the negative lookahead expression $\$ = !(a)$.

We emphasize the known result $L_{2exp} \notin \mathbf{IL}$, which is shown by the pumping or shrinking lemma for indexed languages [14, 11]. Since we can carry out a similar construction of E_{2exp} in REWB(+) and REWB(−), we have the following result.

▶ **Theorem 4.** *REWB(+) and REWB(−) can represent unary non-indexed languages.*

Proof (Sketch). Due to the page limitation, we provide a proof sketch for the REWB(−) part and put the complete proof in the Appendix of the long version. Let us consider the following REWB(−) expression:

$$\begin{aligned} E'(\alpha,\beta) &= \big((\backslash\alpha\, a)_\alpha\ (\backslash\beta\backslash\beta)_\beta\big)^*, \\ E'_{2exp} &= (a)_m\ E'(n,m)\ (a)_x\ E'(y,x)\ !(!(\backslash m\$))\ !(!(\backslash y\$))\ a^*. \end{aligned}$$

While the expression E'_{2exp} resembles E_{2exp}, it lacks positive lookaheads. Let us explain E'_{2exp} step-by-step:

1. The expressions $(a)_m$ and $(a)_x$ initialize m and x by a as with E_{2exp}.
2. The subexpression $E'(n,m)$ repeatedly expands variables n and m as with E_{2exp}. So, executing $E'(n,m)$ *actually* consumes inputs as follows without positive lookaheads:

$$\underline{a^1}_n\ \underline{a^{2^1}}_m\ \underline{a^2}_n\ \underline{a^{2^2}}_m\ \underline{a^3}_n\ \underline{a^{2^3}}_m \cdots \underline{a^i}_n\ \underline{a^{2^i}}_m \cdots$$

3. The same holds for the expression $E'(y,x)$.

The part $!(!(\backslash m\$))$ is a non-destructive positive lookahead by $\backslash m\$$ that is simulated by double negative lookaheads; therefore, the part $!(!(\backslash m\$))\ !(!(\backslash y\$))$ requires $m = y$. If we pass the assertion, we consume the rest input by a^*. By replacing positive lookaheads with actual consuming, the language $L(E'_{2exp})$ *grows faster* (the notion *fast growth* is formalized in the Appendix) than L_{2exp}. This property implies that $L(E'_{2exp})$ is not an indexed language. ◀

It states that, even if restricted to unary languages, positive or negative lookaheads make REWB expressive and incomparable to **IL**. We can also show the undecidability of the emptiness problem, which is checking if $L(E) = \emptyset$ for a given expression E, of REWB(+) and REWB(−) over $\Sigma = \{a\}$.

▶ **Theorem 5.** *The emptiness problems of REWB(+) over a unary alphabet and REWB(−) over a unary alphabet are undecidable.*

The two undecidability results can be shown by translating the Post Correspondence Problem to the emptiness problems. Due to the page limitation, we put the proof of Theorem 5 in the Appendix of the long version.

4.2 Simulating Two-Way Multihead Automata by REWBLk

We show that REWBLk can simulate *two-way multihead automata*, which are a classical extension of automata and capture **NLOG** [12].

Simulating Two-Way One-Head Automata

We start from two-way *one*-head automata. Let $\mathcal{A} = (Q, q_{\text{init}}, q_{\text{acc}}, \Sigma, \Delta)$ be a two-way automata where $Q = \{q_0, q_1, \ldots, q_{|Q|-1}\}$ is a finite set of states, $q_{\text{init}} \in Q$ is the initial state, $q_{\text{acc}} \in Q$ is the accepting state, Σ is an input alphabet, and Δ is a set of transition rules. Each transition rule is of the form $p \xrightarrow{\tau/\theta} q$ where $p, q \in Q$, $\tau \in (\Sigma \cup \{\vdash, \dashv\})$, and $\theta \in \{-1, 0, 1\}$. The component θ indicates a head moving direction: (1) if $\theta = -1$ (resp. $\theta = 1$), we move the scanning head left (resp. right); (2) if $\theta = 0$, we *do not* move the scanning head.

For an input $w \in \Sigma^*$, we run $\mathcal{A}$ on the extended string $\vdash w \dashv$, which are surrounded by the left and right end markers. A configuration of $\mathcal{A}$ for $\vdash w \dashv$ is a tuple (q, i) where $q \in Q$ and $0 \leq i < 2 + |w|$, and thus the current scanning symbol is $(\vdash w \dashv)[i]$.

A transition rule $\delta = p \xrightarrow{\tau/\theta} q \in \Delta$ gives a labelled transition relation $\overset{\delta}{\Rightarrow}$ as follows:

$$(p, i) \overset{\delta}{\Rightarrow} (q, i + \theta) \quad \text{if } (\vdash w \dashv)[i] = \tau \text{ and } 0 \leq i + \theta < |w| + 2$$

The word w is accepted by $\mathcal{A}$ if the initial configuration $(q_{\text{init}}, 0)$, reading $\vdash$, has a computation path to a configuration with the accepting state q_{acc}. We now define the language of $\mathcal{A}$ as follows:

$$L(\mathcal{A}) = \{w : (q_{\text{init}}, 0) \overset{\delta_1}{\Rightarrow} (q_1, i_1) \overset{\delta_2}{\Rightarrow} \cdots \overset{\delta_n}{\Rightarrow} (q_{\text{acc}}, i_n)\}.$$

To simulate $\mathcal{A}$ by REWBLk, we use some variables $L, R, S \in \Sigma^*$. Intuitively, each variable means the following:

- If $L = w$ (resp. $R = w$), $\mathcal{A}$ is located on $\dashv$ (resp. $\vdash$). Otherwise, $\exists \sigma \in \Sigma.\, w = L\sigma R$. So, L (resp. R) means the left (resp. right) part of w.
- The length of S denotes the index i of the current state q_i of $\mathcal{A}$.

We formalize the above intuition as the following simulation $\sim$ between (q, i) and $\langle L, R, S\rangle$:

$$\begin{array}{ll} (q_j, 0) \sim \langle \epsilon, w, S\rangle & \text{if } |S| = j, \\ (q_j, |w| + 1) \sim \langle w, \epsilon, S\rangle & \text{if } |S| = j, \\ (q_j, i) \sim \langle L, R, S\rangle & \text{if } 1 \leq i \leq |w|,\ \exists \sigma.\ w = L\,\sigma\,R,\ |L| = i - 1, \text{ and } |S| = j. \end{array}$$

To represent all states, we need $|w| \geq |Q| - 1$. So, we mainly consider to represent $L(\mathcal{A}) \setminus L'$ where $L' = \{w \in L(\mathcal{A}) : |w| < |Q| - 1\}$. For instance, our simulation proceeds as follows:

$$\begin{array}{lll} (1) & \vdash^{q_0} ab \dashv \sim \langle L = \epsilon,\ R = ab,\ S = \epsilon\rangle, & (\text{if } R = w, \text{ then } L = \epsilon \text{ and } \mathcal{A} \text{ is on } \vdash) \\ (2) & \vdash a^{q_1} b \dashv \sim \langle L = \epsilon,\ R = b,\ S = a\rangle, & (\text{move right from (1)}) \\ (3) & \vdash ab^{q_1} \dashv \sim \langle L = a,\ R = \epsilon,\ S = a\rangle, & (\text{move right from (2)}) \\ (4) & \vdash ab \dashv^{q_1} \sim \langle L = ab,\ R = \epsilon,\ S = a\rangle, & (\text{if } L = w, \text{ then } R = \epsilon \text{ and } \mathcal{A} \text{ is on } \dashv) \\ (5) & \vdash ab^{q_2} \dashv \sim \langle L = a,\ R = \epsilon,\ S = ab\rangle, & (\text{move left from (4) and change } q_1 \text{ to } q_2) \\ (6) & \vdash a^{q_2} b \dashv \sim \langle L = \epsilon,\ R = b,\ S = ab\rangle. & \end{array}$$

As initialization, we use the expression $E_{\text{init}} = (\epsilon)_L\ ?((\Sigma^*)_R\,\$)\ (\epsilon)_S$, which sets $L = S = \epsilon$ and $R = w$ for the input w. To move the head right, we use the following expression:

$$E_{+1} = ?((\backslash L\Sigma)_L\ \Sigma\,(\Sigma^*)_R\,\$) + ?((\backslash L\Sigma)_L\,(\epsilon)_R\,\$).$$

The part $?((\backslash L\Sigma)_L\,\Sigma\,(\Sigma^*)_R\,\$)$ first attempts to expand L toward the right and then updates R. Similarly, we define the expression E_{-1} to move the head left as follows:

$$E_{-1} = ?((\Sigma^*)_L\,\Sigma\,(\Sigma\backslash R)_R\,\$) + ?((\epsilon)_L\,(\Sigma\backslash R)_R\,\$).$$

To check if the current scanning symbol is $\dashv$, $\vdash$, or $\sigma \in \Sigma$, we use the following expressions:

$$E_{\dashv} = ?(\backslash L\$),\ E_{\vdash} = ?(\backslash R\$),\ E_{\sigma} = ?(\backslash L\,\sigma\,\backslash R\$).$$

To check if the current state is q_i, we use the expression $E_{q_i} = ?\big(\Sigma^*\ ?(\backslash S)\$\ ?(\Sigma^i)\$\big)$. To change the current state q_i to q_j, we use the expression $E_{i\text{-to-}j} = E_{q_i}\,?(\Sigma^*\,(\Sigma^j)_S\,\$)$.

Now, each transition rule δ is simulated by the following expression $E(\delta)$ defined as:

$$E(q_i \xrightarrow{\tau/0} q_j) = E_{i\text{-to-}j}\ E_\tau, \quad E(q_i \xrightarrow{\tau/\theta} q_j) = E_{i\text{-to-}j}\ E_\tau\ E_\theta\ \ (\theta \in \{-1,+1\}).$$

Finally, the following expression $E_{\mathcal{A}}$ simulates $\mathcal{A}$, and $L(E_{\mathcal{A}}) = L(\mathcal{A})$ holds:

$$E_{\mathcal{A}} = E_{L'} + ?(E_{q_{\text{init}}}\,(E(\delta_1) + E(\delta_2) + \cdots + E(\delta_n))^*\,E_{q_{\text{acc}}})\,\Sigma^*$$

where $E_{L'}$ is a regular expression for the finite language L', and $\Delta = \{\delta_1, \delta_2, \ldots, \delta_n\}$.

We summarize the our translation as follows.

▶ **Lemma 6.** *For a two-way one-head automata $\mathcal{A}$, there is an expression $E_{\mathcal{A}}$ with 3 variables (L, R, and S) such that $L(E_{\mathcal{A}}) = L(\mathcal{A})$.* Especially, *the expression uses negative lookaheads only in the form of $\$$.*

Simulating Two-Way Multihead Automata

We extend the above argument to two-way *multihead* automata $\mathcal{M}$ [12, 15]. Compared to two-way one-head automata $\mathcal{A}$, $\mathcal{M}$ has multiple-heads on input strings. We write K for the number of heads. The difference between $\mathcal{A}$ and $\mathcal{M}$ are the following:

- Each configuration of $\mathcal{M}$ is a tuple $(q, i_1, i_2, \ldots, i_K)$ where q is the current state and i_j is the j-th head position.
- Each transition rule is $p \xrightarrow{(\tau_1,\ldots,\tau_K)/(\theta_1,\ldots,\theta_K)} q$ where $p, q \in Q$, $\tau_j \in \Sigma \cup \{\vdash, \dashv\}$ is used for inspecting the scanned symbol by j-th head, and θ_j denotes the head moving direction for the j-th head.

We define a transition relation $\Rightarrow$ in the same way as for $\mathcal{A}$. Let $\delta = p \xrightarrow{(\tau_1,\ldots,\tau_K)/(\theta_1,\ldots,\theta_K)} q$ be a rule and $C = (p, i_1, i_2, \ldots, i_K)$ be a valid configuration. If $\forall 1 \le j \le K.\,(\vdash w \dashv)[i_j] = \tau_j$, then we have $C \overset{\delta}{\Rightarrow} (q, i_1 + \theta_1, i_2 + \theta_2, \ldots, i_K + \theta_K)$. We define the language as follows:

$$L(\mathcal{M}) = \{w : (q_{\text{init}}, 0, 0, \ldots, 0) \overset{\delta_1}{\Rightarrow}\overset{\delta_2}{\Rightarrow} \cdots \overset{\delta_n}{\Rightarrow} (q_{\text{acc}}, i_1, i_2, \ldots, i_K)\}.$$

We can show the following lemma by simply extending our above construction for two-way one-head automata.

▶ **Lemma 7.** *For a given two-way K-head automata $\mathcal{M}$, we have an expression $E_{\mathcal{M}}$ with $3K$ variables such that $L(E_{\mathcal{M}}) = L(\mathcal{M})$. $E_{\mathcal{M}}$ uses negative lookaheads only in the form of $\$$.*

Proof. As with the two-way one-head automata, for each i-th head, we prepare variables L_i, R_i, and S_i. For each i-th head, by using the variables for i, we give expressions E^i_π where $\pi \in \{+1, -1, \sigma, \vdash, \dashv\}$. Employing the same E_{q_i} and $E_{i\text{-to-}j}$, we can give $E(\delta)$ for each transition rule δ of $\mathcal{M}$ and so $E_{\mathcal{M}}$. ◀

It is well-known that the class of languages accepted by two-way multihead automata corresponds to **NLOG** [12]; so, we have the following theorem.

▶ **Theorem 8.** $\mathbf{NLOG} \subseteq \mathbf{REWBLk}$.

4.3 Encoding Quantified Boolean Formula Problem

We translate the **PSPACE**-complete problem **QBF**, checking if a *quantified boolean formula* (QBF) is true, into the membership problem of REWBLK. We only consider QBFs in CNF since QBF restricted to CNF remains **PSPACE**-complete [3]. For instance, let us consider the following QBF Q and translate it to the equivalent one Q' by replacing $\forall$ with $\neg\exists\neg$:

$$Q : \forall a.\, \exists b.\, \forall c. \forall d.\, (a \vee b \vee c) \wedge (\overline{b} \vee c \vee d) \Rightarrow Q' : \neg\exists a.(\neg\exists b.(\neg\exists c.(\exists d.(\neg((a \vee b \vee c) \wedge (\overline{b} \vee c \vee d)))))).$$

In order to check if Q is true, we first structurally translate Q' into the following $E_{Q'}$:

$$\begin{aligned} E(v) &= \big((T)_v(F)_{\overline{v}} \;+\; (T)_{\overline{v}}(F)_v\big) \quad \text{where } v \text{ is a propositional variable,} \\ E_{Q'} &= !(E(a)\; !(E(b)\; !(E(c)\; E(d)\; !((\backslash a + \backslash b + \backslash c)(\overline{\backslash b} + \backslash c + \backslash d))))), \end{aligned}$$

where we replace $\neg$ with $!$, $\exists x$ with $E(x)$, x with $\backslash x$, $\overline{x}$ with $\overline{\backslash x}$, and $\vee$ with $+$.

We then check $w = TF\,TF\,TF\,TF\,TT \in_? L(E_{Q'})$. We explain the string w using the annotated version $T_1F_2T_3F_4T_5F_6T_7F_8T_9T_{10}$: (1) the first two characters T_1F_2 makes the two cases where $(a = T, \overline{a} = F)$ or $(a = F, \overline{a} = T)$; (2) similarly, T_3F_4 (resp. T_5F_6 and T_7F_8) works for b and $\overline{b}$ (resp. $c, \overline{c}$ and $d, \overline{d}$) ; (3) by T_9, we check if the expression $(a \vee b \vee c)$ holds (in the negative context); (4) by T_{10}, we also check if $(\overline{b} \vee c \vee d)$ holds. Thus, Q is true iff $w \in L(E_Q)$.

On the basis of the above translation using $E(v)$, we can translate every CNF-QBF Q to the corresponding expression E_Q and give the membership problem $TFTF \ldots TF\,TT \ldots T \in_? L(E_Q)$ in polynomial time for the size of Q. It implies the following result.

▶ **Theorem 9.** *The membership problem of REWBLK is **PSPACE**-hard.*

5 Log-space Nested-Oracles Nondeterministic Turing Machines

As we have stated in the Introduction, we utilize log-space nested-oracles NTMs. We will translate REWBLK to them in the next section.

We first review log-space NTMs. Here we especially consider *c-bounded k-working-tapes* log-space NTM $M = (k, c, Q, q_{\text{init}}, Q_F, \Sigma, \Gamma, \square, \Delta)$. Each component of M means:

- k is the number of working tapes $T_1, T_2, \ldots, T_k$.
- c is used to bound the size of working tapes. It will be defined precisely below.
- Q is a finite set of states, q_{init} is the initial state, and $Q_F \subseteq Q$ is a set of accepting states.
- Σ is an input alphabet.
- Γ is a working tape alphabet. $\square \in \Gamma$ is the blank symbol for working tapes.
- Δ is a set of transition rules. Each rule is either $p \xrightarrow{\tau \mid \theta} q$ or $p \xrightarrow[T_i]{\kappa \mapsto \kappa' \mid \theta} q$ where $p, q \in Q$, $\tau \in \Sigma \cup \{\epsilon, \vdash, \dashv\}$, $\kappa, \kappa' \in \Gamma \cup \{\vdash, \dashv\}$, and $\theta \in \{-1, +1, 0\}$.

Let $\vdash w \dashv$ ($w \in \Sigma^*$) be a string surrounded by the left and right end markers. Valid configurations of M for $\vdash w \dashv$ are tuples $\langle q, i, (T_1, i_1), \ldots, (T_k, i_k)\rangle$ where

- $q \in Q$ is the current state. $i \in \mathbb{N}$ $(0 \le i < |w| + 2)$ is the current head position on $\vdash w \dashv$.
- $T_x \in (\vdash \Gamma^C \dashv)$ where $C = c \cdot \lceil \log |w| \rceil$ is the x-th working tape surrounded by the end markers. $\lceil \cdot \rceil$ is the ceiling function to integers; for example, $\lceil \log 3 \rceil = \lceil 1.584 \ldots \rceil = 2$.
  Remark: The tape capacity C is determined by the parameter c and the input w.
- i_x is the x-th tape head position on T_x $(0 \le i_x < C + 2)$.

We write $\mathbf{Valid}_M(w)$ (or, simply $\mathbf{Valid}(w)$) for the set of valid configurations for the input w. It is clear that $|\mathbf{Valid}(w)| = |Q| \times (|w|+2) \times (|\Gamma|^C \times (C+2))^k$ where $C = c \cdot \lceil \log |w| \rceil$.

For an input string w, we write $\mathcal{I}(w)$ to denote the initial configuration on $\vdash w \dashv$:

$$\mathcal{I}(w) = \langle q_{\text{init}},\ 0,\ (\vdash \square^C \dashv, 0), \ldots, (\vdash \square^C \dashv, 0)\rangle \text{ where } C = c \cdot \lceil \log |w| \rceil.$$

Let $\xi = \langle p, i, (T_1, i_1) \ldots, (T_x, i_x), \ldots, (T_k, i_k)\rangle$ be a valid configuration on $\vdash w \dashv$. For each transition rule δ, we define a labelled transition relation $\overset{\delta}{\Rightarrow}$ on *valid* configurations as follows:

$$\frac{\delta = p \xrightarrow{\tau \mid \theta} q \qquad (\vdash w \dashv)[i] = \tau \ (\text{if } \tau \neq \epsilon)}{\xi \overset{\delta}{\Rightarrow} \langle q,\ i + \theta,\ (T_1, i_1), \ldots, (T_k, i_k)\rangle} \qquad \frac{\delta = p \xrightarrow[T_x]{\kappa \mapsto \kappa' \mid \theta} q \qquad \kappa = T_x[i_x]}{\xi \overset{\delta}{\Rightarrow} \langle q, i, \ldots (T_x[i_x] := \kappa', i_x + \theta) \ldots\rangle}$$

where $T_x[i_x] := \kappa'$ is the new working tape obtained by writing κ' to the position i_x.

We also simply write $\xi \Rightarrow \xi'$ if there is a transition rule $\delta \in \Delta$ such that $\xi \overset{\delta}{\Rightarrow} \xi'$.

We write $\mathbf{NLOG}(c, k)$ for the set of c-bounded k-working-tapes log-space NTMs. If c and k is not important, by abusing notation, we simply write $\mathbf{NLOG}$. For $M \in \mathbf{NLOG}$ and an input string w, we write $M(w, \xi)$ to denote the set of valid and acceptable configurations that are reachable from a valid configuration ξ on $\vdash w \dashv$:

$$M(w, \xi) = \{\xi' \ :\ \xi \Rightarrow^* \xi',\ \xi' = \langle q_{\text{acc}}, i, \mathcal{T}\rangle,\ q_{\text{acc}} \in Q_F\},$$

where $\mathcal{T} = (T_1, i_1) \ldots (T_k, i_k)$ is a sequence of pairs of a working tape and an index. Now the language $L(M)$ is defined as:

$$L(M) = \{w : M(w, \mathcal{I}(w)) \neq \emptyset\}.$$

Here we state a useful proposition, which will be used below sometimes.

▶ **Proposition 10.** *Let $M \in \mathbf{NLOG}(c, k)$. For any input w, to represent a single valid configuration or store $|\mathbfit{Valid}(w)|$, we need an extra $O(c \cdot k)$-bounded working tape.*

Proof. Since $|\mathbf{Valid}(w)| = |Q| \times (|w| + 2) \times (|\Gamma|^C \times (C + 2))^k$ where $C = c \cdot \lceil \log |w| \rceil$, $\log |\mathbf{Valid}(w)| = (k \cdot C) \log |\Gamma| + \cdots = O(k \cdot c) \log |w|$. So, we need an $O(c \cdot k)$-bounded tape. ◀

On log-space NTMs, we can solve the problem-***(B)*** in Section 1.1.

▶ **Proposition 11.** *Let $M \in \mathbf{NLOG}(c, k)$. There exists $N \in \mathbf{NLOG}(O(c \cdot k), k + 1)$ such that $L(M) = L(N)$ and, for any input w, all computations of N starting from w eventually halt.*

Proof. The number of reachable configurations is bounded by $\mathcal{B} = |\mathbf{Valid}_M(w)|$. So, we can safely ignore all paths P whose length $> \mathcal{B}$ without changing the accepting language. To check if the current path length $> \mathcal{B}$, we need an $O(c \cdot k)$-bounded tape by Proposition 10. ◀

We note that properties, like Proposition 11, are insufficient to show that a language class is closed under complement.[1] Thus, the problem-(***A***) in Section 1.1 is essentially hard; indeed, it is the interesting part of Immerman–Szelepcsényi theorem [16, 27]. In the following subsection, we revisit their theorem along with introducing log-space nested-oracles NTM.

[1] For example, we can translate any nondeterministic pushdown automata to real-time ones, which do not have ϵ-transitions. However, the class of context free languages is not closed under complement.

