Similarly to P-GLCP and its binary variant P-LCP, we also define SWS-2P-Colorful-Tangent as the restriction of SWS-Colorful-Tangent to inputs where $|P_i| = 2$ for all $i \in [d]$. We now wish to prove these two problems polynomial-time equivalent to P-Lin-Bellman. To achieve this, we reduce SWS-Colorful-Tangent to P-Lin-Bellman, and P-Lin-Bellman to SWS-2P-Colorful-Tangent, with the reduction by inclusion from SWS-2P-Colorful-Tangent to SWS-Colorful-Tangent closing the cycle.

For our reductions, we will use the concept of *point-hyperplane duality*, as described by Edelsbrunner in [8, p.13]. Point-hyperplane duality is a bijective mapping from all points in $\mathbb{R}^d$ to all non-vertical hyperplanes in $\mathbb{R}^d$. A point $p = (p_1, \ldots, p_d)$ is mapped to the hyperplane $p^* = \{x \in \mathbb{R}^d \mid 2p_1x_1 + \ldots 2p_{d-1}x_{d-1} - x_d = p_d\}$. The hyperplane p^* is called *the dual of* p, and for a non-vertical hyperplane h, its dual h^* is the unique point p such that $p^* = h$.

Point-hyperplane duality has the nice properties of *incidence preservation* and *order preservation*: for any point p and non-vertical hyperplane h, we have that $p \in h$ if and only if $h^* \in p^*$, and furthermore we have that p lies above h if and only if h^* lies above p^*.

We are now ready to begin presenting our reductions. For all of these reductions, we use the following crucial yet simple observation on strongly well-separated point sets:

▶ **Observation 23.** *If a set of point sets $P_1, \ldots, P_d$ is strongly well-separated, then every set of point sets $P'_1, \ldots, P'_d$ obtained by moving points $p_{i,j}$ $(j \neq 1)$ orthogonally to the hyperplane spanned by $p_{1,1}, \ldots, p_{d,1}$ is also strongly well-separated.*

The general idea of the reduction is to represent the linear inputs to a min or max operation in a Lin-Bellman system by a point $p_{i,1}$ and the affine inputs by a point $p_{i,j}$ $(j \neq 1)$. As a warm-up, we first only reduce from the two-point version.

▶ **Lemma 24.** *SWS-2P-Colorful-Tangent poly-time reduces to P-Lin-Bellman.*

Proof. We first linearly transform our point sets such that the plane through $p_{1,1}, \dots, p_{d,1}$ is mapped to the horizontal plane $\{(x_1, \dots, x_d) \in \mathbb{R}^d \mid x_d = 0\}$. Without loss of generality, we assume that after this transformation the colorful hyperplane h spanned by $p_{1,1}, \dots, p_{d,1}$ is oriented upwards, i.e., its positive halfspace contains $(0, \dots, 0, +\infty)$.

Then, we apply point-hyperplane duality. Each point $p_{i,j}$ becomes a hyperplane $h_{i,j} = p^*_{i,j}$, which can be described by some function $h_{i,j} : \mathbb{R}^d \to \mathbb{R}$ such that a point $x \in \mathbb{R}^d$ lies strictly above $h_{i,j}$ if $h_{i,j}(x) > 0$, and on $h_{i,j}$ if $h_{i,j}(x) = 0$. For the hyperplanes $h_{i,1}$ dual to our points $p_{i,1}$, we furthermore have that they go through the origin, i.e., $h_{i,j}$ is a linear function (and not only an affine function; it has no additive constant term).

Before applying duality, the desired $(\alpha_1, \dots, \alpha_d)$-cut hyperplane is a hyperplane h containing at least one point p'_i per set P_i, such that the other point of P_i lies on or above h if and only if $\alpha_i = |P_i|$, and on or below h if and only if $\alpha_i = 1$. In the dual, this now means that we need to find a point p which lies on at least one of the hyperplanes $h_{i,1}, h_{i,2}$ for each i, and such that it lies above (below) or on both of these hyperplanes if $\alpha_i = |P_i|$ ($\alpha_i = 1$). This can be described by the equations $\min\{h_{i,1}(x), h_{i,2}(x)\} = 0$ if $\alpha_i = |P_i|$ (and max instead of min, otherwise). This can of course be rewritten as $x_i = \min\{h_{i,2}(x) + x_i, h_{i,1}(x) + x_i\}$. Note again that the second input to this minimum is *linear* in x (there is no additive term). With one such constraint each per point set P_i, we thus get a system of d equations over d variables, which together form a Lin-Bellman system.

It remains to check whether this system is also a P-Lin-Bellman instance. We first see that changing q simply corresponds to moving the hyperplanes $h_{i,2}$ in a parallel fashion (i.e., without changing their normal vectors), which in the primal corresponds to moving them in direction x_d. By Observation 23 and Theorem 20, we always have unique $(\alpha_1, \dots, \alpha_d)$-cuts in this modified family of point sets, and thus the Lin-Bellman instance has a unique solution for all q'. ◀

▶ **Theorem 25.** *SWS-Colorful-Tangent poly-time reduces to P-Lin-Bellman.*

Proof (sketch). The proof works exactly the same way as the previous proof of Lemma 24. The only difference is that the equations that need to be encoded are of the form

$$x_i = \min\{h_{i,1}(x) + x_i, \dots, h_{i,|P_i|}(x) + x_i\}, \tag{12}$$

where still only $h_{i,1}(x)$ is guaranteed to be a linear function. To encode this as a Lin-Bellman system, we apply the same trick as in the proof of Lemma 14 to split the multi-input minimum into multiple two-input minima, with the remaining details found in the full version of the paper. ◀

To complete our cycle of reductions, we need to reduce from P-Lin-Bellman to SWS-2P-Colorful-Tangent. For this reduction we basically perform the process from the proof of Lemma 24 in reverse. The details are found in the full version of the paper.

▶ **Theorem 26.** *P-Lin-Bellman poly-time reduces to SWS-2P-Colorful-Tangent.*

To end this section, we want to note that the assumption of strong well-separation is not too strong, at least combinatorially:

▶ **Theorem 27.** *For every family of well-separated point sets, there exists a family of strongly well-separated point sets with the same combinatorial structure, i.e., the two families have the exact same order type.*

The proof can be found in the full version of the paper. Note that the proof is merely existential and it is unlikely that the translation can be performed efficiently.

5 Grid-USO and Cube-USO

We saw in the two previous sections that both P-GLCP and SWS-Colorful-Tangent can be reduced to their respective "binary" variants, P-LCP and SWS-2P-Colorful-Tangent. In this section we discuss grid USOs and cube USOs, which are a combinatorial framework that can be used to model all the problems studied in the sections above as well as many more algebraic and geometric problems. Similarly to the previous sections, cube USOs are a restriction of grid USOs to the "binary" case.

5.1 Definitions

We define C as a d-dimensional hypercube. We say $V(C) := \{0,1\}^d$ and $\{J,K\} \in E(C)$ iff $|J \oplus K| = 1$, where $\oplus$ is the bit-wise xor operation (i.e., addition in $\mathbb{Z}_2^d$) and $|\cdot|$ counts the number of 1-entries. For notational simplicity, in this section we use the same name both for a bitvector in $\{0,1\}^d$ and for the set of dimensions $i \in [d]$ in which the vector is 1. For example for $J, K \in \{0,1\}^d$ we write $J \subseteq K$ if for all $i \in [d]$ with $J_i = 1$ we also have $K_i = 1$.

The orientation of the edges of the cube C is given by an *orientation* function $O : V(C) \to \{0,1\}^d$, where $O(J)_i = 0$ means J has an incoming edge in dimension i and $O(J)_i = 1$ is an outgoing edge in dimension i.

▶ **Definition 28.** *An orientation is a* unique sink orientation (USO) *if and only if every induced subcube has a unique sink.*

The common search problem version of this problem is to find the global sink of the cube, given the function O as a boolean circuit. Note that it is co-NP-complete to test whether a given orientation is USO [13]. We consider the promise version Cube-USO, which was one of the first search problems proven to lie in the complexity class Promise-UEOPL [9].

▶ **Definition 29.** *Cube-USO*
Input: *A circuit computing the orientation function O on a d-dimensional cube C.*
Promise: *O is a Unique Sink Orientation.*
Output: *A vertex $J \in V(C)$ which is a sink, i.e., $\forall i \in [d] : O(J)_i = 0$.*

While the d-dimensional hypercube is the product of d copies of K_2 (the complete graph on two vertices), a *grid graph* is the product of complete graphs of arbitrary size: A d-dimensional grid graph Γ is given by $n_1, \ldots, n_d \in \mathbb{N}^+$:

$$V(\Gamma) := \{0, \ldots, n_1\} \times \cdots \times \{0, \ldots, n_d\},$$
$$E(\Gamma) := \{\{v, w\} \mid v, w \in V(\Gamma), \exists! i \in [d] : v_i \neq w_i\}.$$

We say the grid has d *dimensions* and each dimension i has $n_i + 1$ *directions*.

The subgraph Γ' of Γ induced by the vertices $V(\Gamma') = N_1 \times \cdots \times N_d$ for non-empty $N_i \subseteq \{0, \ldots, n_i\}$ is called an *induced subgrid* of Γ. Note that if for some i we have $|N_i| = 1$, the induced subgrid loses a dimension. If $|N_i| = 1$ for all $i \in [d]$ except one, we say that the induced subgrid Γ' is a *simplex*. A simplex is a complete graph K_{n_j+1} for some $j \in [d]$.

The orientation of a grid is given by the *outmap function*, which assigns each vertex a binary vector that encodes whether its incident edges are incoming or outgoing. More formally, the outmap function is a function $\sigma : V(\Gamma) \to \{0,1\}^{n_1+\ldots+n_d}$, where $\sigma(v)_{n_1+\ldots+n_i+j} = 1$ denotes that the edge from v to its j-th neighbor w in dimension $i+1$ is outgoing, i.e., oriented from v to w. Note that any circuit computing σ has $n_1 + \ldots + n_d$ outputs, and is thus of size $\Omega(n_1 + \ldots + n_d)$.

For notational convenience, we denote the entry of $\sigma(v)$ relevant to the edge $\{v, w\}$ by $\sigma(v, w)$. In other words, for each pair of vertices v, w such that $\{v, w\} \in E(\Gamma)$, $\sigma(v, w) = 1$ iff the edge between v and w is oriented towards w.

▶ **Definition 30** (Gärtner, Morris, Rüst [10]). *An orientation of a grid graph is a* unique sink orientation (USO) *if and only if every induced subgrid has a unique sink.*

A unique sink orientation of a simplex with n vertices is equivalent to a permutation of n elements, i.e. every unique sink orientation of one simplex can be given by a total order of its vertices. The minimum element of the order is the source, the maximum element is the sink.

Since every cube is also a grid, the complexity of checking whether σ is USO is also co-NP-hard. So again, we consider the promise search version of this problem:

▶ **Definition 31.** *Grid-USO*
Input: *A d-dimensional grid $\Gamma = (n_1, \ldots, n_d)$ and a circuit computing its outmap σ.*
Promise: *σ is a Unique Sink Orientation.*
Output: *A sink, i.e. a vertex $v \in V(\Gamma)$ s.t. $\forall w \in V(\Gamma)$ with $\{v, w\} \in E(\Gamma) : \sigma(v, w) = 0$.*

Just like Cube-USO, Grid-USO also lies in the search problem complexity class Promise-UEOPL [1]. It is well known that P-LCP reduces to Cube-USO [22] and P-GLCP reduces to Grid-USO [10]. Since SWS-2P-Colorful-Tangent and SWS-Colorful-Tangent can both be reduced to P-LCP and P-GLCP respectively, they also reduce to Cube-USO and Grid-USO respectively. However, we show a direct and straightforward reduction from SWS-2P-Colorful-Tangent to Cube-USO, and from SWS-Colorful-Tangent to Grid-USO. These direct reductions do not require strong well-separation, only classical well-separation. The proof can be found in the full version of the paper.

▶ **Lemma 32.** *Assuming general position of the input points, finding an α-cut in a well-separated point set family $P_1, \ldots, P_d \subset \mathbb{R}^d$ for $\alpha_i \in \{1, |P_i|\}$ can be reduced to Grid-USO in polynomial time. The reduction goes to Cube-USO if for all i, $|P_i| = 2$.*

▶ Remark 33. If we instead want to find an α'-cut for arbitrary α', we can use the reduction from Lemma 32 with $\alpha = (1, \ldots, 1)$, but instead of searching for a sink in the resulting grid USO Γ, we need to find a vertex with $\alpha'_i - 1$ outgoing edges in each dimension i.

By [10, Theorem 2.14], this vertex is guaranteed to exist and to be unique. We call the problem of searching for such a vertex α-Grid-USO. Note that α-Grid-USO is not known to reduce to regular Grid-USO, nor is it known to lie in Promise-UEOPL (compared to α-Ham Sandwich which does lie in Promise-UEOPL [3]).

5.2 Grid-USO to Cube-USO

In this section we show that every Grid-USO instance (Γ, σ) can be reduced to a Cube-USO instance (C,O) in polynomial time such that given the global sink of O, we can derive the global sink of σ in polynomial time.

We are given a d-dimensional grid $\Gamma = (n_1, \ldots, n_d)$ and turn it into a hypercube of dimension $n := \sum n_i$. Note that Γ is n-regular and so is C. For every dimension of the grid spanned by $n_i + 1$ directions, we assign a block of n_i dimensions in C. For simplicity, we index into the dimensions of the hypercube using double indices: for every bitstring $J \in \{0, 1\}^n$, we write $J_{i,j}$ (where $j \in [n_i]$) as a shorthand for $J_{j+\sum_{l \in [i-1]} n_l}$.

Each vertex $J \in V(C)$ is assigned a corresponding vertex in the grid Γ as follows: For every grid dimension $i \in [d]$, we assign J a *color* j_i with

$$j_i := max(\{0\} \cup \{h \mid h \in [n_i], J_{i,h} = 1\}). \tag{13}$$

The tuple of colors $(j_1, \ldots, j_d)$ is the vertex in the grid that we associate with J. When we orient J, we orient each block i of dimensions of C independently, according to the corresponding simplex in dimension i in Γ that contains this vertex $(j_1, \ldots, j_d)$.

A single simplex of Γ with $n_i + 1$ directions is turned into an n_i-cube as shown in Figure 5. The vertex (0) of the simplex is mapped to the vertex 0^{n_i}, and all the other vertices of the grid are mapped to its neighbors. We call these $n_i + 1$ vertices the *grid-vertices*, all others are called *non-grid-vertices*. The paths of length one and two between these grid-vertices encode the orientation of the grid. This completely orients the grid-vertices. The rest of the cube is oriented according to the colors of the non-grid-vertices; edges between vertices of two different colors are oriented as the corresponding edge in the grid. Vertices of the same color are oriented in such a way that in the subcube corresponding to all vertices of the same color all the edges of the same dimension are oriented the same way. This orientation is uniquely defined since the unique grid-vertex of this color is already completely oriented.

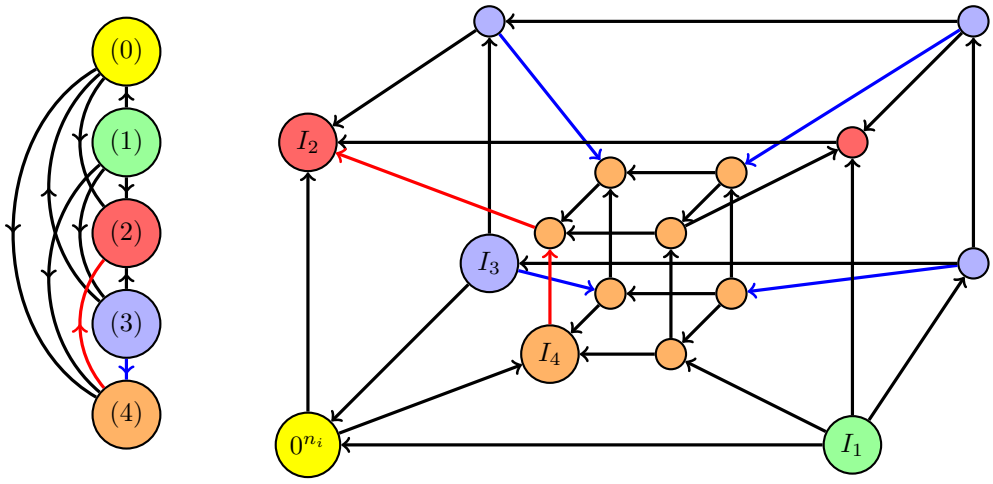

Figure 5 Example of placing grid-vertices (large) in the cube, coloring the non-grid-vertices (small) and orienting the edges. Each edge of the grid becomes a path of length two between two grid-vertices, see the red edges. Edges between vertices of different colors are oriented the same as in the grid, see the blue edges. Each subcube of the same color is oriented in a uniform way.

To formalize this construction for the complete grid, we need to define a secondary color j_i^* for each vertex $J \in V(C)$ and each grid dimension $i \in [d]$, which for all vertices with color $j_i \neq 0$ corresponds to the color of the neighboring vertex of J in dimension (i, j_i):

$$j_i^* := max(\{0\} \cup \{h \mid h \in [n_i] \setminus \{j_i\}, J_{i,h} = 1\}). \tag{14}$$

The orientation O of the cube C is now defined as follows:

$$O(J)_{i,h} := \begin{cases} \sigma((j_1, \ldots, j_i, \ldots, j_d), (j_1, \ldots, h, \ldots j_d)) \oplus J_{i,h} & \text{for } h < j_i, \\ \sigma((j_1, \ldots, j_i, \ldots, j_d), (j_1, \ldots, h, \ldots j_d)) & \text{for } h > j_i, \\ \sigma((j_1, \ldots, j_i, \ldots, j_d), (j_1, \ldots, j_i^*, \ldots j_d)) & \text{for } h = j_i. \end{cases} \tag{15}$$

▶ **Theorem 34.** *If σ is a unique sink orientation, then the orientation constructed by Equation (15) is a unique sink orientation. A circuit computing O can be computed in polynomial time. Given the sink of O, the sink of σ can be found in polynomial time.*

The proof can be found in the full version of the paper.

6 Open Questions

Total Search Problem Versions. All reductions we provided in this paper are between the promise problem versions of the involved problems. It may be interesting to also find reductions between the total search problem versions.

Missing Reductions. We were unable to show that finding an α-cut for arbitrary α is not more difficult than finding it for $\alpha_i \in \{1, |P_i|\}$. There might thus be a difference in the computational complexity of α-Ham-Sandwich and SWS-Colorful-Tangent. Similarly, in Grid-USO, we also do not know whether it is not more difficult to find a vertex with a specific refined index (which must also be unique) rather than searching for a sink. Note that in the case of α-Ham-Sandwich, it is at least known that the problem is contained in UEOPL. This is not known for α-Grid-USO.

Semantics of the Grid-USO to Cube-USO Reduction. On the levels of USOs, we do not know the exact operations that the reductions from P-GLCP to P-LCP and SWS-Colorful-Tangent to SWS-2P-Colorful-Tangent perform. It would be very interesting to analyze whether these reductions actually perform the same operation as the Grid-USO to Cube-USO reduction (Theorem 34), i.e., whether these reductions commute. It would also be interesting to study whether the Grid-USO to Cube-USO preserves realizability, i.e., whether if there exists a P-GLCP instance inducing a certain grid USO, there also exists a P-LCP instance inducing the resulting cube USO.

Kernelization Dichotomies for Hitting Subgraphs Under Structural Parameterizations

Abstract

For a fixed graph H, the H-Subgraph Hitting problem consists in deleting the minimum number of vertices from an input graph to obtain a graph without any occurrence of H as a subgraph. This problem can be seen as a generalization of Vertex Cover, which corresponds to the case $H = K_2$. We initiate a study of H-Subgraph Hitting from the point of view of characterizing structural parameterizations that allow for polynomial kernels, within the recently active framework of taking as the parameter the number of vertex deletions to obtain a graph in a "simple" class $\mathcal{C}$. Our main contribution is to identify graph parameters that, when H-Subgraph Hitting is parameterized by the vertex-deletion distance to a class $\mathcal{C}$ where any of these parameters is bounded, and assuming standard complexity assumptions and that H is biconnected, allow us to prove the following sharp dichotomy: the problem admits a polynomial kernel if and only if H is a clique. These new graph parameters are inspired by the notion of *$\mathcal{C}$-elimination distance* introduced by Bulian and Dawar [Algorithmica 2016], and generalize it in two directions. Our results also apply to the version of the problem where one wants to hit H as an induced subgraph, and imply in particular, that the problems of hitting minors and hitting (induced) subgraphs have a substantially different behavior with respect to the existence of polynomial kernels under structural parameterizations.

1 Introduction

The theory of parameterized complexity deals with *parameterized problems*, which are decision problems in which a positive integer k, called the *parameter*, is associated with every instance x. One of the pivotal notions in the domain is that of *kernelization* [5, 15, 20, 24, 39], which is a polynomial-time algorithm that reduces any instance (x, k) of a parameterized problem to an equivalent instance (x', k') of the same problem whose size is bounded by $f(k)$ for some function f, which is the *size* of the kernelization. A kernelization algorithm, or just *kernel*, can be seen as a preprocessing procedure with provable guarantees, and it is fundamental to

find kernels of the smallest possible size, ideally polynomial. Identifying which parameterized problems admit polynomial kernels is one of the most active areas within Parameterized Complexity (cf. for instance [24]).

When dealing with a problem where the goal is to find a (say, small) subset of vertices S of an input graph G satisfying some property, such as Vertex Cover, it is natural to consider as the parameter the size of the desired set S. Assuming that the problem admits a polynomial kernel parameterized by $|S|$, as it is the case for Vertex Cover and many other problems [15, 24], we can ask whether the problem still admits polynomial kernels when the parameter is (asymptotically) smaller than the solution size. The goal of this approach is to provide better preprocessing guarantees, as well as to understand what is the limit of the polynomial-time "compressibility" of the considered problem. For problems defined on graphs, apart from using the solution size as a parameter, it is common to consider so-called *structural parameters*, which quantify some structural property of the input graph that can be seen as a measure of its "complexity". Among structural parameters, the most successful is probably *treewidth* [15, 35], but unfortunately taking the treewidth of the input graph as the parameter does not allow for polynomial kernels for essentially all natural optimization problems, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ [6, 8]. The same applies to another relevant graph parameter called *treedepth*, denoted by td and defined as the minimum number of rounds needed to obtain the empty graph, where each round consists of removing one vertex from each connected component.

In fact, the lower bound proofs go through for parameterizations for which the value on a disconnected graph is the *maximum*, rather than the *sum*, of the values of its components, and whose value is polynomially bounded in the size of the graph. Hence, to be able to obtain positive kernelization results, we need to turn to parameterizations other than *width measures*. This motivates to consider structural parameters that quantify the "distance from triviality", a concept first coined by Guo, Hüffner, and Niedermeier [28]. The idea is to take as the parameter the vertex-deletion distance of a graph to a "trivial" graph class where the considered problem can be solved efficiently. This paradigm has proved very successful for a number of problems, in particular for Vertex Cover. In an influential work, Jansen and Bodlaender [30] showed that Vertex Cover admits a polynomial kernel when parameterized by the feedback vertex number of the input graph, which is the vertex-deletion distance to the "trivial" class of forests. This result triggered a number of results in the area, aiming to characterize the "trivial" families $\mathcal{F}$ for which Vertex Cover admits a polynomial kernel under this parameterization [10, 12, 25, 29, 40].

Let us mention some of these results that are relevant to our work. Bougeret and Sau [12] proved that Vertex Cover admits a polynomial kernel parameterized by the vertex-deletion distance to a graph of bounded treedepth. This result was further generalized into two orthogonal directions, namely by considering a more general problem or a more general target graph class $\mathcal{F}$. For the former generalization, Jansen and Pieterse [33] proved that the following problem also admits a polynomial kernel parameterized by the vertex-deletion distance to a graph of bounded treedepth: for a fixed finite set of connected graphs $\mathcal{M}$, the $\mathcal{M}$-Minor Deletion problem consists in deleting the minimum number of vertices from an input graph to obtain a graph that does not contain any of the graphs in $\mathcal{M}$ as a minor. Note that this problem (vastly) generalizes Vertex Cover, which corresponds to the case $\mathcal{M} = \{K_2\}$. For the latter generalization, Bougeret, Jansen, and Sau [10] proved that Vertex Cover admits a polynomial kernel parameterized by the vertex-deletion distance to a graph of bounded *bridge-depth*, which is a parameter that generalizes treedepth and the feedback vertex number. It turns out that, under the assumption that the target

graph class $\mathcal{F}$ is minor-closed, the property of $\mathcal{F}$ having bounded bridge-depth is also a *necessary* condition for Vertex Cover admitting a polynomial kernel. Another complexity dichotomy of this flavor has been achieved by Dekker and Jansen [18] for the Feedback Vertex Set problem (with another characterization of the target graph class $\mathcal{F}$). These complexity dichotomies, while precious, are unfortunately quite hard to obtain, and the current knowledge seems still far from obtaining dichotomies of this type for general families of problems, such as for $\mathcal{M}$-Minor Deletion for any finite family of graphs $\mathcal{M}$. Indeed, it is wide open whether $\mathcal{M}$-Minor Deletion admits a polynomial kernel parameterized by the solution size for any set $\mathcal{M}$ containing only non-planar graphs [23, 34], so considering parameters smaller than the solution size is still out of reach.

Our contribution. We consider an alternative generalization of Vertex Cover by considering (induced) *subgraphs* instead of *minors*. Namely, for a fixed graph H, the H-Subgraph Hitting problem is defined as deleting the minimum number of vertices from an input graph to obtain a graph without any occurrence of H as a subgraph. The H-Induced Subgraph Hitting problem is defined analogously by forbidding occurrences of H as an *induced* subgraph. (As we shall see later, both problems behave in the same way with respect to our results.) Note that both problems correspond to Vertex Cover for the case $H = K_2$ and therefore are indeed generalization of it. As opposed to the case for hitting minors, it is well-known that both the H-Subgraph Hitting and H-Induced Subgraph Hitting problems admit polynomial kernels parameterized by the solution size for any graph H [1, 21].

Therefore, it does make sense to parameterize these problems by structural parameters in the "distance from triviality" spirit, and this is the main focus of this article. To the best of our knowledge, this is an unexplored topic, besides all the literature for Vertex Cover discussed above. Our main result is to identify structural parameters that allow to provide sharp dichotomies for these problems *depending on the forbidden (induced) subgraph* H.

Before presenting our results, we proceed to motivate and define these structural parameters. They are inspired by the following parameter, first introduced by Bulian and Dawar [13, 14] and further studied, for instance, in [2, 22, 29, 31, 41, 42]. For a fixed class of graphs $\mathcal{H}$, the $\mathcal{H}$-*elimination distance* of a graph G, denoted by $\mathsf{ed}_{\mathcal{H}}(G)$, is defined by mimicking the above definition of treedepth and replacing "empty graph" with "a graph in $\mathcal{H}$". The recursive definitions of treedepth and $\mathcal{H}$-elimination distance suggest the notion of *elimination forest*, which is the forest-like process of vertex removals from the considered graph to obtain either an empty graph for treedepth, or a graph in $\mathcal{H}$ for $\mathcal{H}$-elimination distance. Suppose now that $\mathcal{H}$ is defined by the exclusion of a fixed graph H as a subgraph or as an induced subgraph. Formally, let $\mathcal{F}_{\bar{H}}$ (resp. $\mathcal{F}_{\bar{H}}^{\mathsf{ind}}$) be the class of graphs that exclude a fixed graph H as a subgraph (resp. induced subgraph). For this particular case, the notion of $\mathcal{F}_{\bar{H}}$-elimination distance (or $\mathcal{F}_{\bar{H}}^{\mathsf{ind}}$-elimination distance) can be interpreted as a generalization of treedepth where, in the last round of the elimination process, the vertices that do not belong to any occurrence of $\mathcal{H}$ as a subgraph (or induced subgraph) can be deleted "for free". We generalize the notion of $\mathcal{H}$-elimination distance by allowing "free removal" of vertices not contained in a copy of H in *every round* of the elimination process, rather than just the last; we denote the corresponding parameter by $\mathsf{ved}^{+}_{\mathcal{F}_{\bar{H}}}$ (or $\mathsf{ved}^{+}_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$), where "$\mathsf{v}$" stands for the removal of *vertices*, in order to distinguish this parameter from the one defined below (see Section 2 for the formal definitions of these parameters). Our first main result is the following somehow surprising dichotomy, which states that, under the assumption that H is biconnected, whenever H has a non-edge, the problem is unlikely to admit a polynomial kernel. Our result applies to both the induced and non-induced versions of the problem.

▶ **Theorem 1.1.** *Let H be a biconnected graph, let $\lambda \geq 1$ be an integer, and assume that* $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$. *$H$-*Subgraph Hitting *(resp. H-*Induced Subgraph Hitting*) admits a polynomial kernel parameterized by the size of a given vertex set X of the input graph G such that $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X) \leq \lambda$ (resp. $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}(G - X) \leq \lambda$) if and only if H is a clique.*

Note that a graph G satisfies $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G) = 0$ (resp. $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}(G) = 0$) if and only if G does not contain H as a subgraph (resp. induced subgraph), so the setting $\lambda = 0$ corresponds to the parameterization by solution size which always admits a polynomial kernel [1, 21]; this is why we assume that $\lambda \geq 1$ in the statement of Theorem 1.1.

Theorem 1.1 shows that the behavior of the considered problems in terms of the existence of polynomial kernels drastically changes as soon as one edge is missing from H (under the biconnectivity assumption, which is needed in the reduction). To the best of our knowledge, this is the first time that such a dichotomy, in terms of H, is found with respect to the existence of polynomial kernels. It is worth mentioning that, with respect to the existence of certain fixed-parameter tractable algorithms parameterized by treewidth, dichotomies of this flavor exist for hitting subgraphs [17], induced subgraphs [43], or minors [4].

The proof of Theorem 1.1 consists of two independent pieces. On the one hand, we need to prove that both problems admit a polynomial kernel when H is a clique (note that, in that case, both problems are equivalent, as any H-subgraph is induced). On the other hand, we need to provide a kernelization lower bound for all other graphs H (cf. Theorem 3.2), and here is where we need the hypothesis that $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$ and, for technical aspects of the reduction, that H is biconnected.

In fact, we provide a kernel that is more general than the one stated in Theorem 1.1. Also, on the negative side, we present another lower bound incomparable to that of Theorem 1.1. For the former, we provide a polynomial kernel, when H is a clique, for a parameter that is more powerful than $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}$ (or $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$). This more powerful parameter is somehow inspired by the parameter bridge-depth mentioned before [10], which is a generalization of treedepth in which, in every round of the elimination process, we are allowed to remove subgraphs in each component that are more general than just single vertices. In our setting, it turns out that we can afford to remove vertex sets $T \subseteq V(G)$ that induce connected subgraphs that do not contain H as a subgraph (or induced subgraph) and that are "weakly attached" to the rest of the graph, meaning that each connected component of $G - T$ has at most one neighbor in T. If H is biconnected, it is easily seen that the "candidate" sets T to be removed can be assumed to be connected unions of blocks (biconnected components) of G, and this is why we call this parameter $\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}$ (or $\mathsf{bed}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$), where "$\mathsf{b}$" stands for the removal of *blocks*. For any two graphs G and H, the following inequalities, as well as the corresponding ones for the induced version, follow easily from the definitions (cf. Section 2):

$$\mathsf{td}(G) \geq \mathsf{ed}_{\mathcal{F}_{\bar{H}}}(G) \geq \mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G) \geq \mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}(G). \tag{1}$$

We prove the following result, where K_t denotes the clique on t-vertices, and note that in this case the induced and non-induced versions of the problem coincide.

▶ **Theorem 1.2.** *Let $t \geq 3$ and $\lambda \geq 1$ be fixed integers. The K_t-*Subgraph Hitting *problem admits a polynomial kernel parameterized by the size of a given vertex set X of the input graph G such that $\mathsf{bed}^+_{\mathcal{F}_{\bar{K}_t}}(G - X) \leq \lambda$.*

Note that for $t = 2$, the parameter $\mathsf{bed}^+_{\mathcal{F}_{\bar{K}_t}}$ is exactly treedepth, and therefore Theorem 1.2 can be seen as a far-reaching generalization of the main result of [12], that is, a polynomial kernel for Vertex Cover parameterized by the vertex deletion distance to a graph of bounded

treedepth. Also, note that Equation 1 and Theorem 1.2 imply that the same dichotomy stated in Theorem 1.1 holds if we substitute "$\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G-X) \leq \lambda$" for "$\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}(G-X) \leq \lambda$", and the same for the induced version.

As for strengthening our hardness results, we present kernelization lower bounds for H-Subgraph Hitting and H-Induced Subgraph Hitting, when H is not a clique, parameterized by the vertex-deletion distance to a graph of constant *treedepth*. By Equation 1, lower bounds for treedepth are stronger than the ones of Theorem 1.1. However, in our next main result, we need a condition on H that is stronger than biconnectivity, namely the non-existence of a *stable cutset*, that is, a vertex separator that induces an independent set.

▶ **Theorem 1.3.** *Let H be a graph on h vertices that is not a clique and that has no stable cutset. H-Subgraph Hitting and H-Induced Subgraph Hitting do not admit a polynomial kernel parameterized by the size of a given vertex set X of the input graph G such that $\mathsf{td}(G-X) = \mathcal{O}(h)$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.*

Note that, for $t \geq 4$, the graph K_t minus one edge satisfies the conditions of Theorem 1.3. The mere existence of a graph H satisfying the conditions of Theorem 1.3 is remarkable, as it shows that (induced) subgraph hitting problems behave differently than minor hitting problems. Indeed, as mentioned before, it is known [33] that, for *every* finite family $\mathcal{M}$ of connected graphs, the $\mathcal{M}$-Minor Deletion problem admits a polynomial kernel parameterized by the vertex-deletion distance to a graph of constant treedepth.

Dekker and Jansen [18] asked if for every finite set of graphs $\mathcal{M}$, $\mathcal{M}$-Minor Deletion admits a polynomial kernel parameterized by the vertex-deletion distance to a graph with constant $\mathsf{exc}(\mathcal{M})$-elimination distance, where $\mathsf{exc}(\mathcal{M})$ is the class of graphs that excludes all the graphs in $\mathcal{M}$ as a minor. Theorem 1.3 shows that, by Equation 1, for the problems of excluding subgraphs or induced subgraphs, the answer to this question is negative.

Finally, let us mention another consequence of our results. Agrawal et al. [2] proved, among other results, that for every hereditary target graph class $\mathcal{C}$ satisfying some mild assumptions, parameterizing by the vertex-deletion distance to $\mathcal{C}$ and by the $\mathcal{C}$-elimination distance are equivalent from the point of view of the existence of fixed-parameter tractable algorithms. Our results imply, in particular, that the same equivalence does *not* hold with respect to the existence of polynomial kernels in this "distance from triviality" setting, namely for problems defined by the exclusion of (induced) subgraphs.

Organization of the paper. In Section 2 we provide an overview of the main ideas of the kernelization algorithm, which is our main technical contribution. The formal description of the kernel and its analysis, which are quite lengthy, can be found in the full version of the article [11]. In Section 3 we present our hardness results (with some proofs deferred to the full version as well), and in Section 4 we discuss some directions for further research.

2 Overview of the kernelization algorithm

In this section we sketch the main ideas of the kernelization algorithm stated in Theorem 1.2, along with intuitive explanations and the required definitions.

Preliminaries. Given a graph G and $C \subseteq V(G)$, we denote by $N(C) = \bigcup_{v \in C} N(v) \setminus C$ and $G - C = G[V(G) \setminus C]$. Given a graph H, and a subgraph (resp. induced subgraph) F of G, we say that F is a *copy* (resp. *induced copy*) of H if F is isomorphic to H. We say that G is H-free (resp. H-induced free) if there is no copy of H (resp. induced copy) in G. Given two

disjoint subsets $A, B \subseteq V(G)$, we say that there is an edge between A and B if there exists $e \in E(G)$ such that $|e \cap A| = |e \cap B| = 1$. Otherwise, A and B are said to be *anticomplete*. When $\mathcal{P} = \{V_1, \ldots, V_m\}$ is a set of subsets of $V(G)$, we let $V(\mathcal{P}) = \bigcup_{V_i \in \mathcal{P}} V_i$. A *$t$-clique* is a set $K \subseteq V(G)$ such that $G[K]$ is a clique and $|K| = t$. For any integer $n \in \mathbb{N}$, we denote by $[n] = \{1, \ldots, n\}$. We study the following problem(s) for a fixed graph H.

H-SH (for H-Subgraph Hitting)
Input: A graph G.
Objective: Find a set $S \subseteq V(G)$ of minimum size such that $G - S$ is H-free.

We denote by H-ISH (for H-Induced Subgraph Hitting) the variant of the above problem where we impose that $G - S$ is *H-induced* free. We denote by $\mathsf{opt}^H(G)$ the optimal value of the considered problem for G, or simply $\mathsf{opt}(G)$ when H is clear from the context.

Let us now introduce the main graph measures used in this paper.

▶ **Definition 2.1.** *Let H be a fixed graph. For a graph G, define $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G)$ as*

$$\begin{cases} 0 & \text{if } V(G) = \emptyset, \\ \mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - v) & \text{if } v \text{ is a vertex that is not in any copy of } H, \\ \max_{C_i} \mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(C_i) & \text{if } G \text{ has connected components } C_1, \ldots, C_c \text{ with } c \geq 2, \\ 1 + \min_{v \in V(G)} \mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - v) & \text{otherwise.} \end{cases}$$

We define $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$ in the same way as $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}$, except that we replace "in any copy of H" by "in any induced copy of H". Note that the notation $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}$ is motivated by the fact that it corresponds to *vertex* elimination distance, with additional power of removing "free" vertices not in any copy of H. Note also that even though there could be multiple vertices v which satisfy the second criterion, the value is well-defined since it does not matter which one is picked; the second case will apply until all such vertices have been removed. As the case where $H = K_t$ plays an important role in this paper, for the sake of shorter notation we use the shortcut ved^+_t to denote the parameter $\mathsf{ved}^+_{\mathcal{F}_{\bar{K}_t}}$ (or $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{K}_t}}$, which is the same).

To define the parameters $\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}$ and $\mathsf{bed}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$, it is convenient to introduce the following definitions (see Figure 1).

▶ **Definition 2.2** (root and pending component)**.** *Given a fixed graph H and a connected graph G, we say that a set $T \subseteq V(G)$ is a* root of G *if*

- *$T \neq \emptyset$, $G[T]$ is connected and H-free, and*
- *for any connected component C of $G - T$, $|N(C) \cap T| = 1$.*

We extend to notion of root to any graph G as follows. For any graph G with connected components $\mathcal{C}$, we say that a set $\mathcal{T} = \{T_C \mid C \in \mathcal{C}\}$ is a root of G *if for any $C \in \mathcal{C}$, T_C is a root of $G[C]$. We define $V(\mathcal{T}) = \bigcup_{C \in \mathcal{C}} T_C$, and $E(\mathcal{T})$ as the set of edges that have both their endpoints inside $V(\mathcal{T})$.*

Given a graph G, a root $\mathcal{T}$ of G, and a vertex $v \in V(\mathcal{T})$, we define the pending component *of v relatively to $\mathcal{T}$, denoted by $C^{\mathcal{T}}(v)$, as the connected component of v in the graph obtained from G by removing all edges $e \subseteq E(\mathcal{T})$. We extend the notation to any subset $Z \subseteq V(\mathcal{T})$ with $C^{\mathcal{T}}(Z) = \bigcup_{v \in Z} C^{\mathcal{T}}(v)$. When the root is clear from context, we use $C(v)$ instead of $C^{\mathcal{T}}(v)$.*

We define an *induced root* in the same way, except that we replace "$G[T]$ is connected and H-free" by "$G[T]$ is connected and H-induced free". Note that any graph admits a root, by taking for example a single vertex (to play the role of T_C) in each connected component.

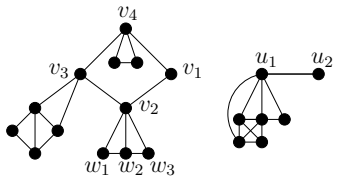

Figure 1 In this example we consider that $H = K_4$, and we denote by C_1 and C_2 the two connected components of G (where $v_1 \in C_1$). Observe that $\mathcal{T} = (T_1, T_2)$ is a root of the depicted graph with $T_1 = \{v_1, v_2, v_3, v_4\}$ and $T_2 = \{u_1, u_2\}$. We have $C(v_1) = \{v_1\}$ and $C(v_2) = \{v_2, w_1, w_2, w_3\}$. Finally, taking $T_1' = T_1 \cup \{w_1\}$ and $\mathcal{T}' = \{T_1', T_2\}$ would not be a root as T_1' is not a root of $G[C_1]$.

▶ **Observation 2.3.** *Let G be a graph and $\mathcal{T}$ be a root of G. For any $v \in V(\mathcal{T})$, there is no edge between $C(v) \setminus \{v\}$ and $V(G) \setminus C(v)$.*

▶ **Definition 2.4.** *Let H be a fixed graph. For a graph G, we define $\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}(G)$ as*

$$\begin{cases} 0 & \text{if } V(G) = \emptyset, \\ \mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}(G - v) & \text{if } v \text{ is a vertex that is not in any copy of } H, \\ \max_{C_i} \mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}(C_i) & \text{if } G \text{ has connected components } C_1, \ldots, C_c \text{ with } c \geq 2, \\ 1 + \min_{T \subset V(G)} \mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}(G - T) & \text{otherwise, where } T \text{ ranges over all roots of } G. \end{cases}$$

We define $\mathsf{bed}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$ in the same way as $\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}$, except that we replace "where T ranges over all roots of G" by "where T ranges over all induced roots of G". Again, as the case where $H = K_t$ plays an important role in this paper, for the sake of shorter notation we use the shortcut ved^+_t to denote the parameter $\mathsf{bed}^+_{\mathcal{F}_{\bar{K}_t}}$ (or $\mathsf{bed}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{K}_t}}$, which is the same). We point out that, to make the definition of $\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}$ as simple as possible, we allowed T to range over all roots of G. However, as shown in [11, Lemma 6.9], as soon as H is biconnected, there always exists a root that is the connected union of H-(induced-)free blocks of G, hence our choice of notation to differentiate $\mathsf{bed}^+_{\mathcal{F}_{\bar{H}}}$ from $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}$.

Given $\lambda \in \mathbb{N}$, let us now define the following variant of the considered problem, where we suppose that we are given as an additional input a modulator (corresponding to set X) to a "simple" graph $G - X$, where the simplicity is captured by bed^+_t being at most λ.

K_t-SHM$^\lambda$ (for K_t-Subgraph Hitting given a modulator to bed^+_t at most λ)
Input: A graph G and a set $X \subseteq V(G)$ such that $\mathsf{bed}^+_t(G[R]) \leq \lambda$, where $R = V(G) \setminus X$.
Objective: Find a set $S \subseteq V(G)$ of minimum size such that for any t-clique Z of G, $S \cap Z \neq \emptyset$.

We denote by K_t-SHM$^\lambda_{\mathsf{p}}$ the associated parameterized decision problem with an additional k in the input, where the goal to decide whether $\mathsf{opt}(G) \leq k$, and the parameter is $|X|$.

In [11, Section 5] we prove our main positive result that we restate here with less details, and which is a reformulation of Theorem 1.2 with the notation introduced in this section:

▶ **Theorem 2.5.** *There is a polynomial kernel for K_t-SHM$^\lambda_{\mathsf{p}}$ of size $\mathcal{O}_{\lambda,t}(|X|^{\delta(\lambda,t)})$ for some function $\delta(\lambda, t)$.*

Let us now present an overview of the techniques used to establish the above result.

Warming up with Vertex Cover**.** As an extreme simplification of our set up, let us consider the case where $t = 2$, corresponding to Vertex Cover, and assume that X is a modulator to the simplest graph class, namely an independent set. Our kernel uses a marking procedure (cf. [11, Definition 5.5]) that corresponds to the following marking algorithm for Vertex Cover. For any $u \in X$, mark up to $|X|+1$ vertices $v \in R$ such that $\{u, v\} \in E(G)$. Let $M \subseteq R$ be the set of marked vertices. Observe the following "packing property" of the marking algorithm: if there exists $v \in R \setminus M$ and $u \in X$ with $\{u, v\} \in E(G)$, then there exists a "packing" $\mathcal{P} \subseteq M$ of $|X| + 1$ vertices such that for any $v' \in \mathcal{P}$, $\{v', u\} \in E(G)$ (the term "packing" may seem inappropriate here, but becomes natural for $t > 2$ as the marking algorithm will mark disjoint sets of vertices instead of distinct vertices). Now, if $R = M$ then $|R| \leq \mathcal{O}(|X|^2)$ and the instance is kernelized. Otherwise, if there exists $v \in R \setminus M$, then define a *reduced instance* as $G' = G - v$ and $k' = k$. Let us sketch why this removing step is safe, as the arguments also correspond to a very simplified version of [11, Lemma 5.14]. The only non-trivial direction is that if (G', k') is a yes-instance, then (G, k) is also a yes-instance. Given a solution Z' of (G', k'), if there exists $u \in X \setminus Z'$ such that $\{u, v\} \in E(G)$, then the packing property implies the existence of the above set $\mathcal{P}$. Thus, we get that Z' *overpays for* u: it contains one extra vertex (in this case, one instead of zero) for each $v' \in \mathcal{P}$ as we must have $\mathcal{P} \subseteq Z'$. This implies that we can restructure Z' into $\tilde{Z} = X$, while ensuring that $|\tilde{Z}| \leq |Z'|$. Now, $\tilde{Z}$ can be easily completed to a solution of G of size k (in this case, by doing nothing). By repeating this reduction rule, we get the kernel of size $\mathcal{O}(|X|^2)$.

Parts, chunks, and conflicts. Let us now point out some important ideas used to lift up the previous kernel for Vertex Cover to K_t-SHM$^{\lambda}_{\mathsf{p}}$. In the previous setting, the key property when proving the safeness of the reduction rule, given a solution Z' of (G', k'), is the following: when "adding back" a non-marked vertex $v \in R \setminus M$ to G', either there exists $u \in X \setminus Z'$ such that Z' overpays for u, or there is no edge $\{u, v\}$ for any $u \in X \setminus Z'$.

Let us now rephrase this key property in the setting of hitting t-cliques using the adapted concepts of part, chunk, and conflict; we will formally define these terms later. When "adding back" a non-marked *part* $V' \subseteq R \setminus M$ to G', we know that either there exists *a chunk* $X' \subseteq X \setminus Z'$ such that Z' overpays for X', or there is no *conflict between* X' *and* V' for any chunk X'. Observe first that, as $G - X$ is now more general than an independent set, we have to consider a packing of "parts" (subsets of vertices of R), meaning that if there is a non-marked part V' that we remove, we now set $k' = k - \mathsf{opt}(G[V'])$. The second difference is the notion of "conflict between X' and V'" that plays the role of "edge $\{u, v\}$". We say that there is no *conflict* between X' and V' if $\mathsf{conf}^t_{X'}(V') = 0$, the condition $\mathsf{conf}^t_{X'}(V') = 0$ being equivalent to the fact that we can pick only $\mathsf{opt}(G[V'])$ vertices in V', while still hitting all t-cliques in $G[X' \cup V']$ (see [11, Definition 5.2] for the formal definition of conf^t). The third difference is the notion of chunk and blocking set. A good starting point when trying to complete a solution Z' of G' to a solution Z of G is that $\mathsf{conf}^t_{X \setminus Z'}(V') = 0$. Indeed, this condition implies that there exists a set $S^\star_{V'}$ of size $\mathsf{opt}(G[V'])$ such that $S^\star_{V'}$ hits all t-cliques in $G[V' \cup (X \setminus Z')]$. Thus, $S^\star_{V'}$ is a good candidate to build a solution $Z = Z' \cup S^\star_{V'}$ of (G, k). Note that this only remains a good starting point, as Z may not be a solution: it could miss cliques using V', $(X \setminus Z')$, and other vertices in $R \setminus V'$. This condition $\mathsf{conf}^t_{X \setminus Z'}(V') = 0$ could be achieved by a marking algorithm that, for any $U \subseteq X$, marks up to $|X| + 1$ parts V' such that $\mathsf{conf}^t_U(V') > 0$, which is a generalization of the previous marking algorithm for Vertex Cover. However, the running time and the number of marked parts by such an algorithm would not be polynomial in $|X|$, as there are too many subsets U to consider.

To overcome this issue, the trick is the notion of *maximum minimal blocking sets*, denoted by mmbs_t (cf. [11, Definition 4.1]), which is a graph parameter for which we skip the definition for the moment. What is important to state about mmbs_t here is that in [11, Theorem 2.6] we prove that there exists a function $\beta : \mathbb{N}^2 \to \mathbb{N}$ such that for every graph G, $\mathsf{mmbs}_t(G) \leq \beta(\mathsf{bed}_t^+(G), t)$. As in the kernelization algorithm we apply this to $G[R]$ and $\mathsf{bed}_t^+(G[R]) \leq \lambda$, we obtain $\mathsf{mmbs}_t(G[R]) \leq \beta(\lambda, t)$. Moreover, [11, Lemma 5.4] implies that the previous marking condition "there exists $U \subseteq X$ such that $\mathsf{conf}_U^t(V') > 0$" is equivalent to "there exists $X' \in \mathcal{X}$ such that $\mathsf{conf}_{X'}^t(V') > 0$", where $\mathcal{X} = \{X' \subseteq X \mid |X'| \leq (t-1)\beta(\lambda, t)$ and X' does not contain a t-clique$\}$ is the set of *chunks*. Observe that, as the chunks have bounded size, the marking algorithm runs in time $\mathcal{O}^\star(|X|^{(t-1)\beta(\lambda,t)})$. The conclusion is that the "triviality" of $G[R]$ ($\mathsf{bed}_t^+(G[R]) \leq \lambda$) implies that $G[R]$ has bounded mmbs_t, which allows to certify the absence of conflict (for any $U \subseteq X$) in polynomial time.

These notions of conflict, chunk, and minimal blocking set were also critical in previous work on kernelization: the notion of conflict was introduced in [30], and bounds on mmbs_2 (for Vertex Cover) have been proved for different triviality measures of $G[R]$ [3, 10, 12, 29, 30]. A first difference here is the study of mmbs_t for K_t-Subgraph Hitting, whose behavior is more complex than Vertex Cover, as discussed below when mentioning the new challenges.

Decreasing $\mathsf{bed}_t^+(G[R])$ and using recursion. Let us now informally describe the main steps of the kernel (see Figure 2). Given a graph G, we denote by $N^t(G) = \{v \in V(G) \mid \nexists\ t$-clique K with $v \in K\}$ the set of vertices of G that do not occur in any copy of K_t, called the *non-K_t-vertices*. Given an input (G, X, k) of K_t-SHM$_\mathsf{p}^\lambda$, we first compute $N^t(G[R])$ and, using the algorithm of [11, Lemma 6.9], a bed_t^+-root $\mathcal{T}$ of $G[R] - N^t(G[R])$, where a *bed_t^+-root* of G is a root $\mathcal{T}$ such that $\mathsf{bed}_t^+(G - V(\mathcal{T})) = \mathsf{bed}_t^+(G) - 1$. We point out that, unlike the case for treedepth or bridge-depth, computing such a root is not straightforward, as one cannot try the a priori exponentially many possible roots to find one that decreases bed_t^+. However, the algorithm of [11, Lemma 6.9] relies on the fact that it is possible to compute in polynomial time a set of size $\mathcal{O}(n)$ that contains a bed_t^+-root. Coming back to the kernel strategy, observe that there may be edges between some $C(v)$ and $N^t(G)$, but not between $C(v)$ and $C(u)$ for $u \neq v$, and that by definition of a bed_t^+-root, $\mathsf{bed}_t^+(G[R']) < \lambda$, where $R' = R - V(\mathcal{T})$. Then, we mark a small (polynomial in $|X|$) set $M(\mathcal{T}, N^t(G[R]), G, X)$ of vertices (cf. [11, Definition 5.8]) of $V(\mathcal{T})$ using the `mark` algorithm (cf. [11, Definition 5.5]). If there exists $v \in V(\mathcal{T}) \setminus M(\mathcal{T}, N^t(G[R]), G, X)$, then we can remove $C(v)$ and decrease k by $\mathsf{opt}(G[C(v)])$ (cf. [11, Lemma 5.14]). Otherwise, $|M(\mathcal{T}, N^t(G[R]), G, X)| = \mathcal{O}(|X|^{f(\lambda,t)})$ for some function f, and thus we can move $M(\mathcal{T}, N^t(G[R]), G, X)$ to the modulator and get a new modulator $X' = X \cup M(\mathcal{T}, N^t(G[R]), G, X)$ whose size is still polynomial in $|X|$. The key point is that $\mathsf{bed}_t^+(G - X') = \mathsf{bed}_t^+(G[R']) < \lambda$, and thus we use induction on λ and make a recursive call to (G, X'), which is an input of K_t-SHM$_\mathsf{p}^{\lambda-1}$, leading to a kernel polynomial in $|X'|$, and thus in $|X|$.

This idea of shrinking the "root" of a decomposition of $G - X$ to decrease the "triviality measure" (here, bed_t^+) and recurse originates in [27], and was used in [12] for treedepth. It was subsequently generalized in [10], where the triviality measure is a parameter called *bridge-depth* and the equivalent of a root is a so-called *tree of bridges* for each connected component of $G[R]$.

New challenges. With respect to the strategies followed in previous work on related topics [10, 12, 18, 29, 30, 32, 33], in our setting we encounter (at least) the following three orthogonal difficulties, for which we have to develop new ideas: dealing with the non-K_t-vertices, dealing with cliques K_t for arbitrary fixed t instead of $t = 2$, and proving that there exists a function β such that for every graph G, $\mathsf{mmbs}_t(G) \leq \beta(\mathsf{bed}_t^+(G))$.

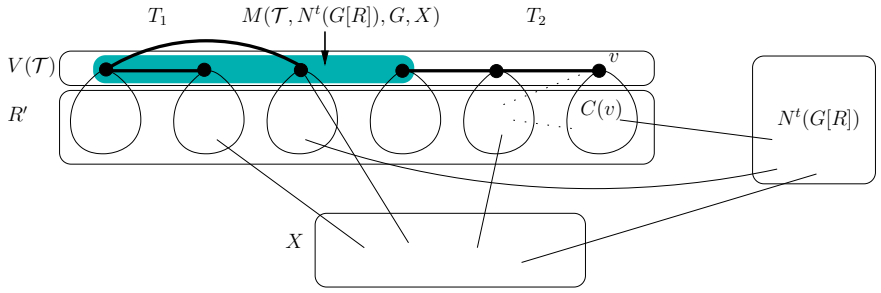

Figure 2 Main steps of the kernel. In this example $\mathcal{T} = \{T_1, T_2\}$ (edges inside T_i are in bold, and dotted edges cannot exist), and there exists a non-marked vertex v, implying that the pending component $C(v)$ will be removed.

The first difficulty is handling vertices of $N^t(G[R])$, which are vertices not belonging to a t-clique in $G[R]$. Indeed, observe that these non-K_t-vertices are "free" for bed_t^+, in the sense that $\mathsf{bed}_t^+(G[R]) = \mathsf{bed}_t^+(G[R] - N^t(G[R]))$. However, these vertices make the structure of $G[R]$ more complicated. Indeed, $\mathcal{T}$ being a root of $G[R] - N^t(G[R])$ implies that for any $T \in \mathcal{T}$ and $v \in T$, there are no edges between $C(v) \setminus \{v\}$ and other vertices in $C(u)$ for $u \in V(\mathcal{T}) \setminus \{v\}$, but there could be edges between $C(v)$ and $N^t(G[R])$. Thus, unlike in [10, 12], we cannot just bound the number of connected components of $G[R]$, and then assume that we have a single root T with simple properties (again, the root being a single vertex in [12], and a tree of bridges in [10]). Typically, here $G[R]$ could have only one connected component, but the nice structure given by $\mathcal{T}$ could be "polluted" by vertices of $N^t(G[R])$. We handle these vertices by considering a packing of "bidimensional" parts (V_i, N_i), where in particular $V_i \subseteq V(\mathcal{T})$ is a clique of size at most $t-1$ and $N_i \subseteq N^t(G[R])$, and we use a kind of generalized "sunflower-like" marking by first creating a maximal packing $\mathcal{P}$ of parts (V_i, N_i), of size at most $|X|+1$, and then recursively marking around each possible $g \in \bigcup N_i$ (see the last line of [11, Definition 5.5]).

The second difficulty is to handle t-cliques instead of edges. Indeed, assume that we just removed a pending component $C(v)$ for some $v \in V(\mathcal{T})$ and defined $k' = k - \mathsf{opt}(G[C(v)])$. Assume also that, given a solution Z' of (G', k'), we have the good starting point $\mathsf{conf}^t_{(X \cup N^t(G[R])) \setminus Z'}(C(v)) = 0$, implying, by the definition of conflict, that there exists a locally optimal solution $S_v^\star$ of $G[C(v)]$ that intersects all t-cliques of $G[C(v) \cup ((X \cup N^t(G[R])) \setminus Z')]$. However, there could also exist "spread" cliques K containing v and using vertices of $((X \cup N^t(G[R])) \setminus Z')$ and $M' \subseteq (V(\mathcal{T}) \setminus \{v\})$. These cliques may be spread across several vertices of $V(\mathcal{T})$, and by definition of a root they cannot use vertices in $C(u) \setminus \{u\}$ for any $u \in M' \cup \{v\}$ (according to Observation 2.3). To take into account the potential conflicts generated by these spread cliques, we perform $t-1$ marking steps (cf. [11, Definition 5.8]), where informally at each step we guess all possible subsets M', with $|M'| \leq t-1$, corresponding to a guessed intersection of a spread clique with previously marked vertices.

The last difficulty is to bound $\mathsf{mmbs}_t(G)$ as a function of $\mathsf{bed}_t^+(G)$ for any graph G. We first need to define the notion of blocking set adapted to our problem. Let EK_t-SH (for *Extended* K_t-Subgraph Hitting) be the problem where given $(G, \mathcal{F})$, where $\mathcal{F}$ is a set of subsets of $V(G)$ such that for any $Z \in \mathcal{F}, 1 \leq |Z| \leq t-1$ and $G[Z]$ is a clique, a solution must intersect all t-cliques of G and all $Z \in \mathcal{F}$. A *blocking set* $\mathcal{B}$ of G is a set of subsets of vertices of G such that $\mathsf{opt}(G, \mathcal{B}) > \mathsf{opt}(G)$, where $\mathsf{opt}(G, \mathcal{B})$ is the minimum size of a solution of the EK_t-SH problem with input $(G, \mathcal{B})$, meaning that any set hitting all t-cliques of G and all $Z \in \mathcal{B}$ cannot be an optimal solution of G for K_t-SH. Then, $\mathsf{mmbs}_t(G)$ is the

maximum size of an inclusion-wise minimal blocking set of G. The "max-min" taste of this definition makes it difficult to handle, but fortunately we will use [11, Property 1] stating that for any β, $\mathsf{mmbs}_t(G) \leq \beta$ is equivalent to the fact that for any blocking set $\mathcal{B}$ of G, there exists $\overline{\mathcal{B}} \subseteq \mathcal{B}$ such that $\overline{\mathcal{B}}$ is still a blocking set of G and $|\overline{\mathcal{B}}| \leq \beta$. We obtain the following upper bound, which requires a considerable amount of technical work.

▶ **Theorem 2.6.** *For any graph G and any integer $t \geq 3$, it holds that $\mathsf{mmbs}_t(G) \leq \beta(\mathsf{bed}_t^+(G), t)$, where $\beta(x,t) = \underbrace{2^{t2^{t2^{\cdots^t}}}}_{x \text{ times}}$ (i.e., $\beta(1) = 2^t, \beta(2) = 2^{t2^t}$, etc.)*

To explain the difficulty of proving the above theorem, let us sketch how such a bound is obtained for Vertex Cover as a function of treedepth, for example in the proof in [12] that, for every graph G, $\mathsf{mmbs}_2(G) \leq 2^{\mathsf{td}(G)}$.

Observe first that for the Vertex Cover problem, a blocking set $\mathcal{B}$ is a set of singletons, which we consider as a subset of vertices, such that any vertex cover S containing $\mathcal{B}$ is not optimal. Let us now use [11, Property 1] and consider a blocking set $\mathcal{B}$ of G, and let us show that there exists $\overline{\mathcal{B}} \subseteq \mathcal{B}$ such that $\overline{\mathcal{B}}$ is still a blocking set of G and $|\overline{\mathcal{B}}| \leq 2^{\mathsf{td}(G)}$. Consider a graph G and a "root" v of a treedepth decomposition of G, meaning that $\mathsf{td}(G-v) < \mathsf{td}(G)$. Let us consider the most complex case where there exists an optimal solution using v, another avoiding v, and $v \notin \mathcal{B}$. It is not difficult to prove that, as $\mathcal{B}$ is a blocking set of G, $\mathcal{B}_1 = \mathcal{B}$ is a blocking set of $G_1 := G - v$, and $\mathcal{B}_2 = \mathcal{B} \setminus N(v)$ is a blocking set of $G_2 := G - (\{v\} \cup N(v))$. Thus, as for any $i \in [2]$, $\mathsf{td}(G_i) < \mathsf{td}(G)$, by induction we get that there exists $\overline{\mathcal{B}}_i \subseteq \mathcal{B}_i$ such that $\overline{\mathcal{B}}_i$ is a blocking set of G_i and $|\overline{\mathcal{B}}_i| \leq 2^{\mathsf{td}(G)-1}$. As $\overline{\mathcal{B}}_1 \cup \overline{\mathcal{B}}_2$ is a blocking set of G, we get the desired bound. The problem when lifting this idea to K_t-Subgraph Hitting instead of Vertex Cover is that, when considering an optimal solution S that avoids a root v, we do not know which vertex the solution S will pick in $N(v)$. This is the reason for which we consider the more general version of the problem, namely EK_t-SH, to encode the fact that a solution of $(G, \emptyset)$ avoiding a root v must be a solution of $(G-v, \mathsf{pr}_v^t(V(G) \setminus \{v\}))$, where given two disjoint sets $A, B \subseteq V(G)$, $\mathsf{pr}_A^t(B) = \{K \cap B \mid K \text{ is a } t\text{-clique in } G[A \cup B] \text{ and } K \cap A \neq \emptyset \text{ and } K \cap B \neq \emptyset\}$. We also need to define the corresponding generalized notion of blocking set of an instance $(G, \mathcal{F})$ of EK_t-SH (cf. [11, Definition 4.1]), and not only of a graph G. Moreover, we have to keep track of the structure of $\mathcal{F}$, as there is no hope to bound $\mathsf{mmbs}_t(G, \mathcal{F})$ as a function of $\mathsf{bed}_t^+(G)$ for an arbitrary set $\mathcal{F}$. Indeed, for example, let G_ℓ be a chain of triangles of length ℓ, as depicted in Figure 4. We have $\mathsf{mmbs}_2(G_\ell) \geq \ell$, as if we let $\mathcal{B}$ be the set of top vertices of the ℓ triangles, then it can be easily seen that $\mathcal{B}$ is a minimal blocking set of G_ℓ with $|\mathcal{B}| = \ell$. Now, take $\mathcal{F} = E(G_\ell)$, $t = 4$, and observe that any solution of instance $(G_\ell, \mathcal{F})$ of EK_t-SH is a vertex cover of G_ℓ, and thus $\mathcal{B}$ is also a minimal blocking set of size ℓ for the input $(G_\ell, \mathcal{F})$ with $t = 4$, while $\mathsf{bed}_t^+(G_\ell) = 0$ as G_ℓ is K_4-free.

We resolve this problem by proving bounds on $\mathsf{mmbs}_t(G, \mathcal{F})$ only for a special type of instances that we call *clean*, which are pairs $(G, \mathcal{F})$ such that $\mathsf{opt}(G, \mathcal{F}) = \mathsf{opt}(G)$. The first main difficulty is that, when starting with a blocking set $\mathcal{B}$ of $(G, \mathcal{F})$, reducing to a graph G' with $\mathsf{bed}_t^+(G') < \mathsf{bed}_t^+(G)$ requires to remove the entire root $\mathcal{T}$ of $G - N^t(G)$, instead of just one vertex as in the treedepth case. As $|V(\mathcal{T})|$ may be arbitrarily large, we need to prove (see [11, Lemma 4.8]) that it is enough to "zoom in" on a small number of subgraphs (pending components here), allowing us to extract (by induction) a small blocking set only in each of these subgraphs. The second main difficulty is to ensure that we can reduce via recursion to smaller *clean* instances. Indeed, even if we initially consider a clean instance $(G, \emptyset)$, and even in the favorable case where $\mathcal{T}$ is just one vertex v (as in treedepth), we have to consider

the case where there exists an optimal solution of G using v, another avoiding v, and $v \notin \mathcal{B}$, where $\mathcal{B}$ is fixed blocking set from which we try to extract a small one. However, observe that optimal solutions avoiding v are optimal solutions of $(G-v, \mathsf{pr}_v^t(V(G)\setminus\{v\}))$, and that $\mathsf{opt}(G-v, \mathsf{pr}_v^t(V(G)\setminus\{v\})) = \mathsf{opt}(G) = 1+\mathsf{opt}(G-v)$ (the last equality holds since there are optimal solutions taking v). Thus, we observe that this situation leads to a *non*-clean instance $(G-v, \mathsf{pr}_v^t(V(G)\setminus\{v\}))$, but "almost clean" as $\mathsf{opt}(G-v, \mathsf{pr}_v^t(V(G)\setminus\{v\})) = \mathsf{opt}(G-v)+1$. We treat these almost clean instances in [11, Lemma 4.5], which is the main cause of the huge growth of function β in the final bound $\mathsf{mmbs}_t(G) \leq \beta(\mathsf{bed}_t^+(G), t)$ given in Theorem 2.6. As this bound directly reverberates both in the running time and the size of the kernel (see [11, Theorem 5.16], where $\delta(\lambda, t)$ is dominated by $\beta(\lambda, t)$ for an instance (G, X) of K_t-SHM where $\mathsf{bed}_t^+(G-X) \leq \lambda$), improving this bound is crucial in order to improve the kernel size. In this direction, we provide in [11, Lemma 4.12] a significantly better upper bound for minimal blocking sets of the K_t-SH problem as a function of td instead of bed_t^+. As the proof technique is also different, we believe that this result might be of independent interest.

Finally, let us mention that in several earlier papers on kernelization using structural parameterizations, it was also crucial to understand the maximum size of an inclusion-minimal set with additional requirements on the solution to a vertex-deletion problem, for which no optimal solution can satisfy all additional requirements; these correspond to variations on the notion of blocking sets. They were explored for the problems of hitting forbidden connected minors in graphs of bounded treedepth [33], and for hitting cycles in graphs of bounded elimination distance to a forest [18], both of which lead to super-exponential bounds in terms of the graph parameter.

3 Hardness results

In this section we present two reductions from CNF-SAT, and to transfer the non-existence of polynomial kernels (under reasonable complexity assumptions), we use the notion of *polynomial parameter transformation*, introduced by Bodlaender, Thomassé, and Yeo [9]. A polynomial parameter transformation from a parameterized problem P to a parameterized problem Q is an algorithm that, given an instance (x, k) of P, computes in polynomial time an equivalent instance (x', k') of Q such that k' is bounded by a polynomial depending only on k. It follows easily from the definition that if P does not admit a polynomial generalized[1] kernel under some complexity assumption, then the same holds for Q. The complexity hypothesis in the following proposition builds on the results by Fortnow and Santhanam [26].

▶ **Proposition 3.1** (Dell and van Melkebeek [19])**.** CNF-SAT *does not admit a polynomial generalized kernel parameterized by the number of variables of the input formula, unless* $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.

We are ready to present our main hardness result, which is inspired by other reductions for related problems [10, 16, 18, 25, 32]. The crucial issue of this reduction, and its main conceptual novelty, is the following fact: when H is not a clique, the intersection of an occurrence of H with (a subgraph of) $G-X$ may be *disconnected*. We exploit this fact by

[1] A *generalized kernel* for a parameterized problem P, also called sometimes *compression* in the literature [15], is a polynomial-time algorithm reducing any instance (x, k) of P to an equivalent instance (x', k') with size bounded by a function $f(k)$ depending only on k of a fixed but potentially *different* parameterized problem Q. A generalized kernel is *polynomial* if $f(k)$ is a polynomial function.

creating clause gadgets with large minimal blocking sets whose elements are disconnected (in Figure 3, each pair of consecutive non-adjacent vertices u, v is an element of a blocking set), and this results in clause gadgets behaving as "chains" where the propagation of information (that is, the vertices picked by the solution) is done without needing edges connecting the elements of the chain (thus, in a "wireless" fashion), easily implying that the corresponding parameter in $G - X$ is bounded by a constant.

▶ **Theorem 3.2.** *Let H be a biconnected graph that is not a clique. The H-*Subgraph Hitting *(resp. H-*Induced Subgraph Hitting*) problem does not admit a polynomial kernel parameterized by the size of a given vertex set X of the input graph G such that $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X) \leq 1$ (resp. $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}(G - X) \leq 1$), unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.*

Proof. We present a polynomial parameter transformation from the CNF-SAT problem parameterized by the number of variables, which does not admit a polynomial generalized kernel by Proposition 3.1, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. We present our reduction for the H-Subgraph Hitting problem, and at the end of the proof we observe that the same reduction applies to H-Induced Subgraph Hitting as well.

Given a CNF-SAT formula ϕ with n variables $x_1, \ldots, x_n$ and m clauses $C_1, \ldots, C_m$, we proceed to construct in polynomial time an instance G of H-Subgraph Hitting, together with a set $X \subseteq V(G)$ with $\mathsf{ved}^+_H(G - X) \leq 1$ and $|X| = |V(H)| \cdot n$, such that ϕ is satisfiable if and only if G contains a solution of H-Subgraph Hitting of size at most $n - m + \sum_{j=1}^{m} c_j$, where c_j denotes the number of literals in clause C_j. Since $|V(H)|$ is a constant, this would indeed define a polynomial parameter transformation from CNF-SAT parameterized by the number of variables to H-Subgraph Hitting parameterized by the size of a given vertex set X of the input graph G such that $\mathsf{ved}^+_H(G - X) \leq 1$.

For each variable x_i, we add a disjoint copy of H to G. We call such a copy of H the *i-variable-copy* of H. For each clause C_j, we add $c_j - 1$ disjoint copies of H to G, and we order them arbitrarily from 1 to $c_j - 1$. Moreover, we add two new vertices u_j^0 and $v_j^{c_j}$ to G. We call each of these $c_j - 1$ copies of H a *j-clause-copy* of H. Note that, so far, we have introduced $n - m + \sum_{j=1}^{m} c_j$ disjoint copies of H in G.

We now proceed to interconnect these copies of H according to ϕ. Since H is a biconnected graph that is not a clique (hence, it is 2-connected), it follows that $|V(H)| \geq 4$. Thus, in particular there exist two *non-adjacent* vertices $u, v \in V(H)$ and another vertex $w \in V(H)$ distinct from u and v. Let $H' = H - \{u, v, w\}$. (Even if it is not critical for the proof, note that $|V(H')| \geq 1$.) Let also z^+ and z^- be two distinct vertices of H (not necessarily different from u, v, w). We will use the copies of these vertices in the variable-copies and clause-copies of H to interconnect them in G. To this end, for three distinct vertices $a, b, c \in V(G)$ and a subgraph F of G isomorphic to H' not containing any of a, b, c, by *adding an $(a, b, c, V(F))$-copy of H to G* we mean the operation of, starting from $G[\{a, b, c\} \cup V(F)]$, adding the missing edges to complete a copy of H, where vertex a (resp. b, c) of G plays the role of vertex w (resp. u, v) of H, and F plays the role of H', with a fixed isomorphism that we suppose to have at hand.

For each clause C_j of ϕ, consider an arbitrary ordering of its literals as $\ell_1, \ldots, \ell_{c_j}$, and recall that G contains $c_j - 1$ ordered disjoint j-clause-copies of H together with two extra vertices u_j^0 and $v_j^{c_j}$. For $i \in [c_j]$, we add a new copy of H' to G, which we denote by F_j^i. For $i \in [c_j - 1]$, let u_j^i and v_j^i be the copies of vertices u and v of H, respectively, in the i-th j-clause-copy of H. For $i \in [c_j]$, if literal ℓ_i of clause C_j corresponds to a positive (resp. negative) occurrence of a variable x_p, let z be the copy of vertex $z^+ \in V(H)$ (resp. $z^- \in V(H)$) in the p-variable-copy of H. Then we add a $(z, u_j^{i-1}, v_j^i, V(F_j^i))$-copy of H to G,

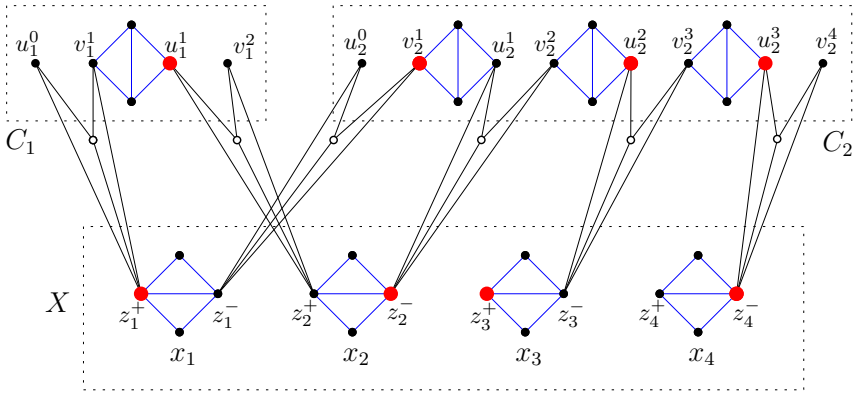

Figure 3 Example of the construction of graph G in the proof of Theorem 3.2 for H-Subgraph Hitting. In this example, H is the diamond (that is, K_4 minus one edge), u and v are the only pair of non-adjacent vertices in H, and w is any other vertex. The construction corresponds to a CNF-SAT formula ϕ consisting of two clauses $C_1 = (x_1 \vee x_2)$ and $C_2 = (\bar{x}_1 \vee \bar{x}_2 \vee \bar{x}_3 \vee \bar{x}_4)$, and the satisfying assignment $\alpha(x_1) = 1$, $\alpha(x_2) = 0$, $\alpha(x_3) = 1$, and $\alpha(x_4) = 0$. The variable-copies and clause-copies of H are depicted in blue, the vertices in the copies of $H' = H - \{u, v, w\}$ (which is a single vertex) are the white ones, and the vertices in the solution S are the large red ones. Note that clause C_2 is satisfied by both $\bar{x}_2$ and $\bar{x}_4$; in the example we have taken $\bar{x}_2$ as the satisfying literal.

and we call such a copy of H a *transversal-copy* of H, denoted by H_j^i. We define $X \subseteq V(G)$ to be the union of the vertex sets of all the variable-copies of H, and note that $|X| = |V(H)| \cdot n$. This completes the construction of G and X, which is illustrated in Figure 3.

In the next claim we prove one of the properties claimed in the statement of the theorem.

▷ Claim 3.3. $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X) = 1$ and $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}(G - X) = 1$.

Proof. Note that each connected component of $G - X$ corresponds to the clause-copies of H associated with a clause C_j and isolated vertices, together with the copies of H' between those j-clause-copies of H and isolated vertices. By construction of G, each such a copy of H', say F_j^i, has at most two neighbors in $G - X$, namely vertices u_j^{i-1} and v_j^i. If an occurrence of H as a subgraph in $G - X$, say F, contained a vertex of F_j^i, since $|V(H')| = |V(H)| - 3$, necessarily F contains at least one of u_j^{i-1} and v_j^i, and at least one more vertex in the $(i-1)$-th or i-th j-clause-copies of H. Thus, u_j^{i-1} or v_j^i is a separator of size one of F, contradicting the hypothesis that H is biconnected.

That is, we have proved that no vertex in a copy F_j^i of H' in $G - X$ is contained in an occurrence of H as a subgraph, hence neither as an induced subgraph. Therefore, those vertices can be removed while preserving the value of $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X)$. Formally,

$$\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X) = \mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X - \bigcup_{j=1}^{m} \bigcup_{i=1}^{c_j} V(F_j^i)),$$

and the same holds for $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}(G - X)$. To conclude the proof of the claim, it suffices to note that $G - X - \bigcup_{j=1}^{m} \bigcup_{i=1}^{c_j} V(F_j^i)$ consists of a disjoint union of clause-copies of H and isolated vertices, and using the fact that $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}$ (resp. $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$) of a disconnected graph is the maximum of $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}$ (resp. $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}$) over its connected components, by removing one arbitrary vertex from each such a copy of H we get that $\mathsf{ved}^+_{\mathcal{F}_{\bar{H}}}(G - X) = 1$ and $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_{\bar{H}}}(G - X) = 1$. ◁

We now claim that ϕ is satisfiable if and only if G contains a solution $S \subseteq V(G)$ of H-Subgraph Hitting of size at most $n - m + \sum_{j=1}^{m} c_j$.

Suppose first that ϕ is satisfiable and let $\alpha\colon \{x_1, \ldots, x_n\} \to \{0,1\}$ be a satisfying assignment of the variables. We define a set $S \subseteq V(G)$ of size $n - m + \sum_{j=1}^{m} c_j$ as follows (cf. the red vertices in Figure 3). For each variable x_i, if $\alpha(x_i) = 1$ (resp. $\alpha(x_i) = 0$), we add to S the copy of z^+ (resp. z^-) in the i-variable-copy of H, which we denote by z_i^+ (resp. z_i^-). For each clause C_j, let ℓ_{s_j} be a literal in C_j that is satisfied by the assignment α. Recall that the $c_j - 1$ j-clause-copies of H are ordered (arbitrarily) from 1 to $c_j - 1$. We add to S the vertex set

$$\{v_j^i \mid 1 \leq i \leq s_j - 1\} \cup \{u_j^i \mid s_j \leq i \leq c_j - 1\}.$$

In words, we add to S the copy of vertex v in all the j-clause-copies of H from 1 to $s_j - 1$, and the copy of vertex u in all the j-clause-copies of H from s_j to $c_j - 1$. Note that $|S| = n - m + \sum_{j=1}^{m} c_j$, and it remains to prove that $G - S$ does not contain H as a subgraph. Note that each variable-copy and clause-copy of H contains exactly two vertices that have neighbors outside of that copy – let us call these vertices *boundary vertices* of that copy – , and that S contains exactly one of these two boundary vertices for each of these copies of H. Hence, since H is biconnected, no occurrence of H in $G - S$ can contain a non-boundary vertex in a variable-copy or clause-copy of H.

Moreover, there do not exist two pairs of integers (i_1, j_1) and (i_2, j_2), with $i_1 \neq i_2$ or $j_1 \neq j_2$, such that there exists an occurrence F of H in $G - S$ with $F \cap (V(H_{j_1}^{i_1}) \setminus X) \neq \emptyset$ and $F \cap (V(H_{j_2}^{i_2} \setminus X) \neq \emptyset$. Indeed, if such (i_1, j_1) and (i_2, j_2) existed, then, as $|N(V(H_j^i) \setminus X) \cap X| = 1$ for any two indices i, j, and as F cannot contain a non-boundary vertex of a variable-copy of H, there would exist $z \in X$ such that $F \cap X = \{z\}$, implying that z is a separator of F, contradicting the 2-connectivity of H.

Thus, if an occurrence of H in $G - S$ existed, say F, then the above discussion and the construction of G imply that F should be one of the transversal-copies of H. But such an F cannot exist in $G - S$ by the choice of S: either S contains one of the boundary vertices in the two j-clause-copies intersected by F for some $j \in [m]$ or, if it is not the case, then S contains the vertex in a variable-copy of H corresponding to the literal that satisfies clause C_j.

Conversely, let $S \subseteq V(G)$ be a solution of H-Subgraph Hitting of size $n - m + \sum_{j=1}^{m} c_j$. Since G contains $|S|$ disjoint variable-copies and clause-copies of H, necessarily S consists of exactly one vertex in each of these copies. Since the boundary vertices in each of the variable-copies and clause-copies of H are the only vertices with neighbors outside of the corresponding copy, we may assume that all the vertices in S are boundary vertices. We define from S a satisfying assignment α of ϕ as follows. If S contains z_i^+ (resp. z_i^-) we set $\alpha(x_i) = 1$ (resp. $\alpha(x_i) = 0$). Let us verify that α indeed satisfies all the clauses of ϕ. Consider an arbitrary clause C_j with c_j literals, and note that S contains $c_j - 1$ vertices in the j-clause-copies of H. Therefore, since by construction no two transversal-copies intersect a clause-copy in a common vertex, there exists $s_j \in [c_j]$ such that the s_j-th transversal-copy of H associated with C_j, say F, is *not* hit by a vertex in a clause-copy of H. Thus, since $S \cap V(F) \neq \emptyset$, necessarily there exists an index $i \in [n]$ such that $S \cap V(F)$ is equal to either z_i^+ or z_i^-, and thus the defined assignment of variable x_i satisfies clause C_j.

To conclude the proof, we claim that the same reduction presented above proves the hardness result for the H-Induced Subgraph Hitting problem. Indeed, in the proof of the equivalence between the satisfiability of ϕ and the existence of a solution S of H-Subgraph Hitting with the appropriate size, all that is relevant to the proof are the variable-copies, clause-copies, and transversal-copies of H. As all these occurrences of H in G occur as induced subgraphs, the same reduction implies the non-existence of polynomial kernels for H-Induced Subgraph Hitting. ◀

In Theorem 1.3 we replace the condition "$\mathsf{ved}^+_H(G-X) \leq 1$" of Theorem 3.2 with the condition that $\mathsf{td}(G-X)$ is bounded by a constant. However, in the proof of Theorem 1.3 we need an extra condition on H stronger than biconnectivity, namely the non-existence of a stable cutset. The reduction in the proof of Theorem 1.3 follows essentially the same lines as the one described in Theorem 3.2, but in order to guarantee that $\mathsf{td}(G-X)$ is bounded by a constant (depending on H), we need to be more careful. Namely, in the interconnection among the variable and clause gadgets, now we cannot afford to add a distinct gadget for each literal in a clause, as it was the case for the copies of H' in the proof of Theorem 3.2 (cf. the white vertices in Figure 3). Indeed, these copies of H' can be removed "for free" when dealing with ved^+_H, but it is not the case anymore when dealing with treedepth, as they may blow up the value of $\mathsf{td}(G-X)$. In a nutshell, we overcome this issue by "reusing" these copies of a (now, carefully chosen) subgraph $H' \subseteq H$ for all the literals of the same clause. However, having a single common H' for each clause may create undesired occurrences of H (other than the variable-copies, clause-copies, and transversal-copies, as we wish), and preventing the existence of these undesired copies is the reason why we need an assumption on H stronger than biconnectivity. The proof of Theorem 1.3 can be found in the full version [11].

4 Further research

In this paper we studied the existence of polynomial kernels for the H-Subgraph Hitting and H-Induced Subgraph Hitting problems under structural parameterizations, namely parameterized by the size of a modulator to a graph class $\mathcal{C}$ that has a "simple structure". Our main achievement is the identification of two arguably natural graph parameters $\mathsf{ved}^+_{\mathcal{F}_H}$ and $\mathsf{bed}^+_{\mathcal{F}_H}$ (or $\mathsf{ved}^+_{\mathcal{F}^{\mathsf{ind}}_H}$ and $\mathsf{bed}^+_{\mathcal{F}^{\mathsf{ind}}_H}$ for the induced version) that allowed us to prove complexity dichotomies in terms of the forbidden graph H. Our results pave the way to a systematic investigation of this topic, where we identify the following avenues for further research.

Getting rid of the hypothesis on H. In our hardness results we need additional assumptions on H, mainly that H is biconnected in Theorem 3.2. Observe that the requirement that H is connected is necessary to obtain polynomial kernels. Indeed, when H is the union of a K_5 and a $K_{1,3}$, it is known [31] that H-Subgraph Hitting is para-NP-hard, even for $\mathsf{ed}_{\mathcal{H}} = 0$. Moreover, when H is a non-edge, H-Induced Subgraph Hitting parameterized by vertex cover (which is a larger parameter than $\mathsf{ed}_{\mathcal{H}}$) is equivalent to maximum clique parameterized by vertex cover, which does not admit a polynomial kernel under standard complexity assumptions [7]. Thus, it is natural to wonder whether the biconnectivity hypothesis could be replaced by just connectivity.

Improving the degree of the kernel. The degree of our polynomial kernel depends on the size t of the excluded clique and on the value λ of the promised upper bound $\mathsf{bed}^+_t(G-X) \leq \lambda$. Namely, as stated in Theorem 2.5, the kernel has size $\mathcal{O}_{\lambda,t}(|X|^{\delta(\lambda,t)})$, where function δ mainly depends on the upper bound on mmbs_t given in Theorem 2.6. This function behaves as a tower of exponents in t of height λ. Hence, improving the bound on mmbs_t directly translates to an improvement of the kernel size. We did obtain such an improvement if instead of assuming that $\mathsf{bed}^+_t(G-X) \leq \lambda$, one assumes that $\mathsf{td}(G-X) \leq \lambda$, namely with a function $\lambda^\lambda \cdot 2^{\lambda^2}$; see [11, Lemma 4.12]. We leave as an open problem to obtain improved upper bounds for mmbs_t in terms of ved^+_t and bed^+_t.

Computing the modulator. In our kernelization algorithm we assume that we are *given* a modulator, namely a set $X \subseteq V(G)$ such that $\mathsf{bed}_t^+(G - X) \leq \lambda$. Note that this hypothesis appears also in the related work dealing with Feedback Vertex Set [18]. Obtaining a constant factor or even $\mathsf{poly}(\mathsf{opt})$-approximation of the modulator in polynomial time for fixed t and λ, which will be enough for our kernelization algorithm (note that minimizing its size is NP-hard [38]), remains an interesting direction. One may start with the probably simpler cases of a modulator to bounded $\mathcal{F}_{\bar{H}}$-elimination distance or bounded ved_t^+.

Finding the right measure. The focus of this article is on obtaining kernelization dichotomies as a function of the forbidden (induced) subgraph H. Of course, it is also relevant to characterize, for a fixed graph H, which is the most general (monotone or hereditary) target family $\mathcal{C}_H$ such that H-(Induced) Subgraph Hitting admits a polynomial kernel parameterized by the size of a modulator to a graph in $\mathcal{C}_H$. Needless to say, solving this general problem seems quite challenging. Indeed, even the case of Vertex Cover, that is, $H = K_2$, is far from being well understood for monotone or hereditary target graph classes, as for instance the only known polynomial kernel for Vertex Cover parameterized by a modulator to a bipartite graph (i.e., an odd cycle transversal) is randomized and relies on quite powerful tools [36, 37]. One may hope that larger cliques allow for simpler characterizations, the natural first candidate being the case where H is a triangle. Let $\mathcal{C}_\Delta$ be the, say, hereditary target graph class that we want to characterize. Following the approach of [10] that characterized the target *minor-closed* graph classes for Vertex Cover, one may hope that K_3-Subgraph Hitting admits a polynomial kernel parameterized by a modulator to $\mathcal{C}_\Delta$ if and only if the graphs in $\mathcal{C}_\Delta$ have bounded mmbs_3. With no extra assumption on $\mathcal{C}_\Delta$, this property is probably false due to the results of Hols, Kratsch, and Pieterse [29], but we conjecture that it is true if we ask $\mathcal{C}_\Delta$ to be hereditary and closed under disjoint union, even for hitting K_t for every $t \geq 3$, replacing mmbs_3 by mmbs_t. Toward an eventual proof of this conjecture, having unbounded minimal blocking sets seems to permit a generic reduction to obtain the lower bound, in the spirit of the one of Theorem 3.2 or any similar one in previous work [10, 16, 18, 25, 32]. Indeed, Hols, Kratsch, and Pieterse [29, Thm 1.1] show that for Vertex Cover, lower bounds on kernel sizes directly follow from lower bounds on mmbs_2. However, the opposite direction seems way more challenging. In [10], this fact was established for Vertex Cover and minor-closed target classes via the notion of bridge-depth by proving, in particular, that there is a *single* minor-obstruction for having large maximum minimal blocking sets, namely the chains of triangles (cf. left part of Figure 4). Unfortunately, we cannot hope the same nice behavior for K_3-Subgraph Hitting and monotone or hereditary graph classes, as chains of triangles are still an obstruction in this setting, but there exist other incomparable ones, as depicted in Figure 4.

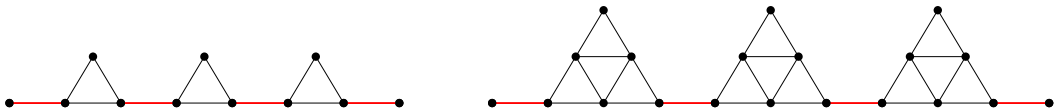

Figure 4 Two chains of length three incomparable with respect to the (induced) subgraph relation. In both graphs, it can be verified that the set of four red thicker edges is a minimal blocking set.

Finally, in the ambitious quest for finding the appropriate measures that characterize the hereditary or monotone classes $\mathcal{C}_t$ for which K_t-Subgraph Hitting admits a polynomial kernel parameterized by the size of a modulator X to $\mathcal{C}_t$, we hope that the techniques we developed to provide a polynomial kernel for the case $\mathsf{bed}_t^+(G - X) \leq \lambda$ will play an

important role. A natural attempt to generalize bed_t^+ to a more powerful measure is to relax, or even drop, the "weak attachment" condition on the sets to be removed in every round of the elimination process. This raises new challenges for obtaining a polynomial kernel that do not seem easy to overcome, at least with the existing tools in this area.

Abstract

It is known for many algorithmic problems that if a tree decomposition of width t is given in the input, then the problem can be solved with exponential dependence on t. A line of research initiated by Lokshtanov, Marx, and Saurabh [SODA 2011] produced lower bounds showing that in many cases known algorithms already achieve the best possible exponential dependence on t, assuming the Strong Exponential-Time Hypothesis (SETH). The main message of this paper is showing that the same lower bounds can already be obtained in a much more restricted setting: informally, a graph consisting of a block of t vertices connected to components of constant size already has the same hardness as a general tree decomposition of width t.

Formally, a (σ, δ)-*hub* is a set Q of vertices such that every component of Q has size at most σ and is adjacent to at most δ vertices of Q. We explore if the known tight lower bounds parameterized by the width of the given tree decomposition remain valid if we parameterize by the size of the given hub.

- For every $\varepsilon > 0$, there are $\sigma, \delta > 0$ such that Independent Set (equivalently Vertex Cover) cannot be solved in time $(2-\varepsilon)^p \cdot n$, even if a (σ, δ)-hub of size p is given in the input, assuming the SETH. This matches the earlier tight lower bounds parameterized by width of the tree decomposition. Similar tight bounds are obtained for Odd Cycle Transversal, Max Cut, q-Coloring, and edge/vertex deletions versions of q-Coloring.
- For every $\varepsilon > 0$, there are $\sigma, \delta > 0$ such that $\triangle$-Partition cannot be solved in time $(2-\varepsilon)^p \cdot n$, even if a (σ, δ)-hub of size p is given in the input, assuming the Set Cover Conjecture (SCC). In fact, we prove that this statement is *equivalent* to the SCC, thus it is unlikely that this could be proved assuming the SETH.
- For Dominating Set, we can prove a non-tight lower bound ruling out $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ algorithms, assuming *either* the SETH or the SCC, but this does not match the $3^p \cdot n^{\mathcal{O}(1)}$ upper bound.

Thus our results reveal that, for many problems, the research on lower bounds on the dependence on tree width was never really about tree decompositions, but the real source of hardness comes from a much *simpler* structure.

Additionally, we study if the same lower bounds can be obtained if σ and δ are fixed universal constants (not depending on ε). We show that lower bounds of this form are possible for Max Cut and the edge-deletion version of q-Coloring, under the Max 3-Sat Hypothesis (M3SH). However, no such lower bounds are possible for Independent Set, Odd Cycle Transversal, and the vertex-deletion version of q-Coloring: better than brute force algorithms are possible for every fixed (σ, δ).

1 Introduction

Starting with the work of Lokshtanov, Marx, and Saurabh [24], there is a line of research devoted to giving lower bounds on how the running time of parameterized algorithms can depend on treewidth (or more precisely, on the width of a given tree decomposition) [32, 31, 11, 7, 4, 19, 27, 8, 13, 28, 12]. The goal of this paper is to revisit the fundamental results from [24] to point out that previous work could have considered a *simpler* parameter to obtain *stronger* lower bounds in a more uniform way. Thus, in a sense, this line of research was never really about treewidth; a fact that future work should take into account.

Suppose we want to solve some algorithmic problem on a graph G given with a tree decomposition of width t. For many NP-hard problems, standard dynamic program techniques or meta theorems such as Courcelle's Theorem [5] show that the problem can be solved in time $f(t) \cdot n^{\mathcal{O}(1)}$ for some computable function f [10, Chapter 7]. In many cases, the running time is actually $c^t \cdot n^{\mathcal{O}(1)}$ for some constant $c > 1$, where it is an obvious goal to make the constant as small as possible. A line of work started by Lokshtanov, Marx, and Saurabh [24] provides tight conditional lower bounds for many problems with known $c^t \cdot n^{\mathcal{O}(1)}$-time algorithms. The lower bounds are based on the Strong Exponential-Time Hypothesis, formulated by Impagliazzo, Paturi, and Zane [16, 17].

▶ **Strong Exponential-Time Hypothesis (SETH).** *There is no $\varepsilon > 0$ such that for every k, every n-variable instance of k-SAT can be solved in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$.*

The goal of these results is to provide evidence that the base c of the exponent in the best known $c^t \cdot n^{\mathcal{O}(1)}$-time algorithm is optimal: if a $(c-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$-time algorithm exists for any $\varepsilon > 0$, then SETH fails. The following theorem summarizes the basic results obtained by Lokshtanov, Marx, and Saurabh [24].

▶ **Theorem 1.1** ([24]). *If there exists an $\varepsilon > 0$ such that*
1. Independent Set *can be solved in time $(2-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, or*
2. Dominating Set *can be solved in time $(3-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, or*
3. Max Cut *can be solved in time $(2-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, or*
4. Odd Cycle Transversal *can be solved in time $(3-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, or*
5. q-Coloring *can be solved in time $(q-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$ for some $q \geqslant 3$, or*
6. Triangle Partition *can be solved in time $(2-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$,*

on input an n-vertex graph G together with a tree decomposition of width at most t, then the SETH fails.

Already in [24] it is pointed out that many of the lower bounds remain true even in the more restricted setting where the input is not a tree decomposition, but a path decomposition. This raises the following natural questions:

- How much further can we restrict the input and still obtain the same lower bounds?
- What is the *real* structural source of hardness in these results?

In this paper, we show that many of these lower bounds remain true in a much more restricted setting where a block of p vertices is connected to constant-size components. Additionally, we demonstrate that our results are very close to being best possible, as further restrictions of the structure of the graphs allow better algorithms.