5.1 Augmenting NTM with Nested Oracles

We extend log-space NTM with finitely nested oracles (or subroutines) to naturally handle nested lookaheads of REWBLk. Similar to our definition of log-space NTMs, we consider c-bounded k-tapes log-space nested oracles NTMs.

To allow nested oracle calling, we inductively define our machines. First, as the base case, we write $\mathbf{OLOG}^0(c,k) = \mathbf{NLOG}(c,k)$ to denote machines without oracles. Next, as the induction step, we define $\mathbf{OLOG}^{x+1}(c,k)$ using $\mathbf{OLOG}^x(c,k)$ as follows:

- Each $M \in \mathbf{OLOG}^{x+1}(c,k)$ is a tuple $(k, c, Q, q_{\text{init}}, Q_F, \Sigma, \Gamma, \square, \Delta)$.
- There are new transition rules, *oracle transition rules*, of the form $p \xrightarrow{\in N} q$ and $p \xrightarrow{\notin N} q$ where $N \in \mathbf{OLOG}^y(c,k)$ and $y \leq x$. Their semantics will be defined immediately later.

We write $\mathbf{OLOG}^\omega(c,k)$ for $\bigcup_{i=0}^{\infty} \mathbf{OLOG}^i(c,k)$. If c and k are not important, we simply write as $\mathbf{OLOG}^n$ and $\mathbf{OLOG}^\omega$. To denote the nesting level of machines $M \in \mathbf{OLOG}^\omega(c,k)$, we inductively define the function *depth* as follows:

$$\mathit{depth}(M) = \begin{cases} 0 & \text{if } M \in \mathbf{OLOG}^0(c,k), \\ 1 + \max\{\mathit{depth}(N) : p \xrightarrow{\in N} q,\ p' \xrightarrow{\notin N} q \in \Delta(M)\} & \text{otherwise.} \end{cases}$$

Now, we define the semantics of oracle transition rules as follows:

$$\frac{p \xrightarrow{\in N} q \qquad N(w, \langle q^N_{\text{init}}, i, \mathcal{T}\rangle) \ni \langle r,\ j,\ \mathcal{U}\rangle}{\langle p, i, \mathcal{T}\rangle \Rightarrow \langle q, i, \mathcal{U}\rangle} \qquad \frac{p \xrightarrow{\notin N} q \qquad N(w, \langle q^N_{\text{init}}, i, \mathcal{T}\rangle) = \emptyset}{\langle p, i, \mathcal{T}\rangle \Rightarrow \langle q, i, \mathcal{T}\rangle}$$

where q^N_{init} is the initial state of N, $\mathcal{T}$ and $\mathcal{U}$ is a sequence of pairs of a working tape and an index $(T_1, i_1)\dots(T_k, i_k)$, and the function

$$N(w, \xi) = \{\xi' : \xi \Rightarrow^* \xi', \xi' = \langle q, i, \mathcal{T}\rangle, q \in Q_F(N)\}$$

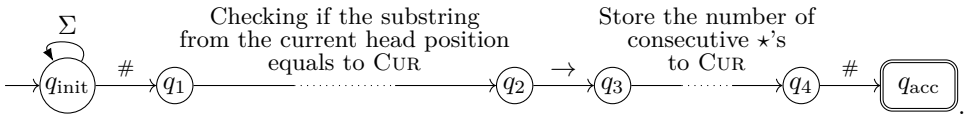
is defined inductively on the depth of machines.

The semantics of $p \xrightarrow{\in N} q$ means that: (1) we call an oracle (subroutine) N for $\vdash w \dashv$ with the current position i and the current working tapes $\mathcal{T}$ as its initial working tapes; and (2) if N accepts w, then we enter a state q with the original position i and working tapes $\mathcal{U}$ of N's accepting configuration. The semantics of $p \xrightarrow{\notin N} q$ means that, if N does not accept w, we enter a state q with the original position and working tapes $\mathcal{T}$.[2]

▶ **Example 12.** Using log-space nested-oracles NTMs, we simulate the following REWBLk:

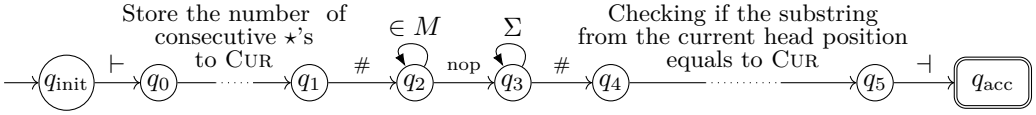
$$E_{\text{reach}} = (V^*)_{\text{Cur}}\,\#\,\left(?(\Sigma^*\,\#\setminus\text{Cur} \to (V^*)_{\text{Cur}}\,\#)\right)^*\,\Sigma^*\,\#\setminus\text{Cur}.$$

For the sake of simplicity, we assume that $V = \{\star\}$ is a unary alphabet. The subexpression $(\Sigma^*\,\#\setminus\text{Cur} \to (V^*)_{\text{Cur}}\,\#)$ is simulated by the following log-space NTM $M \in \mathbf{NLOG}$:



[2] For simplicity, our oracle formalization differs from traditional treatments [17, 21, 26, 3] in some points: (1) we omit the use of oracle tapes, and (2) we allow inheriting configurations from called oracles. Despite these differences, our definition is adequate for Theorem 13 and for REWBLk in Section 6.

Using M, we give the following machine $N \in \mathbf{OLOG}^1$, clearly accepting $L(E_{\text{reach}})$:

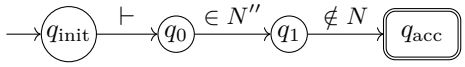


where edges labelled with "nop", $\xrightarrow{\text{nop}}$, mean transitions that only change states and do not depend scanning symbol. It just a syntax sugar because we can define $p \xrightarrow{\text{nop}} q$ by $p \xrightarrow{\epsilon \mid 0} q$.

▶ **Example 13.** We can also accept the language of non-reachability problems:

$$L_{\text{non-reach}} = \{s \# x_1 \to y_1 \# \cdots \# x_n \to y_n \# t : \text{there is no path from } s \text{ to } t\}.$$

To recognize this language, we use the following $M_{\text{non-reach}} \in \mathbf{OLOG}^2$:



where $N'' \in \mathbf{NLOG}$ recognizes the language defined by $V^* \# (V^* \to V^* \#)^* V^*$.

5.2 Collapsing OLOG$^\omega$ by Immerman–Szelepcsényi Theorem

Thanks to Proposition 11, we can give a decision procedure to check $w \in_? L(M_{\text{non-reach}})$ for our above examples. However, it is not clear that $\mathbf{OLOG}^2 =_? \mathbf{NLOG}$ and more generally $\mathbf{OLOG}^\omega =_? \mathbf{NLOG}$. For example, is there a log-space NTM N that recognizes $L_{\text{non-reach}}$?

Fortunately, the class **NLOG** is closed under complement, **NLOG** = **co-NLOG**. This result is known as Immerman–Szelepcsényi theorem [16, 27]. We employ their proof to collapse $\mathbf{OLOG}^x$ for some x to log-space NTMs $\mathbf{OLOG}^0 = \mathbf{NLOG}$.

▶ **Lemma 14.** *Let $M \in \mathbf{NLOG}(c, k)$. There is a machine $\overline{M} \in \mathbf{NLOG}(O(c \cdot k), k + \partial)$ where $L(\overline{M}) = \Sigma^* \setminus L(M)$ and ∂ is independent of M, c, and k.*

Proof. We review Immerman's original construction in [16]. For the reader who would like to know more detailed explanation about his construction, we recommend some literature [26]. His construction consists of the following two parts:

- Let START be a configuration of M. First, we compute the number C, the total number of configurations reachable from START.
- Next, using C, we check if there is a path from START to an acceptable configuration.

The first part is accomplished by the following pseudocode [16, Lemma 2].

```
global w; // input string

// For configurations x and x', we check if x ⇒ x'
def one_step_M(x, x'):
    foreach δ ∈ Δ(M): // Δ(M) is the set of transition rules of M
        if x ⇒^δ x': return True;
    return False;

// calculate the total number of configurations reachable from START
def counting_M(START):
    cur ← 1; // the number of reachable configurations within ≤ dist steps
```

```
    for(dist ← 0,next ← 0; dist < |Valid_M(w)|; dist += 1, cur ← next, next ← 0):
        foreach x ∈ Valid_M(w):
            count ← 0; found_x ← false;
            foreach y ∈ Valid_M(w):
                z ← START; // search a path from START to y
                for(i ← 0; z ≠ y & i < dist; i += 1):
                    z' ← Nondeterministically generated configuration;
                    if one-step(z, z'): z ← z';
                    else: break;
                if z = y:
                    count += 1;
                    if one-step(y, x): { next += 1; found_x ← true; break; }
            if ¬found_x & count ≠ cur: Halt and reject;
    return cur;
```

These functions require extra working tapes at least for variables of δ, *cur*, *dist*, *next*, x, *count*, y, i, z, and z'. By Proposition 10, for each variable, we need an $O(c \cdot k)$-bound working tape.

The second part is accomplished by the following pseudocode [16, Lemma 1].

```
// Judge whether an acceptable configuration can be reached from START.
// If so, it returns such a configuration y by SOME(y).
// Otherwise, we return the nothing by NONE.
def judge_M(START):
    C ← counting_M(START);
    count ← 0;
    foreach x ∈ Valid_M(w):
        y ← START;
        for(i ← 0; i ≤ C; i += 1):
            y' ← Nondeterministically generated configuration;
            if one-step(y, y'):
                y ← y';
                if y is an accepting configuration: return SOME(y);
                if y = x: { count += 1; break; }
            else: break;
    if count = C: return NONE;
    else: Halt and reject;
```

This function also requires extra $O(c \cdot k)$-bound working tapes.

Now we can build $\overline{M} \in \mathbf{NLOG}(O(c \cdot k), k + \partial)$ as a log-space NTM that simulates the function `judge` and then accepts inputs if $\texttt{judge}_M(\textsc{Start})$ is NONE. ◀

Repeatedly applying Immerman's construction collapses nested oracle machines to machines without oracles [16, Corollary 2].

▶ **Theorem 15.** *Let $M \in \boldsymbol{OLOG}^n(c, k)$ be a log-space n-nested-oracles NTM. There exists a log-space NTM $N \in \mathbf{NLOG}(O(c \cdot k^n), O(k \cdot n))$ such that $L(M) = L(N)$.*

Proof. We eliminate oracle transitions from the innermost to the outermost for M as follows. We replace $p \xrightarrow{\in N} q$ with $N \in \mathbf{OLOG}^0$ with multiple transition rules that perform: (1) save the head position H to an extra tape; (2) run N; (3) if we reach an accepting configuration

$\langle q_f, \mathcal{T}\rangle$, then we continue $\langle q, H, \mathcal{T}\rangle$. Similarly, we replace $p \xrightarrow{\notin N} q$ with $N \in \mathbf{OLOG}^0$ with multiple transition rules using $\overline{N}$ obtained by Immerman's construction. We emphasize that each generation of $\overline{N}$ increases c and k in the order of the statement of Lemma 14. ◀

5.3 Membership Problem of OLOG$^\omega$

We now show that the membership problem of log-space nested-oracles machines is in **PSPACE**. We first formally state our membership problem.

▶ **Definition 16** (Membership problem of **OLOG**$^\omega$). *The membership problem of* ***OLOG***$^\omega$ *is a decision problem of the following form:*
Inputs *Binary encoded integers c and k. A machine $M \in \boldsymbol{OLOG}^\omega(c,k)$. A word $w \in \Sigma^*$.*
Output *If $w \in_? L(M)$, return Yes. Otherwise, No.*

To show that the problem belongs to **PSPACE**, we would like to employ Theorem 15. However, it is not feasible because the theorem gives a log-space $O(c \cdot k^{|M|})$-bounded tapes machine N in general; i.e., N demands $O(c \cdot k^{|M|}) \cdot \log|w|$ space. Thus, we cannot simulate N in polynomial size in c, k, $|M|$, and $|w|$. To address this problem, we adopt Immerman's construction for **OLOG**$^\omega$ in an interpreter style.

▶ **Theorem 17** (Membership problem of **OLOG**$^\omega$ belongs to **PSPACE**). *Let w be an input word and $M \in \boldsymbol{OLOG}^\omega(c,k)$ be an input machine where c and k are binary encoded. We can decide if $w \in_? L(M)$ in polynomial space in c, k, $|w|$, and $|M|$.*

Proof. First, we extend the function `one-step` for oracle transitions as follows:

```
def one-step_{M_i}(x, x'): // return True if x ⇒ x'. Otherwise, False.
    foreach δ ∈ Δ(M_i):
        if δ is a non-oracle transition & x ⇒^δ x': return True;
        else: // δ is an oracle transition
            (p, i, T) ← x; // extract state, position, and tape contents from x
            if δ = p --∈N--> q:
                match judge_N(⟨q^N_init, i, T⟩): // pattern matching
                case Some(⟨p', i', U⟩) -> return (x' =_? ⟨q, i, U⟩);
                case None -> return False;
            if δ = p --∉N--> q:
                match judge_N(⟨q^N_init, i, T⟩):
                case Some(⟨p', i', U⟩) -> return False;
                case None -> return (x' =_? ⟨q, i, T⟩);
    return False;
```

Next, we generate the codes of $\texttt{one-step}_{M_i}$, $\texttt{counting}_{M_i}$, and $\texttt{judge}_{M_i}$ for all oracle machines M_i that appears in M. Such generation is carried out in polynomial-time for $|M|$. The total size of generated code is also polynomial in $|M|$.

We can also provide an interpreter for the generated code in polynomial time for $|M|$. While this interpreter needs a call stack for function calls, its depth is bounded by $\mathit{depth}(M) \leq |M|$. Additionally, the size of each stack frame is bounded by $O((c{\cdot}k)\log|w|)$ by Proposition 10. From the above argument, we can check $w \in_? L(M)$ using (nondeterministic) polynomial space with respect to c, k, $|w|$, and $|M|$. ◀

We will use this theorem to show that the membership problem of REWBLk belongs to **PSPACE** in the following section. To this end, we put remarks about this theorem.

Remark (Drop k from Theorem 17). We can decide $w \in_? L(M)$ in polynomial space for c, $|w|$, and $|M|$. Compared with Theorem 17, this refined version does not depend on k. This is because $k \leq |M|$ holds, even when k is binary encoded.

Of course, to establish this property, we assume a natural restriction that all tapes $T_1, \ldots, T_k$ are used in some transition rules. Indeed, if $M \in \mathbf{OLOG}^\omega(c, k)$ has a working tape T_i with $1 \leq i \leq k$ that is not engaged by M, a better parameter k' (where $k' < k$) should be employed, ensuring $M \in \mathbf{OLOG}^\omega(c, k')$. Given such constraints, $|M| \geq k \cdot \log(k) \geq k$ since k tapes necessitate $\log(k)$-space for tape identification.

Remark (Cannot drop c from Theorem 17). On the other hand, we cannot drop c from Theorem 17. Namely, we cannot decide $w \in_? L(M)$ in polynomial space for $|w|$ and $|M|$ because c is not bounded by Poly($|M|$) in general. (Please recall that $k \leq |M|$.) It can be understood from the following argument, which establishes $c = \Omega(2^{|M|})$. Let us consider a machine M that runs as follows:

- First, M fills a tape T_1 with N 1's by using states $q_1, q_2, \ldots, q_N$.
- Next, M interprets T_1 as a binary number t_1 and fills a tape T_2 with t_1 1's.
- Finally, M writes the contents of T_2 N times to T_3.
- For example, if $N = 3$, then M makes $T_1 = 111$ and then makes $T_2 = 1111111 = 1^{2^3-1}$ and then $T_3 = 3\,T_2 = 1^{3\cdot(2^3-1)} = 1^{N\cdot(2^N-1)}$.

The size of M satisfies $|M| = O((\log N)N)$ since it contains binary-encoded N states; thus, the length of T_3, $|T_3|$, satisfies $|T_3| = \Omega(2^{|M|})$. By appending the content of T_3 onto another tape $\log|w|$ times (where w is the input word), we establish that $c = \Omega(2^{|M|})$.

However, fortunately we can assume $c = 1$ when simulating REWBLK by $\mathbf{OLOG}^\omega$ as we will see below. It is crucial for showing that the membership problem of REWBLK belongs to **PSPACE**.

6 From REWBLk to Log-space NTM via OLOG$^\omega$

We finally show **REWBLk** $\subseteq$ **NLOG** by translating REWBLKs to $\mathbf{OLOG}^\omega$.

▶ **Theorem 18.** *Given a REWBLK expression E, we can translate it to $M \in \mathbf{OLOG}^\omega(1, O(|E|))$ in polynomial time in the size of $|E|$ where $L(E) = L(M)$.*

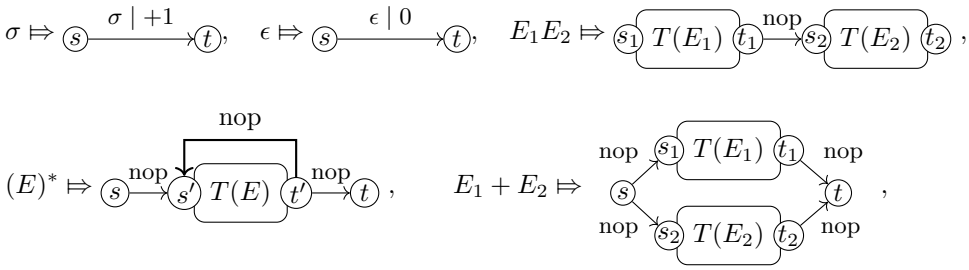
Proof. We inductively translate a REWBLK expression E to an $\mathbf{OLOG}^\omega$ $T(E)$ such that $w \in L(E)$ if and only if $T(E)$ successfully runs through w when started with w instead of $\vdash w \dashv$.

As we will see below, the generated $T(E)$ has a unique source state s, which does not have incoming edges, and a unique sink state t, which does not have outgoing edges. Please recall that E accepts an input w if it consumes all the input, i.e., if we have $\langle p, \Lambda\rangle \in [\![\langle E, w, 0, \iota\rangle]\!]$ with $p = |w|$. To build our M, we add two transition rules to $T(E)$ to treat the end markers $\vdash$ and $\dashv$ as follows:

$M =$ 
where i and f are initial and accepting states of M.

Translating REGEX Part

First, we give a translation for the REGEX as follows:

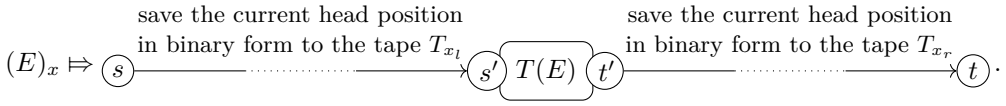


where the edges labelled with "nop" are the same ones used in Example 12, which just change states. This translation is identical to the McNaughton–Yamada–Thompson algorithm, which is well-known and found in textbooks of automata theory.

Translating Backreference and Capturing Expressions

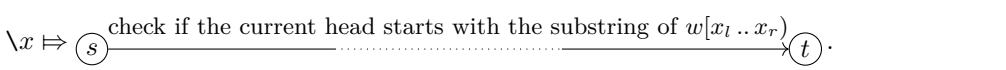
Using Theorem 2, we can assume that every variable x does not appear inside an expression capturing x; i.e., we avoid patterns such that $(\cdots x \cdots)_x$. The following translation heavily depends on the theorem.

We now focus on the part $(E)_x$ of REWB:



In order to keep the start position of the variable x, we first copy the current head position to the special working tape T_{x_l} in binary form. Then, we execute the expression E by running from the state s to t. Finally, we record the new head position into the working tape T_{x_r}. Now, $w[x_l \,..\, x_r) = w[x_l]w[x_l+1]\cdots w[x_r-1]$ is a substring matched with the expression E where x_l and x_r are the numbers corresponding to the contents of T_{x_l} and T_{x_r}.

Next, we focus on the part $\backslash x$ of REWB:



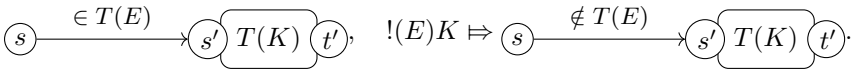
As we have seen above, the substring $w[x_l \,..\, x_r)$ denotes the value of the variable x. This checking task is accomplished using an extra tape T_{tmp} without changing T_{x_l} and T_{x_r}.

Remark: Why do we need Theorem 2. Let us consider an expression $E = (a)_x\ (\backslash x \backslash x)_x$ and run it for an input string a. We underline $a \notin L(E)$. By interpreting $(a)_x$, we set the position 0 to T_{x_l} and 1 to T_{x_r}. On the translation of $(\backslash x \backslash x)_x$, we first save the current head position 1 to the tape T_{x_l} and then proceed to the part $\backslash x \backslash x$. It should be noted that, at this point, T_{x_l} denotes 1; so, we cannot correctly recover the captured content by $(a)_x$. When meeting $\backslash x$, we check if the substring between $T_{x_l}(=1)$ and $T_{x_r}(=1)$ starts from the current head position. Since the substring is the empty string ϵ, we go through the part $\backslash x \backslash x$ and accepts a incorrectly.

To prevent us from this situation, we use Theorem 2. It rewrites E to $(a)_x\ ?((\backslash x \backslash x)_y)(\backslash y)_x$, and the rewritten expression is safely interpreted thanks to the variable y.

Translating Positive and Negative Lookaheads

For our construction, we need that lookahead are augmented with a continuation K, for instance $?(E)K$ and $!(E)K$. If a given expression does not satisfy this property, we add the expression ϵ, which always succeeds. For example, $(E_1E_2!(E_3))^*E_4 \Rightarrow (E_1E_2(!(E_3)\epsilon))^*E_4$. Now, we can easily translate $?(E)K$ and $!(E)K$ using oracle transition rules as follows:



By the semantics of our nested oracle machines, it is clear that $L(E) = L(M)$. ◀

As corollaries of Theorem 18, we have the following main results.

▶ **Corollary 19.** **REWBLk** = **NLOG**.

Proof. We already have **NLOG** ⊆ **REWBLk** by Theorem 8. It is an immediate result from Theorem 15 and 18 that **REWBLk** ⊆ **NLOG**. ◀

▶ **Corollary 20.** *The membership problem of REWBLk is* ***PSPACE****-complete.*

Proof. By Theorem 9, the membership problem of REWBLk is **PSPACE**-hard.

The result that the problem belongs to **PSPACE** is shown as follows. Let E be an input REWBLk expression and w be an input string. By Theorem 17, we translate $M \in \mathbf{OLOG}^{\omega}(1, O(|E|))$ such that $L(E) = L(M)$. This translation is carried out in polynomial time in $|E|$; so, $|M| = \mathrm{Poly}(|E|)$. By Theorem 17 and its remarks, we can check if $w \in_? L(M)$ in polynomial space in $|w|$ and $|M|$. This also derives that we can check if $w \in_? L(E)$ in polynomial space in $|w|$ and $|E|$. ◀

7 Future Work and Conclusion

We have shown that the language class REWBLk – regular expressions plus backreferences and lookaheads (without any restrictions) – captures the class **NLOG**. Our result closes the expressiveness about REWBLk. Furthermore, we have shown that the membership problem of REWBLk is **PSPACE**-complete. On the other hand, it remains unclear whether REWB(+) and REWB(−) are proper subclasses of REWBLk. For example, we conjecture that REWB(+) cannot recognize the language $L_{\text{prime}} = \{a^n : n \text{ is a prime number}\}$.[3] It is known that the language can be represented by REWB(−). Also, we conjecture that some **NLOG**-languages cannot be recognized by REWB(−).

Abstract

Population protocols are a well-studied model of distributed computation in which a group of anonymous finite-state agents communicates via pairwise interactions. Together they decide whether their initial configuration, i. e., the initial distribution of agents in the states, satisfies a property. As an extension in order to express properties of multisets over an infinite data domain, Blondin and Ladouceur (ICALP'23) introduced population protocols with unordered data (PPUD). In PPUD, each agent carries a fixed data value, and the interactions between agents depend on whether their data are equal or not. Blondin and Ladouceur also identified the interesting subclass of immediate observation PPUD (IOPPUD), where in every transition one of the two agents remains passive and does not move, and they characterised its expressive power.

We study the decidability and complexity of formally verifying these protocols. The main verification problem for population protocols is well-specification, that is, checking whether the given PPUD computes some function. We show that well-specification is undecidable in general. By contrast, for IOPPUD, we exhibit a large yet natural class of problems, which includes well-specification among other classic problems, and establish that these problems are in ExpSpace. We also provide a lower complexity bound, namely coNExpTime-hardness.

1 Introduction

Population protocols (PP) model distributed computation and have received a lot of attention [1, 2, 9, 12, 14, 18] since their introduction in 2004 [3]. In a PP, a collection of indistinguishable mobile agents with constant-size memory communicate via pairwise interactions. When two agents meet, they exchange information about their states and update their states accordingly. The agents collectively compute whether their input configuration, i. e., the initial distribution of agents in each state, satisfies a certain predicate. For a PP to compute a predicate, the protocol must be *well-specified*, i. e., for every initial configuration, all fair runs starting in this configuration must converge to the same answer. It was shown that PP compute exactly the predicates of Presburger arithmetic [4]. Moreover, well-specification is known to be decidable but as hard as the reachability problem for Petri nets [17]. Note that deciding well-specification is a problem that concerns *parameterised verification* in the sense of [8, 15], i. e., one must decide that something holds with respect to every value of the parameter. Here the parameter is the number of agents that are present – the PP must converge to one answer for every initial configuration, no matter the number of agents.

Population protocols with unordered data (PPUD) were introduced by Blondin and Ladouceur as a means to compute predicates over arbitrarily large domains [10]. In this setting, each agent holds a read-only datum from an infinite set $\mathbb{D}$. When interacting, agents may check (dis)equality of their data. While PP can compute properties like "there are more than 5 agents in state q_1", PPUD can express, e. g., "there are more than 2 data with 5 agents each in state q_1". In [10], the authors construct a PPUD computing the absolute majority predicate, i. e., whether a datum is held by more than half of the agents. They also characterise the expressive power of *immediate observation PPUD* (IOPPUD), a subclass of interest in which interactions are restricted to observations. That is, in every interaction, one of the two agents is passive and does not change its state. The decidability and complexity of the main verification question for PPUD, namely well-specification, is left open in Blondin's and Ladouceur's article [10]. It is the subject of this paper.

Contributions. We start by showing that well-specification is *undecidable* for PPUD. This follows from a reduction from 2-counter machines; in fact, the presence of data allows us to encode zero-tests. Contrasting this, we show that deciding well-specification is in ExpSpace for IOPPUD. To this end, we define *generalised reachability expressions* (GRE) and establish that, for IOPPUD, deciding whether the set of configurations that satisfy a given GRE is empty is in ExpSpace. This decidability result is powerful; indeed, this emptiness problem subsumes classic verification problems like reachability and coverability, as well as parameterised verification problems such as well-specification and correctness, where the latter asks whether a given protocol computes a given predicate. Lastly, we exhibit a coNExpTime lower bound for deciding emptiness of GRE for IOPPUD.

Related work. For a recent survey of the research on verification of PP (without data), see [16]. In particular, the well-specification problem for PP is known to be decidable, but as hard as Petri net reachability [17] and therefore Ackermann-complete [13, 24, 25]. In their seminal paper on the computational power of PP, Angluin, Aspnes, Eisenstat, and Ruppert

also introduced five subclasses of PP that model one-way communication [4]. One of these is immediate observation population protocols (IOPP), which correspond to IOPPUD without data. The complexity of well-specification for all five subclasses is determined in [18]. In particular, the paper shows that well-specification for IOPP is PSpace-complete. IOPP were modelled by immediate observation Petri nets, where classic parameterised problems can be decided in polynomial space. The notion of generalised reachability expression was first phrased in this setting, and one of the consequences is that the emptiness problem of GRE for IOPP is PSpace-complete [29]. Our result shows that adding data to the model as in [9] (and extending GRE naturally) pushes the emptiness problem between coNExpTime and ExpSpace.

While the introduction of data in the PP model happened recently [10], a similar approach has been studied in the related model of Petri nets, under the name of *data nets*. In this setting, the classic problem of coverability (or control-state reachability) is decidable but non-primitive recursive [23] and in fact $\mathbf{F}_{\omega^\omega}$-complete [27]. While PPUD can be encoded into data nets, our results show that the problems that we study cannot be reduced to coverability. Another related model is formed by broadcast networks of register automata (BNRA) [20], an extension of reconfigurable broadcast networks (RBN) with data. RBN subsume IOPP [6], and consequently BNRA subsume IOPPUD. However, the complexity of coverability in BNRA is known to be $\mathbf{F}_{\omega^\omega}$-complete, hence non-primitive recursive, and more complex problems quickly become undecidable [20]. These hardness results contrast with the ExpSpace membership.

Organisation. In Section 2, we introduce the models of PPUD and IOPPUD, the notion of GRE, and we state our main results. We prove undecidability of well-specification for PPUD in Section 3. The next sections are dedicated to the study of IOPPUD. In Section 4, we establish bounds on the number of observed agents. In Section 5, we introduce the technical notions of boxes and containers and use the bounds from the previous section to translate GRE into containers. We present the complexity bounds for emptiness of GRE in Section 6.

2 Population Protocols and Main Results

We use the notation $[m, n] \coloneqq \{\ell \in \mathbb{N} \mid m \leq \ell \leq n\}$ for $m, n \in \mathbb{N}$ and $[m, +\infty) \coloneqq \{\ell \in \mathbb{N} \mid m \leq \ell\}$.

2.1 Population Protocols with Unordered Data

We fix an infinite *data* domain $\mathbb{D}$, an infinite set of *agents* $\mathbb{A}$, and a function $\mathbf{dat}\colon \mathbb{A} \to \mathbb{D}$ such that $\mathbf{dat}^{-1}(d)$ is infinite for all $d \in \mathbb{D}$. For $d \in \mathbb{D}$, a *d-agent* is an agent $a \in \mathbb{A}$ with $\mathbf{dat}(a) = d$.

▶ **Definition 1.** *A* population protocol with unordered data *(PPUD) is a tuple* (Q, Δ, I, O) *where Q is a finite set of* states*, $\Delta \subseteq Q^2 \times \{=, \neq\} \times Q^2$ the set of* transitions*, $I \subseteq Q$ the set of* initial states*, and $O\colon Q \to \{\top, \bot\}$ the* output function*.*

The size of a PPUD $\mathcal{P}$, written $|\mathcal{P}|$, is its number of states. We fix a PPUD (Q, Δ, I, O).

A *configuration* is a function $\gamma\colon \mathbb{A} \to Q \cup \{*\}$ such that $\gamma(a) \in Q$ only holds for finitely many agents $a \in \mathbb{A}$ (the agents *appearing* in γ). We denote by Γ the set of all configurations, and by $\Gamma_{\mathsf{init}} \coloneqq \{\gamma \in \Gamma \mid \forall a \in \mathbb{A},\, \gamma(a) \notin Q \setminus I\}$ the set of *initial configurations*. Given $\gamma \in \Gamma$ and $d \in \mathbb{D}$, we let $\gamma_d^{\#}\colon Q \to \mathbb{N}$ be the function that maps each state q to the number of d-agents in q in γ.

Given $\gamma, \gamma' \in \Gamma$, we write $\gamma \to \gamma'$, and call it a *step* from γ to γ', when there are states $q_1, q_2, q_3, q_4 \in Q$ and two distinct agents $a_1, a_2 \in \mathbb{A}$ such that $((q_1, q_2), \bowtie, (q_3, q_4)) \in \Delta$, $\gamma(a_1) = q_1$, $\gamma(a_2) = q_2$, $\gamma'(a_1) = q_3$, $\gamma'(a_2) = q_4$, $\gamma(a) = \gamma'(a)$ for all $a \in \mathbb{A} \setminus \{a_1, a_2\}$, and, additionally, if $\bowtie$ is an equality (resp. disequality), then $\mathbf{dat}(a_1) = \mathbf{dat}(a_2)$ (resp. $\mathbf{dat}(a_1) \neq \mathbf{dat}(a_2)$). A *run* ρ is a (finite or infinite) sequence of consecutive steps $\rho\colon \gamma_1 \to \gamma_2 \to \gamma_3 \to \dots$. We write $\rho\colon \gamma \xrightarrow{*} \gamma'$ to denote that ρ is a finite run from γ to γ', and simply $\gamma \xrightarrow{*} \gamma'$ to denote the existence of such a run. For every $\gamma \in \Gamma$, let $\mathsf{Post}^*(\gamma) \coloneqq \{\gamma' \in \Gamma \mid \gamma \xrightarrow{*} \gamma'\}$ and $\mathsf{Pre}^*(\gamma) \coloneqq \{\gamma' \in \Gamma \mid \gamma' \xrightarrow{*} \gamma\}$. A run ρ *covers* a state $q \in Q$ if there is a configuration γ in ρ such that $\gamma(a) = q$ for some agent a.

In accordance with [3] and [10], we consider a run $\gamma_1 \to \gamma_2 \to \dots$ *fair* if it is infinite[1] and for every configuration γ with $\left|\{i \in \mathbb{N} \mid \gamma_i \xrightarrow{*} \gamma\}\right| = \infty$, it holds that $\left|\{i \in \mathbb{N} \mid \gamma_i = \gamma\}\right| = \infty$. That is, every infinitely often reachable configuration also occurs infinitely often along the run. For $b \in \{\top, \bot\}$, a *b-consensus* is a configuration γ in which, for all agents $a \in \mathbb{A}$ appearing in γ, it holds that $O(\gamma(a)) = b$. A fair run $\rho\colon \gamma_1 \to \gamma_2 \to \cdots$ *stabilises* to $b \in \{\top, \bot\}$ if there is an $n \in \mathbb{N}$ such that for every $i \geq n$, γ_i is a b-consensus. A protocol is *well-specified* if, for every initial configuration $\gamma_0 \in \Gamma_{\mathsf{init}}$, there is $b \in \{\top, \bot\}$ such that all fair runs starting in γ_0 stabilise to b. The *well-specification problem* for PPUD asks, given a PPUD $\mathcal{P}$, whether $\mathcal{P}$ is well-specified. Given a PPUD $\mathcal{P}$ and a function $\Pi\colon \Gamma_{\mathsf{init}} \to \{\top, \bot\}$, $\mathcal{P}$ *computes* Π if, for every $\gamma_0 \in \Gamma_{\mathsf{init}}$, every fair run of $\mathcal{P}$ starting in γ_0 stabilises to $\Pi(\gamma_0)$.

▶ **Example 2.** Consider the following PPUD $\mathcal{P}$. Its set of states is $Q = \{\ell_0, \ell_1, \mathsf{f}_0, \mathsf{f}_1, \mathsf{dead}\}$, with $I = \{\ell_1\}$, $O(\ell_0) = O(\mathsf{f}_0) = \top$, $O(\ell_1) = O(\mathsf{f}_1) = O(\mathsf{dead}) = \bot$ and its transitions are:

$$\forall b, b' \in \{0,1\},\ (\ell_b, \ell_{b'}) \mapsto (\ell_{b \oplus b'}, \mathsf{f}_{b \oplus b'}) \qquad \forall b, b' \in \{0,1\},\ (\ell_b, \mathsf{f}_{b'}) \mapsto (\ell_b, \mathsf{f}_b)$$
$$\forall q, q' \in Q,\ (q, q') \mapsto_{=} (\mathsf{dead}, \mathsf{dead}) \qquad \forall q \in Q,\ (q, \mathsf{dead}) \mapsto (\mathsf{dead}, \mathsf{dead})$$

where $\mapsto_{=}$ denotes that the data of the agents must be equal, $\mapsto$ without subscript means no condition on data (or equivalently, the transition exists both for equality and disequality), and $\oplus$ denotes the XOR operator. $\mathcal{P}$ is well-specified and computes the function Π that is equal to $\top$ whenever there is an even number of appearing data and they all have exactly one corresponding agent. To see this, if there are two agents of equal datum, then all fair runs eventually have all agents on dead and stabilise to $\bot$. Otherwise, there will eventually be a single agent in $\{\ell_0, \ell_1\}$, and it will be on ℓ_b if and only if the number of agents has parity b, in which case all other agents will eventually go to f_b and the run stabilises to $\bot$ if $b = 1$ (odd number of agents) and to $\top$ if $b = 0$ (even number of agents).

A more interesting but also more complex example is the majority protocol described in [10, Section 3]; it computes whether a datum has the absolute majority, i. e., strictly more agents than all other data combined.

Well-specification is the fundamental verification problem for population protocols. However, as we will see in Section 3, this problem is undecidable for PPUD.

▶ **Theorem 3.** *The well-specification problem for PPUD is undecidable.*

This motivates the study of the restricted class of *immediate observation* PPUD.

[1] One often considers that a finite run $\gamma_f \xrightarrow{*} \gamma_\ell$ is fair when there is no γ such that $\gamma_\ell \to \gamma$. In the following, we rule out this possibility by implicitly assuming that, for all $q_1, q_2 \in Q$ and $\bowtie \in \{=, \neq\}$, it holds that $((q_1, q_2), \bowtie, (q_1, q_2)) \in \Delta$, and ignoring the trivial cases of runs with at most one agent.

2.2 Immediate Observation Protocols

Immediate observation protocols [4] are a restriction of population protocols where, when two agents interact, one of the two agents does not change its state. The restriction of the model with data to immediate observation was first considered in [10].

▶ **Definition 4.** *An* immediate observation population protocol with unordered data *(or* IOPPUD*) is a PPUD* $\mathcal{P} = (Q, \Delta, I, O)$ *where every transition* $\delta \in \Delta$ *is of the form* $(q_1, q_2, \bowtie, q_1, q_3)$*, with* $q_1, q_2, q_3 \in Q$ *and* $\bowtie \in \{=, \neq\}$*, i. e., the first agent does not change its state.*

For IOPPUD, we denote a transition $(q_1, q_2, \bowtie, q_1, q_3)$ by $q_2 \xrightarrow{\bowtie q_1} q_3$. If we have a step $\gamma \to \gamma'$ with transition $q_2 \xrightarrow{\bowtie q_1} q_3$ that involves agents $a, a_o \in \mathbb{A}$ where a is the agent moving from q_2 to q_3 and a_o is the agent in q_1, we denote it by $\gamma \xrightarrow{\bowtie a_o}_a \gamma'$. We say that agent a *observes* agent a_o, and call a_o the *observed* agent. Intuitively, a "observes" a_o and reacts, whereas a_o may not even know it has been observed.

▶ **Example 5.** Consider the following IOPPUD $\mathcal{P} = (Q, \Delta, I, O)$, with $Q \coloneqq \{q_0, q_1, q_2, q_3\}$, $I \coloneqq \{q_0, q_1\}$, $O(q_3) = \top$, $O(q) = \bot$ for all $q \neq q_3$, and transitions in Δ as follows:

$$q_0 \xrightarrow{=q_1} q_2 \quad q_1 \xrightarrow{=q_0} q_2 \quad q_2 \xrightarrow{\neq q_2} q_3 \qquad \forall q \in \{q_1, q_2\}, \forall \bowtie \in \{=, \neq\}, q \xrightarrow{\bowtie q_3} q_3$$

This protocol is well-specified: from $\gamma_0 \in \Gamma_{\mathsf{init}}$, all fair runs stabilise to $\top$ if two data have agents on both q_0 and q_1, and all fair runs stabilise to $\bot$ otherwise. Indeed, if there is a datum with agents on both q_0 and q_1, by fairness eventually an agent with this datum is sent to q_2; if there are two such data, then eventually some agent covers q_3, and then all agents are sent to q_3 and the run stabilises to $\top$. Conversely, if it is not the case, then q_3 cannot be covered and all fair runs stabilise to $\bot$.

Let $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ be a run. Agent a_o is *internally observed* (resp. *externally observed*) in ρ if ρ contains a step of the form $\gamma_1 \xrightarrow{=a_o}_a \gamma_2$ (resp. $\gamma_1 \xrightarrow{\neq a_o}_a \gamma_2$); it is *observed* if one of the two cases holds. Similarly, a datum d is *observed* in ρ if an agent a with $\mathbf{dat}(a) = d$ is observed in ρ; we define similarly a datum being internally or externally observed.

While the set of functions that can be computed by PPUD remains an open question, it is known that IOPPUD exactly compute interval predicates [10], defined as follows. Let S be a finite set. A *simple interval predicate* over S is a formula ψ of the form $\dot{\exists}\mathsf{d}_1, \ldots, \mathsf{d}_m, \bigwedge_{q \in S} \bigwedge_{j=1}^{m} \#(q, \mathsf{d}_j) \in [A_{q,j}, B_{q,j}]$ where, for all $q \in S$ and $j \in [1, m]$, we have $A_{q,j} \in \mathbb{N}$ and $B_{q,j} \in \mathbb{N} \cup \{+\infty\}$. The dotted quantifiers quantify over *pairwise distinct* data. Formally, given a protocol $\mathcal{P}$ with set of states Q such that $S \subseteq Q$ and given $\gamma \in \Gamma$, the predicate ψ is *satisfied* by γ if there exist pairwise distinct data $d_1, \ldots, d_m \in \mathbb{D}$ such that for all $q \in S$ and $j \in [1, m]$, it holds that $\gamma^{\#}_{d_j}(q) \in [A_{q,j}, B_{q,j}]$ (resp. $\gamma^{\#}_{d_j}(q) \in [A_{q,j}, B_{q,j})$ in the case that $B_{q,j} = +\infty$). An *interval predicate* over S is a Boolean combination φ of simple interval predicates over S; we define that φ is *satisfied* by a configuration γ if the simple interval predicates satisfied by γ satisfy the Boolean combination.

▶ **Theorem 6** ([10], Theorem 18 and Corollary 29)**.** *Given a finite set* I*, the functions computed by IOPPUD with set of initial states*[2] I *are exactly the interval predicates over* I*.*

▶ **Example 7.** The protocol described in Example 2 and the majority protocol of [10, Section 3] cannot be turned into immediate observation protocols, as they compute functions that cannot be expressed as interval predicates. The immediate observation protocol from Example 5 computes the following interval predicate, which is actually a simple interval predicate:

$$\dot{\exists}\mathsf{d}_1, \mathsf{d}_2, (\#(q_0, \mathsf{d}_1) \geq 1) \wedge (\#(q_1, \mathsf{d}_1) \geq 1) \wedge (\#(q_0, \mathsf{d}_2) \geq 1) \wedge (\#(q_1, \mathsf{d}_2) \geq 1).$$

[2] This does not limit the number of states of said protocols, as their set of states Q may be larger than I.

Given a simple interval predicate $\psi = \dot{\exists}\mathsf{d}_1, \ldots, \mathsf{d}_m, \bigwedge_{q \in I} \bigwedge_{j=1}^{m} \#(q, \mathsf{d}_j) \in [A_{q,j}, B_{q,j}]$, we define its *width* as m, its *height* h as the maximum of all finite $A_{q,j}$ and $B_{q,j}$, and its *size* as $|I| \cdot m \cdot \mathsf{log}(h)$. We also define the *width* (resp. *height*) of an interval predicate as the maximum of the widths (resp. heights) of its simple interval predicates, and its *size*, measuring the space taken by its encoding, as the sum of their sizes plus its number of Boolean operators.

▶ Remark 8. In [10], predicates refer to an input alphabet Σ, which is converted into initial states using an input mapping. For convenience, we have not included the input alphabet in our model, which is why we arbitrarily fix a set of initial states I in Theorem 6.

2.3 Generalised Reachability Expressions

We define a general class of specifications, called generalised reachability expressions, which are formulas constructed using interval predicates as atoms and using union, complement, Post^*, and Pre^* as operators. This concept is inspired by [29, Section 2.4], although our choice of atoms is more general and adapted to the data setting.

▶ **Definition 9.** *Let $\mathcal{P} = (Q, \Delta, I, O)$ be a protocol.*
Generalised Reachability Expressions *(GRE) over $\mathcal{P}$ are produced by the grammar*

$$E ::= \varphi \mid E \cup E \mid \overline{E} \mid \mathsf{Post}^*(E) \mid \mathsf{Pre}^*(E),$$

where φ ranges over interval predicates over Q.

Given a GRE E, we define the set of configurations defined by E, denoted $[\![E]\!]_{\mathcal{P}}$, as the set containing all configurations of $\mathcal{P}$ that satisfy the formula, where the predicates are interpreted as above and the other operators are interpreted naturally (the overline denotes set complementation). This set is denoted $[\![E]\!]$ when $\mathcal{P}$ is clear from context.

The *length* $|E|$ of a GRE E is its number of operators. Letting $\varphi_1, \ldots, \varphi_k$ be the interval predicates used as atoms in E, the *norm* $||E||$ of E is the maximum of the heights and widths of the φ_i. Its *size* is the sum of the sizes of the φ_i plus $|E|$. The *emptiness problem for GRE* asks, given as input a protocol $\mathcal{P}$ and a GRE E over $\mathcal{P}$, whether $[\![E]\!]_{\mathcal{P}} = \emptyset$. We will show in Section 6 that, for IOPPUD, this problem is decidable.

▶ **Theorem 10.** *The emptiness problem for GRE over IOPPUD is in ExpSpace.*

We now argue that this decidability result is powerful, as it implies decidability of many classic problems on IOPPUD. We start with well-specification. We use the notation $\dot{\forall}\mathsf{d}, \varphi$ as a short form for $\neg\dot{\exists}\mathsf{d}, \neg\varphi$. Given a PPUD $\mathcal{P}$ and $b \in \{\top, \bot\}$, let $\mathsf{Out}_b := \dot{\forall}\mathsf{d}, \bigwedge_{q \notin O^{-1}(\{b\})} \#(q, \mathsf{d}) = 0$ be the GRE for b-consensus configurations; moreover, let $\mathsf{Stable}_b := \overline{\mathsf{Pre}^*(\overline{\mathsf{Out}_b})}$ be the GRE for *stable* b-consensus, i. e., configurations from which all runs lead to a b-consensus.