We say that a set Q of vertices is a (σ, δ)-*hub* of G if every component of $G-Q$ has at most σ vertices and each such component is adjacent to at most δ vertices of Q in G[1]. Our goal is to prove lower bounds parameterized by the size of a (σ, δ)-hub given in the input, where σ and δ are treated as constants. One can observe that a (σ, δ)-hub of size p in G can be easily turned into a tree decomposition of width less than $p+\sigma$, hence the treewidth of G is at most $p+\sigma$. Therefore, any lower bound parameterized by the size p of hub immediately implies a lower bound parameterized by the width of the given tree decomposition. We systematically go through the list of problems investigated by Lokshtanov, Marx, and Saurabh [24], to see if the same lower bound can be obtained with this parameterization. Our results show that, in most cases, the results remain valid under parameterization by hub size. However, new insights, techniques and arguments are needed; in particular, we require different complexity assumptions for some of the statements.

1.1 Coloring Problems and Relatives

Let us first consider the q-Coloring problem: given a graph G, the task is to find a coloring of the vertices of G with q colors such that adjacent vertices receive different colors. Given a (σ, δ)-hub Q of size p, we can try all possible q-colorings on Q and check if they can be extented to every component of $G - Q$. Assuming σ and δ are constants, this leads to a $q^p \cdot n^{\mathcal{O}(1)}$ algorithm. Our first result shows that this is essentially best possible, assuming the SETH; note that this result immediately implies Theorem 1.1(5).

▶ **Theorem 1.2.** *Let $q \geqslant 3$ be an integer.*

1. *For every $\sigma, \delta \geqslant 1$, q-Coloring on n-vertex graphs can be solved in time $q^p \cdot n^{\mathcal{O}(1)}$ if a (σ, δ)-hub of size p is given in the input.*
2. *For every $\varepsilon > 0$, there exist integers $\sigma, \delta \geqslant 1$ such that if there is an algorithm solving in time $(q-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ every n-vertex instance of q-Coloring given with a (σ, δ)-hub of size at most p, then the SETH fails.*

The q-ColoringED problem is an edge-deletion optimization version of q-Coloring: given a graph G, the task is to find a set X of edges of minimum size such that $G \setminus X$ has a q-coloring. We show that $q^p \cdot n^{\mathcal{O}(1)}$ running time is essentially optimal for this problem as well.

▶ **Theorem 1.3.** *Let $q \geqslant 2$ be an integer.*

1. *For every $\sigma, \delta \geqslant 1$, q-ColoringED on n-vertex graphs can be solved in time $q^p \cdot n^{\mathcal{O}(1)}$ if a (σ, δ)-hub of size p is given in the input.*
2. *For every $\varepsilon > 0$, there exist integers $\sigma, \delta \geqslant 1$ such that if there is an algorithm solving in time $(q-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ every n-vertex instance of q-ColoringED given with a (σ, δ)-hub of size at most p, then the SETH fails.*

[1] This notion is related to *component order connectivity*, which is the size of the smallest set Q of vertices such that deleting Q leaves components of size not larger than some predefined constant σ [37, 33, 26, 3, 20, 22, 1, 14, 34, 6, 25]. Our definition has the additional constraint on the neighborhood size of each component. As we often refer to the set Q itself (not only its smallest possible size) and we want to make the constants σ, δ explicit, the terminology (σ, δ)-hub is grammatically more convenient than trying to express the same using component order connectivity.

For $q \geqslant 3$, the lower bound of Theorem 1.2 for q-Coloring immediately implies the same lower bound for the more general problem q-ColoringED. Observe that for $q = 2$, the q-ColoringED problem is equivalent to the Max Cut problem: deleting the minimum number of edges to make the graph bipartite is equivalent to finding a bipartition with the maximum number of edges going between the two classes. Thus the lower bound for Max Cut is needed to complete the proof of Theorem 1.3.

Let us consider now the vertex-deletion version q-ColoringVD, where given a graph G, the task is to find a set X of vertices of minimum size such that $G - X$ has a q-coloring (equivalently, we want to find a partial q-coloring on the maximum number of vertices). For this problem, a brute force approach would need to consider $(q+1)^p$ possibilities on a (σ, δ)-hub of size p: each vertex can receive either one of the q colors, or be deleted.

▶ **Theorem 1.4.** *Let $q \geqslant 1$ be an integer.*

1. *For every $\sigma, \delta \geqslant 1$, q-ColoringVD on n-vertex graphs can be solved in time $(q+1)^p \cdot n^{\mathcal{O}(1)}$ if a (σ, δ)-hub of size p is given in the input.*
2. *For every $\varepsilon > 0$, there exist integers $\sigma, \delta \geqslant 1$ such that if there is an algorithm solving in time $(q+1-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ every n-vertex instance of q-ColoringVD given with a (σ, δ)-hub of size at most p, then the SETH fails.*

Observe that Vertex Cover is equivalent to 1-ColoringVD and Odd Cycle Transversal is equivalent to 2-ColoringVD. Furthermore, Independent Set and Vertex Cover have the same time complexity (due to the well-known fact that minimum size of a vertex cover plus the maximum size of an independent set is always equal to the number of vertices). Thus the definition of q-ColoringVD gives a convenient unified formulation that includes these fundamental problems.

1.2 Packing Problems

Given a graph G, the Triangle Partition (denoted by $\triangle$-Partition for short) problem asks for a partition of the vertex set into triangles. Triangle Packing (denoted by $\triangle$-Packing) is the more general problem where the task is to find a maximum-size collection of vertex-disjoint triangles. Given a tree decomposition of width t, Theorem 1.1(6) shows that $2^t \cdot n^{\mathcal{O}(1)}$ is essentially the best possible running time. It seems that the same lower bound holds when parameterizing by the size of a hub, but the source of hardness is somehow different. Instead of assuming the SETH, we prove this lower bound under the *Set Cover Conjecture (SCC)* [9, 10]. In the d-Set Cover problem, we are given a universe U of size n and a collection $\mathcal{F}$ of subsets of U, each with size at most d. The task is to find a minimum-size collection of sets whose union covers the universe.

▶ **Set Cover Conjecture (SCC).** *For all $\varepsilon > 0$, there exists $d \geqslant 1$ such that there is no algorithm that solves every $\leqslant d$-Set Cover instance $(U, \mathcal{F})$ in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$ where $n = |U|$.*

We actually show that the lower bounds for $\triangle$-Partition/$\triangle$-Packing are *equivalent* to the SCC.

▶ **Theorem 1.5.** *The following three statements are equivalent:*

- *The SCC is true.*
- *For every $\varepsilon > 0$, there are $\sigma, \delta > 0$ such that $\triangle$-Partition on an n-vertex graph cannot be solved in time $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$, even if the input contains a (σ, δ)-hub of size p.*
- *For every $\varepsilon > 0$, there are $\sigma, \delta > 0$ such that $\triangle$-Packing on an n-vertex graph cannot be solved in time $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$, even if the input contains a (σ, δ)-hub of size p.*

Ideally, one would like to prove lower bounds under the more established conjecture: the SETH. However, Theorem 1.5 shows that it is no shortcoming of our technique that we prove the lower bound based on the SCC instead. If we proved statement 2 or 3 under the SETH, then this would prove that the SETH implies the SCC, resolving a longstanding open question.

1.3 Dominating Set

Given an n-vertex graph with a tree decomposition of width t, a minimum dominating set can be computed in time $3^t \cdot n^{\mathcal{O}(1)}$ using an algorithm based on fast subset convolution [35, 36]. By Theorem 1.1 (2), this running time cannot be improved to $(3-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$ for any $\varepsilon > 0$, assuming the SETH. Can we get a $(3-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ algorithm if a hub of size p is given in the input? We currently have no answer to this question. In fact, we do not even have a good guess whether or not such algorithms should be possible. What we do have are two very simple weaker results that rule out $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ algorithms, with one proof based on the SETH and the other proof based on the SCC.

▶ **Theorem 1.6.** *For every $\varepsilon > 0$, there are $\sigma, \delta > 0$ such that* Dominating Set *on an n-vertex graph with a (σ,δ)-hub of size p given in the input cannot be solved in time $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$, unless* both *the SETH and the SCC fail.*

Theorem 1.6 suggests that, if there is no $(3-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ time algorithm for Dominating Set, then perhaps the matching lower bound needs a complexity assumption that is stronger than both the SETH and the SCC.

1.4 Universal Constants for σ and δ?

The lower bounds in Theorems 1.2–1.6 are stated in a somewhat technical form: "for every $\varepsilon > 0$, there are σ and δ such that…". The statements would be simpler and more intuitive if they were formulated in a setting where σ and δ are universal constants, say, 100. Can we prove statements that show, for example, that there is no $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ algorithm, where p is the size of a $(100, 100)$-hub given in the input? The answer to this question is complicated. For the vertex-deletion problem q-ColoringVD (which includes Vertex Cover and Odd Cycle Transversal) there are actually better than brute force algorithms for fixed constant values of σ and δ.

▶ **Theorem 1.7.** *For every $q \geqslant 3$ and $\sigma, \delta > 0$, there exists $\varepsilon > 0$ with the following property: every instance (G, L) of q-ColoringVD with n vertices, given with a (σ,δ)-hub of size p, can be solved in time $(q+1-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$.*

Thus Theorem 1.7 explains why the formulation of Theorem 1.4 needs to quantify over σ and δ, and cannot be stated for a fixed pair (σ, δ).

On the other hand, for the edge-deletion problem q-ColoringED (which includes Max Cut), we can prove stronger lower bounds where σ and δ are universal constants. However, we need a complexity assumption different from the SETH.

An instance of Max 3-Sat is a CNF formula φ with at most three literals in each clause. We ask for the minimum number of clauses that need to be deleted in order to obtain a satisfiable formula. Equivalently, we look for a valuation of the variables which violates the minimum number of clauses. Clearly, an instance of Max 3-Sat with n variables can be solved in time $2^n \cdot n^{\mathcal{O}(1)}$ by exhaustive search. It is a notorious problem whether this running time can be significantly improved, i.e., whether there exists an $\varepsilon > 0$ such that every n-variable instance of Max 3-Sat can be solved in time $(2-\varepsilon)^n$.

▶ **Max 3-Sat Hypothesis (M3SH).** *There is no $\varepsilon > 0$ such that every n-variable instance of* Max 3-Sat *can be solved in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$.*

Under this assumption, we can prove a lower bound where $\delta = 6$ and σ is a constant (depending only on q).

▶ **Theorem 1.8.** *For every $q \geqslant 2$ there is an integer σ such that the following holds. For every $\varepsilon > 0$, no algorithm solves every n-vertex instance of q-ColoringED that is given with a $(\sigma, 6)$-hub of size p, in time $(q-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$, unless the M3SH fails.*

For the case $q = 2$ we even show a slight improvement over Theorem 1.8 – in this case it suffices to consider instances with a constant σ and $\delta = 4$.

For $\triangle$-Partition, we do not know if the lower bound of Theorem 1.5, ruling out $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ running time under the SCC, remains valid for some fixed universal σ and δ independent of ε. Note that the proof of Theorem 1.5 provides a reduction from $\triangle$-Partition to d-Set Packing for some d. It is known that d-Set Packing over a universe of size n can be solved in time $(2-\varepsilon)^n \cdot (n+m)^{\mathcal{O}(1)}$ with some $\varepsilon > 0$ depending on d [30, 21, 2]. However, our reduction from $\triangle$-Partition to d-Set Packing chooses d in a way that it cannot be used to reduce the case of a fixed σ and δ to a d-Set Packing problem with fixed d. It seems that we would need to understand if certain generalizations of d-Set Packing can also be solved in time $(2-\varepsilon)^n \cdot (n+m)^{\mathcal{O}(1)}$ for fixed d. The simplest such problem would be the generalization of d-Set Packing where the sets in the input are partitioned into pairs and the solution is allowed to use at most one set from each pair.

1.5 Discussion

Given the amount of attention to algorithms on tree decompositions and the number of nontrivial techniques that were developed to achieve the best known algorithms, it is a natural question to ask if these algorithms are optimal. Even though understanding treewidth is a very natural motivation for this line of research, the actual results turned out to be less related to treewidth than one would assume initially: the lower bounds remain valid even under more restricted conditions. Already the first paper on this topic [24] states the lower bounds in a stronger form, as parameterized by pathwidth or by feedback vertex set number (both of which are bounded below by treewidth). Some other results considered parameters such as the size of a set Q where every component of $G - Q$ is a path [18] or has bounded treewidth [15]. However, our results show that none of these lower bounds got to the fundamental reason why known algorithms on bounded-treewidth graphs cannot be improved: Theorems 1.2–1.5 highlight that these algorithms are best possible already if we consider a much more restricted problem setting where constant-sized gadgets are attached to a set of hub vertices. Moreover, Theorems 1.2 and 1.4 are likely to be best possible: as we have seen, for coloring and its vertex-deletion generalizations, σ and δ cannot be made a constant independent from ε (Theorem 1.7). Therefore, one additional conceptual message of our results is understanding where the hardness of solving problems on bounded-treewidth graphs really stems from, by reaching the arguably most restricted setting in which the lower bounds hold.

The success of Theorems 1.2–1.4 (for coloring problems and relatives) suggests that possibly all the treewidth optimality results could be revisited and the same methodology could be used to strengthen to parameterization by hub size. But the story is more complicated than that. For example, for $\triangle$-Packing, the ground truth appears to be that the lower bound parameterized by width of the tree decomposition can be strengthened to a lower

bound parameterized by hub size. However, proving the lower bound parameterized by hub size requires a different proof technique, and we can do it only by assuming the SCC – and for all we know this is an assumption orthogonal to the SETH. In fact, we showed that the lower bound for $\triangle$-Packing is equivalent to the SCC, making it unlikely that a simple proof based on the SETH exists. For Dominating Set, we currently do not know how to obtain tight bounds, highlighting that it is far from granted that all results parameterized by width of tree decomposition can be easily turned into lower bounds parameterized by hub size.

Another important aspect of our results is the delicate way they have to be formulated, with the values of σ and δ depending on ε. Theorem 1.8 shows that in some cases it is possible to prove a stronger bound where σ and δ are universal constants, but this comes at a cost of choosing a different complexity assumption (M3SH). Thus, there is a tradeoff between the choice of the complexity assumption and the strength of the lower bound. In general, it seems that the choice of complexity assumption can play a crucial role in these kind of lower bounds parameterized by hub size. This has to be contrasted with the case of parameterization by the width of the tree decomposition, where the known lower bounds are obtained from the SETH (or its counting version).

It would be natural to try to obtain lower bounds parameterized by hub size for other algorithmic problems as well. The lower bounds obtained in this paper for various fundamental problems can serve as a starting point for such further results. Concerning the problems studied in this paper, we leave two main open questions:

- For Dominating Set, can we improve the lower bound of Theorem 1.6 to rule out $(3-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ algorithms, under some reasonable assumption? Or is there perhaps an algorithm beating this bound?
- For $\triangle$-Partition/$\triangle$-Packing, can we improve the lower bound of Theorem 1.5 such that σ and δ are universal constants? Or is it true perhaps that for every fixed σ and δ, there is an algorithm solving these problems in time $(2-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ for some $\varepsilon > 0$?

2 Technical Overview

In this section, we overview some of the most important technical ideas in our results.

2.1 q-Coloring

The algorithmic statement in Theorem 1.2 is easily obtained via a simple branching procedure. For the hardness part, we use a lower bound of Lampis [23] for constraint satisfaction problems (CSP) as a starting point: for any $\varepsilon > 0$ and integer d, there is an integer r such that there is no algorithm solving CSP on n variables of domain size d and r-ary constraints in time $(d-\varepsilon)^n$. Therefore, to prove Theorem 1.2 (2), we give a reduction that, given an n-variable CSP instance where the variables are over $[q]$ and the arity of constraints is some constant r, creates an instance of q-Coloring having a hub of size roughly n.

First, we introduce a set of n main vertices in the hub, representing the variables of the CSP instance. We would like to represent each r-ary constraint with a gadget that is attached to a set S of r vertices. We will first allow our gadgets to use lists that specify to which colors certain vertices are allowed to be mapped. In a second step we then remove these lists.

A bit more formally, we say that an *r-ary q-gadget* is a graph J together with a list assignment $L\colon V(J) \to 2^{[q]}$ and r distinguished vertices $\mathbf{x} = (z_1, \ldots, z_r)$ from J. The vertices $z_1, \ldots, z_r$ are called *portals*. A *list coloring* of (J, L) is an assignment $\varphi\colon V(J) \to [q]$ that respects the lists L, i.e., with $\varphi(v) \in L(v)$ for all $v \in V(J)$.

A construction by Jaffke and Jansen [18] gives a gadget that enforces that a set of vertices forbids one prescribed coloring. We use this statement to construct a gadget extends precisely the set of colorings that are allowed according to some relation.

▶ **Proposition 2.1.** *Let $q \geqslant 3$ and $r \geqslant 1$ be integers, and let $R \subseteq [q]^r$ be a relation. Then there exists an r-ary q-gadget $\mathcal{F} = (F, L, (z_1, \ldots, z_r))$ such that*

- *the list of every vertex is contained in $[q]$,*
- *for each $i \in r$, it holds that $L(z_i) = [q]$,*
- *$\{z_1, \ldots, z_r\}$ is an independent set,*
- *for any $\psi : \{z_1, \ldots, z_r\} \to [q]$, coloring vertices $z_1, \ldots, z_r$ according to ψ can be extended to a list coloring of (F, L) if and only if $(\psi(z_1), \ldots, \psi(z_r)) \in R$.*

Then, by introducing one gadget per constraint and attaching it to the vertices of the hub, from the q^n possible behaviors of the hub vertices, only those can be extended to the gadgets that correspond to a satisfying assignment of the CSP instance. Note that gadgets are allowed to use lists and they model the relational constraints using list colorings. So the final step to obtain a reduction to q-Coloring is to remove these lists. This can be done using a standard construction, where a central clique of size q is used to model the q colors, and a vertex v of the graph is adjacent to the ith vertex of the clique, whenever $i \notin L(v)$.

2.2 Vertex Deletion to q-Coloring

Similarly to q-Coloring, the algorithmic statement in Theorem 1.4 is easily obtained via a simple branching procedure. However, for q-ColoringVD, we need to consider $q + 1$ possibilities at each vertex: assigning to it one of the q colors, or deleting it. This leads to the running time $(q + 1)^p \cdot n^{\mathcal{O}(1)}$. The hardness proof is also similar, but this time we have to give a reduction that, given an n-variable CSP instance where the variables are over $[q+1]$ and the arity of constraints is some constant r, creates an instance of q-ColoringVD having a hub of size roughly n. Intuitively, we are using deletion as the $(q + 1)$-st color: the $(q+1)^n$ possibilities for these vertices in the q-ColoringVD problem (coloring with q colors + deletion) correspond to the $(q + 1)^n$ possible assignments of the CSP instance. To enforce this interpretation, we attach to these vertices small gadgets representing each constraint. We attach a large number of copies of each such gadget, which means that it makes no sense for an optimum solution to delete vertices from these gadgets and hence deletions occur only in the hub. This means that we can treat the vertices of the gadgets as "undeletable".

We would like to use again the construction from Proposition 2.1 to create gadgets that enforce that a set of vertices has one of the prescribed colorings/deletions. A gadget can force the deletion of a vertex if its neighbors are colored using all q colors. However, there is a fundamental limitation of this technique: deleting a vertex is always better than coloring it. That is, a gadget cannot really force a set S of vertices to the color "red": from the viewpoint of the gadget, deleting some of them and coloring the rest red is equally good. In other words, it is not true that every relation $R \subseteq [q + 1]^r$ can be represented by a gadget that allows only these combinations of q colors + deletion on a set S of r vertices.

To get around this limitation, we use a grouping technique to have control over how many vertices are deleted. Let us divide the n variables into $M = n/b$ blocks $B_1, \ldots, B_M$ of size b each. Let us guess the number f_i of variables in B_i that receive the value $q + 1$ in a hypothetical solution; that is, we expect f_i deletions in block B_i of central vertices. Instead of just attaching a gadget to a set S of at most r vertices, now each gadget is attached to the at most r blocks containing S. Besides ensuring a combination of values on S that satisfies the constraint, the gadget also ensures that each block B_i it is attached to has at

least the guessed number f_i of deletions. This way, if we have a solution with exactly $\sum_{i=1}^{M} f_i$ deletions, then we know that it has exactly f_i deletions in the i-th block. Therefore, if a gadget forces the deletion of f_i vertices of B_i and forces a coloring on the remaining vertices of B_i, then we know that that block has exactly this behavior in the solution.

2.3 Edge Deletion to q-Coloring

Let us turn our attention to the edge-deletion version now. Similarly to the vertex-deletion version, the algorithmic results are simple, thus we discuss only the hardness proofs here. As starting point for all our reductions, we use a CSP problem with domain size q that naturally generalizes Max 3-Sat: the task is to find an assignment of variables that satisfies the maximum number of constraints. For $q = 2$, the hardness of this problem follows from the SETH and the M3SH. For $q \geqslant 3$, we prove a new tight lower bound based on M3SH.

For $q \geqslant 3$, the lower bound of Theorem 1.3 (hardness of q-ColoringED under the SETH) already follows from our result for *finding* a q-coloring *without deletions* (Theorem 1.2). So, in order to complete the proof of Theorem 1.3, we give a reduction from the CSP problem with $q = 2$ to 2-ColoringED (i.e., Max Cut), which shows hardness under SETH. As the gadgets of Proposition 2.1 work only for $q \geqslant 3$, we need to design new gadgets using only 2 colors for this case.

The same reduction can be used to establish the lower bound from Theorem 1.8 (hardness of q-ColoringED under the M3SH) in the $q = 2$ case. For the $q \geqslant 3$ case, we present a reduction from the CSP problem with domain size q to q-ColoringED. Here we can once again use the gadgets from Proposition 2.1.

In all cases, as the gadgets we design may use lists, we establish respective lower bounds for the list coloring problem on the way. In a second step, we then show how to remove the lists.

Max CSP – Hardness under the M3SH

For some positive integers d and r, we define Max (d,r)-CSP: Given v variables over a q-element domain and a set of n relational constraints of arity 3, the task is to find an assignment of the variables such that the maximum number of constraints are satisfied. The problem can be solved in time $q^v \cdot n^{\mathcal{O}(1)}$ by brute force. For $q = 2$, the problem is clearly a generalization of Max 3-Sat, hence the M3SH immediately implies that there is no $(q-\varepsilon)^v \cdot n^{\mathcal{O}(1)}$ algorithm for any $\varepsilon > 0$. We show that the M3SH actually implies this for any $q \geqslant 2$. This might also be a helpful tool for future work.

▶ **Theorem 2.2.** *For $d \geqslant 2$ and any $r \geqslant 3$, there is no algorithm solving every n-variable instance of Max (d,r)-CSP in time $(d-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$ for $\varepsilon > 0$, unless the M3SH fails.*

In order to show Theorem 2.2, if q is a power of 2, then a simple grouping argument works: for example, if $q = 2^4 = 16$, then each variable of the CSP instance can represent 4 variables of the Max 3-Sat instance, and hence it is clear that a $(q-\varepsilon)^v$ algorithm would imply a $(2-\varepsilon)^{4v}$ algorithm for a Max 3-Sat instance with $4v$ variables.

The argument is not that simple if q is not a power of 2, say $q = 15$. Then a variable of that CSP instance cannot represent all 16 possibilities of 4 variables of the Max 3-Sat instance, and using it to represent only 3 variables would be wasteful. We cannot use the usual trick of grouping the CSP variables such that each group together represents a group of Max 3-Sat variables: then each constraint representing a clause would need to involve not only 3 variables, but 3 blocks of variables, making δ larger than 3. Instead, for each block of 4 variables of the Max 3-Sat instance, we randomly choose 15 out of the 16 possible

assignments, and use a single variable of the CSP instance to represent these possibilities. An optimum solution of a $4v$-variable Max 3-Sat instance "survives" this random selection with probability $(15/16)^v$. Thus a $(15-\varepsilon)^v \cdot n^{\mathcal{O}(1)}$ time algorithm for the CSP problem would give a randomized $(16/15)^v \cdot (15-\varepsilon)^v \cdot n^{\mathcal{O}(1)} = (16-\varepsilon')^v \cdot n^{\mathcal{O}(1)} = (2-\varepsilon'')^{4v} \cdot n^{\mathcal{O}(1)}$ time algorithm for Max 3-Sat, violating (a randomized version of) the M3SH. Furthermore, we show in the full version that the argument can be derandomized using the logarithmic integrality gap between integer and fractional covers in hypergraphs.

Realizing Relations using Lists

Recall that an r-ary q-gadget is a graph with lists in $[q]$ and r specified portal vertices. For our hardness proofs, we reduce from Max (q,r)-CSP, and we use gadgets to "model" the relations in $[q]^r$. We say that an r-ary q-gadget *realizes* a relation $R \in [q]^r$ if there is an integer k such that (1) for each $\mathbf{d} \in R$, if the portals are colored according to $\mathbf{d}$, then it requires precisely k edge deletions to extend this to a full list coloring of the gadget, and (2) extending a state that is *not* in R requires strictly more than k edge deletions. We say that such a gadget 1-realizes R, if for each state outside of R it takes precisely $k+1$ edge deletions to extend this state. So, this is a stronger notion in the sense that now the violation cost is the same for all tuples outside of R. Moreover, with a 1-realizer in hand, by identifying copies of this gadget with the same portal vertices one can freely adjust the precise violation cost – this works as long as the portals form an independent set and therefore no multiedges are introduced in the copying process.

For our treatment of the case $q \geqslant 3$, we again use Proposition 2.1 to show that arbitrary relations over a domain of size q can be realized. As Proposition 2.1 is for the decision problem without deletions, it does not help for the case $q = 2$, i.e., for Max Cut/2-Coloring. In this case, we need a different approach to show that every relation over a domain of size 2 can be realized. For 2-Coloring, a single edge is essentially a "Not Equals"-gadget as the endpoints have to take different colors or otherwise the edge needs to be deleted. Starting from this, we show how to model OR-relations of any arity. With these building blocks we then obtain the following result.

▶ **Theorem 2.3.** *For each $r \geqslant 1$, and $R \subseteq [2]^r$, there is an r-ary 2-gadget that 1-realizes R.*

Removing the Lists

Note that gadgets may use lists and therefore, on the way, we first obtain the following lower bounds for the respective list coloring problems.

▶ **Theorem 2.4.** *For every $q \geqslant 2$ and $\varepsilon > 0$, there are integers σ and δ such that if an algorithm solves in time $(q-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ every n-vertex instance of List-q-ColoringED that is given with a (σ,δ)-hub of size p, then the SETH fails.*

▶ **Theorem 2.5.** *For every $q \geqslant 2$, there is a constant σ_q such that, for every $\varepsilon > 0$, if an algorithm solves in time $(q-\varepsilon)^p \cdot n^{\mathcal{O}(1)}$ every n-vertex instance of List-q-ColoringED that is given with a $(\sigma_q,3)$-hub of size p, then the M3SH fails.*

In a second step, we show how to remove the lists by adding some additional object of size roughly q (a central vertex or a q-clique for $q = 2$ or $q \geqslant 3$, respectively). This addition is then considered to be part of the hub, thereby increasing the size of the hub by some constant. However, this modification means that for the other gadgets the number of neighbors in the hub increases slightly. This is irrelevant for the SETH-based lower bound, but it leads to a slight increase in the universal constant δ that we obtain for our M3SH-based lower bounds for the coloring problems without lists.

2.4 Covering, Packing, and Partitioning

Theorem 1.5 gives lower bounds for $\triangle$-Partition and $\triangle$-Packing based on the Set Cover Conjecture. This hypothesis was formulated in terms of the d-Set Cover problem. For our purposes, it is convenient to consider slightly different covering/partitioning problems. To facilitate our reductions and as a tool for future reductions of this type, we establish equivalences between eight different covering type problems. Before we make this more formal in Theorem 2.6, let us briefly introduce the corresponding problems.

First, we use $=d$-Set Cover and $\leqslant d$-Set Cover to distinguish between the problem for which the sets have size exactly d or at most d, respectively. For $\triangle$-Partition, it is more natural to start a reduction from the partitioning problems $=d$-Set Partition or $\leqslant d$-Set Partition, in which the task is to find pairwise disjoint sets that cover the universe. The $\leqslant d$-Set Partition problem can be considered as a decision problem. However, we can also consider the corresponding optimization problem in which the task is to minimize the number of selected sets, and we use $\leqslant d$-Set Partition (#Sets) to denote this problem. Further variants are the optimization problems $=d$-Set Packing (#Sets) and $\leqslant d$-Set Packing (#Sets), in which we need to select the maximum number of pairwise disjoint sets. For $\leqslant d$-Set Packing, an equally natural goal is to maximize the total size of the selected sets (for $= d$-Set Packing, this is of course equivalent to maximizing the number of selected sets). So we use $\leqslant d$-Set Packing (Union) to denote the packing problem in which the union/total size of the selected sets is maximized.

Given the large number of variants of d-Set Cover, one may wonder how they are related to each other. In particular, does the SCC imply lower bounds for these variants? There are obvious reductions between some of these problems (e.g., from $= d$-Set Cover to $\leqslant d$-Set Cover) and there are also reductions that are not so straightforward. We fully clarify this question by showing that choosing *any* of these problems in the definition of the SCC leads to an equivalent statement. Thus in our proofs to follow we can choose whichever form is most convenient for us. Knowing this equivalence could prove useful for future work as well.

▶ **Theorem 2.6.** *Suppose that for one of the problems below, it is true that for every $\varepsilon > 0$, there is an integer d such that the problem cannot be solved in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$, where n is the size of the universe. Then this holds for all the other problems as well. In particular, any of these statements is equivalent to the SCC.*

1. *$=d$-Set Cover*
2. *$=d$-Set Partition*
3. *$=d$-Set Packing (#Sets)*
4. *$\leqslant d$-Set Cover*
5. *$\leqslant d$-Set Partition*
6. *$\leqslant d$-Set Partition (#Sets)*
7. *$\leqslant d$-Set Packing (#Sets)*
8. *$\leqslant d$-Set Packing (Union)*

To make the statements about relationships between the problems from the list in Theorem 2.6 more concise, it will be convenient to introduce some shorthand notation. Let $\mathbb{A} = \{A_d\}_{d\geqslant 1}$ and $\mathbb{B} = \{B_d\}_{d\geqslant 1}$ be two families of problems where A_d and B_d belong to the list in Theorem 2.6. To shorten notation, we speak of an *n-element instance* if the universe U of an instance has size n. We say that $\mathbb{A}$ is 2^n-hard if the following lower bound holds

> For each $\varepsilon > 0$ there is some $d \geqslant 1$ such that no algorithm solves A_d on all n-element instances in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$.

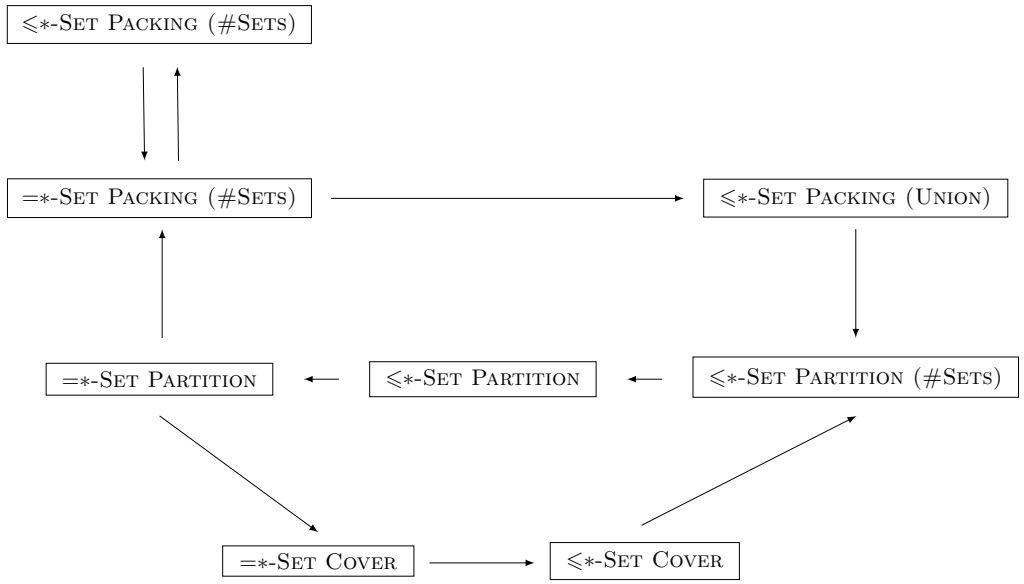

Figure 1 An overview of the proof of Theorem 2.6. An arrow from $\mathcal{A}$ to $\mathcal{B}$ indicates an implication stating that if $\mathcal{A}$ is 2^n-hard then $\mathcal{B}$ is 2^n-hard as well. The details are in the full version.

Using this language, the SCC states that $\{\leqslant d\text{-Set Cover}\}_{d\geqslant 1}$ is 2^n-hard. To establish Theorem 2.6, we show reductions, stating that if $\mathcal{A}$ is 2^n-hard then $\mathcal{B}$ is 2^n-hard as well. Spelled out this means:

> Suppose for each $\varepsilon > 0$ there is some $d \geqslant 1$ such that no algorithm solves A_d on all n-element instances in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$.
>
> Then, for each $\varepsilon > 0$ there is some $d' \geqslant 1$ such that no algorithm solves $B_{d'}$ on all n-element instances in time $(2-\varepsilon)^n \cdot n^{\mathcal{O}(1)}$.

This shows that this is really a relationship between two classes of problems, and not necessarily a relationship between A_d and B_d for the same value d. To make this distinction explicit, we write $=*$-Set Cover if we refer to the class of problems $\{=d\text{-Set Cover}\}_{d\geqslant 1}$. We use analogous notation for the other problems on the list. For example, a simple observation is that if $=*$-Set Cover is 2^n-hard then so is $\leqslant*$-Set Cover as the latter is a generalization of the former. The reductions we use to prove Theorem 2.6 are illustrated in Figure 1.

2.5 Triangle Partition and Triangle Packing

Now let us discuss the proof of Theorem 1.5 that can be found in the full version. The proof consists of two main steps: (1) a reduction from $=*$-Set Partition to $\triangle$-Partition, and (2) a reduction from $\triangle$-Packing to $\leqslant*$-Set Packing (#Sets) (see Figure 2). Recall that by Theorem 2.6, assuming the SCC, all of $=*$-Set Partition, $\leqslant*$-Set Packing (#Sets), and $\leqslant*$-Set Cover are 2^n-hard. Finally, $\triangle$-Partition trivially reduces to $\triangle$-Packing, so indeed, the statements in Theorem 1.5 are equivalent.

Reducing Set Partition to $\triangle$-Partition

We start with step (1), i.e., reducing an instance $(U, \mathcal{F})$ of $=d$-Set Partition to an equivalent instance G of $\triangle$-Partition. With a simple technical trick we can ensure that d is divisible by 3.

Figure 2 An overview of the reductions in the proof of Theorem 1.5. The two dashed arrows refer to 2^n-hardness reductions from Theorem 2.6. To establish these two connections, note that we actually utilize almost all the reductions shown in Figure 1. The arrows annotated with (1) and (2) refer to another two reductions proved in the full version.

The main building block used in the reduction is the so-called $\triangle$-eq gadget. For fixed d, it is a graph with d designated vertices called *portals*. The gadget essentially has exactly two triangle packings that cover all non-portal vertices:

- one that also covers *all portals* (i.e., is actually a triangle partition), and
- one that covers *no portal*.

Now the construction of G is simple: we introduce the set Q containing one vertex for each element of U, and for each set $S \in \mathcal{F}$ we introduce a copy of the $\triangle$-eq gadget whose portals represent elements of S and are identified with corresponding vertices from Q. It is straightforward to verify that there is $\mathcal{F}' \subseteq \mathcal{F}$ that partitions U if and only if G has a triangle partition: the sets from $\mathcal{F}'$ correspond to $\triangle$-eq gadgets whose non-portal vertices are covered in the first way. Note that Q is a (σ, d)-hub of G, where σ is the number of vertices of the $\triangle$-eq gadget, i.e., is a constant that depends only on d.

Reducing $\triangle$-Packing to Set Packing.

Now let us consider a graph G given with a (σ, δ)-hub Q of size p, and an integer t. We will show that a hypothetical fast algorithm for $\leqslant d$-Set Packing (#Sets) can be used to determine whether G has a triangle packing of size at least t.

For simplicity of exposition, assume that G has no triangles contained in Q; dealing with such triangles is not difficult but would complicate the notation. We say that a component C of $G - Q$ is *active* in some triangle packing Π if there is a triangle in Π that intersects both C and Q. Note that for any triangle packing there are at most p active components.

We would like to guess components that are active for some (unknown) solution Π. However, this results in too many branches. We deal with it by employing color-coding and reducing the problem to its auxiliary *precolored variant*. Suppose for a moment that we are given a coloring ψ of components of $G - Q$ into p/c colors, where c is a large constant, with a promise that at most c components in each color are active in Π.

For a color $i \in [p/c]$, let $\mathcal{C}_i$ denote the set of components of $G - Q$ colored i by ψ. The *contribution* of the color i to Π is the number of triangles that intersect vertices in components from $\mathcal{C}_i$. Note that the size of Π is the sum of contributions of all color (since we assumed that there are no triangles contained in Q). What can be said about the contribution of i? Certainly picking a maximum triangle packing in the graph consisting only of components from $\mathcal{C}_i$ is a lower bound. Let X_i denote the number of triangles in such a triangle packing and note that X_i can be computed in polynomial time as each component of $G - Q$ is of constant size. Moreover, for each active component $C \in \mathcal{C}_i$, there are at most σ triangles that

intersect both C and Q (as each of them has to use a distinct vertex from C). As, by the promise on ψ, there are at most c active components in $\mathcal{C}_i$, we observe that the contribution of i is at most $X_i + c\sigma$. We exhaustively guess the contribution of each color by guessing the offset q_i against X_i; it gives a constant number of options per color. We reject guesses where the total contribution of all colors, i.e., the number of all triangles packed, is less than t.

For each color i, we enumerate all sets $S \subseteq Q$ that are candidates for these vertices of Q that form triangles with vertices from components of $\mathcal{C}_i$; call such sets *i-valid*. An i-valid set S must satisfy the following two conditions. First, the size of S is at most $2c\sigma$, as there are at most $c\sigma$ vertices in active components from $\mathcal{C}_i$ and each such vertex belongs to a triangle with at most two vertices from Q. Second, there exists a triangle packing Π_S in the graph induced by S together with components of $\mathcal{C}_i$ such that

- at most c elements from $\mathcal{C}_i$ are active in Π_S (this follows from the promise on ψ), and
- the number of triangles in Π_S is at least $X_i + q_i$ (by our guess of q_i).

It is not difficult to verify that i-valid sets can be enumerated in polynomial time, where the degree of the polynomial depends on c and σ.

Now we are ready to construct an instance $(U, \mathcal{F}, p/c)$ of $\leqslant d$-Set Packing (#Sets). The universe U is $Q \cup \{a_i \mid i \in [p/c]\}$, i.e., it consists of the hub of G and one extra vertex per color. For each i-valid set S, we include in $\mathcal{F}$ the set $S \cup \{a_i\}$. Again, one can verify that $\mathcal{F}$ contains p/c pairwise disjoint sets if and only if G has a packing of t triangles that agree both with ψ and with the guessed values of q_i's.

By adjusting c, we can ensure that the whole algorithm works in time $(2-\varepsilon')^p \cdot |V(G)|^{\mathcal{O}(1)}$, for some $\varepsilon' > 0$, provided that we have a fast algorithm for $\leqslant d$-Set Packing (#Sets).

The only thing left is to argue how we obtain the coloring ψ satisfying the promise. Here we use *splitters* introduced by Naor, Schulman, and Srinivasan [29]. Informally, a splitter is a family of colorings of a "large set" $\mathcal{X}$, such that for each "small subset" $\mathcal{Y} \subseteq \mathcal{X}$ there is a coloring that splits $\mathcal{Y}$ evenly. In our setting, the "large set" $\mathcal{X}$ is the set of all components of $G - Q$ and the "small subset" $\mathcal{Y}$ is the set of all active components with respect to some fixed (but unknown) solution; recall that there are at most p such active components. Since our colorings use p/c colors, we are sure that there is some ψ for which at most $\frac{p}{p/c} = c$ components in each color are active. Calling the result of Naor, Schulman, and Srinivasan [29], we can find a small splitter Ψ, and then just exhaustively try every coloring $\psi \in \Psi$. Again, carefully adjusting the constants, we can ensure that the overall running time is $(2-\varepsilon)^p \cdot |V(G)|^{\mathcal{O}(1)}$, for some $\varepsilon > 0$.

Abstract

We give a randomized algorithm that approximates the number of independent sets in a dense, regular bipartite graph – in the language of approximate counting, we give an FPRAS for #BIS on the class of dense, regular bipartite graphs. Efficient counting algorithms typically apply to "high-temperature" problems on bounded-degree graphs, and our contribution is a notable exception as it applies to dense graphs in a low-temperature setting. Our methods give a counting-focused complement to the long line of work in combinatorial optimization showing that CSPs such as Max-Cut and Unique Games are easy on dense graphs via spectral arguments.

Our contributions include a novel extension of the method of graph containers that differs considerably from other recent low-temperature algorithms. The additional key insights come from spectral graph theory and have previously been successful in approximation algorithms. As a result, we can overcome some limitations that seem inherent to the aforementioned class of algorithms. In particular, we exploit the fact that dense, regular graphs exhibit a kind of small-set expansion (i.e., bounded threshold rank), which, via subspace enumeration, lets us enumerate small cuts efficiently.

1 Introduction

Exactly computing the number $i(G)$ of independent sets in a graph G is #P-hard, even when restricted to bipartite graphs [41]. In the general case, approximating $i(G)$ (to within, say, a constant factor) is NP-hard, even when restricted to d-regular graphs with $d \geq 6$ [20, 46, 45]. Restricted to *bipartite* graphs the problem of counting independent sets is known as #BIS, and the prospect of hardness of approximation is less clear because finding a maximum

[1] Corresponding author

independent set can be done in polynomial time. Under polynomial-time approximation-preserving reductions, many natural counting problems are equivalent to #BIS [17], and the complexity of approximating #BIS has received a lot of attention. Existing approximation algorithms for #BIS include "high-temperature" algorithms that work when degrees on one side of the bipartition are small [38], "low-temperature" algorithms that require additional assumptions such as expansion [11, 29] or unbalanced degrees [8], and exponential-time algorithms that are nonetheless faster than algorithms for the general, non-bipartite case [24]. The description of these methods in terms of temperature is due to a common generalization in terms of weighted counting and strong connections to statistical physics, where counting (weighted) independent sets corresponds to computing the partition function of the hard-core model.

The idea that Max-CSP optimization problems such as Max-Cut and Unique Games should be easy to approximate on dense graphs – perhaps because they have good expansion properties – is well-established [3, 18, 19]. Many of the techniques that apply to dense or expanding graphs have been generalized in interesting directions. In particular, spectral methods give good results in both dense graphs and expanders, and in many cases can be extended to more refined structural properties such as small-set expansion and threshold rank to great effect. Most of the prominent approaches to Max-CSPs relevant to this work fall into three categories: algorithmic regularity lemmas which began with Frieze and Kannan [19] and were extended to threshold rank by Oveis Gharan and Trevisan [39]; convex hierarchies and correlation rounding [4, 6, 25]; and the spectral technique of subspace enumeration due to Kolla and Tulsiani [36, 37]. Prior to these developments were several algorithms demonstrating that counting problems on dense graphs admit efficient approximation algorithms [1, 16, 33], though these results do not apply to counting independent sets.

An analogous theme in approximate counting is to obtain algorithms on expander graphs or random graphs [7, 10, 21, 26, 29]. Despite superficial similarity to the aforementioned work on Max-CSPs in the sense that these works give algorithms for dense or expanding instances, there is relatively little work establishing any common underlying phenomenon that makes Max-CSP problems and counting problems easy on dense or expanding graphs. A notable exception is due to Risteski [42], who connected the work on correlation rounding and convex hierarchies [6] to the broad and well-studied problem of approximating partition functions. His approach is also known as the variational method. Regularity methods and correlation rounding do provide some evidence of structure common to these problems; for example, Coja–Oghlan and various coauthors have developed a range of regularity lemmas and applied them to both Max-CSPs and spin models on random graphs [5, 13, 14], and Coja–Oghlan and Perkins independently discovered correlation rounding in the context of Gibbs measures and partition functions [15]. Counting independent sets is not typically one of the examples studied, though occasionally this is more for convenience than for fundamental reasons.

In the specific context of #BIS, connections to Max-CSP research are even more scarce. The polymer approach of Jenssen, Keevash and Perkins [29] is a major algorithmic breakthrough for #BIS which shows that several prominent #BIS-hard problems can be approximated in polynomial time on bounded-degree expander graphs (and thus random d-regular graphs for $d = O(1)$). Further refinements of the method broaden the range of problems covered [21, 26], provide faster algorithms based on rapid mixing of Markov chains known as polymer dynamics [11], or weaken the structural properties required by applying container theorems to combinatorial enumeration problems that arise in the method [10, 32]. None of these developments give polynomial-time algorithms in dense graphs, however. Carlson, Davies, and Kolla [9] applied the polymer method to approximate the Potts model partition

function on (bounded-degree) graphs with bounded threshold rank, but the conditions their analysis requires are prohibitively restrictive, and it is unclear whether their techniques can be applied to #BIS. While Risteski's approach has been extended and improved [28, 35], results are stated for spin models with soft constraints such as the Ising and Potts models, and the approximation guarantees degrade in the presence of the hard constraints that are inherent to independent sets.

1.1 Main result

We specifically address the superficial similarities between algorithms for Max-CSPs and counting independent sets by giving an algorithm for approximately counting independent sets in dense, regular bipartite graphs which combines the highly successful techniques of polymer models, subspace enumeration, and container theorems for the enumeration of independent sets in bipartite graphs. Our approximation guarantee is of the strong type typically sought in approximate counting. We say that a relative ϵ-approximation of a real number x is a real number y such that $e^{-\epsilon} \leq x/y \leq e^{\epsilon}$, and a fully polynomial randomized approximation scheme (FPRAS) for a counting problem is an algorithm that with probability at least $3/4$ outputs a relative ϵ-approximation to the solution in time polynomial in the instance size and $1/\epsilon$.

▶ **Theorem 1.** *For each $\delta \in (0,1)$ there is an FPRAS for #BIS on the class of d-regular bipartite graphs G with $d = \lfloor \delta |V(G)|/2 \rfloor$.*

We use spectral methods and subspace enumeration to enumerate small cuts in d-regular bipartite graphs via an ϵ-net of the vector space spanned by small eigenvalues of the Laplacian matrix of the graph, influenced by the use of these methods in combinatorial optimization [2, 36, 37] and approximate counting. Some of our analysis builds upon the perturbative approach of [27, 29] and an important refinement of this method due to Jenssen and Perkins [30] (and with Potukuchi [31]) that uses graph container lemmas of the type developed by Sapozhenko [43, 44]. While container theorems for independent sets have been used to control enumeration problems that arise in establishing the convergence of the cluster expansion [30, 31, 32], and these have inspired container-like theorems for controlling analogous enumeration problems [10], our addition of subspace enumeration here has a different purpose.

In terms of running time, our result improves upon the dense case of an algorithm of Jenssen, Perkins, and Potukuchi [32] which runs in subexponential time on d-regular bipartite graphs for all $d \geq \omega(1)$. In the case $d = \Theta(n)$ their algorithm takes time $\exp(\Omega(\log^4 n))$, and our contribution works for any accuracy parameter ϵ, which is not given by the methods in [32]. The improvement stems from incorporating the spectral techniques mentioned above, which lets us sidestep algorithmic cluster expansion. That is, our spectral techniques overcome an obstacle in the algorithm of [32] related to polynomial accuracy: we can achieve arbitrary accuracy without resorting to a naive enumeration of polymers (which in this setting are connected subgraphs of the square of the instance).

An interesting question posed in [32] is whether #BIS admits a general subexponential-time algorithm. One of our technical contributions is to show that a perspective on graph spectra involving higher-order eigenvalues and eigenvectors advances our understanding of #BIS.

2 Overview

Fix $\delta > 0$ and for $d = \lfloor \delta n \rfloor$, a bipartite graph $G = (X \cup Y, E)$ on $2n$ vertices. Let $\epsilon > 0$ and note that we allow ϵ to depend on n.

Our proof begins with the well-known observation that to enumerate independent sets in a bipartite graph it suffices to enumerate deviations from the "ideal" independent set X. That is, we have the identity

$$i(G) = \sum_{A \subseteq X} 2^{|Y \setminus N(A)|} \tag{1}$$

because, for a fixed $A \subseteq X$, any vertex of $Y \setminus N(A)$ can be added to A without spanning an edge. There is a similar formula for $i(G)$ based on enumerating deviations from Y. An important achievement of [29] is to give a rigorous proof that in bipartite graphs with strong expansion, typical independent sets are small deviations from either X or Y. Intuitively, we see a hint of this idea in equation (1) as when G is an expander we expect that $N(A) \gg |A|$ and so the terms on the right-hand side are small unless $|A|$ is small. Given this, one might hope to obtain an algorithm provided one can solve the problem of efficiently enumerate the small deviations and quantifing their contributions to $i(G)$. This is done in [29] by approximating $i(G)$ with the sum of two polymer models, and brute force enumeration of terms in the cluster expansion for these models.

If the bipartite graph is not an expander, then large deviations from X and Y must be handled. For example, in a $2n$-vertex disjoint union of complete d-regular bipartite graphs, a significant number of independent sets intersect both X and Y on $\Omega(n)$ vertices. To extend the algorithm to all bipartite graphs, using an idea from [32] we can separate contributions from expanding and non-expanding pieces of the deviation A. The first step is to break $A \subseteq X$ in the sum in (1) into pieces with disjoint neighborhoods. We say that a subset $A \subseteq X$ is *polymer*[2] if it is connected in the square G^2 of G, and note that any $A \subseteq X$ admits a unique partition into polymers which have disjoint neighborhoods. We call the polymers in this partition the *components* of A and denote the set of components of A by $\mathcal{K}(A)$. We say that two polymers are *compatible* if their neighborhoods are disjoint, and that a set or tuple of polymers is *compatible* if the polymers in it are pairwise compatible. Thus, subsets $A \subseteq X$ correspond to compatible sets of polymers via the unique partition into polymers with disjoint neighborhoods.

▷ Claim 2.

$$i(G) = \sum_{k \geq 0} \frac{1}{k!} \sum_{\substack{(A_1,\ldots,A_k) \text{ s.t.} \\ \text{each } A_i \text{ is a polymer and} \\ (A_1,\ldots,A_k) \text{ compatible}}} 2^{\left|Y \setminus \bigcup_{j=1}^{k} N(A_j)\right|}. \tag{2}$$

Proof. The claim follows from the correspondence between subsets $A \subseteq X$ and sets of compatible polymers given by $A \mapsto \mathcal{K}(A)$. By convention, we sum over compatible tuples of polymers which leads to the term $1/k!$ to account for the permutations of each tuple. We use the fact that compatible polymers have disjoint neighborhoods for the correspondence of the summands. ◁

The *closure* $[A]$ of a subset $A \subseteq X$ is $[A] := \{x \in X : N(x) \subseteq N(A)\}$, and we say that A is *closed* if $A = [A]$. Note that A is closed if and only if each component of A is closed. A subset $A \subseteq X$ is called t-*expanding* if $|N(A)| = |[A]| + t$, and (in a slight abuse of terminology

[2] In related works the term "2-linked" is used for the property of being connected in G^2.

that we hope the reader permits) t-contracting if $|N(A)| < |[A]| + t$. For a fixed t_0 that we determine later, we split the sum over polymers in (2) according to t_0-contraction. To do this, for each subset $A \subseteq X$, let $X_A = X \setminus N(N(A))$ and $Y_A = Y \setminus N(A)$. Let $\mathcal{P}_A$ be the set of polymers which are subsets of X_A and define

$$\Xi(A) := \sum_{k \geq 0} \frac{1}{k!} \sum_{\substack{(B_1,\ldots,B_k) \text{ s.t.} \\ B_i \in \mathcal{P}_A \text{ is not } t_0\text{-contracting} \\ \text{and } (B_1,\ldots,B_k) \text{ compatible}}} 2^{-\sum_{i=1}^{k} |N(B_i)|},$$

where the inner sum is over compatible k-tuples of polymers, each of which is not t_0-contracting (equivalently, t-expanding for some $t \geq t_0$).

▷ Claim 3.

$$i(G) = \sum_{k \geq 0} \frac{1}{k!} \sum_{\substack{(A_1,\ldots,A_k) \text{ s.t.} \\ \text{each } A_i \text{ is a } t_0\text{-contracting polymer} \\ \text{and } (A_1,\ldots,A_k) \text{ compatible}}} 2^{\left|Y \setminus \bigcup_{j=1}^{k} N(A_j)\right|} \cdot \Xi\left(\bigcup_{j=1}^{k} A_j\right). \tag{3}$$

Proof. From Claim 2 we can split the sum over tuples of polymers into a sum over tuples of t_0-contracting polymers and tuples of non-t_0-contracting polymers. The idea is to first sum over tuples $(A_1, \ldots, A_k)$ of t_0-contracting polymers and then use the fact that for $A = \bigcup_{j=1}^{k} A_j$ the quantity $\Xi(A)$ contains a sum over the ways to extend this tuple to one containing non-t_0-contracting polymers and the summand is the additional contribution that each such extension makes. The definition of $\mathcal{P}_A$ means that any $B_i \in \mathcal{P}_A$ is compatible with each component of A. With a little care, one can check that the permutaions of the tuples are correctly taken into account and the claim follows. ◁

A further refinement of the expression for $i(G)$ groups t_0-contracting polymers according to their neighborhoods. The motivation for this is that two subsets $A \subseteq X$ and $B \subseteq X$ (each corresponding to the union of some compatible tuple of t_0-contracting polymers) have the same contribution in the sum if $N(A) = N(B)$ because this implies that $\Xi(A) = \Xi(B)$. For a subset $A \subseteq X$ write

$$\mathcal{D}(A) := \prod_{A' \in \mathcal{K}(\mathcal{A})} \left|\{B' \subseteq A' : B' \text{ is a polymer and } N(B') = N(A')\}\right|.$$

The quantity $\mathcal{D}(A)$ counts the number of subsets B of A such that $N(B) = N(A)$ and which are formed by choosing for each component A' of A, a subset $B' \subseteq A'$ which is a polymer. Note that if A' is t_0-contracting then so is any polymer $B' \subseteq A'$ with $N(B') = N(A')$. For convenience, we define $\mathcal{A}$ to be the set of all $A \subseteq X$ with closed, t_0-contracting components.

▷ Claim 4.

$$i(G) = \sum_{A \in \mathcal{A}} \mathcal{D}(A) \cdot 2^{|Y \setminus N(A)|} \cdot \Xi(A), \tag{4}$$

Proof. From Claim 3 we can restrict the sum over tuples of t_0-contracting polymers to closed t_0-contracting polymers provided, for each compatible tuple $(A_1, \ldots, A_k)$ of closed t_0-contracting polymers, we multiply their contribution to the sum by a term counting the number of ways of getting that contribution with polymers that are not necessarily closed. Identifying compatible tuples of closed polymers with their union, i.e. setting $A = \bigcup_{j=1}^{k} A_j$, the contribution to the sum from A is $2^{|Y \setminus N(A)|} \cdot \Xi(A)$. The term $\mathcal{D}(A)$ is exactly the number

of ways of getting this contribution. The claim follows from the conversion of the sum back into one over suitable subsets of X, namely those in $\mathcal{A}$, instead of a sum over compatible tuples of polymers. ◁

Now that we have a suitable expression (4) for $i(G)$, we can describe how our algorithm approximates $i(G)$. Our algorithm simply enumerates the sets $A \in \mathcal{A}$, approximates each $\mathcal{D}(A)$ term, and uses the fact (which we must prove) that 1 is a good approximation of each $\Xi(A)$ to approximate $i(G)$. Given these subroutines, computing the sum (4) is straightforward. The analysis of our algorithm thus splits into three separate components. Recall that the input is a d-regular bipartite graph G on $2n$ vertices such that for some constant $\delta > 0$ we have $d = \lfloor \delta n \rfloor$, and an approximation error ϵ. We set $t_0 = C \log(n/\epsilon)$, where $C = C(\delta)$ is large enough, and the correctness and running time of our algorithm follows from the results below. Note that for this choice of t_0 an exponential such as 4^{t_0} is polynomial in n and $1/\epsilon$.

▶ **Lemma 5.** *For $t_0 \leq 2^{-8}d$, the set $\mathcal{A} = \{A \subseteq X : A$ closed and t_0-contracting$\}$ has size at most $n^{O(1/\delta)} \cdot 4^{t_0}$ and can be enumerated in the same time.*

The proof of this lemma uses subspace enumeration to find small cuts in G, and then for each such small cut enumerates the sets $A \in \mathcal{A}$ which are close to the cut. See Section 4.

▶ **Lemma 6.** *Let $A \subseteq X$ be a closed t_0-contracting polymer. Then for $\epsilon', \rho' > 0$ there is a randomized algorithm running in time polynomial in n, $1/\epsilon'$ and $\log(1/\rho')$ that with probability at least $1 - \rho'$ outputs a relative ϵ'-approximation to the number of polymers $B \subseteq A$ such that $N(B) = N(A)$.*

This lemma uses straightforward estimation of an expectation by repeated sampling, and is very similar to the analogous result in [32]. The proof is in Section 5. We use the lemma in each component of the sets $A \in \mathcal{A}$ in the claim below. This claim requires an upper bound on t_0, but this is a small technical detail as the only way to violate this bound is to choose an error parameter ϵ so small that one has time for brute force because an FPRAS can take time polynomial in $1/\epsilon$, see Section 3 where we use the claim.

▷ Claim 7. Suppose that $t_0 \leq d/2$. Then each set $A \in \mathcal{A}$ has at most $2/\delta = O(1)$ components, and for $\epsilon', \rho' > 0$ there is a randomized algorithm running in time polynomial in n, $1/\epsilon'$ and $\log(1/\rho')$ that, given a set $A \in \mathcal{A}$ as input, with probability $1 - \rho'$ obtains an ϵ'-approximation of $\mathcal{D}(A)$.

Proof. Any t_0-contracting set must have size at least $d - t_0$, and in the case $t_0 \leq d/2$ we have $d - t_0 \geq d/2$ and hence each $A \in \mathcal{A}$ has at least $2n/d = 2/\delta$ components.

Observe that if $A \in \mathcal{A}$ has ℓ components then running the algorithm of Lemma 6 on each component with error parameter ϵ'/ℓ and probability parameter ρ'/ℓ yields, with probability at least $1 - \rho'$, a relative ϵ-approximation to $\mathcal{D}(A)$ in time polynomial in n, ℓ/ϵ' and $\log(\ell/\rho')$. When $t_0 \leq d/2$ we have the upper bound $\ell = O(1)$ from above and the claim follows. ◁

▶ **Lemma 8.** *Let $A \in \mathcal{A}$, then $1 \leq \Xi(A) \leq e^{\epsilon/2}$.*

This result means that 1 is a relative $\epsilon/2$-approximation for each of the $\Xi(A)$ terms appearing in (4). The proof is based on graph container methods due to Sapozhenko [43, 44], which have since been refined, [23, 22, 34, 40], and their application to algorithmic counting [30, 31, 32]. We give the proof in Section 6.

3 The algorithm and proof of Theorem 1

Input A $\lfloor \delta n \rfloor$-regular bipartite graph $G = (X \cup Y, E)$ on $2n$ vertices and an approximation error $\epsilon > 0$.

Output A relative ϵ-approximation i' of $i(G)$.

Recall that $C = C(\delta)$ is a large enough constant, and that $t_0 = C \log(n/\epsilon)$. In the following proof, implicit constants in the $O(\cdot)$ notation and implicit polynomials are allowed to depend on δ but not ϵ. If $\epsilon \leq n \exp(-d/(2^8 C))$ then we can afford to run a brute force algorithm that computes $i(G)$ exactly in time $e^{O(n)}$ and the running time is still polynomial in $1/\epsilon$. Otherwise, we note that for all large enough n we have $d - 2^7 t_0 \geq d/2$ and run the following algorithm. For convenience, we assume that $\epsilon \leq 1$ and simply run the algorithm for $\epsilon = 1$ if the given ϵ is larger.

First, construct the set $\mathcal{A}$, which can be done in time $(n/\epsilon)^{O(1)}$ by Lemma 5. Note also that $|\mathcal{A}|$ is polynomial in n and $1/\epsilon$. Then, for each $A \in \mathcal{A}$ compute an $\epsilon/2$-approximation $\tilde{\mathcal{D}}_A$ of $\mathcal{D}_A$ with the algorithm of Claim 7 and probability parameter $\rho' = 3/(4|\mathcal{A}|)$. Then $\log(1/\rho')$ is polynomial in $\log n$ and $\log(1/\epsilon)$ so the running time of this step is polynomial in n and $1/\epsilon$. By a union bound, with probability at least $3/4$ we get the desired approximation in each application of the claim, and thus a valid relative $\epsilon/2$-approximation $\tilde{\mathcal{D}}_A$ of each $\mathcal{D}_A$. Then output $i' = \sum_{A \in \mathcal{A}} \tilde{\mathcal{D}}_A 2^{|Y \setminus N(A)|}$. By Lemma 8 and the analysis above, the output is a valid ϵ-approximation of $i(G)$ obtained in time $(n/\epsilon)^{O(1)}$, thus proving Theorem 1.

4 Subspace enumeration and contracting sets

The proof of Lemma 5 has two parts. First, we show how to enumerate small cuts using subspace enumeration. For related results see [2, 36, 37]. We use the term *cut* to mean a subset of $V = X \cup Y$, and the *value* $|\nabla(C)|$ of a cut C is the number of edges with precisely one endpoint in C. Subspace enumeration involves what is commonly called an ϵ-net of a subset U' of a vector space, which is a collection of points such that U' is contained in the union of the balls of radius ϵ around each point. Since we reserve ϵ for the error parameter in our algorithm, our nets are ξ-nets.

▶ **Lemma 9.** *Let $G = (V, E)$ be a d-regular bipartite graph on $N = 2n$ vertices. There is a set $\mathcal{C}^{\text{cut}} \subseteq 2^V$ such that $|\mathcal{C}^{\text{cut}}| \leq n^{O(n/d)}$ and $\mathcal{C}^{\text{cut}}$ has the following property. For all $t \geq 1$ and cuts $S \subseteq V$ with value $|\nabla(S)| \leq td$, there is some $C \in \mathcal{C}^{\text{cut}}$ such that $|S \triangle C| \leq 32t$ and $|\nabla(C)| \leq 33td$. Moreover, the set $\mathcal{C}^{\text{cut}}$ can be constructed in time $n^{O(n/d)}$.*

Proof. Let $d = \lambda_1 \geq \cdots \geq \lambda_N = -d$ be the spectrum of the adjacency matrix A of G. The facts that $\lambda_1 = d = -\lambda_N$ and that the spectrum of A is symmetric about zero are standard, see e.g. [12]. Let k be such that A has precisely $2k$ eigenvalues of absolute value at least $d/2$. Counting closed walks of length two gives

$$\operatorname{Tr}(A^2) = Nd = \sum_{i=1}^{N} \lambda_i^2 \geq kd^2/2,$$

and hence $k \leq 4n/d$.

Let $L = dI - A$ be the Laplacian matrix of G and let $\mathbf{e}_1, \ldots, \mathbf{e}_N$ be an orthonormal basis of eigenvectors of L such that $\mathbf{e}_i$ has eigenvalue μ_i with $0 = \mu_1 \leq \cdots \leq \mu_N = 2d$. By the definition of k, it must be the case that $\mu_{k+1} > d/2$. Let U be the span of $\mathbf{e}_1, \ldots \mathbf{e}_k$, and $U^\perp$ be the orthogonal complement of U. For $\xi = \sqrt{2}$, we require an efficient construction of a ξ-net $\mathcal{E} \subseteq U$ covering all vectors of L^2-norm at most $\sqrt{n}$ in U. For example, we can take

$$\mathcal{E} := \left\{ \mathbf{p} = \sum_{i=1}^{k} x_i \mathbf{e}_i : x_1, \ldots, x_k \in (\xi/\sqrt{k}) \cdot \mathbb{Z},\ \|\mathbf{p}\| \leq \sqrt{n} \right\},$$

yielding $|\mathcal{E}| \leq (2\sqrt{nk}/\xi)^k$. Then every vector in U with L^2-norm at most $\sqrt{n}$ lies at most distance ξ from a vector in $\mathcal{E}$.

The algorithm to construct $\mathcal{C}^{\text{cut}}$ is as follows. Start with $\mathcal{C}^{\text{cut}} = \emptyset$ and for each point $\mathbf{p} \in \mathcal{E}$, form $\mathbf{p}'$ by rounding each coordinate of $\mathbf{p}$ to $\{0, 1\}$ (breaking ties with $1/2 \mapsto 1$) and add the vertex subset with indicator vector $\mathbf{p}'$ to $\mathcal{C}^{\text{cut}}$.

We now show that $\mathcal{C}^{\text{cut}}$ has the desired properties. By the construction of $\mathcal{C}^{\text{cut}}$ and $\mathcal{E}$ we have $|\mathcal{C}^{\text{cut}}| \leq |\mathcal{E}| \leq n^{O(n/d)}$. To establish the other property of $\mathcal{C}^{\text{cut}}$, let $t \geq 1$ and consider an arbitrary subset $S \subseteq V$ with $|\nabla(S)| \leq td$. Let $\mathbf{s}$ be the indicator vector of the set S and write this vector in the eigenbasis of L as $\mathbf{s} = \sum_{i=1}^{N} s_i \mathbf{e}_i$. Let $\mathbf{u} = \sum_{i=1}^{k} s_i \mathbf{e}_i$ be the projection of $\mathbf{s}$ onto U and let $\mathbf{p}$ be the point in $\mathcal{E}$ closest to $\mathbf{u}$. Indicator vectors of subsets of V have L^2-norm at most $\sqrt{n}$, and hence $\|\mathbf{u} - \mathbf{p}\| \leq \xi$.

Without considering our need for an efficient construction, the idea is that because $\nabla(S)$ is small we know that $\mathbf{s}$ is an indicator vector close to its projection $\mathbf{u}$ onto U. Thus, if we form $\mathcal{C}^{\text{cut}}$ as the union of all sets whose indicator vectors are close to vectors in U, each set S of interest has an indicator vector that lies within a distance twice the definition of "close" to a set in C.

To make the above sketch efficient, we replace U with the ξ-net $\mathcal{E}$. Note that

$$td \geq |\nabla(S)| = \mathbf{s}^{\mathrm{T}} L \mathbf{s} = \sum_{i=1}^{N} \mu_i s_i^2 \geq \frac{d}{2} \sum_{i=k+1}^{N} s_i^2.$$

But $\sum_{i=k+1}^{N} s_i^2 = \|\mathbf{s} - \mathbf{u}\|^2$, so we have the bound $\|\mathbf{s} - \mathbf{u}\| \leq \sqrt{2t}$. Then we immediately have $\|\mathbf{s} - \mathbf{p}\| \leq \sqrt{2t} + \xi$ from the triangle inequality. Let $\mathbf{p}'$ be obtained from $\mathbf{p}$ by rounding each coordinate to $\{0, 1\}$, breaking ties with $1/2 \mapsto 1$, and let $C \subseteq V$ be the set whose indicator vector is $\mathbf{p}'$. We have $|S \triangle C| = \|\mathbf{s} - \mathbf{p}'\|^2$ and we bound the latter with the triangle inequality. In particular, $\mathbf{s}$ is an indicator vector of distance at most $\sqrt{2t} + \xi$ from $\mathbf{p}$ and $\mathbf{p}'$ must be the closest indicator vector to $\mathbf{p}$, hence $\|\mathbf{p} - \mathbf{p}'\| \leq \sqrt{2t} + \xi$. Then $\|\mathbf{s} - \mathbf{p}\| \leq 2(\sqrt{2t} + \xi)$, and because $t \geq 1$ and $\xi = \sqrt{2}$ we have

$$|S \triangle C| \leq 4 \left(\sqrt{t} + \xi \right)^2 \leq 32t.$$

It remains to bound the value of the cut $|\nabla(C)|$, and the desired bound follows from the observation that

$$|\nabla(C)| \leq |\nabla(S)| + d|S \triangle C| \leq td + 32td = 33td. \qquad \blacktriangleleft$$

Lemma 9 tells us that there is an efficient construction of a collection $\mathcal{C}^{\text{cut}}$ of cuts such that any small cut S must be close to a cut in $\mathcal{C}^{\text{cut}}$ in Hamming distance. We now show that given a small cut S we can enumerate the sets $A \in \mathcal{A}$ which are close to S. For this to be useful, it must be that each $A \in \mathcal{A}$ is close to some small cut, and we give the details of this later.

▶ **Lemma 10.** *Fix any $c \geq 1$ and let $t \leq \frac{d}{8c}$. Given a cut C with value at most td, there are at most 4^t closed t-contracting subsets $A \subseteq X$ such that $|A \triangle (C \cap X)| \leq ct$ and $|N(A) \triangle (C \cap Y)| \leq ct$. Moreover, these sets A can be enumerated in time $4^t \cdot n^{O(1)}$.*

Proof. Let $A' := C \cap X$ and $W' := C \cap Y$. By the fact that G is d-regular, $|E(A', W')| \leq d\min\{|A'|, |W'|\}$ and hence $|\nabla(C)| \geq d\max\big\{|W'| - |A'|, |A'| - |W'|\big\}$. By assumption, we have $|\nabla(C)| \leq td$ and therefore $\big||W'| - |A'|\big| \leq t$.

Set

$$S_X := \big\{v \in X \setminus A' : |N(v) \setminus W'| \leq 3ct\big\}, \text{ and}$$
$$S_Y := \big\{v \in W' : |N(v) \cap A'| \leq ct\big\},$$

so that $S_X \subseteq X$ consists of vertices in $X \setminus A'$ with almost all of their neighbors in W' and $S_Y \subseteq Y$ consists of vertices in W' with almost all of their neighbors in $X \setminus A'$. We have the following claims.

▷ Claim 11. For any closed t-contracting subset $A \subseteq X$ such that $|A \triangle A'| \leq ct$, $A \setminus A' \subseteq S_X$.

Proof. Suppose for contradiction that there is a vertex $v \in A \setminus A'$ such that

$$|N(v) \setminus W'| > 3ct.$$

We derive the contradiction using the facts that $|\nabla(A \cap A')| = d|A \cap A'|$ and that any of the edges in $\nabla(A \cap A')$ not incident to W' contribute to the value of the cut C. These facts imply that $|E(A \cap A', W')| \geq d|A \cap A'| - t \cdot d$, and hence

$$|N(A \cap A') \cap W'| \geq |A \cap A'| - t.$$

Then because A is closed and non-expanding,

$$\begin{aligned} |A| + t &\geq |N(A)| \geq |N((A \cap A') \cup \{v\})| \\ &> |N((A \cap A') \cup \{v\}) \cap W'| + 3ct \\ &\geq |A \cap A'| + 2ct \geq |A| + ct, \end{aligned}$$

which is a contradiction because there is a strict inequality in the chain and $c \geq 1$. ◁

▷ Claim 12. For any t-contracting subset $A \subseteq X$ such that $|A \triangle A'| \leq ct$, $W' \setminus N(A \cap A') \subseteq S_Y$.

Proof. We note that for each vertex v in $W' \setminus N(A \cap A')$, we have that

$$N(v) \cap A' \subseteq A' \setminus A.$$

Since $|A' \setminus A| \leq ct$, it follows that $|N(v) \cap A'| \leq ct$. ◁

We can now complete the proof of the lemma. Using the degree constraints in the definitions of S_X and S_Y, we have

$$\begin{aligned} td &\geq |\nabla(C)| \\ &\geq |S_X|(d - 3ct) + |S_Y|(d - ct) \\ &\geq (d/2) \cdot (|S_X| + |S_Y|) \end{aligned}$$

where the last inequality uses $t < \frac{d}{8c}$. As a result, we have

$$|S_X| + |S_Y| \leq 2t.$$

Putting Claim 11 and Claim 12 together, we have that each closed t-contracting sets A with $|A \triangle A'|,\ |N(A) \triangle W'| \leq ct$ must be of the form

$$A = [(A' \setminus N(S'_Y)) \cup S'_X]$$

for some subsets $S'_Y \subseteq S_Y$ and $S'_X \subseteq S_X$. Thus, the total number of such A is at most $2^{|S_X|+|S_Y|} \leq 4^t$. Since we are given the cut C, S_X and S_Y can be found in time polynomial in n as required. ◀

With these ingredients we can proof Lemma 5, which we recall states that $\mathcal{A}$ can be enumerated in time $n^{O(1/\delta)}4^{t_0}$.

Proof of Lemma 5. Since $d = \lfloor \delta n \rfloor$, we construct $\mathcal{C}^{\text{cut}}$ as in Lemma 9 in time $n^{O(1/\delta)}$. We then choose $c = 32$ and enumerate for each $C \in \mathcal{C}^{\text{cut}}$, every closed t_0-contracting subset A with $|A \triangle (C \cap X)| \leq 32t_0$ and $|N(A) \triangle (C \cap Y)| \leq 32t_0$ using Lemma 10. We are done if every $A \in \mathcal{A}$ appears in this enumeration process, as the running times combine to give the required $n^{O(1/\delta)}4^{t_0}$. This holds because each $A \in \mathcal{A}$ is closed and t_0-contracting and hence setting $S_A = A \cup N(A)$, by a double counting argument, we have $|\nabla(S_A)| = d|N(A)| - d|A| \leq t_0 d$. So each $A \in \mathcal{A}$ corresponds to a cut of value at most $t_0 d$ and hence some $C \in \mathcal{C}^{\text{cut}}$ has $|S_A \triangle C| \leq 32t_0$ by Lemma 9. ◀

5 Approximating the number of covers

For convenience, we restate Lemma 6 here.

▶ **Lemma 6.** *Let $A \subseteq X$ be a closed t_0-contracting polymer. Then for $\epsilon', \rho' > 0$ there is a randomized algorithm running in time polynomial in n, $1/\epsilon'$ and $\log(1/\rho')$ that with probability at least $1 - \rho'$ outputs a relative ϵ'-approximation to the number of polymers $B \subseteq A$ such that $N(B) = N(A)$.*

Proof. The method is exactly the same as [32, Lem. 17], but in our setting with $d = \lfloor \delta n \rfloor$ the resulting algorithm runs in time polynomial in n.

Let $|A| = a$, $N(A) = W$ have size $|W| = w$, and let $W' = \{v \in W : |N(v) \cap A| \leq d/2\}$ have size $|W'| = w'$. Let

$$\mathcal{D} = \{B \subseteq A : N(B) = W \text{ and } B \text{ is a polymer}\}$$

be the set whose size we wish to estimate.

By [32, Cor. 10], there is a polymer $A' \subseteq A$ of size at most

$$\frac{2a}{d} \log d + \frac{2w}{d} + 2(w - a) \leq \frac{2}{\delta}(1 + \log n) + 2t_0$$

such that $N(A') = W$. Then $|\mathcal{D}| \geq 2^{a - \left(\frac{2}{\delta}(1+\log n) + 2t_0\right)}$, because any subset of A which contains A' is a polymer. Now $|\mathcal{D}|$ can be estimated to relative error ϵ' with probability at least $1 - \rho$ by sampling

$$\frac{1}{(\epsilon')^2} \log(1/\rho) n^{O(1/\delta)} 4^{t_0}$$

subsets of A uniformly at random, and this can be proved with a suitable application of the Chernoff bound. ◀

6 Enumerative lemmas

In this section we prove Lemma 8 which states that for $A \in \mathcal{A}$ we have $1 \leq \Xi_A \leq e^{\epsilon/2}$.

Proof of Lemma 8. For the proof, we fix an arbitrary $A \in \mathcal{A}$. The terms in the sum giving Ξ_A are non-negative, and the lower bound comes from the term $k = 0$ which contributes 1. For the upper bound, we use recent results on graph containers and adapt them to our purposes.

Recall that a polymer is a 2-linked subset $B \subseteq X$ and that the function Ξ_A involves a sum over tuples of non-t_0-contracting polymers. For convenience, we define $\mathcal{G}(w,t)$ to be the set of t-expanding polymers with neighborhood size w,

$$\mathcal{G}(w,t) = \{B \subseteq X,\ \text{polymer} : |N(B)| = w, |N(B)| - |[B]| = t\}.$$

In terms of this notation, we have

$$\Xi_A = \sum_{k\geq 0} \sum_{\substack{\{B_1,\ldots,B_k\}\in\mathcal{P}_A \text{ compatible} \\ \text{s.t. each } B_i \text{ not } t_0\text{-contracting}}} 2^{-\sum_{i=1}^k |N(B_i)|} \tag{5}$$

$$\leq \sum_{k\geq 0} \frac{1}{k!} \left(\sum_{t\geq t_0} \sum_{w\geq 0} |\mathcal{G}(w,t)| 2^{-w} \right)^k, \tag{6}$$

where we drop the requirement on the tuples of being compatible and relax the requirement that the B_i are subsets of X_A to being subsets of X, and hence have an upper bound. To proceed, we require upper bounds on $|\mathcal{G}(w,t)|$ and split into two cases according to t. The following result is proved in the rest of this section and Appendix A.

▶ **Lemma 13.** *There is an absolute constant $\gamma > 0$ such that for $t_0 \leq t$, and any integer w,*

$$|\mathcal{G}(w,t)| \leq 2^{w-\gamma t}.$$

With this lemma in hand, and because each neighborhood size w that we see is in $[1,n]$, there is an absolute constant $\gamma > 0$ such that

$$\Xi_A \leq \sum_{k\geq 0} \frac{1}{k!} \left(\sum_{t\geq t_0} n 2^{-\gamma t} \right)^k \tag{7}$$

$$= \sum_{k\geq 0} \frac{1}{k!} \left(n \frac{2^{-\gamma t_0}}{1-2^{-\gamma}} \right)^k = \exp\left(n \frac{2^{-\gamma t_0}}{1-2^{-\gamma}} \right). \tag{8}$$

This at most the required $e^{\epsilon/2}$ provided that

$$t_0 \geq \frac{1}{\gamma} \log_2 \left(\frac{2}{1-2^{-\gamma}} \frac{n}{\epsilon} \right),$$

which our choice $t_0 = C \log(n/\epsilon)$ satisfies for all large enough constants $C = C(\delta)$. ◀

Before we proceed with the proof of Lemma 13, we would like to remark out that one of the main contributions of this paper is to handle the case when t is small.

Proof of Lemma 13. We first take care of the case when $t \geq \log^4 n$. For each $v \in V$, let us define

$$\mathcal{G}'(v,w,t) = \{A \in \mathcal{G}(w,t) : v \in A\}.$$

First, we observe that $\log^2 d \cdot \frac{t}{d} \leq \log^2 n \cdot \frac{n}{\delta n} \ll \log^4 n$. Lemma 4 in [32] gives us that there is a constant c such that for each v, $\mathcal{G}'(v,w,t) \leq 2^{w-ct}$. Thus, we have

$$|\mathcal{G}(w,t)| \leq \sum_v |\mathcal{G}'(v,w,t)| \leq n \cdot 2^{n-ct} \leq 2^{n-ct/2}$$

for n large enough.

Before we address the case when $t_0 \leq t < \log^4 n$, let us set up some additional notation. Given a vertex $v \in V$ and a subset $S \subseteq V$, we write $d_S(v)$ for the number of neighbors of v in S.

▶ **Definition 14** (Essential subset). *For a subset $A \subseteq X$, we write $W = N(A)$ and $W_s = \{y \in W : d_A(y) \geq s\}$. We say that F is an* essential set *for A if $W \supseteq F \supseteq W_{d/2}$ and $N(F) \supseteq [A]$.*

It may be useful to consider such an F an approximation for the neighborhood $W = N(A)$.

▶ **Definition 15** (Container). *We call a tuple $(S', T') \in 2^X \times 2^Y$ a γ'-container for a subset $A \subseteq X$ that is t-contracting, with neighborhood $W = N(A)$ if*

1. *$S' \supseteq [A]$ and $W_{d/2} \subseteq T' \subseteq W$,*
2. *$d_{Y \setminus T'}(v) \leq \gamma' t$ for each $v \in S'$, and*
3. *$d_{S'}(v) \leq \gamma' t$ for each $v \in Y \setminus T'$.*

The following two results show the existence of containers and bound the number of sets for which a given container is a γ'-container.

▶ **Lemma 16.** *For any $\gamma' > 0$ and any set $F \subseteq Y$, there is a set $\mathcal{C}^{\text{ind}} \subseteq 2^X \times 2^Y$ of size at most $n^{O(1/\gamma')}$ such that any $A \subseteq X$ for which F is an essential set, has a γ'-container in $\mathcal{C}^{\text{ind}}$.*

▶ **Lemma 17.** *There is an absolute constant $\gamma'' > 0$ such that the following holds.*

For any $\gamma' > 0$, $w < n$, $t < \log^4 n$, and tuple $(S', T') \in \mathcal{C}^{\text{ind}}$, there are at most $2^{w - \gamma'' t}$ sets $A \in \mathcal{G}(w, t)$ such that (S', T'), and is a γ'-container for A.

Since the proofs of these results are small modifications of existing container results, e.g. [40], we defer their proofs to Appendix A. We are now ready to handle the case of small t as follows. Consider an integer $t \in [t_0, \log^4 n]$ and a set $A \in \mathcal{G}(w, t)$. Define $S_A := [A] \cup N(A)$. As in the proof of Lemma 5, we have that $|\nabla(S_A)| = d|N(A)| - d|[A]| = td$. By Lemma 9, there is a cut $C \in \mathcal{C}^{\text{cut}}$ such that $g := |S_A \triangle C| \leq O(t)$. Let $A' := C \cap X$ and $W' := C \cap Y$.

Consider the set $W'_g = \{u \in Y : d_{A'}(u) > g\}$. We have the following two claims.

▷ Claim 18. $W \supseteq W'_g \supseteq W_{d/2}$.

Proof. Consider a vertex $u \in W_{d/2}$. We have

$$d_{A'}(u) \geq d_A(u) - |A \setminus A'| \geq d/2 - |L \triangle L'| \geq d/2 - g > g,$$

where the last inequality holds since $d = \lfloor \delta n \rfloor$ and $g = O(\log^4 n)$. Therefore $u \in W'_g$. Moreover, consider a vertex $u \in W'_g$. We have

$$d_A(u) \geq d_{A'}(u) - |A' \setminus A| > g - |L \triangle L'| > 0,$$

and hence $u \in W$. ◁

▷ Claim 19. $A \subseteq N(W'_g)$.

Proof. Suppose otherwise, i.e. there is a vertex $u \in A$ such that for each vertex $v \in N(u)$ we have $d_{A'}(v) \leq g$. For any such v, we have

$$d_A(v) \leq d_{A'}(v) + |A \setminus A'| \leq d_{A'}(v) + |L \triangle L'| \leq 2g.$$

This gives us that

$$t \cdot d = |E(W, X \setminus A)| \geq |E(N(u), W \setminus A)| \geq d(d - 2g),$$

contradicting the assumptions that $d = \lfloor \delta n \rfloor$ and t and g are both $O(\log^4 n)$. ◁

Claims 18 and 19 show that W'_g is an essential set for A. The set $A \in \mathcal{G}(w,t)$ may be constructed by

1. choosing the appropriate cut C in the set $\mathcal{C}^{\text{cut}}$ constructed in Lemma 9,
2. constructing the essential subset W'_g for it as above,
3. using Lemma 16 to obtain a γ'-container of A, where γ' is the absolute constant of Lemma 17, and finally
4. reconstructing A from the γ'-container with Lemma 17.

There are $n^{O(1/\delta)}$ choices for L' in the first step, a unique construction of W'_g for the second, $n^{O(1/\gamma')}$ possible containers in the third step, and $2^{w-\gamma'' t}$ ways for the final step. In total there are

$$2^{w-\gamma'' t + O(1/\gamma' + 1/\delta)\log n} \leq 2^{w-\gamma'' t/2}$$

such sets $A \in \mathcal{G}(w,t)$. The last inequality comes from our assumption that $t \geq t_0$ for our choice of $t_0 = C(\delta)\log(n/\epsilon) \geq C\log(n)$ (because wlog $\epsilon \leq 1$) satisfying

$$t_0 \geq \Omega\left(\frac{\log n}{\gamma''}\left(\frac{1}{\gamma'} + \frac{1}{\delta}\right)\right). \qquad \blacktriangleleft$$

7 Concluding remarks and future directions

1. Naturally, a next goal is to understand the power and limitations of the methods presented, especially in conjunction with existing cluster expansion methods. More specifically, we are curious about the following two questions:
   a. Can this spectral point of view help with our understanding of independent sets in a larger class of bipartite graphs?
   b. To what extent do these methods help in reducing the computation needed to implement algorithmic cluster expansion?

   In this context, the problem of approximating the number of independent sets in *small-set expanders* feels within striking distance.
2. Our next remark concerns Lemma 9. As mentioned before, similar results have had other applications in optimization and Unique Games [2, 36, 37], though we take a subtly different viewpoint worth noting: we seek to approximate *all* cuts in the graph, not just small ones. In any case, we find the lemma interesting in its own right and conjecture something stronger.

   ▶ **Conjecture 20.** *Lemma 9 holds with* $|\mathcal{C}^{\text{cut}}| \leq 2^{O(n/d)}$.

   If true, this would be best possible, as evidenced by a disjoint union of $1/\delta$ components. Setting $t = 0$ in this case gives exactly $2^{1/\delta}$ cuts of size 0.
3. Finally, we leave open the problem of making our algorithm deterministic. At the moment, the only step where randomness is used is Lemma 6.

A Deferred proofs

A.1 Proof of Lemma 16

We restate the result for convenience.

▶ **Lemma 16.** *For any $\gamma' > 0$ and any set $F \subseteq Y$, there is a set $\mathcal{C}^{\text{ind}} \subseteq 2^X \times 2^Y$ of size at most $n^{O(1/\gamma')}$ such that any $A \subseteq X$ for which F is an essential set, has a γ'-container in $\mathcal{C}^{\text{ind}}$.*

Proof. Let $A \subseteq X$ be a subset for which F is an essential set and let $W = N(A)$, $t := |N(A)| - |[A]|$. Consider the following algorithm

---

initialize $T' \leftarrow F$
while $\exists\ v \in [A]$ s.t. $d_{W \setminus T'}(v) > \gamma' t$, pick such a v **do**
  $T' \leftarrow T' \cup N(v)$
end while
initialize $S' \leftarrow \{v \in X : d_{Y \setminus T'}(v) \leq \gamma' t\}$
while $\exists\ v \in Y \setminus W$ s.t. $d_{S'}(v) > \gamma' t$, pick such a v **do**
  $S' \leftarrow S' \setminus N(v)$
end while
$T' \leftarrow T' \cup \{v \in Y : d_S(v) > \gamma' t\}$
return (S', T')

The lemma follows provided we can show that (S', T') as given by the algorithm above is a γ'-container for A by establishing properties 1–3, and provided we can show a good enough bound on the total number of outputs (S', T') which can occur for a fixed F as A varies.

To prove that the output (S', T') is a γ'-container of A, we first show that $S' \supseteq [A]$ and $W_{d/2} \subseteq T' \subseteq W$, establishing 1. Since F is an essential subset for A, we initialize $T' \leftarrow F$, and T' can then only grow, we have $W_{d/2} \subseteq T'$. Clearly, $T' \subseteq W$ at the end of the first while loop. After the second initialize statement, we have that each vertex $v \in [A]$ satisfies $d_{W \setminus T'}(v) \leq d_{Y \setminus T'}(v) \leq \gamma' t$. Therefore, $S' \supseteq A$ at the end of this line. This property is maintained during the second while loop since we only delete $N(v)$ from S for $v \notin W$. This also means that in the penultimate line, all vertices added to T' are from W. Thus $T' \subseteq W$ is also maintained at the end of the algorithm. Next, we prove 3. At the beginning of the second loop, every $v \in S'$ satisfies $d_{Y \setminus T'}(v) \leq \gamma' t$. Since vertices are only removed from S and added to T' after this point, this property is preserved till the end. Finally, to prove 2 note that the penultimate line of the algorithm ensures that every $v \in Y \setminus T$ satisfies $d_S(v) \leq \gamma' t$.

To bound the number of possible outputs for a fixed F, note that before the start of the first loop we have $|W \setminus T'| \leq O(t)$. Each step in the first loop of the algorithm removes γt vertices from $W \setminus T'$. Therefore, this loop runs at most $O(1/\gamma')$ times. Next, each step in the second loop removes at least $\gamma' t$ vertices from $S \setminus [A]$. Immediately after the second initialize statement, we have

$$dt \geq |E(S' \setminus [A], T')| \geq (d - \gamma' t)|S' \setminus [A]|.$$

As a result, $|S' \setminus [A]| = O(t)$. So the second loop runs for at most $1/\gamma'$ steps. The output is determined by the set of $O(1/\gamma')$ vertices chosen in both loops, so the number of possible outputs for the algorithm for a given F is at most $n^{O(1/\gamma')}$. ◀

A.2 Proof of Lemma 17

We restate the result for convenience.

▶ **Lemma 17.** *There is an absolute constant $\gamma'' > 0$ such that the following holds.*

For any $\gamma' > 0$, $w < n$, $t < \log^4 n$, and tuple $(S', T') \in \mathcal{C}^{\text{ind}}$, there are at most $2^{w - \gamma'' t}$ sets $A \in \mathcal{G}(w, t)$ such that (S', T'), and is a γ'-container for A.

We need the following lemma

▶ **Lemma 21.** *Let (S', T') be a γ'-container for a set $A \in \mathcal{G}(w, t)$. Then $|S'| \leq |T'|$.*

Proof. Let us denote $W = N(A)$. First, we observe that $|E(S', W)| \leq d|T'| + \gamma' t|W \setminus T'|$ by 3. We also have that $|E(S', W)| \geq d|[A]| + |S' \setminus [A]|(d - \gamma' t) = d|S'| - \gamma' t|S' \setminus [A]|$ by 1 and 2. Combining these inequalities, we have

$$|S'| \leq |T'| + \frac{\gamma' t(|S' \setminus [A]| + |W \setminus |T'||)}{d}. \tag{9}$$

Since $T' \supseteq W_{d/2}$, we have that $|W \setminus T'| \leq O(t)$ and

$$td = |E(W, X \setminus [A])| \geq \sum_{v \in S' \setminus [A]} d_{T'}(v) \geq |S' \setminus [A]|(d - \gamma' t)$$

which gives $|S' \setminus [A]| = O(t)$. So (9) implies

$$|S'| \leq |T'| + O\left(\frac{\gamma' t^2}{d}\right).$$

Since $t \leq \log^4 n$, $d = \lfloor \delta n \rfloor$, and $|S'|$ and $|T'|$ are both integers, we have that $|S'| \leq |T'|$. ◀

We finish the proof using the following lemma from [40], whose proof we reproduce for clarity.

▶ **Lemma 22** ([40], Lemma 11). *There is an absolute constant $\gamma'' > 0$ such that the following holds.*

For any tuple $(S', T') \in 2^X \times 2^Y$ such that $|S'| \leq |T'|$, there are at most $2^{w-\gamma''t}$ sets $A \in \mathcal{G}(w,t)$ such that $[A] \subseteq S'$ and $T' \subseteq N(A)$.

To be precise, in [40] the graph in question is the d-dimensional hypercube and additional hypotheses are stated, namely $w - t < n/4$ and $w > d^4$. These play no role in the proof, however, and it extends verbatim to the result stated above.

Proof. Throughout, we denote $W = N(A)$, and let $\alpha > 0$ be a constant that will be determined later.

If $|S'| < w - \alpha t$, then A is among the possible $2^{w-\alpha t}$ subsets of S'. Suppose otherwise, that $|S'| > w - \alpha t$. Let $A^* \in \mathcal{G}(w,t)$ such that (S', T') is a γ'-container for A^* and let $W^* = N(A^*)$. We have that $[A]$ is completely determined by $W \setminus W^*$ and $W^* \setminus W$. Since $W^* \setminus W \subseteq W^* \setminus T$, and

$$|W^* \setminus T'| \leq |W^*| - |T'| = |W| - |T'| \leq |W| - |S'| \leq \alpha t,$$

there are at most $2^{\alpha t}$ choices for $W^* \setminus W$. Next, for each vertex in $W \setminus W^*$, we choose a neighbor in $A \setminus A^* \subseteq S' \setminus A^*$. Observe that $W \setminus W^* = N(A \setminus A^*) \setminus W^*$. Since

$$|W \setminus W^*| \leq |W \setminus F| = |W| - |F| \leq |W| - |S'| \leq \alpha t,$$

and

$$|S' \setminus A^*| \leq |S'| - |A^*| = |S'| - |A| \leq |T'| - |A| \leq |W| - |A| = t.$$

Therefore, the number of choices for $W \setminus W^*$ is at most

$$\binom{t}{\alpha t} \leq 2^{H(\alpha)t}.$$

Once we have $[A]$, there are at most 2^{w-t} possibilities for A. Thus the total number of choices is at most

$$2^{w-t+t(\alpha+H(\alpha))}.$$

Choosing e.g., $\alpha = 0.17$ allows one to choose $\gamma'' = 0.17$. ◀

Abstract

We study the notion of k-stabilizer universal quantum state, that is, an n-qubit quantum state, such that it is possible to induce any stabilizer state on any k qubits, by using only local operations and classical communications. These states generalize the notion of k-pairable states introduced by Bravyi et al., and can be studied from a combinatorial perspective using graph states and k-vertex-minor universal graphs. First, we demonstrate the existence of k-stabilizer universal graph states that are optimal in size with $n = \Theta(k^2)$ qubits. We also provide parameters for which a random graph state on $\Theta(k^2)$ qubits is k-stabilizer universal with high probability. Our second contribution consists of two explicit constructions of k-stabilizer universal graph states on $n = O(k^4)$ qubits. Both rely upon the incidence graph of the projective plane over a finite field $\mathbb{F}_q$. This provides a major improvement over the previously known explicit construction of k-pairable graph states with $n = O(2^{3k})$, bringing forth a new and potentially powerful family of multipartite quantum resources.

1 Introduction

Quantum communication networks often rely on classical communication along with pre-shared entanglement. In this context, a highly pertinent problem is to explore which resource states enable a group of n parties, equipped with the capability of employing Local Operations and Classical Communication (LOCC), to create entangled EPR pairs among any k pairs

of qubits. It is only recently that Bravyi et al. addressed this fundamental question and provided both upper and lower bounds for what they called the k-pairability of quantum states, in terms of the number of parties and the number of qubits per party needed for a quantum state to be k-pairable [2]. Formally, an n-party state $|\psi\rangle$ is said to be *k-pairable* if, for every k disjoint pairs of parties $\{a_1, b_1\}, \ldots, \{a_k, b_k\}$, there exists a LOCC protocol that starts with $|\psi\rangle$ and ends up with a state where each of those k pairs of parties shares an EPR pair. Bravyi et al. studied n-party states in the case where each party holds m qubits, with m ranging from 1 to $\log(n)$. In the case where each party holds at least $m = 10$ qubits, they showed the existence of k-pairable states where k is of the order of $n/\text{polylog}(n)$, which is nearly optimal when m is constant. They also showed that if one allows a logarithmic number of qubits per party, then there exist k-pairable states with $k = n/2$. Moreover, before their work, numerous variations of this problem had surfaced in the literature, some in the context of entanglement routing [16, 26, 27], and some about problems that can be described as variants of k-pairability [5, 7–9, 12, 13, 18, 24, 25].