▶ **Proposition 11.** *Let $\mathcal{P}$ be a PPUD, $E_{ws} := \Gamma_{\mathsf{init}} \cap \mathsf{Pre}^*(\overline{\mathsf{Pre}^*(\mathsf{Stable}_\top)}) \cap \mathsf{Pre}^*(\overline{\mathsf{Pre}^*(\mathsf{Stable}_\bot)})$. $\mathcal{P}$ is well-specified if and only if $[\![E_{ws}]\!]_{\mathcal{P}} = \emptyset$.*

Proof. First, $\Gamma_{\mathsf{init}} = [\![\dot{\forall}\mathsf{d}, \bigwedge_{q \notin I} \#(q, d) = 0]\!]$ and E_{ws} is indeed a GRE over $\mathcal{P}$. For every $\gamma \in \Gamma$, $\mathsf{Post}^*(\gamma)$ is finite as all configurations reachable from γ have the same number of agents. Therefore, a fair run ρ that visits $\mathsf{Pre}^*(\mathcal{S})$ infinitely often for $\mathcal{S} \subseteq \Gamma$ must visit $\mathcal{S}$ infinitely often. Let $\gamma_0 \in \Gamma_{\mathsf{init}}$ and $b \in \{\top, \bot\}$; it suffices to prove that there is a fair run from γ_0 that does *not* stabilise to b if and only if $\gamma_0 \in [\![\mathsf{Pre}^*(\overline{\mathsf{Pre}^*(\mathsf{Stable}_b)})]\!]$. If, from γ_0, one can reach $\gamma \notin [\![\mathsf{Pre}^*(\mathsf{Stable}_b)]\!]$, then one can build a fair run from γ_0 that first goes to γ, and

then forever performs arbitrary steps in a fair way; since $\gamma \notin [\![\mathsf{Pre}^*(\mathsf{Stable}_b)]\!]$, it will stay in $[\![\mathsf{Pre}^*(\overline{\mathsf{Out}_b})]\!]$, so by fairness it visits $[\![\overline{\mathsf{Out}_b}]\!]$ infinitely often and does not stabilise to b. Conversely, if there is a fair run that does not stabilise to b, then it never visits $[\![\mathsf{Stable}_b]\!]$, hence by fairness it eventually stops visiting $[\![\mathsf{Pre}^*(\mathsf{Stable}_b)]\!]$; this proves that it visits a configuration $\gamma \in [\![\overline{\mathsf{Pre}^*(\mathsf{Stable}_b)}]\!]$, and γ is reachable from γ_0 hence $\gamma_0 \in [\![\mathsf{Pre}^*(\overline{\mathsf{Pre}^*(\mathsf{Stable}_b)})]\!]$. ◀

Many other problems can be expressed as emptiness problems for GRE; we list a few.

- The *correctness* problem for IOPPUD asks, given an IOPPUD $\mathcal{P} = (Q, I, O, \Delta)$ and an interval predicate φ over I, whether $\mathcal{P}$ computes φ. This can be equivalently phrased as $[\![\varphi^{-1}(b) \cap \mathsf{Pre}^*(\overline{\mathsf{Pre}^*(\mathsf{Stable}_b)})]\!] = \emptyset$ for all $b \in \{\top, \bot\}$, where $\varphi^{-1}(b)$ is the set of initial configurations that φ maps to b. Note that the previous expression is a GRE because, in Definition 9, we chose as atoms interval predicates such as φ.
- The *set-reachability* problem (called cube-reachability in [5]) asks, given two sets of configurations $\mathcal{S}_1, \mathcal{S}_2$, whether $\mathcal{S}_2$ is reachable from $\mathcal{S}_1$; this typically expresses safety problems where $\mathcal{S}_2$ represents "bad configurations" that must not be reached. If $\mathcal{S}_1 = [\![E_1]\!]$ and $\mathcal{S}_2 = [\![E_2]\!]$, then this amounts to checking whether $[\![E_1 \cap \mathsf{Pre}^*(E_2)]\!]$ is empty.
- The *home-space problem* asks, given a protocol $\mathcal{P}$ and a set of configurations $\mathcal{H}$, whether $\mathcal{H}$ can be reached from every configuration reachable from an initial configuration. If $\mathcal{H}$ can be expressed as a GRE E, then it suffices to check whether $[\![\mathsf{Post}^*(\Gamma_{\mathsf{init}})]\!] \subseteq [\![\mathsf{Pre}^*(E)]\!]$. This problem has been studied in Petri nets [22], but also in probabilistic settings, for example in [11] for asynchronous shared-memory systems; indeed, in systems with uniform probabilistic schedulers where $\mathsf{Post}^*(\gamma_0)$ is finite for every initial configuration γ_0, this problem is equivalent to asking whether the probability of reaching $\mathcal{H}$ is equal to 1.

Theorem 10 entails that, for IOPPUD, all these problems are decidable and in ExpSpace.

3 Undecidability of Verification of Population Protocols with Unordered Data

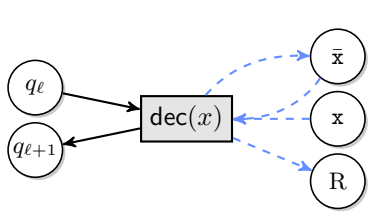
In this section, we establish that the most fundamental verification problem for PPUD, i. e., the well-specification problem, is already undecidable.

▶ **Theorem 3.** *The well-specification problem for PPUD is undecidable.*

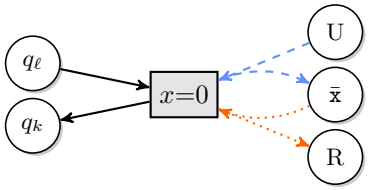
We proceed by reduction from the halting problem for 2-counter machines with zero-tests, a famously undecidable problem [26]. Here, we give a proof sketch. The detailed reduction can be found in [7], which is the full version of this paper.

We fix a 2-counter machine and build a protocol $\mathcal{P}$ which is *not* well-specified if and only if the counter machine halts. A 2-*counter machine* performs increments, decrements and zero-tests on two counters. The main difficulty are the zero-tests. Let us first recall how increments and decrements are simulated in many prior undecidability results for population protocols and Petri nets [21, 27]. The protocol has a control part $Q_{CM} := \{q_i \mid i \in [1, n]\}$ where a single *instruction agent* evolves; this part has one state per instruction of the machine. Increments and decrements are simulated as follows: The instruction agent interacts with states of $\{R\} \cup \{\mathtt{x}, \mathtt{y}\}$, where R is a *reservoir state* and $\mathtt{x}$ and $\mathtt{y}$ are states in which the number of agents represents the value of the counters. For example an increment on counter x moves one agent from the reservoir R to $\mathtt{x}$ and advances the instruction agent to the next instruction. The reservoir is hence implicitly assumed to start with arbitrarily many agents.

The main difficulty is that one does not want to take the $= 0$ branch of a zero-test when the value of the counter is non-zero. Actually, similar to [21, 27], we will not prevent the existence of such runs. Instead, our protocol will have "violating" runs which take the wrong



(a) Gadget for performing dec(x). Agents of the blue dashed edges must have the same datum.



(b) Gadget for x=0 branch of "`if` x=0 `then goto` k". The same agent takes the two blue dashed edges and the same agent takes the orange dotted edges.

Figure 1 For simplicity, we use Petri net notation: circles are states, rectangles are Petri net transitions. To encode this into our protocols, we split each transition into pairwise interactions.

branch of a zero-test, but our well-specification check will consider only *violation-free* runs. The correctness of the reduction is then established in two steps: The CM halts if and only if some *violation-free* run to the halting state exists, and this is true if and only if our protocol is not well-specified. We establish the connection between non-well-specification and the existence of a *violation-free* run in our protocol.

In the first place, we guarantee that every initial configuration of our protocol has a fair run stabilising to $\bot$, so that $\mathcal{P}$ is not well-specified if and only if there exists a fair run which does not stabilise to $\bot$[3]. Second, we introduce *violation detection*, a mechanism which guarantees that *fair* runs which contain a violation stabilise to $\bot$, hence preserving well-specification. To do so, we add a sink state $q_\bot$, which has output $\bot$ and is attracting, i. e., all other states have a transition to $q_\bot$ available when observing that $q_\bot$ is non-empty. Violation detection then entails adding transitions into $q_\bot$ that will be available infinitely often if the run (or its initial configuration) contained a violation. By fairness, any run containing a violation will then eventually put an agent into $q_\bot$, and hence, because $q_\bot$ is attracting, the run ends in a deadlock with all agents in $q_\bot$. In particular, any fair run containing a violation will output $\bot$ as claimed. There are two types of violation detection.

First, we want to only mark those runs as violation-free that start in initial configurations where $U \in Q$ has at most one agent of each datum. To do so, we make agents remember whether their initial state was U or not (by encoding it into the state space), and, from every state, we add a transition to $q_\bot$ such that this transition is enabled when an agent who started in U observes another agent of same datum that also started in U.

Second, we want to detect violations which consist in falsely simulating a zero-test, as discussed above. Here our technique shares some similarities with [27]. Let $c \in \{x, y\}$ be a counter; for every zero-test of the counter machine, we add two types of transitions to the protocol. The first type simulates the $c \neq 0$ branch and can be taken by the instruction agent upon interacting with some agent on state $\mathtt{c}$; by contrast, the $c = 0$ branch can always be taken. However, if it was taken with $c \neq 0$, then violation detection will eventually detect this. For this mechanism, we introduce a counter control state $\bar{\mathtt{c}} \in Q$. At any point in time, $\bar{\mathtt{c}}$ contains one agent, similar to the instruction agent. The crux of our violation detection is that only agents which share the datum with the agent in $\bar{\mathtt{c}}$ will be allowed to move in and out of state $\mathtt{c}$, as illustrated in Figure 1a.

The $= 0$ branch of a zero-test is depicted in Figure 1b. It replaces the agent on $\bar{\mathtt{c}}$ with an agent with fresh datum from state U. Thus, when the $c = 0$ branch is taken, any remaining agent in $\mathtt{c}$ is stuck in $\mathtt{c}$ as it will never again share datum with the agent in $\bar{\mathtt{c}}$. Violation detection then sends an agent in $\mathtt{c}$ to $q_\bot$ upon observing an agent in $\bar{\mathtt{c}}$ with different datum.

[3] This can be done with the addition of a fresh state that is the only initial state and that has internal transitions to all former initial states and an internal transition to a sink state that has output $\bot$.

Now that we have violation detection in place, it only remains to explain the connection to halting. The halting instruction q_n in Q_{CM} is the only state with output $\top$. Hence, any run not outputting $\bot$ must contain an agent in the halting instruction at some point, and be violation-free by the above. That is, the counter machine reached the halting state without violations. Conversely, if the machine halts, one can build a finite run that puts an agent into the halting state without any violation occurring. The corresponding configuration is then a deadlock, and hence the extension to an infinite run (by staying there forever) is a fair run not outputting $\bot$. This proves that well-specification is undecidable for PPUD, which motivates restricting ourselves to immediate observation PPUD.

4 An Analysis of Immediate Observation Protocols with Data

To obtain our complexity bounds on the emptiness problem for GRE, we first show some transformations on runs that allow us to bound the number of observed agents. All runs that we consider in this section are finite, and we therefore write them as $\gamma_1 \to \cdots \to \gamma_m$ or $\gamma_{start} \xrightarrow{*} \gamma_{end}$. In the rest of this section, we fix an IOPPUD $\mathcal{P} = (Q, \Delta, I, O)$.

We introduce some notation for agents in runs. Let $\rho\colon \gamma_1 \xrightarrow{*} \gamma_m$ and $d \in \mathbb{D}$. We let $\mathbb{A}_\rho$ be the set of agents appearing in ρ, and set $\mathbb{A}_\rho^d := \{a \in \mathbb{A}_\rho \mid \mathbf{dat}(a) = d\}$. We let $\mathbb{A}_{\rho,o}^d$ be the set of agents with datum d that are observed in ρ, i. e., the $a_o \in \mathbb{A}_\rho^d$ such that there exists a step $\gamma \xrightarrow{\bowtie a_o}_a \gamma'$ in ρ. For all $q_1, q_m \in Q$, we let $\mathbb{A}_{\rho,q_1,q_m}^d$ be the set of agents with datum d that start in q_1 and end in q_m, i. e., the $a \in \mathbb{A}_\rho^d$ such that $\gamma_1(a) = q_1$ and $\gamma_m(a) = q_m$. Moreover, we let $\mathbb{D}_\rho := \{d \in \mathbb{D} \mid \mathbb{A}_\rho^d \neq \emptyset\}$ be the set of data appearing in ρ. We may omit ρ in the subscript if the run is clear from the context.

4.1 Bounds on the Number of Observed Agents per Datum

Let $\rho\colon \gamma_1 \to \cdots \to \gamma_m$ be a run. For $i \in [1, m]$, we call $\gamma_i \to \gamma_{i+1}$ the *i-th step* in ρ. Let $\rho[\to i]$ (resp. $\rho[i \to]$) denote the prefix of ρ ending on its i-th configuration (resp. the suffix of ρ starting on its i-th configuration). Let $a, b \in \mathbb{A}_\rho$. Agent a is *active* in the i-th step if $\gamma_i \xrightarrow{\bowtie a_o}_a \gamma_{i+1}$ for some agent a_o. Otherwise, a is *idle* in that step. We say b *copies* a in ρ if after every step $\gamma_i \xrightarrow{\bowtie a_o}_a \gamma_{i+1}$ in ρ via some transition t, there is a step $\gamma_{i+1} \xrightarrow{\bowtie a_o}_b \gamma_{i+2}$ via t and, additionally, b is idle in every step not immediately following an active step of a.

The following lemma allows us to add agents to a run that copy an agent of the same datum.

▶ **Lemma 12** (Agents copycat). *Let $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ be a run. Let $a \in \mathbb{A}_\rho$ and $\tilde{a} \in \mathbb{A} \setminus \mathbb{A}_\rho$ with $\mathbf{dat}(a) = \mathbf{dat}(\tilde{a})$. Then there exist configurations $\tilde{\gamma}_{start}, \tilde{\gamma}_{end}$ and a run $\tilde{\rho}\colon \tilde{\gamma}_{start} \xrightarrow{*} \tilde{\gamma}_{end}$ such that:*

- **(i)** *$\mathbb{A}_{\tilde{\rho}} = \mathbb{A}_\rho \uplus \{\tilde{a}\}$, and for all $a' \in \mathbb{A}_\rho$, $\tilde{\gamma}_{start}(a') = \gamma_{start}(a')$ and $\tilde{\gamma}_{end}(a') = \gamma_{end}(a')$;*
- **(ii)** *$\tilde{\gamma}_{start}(\tilde{a}) = \gamma_{start}(a)$ and $\tilde{\gamma}_{end}(\tilde{a}) = \gamma_{end}(a)$;*
- **(iii)** *$\tilde{a}$ is not observed in $\tilde{\rho}$.*

Proof. We let $\tilde{\gamma}_{start}$ be such that $\tilde{\gamma}_{start}(\tilde{a}) = \gamma_{start}(a)$ and $\tilde{\gamma}_{start}(a') = \gamma_{start}(a')$ for all $a' \neq \tilde{a}$. We construct $\tilde{\rho}$ by going through ρ step by step, making $\tilde{a}$ copy a: whenever ρ takes a step $\xrightarrow{\bowtie a_o}_a$, then we take this step followed by step $\xrightarrow{\bowtie a_o}_{\tilde{a}}$ to $\tilde{\rho}$. We can do so because $\mathbf{dat}(\tilde{a}) = \mathbf{dat}(a)$ and because agent $a_o \neq a$ has not moved and thus can be observed again. These are the only steps where $\tilde{a}$ is involved, hence it is never observed. ◀

The following result shows that, given a run ρ, we can construct a new run with a small subset of the agents of $\mathbb{A}_\rho$ such that, for all $d \in \mathbb{D}$ and all states q_1 and q_2, if there is a d-agent starting in q_1 and ending in q_2 in ρ, then this is also true in the new run. We refer to [7] for proof details.

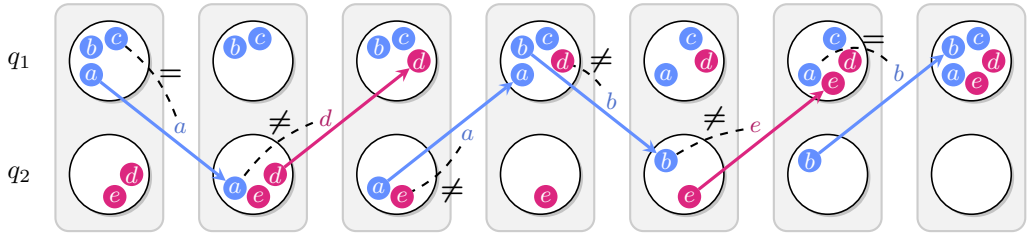


Figure 2 An example of a run with six steps on a protocol with two states q_1, q_2. $\mathsf{a}, \mathsf{b}, \mathsf{c}, \mathsf{d}, \mathsf{e}$ denote agents; $\mathsf{a}, \mathsf{b}, \mathsf{c}$ have the same datum and d, e have the same datum. Dashed lines are observations.

▶ **Lemma 13** (Agents core). *Let $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ be a run. Then there exist configurations γ'_{start}, γ'_{end} and a run $\rho'\colon \gamma'_{start} \xrightarrow{*} \gamma'_{end}$ with $\mathbb{A}_{\rho'} \subseteq \mathbb{A}_\rho$ such that:*

(i) *for all $a \in \mathbb{A}_{\rho'}$, $\gamma'_{start}(a) = \gamma_{start}(a)$ and $\gamma'_{end}(a) = \gamma_{end}(a)$;*
(ii) *for all $d \in \mathbb{D}$ and $q_s, q_e \in Q$, if $\mathbb{A}^d_{\rho,q_s,q_e} \neq \emptyset$, then $\mathbb{A}^d_{\rho',q_s,q_e} \neq \emptyset$;*
(iii) *for all $d \in \mathbb{D}$, we have $|\mathbb{A}^d_{\rho'}| \leq |Q|^3$.*

Proof sketch. We adapt the bunch argument from the case of IO protocols without data [19]. Suppose there is $d \in \mathbb{D}$ and $q_s, q_e \in Q$ such that $|\mathbb{A}^d_{\rho,q_s,q_e}| > |Q|$. Let $\mathcal{R}$ be the set of states visited by agents of $\mathbb{A}^d_{\rho,q_s,q_e}$ in ρ. Notice that $|\mathcal{R}| \leq |Q|$. We define a family $(a_q)_{q\in\mathcal{R}}$ of pairwise distinct agents such that reducing $\mathbb{A}^d_{\rho,q_s,q_e}$ in ρ to $(a_q)_{q\in\mathcal{R}}$ still yields a valid run.

We iterate through $\mathcal{R}$ as follows. Let $q \in \mathcal{R}$ and let f be the first moment q is reached in ρ, i. e., the minimal index such that there exists an $a \in \mathbb{A}^d_{\rho,q_s,q_e}$ with $\gamma_f(a) = q$. Let ℓ be the last moment q is occupied in ρ, i. e., the maximal index such that there exists an $a \in \mathbb{A}^d_{\rho,q_s,q_e}$ with $\gamma_\ell(a) = q$. Let α_q be the agent in $\mathbb{A}^d_{\rho,q_s,q_e}$ that reaches q first, i. e., $\gamma_f(\alpha_q) = q$, and let β_q be the agent in $\mathbb{A}^d_{\rho,q_s,q_e}$ that leaves q last, i. e., $\gamma_l(\beta_q) = q$. Note that these agents do not have to be distinct. We pick a fresh agent $a_q \notin \mathbb{A}_\rho$ with $\mathbf{dat}(a_q) = d$ and modify ρ as follows. We let a_q copy α_q in $\rho[\to f]$, then a_q stays idle until β_q leaves q (for the last time) and then a_q copies β_q in $\rho[\ell \to]$. We do this for every $q \in \mathcal{R}$.

Then, for every step in which an a_o in $\mathbb{A}^d_{\rho,q_s,q_e}$ is observed in state q, let a_q be observed instead, i. e., replace steps $\xrightarrow{\bowtie a_o}_a$ with $\xrightarrow{\bowtie a_q}_a$. Finally, remove all the agents of $\mathbb{A}^d_{\rho,q_s,q_e}$ from the run, and identify (or substitute) each a_q with a distinct agent in $\mathbb{A}^d_{\rho,q_s,q_e}$, so that $(a_q)_{q\in\mathcal{R}} \subseteq \mathbb{A}^d_{\rho,q_s,q_e}$. We do this for every $d \in \mathbb{D}$ and $q_s, q_e \in Q$ such that $|\mathbb{A}^d_{\rho,q_s,q_e}| > |Q|$. ◀

▶ **Example 14.** Consider the run ρ depicted in Figure 2. Applying Lemma 13 on ρ yields a new run ρ' with 4 agents instead of 5. Indeed, let d denote the datum of a, b and c; we have $|\mathbb{A}^d_{\rho,q_1,q_1}| = |\{\mathsf{a}, \mathsf{b}, \mathsf{c}\}| = 3$ whereas $|Q| = 2$. In ρ, agents a and b successively go from q_1 to q_2 and back to q_1. In ρ', these two agents are replaced by a single agent (named b again) who goes to q_2 on the first step and only leaves q_2 on the last step. In ρ', the new agent b is observed by d in the second step, and by e in the penultimate step.

4.2 Bounds on the Number of Observed Data

Given a run and a datum d appearing in it, we define the *trace* of d in ρ as the function $\mathtt{tr}^d_\rho\colon Q^2 \to \mathbb{N}$ such that for all $q_1, q_2 \in Q$, it holds that $\mathtt{tr}^d_\rho(q_1, q_2) = |\mathbb{A}^d_{\rho,q_1,q_2}|$. For each pair of states q_1, q_2, the trace counts the number of d-agents starting in q_1 and ending in q_2. For example, the trace of the run ρ of Example 14, with d the datum of agents a, b and c, is such that $\mathtt{tr}^d_\rho(q_1, q_1) = 3$ and $\mathtt{tr}^d_\rho(q, q') = 0$ for all $(q, q') \neq (q_1, q_1)$. The trace is the information we need to copy data: if there is a datum d with trace tr in a run, then we can add data to the run that mimic d and have the same trace. The following lemma echoes Lemma 12.

▶ **Lemma 15** (Data copycat). *Let $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ be a run. Let $d \in \mathbb{D}_\rho$ and $\tilde{d} \in \mathbb{D} \setminus \mathbb{D}_\rho$. Then there exist configurations $\tilde{\gamma}_{start}$, $\tilde{\gamma}_{end}$ and a run $\tilde{\rho}\colon \tilde{\gamma}_{start} \xrightarrow{*} \tilde{\gamma}_{end}$ such that:*

(i) *$\mathbb{A}_{\tilde{\rho}} = \mathbb{A}_\rho \uplus \mathbb{A}^{\tilde{d}}_{\tilde{\rho}}$, and for all $a \in \mathbb{A}_\rho$, $\tilde{\gamma}_{init}(a) = \gamma_{init}(a)$ and $\tilde{\gamma}_{end}(a) = \gamma_{end}(a)$,*

(ii) *$\mathtt{tr}^{\tilde{d}}_{\tilde{\rho}} = \mathtt{tr}^{d}_{\rho}$ and $\mathtt{tr}^{d'}_{\tilde{\rho}} = \mathtt{tr}^{d'}_{\rho}$ for all $d' \neq \tilde{d}$,*

(iii) *$\tilde{d}$ is not externally observed in $\tilde{\rho}$.*

Proof. For all $q_s, q_e \in Q$ and all $a \in \mathbb{A}^d_{q_s,q_e}$, we add an agent $\tilde{a}$ with datum $\tilde{d}$ in q_s at the start. We do this in a way similar to Lemma 12: after every step $\xrightarrow{\neq a_o}_a$ in ρ, we insert a step $\xrightarrow{\neq a_o}_{\tilde{a}}$, and after every step $\xrightarrow{=a_o}_a$ in ρ, we insert a step $\xrightarrow{=\tilde{a}_o}_{\tilde{a}}$. We thus maintain the fact that each added agent $\tilde{a}$ is in the same state as its counterpart a. In particular, they are in the same state at the end of the run. This yields a run $\tilde{\rho}$ with $\mathtt{tr}^{\tilde{d}}_{\tilde{\rho}} = \mathtt{tr}^{d}_{\rho}$, and such that for all $d' \neq \tilde{d}$, $\mathtt{tr}^{d'}_{\tilde{\rho}} = \mathtt{tr}^{d'}_{\rho}$. Since $\tilde{d} \notin \mathbb{D}_\rho$, it is not externally observed in $\tilde{\rho}$. ◀

Like we showed for the agents, we show that we can reduce the number of data in a run. We lift the proof strategy of Lemma 13 from agents to data, exploiting the sets of data with equal traces. We refer to [7] for proof details.

▶ **Lemma 16** (Data core). *Let $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ be a run and let K be a number such that there are at most K agents of each datum in ρ. Then there exist configurations γ'_{start}, γ'_{end}, a run $\rho'\colon \gamma'_{start} \xrightarrow{*} \gamma'_{end}$, and a subset of data $\mathbb{D}_{\rho'} \subseteq \mathbb{D}_\rho$ such that:*

(i) *for all $d \in \mathbb{D}_{\rho'}$ and all agents a of datum d, $\gamma_{start}(a) = \gamma'_{start}(a)$ and $\gamma_{end}(a) = \gamma'_{end}(a)$,*

(ii) *for all $d \in \mathbb{D}_\rho$, there exists $d' \in \mathbb{D}_{\rho'}$ such that $\mathtt{tr}^{d'}_{\rho'} = \mathtt{tr}^{d}_{\rho}$,*

(iii) *$|\mathbb{D}_{\rho'}| \leq (K+1)^{|Q|^3+|Q|^2}$.*

Proof sketch. We define the notion of split trace. The split trace of a datum d at the i-th configuration of a run ρ maps every triple of states (q_1, q_2, q_3) to the number of d-agents that are in q_1 at the start of ρ, then in q_2 in the i-th configuration, and finally in q_3 at the end. Since there are at most K agents per datum, there are at most $(K+1)^{|Q^2|}$ possible traces and $M = (K+1)^{|Q^3|}$ possible split traces.

For every trace tr, if there are more than M data that have trace tr in ρ, we apply a similar argument to Lemma 13: we select one datum for each possible split trace, and use it to cover all external observations of agents whose datum matches that split trace. We remove the other data, and show that this is still a valid run. The bound on the total number of data comes from the number of traces and split traces. ◀

▶ **Corollary 17.** *For every run $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$, there exists a run $\tilde{\rho}\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ such that for all $d \in \mathbb{D}$, it holds that $|\mathbb{A}^d_{\tilde{\rho},o}| \leq |Q|^3$ and that agents of at most $(|Q|^3+1)^{|Q|^3+|Q|^2}$ different data are externally observed.*

Proof. We first apply Lemma 13 to ρ to obtain $\rho^{(1)}\colon \gamma^{(1)}_{start} \xrightarrow{*} \gamma^{(1)}_{end}$ over the same data such that for all $d \in \mathbb{D}$, it holds that $|\mathbb{A}^d_{\rho^{(1)}}| \leq |Q|^3$. Then we apply Lemma 16 to obtain $\rho^{(2)}\colon \gamma^{(2)}_{start} \xrightarrow{*} \gamma^{(2)}_{end}$ with at most $(|Q|^3+1)^{|Q|^3+|Q|^2}$ data. By Lemma 13-(i) and Lemma 16-(i), the remaining agents have the same initial and final states in ρ and $\rho^{(2)}$. It remains to put back the agents and data we removed, without increasing the number of externally observed data or observed agents per datum.

By Lemma 16-(ii), every trace of a datum in $\rho^{(1)}$ appears as the trace of a datum in $\rho^{(2)}$. Thus, it is possible to re-add data of $\mathbb{D}_{\rho^{(1)}}$ to $\mathbb{D}_{\rho^{(2)}}$ using repeated applications of Lemma 15. By Lemma 15-(iii), this does not add any external observation. So we obtain a run $\tilde{\rho}^{(1)}$ from

$\gamma^{(1)}_{start}$ to $\gamma^{(1)}_{end}$ such that at most $(|Q|^3+1)^{|Q|^3+|Q|^2}$ data are externally observed by Lemma 15-(iii). Recall that there are at most $|Q|^3$ agents per datum in $\gamma^{(1)}_{start}$ by Lemma 13-(iii); in particular there are at most $|Q|^3$ observed agents per datum in $\tilde{\rho}^{(1)}$.

By Lemma 13-(ii), for each datum d and states q_s, q_e, if there is a d-agent a such that $\gamma_{start}(a) = q_s$ and $\gamma_{end}(a) = q_e$ then there is an agent a' such that $\gamma^{(1)}_{start}(a') = q_s$ and $\gamma^{(1)}_{end}(a') = q_e$ in ρ. Therefore, due to Lemma 13-(ii), we can apply Lemma 12 repeatedly to add back the missing agents in $\tilde{\rho}^{(1)}$ and obtain a run $\tilde{\rho}$ from γ_{start} to γ_{end}. By Lemma 12-(iii), this does not add any observation. As a result, we obtain a run from γ_{start} to γ_{end} in which at most $(|Q|^3+1)^{|Q|^3+|Q|^2}$ data are externally observed and for all datum d, at most $|Q|^3$ d-agents are observed. ◀

5 From Expressions to Containers

In this section, we define the technical notions of boxes and containers, which are meant to represent sets of configurations defined by counting agents and data up to some thresholds. In Proposition 21, we will prove that the set of configurations defined by a generalised reachability expression E can be described as a union of containers whose thresholds are exponential in the length of E and polynomial in its norm. To do so, we will leverage the bounds on the number of observed agents from Section 4 to bound the description of the GRE $\mathsf{Post}^*(F)$ with respect to the one of GRE F. The key result of Proposition 21 will be used in Section 6 to obtain the decidability of the emptiness problem for GRE.

5.1 Equivalence of Predicates and Containers

In this subsection, we fix an IOPPUD $\mathcal{P} = (Q, \Delta, I, O)$.

Let $n, M \in \mathbb{N}$. An *n-box* is a vector $\mathsf{b}\colon Q \to [0, n]$. Given a configuration γ and a datum $d \in \mathbb{D}$, we define *the n-box of d in γ* as $\lceil \gamma, d \rceil^n \colon Q \to [0, n]$ such that for all $q \in Q$, $\lceil \gamma, d \rceil^n(q) = \min\{n, \gamma^{\#}_d(q)\}$; in words, the n-box of d truncates the number of agents of d if it exceeds n. We write $\mathbf{Boxes}_n$ for the set of all n-boxes. We define the equivalence relation $\equiv_n$ over $\Gamma \times \mathbb{D}$ by $(\gamma_1, d_1) \equiv_n (\gamma_2, d_2)$ whenever $\lceil \gamma_1, d_1 \rceil^n = \lceil \gamma_2, d_2 \rceil^n$. An equivalence class of $\equiv_n$ is a set of the form $\{(\gamma, d) \in \Gamma \times \mathbb{D} \mid \lceil \gamma, d \rceil^n = \mathsf{b}\}$ for $\mathsf{b} \in \mathbf{Boxes}_n$; we represent such an equivalence class for $\equiv_n$ by the associated n-box b.

To lift this concept to data, we count the number of data with the same n-box up to bound M. The *(n, M)-container* of a configuration γ is the function $\lceil \gamma \rceil^{n,M} \colon \mathbf{Boxes}_n \to [0, M]$ such that $\lceil \gamma \rceil^{n,M}(\mathsf{b}) = \min\{M, |\{d \in \mathbb{D} \mid \lceil \gamma, d \rceil^n = \mathsf{b}\}|\}$ for all $\mathsf{b} \in \mathbf{Boxes}_n$. We define the equivalence relation $\equiv_{n,M}$ over Γ by $\gamma_1 \equiv_{n,M} \gamma_2$ whenever $\lceil \gamma_1 \rceil^{n,M} = \lceil \gamma_2 \rceil^{n,M}$. An equivalence relation for $\equiv_{n,M}$ is the preimage of some (n, M)-container by the previously described function; we represent such an equivalence class by the associated (n, M)-container. Figure 3 illustrates the function mapping a given configuration to its container.

> In all the following, we use the terms n-boxes and (n, M)-containers to designate both the vectors and the equivalence classes of $\equiv_n$ and $\equiv_{n,M}$ that they represent. For instance, we write *union of n-boxes* for the union of the corresponding equivalence classes of $\equiv_n$.

The partition of Γ into (n, M)-containers becomes finer as n and M grow.

▶ **Lemma 18.** *Let $n_1, n_2, M_1, M_2 \in \mathbb{N}$. If $n_1 \leq n_2$ and $M_1 \leq M_2$, then every (n_1, M_1)-container is a union of (n_2, M_2)-containers.*

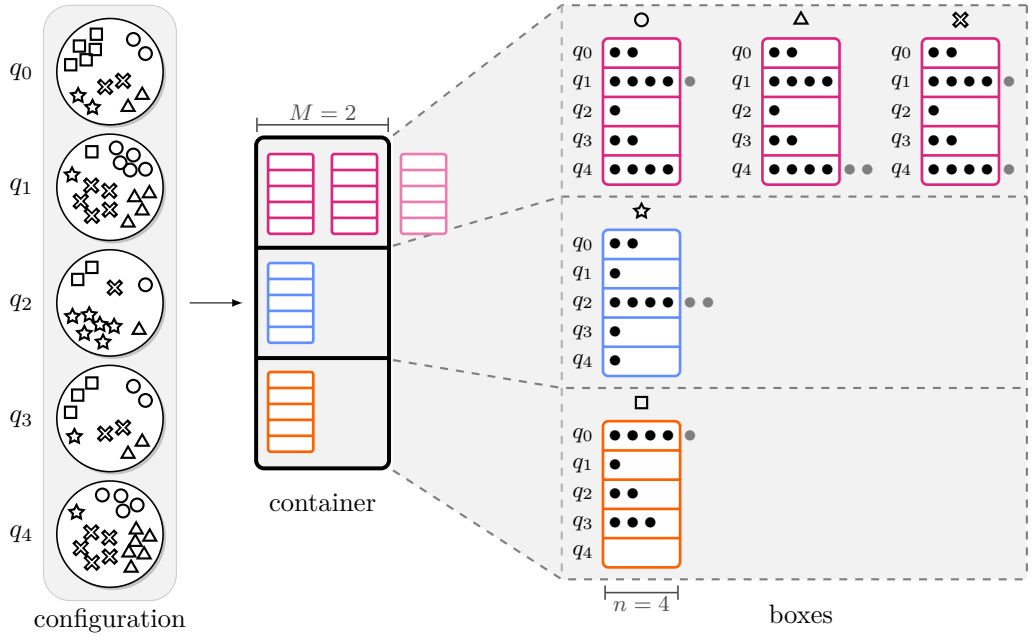

Figure 3 How a configuration is mapped to a $(4, 2)$-container. Here, the protocol has five states $q_0, \dots, q_4$. Five distinct data appear in the configuration, and they are represented using symbols.

Algorithmically, we represent an n-box as a list of appearing states with associated numbers from $[1, n]$ encoded in binary. Similarly, we represent an (n, M)-container as a list of appearing n-boxes with associated numbers from $[1, M]$ encoded in binary.

In fact, interval predicates exactly describe finite unions of containers.

▶ **Proposition 19.** *The sets of configurations defined by interval predicates of height at most n and width at most M are exactly the sets formed by unions of (n, M)-containers.*

Proof sketch. For the translation from predicates to containers, consider a simple interval predicate $\dot{\exists}\mathsf{d}_1, \dots, \mathsf{d}_M, \bigwedge_{q\in Q}\bigwedge_{j=1}^{M} \#(q, \mathsf{d}_j) \in [A_{q,j}, B_{q,j}]$ of height n. This predicate cannot distinguish data mapped to the same n-box, hence cannot distinguish configurations in the same equivalence class for $\equiv_{n,M}$, i. e., (n, M)-containers. The same directly extends to interval predicates.

For the other direction, we prove that a given (n, M)-container can be expressed as an interval predicate of height at most n and width at most M. To do so, given a box $\mathsf{b} \in \mathbf{Boxes}_n$ and $m \leq M$, we define the simple interval predicate $\varphi_{\mathsf{b},\geq m}$ expressing that at least m data are mapped to box b. Formally, $\varphi_{\mathsf{b},\geq m} \coloneqq \dot{\exists}\mathsf{d}_1, \dots, \mathsf{d}_m, \bigwedge_{q\in Q}\bigwedge_{j=1}^{m} \#(q, \mathsf{d}_j) \in [A_q, B_q]$, where, for all $q \in Q$, $A_q \coloneqq \mathsf{b}(q)$, $B_q \coloneqq \mathsf{b}(q)$ if $\mathsf{b}(q) < n$ and $B_q \coloneqq +\infty$ if $\mathsf{b}(q) = n$. This predicate has height at most n and width at most M. A Boolean combination of such predicates allows us to express an (n, M)-container. We refer to [7] for a detailed proof. ◀

We therefore have two equivalent representations. Both are useful: interval predicates allow us to express properties more naturally, but containers are more convenient for the proofs in the remainder of this section. While they are equally expressive, each can be much more succinct than the other, as stated below. We refer to [7] for details.

▶ Remark 20. Containers can be exponentially more succinct than interval predicates, while interval predicates can be doubly exponentially more succinct than unions of containers.

5.2 A Translation from Expressions to Containers

Based on the translation from interval predicates to containers from Proposition 19, we can now show that for all generalised reachability expressions E over an IOPPUD $\mathcal{P}$, the set $[\![E]\!]_{\mathcal{P}}$ is a union of (n, M)-containers with n and M bounded in terms of E and $\mathcal{P}$.

▶ **Proposition 21.** *There is a polynomial function* $\mathtt{poly}\colon \mathbb{N} \to \mathbb{N}$ *such that for all IOPPUD* $\mathcal{P}$ *and GRE* E*, the set* $[\![E]\!]_{\mathcal{P}}$ *is a union of* $\left(||E|| \cdot \left(\mathtt{poly}(|\mathcal{P}|)\right)^{|E|}, ||E||^{\mathtt{poly}(|\mathcal{P}|)\cdot|E|^2}\right)$*-containers.*

The detailed proof of Proposition 21 can be found in [7]. We show the result by structural induction on E. The base case, when E is an interval predicate, is provided by Proposition 19. For the induction step, handling Boolean operators is straightforward; the difficulty lies in operators Pre^* and Post^*. This is handled by the following lemma, which relies on the bounds from Section 4.

Equivalence classes for fixed values of n and M do not behave well with respect to the reachability relation, in the sense that it can happen that $\gamma_{start} \xrightarrow{*} \gamma_{end}$ and $\gamma_{start} \equiv_{n,M} \chi_{start}$, but there is no $\chi_{end} \equiv_{n,M} \gamma_{end}$ such that $\chi_{start} \xrightarrow{*} \chi_{end}$. However, this will hold if we take some margin on the equivalence relation of configurations at the start; the following two functions express this margin. For all $n, M \in \mathbb{N}$, let $f(n) \coloneqq (n + |\mathcal{P}|^3) \cdot |\mathcal{P}|$ and $g(n, M) \coloneqq \big(M + (|\mathcal{P}|^3 + 1)^{|\mathcal{P}|^3+|\mathcal{P}|^2}\big)(n+1)^{|\mathcal{P}|}$.

The following lemma states that, if a set of configurations C cannot distinguish $\equiv_{n,M}$-equivalent configurations, then $\mathsf{Pre}^*(C)$ cannot distinguish $\equiv_{f(n),g(n,M)}$-equivalent configurations. In other words, if C is a union of $\equiv_{n,M}$-equivalence classes, (i. e., of (n, M)-containers), then $\mathsf{Pre}^*(C)$ is a union of $\equiv_{f(n),g(n,M)}$-equivalence classes.

▶ **Lemma 22.** *For all* $n, M \in \mathbb{N}$ *and all configurations* $\gamma_{start}, \gamma_{end}, \chi_{start} \in \Gamma$*, if there is a run* $\rho\colon \gamma_{start} \xrightarrow{*} \gamma_{end}$ *and* $\gamma_{start} \equiv_{f(n),g(n,M)} \chi_{start}$*, then there is a configuration* $\chi_{end} \in \Gamma$ *with* $\gamma_{end} \equiv_{n,M} \chi_{end}$ *and a run* $\pi\colon \chi_{start} \xrightarrow{*} \chi_{end}$*.*

Proof sketch. We first apply Corollary 17 to ρ, so that we can assume that ρ has a limited number of externally observed data and of observed agents per datum.

In this proof sketch, we first handle the case with only one datum. Then, we explain how to generalise this. We refer to [7] for proof details.

Suppose that all agents in γ_{start} and χ_{start} share a single datum d, and suppose $(\gamma_{start}, d) \equiv_{f(n)} (\chi_{start}, d)$. Let $\mathbb{A}_\gamma$ and $\mathbb{A}_\chi$ be the agents in γ_{start} and χ_{start}, respectively. For all $q, q' \in Q$, we set $\mathbb{A}_\gamma^{q\to} \coloneqq \{a \in \mathbb{A}_\gamma \mid \gamma_{start}(a) = q\}$, $\mathbb{A}_\chi^{q\to} \coloneqq \{a \in \mathbb{A}_\chi \mid \chi_{start}(a) = q\}$, $\mathbb{A}_\gamma^{\to q'} \coloneqq \{a \in \mathbb{A}_\gamma \mid \gamma_{end}(a) = q'\}$, and $\mathbb{A}_\gamma^{q\to q'} \coloneqq \mathbb{A}_\gamma^{q\to} \cap \mathbb{A}_\gamma^{\to q'}$.

Our aim is to assign to each agent in χ_{start} an agent in γ_{start} to mimic. To do so, we construct a mapping $\nu\colon \mathbb{A}_\chi \to \mathbb{A}_\gamma$ such that

(A) for all $a \in \mathbb{A}_\chi$, we have $\chi_{start}(a) = \gamma_{start}\big(\nu(a)\big)$,
(B) for all $a' \in \mathbb{A}_\gamma$ observed in ρ, we have $\nu^{-1}(a') \neq \emptyset$, and
(C) for all $q' \in Q$, we have $|\nu^{-1}(\mathbb{A}_{\gamma,d}^{\to q'})| = |\mathbb{A}_{\gamma,d}^{\to q'}|$, or $|\nu^{-1}(\mathbb{A}_{\gamma,d}^{\to q'})| \geq n$ and $|\mathbb{A}_{\gamma,d}^{\to q'}| \geq n$.

We build ν separately on each set $\mathbb{A}_\chi^{q\to}$ by defining, for each $q \in Q$, a mapping $\nu_q\colon \mathbb{A}_\chi^{q\to} \to \mathbb{A}_\gamma^{q\to}$. Let $q \in Q$. As $(\chi_{start}, d) \equiv_{f(n)} (\gamma_{start}, d)$, either $|\mathbb{A}_\gamma^{q\to}| = |\mathbb{A}_\chi^{q\to}|$, or both $|\mathbb{A}_\gamma^{q\to}|$ and $|\mathbb{A}_\chi^{q\to}|$ are at least $f(n)$. If $|\mathbb{A}_\gamma^{q\to}| = |\mathbb{A}_\chi^{q\to}|$, we let ν_q form a bijection between $\mathbb{A}_\chi^{q\to}$ and $\mathbb{A}_\gamma^{q\to}$. Consider now the second case, where $|\mathbb{A}_\gamma^{q\to}|$ and $|\mathbb{A}_\chi^{q\to}|$ are at least $f(n)$. We aim at selecting, for every $q' \in Q$, a set $A_{q\to q'} \subseteq \mathbb{A}_\gamma^{q\to q'}$ of agents that must be copied in π. If $|\mathbb{A}_\gamma^{q\to q'}| \leq n$, then we let $A_{q\to q'} \coloneqq \mathbb{A}_\gamma^{q\to q'}$. Otherwise, we first put in $A_{q\to q'}$ all agents in $\mathbb{A}_\gamma^{q\to q'}$ that are observed in ρ, at most $|\mathcal{P}|^3$ in total by Corollary 17. If $|A_{q\to q'}| < n$, we add

arbitrary agents from $\mathbb{A}_\gamma^{q\to q'}$ to $A_{q\to q'}$ until $|A_{q\to q'}| \geq n$. Either way, we have selected $A_{q\to q'}$ of size at most $|\mathcal{P}|^3 + n$ for each q', hence at most $f(n)$ agents in total. For every q', we have $|A_{q\to q'}| \leq |\mathbb{A}_\gamma^{q\to q'}|$, and either $|A_{q\to q'}| = |\mathbb{A}_\gamma^{q\to q'}|$ or the two sets have size more than n.