The notion of k-pairability that we focus on in the present paper relates to the scenario that is both the most natural and challenging [2], when each party possesses precisely one qubit, *i.e.*, $m = 1$. Protocols with multi-qubit parties, require the use of quantum operations acting on two (or more) qubits, which are significantly harder to implement in all the known technologies. For instance in quantum optics, whose 'flying' qubits are well suited for pairability protocols, one-qubit operations are easy to perform using off-the-shelf standard devices, whereas two-qubit operations, like those required by the protocols using multi-qubit parties, can only be performed probabilistically with a non-negligible probability of failure [1,14,21,22]. Bravyi et al. provided some results in the setup where each party holds one single qubit, although arguably weaker than those obtained in the case where each party holds at least 10 qubits. Using Reed-Muller codes, they were able to construct a k-pairable state of size exponential in k, namely $n = 2^{3k}$, leaving the existence of a k-pairable states of size $n = poly(k)$ as an open problem. They also found a 2-pairable graph state of size 10 and proved that there exists no stabilizer state on less than 10 qubits that is 2-pairable using LOCC protocol based on Pauli measurements.

A natural generalization is to consider quantum states satisfying a stronger property: for some integer k, it is possible to induce any stabilizer state on any subset of k qubits, by means of LOCC protocols. We call these states k-stabilizer universal. Stabilizer states constitute a powerful resource for multipartite quantum protocols [17, 19, 23, 28], and can be described, up to local [1] unitaries, by the formalism of graph states: a subset of quantum states which are in one-to-one correspondence with (undirected, simple) graphs. $2k$-stabilizer universality is a stronger notion than k-pairability: any $2k$-stabilizer universal state is k-pairable, as EPR pairs are stabilizer states.

Our contributions rely on the graph state formalism and the ability to characterize properties of quantum states using tools from graph theory. In particular, we reformulate k-pairability as a property of a graph (rather than a property of a quantum state), such that the graph state corresponding to a k-pairable graph, is k-pairable. Furthermore, we relate pairability to the standard notion of vertex-minor (a complete and up-to-date survey on vertex-minors can be found in [20]). A graph H is a vertex-minor of G if one can transform G into H by means of local complementations[2] and vertex deletions. If H is a vertex-minor of G then the graph state $|H\rangle$ can be obtained from $|G\rangle$ using only local Clifford operations,

[1] As we consider one qubit per party, "local" is to be understood as "on each single qubit independently".
[2] Local complementation on a vertex u consists in complementing the subgraph induced by its neighbors.

local Pauli measurements and classical communications. Dahlberg, Helsen, and Wehner proved that the converse is also true when H has no isolated vertices [10]. In [9], they proved that it is NP-complete[3] to decide whether a graph state can be transformed into a set of EPR pairs on specific qubits using using only local Clifford operations, local Pauli measurements and classical communications. In [8], they showed that it is also NP-complete to decide whether a graph state can be transformed into another one using using only local Clifford operations, local Pauli measurements and classical communications.

The graphical counterpart of k-stabilizer universal graph states are called k-vertex-minor universal graphs, introduced by some of the authors in [6]: a graph is k-vertex minor universal if it has any graph defined on any k of its vertices as a vertex minor. If a graph is k-vertex-minor universal then the corresponding graph state is k-stabilizer universal. Stabilizer universal states (and thus k-vertex-minor universal graphs) are useful in themselves beyond the fact that they imply pairability, as they can serve as a primitive for quantum protocols using multipartite entanglement. For instance, in [6], it is shown that stabilizer universal states constitute a resource to perform a robust pairability protocol, in the sense that it allows some known parties to be malicious, while ensuring the correctness of the protocol. Furthermore, the notion of stabilizer universality is stronger than the notion of pairability. Nevertheless, while previous work [6] establishes the existence of k-stabilizer universal graph states of size $n = O(k^4 \ln(k))$ and of k-pairable graph states of size $n = O(k^3 \ln^3(k))$, there are no known graph states that are k-pairable but not $2k$-stabilizer universal.

In this work, we provide both probabilistic and explicit constructions of k-stabilizer universal graph states resulting from k-vertex-minor universal graphs. While the results are interesting in themselves from a combinatorial perspective, they allow one to explicitly define quantum communication protocols: if a k-stabilizer universal graph state is prepared, and each qubit is sent to a different party, then, with the assumption that each party can perform local quantum operations and that they can share classical information, any stabilizer state on any k qubits can be generated. Note that this includes any set of disjoint EPR pairs on less than k qubits. The local operations to perform in order to induce a given subgraph state derive directly from the proofs of our results.

The main contributions of the paper are as follows. In the first part of the paper, we prove the existence of k-vertex-minor universal graphs of order $n = \Theta(k^2)$, which is optimal as shown in [6]. We adopt a probabilistic approach, exhibiting a family of random bipartite graphs of quadratic order in k, which are k-vertex-minor universal with probability going to 1 exponentially fast in k. On the practical side, in the proof we introduce an efficient algorithm that tries to generate any induced graph of order k as a vertex-minor on any k vertices of a random bipartite graph, and the proof yields a bound on the probability of failure of the algorithm. The second part of the paper focuses on explicit constructions of k-vertex-minor universal graphs. We derive our constructions from the incidence graph of the projective plane over the finite field $\mathbb{F}_q$, where q is a prime power. It is a bipartite graph of order $n = 2(q^2 + q + 1)$, with the same number $(n/2)$ of left and right vertices, corresponding respectively to points and lines of the projective plane (equivalently, 1-dimensional and 2-dimensional linear subspaces of $\mathbb{F}_q^3$). We show it satisfies the k-vertex-minor universality property, with $k = \Theta(n^{1/4})$. Furthermore, we show that the graph on the points of the projective plane, with edges connecting points corresponding to orthogonal 1-dimensional linear subspaces of $\mathbb{F}_q^3$, is k-vertex-minor universal, again with $k = \Theta(n^{1/4})$. To the best of our knowledge, these are the first explicit constructions of k-vertex-minor universal graphs of order polynomial in k, significantly improving on the previous explicit construction of k-pairable states based on Reed-Muller codes from [2], with exponential overhead.

[3] Where the size of the input is the number of bits needed to describe the given graph state.

2 Vertex-minor and stabilizer universality

The goal of this section is to cover different notions related to k-pairability and k-vertex-minor universality properties. We first define the above properties for graphs, then we discuss their implications on the corresponding graph states.

We denote a graph as $G = (V, E)$, where V is the vertex set and E is the edge set. All graphs are assumed to be undirected and simple (without loops or multiple edges). A vertex subset $S \subseteq V$ is said to be **stable** if no two vertices in S are adjacent. Bipartite graphs are denoted as $G = (L, R, E)$, where $V = L \sqcup R$, with L and R disjoint stable sets referred to as **left and right vertex sets**, respectively. To avoid possible confusion, we may sometimes write $V(G), E(G), L(G)$, or $R(G)$. A **pairing** is a graph G such that any vertex is incident to exactly one edge. Given a vertex $v \in V$, we denote by $N_G(v)$ the **neighborhood** of v in G, consisting of vertices $v \in V$ adjacent to v.

A **local complementation** on a vertex v of a graph G consists in complementing the subgraph induced by the neighborhood of v, more precisely, it leads to a graph $G \star v$ such that $V(G \star v) = V(G)$ and $E(G \star v) = E(G) \oplus E(K_{N_G(v)})$ where K_S denotes the complete graph on the vertices in S, and $\oplus$ denotes the symmetric difference of two sets. We say that G' is a **vertex-minor** of G, if G' can be obtained from G by means of local complementations and vertex deletions. Here we consider $V(G') \subseteq V(G)$ and require G' to be obtained exactly (not up to an isomorphism of graphs), meaning that there exists a sequence of graph transformations consisting of local complementations and the deletions of the vertices of $V(G) \setminus V(G')$.

▶ **Definition 1.** *Given a graph G, a vertex subset $V' \subseteq V(G)$, and an integer $k > 0$, we say that:*

- *G is k-**vertex-minor universal** on V', if $k \leqslant |V'|$ and any graph on any k vertices in V' is a vertex-minor of G.*
- *G is k-**pairable** on V', if $k \leqslant |V'|/2$ and any pairing on any $2k$ vertices in V' is a vertex-minor of G.*

If any of the above properties is satisfied with $V' = V(G)$, we say that G is k-vertex-minor universal *or that G is* k-pairable*, respectively.*

▶ **Definition 2.** *We say that a bipartite graph $G = (L, R, E)$ is **left** (resp. **right**) k-**vertex-minor universal** or k-**pairable** if the corresponding condition from Definition 1 is satisfied for $V' = L$ (resp. $V' = R$). We say that G is **two-side** k-vertex-minor universal / k-pairable if it is both left and right k-vertex-minor universal / k-pairable.*

Graph states form a standard family of quantum states that can be represented using simple undirected graphs (Ref. [17] is an excellent introduction to graph states). Given a graph $G = (V, E)$, the corresponding **graph state** $|G\rangle$ is the $|V|$-qubit state:

$$|G\rangle = \frac{1}{\sqrt{2}^{|V|}} \sum_{x \in 2^V} (-1)^{|G[x]|} |x\rangle$$

where $|G[x]|$ is the size (number of edges) of the subgraph induced by x, and $|x\rangle$ is the corresponding base vector in the Hilbert space[4].

[4] With a slight abuse of notation we identify a subset (say $x = \{u_2, u_4\}$) of the set of qubits $V = \{u_1, \ldots, u_5\}$ with its characteristic binary word ($x = 01010$).

We shall alternatively refer to the vertex set V as qubit set. A graph state $|G\rangle$ can be prepared as follows: initialize every qubit in $|+\rangle = \frac{|0\rangle+|1\rangle}{\sqrt{2}}$ then apply for each edge of the graph a CZ gate on the corresponding pair of qubits, where $CZ : |ab\rangle \mapsto (-1)^{ab}|ab\rangle$. The graph state $|G\rangle$ is the unique quantum state (up to a global phase) that, for every vertex $u \in V$, is a fixed point of the Pauli operator $X_u Z_{N_G(u)}$.[5] Hence, graph states form a subfamily of stabilizer states. Formally, an n-qubit **stabilizer state** [15] is a quantum state that is the simultaneous eigenvector with eigenvalue 1 of n commuting and independent Pauli operators. A useful property is that any stabilizer state is related to some graph state by the application of local Clifford unitaries, and these unitaries can be computed efficiently [11]. For instance, an EPR pair is equal to $|K_2\rangle$ up to local Clifford unitaries, where K_2 is the graph with two vertices and one edge. Thus, under LOCC protocols, generating any graph state on a given set of qubits is equivalent to generating any stabilizer state. We introduce below the notion of k-stabilizer universal states.

▶ **Definition 3.** *A quantum state $|\psi\rangle$ is k-**stabilizer universal** (resp., k-**pairable**) if any stabilizer state on any k qubits in V (resp., any k EPR pairs on any $2k$ qubits in V) can be induced by means of LOCC protocols.*

If H is a vertex-minor of a G then the graph state $|H\rangle$ can be obtained from $|G\rangle$ using only local Clifford operations, local Pauli measurements and classical communications, and the converse is true when H has no isolated vertices [10]. As a pairing on $2k$ vertices has no isolated vertices, we have the following:

▶ **Proposition 4.** *A graph G is k-pairable if and only if the corresponding graph state $|G\rangle$ is k-pairable using only local Clifford operations, local Pauli measurements, and classical communication.*

In the case of vertex-minor universality and stabilizer universality, the characterization from [10] does not apply directly, because of possible isolated vertices. For instance, K_2 is not 2-vertex-minor universal since no local complementation can turn it into an empty graph. However, $|K_2\rangle$ is 2-stabilizer universal: with *e.g.* an X-measurement on each qubit, one can map the corresponding graph state (a maximally entangled pair of qubits) to the graph state composed of a tensor product of two qubits. To be able to state a characterization, a solution is to introduce *destructive* measurements (*i.e.*, the measured qubit is removed from the system and can no longer be used).

▶ **Proposition 5.** *Given two graphs G and H such that $V(H) \subseteq V(G)$, H is a vertex-minor of G if and only if $|H\rangle$ can be obtained from $|G\rangle$ (on the qubits corresponding to $V(H)$) using only local Clifford operations, local destructive Pauli measurements, and classical communications.*

Proof. Notice that a similar statement – involving non-destructive measurements and only valid when H does not contain isolated vertices – has been proved in [10] (Theorem 2.2). We provide here a direct proof of Proposition 5 which is actually slightly simpler thanks to the use of destructive measurements. In the following proof all measurements are destructive. ($\Rightarrow$) Local complementations can be implemented by means of local Clifford unitaries, and vertex deletions by means of Z-measurements together with classical communications and Pauli corrections [11]. ($\Leftarrow$) We prove the property by induction on the number of measurements. If

[5] It consists in applying $X : |a\rangle \mapsto |1-a\rangle$ on u and $Z : |a\rangle \mapsto (-1)^a|a\rangle$ on each of its neighbors in G.

there are no measurements the property is true [11]. Otherwise, let u be the first qubit to be measured. Assume u is measured according to P and C_u is the Clifford operator applied on u before the measurement. $C_u^\dagger P C_u$ is proportional to some Pauli operator $P_0 \in \{X, Y, Z\}$:

(i) if $P_0 = Z$, then the measurement of u can be interpreted as a vertex deletion and leads to $|G \setminus u\rangle$ up to Pauli corrections. By the induction hypothesis, H is a vertex minor of $G \setminus u$, thus of G.

(ii) if $P_0 = Y$, then the measurement of u can be interpreted as a Z-measurement on $|G \star u\rangle$ (up to a Clifford operator on some other qubits), thus according to (i), H is a vertex minor of $G \star u$, so is of G.

(iii) if $P_0 = X$ and $N_G(u) \neq \emptyset$, then the measurement u can be interpreted as a Y-measurement on $|G \star v\rangle$ with $v \in N_G(u)$ (up to local Clifford operations on qubits different from u), thus according to (ii) H is a vertex minor of $G \star v$, so is of G.

(iv) if $P_0 = X$ and $N_G(u) = \emptyset$, then $|G\rangle = |G \setminus u\rangle \otimes |+\rangle_u$ so after the measurement of u the state is $|G \setminus u\rangle$, thus, by the induction hypothesis, H is a vertex minor of $G \setminus u$, so is of G. ◀

▶ **Corollary 6.** *A graph G is k-vertex-minor universal if and only if the corresponding graph state $|G\rangle$ is k-stabilizer universal using only local Clifford operations, local destructive Pauli measurements, and classical communication.*

Relations between pairability, vertex-minor universality and stabilizer universality of graph and graph states, are shown in Figure 1. To the best of our knowledge, all known examples of k-stabilizer universal (resp. k-pairable) graph states come from k-vertex-minor universal (resp. k-pairable) graphs. Furthermore, to date, it is not known whether there exist k-pairable states which are not $2k$-stabilizer universal. Throughout this paper, we will essentially focus on the existence and the explicit construction of k-vertex-minor universal graphs.

$$\begin{array}{ccc} G \text{ is } 2k\text{-vertex-minor universal} & \Longrightarrow & |G\rangle \text{ is } 2k\text{-stabilizer universal} \\ \Downarrow & & \Downarrow \\ G \text{ is } k\text{-pairable} & \Longrightarrow & |G\rangle \text{ is } k\text{-pairable} \end{array}$$

Figure 1 Implications between pairability, vertex-minor universality and stabilizer universality of graphs and graph states.

3 Existence of k-vertex-minor universal graphs of order quadratic in k

Given any k, a k-vertex-minor universal graph has at least a quadratic order in k:

▶ **Proposition 7** ([6]). *If a graph G of order n is k-vertex-minor universal then*

$$k < \sqrt{2n \log_2(3)} + 2.$$

In this section we prove that this bound is tight asymptotically, *i.e.* there exists k-vertex-minor universal graphs whose order grows quadratically with k. This greatly improves over the probabilistic construction obtained by some of us in [6], where the existence of k-vertex-minor universal graphs of order $O(k^4 \ln(k))$ was proven.

▶ **Theorem 8.** *For any constant $\alpha > 2$, there exists k_0 s.t. for any $k > k_0$, there exists a k-vertex-minor universal graph G of order at most αk^2.*

The remaining of this section is a proof of Theorem 8. First we bound the probability that some graph of order k is not a vertex-minor of a random bipartite graph G, in Lemma 10. Then we bound the probability that such a random bipartite graph is k-vertex-minor universal, in Lemma 11, by defining some algorithm that tries to generate any graph as a vertex-minor of G. Finally, we prove that there exists a k-vertex-minor universal bipartite graph of quadratic order in k. More precisely, the probability of a random bipartite graph of quadratic order being k-vertex-minor universal goes to 1 exponentially fast in k:

▶ **Proposition 9.** *Fix constants $\epsilon > 0$, $c > 2$, and $c' > \frac{1+\epsilon}{\ln(2)}$. There exists k_0 s.t. for any $k > k_0$, the random bipartite graph G (the probability of an edge existing between two vertices, one in $L(G)$ and one in $R(G)$, is $1/2$, independently of the other edges) with $|L(G)| = \lfloor c' k \ln(k) \rfloor$ and $|R(G)| = \lfloor ck^2 \rfloor$, is k-vertex-minor universal with probability at least $1 - e^{-\epsilon k \ln(k)}$.*

Proposition 9 will be proved alongside Theorem 8 in this section. Notation-wise, given a set A and an integer k, $\binom{A}{k}$ refers to $\{B \subseteq A \mid |B| = k\}$.

▶ **Lemma 10.** *Consider a random bipartite graph G with $|L(G)| \geqslant k$, $|R(G)| \geqslant 4\binom{k}{2} + 5$: the probability of an edge existing between two vertices (one in $L(G)$ and one in $R(G)$) is $1/2$, independently of the other edges. Take $k \in \mathbb{N}$ and consider a set of vertices $K \in \binom{L(G)}{k}$. The probability that there exists a graph defined on K which is not a vertex-minor of G is upper bounded by $e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2} + 1\right)^2}{\left(\frac{7|R(G)|}{4} - \binom{k}{2} + 1\right)}}$.*

Proof. For some $j \in \mathbb{N} \setminus \{0\}$ and $X \in \binom{R(G)}{j}$, consider the incidence matrix M_X of size $j \times \binom{k}{2}$, whose column i represents the pairs of vertices of K that are in the neighborhood of the i^{th} vertex of X, in the sense that its entries are 1 if the pair of vertices u,v is in its neighborhood, 0 else. Note that if there exists some $X \in \binom{R(G)}{\binom{k}{2}}$ whose incidence matrix M_X is of full column-rank, then any $2^{\binom{k}{2}}$ graph defined on K is a vertex-minor of G. Indeed, column number i represents the edges (resp. non-edges) of K to be toggled by a local complementation on the i^{th} vertex of X. So now we will bound the probability of such a set X existing within $R(G)$.

For this purpose we will greedily try to construct the set $X \in \binom{R(G)}{\binom{k}{2}}$, one vertex after the other, by considering each vertex in $R(G)$ one by one, and we will lower bound the probability of the event "there exists some $X \in \binom{R(G)}{\binom{k}{2}}$ whose incidence matrix M_X is of full column-rank" by the probability of success of the algorithm. The algorithm works as follows. Arbitrarily order the vertices of $R(G)$. At each step (say that we have j vertices in X at some step), suppose the corresponding matrix of incidence (of size $j \times \binom{k}{2}$) full column-rank. We consider the next vertex $u \in R(G)$ in the list: if adding its corresponding vector to M_X increases its column-rank, then we add u to X, else we remove u from the vertices to consider. The algorithm stops (and succeeds) if M_X has $\binom{k}{2}$ columns and is full column-rank. Let us show that the probability of a vertex u increasing the column-rank of M_X (if $j < \binom{k}{2}$) is lower-bounded by $1/4$.

If M_X is of rank $j < \binom{k}{2}$, there exists a non-zero vector W (*i.e.* a set of pairs of vertices of K) which is orthogonal to all j first vectors. W can be seen as the characteristic function of the edges of some graph H on the vertices of $L(G)$. Adding a vertex u to X increases the

rank of M_X if the vector U of incidence of u in K is such that $U \cdot W = 1 \mod 2$ (because then U is not in the span of M_X). Note that, if H has exactly one edge, then there is exactly probability $\frac{1}{4}$ that $U \cdot W = 1 \mod 2$ (in this case the two ends of the unique edge of H are connected to u, which happens with probability $\frac{1}{2} \times \frac{1}{2}$). As H has at least one edge, it has at least one vertex of non-zero degree z. Let us draw randomly the neighborhood of u: first we draw among the vertices of $H \setminus \{z\}$, then we add z with probability $\frac{1}{2}$. The probability that an odd number of neighbors of z are neighbors of u is $1/2$, so drawing z changes the parity of the number of edges in H whose ends are both neighbors of u, with probability $1/2$. At the end of the day there is a probability of at least $\frac{1}{4}$ that $U \cdot W = 1 \mod 2$, so that u increases the column-rank of M_X.

Finally, the algorithm fails if we encounter more than $|R(G)| - \binom{k}{2} + 1$ vertices that did not increase the column-rank of M_X. Let us introduce a random variable T that follows the distribution $B(|R(G)|, 3/4)$. The probability that the algorithm fails is upper bounded by $\Pr(T \geqslant |R(G)| - \binom{k}{2} + 1)$. We will use the Chernoff bound: With $\mu = \mathbb{E}[T] = \frac{3|R(G)|}{4}$, for any $\delta > 0$, $\Pr(T \geqslant (1+\delta)\mu) \leqslant e^{-\frac{\delta^2}{2+\delta}\mu}$. As we need $(1+\delta)\mu = |R(G)| - \binom{k}{2} + 1$, we take $\delta = \frac{|R(G)| - \binom{k}{2} + 1 - \mu}{\mu}$. From $|R(G)| \geqslant 4\binom{k}{2} + 5$ it follows that $\delta > 0$. The Chernoff bound then gives

$$\Pr\left(T \geqslant |R(G)| - \binom{k}{2} + 1\right) \leqslant e^{-\frac{\left(\frac{|R(G)| - \binom{k}{2} + 1 - \mu}{\mu}\right)^2}{\left(\frac{|R(G)| - \binom{k}{2} + 1 + \mu}{\mu}\right)}\mu} = e^{-\frac{\left(|R(G)| - \binom{k}{2} + 1 - \mu\right)^2}{\left(|R(G)| - \binom{k}{2} + 1 + \mu\right)}} = e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2} + 1\right)^2}{\left(\frac{7|R(G)|}{4} - \binom{k}{2} + 1\right)}}$$

So the probability of the existence of $X \subseteq \binom{R(G)}{k}$ whose incidence matrix M_X if of full column-rank is lower bounded by $1 - e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2} + 1\right)^2}{\left(\frac{7|R(G)|}{4} - \binom{k}{2} + 1\right)}}$. ◀

▶ **Lemma 11.** *Consider a random bipartite graph G with $|L(G)| \geqslant k$, $|R(G)| \geqslant 4\binom{k}{2} + 5$: the probability of an edge existing between two vertices (one in $L(G)$ and one in $R(G)$) is $1/2$, independently of the other edges. The probability that G is k-vertex-minor universal is lower bounded by*

$$1 - \left(\frac{k}{2^{|L(G)|-k+1}} + e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2} + 1\right)^2}{\left(\frac{7(|R(G)|-k)}{4} - \binom{k}{2} + 1\right)}} \right) \times \binom{|L(G)| + |R(G)|}{k}$$

The proof makes use of the union bound along with Lemma 10, and can be found in the extended version of this paper [3]. Roughly speaking, the proof introduces an algorithm that makes use of pivoting to get all k vertices of some set $K \subseteq V(G)$ on the left side of the bipartite graph, in order to use Lemma 10 properly.

▶ Remark 12. Lemma 11 has concrete applications on its own right: in particular for any integer k, it yields an integer n such that there exists a (bipartite) k-vertex-minor universal graph of order n. In general, one can infer a lower bound on the probability of generating a k-vertex-minor universal graph, for any choice of k and n, using the algorithm presented in the proof of Lemma 11. A table presenting orders for which some bipartite k-vertex-minor universal graph exists, as well as orders for with a randomly generated bipartite graph is k-vertex-minor universal with at least 99% probability, for particular values of k ranging from 3 to 100, can be found in Appendix A. Surprisingly enough, we observe that a small constant additive overheard in the order of the graph is sufficient to attain a high probability of generating a k-vertex-minor universal graph.

Now we are ready to conclude. Fix some constants $c > 2$ and $c' > \frac{1}{\ln(2)}$. Let G be a random bipartite graph G with $|L(G)| = \lfloor c'k\ln(k)\rfloor$ and $|R(G)| = \lfloor ck^2\rfloor$: the probability of an edge existing between two vertices (one in $L(G)$ and one in $R(G)$) is $1/2$, independently of the other edges.

Note $n = |V| = |L(G)| + |R(G)| = \lfloor c'k\ln(k)\rfloor + \lfloor ck^2\rfloor$. Using Lemma 11, the probability that G is k-vertex-minor universal is lower bounded by

$$1 - \left(\frac{k}{2^{|L(G)|-k+1}} + e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2}+1\right)^2}{\left(\frac{7(|R(G)|-k)}{4} - \binom{k}{2}+1\right)}} \right) \times \binom{n}{k}$$

Let us prove that this probability is positive with our choice of parameters, for some big enough k. It is sufficient to have:

$$\textbf{(1)}\quad \frac{k}{2^{|L(G)|-k+1}}\binom{n}{k} < \frac{1}{2} \quad \text{and} \quad \textbf{(2)}\quad e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2}+1\right)^2}{\left(\frac{7(|R(G)|-k)}{4} - \binom{k}{2}+1\right)}}\binom{n}{k} < \frac{1}{2}$$

Let us show that these equations are satisfied for any large enough k. Recall that $\binom{n}{k} \leqslant 2^{nH(k/n)}$ where $H(x) = -x\log_2(x) - (1-x)\log_2(1-x)$ is the binary entropy.

(1): It is sufficient that $\log_2(k) + nH(k/n) - |L(G)| + k - 1 < -1$.

$\log_2(k) + nH(k/n) - |L(G)| + k - 1 \sim_{k\to\infty} n\frac{k}{n}\log_2(\frac{k}{n}) - c'k\ln(k) = k(\log_2(k) - \log_2(n)) - c'k\ln(k) \sim_{k\to\infty} \frac{1}{\ln(2)}k\ln(k) - c'k\ln(k)$. The choice of c' guarantees that for any large enough k, **(1)** is satisfied.

(2): It is sufficient that $nH(k/n)\ln(2) - \frac{\left(\frac{|R(G)|}{4} - \binom{k}{2}+1\right)^2}{\left(\frac{7(|R(G)|-k)}{4} - \binom{k}{2}+1\right)} < -\ln(2)\cdot\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2}+1\right)^2}{\left(\frac{7(|R(G)|-k)}{4} - \binom{k}{2}+1\right)}$ $\sim_{k\to\infty} \frac{\left(\frac{ck^2}{4} - \frac{k^2}{2}\right)^2}{\left(\frac{7ck^2}{4} - \frac{k^2}{2}\right)} = k^2\frac{(c-2)^2}{4(7c-2)}$. We saw above that $nH(k/n)\ln(2) \sim_{k\to\infty} k\ln(k)$. The choice of c guarantees that for any large enough k, **(1)** is satisfied.

This proves that, for any large enough k, G of order $\lfloor c'k\ln(k)\rfloor + \lfloor ck^2\rfloor$, is k-vertex-minor universal with non-zero probability. Taking $\alpha > c$, for any large enough k, $\lfloor c'k\ln(k)\rfloor + \lfloor ck^2\rfloor \leqslant \alpha k^2$, proving Theorem 8.

Furthermore, we just saw that side **(1)** of the equation dominates **(2)** asymptotically. Thus, the probability of G being k-vertex-minor universal is roughly lower bounded by $1 - 2^{\frac{1}{\ln(2)}k\ln(k) - c'k\ln(k)} = 1 - e^{-(\ln(2)c'-1)k\ln(k)}$ as k grows. Then, for any $\epsilon > 0$ such that $\epsilon < ln(2)c' - 1$, for any large enough k, G of order $\lfloor c'k\ln(k)\rfloor + \lfloor ck^2\rfloor$, is k-vertex-minor universal with probability at least $1 - e^{-\epsilon k\ln(k)}$, proving Proposition 9.

4 Vertex-minor universal graphs from projective planes

In this section, we provide explicit constructions of families of k-vertex-minor universal graphs, of order n proportional to k^4. Thus, the order of the constructed graphs scales as the square of the asymptotically optimal graph order from Section 3. We start in Section 4.1 with some preparatory lemmas. In Section 4.2, we introduce a family of *bipartite incidence graphs* of projective planes, and study their k-pairability and k-vertex-minor universality properties. In Section 4.3 we introduce a new family of so-called *reduced graphs* from projective planes, and investigate their k-vertex-minor universality properties.

4.1 Sufficient conditions for k-pairability and k-vertex-minor universality

Below and throughout Section 4, given a graph G, a vertex $v \in V(G)$, and a vertex subset $U \subseteq V(G)$, we shall use the **shorthand notation** $N_U(v) := N_G(v) \cap U$, that is, **the set of neighbors of v that belong to U** (in such a case, we shall always ensure that the context makes the choice of G unambiguous).

The following two lemmas give sufficient conditions for a bipartite graph G to be one-side (*i.e.*, left or right) k-pairable or k-vertex-minor universal. For simplicity, we state these conditions for the set of left vertices.

▶ **Lemma 13.** *Let G be a bipartite graph satisfying the following property:*

(P) *For any set of $2k$ vertices $K = \{u_1, v_1, u_2, v_2, \ldots, u_k, v_k\} \subseteq L(G)$, there exist:*

- **(i)** *a set of k vertices $C = \{c_1, c_2, \ldots, c_k\} \subseteq L(G)$, with $C \cap K = \emptyset$, and*
- **(ii)** *a set of $2k$ vertices $S = \{\alpha_1, \beta_1, \alpha_2, \beta_2, \ldots, \alpha_k, \beta_k\} \subseteq R(G)$, such that $N_{K \cup C}(\alpha_i) = \{u_i, c_i\}$ and $N_{K \cup C}(\beta_i) = \{v_i, c_i\}$, for all $i = 1, \ldots, k$.*

Then G is left k-pairable.

Proof. We use first local complementation on vertices α_i and β_i to create edges (u_i, c_i) and (v_i, c_i), followed by local complementation on vertices c_i to create edges (u_i, v_i), as desired. It is easily seen that no edges are created between u_i and $K \setminus \{v_i\}$, or between v_i and $K \setminus \{u_i\}$. ◀

▶ **Lemma 14.** *Let G be a bipartite graph satisfying the following property:*

(VMU) *For any set of k vertices $K = \{u_1, u_2, \ldots, u_k\} \subseteq L(G)$, there exist:*

- **(i)** *a set of $k(k-1)/2$ vertices $C = \{c_{ij} \mid 1 \leqslant i < j \leqslant k\} \subseteq L(G)$, with $C \cap K = \emptyset$, and*
- **(ii)** *a set of $k(k-1)$ vertices $S = \{\alpha_{ij}, \beta_{ij} \mid 1 \leqslant i < j \leqslant k\} \subseteq R(G)$, such that $N_{K \cup C}(\alpha_{ij}) = \{u_i, c_{ij}\}$ and $N_{K \cup C}(\beta_{ij}) = \{u_j, c_{ij}\}$, for all $1 \leqslant i < j \leqslant k$.*

Then G is left k-vertex-minor universal.

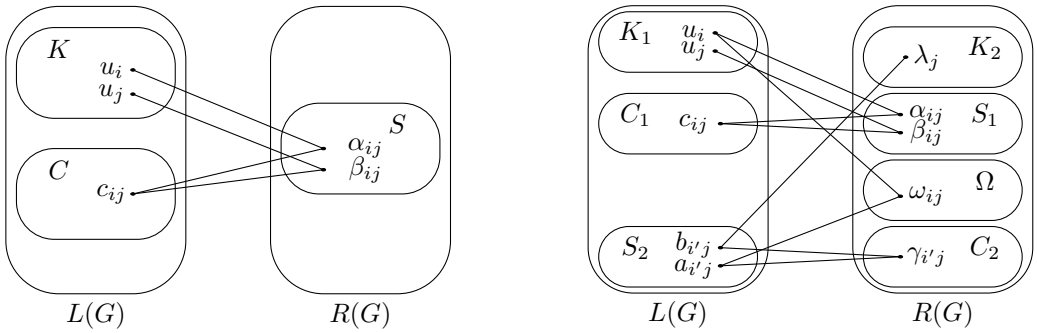
Proof. (See also Figure 2a.) The proof is similar to that of Lemma 13. To create an edge between u_i and u_j, we use first local complementation on vertices α_{ij} and β_{ij}, followed by local complementation on vertex c_{ij}. This procedure does not create any other edge between the vertices of K. ◀

Providing sufficient conditions for a bipartite graph G to be k-vertex-minor universal (on the entire vertex set) is more involved. To induce an arbitrary graph with vertex set $K = K_1 \sqcup K_2$, where $K_1 \subseteq L(G)$ and $K_2 \subseteq R(G)$, we may need to create edges with both endpoints in either K_1 or K_2, which can be dealt with by using conditions similar to those in Lemma 14, but also "toggle" (*i.e.*, either create or remove, as needed) edges between K_1 and K_2, which represents an additional difficulty. We give sufficient conditions for doing so, in the lemma below (see also Figure 2b).

▶ **Lemma 15.** *Let G be a bipartite graph satisfying the following property:*

(VMU*) *For any set of k vertices $K = K_1 \sqcup K_2$, with $K_1 = \{u_1, \ldots, u_{k_1}\} \subseteq L(G)$, and $K_2 = \{\lambda_1, \ldots, \lambda_{k_2}\} \subseteq R(G)$, there exist:*

- **(i)** *a subset $C_1 = \{c_{ij} \mid 1 \leqslant i < j \leqslant k_1\} \subseteq L(G)$, such that $C_1 \cap K_1 = \emptyset$ and $N_{K_2}(C_1) = \emptyset$,*
- **(ii)** *a subset $S_1 = \{\alpha_{ij}, \beta_{ij} \mid 1 \leqslant i < j \leqslant k_1\} \subseteq R(G)$, such that $S_1 \cap K_2 = \emptyset$ and for all $1 \leqslant i < j \leqslant k_1$, $N_{K_1 \sqcup C_1}(\alpha_{ij}) = \{u_i, c_{ij}\}$ and $N_{K_1 \sqcup C_1}(\beta_{ij}) = \{u_j, c_{ij}\}$,*
- **(iii)** *a subset $\Omega = \{\omega_{ij} \mid 1 \leqslant i \leqslant k_1, 1 \leqslant j \leqslant k_2\} \subseteq R(G)$ such that $\Omega \cap (K_2 \sqcup S_1) = \emptyset$ and for all $1 \leqslant i \leqslant k_1, 1 \leqslant j \leqslant k_2$, $N_{K_1 \sqcup C_1}(\omega_{ij}) = \{u_i\}$,*
- **(iv)** *a subset $C_2 = \{\gamma_{ij} \mid 1 \leqslant j \leqslant k_2, j < i \leqslant k_1 + k_2\} \subseteq R(G)$ such that $C_2 \cap (K_2 \sqcup S_1 \sqcup \Omega) = \emptyset$ and $N_{K_1 \sqcup C_1}(C_2) = \emptyset$,*



(a) (VMU) conditions.

(b) (VMU*) conditions where $i' := i + k_2$.

Figure 2 Illustration of the (VMU) and (VMU*) conditions from Lemma 14 and Lemma 15.

(v) *a subset* $S_2 = \{a_{ij}, b_{ij} \mid 1 \leqslant j \leqslant k_2, j < i \leqslant k_1+k_2\} \subseteq L(G)$ *such that* $S_2 \cap (K_1 \sqcup C_1) = \emptyset$ *and for all* $1 \leqslant j \leqslant k_2$, $j < i \leqslant k_1 + k_2$,
- $N_{K_2 \sqcup S_1 \sqcup \Omega \sqcup C_2}(a_{ij}) = \{\lambda_i, \gamma_{ij}\}$ *and* $N_{K_2 \sqcup S_1 \sqcup \Omega \sqcup C_2}(b_{ij}) = \{\lambda_j, \gamma_{ij}\}$, *if* $i \leqslant k_2$
- $N_{K_2 \sqcup S_1 \sqcup \Omega \sqcup C_2}(a_{ij}) = \{\omega_{(i-k_2)j}, \gamma_{ij}\}$ *and* $N_{K_2 \sqcup S_1 \sqcup \Omega \sqcup C_2}(b_{ij}) = \{\lambda_j, \gamma_{ij}\}$, *otherwise.*

Then G *is* k*-vertex-minor universal.*

Proof. We start by removing all vertices that are not in any set defined in (VMU*). Then we proceed in the following three steps.

1) In case we need to create an edge (u_i, u_j) for $1 \leqslant i < j \leqslant k_1$ between two vertices in K_1. We first use local complementations on α_{ij} and β_{ij} to create edges (u_i, c_{ij}) and (u_j, c_{ij}) (no other edges are created) and then remove α_{ij} and β_{ij}. Then, we use local complementation on c_{ij} to create the edge (u_i, u_j) (no other edges are created). Finally, we remove vertex c_{ij}, thus only the edge (u_i, u_j) has been constructed.
2) In case we need to create an edge (λ_i, λ_j) for $1 \leqslant j < i \leqslant k_2$ between two vertices in K_2. We first use local complementations on a_{ij} and b_{ij} to create edges (λ_i, γ_{ij}) and (λ_j, γ_{ij}) (no other edges are created) and then remove a_{ij} and b_{ij}. Then, we use local complementation on γ_{ij} to create the edge (λ_i, λ_j) (no other edges are created). Finally, we remove vertex γ_{ij}, thus only the edge (λ_i, λ_j) has been constructed.
3) In case we need to toggle an edge (u_i, λ_j) for $1 \leqslant i \leqslant k_1$ and $1 \leqslant j \leqslant k_2$ between two vertices in K_1 and K_2. We first use local complementations on $a_{(i+k_2)j}$ and $b_{(i+k_2)j}$ to create edges $(\omega_{ij}, \gamma_{(i+k_2)j})$ and $(\lambda_j, \gamma_{(i+k_2)j})$ (no other edges are created) and then remove $a_{(i+k_2)j}$ and $b_{(i+k_2)j}$. Then, we use local complementation on $\gamma_{(i+k_2)j}$ to create the edge (ω_{ij}, λ_j) (no other edges are created). After that, we remove vertex γ_{ij}, thus only the edge (ω_{ij}, λ_j) has been constructed. Finally, we use local complementation on ω_{ij} to create the edge (u_i, λ_j) (no other edges are created). Then, we remove vertex ω_{ij}, thus only the edge (u_i, λ_j) has been toggled. ◀

The following lemma is a generalization of Lemma 14 to the case of general (not necessarily bipartite) graphs.

▶ **Lemma 16.** *Let* G *be a graph satisfying the following property:*

(VMU$^\circ$) *For any set of* k *vertices* $K = \{u_1, u_2, \ldots, u_k\} \subseteq V(G)$*, there exist:*
- **(i)** *a set of* $k(k-1)/2$ *vertices* $C = \{c_{ij} \mid 1 \leqslant i < j \leqslant k\} \subseteq V(G)$*, such that* C *is stable,* $C \cap K = \emptyset$*, and* $N_K(c_{ij}) = \emptyset$*, for all* $1 \leqslant i < j \leqslant k$*, and*
- **(ii)** *a set of* $k(k-1)$ *vertices* $S = \{a_{ij}, b_{ij} \mid 1 \leqslant i < j \leqslant k\} \subseteq V(G)$*, such that* S *is stable,* $S \cap (K \cup C) = \emptyset$*,* $N_{K \cup C}(a_{ij}) = \{u_i, c_{ij}\}$ *and* $N_{K \cup C}(b_{ij}) = \{u_j, c_{ij}\}$*,* $\forall 1 \leqslant i < j \leqslant k$*.*

Then G *is* k*-vertex-minor universal.*

Proof. Whenever we need to create or to remove an edge between vertices $u_i, u_j \in K$, we use first local complementation on vertices a_{ij} and b_{ij} to create edges between u_i and c_{ij}, and between u_j and c_{ij}, and then we use local complementation on c_{ij}. ◀

4.2 Bipartite graphs from projective planes

Let $q > 0$ be a prime power, $\mathbb{F}_q$ be the finite field with q elements, and $\mathrm{PG}(2,q) := \left(\mathbb{F}_q^3\right)^* / \mathbb{F}_q^*$ be the *projective plane* over $\mathbb{F}_q$. *Points* and *lines* of $\mathrm{PG}(2,q)$ are identified respectively to 1-dimensional and 2-dimensional linear subspaces of $\mathbb{F}_q^3$. A line λ passes through a point a (we write $a \in \lambda$) if the 2-dimensional linear subspace of $\mathbb{F}_q^3$ corresponding to λ contains the 1-dimensional linear subspace corresponding to a. We will use the following properties of the projective plane:

- $\mathrm{PG}(2,q)$ has q^2+q+1 points and q^2+q+1 lines.
- Any line contains exactly $q+1$ points, and any point is contained in exactly $q+1$ lines.
- Any two distinct lines intersect in one point, and for any two distinct points there is one unique line containing them.

We denote by $\mathbb{G}_q$ the bipartite incidence graph of the projective plane $\mathrm{PG}(2,q)$. Precisely, the set of left vertices $L(\mathbb{G}_q)$ is the set of points of $\mathrm{PG}(2,q)$, the set of right vertices $R(\mathbb{G}_q)$ is the set of lines of $\mathrm{PG}(2,q)$, and the set of edges $E(\mathbb{G}_q)$ corresponds to incidences between points and lines, that is $E(\mathbb{G}_q) = \{(a,\lambda) \in L(\mathbb{G}_q) \times R(\mathbb{G}_q) \mid a \in \lambda\}$.

▶ **Theorem 17.** *Let k be such that $k \leqslant (q+4)/5$. Then $\mathbb{G}_q$ is two-side k-pairable.*

Proof. Due to the symmetry of $\mathbb{G}_q$, it is enough to prove it is left k-pairable. For this, we will use Lemma 13. Let $K = \{u_1, v_1, u_2, v_2, \ldots, u_k, v_k\} \subseteq L(\mathbb{G}_q)$ be a set of $2k$ points. To construct the sets $C = \{c_1, c_2, \ldots, c_k\} \subseteq L(\mathbb{G}_q)$ and $S = \{\alpha_1, \beta_1, \alpha_2, \beta_2, \ldots, \alpha_k, \beta_k\} \subseteq R(\mathbb{G}_q)$ from the property (P) in Lemma 13, we will proceed by recursion.

First, since there are $q+1$ lines passing through u_1 and $|K \setminus \{u_1\}| = 2k-1 \leqslant q$, we may choose a line α_1 passing through u_1 and not passing through any other point in $K \setminus \{u_1\}$. Similarly, let β_1 be a line passing through v_1 and not passing through any other point in $K \setminus \{v_1\}$. We take c_1 to be the intersection point between α_1 and β_1.

For $1 \leqslant j < k$, assume that we have constructed a set of j points $C_j = \{c_1, \ldots, c_j\} \subseteq L(\mathbb{G}_q)$ and a set of $2j$ lines $S_j = \{\alpha_1, \beta_1, \ldots, \alpha_j, \beta_j\} \subseteq R(\mathbb{G}_q)$, satisfying the following conditions:

(i) $C_j \cap K = \emptyset$,

(ii) $N_{K \cup C_j}(\alpha_i) = \{u_i, c_i\}$ and $N_{K \cup C_j}(\beta_i) = \{v_i, c_i\}$, for all $i = 1, \ldots, j$.

To construct $\alpha_{j+1}, \beta_{j+1}$, and c_{j+1}, we proceed in the following steps (see also Figure 3).

- **We take α_{j+1} to be any line passing through u_{j+1} and not passing through any other point in $(K \setminus \{u_{j+1}\}) \cup C_j$.**
  This is possible since $|(K \setminus \{u_{j+1}\}) \cup C_j| = 2k-1+j \leqslant 3k-2 \leqslant q$. Moreover, $\alpha_{j+1} \notin S_j$, since by construction no line in S_j passes through u_{j+1}. We further denote by $I_{j+1} \subseteq L(\mathbb{G}_q)$ the set consisting of the intersection points between α_{j+1} and the $2j$ lines in S_j. Thus, $|I_{j+1}| \leqslant 2j$.
- **We take β_{j+1} to be any line passing through v_{j+1} and not passing through any other point in $(K \setminus \{v_{j+1}\}) \cup C_j \cup I_{j+1}$.**
  This is possible since $|(K \setminus \{v_{j+1}\}) \cup C_j \cup I_{j+1}| \leqslant 2k-1+3j \leqslant 5k-4 \leqslant q$. Clearly, $\beta_{j+1} \notin S_j \cup \{\alpha_{j+1}\}$, since no line in $S_j \cup \{\alpha_{j+1}\}$ passes through v_{j+1}.
- **We take c_{j+1} to be the intersection point between α_{j+1} and β_{j+1}.**
  Clearly, $c_{j+1} \notin C_j$, since neither one of α_{j+1} nor β_{j+1} passes through the points in C_j.

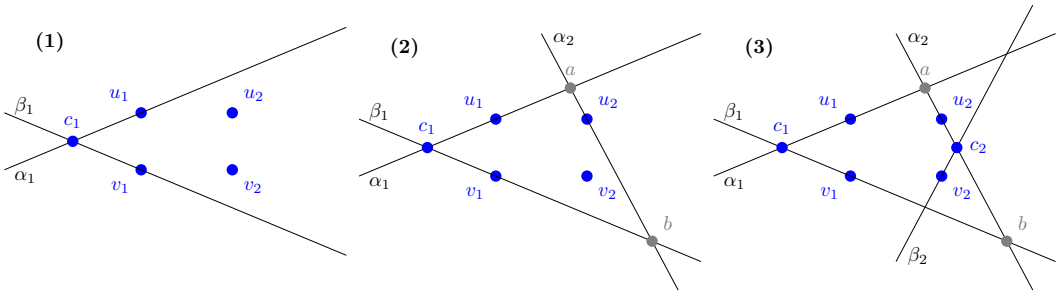


Figure 3 Recursive construction of sets C and S in the proof of of Theorem 17, for $k = 2$. (1) We chose α_1 any line passing through u_1, and not passing through v_1, u_2, v_2. Similarly, we choose β_1 passing through v_1, and not passing through u_1, u_2, v_2. We take c_1 the intersection point between α_1 and β_1. (2) We chose α_2 any line passing through u_2, and not passing through u_1, v_1, c_1, v_2. We determine the intersection points a and b of α_2 with α_1 and β_1. (3) We chose β_2 any line passing through v_2, and not passing through u_1, v_1, c_1, u_2, as well as a, b (to avoid α_2 and β_2 intersecting on these points). We take c_2 the intersection point between α_2 and β_2.

To complete our recursion, we need to prove:

(i) $C_{j+1} \cap K = \emptyset$. We only have to prove that $c_{j+1} \notin K$. This follows from the fact that each of α_{j+1} and β_{j+1} passes through only one point in K, namely u_{j+1} and v_{j+1}, respectively, and they are distinct.

(ii) $N_{K \cup C_{j+1}}(\alpha_i) = \{u_i, c_i\}$ and $N_{K \cup C_{j+1}}(\beta_i) = \{v_i, c_i\}$, for all $i = 1, \dots, j+1$.
For $i = j+1$, the above equalities follow by construction. Indeed, α_{j+1} passes through u_{j+1} and c_{j+1}, but it does not pass through any other point in $(K \setminus \{u_{j+1}\}) \cup C_j$, and similarly, β_{j+1} passes through v_{j+1} and c_{j+1}, but it does not pass through any other point in $(K \setminus \{v_{j+1}\}) \cup C_j$.
For $1 \leqslant i \leqslant j$, we only need to prove that neither α_i nor β_i passes through c_{j+1}. This follows from the fact that β_{j+1} does not pass through any point of I_{j+1}. Indeed, assuming that c_{j+1} belongs to either α_i or β_i, implies it belongs to I_{j+1}, the set of intersection points between α_{j+1} and the lines in S_j. This contradicts the fact that β_{j+1} does not pass through any point of I_{j+1}.

By recursion, we can construct sets $C := C_k$ and $S := S_k$ satisfying the property (P) from Lemma 13, and thus we conclude that $\mathbb{G}_q$ is left k-pairable. ◀

▶ **Theorem 18.** *Let k be such that $3k^2 - k - 8 \leqslant 2q$. Then $\mathbb{G}_q$ is two-side k-vertex-minor universal.*

Proof. Due to the symmetry of $\mathbb{G}_q$, it is enough to prove it is left k-vertex-minor universal. We prove $\mathbb{G}_q$ satisfies the property (VMU) from Lemma 14. Let $K = \{u_1, u_2, \dots, u_k\} \subseteq L(\mathbb{G}_q)$ be a set of k points. To construct the sets $C = \{c_{ij} \mid 1 \leqslant i < j \leqslant k\} \subseteq L(\mathbb{G}_q)$ and $S = \{\alpha_{ij}, \beta_{ij} \mid 1 \leqslant i < j \leqslant k\} \subseteq R(\mathbb{G}_q)$ from Lemma 14 we will proceed again by recursion, by running through pairs (u_i, u_j) in some particular order, say in lexicographical order with respect to indexes (i, j).

The recursion is similar to the one in the proof of Lemma 13. We construct recursively lines α_{ij} and β_{ij}, passing through u_i and u_j, respectively, and take $c_{ij} = \alpha_{ij} \cap \beta_{ij}$. In the recursion, we take α_{ij} to be any line passing through u_i and not passing through any other point in $(K \setminus \{u_i\}) \cup C_{ij}$, where $C_{ij} := \{c_{i'j'} \mid (i', j') < (i, j)\}$. Since $|(K \setminus \{u_i\}) \cup C_{ij}| \leqslant (k-1) + (k(k-1)/2 - 1) = \frac{1}{2}(k^2 + k - 4)$, such a choice of α_{ij} is possible if $k^2 + k - 4 \leqslant 2q$.

A stronger constraint on the value of k comes from the choice of β_{ij}. Indeed, for β_{ij} we take any line passing through u_j and not passing through any other point in $(K \setminus \{u_j\}) \cup C_{ij} \cup I_{ij}$, where I_{ij} is the set of intersection points between α_{ij} and the previously constructed lines $\alpha_{i'j'}$ and $\beta_{i'j'}$, with $(i', j') < (i, j)$. Since $|(K \setminus \{u_j\}) \cup C_{ij} \cup I_{ij}| \leqslant (k-1)+3(k(k-1)/2-1) = \frac{1}{2}(3k^2-k-8)$, we conclude that such a choice of β_{ij} is possible as long as $\frac{1}{2}(3k^2-k-8) \leqslant q$, as stated in the lemma. ◀

▶ **Theorem 19.** *Let k be such that $7k^2 - 16 \leqslant 4q$. Then $\mathbb{G}_q$ is k-vertex-minor universal.*

The proof is done by showing that $\mathbb{G}_q$ satisfies the property (VMU*) from Lemma 15, and can be found in the extended version of this paper [3].

4.3 Reduced graphs from projective planes

▶ **Definition 20.** *Let G be a bipartite graph and $\varphi : L(G) \to R(G)$. The φ-**reduction** of G is the graph G_φ such that:*

- *The vertex set of G_φ is the left vertex set of G, that is $V(G_\varphi) = L(G)$,*
- *There is an edge between $a, b \in V(G_\varphi)$, if $a \neq b$ and either (a and $\varphi(b)$) or (b and $\varphi(a)$) are neighbors in G, that is,*

$$E(G_\varphi) = \{(a, b) \mid a \neq b \text{ and } [\,(a, \varphi(b)) \in E(G) \text{ or } (b, \varphi(a)) \in E(G)\,]\,\}$$

*The reduction is said to be **bijective** if φ is bijective. It is said to be **symmetric** if φ is such that $(a, \varphi(b)) \in E(G) \Leftrightarrow (b, \varphi(a)) \in E(G), \forall a, b \in L(G)$.*

We enforce the condition $a \neq b$ in the definition of $E(G_\varphi)$, in order to avoid loops in case $(a, \varphi(a)) \in E(G)$ for some $a \in L(G)$.

Let G_φ be a bijective, symmetric reduction of G. For any vertex $a \in V(G_\varphi) = L(G)$, let $N_{G_\varphi}(a) \subseteq L(G)$ be the set of neighbors of a in G_φ, and $N_G(a) \subseteq R(G)$ be the set of neighbors of a in G. By definition, if $b \in N_{G_\varphi}(a)$ then $\varphi(b) \in N_G(a)$. The converse is also true, except if $\varphi(a) \in N_G(a)$, or equivalently, $(a, \varphi(a)) \in E(G)$. Hence, $N_{G_\varphi}(a) = \{b \mid \varphi(b) \in N_G(a)\} \setminus \{a\}$, and therefore:

- If $(a, \varphi(a)) \notin E(G)$, the map φ induces a bijection between $N_{G_\varphi}(a)$ and $N_G(a)$. In particular, $|N_{G_\varphi}(a)| = |N_G(a)|$.
- If $(a, \varphi(a)) \in E(G)$, the map φ induces a bijection between $N_{G_\varphi}(a)$ and $N_G \setminus \{\varphi(a)\}$. In particular, $|N_{G_\varphi}(a)| = |N_G(a)| - 1$.

In what follows, we take $\mathbb{G}_q$ to be the bipartite incidence graph of the projective plane $\mathrm{PG}(2, q)$ from the previous section. Let $\varphi : L(\mathbb{G}_q) \to R(\mathbb{G}_q)$ be defined as follows. Recall that a vertex $a \in L(\mathbb{G}_q)$ (that is, a point of the projective plane) corresponds to a 1-dimensional linear subspace of $\mathbb{F}_q^3$, while a vertex $\lambda \in R(\mathbb{G}_q)$ (that is, a line of the projective plane) corresponds to a 2-dimensional linear subspace of $\mathbb{F}_q^3$. Hence, for $a \in L(\mathbb{G}_q)$, we define $\varphi(a) \in R(\mathbb{G}_q)$ as the projective line corresponding to the 2-dimensional linear subspace orthogonal to a. Clearly, φ is bijective. It is also symmetric, since $a \in \varphi(b) \Leftrightarrow$ (a and b are orthogonal 1-dimensional linear subspaces) $\Leftrightarrow b \in \varphi(a)$. Note also that $(a, \varphi(a)) \in E(\mathbb{G}_q)$ if and only if a is self-orthogonal.

Let $\mathbb{G}_{q|\phi}$ be the bijective, symmetric reduction of $\mathbb{G}_q$ induced by φ. We will not use the explicit definition of φ, but only the fact it is bijective and symmetric. Note that $\mathbb{G}_{q|\phi}$ is a graph with $q^2 + q + 1$ vertices, and vertex degree equal to either q (vertices corresponding to self-orthogonal linear subspaces) or $q + 1$ (other vertices). The diameter of $\mathbb{G}_{q|\phi}$ is equal to 2, and for any two non-adjacent vertices $a, b \in V(\mathbb{G}_{q|\phi})$, there is a unique path of length 2 connecting them.

▶ **Theorem 21.** *Let k be such that $5k^2 - k - 10 \leqslant 2q$. Then $\mathbb{G}_{q|\phi}$ is k-vertex-minor universal.*

The proof is done by showing that $\mathbb{G}_{q|\phi}$ satisfies the property (VMU°) from Lemma 16, and can be found in the extended version of this paper [3]. Here, we briefly discuss the implications of the two constructions from Theorem 19 and Theorem 21. We denote by $\lceil x \rceil_{\mathrm{p}}$ the smallest prime power greater than or equal to a real number $x > 1$. For a given $k > 1$, let $q_2 := \left\lceil \frac{7}{4}k^2 - 4 \right\rceil_{\mathrm{p}}$ and $q_1 := \left\lceil \frac{5}{2}k^2 - \frac{1}{2}k - 5 \right\rceil_{\mathrm{p}}$ given by the inequalities in Theorem 19 (bipartite graph) and Theorem 21 (reduced graph), respectively. It follows that $\mathbb{G}_{q_2}$ is a k-vertex-minor universal of order $n_2 = 2(q_2^2 + q_2 + 1) \sim \frac{49}{8}k^4$, while $\mathbb{G}_{q_1|\phi}$ is a k-vertex-minor universal of order $n_1 = q_1^2 + q_1 + 1 \sim \frac{25}{4}k^4$ (where $\sim$ indicates asymptotic equivalence, as k goes to infinity). Thus, asymptotically, the bipartite graph construction yields k-vertex-minor universal graphs of slightly lower order than the reduced graph construction. Another interesting property of the bipartite graph is that the corresponding graph state $|\mathbb{G}_{q_2}\rangle$ is equivalent, up to local Clifford unitaries, to a Calderbank-Shor-Steane (CSS) state [4, Section IV]. However, to construct a desired graph on k-vertices of the bipartite-graph $\mathbb{G}_{q_2}$, we need to follow Lemma 15, thus to construct the sets $C_1, C_2, S_1, S_2, \Omega$ therein, which is done by following the steps highlighted in bold in the proof of Theorem 19. Note that this directly translates into a LOCC protocol to induce a desired graph state on k qubits of the state $|\mathbb{G}_{q_2}\rangle$, using Proposition 5. For the reduced graph the corresponding protocol is simpler, as we only have to construct the sets C, S from Lemma 16, which is again done by following the steps highlighted in bold in the proof of Theorem 21.

5 Conclusion

We showed the existence of k-vertex-minor universal graphs of order quadratic in k, which attain the optimum. This implies the existence of k-vertex-minor universal and thus k-pairable graph states with a quadratic number of qubits. Then, our study of the incidence graph of a finite projective plane exhibited two families of k-vertex-minor universal graphs of linear order in k^4. These two families being, to our knowledge, the first k-stabilizer universal quantum states, and so k-pairable quantum states, that can be constructed on a polynomial number of qubits in k.

This leaves open some questions for future work.

- The logical next step is the explicit, deterministic construction of an infinite family of k-vertex-minor universal graphs whose order is cubic, or even quadratic in k, asymptotically matching the order of the k-vertex-minor universal graphs which can be constructed in a probabilistic, non-deterministic way (although with arbitrarily high probability).
- Our probabilistic construction for k-vertex-minor universal graphs is asymptotically optimal. The graph states corresponding to $2k$-vertex-minor universal graphs are also k-pairable: however the only known lower bound on the size of k-pairable states (where one party holds only one qubit) is quasi-linear [2]. Does there exist k-pairable states with a quasi-linear number of qubits?
- Even though $2k$-stabilizer universality is a stronger requirement than k-pairability, it is not clear whether there exist k-pairable states which are not $2k$-stabilizer universal. A similar question can be asked for graphs: it is not clear whether there exist k-pairable graphs on more than 2 vertices which are not $2k$-vertex-minor universal.
- Bravyi et al. presented a construction of k-pairable states with an asymptotically optimal number of parties, in the case where each party holds at least 10 qubits [2]. How does k-stabilizer universality evolve when considering quantum communication networks where each party holds more than one qubit? Note that the construction of Bravyi et al. where each party holds at least 10 qubits does not translate well for k-stabilizer universality.

A Some data on the size of the existence constraints

By Lemma 11, given some $k \in \mathbb{N} \setminus \{0\}$, there exists a k-vertex-minor universal bipartite graph G with $|L(G)| \geqslant k$, $|R(G)| \geqslant 4\binom{k}{2} + 5$ if

$$\left(\frac{k}{2^{|L(G)|-k+1}} + e^{-\frac{\left(\frac{|R(G)|}{4} - \binom{k}{2}+1\right)^2}{\left(\frac{7(|R(G)|-k)}{4} - \binom{k}{2}+1\right)}} \right) \times \binom{|L(G)| + |R(G)|}{k} < 1$$

In Table 1 we provide values for which there exists a k-vertex-minor universal bipartite graph of this order, for some particular values of k. In Table 2 we provide values for which a randomly generated bipartite graph is k-vertex-minor universal with at least 99% probability. Experimentally, adding a small, constant number of vertices to the randomly generated bipartite graph, greatly increases the probability of it to be k-vertex-minor universal.

Table 1 Parameters for which some k-vertex-minor universal bipartite graph exists.

Abstract

We consider the problem of approximate counting of triangles and longer fixed length cycles in directed graphs. For triangles, Tětek [ICALP'22] gave an algorithm that returns a $(1 \pm \varepsilon)$-approximation in $\tilde{O}(n^\omega/t^{\omega-2})$ time, where t is the unknown number of triangles in the given n node graph and $\omega < 2.372$ is the matrix multiplication exponent. We obtain an improved algorithm whose running time is, within polylogarithmic factors the same as that for multiplying an $n \times n/t$ matrix by an $n/t \times n$ matrix. We then extend our framework to obtain the first nontrivial $(1 \pm \varepsilon)$-approximation algorithms for the number of h-cycles in a graph, for any constant $h \geq 3$. Our running time is

$$\tilde{O}\left(\mathsf{MM}\left(n, n/t^{1/(h-2)}, n\right)\right), \text{the time to multiply } n \times \frac{n}{t^{1/(h-2)}} \text{ by } \frac{n}{t^{1/(h-2)}} \times n \text{ matrices.}$$

Finally, we show that under popular fine-grained hypotheses, this running time is optimal.

1 Introduction

Detecting small subgraph patterns inside a large graph is a fundamental computational task with many applications. Research in this domain has flourished, leading to fast algorithms for many tractable versions of the subgraph isomorphism problem: given a fixed (constant size) graph H, detect whether a large graph G contains H as a subgraph, list all copies of H in G, count the copies (exactly or approximately) and more.

The topic of this paper is the fast estimation of the number of copies of a pattern H in a graph G. One of the most studied patterns H is the *triangle* whose detection, listing and approximate counting has become a prime testing ground for ideas in classic graph algorithms [25, 3, 30, 8, 31], sublinear and distributed algorithms [24, 23, 20, 22, 21, 12, 15, 26, 19, 33, 11, 13, 14], streaming [10, 6, 5, 27, 28], parallel [7, 29, 32] algorithms and more. This is largely because triangles are arguably the simplest subgraph patterns and moreover, often algorithms for the triangle version of the (detection, counting or listing) problem formally lead to algorithms for other patterns as well (see Nešetril and Poljak [30]).

Detecting and finding a triangle, and counting the number of triangles in an n-vertex graph can all be reduced to fast matrix multiplication [25], and the fastest algorithm for these versions has running time $O(n^\omega)$, where ω is the exponent of square matrix multiplication, currently $\omega \leq 2.371552$ [35]. It is also believed that even detecting a triangle requires $n^{\omega-o(1)}$ time, due to known fine-grained reductions that show that Boolean matrix multiplication and triangle detection are equivalent, at least for combinatorial algorithms [34].

Obtaining an approximate count $\hat{t}$ to the number of triangles t in an n-node graph such that $(1-\varepsilon)t \leq \hat{t} \leq (1+\varepsilon)t$ for an arbitrarily small constant $\varepsilon > 0$ can be used to detect whether a graph has a triangle, as the algorithm would be able to distinguish between $t = 0$ and $t = 1$. Thus, it is plausible that when the number of triangles is $O(1)$, $n^{\omega-o(1)}$ time is needed to obtain an approximate triangle count.

When the number of triangles t in G is large, however, a simpler sampling approach can obtain a good estimate of t: repeatedly sample a triple of vertices and check whether they form a triangle; in expectation $O(n^3/t)$ samples are sufficient to get a constant factor approximation.

The best known algorithm for approximately counting triangles is by Tětek [33], with running time $\tilde{O}(n^\omega/t^{\omega-2})$. When t becomes constant, the running time becomes $\tilde{O}(n^\omega)$, which is believed to be optimal, as we mentioned earlier. When t becomes $\Theta(n)$, the running time is the same as the naïve sampling algorithm, $\tilde{O}(n^2)$. This quadratic running time is provably necessary even for randomized algorithms (see [21]). Nevertheless, it is unclear whether $\tilde{O}(n^\omega/t^{\omega-2})$ time is needed for all values of t between $O(1)$ and $\Omega(n)$.

Is there a faster algorithm for approximate triangle counting when the triangle count is in $[\Omega(1), O(n)]$?

As triangle counting is an important special case of fixed subgraph isomorphism counting, a natural question is, what is the fastest algorithm for approximately counting arbitrary subgraphs H?

Dell, Lapinskas and Meeks [18] provide a general reduction from approximate H counting to detecting a "colorful" H in an n-node, m-edge graph, so that a $T(n,m)$ time detection algorithm can be converted into an $\tilde{O}(\varepsilon^{-2}T(n,m))$ time $(1\pm\varepsilon)$-approximation algorithm. For many patterns [1] such as triangles and k-cliques or directed h-cycles, the colorful and normal versions of the detection problems are equivalent (e.g. via color-coding [2] and layering). While the detection running time is provably necessary to approximately count when the number of copies of the pattern is constant, similarly to the case of triangles, when the number of copies t is large, faster sampling algorithms are possible. Unfortunately, the reduction of [18] doesn't seem easy to extend to provide runtime savings that grow with t. Thus, we ask:

What is the best approximate counting algorithm for subgraph patterns H with running time depending on the number t of copies of H?

As triangles are also cycles, one special case of the above question is when H is a cycle on h vertices.

[1] This equivalence is not true in general: detecting cycles of fixed even length is believed to be computationally easier than detecting colorful even cycles which are known to be equivalent to the directed version of the problem.

1.1 Our Contribution

The main result of our paper is a new algorithm for approximating the number of h-cycles in a given *directed* graph, for any constant $h \geq 3$, together with a conditional lower bound from a fine-grained hypothesis, showing that the running time of our algorithm is likely tight.

Our main theorem is:

▶ **Theorem 1** (Approximating the Number of h-Cycles). *Let G be a given graph with n vertices and let $h \geq 3$ be a fixed integer. There is a randomized algorithm that outputs an approximation $\hat{t}$ for the number t of h-cycles in G such that $\Pr\left[(1-\varepsilon)t \leq \hat{t} \leq (1+\varepsilon)t\right] \geq 1 - 1/n^2$, for any constant $\varepsilon > 0$. The running time is bounded by $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n/t^{1/(h-2)}, n\right)\right)$, the fastest running time to multiply an $n \times n/t^{1/(h-2)}$ matrix by an $n/t^{1/(h-2)} \times n$ matrix.*

As long as $\omega > 2$, the running time in the theorem is always upper-bounded by $\tilde{\mathcal{O}}\left(n^\omega / t^{\frac{\omega-2}{(h-2)(1-\alpha)}} + n^2\right)$, where $\omega \leq 2.371552$ is the square matrix multiplication exponent mentioned earlier and $\alpha \geq 0.321334$ [35] is the largest real number such that one can multiply $n \times n^\alpha$ by $n^\alpha \times n$ matrices in $n^{2+o(1)}$ time.[2] It is easy to see that for any value $\omega > 2$, our $\tilde{\mathcal{O}}\left(n^\omega / t^{\frac{\omega-2}{1-\alpha}}\right)$ time for *triangles* is faster than the previous state of the art $\tilde{\mathcal{O}}\left(n^\omega / t^{\omega-2}\right)$ for approximate counting of triangles [33] for all t between $\Omega(1)$ and $O(n)$, answering our first question in the introduction. Figure 1 plots our two running times for approximate triangle counting together with Tětek's algorithm, naive sampling and the $O(n^\omega)$ time exact counting algorithm.

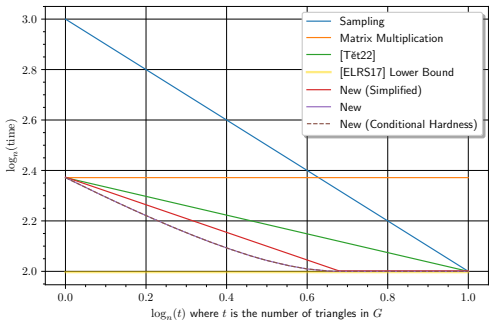

Figure 1 A comparison between our new running times for approximate triangle counting with prior work, together with the lower bounds, both conditional and unconditional.

Method	Runtime
Sampling	n^3/t
Matrix Multiplication	n^ω
[33]	$n^\omega/t^{\omega-2}$
[21] Lower Bound	n^2
New (Simplified)	$n^\omega/t^{(\omega-2)/(1-\alpha)}$
New	$\mathsf{MM}(n,n,n/t)$
New (Conditional Hardness)	$\mathsf{MM}(n,n,n/t)$

Figure 2 Comparative Runtime Analysis.

We obtain our algorithm via a simplification and generalization of Tětek's approach that allows us to both obtain an improved running time for triangles, but also to get faster algorithms for longer cycles. The approach can also extend to other patterns; we leave this as future work.

Our algorithm for longer cycles is arguably the first non-trivial algorithm for the problem with a negative dependence on the number of cycles t. To our knowledge, prior to our work the only approximate counting algorithms for h-cycles for $h > 3$ in directed graphs (or in

[2] We use $\mathsf{MM}(a,b,c)$ to denote the time complexity of multiplying two matrices with dimensions $a \times b$ and $b \times c$.

undirected graphs when h is odd[3]) were to either use naive random sampling resulting in an $O(n^4/t)$ time or to approximate the answer in the best h-cycle detection time, $O(n^\omega)$ (e.g. via [18]), a running time that does not depend on t.

We complement our algorithms for approximately counting h-cycles with a *tight* conditional lower bound under a popular fine-grained hypothesis. The k-Clique Hypothesis of fine-grained complexity (e.g. [1, 4, 9, 16]) postulates that the current fastest algorithms for detecting a k-clique in a graph (for constant $k \geq 3$) are optimal, up to $n^{o(1)}$ factors. We formulate a natural hypothesis about the complexity of *triangle detection* in unbalanced tripartite graphs that is motivated by and in part implied by the k-Clique Hypothesis. Then we show, under that hypothesis:

▶ **Theorem 2.** *Under fine-grained hypotheses, in the word-RAM model with $O(\log n)$ bit words, for any constant integer $h \geq 3$, any randomized algorithm that, when given an n node directed graph G, can distinguish between G being h-cycle-free and containing $\geq t$ h-cycles needs $\mathsf{MM}\left(n, n/t^{1/(h-2)}, n\right)^{1-o(1)}$ time. The same result holds for undirected graphs as well whenever h is odd.*

As any algorithm that can approximate the number t of h-cycles multiplicatively, can distinguish between 0 and t h-cycles, we get that our algorithm running times are essentially tight. We present our lower bound for triangles in Figure 1 as a dotted line. Together with the lower bound by [21], our lower bound shows that our algorithm is (conditionally) optimal for all values of t. Due to space considerations, the lower bound proof is deferred to the full version.

Similarly to Tětek's algorithm, our algorithms for approximate h-cycle counting can be used to obtain improved h-cycle counting algorithms for *sparse* graphs, where the running time is measured in terms of the number of edges m. In particular, for triangles, one can simply substitute our new algorithm in terms of n in Tětek's argument [33] to obtain an approximate counting algorithm that runs in time $\tilde{\mathcal{O}}\left(m^{2\omega/(\omega+1)}/t^{\frac{2(\omega-1)}{\omega+1}+\frac{\alpha(\omega-2)}{(1-\alpha)(\omega+1)}}\right)$. This running time is always faster than Tětek's $\tilde{\mathcal{O}}\left(m^{2\omega/(\omega+1)}/t^{\frac{2(\omega-1)}{\omega+1}}\right)$ for any $\omega > 2$. One can similarly adapt the algorithms of Yuster and Zwick [37] and their analysis in [17] to obtain approximate counting algorithms for longer cycles. We leave this to future work.

1.2 Technical Overview

To frame our technical contribution, we first briefly overview the approach of [33]. The latter gives a randomized approximate counting algorithm for triangles, in time $\tilde{\mathcal{O}}\left(n^\omega/t^{\omega-2}\right)$. In a nutshell, the algorithm finds a subset of vertices S that contains all Λ-heavy vertices and no $\Lambda/\mathrm{polylog}\,(n)$-light vertices – a vertex is called Λ-heavy if it participates in at least Λ triangles, and otherwise it is called Λ-light. Then, the algorithm approximately counts the number of Λ-heavy triangles, which are triangles with at least one heavy vertex. The algorithm then continues by sampling subsets of vertices from the set $V - S$, where each vertex is kept independently uniformly at random with some probability, and processing the sampled graphs by recursion.

[3] The detection problem for even h-cycles in undirected graphs is known to be much easier than that for odd cycles, and for directed graphs, as for every even constant integer h, an $O(n^2)$ time algorithm was developed by Yuster and Zwick [36]. Meanwhile, directed h-cycles and undirected odd h-cycles are believed to require $n^{\omega-o(1)}$ time to detect.

Our technical contribution consists of three parts: (I) We simplify the above recursive approach, (II) we improve upon the component that finds heavy vertices, and (III) we improve upon the component that counts the number of cycles that contain heavy vertices. A compelling aspect of our technique is that it applies to any constant-length cycle. In what follows, we overview each of these aspects.

I. The Recursive Template. In [33], each recursive invocation triggers seven further recursive calls and takes the median of their return values. As the depth of the recursion increases, the algorithm needs to use a precision parameter that becomes exponentially tighter.

In contrast, our algorithm initiates only a single recursive call. This allows us to avoid having to compute the median of several subcalls, which makes it easier to apply standard amplification tools. In particular, it allows us to *fix the precision parameter*.

In addition, by reducing the recursive tree to a "path", we *simplify the analysis* of the running time.

A prime feature of our simplification of the recursion is that it allows us to present it as a *template* for approximate subgraph counting for any fixed subgraph $\mathtt{H}$, provided one designs the two black boxes (one for finding a superset S of the Λ-heavy vertices with no $\Lambda/\text{polylog}(n)$-light vertices, and another for approximately counting the number of copies of $\mathtt{H}$ that intersect the set S).

For triangles, our improvement comes from simplifying the recursion and implementing the black box that finds heavy vertices faster, using rectangular matrix multiplication. Crucially, our implementations of these black boxes are general, in the sense that they apply to constant length h-cycle. Specifically, we find the set S in time $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n/\Lambda^{1/(h-2)}, n\right)\right)$. For such S, we find an $(1+\epsilon)$ approximation for the number of copies of $\mathtt{H}$ that intersect S in time $\tilde{\mathcal{O}}\left(n^2/\varepsilon^3\right)$, which is independent of Λ and of the cardinality of S.

II. Finding the Heavy Vertices. The algorithm in [33] finds Λ-heavy vertices by sampling a subset of vertices uniformly at random, and using matrix multiplication to detect triangles inside the induced sampled subgraph. This takes $\tilde{\mathcal{O}}\left(n^\omega/\Lambda^{\omega-2}\right)$ time, by $\tilde{\mathcal{O}}\left(\Lambda^2\right)$ repetitions of multiplying $n/\Lambda \times n/\Lambda$ matrices.

At the heart of our approach for finding the heavy vertices lies non-uniform sampling, and computing the product of rectangular matrices rather than square ones. We obtain a running time of $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n/\Lambda^{1/(h-2)}, n\right)\right) = \tilde{\mathcal{O}}\left(n^\omega/\Lambda^{\gamma_h}\right)$ for h-cycles, where $\gamma_h \triangleq \frac{\omega-2}{(1-\alpha)(h-2)}$. This comes from multiplying an $n \times n/\Lambda^{1/(h-2)}$ matrix by an $n/\Lambda^{1/(h-2)} \times n$ matrix. In [35] it was shown that $\alpha \geq 0.321334$, and therefore $\frac{\omega-2}{1-\alpha} \geq 1.47(\omega-2)$, which establishes that our algorithm is never slower, and is faster (if $\omega > 2$), where the gap increases with Λ (for sufficiently large Λ, the folklore naïve sampling algorithm is superior).

Our starting point for finding the heavy vertices is the *color-coding* technique of [2], which is widely employed for detecting h-cycles for $h = \mathcal{O}(1)$. This technique colors the vertices using h colors uniformly independently at random and looks for *colorful* h-cycles, which are h-cycles with exactly one vertex of each color. This restriction allows for faster detection but suffers some probability of missing h-cycles that are colored out of order, which can be overcome with sufficiently large probability by repeating this process.

To find colorful h-cycles, we utilize matrix multiplication. However, we do so in a refined manner. Rather than considering all vertices, we sample a subset of vertices from each color class in a nonuniform manner. To illustrate this, consider the task of finding Λ-heavy vertices w.r.t. triangles. We assign a random color to each vertex, and denote the three color classes by V_1, V_2, V_3. We focus on identifying the Λ-heavy vertices within V_1. Fix some $i \in [\log \Lambda]$.

We sample each vertex from V_2 with probability $2^i/\Lambda$, and we sample each vertex from V_3 with probability $1/2^i$. Let H_i denote the induced graph obtained by all vertices from V_1 and the sampled vertices from V_2 and V_3, where we also direct edges from V_j to $V_{j+1 \mod 3}$ and discard monochromatic edges. We show that for every Λ-heavy vertex v, there exists an index $i \in [\log \Lambda]$ such that v is in a triangle in H_i with some probability at least p_{heavy}, where $1/p_{\text{heavy}} = \tilde{\mathcal{O}}(1)$. On the other hand, for $\Lambda/\text{polylog}(n)$-light vertex u, we show that for every $i \in [\log \Lambda]$, the vertex v is in a triangle in H_i with probability at most $p_{\text{heavy}}/2$. Therefore, we can distinguish between these cases. Checking whether v is in a triangle in H_i can be done in $\tilde{\mathcal{O}}(\mathsf{MM}(n, n, n/\Lambda))$ time. Using amplification, we approximate the probability that v is in a triangle in H_i for every $v \in V_1$, and thus distinguish heavy vertices from lighter ones.

We generalize our approach for h-cycles by coloring the vertices with h colors, and directing edges and discarding monochromatic edges, as for triangles. We also discard edges between non-consecutive color classes. To find Λ-heavy vertices in the first color class, we sample in a nonuniform manner a subset of vertices from the j-th color class for $2 \leq j \leq h$, where the product of the sampling probabilities of the color classes should be at most $1/\Lambda$, as for triangles. Let H denote the obtained random induced subgraph. The running time of computing the exact number of h-cycles each vertex in H participates in, which is dominated by the size of the smallest color class in H, becomes $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right)\right)$. To see why, consider an h-partite graph G with n vertices in each part. Suppose G has a vertex $v \in V_1$ with a neighbor $u \in V_2$, such that all h-cycles that intersect v, also intersect the edge (u, v). Now, suppose each vertex set V_j, for $3 \leq j \leq h$ has a subset W_j of $\Lambda^{1/(h-2)}$ vertices, such that any h-tuple of the form $(v, u, w_3, w_4, \ldots, w_h)$ is an h-cycle in G, where $w_j \in W_j$ for $3 \leq j \leq h$. This implies that v is Λ-heavy. Note that if we keep each vertex from the j-th color class with a probability of $o(1/\Lambda^{1/(h-2)})$, we are unlikely to sample any vertex from W_j, and therefore we fail to learn that v is Λ-heavy. On the other hand, if we sample vertices from each class with probability $\Omega\left(1/\Lambda^{1/(h-2)}\right)$, the smallest color class is of size $\Omega\left(n/\Lambda^{1/(h-2)}\right)$.

III. Counting the Heavy Copies. Given a graph G and a subset of vertices S, where each vertex in S participates in at least a and at most b copies of h-cycles for $h = \mathcal{O}(1)$, we show how to compute a $(1+\epsilon)$ approximation for the number of h-cycles that intersect the set S, in time $\tilde{\mathcal{O}}\left(n^2 b/\varepsilon a\right)$. In particular, the runtime is independent of size of the set S.

Consider a naïve approach, which approximates the average number of h-cycles that a vertex from S intersects, and let us see why it fails to provide a good approximation for the total number of h-cycles intersecting S. Suppose $h = 3$ and $|S| = 3$ and each vertex $v \in S$ participates in exactly one triangle in G. Based solely on the number of triangles in which a vertex participates, it is impossible to distinguish the case where the set S intersects one triangle in G from the case in which it intersects three triangles in G. The issue here is double counting, as we did not avoid counting the same cycle more than once. For triangles, this obstacle can be avoided by replacing G with a tripartite graph G', where each of the three parts is a copy of V, and for each edge in G there are six edges in G', one for every ordered pair of parts. It is easy to see that every triangle in G corresponds to six triangles in G', and thus an estimate on G' directly gives an estimate on G. That is, we sample a subset F of vertices from S, and for each copy v' of $v \in F$ in the, say, first part of in the tri-partition G', we compute the number of triangles that go through it in G'. This avoids double counting, because each triangle in G' intersects copies of the set F from the first part at most once (as vertices in the same part form an independent set and hence cannot be in

the same triangle). To summarize, restricting to triangles would significantly simplify this part to a single Chernoff inequality for independent random variables. The source of this simplicity is that triangles are cliques. However, larger cycles are not cliques. If we simply repeat every vertex h times to create a new graph G' as in the triangle case, we could create h-cycles in G' that do not correspond to h-cycles in G: every *closed walk* of length h would become an h-cycle. As in [2], we use color-coding to overcome this, and this necessitates a more careful probabilistic analysis .

First, we sample a subset of vertices from S and for each sampled vertex v we approximate the number of h-cycles which go through v (and therefore intersect the set S). The crux of our algorithm is that in order to approximate the above, we approximate the number of h-cycles which go through v and intersect the set S exactly k times, for each $1 \leq k \leq h$. The summation of these approximations yields our final result, and it naturally avoids the pitfall of double-counting.

To approximate the number of h-cycles intersecting the set S exactly k times for some k, we color the graph with $h-1$ colors and color vertex v with the color h. This ensures that any colorful h-cycle intersects v. Then, we choose $k-1$ color classes from the first $h-1$ classes, and retain only vertices of S within those classes. For the remaining color classes, we keep only vertices that are not in S. The color class h is fixed and always contains only v. This promises that each colorful h-cycle with v in this auxiliary graph intersects S exactly k times. The number of ways to choose exactly $k-1$ color classes that keep only vertices from S is $\binom{h-1}{k-1}$. We compute the number of h-cycles in each such auxiliary graph. We prove that the expectation of this number is some fixed constant multiplicative factor off from the number of h-cycles intersecting v and S exactly k times. Finally, we prove that the variance of this random variable is suitably bounded. Therefore, conducting this process $\tilde{\mathcal{O}}\left(b/(a\varepsilon)\right)$ times enables us to obtain an $(1 \pm \varepsilon)$ approximation for its expectation by Chebyshev's inequality. We compute the number of h-cycles in this auxiliary graph using rectangular matrix multiplication. Since the auxiliary graph is h-partite and one part contains only a single vertex, we get a running time of $\mathsf{MM}(n, n, 1) = \tilde{\mathcal{O}}\left(n^2\right)$. Thus, we achieve our claimed running time of $\tilde{\mathcal{O}}\left(n^2 b/\varepsilon a\right)$.

We mention that we invoke this procedure on the set of vertices given by the previous component of finding heavy vertices, which is called upon in every recursion step. A crucial observation that we make is that not only does this set contain all Λ-heavy vertices and no $\Lambda/\mathrm{polylog}(n)$-light vertices, but rather we also know that it does not contain $(2^h\Lambda)$-heavy vertices, because those are handled during previous steps of the recursion. This means that we invoke this procedure for a, b that differ only by $\mathrm{polylog}(n)$ and ε^2 factors, and thus we effectively get a running time of $\tilde{\mathcal{O}}\left(n^2/\varepsilon^3\right)$ for counting h-cycles through Λ-heavy vertices.

Roadmap. Section 2 contains our template for the recursion, and proves its correctness for any graph $\mathtt{H}$ given implementations of two black boxes, one that finds heavy vertices and another that counts the copies of $\mathtt{H}$ that contain heavy vertices. Section 3 proves the running time that our template obtains for h-cycles, given the running times of implementations of the two black boxes. We implement our black boxes for h-cycles in Sections 4 and 5. Missing proofs, as well as our hardness result, appear in the full version.

1.3 Preliminaries

Let G be a graph on n vertices. Let $\mathtt{H}$ be a fixed graph with $h = \mathcal{O}(1)$ vertices. For a subgraph $G' \subseteq G$, and a subset of vertices S, denote by $t_{G'}(S)$ number of copies of $\mathtt{H}$ in G' which intersect S. Denote by $\tau = \tau_{G'}$ the maximal number of copies of $\mathtt{H}$ in G' in which a

vertex participates. We say that a vertex v is Λ-heavy (in G) if $t_G(v) \geq \Lambda$, and otherwise it is Λ-light. We say that a copy C of $\mathtt{H}$ is Λ-heavy if C contains at least one Λ-heavy vertex. Let G be a graph and p some parameter that could depend on G. We denote by $G[p]$ a random induced subgraph of G obtained by keeping each vertex from G independently with probability p. We use $t(1 \pm \varepsilon)$ to denote the closed interval $[t(1-\varepsilon), t(1+\varepsilon)]$. We say that a value $\hat{t} = t(1 \pm \varepsilon)$ if $\hat{t} \in [t(1-\varepsilon), t(1+\varepsilon)]$. We assume that $\varepsilon \in (0, 1/2]$, which might depend on n. If ε is bigger, our algorithm assumes $\varepsilon \leq 1/2$. Finally, all logarithms in this paper are base 2.

▶ **Definition 3** (Fast Matrix Multiplication Definitions). *We denote the time it takes to compute the product of two matrices of dimension $n^a \times n^b$ and $n^b \times n^c$ by either $\mathsf{MM}\left(n^a, n^b, n^c\right)$ or $n^{\omega(a,b,c)}$. We also abuse the notation and write $\omega = \omega(1,1,1)$, and $\omega(k) = \omega(1,k,1)$. Note that for any permutation $\pi : [3] \to [3]$ we have $\omega(x_1, x_2, x_3) = \omega(x_{\pi(1)}, x_{\pi(2)}, x_{\pi(3)})$. In addition to ω, we will also use α to be the largest real number such that n by n^α by n matrix multiplication can be done in $n^{2+o(1)}$ time.*

2 The Recursive Template

Organization. In this section, we present an algorithm for approximating the number of copies of a graph $\mathtt{H}$ in a graph G, denoted by t, which builds upon two black boxes. The first black box, called Find-Heavy, takes a graph H and a parameter Λ as input and computes a superset of the Λ-*heavy* vertices, excluding any $\Lambda/\mathrm{polylog}\,(n)$-light vertices. We denote the computed superset of heaviest vertices as S. The second black box, called Count-Heavy, is used to compute an approximation for the number of *heavy-copies* of $\mathtt{H}$ in G, which is the set of all copies that contain at least one vertex from S. Our algorithm for subgraph approximate counting that uses the specified black boxes consists of two parts: a doubling algorithm called Doubling-Template, and a recursive algorithm called Template, which is the main focus of this section.

The Template Algorithm. The $\mathsf{Template}_{\varepsilon'}(G, \Lambda)$ algorithm takes two parameters: a graph G and a heaviness threshold Λ. The output of the algorithm is a value $\hat{t}$, which, with a probability of at least $2/3$, is within the range $t \pm (t \cdot \varepsilon' + \Lambda \cdot \mathrm{polylog}\,(n)/\varepsilon')$, where ε' is the fixed precision parameter of the algorithm.

We next explain how the recursive Template algorithm works. The algorithm does the following. (1) Find the heaviest vertices using the Find-Heavy black box, and denote this set by V_Λ. (2) Compute an approximation to the number of heavy copies of $\mathtt{H}$, i.e., copies of $\mathtt{H}$ with at least one vertex from V_Λ, using the Count-Heavy black box, and denote the output by $\hat{t}_\Lambda$. (3) Let $H = G[V(G) - V_\Lambda]$, and let $F \leftarrow H[p]$. That is, F is an induced subgraph of H, where each vertex from H joins F independently with probability p. (4) Make a recursive call to $\mathsf{Template}_{\varepsilon'}\left(H, \Lambda \cdot p^{|\mathtt{H}|}\right)$ and let $\hat{t}_H$ denote its output. (5) Return $\hat{t}_\Lambda + \hat{t}_H/p^{|\mathtt{H}|}$. The analysis of the probability that the algorithm produces a good approximation appears in the proof of Lemma 7. The running time of the algorithm depends on the implementation of the black boxes. In the next section, we analyze the running time of the algorithm for the case where $\mathtt{H}$ is a cycle.

The Doubling-Template Algorithm. The Doubling-Template algorithm is a doubling algorithm, which starts with an initial guess for t, denoted by $\mathsf{W}_0 = n^{|\mathtt{H}|}$. This is the maximal number of copies of $\mathtt{H}$ an n vertex graph can contain ($h! \cdot \binom{n}{|\mathtt{H}|} \leq n^{|\mathtt{H}|}$). The algorithm then makes $\tilde{\mathcal{O}}(1)$ calls to $\mathsf{Template}_{\varepsilon'}(G, \Lambda_0)$, where $\Lambda_0 \leftarrow \mathsf{W} \cdot \varepsilon^2/8Q$, where $Q = 8\log^4(n)$, and

computes their median, which we denote by $\hat{t}_0$. If $\hat{t}_0 \geq \mathsf{W}_0$ the doubling algorithm stops and outputs $\hat{t}_0$ as its approximation for t. Otherwise, the guess for the value of t is decreased by a factor of 2. The main point here is that the smaller the value of Λ given to the recursive algorithm is, the better approximation we get, while simultaneously increasing the running time. The guess W is a guess for the highest heaviness threshold the algorithm can start with to output a good approximation, and not an actual guess for the value of t (although both quantities are related).

Formally, the black boxes that we assume are the following.

Find-Heavy(G, Λ)

Input: A graph G, some parameter Λ.
Output: A subset V_Λ of vertices, such that with probability at least $1 - \frac{1}{n^4}$, $\forall v \in V(G)$:
1. If $t_G(v) \geq \Lambda$, then $v \in V_\Lambda$.
2. If $t_G(v) \leq \Lambda/(\log n)^{h^2}$, then $v \notin V_\Lambda$.

Count-Heavy$_{\varepsilon'}(G, V_\Lambda, a, b)$

Input: A graph G, a precision parameter ε', a subset of vertices V_Λ, and two real numbers $0 < a \leq b$, such that $\forall v \in V_\Lambda$ we have $t_G(v) \in [a, b]$.
Output: $\hat{t}_\Lambda$ which satisfies $\Pr\left[\hat{t}_\Lambda = t_G(V_\Lambda)(1 \pm \varepsilon')\right] \geq 1 - \frac{1}{n^4}$.

It should be noted that Count-Heavy cannot be applied to the entire graph, as it might contain a vertex v with $t_G(v) = 0$. Moreover, even if all vertices have $t_G(v) > 0$, employing this black box on the entire graph might result in slower running time. Indeed, in our implementation of the black box, the runtime is contingent on the ratio b/a. Therefore, we only employ this black box with $b/a = \mathcal{O}(1/\varepsilon^2)$.

Algorithm 1 Template$_{\varepsilon'}(G, \Lambda)$.

Input: A graph $G = (V, E)$, a heaviness threshold Λ, and a precision parameter ε'.

1 $V_\Lambda \leftarrow$ Find-Heavy(G, Λ) ; ▷ V_Λ is a superset of Λ-heavy vertices in G with no $\Lambda/(\log n)^{h^2}$-light vertices
2 $a_\Lambda \leftarrow \frac{\Lambda}{(\log n)^{h^2}}$, $b_\Lambda \leftarrow \Lambda \cdot \frac{8Q}{\varepsilon^2}$; ▷ $Q = 8\log^4(n)$
3 $\hat{t}_\Lambda \leftarrow$ Count-Heavy$_{\varepsilon'}(G, V_\Lambda, a_\Lambda, b_\Lambda)$; ▷ $\hat{t}_\Lambda$ is a $(1 \pm \varepsilon')$ approximation for $t_G(V_\Lambda)$ (the number of copies of H intersecting V_Λ)
4 **if** $\Lambda \leq 1$ **then return** $\hat{t}_\Lambda$;
5 $H \leftarrow G[V - V_\Lambda]$;
6 $p \leftarrow 1/2$; ▷ We keep p instead of $1/2$ for readability
7 $F \leftarrow H[p]$; ▷ F is a random subgraph of H
8 $\hat{t}_F \leftarrow$ Template$_{\varepsilon'}\left(F, \Lambda \cdot p^h\right)$;
9 **return** $\hat{t}_\Lambda + \hat{t}_F/p^h$;

The depth of the recursion in Template$_{\varepsilon'}(G, \Lambda)$ is at most $\log_{1/p^h}(\Lambda) + 1$. Since we will only call this algorithm with $\Lambda \leq |V(G)|^h$, we can conclude that the depth of the recursion is at most $\log n + 1$. The guarantees for the template are given in the following lemma.

▶ **Lemma 4** (Guarantees for the Template Algorithm). *For every* $\varepsilon \in (0, 1/2]$ *and every* $\Lambda \geq \tau_G \cdot \frac{\varepsilon^2}{8Q}$, *we have* $\Pr\left[\mathsf{Template}_{\varepsilon'}(G, \Lambda) = t_G(1 \pm \frac{\varepsilon}{2}) \pm \Lambda \cdot \frac{\log^4(n)}{2\varepsilon}\right] \geq \frac{2}{3}$, *where* $\varepsilon' = \frac{\varepsilon}{4 \log n}$.

Algorithm 2 Doubling-Template (G, ε).

Input: A graph $G = (V, E)$ with t_G copies of $\mathtt{H}$ and a precision parameter $\varepsilon \leq 1/2$.
Output: $\hat{t}$, which is a $(1 \pm \varepsilon)$ approximation for t w.h.p.

$\varepsilon' \leftarrow \frac{\varepsilon}{4 \log n}$, $\mathsf{W} \leftarrow n^h$, $Q \leftarrow 8 \log^4(n)$, $\Lambda \leftarrow \mathsf{W} \cdot \varepsilon^2 / Q$
for $i = 0$ *to* $i = h \log n$ **do**
  $\hat{t}_i \leftarrow \mathsf{Median}\left[\mathsf{Template}_{\varepsilon'}\left(G, \Lambda/2^i\right), 400 \log n\right]$; ▷ $\hat{t}_i$ `is the median of` $400 \log n$ `independent executions of` $\mathsf{Template}_{\varepsilon'}\left(G, \Lambda/2^i\right)$.
  if $\hat{t}_i \geq \mathsf{W}/2^i$ **then return** $\hat{t}_i$;
return *Exact deterministic count of* t_G.