We now build ν_q such that its image over $\mathbb{A}_\chi^{q\to}$ is $\bigcup_{q'\in Q} A_{q\to q'}$. We build this in two steps. First, we assign to each $\bigcup_{q'\in Q} A_{q\to q'}$ one antecedent by ν_q in $\mathbb{A}_\chi^{q\to}$. This is possible because $|\bigcup_{q'\in Q} A_{q\to q'}| \leq f(n) \leq |\mathbb{A}_\chi^{q\to}|$. We then identify some q'' such that $|A_{q\to q''}| > n$ and map all remaining agents of $\mathbb{A}_\chi^{q\to}$ to an arbitrary agent in $A_{q\to q''}$. Such a q'' exists because $|\mathbb{A}_\gamma^{q\to}| \geq f(n) \geq n \cdot |\mathcal{P}|$, so there is a q' such that $|\mathbb{A}_\gamma^{q\to q'}| \geq n$, and hence $|A_{q\to q'}| \geq n$ by construction.

This concludes the construction of ν. It remains to prove that ν fulfils Items A–C. Items A and B are immediate from the definition. We prove Item C. Let $q' \in Q$. We distinguish two cases:

- if $|\mathbb{A}_\gamma^{q\to q'}| < n$ for all $q \in Q$, then for all q, we have $|\nu^{-1}(\mathbb{A}_\gamma^{q\to q'})| = |\nu^{-1}(A_{q\to q'})| = |A_{q\to q'}| = |\mathbb{A}_\gamma^{q\to q'}|$, so $|\nu^{-1}(\mathbb{A}_\gamma^{\to q'})| = |\mathbb{A}_\gamma^{\to q'}|$;
- if $|\mathbb{A}_\gamma^{q\to q'}| \geq n$ for some $q \in Q$, then $|A_{q\to q'}| \geq n$, so $|\nu^{-1}(\mathbb{A}_\gamma^{q\to q'})| \geq n$, and thus both $|\nu^{-1}(\mathbb{A}_\gamma^{\to q'})|$ and $|\mathbb{A}_\gamma^{\to q'}|$ are at least n.

We construct a run π from χ_{start} by copying ρ as follows. For each step of ρ where an agent a performs some transition t, we make $|\nu^{-1}(a)|$ steps in π so that all agents in $\nu^{-1}(a)$ perform transition t one by one. If a observed some agent a', there is a'' in π that can be observed because $\nu^{-1}(a') \neq \emptyset$: we made sure to map an agent to each observed agent in ρ.

For the general case with more data, we similarly construct two mappings μ and ν. First we define μ, which maps each datum d of χ_{start} to one of γ_{start} such that $(\gamma_{start}, \mu(d)) \equiv_{f(n)} (\chi_{start}, d)$. Then, for each datum d, ν maps each agent a with datum d of χ_{start} to one with datum $\mu(d)$ of γ_{start}.

Once μ and ν are defined, we build a run from χ_{start} to a configuration χ_{end} in which each agent a mimics the behaviour of $\nu(a)$ in ρ. We make sure that agents (resp. data) observed in ρ have agents (resp. data) mapped to them, so that we can take the same transitions in ρ and π. The construction of ν ensures that, for all data d, we have $(\gamma_{end}, \mu(d)) \equiv_{f(n)} (\chi_{end}, d)$. The construction of μ ensures that $\gamma_{end} \equiv_{f(n),g(n,M)} \chi_{end}$. ◀

6 Decidability and Complexity Bounds

6.1 Decidability in Exponential Space

In this section, we use the results on GRE from Section 5 to provide an ExpSpace upper bound for the emptiness problem for GRE. In the following, we assume that the representation of a GRE E takes $|E| + \log(||E||)$ space.

We first prove that we can decide membership of a configuration (encoded in a naive way) in a GRE in PSpace. A configuration is represented *data-explicitly* if it is represented as a list of vectors of $\mathbb{N}^Q$, one vector for each datum. The *size* of this representation is $k \cdot |\mathcal{P}| \cdot log(m)$ where k is the number of data and m is the number of agents appearing in γ.

▶ **Proposition 23.** *The following problem is decidable in* PSpace*: given a PPUD $\mathcal{P}$, a GRE E, and a configuration γ described data-explicitly, decide if $\gamma \in [\![E]\!]_{\mathcal{P}}$.*

We refer to the full version [7] for the proof. It uses a relatively straightforward induction on E to show that this problem can be decided in polynomial space using a recursive algorithm (with a polynomial whose degree does not depend on E). For the case where $E = \mathsf{Post}^*(F)$, we rely on the fact that the numbers of agents and data remain the same throughout a run;

we therefore can guess the configuration γ' such that $\gamma' \in [\![F]\!]_{\mathcal{P}}$ (which can be checked with a recursive call) and $\gamma \xrightarrow{*} \gamma'$ (which can be checked by exploration of the graph containing configurations with as many agents and data as γ). The case $E = \mathsf{Pre}^*(F)$ is similar.

Proposition 23 allows us to check if a given configuration of a PPUD is in the set described by a GRE[4]. In the case of IOPPUD, Proposition 21 allows us to search for a witness configuration within some bounded set, yielding decidability.

▶ **Theorem 10.** *The emptiness problem for GRE over IOPPUD is in* ExpSpace.

Proof. Suppose $[\![E]\!]_{\mathcal{P}}$ is not empty. By Proposition 21, it contains an (n, M)-container cont with $n \coloneqq ||E|| \cdot \mathtt{poly}(|\mathcal{P}|)^{|E|}$ and $M \coloneqq ||E||^{\mathtt{poly}(|\mathcal{P}|)\cdot|E|^2}$. We construct a configuration $\gamma \in \mathsf{cont}$ as follows. For each n-box b, we select $\mathsf{cont}(\mathsf{b})$ many data such that over all n-boxes, the selected data are pairwise distinct. Then, for each n-box b, each state $q \in Q$ of $\mathcal{P}$, and each datum d_{b} selected for b, we put $\mathsf{b}(q)$ many agents with datum d_{b} in q. Note that the configuration γ is in cont, and the number of agents it contains it at most $n \cdot |\mathcal{P}| \cdot |\mathbf{Boxes}_n| \cdot M$. We have $|\mathbf{Boxes}_n| = (n+1)^{|\mathcal{P}|} = ||E|| \cdot \mathtt{poly}(|\mathcal{P}|)^{|E||\mathcal{P}|}$. We assumed at the beginning of Section 6 that the encoding of E uses memory $|E| + \mathsf{log}(||E||)$. As a result, n, M, $|\mathcal{P}|$ and $|\mathbf{Boxes}_n|$ are all at most exponential in the size of the input. Therefore, if $[\![E]\!]_{\mathcal{P}}$ is not empty, then it contains a configuration with at most exponentially many agents. We can guess the data-explicit description of such a configuration in non-deterministic exponential space, and then check that the guessed configuration is in $[\![E]\!]_{\mathcal{P}}$ in exponential space by Proposition 23 (we apply the PSpace algorithm on an exponential input). As a result, deciding emptiness of $[\![E]\!]_{\mathcal{P}}$ is in NExpSpace, which is identical with ExpSpace. ◀

6.2 A Lower Complexity Bound

We now provide the following lower complexity bound.

▶ **Theorem 24.** *The emptiness problem for GRE over IOPPUD is* coNExpTime*-hard.*

Proof sketch. We proceed by reduction from the problem of tiling an exponentially large grid, a NExpTime-complete problem [28], to the complement of the emptiness problem for GRE. We refer to [7] for proof details.

A *tiling instance* is a tuple $(2^n, \mathcal{C}, \mathcal{T})$, with $n \geq 1$, $\mathcal{C}$ a finite set of *colours* with special colour white, and $\mathcal{T} = \{t_1, \ldots, t_m\} \subseteq \mathcal{C}^4$ a finite set of *tiles*. We can view a tile as a square whose four edges are coloured. The *tiling problem* asks whether there is a *tiling*, that is, a mapping $\tau \colon [0, 2^n{-}1] \times [0, 2^n{-}1] \to \mathcal{T}$ such that the colours of neighbouring tiles match and the borders of the grid are white.

Given a tiling instance $(2^n, \mathcal{C}, \mathcal{T})$, we build an instance $(\mathcal{P}, E)$ of the emptiness problem for GRE. In $\mathcal{P}$, witness tilings can be encoded in the configurations, and we construct $(\mathcal{P}, E)$ such that $[\![E]\!]$ contains exactly the configurations that correspond to a correctly encoded witness tiling. More precisely, $\gamma \in [\![E]\!]$ when:

(Cond1) for all $(i, j) \in [0, 2^n - 1]^2$, some datum encodes coordinates (i, j) and a tile type;
(Cond2) for all $(i, j) \in [0, 2^n - 1]^2$, there is at most one datum encoding (i, j);
(Cond3) the mapping $[0, 2^n - 1]^2 \to \mathcal{C}$ defined by the data is a tiling.

The GRE E will be of the form of a conjunction, i. e., a list of *constraints* that the configuration must satisfy. Our first constraint is $\overline{\mathsf{Pre}^*(\mathsf{Pres}(q_\perp))}$ where $q_\perp$ is a special error state and $\mathsf{Pres}(q)$ is the GRE expressing that some agent is in q. This forbids, in $[\![E]\!]$, configurations from which $q_\perp$ can be covered.

[4] This implies that the emptiness problem for GRE over PPUD, while undecidable due to Theorem 3, is semi-decidable: one can simply enumerate all configurations and test membership for each of them.

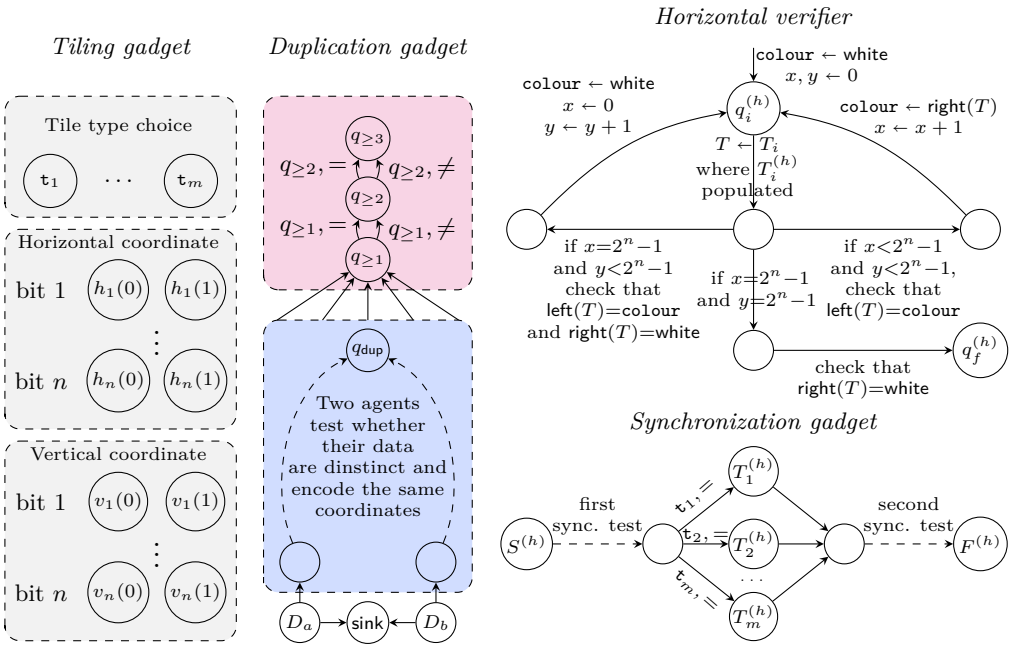

Figure 4 Partial depiction of the protocol constructed in Theorem 24.

(Cond1) is obtained using the *tiling gadget* in Figure 4. States $\mathtt{t}_1, \ldots, \mathtt{t}_m$ represent the available tiles of $\mathcal{T}$, and coordinate states allow for a binary representation of the horizontal and vertical coordinates of a square in the grid. For a datum d, the agents of datum d in the coordinate states encode the position of the square corresponding to d, and an agent of datum d in state $\mathtt{t}_i$ indicates that the square in the grid corresponding to d should be coloured according to tile t_i. Configurations in $[\![E]\!]$ are not allowed to have two agents of same datum playing the same role; otherwise, one of them may observe the other and go to $q_\perp$. In particular, each datum has at most $2n+1$ agents in the tiling gadget.

To obtain (Cond2), we use a *duplication gadget*, partially represented in Figure 4. We enforce that any configuration in $[\![E]\!]$ has one agent of each datum in D_a, one in D_b and none in the rest of the duplication gadget. The blue part implements a test (depicted in [7, Figure 5b]) where two agents of distinct data, one from D_a and one from D_b, may test that their data encode the same coordinates; if this is the case, they may go to q_{dup}. If there are more than two agents in the blue part, this test is not reliable but $q_{\geq 3}$ can be covered. (Cond2) can therefore be achieved by enforcing that configurations in $[\![E]\!]$ are *not* in $\mathsf{Pre}^*(\mathsf{Pres}(q_{\mathsf{dup}}) \cap \overline{\mathsf{Pre}^*(\mathsf{Pres}(q_{\geq 3}))})$.

Finally, we explain how (Cond3) is achieved; we describe only how the horizontal (left-right) borders are verified. We use a gadget, named *horizontal verifier* in Figure 4. In this gadget, a single agent, called *verifier*, is in charge of verifying that colours of left-right borders match. The verifier uses $2n$ auxiliary agents to encode two variables $x, y \in [0, 2^n - 1]$ in binary. Again, transitions to $q_\perp$ detect when two agents play the same role, so that there is only one verifier and so that variables x and y can be implemented faithfully. The initialisation $x = y = 0$ is enforced as a constraint in E. We now sketch how the verifier reads the encoded tiling; to do that, it must synchronise with the datum encoding (x, y).

This is done using the synchronisation gadget of Figure 4. In $[\![E]\!]$, all agents in the synchronisation gadget are in $S^{(h)}$. Moreover, we add a constraint in E so that $\gamma \in [\![E]\!]$ requires that there is a run from γ where all agents in the synchronisation gadget end in

$F^{(h)}$ and where the verifier ends in $q_f^{(h)}$. The synchronisation tests guarantee that, whenever there is an agent in $T_i^{(h)}$, this agent's datum encodes square (i, j) where i is equal to the current value of x and j is equal to the current value of y. The synchronisation is challenging to design because the values of x and y may change throughout a run and only one bit can be tested at a time. However, as proved in [7, Lemma 37], this can be achieved by having a first synchronisation test that checks equality of bits from most to least significant, and a second test that checks equality from least to most significant. ◀

6.3 Discussion on Complexity Gaps

We now discuss some complexity gaps left open by this paper. First, there remains a complexity gap for the emptiness problem for GRE, which is known to be between coNExpTime (Theorem 24) and ExpSpace (Theorem 10). Closing the gap appears challenging. On one hand, if the problem is below ExpSpace, then this probably requires developing new techniques. On the other hand, proving ExpSpace-hardness does not seem easy. In particular, the synchronisation techniques from Theorem 24 assumes that each datum synchronises only once with the verifier. This synchronisation technique would not suitable for, e. g., multiple interactions between the head and the cells of a Turing machine.

Another, arguably more important open question is the exact complexity of well-specification, which is only known to be between PSpace (model without data, [19]) and ExpSpace (Theorem 10). On the one hand, it is unclear whether relevant configurations can be stored in polynomial space.

▷ Claim 25. The number of data that need to be considered for well-specification may be exponential.

The claim is formalised and proven in [7]. As a consequence, proving that the problem is in PSpace cannot be achieved with a procedure that explicitly stores configurations. On the other hand, in order to build a reduction from the tiling problem as in Theorem 24, we need a new idea to enforce that *at most* one datum encodes each tile. In Theorem 24, we had states q_{dup} and $q_{\geq 3}$ and duplication meant being able to cover q_{dup} and, at the same, forbid that $q_{\geq 3}$ can ever be covered in the future. We do not know how to encode this constraint when working with an instance of well-specification.

7 Conclusion

We have studied the verification of population protocols with unordered data [10], an extension of population protocols where agents carry data from an infinite unordered set. We first proved that the well-specification problem is undecidable (Theorem 3), which then led us to consider the restriction to protocols with immediate observation. This subclass was defined in [10], where the authors proved that these protocols compute exactly the interval predicates. We defined a general class of problems on this model, which consists in deciding the existence of a configuration satisfying a so-called generalised reachability expression; this class of problems subsumes many classic problems, one of which is well-specification. Despite its generality, we showed the problem to be decidable in exponential space (Theorem 10); we also provided a coNExpTime lower bound. A remaining open question is the exact complexity of well-specification for immediate observation population protocols with unordered data, which is located between PSpace (model without data, [19]) and ExpSpace (Theorem 10).

Domain Reasoning in TopKAT

Abstract

TopKAT is the algebraic theory of Kleene algebra with tests (KAT) extended with a top element. Compared to KAT, one pleasant feature of TopKAT is that, in relational models, the top element allows us to express the domain and codomain of a relation. This enables several applications in program logics, such as proving under-approximate specifications or reachability properties of imperative programs. However, while TopKAT inherits many pleasant features of KATs, such as having a decidable equational theory, it is incomplete with respect to relational models. In other words, there are properties that hold true of all relational TopKATs but cannot be proved with the axioms of TopKAT. This issue is potentially worrisome for program-logic applications, in which relational models play a key role.

In this paper, we further investigate the completeness properties of TopKAT with respect to relational models. We show that TopKAT is complete with respect to (co)domain comparison of KAT terms, but incomplete when comparing the (co)domain of arbitrary TopKAT terms. Since the encoding of under-approximate specifications in TopKAT hinges on this type of formula, the aforementioned incompleteness results have a limited impact when using TopKAT to reason about such specifications.

1 Introduction

Kleene algebra with tests (KAT) is an algebraic framework that extends Kleene algebra with an embedded Boolean algebra to model control structures like if-statement and while-loops [20]. This extension enables us to reason about several properties of imperative programs. For example, one of the key early results in the area was that KAT can encode Hoare logic, in the sense that any proof in the logic's propositional fragment can be carried out faithfully using KAT equations [27, 21].

Some applications, however, require us to look beyond KAT. For example, Zhang et al. [41] recently proved that KAT alone cannot be used to encode incorrectness logic [31, 7] – a close cousin of Hoare logic with applications in bug finding [25, 36]. A similar result was proved by Struth [39], who showed that KAT cannot encode weakest liberal preconditions. If we view a program as a relation between its input and output states, both of these limitations

arise from KAT's lack of power to encode the (co)domain of a relation. Indeed, Möller et al. [30] proved that incorrectness logic could be encoded by extending KAT with a codomain operation. Independently, Zhang et al. provided a similar encoding [41] by extending KAT with a top element, which can be used to express inequalities between codomains. They dubbed the resulting algebraic structure a TopKAT.

The present paper investigates the expressive power of TopKAT as a tool for (co)domain reasoning. As noted by Zhang et al. [41], one limitation of TopKAT is that it is not expressive enough to derive all valid equations between relations. More precisely, Zhang et al.'s encoding of incorrectness logic interprets the top element of the algebra as the complete relation, which relates all pairs of program states. Under this interpretation, the inequality $p\top p \geq p$ is valid, but unprovable using the theory of TopKAT [41]. This a potential issue when using TopKAT to reason in incorrectness logic: though Zhang et al.'s encoding covers all the rules of propositional incorrectness logic, there could be inequalities about (co)domain that fall outside this fragment and cannot be established solely by the theory of TopKAT.

Pous et al. [34, 35] were able to make some progress on the issue, by showing we can obtain a complete axiomatic system for relational models TopKATs by adding in the inequality $p\top p \geq p$ as an additional axiom. In this paper, we look at the question from a different angle, instead of working with a more complex theory, we show that the original theory of TopKAT is complete with respect to relational models for (co)domain comparisons, namely the inequalities of the form $\top t_1 \geq \top t_2$ or $t_1\top \geq t_2\top$ where t_1, t_2 are KAT terms. Since these inequalities suffice to encode incorrectness logic, this completeness result lays a solid foundation for encoding program logics in TopKAT. We have also showed that this completeness result is tight, in the sense that it does not extend to the case where t_1 and t_2 contain the top element, by explicitly constructing two TopKAT terms that witness the incompleteness.

The result above is enabled by the homomorphic structure of the reduction [41, 33] from TopKAT to KAT. This discovery also let us shorten the proofs of previous results [41], and enables systematic generation of TopKAT complete interpretations from complete interpretations of KAT. We believe that this new representation of the reduction technique could also be of independent interest.

Structure of this paper and contributions. In Section 2, we present several previous results on KAT and TopKAT. Inspired by universal algebra [4], we characterize fundamental concepts, like interpretation and completeness, using homomorphisms. In Section 3, we uncover additional structure of the reduction technique [24, 33] in the case of TopKAT: the reduction from TopKAT to KAT is a TopKAT homomorphism. This discovery not only allows us to simplify several previous results [41] by avoiding tedious induction proofs; but also enables the techniques used in the later section. Section 4 presents the completeness results of TopKAT with respect (co)domain comparison. The codomain completeness result is proven by an equality that connects codomain operation with the language interpretation, and the domain completeness is then proven by applying the codomain completeness result to the opposite TopKAT.

2 Preliminaries

2.1 Extensions of Kleene algebra And Their Models

A *Kleene algebra* is an idempotent semiring with a star operation, written p^*, that satisfies the following *unfolding*, *left induction*, and *right induction* rules:

$$p^* = 1 + pp^* = 1 + p^*p, \qquad pr + q \leq r \implies p^*q \leq r, \qquad rp + q \leq r \implies qp^* \leq r;$$

the ordering here is the conventional ordering in idempotent semirings: $p \leq q \triangleq p + q = q$. It is known that the right-hand version of unfolding and induction rule can be removed while preserving the same equational theory [23]. Yet, we will focus on the standard definition of KA in this paper.

▶ **Lemma 1.** *Following are well-known facts in Kleene algebra*

- *All the Kleene algebra operations preserve order.*
- *The following equations are true for the star operation:*

$$p^* \cdot p^* = p^* \qquad\qquad (p^*)^* = p^*.$$

A Kleene algebra with tests (KAT) is a Kleene algebra with an embedded Boolean algebra, where the conjunction, disjunction, and identities in the Boolean algebra coincide with the addition, multiplication, and the identities of Kleene algebra. We refer to elements of this embedded Boolean algebra as *tests*.

Given an algebraic theory, we can construct its *free model* over a finite set Σ, called the *alphabet* [4]. The free model consists of all the terms formed by Σ modulo provable equivalences of the algebra. The operations of the free model are obtained by lifting the term-level operations to equivalence classes.

The above construction can be extended to the case of KAT and TopKAT, suppose that we are given two disjoint finite sets K (the *action alphabet*) and B (the *test alphabet*). Elements of K and B are called *primitive actions and primitive tests*, respectively. KAT terms over the alphabet K, B are defined with the following grammar:

$$t \triangleq b \in B \mid p \in K \mid 1 \mid 0 \mid t_1 + t_2 \mid t_1 \cdot t_2 \mid t^* \mid \overline{t_b},$$

where t_b does not contain primitive actions. The *free KAT* over K, B, written $\mathsf{KAT}_{K,B}$, consists of terms over K, B modulo provable KAT equivalences. The tests of the free KAT are Boolean terms, i.e. terms formed by primitive tests and Boolean operations modulo Boolean axioms. A similar construction applies to TopKAT, where an additional symbol $\top$ was added as the largest element in the theory; we denote the free TopKAT over K, B as $\mathsf{TopKAT}_{K,B}$. We sometimes omit the alphabets K and B when they are irrelevant or can be inferred.