▶ **Lemma 5** (Guarantees for the Doubling-Template Algorithm). *Let* G *be a graph with* n *vertices and* t_G *copies of* $\mathtt{H}$. *Fix some* $\varepsilon > 0$ *that may depend on* n. *Let* $\hat{t}$ *denote the output of* Doubling-Template (G, ε) *(specified in Algorithm 2). Then,* $\Pr\left[\hat{t} = t(1 \pm \varepsilon)\right] \geq 1 - 1/n^2$.

The main result that we prove in this section is Lemma 5. We prove it using Lemma 4. First, we use amplification, to show that the event specified in Lemma 4 occurs with high probability, and not only with probability at least 2/3. The rest assumes that this event always occurs. We then use case analysis on $\Lambda/2^i$.

1. For i such that $\Lambda/2^i \geq 4t_G$, we show that $\hat{t}_i < \Lambda/2^i$ w.h.p., meaning the doubling algorithm does not stop for such i w.h.p., and makes another iteration with a refined initial heaviness threshold.
2. For i such that $\Lambda/2^i \leq 4t_G$, we show that $\hat{t}_i = t_G(1 \pm \varepsilon)$ w.h.p.
3. For i such that $\Lambda/2^i \leq t_G/2$, we show that $\hat{t}_i \geq \Lambda/2^i$ w.h.p., which means the algorithm stops as soon as $\Lambda/2^i \leq t_G/2$ w.h.p.

To summarize, the doubling algorithm always stops (by the third property). It does not stop when $\Lambda/2^i \geq 4t_G$ w.h.p. Therefore, when it does stop we have that $\Lambda/2^i \leq 4t_G$, and then it obtains a $(1 \pm \varepsilon)$ approximation for t_G.

To prove Lemma 4, we state and prove a more refined version of the guarantees of the template algorithm. We need the following definition to restate it.

▶ **Definition 6** ($\hat{\mathsf{D}}(\Lambda)$). *We define the depth of the call* $\mathsf{Template}_{\varepsilon'}(F, \Lambda)$ *as* $\hat{\mathsf{D}}(\Lambda) = \max\left\{0, \left\lceil \log_{1/p^h}(\Lambda) \right\rceil\right\}$.

We assume $\Lambda \leq (h!) \cdot \binom{n}{h} \leq n^h$, and therefore that $\hat{\mathsf{D}}(\Lambda) \leq \log n + 1$.

▶ **Lemma 7** (Induction Hypothesis). *Given a graph* G *and* ε, *we set* $p = 1/2$, *and* $\varepsilon' = \frac{\varepsilon}{4 \log n}$. *Then, for any* $\Lambda \geq \tau_G \cdot \frac{\varepsilon^2}{8Q}$, *and any* $\mathsf{K} = o(n)$ *that could depend on* $n, \hat{\mathsf{D}}(\Lambda)$ *and* p, *we have*

$$\Pr\left[\mathsf{Template}_{\varepsilon'}(G, \Lambda) = t_G(1 \pm \varepsilon')^{\hat{\mathsf{D}}(\Lambda)} \pm 2\hat{\mathsf{D}}(\Lambda)\,\mathsf{K} \cdot \Lambda/\varepsilon'\right] \geq 1 - 4h\hat{\mathsf{D}}(\Lambda)/(\mathsf{K}p^h) .$$

Proof Sketch. We prove using induction on the depth of the recursion. We skip the proof of the base case and state the induction hypothesis. The full proof appears in the full version.

Step. We first define some notation and events. We have three graphs $F \subseteq H \subseteq G$, where G is the input graph, H is an induced subgraph of G without the Λ-heavy vertices, and F is a random induced graph of H obtained by keeping each vertex of H independently with probability p. Let $\hat{t}_G$ denote the output of $\mathsf{Template}_{\varepsilon'}(G, \Lambda)$, and let $\hat{t}_F$ denote the output of $\mathsf{Template}_{\varepsilon'}\left(F, \Lambda \cdot p^h\right)$. We use t_Λ to denote $t_G(V_\Lambda)$, and let $\hat{t}_\Lambda$ denote the output of $\mathsf{Count\text{-}Heavy}_{\varepsilon'}(G, V_\Lambda)$. Note that $\hat{\mathsf{D}}(\Lambda) \geq \hat{\mathsf{D}}(\Lambda p^h) + 1$ (unless $\hat{\mathsf{D}}(\Lambda) = 0$, in which case $\hat{\mathsf{D}}(\Lambda) = \hat{\mathsf{D}}(\Lambda p^h) = 0$).

Intuition. We compute two values, $\hat{t}_\Lambda$ and $\hat{t}_F$. We then output $\hat{t} = \hat{t}_\Lambda + \hat{t}_F/p^h$ as an approximation for t_G. By the black box guarantees, we have that $\hat{t}_\Lambda$ is a good approximation for t_Λ. What is left is to show that $\hat{t}_F/p^h$ is a good approximation for t_H. We split this into two parts. First, we show that t_F/p^h is "close" to the value of t_H. Next, we use the induction hypothesis, to show that $\hat{t}_F$ is a good approximation of t_F. We need to show that the "composition" of these approximations is also good. Let $\mathcal{E}_{\text{Find-Heavy}}$ denote the event that all calls made to the $\mathsf{Find\text{-}Heavy}$ black box produce a valid output. That is, the event that V_Λ contains a superset of the Λ-heavy vertices, without any $\Lambda/(\log n)^{h^2}$ n-light vertices. **We prove the correctness of the algorithm under the assumption that $\mathcal{E}_{\text{Find-Heavy}}$ occurs**. We define:

1. $\mathcal{E}_1 \triangleq \{\hat{t}_\Lambda = t_\Lambda(1 \pm \varepsilon')\}$. The heavy copies of $\mathtt{H}$ are approximated correctly.
2. $\mathcal{E}_2 \triangleq \{\hat{t}_F = t_F(1 \pm \varepsilon')^{\hat{\mathsf{D}}(\Lambda p^h)} \pm 2\hat{\mathsf{D}}(\Lambda p^h) \cdot \mathsf{K} \cdot (\Lambda \cdot p^h)/\varepsilon'\}$. This is the event in the induction hypothesis.
3. $\mathcal{E}_3 \triangleq \{t_F/p^h = t_H(1 \pm \varepsilon') \pm \mathsf{K} \cdot \Lambda/\varepsilon'\}$. This is a concentration bound on t_F.
4. $\mathcal{E}_4 \triangleq \{\hat{t}_F/p^h = t_H(1 \pm \varepsilon')^{\hat{\mathsf{D}}(\Lambda)} \pm 2\hat{\mathsf{D}}(\Lambda)\,\mathsf{K} \cdot \Lambda/\varepsilon'\}$. This event contains $\mathcal{E}_2 \cap \mathcal{E}_3$.
5. $\mathcal{E}_5 \triangleq \{\hat{t}_G = t_G(1 \pm \varepsilon')^{\hat{\mathsf{D}}(\Lambda)} \pm 2\hat{\mathsf{D}}(\Lambda)\,\mathsf{K} \cdot \Lambda/\varepsilon'\}$. This is the event specified in Lemma 7.

Lemma 7 requires us to show that $\Pr[\mathcal{E}_5] \geq 1 - \frac{4h\hat{\mathsf{D}}(\Lambda)}{\mathsf{K}p^h}$. We show this by proving that $\mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3 \subseteq \mathcal{E}_5$, which implies that it is sufficient to prove that $\Pr[\mathcal{E}_{\text{Find-Heavy}} \cap \mathcal{E}_1 \cap \mathcal{E}_2 \cap \mathcal{E}_3] \geq 1 - \frac{4h\hat{\mathsf{D}}(\Lambda)}{\mathsf{K}p^h}$. To show the latter, we show that $\Pr[\mathcal{E}_{\text{Find-Heavy}} \cap \mathcal{E}_1 \cap \mathcal{E}_2] \geq 1 - \frac{4h\hat{\mathsf{D}}(\Lambda p^h)+2}{\mathsf{K}p^h}$ and that $\Pr[\mathcal{E}_3] \geq 1 - \frac{h+1}{\mathsf{K}p^h}$. Summing up the two error probabilities in the above expressions gives the desired result. ◀

3 Application: Approximating the Number of h-Cycles

In this section, we analyze the running time of the recursive and doubling algorithm, when the counted subgraph is an h-cycle for $h = \mathcal{O}(1)$. For this task, we assume the black boxes can be implemented in specific runtime, as stated in the following lemma which is proven in the next sections.

▶ **Lemma 8.** *Let G be a graph with n vertices, let $\mathtt{H}$ be an h-cycle for some $h = \mathcal{O}(1)$, and let ε' be some parameter. Then, each call to $\mathsf{Find\text{-}Heavy}(G, \Lambda)$ can be implemented in time $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, \frac{n}{\Lambda^{1/(h-2)}}\right)\right)$ and each call to $\mathsf{Count\text{-}Heavy}_{\varepsilon'}(G, V_\Lambda, a_\Lambda, b_\Lambda)$ can be implemented in time $\tilde{\mathcal{O}}\left(\mathsf{MM}(n, n, 1) \cdot \frac{b_\Lambda}{a_\Lambda \cdot \varepsilon}\right) = \tilde{\mathcal{O}}\left(n^2 \cdot \frac{b_\Lambda}{a_\Lambda \cdot \varepsilon}\right)$.*

▶ **Theorem 1** (Approximating the Number of h-Cycles)**.** *Let G be a given graph with n vertices and let $h \geq 3$ be a fixed integer. There is a randomized algorithm that outputs an approximation $\hat{t}$ for the number t of h-cycles in G such that $\Pr\left[(1-\varepsilon)t \leq \hat{t} \leq (1+\varepsilon)t\right] \geq 1 - 1/n^2$, for any constant $\varepsilon > 0$. The running time is bounded by $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n/t^{1/(h-2)}, n\right)\right)$, the fastest running time to multiply an $n \times n/t^{1/(h-2)}$ matrix by an $n/t^{1/(h-2)} \times n$ matrix.*

Proof Sketch. Consider the Doubling-Template (G, ε). Its correctness follows from Lemma 5. We analyze its running time. We prove that given Lemma 8, the running time of the recursive algorithm Template$_{\varepsilon'}$ (G, Λ) is bounded by $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, \frac{n}{\Lambda^{1/(h-2)}}\right) + \frac{n^2}{\varepsilon^3}\right)$ with probability at least $1 - \exp(-\log^2 n)$. Then, we show that the complexity of the doubling algorithm is bounded by $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^3} \cdot \mathsf{MM}\left(n, n, \frac{n}{t^{1/(h-2)}}\right)\right)$ with probability at least $1 - \frac{1}{n^3}$. The full details appear in the full version. Here we give a sketch of why the running time of Template$_{\varepsilon'}$ (G, Λ) is bounded by $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, \frac{n}{\Lambda^{1/(h-2)}}\right) + \frac{n^2}{\varepsilon^3}\right)$ with probability at least $1 - \exp(-\log^2 n)$.

We unroll the recursion of the algorithm: it makes a single call to Find-Heavy, then a single call to Count-Heavy$_{\varepsilon'}$, and then a recursive call. The algorithm's runtime can be analyzed by bounding $\{\mathsf{Find\text{-}Heavy}(G_k, \Lambda_k)\}_{k=0}^{r}$, and $\{\mathsf{Count\text{-}Heavy}_{\varepsilon'}(G_k, V_{\Lambda_k}, a_{\Lambda_k}, b_{\Lambda_k})\}_{k=0}^{r}$, where r is the recursion depth and G_k denotes the input graph for the k-th call of the recursive algorithm, where $G_0 = G$. Let $\Lambda_k = \Lambda_0 \cdot p^{kh}$ denote the heaviness threshold, and let V_{Λ_k} denote the set of Λ_k-heavy vertices in the k-th iteration. We bound the running time of the k-th call to each of the black boxes. We prove in the full version that the total running time for all calls to the Count-Heavy$_{\varepsilon'}$ black-box is $\tilde{\mathcal{O}}\left(n^2/\varepsilon^3\right)$. Next, we bound the running time of the k-th call to the Find-Heavy black-box. Note that for any k, the call $\mathsf{Find\text{-}Heavy}(G_k, \Lambda_k)$ takes $\tilde{\mathcal{O}}(\mathsf{MM}\left(|V(G_k)|, |V(G_k)|, |V(G_k)|/\Lambda_k^{1/(h-2)}\right))$ by Lemma 8. We use Chernoff's inequality to show that the number of vertices in G_k is $\tilde{\mathcal{O}}\left(\max\left\{1, np^k\right\}\right)$, thus we can replace $|V(G_k)|$ by np^k in the above expression.

The crux is that the running time of the first call to Find-Heavy also applies to subsequent calls. This is because $\mathsf{MM}\left(np^k, np^k, np^k/\left(\Lambda \cdot p^{hk}\right)^{1/(h-2)}\right) \leq \mathsf{MM}\left(n, n, \frac{n}{\Lambda^{1/(h-2)}} \cdot p^{k\cdot(3-h/(h-2))}\right) \leq \mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right)$, where the first inequality is a simple observation that we prove in the full version, and the second inequality follows since $3 - h/(h-2) = 2\frac{h-3}{h-2}$ is non-negative for $h \geq 3$ and therefore $p^{k\cdot(3-h/(h-2))} \leq 1$. We conclude that the running time of each call in $\{\mathsf{Find\text{-}Heavy}(G_k, \Lambda_k)\}_{k=0}^{r}$ is at most $r \cdot \mathcal{O}\left(\mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right)\right)$. As $r \leq \log n$, we get that all calls take a total of $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right)\right)$ time.

This completes the proof, as all calls to the Find-Heavy black box and the Count-Heavy$_{\varepsilon'}$ black box take at most $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right) + n^2/\varepsilon^3\right)$ time in total. ◀

4 Implementing the Black Box Count-Heavy$_\varepsilon$

In this section, we implement Count-Heavy$_\varepsilon$. We prove the second part of Lemma 8, stated next.

▶ **Theorem 9.** *There is an algorithm that implements the* Count-Heavy$_\varepsilon(G, S, a, b)$ *black box, when* H *is an* h*-cycles, for* $h = \mathcal{O}(1)$*, in time* $\tilde{\mathcal{O}}\left(n^2 \cdot \frac{b}{a\cdot\varepsilon}\right)$.

For this entire section, the graph G is fixed, and the set S is a fixed subset of vertices, where for every $v \in S$ we have $t_G(v) \in [a, b]$. We emphasize that a is only a lower bound on $\min_{v\in S} t_G(v)$ and b is only an upper bound on $\max_{v\in S} t_G(v)$. Denote $N_k \triangleq |S|/k$. As explained in the introduction, it is insufficient to sample a few vertices from S, estimate $t_G(v)$ for each one, and apply a concentration bound to compute $t_G(S)$. Formally, this approach fails because $\sum_{v\in S} t_G(v) \neq t_G(S)$ due to possible double counting. We overcome this issue by sampling a small subset of vertices $S' \subseteq S$, and then, for every $v \in S'$ we approximate the number of copies of H which intersect v and exactly i additional vertices from S for $0 \leq i \leq h-1$. This will allow us to estimate the number of multiple countings and therefore get an estimation of $t_G(S)$.

That is, the key ingredient of our approach for approximating $\hat{t}$ as required by $\mathsf{Count\text{-}Heavy}_\varepsilon$ is to approximate the number of cycles that intersect S in exactly k vertices. To this end, we define the following.

▶ **Definition 10.** *Let $\mathcal{C}$ denote the set of copies of $\mathtt{H}$ in G. For $U \subseteq V$, define $\mathcal{C}(U) \triangleq \{C \in \mathcal{C} \mid C \cap U \neq \emptyset\}$. Denote $t \triangleq |\mathcal{C}|$ and $t(U) \triangleq |\mathcal{C}(U)|$. In general, we replace the symbol $\mathcal{C}$ by t, to denote the cardinality of a set. Let $\mathcal{C}^k$ denote the set of copies $C \in \mathcal{C}$ with $|C \cap S| = k$. Let $\mathcal{C}^k(v) \triangleq \mathcal{C}^k \cap \mathcal{C}(v)$. Let $t^k = \left|\mathcal{C}^k\right|$.*

The following lemma shows that we can efficiently approximate t^k.

▶ **Lemma 11** (Algorithm Approx_{t^k})**.** *There exists a randomized algorithm Approx_{t^k} with the following characteristics. The input is a graph G, a set S, a precision parameter δ, a parameter $k \in [h]$, and a tuple (a, b), such that for every $v \in S$ we have $t_G(v) \in [a, b]$. The algorithm produces an output $\hat{t}^k$ which satisfies $\Pr\left[\hat{t}^k = t^k \pm t_G(S) \cdot \delta\right] \geq 1 - \frac{1}{n^4}$. The running time of the algorithm is bounded by $\tilde{\mathcal{O}}\left(n^2 \cdot \frac{b}{a} \cdot \frac{1}{\delta}\right)$.*

Approximating t^k directly leads to Theorem 9 because $\sum_{k\in[h]} t^k = t_G(S)$. A formal proof appears in the full version. To approximate t^k as required by Lemma 11, we find a value whose expectation is t^k and whose variance is at most $\mathcal{O}\left((N_k \cdot b)^2\right)$ (recall that $N_k = |S|/k$). We can do this efficiently, as follows.

▶ **Lemma 12** (Algorithm $\mathsf{Approx}_{\mathbb{E}[t^k]}$)**.** *There is a randomized algorithm $\mathsf{Approx}_{\mathbb{E}[t^k]}$ whose input is G, S, δ and k. Note that unlike Approx_{t^k}, the algorithm $\mathsf{Approx}_{\mathbb{E}[t^k]}$ does not require a and b as part of its input parameters. $\mathsf{Approx}_{\mathbb{E}[t^k]}$ computes a value X such that $\mathbb{E}[X] = t^k$ and $\mathsf{Var}[X] \leq C \cdot (N_k \cdot b)^2$, where C is a constant. The running time of the algorithm is bounded by $\tilde{\mathcal{O}}\left(n^2\right)$.*

The reason that Lemma 12 is helpful is that we can run the algorithm it provides r times and take the median of means of these invocations. A formal proof of Lemma 11 appears in the full version. To get a sample X with $\mathbb{E}[X] = t^k$ and $\mathsf{Var}[X] \leq C \cdot (b \cdot N_k)^2$ as needed by Lemma 12, we find samples Y_v with $\mathbb{E}[Y_v] = t^k(v)$ and $\mathsf{Var}[Y_v] \leq C \cdot b^2$. We can do this efficiently, as follows.

▶ **Lemma 13.** *There is a randomized algorithm $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ whose input is G, S, δ, k and a vertex $v \in S$. Unlike $\mathsf{Approx}_{\mathbb{E}[t^k]}$, $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ additionally takes a vertex $v \in S$ as input. $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ computes a value Y_v such that $\mathbb{E}[Y_v] = t^k(v)$ and $\mathsf{Var}[Y_v] \leq C \cdot b^2$, where C is a constant. The running time of the algorithm is bounded by $\tilde{\mathcal{O}}\left(n^2\right)$.*

The reason that Lemma 13 is helpful is that we can sample a vertex v uniformly at random from S, and get, using Lemma 13, an unbiased estimator for the number of copies of $\mathtt{H}$ which contains v, and intersect S exactly k times, i.e., $t^k(v)$. By the law of total expectation, we get that the expected value of this quantity, is equal to $\frac{1}{|S|}\sum_{u\in S}\mathbb{E}\left[t^k(u)\right] = t^k/N_k$. Therefore, we get an unbiased estimator for t^k up to a known value N_k. A formal proof of Lemma 12 appears in the full version.

To prove Lemma 13, we utilize the color-coding technique introduced by [2]. The high level approach of the technique is to randomly color vertices with h colors and detect *colorful* h-cycles that are ordered by, say, increasing colors. This additional structure allows for faster detection, at the cost of some probability of missing h-cycles that are colored out of order, which is overcome by repeated experiments.

A pertinent question arises: why are the algorithms $\mathsf{Approx}_{\mathbb{E}[t^k]}, \mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ necessary? Why not just choose a random coloring, compute the number of colorful copies of $\mathtt{H}$ intersecting a set S exactly k times, and apply Chebyshev's inequality to conclude that repeating this process $\tilde{\mathcal{O}}\left(n^2 \cdot \frac{b}{a\delta}\right)$ times suffices for a good approximation of t^k? The answer lies in the execution time of the matrix multiplication algorithm for counting colorful copies, which is dominated by the sizes of the largest, second largest, and smallest color classes. Roughly speaking, the smaller the product of these sizes, the faster the algorithm runs. Under random coloring, color classes each have a size of $\Omega(n)$ with high probability. Conversely, $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ produces a color class containing just a single vertex, which significantly improves the running time in the worst case, compared to the approach which does not use the algorithms $\mathsf{Approx}_{\mathbb{E}[t^k]}, \mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$. We need the following definitions to explain how color-coding works, and how the algorithm $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ uses rectangular matrix multiplication.

▶ **Definition 14.** *Fix some coloring $\varphi : V \to [\ell]$ for some $\ell \in \mathbb{N}$ (ℓ will usually be h). Let $\mathcal{C}_\varphi$ denote the set of all copies $C \in \mathcal{C}$, such that $\varphi(C) = [\ell]$. If $C \in \mathcal{C}_\varphi$, we say that C is* φ-colorful. *Also define $\mathcal{C}_\varphi(v) = \mathcal{C}_\varphi \cap \mathcal{C}(v)$, $t_\varphi \triangleq |\mathcal{C}_\varphi|$, and $t_\varphi(v) \triangleq |\mathcal{C}_\varphi(v)|$. Let $\mathcal{C}^k_\varphi \triangleq \mathcal{C}^k \cap \mathcal{C}_\varphi$. That is, $\mathcal{C}^k_\varphi$ is the set of copies of $\mathtt{H}$ in G, where each such copy is colorful w.r.t. φ, and additionally intersects the set S exactly k times. Let $t^k_\varphi = \left|\mathcal{C}^k_\varphi\right|$.*

Let A, B be two finite sets. We say that a function $\varphi : A \to B$ is a random coloring, *if the value of each $a \in A$ is set to some value $b \in B$, where b is chosen uniformly at random from B and independently of values chosen for other elements in A.*

Let $\varphi : V \to [h]$. For $i \in [h]$, we denote by $\varphi^{-1}(i)$ the set of all vertices v with $\varphi(v) = i$, and call this set the i-th color class. Assume without loss of generality that the color classes are sorted according their cardinalities, in a non-decreasing order. That is, for every $i < h$ we have $\left|\varphi^{-1}(i)\right| \geq \left|\varphi^{-1}(i+1)\right|$.

The last part of the above definition is used to quantify the complexity of computing t^k_φ as a function of the sizes of the color classes that the coloring φ induces, as follows.

▶ **Lemma 15.** *Let $(\varphi_1, \varphi_2, \varphi_h)$ denote the cardinality of the largest, second largest, and smallest color classes, respectively. For any fixed $k \in [h]$, there is a deterministic algorithm for computing $\left\{t^k_\varphi(v)\right\}_{v \in V}$ in time $\mathcal{O}\left((h!)^2 \cdot h^2 \cdot \mathsf{MM}\left(\varphi_1, \varphi_2, \varphi_h\right)\right)$.*

Next, we explain how to implement the algorithm $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$ given that we can compute the number t^k_φ of colorful copies of $\mathtt{H}$. The algorithm works as follows. It colors each vertex with a random color from the set $[h-1]$. It then recolors the input vertex by a new color h. Let φ denote this coloring. The algorithm then computes t^k_φ and outputs t^k_φ / q for some constant q such that $\mathbb{E}\left[t_\varphi / q\right] = t^k(v)$. We prove in the full version that the expectation and variance of this output satisfy the claimed requirements.

We are left with proving Lemma 15, which is the final step in the implementation of the algorithm $\mathsf{Approx}_{\mathbb{E}[\mathsf{vertex}\text{-}t^k]}$. To prove it, we reduce the problem of computing t^k_φ to the problem of computing t_φ on an auxiliary graph, in which every h-cycle is colorful and also intersects the set S exactly k times. We construct the auxiliary graph by randomly coloring the vertices with h colors, then selecting k color classes and keeping only vertices from S in them, while discarding the rest of the vertices in those classes. For the remaining $h-k$ color classes, we retain only vertices that are not part of S. We get a graph in which each color class is either contained in S or disjoint from S. This reduces the problem of computing t^k_φ on the auxiliary graph, to computing t_φ on it. The next claim addresses the running time of computing t_φ (on the auxiliary graph) instead of computing t^k_φ, and is the final missing piece for the proof of Theorem 9.

▷ Claim 16. Let G be a graph and let $\sigma \triangleq (U_1, \ldots, U_h)$ be an (ordered) sequence of disjoint subsets of vertices of $V(G)$. Let t_G^σ denote the number of copies $C \in \mathcal{C}_G$ where $C = (v_1, v_2, \ldots, v_h)$ and $v_i \in U_i$ for every $i \in [h]$. Let $U_{(1)}, U_{(2)}, U_{(h)}$ denote the cardinality of the largest, second largest, and smallest subset, respectively. Then, there is a deterministic algorithm that outputs $\{t_G^\sigma(v)\}_{v \in V}$ in time $\mathcal{O}\left(h^2 \cdot \mathsf{MM}\left(U_{(1)}, U_{(2)}, U_{(h)}\right)\right)$.

Proof of Claim 16. We assume without loss of generality that $|U_1| = U_{(h)}$, i.e., that U_1 is the smallest set. We first explain how to compute $\{t_G^\sigma(v)\}_{v \in U_1}$, and then we generalize this for U_j for any $j \in [h]$.

Let A denote the adjacency matrix of G. For $X, Y \subseteq V(G)$ let $A[X, Y]$ denote the submatrix containing all rows v for $v \in X$ and all columns u for $u \in Y$. Combinatorially, define a new directed graph H' with vertex set $X \cup Y$, and a directed edge (x, y) between a pair of vertices $x \in X$ and $y \in Y$ if and only if (x, y) is an edge in G. Note that $A[X, Y]$ is exactly the adjacency matrix of the new graph H'. Define $B_0 \triangleq I_{|U_1|}$, and for $0 \leq i < h$, define $A_i^\sigma \triangleq A[U_i, U_{i+1}]$ and $B_i^\sigma \triangleq B_{i-1} \cdot A_i$. We compute B_i^σ for $0 \leq i < h$. Note that $B_i^\sigma[x, y]$ denotes the number of paths with i edges between a vertex $x \in U_1$, and a vertex $y \in U_{i+1}$, which are of the form $(x, u_2, u_3, \ldots, u_{i-1}, y)$ where $u_j \in U_j$ for $2 \leq j < i$. Let $A_h \triangleq A[U_h, U_1]$. After computing B_h, we compute $M = B_h^\sigma \cdot A_h^\sigma$ and return all entries on the diagonal of M. Note that for $v \in U_1$, we have that $M[v, v] = t_G^\sigma(v)$.

The generalization to other values $j \in [h]$ has only a small modification and appears in the full version.

Running Time. In the i-th iteration, for $1 \leq i \leq h$, we compute the product of the matrices B_{i-1} with the matrix A_i. Let a', b' denote the dimensions of A_i. The dimensions of B_{i-1} are $U_{(h)}, a'$, and therefore the running time is $\mathsf{MM}\left(a', b', U_{(h)}\right)$. Without loss of generality, we can assume $b' \leq a'$, because $\mathsf{MM}(a', b', X) = \mathsf{MM}(X, b', a')$ for any a', b', X. We also have $a' \leq U_{(1)}$ and $b' \leq U_{(2)}$. This bounds the time for the i-th iteration by $\mathcal{O}\left(h^2 \cdot \mathsf{MM}\left(a', b', U_{(h)}\right)\right) \leq \mathcal{O}\left(h^2 \cdot \mathsf{MM}\left(U_{(1)}, U_{(2)}, U_{(h)}\right)\right)$, which proves the claim. ◁

5 Implementing the Find-Heavy Black Box

In this section, we prove the first part of Lemma 8, as is specified in the following theorem.

▶ **Theorem 17.** *There is an algorithm that implements the* $\mathsf{Find\text{-}Heavy}(G, \Lambda)$ *black box when* $\mathtt{H}$ *is an* h*-cycle with* $h = \mathcal{O}(1)$*, in time* $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right)\right)$.

An algorithm for Theorem 17 is given a graph G and a heaviness threshold Λ, and needs to output a superset of the Λ-heavy vertices, which contains no $\Lambda/(\log n)^{h^2}$-light vertices. Our algorithm works as follows. The algorithm selects a vector $P = (p_1, \ldots, p_h)$, where $p_i \in [0, 1]$ for $i \in [h]$, which we explain shortly how to select. The algorithm then samples a uniform coloring φ for the vertices, and keeps each vertex of the i-th color class with probability p_i. We emphasize that not all vertices are kept with the same probability. Let F denote the obtained graph. If v is in at least one φ-colorful cycle in F, we say that v is *P-discovered*. We can find all P-discovered vertices over F using Lemma 15. For every vertex $v \in V$, let $v[P]$ denote the probability that v is P-discovered. The randomness is taken over the choice of the coloring and the sampling of vertices. We call this experiment the *P-discovery experiment*. We repeat this P-discovery experiment k times. If v is P-discovered more than $k\tau$ times, where τ is a threshold we set later, then P adds v into the set of heavy vertices. In this case, we say that v is *P-added* to the set of heavy vertices.

The final step of our algorithm is choosing a vector P, or rather a set of vectors $\mathcal{P}$, and then performing the P-discovery experiment with each vector in the set k times. Before specifying how we should choose $\mathcal{P}$, k, and τ, we state the properties we hope to achieve.

(1) Each vector $P \in \mathcal{P}$ induces a graph F, such that invoking Lemma 15 for computing the set of P-discovered vertices, takes $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, n/\Lambda^{1/(h-2)}\right)\right)$ time. (2) Each vertex with $t_G(v) \geq \Lambda$ has at least one $P \in \mathcal{P}$ that P-adds v to the set of heavy vertices, w.h.p. (3) Any vertex v with $t_G(v) \leq \Lambda/(\log n)^{h^2}$ is w.h.p. not P-added to the heavy vertex set for any $P \in \mathcal{P}$. (4) The set $\mathcal{P}$ has only $\tilde{\mathcal{O}}(1)$ vectors, allowing us to avoid repeating this experiment too many times.

The set of all vectors we will use is as follows. We take a (finite) subset of the all vectors $(p_1, \ldots, p_h) \in [0,1]^h$ which satisfy $\prod_{i\in[h]} p_i \leq \tilde{\mathcal{O}}(1/\Lambda)$. That is, all such vectors for which $p_i \in \{2^{-j} \mid 0 \leq j \leq \log(\Lambda) + 1\}$ for $i \in [h]$. We denote this set of vectors by $\mathsf{Product}_h(\Lambda)$. Note that $|\mathsf{Product}_h(\Lambda)| \leq (\log(\Lambda) + 2)^h = \tilde{\mathcal{O}}(1)$, where the last inequality follows because $\Lambda \leq n^h$, since no vertex in G participates in more than n^h copies of any h-vertex graph (that is, if the input was $\Lambda > n^h$, the algorithm could simply output an empty set). This means that $\log(\Lambda) \leq h \log n = \tilde{\mathcal{O}}(1)$. This proves Property (4) above.

The rest of the section proves that this set satisfies Properties (1)–(3). We first prove the first property, stating that for each $P \in \mathsf{Product}_h(\Lambda)$, the P-discovery experiment can be implemented in the desired time.

▶ **Lemma 18.** *Let G be a graph with n vertices and let Λ be some positive number. Let $P = (p_1, \ldots, p_h)$ be a vector in $[0,1]^h$ with $\prod_{i=1}^h p_i = \tilde{\mathcal{O}}\left(\frac{1}{\Lambda}\right)$. Let F be the (random) graph obtained in a P-discovery experiment. Then, we can find all the P-discovered vertices in time $\tilde{\mathcal{O}}\left(\mathsf{MM}\left(n, n, n \cdot \Lambda^{-1/(h-2)}\right)\right)$, w.h.p.*

Proof Sketch. The proof is included in the full version, and we provide the proof sketch here. Fix some $P \in [0,1]^h$ where $P = (p_1, \ldots, p_h)$, and $\prod_{i=1}^h p_i \leq 1/X$, for $X \geq 1$. Assume without loss of generality that $p_i \geq p_j$ for $i > j$. This implies that p_1 is the largest coordinate. Let F be the random graph, and let F_1, F_2, F_h denote the sizes of the first, second, and h color classes in F. First, note that we can use Lemma 15 to compute the set of discovered vertices in time $\mathcal{O}(\mathsf{MM}(F_1, F_2, F_h))$. We analyze the running time of the algorithm specified in Lemma 15 on the random graph F. Using a standard Chernoff's inequality, we can get that $\mathcal{O}(\mathsf{MM}(F_1, F_2, F_h)) = \tilde{\mathcal{O}}(\mathsf{MM}(np_1, np_2, np_h))$ w.h.p. The crux of the algorithm is the following inequalities $\mathsf{MM}(np_1, np_2, np_h) \leq \mathsf{MM}(n, n, n \cdot (p_1 p_2 p_h)) \leq \mathsf{MM}\left(n, n, n/X^{1/(h-2)}\right)$, which completes the proof by setting $X \leftarrow \Lambda$. The first inequality is proved in the full version. The second inequality reduces to solving the following optimization task. Maximize $p_1 \cdot p_2 \cdot p_h$, under the constraints $p_i \geq p_{i+1}$, and $\prod_{i\in[h]} p_i = 1/X$. The proof is also in the full version, where we show that an optimal value is obtained when $p_1 = p_2 = 1$ and $p_i = X^{1/(h-2)}$, which completes the proof sketch. ◀

It remains to prove Properties $(2) - (3)$. For this, we prove that each $\Lambda \cdot (2h \log(n))^{h+1}$-heavy vertex v, has a vector $P \in \mathsf{Product}_h(\Lambda)$ for which $v[P] = \Omega(1)$. On the other hand, for every $\Lambda/\log n$-light vertex v, and any vector $P \in \mathsf{Product}_h(\Lambda)$, we have $v[P] = \mathcal{O}(1/\log n)$, and therefore, we can distinguish between the two. The full details appear in the full version.

The upper bound on $v[P]$ for light vertex uses Markov's inequality. For the rest of this section we prove the statement on heavy vertices, by induction on h, for which the base case is $h = 3$. The intuition for the proof is as follows. Consider the base case of triangles. Let V_i denote the i-th color class. Consider finding the heavy vertices in the first color class. Consider all vectors $P_i = (1, 2^{-i}, 2^i/\Lambda)$, for $0 \leq i \leq \log(\Lambda) + 1$. These vectors form a subset of $\mathsf{Product}_h(\Lambda)$. Fix some Λ-heavy vertex $v \in V_1$. We want to prove that for at least one

$i \in [\log(\Lambda)]$ we have $v[P_i] \geq \Omega(1)$. Our choice for the vectors is designed to deal with the following two extreme cases. The first case is that every $C \in \mathcal{C}_\varphi(v)$ intersects one specific vertex $u \in V_2$. For this case, the vector $P_0 = (1, 1, \frac{1}{\Lambda})$ is the right choice for discovering v because it maximizes the probability we hit u and a common neighbor of v and u, under the constraint that the sampling probability $p_1 \cdot p_2 \cdot p_3 \leq 1/\Lambda$. The second case is that among each of $V_2 \cap N(v)$ and $V_3 \cap N(v)$, there are $\sqrt{\Lambda}$ vertices that are connected as a complete bipartite graph (contained in $V_2 \times V_3$). For this case, the vector P_i for $i = \log(\Lambda)/2$ is the right choice for discovering v, because $P_i = (1, \frac{1}{\sqrt{\Lambda}}, \frac{1}{\sqrt{\Lambda}})$. For a larger h, the "hard" case is the following generalization of the above. From each color class V_i for $i \in \{3, \ldots, h\}$ we take $k = \Lambda^{1/(h-2)}$ vertices and connect them by a complete $(h-2)$-partite graph. We then take $v \in V_1$ and $u \in V_2$, we add an edge between v and u, and we connect v to all the aforementioned k vertices from V_h and we connect u to all the aforementioned k vertices from V_3. The vector $(1, 1, \frac{1}{k}, \ldots, \frac{1}{k})$ is the right choice for this case.

Roughly speaking, we show the set $\mathsf{Product}_h(\Lambda)$ gradually shifts from handling one extreme case to another, and therefore "covers" all cases in between, which are the different ways to split vertices in h-cycles into h pieces whose product of sizes is Λ.

We need a final technical step before presenting the proof. First, we construct an h-partite graph which is easier to work with. For this, we sample uniform h coloring of the vertices of G. For $i \in [h]$ let V_i denote the set of vertices colored in the i-th color. For every $i \in [h]$ we keep only edges between the vertices of V_i and $V_{i+1 \mod h}$, and direct those edges from V_i to V_{i+1}. Let G_φ denote the obtained directed graph. We emphasize that $t_{G_\varphi}(v) \leq t_\varphi(v)$, as the latter counts all colorful cycles in which v participates in, whereas the former counts only colorful cycles with edges between V_i and V_{i+1} in which v participates in. We prove that a heavy vertex will be P discovered in G_φ, with probability at least $\Omega(1)$, by some $P \in \mathsf{Product}_h(\Lambda)$, whereas light vertices will only be discovered with probability $\mathcal{O}(1/\log n)$. In other words, since the gap between the heavy and light vertices is sufficiently large, we can still distinguish between the two in G_φ.

The rest of this section is dedicated to proving the following proposition.

▶ **Proposition 19.** *Fix a vertex v, and an h-coloring of the vertices of G. Suppose $t_{G_\varphi}(v) \geq \Lambda \cdot (2h\log(n))^{(h-1)^2}$. Then, there exists a vector $P \in \mathsf{Product}_h(\Lambda)$ such that the probability that v gets P-discovered in G_φ is at least $(1-1/e)^{h-1}$.*

Due to space considerations, we prove here only the base case where the induction step is deferred to the full version.

Proof of Proposition 19. We prove this by induction on h. We start with the base case, that is, $h = 3$. We fix some h-coloring φ. Recall that we denote the i-th color class by V_i. Consider a vertex $v \in V_1$ with $t_{G_\varphi(\pi)}(v) \geq \Lambda \cdot (2h\log(n))^4$ To simplify the notation, we use $G' = G_\varphi$. We will prove that there exists a vector $P \in \mathsf{Product}_h(\Lambda)$, such that the probability that the vertex v is P-discovered over G' is at least $(1-1/e)^2$. Let $K_0 = \log(\Lambda) + 1$. We consider a subset of vectors in $\mathsf{Product}_h(\Lambda)$ of the form $P_i = (1, p_i, q_i)$, for $i \in \{0, 1, \ldots, K_0\}$, where $p_i \triangleq 2^{-i}$, $q_i \triangleq \frac{2^i}{\Lambda}$. We partition V_2 into classes as follows. For $k \in \{1, 2, \ldots, K_0\}$, let $Q_k = \{u \in V_2 \mid |\mathcal{C}_{G'}(v) \cap \mathcal{C}_{G'}(u)| \in [1/q_k, 2/q_k)\}$, $Q_0 = \{u \in V_2 \mid |\mathcal{C}_{G'}(v) \cap \mathcal{C}_{G'}(u)| \geq 1/q_0\}$. In words, $u \in Q_k$ if and only if the number of 3-cycles in G' that contain both v and u is at least $1/q_k$ and less than $2/q_k$. The set Q_0 consists of all vertices $u \in V_2$, such that the number of 3-cycles in G' that contain both v and u is at least $1/q_0 = \Lambda$. We claim that there exists $k \in \{0, 1, \ldots, K_0\}$ such that $|Q_k| \geq 1/p_k$. The proof appears in the full version. We next show that for such k, we have $v[P_k] \geq (1-1/e)^{h-1}$ which completes the proof of the base case. Fix $k \in \{0, 1, \ldots, K_0\}$ where $|Q_k| \geq 1/p_k$. For any non-empty subset $S \subseteq Q_k$,

let $\mathcal{E}_1(S)$ denote the event that $\{Q_k \cap V_2[p_k] = S\}$. That is, $\mathcal{E}_1(S)$ denote the event that during the P_k-discovery experiment, the set of vertices that were sampled from $V_2 \cap Q_k$ is exactly the set S. Let $R(S)$ denote the subset of vertices in V_3 which participate in a 3-cycle (in G') that contains v and some additional vertex from S. Let $\mathcal{E}_2(S)$ denote the event that $\{V_3[q_k] \cap R(S) \neq \emptyset\}$. That is, $\mathcal{E}_2(S)$ denotes the event that during the P_k-discovery experiment, the set of vertices that were sampled from $V_3 \cap R(S)$ is not empty. Next, we show that

$$v[P_k] \geq \sum_{S:\emptyset \subsetneq S \subseteq Q_k} \Pr\left[\mathcal{E}_1(S) \cap \mathcal{E}_2(S)\right] \geq (1-1/e)^2 \ . \tag{1}$$

For every fixed $S \subseteq Q_k$, which is not empty, the events $\mathcal{E}_1(S)$ and $\mathcal{E}_2(S)$ are independent, since $\mathcal{E}_1(S)$ addresses sampling vertices from V_2, while $\mathcal{E}_2(S)$ addresses sampling vertices from V_3, where the two samples are independent of each other. Also note that $\mathcal{E}_1(S) \cap \mathcal{E}_2(S)$ is contained in the event that v is P_k-discovered, and since the events $\{\mathcal{E}_1(S)\}_{S \subseteq Q_k}$ are disjoint, so are the events $\{\mathcal{E}_1(S) \cap \mathcal{E}_2(S)\}_{S \subseteq Q_k}$. Therefore, the event that v is P_k-discovered, contains the union of the following disjoint events $\{\bigcup_{S:\emptyset \subsetneq S \subseteq Q_k} \mathcal{E}_1(S) \cap \mathcal{E}_2(S)\}$. We get

$$\begin{aligned} v[P_k] \geq \Pr[\bigcup_{S:\emptyset \subsetneq S \subseteq Q_k} \mathcal{E}_1(S) \cap \mathcal{E}_2(S)] &= \sum_{S:\emptyset \subsetneq S \subseteq Q_k} \Pr\left[\mathcal{E}_1(S) \cap \mathcal{E}_2(S)\right] \\ &= \sum_{S:\emptyset \subsetneq S \subseteq Q_k} \Pr\left[\mathcal{E}_1(S)\right] \Pr\left[\mathcal{E}_2(S)\right] \ . \end{aligned}$$

To complete the proof, we need to show that (1) $\sum_{S:\emptyset \subsetneq S \subseteq Q_k} \mathcal{E}_1(S) \geq 1-1/e$, and (2) that for every $S \subseteq Q_k$, which is not empty, we have $\mathcal{E}_2(S) \geq 1-1/e$. The first claim follows as

$$\sum_{S:\emptyset \subsetneq S \subseteq Q_k} \mathcal{E}_1(S) = \Pr\left[Q_k[p_k] \neq \emptyset\right] = 1-(1-p_k)^{|Q_k|} \geq 1-1/e \ ,$$

where the inequalities hold for the following reasons. The first two equalities follows from definition, and the last inequality follows from the assumption that $|Q_k| \geq 1/p_k$.

The second claim follows as every non-empty subset $S \subseteq Q_k$ satisfies $|R(S)| \geq 1/q_k$. To see this, fix some vertex $u \in S$. We have $R(u) \subseteq R(S)$, and $|R(u)| \geq 1/q_k$ because $u \in Q_k$. Therefore, for any such S, we have

$$\Pr\left[\mathcal{E}_2(S)\right] = \Pr\left[R(S)[q_k] \neq \emptyset\right] = 1-(1-q_k)^{|R(S)|} \geq 1-(1-q_k)^{1/q_k} \geq 1-1/e \ .$$

This completes the proof of Equation (1). The rest of the proof appears in the full version. ◀

Abstract

The access lemma (Sleator and Tarjan, JACM 1985) is a property of binary search trees (BSTs) that implies interesting consequences such as static optimality, static finger, and working set property on any access sequence $X = (x_1, x_2, \ldots, x_m)$. However, there are known corollaries of the dynamic optimality that cannot be derived via the access lemma, such as the dynamic finger, and any $o(\log n)$-competitive ratio to the optimal BST where n is the number of keys.

In this paper, we introduce the *group access bound* that can be defined with respect to a reference *group access tree*. Group access bounds generalize the access lemma and imply properties that are far stronger than those implied by the classical access lemma. For each of the following results, there is a group access tree whose group access bound

1. Is $O(\sqrt{\log n})$-competitive to the optimal BST.
2. Achieves the k-finger bound with an *additive* term of $O(m \log k \log\log n)$ (randomized) when the reference tree is an almost complete binary tree.
3. Satisfies the unified bound with an *additive* term of $O(m \log\log n)$.
4. Matches the unified bound with a time window k with an *additive* term of $O(m \log k \log\log n)$ (randomized).

Furthermore, we prove the simulation theorem: For every group access tree, there is an online BST algorithm that is $O(1)$-competitive with its group access bound. In particular, any new group access bound will automatically imply a new BST algorithm achieving the same bound. Thereby, we obtain an improved k-finger bound (reference tree is an almost complete binary tree), an improved unified bound with a time window k, and matching the best-known bound for Unified bound in the BST model. Since any dynamically optimal BST must achieve the group access bounds, we believe our results provide a new direction towards proving $o(\log n)$-competitiveness of the Splay tree and Greedy, two prime candidates for the dynamic optimality conjecture.

1 Introduction

In the amortized analysis of a self-adjusting binary search tree (BST), the *access lemma* [32] is perhaps the most fundamental property of a BST algorithm that allows us to prove the competitiveness against many performance benchmarks, including temporal and spatial locality. If a BST algorithm satisfies the access lemma, then, by plugging in appropriate parameters, the algorithm also satisfies many interesting corollaries of the *dynamic optimality conjecture* including, for example, *balance theorem [32], static optimality [32, 20], static finger property [32], working set property [32], and key-independent optimality [19].* For example, Splay tree [32], Greedy [14, 30], and Multi-splay tree [34] are all known to satisfy the access lemma [32, 20, 34].

Despite these many applications, several strong BST properties cannot be implied via the access lemma, including *"non-trivial" competitiveness*, *k-finger property* (or even the (weaker) dynamic finger property [13]), and the *unified bound* [24, 17]. For completeness, we discuss each one of them in turn.

Competitiveness. Dynamic optimality conjecture [32] postulates that there is an online binary search tree (BST) on n keys whose cost to perform a search (access) sequence $(x_1, \ldots, x_m) \in \{1, 2, \ldots, n\}^m$ (including the cost to adjust the internal structure in between the sequence) is at most that of the offline optimum up to a constant factor. We say that a BST algorithm is $f(n)$-*competitive* if its total cost is, at most, the cost of the offline optimum up to a factor of $f(n)$. A BST algorithm is dynamically optimal if it is $O(1)$-competitive.

Splay tree [32] and Greedy [14] are widely regarded as the prime candidates for dynamic optimality conjecture. However, the best-known competitiveness of both the algorithms remains $O(\log n)$, which can be shown from the access lemma or (via static optimality) using any balanced trees. The access lemma cannot be used to prove $o(\log n)$-competitive (for example, we cannot even derive the *sequential access theorem* [33] via the access lemma). In contrast, there are BST algorithms with $O(\log \log n)$-competitiveness. In [15], the authors presented the first $O(\log \log n)$-competitive binary search tree, which they call Tango Trees. Several subsequent results provided alternate $O(\log \log n)$-competitive algorithms [21, 35, 3, 11]. Despite achieving the best-known competitive ratios, the fact that these algorithms do not satisfy many corollaries of the dynamic optimality conjecture makes them less promising than Splay and Greedy.

***k*-Finger Bound.** Several notions of finger bounds [32, 13, 26] have been introduced to capture the "locality" of input sequences. The strongest finger bound, called k-Finger bound, was motivated by the connection between BSTs and the k-server problem [8]. It has still remained unclear whether any online BST algorithm achieves this property.

We define k-Finger bound as follows. Assume we have an almost complete binary tree where each leaf represents a distinct key from $\{1, \ldots n\}$. This tree is called the *reference tree*. Assume that there are k-fingers stationed at k arbitrary leaves in the reference tree.

▶ **Definition 1 (k-Finger Bound).** *When a key x_t is searched at time t, we must move one finger from its current position to the node containing x_t. The cost of the search is the number of nodes on the unique path connecting the finger's source to its destination. We define $F^k(X)$ as the minimum, overall finger movement strategies distance traversed by the fingers to process the sequence X when the reference tree is an almost complete binary tree.*

The classical access lemma cannot imply the k-finger property even when $k = 1$ (called the lazy finger bound [26], which generalizes the dynamic finger bound [13]). Nonetheless, it is possible to prove a non-trivial bound w.r.t. k-Finger using different techniques. In [8],

the authors claimed the existence of an online BST algorithm with cost $O((\log k)^7 \mathrm{F}^k(X))$. However, this claim has an error since the algorithm employs Lee's [29] k-server result, which the author has retracted. Instead of Lee's result, we can use the k-server result of Koutsoupias and Papadimitriou [27], $(2k-1)$-competitive. By using [8], it implies that an online BST algorithm exists with a running time of $O(k\mathrm{F}^k(X))$. This is a relatively large gap when compared with the best achievable offline BST bound of $O(\log k)F^k(X)$ [8]; in fact, whether there exists a BST whose cost is additive in the k-finger bound, that is $O(F^k(X) + m \log k)$, has remained open.

Unified Bound. To describe the unified bound, we should first understand the *working set bound* [25, 32] and the *dynamic finger bound* [13, 32, 26]. If x_t is a search key, then the working set bound requires x_t to be searched in amortized time $O(\log \mathrm{Ws}(x_t))$, where $\mathrm{Ws}(x_t)$ is the number of distinct keys searched since the last search of x_t. The working set bound is based on temporal locality and implies many more bounds, such as the static finger bound, the static optimality bound, etc. The dynamic finger bound states that the amortized time to search x_t is $O(\log |x_t - x_{t-1}| + 2)$. The dynamic finger bound is based on spatial locality.

The *unified bound* [24] implies both the working set and the dynamic finger.

▶ **Definition 2.** *The unified bound can be defined as* $\mathrm{UB}(X) = \sum_{t=2}^{m} \log(\min_{t'<t}\{t - t' + |x_t - x_{t'}| + 2\})$.

The unified bound is stronger than both the working set and the dynamic finger, as it suggests that it is in-expensive to search a key that is close to a recently searched key. It is true that the access lemma cannot prove the unified bound, although there are data structures that satisfy the unified bound. Iacono [24] gave a comparison-based data structure called the unified structure that achieves the unified bound. In [1], the authors gave a dynamic comparison-based data structure that achieves the unified bound. Derryberry and Sleator [17] designed the first BST algorithm called Skip-Splay tree that nearly achieves the unified bound with its running time of $O(\mathrm{UB}(X) + m \log\log n)$. In [4], the authors modified Skip-Splay using layered working-set trees to get amortized $O(\mathrm{UB}(x_i) + \log\log n)$ time, where x_i is a search key at time i. In Derryberry's thesis [18], Cache trees were introduced as the first BST algorithm aiming to achieve the Unified bound. However, this assertion was later questioned by Sleator in [31]. The question of whether a BST algorithm can truly achieve the Unified bound remains open and intriguing.

Unified Bound with time window. In the unified bound, for each x_t, we find a key $x_{t'}$ that minimizes the term $(t - t' + |x_t - x_{t'}| + 2)$ where $t' < t$. We can add another condition that t' should be one of the last k searched keys before time t. Thus, t' comes from some time window. We call this variant *Unified Bound with a time window*. We formally define it as follows.

▶ **Definition 3.** *Given an integer* k*, the unified bound with a time window is*

$$UB^k(X) = \sum_{t=2}^{m} \log\Big(\min_{t' \in [t-k \ldots t-1]} \{t - t' + |x_t - x_{t'}| + 2\}\Big).$$

This bound can be seen as "interpolating" between the dynamic finger and the unified bounds: When $k = 1$, $\mathrm{UB}^k(X)$ is the dynamic finger bound, and when $k = m$, $\mathrm{UB}^m(X)$ is the unified bound. For $k = 1$, we know that both Splay tree and Greedy satisfy the dynamic finger bound. The authors of [8], showed a relation between $\mathrm{UB}^k(X)$ and $\mathrm{Opt}(X)$, i.e,

$$\textsc{Opt}(X) \leq \beta(k)\textsc{Ub}^k(X)$$

where $\beta(\cdot)$ is some fixed (super exponentially growing) function.

In sum, the access lemma is an intrinsic property of a BST which implies nice properties but cannot seem to imply any of the aforementioned properties.

1.1 Our New Concept: The Group Access Bounds

The main conceptual contribution of this paper is to introduce the *group access bounds* that generalize the bound from the access lemma. Informally, the access lemma states that the amortized cost to access x_t at time is $O\left(\log \frac{W}{w(x_t)}\right)$, where $w(x_t)$ is the weight of x_t and W is the sum of weights of all the keys in the BST.

We give an informal definition of the group access bounds (see Section 3 for the formal definitions). Denote $[n] = \{1, \ldots, n\}$. The key gadget to describe our bound is the notion of *group access tree*, which captures a hierarchical partition of $[n]$ until singletons are obtained. That is, in a group access tree $\mathcal{T}$, each node $v \in V(\mathcal{T})$ is associated with an "interval" $I_v \subseteq [n]$ (consecutive integers). The root $r \in V(\mathcal{T})$ has $I_r = [n]$, if a node v has children $v_1, \ldots, v_k$, then we have that $\{I_{v_1}, \ldots, I_{v_k}\}$ forms a partition of I_v. This process continues until each leaf $v \in V(\mathcal{T})$ is associated with a singleton. Note that the tree does not have to be binary. See Figure 1 for illustration.

Figure 1 Examples of two group access trees. Each represents a hierarchical partition of $[n]$ until singletons are obtained. When a group access tree is a star (LHS), our bound is simply the access lemma.

Let w be a positive weight function that assigns a real-valued weight to each node in $\mathcal{T}$. We define the cost to access the tree $\mathcal{T}$ w.r.t. the weight function w as follows. For any edge (u, v) where u is the parent of v, the cost on (u, v) is $\log \frac{W(u)}{w(v)}$ where $W(u)$ is the total weight of all the children of u. The access cost of a key $a \in [n]$, denoted as $\text{cost}_{\mathcal{T},w}(a)$, is defined as the total cost of all the edges in the path P_a from the root to the leaf containing a in the group access tree $\mathcal{T}$. That is,

$$\text{cost}_{\mathcal{T},w}(a) = \sum_{(u,v)\in P_a} \log \frac{W(u)}{w(v)}.$$

Some readers may have observed the similarity between our cost function and that of the access lemma. Indeed, one can show that it generalizes the access lemma.

▶ **Observation 4.** *If the group access tree $\mathcal{T}$ is a star, then the access $a \in [n]$ on $\mathcal{T}$ gives the same (amortized) cost as the access lemma on the same weight function.*

Intuitively, the group access bound offers a "search tree" (which is not necessarily binary) where the cost of searching a is the sum of the cost of the edges on the search path P_a.

Let $\mathcal{W} = (w^{(1)}, \ldots, w^{(m)})$ be a sequence of weight functions. The total cost of the group access tree $\mathcal{T}$ on an access sequence $X = (x_1, \ldots, x_m)$, where $x_t \in [n]$ for all t, is

$$\text{cost}_{\mathcal{T},\mathcal{W}}(X) = \sum_t \text{cost}_{\mathcal{T},w^{(t)}}(x_t).$$

Similar to the access lemma, the weight functions should change in a controllable manner in order to be meaningful (e.g., the weight functions for the working set bound are changed in a structured way in the access lemma). Here, we introduce the notion of *locally bounded* weight families. We say that a sequence of weight functions $\mathcal{W} = (w^{(1)}, \ldots, w^{(m)})$ is *locally bounded* if for all t, the weight increase from time t to $t+1$ can happen only at the nodes in the path from root to x_t in the group access tree $\mathcal{T}$.

Given an input sequence $X = (x_1, \ldots, x_m)$, *the group access bound* $\mathsf{GAB}(\mathcal{T}, X)$ w.r.t. a group access tree $\mathcal{T}$ is

$$\mathsf{GAB}(\mathcal{T}, X) = \min_{\mathcal{W} \text{ locally bounded}} \text{cost}_{\mathcal{T},\mathcal{W}}(X).$$

1.2 Our Technical Results: Deriving BST Bounds from GAB

We show that the cost of the group access tree (with respect to certain weight functions) is competitive against many strong BST bounds that are not known via the access lemma. We say a group access bound is *randomized* if the group access tree $\mathcal{T}$ is obtained by a random process that iteratively partitions $[n]$ until singletons are obtained.

▶ **Theorem 5.** *For each of the following bounds, there exists deterministic group access trees $\mathcal{T}_1, \mathcal{T}_3$ and randomized group access trees $\mathcal{T}_2, \mathcal{T}_4$ such that for all access sequences $X = (x_1, \ldots, x_m)$ where $x_t \in [n]$ for all t,*

1. $\mathsf{GAB}(\mathcal{T}_1, X) = O(\sqrt{\log n}) \cdot \textsc{Opt}(X)$ *where $\textsc{Opt}(X)$ is the cost of offline optimal BST on X.*
2. $\mathsf{GAB}(\mathcal{T}_2, X) = O(F^k(X) + m \log k \log\log n)$ *(randomized). That is, it is competitive with k-finger up to an additive term when the reference tree is an almost complete binary tree.*
3. $\mathsf{GAB}(\mathcal{T}_3, X) = O(\textsc{Ub}(X) + m \log\log n)$*. That is, it is competitive with the unified bound up to an additive term.*
4. $\mathsf{GAB}(\mathcal{T}_4, X) = O(\textsc{Ub}^k(X) + m \log k \log\log n)$ *(randomized). That is, it is competitive with unified bound with a time window up to an additive term.*

The group access tree for the second and the fourth bound can be efficiently constructed from a probability distribution.

It is not immediately clear that these group access bounds can be realized by BST algorithms. We show that every group access tree $\mathcal{T}$ can be simulated by an online BST algorithm. Let $\mathcal{A}$ be a BST algorithm. We denote $\text{cost}_{\mathcal{A}}(X)$ to be the cost of algorithm $\mathcal{A}$ running on a sequence $X = (x_1, \ldots, x_m)$.

▶ **Theorem 6** (Simulation Theorem)**.** *For any group access tree $\mathcal{T}$, there exists an online BST algorithm $\mathcal{A}$ such that for any sufficiently long access sequence X , $\text{cost}_{\mathcal{A}}(X) = O(\mathsf{GAB}(\mathcal{T}, X))$. Furthermore, if the group access tree $\mathcal{T}$ is randomized, then $\mathcal{A}$ is randomized, where the competitive ratio is measured in the oblivious adversary model.*

The Simulation Theorem (Theorem 6) signifies that one can prove new BST bounds by just proving the existence of a group access tree along with locally bounded weight families.

Table 1 Summary of the new bounds that can be derived via the group access bound. The first two columns show the best-known results prior to this paper. Asymptotic notations (Big-Oh and Big-Omega) are hidden for brevity.

	Offline Upper	**Online Upper**	**Our new bounds**

1.3 Significance of our results

Beyond the access lemma, group access bounds serve as the first step towards providing a unified framework for proving binary search tree bounds systematically. To resolve the dynamic optimality conjecture, a candidate algorithm must satisfy all dynamic optimality corollaries simultaneously, and we believe group access bounds are the starting point for this.

Apart from the competitiveness result, the results we present here either match the best-known bounds (such as unified bound) or provide an improvement upon even the best-known offline algorithms (k-finger bound when reference tree is an almost complete binary tree and unified bound with bounded time window) in the BST model.

We remark that even though our competitive ratio does not match the $O(\log\log n)$ best-known factor, what we prove is more general where any BST algorithm satisfying the GAB will automatically be $O(\sqrt{\log n})$- competitive. The BST algorithm we present here is called GGREEDY, a very similar algorithm to GREEDY – a prime candidate for dynamic optimality. GGREEDY resembles Greedy and inherits its conceptual simplicity. Even after a lot of work in this area [20, 26, 5, 7, 6, 8, 11, 22, 23, 17, 28, 9], only the trivial bound for GREEDY is known: $\textsc{Greedy}(X) = O(\log n)\ \textsc{Opt}(X)$ for all possible X. Thus, GREEDY is $O(\log n)$-competitive. Our result raises some hope of proving $o(\log n)$-competitive ratio for Greedy by showing that Greedy satisfies the group access bound.

We illustrate the power of the group access bound by deriving two new BST bounds that have not been known for even offline BST algorithms.

▶ **Corollary 7.** *For each of the following items, there is a randomized online BST algorithm $\mathcal{A}$ such that the expected cost for any search sequence $X = (x_1, \ldots, x_m)$ where $x_t \in [n]$ for all t,*

- $cost_{\mathcal{A}}(X) = O(F^k(X) + m \log k \log\log n)$, *and*
- $cost_{\mathcal{A}}(X) = O(UB^k(X) + m \log k \log\log n)$.

The algorithms are randomized because the group access trees are chosen based on a probability distribution. The bound $O(F^k(X) + m \log k \log\log n)$ gives an improvement from the best known online BST that costs $O(kF^k(X))$ in [8] and improves upon the offline bound $O(\log k)F^k(X)$ for some range of parameter k when the reference tree is an almost complete binary tree.

From such an improvement, we can derive a new "pattern-avoiding" bound for BSTs. We say that a sequence *contains* another sequence (or pattern) π if it contains a subsequence that is order-isomorphic to π.

▶ **Corollary 8.** *Let $X \in [n]^m$ be a sequence that does not contain the pattern $(k, k-1, \ldots, 1)$. Then there exists a randomized BST that accesses X with cost $O(nk + m \log k \log\log n)$.*

This bound improves the best-known online algorithm [9] that gives a bound of $O(mk^2)$ and the best-known bound on the offline optimum $O(mk)$ [8] for some range of parameters when the reference tree used to calculate $F^k(X)$ is an almost complete binary tree.

The unified bound obtained in this paper matches the best-known bound of $O(\text{UB}(X) + m \log \log n)$ by Derryberry and Sleator [17]. In fact, we show that we can use the analysis of [17] as a black box once we obtain the group access tree for Unified bound.

We do expect more applications of the group access bounds in binary search trees since group access bounds are generic and yet (unlike the dynamic optimality conjecture) maintain a certain flavor of being "static" (since $\mathcal{T}$ is still fixed). We show that this static component can be algorithmically leveraged. We believe that our bound offers a "bridge" between the relatively static access lemma to the dynamic optimality conjecture, which requires a full understanding of dynamic BSTs.

Contribution to potential function analysis. Another interesting aspect of our work is that once the group access bound is formulated, the proof relies solely on the use of the standard Sum-of-logs potential function, which in general, does not seem sufficient to prove any strong bounds beyond the access lemma. We show that by "augmenting" the access lemma with a group access tree, a natural and standard sum-of-logs potential function immediately provides significantly stronger BST bounds.

In general, designing a potential function for analyzing a given algorithm is a highly innovative but rather ad-hoc task. Our work suggests that the sum-of-logs potential function on the group access tree might be a good candidate for proving that Greedy or Splay is $O(\sqrt{\log n})$-competitive.

Combining BSTs. In [16], the authors showed that different BSTs with well-known bounds can be combined into a single BST that achieves all the properties of the combined BSTs. For example, Tango trees and Skip-Splay trees can be combined to get a BST, which is $O(\log \log n)$-competitive and achieves the Unified bound with an additive term of $O(\log \log n)$. The combined BST from their approach, however, results in a different BST algorithm. Our group access bounds offer another way to combine known BST bounds, as we have illustrated in the above discussion, while retaining the original algorithm, e.g., proving that Splay satisfies the group access bound implies that Splay itself possesses all the nice properties derived from GAB.

1.4 Concluding Remarks

We propose the group access bound – a far-reaching extension of the standard access lemma and present applications in deriving new and unifying old bounds. Some of our bounds even improve the best-known upper bound on the offline optimum on some range of parameters.

An immediate (and perhaps most interesting) open question is whether Greedy or Splay satisfies the group access bound via the sum-of-logs potential function. We believe that this question is very concrete (since it involves a specific potential function), so proving or refuting it would not be beyond our reach.

Developing further understanding and finding more applications of our group access bounds are interesting directions. For instance, what are other BST bounds that can be implied by the group access bounds? Can we show that $\mathsf{GAB}(\mathcal{T}, X) \leq O(\mathsf{OPT}(X))$ for some (distribution of) group access tree $\mathcal{T}$? Can one derive a non-trivial result about more general pattern-avoiding bounds [6, 23, 10, 12]? It was shown that optimal BST takes linear time for a pattern of bounded length [2]. Can we design a BST algorithm with a running time $O(\text{F}^k(X) + m \log k)$ for any sequence X of length m where the k-finger bound is calculated on any arbitrary reference tree?

There are also open questions to settle the complexity of specific BST bounds both in the online and offline settings. Most notably, is there any BST data structure that satisfies the unified bound?

1.5 Organization

We introduce notation and terminology in Section 2. We formalize the description of the group access bounds in Section 3. We prove $O(\sqrt{\log n})$-competitiveness in Section 4. Owing to space limitations, the k-finger bound, unified bound and unified bound with a time window can be found in the full version of the paper. To prove the Simulation theorem (Theorem 6), we first define an algorithm, called GGREEDY, that simulates the group access tree in Section 5. We derive the group access lemma in Section 6 and finally prove the Simulation theorem (See to the full version of the paper). Certain proofs and sections are removed which can be found in the full version of the paper.

2 Preliminaries

Let $X = (x_1, x_2, \ldots, x_m)$ be a sequence of m accesses where each access is from the set $\{1, 2, ..., n\}$. This sequence can be represented as points in the plane, that is, $X_p = \{(x_t, t) : t \in [m]\} \subseteq \mathbb{R}^2$. Imagine these points on a plane with an origin and X-Y axis. Since both the coordinates of a point are positive, all points lie in the first quadrant. The positive x-axis represents the key space, and the y-axis represents time. For any two points p, q in a point-set P, if they are not in the same horizontal or vertical line, we can form a rectangle $\square pq$. A rectangle $\square pq$ is said to be *arborally satisfied* if $\exists r \in P \setminus \{p, q\}$ such that r lies in $\square pq$. [14] introduced us to the following beautiful problem:

▶ **Definition 9** (Arborally Satisfied Set). *Given a point set X_p, find a point set Y such that $|X_p \cup Y|$ is minimum and every pair of points in $X_p \cup Y$ is arborally satisfied.*

[14] showed that finding the best BST execution for a sequence X is equivalent to finding the minimum cardinality set Y such that $X_p \cup Y$ is arborally satisfied.

▶ **Lemma 10** (See Lemma 2.3 in [14]). *Let A be an online algorithm that outputs an arborally satisfied set on any input representing X. Then, there is an online BST algorithm A' such that the cost of A' is asymptotically equal to the cost of A, where the cost of A is the number of points added by A plus the size of X.*

At time t, we say that x_t is an *access key*. An algorithm adds (or touches) *points* while processing a key with the aim of making the final point set arborally satisfied. For a point p, denote $p.x$ and $p.y$ as its x-coordinate and y-coordinate, respectively. Note that $p.x$ denotes a key, and $p.y$ denotes the time when the point p was added.

Let q be a key. When we say that GREEDY (or any other algorithm) adds a *point at key* q at time t, it means that GREEDY adds a point at coordinates (q, t). Given two points p_1 and p_2, p_2 lies to the right of p_1 if $p_2.x > p_1.x$, else it lies to the left of p_1. For brevity, we will avoid using ceil and floor notation for various parameters used in this paper.

3 The Group Access Bound

In this section, we describe the *group access bound*, which generalizes the access lemma. The concept of group access bound consists of two ingredients:

- **Hierarchical partition**: An **interval partition** of $[n]$ is a partition π such that each set $S \in \pi$ is an interval (i.e. consecutive integers). Let π be an interval partition of $[n]$. We say that π is a refinement of another partition π' if for all $S \in \pi$ and $S' \in \pi'$, we have $S \subseteq S'$ or $S \cap S' = \emptyset$. For instance $\{\{1,2\},\{3,4\},\{5,6\}\}$ is a refinement of $\{\{1,2,3,4\},\{5,6\}\}$.
  A hierarchical partition is a sequence of partitions $\mathcal{P} = \{\pi_0, \pi_1, \ldots, \pi_k\}$ such that (i) for all i, π_{i+1} is a refinement of π_i, (ii) $\pi_0 = \{[n]\}$ and (iii) $\pi_k = \{\{i\}\}_{i\in[n]}$ (singletons). Given such $\mathcal{P}$, each interval (set) in π_i is referred to as a **group**. The sets in π_i are called level-i groups for $\mathcal{P}$.
  A hierarchical partition $\mathcal{P}$ has a natural corresponding tree $\mathcal{T}$ where each node in $V(\mathcal{T})$ corresponds to a group. The root of $\mathcal{T}$ is $[n]$ (the group in π_0). Level-i of the tree contains nodes that have 1-to-1 correspondence with sets in π_i. Moreover, there is an edge connecting $S \in \pi_i$ to $S' \in \pi_{i+1}$ if $S' \subseteq S$.
- **Weight functions**: Given a canonical hierarchical partition $\mathcal{P}$, a $\mathcal{P}$-weight function is an assignment of positive real values to nodes in $V(\mathcal{T})$, i.e., $w : V(\mathcal{T}) \to \mathbb{R}_{>0}$.

We use the term **group access tree** to denote a hierarchical partition $\mathcal{P}$ (as well as its corresponding tree $\mathcal{T}$). See Figure 2 for illustration.

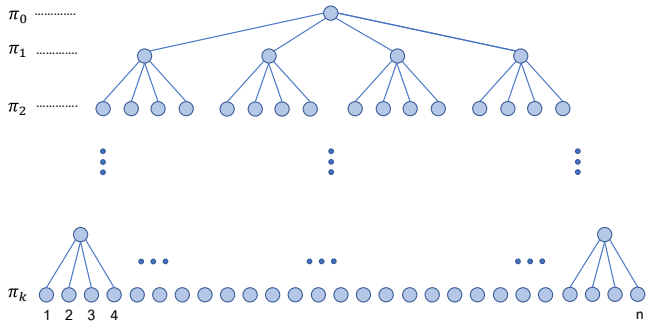

Figure 2 An illustration of group access tree.

▶ **Definition 11** (Group given a key). *Let $\mathcal{P}$ (or $\mathcal{T}$) be a group access tree and let $p \in [n]$ be a key. Then, for each j, we use $g_j(p)$ to denote the (unique) level-j group $S \in \pi_j$ in which p lies.*

▶ **Definition 12** (Level j groups of a group). *Given a level-$(j-1)$ group (interval) g, denote by $\mathsf{CG}(g)$ the set of children groups in level j that are contained in g, i.e., $\mathsf{CG}(g) = \{g' \in \pi_j : g' \subseteq g\}$. These are exactly the same as the groups that are children of node $g \in V(\mathcal{T})$.*

We are now ready to define the access cost in the group access tree. When accessing key $a \in [n]$ in the group access tree $\mathcal{T}$ and $\mathcal{P}$-weight w, denote by $\mathcal{T}(a)$ the path from root to a in the tree $\mathcal{T}$; in particular, this path contains $\mathcal{T}(a) = (g_0(a), g_1(a), \ldots, g_k(a) = \{a\})$. The cost incurred on edge $e = (g_{j-1}(a), g_j(a))$ is

$$c_e(\mathcal{T}, w, a) = \log\left(\frac{W^j}{w(g_j(a))}\right)$$

where $W^j = \sum_{g' \in \mathsf{CG}(g_{j-1}(a))} w(g')$. The total access cost is $c(\mathcal{T}, w, a) = \sum_{e\in\mathcal{T}(a)} c_e(\mathcal{T}, w, a)$. Notice that this access cost is very similar to the access lemma cost. In fact, one can show that it generalizes the access lemma:

▶ **Observation 13.** *The access lemma corresponds to the cost $c(\mathcal{T}, w, a)$ when $\mathcal{T}$ is a star.*

In this way, our group access bound can be seen as an attempt to strengthen the standard access lemma by introducing hierarchical partitioning. As in the access lemma, the interesting application to BSTs happens when the changes of weights are "controllable" (e.g., in the working set bound). We introduce the concept of *locally bounded* weight families $\mathcal{W}$ to capture this property.

▶ **Definition 14.** *The weight family $\mathcal{W}$ is locally bounded if for all time t, for every group $g \notin \mathcal{T}(x_t)$, we have $w_{t+1}(g) \leq w_t(g)$. This means that the weight can increase only when $g \in \mathcal{T}(x_t)$.*

We are interested in the total access cost on a sequence $X = (x_1, \ldots, x_m) \in [n]^m$ where the group access trees are allowed weight changes over time, that is, we are given a sequence of weight functions $\mathcal{W} = \{w_1, \ldots, w_m\}$ where w_t denotes the weight function at time t.

The **group access bound** w.r.t. $(\mathcal{T}, X)$ is:

$$\mathsf{GAB}(\mathcal{T}, X) = \min_{\mathcal{W} \text{ locally bounded}} \sum_{t \in [m]} c(\mathcal{T}, w_t, x_t).$$

Note that the use of "minimum" in the definition of group access bound serves to select the weight family with the lowest weight among multiple locally bounded weight families.

Our main contribution is in showing that the group access bound is competitive to many strong bounds in the binary search tree model. We say that the group access bound is (α, β)-**competitive** to function $f : [n]^m \to \mathbb{R}$ if there exists a group access tree $\mathcal{T}$ such that $\mathsf{GAB}(\mathcal{T}, X) \leq \alpha f(X) + \beta|X|$.

▶ **Theorem 15.** *The group access bound is $(O(\sqrt{\log n}), O(1))$-competitive to* OPT.

The group access bound can also be used by allowing randomization in choosing the hierarchical partition $\mathcal{P}$. We say that the group access bound is randomized (α, β)-**competitive** to function $f : [n]^m \to \mathbb{R}$ if there is an efficiently computable distribution $\mathcal{D}$ that samples $\mathcal{T}$ such that

$$\mathbb{E}_{\mathcal{T} \sim \mathcal{D}}[\mathsf{GAB}(\mathcal{T}, X)] \leq \alpha f(X) + \beta|X|.$$

▶ **Theorem 16.** *The group access bound is (randomized) $(O(1), O(\log k \log\log n))$-competitive to the k-finger bound when the reference tree is an almost complete binary tree.*

▶ **Theorem 17.** *The group access bound is $(O(1), O(\log\log n))$-competitive to the unified bound.*

▶ **Theorem 18.** *The group access bound is (randomized) $(O(1), O(\log k \log\log n))$-competitive to the unified bound with a time window of size k.*

We say that a BST algorithm $\mathcal{A}$ **satisfies the group access bound** w.r.t. group access tree $\mathcal{T}$ if the cost of the algorithm is at most $O(\mathsf{GAB}(\mathcal{T}, X))$ for all input sequence X.

▶ **Proposition 19.** *If a BST algorithm satisfies the group access bound and the group access bound is (α, β)-competitive to function f, then the cost of the BST algorithm on any sequence X is at most $O(\alpha \cdot f(X) + \beta|X|)$.*

We will later show that a family of BST algorithms (named Ggreedy) satisfies the group access bound and possesses all the aforementioned properties.

4 $(O(\sqrt{\log n}), O(1))$-competitiveness

In this section, we prove Theorem 15. We will define the appropriate group access tree so that the group access bound is upper bounded by $(O(\sqrt{\log n}), O(1)) \cdot \mathsf{OPT}(X)$.

Group access tree

Define the partition $\mathcal{P}$ inductively as follows. Let $M = 2^{\sqrt{\log n}}$. First $\pi_0 = \{[n]\}$. Given π_i, we define π_{i+1} by, for each interval $S \in \pi_i$, partitioning S into $S_1, S_2, \ldots, S_M$ equal-sized intervals and adding them into π_{i+1}. This would give us a group access tree where each non-leaf node has M children and its height is at most $h = O(\sqrt{\log n})$.

Weight function

Given a sequence $X = (x_1, x_2, \ldots, x_m)$, we define a weight function $\mathcal{W}$ which is locally bounded and such that $c(\mathcal{T}, \mathcal{W}, X) = \sum_t c(\mathcal{T}, \mathcal{W}, x_t) \leq O(\sqrt{\log n}) \cdot (\mathsf{OPT}(X) + m)$. This will give us the desired result. Our weight function uses the notion of *last access*.

▶ **Definition 20.** *Consider time t and the group $g = g_{j-1}(x_t)$. Let $t' < t$ be the last time before t at which g is on the search path $\mathcal{T}(x_t)$. We say that a child $g_1 \in \mathsf{CG}(g)$ is **last accessed (child) group** of g at time t if the edge (g, g_1) is on search path $\mathcal{T}(x_{t'})$.*

Remark that each group can have at most one child in $\mathcal{T}$ that is the last access group. Now, we are ready to define the weight function:

$$w_t(g) = \begin{cases} M & \text{if } g \text{ is the last accessed group of its parent} \\ 1 & \text{otherwise} \end{cases}$$

It is easy to verify that this family of weight functions $\mathcal{W}$ is locally bounded (there is only one key whose weight can increase between time t and $(t+1)$).

▶ **Lemma 21.** *Consider edge $e = (g_{j-1}(x_t), g_j(x_t))$. We have*

$$c_e(\mathcal{T}, \mathcal{W}, x_t) = \begin{cases} O(\log M) & \text{if } g_j(x_t) \text{ is not the last accessed group of } g_{j-1}(x_t) \\ O(1) & \text{otherwise} \end{cases}$$

Proof. By definition, $W^j = \sum_{g' \in \mathsf{CG}(g_{j-1}(x_t))} w_t(g') \leq 2M$ because there is only one group in $\mathsf{CG}(g_{j-1}(x_t))$ with weight M (the last accessed group) and there can be at most M groups with weight 1.

We analyze the cost in two cases: If $g = g_j(x_t)$ is the last accessed group, then we have $c_e(\mathcal{T}, \mathcal{W}, x_t) \leq \log(W^j / w_t(g)) \leq \log(2M/M) = O(1)$. Otherwise, if $g_j(x_t)$ is not the last accessed group, then we have $\log(2M) \leq O(\log M)$. ◀

Cost analysis

Consider the search path $\mathcal{T}(x_t)$. Denote by γ_t the number of groups on $\mathcal{T}(x_t)$ that are not the last accessed group of its parents. The cost $c(\mathcal{T}, w_t, x_t) = \sum_{e \in \mathcal{T}(x_t)} c_e(\mathcal{T}, w_t, x_t)$, and from the above lemma, the cost is at most $O(\log M) \cdot \gamma_t + O(h) \leq O(\sqrt{\log n})(\gamma_t + 1)$. Therefore, the total cost is $O(\sqrt{\log n}) \cdot (\sum_t \gamma_t + m)$. The sum of γ_t will be upper bounded by the Wilber bound.

The Wilber bound. Wilber [36] gave two lower bounds on the running time of any BST on a sequence X. These bounds are known as Wilber1 and Wilber2.[1] We now describe Wilber1(X). Let R be a leaf-oriented (keys at the leaves) binary search tree, and for each $a \in [n]$, denote by $R(a)$ the search path in R of key a. When searching a sequence X in R, for each node $v \in V(R)$, the **preferred child** of node v at time t (denoted by Preferred-Child$_t(v)$) is the child of v on the last search path in R at time t. If node v is not on the search path $R(x_t)$, we know that the preferred child cannot change, i.e., Preferred-Child$_t(v)$ = Preferred-Child$_{t-1}(v)$.

The Wilber bound with respect to R at time t and node v is:

$$\text{Wilber1}_R^t(v) = \begin{cases} 1 & \text{if Preferred-Child}_t(v) \neq \text{Preferred-Child}_{t-1}(v) \\ 0 & \text{otherwise} \end{cases}$$

The total Wilber bound of a sequence X is $\text{Wilber1}_R(X) = \sum_t \sum_v \text{Wilber1}_R^t(v)$. The Wilber bound is defined as the maximum, overall reference BST R, of Wilber1$_R(X)$.

▶ **Lemma 22.** *We have that* $\sum_t \gamma_t \leq O(\textit{Wilber1}(X))$

Proof. It is sufficient to define a reference tree R that allows us to charge the cost of $\sum_t \gamma_t$ to Wilber1$_R(X)$. Notice that our group access tree $\mathcal{T}$ is not a binary search tree. However, it can be naturally extended into a binary search tree R as follows: We process the non-leaf nodes in $V(\mathcal{T})$ in a non-decreasing order of distance from the root. When a group $g \in V(\mathcal{T})$ is processed, we remove the edges from g to its children. Let T_g be an arbitrary BST rooted at g and leave $\mathsf{CG}(g)$; we add the tree T_g in place of the deleted edges (See Figure 3). After all vertices are processed, it is straightforward to see that the resulting tree is a (leaf-oriented) BST.

Now we claim that $\sum_t \gamma_t$ can be upper bounded by Wilber1$_R(X)$. Recall that γ_t is the number of groups on the search path $\mathcal{T}(x_t)$ that are not last accessed. Let $G_t \subseteq V(\mathcal{T}(x_t))$ be those groups on the search path that are not last accessed. For each such group $g_1 \in G_t$, let g be its parent, so we know that the last time g was on the search path, some other group $g_2 \in \mathsf{CG}(g)$ was instead chosen. Notice that the search paths $R(g_1)$ and $R(g_2)$ also visit g but branch away at some vertex b inside T_g (it could be that $b = g$). This would imply that Preferred-Child$_t(b) \neq$ Preferred-Child$_{t-1}(b)$ and therefore $\text{Wilber1}_R^t(b) = 1$. This implies that $\gamma_t \leq \sum_v \text{Wilber1}_R^t(v)$ and hence the lemma. ◀

The lemma implies that the total group access bound is at most

$$O(\sqrt{\log n})(\text{Wilber1}(X) + m) \leq O(\sqrt{\log n}) \cdot (\mathsf{OPT}(X)).$$

See the full version of the paper for sections related to the *k-finger bound*, *Unified bound*, and *Unified bound with a time window*.

5 Ggreedy algorithm

This section will define a new BST algorithm named Ggreedy, which satisfies the *group access bound*. The Ggreedy algorithm is very similar to Greedy. Therefore, we first describe the Greedy algorithm and then provide some intuition about the Ggreedy algorithm before describing it formally.

[1] They can also be derived using an elegant geometric language of [14].

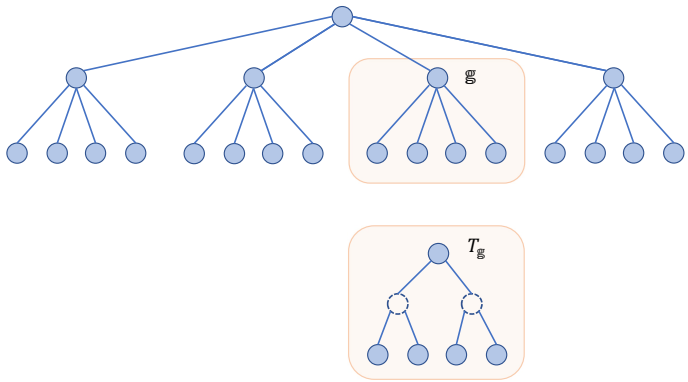

Figure 3 An example of g and T_g.

Given a search sequence $X = \{x_1, x_2, \ldots, x_m\}$, intuitively the GREEDY algorithm works as follows:
At time t, the GREEDY algorithm performs a horizontal line sweep of the points at $y = t$. By induction, we can assume that all the pairs of the points below the line $y = t$ are arborally satisfied. So, at time t, we find all the rectangles with one endpoint x_t and the other endpoint q, where q is a point below the sweep line. If the rectangle $\square x_t q$ is not arborally satisfied, then add a point at the corner of the rectangle $\square x_t q$ on the sweep line to make it arborally satisfied. See Algorithm 2 for the formal definition of GREEDY (Figure 4b illustrates the execution of GREEDY).

Algorithm 1 ADDPOINTS(A,x_t).

```
1 foreach □x_t q in A do
2 |   Add a point at (q.x, x_t.y)
3 end
```

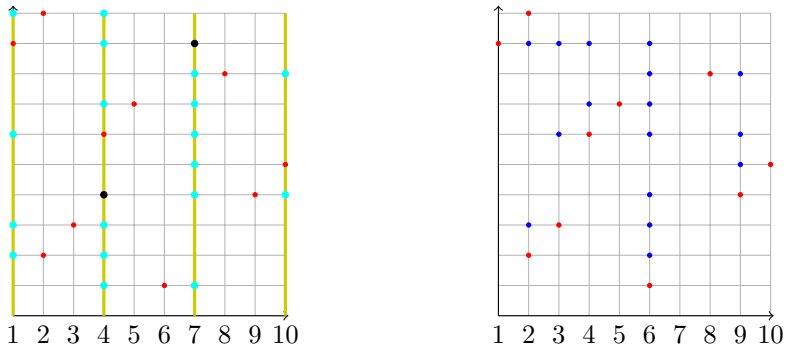
Algorithm 2 Processing GREEDY at time t.

```
1 Let A be the set of all the arborally
    unsatisfied rectangles with one endpoint as
    x_t and another endpoint below the line
    y = t;
2 AddPoints(A, x_t);
```

We will now try to provide some intuition (motivation) behind the GGREEDY algorithm. While analyzing the GREEDY algorithm, we observed that if we can partition the keys into groups (containing consecutive keys) and treat these groups as keys, then we can apply the GREEDY algorithm to this new set of keys. We can then recursively do this within each group, making the analysis easy.

As an example, we can divide the key space into three groups, say from $[1, \ldots, n/3]$, $[n/3+1, \ldots, 2n/3]$ and $[2n/3+1, \ldots, n]$ which we can represent as keys k_1, k_2 and k_3. We can now run the GREEDY algorithm on this set of keys. When a key in the range $[n/3+1, \ldots, 2n/3]$ is searched at time t, we can assume that the key k_2 is searched and perform the GREEDY algorithm accordingly on the keys k_1, k_2 and k_3. We can recursively do this procedure inside each group. To separate the groups and to ensure that the resultant point set is *arborally satisfied*, we add points at the boundaries of the groups.

One can observe that the recursive partition of the keys corresponds to a *group access tree*. An astute reader can see that GGREEDY is not a single algorithm but a family of BST algorithms, which depends on the group access tree.



(a) GGREEDY. **(b)** GREEDY.

Figure 4 GGREEDY(on level 1) vs GREEDY on a sequence $(6, 2, 3, 9, 10, 4, 5, 8, 1, 2)$. There are three groups $\{[1 \dots 4], [4 \dots 7], [7 \dots 10]\}$ in level 1, recursively we can define groups within each group. Red points are the searched keys. (a) Light blue points are added at the boundary of a group $g = g_1(x_t)$. Black points are added to make GGREEDY arborally satisfied with other groups in level 1 (b) Blue points are added to make GREEDY arborally satisfied.

We are now ready to define the GGREEDY algorithm. Pick a group access tree $\mathcal{T}$. Let g be a group at any level in the group access tree. The group g contains a set of consecutive keys at the leaves of $\mathcal{T}$. The group g has two end keys, which we denote as the boundary keys of the group.

▶ **Definition 23** (Boundary of a group)**.** *Let g be a group that contains consecutive keys $(a, a+1, a+2, \dots, b)$, then left$(g) = a$ is called the left boundary key of the group g. Similarly, right$(g) = b$ is called the right boundary key. Together, they are called the boundary keys of the group g.*

In GREEDY, we access a search key x_t at time t, but in GGREEDY, when a key is searched at time t, we access a group per level of the group access tree $\mathcal{T}$. We define the access of a group as follows:

▶ **Definition 24** (Accessed group at time t in level j)**.** *A group g is said to be accessed at time t in level j if $g = g_j(x_t)$.*

▶ **Definition 25** (Accessed boundary key at time t in level j)**.** *The boundary keys of a group are accessed at time t in level j when the group g is accessed at time t in level j. We denote the boundary key access by adding points at the two boundaries of the group g at time t in level j.*

While accessing a key in GREEDY at time t, the algorithm touches keys to form an arborally satisfied set. Similarly, in GGREEDY, when a group is accessed at time t, we might touch other groups. We define a touch group in GGREEDY as follows:

▶ **Definition 26** (Touched group at time t in level j)**.** *A group g is said to be touched at time t in level j if one of the boundary keys of g is touched.*

▶ Remark 27. An accessed group is also a touch group at time t in level j, where both the boundary keys are touched.

Similar to the definition of *unsatisfied rectangle* for GREEDY, we define an *unsatisfied group* in GGREEDY as follows:

▶ **Definition 28** (Unsatisfied group at time t in level j)**.** *A group g_1 is said to be unsatisfied at time t in level j if one of the boundary keys of g_1 forms an unsatisfied rectangle with the boundary keys of $g = g_j(x_t)$ at time t. We denote the unsatisfied group by $\square g_1 g$.*

Let g_1 be a group at time t in level j, which is unsatisfied when the group g is accessed. We touch g_1 at time t in level j to make it an *arborally satisfied* group.

Let us now informally describe the GGREEDY algorithm. When a key x_t is accessed at time t, we access one group per level in the group access tree $\mathcal{T}$. While accessing the group $g = g_j(x_t)$ in level j, we find all the unsatisfied groups in level j which lie inside the group $g_{j-1}(x_t)$ and make them arborally satisfied. We recursively do this for level $j+1$ and so on. The GGREEDY algorithm can be viewed as if we are applying the GREEDY algorithm on groups at each level of the group access tree $\mathcal{T}$. Hence the name, GREEDY on groups or GGREEDY.

We now describe the GGREEDY algorithm formally (See Algorithm 4).

Algorithm 3 Touchgroups(A,g,j).

```
1 Touch g in level j;
2 foreach □g1g in A do
3 |   Touch g1 in level j;
4 end
```

Algorithm 4 Processing of GGREEDY at time t.

```
1 foreach j = 1 to k do
2 |   Let A_j be the set of all arborally
  |     unsatisfied groups in level j when
  |     accessing g = g_j(x_t);
3 |   Touchgroups(A_j, g, j);
4 end
```

In the above algorithm, at iteration j, we first add points at left($g_j(x_t)$) and right($g_j(x_t)$) (same as touching group $g_j(x_t)$). Then, we process all the arborally unsatisfied groups with one endpoint as $g_j(x_t)$ and the other endpoint inside the group $g_{j-1}(x_t)$ (See Figure 4a for the execution of GGREEDY on level 1).

▶ **Observation 29.** *Although the GGREEDY algorithm is very similar to GREEDY, it is not a candidate for dynamic optimality conjecture because of the inherent cost of the groups at each level in the group access tree $\mathcal{T}$.*

We will now try to bound the number of groups touched by GGREEDY in iteration j of Algorithm 4. Let us give it a special notation:

▶ **Definition 30.** *Let $\mathcal{T}_j(t)$ be the set of groups touched by GGREEDY in the j-th iteration of Algorithm 4 at time t.*

Touching a group is the same as touching the group's boundary key(s). Therefore, we consider the boundary keys of the group for the rest of this section to provide better-detailed proofs. We now show some essential properties of $\mathcal{T}_j(t)$.

▶ **Lemma 31.** *$\mathcal{T}_j(t)$ only contains points that are at the boundaries of level j groups that lie inside $g_{j-1}(x_t)$.*

For proof, refer to the full version.

An immediate corollary of the above lemma is:

▶ **Corollary 32.** *Let p be a point that lies strictly inside $g_{j-1}(x_t)$. If GGREEDY adds p at time t then x_t lies in $g_j(p)$.*

We will now show that GGREEDY outputs an arborally satisfied set. Let us assume that we are processing x_t. We can visualize GGREEDY as running GREEDY first on the level 1 group. This execution is the same as GREEDY. Then, we add points at the boundary of $g_1(x_t)$. This is the first step when we deviate from the GREEDY algorithm. Once we have added the boundary points, we again run GREEDY on level 2 groups, and the process continues. One may feel that touching the boundary keys may create some unsatisfied rectangles. But in the following lemma, we show that this is not the case.

▶ **Lemma 33.** *GGREEDY outputs an arborally satisfied set on any input representing X.*

The proof can be found in the full version of the paper.

In the next section, we generalize the *access lemma*, which have been proved for the Splay tree and GREEDY [33, 20]. Let us define a notation before we move to the next section.

▶ **Definition 34.** *Let $\hat{\mathcal{T}}_j(t)$ denote the amortized number of groups touched by GGREEDY in the j-th iteration of Algorithm 4 at time t.*

6 The Group Access Lemma

In this section, we introduce the *group access lemma*, which is a generalization of the *access lemma* and show that the GGREEDY algorithm satisfies it.

Consider the group access tree $\mathcal{T}$. When a BST algorithm $\mathcal{A}$ accesses x_t at time t, after the access, it adjusts itself to $\mathcal{A}'$. Let $g_1 = g_j(x_t)$ be the group that contains x_t. Let Φ_t^j be a potential function that depends on the state of the algorithm with respect to the groups at level j in $\mathcal{T}$. Define $\Phi_t = \sum_j \Phi_t^j$. Define the group access lemma as follows:

▶ **Definition 35** (Group Access Lemma)**.** *A BST algorithm $\mathcal{A}$ satisfies the group access lemma if the amortized cost to access x_t at time t in level j is:*

$$\hat{\mathcal{T}}_j(t) \leq O\left(\log \frac{W^j}{w_{t-1}(g_1)}\right) + \Phi_{t-1}^j - \Phi_t^j$$

The amortized cost of the algorithm $\mathcal{A}$ at time t can be denoted as:

$$\hat{\mathcal{T}}(\mathcal{A}, x_t) = \sum_j \hat{\mathcal{T}}_j(t)$$

and the amortized cost of the algorithm $\mathcal{A}$ on the access sequence X can be defined as:

$$\hat{\mathcal{T}}(\mathcal{A}, X) = \sum_t \hat{\mathcal{T}}(\mathcal{A}, x_t).$$

With the definition of the group access lemma in hand, we will now show that GGREEDY satisfies the group access lemma.

Please refer to the full version of the paper for the proof that GGREEDY satisfies the group access lemma and the simulation theorem.

Abstract

A fundamental concept related to strings is that of repetitions. It has been extensively studied in many versions, from both purely combinatorial and algorithmic angles. One of the most basic questions is how many distinct squares, i.e., distinct strings of the form UU, a string of length n can contain as fragments. It turns out that this is always $\mathcal{O}(n)$, and the bound cannot be improved to sublinear in n [Fraenkel and Simpson, JCTA 1998].

Several similar questions about repetitions in strings have been considered, and by now we seem to have a good understanding of their repetitive structure. For higher-dimensional strings, the basic concept of periodicity has been successfully extended and applied to design efficient algorithms – it is inherently more complex than for regular strings. Extending the notion of repetitions and understanding the repetitive structure of higher-dimensional strings is however far from complete.

Quartics were introduced by Apostolico and Brimkov [TCS 2000] as analogues of squares in two dimensions. Charalampopoulos, Radoszewski, Rytter, Waleń, and Zuba [ESA 2020] proved that the number of distinct quartics in an $n \times n$ 2D string is $\mathcal{O}(n^2 \log^2 n)$ and that they can be computed in $\mathcal{O}(n^2 \log^2 n)$ time. Gawrychowski, Ghazawi, and Landau [SPIRE 2021] constructed an infinite family of $n \times n$ 2D strings with $\Omega(n^2 \log n)$ distinct quartics. This brings the challenge of determining asymptotically tight bounds. Here, we settle both the combinatorial and the algorithmic aspects of this question: the number of distinct quartics in an $n \times n$ 2D string is $\mathcal{O}(n^2 \log n)$ and they can be computed in the worst-case optimal $\mathcal{O}(n^2 \log n)$ time.

As expected, our solution heavily exploits the periodic structure implied by occurrences of quartics. However, the two-dimensional nature of the problem introduces some technical challenges. Somewhat surprisingly, we overcome the final challenge for the combinatorial bound using a result of Marcus and Tardos [JCTA 2004] for permutation avoidance on matrices.

1 Introduction

Repetitions are a staple topic of both combinatorics on words [22] and algorithms on strings [33]. In both areas, the classical objects of study are linear sequences of characters from a finite alphabet. Depending on whether we are more interested in their combinatorial properties or designing efficient algorithms for them, it is customary to call such sequences words or strings, respectively. In this paper, we use the latter convention.

Perhaps the most natural example of a repetition in a string is a square, that is, a string of the form UU, also known as a "tandem repeat" in the biological literature [53]. The basic question concerning squares is whether any of the fragments of a string of length n is a

square, and, if so, what is the number of such fragments. The origins of this question can be traced back to Thue [75], who constructed an infinite string over a ternary alphabet that contains no squares. Thus, we can construct arbitrarily long square-free strings over such alphabets. The next question is what is the largest possible number of fragments that are squares. However, any even-length fragment of $\mathtt{a}^n$ is a square. One way to make the question non-trivial is to only consider the primitively rooted squares, meaning that U is not a power of another string. This decreases the possible number of occurrences to $\mathcal{O}(n \log n)$, which is asymptotically tight [30]. Another way is to only consider distinct squares.

Fraenkel and Simpson [46] showed that any string of length n contains at most $2n$ distinct squares and constructed an infinite family of strings such that each string S in this family contains $|S| - \Theta(\sqrt{|S|})$ distinct squares. For many years, it was conjectured that the upper bound should be at most n. After a series of simplifications and improvements [41,57,58,65,74], the conjecture was finally proven by Brlek and Li [24], who showed an upper bound of $n - \sigma + 1$, where σ is the size of the alphabet. The same authors [25] also showed an upper bound of $n - \Theta(\log n)$. On the algorithmic side, Apostolico and Preparata [16], Main and Lorentz [67] and Crochemore [30] showed how to find a compact representation of all squares (in particular, test square-freeness) in a string of length n in $\mathcal{O}(n \log n)$ time. Specifically, such a representation stores all distinct squares. To obtain a faster algorithm for finding only the distinct squares, one needs to restrict the size of the alphabet. For constant alphabets, Gusfield and Stoye [54] designed an $\mathcal{O}(n)$ time algorithm. This was later generalized to the more general case of an integer alphabet (that can be sorted in linear time) [20, 36]. The complexity of testing square-freeness over general ordered and unordered alphabets of size σ was very recently settled by Ellert and Fischer [43] providing a linear time algorithm, and Ellert et al. [44] providing an $\mathcal{O}(n \log \sigma)$ time algorithm, respectively; this problem has been also studied in the parallel [13, 14, 37, 38] and the online settings [55, 63, 64, 66]. Thus, by now we seem to have obtained a rather good understanding of both the combinatorial and the algorithmic properties of distinct squares. We stress that, while these properties are interesting on their own, and naturally the combinatorial bound was used to design efficient enumeration algorithms [21, 54], they were also crucial in designing efficient algorithms and data structures for other problems. For example, the Maximal Augmented Suffix Tree (MAST) introduced by Apostolico and Preparata [17] which enables counting the maximum number of non-overlapping occurrences uses $\mathcal{O}(n)$ space due to the linear upper bound on the number of distinct squares (as observed by Brodal et al. [26]). The same applies to the construction time and the space of the Cover Suffix Tree (CST) [61, 71].

Arguably, linear sequences are not always best suited to model the objects that we would like to study. A natural extension is to consider rectangular arrays of characters from a finite alphabet, which can be seen as 2D strings. Possible applications in image processing [72] sparked interest in designing algorithms for searching in 2D strings already in the late 1970s [18, 23]. This turned out to be significantly more challenging than searching in 1D strings: both versions were studied already in the 70s, but while for 1D strings an alphabet-independent linear-time algorithm had been soon found [60], achieving the same goal for 2D strings took till the 90s [3, 39, 47]. Extensions of this basic problem such as approximate searching [9, 29], indexing [28, 49, 50], searching in smaller space [32], scaled searching [6, 7], searching in random 2D strings [59], dictionary searching [8, 56, 69], and searching in compressed 2D strings [1, 4, 11] have been also considered.

The combinatorial structure of 2D strings seems to be significantly more involved than that of 1D strings. As a prime example, the basic tool used in algorithms and combinatorics on 1D strings is periodicity. We say that p is a period of a 1D string $S[1\,..\,n]$ when $S[i] = S[i+p]$

for all $i = 1, 2, \ldots, n - p$. The set of all periods is very structured due to a classical result of Fine and Wilf [45] according to which for any two periods p, q such that $p + q \leq n$, the greatest common divisor of p and q is also a period. The natural way to extend this notion to 2D strings is to define (x, y) to be a period of a 2D string $S[1\,..\,n][1\,..\,n]$ when $S[i][j] = S[i + x][j + y]$ for all $i = 1, 2, \ldots, n - x$ and $j = 1, 2, \ldots, n - y$. This notion was introduced by Amir and Benson [2], who provided a detailed study based on classifying 2D strings into four periodicity classes. This classification was later crucial in designing solutions for pattern matching, namely, an alphabet-independent linear-time algorithms [39, 47] and alphabet-independent optimal parallel algorithms [5, 31].

The rich combinatorial structure of 2D strings brings the challenge of finding the right generalization of the concept of repetitions. Apostolico and Brimkov [12] introduced two notions of repetitions in 2D strings that can be seen as natural analogues of squares in 1D strings. A tandem $W^{1,2}$ (or $W^{2,1}$) consists of 2 occurrences of the same block W arranged in a 1×2 (or 2×1) pattern. Next, a quartic $W^{2,2}$ consists of 4 occurrences of the same block W arranged in a 2×2 pattern. Note that Apostolico and Brimkov [12] additionally required that W is primitive, meaning that it cannot be partitioned into non-overlapping copies of another block. However, it is more natural to call such tandems and quartics primitively rooted, as in [27]. Apostolico and Brimkov [12] showed asymptotically tight bounds of $\mathcal{O}(n^3 \log n)$ and $\mathcal{O}(n^2 \log^2 n)$ for the number of primitively rooted tandems and quartics, respectively. The former bound was later complemented with a worst-case optimal $\mathcal{O}(n^3 \log n)$-time algorithm [15]. Finally, Amir, Landau, Marcus, and Sokol [10] introduced the notion of maximal repetitions in 2D strings, as an analogue of so-called runs in 1D strings.

Two tandems $T = W^{1,2}$ and $T' = V^{1,2}$ are distinct when $W \neq V$. Similarly, two quartics $Q = W^{2,2}$ and $Q' = V^{2,2}$ are distinct when $W \neq V$. It is easy to see that an $n \times n$ 2D string contains $\mathcal{O}(n^3)$ distinct tandems by applying the bound on the number of 1D distinct squares on every horizontal slice of the 2D string. It is also not hard to show that this bound is asymptotically tight, even over a binary alphabet [48]. Thus, tandems do not seem to be the right generalization of squares, and we should rather focus on quartics.

Recently, Charalampopoulos, Radoszewski, Rytter, Waleń, and Zuba [27] showed a non-trivial upper bound of $\mathcal{O}(n^2 \log^2 n)$ on the number of distinct quartics in an $n \times n$ 2D string, and an algorithm that finds them in the same time complexity. At this point, it was quite unclear to what extent distinct quartics suffer from the "curse of dimensionality". Could it be that, similarly to the number of distinct squares, their number is also linear in the size of the input? Gawrychowski, Ghazawi, and Landau [48] very recently showed that this is not the case, by constructing an infinite family of $n \times n$ 2D strings over a binary alphabet containing $\Omega(n^2 \log n)$ distinct quartics. This shows that there is a qualitative difference between distinct squares and distinct quartics, but leaves a significant gap between the lower bound of $\Omega(n^2 \log n)$ and the upper bound of $\mathcal{O}(n^2 \log^2 n)$ [27].

Our Results. Our contribution is twofold. First, we show an asymptotically tight bound of $\mathcal{O}(n^2 \log n)$ on the number of distinct quartics in an $n \times n$ 2D string. Thus, the "curse of dimensionality" for this problem is a single logarithm for going from 1D to 2D. Second, we show how to find all distinct quartics in worst-case optimal $\mathcal{O}(n^2 \log n)$ time. We thus resolve both the combinatorial and algorithmic complexity of distinct quartics.

A notable difference of our algorithm from the previously fastest algorithm for computing distinct quartics [27] is that the algorithm of [27] first finds all 2D runs[1] of the 2D string, which are not even known to be $\mathcal{O}(n^2 \log n)$, and then infers the quartics from those. We manage to circumvent this, by focusing on some selected occurrences of 2D strings of the form $Q^{5,5}$, instead of considering all of them via 2D runs.

Overview of the Combinatorial Upper Bound. When bounding the number of distinct squares, one begins with fixing the rightmost occurrence of every distinct square [46]. In two dimensions, it is less clear what an extreme occurrence could mean. We simply say that it is an occurrence at a position (i, j) such that there is no other occurrence at a different position (i', j') such that $i' \geq i$ and $j' \geq j$. Next, a standard trick used when working with strings is to partition them into groups with length in $[2^a \,..\, 2^{a+1})$ for different integers a. Similarly to previous work [27], we partition quartics into groups $C_{(a,b)}$ with height in $[2^a \,..\, 2^{a+1})$ and width in $[2^b \,..\, 2^{b+1})$ for pairs of integers (a, b). We begin with proving that, for any position (i, j), the set of extreme occurrences at (i, j) may have a non-empty intersection with only $\mathcal{O}(\log n)$ such groups. Next, we partition all quartics into *thin* and *thick* (note that the meaning of thin and thick is slightly different than in the previous work [27]). More specifically, a quartic Q is thick if and only if it can be partitioned into $x \times y$ occurrences of a primitive 2D string R, i.e., $Q = R^{x,y}$ for some $x, y \geq 5$. Then, we show that for any position (i, j) and group $C_{(a,b)}$, there can be at most 10 extreme occurrences of thin quartics in $C_{(a,b)}$ at position (i, j). Overall, we thus have only $\mathcal{O}(n^2 \log n)$ distinct thin quartics.

The main part of our proof for the combinatorial upper bound is the analysis of the number of distinct thick quartics. Our starting point is the observation (already present in [27]) that this number can be upper bounded by the number of occurrences of 2D strings of the form $R^{5,5}$, for primitive R, that participate in the partition of an extreme occurrence of some quartic $R^{x,y}$. To bound the number of such occurrences, we assign an occurrence of $R^{5,5}$ at position (i, j) to position $(x, y) = (i + 2 \cdot \mathsf{height}(R), j + 2 \cdot \mathsf{width}(R))$ and say that this occurrence is *anchored* at position (x, y). Then, our goal is to show that the number of occurrences assigned to every position is only $\mathcal{O}(\log n)$. For a fixed position (i, j), this is done by first arguing that the pairs $(\lfloor \log(\mathsf{height}(R)) \rfloor, \lfloor \log(\mathsf{width}(R)) \rfloor)$ are pairwise distinct among occurrences of different $R^{5,5}$ assigned to (i, j). This requires a careful analysis of the implied periodic structure and allows us to focus on bounding the number of such pairs. What we do next is the main novelty of our approach for the combinatorial upper bound. We treat the pairs as a set of points $\mathcal{P} \subseteq [1 \,..\, m]^2$, where $m = \lfloor \log n \rfloor$, and argue that, for each $(a, b) \in \mathcal{P}$, the set of points of $\mathcal{P}$ that are strictly dominated by (a, b) can be partitioned into at most two chains. Next, our goal is to upper bound the size of any set $\mathcal{P}$ with this property by $\mathcal{O}(m)$. To this end, we leverage a result from extremal combinatorics, namely, the proof of the Füredi-Hajnal conjecture by Marcus and Tardos [68]. This result states that, if an $m \times m$ binary matrix M avoids a fixed permutation matrix P as a submatrix, i.e., if P cannot be obtained by deleting some rows and columns of M and changing some 1s to 0s, then M contains at most $c_P \cdot m$ 1s, where c_P is a constant if the size of P is a constant. We reformulate the constraint on $\mathcal{P}$ to avoid the permutation matrix shown below as a submatrix. Overall, this allows us to conclude that the number of extreme occurrences of thick quartics is also $\mathcal{O}(n^2 \log n)$.

[1] 2D runs are subarrays that are periodic both vertically and horizontally and cannot be extended without any of the periods changing.

			1

A high-level description of our approach for the algorithmic part is provided in Section 4, as it is best read after the full proof of the combinatorial upper bound.

Open Problem. An interesting follow-up question on repetitions in 2D strings is that of settling the number of 2D runs that a 2D string can have. Charalampopoulos et al. [27] proved an $\mathcal{O}(n^2 \log^2 n)$ upper bound for the number of 2D runs that an $n \times n$ 2D string can contain, while Gawrychowski et al. [48] constructed an infinite family of $n \times n$ 2D strings (over a binary alphabet) with $\Omega(n^2 \log n)$ 2D runs. On the algorithms' side, Amir et al. [10] devised an algorithm that computes all 2D runs in an $n \times n$ 2D string in $\mathcal{O}(n^2 \log n + |\mathsf{output}|)$ time, and is thus optimal. For 1D strings, after a long line of results [34, 35, 51, 52, 62, 70, 73] the number of runs was shown to be less than n [19] and they can be computed in $\mathcal{O}(n)$ time for strings over ordered alphabets [43] (see [19, 62] for earlier algorithms for strings over linear-time sortable alphabets).

2 Preliminaries

For integers $i, j \in \mathbb{Z}$, we denote the set $\{k \in \mathbb{Z} : i \leq k \leq j\}$ by either of $[i\,..\,j]$, $(i-1\,..\,j+1)$, $[i\,..\,j+1)$, and $(i-1\,..\,j]$.

Let us consider a string $S = S[1]S[2]\cdots S[n]$ of length $|S| = n$. For integers $i \leq j$ in $[1\,..\,n]$, we denote the *fragment* $S[i]\cdots S[j]$ by $S[i\,..\,j]$. A positive integer $p \leq n$ is a *period* of S if and only if $S[i] = S[i+p]$ for all $i \in [1\,..\,n-p]$. The smallest period of S is called *the period* of S and is denoted by $\mathsf{per}(S)$. A string is called *periodic* if and only if its period is at most half its length. We will extensively use the following property of periods.

▶ **Lemma 2.1** (Periodicity Lemma [45]). *If p and q are periods of a string S and satisfy $p + q \leq |S|$, then $\gcd(p, q)$ is also a period of S.*

We denote the concatenation of two strings U and V by UV. Further, for $k \in \mathbb{Z}_+$, we denote the concatenation of k copies of U by U^k. A string V that cannot be written as U^k for a string U and an integer $k > 1$ is called *primitive*. A string of the form UU is called a *square*. A square UU is said to be primitively rooted if U is primitive. More generally, a string of the form U^k is called a k-th power, and it is said to be primitively rooted if U is primitive. We extensively use the following property of squares.

▶ **Lemma 2.2** (Three Squares Lemma [40][2]). *If squares U^2 and V^2 are proper prefixes of a square W^2, $|U| < |V|$, and U is primitive, then $|U| + |V| \leq |W|$.*

We next summarise some combinatorial properties of squares and higher powers.

▶ **Proposition 2.3.** *Consider a string S and an integer a. At most two prefixes of S with lengths from $[2^a\,..\,2^{a+1})$ can be primitively rooted squares.*

Proof. Assume that there are three such prefixes, and denote them by UU, VV, WW, where $|U| < |V| < |W|$. Since $|UU|, |VV|, |WW| \in [2^a\,..\,2^{a+1})$, we have $|U| + |V| > |W|$, which together with the primitivity of $|U|$ leads to a contradiction. ◀

[2] This formulation comes from [46].

W	W	W	W	W
W	W	W	W	W

Figure 1 2D string $W^{2,5}$ is shown for some 2D string W.

▶ **Proposition 2.4.** *Consider a string S and an integer a. All prefixes of S with lengths in $[2^a\,..\,2^{a+1})$ that are powers higher than 2 are of the form U^k for the same primitive string U.*

Proof. Assume that there are two such prefixes U^k and V^ℓ, where U is primitive, $k, \ell \geq 3$, and $|U| < |V|$. First, $|V|$ is a period of $Z := S[1\,..\,|U| + |V|]$. Second, $|V| < 2^{a+1}/3$ and consequently $|U^{k-1}| \geq |V|$, as otherwise we would have $|U^k| < k \cdot |V|/(k-1) \leq 3|V|/2 < 2^a$, hence $|U|$ is also a period of Z. We thus have that both $|U|$ and $|V|$ are periods of Z. Then, an application of Lemma 2.1 yields that $\gcd(|U|, |V|)$ is a period of Z. But U is primitive so $\gcd(|U|, |V|) = |U|$, and V hence is a power of U, a contradiction. ◀

A fragment $S[i\,..\,j]$ of a string S is a *run* if and only if it is periodic and it cannot be extended by a character in either direction with its period remaining unchanged.

An $m \times n$ 2D string A is simply a two-dimensional array with m rows and n columns, where $\mathsf{height}(A) = m$ and $\mathsf{width}(A) = n$. The position that lies on the i-th row and the j-th column of A is position (i, j). We regard the top-left position of a 2D string as position $(1, 1)$, and the bottom-right position as position (m, n). That is, we index rows from top to bottom and columns from left to right. We say that a 2D string P occurs at a position (i, j) of a 2D string T if and only if the *subarray* (also called *fragment*) $T[i\,..\,i+\mathsf{height}(P))[j\,..\,j+\mathsf{width}(P))$ of T equals P. We write $\Sigma^{*,*}$ to denote the set of all 2D strings over alphabet Σ.

A positive integer p is a *horizontal period* of a 2D string A such that $\mathsf{width}(A) \geq p$ if and only if the j-th column of A is equal to the $(j+p)$-th column of A for all $j \in [1\,..\,\mathsf{width}(A)-p]$. The smallest horizontal period of A is *the horizontal period* of A. An integer q is a (the) *vertical period* of A if and only if q is a (resp. the) horizontal period of the transpose of A.

It will be sometimes convenient to view a 2D string as a 1D metastring by viewing each column (or row) as a metacharacter such that metacharacters are equal if and only if the corresponding columns (resp. rows) are equal. Observe that the horizontal periods (resp. vertical periods) of a 2D string A are in one-to-one correspondence with the periods of the metastring obtained from A by viewing each column (resp. row) as a metacharacter.

For a 2D string W and $x, y \in \mathbb{Z}_+$, we denote by $W^{x,y}$ the 2D string that consists of $x \times y$ copies of W; see Figure 1 for an illustration. A 2D string W is *primitive* if it cannot be written as $Y^{a,b}$ for any 2D string Y and $a, b \in \mathbb{Z}_+$ that are not both equal to 1. The primitive root of a 2D string X is the unique primitive 2D string Y such that $X = Y^{a,b}$ for $a, b \in \mathbb{Z}_+$. Note that the primitive root is indeed unique by the periodicity lemma applied to the horizontal and vertical 1D metastrings obtained from X.

Model of computation. For our algorithm, we assume the standard word-RAM model of computation with word-size $\Omega(\log n)$, where n is the size of the input.

3 The Combinatorial Bound

We consider an $n \times n$ 2D string A, whose entries are over an arbitrary alphabet Σ. We say that a fragment $A[i\,..\,i')[j\,..\,j')$ is a quartic-fragment if and only if it equals some quartic Q; further, we say that it is an *extreme* or *bottom-right* quartic-fragment if Q does not have any occurrence at another position (i'', j'') with $i'' \geq i$ and $j'' \geq j$. We refer to such an

occurrence of Q as an extreme or bottom-right occurrence. We denote by $\mathsf{BR}(i,j)$ the set of extreme quartic-fragments with top-left corner (i,j). Further, we denote the union of all $\mathsf{BR}(i,j)$ by BR. Observe that the distinct quartics in BR are exactly the distinct quartics in A as every quartic that occurs in A has at least one extreme occurrence. Note that a quartic may have $\Theta(n)$ extreme occurrences; an example is provided in Figure 2.

0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	1
0	0	0	0	0	0	1	1
0	0	0	0	0	1	1	1
0	0	0	0	1	1	1	1
0	0	0	1	1	1	1	1
0	0	1	1	1	1	1	1
0	1	1	1	1	1	1	1

Figure 2 Consider an $n \times n$ 2D string A all of whose entries that lie weakly above the main diagonal are equal to 0 and all of whose entries that lie strictly below the main diagonal are equal to 1. The quartic that equals $0^{2,2}$ has $n-2$ extreme occurrences in A. This is illustrated for $n=8$: the bottom-right corners of extreme occurrences of said quartic are marked.

Let us consider a partition of the quartic-fragments of A into $\mathcal{O}(\log^2 n)$ *canonical sets*, such that, for each $(a,b) \in [1\,..\,\lfloor \log n \rfloor]^2$, the canonical set $C_{(a,b)}$ consists of all quartic-fragments of A whose height is in $[2^a\,..\,2^{a+1})$ and whose width is in $[2^b\,..\,2^{b+1})$.[3]

▶ **Lemma 3.1.** *For each position (i,j) of A, $\mathsf{BR}(i,j)$ has a non-empty intersection with $\mathcal{O}(\log n)$ canonical sets.*

Proof. We say that the *aspect ratio* of a quartic Q is equal to 2 raised to the power $\lfloor \log(\mathsf{height}(Q)) \rfloor - \lfloor \log(\mathsf{width}(Q)) \rfloor$. The aspect ratio of all quartic-fragments in a canonical set $C_{(a,b)}$ is 2^{a-b}. Observe, that there are $2 \cdot \lfloor \log n \rfloor - 1$ different possible values for the aspect ratio of a quartic. For each $d \in [-\lfloor \log n \rfloor + 1\,..\,\lfloor \log n \rfloor - 1]$, let $\mathsf{BR}_d(i,j)$ be the subset of $\mathsf{BR}(i,j)$ that contains exactly the elements of $\mathsf{BR}(i,j)$ with aspect ratio 2^d.

Next, we show that, for each d, we have at most two canonical sets contributing to $\mathsf{BR}_d(i,j)$. Let us suppose towards a contradiction that we have three canonical sets $C_{(a,b)}$, $C_{(a',b')}$, and $C_{(a'',b'')}$ that contribute to $\mathsf{BR}_d(i,j)$. In other words, there are quartic-fragments

- $Q \in \mathsf{BR}_d(i,j)$ with height in $[2^a\,..\,2^{a+1})$ and width in $[2^b\,..\,2^{b+1})$,
- $Q' \in \mathsf{BR}_d(i,j)$ with height in $[2^{a'}\,..\,2^{a'+1})$ and width in $[2^{b'}\,..\,2^{b'+1})$, and
- $Q'' \in \mathsf{BR}_d(i,j)$ with height in $[2^{a''}\,..\,2^{a''+1})$ and width in $[2^{b''}\,..\,2^{b''+1})$.

Since $a-b = a'-b' = a''-b'' = d$, we can assume without loss of generality that $a < a' < a''$ and $b < b' < b''$. We thus have that $a+1 < a''$ and $b+1 < b''$, which implies that Q is fully contained in the top left quarter of Q''. Thus, Q has an occurrence at position $(i + \mathsf{height}(Q'')/2, j + \mathsf{width}(Q'')/2)$; see Figure 3. This contradicts our assumption that the occurrence of Q at position (i,j) is an extreme occurrence.

Thus, $\mathcal{O}(\log n)$ canonical sets contribute to $\mathsf{BR}(i,j)$: at most two for each aspect ratio. ◀

Henceforth, we call a quartic Q with primitive root P *thick* if $Q = P^{x,y}$ for $x, y \geq 5$ and *thin* otherwise.

[3] Throughout this work, logarithms have base 2.

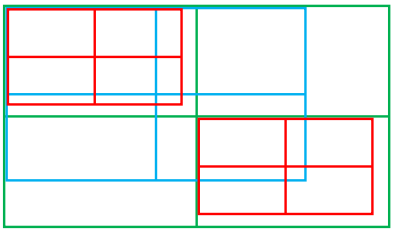

Figure 3 An illustration of the proof of Lemma 3.1 with quartics Q, Q', and Q'' drawn in red, blue, and green, respectively.

▶ **Lemma 3.2.** *For any position (i, j) of A and any pair $(a, b) \in [1 \,..\, \lfloor \log n \rfloor]^2$, $C_{(a,b)} \cap \mathit{BR}(i, j)$ can contain at most 10 thin quartics.*

Proof. The possible forms of *thin* quartics are $P^{2,2}$, $P^{2,2x}$, $P^{2y,2}$, $P^{4,2x}$, and $P^{2y,4}$ for $x > 1$ and $y > 1$. We will consider each form separately.

First, we consider quartics of the form $P^{2,2}$ in $C_{(a,b)} \cap \mathsf{BR}(i, j)$. We analyse the fragment $A[i \,..\, n][j \,..\, j + 2^b)$ and treat it as a metastring by viewing rows as metacharacters. We observe that each considered quartic defines a prefix of this string that is a square. Further, all those squares need to be primitive, as otherwise P could be written as $P = Q^{k,1}$, for some $k > 1$, in contradiction with the primitivity of P. Thus, by Proposition 2.3 we have at most two possible heights for the considered quartics. By a symmetric argument, we have at most two possible widths, and so at most 4 quartics.

Second, we consider quartics of the form $P^{2,2x}$ in $C_{(a,b)} \cap \mathsf{BR}(i, j)$. By the same reasoning as above, we have at most two possible heights for the considered quartics; let h by one of them. We analyse the fragment $A[i \,..\, i + h)[j \,..\, n]$ and treat it as a metastring by viewing columns as metacharacters. Each considered quartic with height h corresponds to a prefix that is a $(2x)$-th power, for some $x > 1$. By Proposition 2.4, all such prefixes are powers of the same U; let U^{2x} be the longest such prefix. Then, for any $x' < x$, the prefix $U^{2x'}$ also occurs at position $(i, j + |U|)$, so the occurrence at position (i, j) cannot be an extreme occurrence. Therefore, for every possible height, we have at most one quartic, so at most 2 in total.

Third, we consider quartics of the form $P^{4,2x}$ for $x > 1$ in $C_{(a,b)} \cap \mathsf{BR}(i, j)$. We (again) analyse the fragment $A[i \,..\, n][j \,..\, j + 2^b)$ and treat it as a metastring by viewing its rows as metacharacters. We observe that each considered quartic defines a prefix that is a primitively rooted fourth power there. Thus, by Proposition 2.4 we have at most one possible height, and, by the same reasoning, as above at most one quartic.

Symmetric arguments bound the number of quartics of the forms $P^{2y,2}$ and $P^{2y,4}$. ◀

▶ **Lemma 3.3.** *The number of distinct thin quartics in A is $\mathcal{O}(n^2 \log n)$.*

Proof. For each position (i, j) of A, $\mathsf{BR}(i, j)$ has a non-empty intersection with at most $\mathcal{O}(\log n)$ canonical sets due to Lemma 3.1. Further, by Lemma 3.2, there are at most 10 thin quartics in each such intersection. Since A has n^2 positions, the stated bound follows. ◀

3.1 Reduction to a Geometric Problem

We next partition the thick quartics by primitive root. For each primitive 2D string R, we choose any bottom-right occurrence of each distinct thick quartic with primitive root R. We denote the obtained set of quartic-fragments by Thick_R. Additionally, let us denote

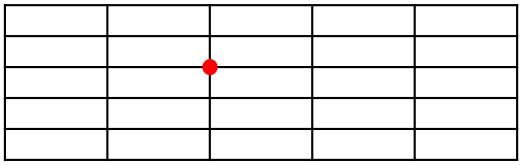

Figure 4 The red point corresponds to the anchor of the shown occurrence of $R^{5,5}$.

by $\mathsf{occ}_{5\times5}(R)$ the set of all positions (i,j) of A where $R^{5,5}$ occurs such that there is an element of Thick_R that fully contains this occurrence of $R^{5,5}$ and has top-left corner equal to $(i - x\cdot\mathsf{height}(R), j - y\cdot\mathsf{width}(R))$ for some non-negative integers x and y.

The proof of the following lemma proceeds almost exactly as the proof of Claim 18 in [27], except that we work with occurrences of $R^{5,5}$ instead of $R^{3,3}$ and do not need the notion of special points. We provide a detailed description for completeness.

▶ **Lemma 3.4** (cf. the proof of [27, Claim 18]). *For any 2D string R, $|\mathit{Thick}_R| \le |\mathit{occ}_{5\times5}(R)|$.*

Proof. We will map each $Q \in \mathsf{Thick}_R$ to an occurrence of $R^{5,5}$ in such a way that two distinct quartic-fragments $Q, Q' \in \mathsf{Thick}_R$ are mapped to distinct occurrences. This will imply that the number of occurrences of R is at least as large as the number of elements of Thick_R.

For each $x = 6, 8, \ldots$ in this order, we select $Q \in \mathsf{Thick}_R$ such that $\mathsf{height}(Q) = x\cdot\mathsf{height}(R)$ and $\mathsf{width}(Q) = y\cdot\mathsf{width}(R)$ is the largest among all $Q' \in \mathsf{Thick}_R$ with $\mathsf{height}(Q') = x\cdot\mathsf{height}(R)$. We note that the number of $Q' \in \mathsf{Thick}_R$ with $\mathsf{height}(Q') = x\cdot\mathsf{height}(R)$ is at most $y/2-2$, and our goal is to map them to occurrences of $R^{5,5}$ that have not been used so far. Additionally, we will ensure that those occurrences are all in the same row. Let (i,j) be the position of an extreme occurrence of Q. We observe that $R^{5,5}$ occurs at every position (i',j') with $i' = i + k\cdot\mathsf{height}(R)$ and $j' = j + \ell\cdot\mathsf{width}(R)$, for every $k \in [0\,..\,x-5]$ and $\ell \in [0\,..\,y-5]$. We choose $k \in [0\,..\,x-5]$ such that none of the occurrences of $R^{5,5}$ at positions $(i + k\cdot\mathsf{height}(R), j + \ell\cdot\mathsf{width}(R))$, for $\ell = 0, 1, \ldots, y-3$ have been used so far. This is possible because so far we have used occurrences of $R^{5,5}$ in only $x/2-3 < x-4$ rows. Then, we map every $Q' \in \mathsf{Thick}_R$ with $\mathsf{height}(Q') = x\cdot\mathsf{height}(R)$ to an occurrence of $R^{5,5}$ at position $(i + k\cdot\mathsf{height}(R), j + \ell\cdot\mathsf{width}(R))$, for some $\ell \in [0\,..\,y-5]$, which is possible due to $y/2-2 \le y-4$. ◀

Thus, it remains to upper bound $\sum_R |\mathsf{occ}_{5\times5}(R)|$, i.e., the sum, over all R, of the number of occurrences of $R^{5,5}$ which are contained in some element of Thick_R.

Consider an occurrence of a 2D string of the form $R^{5,5}$, for a primitive string R, at a position (i,j) of A. We call position $(i + 2\cdot\mathsf{height}(R), j + 2\cdot\mathsf{width}(R))$ the *anchor* of this occurrence; see Figure 4.

Now, for each primitive string R, for each element of $\mathsf{occ}_{5\times5}(R)$, we assign the corresponding occurrence of $R^{5,5}$ to its anchor. Let $\mathsf{assign}(i,j)$ be the set of primitive 2D strings R such that an occurrence of $R^{5,5}$ has been assigned to position (i,j). We have

$$\sum_R |\mathsf{occ}_{5\times5}(R)| = \sum_{i=1}^{n}\sum_{j=1}^{n} |\mathsf{assign}(i,j)|. \tag{1}$$

It now suffices to show that $\sum_{i=1}^{n}\sum_{j=1}^{n} |\mathsf{assign}(i,j)| = \mathcal{O}(n^2\log n)$. We will show that $|\mathsf{assign}(i,j)| = \mathcal{O}(\log n)$ for all i,j, which straightforwardly yields the desired bound.

Let us fix a position (i,j). By applying Proposition 2.4 horizontally and vertically one easily obtains the following fact.

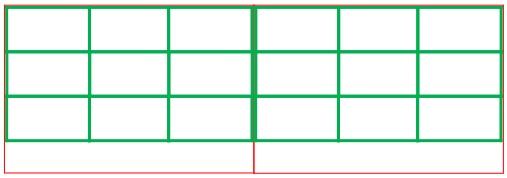

Figure 5 The red rectangles correspond to $T^{1,2}$ and the green rectangles correspond to $S^{3,6}$.

▶ **Fact 3.5** ([27, Corollary 13]). *Let a, b be non-negative integers and W, Z be different 2D strings with height in $[2^a\,..\,2^{a+1})$ and width in $[2^b\,..\,2^{b+1})$. If $W^{3,3}$ and $Z^{3,3}$ occur at some position of A, then at least one of W and Z is not primitive.*

This, together with the fact that, for each $R \in \mathsf{assign}(i,j)$, $R^{3,3}$ occurs at position (i,j), implies the following.

▶ **Fact 3.6.** *For each pair $(a,b) \in [1\,..\,\lfloor \log n \rfloor]^2$, for each position (i,j) of A, the set $\mathsf{assign}(i,j)$ contains at most one element with height in $[2^a\,..\,2^{a+1})$ and width in $[2^b\,..\,2^{b+1})$.*

Let us define a map $\Sigma^{*,*} \to [1\,..\,\lfloor \log n \rfloor]^2$ as $g(R) \mapsto (\lfloor \log(\mathsf{height}(R)) \rfloor, \lfloor \log(\mathsf{width}(R)) \rfloor)$. Let f be the restriction of g to the domain $\mathsf{assign}(i,j)$. Due to Fact 3.6, f is an injective function. We henceforth identify each element R of $\mathsf{assign}(i,j)$ with point $f(R)$. We denote the image of f by $\mathcal{P}$.

We say that a point $(a,b) \in \mathbb{Z}^2$ *dominates* or *weakly dominates* a point (a',b') if $a' \le a$ and $b' \le b$; the dominance is *strict* if $a' < a$ and $b' < b$. (If we require some dominance to be strict we explicitly say so; that is, whenever we refer to some dominance without explicitly mentioning whether it is weak or strict, we refer to weak dominance.) A set of points on which the domination relation forms a total order is called a *chain*. A set of points such that none dominates another is called an *antichain*. We are going to use Dilworth's theorem [42], which states that, in any finite partially ordered set, the size of the largest antichain is equal to the minimum number of chains in which the elements of the set can be decomposed.

For two primitive 2D strings S and T, with $3 \cdot \mathsf{height}(S) < \mathsf{height}(T)$ and $\mathsf{width}(S) < \mathsf{width}(T)$, we say that S *horizontally spans* T when the 2D string $\mathsf{row}_{3\cdot\mathsf{height}(S)}(T^{1,2})$, consisting of the $3 \cdot \mathsf{height}(S)$ topmost rows of $T^{1,2}$, equals $S^{3,y}$ for some even integer $y \ge 4$; see Figure 5. Similarly, when $\mathsf{width}(S) < \mathsf{width}(T)$ and $\mathsf{height}(S) < \mathsf{height}(T)$, we say that S *vertically spans* T when the 2D string $\mathsf{col}_{3\cdot\mathsf{width}(S)}(T^{2,1})$, consisting of the $3 \cdot \mathsf{width}(S)$ leftmost columns of $T^{2,1}$, equals $S^{x,3}$ for some even integer $x \ge 4$.

▶ **Fact 3.7.** *Let S and T be two primitive 2D strings. If S spans T horizontally, then the horizontal period of $\mathsf{row}_{3\cdot\mathsf{height}(S)}(T^{1,2})$ is $\mathsf{width}(S)$. Symmetrically, if S spans T vertically, then the vertical period of $\mathsf{col}_{3\cdot\mathsf{width}(S)}(T^{2,1})$ is $\mathsf{height}(S)$.*

Proof. We only prove the first statement as the second one follows by symmetry. Let us view $\mathsf{row}_{3\cdot\mathsf{height}(S)}(T^{1,2})$ as a metastring Z by viewing each of its columns as a metacharacter; the horizontal period of $\mathsf{row}_{3\cdot\mathsf{height}(S)}(T^{1,2})$ equals $p := \mathsf{per}(Z)$. Note that $\mathsf{width}(S)$ is a period of Z. Towards a contradiction, suppose that $p < \mathsf{width}(S)$. Then, an application of the periodicity lemma to Z implies that p must divide $\mathsf{width}(S)$. This fact contradicts the primitivity of S, as we would have that $S = (S[1\,..\,\mathsf{height}(S)][1\,..\,p])^{1,k}$ for $k = \mathsf{width}(S)/p$; see Figure 5. ◀

When reading the following lemma, one can think of M being in $\mathsf{assign}(i,j)$. However, the lemma is slightly more general, as needed for the algorithm that is presented in the full version.

▶ **Lemma 3.8.** *Let $R \in \mathsf{assign}(i,j)$ and M be a primitive 2D string such that:*
- *$M^{5,5}$ has an occurrence with anchor (i,j);*
- *$g(M)$ strictly dominates $g(R)$.*

Then, R spans M either horizontally or vertically (or both).

Proof. By the definition of $\mathsf{assign}(i,j)$, the occurrence of $R^{5,5}$ assigned to position (i,j) appears inside an element of Thick_R, which is necessarily a bottom-right occurrence of a thick quartic with primitive root R. Let us denote this quartic by Q. Observe that the considered occurrence of Q cannot be fully contained inside the occurrence of $M^{4,4}$ at position $(i-2\cdot\mathsf{height}(M), j-2\cdot\mathsf{width}(M))$ as this would contradict the fact that the considered occurrence of Q is bottom-right: there would be another occurrence $\mathsf{width}(M)$ positions to the right. Therefore, Q must contain at least one of the following four fragments of A, depicted in Figure 6: $A[i\,..\,i{+}3{\cdot}\mathsf{height}(R))[j\,..\,j{+}2{\cdot}\mathsf{width}(M))$, $A[i\,..\,i{+}3{\cdot}\mathsf{height}(R))[j{-}2{\cdot}\mathsf{width}(M)\,..\,j)$, $A[i\,..\,i+2\cdot\mathsf{height}(M))[j\,..\,j+3\cdot\mathsf{width}(R))$, $A[i-2\cdot\mathsf{height}(M)\,..\,i)[j\,..\,j+3\cdot\mathsf{width}(R))$.

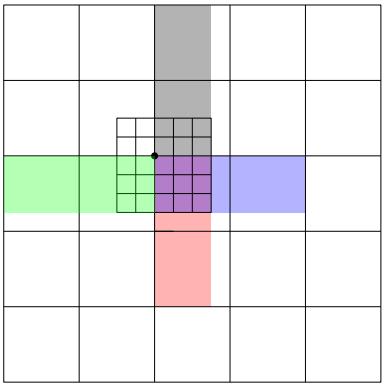

Figure 6 The considered occurrences of each of $M^{5,5}$ and $R^{5,5}$ are shown, together with the four specified fragments, at least one of which must be fully contained in Q.

We next show that in either of the first two cases, R horizontally spans M. In the remaining cases, a symmetric argument yields that R vertically spans M. First, observe that we have $\mathsf{width}(R) < \mathsf{width}(M)$ as a direct consequence of $g(M)$ strictly dominating $g(R)$. We next need to argue that $3\mathsf{height}(R) < \mathsf{height}(M)$. If this were not the case, $\mathsf{width}(R)$ would be a horizontal period of $M^{1,2}$, contradicting the primitivity of M. This completes the proof. ◀

▶ **Lemma 3.9.** *Two primitive 2D strings R_1 and R_2 such that $g(R_1)$ and $g(R_2)$ form an antichain cannot both horizontally span a 2D string R.*

Proof. Let $g(R_1) = (a_1, b_1)$ and $g(R_2) = (a_2, b_2)$. Without loss of generality, we can assume that $a_1 < a_2$ and $b_1 > b_2$. Suppose towards a contradiction that both R_1 and R_2 horizontally span R. By applying Fact 3.7, we obtain that
- $\mathsf{width}(R_1)$ is the horizontal period of $\mathsf{row}_{3\cdot\mathsf{height}(R_1)}(R^{1,2})$ and
- $\mathsf{width}(R_2)$ is the horizontal period of $\mathsf{row}_{3\cdot\mathsf{height}(R_2)}(R^{1,2})$.

Note that, for any $k \in [1\,..\,\mathsf{height}(R)]$, the horizontal period of the string comprised of the k topmost rows of $R^{1,2}$ equals the least common multiple of the periods of those k rows. Hence, the period cannot decrease as we increase the number of considered rows. We thus have $\mathsf{width}(R_1) \le \mathsf{width}(R_2)$ since our assumption that $a_2 > a_1$ implies that $\mathsf{height}(R_2) > \mathsf{height}(R_1)$. This is a contradiction to our assumption that $b_1 > b_2$, which implies that $\mathsf{width}(R_1) > \mathsf{width}(R_2)$. ◀

The above lemma, Fact 3.6, and Dilworth's theorem together imply the following.

▶ **Corollary 3.10.** *All primitive 2D strings that span a primitive 2D string R can be decomposed to two sets H and V, such that*
- *the elements of H span R horizontally;*
- *the elements of V span R vertically;*
- *the restriction of g to $H \cup V$ is an injective function;*
- *each of the sets $g(H)$ and $g(V)$ is a chain.*

Finally, as mentioned in the introduction, we need the following purely geometric lemma that follows from the result of Marcus and Tardos [68] on the number of 1s in an $m \times m$ binary matrix M that avoids a fixed permutation P as a submatrix.

▶ **Lemma 3.11.** *Consider a positive integer m and a set $\mathcal{P} \subseteq [1\,..\,m]^2$. If, for each $p \in \mathcal{P}$, the set of points of $\mathcal{P}$ that are strictly dominated by p can be partitioned into at most two chains, then $|\mathcal{P}| = \mathcal{O}(m)$.*

Proof. We think of $\mathcal{P}$ as an $m \times m$ matrix $M[1\,..\,m][1\,..\,m]$, where $M[a][b] = 1$ when $(a, b) \in \mathcal{P}$ and $M[a, b] = 0$ otherwise. Next, we say that M contains a matrix P as a submatrix when P can be obtained from M by removing rows, removing columns, and changing 1s into 0s. We claim that, by the assumptions in the lemma, M does not contain the following matrix P as a submatrix:

		1	
	1		
1			
			1

To establish this, assume otherwise towards a contradiction. Then, there exists $(a, b) \in \mathcal{P}$ and $(a_1, b_1), (a_2, b_2), (a_3, b_3) \in \mathcal{P}$ such that (a, b) strictly dominates $(a_1, b_1), (a_2, b_2), (a_3, b_3)$ and further $(a_1, b_1), (a_2, b_2), (a_3, b_3)$ create an antichain. By Dilworth's theorem, this implies that the points in $\mathcal{P}$ dominated by (a, b) cannot be partitioned into two chains, a contradiction. Thus, M indeed does not contain P as a submatrix. Because P is a permutation matrix, this implies $|\mathcal{P}| = \mathcal{O}(m)$. ◀

We now complete the proof of our main result with the aid of Lemma 3.11.

▶ **Theorem 3.12.** *An $n \times n$ 2D string has $\mathcal{O}(n^2 \log n)$ distinct quartics.*

Proof. The number of distinct thin quartics is $\mathcal{O}(n^2 \log n)$ by Lemmas 3.2 and 3.3. The number of distinct thick quartics is

$$\sum_R |\mathsf{Thick}_R| \le \sum_R |\mathsf{occ}_{5\times 5}(R)| \qquad \text{(Lemma 3.4)}$$

$$\le \sum_{i=1}^{n} \sum_{j=1}^{n} |\mathsf{assign}(i, j)|. \qquad (1)$$

To conclude the proof, it remains to show that $|\mathsf{assign}(i, j)| = \mathcal{O}(\log n)$ for all $(i, j) \in [1\,..\,n]^2$. Let $m = \lfloor \log n \rfloor$, and recall that $\mathcal{P} \subseteq [1\,..\,m]^2$ was defined as the image of f, which in turn was the restriction of g to the domain $\mathsf{assign}(i, j)$. By Fact 3.6, we only need to show that $|\mathcal{P}| = \mathcal{O}(m)$. By Lemma 3.8 and Corollary 3.10, for each $p \in \mathcal{P}$, the set of all points of $\mathcal{P}$ that are strictly dominated by p can be partitioned into at most two chains. Thus, by Lemma 3.11 we conclude that indeed $|\mathcal{P}| = \mathcal{O}(m)$, concluding the proof. ◀

4 Overview of the Algorithm

The detailed algorithm can be found in the full version of this work. After preprocessing the input 2D string, we compute thin and thick quartics separately. Here, we provide an overview of the main ideas of our $\mathcal{O}(n^2 \log n)$-time algorithm for computing distinct quartics in an $n \times n$ 2D string A over an ordered alphabet.

Computation of Thin Quartics

For thin quartics, our algorithm is quite similar to the combinatorial analysis. For each position (i, j), we compute an $\mathcal{O}(\log n)$-size superset $\mathcal{C}$ of the canonical sets that have a non-empty intersection with $\mathsf{BR}(i, j)$. We do this by relating extreme occurrences of quartics with occurrences of squares in metastrings obtained by viewing the columns of $A[i \,..\, i + 2^a)[1 \,..\, n]$, where $a \in [1 \,..\, \lfloor \log n \rfloor]$, as metacharacters. These squares can be efficiently computed and give us a handle on the sought thin quartics. Then, we compute the intersection of each canonical set in $\mathcal{C}$ with $\mathsf{BR}(i, j)$ in constant time using known tools that allow us to efficiently operate on the metastrings. We do this by fixing $(a, b) \in [1 \,..\, \lfloor \log n \rfloor]^2$ and computing all quartics with height in $[2^a \,..\, 2^{a+1})$ and width $[2^b \,..\, 2^{b+1})$ that occur at position (i, j) of A, of the form $P^{2y,2}$, $P^{2y,4}$, $P^{2,2x}$, and $P^{4,2x}$, for a primitive 2D string P and $x, y \geq 1$.

Computation of Thick Quartics

For thick quartics, our algorithmic approach follows our combinatorial approach in a more relaxed sense. The main technical challenge is to compute, for each position (i, j), an $\mathcal{O}(\log n)$-size set $\mathcal{R}$ of primitive 2D strings R, such that $\mathsf{assign}(i, j) \subseteq \mathcal{R}$. Then, those supersets can be postprocessed as in [27] in time linear in their total size to yield the sought distinct thick quartics. The computation of $\mathcal{R}$ is split into two major steps outlined next.

Skyline Computation. First, we compute a set $\mathcal{S}$ of *skyline primitive 2D strings* such that $S \in \mathcal{S}$ when (a) $S^{5,5}$ has an occurrence anchored at position (i, j), and (b) there is no other primitive 2D string T with $g(T) \geq g(S)$ such that $T^{5,5}$ has an occurrence anchored at position (i, j). This part of the proof is quite technical: it heavily relies on the analysis of periodicity for 1D (meta)strings and, roughly speaking, on the analysis of the evolution of the horizontal periodic structure of a 2D string as rows are appended to it. We show that, for each $a \in [1 \,..\, \lfloor \log n \rfloor]$, there is a single candidate $h \in [2^a \,..\, 2^{a+1})$ to be considered as the height of an element of $\mathcal{S}$. Then, using runs in 1D metastrings whose origins in A have sufficient overlap and bit-tricks, we can compute the widest 2D string S with height h such that an occurrence of $S^{5,5}$ is anchored at position (i, j) in constant time (using batched computations), if one exists.

Computation of Dominated 2D strings. This turned out to be the most challenging part of our approach. For this exposition, let us treat $\Sigma^{*,*}$ as a partially ordered set, in the order of decreasing widths. Let $\mathcal{S} = \{S_1, \ldots, S_\ell\}$ in accordance with this order. To obtain $\mathcal{R}$ from $\mathcal{S}$, we need to add to it the 2D strings $R \in \mathsf{assign}(i, j) \setminus \mathcal{S}$. By the construction of $\mathcal{S}$ we know that there exists $S \in \mathcal{S}$ such that $g(R) \leq g(S)$.

Our combinatorial analysis implies that each $R \in \mathsf{assign}(i, j)$ spans each element $S \in \mathcal{S}$ for which $g(S)$ strictly dominates $g(R)$ either vertically or horizontally. It turns out that if R spans all of these elements of $\mathcal{S}$ either vertically or horizontally, it is easy to compute it efficiently. This is, unfortunately, not the case in general. However, we observe that R spans

vertically (resp. horizontally) a contiguous subset of $\mathcal{S}$. We show that the problem boils down to computing the union, over all k, of sets I_k, where I_k contains exactly those primitive 2D strings that span S_{k-1} vertically and span S_k horizontally. Crucially, we observe that due to a strong form of transitivity of the spanning property, the intersection of any two such I_k and $I_{k'}$ consists of a number of the smallest elements of both (i.e., their longest common prefix if viewed as strings). Hence, by computing the elements of I_k from the largest to the smallest, we can stop whenever we encounter an element that has already been reported by this procedure. This allows us to reduce the computation of $\mathcal{R}$ to the problem of efficiently computing sets I_k. To this end, we prove that an $\mathcal{O}(\log n)$-bits representation of the evolution of the periodic structure of certain fragments of A as rows and columns are appended to them suffices for inferring I_k; we then use tabulation to infer it efficiently.

Streaming Edge Coloring with Subquadratic Palette Size

Abstract

In this paper, we study the problem of computing an edge-coloring in the (one-pass) W-streaming model. In this setting, the edges of an n-node graph arrive in an arbitrary order to a machine with a relatively small space, and the goal is to design an algorithm that outputs, as a stream, a proper coloring of the edges using the fewest possible number of colors.

Behnezhad et al. [Behnezhad et al., 2019] devised the first non-trivial algorithm for this problem, which computes in $\tilde{O}(n)$ space a proper $O(\Delta^2)$-coloring w.h.p. (here Δ is the maximum degree of the graph). Subsequent papers improved upon this result, where latest of them [Ansari et al., 2022] showed that it is possible to deterministically compute an $O(\Delta^2/s)$-coloring in $O(ns)$ space. However, none of the improvements succeeded in reducing the number of colors to $O(\Delta^{2-\epsilon})$ while keeping the same space bound of $\tilde{O}(n)$[1]. In particular, no progress was made on the question of whether computing an $O(\Delta)$-coloring is possible with roughly $O(n)$ space, which was stated in [Behnezhad et al., 2019] to be an interesting open problem.

In this paper we bypass the quadratic bound by presenting a new randomized $\tilde{O}(n)$-space algorithm that uses $\tilde{O}(\Delta^{1.5})$ colors.

1 Introduction

The last few decades have witnessed significant technological advancements, which have led to an exponential increase in the volume of data sets and network traffic that require efficient processing. However, many of the devices that we use to perform these tasks lack sufficient storage capacity to store even a small fraction of the input data, which typically arrives in an unordered stream. Consequently, we often find ourselves processing this data using partial information. This scenario is commonplace, especially when attempting to receive information from remote servers over the internet or fetch data from an external memory unit.

[1] $\tilde{O}(f)$ hides $\log^{O(1)} f$ factors.

To gain a better understanding of computing capabilities in such scenarios, the *data stream model* has been introduced. This model involves receiving an arbitrary stream of tokens as input, and the objective is to compute a function of this input by performing one or more passes over the stream while using minimal working memory. The model has been primarily applied to problems on graphs. In this context, the data stream consists of a sequence of updates that defines the edge-set of a graph with a known number of vertices, and the aim is to compute various properties of this graph.

Clearly, our aim in such problems is to design algorithms whose space complexity is asymptotically much less than the number of edges - preferably linear in the number of vertices. However, in some cases, the size of the output may be as large as the size of the input, forcing us to use a very large space to store it. To get around this, we use a known variant of the streaming model, called the W-steaming model [5], which allows us to stream parts of the output along the computation. However, it forces the algorithm to commit to parts of the output without even seeing the entire input.

Many important problems have been studied in the W-streaming model. In this paper we focus on the problem of properly coloring the edges of a given graph with a small number of colors. This problem is considered to be one of the most fundamental and well-studied problems in graph theory, with many applications in scheduling and communications.

Behnezhad et al. [2] were the first to consider the problem of edge-coloring in the W-streaming model. They distinguished between two variants: random order streams – in which the edges arrive according to a random permutation that was chosen uniformly at random before the start of the algorithm, and adversarial order streams – in which the edges arrive in an arbitrary order. For the first variant, they provided a simple one-pass algorithm that uses $O(\Delta)$ colors and $\tilde{O}(n)$ space (where as usual Δ and n respectively denote the maximum degree of the input graph and the number of its vertices). For the second one, they provided a different one-pass algorithm that in $\tilde{O}(n)$ space computes w.h.p. a proper $O(\Delta^2)$-coloring. Charikar and Liu [7] improved the above results by devising a one-pass $\tilde{O}(n)$-space algorithm that uses $\Delta + o(\Delta)$ colors for random order streams, and a one-pass randomized algorithm that uses $\tilde{O}(ns)$ space and $(1+o(1))\Delta^2/s$ colors for adversarial order streams. More recently, Ansari et al. [1] provided two simple deterministic algorithms that in one pass and $O(ns)$ space compute a proper coloring that uses no more than $(1+o(1))\Delta^2/s$ colors for adversarial order streams, improving the result of [7].

Interestingly, for the more challenging model of adversarial order streams, all of the above results require $\tilde{\Omega}(\Delta^2)$ colors when the available space is $\tilde{O}(n)$. This raises the question of whether one can get asymptotically below this number of colors, while retaining the same space bound, or if $\tilde{\Omega}(\Delta^2)$ is an inherent limitation. In this paper we resolve this question, and show that it is possible to reduce the number of colors without compromising on increasing the given space.

1.1 Our result

We break the quadratic barrier for the first time by providing a new randomized algorithm that in one pass and $\tilde{O}(n)$-space (in expectation) computes a proper edge-coloring which uses, in expectation, no more than $\tilde{O}(\Delta^{1.5})$ colors (for adversarial order streams).

▶ **Theorem 1.** *For an undirected (multi-)graph $G = (V, E)$ on n vertices and maximum degree Δ, there is a single-pass randomized streaming algorithm using $\tilde{O}(n)$ space for edge coloring that uses $\tilde{O}(\Delta^{1.5})$ colors with high probability.*

1.2 Related work

The edge-coloring problem has been studied in several models of computation (see, e.g. [12, 10, 6, 2]). A closely related model to the W-Streaming is known as the Online model. In the online edge-coloring problem, we also assume that the edges of the input graph arrive as a data stream (which can be either random or arbitrary). There is no space limitation, but there is a requirement to instantly compute and output a color for each newly received edge, as opposed to the W-Streaming model in which we can delay the announcement of some of the edges by buffering them. See [15, 11, 13, 4, 8] for some latest results on this problem.

Independent work

In a concurrent work [3], Behnezhad and Saneian have obtained the same result as Theorem 1; besides, they have a general trade-off of $\tilde{O}(ns)$ space and $\tilde{O}(\Delta^{1.5}/s)$ colors, for any parameter s. In another concurrent work [9], Ghosh and Stoeckl have achieved a trade-off of $\tilde{O}(ns)$ space and $\tilde{O}(\Delta^2/s^2)$ colors, for any parameter s.

1.3 Technical Overview

Ansari et al. [1] used, in their second algorithm, a very simple buffering approach to color the graph's edges. Let $G = (V, E)$ be the input graph, n be its number of vertices and Δ be its maximum degree. Assuming that we have a working space of at least n words, we divide the edge-stream E into continuous intervals $E_1, ..., E_k$ of n edges each, buffer each one of them in order, and color each graph $G_i = (V, E_i)$ separately by using a different set of $O(\Delta)$ colors. This gives us a proper $O(\Delta^2)$-coloring as there can be at most Δ such intervals.

To reduce the number of colors in such an approach, we have to avoid somehow the allocation of a new $O(\Delta)$-color palette for each interval. Our main observation here is that we may not be able to edge-color the graph of a given interval G_i with much less than $\Omega(\Delta)$ colors (as it may contain vertices of high degree), but we can use fewer colors to color all the edges in G_i that are between vertices of a sufficiently low vertex degrees. We will still have to use palettes of $O(\Delta)$ colors to color the rest of the edges, but these edges are now adjacent to high degree vertices. As the number of these vertices in each of the intervals cannot be too large, we can afford to store in the machine more information about the colorings that were used to color these edges across several intervals (which we call a phase). This way, it will hopefully be sufficient to allocate a few palettes of $O(\Delta)$-colors per phase, instead of allocating a new one for each interval.

Let us develop this idea further. We divide the intervals $E_1, ..., E_k$ into contiguous phases $P_1, ..., P_{k'}$ of D intervals each. In each phase $i \in \{1, ..., k'\}$, we are going to process the intervals one by one, and color their edges. To do that, we distinguish, in each interval $E_j \in P_i$, between the "low" edges - those whose endpoints are of low degree (at most some parameter $t = \Theta(\sqrt{\Delta})$) in G_j, the "high" edges - those whose endpoints are of high degree (greater than t in G_j) and the "mixed" - all the rest. As we discussed above, in each interval $E_j \in P_i$, the number of nodes whose degree in G_j is greater than t, cannot be that large (less than $2n/t$). Thus, as long as $t \geq D$, we can store for the current phase, $O(1)$ words for each node and each interval such that this node is of degree greater than t in this interval.

With that in mind, consider the following procedure for coloring the high edges. We allocate at the start of the phase, c palettes $A_1, ..., A_c$ of $O(\Delta)$ colors each. In each interval, we choose uniformly at random a set A from the collection, and color all the high edges that are incident only to vertices that weren't previously incident to high edges that were colored using A. (that is, we store for each node that was incident to a high edge, the IDs of all the

palettes that were used to color its incident edges.) Note that each vertex may have a high degree in no more than Δ/t intervals. Therefore, the probability that a high edge will not be colored in a certain interval is at most $2\Delta/tc$, which for $c = C(\Delta/t)$ is $2/C$. This means that in expectation only a fraction of the edges remains uncolored. Let us ignore these edges for a moment, and discuss how we color the rest of the edges.

Coloring the low edges of each interval is simple as we don't need big palettes for them. So we just allocate a new set of $O(t)$ colors for each interval, and properly color the low edges of that interval with it.

We move now for the task of coloring the mixed edges. Note that this case is more complicated than the previous ones, as we need to use palettes of $K = O(\Delta)$-colors, but cannot store too much information for the nodes with low degree. As before, we start by assigning at the start of the phase a set of $c = C(\Delta/t)$ palettes $B_1, ..., B_c$ of $O(\Delta)$ colors each. In each interval, we choose uniformly at random a set B from the collection, and the idea now is that the vertex with the low degree of each mixed edge will choose a color from B to color this edge.

We illustrate the problems that could arise (when trying to color these edges) and the way we handle them, by focusing on two edges $\{u, v\}$ and $\{u, w\}$ that belong to two different intervals. Note that since these edges share a vertex, they cannot be colored with the same color. In the first case, u has a high degree in both of the intervals. A possible conflict can occur if we happen to chose the same set B in both of them. To solve this, we do the same thing that we did for the high edges (i.e. we store at the high degree vertices the IDs of the palettes with which previous incident edges were colored, and avoid coloring an edge if a conflict was detected). This will guarantee that in expectation only a fraction of them remains uncolored. In the second case, u has a low degree in both of the intervals. This means that both w and v have a high degree in their intervals, but they may be different, and so we cannot know the IDs of the previous palettes. To solve this, we maintain for u a counter c_u, which counts the total number of edges that connected u to high degree vertices when it had low degree. When u wants to choose a color from B it simply takes the c_u color in it, this will guarantee that no conflict can occur in such cases. In the third and last case, u has a high degree in one of the intervals and a low in the other. For resolving possible conflicts in this case, we make use of random offsets. At the start of the phase, we choose for each vertex v a uniformly random integer r_v between 0 and $K - 1$, and use it to permute the colors in the set (that is, v considers the first color in B to be the color in the position r_v, and so on). Before we color an edge $\{u, v\}$ we check whether the offsets r_v and r_u are far enough. If this is not the case we skip it (this happens with small probability).

To summarize, in each phase we use $O(c\Delta + tD)$ colors. As we have $O(\Delta/D)$ phases, we get that the total number of colors is $O(\Delta^3/(tD) + t\Delta)$. The edges that were left uncolored, we treat as a new virtual stream, and apply recursively the algorithm on it. As in expectation the number of uncolored edges reduces each time by a constant factor, we get that it only increases the space bound and the number of colors by a factor of $O(\log \Delta)$.

2 Edge coloring with subquadratic palette size

2.1 Algorithm description

Preparation

Our algorithm assumes prior knowledge of the maximum degree Δ. Without loss of generality, assume $\sqrt{\Delta}$ is an integer power of 2. If the data stream contains at most $O(n)$ edges, then the entire stream fits in the memory, so we can color the graph with $O(\Delta)$ colors straightforwardly (more precisely, $\lceil \frac{3\Delta}{2} \rceil$ colors for multi-graphs, and $\Delta + 1$ colors for simple graphs [14, 16]).

The algorithm divides the data stream into intervals, each interval consisting of n edges from E (the last interval may have less than n edges). In general, there are at most $|E|/n = O(\Delta)$ intervals in the data stream. Let $E_l \subseteq E$ be the set of edges in the l-th interval. Denote by $G_l = (V, E_l)$ the subgraph collected from this interval. We further partition all intervals into *phases*, each phase consisting of $\Delta^{1/2}$ consecutive intervals (the last phase may have less). Different phases will use different sets of edge colors and thus are independent. For the rest of this section, we will describe our algorithm for an individual phase.

Fix any degree threshold d be any integral power of 2. If $d < \sqrt{\Delta}$, we will create $O(\sqrt{\Delta})$ new colors for each interval which should be enough to color all edges (u, v) such that

$$\max\{\deg_{G_l}(u), \deg_{G_l}(v)\} < 2d$$

Otherwise if $d \geq \sqrt{\Delta}$, then for each interval E_l, we will describe an algorithm that assigns colors to all edges (u, v) such that

$$\max\{\deg_{G_l}(u), \deg_{G_l}(v)\} \in [d, 2d)$$

Ranging over all choices of d, we would be able to color the whole graph G_l, by blowing up the total number of colors by a factor of $O(\log \Delta)$.

A vertex $v \in V$ is called *high-degree* in G_l, if $\deg_{G_l}(v) \in [d, 2d)$, and if $\deg_{G_l}(v) < d$, then it is called *low-degree*; we will not consider any vertices whose degree in G_l is at least $2d$.

Let $\kappa \geq 32$ be a constant which is an integer power of 2. At the beginning of a single phase, the algorithm prepares three sequences of disjoint color palettes: $A_1, A_2, \cdots, A_{\kappa\Delta/d}$, and $B_1, B_2, \cdots, B_{\kappa\Delta/d}$, and $C_1, C_2, \cdots, C_{\kappa\Delta/d}$. All palettes A_i, B_i, C_i have size $K = 2\kappa d$.

For each palette X ($X \in \{A_i, B_i, C_i\}$), its colors will be indexed by $0, 1, 2 \cdots, K-1$. Each A_i will only be used to color edges between high-degree vertices in some intervals, and each $B_i \cup C_i$ will only be used to color edges between high-degree vertices and low-degree vertices in some intervals. For each vertex $v \in V$, take a uniformly random integer offset $r_v \in [0, K-1]$. Additionally, for each palette index i, maintain a counter $c_v[i] \in \{\perp\} \cup [0, K-1]$ which will bound the number of edges incident on v with colors from palette C_i; when $c_v[i] = \perp$, it means this counter $c_v[i]$ has not been initialized yet, so it does not take any space in the storage.

During this phase, each vertex v holds a set of indices $I_v \subseteq [\kappa\Delta/d]$, such that $i \in I_v$ if edges incident on v have been colored with colors from palette A_i in any previous intervals. Finally, the algorithm maintains a *virtual stream* of *leftover* edges, which are edges discarded temporarily but will be processed again recursively.

Processing intervals

Let l_0 be the index of the first interval of this phase. For each interval indexed by l, draw a random index $\sigma_l \in [\kappa\Delta/d]$ uniformly at random. For any i, keep a counter $p_l[i] = |\{\sigma_k = i \mid l_0 \leq k < l\}|$. Note that all these counters $\{p_l[i]\}_{1 \leq i \leq \kappa\Delta/d}$ can be stored using $O(\kappa\Delta/d) = O(n)$ space; for the l-th interval, we are only using counters $p_l[*]$, and previous counters will be discarded.

Partition the graph $G_l = (V, E_l)$ into two disjoint subgraphs: $G_l = H_l^1 \cup H_l^2$ defined below; edges in these subgraphs will be colored separately.

(1) H_l^1 consists of all edges between high-degree vertices in G_l.
To color edges in H_l^1, let U be the set of all high-degree vertices such that $\sigma_l \notin I_v$. Then, use the palette A_{σ_l} to color the subgraph $H_l^1[U]$ since $|A_{\sigma_l}| = 2\kappa d > 4d - 1$.

After that, for each high-degree vertex v, add σ_l to I_v by updating $I_v \leftarrow I_v \cup \{\sigma_l\}$. Finally, for each high-degree vertex $v \notin U$, insert all its incident edges in G_l to the virtual stream as leftover edges; we emphasize the point that this also includes its edges connecting to low-degree vertices.

(2) H_l^2 consists of all edges connecting high-degree vertices to low-degree vertices.
To color edges in H_l^2, go over all low-degree vertices u in the alphabetical order. For each low-degree vertex u, if $c_u[\sigma_l] = \perp$, then check if $\deg_{G_l}(u) > \sqrt{\Delta}$; if so, then initialize a counter $c_u[\sigma_l] \leftarrow 0$.
Enumerate its incident edges in H_l^2 in the alphabetical order. For the b-th edge $(u, v) \in E_l$ incident on u (starting with $b = 0$), consider several cases below.

- **(a)** If (u, v) was already inserted to the virtual stream in Step (1) due to the reason that $v \notin U$, then skip it and proceed to the next edge incident on u.
- **(b)** Define $\delta = r_v - r_u \mod K$, so $d \in [0, K-1]$. If $\delta < 2d$ or $\delta > K - 2d$, then insert edge (u, v) to the virtual stream as a leftover edge.
- **(c)** Otherwise, assume $2d \leq \delta \leq K - 2d$. There are several sub-cases.
  - If $c_u[\sigma_l] = 2d$, then simply insert the edge (u, v) to the virtual stream as a leftover edge.
  - If $c_u[\sigma_l] \neq \perp$ and $c_u[\sigma_l] < 2d$, then check if the $(r_u + c_u[\sigma_l])$-th color from palette C_{σ_l} has already been used in H_l^2 on any other edge incident on high-degree vertex v. If so, then insert the edge (u, v) to the virtual stream as a leftover edge; otherwise, assign the $(r_u + c_u[\sigma_l])$-th color from palette C_{σ_l} to edge (u, v).
  - Otherwise if $c_u[\sigma_l] = \perp$, check if $p_l[\sigma_l] \geq 2d/\sqrt{\Delta}$. If so, insert edge (u, v) to the virtual stream as a leftover edge.
    In the case that $c_u[\sigma_l] = \perp$ and $p_l[\sigma_l] < 2d/\sqrt{\Delta}$, check if the $\left(r_u + b + \sqrt{\Delta} \cdot p_l[\sigma_l]\right)$-th color from palette B_{σ_l} has already been used in H_l^2 on any other edge incident on high-degree vertex v. If so, then insert the edge (u, v) to the virtual stream as a leftover edge; otherwise, assign the $\left(r_u + b + \sqrt{\Delta} \cdot p_l[\sigma_l]\right)$-th color from palette B_{σ_l} to edge (u, v).

In all cases (a)(b)(c), if $c_u[\sigma_l] \neq \perp$, increment the counter by one $c_u[\sigma_l] \leftarrow c_u[\sigma_l] + 1$ afterwards (even if (u, v) is inserted to the virtual stream).

Coloring leftover edges

To color all leftover edges in the virtual stream, we apply the above algorithm recursively on this virtual stream as its input data stream, with fresh colors and independent randomness. Some of the notations used in the algorithm description are summarized in Table 1.

2.2 Proof of correctness

Let us first state some basic properties of the algorithm.

▶ **Lemma 2.** *The value of any counter $c_u[i]$ depends on the data stream and randomness of indices $\{\sigma_l\}$, but is independent of the random shifts $\{r_v \mid v \in V\}$.*

Proof. According to the description of the algorithm, each counter $c_u[i]$ is initialized to 0 in the first interval of edges E_k such that $\deg_{G_k}(u) > \sqrt{\Delta}$ and $\sigma_k = i$; this event is independent of random shifts $\{r_v \mid v \in V\}$. Later on, for any $l \geq k$ such that $\sigma_l = i$, $c_u[i]$ will increase by $|\deg_{H_l^2}(u)|$ if u is a low-degree vertex in G_l. Therefore, $c_u[i]$ is always independent of the random shifts $\{r_v \mid v \in V\}$. ◀

Table 1 Some of the notations used in the algorithm.

notation	definition
E_l	the set of $O(n)$ edges in the l-th interval in from the data stream
G_l	$G_l = (V, E_l)$ is the subgraph collected in the l-th interval
phase	a phase consists of $\Delta^{1/2}$ consecutive intervals
κ	a constant at least 32 which is also an integer power of 2
$A_i, B_i, C_i, 1 \le i \le \kappa\Delta/d$	three sequences of sets of palettes of size $K = 2\kappa d$
$c_v[i] \in \{\perp\} \cup [0, K-1]$	a counter bounding using colors from palette C_i
r_v	$r_v \in [0, K-1]$ is a random shift
I_v	$i \in I_v$ if v already has edges with colors from A_i
σ_l	a uniformly random index from $[1, \kappa\Delta/d]$ for the l-th interval
$p_l[i]$	a counter defined by $p_l[i] = \lvert\{\sigma_k = i \mid l_0 \le k < l\}\rvert$
high-degree vertex	high-degree if $\deg_{G_l} \in [d, 2d)$
low-degree vertex	high-degree if $\deg_{G_l} < d$
H_l^1	all edges between high-degree vertices in G_l
H_l^2	all edges connecting high-degree vertices and low-degree vertices

▶ **Lemma 3.** *At the beginning of the l-th interval, for any low-degree vertex u, if $c_u[\sigma_l] \neq \perp$, then all colors from any palette C_{σ_l} indexed by $r_u + c_u[\sigma_l], r_v + c_u[\sigma_l] + 1, \cdots, r_u + 2d - 1$ mod K haven't been used for any edge incident on u.*

Proof. This is because the counter $c_u[\sigma_l]$ increases by one each time we use a color from C_{σ_l} on edges incident on u, so the colors indexed by larger integers have not been used yet. ◀

▶ **Lemma 4.** *For each vertex u, at any moment during the current phase, there are at most $\frac{\Delta}{2d}$ different indices i such that*

$$\sum_{l,\sigma_l=i} \deg_{G_l}(u) \ge 2d$$

Proof. Since $\deg_G(u) \le \Delta$, the number of indices i such that $\sum_{l,\sigma_l=i} \deg_{G_l}(u) \ge 2d$ is bounded by $\frac{\Delta}{2d}$. ◀

Next, we show that our algorithm always produces a valid edge coloring.

▶ **Lemma 5.** *The algorithm always outputs a valid edge coloring of G.*

Proof. Consider any two adjacent edges $(u, v), (u, w) \in E$, and we will show that $(u, v), (u, w)$ must have different colors in the output stream. Note that v does not need to be different from w since G might not be a simple graph. If one of them appears in the virtual stream, then because the recursion for leftover edges uses fresh colors for each interval, we can make sure that $(u, v), (u, w)$ are assigned different colors. For the rest we assume that $(u, v), (u, w)$ are not leftover edges.

First, consider the case where both $(u, v), (u, w)$ appear in the same interval from the input stream. According to the algorithm, if they are colored in different Step (1) and (2) respectively, then they are picking colors from separate palettes; if they are colored in the same Step (1) or (2), then the algorithm must have colored them in a compatible way.

Secondly, consider the case where $(u, v), (u, w)$ appear in different intervals from the input stream. Assume (u, v) is in interval E_l and (u, w) is in interval $E_h, h \neq l$. Consider the following cases.

- One of $(u,v),(u,w)$ is colored in Step (1) and the other in Step (2).
  In this case, they are using different palettes, so their colors are always different.
- Both $(u,v),(u,w)$ are colored in Step (1) but in different intervals.
  In this case, since (u,w) is not a leftover edge, by the algorithm we know that $\sigma_l \neq \sigma_h$. Therefore, $(u,v),(u,w)$ use colors from different palettes $A_{\sigma_l}, A_{\sigma_h}$.
- Both $(u,v),(u,w)$ are colored in Step (2) but in different intervals.
  If u is high-degree in both intervals E_l, E_h, then since neither of $(u,v),(u,w)$ is a leftover edge, it must be $\sigma_l \neq \sigma_h$. Hence, $(u,v),(u,w)$ are taking colors from different palettes.
  Next, assume u is low-degree in both intervals, plus that $\sigma_l = \sigma_h$. If $(u,v),(u,w)$ were selecting colors from $B_{\sigma_l}, C_{\sigma_h}$, then their colors must be different. So, we only need to consider the case where both $(u,v),(u,w)$ were selecting colors from B_{σ_l}, or from C_{σ_l}. Let us analyze these two cases separately.
  - $(u,v),(u,w)$ were selecting colors from B_{σ_l}. Then, by the algorithm description, (u,v) could only take colors from B_{σ_l} taking indices from the range

    $$[r_u + \sqrt{\Delta} \cdot p_l[\sigma_l], r_u + \sqrt{\Delta} \cdot (p_l[\sigma_l]+1) - 1] \mod K$$

    and (u,w) could only take colors from B_{σ_l} taking indices from the range

    $$[r_u + \sqrt{\Delta} \cdot p_h[\sigma_h], r_u + \sqrt{\Delta} \cdot (p_h[\sigma_h]+1) - 1] \mod K$$

    As $l \neq h$ and $\sigma_l = \sigma_h$, we know that $p_l[\sigma_l] \neq p_h[\sigma_h]$, and therefore the two ranges

    $$[r_u + \sqrt{\Delta} \cdot p_l[\sigma_l], r_u + \sqrt{\Delta} \cdot (p_l[\sigma_l]+1) - 1] \mod K$$

    and

    $$[r_u + \sqrt{\Delta} \cdot p_h[\sigma_h], r_u + \sqrt{\Delta} \cdot (p_h[\sigma_h]+1) - 1] \mod K$$

    are disjoint, and thus the colors of the two edges must be different.
  - $(u,v),(u,w)$ were selecting colors from C_{σ_l}.
    Suppose the color indices of $(u,v),(u,w)$ were $r_u + c_u^{(1)}[\sigma_l]$ and $r_u + c_u^{(2)}[\sigma_l]$, where $c_u^{(1)}[\sigma_l] \neq c_u^{(2)}[\sigma_l]$ are the counter values of $c_u[\sigma_l]$ by the time when the color was selected. Hence, $(u,v),(u,w)$ are picking colors with different indices.

  Finally, assume u is high-degree in G_l and low-degree in G_h. Then, when coloring the edge (u,v), by the condition on Step (2)(b), we know that $\delta = r_u - r_v \mod K$ belongs to $[2d, K-2d]$. By Lemma 3, as the color index of (u,v) always belongs to $\{r_v, r_v+1, \cdots, r_v+2d-1\}$ and the color index of (u,w) always belongs to $\{r_u, r_u+1, \cdots, r_u+2d-1\}$, the colors of $(u,v),(u,w)$ should be different as the two index sets are disjoint. ◀

Next, we verify that the total space of each recursion level is at most $O(n)$.

▶ **Lemma 6.** *The space usage of each recursion level of the algorithm is $O(n)$.*

Proof. It is clear that in each phase, the total space of all offsets is at most $O(n)$. For the number of counters in a single phase, every time a new counter $c_u[\sigma_l]$ has been initialized, we must have $\deg_{G_l}(u) > \sqrt{\Delta}$ for some interval index l within this phase. Since the total sum of vertex degrees within this phase is bounded by $O(n\sqrt{\Delta})$, we know that the number of counters is bounded by $O(n)$.

As for the total space sets I_v's, in each interval, any set I_v adds one more element if v is high-degree. As the total number of edges collected from a single phase is $O(n\sqrt{\Delta})$, The total size of $\sum_{v \in V} |I_v|$ would be at most $O(n\sqrt{\Delta}/d) = O(n)$. ◀

To bound the total number different colors in G, we need to analyze the total number of leftover edges of each recursion level.

▶ **Lemma 7.** *Suppose there are m edges from the input stream (across all phases) in total. Then, the expected number of leftover edges to enter the virtual stream is at most $7m/\kappa$, over the randomness of shifts $\{r_v\}_{v\in V}$ and indices $\{\sigma_l\}$.*

Proof. Consider any single phase, and let $(u,v)\in E$ be an arbitrary edge that appears in interval E_l. There are several cases where (u,v) could possibly be a leftover edge that gets inserted to the virtual stream.

- Edge (u,v) becomes leftover on Step (1).
  The condition for (u,v) being cast as a leftover edge is that $\sigma_l \in I_u \cup I_v$; that is, palette A_{σ_l} was already used for edges incident on u or v in a previous interval. Since any vertex can be high-degree in at most Δ/d intervals, the number of non-zero entries of I_u, I_v is at most $2\Delta/d$. As $\sigma_l \in [\kappa\Delta/d]$ is uniformly random, the probability that $\sigma_l \in I_u \cup I_v$ is at most $2/\kappa$, over the randomness of σ_l.
- Edge (u,v) becomes leftover on Step (2) because $c_u[\sigma_l] = 2d$.
  By Lemma 4, there are at most $\frac{\Delta}{2d}$ different indices i such that $\sum_{k=l_0,\sigma_k=i}^{l-1} \deg_{G_k}(v) \geq 2d$; let I be the set of these indices. Then, since σ_l is picked uniformly at random, the probability that $\sigma_l \in I$ is at most $\frac{1}{2\kappa}$.
  As $c_u[i] \leq \sum_{k=l_0,\sigma_k=i}^{l-1} \deg_{G_k}(v)$ for any i, the probability that $c_u[\sigma_l] = 2d$ is at most $\frac{1}{2\kappa}$. Therefore, (u,v) becomes leftover on this step with probability at most $\frac{1}{2\kappa}$.
- Edge (u,v) becomes leftover on Step (2)(b).
  In this case, we have $\delta < 2d$ or $\delta > K - 2d$ for $\delta = r_v - r_u \mod K$. Since r_v, r_u were chosen uniformly at random from $[0, K-1]$, the probability of this event is at most $4d/K < 2/\kappa$, over the randomness of r_v.
- Edge (u,v) becomes leftover on Step (2)(c) due to $p_l[\sigma_l] \geq 2d/\sqrt{\Delta}$.
  Note that since each σ_k was picked uniformly at random, the expectation of $p_l[\sigma_l]$ which counts $|\{\sigma_k = \sigma_l \mid l_0 \leq k < l\}|$ is bounded by $\frac{d}{\kappa\sqrt{\Delta}}$, over the randomness of $\sigma_{l_0}, \sigma_{l_0+1}, \cdots, \sigma_{l-1}$. By Markov's inequality, the probability that $p_l[\sigma_l] \geq 2d/\sqrt{\Delta}$ is at most $\frac{1}{2\kappa}$.
- Edge (u,v) becomes leftover on Step (2)(c) and $p_l[\sigma_l] < 2d/\sqrt{\Delta}$.
  In this case, assume u is low-degree and v is high-degree in interval E_l. We need to consider two more sub-cases below.
  - $c_u[\sigma_l] \neq \perp$.
    In this case, edge (u,v) was attempting to use a color from C_{σ_l}. Right before (u,v) was enumerated, let S be the set of low-degree neighbors w of v whose alphabetical orders are before u, plus that $c_w[\sigma_l] \neq \perp$.
    For each vertex $w \in S$, suppose there are k_w parallel edges between v, w, and let b_w be the value of the counter $c_w[\sigma_l]$ when the first edge (u,w) was enumerated from the perspective of w. Define an index set

$$I = \bigcup_{w\in S} \{r_w + b_w, r_w + b_w + 1, \cdots, r_w + b_w + k_w - 1\}$$

    Note that $|I| < 2d$ since $\sum_{w\in S} k_w \leq \deg_{G_l}(v) < 2d$. As the algorithm enumerates vertices and edges on Step (2)(c) in the alphabetical order, we know that I is the set of all possible color indices of edges $(v,w), w \in S$ in palette C_{σ_l}.
    Now, on the one hand, by Lemma 2, all values of b_w, k_w are independent of the random shifts $\{r_z \mid z \in V\}$. Therefore, as $u \notin S$, we know that r_u is independent of I. On

the other hand, for (u, v) to be a leftover edge, $r_u + c_u[\sigma_l]$ must belong to I. As the value $c_u[\sigma_l]$ is also independent of r_u, the probability that $r_u + c_u[\sigma_l] \in I$ is at most $|I|/K < 1/\kappa$, over the random choice of r_u.

- $c_u[\sigma_l] = \perp$.
  In this case, edge (u, v) was attempting to use a color from B_{σ_l}. Similar to the previous sub-case, right before (u, v) was enumerated, let T be the set of low-degree neighbors w of v whose alphabetical orders are before u, plus that $c_w[\sigma_l] = \perp$.
  For each vertex $w \in T$, suppose there are k_w parallel edges between u, w, and (u, w) (the first copy) is the b_w-th edge incident on w. Define an index set

$$J = \bigcup_{w \in T} \{r_w + b_w + \sqrt{\Delta} \cdot p_l[\sigma_l], r_w + b_w + \sqrt{\Delta} \cdot p_l[\sigma_l] + 1, \cdots, r_w + b_w + \sqrt{\Delta} \cdot p_l[\sigma_l] + k_w - 1\}$$

  Note that $|J| < 2d$ since $\sum_{w \in T} k_w \leq \deg_{G_l}(v) < 2d$. As the algorithm enumerates vertices and edges on Step (2)(c) in the alphabetical order, we know that J is the set of all possible color indices of edges $(v, w), w \in T$ in palette B_{σ_l}.
  Suppose (u, v) is the b-th edge of u in G_l, so $r_u + b + \sqrt{\Delta} \cdot p_l[\sigma_l]$ is the color index that (u, v) attempted to use in B_{σ_l}. Since $u \notin T$, and that r_u is independent of $p_l[\sigma_l]$ and all values in $\{b_w \mid w \in T\}$, we know that the probability that $r_u + b + \sqrt{\Delta} \cdot p_l[\sigma_l] \in J$ is at most $|J|/K < 1/\kappa$, over the random choice of r_u.

Taking a summation of all the cases, the probability that (u, v) becomes a leftover edge is at most $7/\kappa$. Therefore, expected number of leftover edges is bounded by $7m/\kappa$. ◀

▶ **Lemma 8.** *The expected recursion depth of the main algorithm is $O(\log \Delta)$.*

Proof. Consider any recursion where the input stream contains m edges. By Markov's inequality and Lemma 7, at each recursion level, with probability at least $1/2$, the number of leftover edges is at most $14m/\kappa < m/2$. Since the original graph G contains $O(n\Delta)$ edges, after $O(\log \Delta)$ recursion levels in expectation, the input has at most $O(n)$ edges, so the algorithm would not recurse further. ◀

As a corollary, we can bound the total number of different colors and total memory, which concludes the proof of Theorem 1.

▶ **Corollary 9.** *The number of colors used by our algorithm is $\tilde{O}\left(\Delta^{1.5}\right)$, and the total memory is bounded by $O(n \log \Delta)$; both bounds hold in expectation.*

Proof. Consider any recursion level. According to the algorithm, in each phase and each choice of $d \geq \sqrt{\Delta}$ which is an integer power of 2, the total number of colors in the palettes $\{A_i\} \cup \{B_i\} \cup \{C_i\}$ is $O(\Delta)$. Also, each interval creates at most $O(\sqrt{\Delta})$ new colors when $d < \sqrt{\Delta}$. Since there are $O(\sqrt{\Delta})$ phases, the number of colors used for processing intervals is $\tilde{O}(\Delta^{1.5})$, summing over all choices of d. As the expected recursion depth is $O(\log \Delta)$, together with Lemma 6 we can finish the proof. ◀

2.3 Adaptation to an unknown Δ

So far we have assumed that the value of the maximum degree Δ of G is known to the algorithm as prior knowledge. We can adapt our algorithm to an unknown Δ by losing a constant factor in the total number of colors in the following way. Basically, we will maintain the value Δ_t which is the maximum degree of the subgraph containing the first t edges in the data stream. Whenever $\Delta_t \in (2^{k-1}, 2^k]$, we will apply Theorem 1 with $\Delta = 2^k$ to color

all the edges. If k increases at some point, we will restart a new instance of Theorem 1 with a new choice of $\Delta = 2^k$ and continue to color the edges with a separate palette; to clarify, when a new instance of Theorem 1 is restarted, we continue with the current pass of the data stream, not starting over with a new pass. In the end, the total number of colors will be $\tilde{O}(\sum_{k=1}^{\lceil \log \Delta \rceil} 2^{1.5k}) = \tilde{O}(\Delta^{1.5})$ in expectation.

2.4 From expectation to high probability

So far our bounds on memory and the number of colors only hold in expectation, not with high probability. These bounds can actually hold with high probability rather than in expectation. In fact, as shown in Lemma 8, the expected recursion depth can be bounded by $O(\log \Delta)$. We can also show that the depth is $O(\log n)$ with high probability, and therefore the total number of colors is at most $O(\Delta^{1.5} \cdot \log n)$. To get rid of the dependency on $\log n$, we can increase the size of intervals by a factor of $\log n$; that is, each interval now contains $O(n \log n)$ edges. This would decreases the total number of phases by a factor of $\Omega(\log n)$ and thus decreases the number of colors, which cancels out the extra $\log n$ factor in the color bound.

Faster Algorithms for Dual-Failure Replacement Paths

Shiri Chechik

Abstract

Given a simple weighted directed graph $G = (V, E, \omega)$ on n vertices as well as two designated terminals $s, t \in V$, our goal is to compute the shortest path from s to t avoiding any pair of presumably failed edges $f_1, f_2 \in E$, which is a natural generalization of the classical replacement path problem which considers single edge failures only.

This dual failure replacement paths problem was recently studied by Vassilevska Williams, Woldeghebriel and Xu [FOCS 2022] who designed a cubic time algorithm for general weighted digraphs which is conditionally optimal; in the same paper, for unweighted graphs where $\omega \equiv 1$, the authors presented an algebraic algorithm with runtime $\tilde{O}(n^{2.9146})$, as well as a conditional lower bound of $n^{8/3-o(1)}$ against combinatorial algorithms. However, it was unknown in their work whether fast matrix multiplication is necessary for a subcubic runtime in unweighted digraphs.

As our primary result, we present the first truly subcubic combinatorial algorithm for dual failure replacement paths in unweighted digraphs. Our runtime is $\tilde{O}(n^{3-1/18})$. Besides, we also study algebraic algorithms for digraphs with small integer edge weights from $\{-M, -M+1, \cdots, M-1, M\}$. As our secondary result, we obtained a runtime of $\tilde{O}(Mn^{2.8716})$, which is faster than the previous bound of $\tilde{O}(M^{2/3}n^{2.9144} + Mn^{2.8716})$ from [Vassilevska Williams, Woldeghebriela and Xu, 2022].

1 Introduction

In the replacement path problem, we want to understand shortest paths in a directed graph that avoid presumably failed edges. More specifically, let $G = (V, E, \omega)$ be an edge-weighted simple digraph on n vertices and m edges. Fix a pair of source and terminal vertices $s, t \in V$, we want to compute the shortest path from s to t that avoids any designated set $F \subseteq E$ of failed edges.

The most classical setting is when the number of failures is at most one; namely, we want to compute all the values of $\mathsf{dist}(s, t, G \setminus \{f\})$ when f ranges over all edges on the shortest path from s to t in G. The complexity of single-failure replacement path is now well-understood. On the hardness side, it was proved that computing all single-failure replacement paths in weighted graphs requires at least $n^{3-o(1)}$ time [19] assuming the APSP conjecture. To breach the cubic barrier, we need to assume the input digraph has small integer edge weights, or allow approximation errors in the algorithm output. When the edge

weights are integers in the range $\{-M, -M+1, \cdots, M-1, M\}$, there is an algorithm with runtime $\tilde{O}(Mn^{\omega})$[1] [7, 17]. For the special case when the input digraph is unweighted ($\omega \equiv 1$), there is a combinatorial algorithm (algorithms not using fast matrix multiplication) with runtime $\tilde{O}(mn^{1/2})$ [16], which is optimal under the hardness of combinatorial boolean matrix multiplication [19].

A natural extension is to study replacement paths when there are two edge failures. We are interested in fast algorithms that compute for all pairs of edges $f_1, f_2 \in E$ the value of $\mathsf{dist}(s, t, G \setminus \{f_1, f_2\})$. This problem was first studied in [4] and recently revisited in [20]. For general weighted digraphs, the authors of [20] designed an algorithm with runtime $\tilde{O}(n^3)$, which is the same as the easier single failure replacement paths problem. When the graph has small edge weights from range $\{-M, -M+1, \cdots, M-1, M\}$, in the same paper the authors have shown subcubic runtime upper bound of $\tilde{O}(M^{2/3}n^{2.9144} + Mn^{2.8716})$ using fast matrix multiplication. Finally, as complementary to their algorithms, the authors showed a conditional lower bound of $n^{8/3-o(1)}$ against combinatorial algorithms for unweighted digraphs assuming the hardness of boolean matrix multiplication.

According to the results in [20], there is a gap in their understanding about dual-failure replacement paths in unweighted graphs. On the one hand, their algebraic algorithm computes dual-failure replacement paths in $\tilde{O}(n^{2.9144})$ by setting $M = 1$; on the other hand, their conditional lower bound against combinatorial algorithms is also subcubic. So, it is not clear whether combinatorial algorithm can achieve subcubic runtime as well, or the conditional lower bound can be improved to cubic.

1.1 Our results

In this paper, we first study fast combinatorial algorithms for unweighted digraphs and show that subcubic runtime can indeed be achieved without using fast matrix multiplication.

▶ **Theorem 1.** *Given a simple unweighted directed graph $G = (V, E)$ on n vertices, and fix any pair of vertices $s, t \in V$, the values of all dual-failure replacement path distances $\mathsf{dist}(s, t, G \setminus \{f_1, f_2\}), \forall f_1, f_2 \in E$ can be computed in $\tilde{O}(n^{3-1/18})$ time with high probability; most importantly, the algorithm does not use fast matrix multiplication.*

Here, a digraph is simple if it does not contain two edges between the same pair of vertices with the same direction. Secondly, we also study fast algebraic algorithms for dual-failure replacement paths when the edge weights are from the set $\{-M, -M+1, \cdots, M-1, M\}$. The proof of the following statement is presented in the full version.

▶ **Theorem 2.** *Given a simple weighted directed graph $G = (V, E, \omega)$ on n vertices along with integer edge weights $\omega : E \to \{-M, -M+1, \cdots, M-1, M\}$ without negative cycles, and fix any pair of vertices $s, t \in V$, the values of all dual-failure replacement path distances $\mathsf{dist}(s, t, G \setminus \{f_1, f_2\}), \forall f_1, f_2 \in E$ can be computed in time $\tilde{O}(Mn^{2.8716})$.*

1.2 Other related works

The replacement paths problem has also been studied in other settings, including the single-source setting [13, 6, 12, 11] and the approximation setting [8, 2, 15].

[1] $\omega \in [2, 2.371552]$ is the fast matrix multiplication exponent [21, 10, 1, 14, 18].

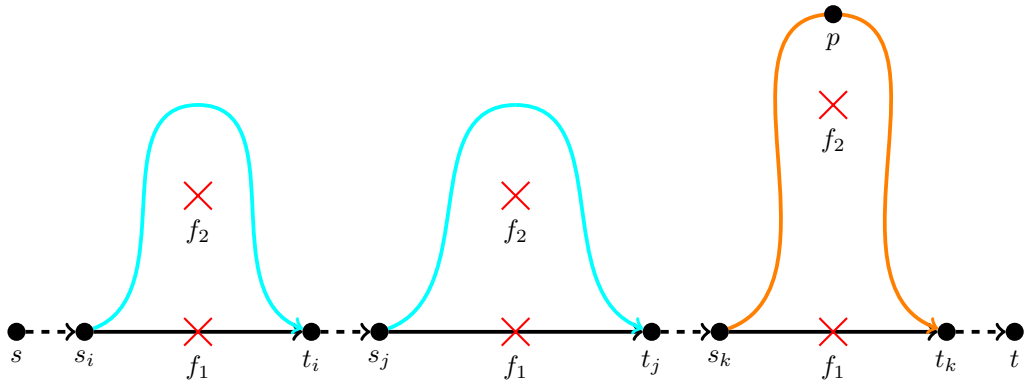

Figure 1 For simplicity, let us assume that when f_1 falls on the sub-paths $\pi[s_i, t_i]$, the dual-failure replacement path also passes through s_i, t_i. In this picture, the two cyan dual-failure replacement paths have length less than L, and we will show that they are vertex-disjoint. The orange dual-failure replacement path has length at least L, and so it hits a vertex $p \in U$ with high probability; in this case, we will compute single-source single-failure replacement paths to and from p in graph $G \setminus E(\pi)$ to help us compute dual-failure replacement paths.

1.3 Subcubic combinatorial algorithm for unweighted digraphs

1.3.1 One failure on a long *st*-path

Let us first consider the case where one edge failure f_1 lies on the shortest st-path π, while the other one f_2 does not. This case would be easy when we use fast matrix multiplication as did by [20], but it becomes complicated when we are restricted to purely combinatorial algorithms.

As a preliminary step, we first show how to deal with the case where $|\pi| > L$ for some parameter L slightly larger than $n^{0.5}$, say $L = n^{0.55}$. Partition the st-path π into sub-paths of length exactly $5L$ as $\pi = \gamma_1 \circ \gamma_2 \circ \cdots \circ \gamma_h, h \leq \lceil n/5L \rceil$, and let s_i, t_i be the endpoints of sub-path γ_i. Assume only one edge failure f_1 falls on sub-path γ_i, and let ρ be the optimal replacement path from s to t avoiding $\{f_1, f_2\}$.

Take a random set of vertices U of size $O(n \log n/L)$. If $|\rho \setminus \pi| > L$, then with high probability $\rho \setminus \pi$ would contain a vertex p from U. Then, we can compute single-source single-failure replacement paths to and from p in graph $G \setminus E(\pi)$ that takes runtime $\tilde{O}(n^{3.5}/L)$ [6], so that for each vertex $z \in V$, we know the shortest path between z, p in graph $G \setminus (E(\pi) \cup \{f_2\})$. Using this information, we will be able to recover ρ.

Now suppose $|\rho \setminus \pi| < L$. Then in this case, we will show that the detour parts of different dual-failure replacement paths ρ are vertex-disjoint from each other when the first edge failure f_1 comes from different choice of sub-paths γ_i. Then, we can partition G into vertex-disjoint subgraphs $G_1, G_2, \cdots, G_h$, such that the dual-failure replacement paths for failures on γ_i belong to subgragh G_i, and solve the dual-failure replacement paths problem for source-terminal pair (s_i, t_i) in graph G_i. See Figure 1 for an illustration.

1.3.2 One failure on a short *st*-path

By the previous subsection, we have reduced to the case that the st-path has length at most L. So, for the rest, let us rename the problem instance and assume that $|\pi| \leq L$. For the i-th edge e_i on π $(0 \leq i < L)$, we can compute the optimal replacement path from s to t avoiding e_i and let α_i be the corresponding detour whose endpoints are a_i and b_i. Again, through

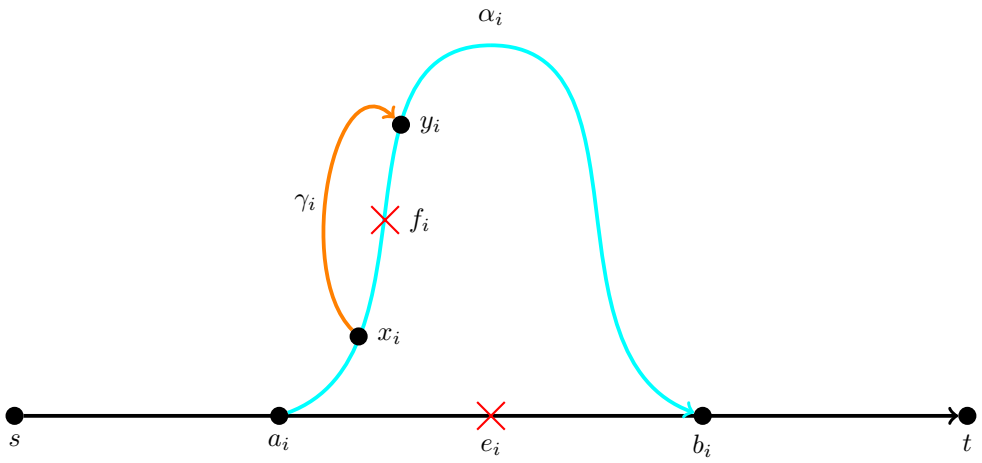

Figure 2 The cyan path is the detour α_i that avoids e_i, and the orange path is the detour γ_i that avoids f_i which lies on α_i. Via some case analysis, we will show the difficult case is that $|\alpha_i| < L$.

some case analysis, we can assume that the span of each detour α_i which is $|\pi[a_i, b_i]|$ is at most g for some parameter g slightly larger than $n^{1/3}$ (say $g = n^{0.35}$). Consider any edge failure $f_i \in E(\alpha_i)$, as a simplification let us assume that the optimal replacement path from s to t avoiding $\{e_i, f_i\}$ is a concatenation:

$$\rho = \pi[s, a_i] \circ \alpha_i[a_i, x_i] \circ \gamma_i \circ \alpha_i[y_i, b_i] \circ \pi[b_i, t]$$

where γ_i is a detour with respect to α_i in $G \setminus E(\pi)$. Via some case analysis, we can assume that $|\alpha_i| < L$. See Figure 2 for an illustration.

Let us first consider the case when $|\gamma_i| < g$. A wishful thought is that for two different choice of dual failures $\{e_i, f_i\}$ and $\{e_j, f_j\}$ where e_i and e_j are well-separated on the shortest path π ($|\pi(e_i, e_j)| \geq 10g$), we are guaranteed that the two dual-failure detours γ_i and γ_j are vertex-disjoint; if this is the case, then we can partition the graph G into $O(L/g)$ vertex-disjoint subgraphs and compute dual-failure replacement paths separately. However, this is generally not true. The key observation is that when f_i and f_j are roughly at the same height on the detour, namely $|\alpha_i[a_i, f_i)| \approx |\alpha_j[a_j, f_j)|$ up to an additive error of at most g, such a disjointness condition indeed holds. Therefore, our algorithm will further partition each detour α_i into sub-paths of length g as $\alpha_i = \beta_1^i \circ \beta_2^i \circ \cdots \circ \beta_l^i$. Then, fix any height index $1 \leq h \leq l$, we will deal with all the dual failures $\{e_i, f_i\}, \forall 1 \leq i \leq L/g, \forall f_i \in E(\beta_h^i)$ at the same time. See Figure 3 for an illustration.

Now, what happens if $|\gamma_i| \geq g$? We can take a random sample U of pivot vertices of size $O(n \log n/g)$. Then, with high probability, γ_i contains a vertex in U. For simplicity, assume both endpoints of the detour γ_i are lying within the sub-path β_h^i which contains the second edge failure f_i, then we could compute single-source shortest paths to and from each vertex $p \in U$ in the subgraph $G \setminus \big(E(\pi) \cup E(\beta_h^i)\big)$ which takes time $\tilde{O}(n^3/g)$, then we can compute each detour γ_i for each choice of f_i on β_h^i in time $\tilde{O}(g^2)$ by guessing the positions of x_i, y_i.

Unfortunately, there are L^2/g different choices for the subgraph $G \setminus \big(E(\pi) \cup E(\beta_h^i)\big)$, and thus we do not have enough time to compute single-source shortest paths for each vertex in U in all these subgraphs. In fact, we can only afford to compute single-source shortest paths for vertices in U in the subgraph $G_h = G \setminus \Big(E(\pi) \cup \bigcup_{i=0}^{L-1} E(\beta_h^i)\Big)$; that is, for each index h, remove all sub-paths $\beta_h^i, \forall 0 \leq i < L$ from $G \setminus E(\pi)$ simultaneously (which becomes G_h), and compute multi-source shortest paths to and from U in G_h. The key observation is that

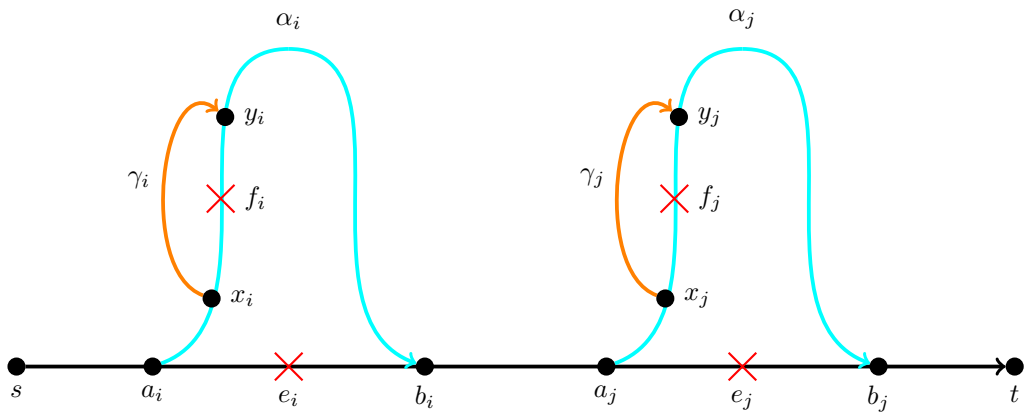

Figure 3 For two well-separated edges e_i, e_j such that $|\pi(e_i, e_j)| \geq 10g$, if both $|\gamma_i|, |\gamma_j|$ are less than g, and f_i, f_j are roughly at the same height (i.e., $|\alpha_i[a_i, f_i)| \approx |\alpha_j[a_j, f_j)|$), then we can show that the two dual-failure detours γ_i, γ_j are vertex-disjoint.

the detour γ_i cannot touch vertices on β_h^j if $|i - j| > 10g$. Therefore, to compute γ_i, we can build a small shortcut graph consisting of all vertices in $U \cup \bigcup_{j=i-10g}^{i+10g} V(\beta_h^j)$ which contains all edges in $\bigcup_{j=i-10g}^{i+10g} E(\beta_h^j) \setminus E(\beta_h^i)$ and all shortcut edges to and from $p \in U$ weighted by the single-source distances we have computed in G_h. See Figure 4 for an illustration.

1.3.3 Both failures on the st-path

Now let us assume both edge failures lie on π. As the same in [20], the main difficulty of dual-failure replacement path for this case comes from the backward paths. More specifically, given two edge failures $\{f_1, f_2\}$, in general the optimal dual replacement path ρ has three parts.

- A prefix of ρ that diverges from π before the first edge failure f_1 on $\pi[s, f_1)$, and then meets somewhere in the middle $y \in V(\pi(f_1, f_2))$ using edges in $G \setminus E(\pi)$.
- A sub-path of ρ that travels from y to another vertex $x \in V(\pi(f_1, y])$ using edges in $(G \setminus E(\pi)) \cup E(\pi(f_1, f_2))$; this sub-path is the so-called *backward* path of ρ which may converge and diverge multiple times with $\pi(f_1, f_2)$.
- A suffix of ρ that converges with π after the second edge failure f_2 on $\pi(f_2, t]$ starting from x using edges in $G \setminus E(\pi)$, and then reach t using the rest of π.

To compute the backward path, let us divide π into sub-paths of length L for some parameter L as $\pi = \gamma_1 \circ \gamma_2 \circ \cdots \circ \gamma_{n/L}$. Take a random pivot vertex set U of size $O(\frac{n \log n}{L})$. The main observation is that if f_1 and f_2 are in different sub-paths $\gamma_i, \gamma_j, j - i > 1$, plus that $x \in V(\gamma_i), y \in V(\gamma_j)$, then the prefix $\rho[s, y]$ must have length at least L and thus contain a pivot $p \in U$ with high probability. Therefore, if we compute single-source replacement paths [6] from p in graph $G \setminus E(\gamma_i)$, then it would provide useful information about the backward path of ρ from y to x. See Figure 5 for an illustration.

1.4 Faster algebraic algorithm for weighted digraphs

Let us divide the shortest path π from s to t into sub-paths of hops at most L; that is, $\pi = \gamma_1 \circ \gamma_2 \circ \cdots \circ \gamma_{\lceil n/L \rceil}$. Given a pair of edge failures $\{f_1, f_2\}$, suppose f_1 and f_2 belong to γ_{l_1} and γ_{l_2} respectively. In the previous paper [20], the difficult case is when f_1, f_2 come from different sub-paths, say $l_1 < l_2$. To compute $\mathsf{dist}(s, t, G \setminus \{f_1, f_2\})$ efficiently, their approach

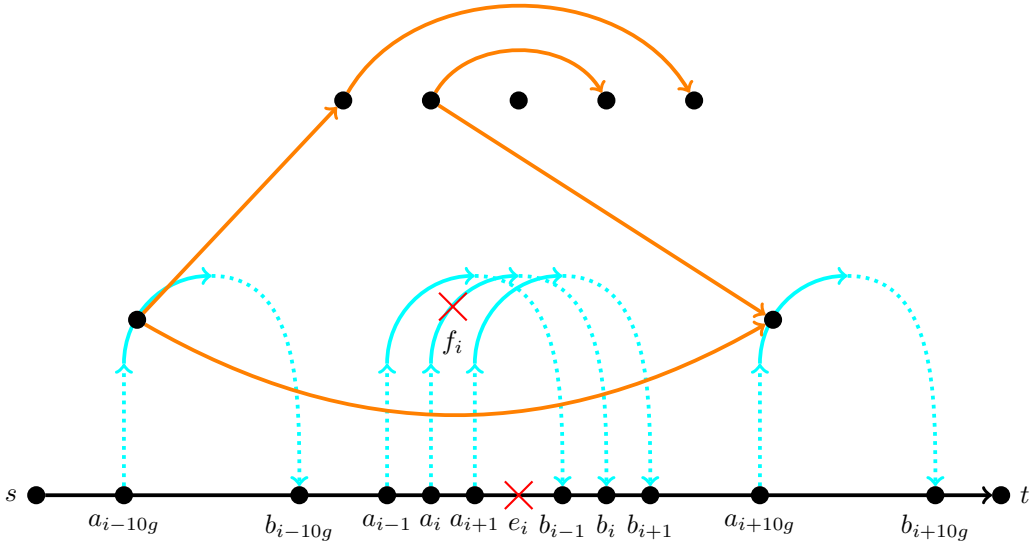

Figure 4 A shortcut graph that helps computing the dual-failure detour γ_i avoiding $\{f_i, g_i\}$, which consists of vertices in $U \cup \bigcup_{j=i-10g}^{i+10g} V(\beta_h^j)$. This shortcut graph includes all edges in $\bigcup_{j=i-10g}^{i+10g} E(\beta_h^j) \setminus E(\beta_h^i)$, and some shortcut edges representing distances to and from U in G_h; actually, it will also contain some shortcut edges between vertices in $\bigcup_{j=i-10g}^{i+10g} V(\beta_h^j)$ which we have not discussed in the overview.

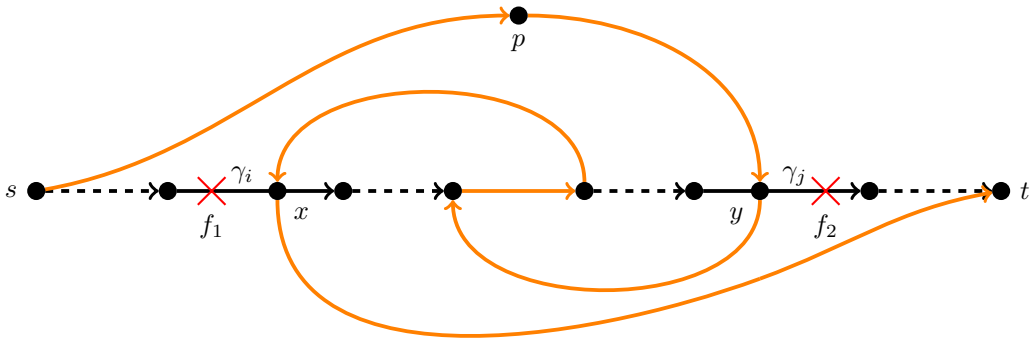

Figure 5 When f_1, f_2 lie in different sub-paths γ_i, γ_j such that $j - i > 1$, we can show that ρ must contain a vertex in U with high probability. Then we can apply the algorithm from [6] to compute single-source replacement path from p in graph $G \setminus E(\gamma_i)$ to learn about the sub-path $\rho[p, x]$ which contains the backward path in the middle.

was to build a sketch graph H_{f_1,f_2} on vertices $\{s,t\} \cup V(\gamma_{l_1}) \cup V(\gamma_{l_2})$ which encodes an optimal replacement path, and then run s-t shortest path in H_{f_1,f_2} which takes $\tilde{O}(L^2)$ time for each $\{f_1, f_2\}$, leading to a total runtime overhead of $\tilde{O}(n^2L^2)$.

Divide each sub-path γ_l into segments $\gamma_l = \alpha_1^l \circ \alpha_2^l \circ \cdots \circ \alpha_{\lceil L/g \rceil}^l$ of hops at most g (for some parameter $g < L$). Assume f_1 lies on $\alpha_{h_1}^{l_1}$ and f_2 lies on $\alpha_{h_2}^{l_2}$, and let ρ be the optimal replacement path from s to t avoiding $\{f_1, f_2\}$. Our main observation is that, if ρ intersects both $\alpha_{h_1}^{l_1}, \alpha_{h_2}^{l_2}$, then we can build a smaller sketch graph H_{f_1,f_2} on $\{s,t\} \cup V\left(\alpha_{h_1}^{l_1}\right) \cup V\left(\alpha_{h_2}^{l_2}\right)$ which still encodes ρ, and so the runtime would be reduced to $\tilde{O}(g^2)$. Otherwise, if ρ skips over $\alpha_{h_2}^{l_2}$ entirely, we will build a sketch graph $H_{f_1,(l_2,h_2)}$ on the vertex set $\{s,t\} \cup V(\gamma_{l_1}) \cup V(\gamma_{l_2})$ which only depends on f_1 and $\alpha_{h_2}^{l_2}$ and not on f_2. As the number of such graphs $H_{f_1,(l_2,h_2)}$ is at most $O(n^2/g)$, the runtime can be bounded by $\tilde{O}(n^2L^2/g)$. Overall, the runtime would be $\tilde{O}(n^2g^2 + n^2L^2/g)$ which is always better than the previous bound of $\tilde{O}(n^2L^2)$.

2 Preliminaries

Throughout the paper, logarithm $\log(*)$ will have base 2, and we assume the number of vertices n in the input graph is an integral power of 2. In any weighted digraph $G = (V, E, \omega)$, for any vertex $u \in V$, let $\deg(u, G)$ be its vertex degree (counting both in-edges and out-edges); for any pair of vertices $u, v \in V$, let $\mathsf{dist}(u, v, G)$ be the weighted length of the shortest path from u to v in G. Throughout the algorithm, we will maintain a distance estimation function $\mathsf{est}(*,*,*)$, such that the value $\mathsf{est}(u, v, G) \geq \mathsf{dist}(u, v, G)$ is always an upper bound. All values of $\mathsf{est}(*,*,*)$ are initially infinity and are non-increasing throughout the algorithms. When we update the value of an estimation $\mathsf{est}(u, v, G)$ with a distance value D, we mean $\mathsf{est}(u, v, G) \leftarrow \{D, \mathsf{est}(u, v, G)\}$.

Given any directed path or walk ρ in G, let $|\rho|$ be the number of edges on ρ, and let $\omega(\rho)$ be its total edge weight. For any two vertices $u, v \in V(\rho)$ where u comes before v on ρ, let $\rho[u, v] \subseteq \rho$ be the sub-path of ρ from u to v. In addition, let $\rho[*, v]$ and $\rho[u, *]$ be the prefix and suffix sub-path of ρ; this notation will be useful when we don't have variable names for the endpoints of path ρ.

For any edge $f \in E(\rho)$ and vertex $u \in V(\rho)$ which comes before edge f, let $\rho[u, f)$ be the sub-path from u to f (excluding edge f); similarly we can define notations $\rho(f, v]$ and $\rho(f_1, f_2)$ in the natural way.

Borrowing a terminology from [20], let us define the notion of canonical paths.

▶ **Definition 3** ([20]). *Let $s, t \in V$ be two vertices, and let π be a shortest path from s to t. For any edge set $F \subseteq E$, a path ρ from s to t in $G \setminus F$ is called* canonical *with respect to π and F, if for any $u, v \in V(\pi) \cap V(\rho)$ such that u appears before v in both π, ρ and $E(\pi[u, v]) \cap F = \emptyset$, then $\rho[u, v]$ is the same as $\pi[u, v]$.*

2.1 Unweighted digraphs

For tie-breaking among shortest paths, we can randomly perturb all unit edge weights slightly so that all replacement shortest paths for at most two edge failures are unique under the perturbed weights. We can show that, under the weight perturbation, all replacement shortest paths are canonical. Next, let us state a basic property regarding shortest replacement paths for one edge failure.

▶ **Lemma 4.** *Consider any edge $f \in E(\pi)$, any canonical shortest path ρ from s to t avoiding f can be decomposed as $\rho = \pi[s, a] \circ \alpha \circ \pi[b, t]$, where $a, b \in V(\pi)$ and α is a shortest path from a to b in $G \setminus E(\pi)$. For convenience, α will be called the* detour *of the replacement path, and a, b are called the* divergence *and* convergence *vertex, respectively.*

It is known that shortest replacement paths for one failure can be computed efficiently.

▶ **Lemma 5** ([16]). *Given an unweighted digraph $G = (V, E)$ on n vertices and m edges. Fixing any source-terminal pair $s, t \in V$, we can compute all canonical shortest replacement paths from s to t avoiding f with high probability in time $\tilde{O}(mn^{1/2} + n^2)$, where f ranges over all edges in E.*

We also need a basic property about replacement paths for dual edge failures where only one edge falls on the st-path π.

▶ **Lemma 6.** *Consider any edge $f_1 \in E(\pi)$ and let α be the detour of the shortest replacement path that avoids f_1. Consider any edge $f_2 \in E(\alpha)$. Then, there is a shortest replacement path ρ avoiding $\{f_1, f_2\}$ such that:*

- *ρ is a canonical shortest path avoiding f_1 in graph $G \setminus \{f_1\}$.*
- *ρ diverges and converges with π for once.*

We will be applying the following algorithm for single-source replacement paths algorithm from [6] as a black-box.

▶ **Lemma 7** ([6]). *Given an unweighted digraph $G = (V, E)$ on n vertices and m edges. Fixing any vertex $s \in V$, we can compute all shortest replacement paths from s to t avoiding f with high probability in time $\tilde{O}(mn^{1/2} + n^2)$, where t ranges over all vertices in $V \setminus \{s\}$ and f ranges over all edges in E.*

To be consistent with our perturbation-based tie-braking, we should also impose the same edge weight perturbation on the graph on which Lemma 7 is applied; although Lemma 7 is only stated for unweighted digraphs, it also works with edge weight perturbation (for example, all hitting set arguments still work, since perturbation only changes path lengths negligibly).

In the original paper [6], they only claim to compute all the length of shortest replacement paths, but here we need the actual shortest paths tree in each graph $G \setminus \{f\}$. To achieve such an augmentation, during the execution of the algorithm in [6], we can keep track of the last edge of each replacement path, and by uniqueness of shortest paths under weight perturbation, the set of these last edges form the shortest paths tree.

Finally, one of our basic tools is a *truncated* version of Dijkstra's algorithm, which is stated below.

▶ **Lemma 8** ([9]). *Given an unweighted digraph $G = (V, E)$ on n vertices. For any vertex $s \in V$ and any threshold L, let $U = \{u \mid \mathsf{dist}(s, u, G) \leq L\}$. Then we can compute shortest paths from s to all vertices in U in time $O(\sum_{u \in U} \deg(u, G) + n \log n)$.*

2.2 Weighted digraphs

When the input graph contains negative edge weights, we assume it does not contain any negative cycles. For weighted graphs, since fast matrix multiplication algorithms only work with small integer edge weights, we will not assume unique shortest paths by perturbing the edge weights.

Our algorithm relies on fast algorithms which computes shortest paths in digraphs with negative edge weights.

▶ **Lemma 9** ([3]). *Given a weighted digraph $G = (V, E, \omega)$ with edge weights $\omega : E \to \{-M, -M + 1, \cdots, M - 1, M\}$ without negative cycles, and fix any source vertex $s \in V$. Then, single-source shortest path from s can be computed in time $\tilde{O}(m \log M)$ with high probability.*

▶ **Lemma 10** ([22]). *Given a weighted digraph $G = (V, E, \omega)$ with edge weights $\omega : E \to \{-M, -M+1, \cdots, M-1, M\}$ without negative cycles, all-pairs shortest paths in G can be computed in time $\tilde{O}(M^{\frac{1}{4-\omega}} n^{2+\frac{1}{4-\omega}})$ with high probability.*

We will apply single-source multi-terminal replacement paths algorithms as a black-box; the currently best known upper bound is stated below.

▶ **Lemma 11** ([13]). *Given a weighted digraph $G = (V, E, \omega)$ with edge weights $\omega : E \to \{-M, -M+1, \cdots, M-1, M\}$ without negative cycles, and fix any source vertex $s \in V$ and a terminal set $T \subseteq V$. Then, the value of all $\mathsf{dist}(s, t, G \setminus \{f\}), \forall t \in T, f \in E$ can be computed in time $\tilde{O}(Mn^{\omega} + M^{\frac{1}{4-\omega}} n^{1+\frac{1}{4-\omega}} \cdot |T|)$ with high probability.*

We will use the following fast algorithm for distance sensitivity oracles in weighted digraphs. In a weighted digraph $G = (V, E, \omega)$ with edge weights $\omega : E \to \{-M, -M+1, \cdots, M-1, M\}$, a distance sensitivity oracle is an efficient data structure that answers $\mathsf{dist}(u, v, G \setminus \{f\})$ for any $u, v \in V, f \in E$.

▶ **Lemma 12** ([5]). *Given a weighted digraph $G = (V, E, \omega)$ with edge weights $\omega : E \to \{-M, -M+1, \cdots, M-1, M\}$ without negative cycles, a distance sensitivity oracle with $\tilde{O}(1)$ query time can be constructed in time $\tilde{O}(Mn^{2.8719})$.*

3 One failure on a short st-path

We use two parameters g and L which will be determined in the end such that $g < n^{1/2} < L$. In this section, we study the case where only one edge failure lies on a short st-path, plus that the input graph is sparse and $\mathsf{dist}(s, t, G) \leq L$. More specifically, let $G = (V, E)$ be an unweighted digraph with n vertices and m edges, and consider a pair of vertices s, t with a shortest st-path $E(\pi)$ of length at most L. The task is to compute for any pairs of edges f_1, f_2 the value of $\mathsf{dist}(s, t, G \setminus \{f_1, f_2\})$, where $f_1 \in E(\pi), f_2 \notin E(\pi)$. The purpose of this section is to prove the following lemma.

▶ **Lemma 13.** *Let $G = (V, E)$ be an unweighted digraph with n vertices and m edges. Fix a pair of source and terminal $s, t \in V$ such that $\mathsf{dist}(s, t, G) \leq L$. Then, all values of $\mathsf{dist}(s, t, G \setminus \{f_1, f_2\})$ can be computed with high probability in time:*

$$\tilde{O}\left(\frac{mn^{1.5} + n^3}{L} + mn^{1/2}L/g + n^2L/g + mL^2/g + mnL^2/g^3 + mLg + L^2g^4 + n^2L^2/g^2\right)$$

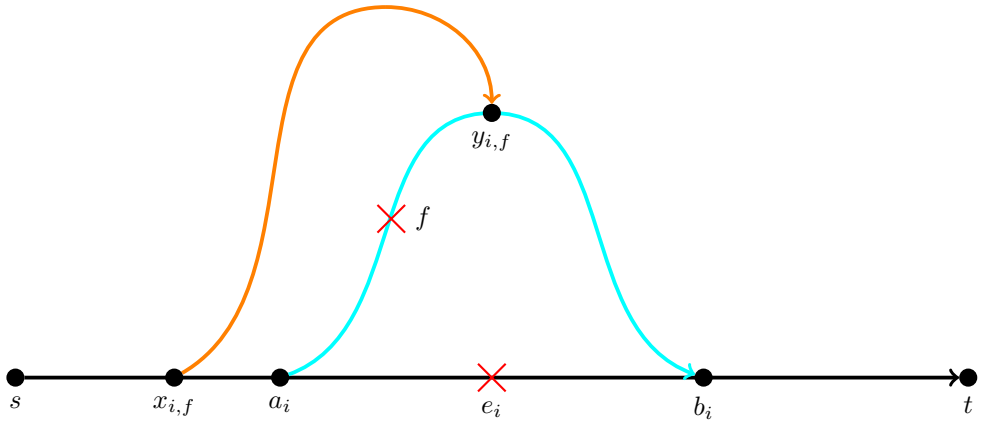
when $f_1 \in E(\pi)$ while $f_2 \notin E(\pi)$; here g is an arbitrary parameter to be determined later.

Let $\pi = \langle s = u_0, u_1, \cdots, u_{|\pi|} = t \rangle$. First, we use Lemma 5 to compute for each $(u_i, u_{i+1}) \in E(\pi)$ the replacement path from s to t that avoids $e_i = (u_i, u_{i+1})$, and let α_i be the corresponding detour avoiding e_i which starts at a_i and ends at b_i.

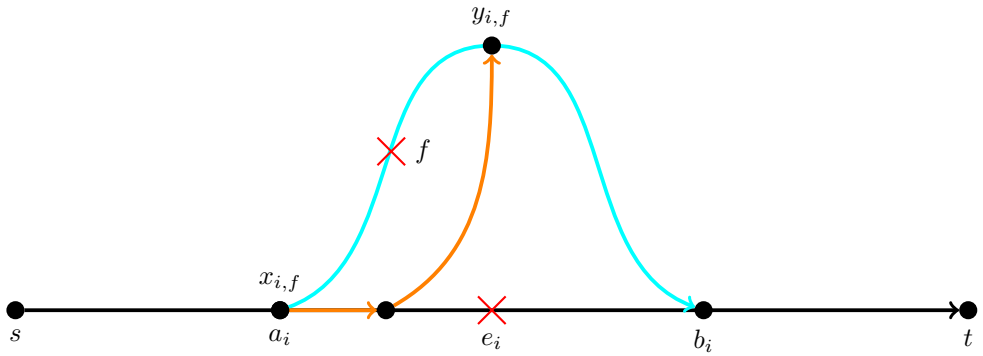
For each detour α_i, divide α_i into sub-paths of length g (except for the last sub-path) and list them as $\beta_1^i, \cdots, \beta_{l_i}^i$, and assume $f \in E(\beta_l^i)$; later on, when we refer to β_l^i, if $l \leq 0$ or $l > l_i$, then β_l^i would simply be an empty path.

Throughout the algorithm, for each $0 \leq i < |\pi|$ and every edge $f \in E(\alpha_i)$, we will maintain a distance estimation $\mathsf{est}(s, t, G \setminus \{e_i, f\}) \geq \mathsf{dist}(s, t, G \setminus \{e_i, f\})$, and in the end it will be guaranteed that $\mathsf{est}(s, t, G \setminus \{e_i, f\}) = \mathsf{dist}(s, t, G \setminus \{e_i, f\})$.

Let $\rho_{i,f}$ be a canonical shortest replacement path for $\{e_i, f\}$. Suppose $\rho_{i,f}$ departs from $\pi[s, a_i] \circ \alpha_i \circ \pi[b_i, t]$ at vertex $x_{i,f}$ and converges with $\pi[s, a_i] \circ \alpha_i \circ \pi[b_i, t]$ at vertex $y_{i,f}$. For the rest, we address different cases depending on the properties regarding $\alpha_i, \rho_{i,f}$; note that our algorithm does not need to know which case it is in advance.



(a) In this case, $x_{i,f} \neq a_i$ and $\rho_{i,f}[x_{i,f}, *]$ diverges from π immediately.



(b) In this case, $x_{i,f} = a_i$ and $\rho_{i,f}[x_{i,f}, *]$ uses some edges on $\pi[a_i, b_i]$ before it diverges.

Figure 6 In this picture, the cyan path is detour α_i, and the orange path is $\rho_{i,f}[x_{i,f}, y_{i,f}]$.

Case 1: $x_{i,f} \in V(\pi[s, a_i])$ or $y_{i,f} \in V(\pi[b_i, t])$

This is an easy case of our algorithm, and the runtime of this part can be bounded by $O(mL)$. See Figure 6 for an illustration. Check the full version for more details.

Case 2: $x_{i,f}, y_{i,f} \in V(\alpha_i)$ and $|\alpha_i| \geq L$

This is an easy case of our algorithm, and the runtime of this part can be bounded by $\tilde{O}(\frac{mn^{1.5}+n^3}{L})$. See Figure 7 for an illustration. Check the full version for more details.

Case 3: $x_{i,f}, y_{i,f} \in V(\alpha_i)$, plus that $|\pi[a_i, u_i]| > g$ or $|\pi[u_{i+1}, b_i]| > g$

This is an easy case of our algorithm, and the runtime of this part can be bounded by

$$\tilde{O}\left(m\sqrt{n}L/g + n^2L/g + L^2\right)$$

See Figure 8 for an illustration. Check the full version for more details.

Case 4: $x_{i,f}, y_{i,f} \in V(\alpha_i)$, plus that $x_{i,f} \notin V(\beta_l^i)$ or $y_{i,f} \notin V(\beta_l^i)$, and $|\alpha_i| < L$

This is an easy case of our algorithm, and the runtime of this part can be bounded by $\tilde{O}(mL^2/g)$. See Figure 9 for an illustration. Check the full version for more details.

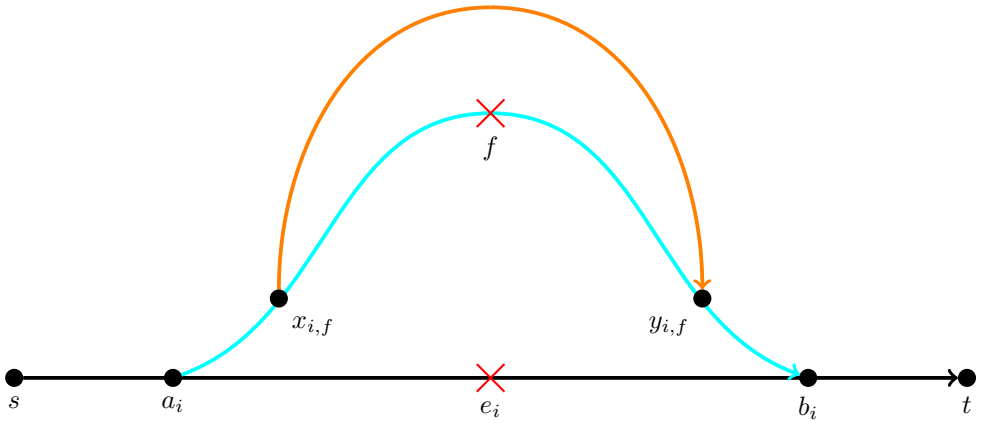


Figure 7 The sub-path $\rho_{i,f}[a_i, b_i]$ has length greater than L.

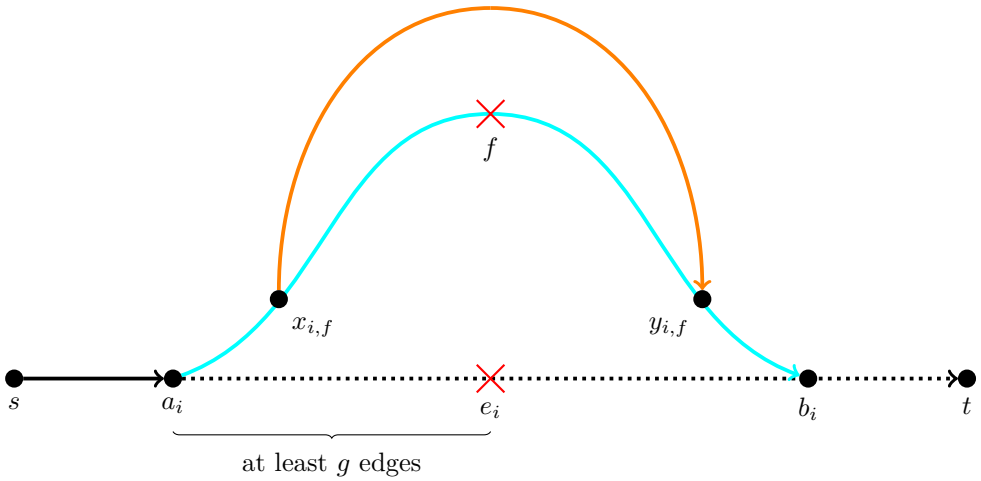

Figure 8 In this picture, $x_{i,f}, y_{i,f} \in V(\alpha_i)$ plus that $|\pi[a_i, u_i]| > g$.

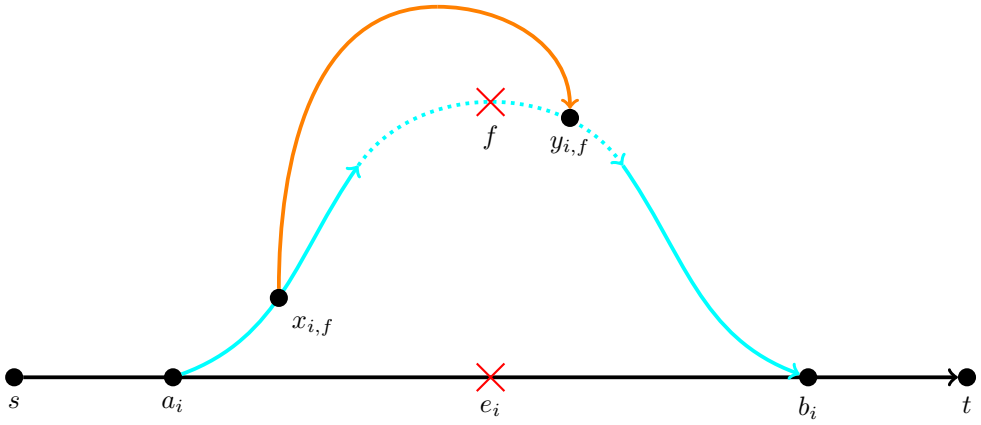

Figure 9 The dotted cyan path is β_l^i.

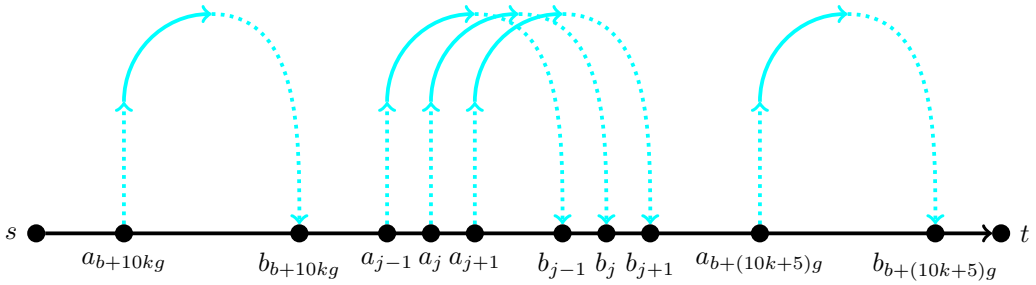

Figure 10 Graph X_l^{b+10kg} excludes all edges in $E(\pi) \cup \bigcup_{j=b+10kg, j\in I}^{b+(10k+5)g} E(\beta_l^j)$ which are drawn and black and cyan solid paths.

Main case: $|\pi[a_i, u_i]|, |\pi[u_{i+1}, b_i]| \leq g$, and $x_{i,f}, y_{i,f} \in V(\beta_l^i)$, and $|\alpha_i| < L$

Algorithm Main case.

Let $I \subseteq [L]$ be the set of all indices such that $|\pi[a_i, u_i]|, |\pi[u_{i+1}, b_i]| \leq g$ and $|\alpha_i| < L$. For each pair of indices $(p, q) \in [L/g] \times [L/g]$, define the set of sub-paths:

$$\mathcal{P}_{p,q} = \{\beta_l^i \mid (l, l_i - l + 1) = (p, q), i \in I\}$$

(1) Let $U \subseteq V$ be the uniformly random subset of size $\frac{10n \log n}{g}$. Then, for each pair of indices $p, q \in [L/g]$, define the graph:

$$G_{p,q} = G \setminus \left(E(\pi) \cup \bigcup_{\beta \in \mathcal{P}_{p,q}} E(\beta) \right)$$

(2) Then, for each vertex $u \in U$, compute single-source shortest paths to and from u in $G_{p,q}$. For any index $1 \leq l \leq \lceil L/g \rceil$, and for any offset $1 \leq b \leq 10g$, initialize two sets of vertices $A_{b,l}, B_{b,l} \leftarrow V$. Then, go over the sequence of all sub-paths $\beta_l^b, \beta_l^{b+10g}, \cdots, \beta_l^{b+10hg}$, where $h \leq \lceil \frac{L}{10g} \rceil$.

Next, for each sub-path β_l^{b+10kg}, define the following two graphs

$$X_l^{b+10kg} = G \setminus \left(E(\pi) \cup \bigcup_{j \in [b+10kg, b+(10k+5)g] \cap I} E(\beta_l^j) \right)$$

$$Y_l^{b+10kg} = G \setminus \left(E(\pi) \cup \bigcup_{j \in [b+(10k-5)g, b+10kg] \cap I} E(\beta_l^j) \right)$$

See Figure 10 for an illustration.

(a) Then, for each vertex $v \in V\left(\beta_l^{b+10kg}\right)$, perform a truncated Dijkstra at v in the induced subgraph $X_l^{b+10kg}[A_{b,l}]$ up to depth g. For each $z \in A_{b,l}$, record the distance value

$$\mu_X(v, z) \leftarrow \mathsf{dist}\left(v, z, X_l^{b+10kg}[A_{b,l}]\right)$$

if $\mathsf{dist}\left(v, z, X_l^{b+10kg}[A_{b,l}]\right) \leq g$.

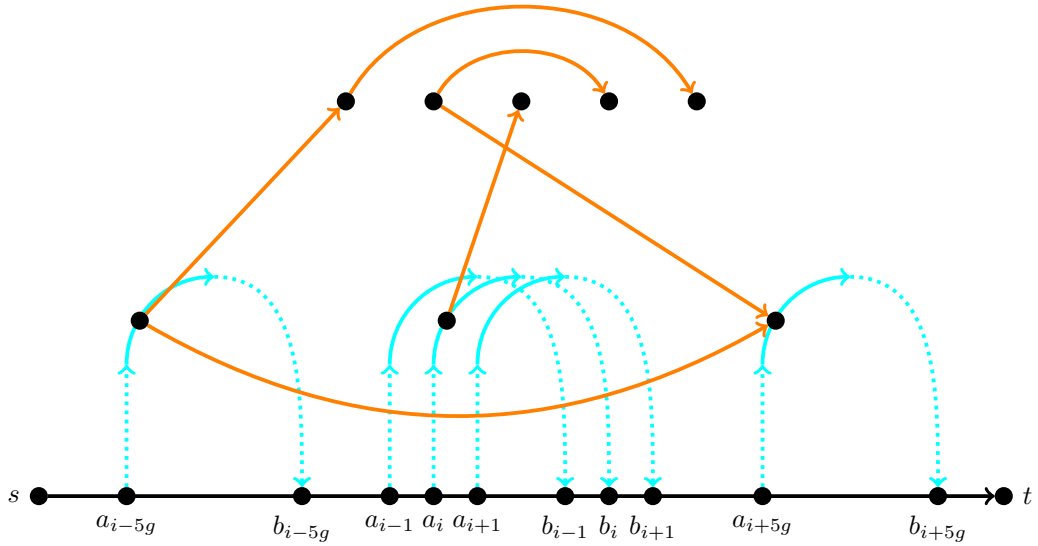

Figure 11 Vertices on the topmost are in U, and orange edges represent shortcut edges in H_l^i.

After we have visited all vertices $v \in V\left(\beta_l^{b+10kg}\right)$, let $P_{b,l}^k \subseteq A_{b,l}$ be the set of all vertices searched by truncated Dijkstra of any $v \in V\left(\beta_l^{b+10kg}\right)$. Then, prune the vertex set

$$A_{b,l} \leftarrow A_{b,l} \setminus P_{b,l}^k$$

(b) Symmetrically, for each vertex $v \in V\left(\beta_l^{b+10kg}\right)$, perform a truncated Dijkstra at v in the induced subgraph $Y_l^{b+10kg}[B_{b,l}]$ up to depth g. For each $z \in B_{b,l}$, record the distance value

$$\mu_Y(v,z) \leftarrow \mathsf{dist}\left(v, z, Y_l^{b+10kg}[B_{b,l}]\right)$$

if $\mathsf{dist}\left(v, z, Y_l^{b+10kg}[B_{b,l}]\right) \leq g$.

After we have visited all vertices $v \in V\left(\beta_l^{b+10kg}\right)$, let $Q_{b,l}^k \subseteq B_{b,l}$ be the set of all vertices searched by truncated Dijkstra of any $v \in V\left(\beta_l^{b+10kg}\right)$. Then, prune the vertex set

$$B_{b,l} \leftarrow B_{b,l} \setminus Q_{b,l}^k$$

(3) For any index $i \in I$ and index $1 \leq l \leq l_i/g$, let us build a shortcut digraph H_l^i with edge weight function ω in the following manner. See Figure 11 for an illustration.

- **Vertices.** Add all vertices in sub-paths $V(\beta_l^j), \forall j \in [i-5g, i+5g] \cap I$, as well as all pivot vertices in U to H_l^i.
- **Edges.** First, add to $E(H_l^i)$ all the sub-paths:

$$\left(\bigcup_{j \in [i-5g, i+5g] \cap I} E\left(\beta_l^j\right)\right) \setminus E\left(\beta_l^i\right)$$

Then, add the following three types of weighted edges.

(a) For any $u \in U$ and any vertex $v \in V(H_l^i)$, add an edge (u, v) with edge weight:

$$\omega(u, v) = \mathsf{dist}(u, v, G_{l,l_i-l+1})$$

and edge (v, u) with edge weight:

$$\omega(v, u) = \mathsf{dist}(v, u, G_{l,l_i-l+1})$$

(b) For any pair of vertices $u, v \in V(H_l^i)$ where $u \in V(\beta_l^j), j \in [i-5g, i]$, add an edge (u, v), and assign a weight:

$$\omega(u, v) = \mu_X(u, v)$$

If $\mu_X(u, v)$ was not assigned in Step (2), then it is infinity by default.

(c) For any pair of vertices $u, v \in V(H_l^i)$ where $u \in V(\beta_l^j), j \in [i, i+5g]$, add an edge (u, v), and assign a weight:

$$\omega(u, v) = \mu_Y(u, v)$$

If $\mu_Y(u, v)$ was not assigned in Step (2), then it is infinity by default.

After that, for each vertex $z \in V\left(\beta_l^i\right)$, apply single-source shortest path on z in H_l^i. In this way, for every pair of vertices $x, y \in V\left(\beta_l^i\right)$, we have computed a distance $\mathsf{dist}\left(x, y, H_l^i\right)$.

Finally, for every edge $f \in E\left(\beta_l^i\right)$, update the estimation $\mathsf{est}(s, t, G \setminus \{e_i, f\})$ with:

$$\min_{x \in V(\beta_l^i[*,f)), y \in V(\beta_l^i(f,*])} \left\{\mathsf{dist}(s, x, G \setminus \{e_i\}) + \mathsf{dist}\left(x, y, H_l^i\right) + \mathsf{dist}(y, t, G \setminus \{e_i\})\right\}$$

Runtime. The runtime of Step (1) is bounded by $\tilde{O}(|U| \cdot mL^2/g^2) = \tilde{O}(\frac{mnL^2}{g^3})$. As for the runtime of Step (2), consider any offset $1 \le b \le 10g$. We argue that the Dijkstra procedure for all vertices on sub-paths $\beta_l^b, \beta_l^{b+10g}, \cdots, \beta_l^{b+10hg}$ has runtime at most $O(mg)$; this is because every vertex in V is visited by at most $O(g)$ instances of Dijkstra rooted at vertices from some sub-paths β_l^{b+10kg}. Therefore, the overall runtime of Step (2) is bounded by $O(mLg)$ summing over all $1 \le b \le 10g$ and $1 \le l \le L/g$.

Finally, let us estimate the runtime of Step (3). For each index $i \in I$, there are at most L/g different sub-paths β_l^i as $|\alpha_i| \le L$. By definition, the shortcut digraph H_i contains at most $O(g^2 + \frac{n \log n}{g})$ vertices, and so the number of edges within is bounded by $\tilde{O}(g^4 + \frac{n^2}{g^2})$, and hence the runtime of multi-source shortest paths computation for all vertices in $V(\beta_l^i)$ in H_l^i is $\tilde{O}(g^5 + \frac{n^2}{g})$. Then, for each $f \in E(\beta_l^i)$, the time of calculating the formula

$$\min_{x \in V(\beta_l^i[*,f)), y \in V(\beta_l^i(f,*])} \{\mathsf{dist}(s, x, G \setminus \{e_i\}) + \mathsf{dist}(x, y, H_i) + \mathsf{dist}(y, t, G \setminus \{e_i\})\}$$

is bounded by $O(g^2)$. Summing over all i, l and $f \in E(\beta_l^i)$, the runtime of this part is bounded by $\tilde{O}(L^2 g^4 + \frac{n^2 L^2}{g^2})$.

Taking a summation, the overall runtime for this case is at most:

$$\tilde{O}\left(mnL^2/g^3 + mLg + L^2 g^4 + n^2 L^2/g^2\right)$$

Correctness. To prove that our algorithm computes the correct value for $|\rho_{i,f}|$, it suffices to prove that $\mathsf{dist}\left(x_{i,f}, y_{i,f}, H_l^i\right) = |\rho_{i,f}[x_{i,f}, y_{i,f}]|$. First we argue that $\mathsf{dist}\left(x_{i,f}, y_{i,f}, H_l^i\right) \geq |\rho_{i,f}[x_{i,f}, y_{i,f}]|$ due to the following reason.

▷ Claim 14. Any weighted edge (u, v) in H_l^i corresponds to a path from u to v in G that does not contain any edge in $E(\pi) \cup E(\beta_l^i)$.

Proof. If the weighted edge (u, v) was defined on Step (3)(a), then it corresponds to a shortest path in G_{l,l_i-l+1} which excludes all edges in $E(\pi) \cup E(\beta_l^i)$.

If the weighted edge (u, v) was defined on Step (3)(b), suppose $u \in V(\beta_l^j)$ where $j \in [i-5g, i]$, then by definition of $\omega(u, v) = \mu_X(u, v)$, which is equal to the length of a path in graph X_l^j which excludes all edges in $E(\pi) \cup E(\beta_l^i)$.

Symmetrically, if the weighted edge (u, v) was defined on Step (3)(c), suppose $u \in V(\beta_l^j)$ where $j \in [i, i+5g]$, then by definition of $\omega(u, v) = \mu_Y(u, v)$, it is equal to the length of a path in graph Y_l^j which excludes all edges in $E(\pi) \cup E(\beta_l^i)$. ◁

For the rest, let us prove that $\mathsf{dist}\left(x_{i,f}, y_{i,f}, H_l^i\right) \leq |\rho_{i,f}[x_{i,f}, y_{i,f}]|$. To do this, we will find a path in H_l^i from $x_{i,f}$ to $y_{i,f}$ with weighted length at most $|\rho_{i,f}[x_{i,f}, y_{i,f}]|$.

▷ Claim 15. $\rho_{i,f}[x_{i,f}, y_{i,f}]$ does not contain any vertices in the following vertex subset:

$$\bigcup_{j=0}^{i-5g-1} V\left(\beta_l^j\right) \cup \bigcup_{j=i+5g+1}^{L} V\left(\beta_{l_j-l_i+l}^j\right)$$

Proof. Suppose otherwise that the sub-path $\rho_{i,f}[x_{i,f}, y_{i,f}]$ contains a vertex $v \in \bigcup_{j=0}^{i-5g-1} V(\beta_l^j) \cup \bigcup_{j=i+5g+1}^{L} V(\beta_{l_j-l_i+l}^j)$. Let us assume that $v \in V(\beta_l^j)$ for some index $0 \leq j < i-5g$; if $v \in V(\beta_{l_j-l_i+l}^j)$ for some $j > i+5g$, the proof will be similar.

By the assumption that $i \in I$, we know that $|\pi[a_i, u_i]| \leq g$. Since $j < i-5g$, we know that vertex u_j lies between s, a_i, and consequently $|\pi[s, a_j]| \leq |\pi[s, u_j]| < |\pi[s, a_i]| - 4g$.

Consider the path $\pi[s, a_j] \circ \alpha_j[a_j, v]$. We first argue that this path does not contain edges from $\{e_i, f\}$. Clearly, $\pi[s, a_j] \circ \alpha_j[a_j, v]$ does not contain the edge e_i, since a_j lies between s and u_i, and $E(\alpha_j[a_j, v]) \cap E(\pi) = \emptyset$. As for the position of f, if $f \in E(\alpha_j[a_j, v])$, then there must be a vertex $z \in V(\alpha_j[a_j, v]) \cap V(\beta_l^i)$. Then $\pi[s, a_j] \circ \alpha_j[a_j, z] \circ \alpha_i[z, b_i] \circ \alpha_i[b_i, t]$ is a replacement path that avoids edge e_i, with length at most:

$$\begin{aligned}
&|\pi[s, a_j]| + |\alpha_j[a_j, z]| + |\alpha_i[z, b_i]| + |\alpha_i[b_i, t]| \\
&< (|\pi[s, a_i]| - 4g) + |\alpha_j[a_j, v]| + |\alpha_i[z, b_i]| + |\alpha_i[b_i, t]| \\
&\leq (|\pi[s, a_i]| - 4g) + l \cdot g + |\alpha_i[z, b_i]| + |\alpha_i[b_i, t]| \\
&\leq (|\pi[s, a_i]| - 4g) + (|\alpha_i[a_i, z]| + g) + |\alpha_i[z, b_i]| + |\alpha_i[b_i, t]| \\
&\leq |\pi[s, a_i] + |\alpha_i[a_i, z]| + |\alpha_i[z, b_i]| + |\alpha_i[b_i, t]| - 3g = |\pi[s, a_i] \circ \alpha_i \circ \pi[b_i, t]| - 3g
\end{aligned}$$

which is a contradiction that $\pi[s, a_i] \circ \alpha_i \circ \pi[b_i, t]$ is a shortest replacement path avoiding e_i.

Next, we argue that $|\pi[s, a_j] \circ \alpha_j[a_j, v]| < |\rho_{i,f}[s, x_{i,f}]| < |\rho_{i,f}[s, v]|$. In fact, by $|\pi[s, a_j]| < |\pi[s, a_i]| - 4g$, we have:

$$\begin{aligned}
&|\pi[s, a_j]| + |\alpha_j[a_j, v]| < (|\pi[s, a_i]| - 4g) + l \cdot g \\
&\leq (|\pi[s, a_i]| - 4g) + (|\alpha_i[a_i, x_{i,f}]| + g) = |\rho_{i,f}[s, x_{i,f}]| - 3g
\end{aligned}$$

As we have proved, $\pi[s, a_j] \circ \alpha_j[a_j, v]$ is a path avoiding $\{e_i, f\}$ of length less than $|\rho_{i,f}[s, v]|$. So, if we replace the prefix $\rho_{i,f}[s, v]$ with $\pi[s, a_j] \circ \alpha_j[a_j, v]$ and consider a new path:

$$\rho' = \pi[s, a_j] \circ \alpha_j[a_j, v] \circ \rho_{i,f}[v, t]$$

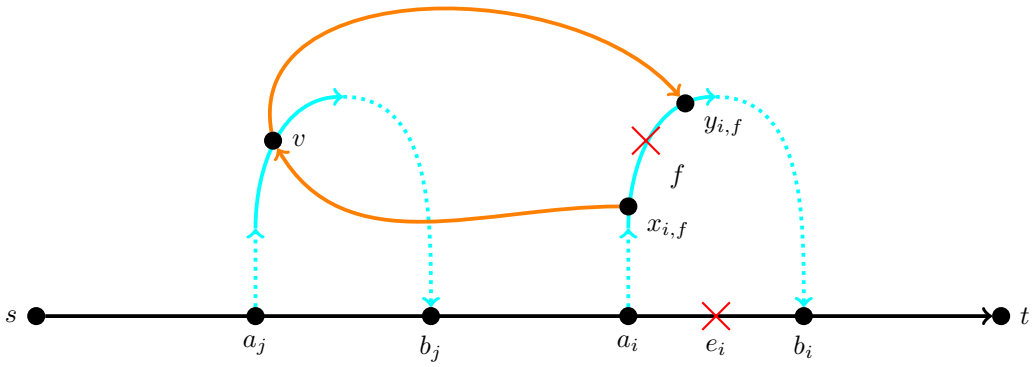

Figure 12 The sub-path $\rho_{i,f}[x_{i,f}, y_{i,f}]$ is drawn as the orange curve. If $\rho_{i,f}[x_{i,f}, y_{i,f}]$ contains a vertex $v \in V\left(\beta_l^j\right)$, then the alternate path $\pi[s, a_j] \circ \alpha_j[*, v] \circ \rho_{i,f}[v, y_{i,f}] \circ \alpha_i[y_{i,f}, b_i] \circ \pi[b_i, t]$ be a shorter replacement path than $\rho_{i,f}$ avoiding $\{e_i, f\}$.

then we have a new replacement path ρ' avoiding $\{e_i, f\}$ from s to t with a strictly better distance, a contradiction. See Figure 12 for an illustration.

◁

Decompose the path $\rho_{i,f}[x_{i,f}, y_{i,f}]$ into minimal sub-paths whose endpoints are belonging to $V(H_l^i)$; this is achievable because both $x_{i,f}, y_{i,f} \in V(H_l^i)$. To prove the upper bound:

$$\mathsf{dist}(x_{i,f}, y_{i,f}, H_l^i) \leq |\rho_{i,f}[x_{i,f}, y_{i,f}]|$$

it suffices to show that for any two consecutive vertices $u, v \in V(H_l^i)$ on path $\rho_{i,f}[x_{i,f}, y_{i,f}]$, we have $\omega(u, v) \leq |\rho_{i,f}[u, v]|$. Consider several cases below.

- One of u, v belongs to the pivot set U.
  Without loss of generality, assume that $u \in U$. It suffices to show that the shortest path from u to v in graph G_{l,l_i-l+1} is has the same length as $\rho_{i,f}[u, v]$.
  Since v is the next vertex in $V(H_l^i)$ after u on the path $\rho_{i,f}$, the sub-path $\rho_{i,f}[u, v]$ does not contain any vertices from $V(H_l^i)$ except for its endpoints; in other words, $\rho_{i,f}[u, v]$ does not contain vertices from $U \cup \bigcup_{j=i-5g}^{i+5g} V(\beta_l^j)$. Additionally, according to Claim 15, $\rho_{i,f}[u, v]$ does not contain (internally) any vertices in

$$\bigcup_{j=0}^{i-5g-1} V\left(\beta_l^j\right) \cup \bigcup_{j=i+5g+1}^{L} V\left(\beta_{l_j-l_i+l}^j\right)$$

  Therefore, $\rho_{i,f}[u, v]$ does not contain (internally) any vertices from the set:

$$U \cup \bigcup_{j \in [i-5g, i+5g] \cap I} V\left(\beta_l^j\right) \cup \bigcup_{j=0}^{i-5g-1} V\left(\beta_l^j\right) \cup \bigcup_{j=i+5g+1}^{L} V\left(\beta_{l_j-l_i+l}^j\right) \supseteq U \cup \bigcup_{\beta \in \mathcal{P}_{l,l_i-l+1}} V(\beta)$$

  By definition of graph G_{l,l_i-l+1}, we know that $\mathsf{dist}(u, v, G_{l,l_i-l+1}) \leq |\rho_{i,f}[u, v]|$.
- Both of u, v are not in U.
  Assume that $u \in V(\beta_l^c)$ for some $c \in [i - 5g, i + 5g]$, and $v \in V(\beta_l^d)$ for some $d \in [i - 5g, i + 5g]$. Without loss of generality, assume that $c \leq i$; if $c \geq i$, a symmetric argument would work.

Since v is the next vertex in $V(H_l^i)$ after u on the path $\rho_{i,f}$ and that U is a uniformly random vertex set of size $\frac{10n\log n}{g}$, with high probability over the randomness of U, we must have $|\rho_{i,f}[u,v]| \leq g$.

Similar to the previous case, we know that $\rho_{i,f}[u,v]$ does not contain (internally) vertices from $\bigcup_{j=i-5g}^{i+5g} V\left(\beta_l^j\right)$. Therefore, by definition of X_l^c, we know that $\rho_{i,f}[u,v] \subseteq X_l^c$; namely, the sub-path $\rho_{i,f}[u,v]$ belongs to graph X_l^c. Therefore, to prove that $\omega(u,v) = \mu_X(u,v) \leq |\rho_{i,f}[u,v]|$, it suffices to show that the truncated Dijkstra procedure correctly computes the value $\mu_X(u,v) = \mathsf{dist}(u,v,X_l^c)$.

Decompose the integer $c = b + 10kg$, where $1 \leq b \leq 10g$, $k \geq 0$. To prove that the truncated Dijkstra procedure correctly computes the value $\mu_X(u,v) = \mathsf{dist}(u,v,X_l^c)$, it suffices to show that the vertex set $A_{b,l}$ contains all vertices on $\rho_{i,f}[u,v]$ when u is performing a truncated Dijkstra in the induced subgraph $X_l^c[A_{b,l}]$; in other words, we need to show that any vertex on $\rho_{i,f}[u,v]$ has not been pruned from $A_{b,l}$ by truncated Dijkstraes from vertices on previous sub-paths $\beta_l^b, \beta_l^{b+10g}, \cdots, \beta_l^{b+10(k-1)g}$.

Assume otherwise there is a vertex $z \in V(\rho_{i,f}[u,v])$ which was also visited by the truncated Dijkstra of some vertices $w \in V(\beta_l^{b+10jg})$ for some $j < k$. As all Dijkstra searches are truncated up to depth g, we know that there is a path γ from w to z in X_l^{b+10jg} of length at most g. Consider the path

$$\theta = \pi[s, a_{b+10jg}] \circ \alpha_{b+10jg}[*, w] \circ \gamma \circ \rho_{i,f}[z,v] \circ \alpha_d[v, b_d] \circ \pi[b_d, t]$$

and claim two properties of it.

▷ Claim 16. θ is a path from s to t that avoids the edge e_d.

Proof. It is clear that path θ departs from π at vertex a_{b+10jg} and converges with π at vertex b_d. So it suffices to show that a_{b+10jg} lies between s and vertex u_d. This is straightforward since a_{b+10jg} lies on path $\pi[s, u_{b+10jg}]$ which is strictly a prefix of $\pi[s,u_d]$, as $d \geq i - 5g \geq b + (10k-5)g > b + 10jg$. ◁

To reach a contradiction, we show that $|\theta|$ is a strictly better replacement path from s to t that avoids e_d than path $\pi[s,a_d] \circ \alpha_d \circ \pi[b_d,t]$. In fact, on the one hand, since $d \in I$, we know that $|\pi[a_d, u_d]| \leq g$. Therefore,

$$|\pi[s, a_{b+10jg}]| \leq |\pi[s, u_{b+10jg}]| = b + 10jg \leq 10(k-1)g \leq i - 10g \leq d - 5g \leq |\pi[s,a_d]| - 4g$$

On the other hand, since $v \in V(\beta_l^d)$ and $w \in V(\beta_l^{b+10jg})$, we know that

$$|\alpha_d[*,v]| \geq (l-1)g + 1 > |\alpha_{b+10jg}[*,w]| - g$$

Finally, as $|\gamma|, |\rho_{i,f}[z,v]| \leq g$, we have:

$$\begin{aligned}
|\theta| &\leq (|\pi[s,a_d]| - 4g) + (|\alpha_d[*,v]| + g) + |\gamma| + |\rho_{i,f}[z,v]| + |\alpha_d[v,b_d]| + |\pi[b_d,t]| \\
&\leq |\pi[s,a_d]| + |\alpha_d[*,v]| + |\alpha_d[v,b_d]| + |\pi[b_d,t]| - g \\
&= |\pi[s,a_d] \circ \alpha_d \circ \pi[b_d,t]| - g
\end{aligned}$$

which contradicts the fact that $\pi[s,a_d] \circ \alpha_d \circ \pi[b_d,t]$ is the shortest replacement path avoiding e_d. See Figure 13 for an illustration.

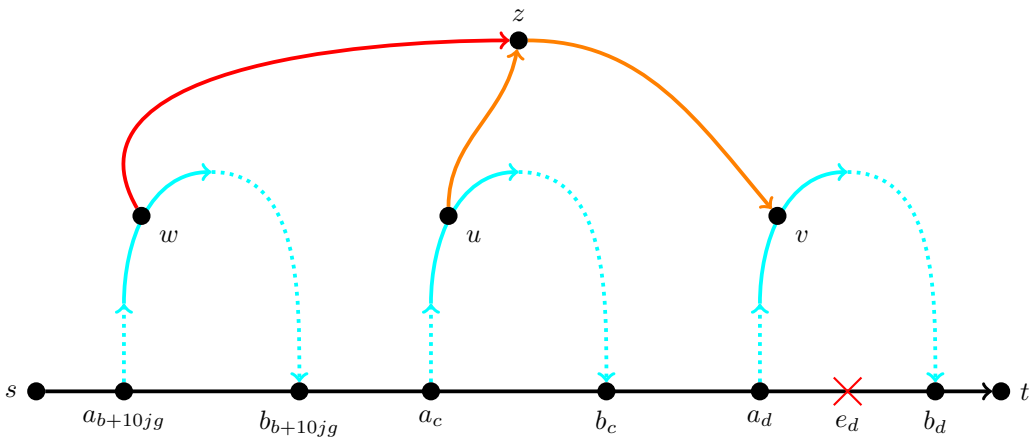

Figure 13 If $\mu_X(u,v)$ does not capture the orange path $\rho_{i,f}[u,v]$, then a previous Dijkstra search from vertex w must have intercepted $\rho_{i,f}[u,v]$ at a vertex z through a path γ drawn as the red curve. In this case, $\alpha_{b+10jg}[*,w] \circ \gamma \circ \rho_{i,f}[z,v] \circ \alpha_d[v,b_d]$ would be a better detour than α_d for avoiding e_d.

Proof of Lemma 13

Summarizing the total runtime of all five cases, the overall runtime is bounded by as following:

$$\tilde{O}\left(\frac{mn^{1.5}+n^3}{L} + mn^{1/2}L/g + n^2L/g + mL^2/g + mnL^2/g^3 + mLg + L^2g^4 + n^2L^2/g^2\right)$$

4 One failure on a long st-path

In this section, we study the case where only one edge failure lies on the shortest path, plus that the input graph is dense and $\mathsf{dist}(s,t,G)$ could be as large as $O(n)$. Let $G=(V,E)$ be a digraph with n vertices, and consider a pair of vertices s,t as well as an st-shortest path $\pi = \langle s = u_0, u_1, u_2, \cdots, u_{|\pi|} = t\rangle$. The task is to compute for any pairs of edges f_1, f_2, the value of $\mathsf{dist}(s,t,G\setminus\{f_1,f_2\})$ where $f_1 \in E(\pi), f_2 \notin E(\pi)$. The following lemma is proved in the full version.

▶ **Lemma 17.** *All values of* $\mathsf{dist}(s,t,G\setminus\{f_1,f_2\})$ *can be computed with high probability in time* $\tilde{O}\left(n^{3-1/18}\right)$ *when* $f_1 \in E(\pi)$ *while* $f_2 \notin E(\pi)$.

5 Both failures on the st-path

In this section, we study the case where both edge failures f_1, f_2 are lying the shortest path. Let $G=(V,E)$ be a digraph with n vertices, and consider a pair of vertices s,t as well as an st-shortest path $\pi = \langle s = u_0, u_1, u_2, \cdots, u_{|\pi|} = t\rangle$. For convenience, define $H = G\setminus E(\pi)$. The task is to compute for any pairs of edges $f_1, f_2 \in V(\pi)$, the value of $\mathsf{dist}(s,t,G\setminus\{f_1,f_2\})$. The following lemma is proved in the full version.

▶ **Lemma 18.** *All values of* $\mathsf{dist}(s,t,G\setminus\{f_1,f_2\})$ *can be computed in time* $\tilde{O}(n^{3-1/7})$ *when both edges* f_1, f_2 *are on* π.

Proof of Theorem 1. This is a direct combination of Lemma 17 and Lemma 18. ◀

Path-Reporting Distance Oracles with Logarithmic Stretch and Linear Size

Abstract

Given an undirected graph $G = (V, E, \mathbf{w})$ on n vertices with positive edge weights, a distance oracle is a space-efficient data structure that answers pairwise distance queries in fast runtime. The quality of a distance oracle is measured by three parameters: space, query time, and stretch. In a landmark paper by [Thorup and Zwick, 2001], they showed that for any integer parameter $k \geq 1$, there exists a distance oracle with size $O(kn^{1+1/k})$, $O(k)$ query time, and $(2k-1)$-stretch error on the approximate distances. After that, there has been a line of subsequent improvements which culminated in the optimal trade-off of $O(n^{1+1/k})$ space, $O(1)$ query time, and $(2k-1)$-stretch [Chechik, 2015].

However, these line of constructions did not require that the distance oracle is capable of printing an actual path besides an approximate distance estimate, and there has been a performance gap between path-reporting distance oracles and ones that are not path-reporting. It is known that the earliest construction by [Thorup and Zwick, 2001] is path-reporting, but the parameters are worse by a factor of k. In a later construction by [Wulff-Nilsen, 2013], the query time was improved from $O(k)$ to $O(\log k)$. Better trade-offs were discovered in [Elkin and Pettie, 2015] where the authors broke the $O(kn^{1+1/k})$ space barrier and achieved $O(n^{1+1/k} \log k)$ space with $O(\log k)$ query time, but their stretch was blown up to a polynomial $O(k^{\log_{4/3} 7})$; they also gave an alternative choice of $O(n^{1+1/k})$ space which is optimal, and $O(k)$-stretch which is also optimal up to a constant factor, but their query time rose exponentially to $O(n^{\epsilon})$. In a recent work [Elkin and Shabat, 2023], the authors obtained significant improvements of $O(n^{1+1/k} \log k)$ space, $O(k)$-stretch, and $O(\log \log k)$ query time, or $O(n^{1+1/k})$ space, $O(k \log k)$-stretch, and $O(\log \log k)$ query time.

All the above constructions of path-reporting distance oracles share a common barrier; that is, they could not achieve optimal space $O(n^{1+1/k})$ and stretch $O(k)$ simultaneously within logarithmic query time; for example, in the natural regime where $k = \lceil \log n \rceil$, previous distance oracles had to pay an extra factor of $\log \log n$ either in the space or stretch. As our result, we bypass this barrier by a new construction of path-reporting distance oracles with $O(n^{1+1/k})$ space and $O(k)$-stretch and $O(\log \log k)$ query time.

1 Introduction

Given an undirected graph $G = (V, E, \mathbf{w})$ on n vertices with positive edge weights , distance oracles are space-efficient data structures that process distance queries with approximate answers in fast runtime. More specifically, given any pair of vertices $s, t \in V$, the distance oracle needs to return a distance estimate $\mathbf{est}(s, t)$ in the range $[\mathbf{dist}_G(s, t), \beta \cdot \mathbf{dist}_G(s, t)]$,

where β is an upper bound on the stretch error. Intuitively, when the distance oracle has smaller size, the stretch error grows larger, and the general goal is to understand the optimal trade-off between space and stretch with a fast query efficiency.

In a pioneering work by Thorup and Zwick [10], they constructed distance oracles for any integer parameter $k \geq 1$ with $O(kn^{1+1/k})$ space, $(2k-1)$-stretch and $O(k)$ query time. This balance between size and stretch is optimal when $k \leq \frac{\log n}{\log \log n}$ because the famous Erdős girth conjecture implies an $\Omega(n^{1+1/k})$ space lower bound for any distance oracle with $(2k-1)$-stretch, and it was left open in [10] if anything better can be achieved for larger choices of parameter k. In a subsequent work by Mendel and Naor [9], using Ramsey partitions and tree embeddings, the authors diverged from the techniques of [10] and devised a new distance oracle with optimal space $O(n^{1+1/k})$ and $O(1)$ query time, but its stretch becomes $O(k)$ which is worse than the optimal $2k-1$ by a constant factor. Later on, still following the old construction of [10], Wulff-Nilsen [11] improved the query time from $O(k)$ to $O(\log k)$ while retaining $O(kn^{1+1/k})$ space and $(2k-1)$-stretch; in the same paper, he could also obtain constant query time $O(1/\epsilon)$ by allowing a slightly larger stretch of $(2+\epsilon)k$. This line of works culminated in an optimal construction of distance oracles that achieve $O(n^{1+1/k})$ space, $(2k-1)$-stretch and $O(1)$ query time simultaneously [5, 4].

However, these works mentioned above did not require that the distance oracles should be capable of printing an actual path between the queried vertex pair that realizes the approximate distance estimate; distance oracles with this extra function are called *path-reporting* distance oracles. More specifically, in this setting, the query efficiency consists of two parts: the query time which is the amount of time to compute a distance estimate $\mathbf{est}(s,t)$, and after that we need to report a path π between the vertex pair with total weight $\mathbf{w}(\pi) \leq \mathbf{est}(s,t)$ in time $O(|\pi|)$.

So far there has been a performance gap between path-reporting distance oracles and ones that do not support reporting paths. It was known that the earliest construction of Thorup and Zwick [10] is path-reporting, but some later improvements including [9, 11, 4, 5] are not, except one by [11] with $O(kn^{1+1/k})$ space, $(2k-1)$-stretch and $O(\log k)$ query time. In a subsequent work [7], the authors achieved optimal $O(n^{1+1/k})$ space by tolerating a constant blowup in the stretch $O\left(k \cdot (1/\epsilon)^{\log_{4/3} 7}\right)$ and a sublinear query time $O(n^{\epsilon})$, or alternatively, a sub-optimal space complexity of $O(n^{1+1/k} \log k)$ and faster query time $O(\log k)$, but a polynomial blowup in the stretch $O\left(k^{\log_{4/3} 7}\right)$.

In a very recent work [8], the authors devised new constructions of path-reporting distance oracles with multiple choices of trade-offs which are significant improvements over prior works: (1) with space $O\left(n^{1+1/k} \cdot \left\lceil \frac{k \log \log n \cdot \log^{(3)} n}{\log n} \right\rceil\right)$, they could achieve $(4+\epsilon)k$-stretch and $O(\log k)$ query time, and (2) with space $O\left(n^{1+1/k} \cdot \left\lceil \frac{k \log \log n}{\log n} \right\rceil\right)$, they could achieve $(24+\epsilon)k$-stretch and $O(\log \log k)$ time, and (3) with optimal space $O(n^{1+1/k})$ they could achieve $O(k \log k)$-stretch and $O(\log \log k)$ query time; here we have not listed all the trade-offs, but only the representative ones in [8].

One common quantitative barrier of all the above constructions of path-reporting distance oracles is that they could not achieve optimal space $O(n^{1+1/k})$ and linear stretch $O(k)$ simultaneously using a fast query time. For example, when k gets close to $\log n$, the trade-offs in [8] needs to pay $O(\log \log n)$ factor either in the space or in the stretch. As for the results from [7], although could achieve $O(n^{1+1/k})$ space and $O\left(k \cdot (1/\epsilon)^{\log_{4/3} 7}\right)$-stretch at the same time, their query time blows up exponentially to $O(n^{\epsilon})$; besides, their stretch upper bound has a large constant coefficient of $O\left((1/\epsilon)^{\log_{4/3} 7}\right)$ in front of k. This leads to the following natural question even for $k = \lceil \log n \rceil$.

▶ **Question 1.** *How to design a path-reporting distance with $O(n)$ space and $O(\log n)$-stretch that supports $O(\log n)$ query time?*

As our result, we give a positive answer to the above question, which is formalized in the statement below.

▶ **Theorem 2.** *Given an undirected graph $G = (V, E, \mathbf{w})$ with positive edge weights on n vertices, for any integer $k \geq 1$, there is a path-reporting distance oracle with $12k$-stretch, $O(n^{1+1/k})$ space, and $O(\log \log k)$ query time; furthermore, an approximate shortest path π can be retrieved in time $O(\log \log k + |\pi|)$ time.*

1.1 Technical overview

To support the function of path-reporting, prior works adopted different strategies: in [7] the authors were heavily exploiting the power of distance preservers [6], and in [8] the authors were utilizing the connection to hopsets. In our construction, we employed another different strategy of using *tree covers* which is adapted from the notion of cluster covers in the design of the optimal but non-path-reporting distance oracles [5].

The approach of [5]

Similar to [10], let us take a hierarchy of random sets $V = A_0 \supseteq A_1 \supseteq A_2 \supseteq \cdots \supseteq A_{k-1} \supseteq A_k$, where A_{i+1} includes each vertex in A_i with probability $n^{-1/k}$ independently. For any A_i, a *cluster cover* is a collection of (not necessarily disjoint) subsets $\mathcal{C}^i$ with the following properties.

- **Weak radius.** Each vertex $v \in V$ is assigned to a unique cluster $\mathcal{C}^i_{\mathsf{home}}(v) \in \mathcal{C}^i$ which contains v. Plus, $\mathcal{C}^i_{\mathsf{home}}(v)$ has weak radius of roughly $\mathbf{dist}_G(v, A_i)$.
- **Packing.** The total size of clusters in $\mathcal{C}$ is bounded by $O(n^{1+1/k})$.
- **Covering.** For any pair of vertices s, t, if $\mathbf{dist}_G(s,t) \leq \frac{1}{i} \cdot \mathbf{dist}_G(s, A_i)$, then $\mathcal{C}^i_{\mathsf{home}}(s)$ contains both s, t.

The idea of using cluster covers to compute approximate distances is to build cluster covers $\mathcal{C}^{(i)}$ for a constant number of indices $i \in \{k/2, k/4, k/8, \ldots, k/128\}$ (assuming k is an integer multiple of 128), and check if $t \in \mathcal{C}^i_{\mathsf{home}}(s)$ for each such i. If we can locate two consecutive indices $i, i/2$ such that $t \in \mathcal{C}^i_{\mathsf{home}}(s)$ and $t \notin \mathcal{C}^{i/2}_{\mathsf{home}}(s)$, then we will estimate $\mathbf{dist}_G(s,t)$ through the weak radius of $\mathcal{C}^i_{\mathsf{home}}(s)$. The reason why this would be a good estimate is because $t \notin \mathcal{C}^{i/2}_{\mathsf{home}}(s)$ and so $\mathbf{dist}_G(s,t) > \frac{2}{i} \cdot \mathbf{dist}_G(s, A_{i/2})$, and therefore $\mathbf{dist}_G(s,t)$ cannot be too much smaller than the weak radius of $\mathcal{C}^i_{\mathsf{home}}(s)$ when $\mathbf{dist}_G(s, A_{i/2})$ and $\mathbf{dist}_G(s, A_i)$ are not too different; if $\mathbf{dist}_G(s, A_{i/2})$ is also way smaller than $\mathbf{dist}_G(s, A_i)$, we will use some other shortcuts between pivots in $A_{i/2}$ to find a better distance estimate.

If we cannot locate any pair of consecutive indices $i, i/2$ such that $t \in \mathcal{C}^i_{\mathsf{home}}(s)$ and $t \notin \mathcal{C}^{i/2}_{\mathsf{home}}(s)$, then this means that both s, t are actually a small cluster $\mathcal{C}^{k/128}_{\mathsf{home}}(s)$. In this case, we should expect that the same distance oracle construction by Thorup and Zwick [10] to give a much better distance estimate with roughly $k/64$-stretch. To take advantage of this slack, we can apply the construction by Mendel and Naor [9] to quickly calculate an estimation.

Tree covers

One of the reasons why the distance oracle of [5] is not path-reporting is that cluster covers only have an upper bound on weak radius rather than strong radius. Therefore, for the cause of reporting paths, we need to ensure that each cluster has a spanning tree whose radius is small; in other words, we are looking for a tree cover $\mathcal{C}^i$ with the following revised properties.

- **Strong radius.** Each vertex $v \in V$ is assigned to a unique cluster $\mathcal{C}^i_{\mathsf{home}}(v) \in \mathcal{C}^i$ which contains v. Plus, $\mathcal{C}^i_{\mathsf{home}}(v)$ has a spanning tree of radius at most $\mathbf{dist}_G(v, A_i)$.

To find such a tree cover, let us start with the basic approach of ball-carving (which is similar to the approach for cluster covers [5]): starting with $W \leftarrow V$, while W is not empty, pick an arbitrary vertex $v \in W$ and grow a tree T in graph $G[W]$ to a radius $r \cdot \rho = \frac{r}{i} \cdot \mathbf{dist}_G(v, A_i)$ such that:

$$\left|\mathbf{Ball}_{G[W]}(v, (r-1)\rho)\right| \geq n^{-1/k} \left|\mathbf{Ball}_{G[W]}(v, r\rho)\right|$$

Then, we add this tree T to $\mathcal{C}^i$ and remove all vertices in $\mathbf{Ball}_{G[W]}(v, (r-1)\rho)$ from W; for those vertices we have just removed, assign their home trees to be T. By doing this we can guarantee the strong radius and the packing property. However, this could damage the covering property. Imagine that for some pair of vertices s, t which are close, some vertices on the shortest path between s, t were removed after adding a spanning tree T to $\mathcal{C}^i$, then the home tree of s might not be able to reach t. To fix this issue, the idea is to assign s to this earlier tree T which might not have removed s at the time it was created.

Graph contraction

Another obstacle of path-reporting is that the construction of Chechik [5] incorporates the construction of Mendel and Naor [9]. To avoid using the distance oracle by Mendel and Naor, we could continue to apply tree covers for smaller indices $i < k/128$, but this would raise the space complexity from $O(n^{1+1/k})$ to $O(n^{1+1/k} \log k)$. Notice that on lower levels, we are obtaining much better stretch than $O(k)$, which gives us some slack when designing our data structures. To take advantage of such slack, the idea is to apply the stretch-friendly partition of a recent work [3] which roughly contracts the graph G into n/τ clusters while blowup the stretch by $O(\tau)$, and then build our tree cover structures on the contracted graph which takes only $O(n^{1+1/k}/\tau)$ space.

2 Preliminaries

Let $\epsilon = 0.01$ be a fixed constant (independent of n, k), and assume $k > 100$. Logarithms are of base 2. For any graph $G = (V, E, \mathbf{w})$ and any vertex subset $S \subseteq V$, let $G[S]$ be the induced subgraph of G on S.

▶ **Definition 3** (bunches and balls). *Let $G = (V, E, \mathbf{w})$ be an undirected weighted graph. For each vertex $v \in V$ and vertex subset $S \subseteq V$, let $\mathbf{piv}_G(v, S) \in S$ be the closest vertex to v, and define the bunch around v with respect to S as:*

$$\mathbf{Bun}_G(v, S) \stackrel{\text{def}}{=} \{u \mid \mathbf{dist}_G(u, v) < \mathbf{dist}_G(u, S)\}$$

Furthermore, for any $\delta > 0$, define

$$\mathbf{Bun}^{\delta}_G(v, S) \stackrel{\text{def}}{=} \{u \mid \mathbf{dist}_G(u, v) < \delta \cdot \mathbf{dist}_G(u, S)\}$$

Balls are similar to bunches, except that the radius is specified by a value, rather than a vertex set. More specifically, for any value $\rho \geq 0$, define the ball around v to be:

$$\mathbf{Ball}_G(v, \rho) = \{u \mid \mathbf{dist}_G(u, v) \leq \rho\}$$

2.1 Stretch-friendly partitions

We need the notion of *stretch-friendly partition* from [3].

▶ **Definition 4** ([3]). *Let $G = (V, E, \mathbf{w})$ be an undirected weighted graph, and fix an integer $\tau \geq 1$. A* stretch-friendly τ-partition *of G is a partition $\mathcal{C} \subset 2^V$ of V with the following guarantees for every $U \in \mathcal{C}$.*

(1) *There is a spanning tree $T[U]$ of $G[U]$ rooted at the cluster center vertex $\mathbf{cntr}[U] \in U$, such that for every $v \in U$, the unique tree path between $\mathbf{cntr}[U], v$ has at most τ edges.*

(2) *If $(x, y) \in E$, $x \in U, y \notin U$, then the weight of every edge on the tree path in $T[U]$ between $x, \mathbf{cntr}[U]$ is at most $\mathbf{w}(x, y)$.*

(3) *If $(x, y) \in E$, $x, y \in U$, then the weight of every edge on the tree path in $T[U]$ between x, y is at most $\mathbf{w}(x, y)$.*

For any stretch-friendly partition $\mathcal{C}$, define $G/\mathcal{C}$ to be the *quotient graph* where each cluster in $\mathcal{C}$ is contracted to a single node. Here are some basic properties of stretch-friendly partitions.

▶ **Lemma 5.** *Let $G = (V, E, \mathbf{w})$ be an undirected weighted graph, and let $\mathcal{C}$ be a stretch friendly τ-partition of G. Consider any pair of vertices $s, t \in V$, then we can find a path π between s, t using edges of $G/\mathcal{C}$ and tree edges of $T[C], C \in \mathcal{C}$, such that:*

$$\mathbf{w}(\pi) \leq 4\tau \cdot \mathbf{dist}_G(s, t)$$

Furthermore, given the shortest path π' between $\mathcal{C}(s), \mathcal{C}(t)$ in $G/\mathcal{C}$, the above path π can be computed in time $O(|\pi|)$.

Proof. If $\mathcal{C}(s) = \mathcal{C}(t)$, then we can take the tree path between s, t in $T[\mathcal{C}(s)]$ which has length at most $2\tau \cdot \mathbf{dist}_G(s, t)$. Otherwise, take the shortest path π_0 between $\mathcal{C}(s), \mathcal{C}(t)$ and suppose it visits contracted nodes $\mathcal{C}(s) = U_0, U_1, \ldots, U_l = \mathcal{C}(t)$. Let $(u_i, v_i) \in E$ be the edge connecting $U_i, U_{i+1}, \forall 0 \leq i < l$. By definition of stretch-friendly τ-partitions, we have:

$$\mathbf{dist}_G(s, t) \geq \frac{1}{\tau} \cdot \min\left\{\mathbf{dist}_{T[U_0]}(s, \mathbf{cntr}[U_0]), \mathbf{dist}_{T[U_l]}(t, \mathbf{cntr}[U_l])\right\}$$

$$\mathbf{w}(u_i, v_i) \geq \frac{1}{2\tau} \cdot \left(\mathbf{dist}_{T[U_i]}(u_i, \mathbf{cntr}[U_i]) + \mathbf{dist}_{T[U_{i+1}]}(v_i, \mathbf{cntr}[U_{i+1}])\right)$$

To find a path between s, t, let π be a concatenation of these paths: tree path between s, u_0 in $T[U_0]$, edge (u_0, v_0), tree path between v_0, u_1 in $T[U_1]$, ... , tree path between v_{l-1}, t in $T[U_l]$. Taking a summation of the above inequalities, we have:

$$\mathbf{w}(\pi) \leq 2\tau \cdot \mathbf{dist}_G(s, t) + 2\tau \cdot \mathbf{dist}_{G/\mathcal{C}}(\mathcal{C}(s), \mathcal{C}(t)) \leq 4\tau \cdot \mathbf{dist}_G(s, t)$$

As for the runtime to compute π, using the tree structure of $T[C]$, it is straightforward to compute π by its definition in time $O(|\pi|)$. ◀

The next statement shows how to construct a hierarchy of stretch-friendly clusters.

▶ **Lemma 6** ([3]). *For any $0 \leq i \leq \lceil \log n \rceil$, there exists a stretch-friendly $(3 \cdot 2^i - 1)$-partition $\mathcal{C}_i$ and each cluster in $\mathcal{C}_i$ has size at least 2^i. Moreover, $\mathcal{C}_i$ is a refinement of $\mathcal{C}_{i+1}$; that is, for each cluster $U \in \mathcal{C}_{i+1}$, U can be partitioned into sub-clusters $U = U_1 \cup U_2 \cup \cdots \cup U_k$, such that $U_j \in \mathcal{C}_i, \forall 1 \leq j \leq k$, and each tree $T[U_j]$ is a sub-tree of $T[U]$.*

2.2 Distance preservers

Throughout this paper, we assume shortest paths are unique by breaking ties using alphabetic ordering. We need a path-reporting distance preserver from [7].

▶ **Definition 7** (branching events, [7]). *For a collection of paths Π in an undirected graph G, a pair of paths together with common vertex (π_1, π_2, x) is called a* branching event*, if $x \in V(\pi_1) \cap V(\pi_2)$, and that the edges incident on x of π_1 and π_2 are different.*

▶ **Lemma 8** ([7]). *Given an undirected weighted graph $G = (V, E, \mathbf{w})$ and a collection of paths Π, there is a distance-preserving path-reporting data structure that reports any path $\pi \in \Pi$ in time $O(|\pi|)$. The data structure has size $O(n + |\Pi| + |\mathbf{br}(\Pi)|)$ where $\mathbf{br}(\Pi)$ is the set of branching events of Π.*

As a by-product, though it is not necessary for our main result, we slightly improve the above lemma as following, thus answering a small open question in [7]. This matches the sparsity bound of distance-preservers which do not require the function of path-reporting [6].

▶ **Lemma 9.** *Given an undirected weighted graph $G = (V, E, \mathbf{w})$ and a collection of shortest paths Π, there is a distance-preserving path-reporting data structure that reports any path $\pi \in \Pi$ in time $O(|\pi|)$. The data structure has size $O\left(n + |\Pi| + \sqrt{n|\mathbf{br}(\Pi)|}\right)$ where $\mathbf{br}(\Pi)$ is the set of branching events of Π.*

3 Tree covers

Before describing our path-reporting distance oracles, we will first need a building block which is adapted from [5]. Our stretch guarantee is worse than [5] roughly by a factor of 3/2 because our data structure is path-reporting, while the data structure from [5] could only report distance values, not any real paths in the graph.

▶ **Lemma 10.** *Let $G = (V, E, \mathbf{w})$ be an undirected weighted graph and let $S \subseteq V$ be a vertex subset. Suppose that there exists an integer parameter $r \geq \log^2 k$ such $|\mathbf{Bun}_G(v, S)| \leq O(n^{\frac{r}{k}} \log^2 n)$ for each $v \in V$. Then, there exists a collection of trees $\mathcal{T}$ of G with the following properties.*

- *The size of all trees in $\mathcal{T}$ is bounded by $O(n^{1+1/k})$.*
- *For any pair of vertices u, v, if $\mathbf{dist}_G(u, v) \leq \frac{2}{3(1+\epsilon)^2 r} \cdot \mathbf{dist}_G(u, S)$, then there exists a tree $T \in \mathcal{T}$ such that T contains both u, v, and more importantly:*

$$\mathbf{dist}_T(u, v) \leq \mathbf{dist}_T(u, \mathbf{rt}[T]) + \mathbf{dist}_T(v, \mathbf{rt}[T]) \leq 2(1+\epsilon) \cdot \mathbf{dist}_G(u, S)$$

where $\mathbf{rt}[T]$ is a fixed root of T; plus, such a tree T can be found in constant time.

Proof. For any integer $0 \leq b \leq \lceil \log_{1+\epsilon} 3 \rceil$, consider the sequence of values $(1+\epsilon)^b, 3(1+\epsilon)^b, 9(1+\epsilon)^b, \cdots, 3^i(1+\epsilon)^b, \cdots$. For any $i \geq 0$, let $V_{i,b} \subseteq V$ be the set of vertices v such that $\mathbf{dist}_G(v, S) \in \left[3^i(1+\epsilon)^b, 3^i(1+\epsilon)^{b+1}\right]$; by definition, we have $V = \bigcup_{i,b} V_{i,b}$.

Constructing a tree cover. Fix any offset $0 \leq b \leq \lceil \log_{1+\epsilon} 3 \rceil$, we will build a collection of trees $\mathcal{T}_b$ by a greedy ball-carving scheme on G; in the end, we will take the union of all trees $\mathcal{T} = \bigcup_b \mathcal{T}_b$. Initially, set $W \leftarrow V$, and go over all integers $i = 0, 1, 2, \cdots$. As long as$V_{i,b} \setminus W \neq \emptyset$, enumerate all vertices $v \in V_{i,b}$. Define a distance value $\rho_v = \frac{1}{(1+\epsilon)r} \cdot \mathbf{dist}_G(v, S)$. Therefore, as $r > \log^2 k$, we have

$$\left|\mathbf{Ball}_{G[W]}(v, (1+\epsilon) r \rho_v)\right| \leq |\mathbf{Bun}_G(v, S)| < O(n^{r/k} \log^2 n) < n^{\left\lfloor \frac{r}{(1-\epsilon)} \right\rfloor \cdot \frac{1}{k}}$$

▷ Claim 11. There must exist an integer $0 \leq r_v < \lfloor (1+\epsilon)r \rfloor$ such that:

$$\left|\mathbf{Ball}_{G[W]}\left(v, (r_v+1)\cdot\rho_v\right)\right| \leq n^{1/k}\left|\mathbf{Ball}_{G[W]}\left(v, r_v\cdot\rho_v\right)\right|$$

Proof of claim. Suppose otherwise, then for any integer $0 \leq l < \lfloor (1+\epsilon)r \rfloor$, we have:

$$\left|\mathbf{Ball}_{G[W]}\left(v, (l+1)\cdot\rho_v\right)\right| > n^{1/k}\left|\mathbf{Ball}_{G[W]}\left(v, l\cdot\rho_v\right)\right|$$

Taking a product of these inequalities over all integers $0 \leq l < \lfloor (1+\epsilon)r \rfloor$, we have:

$$\left|\mathbf{Ball}_{G[W]}\left(v, \lfloor (1+\epsilon)r \rfloor\cdot\rho_v\right)\right| > n^{\left\lfloor \frac{r}{1-\epsilon}\right\rfloor \cdot \frac{1}{k}}$$

Which is a contradiction. ◁

Then, let T be the single-source shortest paths tree rooted at $\mathbf{rt}[T] \leftarrow v$ that spans the vertex set $\mathbf{Ball}_{G[W]}\left(v, (r_v+1)\cdot\rho_v\right)$. All vertices in $\mathbf{Ball}_{G[W]}\left(v, r_v\cdot\rho_v\right) \cap V(T)$ will be called core vertices of T denoted as $\mathbf{core}(T)$, and vertices in $\mathbf{Ball}_{G[W]}\left(v, (r_v+1)\cdot\rho_v\right)$ will be called peripheral vertices of T. After that, add T to $\mathcal{T}_b$, and then remove all the core vertices $\mathbf{Ball}_{G[W]}\left(v, r_v\cdot\rho_v\right)$ from W by updating the vertex set:

$$W \leftarrow W \setminus \mathbf{Ball}_{G[W]}\left(v, r_v\cdot\rho_v\right)$$

After that, move on to the next vertex in $V_{i,b} \setminus W$.

Assigning home trees. To find a tree that meets the requirement in the lemma statement in constant time, we need each vertex to remember a constant number of trees that contain itself, which are called *home trees*. Specifically, for each vertex $v \in V$, we will associate a tree $\mathcal{T}^b_{\mathsf{home}}(v) \in \mathcal{T}_b$ with v which is defined to be the **first tree** T created in $\mathcal{T}_b$ containing v such that:

$$\mathbf{dist}_T(v, \mathbf{core}(T)) \leq \frac{1}{3(1+\epsilon)^2}\rho_v$$

Size of the tree cover. By the algorithm, each time we add a new tree T to $\mathcal{T}_b$, $|T|$ is at most $n^{1/k}|\mathbf{core}(T)|$. As core vertices are removed from W right afterwards, the total size of $\mathcal{T}_b$ is bounded by $O\left(n^{1+1/k}\right)$.

The covering property. Consider any pair of vertices u, v such that $\mathbf{dist}_G(u,v) \leq \frac{2}{3(1+\epsilon)^2 r} \cdot \mathbf{dist}_G(u, S)$. Let us first state an elementary inequality.

▷ Claim 12. $\rho_u \leq (1+\epsilon)\cdot\rho_v$.

Proof of claim. By triangle inequality, we have:

$$\begin{aligned}\mathbf{dist}_G(u,S) &\leq \mathbf{dist}_G(v,S) + \mathbf{dist}_G(u,v)\\ &\leq \mathbf{dist}_G(v,S) + \frac{2}{3(1+\epsilon)^2 r}\cdot\mathbf{dist}_G(u,S)\\ &< \mathbf{dist}_G(v,S) + \frac{\epsilon}{1+\epsilon}\cdot\mathbf{dist}_G(u,S)\end{aligned}$$

The last inequality holds as $r \geq \log^2 k$ and ϵ is a constant. Therefore, by definition of ρ_u, ρ_v, we can conclude the proof. ◁

Let π be the shortest path between u, v in G. Assume $u \in V_{i,b}$ for some $i, b \geq 0$.

▷ Claim 13. Vertices on π cannot be core vertices of trees rooted at any vertices from $V_{j,b}$ for some $j < i$.

Proof of claim. Suppose otherwise that there was a vertex $w \in V_{j,b}$ which grew a tree $T \in \mathcal{T}_b$ whose core includes a vertex $z \in V(\pi)$. Then, by triangle inequality, we would have:

$$\begin{aligned}\mathbf{dist}_G(u,S) &\leq \mathbf{dist}_G(u,z) + \mathbf{dist}_G(z,w) + \mathbf{dist}_G(w,S)\\ &\leq \frac{2}{3(1+\epsilon)r} \cdot 3^i \cdot (1+\epsilon)^{b+1} + 2 \cdot 3^{i-1} \cdot (1+\epsilon)^{b+1}\\ &< \left(\frac{1}{32} + 2\right) \cdot 3^{i-1} \cdot (1+\epsilon)^{b+1}\\ &< 3^i \cdot (1+\epsilon)^b\end{aligned}$$

This contradicts the definition that $u \in V_{i,b}$. ◁

As for the tree covering property, consider the first tree T created whose core intersected with $V(\pi)$, and consider the moment right before T was created. Since $z \in V(\pi)$, it must be:

$$\min\{\mathbf{dist}_{G[W]}(z,u), \mathbf{dist}_{G[W]}(z,v)\} \leq 0.5 \cdot \mathbf{dist}_G(u,v) \leq \frac{\rho_u}{3(1+\epsilon)^2}$$

Consider two possibilities.

- $\mathbf{dist}_{G[W]}(z,u) \leq 0.5 \cdot \mathbf{dist}_G(u,v) \leq \frac{\rho_u}{3(1+\epsilon)^2}$.
  In this case, we have $\mathbf{dist}_T(u, \mathbf{core}(T)) \leq \frac{\rho_u}{3(1+\epsilon)^2}$. Hence, by definition of $\mathcal{T}^b_{\mathsf{home}}(u)$, $\mathcal{T}^b_{\mathsf{home}}(u)$ must have been created no later than T. Therefore, when $\mathcal{T}^b_{\mathsf{home}}(u)$ was being created with root $z \in V_{i,b}$ (Claim 13), all vertices on π was still present in W. Therefore, at the moment, we have:
  $$\begin{aligned}\mathbf{dist}_{G[W]}\left(v, \mathbf{core}\left(\mathcal{T}^b_{\mathsf{home}}(u)\right)\right) &\leq \mathbf{dist}_{G[W]}(u,v) + \mathbf{dist}_{\mathcal{T}^b_{\mathsf{home}}(u)}\left(u, \mathbf{core}\left(\mathcal{T}^b_{\mathsf{home}}(u)\right)\right)\\ &\leq \frac{\rho_u}{(1+\epsilon)^2} < \rho_z\end{aligned}$$
  Hence, v was included in $\mathcal{T}^b_{\mathsf{home}}(u)$. As for their distance in the tree, by our algorithm, the radius of $\mathcal{T}^b_{\mathsf{home}}(u)$ is at most $3^i \cdot (1+\epsilon)^{b+1} \leq (1+\epsilon)\mathbf{dist}_G(u,S)$. Hence, we have:
  $$\mathbf{dist}_{\mathcal{T}^b_{\mathsf{home}}(u)}(u,v) \leq 2(1+\epsilon) \cdot \mathbf{dist}_G(u,S)$$
- $\mathbf{dist}_{G[W]}(z,v) \leq 0.5 \cdot \mathbf{dist}_G(u,v) \leq \frac{1}{3(1+\epsilon)^2}\rho_u$.
  In this case, we have $\mathbf{dist}_T(v, \mathbf{core}(T)) \leq \frac{1}{3(1+\epsilon)^2}\rho_u \leq \frac{1}{3(1+\epsilon)}\rho_v$. Hence, by definition of $\mathcal{T}^b_{\mathsf{home}}(v)$, $\mathcal{T}^b_{\mathsf{home}}(v)$ must have been created no later than T. Therefore, when $\mathcal{T}^b_{\mathsf{home}}(v)$ was being created with root $z \in V_{i,b}$ (Claim 13), all vertices on π was still present in W. Therefore, at the moment, we have:
  $$\begin{aligned}\mathbf{dist}_{G[W]}\left(u, \mathbf{core}\left(\mathcal{T}^b_{\mathsf{home}}(v)\right)\right) &\leq \mathbf{dist}_{G[W]}(u,v) + \mathbf{dist}_{\mathcal{T}^b_{\mathsf{home}}(v)}\left(v, \mathbf{core}\left(\mathcal{T}^b_{\mathsf{home}}(v)\right)\right)\\ &\leq \frac{1}{1+\epsilon}\rho_v \leq \rho_z\end{aligned}$$
  Hence, u was included in $\mathcal{T}^b_{\mathsf{home}}(v)$. As for their distance in the tree, by our algorithm, the radius of $\mathcal{T}^b_{\mathsf{home}}(v)$ is at most $3^i \cdot (1+\epsilon)^{b+1} \leq (1+\epsilon)\mathbf{dist}_G(u,S)$. Hence, we have:
  $$\mathbf{dist}_{\mathcal{T}^b_{\mathsf{home}}(u)}(u,v) \leq 2(1+\epsilon) \cdot \mathbf{dist}_G(u,S)$$ ◀

Given such a collection of trees $\mathcal{T}$ satisfying the conditions of Lemma 10, let us state a subroutine $\mathbf{TreeCover}(s,t,\mathcal{T})$ with constant runtime that checks if the tree cover data structure $\mathcal{T}$ can provide a distance estimation for $\mathbf{dist}_G(s,t)$ as long with the a path.

Algorithm 1 **TreeCover**$(s, t, \mathcal{T})$.

```
Assume s ∈ V_{i,a}, t ∈ V_{j,b};
for v ∈ {s,t}, c ∈ {a,b} do
    if T^c_home(v) contains both {s,t} then
        return dist_{T^c_home(v)}(s,t), along with the tree path in T^c_home(v) between s,t if
          required;
return ⊥;
```

4 Path-reporting distance oracles

4.1 Data structures

Define $\alpha = 3/4 + \epsilon$. Apply Lemma 6 on G to create a sequence of stretch-friendly partitions $\{\mathcal{C}_i\}_{0 \le i \le \lceil \log n \rceil}$. Build a level ancestor data structure with $O(n)$ space so that for any $u \in V$ and any index $0 \le i \le \lceil \log n \rceil$, we can access the cluster $\mathcal{C}_i(u)$ in constant time [2].

Take a hierarchy of vertex sets $V = A_0 \supseteq A_1 \supseteq A_2 \supseteq \cdots \supseteq A_k$, where A_{i+1} includes each vertex in A_i independently with probability $n^{-1/k}$, $\forall 0 \le i < k$. Therefore, with high probability, size of A_i is at most $O(n^{1-\frac{i}{k}} \log n)$.

Define a sequence of integers $h_0, h_1, h_2, \ldots, h_\iota$ satisfying $h_0 = k$, $h_1 = \lceil \alpha k \rceil$, and for $l \ge 1$ define $h_l = \max\left\{\lceil \alpha^l k \rceil, 2\lceil \log^2 k \rceil\right\}$, the sequence stops until it reaches $h_\iota = 2\lceil \log^2 k \rceil$.

Data structures for high levels

Let $\kappa = 50$ be an integer threshold. For every integer $0 \le l \le \iota$, we will build some data structures separately. When $l > \kappa$, let $\mathcal{C}^{(l)} \in \{\mathcal{C}_i\}_{0 \le i \le \lceil \log n \rceil}$ which is a stretch-friendly τ_l-partition where $\tau_l \in [\alpha^{-l/5}, 2\alpha^{-l/5}]$; we can make sure that the sequence $\{\tau_l\}_{\kappa \le l \le \iota}$ is non-decreasing. Plus, if $0 \le l \le \kappa$, then set $\mathcal{C}^{(l)}$ to be singletons (that is, $\tau_l = 1$). For each vertex $v \in V$, let $\mathcal{C}^{(l)}(v) \in \mathcal{C}^{(l)}$ be the unique cluster that contains v. Let $G/\mathcal{C}^{(l)}$ be the quotient graph of G where each cluster in $\mathcal{C}^{(l)}$ is contracted to a single node, and the edges of $G/\mathcal{C}^{(l)}$ are edges in G between different clusters in $\mathcal{C}^{(l)}$.

For the rest, we will build some graph data structures. For each integer $1 \le l \le \iota$, let B_{h_l} be the set of contracted nodes in $G/\mathcal{C}^{(l)}$ containing at least one vertex from the random set A_{h_l}, and let $C_{h_{l-1}}$ be the set of contracted nodes in $G/\mathcal{C}^{(l)}$ containing at least one vertex from the random set $A_{h_{l-1}}$. Build the following data structures.

(i) For each integer $1 \le l \le \iota$, apply Lemma 10 on the quotient graph $G/\mathcal{C}^{(l)}$ to build a tree cover $\mathcal{T}_l$ with respect to the terminal set B_{h_l} by setting the parameter $r = h_l$; we will prove that this parameter r satisfies the requirement of Lemma 10 with high probability over the random choices of $A_1, \ldots, A_k$.

For the special case when $l = 0$, simply set $\mathcal{T}_0$ to be single-source shortest paths trees rooted at each vertex in A_k in G, and each vertex in $u \in V$ has a pointer to the vertex in A_k that is the closest one to u. It is straightforward to see that $\mathcal{T}_0$ is also a valid tree cover for A_k using the definition of Lemma 10 (by setting $r \leftarrow k, S \leftarrow A_k$), and **TreeCover**$(s, t, \mathcal{T}_0)$ can always return a nonempty value whether or not the inequality $\mathbf{dist}_G(u, v) \le \frac{2(1-\epsilon)^2}{3k} \cdot \mathbf{dist}_G(u, A_k)$ is satisfied.

(ii) For each integer $0 \le l \le \iota$ and for each contracted node x in $G/\mathcal{C}^{(l)}$, store a shortest path from x to its nearest node in B_{h_l} denoted as $\mathbf{piv}_{G/\mathcal{C}^{(l)}}(x, B_{h_l})$.

(iii) For each integer $1 \leq l \leq \iota$, we will build a set of paths Π_l in $G/\mathcal{C}^{(l)}$ in the following manner.
For each pair of nodes $x \in B_{h_l}$ and $y \in B_{h_l} \cap \mathbf{Bun}^{1/2}_{G/\mathcal{C}^{(l)}}\left(x, C_{h_{l-1}}\right)$, let $\pi_{x,y}$ the shortest path between x, y in graph $G/\mathcal{C}^{(l)}$, and add $\pi_{x,y}$ to Π_l. After building path set Π_l, apply Lemma 8 to build a path-reporting distance preserver data structure in the quotient graph $G/\mathcal{C}^{(l)}$ with respect to Π_l.

Data structures for low levels

Let $\mathcal{C}^{(\iota)}$ be a stretch-friendly $\Theta(\log^2 k)$-partition of G, and let $G/\mathcal{C}^{(\iota)}$ be the quotient graph. For each $0 \leq i \leq 2\left\lceil \log^2 k \right\rceil$, let B_i be the set of nodes in $G/\mathcal{C}^{(\iota)}$ containing at least one vertex in A_i. Store the following data structures for each $0 \leq i \leq 2\left\lceil \log^2 k \right\rceil$.

(i) For each node x in graph $G/\mathcal{C}^{(\iota)}$, store the shortest paths to all nodes $y \in B_i$ in $G/\mathcal{C}^{(\iota)}$ such that $\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, y) < \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$, as well as the shortest path from x to $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(x, B_i)$. We assume shortest paths are unique by breaking ties alphabetically.

(ii) For each node x in graph $G/\mathcal{C}^{(\iota)}$ and each even index $0 \leq i < 2\left\lceil \log^2 k \right\rceil$, store the difference:

$$\Delta(x, i) \stackrel{\text{def}}{=} \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+2}) - \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, B_i)$$

Then, for each such x, store a range minimum query data structure for all entries $\Delta(x, i), i = 0, 2, \ldots, 2\left\lceil \log^2 k \right\rceil - 2$ with linear space and constant query time [1].

4.2 Query algorithm

Given any query $(s, t) \in V^2$, the query algorithm consists of two phases, one for high levels (in range $\left[2\left\lceil \log^2 k \right\rceil, k\right]$), and one for low levels (in range $\left[0, 2\left\lceil \log^2 k \right\rceil\right]$).

High-level phase

By the design of the data structure, $\mathbf{TreeCover}(s, t, \mathcal{T}_0)$ always returns nonempty value because each tree in $\mathcal{T}_0$ is a spanning tree of G. For each $1 \leq l \leq \iota$, define $u_l = \mathcal{C}^{(l)}(s), v_l = \mathcal{C}^{(l)}(t)$. Next, run the subroutine $\mathbf{TreeCover}(u_\iota, v_\iota, \mathcal{T}_\iota)$; if it successfully returns a nonempty value, then move on to the next phase. Otherwise, the algorithm maintains two indices $l_1 \leftarrow 0, l_2 \leftarrow \iota$ and performs the following binary search procedure; the goal of the binary search procedure is to find a consecutive pair of indices $l-1, l$ such that $\mathbf{TreeCover}(u_l, u_l, \mathcal{T}_l)$ returns an empty value, while $\mathbf{TreeCover}(u_{l-1}, v_{l-1}, \mathcal{T}_{l-1})$ returns successfully a nonempty value.

(1) If $l_1 < l_2 - 1$, define $l_3 = \lfloor (l_1 + l_2)/2 \rfloor$, and run the subroutine $\mathbf{TreeCover}(u_{l_3}, v_{l_3}, \mathcal{T}_{l_3})$. If the subroutine returns an empty value, then assign $l_2 \leftarrow l_3$; otherwise, assign $l_1 \leftarrow l_3$. Then, continue with the new pair (l_1, l_2).

(2) Now suppose $l_1 + 1 = l_2 = l$ and $\mathbf{TreeCover}(u_{l-1}, v_{l-1}, \mathcal{T}_{l-1})$ returns a nonempty value, but the procedure $\mathbf{TreeCover}(u_l, v_l, \mathcal{T}_l)$ returns null. Then, query part (ii) of the data structure in the storage to find the vertices $x = \mathbf{piv}_{G/\mathcal{C}^{(l)}}(u_l, B_{h_l})$ and $y = \mathbf{piv}_{G/\mathcal{C}^{(l)}}(v_l, B_{h_l})$, and check two possibilities below.

(a) The shortest path between nodes x, y in $G/\mathcal{C}^{(l)}$ is preserved in the distance-preserver; that is, there is a path between x, y in Π_l
In this case, query the shortest path π'_1 from u_l to x using part (ii), and the shortest path π'_2 from x to y using the path-reporting distance preserver in part (iii), and the shortest path π'_3 from y to v_l using part (ii). Then, define the concatenation $\pi' = \pi'_1 \circ \pi'_2 \circ \pi'_3$ and then recover a path π between s, t in G by unpacking the contracted nodes in $\mathcal{C}^{(l)}$ using π' by Lemma 5 with runtime $O(|\pi|)$.

(b) The shortest path between nodes x, y in $G/\mathcal{C}^{(l)}$ is not preserved in the distance-preserver.
In this case, as **TreeCover** $(u_{l-1}, v_{l-1}, \mathcal{T}_{l-1})$ returned a nonempty value, we can use the tree in $\mathcal{T}_{l-1}$ that covers both u_{l-1}, v_{l-1} to get a path π' between them. Then, by Lemma 5 we can obtain a path between s, t in G which unpacks the contracted nodes in $\mathcal{C}^{(l-1)}$.

Low-level phase

This part is pretty much the same as the query algorithm from [11]. The difference is that we are making the queries in the contracted graph $G/\mathcal{C}^{(\iota)}$, and total number of levels is at most $2\lceil\log^2 k\rceil$ rather than k. For convenience, rename the variables by $u = \mathcal{C}^{(\iota)}(s)$ and $v = \mathcal{C}^{(\iota)}(t)$. We first check if $u = v$; if it is the case, we can directly retrieve a path using the spanning trees of the stretch-friendly τ_ι-partition $\mathcal{C}^{(\iota)}$ which has stretch error at most $2\tau_\iota < k$. For the rest, let us assume that $u \neq v$.

▶ **Definition 14** ([11]). *For a pair of contracted nodes u, v in $G/\mathcal{C}^{(\iota)}$, and even index $j \in [0, 2\log^2 k]$ is called* (u, v)-terminal *if (1) $j = 2\lceil\log^2 k\rceil$ or (2) $j < 2\lceil\log^2 k\rceil$ and one of the following conditions holds:*

$$\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_j) \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(v, B_{j+1})$$

$$\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(v, B_{j+1}) \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(u, B_{j+2})$$

Next, we will perform a binary search on the interval $[0, 2\lceil\log^2 k\rceil]$ as did in [11]. Initially, set $i_1 \leftarrow 0, i_2 \leftarrow 2\lceil\log^2 k\rceil$. In each iteration we perform the following steps while guaranteeing that i_2 is always (u, v)-terminal.

- If $i_1 = i_2$, since i_2 is (u, v)-terminal, we can consider three different possibilities.
  - $i_2 = 2\lceil\log^2 k\rceil$.
    Since **TreeCover**$(u, v, \mathcal{T}_\iota)$ returns successfully, we can use the tree in $\mathcal{T}_\iota$ that covers both u, v to get a path π' between them. Then, by Lemma 5 we can obtain a path between s, t in G which unpacks the contracted nodes in $\mathcal{C}^{(\iota)}$.
  - $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_2}) \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_2+1})$.
    According to part (i) of our low-level data structures, we have stored the shortest path π_1 from v to $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_2})$ in $G/\mathcal{C}^{(\iota)}$, as well as the shortest path π_2 from u to $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_2})$. Then, we can retrieve a path between s, t by applying Lemma 5 on $\pi_1 \circ \pi_2$.
  - $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_2+1}) \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_2+2})$.
    Similarly, according to part (i) of our low-level data structures, we have stored the shortest path π_1 from u to $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_2+1})$ in $G/\mathcal{C}^{(\iota)}$, as well as the shortest path π_2 from v to $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_2+2})$. Then, we can retrieve a path between s, t by applying Lemma 5 on $\pi_1 \circ \pi_2$.
- Otherwise, let j be the middle even index among $i_1, i_1 + 2, \cdots, i_2 - 2$, and let i_3 be the even index in $i_1, i_1 + 2, \cdots, j$ maximizing $\Delta(u, i_3)$ by querying part (ii) of our low-level data structure. If i_3 is not (u, v)-terminal, then recurse on the index pair $(j + 2, i_2)$; otherwise, recurse on (i_1, i_3).

4.3 Space analysis

Size of high-level data structures

Let us analyze the size of our data structures part by part for each index $0 \leq l < \iota$.

▷ Claim 15. Let $N = O(n \cdot \alpha^{l/5})$ be the number of contracted nodes in $G/\mathcal{C}^{(l)}$. With high probability over the randomness of A_{h_l}, for any contracted node $u \in G/\mathcal{C}^{(l)}$, we have the following bounds.

- $\left|\mathbf{Bun}_{G/\mathcal{C}^{(l)}}(u, B_{h_l})\right| \leq O\left(N^{\frac{h_l}{k}} \log^2 N\right)$.
- $\left|B_{h_l} \cap \mathbf{Bun}_{G/\mathcal{C}^{(l)}}\left(u, C_{h_{l-1}}\right)\right| \leq O\left(n^{\frac{h_{l-1}-h_l}{k}} \log n\right)$.

Proof. Let S be the set of nodes in $G/\mathcal{C}^{(l)}$ which are the nearest $10n^{\frac{h_l}{k}} \log n$ ones to u. Then, since A_{h_l} samples each vertices in V independently with probability $n^{-\frac{h_l}{k}}$, with high probability, A_{h_l} contains at least one vertex contracted in some nodes in S. Therefore, in this case we have $\left|\mathbf{Bun}_{G/\mathcal{C}^{(l)}}(u, B_{h_l})\right| \leq O\left(n^{\frac{h_l}{k}} \log n\right) \leq O\left(N^{\frac{h_l}{k}} \log^2 N\right)$.

As for the second inequality bound, let $u_1, u_2, \ldots, u_j \in B_{h_l}$ be the nearest nodes to u in $G/\mathcal{C}^{(l)}$, for some $j = O\left(n^{\frac{h_{l-1}-h_l}{k}} \log n\right)$. Then, since each u_i belongs to $C_{h_{l-1}}$ with probability at least $n^{-\frac{h_{l-1}-h_l}{k}}$, at least one node $u_i, 1 \leq i \leq j$ should belong to $C_{h_{l-1}}$ with high probability. Therefore, the size of $\left|B_{h_l} \cap \mathbf{Bun}_{G/\mathcal{C}^{(l)}}\left(u, C_{h_{l-1}}\right)\right|$ should be $\leq O\left(n^{\frac{h_{l-1}-h_l}{k}} \log n\right)$. ◁

Using Lemma 10 and Claim 15, we know that the total size of the tree cover data structure for the quotient graph $G/\mathcal{C}^{(l)}$ is bounded by $O\left(n^{1+\frac{1}{k}} \cdot \alpha^{l/5}\right)$. Then, taking a summation over all indices $0 \leq l < \iota$, the size bound becomes $O\left(n^{1+\frac{1}{k}}\right)$. Similarly, we can also bound the total size of shortest paths from all the nodes x to $\mathbf{piv}_{G/\mathcal{C}^{(l)}}(x, B_{h_l})$.

To bound the total size of our path-reporting distance preservers, we need to bound the total number of branching events of Π_l.

▷ Claim 16. For each $0 \leq l \leq \iota$, the expectation of $|\mathbf{br}(\Pi_l)| + |\Pi_l|$ over the randomness of $A_1, \ldots, A_k$ is bounded by $O(n/\log n)$.

Proof. Let $(\pi_1, \pi_2, *) \in \mathbf{br}(\Pi_l)$ be any branching event, and assume π_1, π_2 are shortest paths in $G/\mathcal{C}^{(l)}$ between nodes u_1, v_1 and u_2, v_2 such that $v_b \in \mathbf{Bun}^{1/2}_{G/\mathcal{C}^{(l)}}\left(u_b, C_{h_{l-1}}\right), \forall b \in \{1, 2\}$. Without loss of generality, assume that $\mathbf{w}(\pi_1) \geq \mathbf{w}(\pi_2)$. Then, we have:

$$\mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_1, x) \leq \mathbf{w}(\pi_1) + \mathbf{w}(\pi_2) < \mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(u_1, C_{h_{l-1}}\right), \forall x \in \{v_1, u_2, v_2\}$$

Therefore, $v_1, u_2, v_2 \in B_{h_l} \cap \mathbf{Bun}_{G/\mathcal{C}^{(l)}}\left(u_1, C_{h_{l-1}}\right)$. Therefore, using Claim 15, with high probability, $|\mathbf{br}(\Pi_l)|$ is bounded by the following up to a constant factor (recall that $\alpha = 3/4 + \epsilon$):

$$\begin{aligned}
\sum_{u \in B_{h_l}} \left|B_{h_l} \cap \mathbf{Bun}_{G/\mathcal{C}^{(l)}}\left(u, C_{h_{l-1}}\right)\right|^3 &\leq |B_{h_l}| \cdot O\left(n^{\frac{3h_{l-1}-3h_l}{k}} \log^3 n\right) \\
&\leq |A_{h_l}| \cdot O\left(n^{\frac{3h_{l-1}-3h_l}{k}} \log^3 n\right) \\
&\leq O\left(n^{1-\frac{h_l}{k}+\frac{3h_{l-1}-3h_l}{k}} \log^4 n\right) \\
&< O\left(n^{1-\frac{4\left\lceil \alpha^l k\right\rceil - 3\left\lceil \alpha^{l-1} k\right\rceil}{k}} \log^4 n\right) \\
&\leq O\left(n^{1-\frac{3\epsilon \cdot \alpha^{l-1} k - 3}{k}} \log^4 n\right) \\
&< O\left(n^{1-\epsilon \cdot \log^2 k} \log^4 n\right) \\
&< n/\log n
\end{aligned}$$

As for the size of Π_l, by definition, it is bounded by $\sum_{u \in B_{h_l}} \left| B_{h_l} \cap \mathbf{Bun}^{1/2}_{G/\mathcal{C}^{(l)}}(u, C_{h_{l-1}}) \right|$ which is also at most $O(n/\log n)$ according to the above calculation. ◁

Applying Definition 7 and Claim 16, we can bound the expected size of part-(iii) of our data structures by $O(n)$.

Size of low-level data structures

It is clear that part (ii) only takes space $O(n \log^2 k/\tau_\iota) \leq O(n)$. As for part (i), for each node x, we have stored the shortest path from x to every node $y \in B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ and $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(x, B_i)$. It is clear that the total size of the shortest paths to pivots is at most $O(n/\tau_\iota)$, so it is at most $O(n)$ by taking a summation over all indices $0 \leq i \leq 2\lceil \log^2 k \rceil$. Next, let us focus on shortest paths from x to nodes in $B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$.

▷ Claim 17. For each node x in $G/\mathcal{C}^{(\iota)}$, the expected size of $B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ is at most $n^{1/k}$ over the randomness of $A_1, A_2, \ldots, A_k$.

Proof. Fix any node x, order all nodes in $G/\mathcal{C}^{(\iota)}$ in an increasing order of distances as $y_0, y_1, \ldots, y_l, \ldots$. For each y_j, let $|y_j|$ be the number of vertices in V contracted within. Conditioning on $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ being y_l, the expected total number vertices contracted in nodes from $B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ is equal to $n^{-i/k} \sum_{j=0}^{l-1} |y_j|$. Therefore, the overall expected total number vertices contracted in nodes from $B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ would be:

$$
\begin{aligned}
& n^{-i/k} \sum_{l \geq 1} \sum_{j=0}^{l-1} |y_j| \cdot \Pr\left[\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1}) = y_l\right] \\
&= n^{-i/k} \sum_{l \geq 1} \sum_{j=0}^{l-1} |y_j| \cdot \left(1 - n^{-(i+1)/k}\right)^{\sum_{j=0}^{l-1} |y_j|} \cdot \left(1 - \left(1 - n^{-(i+1)/k}\right)^{|y_l|}\right) \\
&\leq n^{-i/k} \cdot n^{(i+1)/k} = n^{1/k}
\end{aligned}
$$

The inequality holds as the summation is maximized when $|y_j| = 1, \forall j \geq 0$. Therefore, the expected size of $B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ is also at most $n^{1/k}$. ◁

To bound the total size of shortest paths from x to $B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$, we need the one more statement below.

▷ Claim 18. Fix any node x, and for any $y \in B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$ and node z on the shortest path from x to y in graph $G/\mathcal{C}^{(\iota)}$, we have $y \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(z, B_{i+1})$.

Proof. By triangle inequality, we have:

$$
\begin{aligned}
\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(z, y) &= \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, y) - \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, z) \\
&< \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1}) - \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(x, z) \\
&< \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(z, B_{i+1})
\end{aligned}
$$

So by definition of bunches, we have $y \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(z, B_{i+1})$. ◁

By Claim 18, if the data structure needs to store the shortest path $\gamma_{x,y}$ from x to $y \in B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$, then it also needs to store each shortest path $\gamma_{z,y}$ for any $z \in \gamma_{x,y}$. Therefore, to store all the path $\{\gamma_{x,y}\}$ in a space-efficient manner, we only need to store the first edge of $\gamma_{x,y}$ (which is incident on x) for all x in $G/\mathcal{C}^{(\iota)}$ and $y \in B_i \cap \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(x, B_{i+1})$; this also allows us to retrieve the path $\gamma_{x,y}$ in $|\gamma_{x,y}|$ time. Then, by Claim 17, the total size of this shortest path data structure over all node x in $G/\mathcal{C}^{(\iota)}$ would be bounded by $O(n^{1+1/k}/\tau_\iota)$, which is $O(n^{1+1/k})$ summing over all $0 \leq i \leq 2\lceil \log^2 k \rceil$.

4.4 Stretch analysis

Let us analyze the stretch of the high-level phase and the low-level phase separately.

High-level phase

By the algorithm description, suppose that the subroutine $\mathbf{TreeCover}(u_\iota, v_\iota, \mathcal{T}_\iota)$ does not return any nonempty value. Then, by the binary search procedure, in the end we will find an index $1 \le l \le \iota$ such that $\mathbf{TreeCover}(u_l, v_l, \mathcal{T}_l)$ returns null and $\mathbf{TreeCover}(u_{l-1}, v_{l-1}, \mathcal{T}_{l-1})$ returns a nonempty value. Define $x = \mathbf{piv}_{G/\mathcal{C}^{(l)}}(u_l, B_{h_l})$ and $y = \mathbf{piv}_{G/\mathcal{C}^{(l)}}(v_l, B_{h_l})$.

▷ Claim 19. If $1 \le l \le \kappa$, then:

$$\mathbf{dist}_G(x,y) \le \left(3(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_G(s,t)$$

If $\kappa < l \le \iota$, then:

$$\mathbf{dist}_{G/\mathcal{C}^{(l)}}(x,y) \le \left(3(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l)$$

Proof. For the first inequality, since $\mathbf{TreeCover}(s,t,\mathcal{T}_l)$ does not return anything, by the guarantee of Lemma 10, we know that:

$$\mathbf{dist}_G(s,t) > \frac{2}{3(1+\epsilon)^2 h_l} \cdot \max\left\{\mathbf{dist}_G(s, A_{h_l}), \mathbf{dist}_G(t, A_{h_l})\right\}$$

Thus, by triangle inequality, we have:

$$\mathbf{dist}_G(x,y) \le \mathbf{dist}_G(x,s) + \mathbf{dist}_G(s,t) + \mathbf{dist}_G(t,y) \le \left(3(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_G(s,t)$$

Similarly, for the second inequality, since $\mathbf{TreeCover}(u_l, v_l, \mathcal{T}_l)$ does not return anything, by the guarantee of Lemma 10, we know that:

$$\mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l) > \frac{2}{3(1+\epsilon)^2 h_l} \cdot \max\{\mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, B_{h_l}), \mathbf{dist}_{G/\mathcal{C}^{(l)}}(v_l, B_{h_l})\}$$

Thus, by triangle inequality, we have:

$$\begin{aligned}\mathbf{dist}_{G/\mathcal{C}^{(l)}}(x,y) &\le \mathbf{dist}_{G/\mathcal{C}^{(l)}}(x,u_l) + \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l,v_l) + \mathbf{dist}_{G/\mathcal{C}^{(l)}}(v_l,y)\\ &\le \left(3(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l,v_l)\end{aligned}$$ ◁

Next, let us study two possibilities. First, assume that the shortest path between nodes x, y in $G/\mathcal{C}^{(l)}$ belongs to Π_l.

- $1 \le l \le \kappa$.
  In this case, using Claim 19, the path reported by our distance oracle has length at most:
  $$\mathbf{dist}_G(s,x) + \mathbf{dist}_G(x,y) + \mathbf{dist}_G(y,t) \le \left(6(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_G(s,t) \le 5k \cdot \mathbf{dist}_G(s,t)$$
- $\kappa < l \le \iota$.
  In this case, let π' be the concatenation of shortest paths between u_l, x, and x, y, and y, v_l in graph $G/\mathcal{C}^{(l)}$. Using Claim 19 and triangle inequality, we have:
  $$\begin{aligned}\mathbf{w}(\pi') &= \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l,x) + \mathbf{dist}_{G/\mathcal{C}^{(l)}}(x,y) + \mathbf{dist}_{G/\mathcal{C}^{(l)}}(y,v_l)\\ &\le \left(6(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l,v_l)\end{aligned}$$

Applying Lemma 5 on π' and then we can obtain a path between s,t with length at most:

$$\begin{aligned}4\tau_l \cdot \left(6(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l) &\leq 4\tau_l \cdot \left(6(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_G(s,t) \\ &\leq 8\alpha^{-l/5} \cdot \left(6(1+\epsilon)^2 \left\lceil \alpha^l k \right\rceil + 1\right) \cdot \mathbf{dist}_G(s,t) \\ &< 50\alpha^{4l/5} k \cdot \mathbf{dist}_G(s,t) \\ &< 10k \cdot \mathbf{dist}_G(s,t)\end{aligned}$$

Next, consider the case where the shortest path between nodes x, y in $G/\mathcal{C}^{(l)}$ does not belong to Π_l. Consider two possibilities.

- $1 \leq l \leq \kappa$.
  In this case, using Claim 19, we know $\mathbf{dist}_G(x,y) \leq \left(3(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_G(s,t)$. Also, in the proof of Claim 19, we have also shown:

  $$\mathbf{dist}_G(s,t) > \frac{2}{3(1+\epsilon)^2 h_l} \cdot \max\left\{\mathbf{dist}_G\left(s,x\right), \mathbf{dist}_G\left(t,y\right)\right\}$$

  Now, since $y \notin \mathbf{Bun}_G^{1/2}\left(x, A_{h_{l-1}}\right)$ and $x \notin \mathbf{Bun}_G^{1/2}\left(y, A_{h_{l-1}}\right)$, we know that:

  $$\max\left\{\mathbf{dist}_G\left(x, A_{h_{l-1}}\right), \mathbf{dist}_G\left(y, A_{h_{l-1}}\right)\right\} \leq 2\mathbf{dist}_G(x,y)$$

  Therefore, we have:

  $$\begin{aligned}&\max\left\{\mathbf{dist}_G\left(s, A_{h_{l-1}}\right), \mathbf{dist}_G\left(t, A_{h_{l-1}}\right)\right\} \\ &\leq \max\left\{\mathbf{dist}_G(s,x) + \mathbf{dist}_G\left(x, A_{h_{l-1}}\right), \mathbf{dist}_G(t,y) + \mathbf{dist}_G\left(y, A_{h_{l-1}}\right)\right\} \\ &\leq \left(\frac{15(1+\epsilon)^2 h_l}{2} + 2\right) \cdot \mathbf{dist}_G(s,t)\end{aligned}$$

  As $\mathbf{TreeCover}\left(s,t,\mathcal{T}_l\right)$ successfully returns a nonempty value, by Lemma 10, the path retrieved between s,t has length at most ($k > 100, \epsilon < 0.1$):

  $$\begin{aligned}&\left(\frac{15(1+\epsilon)h_l}{(1-\epsilon)} + 4(1+\epsilon)\right) \cdot \mathbf{dist}_G(s,t) \\ &< \left(\frac{15(1+\epsilon)\left\lceil (0.75+\epsilon)k \right\rceil}{(1-\epsilon)} + 4(1+\epsilon)\right) \cdot \mathbf{dist}_G(s,t) \\ &< 12k \cdot \mathbf{dist}_G(s,t)\end{aligned}$$

- $l > \kappa$.
  In this case, using Claim 19, we know that $\mathbf{dist}_{G/\mathcal{C}^{(l)}}(x,y) \leq \left(3(1+\epsilon)^2 h_l + 1\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l)$. Also, in the proof of Claim 19, we have also show:

  $$\mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l) > \frac{2}{3(1+\epsilon)^2 h_l} \cdot \max\left\{\mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(u_l, x\right), \mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(v_l, y\right)\right\}$$

  Now, since $x \notin \mathbf{Bun}_{G/\mathcal{C}^{(l)}}(y, C_{h_{l-1}})$ and $y \notin \mathbf{Bun}_{G/\mathcal{C}^{(l)}}(x, C_{h_{l-1}})$, we know that:

  $$\max\left\{\mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(x, C_{h_{l-1}}\right), \mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(y, C_{h_{l-1}}\right)\right\} \leq 2\mathbf{dist}_{G/\mathcal{C}^{(l)}}(x,y)$$

  Therefore, we have:

  $$\begin{aligned}&\max\left\{\mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(u_l, C_{h_{l-1}}\right), \mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(v_l, C_{h_{l-1}}\right)\right\} \\ &\leq \max\left\{\mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, x) + \mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(x, C_{h_{l-1}}\right), \mathbf{dist}_{G/\mathcal{C}^{(l)}}(v_l, y) + \mathbf{dist}_{G/\mathcal{C}^{(l)}}\left(y, C_{h_{l-1}}\right)\right\} \\ &\leq \left(\frac{15(1+\epsilon)^2 h_l}{2} + 2\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l)\end{aligned}$$

Take an arbitrary vertex $z \in V$ contracted in the node $\mathbf{piv}_{G/\mathcal{C}^{(l)}}(u_l, C_{h_{l-1}})$. Then, applying Lemma 5, we can bound $\mathbf{dist}_G(s, A_{h_{l-1}})$ as:

$$\mathbf{dist}_G(s, A_{h_{l-1}}) \le \mathbf{dist}_G(s,z) \le 4\tau_l \cdot \left(\frac{15(1+\epsilon)^2 h_l}{2} + 2\right) \cdot \mathbf{dist}_{G/\mathcal{C}^{(l)}}(u_l, v_l)$$
$$< 8\alpha^{-l/5} \cdot 8\alpha^l k \cdot \mathbf{dist}_G(s,t) = 64\alpha^{4l/5} k \cdot \mathbf{dist}_G(s,t)$$

Similarly we can prove that $\mathbf{dist}_G(t, A_{h_{l-1}}) < 64\alpha^{4l/5} k \cdot \mathbf{dist}_G(s,t)$.
As $\mathbf{TreeCover}\,(u_{l-1}, v_{l-1}, \mathcal{T}_{l-1})$ successfully returns a nonempty value, by Lemma 10, the path retrieved between u_{l-1}, v_{l-1} in $G/\mathcal{C}^{(l-1)}$ has length at most ($k > 100, \epsilon < 0.1$):

$$2(1+\epsilon)\max\left\{\mathbf{dist}_{G/\mathcal{C}^{(l-1)}}\left(u_{l-1}, B_{h_{l-1}}\right), \mathbf{dist}_{G/\mathcal{C}^{(l-1)}}\left(v_{l-1}, B_{h_{l-1}}\right)\right\}$$
$$\le 2(1+\epsilon) \cdot \max\left\{\mathbf{dist}_G(s, A_{h_{l-1}}), \mathbf{dist}_G(t, A_{h_{l-1}})\right\}$$
$$< 130 \cdot \alpha^{4l/5} k \cdot \mathbf{dist}_G(s,t)$$

Then, applying Lemma 5 again, we can unpack this path and retrieve a path between s, t with weight at most (note that $l > \kappa = 50$ and $\alpha = \frac{3}{4} + \epsilon$):

$$4\tau_l \cdot 130 \cdot \alpha^{4l/5} k \cdot \mathbf{dist}_G(s,t) < 1040 \cdot \alpha^{3l/5} k \cdot \mathbf{dist}_G(s,t) < 10k \cdot \mathbf{dist}_G(s,t)$$

Low-level phase

Next, let us turn to the stretch if the query procedure is in the low-level phase. By the algorithm description, we should assume that the subroutine $\mathbf{TreeCover}\,(u_\iota, v_\iota, \mathcal{T}_\iota)$ returns a nonempty value.

▷ Claim 20. During the binary search procedure on the index pair (i_1, i_2), it always holds that $\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_1}) \le i_1 \cdot \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, v)$. Plus, i_2 is always (u,v)-terminal.

Proof. The second half of the statement is straightforward. So, let us prove the first half by an induction. At the beginning of the algorithm, $i_1 = 0$, and thus $\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_1}) = 0$. In each iteration, if i_3 is (u,v)-terminal, then i_1 does not change, so the induction holds. Otherwise, since $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_3}) \notin \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_3+1})$ and $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_3+1}) \notin \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_3+2})$, we know that by definition of bunches:

$$\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_3+1}) \le \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v) + \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_3})$$

$$\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_{i_3+2}) \le \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v) + \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(v, B_{i_3+1})$$

Hence, $\Delta(u, i_3) \le 2\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v)$. Since $\Delta(u, i_3)$ is the maximum among $\Delta(u,i), i_1 \le i \le j-2$, we know that $\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_j) \le j \cdot \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v)$. ◁

In the end, when the algorithm terminates, we have $i_1 = i_2 = i$. By the above claim, we know that $\mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_i) \le i \cdot \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v)$, and either $i = 2\left\lceil \log^2 k \right\rceil$ or i is (u,v)-terminal. Consider two possibilities.

- $i = 2\left\lceil \log^2 k \right\rceil$.
  In this case, as $\mathbf{TreeCover}(u, v, \mathcal{T}_\iota)$ successfully returned a nonempty value, by Lemma 10, the path length between u, v in $G/\mathcal{C}^{(\iota)}$ reported by our distance oracle is at most:

  $$2(1+\epsilon) \cdot \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u, B_i) < 5\log^2 k \cdot \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v)$$

  If we unpack the clusters in $\mathcal{C}^{(\iota)}$, according to Lemma 5, this path has length at most:

  $$20\tau_\iota \cdot \log^2 k \cdot \mathbf{dist}_G(u,v) < 40k^{1/5}\log^2 k \cdot \mathbf{dist}_G(u,v) < 10k \cdot \mathbf{dist}_G(u,v)$$

- $i < 2\lceil \log^2 k \rceil$.
  In this case, as i is (u,v)-terminal, we know that either $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(u, B_i) \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(v, B_{i+1})$ or $\mathbf{piv}_{G/\mathcal{C}^{(\iota)}}(v, B_{i+1}) \in \mathbf{Bun}_{G/\mathcal{C}^{(\iota)}}(u, B_{i+1})$. Therefore, our data structure can report a path in $G/\mathcal{C}^{(\iota)}$ of length at most $(2i+1) \cdot \mathbf{dist}_{G/\mathcal{C}^{(\iota)}}(u,v)$ between u, v. If we unpack the clusters in $\mathcal{C}^{(\iota)}$, according to Lemma 5, this path has length at most:

$$4\tau_\iota \cdot (2i+1) \cdot \mathbf{dist}_G(u,v) < 10k \cdot \mathbf{dist}_G(u,v)$$

A Missing proofs

▶ **Lemma 21** (restate Lemma 9). *Given an undirected weighted graph $G = (V, E, \mathbf{w})$ and a collection of shortest paths Π, there is a distance-preserving path-reporting data structure that reports any path $\pi \in \Pi$ in time $|\pi|$. The data structure has size $O\left(n + |\Pi| + \sqrt{n|\mathbf{br}(\Pi)|}\right)$ where $\mathbf{br}(\Pi)$ is the set of branching events of Π.*

Proof. First, for any path $\pi \in \Pi$, store both of endpoints in V as well as its first and last edges. Since all paths in Π are shortest paths, there are no two paths sharing the same pair of endpoints. For any path $\pi \in \Pi$, we can identify π with its starting and ending vertex which is denoted by $\mathsf{ID}(\pi)$. This part takes space $O(n + |\Pi|)$.

We will build a routing table data structure $\mathcal{D}_u$ at any vertex $u \in V$. That is, for any path $\pi \in \Pi$ that passes through u through a pair of edges $(v,u),(u,w)$, given the ID of π, the routing data structure $\mathcal{D}_u$ is able to answer the edges $(v,u),(u,w)$ in constant time. Once this is goal is fulfilled, as we have also stored starting and ending edges of each path, our path-reporting distance preserver is complete. For the rest, let us focus on the design of $\mathcal{D}_u$.

For any vertex $u \in V$, let Π_u be the set of paths in Π that pass through u, and for any unordered pairs of different neighbors v, w of u in G, let $\Pi_u^{\{v,w\}}$ be the set of paths that use edges $(v,u),(u,w)$ to go through u, and so $|\Pi_u| = \sum_{v \neq w} \left|\Pi_u^{\{v,w\}}\right|$, and also by definition of branching events, the number of branchings at x is equal to:

$$|\mathbf{br}(\Pi_u)| = \sum_{\{v,w\} \neq \{v',w'\}} \left|\Pi_u^{\{v,w\}}\right| \cdot \left|\Pi_u^{\{v',w'\}}\right| = \frac{1}{2}\left(|\Pi_u|^2 - \sum_{v \neq w}\left|\Pi_u^{\{v,w\}}\right|^2\right)$$

Consider two different cases.

- For any vertex pair v, w, we have $\left|\Pi_u^{\{v,w\}}\right| \leq \frac{1}{2} \cdot |\Pi_u|$.
  In this case, for each path $\pi \in \Pi_u$ using edges $(v,u),(u,w)$, store a triple $(\mathsf{ID}(\pi), v, w)$; all such triples will be stored in a hash table that supports constant-time queries using path IDs.
  As for the space of $\mathcal{D}_u$, on the one hand, it is $O(|\Pi_u|)$. On the other hand, under this condition we have:
  $$|\mathbf{br}(\Pi_u)| = \frac{1}{2}\left(|\Pi_u|^2 - \sum_{v \neq w}\left|\Pi_u^{\{v,w\}}\right|^2\right) \geq \frac{1}{2}\left(|\Pi_u|^2 - \frac{1}{2}|\Pi_u|^2\right) = \frac{1}{4}|\Pi_u|^2$$
  Therefore, $|\mathcal{D}_u| = O\left(\sqrt{|\mathbf{br}(\Pi_u)|}\right)$.
- There exists a vertex pair v_*, w_* such that $\left|\Pi_u^{\{v_*,w_*\}}\right| > \frac{1}{2} \cdot |\Pi_u|$.
  In this case, for each path $\pi \in \Pi_u$ using edges $(v,u),(u,w)$ such that $\{v,w\} \neq \{v_*,w_*\}$, store a triple $(\mathsf{ID}(\pi), v, w)$; all these triples will be stored in a hash table that supports constant-time queries using path IDs. For those paths π which pass through u using edges $(v_*,u),(u,w_*)$, we can query this hash table with $\mathsf{ID}(\pi)$ which returns nothing, and then answer the query with $\{(v_*,u),(u,w_*)\}$.
  As for the size of $\mathcal{D}_u$, on the one hand, its space is $O\left(\Pi_u \setminus \Pi_u^{\{v_*,w_*\}}\right)$. On the other hand, we have:
  $$\begin{aligned}|\mathbf{br}(\Pi_u)| &= \frac{1}{2}\left(|\Pi_u|^2 - \sum_{v \neq w}\left|\Pi_u^{\{v,w\}}\right|^2\right) \geq \frac{1}{2} \cdot \left(|\Pi_u|^2 - \left|\Pi_u^{\{v_*,w_*\}}\right|^2 - \left|\Pi_u \setminus \Pi_u^{\{v_*,w_*\}}\right|^2\right) \\ &\geq \left|\Pi_u^{\{v_*,w_*\}}\right| \cdot \left|\Pi_u \setminus \Pi_u^{\{v_*,w_*\}}\right| \geq \left|\Pi_u \setminus \Pi_u^{\{v_*,w_*\}}\right|^2\end{aligned}$$
  Therefore, we also have $|\mathcal{D}_u| = O\left(\sqrt{\mathbf{br}(\Pi_u)}\right)$

In either case, we are able to show $|\mathcal{D}_u| = O\left(\sqrt{\mathbf{br}(\Pi_u)}\right)$, and so the total size can be bounded by:

$$\sum_{u \in V} |\mathcal{D}_u| \leq \sqrt{n \sum_{u \in V} |\mathcal{D}_u|^2} = O\left(\sqrt{n|\mathbf{br}(\Pi)|}\right)$$ ◀

Robot Positioning Using Torus Packing for Multisets

Abstract

We consider the design of a positioning system where a robot determines its position from local observations. This is a well-studied problem of considerable practical importance and mathematical interest. The dominant paradigm derives from the classical theory of de Bruijn sequences, where the robot has access to a window within a larger code and can determine its position if these windows are distinct. We propose an alternative model in which the robot has more limited observational powers, which we argue is more realistic in terms of engineering: the robot does not have access to the full pattern of colours (or letters) in the window, but only to the intensity of each colour (or the number of occurrences of each letter). This leads to a mathematically interesting problem with a different flavour to that arising in the classical paradigm, requiring new construction techniques. The parameters of our construction are optimal up to a constant factor, and computing the position requires only a constant number of arithmetic operations.

1 Introduction

Consider a robot located on a grid of coloured squares that must determine its position after observing part of the grid through a fixed viewing window. The dominant paradigm for this problem derives from the mathematical theory of de Bruijn sequences, i.e. binary (or bi-coloured) cyclic sequences of length 2^n in which each binary sequence of length n appears exactly once as a subsequence of consecutive entries. Such a sequence can be used for positioning a robot in one dimension: the robot sees a viewing window of length n; this window induces a subsequence with a unique colour pattern; from this colour pattern the robot can then reconstruct its position in the sequence (if we disregard issues of computational efficiency and error correction). Generalisations of this idea to higher dimensions and related combinatorial structures have led to a rich mathematical theory; see Section 1.2.

However, while this theory is mathematically pleasing, we will argue in Section 1.3 that engineering constraints support a model in which the robot does not have access to the full colour pattern in the window, but must infer its position only knowing the intensity of each colour, that is, the multiset of colours. More precisely, given an $n \times n$ grid, a robot with an $m \times m$ viewing window, and a palette of k colours, our task is to colour the grid so that each possible location of the viewing windows produces a different multiset of colours. Furthermore, it will be mathematically more natural to undertake this task for a torus of side n rather than a grid, and also to generalise to an arbitrary dimension d.

► **Example 1.** The grid colouring illustrated in Figure 1 has dimension $d = 2$, size $n = 8$, window size $m = 4$, and $k = 3$ colours (red 0, green 1, and blue 2). No two 4×4 subsquares contain the same multiset of colours. For example, two viewing windows are shown with multisets that have multiplicities for $(0, 1, 2)$ equal to $(6, 2, 8)$ and $(3, 5, 8)$, respectively. Observe that the second window "*wraps around*" because the grid is considered as a torus.

Figure 1 A grid coloring of dimension $d = 2$, size $n = 8$, window size $m = 4$. Observe that the two windows depicted contain distinct multisets of colours.

Our question of study is, given m, d, k, what is the largest grid size n for which position reconstruction is possible? Unfortunately, even the one-dimensional version of this question is the subject of several unsolved problems, discussed in Section 1.2. However, for practical purposes one can be content to relax from finding the optimal n given m, d, k to a value that is optimal up to a constant factor, where we think of d and k as fixed and consider the asymptotics for large m and n. There is a clear information theoretic barrier (see Observation 10) at $n = \Theta_{k,d}(m^{k-1})$, where the subscripts indicate that k and d are constants. The main contribution of this paper is a construction that achieves this theoretical optimum up to a constant factor, and moreover has optimal computational efficiency, in that only a constant number of arithmetic operations are required to compute the location of the window from its multiset of colours. We implemented and tested this construction in Python [13].

1.1 Definitions and Results

Notations. All vectors, tuples and sequences are indexed starting at 0. Integer intervals are denoted with square brackets, such as $[0, n-1]$. Given a length d, the vector $\boldsymbol{e}_i$ has all coordinates equal to 0, except the ith, which is equal to 1. The value of $\mathbb{1}_{\text{condition}}$ is 1 if *condition* is satisfied, and 0 otherwise. We write $i \equiv j \bmod n$ when the integer $i - j$ is divisible by n. Tables are represented with row indices increasing from top to bottom and column indices increasing from left to right, both starting at 0.

We first present general definitions that will be useful for discussing the literature and presenting our construction, starting with *cycle packings* for the one-dimensional case, and continuing with their higher dimensional generalisation, *torus packings*. Then the central objects of this article, *grid colouring*, are formally defined as particular cases of torus packings. Our main result, Theorem 9, is a near-optimal construction for grid colourings. It will make use of *vector sum packings* (Definition 11), which are particular cases of cycle packings.

▶ **Definition 2.** *Given an alphabet $\mathcal{A}$, a size n, a window size m, and a function f on $\mathcal{A}^m$, an $(\mathcal{A}, f, n, m)$-**cycle packing** is a function $W : \mathbb{Z} \mapsto \mathcal{A}$ that satisfies*

- `Periodicity.` *For all $x \in \mathbb{Z}$ we have $W_x = W_{x+n}$.*
- `Injectivity.` *If $f(W_x, W_{x+1}, \ldots, W_{x+m-1}) = f(W_y, W_{y+1}, \ldots, W_{y+m-1})$, for any integers x and y, then $x \equiv y \bmod n$.*

Let us explain this formal definition. Consider a circle composed of n squares, each receiving a letter from $\mathcal{A}$. A robot located on this circle wants to recover its position. It makes a local measurement, function f of the letters in a window of size m around it. The injectivity condition ensures that two positions of the robot (and thus of the window) correspond to two distinct values of f. Thus the robot is always able to deduce its position. Observe that the form of function f matters as different functions induce different types of information that robot can extract from the viewing window. To illustrate this point, consider the following three examples of $(\mathcal{A}, f, n, m)$-cycle packings. These examples all have $\mathcal{A} = \{0, 1, 2\}$ and $m = 3$ but differ in their functions f (which in turn lead to varying sizes of n).

▶ **Example 3.** Take the basic case where f is the identity function. The robot thus receives the entire colour pattern in its viewing window. Thus a cycle packing corresponds to a sequence of length n where all the contiguous subsequences of length m have distinct colour patterns. With $\mathcal{A} = \{0, 1, 2\}$ and window size $m = 3$, we have that $(0, 1, 1, 1, 2, 1, 0, 1, 2, 0, 1, 0, 2, 1, 1, 0, 0, 2, 2, 1, 2, 2, 2, 0, 2, 0, 0)$ is a cycle-packing of size $n = 27$ as each possible string of length 3 appears at most once; thus, the injectivity property holds. In fact, each such string appears *exactly* once (*e.g.* the factor $(0, 0, 0) = f(0, 0, 0)$ appears by wrapping around), making it a de Bruijn sequence. This exactness property is not required for cycle packings, but when it is satisfied the cycle packing is called a *universal cycle*.

▶ **Example 4.** Recall our motivation is that the robot extracts the colour intensities rather than the entire colour pattern. So instead of the identity function, assume that f is the multiset counting function which simply counts the number of appearances of each colour in the viewing window. Now, for the alphabet $\mathcal{A} = \{0, 1, 2\}$ with window size $m = 3$, the sequence $(0, 1, 1, 1, 2, 2, 2, 0, 0)$ is a cycle packing of size $n = 9$ as every multiset appears at most once (*e.g.* the multiset $(3, 0, 0) = f(0, 0, 0)$ arises by wrapping around) and the injectivity property holds. However, this cycle packing is not a universal cycle as no viewing window contains all three colours, so the multiset $(1, 1, 1)$ does not appear.

▶ **Example 5.** Again take $\mathcal{A} = \{0, 1, 2\}$ with window size $m = 3$, but now let f be the summation function. We claim the sequence $(0, 0, 0, 2, 2, 2, 1)$ is a cycle packing of size $n = 7$. To see this, observe that $f(0, 0, 0) = 0 + 0 + 0 = 0$, $f(0, 0, 2) = 0 + 0 + 2 = 2$, etc. Continuing these calculations, the outputted sequence of sums is $(0, 2, 4, 6, 5, 3, 1)$. This has distinct entries, so injectivity is satisfied. The reader may query the relevance of the summation function. In fact, this example is a special case of vector sum packings (Definition 11) which, in turn, will play a critical role in the construction underlying our main theorem.

Of course, our interest lies in dimension $d > 1$, so we now extend the definition of cycle packings to higher dimensions.

▶ **Definition 6.** *Given an alphabet $\mathcal{A}$, a size n, a window size m, a dimension d, and a function f on $\mathcal{A}^{m^d}$, an $(\mathcal{A}, f, n, m, d)$-**torus packing** is a function $W : \mathbb{Z}^d \mapsto \mathcal{A}$ that satisfies*

- `Periodicity`. *For all $\boldsymbol{x} \in \mathbb{Z}^d$ and $j \in [0, d-1]$, we have $W_{\boldsymbol{x}} = W_{\boldsymbol{x}+n\boldsymbol{e}_j}$ where $\boldsymbol{e}_j$ denotes the vector with a 1 in position j and 0 elsewhere.*
- `Injectivity`. *For any $\boldsymbol{x}$ and $\boldsymbol{y}$ in $\mathbb{Z}^d$, if $f\left((W_{\boldsymbol{x}+\boldsymbol{c}})_{\boldsymbol{c}\in[0,m-1]^d}\right) = f\left((W_{\boldsymbol{y}+\boldsymbol{c}})_{\boldsymbol{c}\in[0,m-1]^d}\right)$, then $x_j \equiv y_j \bmod n$ for all j (where x_j denote the jth coordinate of the vector $\boldsymbol{x}$).*

Note the key distinction in this definition is that the viewing window shares the same higher dimension as the torus. Again, by the periodicity property, we can identify a torus packing W with its pattern $(W_{\boldsymbol{x}})_{\boldsymbol{x}\in[0,n-1]^d}$. We are now ready to define the central objects of this paper. These are grid colourings, a particular case of torus packing that correspond exactly to the robot position reconstruction problem.

▶ **Definition 7.** *An (n, m, d, k)-**grid colouring** is an $(\mathcal{A}, f, n, m, d)$-torus packing with $|\mathcal{A}| = k$ and f mapping any sequence to the multiset of its entries.*

▶ **Example 8.** Consider, again, our example in Figure 1. This is an $(\mathcal{A}, f, n, m, d)$-torus packing with $\mathcal{A} = \{0, 1, 2\}$, $n = 8$, $m = 4$, $d = 2$ and where f is the multiset counting function. Consequently, since $|\mathcal{A}| = 3$, this is an $(8, 4, 2, 3)$-grid colouring.

The following is our main result on grid colourings, implemented and tested in Python [13].

▶ **Theorem 9.** *Fix a dimension $d \geq 2$ and a number of colours k of the form $bd+1$ for some $b \geq 1$. For any window size m multiple of $2(k-1)$, there is an (n, m, d, k)-grid colouring W (explicitly constructed in the proof) with*

$$n \sim C_k^{1/d} \cdot m^{k-1} \qquad \text{where} \qquad C_k = \left(\frac{2}{k-1}\right)^{k-1}.$$

Furthermore, for any $\boldsymbol{x}$ in $\mathbb{Z}^d$, given the multiset of colours in $(W_{\boldsymbol{x}+\boldsymbol{c}})_{\boldsymbol{c}\in[0,m-1]^d}$ one can compute $\boldsymbol{x}$ mod n with $O_{k,d}(1)$ arithmetic operations.

Our construction in Theorem 9 of size $n = \Omega_{k,d}(m^{k-1})$ is optimal up to a multiplicative constant. This fact follows from the following observation, which is immediate from counting considerations (injectivity requires the number of possible colour multisets to be at least the number of windows that they must distinguish).

▶ **Observation 10.** *The parameters of any (n, m, d, k)-grid colouring satisfy the inequality*

$$n^d \leq \binom{m^d + k - 1}{k - 1}.$$

In particular, for fixed dimension d and number of colours k, as the window size m tends to infinity, we have

$$n \leq C_k'^{1/d} \cdot m^{k-1}(1 + \mathcal{O}(m^{-1})) \qquad \text{with} \qquad C_k' = \frac{1}{(k-1)!}.$$

We conclude this section by discussing related work and providing technological justifications for our positioning model.

1.2 Related Work

The combinatorial structures associated with torus packings (Definition 6) have a rich mathematical literature, starting from a problem solved in the 19th century, independently rediscovered by de Bruijn and now known as *de Bruijn sequences* (see [12]). The generalisation to higher dimensions was independently considered in several papers starting from the 1960's (see [24]) and has developed an extensive literature (see *e.g.* [17, 18, 20]) under the name of *de Bruijn tori*. The extension to general combinatorial structures encoded by sequences as in Definition 6 was proposed by Chung, Graham and Diaconis [9], who considered the one-dimensional problem ("*universal cycles*") for a variety of combinatorial structures. These early formulations of the problem generally asked for optimal solutions in which every object in a given combinatorial class is realised exactly once; in the context of Definition 6 this corresponds to strengthening injectivity to bijectivity. However, for practical purposes one can be satisfied with approximately optimal solutions, and given the difficulty of finding optimal solutions there is also a substantial literature (see *e.g.* [3, 10, 11]) finding approximate solutions from the perspective of packing (injectivity) and covering (surjectivity).

For the multiset encoding problem considered in this paper, finding the exact optimum is an open problem even for the one-dimensional setting of universal cycles, considered by Knuth [21, Fascicle 3, Section 7.2.1.3, Problem 109]. Hurlbert *et al.* [19] construct universal cycles for multisets with particular parameters, and Blanca and Godbole [3] consider the problem when the multisets have bounded multiplicities. Furthermore, the known results only consider the opposite regime of parameters from those needed for our application: we consider small palettes of colours (*a.k.a.* alphabets) and a large window, whereas previous techniques in the literature only apply to small windows and large alphabets. This comment also applies to the problem replacing "multiset" by "set", which is perhaps even more natural mathematically, given that it can be viewed as a hypergraph version of the Euler tour problem (introduced by Euler in the 18th century). Following many partial results, an exact solution to this problem (for small windows and large alphabets) was found by Glock *et al.* [14], solving a conjecture from Chung *et al.* [9]. We are unaware of any results in the literature on multiset packing in one dimension (meaning maximizing the number of multisets that appear in a sequence, rather than looking for sequences that contain all possible multisets).

Moving on from the abstract mathematical problem, we now consider some of the computer science literature aimed towards the specific application of indoor positioning. Much of the early work was surveyed by Burns and Mitchell [5]. More recent literature (see *e.g.* [2, 4, 6, 25]) has emphasised two further conditions that do not appear in the mathematical formulation but are naturally desirable for practical implementations: namely (a) computational efficiency, and (b) robustness against measurement errors. These works bring a variety of techniques from coding theory to bear on the positioning problem, providing efficient positioning algorithms with error correction. However, while these algorithms make natural use of an existing toolkit and are conceptually pleasing, we will argue that they are not addressing the most appropriate formulation of the problem from the point of view of the target application of robot positioning, for which a new paradigm is needed.

1.3 Motivation and Engineering Aspects

The focus of this paper is theoretical, concerning near-optimal designs for elegant combinatorial structures, namely torus packings. However, as stated, our motivation derives from the problem of position reconstruction (where the dimension is 2 and the torus of is considered a square). The vast number of applications of localization and positioning have prompted the design of a plethora of systems; see [31] and references therein.

Given the great practical importance of positioning systems, it behoves us to justify our claim that the approporiate way to model them is with multiset counting functions. We do this in this section by summarising two systems where our code (and variants of it) will be useful.

Light-Based Positioning. Recently, visible light based positioning systems have gained much attention [23, 26, 31] for two key reasons: (i) there is a strong demand for accurate but low-cost solutions, and (ii) there have been breakthroughs in the energy consumption and life expectancy of light-emitting diodes (LEDs). Contrary to systems requiring several light emitters and relying on triangulation [26], systems based on universal torus packing (such as de Bruijn torus [1, 27, 28] and our construction) rely on only one light source, reducing cost and energy consumption. Consider a room lit by a light-emitting diode (LED). A robot moving on the floor wears a light sensor or camera. A printed film is placed on top of the robot, above this sensor. The film is printed with a coloured grid, distorted so that depending on the position of the robot in the room, the light coming from the LED projects a square window of the coloured grid on the sensor [16]. If the coloured grid code depends on the respective positions of the colours (such as de Bruijn torus), the light detector must be a camera [22, 30] to recognize the pattern. If a torus packing for multisets is used instead, the robot can wear a simple light intensity sensor to recover the multiset of colours: the pattern of the colours is not needed, and we side-step the problematic issue of resolving the image. Such a device is considerably less expensive and has much shorter response time (lower latency) than a camera. It should be noted that the total light intensity (number of coloured rays) received by the detector depends on the position and also the orientation of the robot. Thus, for practical application of the construction presented in this article some redundancy should be added to allow for a unique position decoding in all cases. Positioning systems based on a de Bruijn torus also require redundancy to correct errors [6] and allow different orientations of the receiver [29]. We plan to explore redundancy in universal torus packing for multisets in future work.

Ambient Backscatters. An ambient backscatter is a small and inexpensive device that, upon reception of a radio wave, turns it into electricity and sends back data through a radio signal. Consider a warehouse where ambient backscatter devices are regularly placed, forming a grid. A robot with a radio emitter and receptor needs to locate itself in the warehouse. Each backscatter device, when in reach of the emitted radio wave, sends back its identification number (ID). If all devices have distinct IDs, the robot can determine its position based on the signals it receives. However, in the interest of energy consumption, IDs composed of few bits are preferred [7]. The same ID can be reused by several devices, provided that at any position, the multiset of IDs detected by the robot is unique. The relative position of the robot to its neighbouring backscatter devices is unknown, so the IDs should be chosen following a universal torus packing for multisets (a de Bruijn torus would require the robot to have directional antennas, making the system less practical and more expensive). For this application, our construction should be adapted to account for radial symmetry and decay of signal power in the detection window.

2 Overview

We have reduced the position reconstruction problem to the design of grid colourings. Consequently our main result, Theorem 9, is based upon an near-optimal grid colouring construction. A key building block in this construction will be the following family of cycle packings, which we call vector sum packings.

▶ **Definition 11.** *Given positive integers n, m, b and s, an (n, m, b, s)-**vector sum packing** is an $(\mathcal{A}, f, n, m)$-cycle packing with $\mathcal{A} = [0, s]^b$ and $f(\boldsymbol{z}_0, \ldots, \boldsymbol{z}_{m-1}) = \boldsymbol{z}_0 + \cdots + \boldsymbol{z}_{m-1}$.*

▶ **Example 12.** For the special case of *vector dimension* $b = 1$ we have already encountered a $(8, 3, 1, 2)$-vector sum packing in Example 5.

▶ **Example 13.** Let us see an example of a vector sum packing with vector dimension $b = 3$. Set $m = 2$, $s = 1$, $n = 8$ and $(\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_7) = \left(\begin{pmatrix}0\\0\\0\end{pmatrix}, \begin{pmatrix}1\\0\\0\end{pmatrix}, \begin{pmatrix}0\\1\\0\end{pmatrix}, \begin{pmatrix}0\\0\\0\end{pmatrix}, \begin{pmatrix}0\\0\\1\end{pmatrix}, \begin{pmatrix}1\\0\\0\end{pmatrix}, \begin{pmatrix}0\\1\\1\end{pmatrix}, \begin{pmatrix}0\\0\\0\end{pmatrix}\right)$. Then $f(\boldsymbol{z}_0, \boldsymbol{z}_1) = \begin{pmatrix}1\\0\\0\end{pmatrix}$, $f(\boldsymbol{z}_1, \boldsymbol{z}_2) = \begin{pmatrix}1\\1\\0\end{pmatrix}$, $f(\boldsymbol{z}_2, \boldsymbol{z}_3) = \begin{pmatrix}0\\1\\0\end{pmatrix}$, $f(\boldsymbol{z}_3, \boldsymbol{z}_4) = \begin{pmatrix}0\\0\\1\end{pmatrix}$, $f(\boldsymbol{z}_4, \boldsymbol{z}_5) = \begin{pmatrix}1\\0\\1\end{pmatrix}$, $f(\boldsymbol{z}_5, \boldsymbol{z}_6) = \begin{pmatrix}1\\1\\1\end{pmatrix}$, $f(\boldsymbol{z}_6, \boldsymbol{z}_7) = \begin{pmatrix}0\\1\\1\end{pmatrix}$, and $f(\boldsymbol{z}_7, \boldsymbol{z}_0) = \begin{pmatrix}0\\0\\0\end{pmatrix}$. As these sums all differ, the injectivity property holds and we have a vector sum packing.

The strategy of our construction is encapsulated in the following two key lemmas (proven in Section 3 and Section 4, respectively). The first reduces the construction of a grid colouring to the construction of a vector sum packing.

▶ **Lemma 14.** *Consider a dimension d, size n, window size m, and number of colours k, and assume the existence of integers b and s satisfying $k = bd + 1$ and $s = \frac{m^{d-1}}{bd}$. Then the existence of an (n, m, b, s)-vector sum packing implies the existence of a (n, m, d, k)-grid colouring.*

Given Lemma 14, the final piece in the puzzle is a construction of vector sum packings.

▶ **Lemma 15.** *For any $s \geq 1$, $m \geq 2$ and $b \geq 1$, there exists an $(n_b, m, b, 2s)$-vector sum packing with*

$$n_b = (2ms + 1)^{b-1}\left(2ms - \frac{1}{s}\right) + \frac{1}{s}.$$

To deduce the existence of the construction for Theorem 9, we combine Lemmas 14 and 15, choosing m as a large multiple of $2bd$, with $k = bd + 1$ and $s = \frac{m^{d-1}}{2bd}$. Then the value of n_b in Lemma 15 satisfies $n_b \sim \left(\frac{2}{k-1}\right)^{(k-1)/d} m^{k-1}$ for large m. We will prove in Corollary 22 that the position can be computed with a constant number of arithmetic operations.

We remark that the vector sum packing problem is related to the combinatorial theory of *antimagic labellings* (a natural variant on the classic topic of *magic labellings*) in which one is required to label the edges (or vertices) of a graph (or hypergraph) from a given set of integers (or vectors) so that vertices (or edges) are uniquely determined by the sum of their incident labels. A well-known conjecture of Ringel (cited in [15]) states that for any connected graph with $m > 1$ edges there is an antimagic labelling of its edges by $\{1, \ldots, m\}$. It appears that this connection has not previously been exploited and may be fruitful for further research.

3 From Vector Sum Packing to Grid Colouring

The aim of this section is to prove Lemma 14, which reduces the grid colouring problem to the vector sum packing problem.

3.1 The Separation Property

In this section, we consider a fixed dimension $d \geq 2$, window size $m \geq 2$ and grid size $n \geq m$. For $\boldsymbol{x} \in \mathbb{Z}^d$, let us define the *window* of corner $\boldsymbol{x}$ as the set of points

$$\text{Window}(\boldsymbol{x}) = \{\boldsymbol{x} + \boldsymbol{c} \mid \boldsymbol{c} \in [0, m-1]^d\}.$$

For the grid colouring problem, we require that the coordinates of each point $\boldsymbol{x}$ are uniquely determined modulo n by the multiset of colours of the points from $\text{Window}(\boldsymbol{x})$. This multiset is denoted by $\text{colourMultiset}(\boldsymbol{x})$, and the colour of the point $\boldsymbol{x}$ is denoted by $\text{colour}(\boldsymbol{x})$.

We now present a sufficient condition, called *separation*, that guarantees this property. Each colour is represented as a pair (pigment, shade). We divide the set of colours into d pigment classes, one pigment class C_i for each dimension $i \in [0, d-1]$. Each pigment class contains b shades. Thus $C_i = \{c_{i,0}, c_{i,1}, \ldots, c_{i,b-1}\}$ where if i is the green pigment, say, then $c_{i,0}$ represents very light green and $c_{i,b-1}$ represents very dark green. The idea now is that for each square $\boldsymbol{x} \in \mathbb{Z}^d$, the coordinate x_i modulo n is uniquely determined by the pigment class C_i, for each $i \in [0, d-1]$, precisely by $\text{colourMultiset}(\boldsymbol{x}) \cap C_i$. In particular, x_i is independent of any other pigment class $j \neq i$ on $\text{Window}(\boldsymbol{x})$, for example, shades of red. Evidently, this separation property implies that if $\boldsymbol{x}$ and $\boldsymbol{y}$ have the same colour multiset for every pigment class then $x_i \equiv y_i \bmod n$ for each $i \in [0, d-1]$ and, hence, $\boldsymbol{x} \equiv \boldsymbol{y} \bmod n$. Thus the separation property implies that we have a proper grid colouring.

Rather than working directly with separation, it will be convenient to consider the following two further conditions that together clearly imply separation.

`Dimensional Inconsistency`: Given $\boldsymbol{x}$ and $\boldsymbol{y}$, if $x_i \neq y_i \bmod n$ then

$$\text{colourMultiset}(\boldsymbol{x}) \cap C_i \neq \text{colourMultiset}(\boldsymbol{y}) \cap C_i.$$

`Anti-Dimensional Consistency`: Given $\boldsymbol{x}$ and $\boldsymbol{y}$, if $x_i = y_i \bmod n$ then

$$\text{colourMultiset}(\boldsymbol{x}) \cap C_i = \text{colourMultiset}(\boldsymbol{y}) \cap C_i.$$

To ensure anti-dimensional consistency it will be convenient to focus on the following condition called *quasi-periodicity*, which states that if some $\boldsymbol{x}$ is coloured a shade of pigment i then any translate $\boldsymbol{y}$ of $\boldsymbol{x}$ by distance m in any dimension other than i has the same colour as $\boldsymbol{x}$

$$\forall i \neq j, \text{ if } \text{colour}(\boldsymbol{x}) \in C_i \text{ then } \text{colour}(\boldsymbol{x} + m\,\boldsymbol{e}_j) = \text{colour}(\boldsymbol{x}).$$

▶ **Lemma 16.** *Any quasi-periodic grid colouring satisfies anti-dimensional consistency.*

Proof. Take a quasi-periodic colouring. It suffices to show, given x_i, that $\text{colourMultiset}(\boldsymbol{x}) \cap C_i$ is fixed. This will hold if the number of squares of colour $c_{i,\ell}$ in a window does not change if we translate by one square in any dimension j other than i. Let us define

$$A = \text{Window}(\boldsymbol{x}) \setminus \text{Window}(\boldsymbol{x} + \boldsymbol{e}_j), \qquad B = \text{Window}(\boldsymbol{x} + \boldsymbol{e}_j) \setminus \text{Window}(\boldsymbol{x}).$$

Since B is obtained from A by translation by $m\boldsymbol{e}_j$, quasi-periodicity implies that the number of points of colour $c_{i,\ell}$ in A and B are equal. Thus, the number of points of colour $c_{i,\ell}$ in $\text{Window}(\boldsymbol{x})$ and $\text{Window}(\boldsymbol{x} + \boldsymbol{e}_j)$ are equal as well. As this argument applies for any $j \neq i$, the anti-dimensional consistency property holds. Thus, quasi-periodicity implies anti-dimensional consistency. ◀

3.2 Separation via Vector Sum Packing

Assume we have an (n, m, b, s)-vector sum packing $(\boldsymbol{z}_j)_{j\in\mathbb{Z}}$ of size n and window size m, containing vectors in $[0, s]^b$, where s is a positive integer equal to $\frac{m^{d-1}}{bd}$ for some dimension $d \geq 2$. We will now construct a (n, m, d, k)-grid colouring with number of colours $k = bd + 1$. We detail our algorithm below and illustrate it in Figure 2. As we saw in the previous section, to ensure the separation condition, it is sufficient that our grid colouring satisfies dimensional inconsistency and quasi-periodicity.

(a) We begin with an initial colouring of the grid using only d pigments, each coming in b different shades. Take a pigment $i \in [0, d-1]$ and shade $h \in [0, b-1]$. Then the point $\boldsymbol{x} = (x_0, \ldots, x_{d-1})$ has pigment i and shade h if and only if

$$\sum_{j=0}^{d-1} x_j \equiv i + hd \bmod bd.$$

This initial colouring is quasi-periodic. But, of course, it does not satisfy dimensional inconsistency. To rectify this, we will apply the last unused colour, which we call *blank*, to erase some colours from the initial colouring.

(b) Consider a dimension $i \in [0, d-1]$. We associate to it the pigment i and the set C_i of the corresponding b shades. For each $j \in \mathbb{Z}$, let

$$B_{i,j} = \{\boldsymbol{x} \mid x_i = j \text{ and } \forall \ell \neq i,\ x_\ell \in [0, m-1]\}.$$

We apply the blank colour to erase some of the colours from $B_{i,j}$, so that the number of points of shade $c_{i,\ell}$ is equal to the ℓth component of $\boldsymbol{z}_j$. This is always possible, because in the initial colouring, $B_{i,j}$ contains $s = \frac{m^{d-1}}{bd}$ occurrences of shade $c_{i,\ell}$, and the values of the vectors from the vector sum packing are all in $[0, s]$.

(c) We apply quasi-periodicity to reproduce this construction on the rest of the grid. Specifically, point $\boldsymbol{x} = (x_0, \ldots, x_{d-1})$ of pigment i and shade h in the initial colouring is erased if and only if the point $\boldsymbol{y}$ with $y_i = x_i$ and for all $j \neq i$, $y_j = x_j \bmod m$ was erased at step (b).

The injectivity of the vector sum packing implies the dimensional inconsistency of our grid colouring. By construction, our grid colouring is quasi-periodic, so by Lemma 16, it satisfies the separation property, concluding the proof of Lemma 14.

3.3 An Example

An illustration of the proof of Lemma 14 is given in Figure 2 on a grid of dimension $d = 2$, size $n = 8$, window size $m = 4$, number of colours $k = 3$. To create the grid-colouring we use the vector sum packing $(\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_7) = (0, 0, 0, 0, 2, 2, 2, 1)$ (note each vector has dimension 1, so is represented by its content). In particular, $s = 2$ and $b = 1$; note that $k = bd + 1$ and $s = \frac{m^{d-1}}{bd}$. Recall, the aim is that number of occurrences of 0 (*resp.* 1) in a 4 by 4 square characterizes its row (*resp.* column) number. Following the proof of Lemma 14, we start with a periodic colouring, represented in (a). We now use the blank colour 2 to erase some of the 0. First, in (b), we erase entries in the first 4 columns so the number of occurrences of 0 in these columns for the eight rows are $(0, 0, 0, 0, 2, 2, 2, 1)$. Second in (c), we apply quasi-periodicity on the rest of the grid. Next, in (d) and (e), we apply the same approach to erase some of the 1. The final result is (e). No two 4×4 subsquares contain the same multiset of colours.

Let us now illustrate how this grid is used for localization. Recall that our convention is to number the rows from top to botton, and column from left to right, both starting at 0. Assume we are measuring in a window (*i.e.* a 4×4 subsquare) the multiset of colors

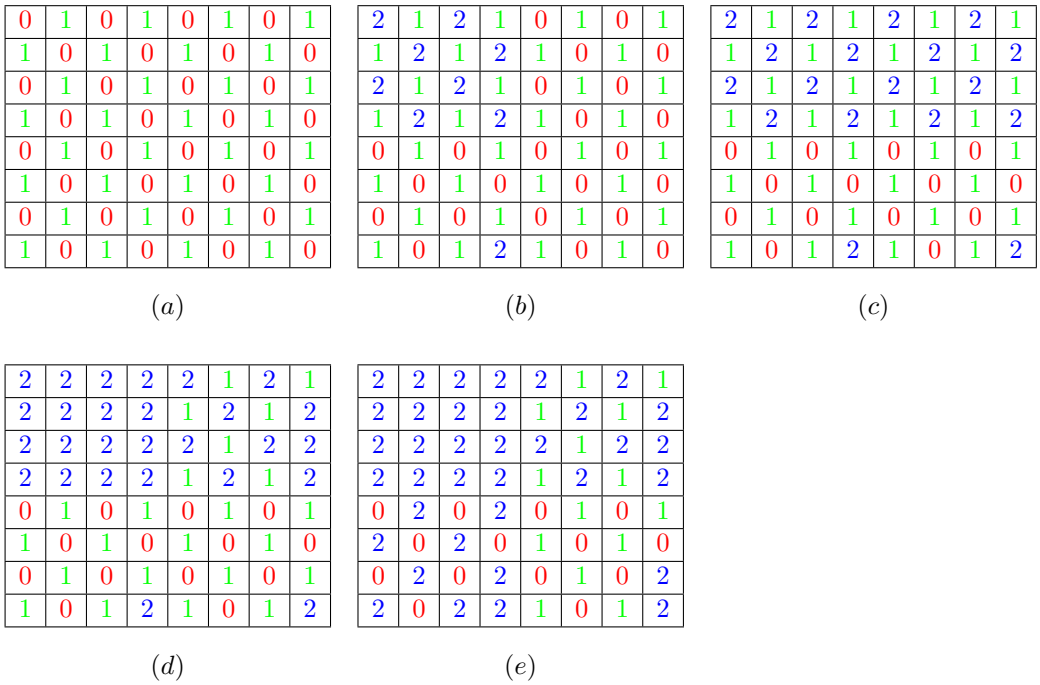

Figure 2 Illustration of the steps of the proof of Lemma 14 on a grid of dimension $d = 2$, size $n = 8$, window size $m = 4$, number of colours $k = 3$.

containing 5 occurrences of 0, 3 occurrences of 1 and 8 occurrences of 2. We wish to locate this window in the grid (e). The naive algorithm is to consider each possible window in the grid and compare the multisets of colors. This becomes costly for large grids, so we present a more efficient algorithm. By convention, color 0 is used to determine the row. Looking at the vector sum packing $(0, 0, 0, 0, 2, 2, 2, 1)$, we observe that the sequence whose jth element is the sum of $m = 4$ consecutive elements starting at position j, is $(0, 2, 4, 6, 7, 5, 3, 1)$. The number 5 is located at position 5 in this sequence, so the upper-left corner of the window we are seeking has row number 5. To determine the column, we consider the color 1. Its number of occurrence 3 has position 6 in $(0, 2, 4, 6, 7, 5, 3, 1)$, so the column number is 6. On the torus (e), the 4×4 subsquare with top left corner in row 5 and column 6 indeed contains 5 occurrences of 0, 3 occurrences of 1 and 8 occurrences of 2.

Observe that for any fixed dimension, the localization problem in the grid reduces in constant complexity to the problem of computing the position of a vector in a vector sum packing. We call this second problem *decoding*. In the next section, we will present our construction for vector sum packings, as well as a decoding algorithm with constant complexity (in the number of arithmetic operations, as the dimension d and parameter b, defined there, are fixed).

A grid colouring of size 256, window size 8, and 5 colours is presented in the appendix.

4 Vector Sum Packing

This section presents our construction of vector sum packings, thus proving Lemma 15, which is the last missing ingredient for the proof of our main result Theorem 9.

4.1 Profiles and Duals

To build vector sum packings (see Definition 11), we introduce certain integer sequences that we call *profiles*. Profiles with different parameters will be used to fill the coordinates of the vector sum packing, in Lemma 21.

The *m-dual* of a profile w is an integer sequence of same length $|w|$, defined as the sum of the elements of w on a cycling window of length m

$$\mathrm{Dual}_m(w) = \left(\sum_{j=i}^{i+m-1} w_{i \bmod |w|} \right)_{i \in [0,|w|-1]}.$$

Consider integers $s \geq 1$ and $m \geq 2$. Let us write sequences of length 1 as (σ) and sequences of length m as $(\sigma_0, \sigma_1, \ldots, \sigma_{m-1})$. For a finite sequence L and a nonnegative integer T, the sequence obtained by concatenating T copies of L one after the other is denoted by L^T. Let $\emptyset$ denote the emptysequence, and let $a \cdot b$ denote the concatenation of the sequences a and b, so $(1,2,3) \cdot (4)$ is equal to $(1,2,3,4)$. In the following tables, the rows and columns are numbered starting at 0, in red. Straight lines have been added between some of the rows to distinguish parts of the tables following different rules.

Let us define the sequence $\mathrm{Profile}(s,m,0)$ as the concatenation of the cells from the following table, read line by line from top left to bottom right.

	0	1	2	$\cdots$	$s-1$
0	$(0,\ldots,0)$	$(2,\ldots,2)$	$(4,\ldots,4)$	$\cdots$	$(2s-2,\ldots,2s-2)$
1	$(2s,\ldots,2s,2s-1)$	$(2s-2,\ldots,2s-2,2s-3)$	$(2s-4,\ldots,2s-4,2s-5)$	$\cdots$	$(2,\ldots,2,1)$

For example, we have $\mathrm{Profile}(1,3,0) = (0,0,0,2,2,1)$ and $\mathrm{Profile}(2,2,0) = (0,0,2,2,4,3,2,1)$.

▶ **Lemma 17.** $\mathrm{Profile}(s,m,0)$ *has length* $2ms$*. Furthermore, its* m*-dual is*

$$\mathrm{Dual}_m(\mathrm{Profile}(s,m,0)) = (0,2,4,\ldots,2ms-2,2ms-1,2ms-3,2ms-5,\ldots,1).$$

Proof. $\mathrm{Profile}(s,m,0)$ has length $2ms$ because each entry in the table is a sequence of cardinality m and there are $2s$ entries in the table. The reader may easily verify that the m-dual begins with non-negative even numbers increasing up to $2ms-2$ followed by positive odd numbers decreasing down from $2ms-2$. Thus, the m-dual contains every integer in $[0, 2m-1]$ exactly once. ◀

Let us define the $(s,m,0)$-decoding function as the function that associates to an integer v its smallest index in the m-dual of $\mathrm{Profile}(s,m,0)$. For example, the $(2,2,0)$-decoding function sends 6 to 3, because the 2-dual of $\mathrm{Profile}(2,2,0) = (0,0,2,2,4,3,2,1)$ is $(0,2,4,6,7,5,3,1)$, where the first (and only) occurrence of 6 is at position 3.

▶ **Corollary 18.** *The* $(s,m,0)$*-decoding function is*

$$v \mapsto \begin{cases} \frac{v}{2} & \text{if } v \text{ is even,} \\ 2ms - 1 - \frac{v-1}{2} & \text{if } v \text{ is odd.} \end{cases}$$

It is computable in a constant number of arithmetic operations.

For any positive integer T and $m \geq 2$, let us define the sequence Profile(s, m, T) as the concatenation of the cells from the following table.

	0	1	2	$\cdots$	$s-1$
0	$(0,\dots,0,0)^T$	$(0,\dots,0,2)^T$	$(0,\dots,0,4)^T$	$\cdots$	$(0,\dots,0,2s-2)^T$
1	$(0,\dots,0,0,2s)^T$	$(0,\dots,0,2,2s)^T$	$(0,\dots,0,4,2s)^T$	$\cdots$	$(0,\dots,0,2s-2,2s)^T$
$\vdots$	$\vdots$	$\vdots$			$\vdots$
$m-1$	$(0,2s,\dots,2s,2s)^T$	$(2,2s,\dots,2s,2s)^T$	$\cdots$	$\cdots$	$(2s-2,2s,\dots,2s)^T$
m	$(2s)^{mT-1}$	$(2s-1,2s,\dots,2s)^T$	$(2s-3,2s,\dots,2s)^T$	$\cdots$	$(3,2s,\dots,2s)^T$
$m+1$	$(1,2s,2s,\dots,2s)^{T-1}$	$(1,2s,\dots,2s,2s-2)^T$	$(1,2s,\dots,2s,2s-4)^T$	$\cdots$	$(1,2s,\dots,2s,2)^T$
$m+2$	$(1,2s,\dots,2s,0)^T$	$(1,2s,\dots,2s-2,0)^T$	$(1,2s,\dots,2s,2s-4,0)^T$	$\cdots$	$(1,2s,\dots,2s,2,0)^T$
$\vdots$	$\vdots$	$\vdots$			$\vdots$
$2m-1$	$(1,2s,0,\dots,0)^T$	$(1,2s-2,0,\dots,0)^T$	$\cdots$	$\cdots$	$(1,2,0,\dots,0)^T$
$2m$	$(1,0,\dots,0)^{T-1}\cdot(1)$	$\emptyset$	$\emptyset$	$\cdots$	$\emptyset$

▶ **Lemma 19.** *For any $m \geq 2$,* Profile(s, m, T) *has length $m((2ms+1)T-2)$. Furthermore, its m-dual is obtained by concatenation of the cells of the following table*

	0	1	2	$\cdots$	$s-1$
0	$(0)^{mT}$	$(2)^{mT}$	$(4)^{mT}$	$\cdots$	$(2s-2)^{mT}$
1	$(2s)^{mT-1}$	$(2s+2)^{mT}$	$(2s+4)^{mT}$	$\cdots$	$(4s-2)^{mT}$
2	$(4s)^{mT-1}$	$(4s+2)^{mT}$	$(4s+4)^{mT}$	$\cdots$	$(6s-2)^{mT}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$		$\vdots$
$m-1$	$(2(m-1)s)^{mT-1}$	$(2(m-1)s+2)^{mT}$	$(2(m-1)s+4)^{mT}$	$\cdots$	$(2ms-2)^{mT}$
m	$(2ms)^{mT-1}$	$(2ms-1)^{mT}$	$(2ms-3)^{mT}$	$\cdots$	$(2(m-1)s+3)^{mT}$
$m+1$	$(2(m-1)s+1)^{mT-1}$	$(2(m-1)s-1)^{mT}$	$(2(m-1)s-3)^{mT}$	$\cdots$	$(2(m-2)s+3)^{mT}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$		$\vdots$
$2m-1$	$(2s+1)^{mT-1}$	$(2s-1)^{mT}$	$(2s-3)^{mT}$	$\cdots$	$(3)^{mT}$
$2m$	$(1)^{mT-1}$	$\emptyset$	$\emptyset$	$\cdots$	$\emptyset$

Proof. In the table, there are $2ms-2$ cells containing sequences of length mT, one cell containing a sequence of length $mT-1$, one cell containing a sequence of length $m(T-1)$ and one celle containing a sequence of length $m(T-1)+1$, so Profile(s, m, T) has length

$$(2ms-2)mT + mT - 1 + m(T-1) + m(T-1) + 1 = mT(2ms+1) - 2m$$

as desired. Again, the reader may verify that the m-dual begins with non-negative even numbers increasing up to $2ms$ followed by positive odd numbers decreasing down from $2ms-1$ (repeated in the quantities specified). ◀

We define the (s, m, T)-decoding function as the function that associates to an integer v its smallest index in the m-dual of Profile(s, m, T).

▶ **Corollary 20.** *The (s, m, T)-decoding function output on the input v is computed using the following algorithm. If v is even, we define $r = \lfloor \frac{v}{2s} \rfloor$ and $c = \frac{v}{2} \bmod [s]$. They represent the row and column in the m-dual from Lemma 19. Then the output of the decoding function is*

$$(r\,m\,T\,s - r + 1)\mathbb{1}_{r>0} + (c\,m\,T - 1 + \mathbb{1}_{r=0})\mathbb{1}_{c>0}.$$

Otherwise, v is odd and we define $r = \lfloor \frac{2\,m\,s-v+1}{2s} \rfloor$ and $c = \frac{2\,m\,s-v+1}{2} \bmod s$. The output is then

$$1 + m(m\,T\,s - 1) + (m\,T\,s\,r - r)\mathbb{1}_{r>0} + (c\,m\,T\ - 1)\mathbb{1}_{c>0}.$$

It is computable in a constant number of arithmetic operations.

4.2 Generating a Vector Sum Packing

We will explicitly construct the vector sum packing by combining profiles, thus proving Lemma 15.

Recall that an (n, m, b, s)-vector sum packing is characterised by its pattern $(\boldsymbol{z}_0, \ldots, \boldsymbol{z}_{n-1})$ where each $\boldsymbol{z}_i$ is a vector in $[0, s]^b$. These vectors will be defined as the columns of a matrix $M^{(b)}$. Furthermore, the rows of this matrix will be constructed using sequences given by the Profile(s, m, T).

The matrix $M^{(b)}$ will have b rows and $m \cdot T_b = n_b$ columns. Specifically, given $s \geq 1$ and $m \geq 2$, we set $T_0 = 0$ and $T_1 = 2s$. Then, for each $b \geq 1$, we recursively set

$$T_{b+1} = (2ms + 1)T_b - 2.$$

Thus we obtain the dimensions of our $M^{(b)}$ matrices. To fill in the entries of the matrices we again apply a recursive construction.

- For $b = 1$, the matrix $M^{(1)}$ has only one row, which is identical to the sequence Profile$(s, m, 0)$. We remark that $M^{(1)}$ does indeed have $n_1 = m \cdot T_1 = 2ms$ columns, as required by Lemma 17.
- Next consider the case $b \geq 2$. The basic idea is that $M^{(b)}$ should simply be the concatenation on $2ms + 1$ copies of $M^{(b-1)}$, plus an additional row identical to the sequence Profile(s, m, T_{b-1}), which will be used to distinguish between the different copies.

However, this basic idea does not scale correctly, so instead of concatenating identical copies of $M^{(b-1)}$, we also concatenate truncated copies of $M^{(b-1)}$. Specifically, we allow for the truncated matrix $M^{(b-1,\star)}$ which is identical to $M^{(b-1)}$ except that its first column is removed.

We now set $M^{(b)} = M^{(b-1,0)} \circ M^{(b-1,2)} \circ \cdots \circ M^{(b-1,2ms)} \circ M^{(b-1,2ms-1)} \circ \cdots \circ M^{(b-1,1)})$, where each $M^{(b-1,\ell)}$ is either $M^{(b-1)}$ or $M^{(b-1,\star)}$ and where $\circ$ denotes the concatenation operation. Thus, it remains, to prescribe, for each for $\ell \in [0, 2ms]$ whether $M^{(b-1,\ell)}$ is set equal to $M^{(b-1)}$ or $M^{(b-1,\star)}$. To do this, we use the m-dual of the Profile(s, m, T_{b-1}). In particular, define I_ℓ to be the set of indices where the m-dual of the profile takes value ℓ. That is,

$$I_\ell = \{i \mid \text{Dual}_m(\text{Profile}(s, m, T_{b-1}))_i = \ell\} \tag{1}$$

Recall that $n_b = mT_b = m \cdot ((2ms + 1) \cdot T_{b-1} - 2)$. Observe then, from Lemma 19, that the (I_ℓ)s are disjoint integer intervals of length either n_{b-1} or $n_{b-1} - 1$ whose union is $[0, n_b - 1]$. For each $\ell \in [0, 2ms]$, we now define

$$M^{(b-1,\ell)} = \begin{cases} M^{(b-1)} & \text{if } |I_\ell| = n_{b-1}, \\ M^{(b-1,\star)} & \text{if } |I_\ell| = n_{b-1} - 1. \end{cases}$$

The resultant construction of $M^{(b)}$ is then illustrated in Figure 3. For example, for $s = 1$, $m = 2$ and $b = 2$, we have $T_0 = 0$ and $T_1 = 2$, so

$$\begin{aligned} \text{Profile}(s, m, T_{b-1}) &= \text{Profile}(1, 2, 2) = (0, 0, 0, 0, 0, 2, 0, 2, 2, 2, 2, 1, 2, 1, 0, 1), \\ \text{Dual}_m(\text{Profile}(s, m, T_{b-1})) &= (0, 0, 0, 0, 2, 2, 2, 4, 4, 4, 3, 3, 3, 1, 1, 1), \\ \text{Profile}(s, m, T_{b-2}) &= \text{Profile}(1, 2, 0) = (0, 0, 2, 1), \end{aligned}$$

so

$$M^{(2)} = \begin{pmatrix} 0 & 0 & 2 & 1 & 0 & 2 & 1 & 0 & 2 & 1 & 0 & 2 & 1 & 0 & 2 & 1 \\ 0 & 0 & 0 & 0 & 0 & 2 & 0 & 2 & 2 & 2 & 2 & 1 & 2 & 1 & 0 & 1 \end{pmatrix}.$$

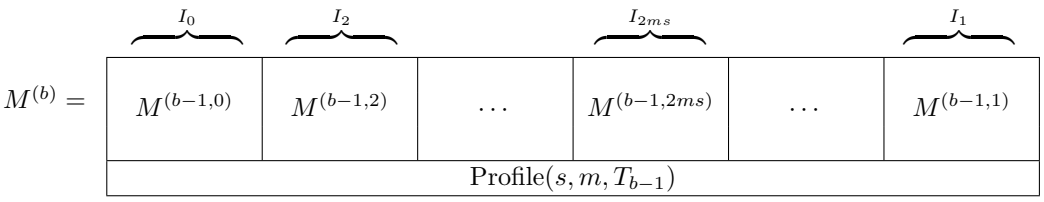

Figure 3 The recursive construction of the matrix $M^{(b)}$. The indices j for the sets I_j on top of the figure are first increasing even numbers, then decreasing odd numbers.

As stated, we will take our vectors $(\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_{n_b-1})$ to be the columns of $M^{(b)}$. That is, let $V_{i,j} = M^{(b)}_{i \bmod n_b, j}$. Then, for any $i \in \mathbb{Z}$, we have $\boldsymbol{z}_i = (V_{i,j})_{j \in [0,b-1]}$.

▶ **Lemma 21.** *The sequence of vectors $(\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_{n_b-1})$ is the pattern of an $(n_b, m, b, 2s)$-vector sum packing.*

Proof. Given $(\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_{n_b-1})$ recall that $f(\boldsymbol{z}_j, \boldsymbol{z}_{j+1}, \ldots, \boldsymbol{z}_{j+m-1}) = \boldsymbol{z}_j + \boldsymbol{z}_{j+1} + \cdots + \boldsymbol{z}_{j+m-1}$, where the indices are taken modulo n_b. Our task is to prove that f is injective.

We will show this by extending the definition of an m-dual to matrices: we define the m-dual of a matrix M with n columns to be the matrix D of the same dimensions where for all i, the ith column of D is equal to the sum of the columns of M of all indices in $[i, i+m-1]$ modulo n.

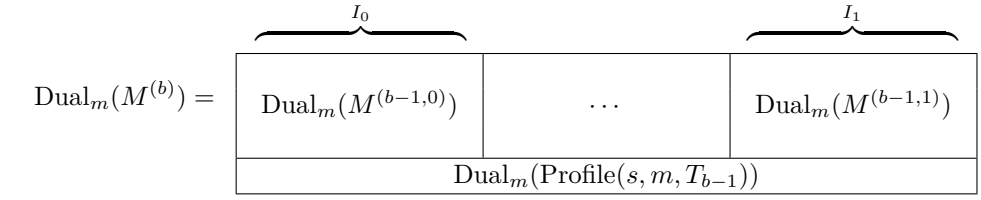
Proving $(\boldsymbol{z}_0, \boldsymbol{z}_1, \ldots, \boldsymbol{z}_{n_b-1})$ is an $(n_b, m, b, 2s)$-vector sum packing is then equivalent to proving that the m-dual of $M^{(b)}$ does not contain any identical columns. We will do so by induction on b.

Initialization. For the base case $b = 1$, recall that $M^{(b)} = \text{Profile}(s, m, 0)$. Hence, by Lemma 17, $\text{Dual}_m(M^{(b)})$ does not contain two identical columns.

Induction Step. For the induction hypothesis, assume that $\text{Dual}_m(M^{(b-1)})$ does not contain two identical columns. Now define $\text{Profile}^*(s, m, T)$ to be equal to $\text{Profile}(s, m, T)$ except with the first 0 removed. By construction, each row $j \in [0, b-1]$ of $M^{(b)}$ is a concatenation of the form $P_0 \circ P_1 \circ \cdots \circ P_r$ where each P_i is equal either to $\text{Profile}(s, m, T_j)$ or to $\text{Profile}^*(s, m, T_j)$. Next observe that both $\text{Profile}(s, m, T_j)$ and $\text{Profile}^*(s, m, T_j)$ start with $m-1$ occurrences of 0. This implies that m-dual and concatenation commutes as

$$\text{Dual}_m(P_0 \circ P_1 \circ \cdots \circ P_r) = \text{Dual}_m(P_0) \circ \text{Dual}_m(P_1) \circ \cdots \circ \text{Dual}_m(P_r).$$

Therefore the m-dual of the matrix $M^{(b)}$ is



(2)

Assume that two columns c and c' with column indices i and i' in $\text{Dual}_m(M^{(b)})$ are equal. Let $\ell \in [0, 2ms]$ denote the value of c in its final row $b-1$. Thus, c' also has entry ℓ in its last row. But the last row $b-1$ of $\text{Dual}_m(M^{(b)})$ is defined to equal $\text{Dual}_m(\text{Profile}(s, m, T_{b-1}))$. Hence, by definition of I_ℓ from Equation (1), we have $i \in I_\ell$ and $i' \in I_\ell$. Let d and d' be

obtained from c and c' by removing their last row $b-1$. By Equation (2), both d and d' belong to $\text{Dual}_m(M^{(b-1,\ell)})$. Thus, they both belong to $\text{Dual}_m(M^{(b-1)})$. By the induction hypothesis, this implies $i = i'$ and concludes the proof. ◀

Let the (n, m, b, s)-decoding function for vector sum packing be defined as the function that inputs an integer vector $\boldsymbol{x}$ and outputs its index in the m-dual of the (n, m, b, s)-vector sum packing we defined.

▶ **Corollary 22.** *For fixed b, the $(n_b, m, b, 2s)$-decoding function for our vector sum packing is computable in a constant number of arithmetic operations.*

Proof. This decoding function is computed recursively, following the recursive construction of matrix $\text{Dual}_m(M^{(b)})$ from Equation (2). It inputs a vector $\boldsymbol{x}$ and an auxiliary Boolean parameter B, initialized at *False*, that indicates if we are looking for localization in a vector sum packing where the first vector has been removed.

We first use the decoding function for profiles from Corollaries 18 and 20 on the last coordinate of $\boldsymbol{x}$ to compute an integer c, and set $p = c$ if B is equal to *False*, and $p = c - 1$ if B is equal to *True*. For $b = 1$, as $\boldsymbol{x}$ is a vector of dimension 1, the algorithm stops and p is returned. Otherwise, by construction, p is the smallest possible index for any vector whose last coordinate is equal to the last coordinate of $\boldsymbol{x}$. Now, in Equation (2), we want to determine whether the matrix $\text{Dual}_m(M^{b-1,j})$ on top of p is equal to $\text{Dual}_m(M^{b-1})$ or to $\text{Dual}_m(M^{b-1,\star})$. As explained in the construction, this is decided by looking at $\text{Dual}_m(\text{Profile}(s, m, T_{b-1}))$ from Lemma 19. In this sequence, let ℓ denote the number of repetition of the element at position p.

- If $\ell = mT_{b-1}$, then we are working with $\text{Dual}_m(M^{b-1})$. In that case, we call recursively the $(n_{b-1}, m, b-1, 2s)$-decoding function on the vector $\boldsymbol{x}$ without its last coordinate, with auxiliary parameter equal to *False*. The output is added to p and returned.
- Otherwise, we have $\ell = mT_{b-1} - 1$, and we are working with $\text{Dual}_m(M^{b-1,\star})$. We call recursively the $(n_{b-1}, m, b-1, 2s)$-decoding function on the vector $\boldsymbol{x}$ without its last coordinate, with auxiliary parameter equal to *True*. The output is added to p and returned.

Deciding whether $\ell = mT_{b-1}$ or $\ell = mT_{b-1} - 1$ is achieved by looking at the parity of p and its value modulo s. This recursive construction has depth b, so for b fixed, it requires only a constant number of arithmetic operations. Python code for this algorithm is provided in [13]. ◀

4.3 Summary and Complexity

Let us summarize our algorithm constructing a grid coloring. It inputs a dimension $d \geq 2$ and two other parameters $b \geq 1$ and $t \geq 1$. The first step is to compute the window size $m = 2bdt$, the number of colors $k = bd + 1$, the parameter $s = (2bd)^{d-2}t^{d-1}$ to ensure $2s = \frac{m^{d-1}}{bd}$, and the grid size $n = (2ms + 1)^{b-1}(2ms - 1/s) + 1/s$. The second step is to construct an $(n, m, b, 2s)$-vector sum packing, as described in Section 4.2, using the *profile* sequences defined in Section 4.1. In the third step, we finally colour the points of our grid of side n and dimension d. Our set of colours is $\{0, 1, \ldots, k-1\}$. Here the last colour $k-1$ is a "*blank*" color used to erase the other colours. The other colours are divided into d sets, called pigment classes. Each pigment class contains b colours, which we call its *shades*. To each dimension of the grid is associated a unique pigment. The vector sum packing is then used, as explained in Section 3, to colour the points of the grid.

Next consider the localization problem. Localization means, given a multiset S of colours, the recovery of the unique window of size m in the grid that contains this multiset of colors (if it exists). To achieve localization, we proceed dimension by dimension. We count in S the colours from the pigment class corresponding to the dimension considered and make a vector out of it. For example, if the dimension corresponds to the colours $4, 5, 6$ and S contains three occurrences of the color 4, zero occurrences of the colour 5 and two occurrences of the colour 6, the vector is $(3, 0, 2)$. We use the decoding algorithm for vector sum packing from Corollary 22 to translate this vector into a coordinate. Having achieved this for every coordinate, we deduce the position of the window whose multiset of colours is equal to S.

The construction of the grid and localization procedure are illustrated in Section 3.3. We measure complexity as the number of arithmetic operations for b and d fixed, while t goes to infinity. The construction of the grid has complexity proportional to the size of its output, which is $\mathcal{O}(n^d) = \mathcal{O}(t^{b\,d^2})$. Corollary 22 implies that the complexity of the localization algorithm is constant.

5 Conclusion

Many interesting directions for future research remain, both theoretical and practical. One nice extension would be to make our grid colouring robust by allowing for error detection and correction. This has been achieved for other cycle and torus packing problems (see, for example, [2, 4, 6, 25]) and is a necessary step for practical applications. Another valuable contribution would be to study disc-like windows rather than the square windows examined in this article. This would match the natural shape of the domain where an emission emitted at a point is detectable.

A Software Implementation

We implemented our algorithm constructing the grid colouring as well as the decoding algorithm in Python. The code is available at [13]. An example of grid colouring computed with this code is presented in Figure 4.

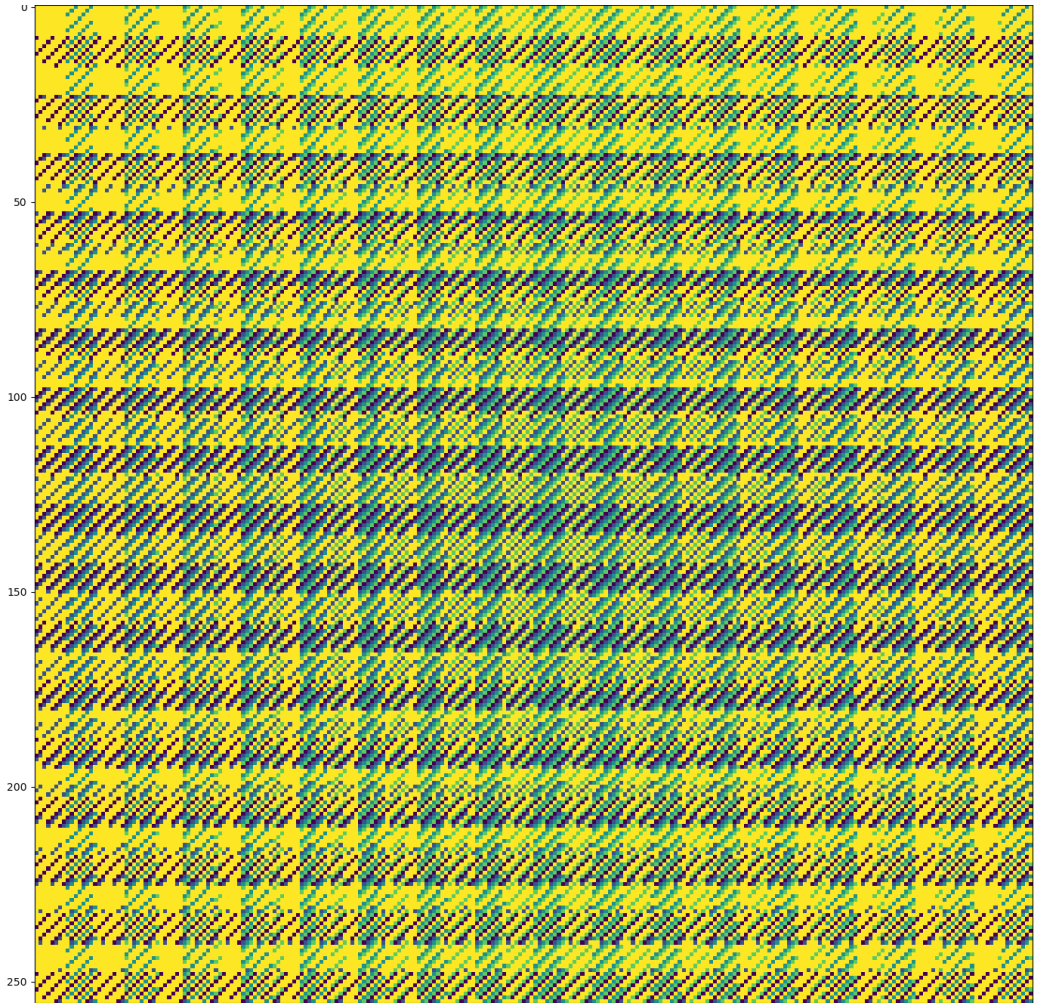

Figure 4 Grid colouring of size 256, window size 8 and number of colours 5. It corresponds to the parameters $d = 2$, $b = 2$ and $t = 1$.

Bayesian Calibrated Click-Through Auctions

Abstract

We study information design in *click-through auctions*, in which the bidders/advertisers bid for winning an opportunity to show their ads but only pay for realized clicks. The payment may or may not happen, and its probability is called the *click-through rate* (CTR). This auction format is widely used in the industry of online advertising. Bidders have private values, whereas the seller has private information about each bidder's CTRs. We are interested in the seller's problem of partially revealing CTR information to maximize revenue. Information design in click-through auctions turns out to be intriguingly different from almost all previous studies in this space since any revealed information about CTRs will never affect bidders' bidding behaviors – they will always bid their true value per click – but only affect the auction's *allocation* and *payment* rule. In some sense, this makes information design effectively a constrained mechanism design problem.

Our first result is an FPTAS to compute an approximately optimal mechanism under a constant number of bidders. The design of this algorithm leverages Bayesian bidder values which help to "smooth" the seller's revenue function and lead to better tractability. The design of this FPTAS is complex and primarily algorithmic. Our second main result pursues the design of "simple" mechanisms that are approximately optimal yet more practical. We primarily focus on the two-bidder situation, which is already notoriously challenging as demonstrated in recent works. When bidders' CTR distribution is symmetric, we develop a simple *prior-free* signaling scheme, whose construction relies on a parameter termed *optimal signal ratio*. The constructed scheme provably obtains a good approximation as long as the maximum and minimum of bidders' value density functions do not differ much.

1 Introduction

Many of the phenomenal Internet Technology companies are powered by online advertising [25]. When an Internet user browses a webpage, an ad auction may be run to determine which ads to be displayed to this user. Such ad auctions can be either done by the webpage owner

or through ad exchange platforms. Large website owners (sellers) sometimes may know the users much better than individual advertisers (bidders) do. It is thus natural for the seller to utilize such information advantage to improve its ad revenue. As an example, the seller's knowledge about the user can be used to better predict an Internet user's *click-through rate* (CTR), which is then used in ad auctions to deliver ad impressions more efficiently.

Interestingly, a recent line of works, starting from Bro Miltersen and Sheffet [14], Emek et al. [26], comes to realize that it may not always be the seller's best interest to use as much information as possible. That is, partially use certain amount – and the right type – of information may be more beneficial for the seller's revenue. This insight has motivated many studies on the algorithmic problem of optimal *information design* – i.e., determining what information to be shared with which bidders – in order to maximize revenue in different auction formats [14, 26, 12, 38, 30, 5].

While there are two main types of bidding strategies in online advertising: autobidding [20, 7, 6] and manual bidding, to better understand the optimal design of information in an auction environment, we follow the rich literature and turn to the cleaner manual bidding where the platform incentivizes buyers to tell the truth. However, different from almost all previous works focusing on stylized auction formats such as the second price auction for independent-value bidders [14, 26, 12, 5] and common-value bidders [38] and Myerson's optimal auction [30], we focus on a different auction format, i.e., the *click-through auction*, which is the main auction format employed by the current online advertising industry [27]. The click-through auction is also widely known as the generalized second-price auction [25] or position auctions [44]. We use the term "click-through auction" as coined by Bergemann et al. [11] to emphasize the sale of *clicks*, since this factor turns out to make information design in click-through auctions significantly different from that in almost all other previously studied auctions. In a click-through auction for selling a single ad position, each bidder i submits a bid b_i expressing his value for each *click* of his ad. Additionally, the seller will estimate a *click through rate* (CTR) r_i for bidder i. The auction runs by ranking bidders according to the *product score* $b_i r_i$, denoted as $b_{(1)}r_{(1)} \geq b_{(2)}r_{(2)} \geq \cdots$, and allocates the item to the bidder with the highest product score $b_{(1)}r_{(1)}$. Crucially, since the auction only sells clicks, the winner does not need to pay *unless a click truly happens* in which case the winner pays the second highest score divided by his own CTR, i.e., $b_{(2)}r_{(2)}/r_{(1)}$. When there is only a single ad slot to allocate, it is straightforward to verify that this auction is truthful, *regardless of the CTR values (even mistakenly estimated)*.[1] As a result, the seller's information advantage of knowing the CTRs *cannot* be exploited to influence the advertisers' bidding behaviors since it is always their best interest to bid the true value per click v_i. In some sense, information design here is effectively a naturally restricted format of mechanism design for multiple items with additive bidder values (which is generally a very difficult question [19]). This crucially differs from the information design task in all previously studied auction formats, in which the seller's information about the item (e.g., the CTR) can be revealed to alter bidders' bidding behaviors. This is intrinsically because bidders pay for realized clicks only thus the probability of receiving a click will not matter in click-through auctions. Note that, even in per-impression ad auctions as studied in [5], bidders pay for impressions but care about clicks or conversions, thus their values do depend on the probability of receiving a click, i.e., the CTR.

[1] Such truthfulness holds only when there is a single slot, which is the case we focus on in this paper. Click-through auctions are well-known to be non-truthful and difficult to analyze when there are multiple slots [25].

Most relevant to ours is the recent work by Bergemann et al. [11], who study the same information design question of optimally revealing the CTR information in click-through auctions. They focused on a simplified setup with *complete information* about the bidders, i.e., the bidders' values are assumed to be fully known to the seller. A natural *calibration* constraint, originating from Foster and Vohra [29], is imposed on their information design, which simply means the disclosed CTR estimation to each bidder has to be consistent with (i.e., equal in expectation) the true CTR of the bidder. They thus call the new model *calibrated click-through auctions*. Notably, the seller is allowed to privately communicate information with each bidder, which is known as private signaling. The main contribution of this paper is to extend the setup of [11] to the more natural and also more widely studied setup of *Bayesian* bidders with independent values. For this reason, We call our model the *Bayesian calibrated click-through auction*.

To our knowledge, Bergemann et al. [11] is the first study of information design in auctions in which the revealed information *cannot* influence bidders' behaviors, but only affect the mechanism itself. This gives rise to an intriguing information design problem – in some sense, it is even in contrast to one's first impression about information design, also known as *persuasion* [33], which seeks to exploit information advantage to influence others' behaviors. In contrast, information design in click-through auctions only affects the final allocation and payment of the mechanism but has no effect on bidders' bidding behaviors. From this perspective, information design here is effectively a form of mechanism design. Indeed, a similar phenomenon was observed by Daskalakis et al. [19], who study the *co-design* of information structure and the auction mechanism. They observe that at the optimal co-design, there is no signaling to bidders whatsoever, and the seller will only use the underlying state to decide the item allocation and payment. Our problem is similar, except that we restrict ourselves to the class of click-through auctions. This restriction is motivated by its practical applications.

Before proceeding to describe our results, we briefly highlight the challenges of information design in our problem. Indeed, the difficulty of information design in strategic games is well documented in previous works [22, 13]. Even just for auctions, Emek et al. [26] shows that computing an optimal information design in a second price auction is NP-hard in general for Bayesian bidder values, though it does become polynomial-time solvable in cases with complete information of bidder values. Unfortunately, such tractability does not transfer to the click-through auctions: in a general environment with complete information about bidder values, even the problem of optimal information design in *two*-bidder click-through auctions is left as an open question in [11]. Bergemann et al. [11] show that when the distributions of CTRs are symmetric, an optimal signaling policy can be characterized. However, back to our Bayesian generalization of their setup, their optimal design for the symmetric information environment is no longer applicable because the design of their signaling scheme relies crucially on knowing the exact identity of the winner for any signal realization, which unfortunately becomes uncertain in our Bayesian setup with random bidder values. This barrier brings challenges, but also brings opportunities to adopt more algorithmic approaches. Next, we elaborate on our findings.

1.1 Results

We study the theoretical aspects of Bayesian calibrated click-through auctions and develop two encouraging positive results.

Our first result, Theorem 3.1, exhibits a Fully Polynomial Time Approximation Scheme (FPTAS) for computing an approximately revenue-optimal signaling scheme in an *arbitrary* information environment, assuming no point mass in bidders' value distributions. This

FPTAS applies to any constant number of bidders. Interestingly, our FPTAS bypasses the notorious challenge of the complete-information general setup of [11] by relaxing it to the more natural Bayesian valuation setup with smooth value distributions. We use signals of the form $k\epsilon$ for some integer k. The key challenge is to enforce the calibration constraint – i.e., the posterior mean of the CTR conditioned on the signal has to equal the signal itself – in the rounding process. We develop a nontrivial technique to address the challenge. Notably, this FPTAS applies to any auction mechanism, as long as its revenue as a function of signals is Lipschitz continuous.

Our second main result, Theorem 4.2, examines the popular recent computational model of unknown value distributions, also known as *prior-free* setups [21]. We give explicit and efficient construction of simple *prior-free* signaling schemes for *symmetric* information environments (as studied also by Bergemann et al. [11]) with strong approximation guarantees. The constructed signaling scheme is based on a parameter coined the *optimal signal ratio*, which we find is at most 1. This allows us to send larger signals (i.e., larger CTR estimations) to the bidder with a high click-through rate than the bidder with a low click-through rate. The proof mainly consists of (i) establishing a connection between the optimal signaling scheme under the unknown value distribution and the optimal signaling scheme under a uniform value distribution and (ii) providing the approximation ratio of the constructed signaling scheme under a uniform value distribution, which is proved to be 0.995. En route to proving (ii), we prove a more general result (Proposition 4.11) which shows that, if the optimal signal ratio is convex in CTR (which is true for various commonly used distributions), then a signaling scheme with better approximation can be devised. This result may be of independent interest.

1.2 Additional Related Works

Due to the space limit, we briefly discuss the related works here, while additional discussions in detail are in Appendix A. The most relevant literature to our work is information design in auctions. Information design has been adopted to second price auctions [14, 26, 18, 5] and Myerson auctions [30] in various setups. Recently, Bergemann et al. [11] provided characterizations for a symmetric calibrated click-through auction but with complete information of bidder values. Another line of related literature is the sale of information, which selectively reveals information for revenue improvement. There are a series of works in this line [2, 17, 9, 15, 39, 46, 37, 10]. Our work is also related to Bayesian persuasion [34, 1, 4, 24, 3, 45, 31]. We also refer interested readers to a comprehensive survey by Dughmi [23]. Finally, our work is partly related to the literature on automated bidding in auctions [36, 35, 28, 40, 8].

2 Preliminaries

We consider the (arguably more natural) Bayesian version of the *calibrated click-through auction* of [11], which is directly motivated by advertising auctions. At a high level, bidders in this auction are ranked by the products of their *private values* (i.e., the willingness-to-pay per click) and the seller's prediction of *click-through-rate* (*abbr.* CTR). Bergemann et al. [11] consider a basic setup in which bidders' private values are perfectly known to the seller. In this paper, we generalize their problem to the Bayesian setup by assuming that bidders' values are independently drawn from distributions. While each bidder knows his own private value, the seller only knows the distributions of bidder values (though our second main result further removes this assumption). This generalization is more aligned with the rich literature

of Bayesian auction design, starting from the seminal work of [41]. Similar to [11], we also aim to design a revenue-maximizing auction. Different from classic auction design, the seller in a click-through auction has an additional knob to tune, i.e., informing bidders about their CTRs through partial information disclosure (also known as *information design* [33]). So the optimal auction requires designs of both *incentives* and *information*.

We now describe the general auction setting. There are n bidders. The private value v_i of bidder (she) $i = 1, 2, 3, \ldots, n$ is independently drawn from some known distribution $F_i(v_i)$ (with a density function $f_i(v_i)$), over some bounded interval $[a, b]$ with $a, b \in R_{\geq 0} \cup \{\infty\}$ and $a < b$. Note that the density functions $f_1(v_1), f_2(v_2), \ldots, f_n(v_n)$ are not necessarily identical. As seen, our problem is a natural Bayesian variant of [11], whose settings can be obtained by allowing $f_i(v_i)$ to be some Dirac δ-function. i.e., a point distribution.

When auctions start, the seller privately observes a CTR vector $r = (r_1, r_2, \ldots, r_n) \in [\underline{r}, 1]^n$ for n bidders, which is drawn from a commonly known joint distribution $\lambda(r)$. $\underline{r} > 0$ is a small positive value close to 0. The CTR r_i represents the probability of bidder i's ad being clicked, which may be estimated by the seller with some machine learning method. For bidder i, assume the marginal probability $\lambda(r_i) \geq \xi$, where ξ is a small positive value since it does not make sense to consider a CTR with a marginal probability arbitrarily close to 0 in practice.

To maximize his revenue, the seller may privately disclose some information about r_i to bidder i. Suppose the seller has the power of commitment[2], and he designs a signaling scheme denoted as π, which is also observed by the bidders. Hence, conditioning on observing CTR vector r, the seller sends signal $s = (s_1, s_2, \ldots, s_n)$ with probability $\pi(s|r)$, where s_i is the signal privately sent to bidder i. In the rest of the paper, we assume that $r_i \in \mathcal{R}$ with $\mathcal{R}$ being a discrete and finite set of CTR values.

Calibrated Click-Through Auction. The calibrated click-through auction was previously studied by Bergemann et al. [11]. Initially, each bidder privately observes her value v_i and the seller privately observes the CTR vector r. The seller then sends a signal s_i to each bidder i privately. Upon receiving the signal s_i, bidder i submits her bid b_i to the auction and the auction determines the winner i^* by selecting the one with the highest product, i.e., $b_{i^*} s_{i^*} = \max_j b_j s_j$, and charges the winner for each realized click by

$$p_{i^*} = \max_{j \neq i^*} \frac{b_j s_j}{s_{i^*}}.$$

The winner only pays when a click is received[2]. Hence, the seller's expected revenue is $r_{i^*} p_{i^*}$. One can easily prove that the auction is truthful[2] for any $s_1, \ldots, s_n$, as it follows the "minimum-bid-to-win" payment rule. Therefore, without loss of generality, we will assume $b_i \equiv v_i$ in the rest of the paper.

Following [11], we adopt the concept *calibration* to information design. That is, given any private signal $s_i = s_i'$, bidder i's posterior estimation of CTR r_i should be equal to s_i', i.e.,

$$E[r_i | s_i = s_i'] = s_i'. \tag{1}$$

The calibration constraint is a consequence of the revelation principle. Given any signal realization $s_i = s_i'$, bidder i will interpret s_i' through Bayes updates by computing the expected CTR value $E[r_i | s_i = s_i']$. The calibration constraint simply requires that the signal

[2] More discussions about *pay-per-click*, commitment power and truthfulness are in Appendix B.

itself directly reflects this expected value so that bidders do not need to compute the expected CTR value by themselves. Such revelation-principle-style simplification is widely adopted in information design [34, 24, 33], where signals can without loss of generality be *persuasive* action recommendations. Analogously, in our auction setup, such direct information scheme will directly signal the posterior mean of the signal, i.e., obeying the calibration constraint (1). Hence, any signal s_i must be within $[\underline{r}, 1] \subseteq [0, 1]$ by (1). One important observation in [11] is that if the CTRs and signals are discrete, we can rewrite (1) as

$$\sum_{(r,s):s_i=s_i'} \lambda(r)\pi(s|r)(r_i - s_i') = 0. \tag{2}$$

Bayesian Calibrated Click-Through Auction. We focus on the seller's information design problem, i.e., to design a signaling scheme π in order to maximize the seller's expected revenue. The problem is formulated as below,

$$\begin{aligned} \max_{\pi,s} \quad & \sum_r \lambda(r) \sum_s \pi(s|r) \int_v f(v)R(r,v,s)dv \\ \text{subject to} \quad & E[r_i|s_i = s_i'] = s_i' \ \ \forall s_i' \in [0,1], \forall i \\ & \pi(s|r) \in [0,1], \sum_s \pi(s|r) = 1, \ \forall r, s \in [0,1]^n, \end{aligned} \tag{3}$$

where $f(v) = f_1(v_1)f_2(v_2)\cdots f_n(v_n)$ is the density function of $v = (v_1, v_2, \ldots, v_n)$, and the revenue $R(r, v, s) = r_{i^*}\frac{\max_{j\neq i^*} v_j s_j}{s_{i^*}}$. Since both the signals s and the probabilities of sending signals $\pi(s|r)$ are variables, the objective of (3) is non-convex.

Given CTR vector r and signal s, denote the seller's expected revenue as $R(r, s) = \int_v f(v)R(r, v, s)dv$. Specifically, $R(r, s)$ for 2 bidders is

$$\begin{aligned} R(r,s) &= \int_v f(v)R(r,v,s)dv \\ &= \int_a^b r_1 \frac{v_2 s_2}{s_1} \mathbf{Pr}\left(v_1 s_1 \geq v_2 s_2 | v_2\right) f_2(v_2)dv_2 + \int_a^b r_2 \frac{v_1 s_1}{s_2} \mathbf{Pr}\left(v_2 s_2 \geq v_1 s_1 | v_1\right) f_1(v_1)dv_1, \end{aligned} \tag{4}$$

where $\mathbf{Pr}\left(v_1 s_1 \geq v_2 s_2 | v_2\right)$ is the probability of bidder 1 winning given that bidder 2's value is v_2 (similarly for $\mathbf{Pr}\left(v_2 s_2 \geq v_1 s_1 | v_1\right)$).

By (4), we can see that our problem differs from [11] in a crucial way: With any fixed s, the winner is also fixed in [11] since they have complete information on v, while in our case, either bidder can be the winner with some probability due to the uncertainty in their valuations. This difference somewhat "smooths" our objective function while at the same time brings new challenges.

3 Click-Through Auctions in General Environments

In this section, we present an FPTAS for (3) achieving $1 - O(\epsilon)$ approximation when the number of bidders is a constant. This result hinges on a minor continuity assumption on bidders' value distribution. That is, we assume every distribution F_i has no point mass[3] and has finite second moment, i.e., $\mathbb{E}_{v_i\sim F_i}[v_i^2] < \infty$. Under these two mild technical assumptions, we prove the following theorem.

[3] The no-point-mass assumption alleviates the tie-breaking problem arising in the case of deterministic bidders' values. A discussion on this assumption is in Appendix D.

▶ **Theorem 3.1.** *For any small $\epsilon > 0$, there is an algorithm that computes a (multiplicative) $1 - O(\epsilon)$ approximate signaling scheme in $\text{poly}(|\mathcal{R}|^n, (\frac{n}{\epsilon})^n)$ time where n is the number of bidders and $|\mathcal{R}|$ is the size of set $\mathcal{R}$ of CTR values.*

To prove Theorem 3.1, we resort to discretizing the strategy space. Our starting point is a reformulation of Program (3) as a linear program with infinite dimension, and then convert the infinite-dimensional program into a finite-dimensional one by discretizing the signal space. The main technical challenge is to prove that the solution to the discrete program approximates the optimal solution to the original infinite-dimensional one. This is more involved than typical rounding approaches and hinges on the following two key properties:

a). For any signaling scheme, the value of the discrete objective is sufficiently close to the original objective. This is a consequence of the following Lipschitz continuity of revenue function $R(r, s)$, whose proof is deferred to Appendix C.

▶ **Lemma 3.2.** *$R(r, s)$ is Lipschitz continuous in $s \in [\underline{r}, 1]^n$ with some constant C_n, for any given CTR $r = (r_1, r_2, \ldots, r_n)$.*

b). For any solution to the original infinite dimensional program, there exists a corresponding feasible solution to the discrete program that is sufficiently close to the original solution.

These two properties together can ensure the existence of a solution to the discrete program yielding the revenue that approximates the optimal solution of the original infinite dimensional program. Thus by solving the discrete program, we can get an approximately optimal solution.

The major challenge here is to prove property b), as any naïve rounding of a signaling scheme from the continuous signal space to a discrete space would break the calibration constraints and hence end up with an infeasible rounded signaling scheme to the discrete program. To circumvent the difficulty, we introduce a novel technique to retain all the calibration constraints.

At a high level, we will reserve a small amount of probability mass from the given signaling scheme at the beginning and only apply rounding to the remaining probability mass. After the rounding step, we will redistribute the reserved probability mass to carefully fix all the calibration constraints broken by the rounding step. In particular, one has to be extremely careful to avoid the straightforward discretization structure of the signal space, because otherwise a large fraction of probability mass reservation will be needed for the fixing stage, which leads to a significant revenue loss and fails the $1 - O(\epsilon)$ approximation. The detailed proof of Theorem 3.1 is involved and relegated to Appendix C.2.

It is worthwhile to compare our FPTAS in Theorem 3.1 with a recent FPTAS for multi-channel Bayesian persuasion by Babichenko et al. [4], and highlight their key differences. While both rely on the continuity of the sender's utility functions, their techniques are significantly different. Specifically, the FPTAS of [4] applies to a constant number of states but many receivers (i.e., bidders) whereas our FPTAS applies to many states but a constant number of bidders. Their FPTAS discretizes the space of distributions over the states (thus requires a constant number of states) whereas our FPTAS discretizes the space of posterior CTR mean, which is why we have to adjust the scheme to satisfy the calibration constraints. Our choice of discretizing posterior means is due to its direct usage in click-through auctions. Such a special structure and the resultant challenges of fixing calibration constraint violation – which is the core difficulty in our proof – is not present in the setup of [4].

We remark that the discretization technique applied to Theorem 3.1 is in fact regardless of the expected revenue $R(r, s)$. To retain the calibration constraint and preserve the approximation simultaneously, one basic requirement is that $R(r, s)$ needs to be Lipschitz-continuous in signal s. Therefore, our algorithm can be treated as a framework that can accommodate different auctions (with Lipschitz continuous expected revenue $R(r, s)$) and

maintain the calibration of signals. Based on this observation, we consider one simple modified auction: a click-through auction with a reserved price. Reserve prices are widely studied in the literature and commonly used in the industry [43, 42]. Similarly, we only need to show $R(r, s)$ of this modified auction is Lipschitz-continuous for Corollary 3.3 to be true, which is deferred to Appendix C.3.

▶ **Corollary 3.3.** *In a click-through auction where winner pays at least some fixed reserve price p, for any constant number of bidders and any small $\epsilon > 0$, there is an algorithm that computes (multiplicatively) $1 - O(\epsilon)$ approximate signaling scheme with time complexity $poly(|\mathcal{R}|, \frac{1}{\epsilon})$.*

4 Click-Through Auctions in Symmetric Environments

While Theorem 3.1 provides an algorithm that can compute an approximately optimal signaling scheme in fairly general setups, the algorithm relies on solving large-scale linear programs thus may be too costly in reality and also lacks interpretability. In this section, we pursue the design of "simple" signaling schemes through the approximation lens. Given the challenge of the problem in general, we shall restrict our attention to a fundamental special case in this section – i.e., 2 bidders and symmetric environments – which is also a major focus of our preceding work by Bergemann et al. [11]. For this basic case, we first characterize that without calibration constraint, the optimal information design is governed by a single parameter called *optimal signal ratio*, which is at most 1. Such an observation motivates an explicit construction of a simple and *prior-free* signaling scheme, which is close to the optimal when bidder values' probability density function does not fluctuate much.

An environment is *symmetric* [11] if 1) the distribution of the products $v_1 r_1, v_2 r_2, \ldots, v_n r_n$ are exchangeable, and 2) the values v_i's are i.i.d. drawn from a distribution $F(v)$. Hence, the symmetric environment further implies that the distribution of $r_1, r_2, \ldots, r_n$ are also exchangeable, i.e., $\lambda(r_1, r_2, \ldots, r_n) = \lambda(perm(r_1, r_2, \ldots, r_n))$ where $perm(\cdot)$ is any permutation function. For the purpose of easy exposition, we allow r_i to be drawn from a slightly enlarged interval $[0, 1]$, with which the results obtained hold for $r_i \in [\underline{r}, 1]$ as in our original setting.

▶ **Definition 4.1.** *The distribution $F(v)$ (with density $f(v)$) has a monotone hazard rate (MHR) if the "hazard rate" of the distribution $\frac{f(v)}{1-F(v)}$ is increasing in v.*

MHR is a standard assumption widely used in economics [5, 32, 16]. Many distributions are MHR, such as uniform distribution, exponential distribution, gamma distribution, etc. Note that MHR implies regularity proposed by Myerson [41].

▶ **Theorem 4.2.** *There exists a prior-free signaling scheme that can be found in polynomial time and guarantees a (multiplicative) $0.995 \cdot (\underline{f}/\overline{f})^2$-approximation for any continuous MHR distribution $f(v)$, where $\overline{f}$ and $\underline{f}$ are the respective maximum and minimum values of $f(v)$ for $v \in [0, c]$ with any $c > 0$.*

The approximation ratio in Theorem 4.2 achieves its best ratio 0.995 for uniform distribution. More generally, the approximation ratio depends on the term $\underline{f}/\overline{f}$ which intuitively captures how much the distribution deviates from being uniform. Notably, both the algorithm and the signaling scheme require no knowledge about the value distribution F, i.e., F could be unknown to the seller (though Section 4.4 provides a better guarantee when F is known and satisfy certain properties). We remark that the signaling scheme in Theorem 4.2 is *simple* in the sense that its construction is parameterized by a single parameter called *optimal signal*

ratio. The information design problem thus can be easily optimized by empirically selecting a value that gives the best performance. More importantly, Theorem 4.2 also provides a robust solution to the problem, which can be very useful when it is hard or costly to accurately estimate the distributions of bidder values.

4.1 Key Primitive of the Construction: the Optimal Signal Ratio

Before presenting the proof, we discuss the main ingredient for the construction of the signaling scheme, the *optimal signal ratio*. Given a CTR vector $r = (h, l)$ (without loss of generality, assume $h \geq l$) and a signal pair $s = (s_1, s_2)$, the expected revenue by (4) can be rewritten as (Recall $f(v) = 0, \forall v \notin [0, c]$. Note that although the seller requires no knowledge about $F(v)$ to construct the scheme, the bidders' value should follow some prior $F(v)$.)

$$R(r, s) = \int_0^c (h\frac{v_2 s_2}{s_1}) \int_{\frac{v_2 s_2}{s_1}}^c f(v_1)dv_1 f(v_2)dv_2 + \int_0^c (l\frac{v_1 s_1}{s_2}) \int_{\frac{v_1 s_1}{s_2}}^c f(v_2)dv_2 f(v_1)dv_1. \tag{5}$$

Clearly, from (5), the expected revenue is determined by the signals through their ratio $x = \frac{s_2}{s_1}$, which we call the *signal ratio*. We define the *optimal signal ratio* to be the signal ratio maximizing (5). In the rest of the paper, without loss of generality, we assume $h = 1$. Then the optimal signal ratio only depends on the smaller CTR l, denoted as $x(l)$ with $l \in [0, 1]$.

▶ **Lemma 4.3.** *The optimal signal ratio $l < x(l) \leq 1$ for $l \in [0, 1)$ and $x(1) = 1$.*

Lemma 4.3 is directly implied by Lemma E.1 and E.2 in Appendix E, where more discussion about $x(l)$ can be found. There are two interesting implications from Lemma 4.3. The first interesting implication is that without the calibration constraint, it would be optimal for the seller to only send pairs of signals with the optimal signal ratio where a larger (*resp.* smaller) signal is observed by the bidder with a higher (*resp.* lower) CTR, which motivates our construction of the signaling scheme. The second implication is that by $l < x(l)$ in Lemma 4.3, information design induces more intensive competition between buyers by partial-information revelation (with signal ratio $x(l)$) than full revelation (with signal ratio l). This again explains the observations in [5] that revenue extraction in auctions needs competition and too "fine-grained" targeting information may lead to a thin market. More detailed discussions on the second implication are in Appendix F.

As an application of Lemma 4.3, we observed that $x(l) = 1$ for $l \in [0, 1]$ for any *exponential distribution*. It turns out that in this special case, the revenue-maximizing calibrated signaling scheme is simply to reveal no information, i.e., always sending one calibrated signal pair with $s_1 = s_2 = E[r_i]$. This leads to the following proposition, whose proof is deferred to Appendix G.5.

▶ **Proposition 4.4.** *If the value distribution is an exponential distribution with density $f(v) = \lambda e^{-\lambda v}, v \geq 0, \lambda > 0$, the signaling scheme revealing no information is revenue-optimal.*

4.2 Construction of the *Simple* Signaling Scheme

In this part, we present the construction of a simple signaling scheme. Recall that given the smaller CTR l, the maximum expected revenue is achieved when $\frac{s_2}{s_1} = x(l)$, i.e., the optimal signal ratio. In other words, one can construct an approximately optimal signaling scheme by sending signal pairs of the optimal signal ratio $x(l)$ as frequently as possible, while maintaining the calibration constraints.

Algorithm 1 Construction of *Simple* Signaling Scheme.

1. Given CTR vector $r = (1, l)$, we compute a list of candidate signals $\sigma_0, \sigma_1, \ldots, \sigma_{K-1}$, where $K = \lfloor \log_{x(l)} l \rfloor$ such that $x(l)^{K+1} \leq l \leq x(l)^K$. The signal σ_i is computed as

$$\sigma_K = 1, \sigma_0 = x(l)^K, \sigma_i = \sigma_{i-1} \cdot x(l), \forall i \in [K]. \tag{6}$$

2. Define $p(r, s) = \lambda(r)\pi(s|r)$ as the probability mass of sending signal s conditioning on CTR r. Let $(l, 1)$ and $(1, l)$ send signals (σ_k, σ_{k+1}) and (σ_{k+1}, σ_k), respectively, with the same probability mass

$$p\Big((l,1),(\sigma_k,\sigma_{k+1})\Big) = p\Big((1,l),(\sigma_{k+1},\sigma_k)\Big) = p_k, \forall k\{1,2,\ldots,K-1\}$$

where p_k is computed as

$$p_k = p_{k-1} \cdot \frac{1-\sigma_k}{\sigma_k - l} = p_0 \prod_{i=1}^{k} \frac{1-\sigma_i}{\sigma_i - l}, \forall k \in \{1, 2, \ldots, K-1\}. \tag{7}$$

3. By the above construction, we know $p\Big((l,1),(\sigma_{K-1},1)\Big) = p\Big((1,l),(1,\sigma_{K-1})\Big) = p_{K-1}$. To maintain calibration constraint, the seller will additionally send signal (σ_0, σ_0) with $p\Big((l,1),(\sigma_0,\sigma_0)\Big) = p\Big((1,l),(\sigma_0,\sigma_0)\Big) = z$, where

$$z = p_0 \cdot \frac{\sigma_0 - l}{l + 1 - 2\sigma_0}. \tag{8}$$

4. Choose a proper p_0 (other parameters z, p_i are then determined) so that

$$z + p_0 + p_1 + \cdots + p_{K-1} = \lambda(r) = \frac{1}{2}$$

Based on the above intuition, we then present the construction of the simple signaling scheme π depicted in Algorithm 1. Since the CTRs of bidders are exchangeable, we can separately consider the signaling scheme for each pair of CTR vectors. Without loss of generality, consider a pair of CTR vectors $(l, 1)$ and $(1, l)$ such that $\lambda(r = (l, 1)) = \lambda(r = (1, l)) = \frac{1}{2}$. In particular, we assume $x(l) < 1$ (otherwise, optimality can be easily achieved by revealing no information). With properly chosen parameter p_0, the constructed signaling scheme is calibrated and valid (see Appendix G.1). Note that by (8), the probability mass $z = 0$ if $\sigma_0 = l$, which implies all the signals sent are of the optimal signal ratio. Therefore, the optimal expected revenue is achieved.

▶ Remark 4.5. As mentioned previously, the construction only depends on one parameter, the optimal signal ratio $x(l)$. Besides, the scheme has a clear structure, i.e., computing a geometric series of signals $\{\sigma_i\}$ and then assigning probabilities, both of which can be done efficiently.

We present the following concrete example that describes the constructed signaling scheme.

▶ **Example 4.6.** Let $f(v)$ be the uniform distribution over $[0, 1]$. The click-through rates are $h = 1$ and $l = 0.6$, with $\lambda((h, l)) = \lambda((l, h)) = 0.5$. By solving (5), we obtain the optimal signal ratio $x = \frac{9}{10}$. We consider $k = 4$ levels of signals within $[0.6, 1)$ as $\sigma_0 = (\frac{9}{10})^4, \sigma_1 =$

Table 1 Example of a signaling scheme. Each entry corresponds to $\lambda(r)\pi(s|r)$, i.e., the probability mass of sending signals $s = (\sigma_i, \sigma_j)$ when observing the CTR vector r.

r \ s	(σ_0, σ_0)	(σ_0, σ_1)	(σ_1, σ_2)	(σ_2, σ_3)	(σ_3, σ_4)	(σ_1, σ_0)	(σ_2, σ_1)	(σ_3, σ_2)	(σ_4, σ_3)
(0.6, 1)	z	p_0	p_1	p_2	p_3	0	0	0	0
(1, 0.6)	z	0	0	0	0	p_0	p_1	p_2	p_3

$(\frac{9}{10})^3, \sigma_2 = (\frac{9}{10})^2, \sigma_3 = \frac{9}{10}, \sigma_4 = (\frac{9}{10})^0 = 1$. The signaling scheme is given by Table 1, where the probabilities z and p_0, p_1, p_2, p_3 are determined according to (7) and (8) to keep the construction a calibrated signaling scheme.

Note that all signal pairs except (σ_0, σ_0) follows the optimal signal ratio $x = \frac{9}{10}$. Hence the revenue suboptimality only happens when sending the signal $s = (\sigma_0, \sigma_0)$, of which the probability mass is $z \approx 0.016$. It turns out that the expected revenue of this calibrated signaling scheme is 0.2698. In contrast, by relaxing the calibration constraint, the maximum revenue one can achieve is 0.27 (i.e., always sending signals of the optimal signal ratio 9/10). Since 0.27 is clearly an upper bound of the optimal revenue for any calibrated signaling scheme, the revenue loss of our construction is less than 0.075%.

We remark that the revenue loss decreases very quickly as the number of signals k increases. In this example, if $l = 0.2$ instead, then the optimal signal ratio $x(l) = \frac{4}{5}$ and we can choose $k = 7$, yielding a much smaller probability mass of sending suboptimal signals $z \approx 1.5 \times 10^{-5}$.

4.3 Proof of Theorem 4.2

We first show a special case of Theorem 4.2, which is also a cornerstone for the main proof. That is, if the value distribution is uniform (i.e., $\underline{f}/\overline{f} = 1$), we can design a 0.995-approximate scheme.

▶ **Proposition 4.7.** *Given a uniform distribution supported on $[0, c]$, the constructed signaling scheme can achieve at least (multiplicative) 0.995-approximation.*

Simple calculation leads to the optimal signal ratio $x(l) = \frac{3+l}{4}$ under the uniform distribution. The proof of Proposition 4.7 is a combination of the following two lemmas. Recall that the constructed signaling scheme sends signal pairs of the optimal signal ratio $x(l)$ with probability $1 - z$ and with the remaining probability z sends the suboptimal signal pair (σ_0, σ_0). Lemma 4.8 bounds the probability z, while Lemma 4.9 lower bounds the revenue approximation when sending out (σ_0, σ_0). We will discuss the proof of Lemma 4.8 in Section 4.4, where a more general result is proved, and defer the proof of Lemma 4.9 to Appendix G.6.

▶ **Lemma 4.8.** *For optimal signal ratio function $x(l) = \frac{3+l}{4}$, there exists a signaling scheme whose worst-case approximation is $1 - z^*$, where $z^* \le 0.04$.*

▶ **Lemma 4.9.** *Sending signal (σ_0, σ_0), i.e., the signal ratio is 1, is (multiplicatively) $\frac{8}{9}$-approximation.*

Proof of Proposition 4.7. Combining Lemma 4.8 and Lemma 4.9, the approximation of the constructed signaling scheme is at least $(1 - z^*) \cdot 1 + z^* \cdot \frac{8}{9} \ge 224/225 \approx 0.995$. ◀

We prove Theorem 4.2 by showing that the signaling scheme we constructed for the uniform distribution is a $0.995\cdot(\underline{f}/\overline{f})^2$-approximation for any value distribution. In particular, sending signal pairs of signal ratio $\frac{3+l}{4}$ is $(\underline{f}/\overline{f})^2$-approximate and sending (σ_0,σ_0) is $\frac{8}{9}\cdot(\underline{f}/\overline{f})^2$-approximate. An analysis similar to Proposition 4.7 finally leads to $0.995\cdot(\underline{f}/\overline{f})^2$ approximation.

Proof of Theorem 4.2. We first derive the upper and lower bound of the expected revenue $R(r,s)$ by connecting to the uniform-distribution case. Given a CTR $r=(1,l)$ and any signal pair $s=(s_1,s_2)$ with ratio $\frac{s_2}{s_1}\le 1$ (by Lemma 4.3, $\frac{s_2}{s_1}\le 1$ is without loss of generality), the upper bound by (5) is computed as

$$\begin{aligned}
R(r,s)=&\int_0^c \frac{v_2s_2}{s_1}\int_{\frac{v_2s_2}{s_1}}^c f(v_1)dv_1f(v_2)dv_2+\int_0^{c\cdot\frac{s_2}{s_1}}(l\cdot\frac{v_1s_1}{s_2})\int_{\frac{v_1s_1}{s_2}}^c f(v_2)dv_2f(v_1)dv_1\\
\le&\int_0^c \frac{v_2s_2}{s_1}\int_{\frac{v_2s_2}{s_1}}^c \overline{f}dv_1\overline{f}dv_2+\int_0^{c\cdot\frac{s_2}{s_1}}(l\cdot\frac{v_1s_1}{s_2})\int_{\frac{v_1s_1}{s_2}}^c \overline{f}dv_2\overline{f}dv_1\\
=&(\overline{f}c)^2\cdot\Big(\int_0^c \frac{v_2s_2}{s_1}\int_{\frac{v_2s_2}{s_1}}^c \frac{1}{c}dv_1\frac{1}{c}dv_2+\int_0^{c\frac{s_2}{s_1}}(l\cdot\frac{v_1s_1}{s_2})\int_{\frac{v_1s_1}{s_2}}^c \frac{1}{c}dv_2\frac{1}{c}dv_1\Big)\\
=&(\overline{f}c)^2\cdot\overline{R}(r,s)
\end{aligned}$$

where $\overline{R}(r,s)$ computes the expected revenue under a uniform value distribution given CTR vector r and signal pair s. Similarly, the lower bound is $R(r,s)\ge(\underline{f}c)^2\cdot\overline{R}(r,s)$. Since $R(r,s)$ is only related to the signal ratio $x=\frac{s_2}{s_1}$, we rewrite $R(r,s)$ as $R(r,x)$. Similarly, rewrite $\overline{R}(r,s)$ as $\overline{R}(r,x)$. Let $x^*\le 1$ and $\overline{x}\le 1$ (by Lemma 4.3) be the optimal signal ratio for $R(r,x)$ and $\overline{R}(r,x)$, respectively. Then,

$$\begin{aligned}
&(\underline{f}c)^2\cdot\overline{R}(r,x^*)\le R(r,x^*)\le(\overline{f}c)^2\cdot\overline{R}(r,x^*)\\
&(\underline{f}c)^2\cdot\overline{R}(r,\overline{x})\le R(r,\overline{x})\le(\overline{f}c)^2\cdot\overline{R}(r,\overline{x})
\end{aligned}$$

Simple calculation leads to $(\underline{f}/\overline{f})^2\cdot R(r,x^*)\le(\underline{f}c)^2\cdot\overline{R}(r,x^*)\le(\underline{f}c)^2\cdot\overline{R}(r,\overline{x})\le R(r,\overline{x})$. The second inequality is due to the optimality of $\overline{x}$ to $\overline{R}(r,x)$. The whole inequality implies that if the seller sends signal pair whose ratio is optimal under a uniform value distribution, the approximation ratio is at least $(\underline{f}/\overline{f})^2$. Notice that Lemma 4.9 shows that under a uniform value distribution, sending a signal pair with signal ratio $\frac{s_2}{s_1}=1$ achieves $\frac{8}{9}$ approximation, i.e., $\frac{8}{9}\overline{R}(r,\overline{x})\le\overline{R}(r,1)$. Hence, we have $\frac{8}{9}(\underline{f}/\overline{f})^2\cdot R(r,x^*)\le\frac{8}{9}(\underline{f}c)^2\cdot\overline{R}(r,\overline{x})\le(\underline{f}c)^2\cdot\overline{R}(r,1)\le R(r,1)$, implying that if the seller sends signal pair with ratio equal to 1, then the approximation is $\frac{8}{9}\cdot(\underline{f}/\overline{f})^2$.

Now, we present the $0.995\cdot(\underline{f}/\overline{f})^2$ approximation. Lemma 4.8 shows that under a uniform distribution, the probability mass z of sending signal (σ_0,σ_0) is upper bounded as $z<0.04$, while $1-z>0.96$ probability mass is for sending signal pairs of the optimal signal ratio $\overline{x}$. Hence, if we construct a signaling scheme by assuming the unknown value distribution to be a uniform distribution, it can achieve at least $0.995\cdot(\underline{f}/\overline{f})^2$-approximation, where $0.995\approx 0.04\times\frac{8}{9}+0.96$. ◀

The above proof implies that the *prior-free* signaling scheme is constructed with signal ratio $x(l)=\frac{3+l}{4}$ obtained by assuming the unknown value distribution to be a uniform distribution. One direct result from the proof is that an easier but loose scheme is revealing no information which gives $\frac{8}{9}\cdot(\underline{f}/\overline{f})^2$ approximation. The improved ratio in Theorem 4.2 demonstrates the benefits of strategic information revelation.

4.4 Completing the Last Piece – Approximation Guarantee with Known Distributions

The only missing piece for completing the proof of Theorem 4.2 is the proof of Lemma 4.8, which is for a special linear optimal signal ratio function $x(l) = \frac{3+l}{4}$. In this part, we prove a more general result for any convex $x(l)$, which directly implies Lemma 4.8 with linear $x(l)$. To formally state the general proposition for convex $x(l)$, we need the following definitions.

▶ **Definition 4.10.** *Given that the optimal signal ratio $x(l)$ is a convex function in $l \in [0,1]$, define the following notations.*

1. *Initial number K_0: it satisfies that i) $x = x(l)^{K_0} \geq l$, and ii) $x = x(l)^{K_0+1}$ crosses the line $x = l$ and intersects at some point (l, l) with $l < 1$.*
2. *Define $S(k, l)$ with $\sigma_0 = x(l)^k$, $\sigma_i = x(l)^{k-i}$ as*

$$S(k,l) = 1 + \frac{l+1-2\sigma_0}{\sigma_0 - l} + \frac{l+1-2\sigma_0}{\sigma_0 - l} \cdot \frac{1-\sigma_1}{\sigma_1 - l} + \cdots + \frac{l+1-2\sigma_0}{\sigma_0 - l} \cdot \prod_{i=1}^{k-1} \frac{1-\sigma_i}{\sigma_i - l} \tag{9}$$

3. *Intersection point $l[k]$: given some $k > K_0$, $l[k] \neq 1$ is a solution to the equation $x(l)^k = l$. In another word, $x = x(l)^k$ crosses the line $x = l$ and intersects at the point $(l[k], l[k])$.*

Recall in the construction of the signaling scheme that given a CTR vector $r = (l, 1)$, at most $K = \lfloor \log_{x(l)} l \rfloor$ signals (i.e., σ_i) are within the interval $[l, 1]$. In fact, the initial number K_0 specifies the minimum number of signals constructed within $[l, 1]$ for any $l < 1$. Also, the probability mass z of sending (σ_0, σ_0) can be computed with the defined $S(k, l)$,

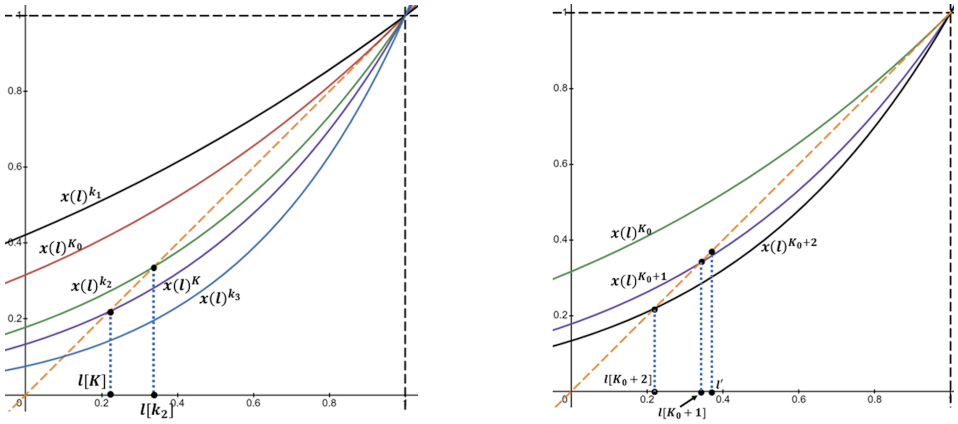
$$z + p_0 + p_1 + \cdots + p_{K-1} = \frac{1}{2} \quad \Longleftrightarrow \quad z \cdot S(K, l) = \frac{1}{2} \tag{10}$$

With the above definition, we present the general result.

▶ **Proposition 4.11.** *Assume $x(l)$ is a convex function. There exists a signaling scheme whose worst-case approximation is $1 - z^*$, where $z^* = 1/S(K_0, l[K_0+1])$ and $S(K_0, l[K_0+1])$ is computed as (9).*

Proposition 4.11 provides a *worst-case* approximation bound for the constructed signaling scheme and shows how it depends on the intrinsic properties of the optimal signal ratio function. Intuitively, by Equation (9), two situations lead to a small z^*: 1) The initial number K_0 is large. In this case, it implies that the seller can send many signal pairs with the optimal signal ratio and thus $S(K_0, l[K_0 + 1])$ grows exponentially; 2) $l[K_0 + 1]$ is close to σ_0 in (9). Later, we will show it is equivalent to that $l[K_0 + 1]$ is close to $x(l[K_0 + 1])^{K_0}$. This case will lead to a large $S(K_0, l[K_0 + 1])$ and thus small z^*. In fact, given the number of signals $k \geq K_0$ and the CTR l, the approximation of the constructed signaling scheme can be calculated similarly as $1 - z$ with $z = 1/S(k, l)$. As we will prove later, the worst-case approximation is obtained only when l is approaching $l[K_0 + 1]$ from above (see Figure 1b for an example). Hence, when l varies, the actual approximation of the constructed scheme may be (much) better than $1 - z^*$.

Proposition 4.11 may be of independent interest. If an estimate for the bidders' value distribution is available, the seller then can construct a signaling scheme as in Section 4.2 that has an approximation guarantee indicated by Proposition 4.11. Note that Proposition 4.11 only requires $x(l)$ to be convex. This condition applies to various classic distributions, e.g., (1) the uniform distribution admits a 0.995-approximation, (2) the exponential distribution can have the exact optimal mechanism, (3) the standard Weibull distribution (truncated on



(a) (b)

Figure 1 K_0 is initial number. $l[k]$ is the intersection point. $k_1 < K_0 < k_2 < K < k_3$. $x(l)$ is convex.

$[0,1]$) with parameter $\gamma \geq 2$ (specifically we let $\gamma = 10$) admits approximation ratio ≈ 0.75. In some cases, it may be difficult to write down the explicit formula of $x(l)$ and verify its convexity. We find it relatively easy to compute $l(x)$, the inverse of $x(l)$. Hence, to verify the convexity of $x(l)$, we only need to verify the concavity of $l(x)$. An example of this idea is in Appendix H.

Before presenting the proof of Proposition 4.11, we show some properties for convex $x(l)$.

▶ **Observation 4.12.** *The function $x = x(l)^k$, for any integer $k > 1$ and $l \in [0,1]$, intersects with line $x = l$ at most twice: one point intersecting is $(1,1)$, and the other one (if exists) is $(l[k], l[k])$ (called intersection point as in Definition 4.10). Furthermore, when $k > K_0$ increases, $l[k]$ decreases and $\lim_{k\to\infty} l[k] = 0$.*

The idea of Observation 4.12 is depicted in Figure 1a. Given an initial number K_0 and $K = \lfloor \log_{x(l')} l' \rfloor$ for some l', we can observe from the figure that: i) If $k \leq K_0$, the curve $x(l)^k$ will be above line $x = l$; ii) If $K_0 \leq k \leq K$, then $l' \leq l[K]$ and $x(l')^k$ will be above point (l', l'). If $l' = l[K]$, then there are exactly K signals constructed within $[l', 1]$; and iii) If $k > K$, $x(l')^k$ will be below (l', l').

The following key lemma characterizes the monotonicity of convex $x(l)$.

▶ **Lemma 4.13.** *$x(l)$ is a monotone increasing function.*

Now we are ready to show the proof of Proposition 4.11. The high-level idea of the proof is by upper bounding the probability mass z of sending (at most one) *non-optimal* signal pair (σ_0, σ_0), because when sending other signal pairs (σ_i, σ_{i+1}) as constructed in the signaling scheme, the signaling scheme achieves the maximum of expected revenue expressed in (5).

Proof of Proposition 4.11. Without loss of generality, we consider the case where there is only one pair of CTR vectors, $(l, 1)$ and $(1, l)$ such that $\lambda((l,1)) = \lambda(1,l)) = \frac{1}{2}$. By the definition of symmetric environments, the analysis can be easily generalized to the case of more than two CTR vectors.

The following lemma segments $[0,1]$ by the intersection points $l[k]$'s, and shows how the probability mass z changes within each segment. Note that starting from $k = K_0 + 1$, $x(l)^k$ crosses the line $x = l$ (see Figure 1b). Then, we define $l[K_0] = 1$.

▶ **Lemma 4.14.** *Given $k \geq K_0 \geq 1$, the probability mass $z > 0$ is decreasing in $l \in (l[k+1], l[k]]$.*

The proof of Lemma 4.14 is in Appendix G.4.The reason we only care about $(l[k+1], l[k]]$ instead of the closed interval $[l[k+1], l[k]]$ is that i) for $l[k+1] < l \leq l[k]$, there will be k signals constructed in the interval $[l, 1]$, and ii) if $l = l[k+1]$, the seller can construct a signaling scheme with a list of $k+1$ signals where all the signal pairs sent have the optimal signal ratio $x(l[k+1])$ and the probability mass $z = 0$.

One implication of Lemma 4.14 is that when there are at most k signals constructed, the probability mass z achieves its maximum when l approaches $l[k+1]$ from above, i.e., $l \downarrow l[k+1]$. Therefore, at the limit $l[k+1]$, the probability mass z is computed with $S(k, l[k+1])$ where $\sigma_0 = x(l[k+1])^k, \sigma_1 = x(l[k+1])^{k-1}, \cdots, \sigma_i = x(l[k+1])^{k-i}$. In another word, when $l = l[k+1]$, instead of constructing a scheme with a list of $k+1$ signals where all the signal pairs sent have signal ratio $x(l[k+1])$, the seller constructs a signaling scheme with a list of k signals starting from $\sigma_0 = x(l[k+1])^k$, which sends signal pair (σ_{i-1}, σ_i) of signal ratio $x(l[k+1])$ and one signal pair (σ_0, σ_0).

By the above analysis, to upper bound z, we only need to compare its values at these limit points $l[k]$'s. Alternatively, we compare $S(k, l[k+1])$ for different k. The following lemma shows that $S(k, l[k+1])$ is increasing in k, whose proof is in Appendix G.7.

▶ **Lemma 4.15.** *Given $k - 1 \geq K_0 \geq 1$, we have $S(k, l[k+1]) \geq S(k-1, l[k])$.*

Lemma 4.15 implies that $S(K_0, l[K_0+1])$ is the minimum compared with other $S(k, l[k+1])$ for $k > K_0$. The quantity $S(K_0, l[K_0+1])$ is computed as (9) with

$$\sigma_0 = x(l[K_0+1])^{K_0}, \sigma_1 = x(l[K_0+1])^{K_0-1}, \ldots, \sigma_i = x(l[K_0+1])^{K_0-i}$$

Since both CTR vectors $(1, l)$ and $(l, 1)$ will send signal (σ_0, σ_0), the upper bound of the probability mass of sending signal pair (σ_0, σ_0) in the constructed signaling scheme is $z^* = 1/S(K_0, l[K_0+1])$.

The above analysis generalizes to the case of more than two CTR vectors. Note that given any CTR vector (h, l), in the symmetric environment, we can find one CTR vector (l, h) with equal probability, i.e., $\lambda((h, l)) = \lambda((l, h))$. Hence, we can separately consider these pairs of CTR vectors when designing a signaling scheme and each of them achieves at least $(1 - z^*)$ (multiplicatively) approximation. Therefore, the constructed signaling scheme can achieve at least $(1 - z^*)$ (multiplicatively) approximation. ◀

5 Conclusions and Open Problems

This paper studies the natural Bayesian variant of the calibrated click-through auction of [11]. We focus on the seller's information design problem to maximize the expected revenue. In general environments, we develop an FPTAS to compute an approximately optimal signaling scheme. In a symmetric environment, we give a simple and prior-free signaling scheme with a constant approximation guarantee for not-too-fluctuating value distributions.

Our results raise many interesting questions for future research. Below we discuss some of them. The first is to develop a simple signaling scheme for more than two bidders in symmetric environments. More generally, it is interesting to study more efficient algorithms for optimal signaling. Though our FPTAS for the general model enriches our understanding of the tractability of the problem, such an algorithm may not be ideal from a practitioner's perspective. The second is to consider the worst-case approximation as in Proposition 4.11 but without the convexity assumption. In Appendix I,we provide more discussions about these two open problems.

High-Accuracy Multicommodity Flows via Iterative Refinement

Abstract

The multicommodity flow problem is a classic problem in network flow and combinatorial optimization, with applications in transportation, communication, logistics, and supply chain management, etc. Existing algorithms often focus on low-accuracy approximate solutions, while high-accuracy algorithms typically rely on general linear program solvers. In this paper, we present efficient high-accuracy algorithms for a broad family of multicommodity flow problems on undirected graphs, demonstrating improved running times compared to general linear program solvers. Our main result shows that we can solve the $\ell_{q,p}$-norm multicommodity flow problem to a $(1+\varepsilon)$ approximation in time $O_{q,p}(m^{1+o(1)}k^2\log(1/\varepsilon))$, where k is the number of commodities, and $O_{q,p}(\cdot)$ hides constants depending only on q or p. As q and p approach to 1 and ∞ respectively, $\ell_{q,p}$-norm flow tends to maximum concurrent flow.

We introduce the first iterative refinement framework for $\ell_{q,p}$-norm minimization problems, which reduces the problem to solving a series of decomposable residual problems. In the case of k-commodity flow, each residual problem can be decomposed into k single commodity convex flow problems, each of which can be solved in almost-linear time. As many classical variants of multicommodity flows were shown to be complete for linear programs in the high-accuracy regime [Ding-Kyng-Zhang, ICALP'22], our result provides new directions for studying more efficient high-accuracy multicommodity flow algorithms.

1 Introduction

The multicommodity flow problem is a classic challenge in network flow and combinatorial optimization, where the goal is to optimally route multiple commodities through a network from their respective sources to their respective sinks, subject to flow conservation constraints. This problem has significant applications in various fields such as transportation, communication, logistics, and supply chain management [43, 6, 57, 9, 71]. Currently, the fastest algorithms for computing high-accuracy solutions involve formulating these problems as linear programs and employing generic linear program solvers [44, 39, 62, 22]. Notably, linear programs can be reduced to multicommodity flow problems with near-linear overhead [35, 26].

Existing research predominantly focuses on obtaining $(1+\varepsilon)$-approximate solutions for maximum concurrent k-commodity flows [49, 48, 73, 27, 37, 30, 56, 51], as summarized in Table 1. However, these low-accuracy algorithms feature running times that are polynomial in $1/\varepsilon$ for computing $(1+\varepsilon)$-approximate solutions. In contrast, high-accuracy algorithms exhibit running times that are polynomial in $\log(1/\varepsilon)$. Importantly, [26] demonstrated that any enhancement in the high-accuracy algorithm for the 2-commodity flow problem would result in a faster general linear program solver.

In this paper, we investigate multicommodity flow problems on undirected graphs, which possess more structure than their directed counterparts. Prior work has shown that maximum concurrent 2-commodity flow on undirected graphs can be reduced to two instances of maximum flow problems, both solvable in almost-linear time [63, 15]. More generally, maximum concurrent k-commodity flows can be reduced to 2^{k-1} maximum flows[1]. Additionally, researchers have discovered that $(1+\varepsilon)$-approximate algorithms for undirected graphs are considerably faster than those for directed graphs [42, 41, 66]. Nevertheless, the fastest high-accuracy algorithms still rely on general linear program solvers. Given these advancements, we pose the following natural question:

> *Is it possible to solve multicommodity flow problems on undirected graphs to high accuracy more efficiently than with general linear program solvers?*

This paper gives an affirmative answer and presents high-accuracy algorithms for a large family of multicommodity flow problems that run in time $m^{1+o(1)}\mathrm{poly}(k, \log(1/\varepsilon))$. Our main result is an algorithm that, for any $1 \le q \le 2 \le p$ with $p = \widetilde{O}(1)$[2] and $\frac{1}{q-1} = O(1)$, given edge weights $\mathbf{w} \in \mathbb{R}^E_+$ and k vertex demands $\mathbf{D} = [\mathbf{d}_1, \cdots, \mathbf{d}_k] \in \mathbb{R}^{V \times k}$, solves the following optimization problem to a $(1+\varepsilon)$-approximation with high probability[3] in time $O_{q,p}(m^{1+o(1)}k^2 \log(1/\varepsilon))$:

$$\min_{k\text{-commodity flow } \mathbf{F} \text{ with residue } \mathbf{D}} \|\mathbf{WF}\|_{q,p}^{pq} \stackrel{\text{def}}{=} \sum_{e \in E} w_e^{pq} \left(\sum_{j=1}^{k} |F_{ej}|^q \right)^p .$$

The problem generalizes the maximum concurrent flow problem by setting the edge weights w_e as the reciprocal of edge capacities and letting $q \to 1, p \to \infty$. Therefore, $\ell_{q,p}$-norm flows are natural relaxations of the combinatorial maximum concurrent flows. However, unlike the typical relaxations using the exponential function (exp(congestion)) in previously efficient approximation schemes, we show that $\ell_{q,p}$-norm problems themselves admit high-accuracy solutions. Thus, we provide a large family of multicommodity flows that admit high-accuracy solutions in almost linear time.

From a technical standpoint, our exploration of multicommodity flows reflects the research trajectory of ℓ_p-norm single commodity flows in recent years [46, 1]. This line of study has led to the development of several novel algorithmic components, some of which have proven beneficial for classical single-commodity flow as well [40, 7]. More significantly, examining ℓ_p-norm flows, particularly their weighted variants, has directed attention towards the core challenges of flow problems. We posit that further investigation of $\ell_{q,p}$-norm flows is likely to yield similar insights, potentially for variants of multicommodity flows not known to be hard, such as unit-capacity maximum concurrent flows on undirected graphs.

---

[1] To see this, the edge capacity constraint $\sum_j |F_{ej}| \le u_e$ is equivalent to $|\sum_j \varepsilon_j F_{ej}| \le u_e$ for any $\varepsilon \in \{\pm 1\}^k$.

[2] We use $\widetilde{O}(f(n))$ to hide $\mathrm{poly}\log f(n)$ factors.

[3] We use "with high probability" (w.h.p.) throughout to say that an event happens with probability at least $1 - n^{-C}$ for any constant $C > 0$.

To summarize, this paper introduces the first iterative refinement framework for solving $\ell_{q,p}$-norm minimization problems. The proposed framework reduces the problem to approximately resolving $O_{p,q}(k\log(1/\varepsilon))$ instances of decomposable residual problems. For the k-commodity flow case, each residual problem can be divided into k single commodity flow problems and solved in $km^{1+o(1)}$-time using the almost-linear time convex flow solver [15]. We are the first to combine the iterative refinement framework [2, 3] with the convex flow solver [15], and give a non-trivial application to $\ell_{q,p}$-norm multicommodity flow problem. As many classical variants of multicommodity flows were shown to be complete for linear programs in the high-accuracy regime [26], our result provides new directions for studying more efficient high-accuracy multicommodity flow algorithms.

1.1 Main Result

Given an undirected graph $G=(V,E)$ and parameters q and p, the *$\ell_{q,p}$-norm multicommodity flow* problem asks for a multicommodity flow $\mathbf{F}=[\mathbf{f}_1,\cdots,\mathbf{f}_k]\in\mathbb{R}^{E\times k}$ that routes the given demands while minimizing the following objective:

$$\min_{\mathbf{B}^\top\mathbf{F}=\mathbf{D}}\|\mathbf{WF}\|_{q,p}^{pq}\stackrel{\text{def}}{=}\sum_{e\in E}w_e^{pq}\left(\sum_{j=1}^{k}|F_{ej}|^q\right)^p. \tag{1}$$

Here, we have

1. $\mathbf{B}\in\mathbb{R}^{E\times V}$, the edge-vertex incidence matrix of G;
2. $\mathbf{D}=[\mathbf{d}_1,\cdots,\mathbf{d}_k]\in\mathbb{R}^{V\times k}$, representing the set of k vertex demands, where $\langle\mathbf{d}_j,\mathbf{1}_V\rangle=0$ for each $j\in[k]$;
3. $\mathbf{w}\in\mathbb{R}_+^E$, the vector of edge weights, and $\mathbf{W}=\operatorname{diag}(\mathbf{w})$.

This problem can be seen as a generalization of the classical maximum concurrent flow problem, which aims to find a feasible flow $\mathbf{F}$ that minimizes edge congestion:

$$\min_{\mathbf{B}^\top\mathbf{F}=\mathbf{D}}\max_{e\in E}\frac{1}{c_e}\sum_{j\in[k]}|F_{ej}|=\left\|\mathbf{C}^{-1}\mathbf{F}\right\|_{1,\infty}. \tag{2}$$

Here, $\mathbf{c}\in\mathbb{R}_+^E$ denotes the vector of edge capacities and $\mathbf{C}=\operatorname{diag}(\mathbf{c})$. Our generalization allows for fractional vertex demands, meaning that for each commodity j, the demand $\mathbf{d}_j$ is not restricted to source-sink pairs.

The main technical result of this paper is presented below.

▶ **Theorem 1.** *Given any $1<q\le 2\le p$ with $p=\widetilde{O}(1)$ and $\frac{1}{q-1}=O(1)$ and an error parameter $\varepsilon>\exp(-\widetilde{O}(1))$, let* OPT *be the optimal value to Problem* (1)*. There is a randomized algorithm that computes a feasible flow $\mathbf{F}$ to Problem* (1) *such that*

$$\|\mathbf{WF}\|_{q,p}^{pq}\le(1+\varepsilon)\,\mathrm{OPT}+\varepsilon.$$

The algorithm runs in time

$$O\left(p^2\cdot\left(\frac{1}{q-1}\right)^{\frac{1}{q-1}}m^{1+o(1)}\cdot k^2\cdot\log\frac{1}{\varepsilon}\right)$$

with high probability.

1.2 Related Works

In this section, we discuss some work related to the problem and the techniques we use.

Multicommodity Flow

The multicommodity flow problem is a classic problem in network flow and combinatorial optimization. Multicommodity flow has a wide range of applications in various fields which are addressed in numerous surveys [43, 6, 57, 9, 71]. These problems can be formulated as linear programs and solved using generic linear program solvers which remain the fastest algorithms for computing high-accuracy solutions [44, 39, 62, 22]. On the other hand, linear programs can be reduced to 2-commodity flow efficiently [35, 26]. Specifically, any linear program can be reduced to a maximum throughput 2-commodity flow on sparse graphs with a near-linear overhead [26]. Recently, Brand and Zhang [13] proposed a faster algorithm for 2-commodity flow on non-sparse graphs with running time $\widetilde{O}(\sqrt{m}n^{\omega-1/2})$ that outperforms the existing time complexities $\widetilde{O}(m^\omega)$ [22] and $\widetilde{O}(\sqrt{m}n^2)$ [36]. For the general k-commodity flow, they proposed an algorithm with time complexity $\widetilde{O}(k^{2.5}\sqrt{m}n^{\omega-1/2})$.

Much of the existing works focus on finding $(1+\varepsilon)$-approximate solutions. [64] gave the first FPTAS to the maximum concurrent flow problem with unit capacity (Problem (2)). Subsequently, a series of work [49, 48, 32, 33, 45, 38, 60, 34, 61, 67] based on Lagrangian relaxation and linear program decomposition gave algorithms with improved running times for various versions of the problem with arbitrary edge capacity. These algorithms iteratively update the current flow and make progress by computing a series of either shortest paths [64, 45, 60, 67], or single commodity minimum cost flows [49, 48, 32, 33, 38, 34, 61]. In particular, [61] and [34] showed that finding $(1+\varepsilon)$-approximate solutions can be reduced to $\widetilde{O}(k/\varepsilon^2)$ min-cost flow computations which take $\widetilde{O}(kmn/\varepsilon^2)$-time in total using the fastest min-cost flow algorithm at the time. Combining with the almost-linear time min-cost flow algorithm yields a randomized $m^{1+o(1)}k/\varepsilon^2$-time max concurrent flow algorithm.

Later, a series of works based on multiplicative weight updates (MWU) gave conceptually simpler and faster algorithms at their time [73, 27, 37, 30, 51]. These methods build the solution from scratch without re-routing the current flow. At each step, they augment the current flow via a shortest path computation that favors relatively uncongested paths. [51] used dynamic APSP data structure to speed up these computations and resulted in an

$\widetilde{O}((m+k)n/\varepsilon^2)$-time max concurrent flow algorithm. At the time, the fastest max concurrent flow runs in $\widetilde{O}(m^{1.5}k/\varepsilon^2)$-time due to the $\widetilde{O}(m^{1.5})$-time min-cost flow algorithm by [24]. The result of [51] was a significant improvement in the case when k is large.

Another line of work focused on improving the $1/\varepsilon^2$ term. [11] found an FPTAS that only has $O(\frac{1}{\varepsilon \log 1/\varepsilon})$ dependence. Later, [56] gave an FPTAS with only $O(1/\varepsilon)$ dependence. In particular, the algorithm by Nesterov runs in $\widetilde{O}(k^2m^2/\varepsilon)$-time.

Similar to the situation of single commodity flows, researchers have discovered approximate algorithms with $m^{1.5-O(1)}$ dependence on undirected graphs. [42] gave the first $\widetilde{O}(m^{4/3}\mathrm{poly}(k, 1/\varepsilon))$ algorithm for max concurrent flow. The algorithm implements the method of [49, 48] using *electrical capacity-constrained flows* instead of min-cost flows. Each electrical capacity-constrained flow can be reduced to, using width-reduction MWU [17], $\widetilde{O}(m^{1/3}\mathrm{poly}(k, 1/\varepsilon))$ graph Laplacian systems. In the breakthrough result of [41], they improved the running time to $m^{1+o(1)}k^2/\varepsilon^2$ based on non-Euclidean gradient descent and fast oblivious routing. Specifically, the algorithm computes an oblivious routing of congestion $m^{o(1)}$ and uses it to reduce the number of gradient descent iterations to $m^{o(1)} \cdot k/\varepsilon^2$. Later, [66] introduced the idea of *area convexity* and improved the iteration count to $\widetilde{O}(1/\varepsilon)$. This resulted in the first $\widetilde{O}(mk/\varepsilon)$-time max concurrent flow algorithm.

ℓ_p-Norm Regression

The ℓ_p-norm regression problem seeks to find a vector $\mathbf{x}$ that minimizes $\|\mathbf{Ax} - \mathbf{b}\|_p$, where $\mathbf{A} \in \mathbb{R}^{d\times n}$ and $\mathbf{b} \in \mathbb{R}^d$. Varying in p interpolates between linear regression ($p = 2$) and linear program ($p \in \{1, \infty\}$). ℓ_p-norm regression has gained significant attention in the past decade due to its wide range of applications and its implications for other convex optimization problems [54, 72]. Many works have focused on low-accuracy algorithms for overconstrained matrices, i.e., $d \gg n$ [25, 54, 72, 19, 20, 18]. These results show various ways to find another matrix $\widetilde{\mathbf{A}}$ with fewer rows such that $\|\widetilde{\mathbf{A}}\mathbf{x}\|_p \approx \|\mathbf{Ax}\|_p$ for any $\mathbf{x}$. Then, approximate ℓ_p-norm regression can be reduced to $\widetilde{\mathbf{A}}$ and solved in time $O(\mathsf{nnz}(\mathbf{A}) + \mathrm{poly}(d, 1/\varepsilon))$ when p is a constant.

High-accuracy solutions can be found using interior point methods (IPM) in $\widetilde{O}(\sqrt{n})$ or $\widetilde{O}(\sqrt{d})$ iterations [47]. [14] showed a homotopy method that finds high accuarcy solution in $\widetilde{O}(n^{|1/2-1/p|})$ iterations of linear system solvers. Based on the idea of iterative refinement and width reduction, a series of works [2, 4, 5, 3] obtained improved iteration complexities of $\widetilde{O}_p(n^{(p-2)/(3p-2)})$ for $p \geq 2$. Motivated by the success of sparse linear system solver [59] and linear program in matrix multiplication time [22], [31] gave a high-accuracy algorithm that runs in time $\widetilde{O}_p(n^\theta)$ for some $\theta < \omega - \Omega(1)$, where ω is the matrix multiplication time exponent.

ℓ_p-Norm Flows

The $\ell_{q,p}$-norm formulation can be viewed as a multicommodity extension of the ℓ_p-norm flows, which seeks to find a flow $\mathbf{f} \in \mathbb{R}^E$ that routes the given demand and minimizes $\|\mathrm{diag}(\mathbf{w})\mathbf{f}\|_p$ where $\mathbf{w} \in \mathbb{R}^E_+$. Varying in p interpolates between the transshipment ($p = 1$), the electrical flow ($p = 2$), and the maximum flow problem ($p = \infty$). Combining the result on ℓ_p-norm regressions and Laplacian solvers, [2] gave an $\widetilde{O}_p(m^{1+|p-2|/(2p+|p-2|)})$-time ℓ_p-norm flow algorithm. Opening up the black box of the Spielman-Teng Laplacian solver [68], [46] gave the first $\widetilde{O}_p(m^{1+O(1/\sqrt{p})})$-time high-accuracy ℓ_p-norm flow algorithm for unweighted graphs, i.e., $\mathbf{w} = \mathbf{1}$. The runtime is almost linear for $p = \omega(1)$ and this was the first almost-linear time high-accuracy algorithm for a large family of single commodity flow problems. In the weighted case, [1] gave a $p(m^{1+o(1)} + n^{4/3+o(1)})$-time high-accuracy ℓ_p-norm flow algorithm

by combining [46] with the idea of sparsification. The study of the ℓ_p-norm flow algorithms has been proved useful for single commodity flow problems such as unit-capacity maximum flows, bipartite matchings, and min-cost flows [40, 7].

Continuous Optimization on Graphs

From a technical point of view, our $\ell_{q,p}$-norm multicommodity flow algorithm is inspired by the recent trend of applying continuous optimization techniques to solve graph problems. As one of the earlier results in this direction, [24] combined interior point methods with fast graph Laplacian system solver [68] and gave an $\widetilde{O}(m^{3/2})$-time min-cost flow algorithm. Later, the idea culminated in a decade of works improving max flow and min-cost flow algorithms [17, 52, 65, 41, 53, 58, 23, 7, 12, 40, 70, 8, 10, 15, 29, 69].

Beyond classical flow problems, the idea of combining continuous and combinatorial techniques gives improved algorithms for approximate shortest paths in parallel/distributed setting [50, 74], faster network flow algorithms in distributed setting [28], flow diffusion [16], ℓ_p-norm flows [46, 1], and more.

1.3 Our Approach

For the clarity of the presentation, we focus on the unweighted version of Problem (1), i.e., $w_e = 1$ for each edge e, which is shown as follows:

$$\min_{\mathbf{B}^\top \mathbf{F} = \mathbf{D}} \|\mathbf{F}\|_{q,p}^{pq} = \sum_{e \in E} \left(\sum_{j=1}^{k} |F_{ej}|^q \right)^p .$$

The algorithm follows an overall *iterative refinement* framework. That is, given the current flow $\mathbf{F}$, we want to find an update direction $\mathbf{\Delta}$ so that $\|\mathbf{F} + \mathbf{\Delta}\|_{q,p}^{pq}$ is smaller than $\|\mathbf{F}\|_{q,p}^{pq}$. However, finding the optimal $\mathbf{\Delta}$ is equivalent to the original problem. The idea of iterative refinement is to find a proxy *residual* function $\mathcal{R}(\mathbf{\Delta}; \mathbf{F})$ that approximates the Bregman divergence of $\|\mathbf{F}\|_{q,p}^{pq}$, i.e.,

$$\mathcal{R}(\mathbf{\Delta}; \mathbf{F}) \approx \|\mathbf{F} + \mathbf{\Delta}\|_{q,p}^{pq} - \|\mathbf{F}\|_{q,p}^{pq} - \langle \mathbf{G}, \mathbf{\Delta} \rangle ,$$

where $\mathbf{G} \stackrel{\text{def}}{=} \frac{\mathrm{d}}{\mathrm{d}\mathbf{F}} \|\mathbf{F}\|_{q,p}^{pq} \in \mathbb{R}^{E \times k}$ is the gradient. Then we can compute the direction $\mathbf{\Delta}$ by solving the *residual problem*:

$$\min_{\mathbf{B}^\top \mathbf{\Delta} = \mathbf{0}} \langle \mathbf{G}, \mathbf{\Delta} \rangle + \mathcal{R}(\mathbf{\Delta}; \mathbf{G}) \approx \|\mathbf{F} + \mathbf{\Delta}\|_{q,p}^{pq} - \|\mathbf{F}\|_{q,p}^{pq}.$$

If $\mathcal{R}(\mathbf{\Delta}; \mathbf{F})$ is a good approximation to the Bregman divergence, i.e., has a "condition number" of κ, we would obtain a $(1+\varepsilon)$-approximate solution in $O(\kappa \log(1/\varepsilon))$ iterations. On the other hand, $\mathcal{R}(\mathbf{\Delta}; \mathbf{F})$ should be computationally easier to minimize so that we can implement each iteration efficiently.

For any $p > 1$, [2] shows that $|x + \delta|^p$ can be locally approximated by a linear term plus an error term $\gamma_p(\delta; |x|)$, which behaves quadratically in δ when $|\delta| \leq |x|$ and as $|\delta|^p$ otherwise. Our key lemma (Lemma 8) extends the observation to approximating $\|\mathbf{F} + \mathbf{\Delta}\|_{q,p}^{pq}$ and gives

$$\begin{aligned} \|\mathbf{F} + \mathbf{\Delta}\|_{q,p}^{pq} - \|\mathbf{F}\|_{q,p}^{pq} - \langle \mathbf{G}, \mathbf{\Delta} \rangle \approx{}& O_{p,q}(k) \sum_{e,j} \|\mathbf{f}^e\|_q^{q(p-1)} \gamma_q(\Delta_{ej}; F_{ej}) \\ &+ O_{p,q}(k^p) \sum_{e,j} |\Delta_{ej}|^{pq}. \end{aligned} \tag{3}$$

Intuitively, the Bregman divergence can be approximated by a decomposable function on each coordinate (e, j). The contribution of each coordinate (e, j) behaves differently depending on the absolute value of Δ_{ej}. When $|\Delta_{ej}| \leq |F_{ej}|$, it behaves quadratically in $|\Delta_{ej}|^q$; when $|\Delta_{ej}| > |F_{ej}|$ but smaller than $\|\mathbf{f}^e\|_q^q$, the summation of k flow values to the power of q on edge $e \in E$, it is dominated by the term $|\Delta_{ej}|^{pq}$. The factors k and k^p in Equation (3) come from that given any k-dimensional vector $\mathbf{x} \in \mathbb{R}^k$, we have

$$\|\mathbf{x}\|_p^p \leq \|\mathbf{x}\|_1^p \leq k^{p-1} \|\mathbf{x}\|_p^p .$$

Surprisingly, this approximation has a conditioner number of $O_{q,p}(k)$ and is decomposable for each commodity $j \in [k]$. To obtain a $(1+\varepsilon)$-approximate solution, we only need to solve $O_{q,p}(k \log(1/\varepsilon))$ iterations of residual problems of the form

$$\min_{\mathbf{B}^\top \boldsymbol{\Delta} = \mathbf{0}} \langle \mathbf{G}, \boldsymbol{\Delta} \rangle + O_{p,q}(k) \sum_{e,j} \|\mathbf{f}^e\|_q^{q(p-1)} \gamma_q(\Delta_{ej}; F_{ej}) + O_{p,q}(k^p) \sum_{e,j} |\Delta_{ej}|^{pq}.$$

The decomposability allows us to use the convex flow solver from [15] and solve the residual problem to high accuracy for each commodity in almost-linear time. Thus, each iteration takes $km^{1+o(1)}$-time and the final running time is $O_{q,p}(k^2 m^{1+o(1)} \log(1/\varepsilon))$.

1.4 Paper Organization

In Section 2, we introduce some preliminaries before presenting the technical parts, including the convex flow solver [15] that is the core tool for solving the residual problem and the iterative refinement framework shown in [2, 3]. We formally present the proposed $\ell_{q,p}$-norm k-commodity flow algorithm in Section 3, and then solve the residual problem in Section 4.

2 Preliminaries

2.1 General Notations

We denote vectors (resp. matrices) by boldface lowercase (reps. uppercase) letters. For a vector $\mathbf{x} \in \mathbb{R}^n$, the scalar x_i, $i \in [n]$ represents the i-th entry of $\mathbf{x}$. For two vectors $\mathbf{x}$ and $\mathbf{y}$, the vector $\mathbf{x} \cdot \mathbf{y}$ represents the entrywise product, i.e., $(\mathbf{x} \cdot \mathbf{y})_i = x_i y_i$. Besides, for a vector $\mathbf{x}$, let $|\mathbf{x}|$ and $\mathbf{x}^p$ denote the entrywise absolute value and entrywise power of $\mathbf{x}$ respectively, that is, $|\mathbf{x}|_i = |x_i|$ and $(\mathbf{x}^p)_i = (x_i)^p$. We use $\langle \mathbf{x}, \mathbf{y} \rangle$ to denote the inner product of $\mathbf{x}, \mathbf{y}$, i.e., $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^\top \mathbf{y}$. For a vector $\mathbf{x}$, let $\mathrm{diag}(\mathbf{x})$ represent a diagonal matrix whose i-th entry is equal to x_i.

Graphs

In this paper, we consider multi-graph G, with edge set $E(G)$ and vertex set $V(G)$. When the graph is clear from context, we use the short-hand E for $E(G)$ and V for $V(G)$ with $|E| = m$ and $|V| = n$. Assume that each edge $e \in E$ has an implicit direction, used to define its edge-vertex incidence matrix $\mathbf{B} \in \mathbb{R}^{E \times V}$. Abusing notation slightly, we often write $e = (u, v) \in E$, where u and v are the tail and head of e respectively (note that technically multi-graph does not allow for edges to be specified by their endpoints). We say a flow $\mathbf{f} \in \mathbb{R}^E$ routes a demand $\mathbf{d} \in \mathbb{R}^V$ if $\mathbf{B}^\top \mathbf{f} = \mathbf{d}$. Given a k-commodity flow $\mathbf{F} \in \mathbb{R}^{E \times k}$, let $\mathbf{f}^e \in \mathbb{R}^k$ denote $\mathbf{F}$'s e-th row vector, a vector of k flow values through edge $e \in E$, and $\mathbf{f}_j \in \mathbb{R}^E$ denote $\mathbf{F}$'s j-th column vector, the flow vector of commodity $j \in [k]$; let $F_{i,j}$ denote the entry at the i-th row and j-th column of $\mathbf{F}$.

Model of Computation

In this paper, for problem instances encoded with z bits, all algorithms work in fixed-point arithmetic where words have $O(\log^{O(1)} z)$ bits, i.e., we prove that all numbers stored are in the interval $[\exp(-\log^{O(1)} z), \exp(\log^{O(1)} z)]$.

2.2 Convex Flow Solver

In this paper, we utilize the almost-linear time convex flow algorithm from [15]. Given a set of *computationally efficient* convex cost functions on edges $\{c_e(\cdot)\}_e$, the algorithm finds a single commodity flow $\mathbf{f}$ that routes the given demand $\mathbf{d}$ and minimizes $\sum_e c_e(f_e)$ up to a small $\exp(-\log^{O(1)} m)$ additive error.

▶ **Assumption 1** (Definition 10.1 and Assumption 10.2, [15]). *Let $K = \widetilde{O}(1)$ be a parameter fixed throughout. Given a convex cost function $c : \mathbb{R} \to \mathbb{R} \cup \{+\infty\}$, c is* computationally efficient *if there is a barrier function $\psi_c(f, y)$ defined on the domain $\mathcal{D}_c \stackrel{\text{def}}{=} \{(f, y) |\ c(f) \le y\}$ such that*

1. *The cost is quasi-polynomially bounded, i.e., $|c(f)| = O(m^K + |f|^K)$ for all $f \in \mathbb{R}$.*
2. *ψ_c is a ν-*self-concordant barrier *for some $\nu = O(1)$, that is, the following holds*

$$\begin{aligned} \psi_c(\mathbf{x}) &\to \infty, \text{ as } \mathbf{x} \text{ approaches the boundary of } \mathcal{D}_c, \\ \left|\nabla^3 \psi_c(\mathbf{x})[\mathbf{v}, \mathbf{v}, \mathbf{v}]\right| &\le 2\left(\nabla^2 \psi_c(\mathbf{x})[\mathbf{v}, \mathbf{v}]\right)^{3/2}, \forall \mathbf{x} \in \mathcal{D}_c, \mathbf{v} \in \mathbb{R}^2, \\ \langle \nabla \psi_c(\mathbf{x}), \mathbf{v}\rangle^2 &\le \nu \cdot \nabla^2 \psi_c(\mathbf{x})[\mathbf{v}, \mathbf{v}]. \end{aligned}$$

3. *The Hessian is quasi-polynomially bounded as long as the function value is $\widetilde{O}(1)$ bounded, i.e., for all points $|f|, |y| \le m^K$ with $\psi_c(f, y) \le \widetilde{O}(1)$, $\nabla^2 \psi_c(f, y) \preceq \exp(\log^{O(1)} m)\mathbf{I}$.*
4. *Both $\nabla \psi_c$ and $\nabla^2 \psi_c$