In the paper, we frequently consider terms modulo provable equalities, i.e. in the context of its corresponding free model. For example, given $t_1, t_2 \in \mathsf{KAT}$, we will say $t_1 = t_2$ when they are provably equal using the theory of KAT. Although the free model seems trivial, it leads to simpler and more modular proofs of some properties of algebraic theories, as we will see in Section 3.

Other important models that we will use in this paper are language (Top)KATs and relational (Top)KATs, which we review here. An *atom* (short for "atomic test") over a test alphabet $B = \{b_1, b_2, \ldots, b_n\}$ is a sequence of the form

$$\hat{b_1} \cdot \hat{b_2} \cdot \cdots \cdot \hat{b_n} \text{ where } \hat{b_i} \in \{b_i, \bar{b_i}\}.$$

We denote atoms as $\alpha, \beta, \gamma, \ldots$ and the set of all atoms as At.

A *guarded string* (or *guarded word*) over K, B is an alternation between atoms and primitive actions that starts and ends in atoms:

$$\alpha_0 p_1 \alpha_1 \cdots p_n \alpha_n \text{ where } p_i \in K, \alpha_i \in \text{At};$$

where each action is "guarded" by an atom. A guarded string is similar to a program trace, where each program state is denoted by an atom; and primitive actions will cause a transition

between program states. We denote the set of all guarded strings over alphabet K, B as $GS_{K,B}$, and we will omit the alphabet K, B when it is irrelevant or can be inferred from context. The notation αs denotes a guarded string starting with atom α with the rest of the string s; similarly, $s\alpha$ denotes a guarded string that ends with atom α with rest of the string being s.

▶ **Definition 2** (Language/trace KAT [24]). *The* language KAT *(also called "*trace KAT*") over an alphabet K, B is denoted as $\mathcal{G}_{K,B}$, or simply $\mathcal{G}$ if no confusion can arise.*

The elements are sets of guarded strings (called guarded languages*), and the tests are sets of atoms. The additive identity 0 is the empty set, and the multiplicative identity 1 is the set of all the atoms* At*. The addition operator is set union, and the multiplication operator is defined as follows:*

$$S_1 \diamond S_2 \triangleq \{s_1 \alpha s_2 \mid s_1\alpha \in S_1, \alpha s_2 \in S_2\}.$$

The star operation is defined non-deterministically iterating the multiplication operator:

$$S^* \triangleq \bigcup_{i\in\mathbb{N}} S^i \text{ where } S^0 = \mathrm{At}, S^{k+1} = S \diamond S^k.$$

Another useful type of KAT are relational ones, where each element is a relation $R \subseteq X \times X$ over a fixed set X. In applications, the set X typically represents the set of all possible program states, and each relation R represents a program by relating each possible input to the corresponding output.

▶ **Definition 3** (Relational KAT). *A relational KAT is a KAT $\mathcal{R}$ consists of relations over a fixed set X (though $\mathcal{R}$ need not contain every relation over X), and it is closed under the following operations. The tests are all the relations that are subsets of the identity relation. The additive identity 0 is the empty set, and the multiplicative identity is the identity relation:*

$$1 \triangleq \{(x, x) \mid x \in X\}.$$

The addition operator is set union, and the multiplication operation is relational composition:

$$R_1; R_2 = \{(x, z) \mid \exists y \in X, (x, y) \in R_1, (y, z) \in R_2\}.$$

Finally, the star operation is defined as:

$$R^* \triangleq \bigcup_{i\in\mathbb{N}} R^i \text{ where } R^0 = 1, R^{k+1} = R; R^k.$$

We denote the class of all relational KATs as REL*.*

TopKAT extends the theory of KAT with the largest element $\top$, i.e. $\top \geq p$ for all elements p. The *language TopKAT* over an alphabet K, B has the same carrier and operations as $\mathcal{G}_{K_\top,B}$, where $K_\top$ is the set K joined with a new primitive action $\top$; and the largest element is the full language $GS_{K_\top,B}$.

The *relational TopKAT* is a relational KAT that contains the complete relation:

$$\top \triangleq \{(x, y) \mid x, y \in X\};$$

we denote the set of all relational TopKATs as TopREL. It is known that there are equations that are valid in relational TopKAT, but are not derivable by the axioms of TopKAT [41]; however, by adding the axiom $p\top p \geq p$, the theory becomes complete over relational

TopKATs [34, 35]. In this paper, instead of working with a more complex theory, we will show that TopKAT without any additional axiom already suffices for the purpose of encoding domain comparisons. Indeed, TopKAT is complete with respect to domain comparison inequalities, which can be used to encode both incorrectness logic and Hoare logic.

In this paper, we will use dom and cod to denote the conventional (co)domain operators on relations, namely, for any relation R:

$$\mathrm{dom}(R) \triangleq \{x \mid \exists y, (x,y) \in R\} \qquad \mathrm{cod}(R) \triangleq \{y \mid \exists x, (x, y \in R)\}.$$

To demonstrate how TopKAT models (co)domain comparisons, we take any relational TopKAT $\mathcal{R}$ and two relations $R_1, R_2 \in \mathcal{R}$, and we denote the complete relation as $\top$:

▶ **Lemma 4** (TopKAT encodes (co)domain comparison).

$$R_1\top \supseteq R_2\top \iff \mathrm{dom}(R_1) \supseteq \mathrm{dom}(R_2) \qquad \top R_1 \supseteq \top R_2 \iff \mathrm{cod}(R_1) \supseteq \mathrm{cod}(R_2)$$

If we regard R_1 and R_2 as the input output relation of two programs, which is typically encoded by KAT terms, we can see that $R_1\top \supseteq R_2\top$ reflects that the domain of R_1 is larger than the domain of R_2; and similarly for the inequality $\top R_1 \supseteq \top R_2$. Thus, given two KAT terms $t_1, t_2 \in \mathsf{KAT}_{K,B}$, we call inequalities like $t_1\top \geq t_2\top$ *domain comparison inequalities*, and $\top t_1 \geq \top t_2$ *codomain comparison inequalities*. Notice that the term $\top t_1$ is a shorthand for $\top \cdot i(t_1)$, where i is the inclusion function $\mathsf{KAT}_{K,B} \hookrightarrow \mathsf{TopKAT}_{K,B}$. In the rest of the paper, we will sometimes leave this inclusion function implicit. These two forms of inequalities will be the focus of our completeness results in Section 4.

We also know another class of TopKATs named *general relational TopKATs*, which is denoted as TopGREL. The top element of general relational TopKAT is not necessarily the complete relation, but the largest relation in the model. All equations in the general relational TopKAT can be derived using the theory of TopKAT.

However, the completeness of TopGREL came at the cost of expressive power: every predicate that is expressible using general relational TopKAT is already expressible using relational KAT [41], so the extension with top, in the case of general relational TopKAT, does not grant any extra expressive power. In Theorem 13, we show that this result is a simple corollary of our new reduction result.

We are also interested in maps between models: A *KAT homomorphism* f is a map between two KATs $\mathcal{K}$ and $\mathcal{K}'$ s.t. it preserves the sorts and operations: given a test b in $\mathcal{K}$ then $f(b)$ is a test in $\mathcal{K}'$; and all the KAT operations (complement, identities, addition, multiplication, and star) are preserved:

$$\begin{aligned} f &: \mathcal{K} \to \mathcal{K}' \\ f(\bar{b}) &= \overline{f(b)} \\ f(1) &= 1 \\ f(0) &= 0 \\ f(p+q) &= f(p) + f(q) \\ f(p \cdot q) &= f(p) \cdot f(q) \\ f(p^*) &= f(p)^*. \end{aligned}$$

Similarly, a *TopKAT homomorphism* is a KAT homomorphism that preserves the largest element.

2.2 Interpretation, Completeness, and Injectivity

Consider a KAT equation such as $p \cdot b \cdot \bar{b} = 0$. To determine its validity in a particular KAT $\mathcal{K}$, we need to assign meaning to it by interpreting each primitive as an element in $\mathcal{K}$; that is, by defining a map $\hat{I}$ of type $K + B \to \mathcal{K}$. Such a map $\hat{I} : K + B \to \mathcal{K}$ induces a unique KAT homomorphism $I : \mathsf{KAT}_{K,B} \to \mathcal{K}$ inductively defined on the term as follows:

$$\begin{aligned} I(p) &\triangleq \hat{I}(p) && \text{where } p \in K + B \\ I(\overline{t_b}) &\triangleq \overline{I(t_b)} && t_b \text{ does not contain primitive actions} \\ I(t_1 + t_2) &\triangleq I(t_1) + I(t_2) \\ I(t_1 \cdot t_2) &\triangleq I(t_1) \cdot I(t_2) \\ I(t^*) &\triangleq I(t)^* \end{aligned} \tag{1}$$

In fact, every KAT homomorphism from a free model arises this way: there is a bijection between functions of type $K + B \to \mathcal{K}$ and KAT homomorphisms of type $\mathsf{KAT}_{K,B} \to \mathcal{K}$, for any KAT $\mathcal{K}$. Because the homomorphism I and the function $\hat{I}$ are equivalent, we will refer to them interchangeably as *KAT interpretations* and denote both of them as I.

The above result enables us to define a homomorphism from the free KAT just by defining its action on the primitives; saving us time to check the equations that a homomorphism must satisfy. It also allows us to prove that two interpretations are equal by arguing that they map the primitives to equal values.

Given a KAT $\mathcal{K}$, and two terms $t_1, t_2 \in \mathsf{KAT}_{K,B}$ we say that $\mathcal{K} \models t_1 = t_2$ if

$$\forall I : \mathsf{KAT}_{K,B} \to \mathcal{K}, I(t_1) = I(t_2).$$

In particular, for two terms in the free model $t_1, t_2 \in \mathsf{KAT}_{K,B}$, $\mathsf{KAT}_{K,B} \models t_1 = t_2$ is equivalent to $t_1 = t_2$. For a collection of models K, we say that $\mathsf{K} \models t_1 = t_2$ if for all $\mathcal{K} \in \mathsf{K}$, $\mathcal{K} \models t_1 = t_2$. For example, $\mathrm{REL} \models t_1 = t_2$ means that $t_1 = t_2$ is valid in all relational KATs. All the above notations and terminologies can be similarly extended to TopKAT.

Theories like KAT and TopKAT are designed to model practical programs, so it is important to know if they can model all the desirable equations between programs. If the theory of KAT can derive all the equalities for a particular interpretation I, namely:

$$\mathsf{KAT}_{K,B} \models t_1 = t_2 \iff I(t_1) = I(t_2),$$

we say that the theory of KAT is *complete* with respect to I. Recall that $\mathsf{KAT}_{K,B} \models t_1 = t_2$ is equivalent to $t_1 = t_2$; thus, by definition, an interpretation I is complete if and only if it is injective. One of such interpretation is the guarded string interpretation $G : \mathsf{KAT}_{K,B} \to \mathcal{G}_{K,B}$ [24], defined by lifting the following action on the primitives:

$$G(b) = \{\alpha \mid b \text{ appears positively in } \alpha\}, \qquad G(p) = \{\alpha p \beta \mid \alpha, \beta \in \mathrm{At}\}.$$

In several previous works, the term "free model" refers to the range (set of reachable elements) of a complete interpretation. Since a complete interpretation is an injective homomorphism, such interpretation induces an isomorphism on its range, thus our definition of free model is equivalent to these definitions.

Many previous proofs can also be explained by seeing complete interpretations as injective homomorphisms: the proof for completeness of relational KATs constructs an injective homomorphism h from a language KAT into a relational KAT [24]. Since both G and h

are injective homomorphisms, $h \circ G$ is also an injective homomorphism, hence a complete interpretation. Since $h \circ G$ is a relational interpretation:

$$\mathsf{KAT}_{K,B} \models t_1 = t_2 \implies \mathrm{REL} \models t_1 = t_2 \implies h \circ G(t_1) = h \circ G(t_2);$$

then the completeness of $h \circ G$ implies $(h \circ G)(t_1) = (h \circ G)(t_2) \iff \mathsf{KAT}_{K,B} \models t_1 = t_2$. Hence,

$$\mathsf{KAT}_{K,B} \models t_1 = t_2 \iff \mathrm{REL} \models t_1 = t_2,$$

i.e. the theory of KAT is complete with respect to relational KAT.

Besides using composition of injective homomorphisms, another technique commonly used to prove injectivity is to construct a left inverse: if a (Top)KAT homomorphism $f : \mathcal{K} \to \mathcal{K}'$ has a left inverse homomorphism $g : \mathcal{K}' \to \mathcal{K}$ i.e. $g \circ f = id_{\mathcal{K}}$, then f is injective. Notice that g does not need to be a homomorphism for f to be injective, however, in the case where f is an interpretation, g being a homomorphism makes the equality $g \circ f = id_{\mathcal{K}}$ easier to check. Because both $g \circ f$ and $id_{\mathcal{K}}$ are all interpretations, they are equal if and only if they have the same action on all the primitives.

Finally, we provide a shorthand for domain reasoning. For two terms $t_1, t_2 \in \mathsf{KAT}$, we write

$$\mathrm{REL} \models \mathrm{dom}(t_1) \geq \mathrm{dom}(t_2),$$

when $\mathrm{dom}(I(t_1)) \supseteq \mathrm{dom}(I(t_1))$ for all relational KAT interpretations I; and similarly for relational TopKAT and general relational TopKAT. Then Lemma 4 implies the following:

▶ **Lemma 5.** *For two KAT terms $t_1, t_2 \in \mathsf{KAT}_{K,B}$:*

$$\mathrm{TopREL} \models t_1 \top \geq t_2 \top \iff \mathrm{REL} \models \mathrm{dom}(t_1) \geq \mathrm{dom}(t_2)$$
$$\mathrm{TopREL} \models \top t_1 \geq \top t_2 \iff \mathrm{REL} \models \mathrm{cod}(t_1) \geq \mathrm{cod}(t_2)$$

3 Reduction, A New Perspective

Our goal in this section is to construct a complete interpretation for TopKAT, by reducing its theory to that of plain KAT. In other words, any equation between two TopKAT terms is logically equivalent to another equation between a pair of corresponding KAT terms. While this result is not new [41, 42, 34], we present a more streamlined proof that hinges on the universal properties of free KATs and TopKATs, without relying explicitly on language models. Similar to previous works, we obtain the decidability of the equational theory of TopKAT as a corollary of reduction. However, because of the new notion of reduction, our decidability result no longer depends on the completeness of the language TopKAT. Moreover, our technique helps us to construct complete models and interpretations simply by computation, as well as simplifying proofs of other results about TopKAT.

3.1 Reduction on free models

We first note that any free KAT over an alphabet K, B is also a TopKAT, where the largest element is $(\sum K)^*$. This fact can be seen by straightforward induction.

▶ **Lemma 6.** *Every free KAT over alphabet K, B forms a TopKAT.*

Proof. Since $\mathsf{KAT}_{K,B}$ is a KAT, we only need to show the term $(\sum K)^*$ is the largest element of $\mathsf{KAT}_{K,B}$, i.e.

$$(\sum K)^* \geq t, \forall t \in \mathsf{KAT}_{K,B}.$$

The above fact can be shown by induction on t; some algebraic manipulations below use facts in Lemma 1:

- $(\sum K)^* \geq 1$ (by unfolding rule), thus $(\sum K)^*$ is larger than $0, 1$ and every Boolean term.
- $(\sum K)^*$ is larger than $\sum K$, which is larger than every primitive action.
- Given two terms t_1 and t_2, assume $(\sum K)^*$ is larger than both. Because $(\sum K)^* = (\sum K)^* + (\sum K)^*$ and addition preserves order,
$$(\sum K)^* = (\sum K)^* + (\sum K)^* \geq t_1 + t_2$$
- Given two terms t_1 and t_2, assume $(\sum K)^*$ is larger than both. Because $(\sum K)^* = (\sum K)^* \cdot (\sum K)^*$ and multiplication preserves order,
$$(\sum K)^* = (\sum K)^* \cdot (\sum K)^* \geq t_1 \cdot t_2.$$
- Given a term t, if $(\sum K)^* \geq t$, then $(\sum K)^* \geq t^*$. Since $(\sum K)^* = ((\sum K)^*)^*$ and star preserves order:
$$(\sum K)^* = ((\sum K)^*)^* \geq t^*.$$ ◀

Since every free KAT is a TopKAT, every KAT interpretation $I : \mathsf{KAT} \to \mathcal{K}$ induces a sub-KAT $\mathbf{Im}(I) \subseteq \mathcal{K}$, and this sub-KAT happens to be a *TopKAT*. Specifically, the image of $(\sum K)^*$ in $\mathcal{K}$ is the largest element of $\mathbf{Im}(I)$, and the restricted $I : \mathsf{KAT} \to \mathbf{Im}(I)$ is a TopKAT homomorphism.

This gives us a powerful tool to construct complete TopKAT interpretations. Since we already know that the KAT interpretations $G : \mathsf{KAT} \to \mathcal{G}$ and $h \circ G : \mathsf{KAT} \to \mathbf{Im}(h)$ are injective TopKAT homomorphisms, we can construct complete TopKAT interpretations by *composition*, if we can construct an injective TopKAT interpretation r of type $\mathsf{TopKAT}_{K,B} \to \mathsf{KAT}_{K_\top,B}$:

$$\mathsf{TopKAT}_{K,B} \xrightarrow{r} \mathsf{KAT}_{K_\top,B} \xrightarrow{G} \mathcal{G}_{K_\top,B}, \quad \mathsf{TopKAT}_{K,B} \xrightarrow{r} \mathsf{KAT}_{K_\top,B} \xrightarrow{G} \mathcal{G}_{K_\top,B} \xrightarrow{h} \mathbf{Im}(h).$$

In fact, such an injective homomorphism can be obtained by lifting the embedding map $K + B \hookrightarrow \mathsf{KAT}_{K_\top,B}$:

$$r : K + B \to \mathsf{KAT}_{K_\top,B}$$
$$r(p) \triangleq p.$$

This homomorphism coincides with the *reduction maps* of the same name in previous works [41, 35]. More concretely, we can picture r as simply replacing the symbol $\top$ in a TopKAT term with $(\sum K_\top)^*$, the largest element in $\mathsf{KAT}_{K_\top,B}$.

We will show that r is injective by constructing a left inverse for it. In fact, the left inverse $[-]_\top$ simply interprets the $\top$ primitive in $\mathsf{KAT}_{K_\top,B}$ as the largest element.

▶ **Lemma 7.** *The map $[-]_\top : \mathsf{KAT}_{K_\top,B} \to \mathsf{TopKAT}_{K,B}$, where each term is mapped to its corresponding equivalence class, is defined by lifting the following action on the primitives:*

$$[p]_\top \triangleq p \qquad \text{if } p \in K + B$$
$$[\top]_\top \triangleq \top.$$

The map $[-]_\top$ is a TopKAT homomorphism.

Proof. Because this map defined by lifting on the primitives, it is automatically a KAT homomorphism. All we need to show is that $[-]_\top$ preserves the top element, that is $[(\sum K_\top)^*]_\top = (\sum K_\top)^*$ is the largest element in $\mathsf{TopKAT}_{K,B}$.

By construction of $\mathsf{TopKAT}_{K,B}$, $\top$ is the largest element in $\mathsf{TopKAT}_{K,B}$. Thus, to prove that $(\sum K_\top)^*$ is also the largest element in $\mathsf{TopKAT}_{K,B}$, it suffices to prove $(\sum K_\top)^* \geq \top$:

$$(\sum K_\top)^* \geq \sum K_\top = \top + \sum K \geq \top. \qquad \blacktriangleleft$$

▶ **Theorem 8** (Reduction). *$[-]_\top$ is the right inverse of r: $[-]_\top \circ r = id_{\mathsf{TopKAT}_{K,B}}$. More explicitly for all $t \in \mathsf{TopKAT}_{K,B}$:*

$$\mathsf{TopKAT}_{K,B} \models [r(t)]_\top = t.$$

Proof. Since $[-]_\top \circ r : \mathsf{TopKAT}_{K,B} \to \mathsf{TopKAT}_{K,B}$ is a TopKAT interpretation, the action on the primitives uniquely determines the interpretation: because both r and $[-]_\top$ are identity on the primitives, therefore $[-]_\top \circ r$ is the identity interpretation on $\mathsf{TopKAT}_{K,B}$. ◀

The above theorem matches one of the soundness condition of reductions in previous works [41, 24, 33], which was typically proven by a monolithic induction on the structure of terms. Our approach, on the other hand, relies on establishing fine-grained algebraic properties, like Lemmas 6 and 7; then the theorem follows simply by computing the action of $[-]_\top \circ r$ on primitives.

Since r has a right inverse, it is indeed the injective interpretation we desired, and it is also a complete interpretation:

$$\mathsf{TopKAT}_{K,B} \models t_1 = t_2 \iff r(t_1) = r(t_2),$$

With the completeness of r, we can already show the complexity of TopKAT. The complexity results echos previous proofs [41, 35], but we are able to obtain this result without completeness of TopKAT language interpretation, which is essential in previous proofs.

▶ **Corollary 9** (Complexity). *Given two terms $t_1, t_2 \in \mathsf{TopKAT}_{K,B}$, deciding whether these two terms are equal is PSPACE-complete.*

Proof. Deciding KAT equality is a sub-problem of deciding TopKAT equality, and KAT equality is PSPACE-hard [6]; therefore TopKAT equality is PSPACE-hard.

To decide the equality of t_1, t_2, we first remove all the redundant primitives that do not appear in t_1, t_2 from the alphabet K, B. Then we compute $r(t_1)$ and $r(t_2)$, each taking polynomial space (of $|t_1| + |t_2|$) to store; and we use the standard algorithm [6] to decide whether $r(t_1) = r(t_2)$ in $\mathsf{KAT}_{K_\top,B}$, this will also take polynomial space. Hence, the decision procedure for TopKAT equality in PSPACE.

Thus deciding TopKAT equality is PSPACE-complete. ◀

3.2 Computing the complete interpretations

Designing complete interpretations and models was not always easy. In fact, in previous works [42], the authors made a mistake in the definition of language TopKAT, which was fixed later [41] by suggestion of Pous et al. [34]. However, with the results in Section 3.1, we can construct the complete interpretation just by composition, and compute the complete model by computing the range of the complete interpretation.

We already know that there are two complete interpretations of TopKAT defined as follows:

$$\mathsf{TopKAT}_{K,B} \xrightarrow{r} \mathsf{KAT}_{K_\top,B} \xrightarrow{G} \mathcal{G}_{K_\top,B}, \quad \mathsf{TopKAT}_{K,B} \xrightarrow{r} \mathsf{KAT}_{K_\top,B} \xrightarrow{G} \mathcal{G}_{K_\top,B} \xrightarrow{h} \mathbf{Im}(h),$$

with a complete language model $\mathcal{G}_{K_\top,B}$, and a complete model consisting of relations $\mathbf{Im}(h)$.

The operations in these models can be recovered by computing these maps. For example, the multiplication operation in the language TopKAT can be computed as follows:

$$G \circ r(t_1 \cdot t_2) = G(r(t_1) \cdot r(t_2)) = G(r(t_1)) \diamond G(r(t_2)).$$

Since r does not change the multiplication operation, the multiplication in the language TopKAT is the same as in language KAT. In fact, as r does not change any operation in KAT, most operations in language TopKAT are the same as language KAT. Thus, we only need to compute the top element in language TopKAT.

The top element in language TopKAT can be computed in the same fashion:

$$G \circ r(\top) = G((\sum K_\top)^*) = GS_{K_\top,B},$$

i.e. the top element is just the complete language.

▶ **Corollary 10.** *The language TopKAT inherits all the operations in language KAT, except the top element, which is defined as the full language. And such models are complete with $G \circ r$ as a complete interpretation.*

In the same way, we know that complete models consisting of relations (a.k.a. general relational TopKAT) will have the same operations as relational KATs. However, in this case the characterization of the computed top: $h \circ G \circ r(\top)$ is not as simple as the full language, but we know it is the largest relation in the range of $h \circ G \circ r$:

▶ **Corollary 11.** *The general relational TopKAT inherits all the operations in relational KAT, except the top element is the largest relation. And such models are complete with $h \circ G \circ r$ as a complete interpretation.*

Finally, to investigate whether we can use general relational TopKAT to encode incorrectness logic, we will provide a short proof that general relational TopKATs are as expressive as relational KATs [41]; that is, every property on relations that can be encoded using general relational TopKAT, is already encodable in the relational KAT. Hence, adding a top element does not give extra expressive power in general relational TopKAT.

The original proof [41, Lemma 2] encodes every TopKAT term using a KAT term, and then uses two pages to prove the soundness of this encoding. Here we show the aforementioned encoding is simply the reduction r.

▶ **Definition 12.** *Given two terms $t_1, t_2 \in \mathsf{TopKAT}$, and n primitives $p_1, p_2, \ldots, p_n \in K + B$, we say that an n-ary predicate P is* expressible *by equation $t_1 = t_2$ for a class of TopKATs K when for all interpretations I into TopKATs in K, the following equivalence holds:*

$$I(t_1) = I(t_2) \iff P(I(p_1), I(p_2), \ldots, I(p_n)).$$

▶ **Theorem 13** (Expressiveness of general relational TopKAT)**.** *Given an alphabet K, B, an n-ary predicate P on relations, the predicate P over primitives $p_1, p_2, \ldots, p_n \in K$ is expressible in general relational TopKAT if and only if it is expressible in relational KAT.*

Proof. A predicate expressible in relational KAT is also expressible in general relational TopKAT using the same pair of terms, we only need to show the converse. Assume a predicate P is expressible in general relational TopKAT, then there exists two TopKAT terms $t_1, t_2 \in \mathsf{TopKAT}_{K,B}$ s.t. for all general relational TopKAT interpretations $I_\top$:

$$I_\top(t_1) = I_\top(t_2) \iff P(I_\top(p_1), I_\top(p_2), \ldots, I_\top(p_n));$$

We take an arbitrary relational KAT interpretation I from $\mathsf{KAT}_{K_\top,B}$. Notice $\mathbf{Im}(I)$, the range of I, is a relational KAT with the largest element $I((\sum K)^*)$, i.e. $\mathbf{Im}(I)$ is a general relational TopKAT. Because I is a KAT interpretation, it preserves all the KAT operations and the largest element. Hence, I is a TopKAT homomorphism from $\mathsf{KAT}_{K_\top,B}$ to $\mathbf{Im}(I)$.

Then we can construct $I \circ r : \mathsf{TopKAT}_{K,B} \to \mathbf{Im}(I)$, a general relational interpretation:

$$\begin{aligned} I(r(t_1)) = I(r(t_2)) &\iff I \circ r(t_1) = I \circ r(t_2) \\ &\iff P(I \circ r(p_1), \ldots, I \circ r(p_n)) \quad I \circ r \text{ is a TopGREL interpretation} \\ &\iff P(I(p_1), \ldots, I(p_n)) \qquad\qquad r(p_i) = p_i \end{aligned}$$

Thus the two KAT terms $r(t_1), r(t_2) \in \mathsf{KAT}_{K_\top,B}$ also can express the predicate P. ◀

Since the image of I is not necessarily a relational TopKAT, where the top element is interpreted as the complete relation, the above trick does not work for relational TopKAT. It is also known that relational TopKAT is strictly more expressive than general relational TopKAT, since relational TopKAT can encode incorrectness logic, where general relational TopKAT cannot [41].

4 (Co)domain Completeness

In general, TopKAT is not complete over relational models, which are crucial for applications in program logics [41]. However, it was later showed that we can obtain a complete theory for relational models by simply adding the axiom $p\top p \geq p$ to the theory of TopKAT [35].

In this paper, we take a different approach than Pous et al. [35]: instead of extending the TopKAT framework, we will restrict the completeness result. In particular, the encoding of incorrectness logic and Hoare Logic in TopKAT [41] relies only on the ability of TopKAT to compare the domain and codomain of two relations. This raises the question of whether TopKAT suffices for proving such properties; that is, whether the following completeness results hold: for $t_1, t_2 \in \mathsf{KAT}_{K,B}$ (i.e. $\top$ does not appear in t_1 and t_2)

$$\begin{aligned} \text{REL} \models \mathrm{cod}(t_1) \geq \mathrm{cod}(t_2) &\iff \mathsf{TopKAT} \models \top t_1 \geq \top t_2 \qquad \text{codomain completeness} \\ \text{REL} \models \mathrm{dom}(t_1) \geq \mathrm{dom}(t_2) &\iff \mathsf{TopKAT} \models t_1\top \geq t_2\top \qquad \text{domain complete} \end{aligned}$$

In this section, we prove that these equivalences hold, even without the additional axiom. However, they do *not* hold if we allow terms that contain top. For example, let $t_1 \triangleq p\top p$, and $t_2 \triangleq p$. Since $p\top p \geq p$ holds in relational TopKAT, thus $\mathrm{dom}(p\top p) \geq \mathrm{dom}(p)$. However, $p\top p\top \geq p\top$ is not provable in TopKAT, because the inequality is not valid with the language interpretation. The incompleteness of codomain comparison can also be shown using the same example.

4.1 Codomain completeness

The core insight to prove the domain completeness result is to construct a specific relational interpretation $h \circ i \circ G$, where its codomain is equivalent to the complete TopKAT interpretation $G \circ r$:

$$\mathrm{cod}(h \circ i \circ G(t)) = G \circ r(\top t),$$

where i is the natural inclusion homomorphism $i : \mathcal{G}_{K,B} \hookrightarrow \mathcal{G}_{K_\top,B}$, that maps every language to itself; and h is the classical embedding of language KAT into relational KAT [24], which we will recall as follows:

$$h(L) = \{(s, s \diamond s') \mid s \in GS, s' \in L\}.$$

Although i will not change the outcome of G, it will add a new primitive action $\top$ to the alphabet, hence changing the outcome of h. Such addition will equate the codomain of $h \circ i \circ G(t)$ with the complete TopKAT interpretation $G \circ r$ of $\top t$. The proof of this equality is by simply computing both sides of the equation.

▶ **Lemma 14.** *For any term $t \in \mathsf{KAT}_{K,B}$,*

$$\mathrm{cod}(h \circ i \circ G(t)) = G \circ r(\top t).$$

Proof. We explicitly write out the domain and codomain of the functions in the relational KAT interpretation $h \circ i \circ G$ for the ease of the reader:

$$\mathsf{KAT}_{K,B} \xrightarrow{G} \mathcal{G}_{K,B} \xrightarrow{i} \mathcal{G}_{K_\top,B} \xrightarrow{h} \mathcal{P}(\mathcal{G}_{K_\top,B} \times \mathcal{G}_{K_\top,B}).$$

In this case, h is a KAT homomorphism from $\mathcal{G}_{K_\top,B}$:

$$h(S) = \{(s, s \diamond s_1) \mid s \in GS_{K_\top,B}, s_1 \in S\}.$$

Since the reduction r preserves terms without $\top$, let $t \in \mathsf{KAT}_{K,B}$ (i.e. t does not contain $\top$),

$$G \circ r(\top) = GS_{K_\top,B} \qquad\qquad G \circ r(t) = G(t).$$

Therefore, for any term $t \in \mathsf{KAT}_{K,B}$

$$\begin{aligned}
\mathrm{cod}(h \circ i \circ G(t)) &= \{s\alpha s_1 \mid s\alpha \in GS_{K_\top,B}, \alpha s_1 \in G(t)\} \\
&= GS_{K_\top,B} \diamond G(t) \\
&= (G \circ r(\top)) \diamond (G \circ r(t)) \\
&= G \circ r(\top t).
\end{aligned}$$

◀

Lemma 14 established a connection between the codomain operator and the language interpretation of TopKAT. Then by completeness of the language interpretation, we will obtain the completeness of codomain comparison.

▶ **Theorem 15** (Codomain completeness)**.** *Given two terms $t_1, t_2 \in \mathsf{KAT}_{K,B}$ (i.e. terms without $\top$), then codomain comparison is complete:*

$$\mathrm{REL} \models \mathrm{cod}(t_1) \geq \mathrm{cod}(t_2) \iff \mathsf{TopKAT} \models \top t_1 \geq \top t_2.$$

Proof. Given the natural inclusion homomorphism: $i : \mathsf{KAT}_{K,B} \to \mathsf{KAT}_{K_\top,B}$, we show that the following are equivalent:

1. $\mathrm{REL} \models \mathrm{cod}(t_1) \geq \mathrm{cod}(t_2)$.
2. $\mathrm{cod}(h \circ i \circ G(t_1)) \geq \mathrm{cod}(h \circ i \circ G(t_2))$.
3. $\mathsf{TopKAT} \models \top t_1 \geq \top t_2$.

We first show that $1 \implies 2$, by definition, $\mathrm{REL} \models \mathrm{cod}(t_1) \geq \mathrm{cod}(t_2)$ implies $\mathrm{cod}(I(t_1)) \geq \mathrm{cod}(I(t_2))$ for all relational KAT interpretations I. Because $h \circ i \circ G$ is a relational KAT interpretation, so $1 \implies 2$.

We show 2 $\implies$ 3, which uses the equality discussed above, and proved in Lemma 14:

$$\begin{aligned}
&\mathrm{cod}(h \circ i \circ G(t_1)) \geq \mathrm{cod}(h \circ i \circ G(t_2)) \\
\iff\ & G \circ r(\top t_1) \geq G \circ r(\top t_2) && \text{Lemma 14} \\
\iff\ & \mathsf{TopKAT} \models \top t_1 \geq \top t_2. && \text{Completeness of } G \circ r
\end{aligned}$$

Finally, we show 3 $\implies$ 1, by Lemma 5:

$$\mathsf{TopKAT} \models \top t_1 \geq \top t_2 \implies \mathrm{TopREL} \models \top t_1 \geq \top t_2 \implies \mathrm{REL} \models \mathrm{cod}(t_1) \geq \mathrm{cod}(t_2). \quad \blacktriangleleft$$

4.2 Domain completeness

The domain completeness result can be derived from codomain completeness by observing properties of opposite TopKAT and the converse operator $(-)^\vee$, both of which we will recall below.

For every TopKAT $\mathcal{K}$, we can construct the opposite TopKAT $\mathcal{K}^{\mathrm{op}}$ by reversing the multiplication operation, keeping the sorts and other operations unchanged:

$$p \mathbin{\hat{\cdot}} q \triangleq q \cdot p,$$

where $\hat{\cdot}$ is multiplication in $\mathcal{K}^{\mathrm{op}}$ and $\cdot$ is multiplication in $\mathcal{K}$. By definition, $(-)^{\mathrm{op}}$ is a involution, that is $(\mathcal{K}^{\mathrm{op}})^{\mathrm{op}} = \mathcal{K}$. Furthermore, $(-)^{\mathrm{op}}$ is a TopKAT functor, this means all TopKAT homomorphisms $h : \mathcal{K} \to \mathcal{K}'$ can be lifted to a TopKAT homomorphism on the opposite TopKAT $h^{\mathrm{op}} : \mathcal{K}^{\mathrm{op}} \to \mathcal{K}'^{\mathrm{op}}$. The lifting h^{op} is point-wise equal to h:

$$\forall p \in \mathcal{K}, h^{\mathrm{op}}(p) \triangleq h(p).$$

The fact that h^{op} is a TopKAT homomorphism can be proven by unfolding the definition, and the functor laws are satisfied because h^{op} is point-wise equal to h.

There are two important homomorphisms involving opposite TopKAT:

$$\begin{aligned}
&(-)^\vee : (X \times X)^{\mathrm{op}} \to (X \times X) && \mathrm{op} : \mathsf{TopKAT}_{K,B} \to \mathsf{TopKAT}^{\mathrm{op}}_{K,B} \\
&(R)^\vee = \{(b,a) \mid (a,b) \in R\}, && \forall p \in K + B, \mathrm{op}(p) = p.
\end{aligned}$$

The $(-)^\vee$ is the relational converse operator, the rules of homomorphism can simply be proven by unfolding of definitions. The crucial property of $(-)^\vee$ is that it flips the domain and codomain:

$$\mathrm{dom}(R^\vee) = \mathrm{cod}(R). \tag{2}$$

Hence, allowing us to flip the result about codomains and apply it to domains.

op is a homomorphism from free TopKAT to its opposite TopKAT; it can be defined by lifting the embedding function $K + B \hookrightarrow \mathsf{TopKAT}_{K,B}$ on primitives. Intuitively, given a term $t \in \mathsf{TopKAT}$, $\mathrm{op}(t)$ will flip all the multiplications in t recursively.

▶ **Lemma 16.** *the left inverse of op can be obtained by lifting itself through the* $(-)^{\mathrm{op}}$ *functor,*

$$\mathrm{op}^{\mathrm{op}} : \mathsf{TopKAT}^{\mathrm{op}} \to (\mathsf{TopKAT}^{\mathrm{op}})^{\mathrm{op}} = \mathsf{TopKAT}.$$

Recall $\mathrm{op}^{\mathrm{op}}$ *is pointwise equal to* op*, thus* $\mathrm{op}^{\mathrm{op}} \circ \mathrm{op} : \mathsf{TopKAT} \to \mathsf{TopKAT}$ *is the identity interpretation because it preserves all the primitives. Thus,* op *has a left inverse, hence it is injective:*

$$t_1 = t_2 \iff \mathrm{op}(t_1) = \mathrm{op}(t_2).$$

Finally, since the elements in $\mathsf{TopKAT}^{\mathrm{op}}$ are the same as TopKAT, which are TopKAT terms modulo provable TopKAT equalities, theorems about TopKAT terms are also true for elements in $\mathsf{TopKAT}^{\mathrm{op}}$. In particular, codomain completeness (Theorem 15) also holds in $\mathsf{TopKAT}^{\mathrm{op}}$: for all terms $t_1, t_2 \in \mathsf{TopKAT}$,

$$\top \cdot \mathrm{op}(t_1) \geq \top \cdot \mathrm{op}(t_2) \iff \mathrm{REL} \models \mathrm{cod}(\mathrm{op}(t_1)) = \mathrm{cod}(\mathrm{op}(t_2)). \tag{3}$$

▶ **Theorem 17** (Domain Completeness). *For all terms $t_1, t_2 \in \mathsf{KAT}$, the following equivalence hold:*

$$\mathrm{REL} \models \mathrm{dom}(t_1) = \mathrm{dom}(t_2) \iff \mathsf{TopKAT} \models t_1\top \geq t_2\top.$$

Proof. $\Longleftarrow$ direction is trivial by Lemma 5; and $\Longrightarrow$ direction can be derived as follows: let I be some relational interpretation, then $I^{\mathrm{op}}(\mathrm{op}(-))^\vee$ is also a relational interpretation:

$$I^{\mathrm{op}}(\mathrm{op}(-))^\vee : \mathsf{TopKAT} \xrightarrow{\mathrm{op}} \mathsf{TopKAT}^{\mathrm{op}} \xrightarrow{I^{\mathrm{op}}} (X \times X)^{\mathrm{op}} \xrightarrow{(-)^\vee} (X \times X).$$

Thus, we let I range over all relational interpretations:

$$\begin{aligned}
&\mathrm{REL} \models \mathrm{dom}(t_1) \supseteq \mathrm{dom}(t_2) \\
&\Longrightarrow \forall I, \mathrm{dom}(I(t_1)) \supseteq \mathrm{dom}(I(t_2)) \\
&\Longrightarrow \forall I, \mathrm{dom}(I^{\mathrm{op}}(\mathrm{op}(t_1))^\vee) \supseteq \mathrm{dom}(I^{\mathrm{op}}(\mathrm{op}(t_2))^\vee) && \text{specialize } I \text{ as } I^{\mathrm{op}}(\mathrm{op}(-))^\vee \\
&\Longrightarrow \forall I, \mathrm{cod}(I^{\mathrm{op}}(\mathrm{op}(t_1))) \supseteq \mathrm{cod}(I^{\mathrm{op}}(\mathrm{op}(t_1))) && \text{Equation (2)} \\
&\Longrightarrow \forall I, \mathrm{cod}(I(\mathrm{op}(t_1))) \supseteq \mathrm{cod}(I(\mathrm{op}(t_1))) && I^{\mathrm{op}} \text{ is pointwise equal to } I \\
&\Longrightarrow \top \cdot \mathrm{op}(t_1) \geq \top \cdot \mathrm{op}(t_2) && \text{Equivalence (3)} \\
&\Longrightarrow \mathrm{op}(\top \cdot t_1) \geq \mathrm{op}(\top \cdot t_2) && \text{Definition of op} \\
&\Longrightarrow t_1\top \geq t_2\top && \text{Lemma 16}
\end{aligned}$$ ◀

▶ Remark 18. Alternatively, Theorem 17 can also be proven by constructing the following h':

$$h' : \mathcal{G}_{K,B} \to \mathcal{P}(\mathcal{G}_{K,B} \times \mathcal{G}_{K,B})$$
$$h'(S_1) \triangleq \{(s_1\alpha s, \alpha s) \mid s_1\alpha \in S_1, \alpha s \in GS_{K,B}\}.$$

Then the proof would mirror that of Theorem 15, replacing h with h' and replacing cod with dom. However, the proof of Theorem 17 reveals more properties of maps like $(-)^\vee$ and op, thus we choose to present the current proof of Theorem 17 instead of the alternative proof.

5 Related Works

Extensions of Kleene algebra and reduction. soon after the completeness of Kleene algebra was proven [18], it was realized that adding an embedded Boolean algebra can help reasoning about control structures, such system is referred to as Kleene algebra with tests (KAT) [24, 6]. Later KAT was further extended to reason about failure [26], indicator variables [13], domain [9], networks [1], and relational reasoning [3]. Kleene algebra has also been extended to reason about concurrency, as concurrent Kleene algebra [14, 17] and concurrent Kleene algebra with observations [16]. Many of these extensions can be seen as Kleene algebra with extra hypotheses [5, 11]. Although many hypotheses make the theory undecidable [19, 22, 11], many useful hypotheses can be eliminated via reduction [33]. Thus, our new perspective on reduction could potentially lead to streamlining of various previous proofs, and more general proofs of completeness results.

Top element. Tarski's relational algebra [40] contains the addition, mulitiplication, and identity operation of KA; in addition, relational algebra also include a top element. Hence attempts to incorporat Kleene star into relational algebra effectively create a super theory of TopKAT. Unfortuantly, several attempts at these algebras turn out to be undecidable because of the presence of intersection and converse operations [2, 32]. With the intersection and converse operators removed, top element is proven to be individually useful in Kleene algebra: for example, Mamouras [26] uses the top element to forget program states, and Antonopoulos et al. [3] uses top to design forward simulation rules for relational verification, and claim that relational incorrectness logic [29] can be encoded using BiKAT extended with top. The completeness and decidability of TopKAT was first studied by Zhang et al. [41], and concluded that TopKAT is not complete with relational models. Later, Pous et al. [34, 35] showed that both TopKA and TopKAT is complete with relational model with one additional axiom: $p\top p \geq p$, and the theory remains PSPACE-complete, like KAT and TopKAT. In this paper, we showed that TopKAT without the additional axiom is complete for a specific form of inequalities, namely when top only appears in the front or the end of the term. Although this form of inequalities seem restrictive, they are enough to encode both Hoare and incorrectness logic [41].

Domain in KAT. The study of axiomatizing (co)domain in KAT has a long and rich history. Domain semiring [10] and Kleene algebra with domain [9] were two popular yet different axiomatizations of (co)domain in Kleene algebra with tests. These two axiomitizations turn out to coincide in a large class of semirings [12]. Various applications for domain in KAT have been discovered, including modeling program correctness, predicate transformers, temporal logics, termination analysis, and many more [8]. Many of these applications can even be efficiently automated [15]. However, although the free relational model of these theories has been characterized [28], the search for general complete interpretation remains unfruitful. The complexity of these theories was recently shown to be EXPTIME-complete [37], a worse complexity class than PSPACE-complete for TopKAT.

6 Conclusion And Open Problems

In this paper, we exploit the homomorphic structure of reduction to simplify the proof of various previous results [41]. We have also showed that TopKAT is complete with respect to (co)domain comparison in the relational models, which lays a solid foundation for the use of TopKAT in (co)domain reasoning.

However, there are still several interesting unsolved problems about TopKAT. Most of the incorrectness logic rules are written using hypotheses, for example, the sequencing rule:

$$\frac{[a]\ p\ [b] \qquad [b]\ q\ [c]}{[a]\ p \cdot q\ [c]}$$

corresponds to the implication $\top ap \leq \top b \wedge \top bp \leq \top c \implies \top apq \leq \top c$. Although each individual inequality in the implication fits the desired form $\top t_1 \geq \top t_2$. it is unclear whether implications of the form

$$\top t_{11} \leq \top t_{12} \wedge \top t_{21} \leq \top t_{22} \wedge \cdots \wedge \top t_{n1} \leq \top t_{n2} \implies \top t_1 \leq \top t_2$$

are complete with relational TopKAT or decidable.

Recently, there is an efficient fragment of KAT proposed, named *Guarded Kleene algebra with tests* [38] or *GKAT*. This fragment not only enjoys nearly-linear time equality checking, but also soundly models probabilistic computations as well. It would be interesting to see whether the completeness and decidability result of TopKAT can be extended to GKAT, and whether the efficiency of GKAT will persist with the addition of top.
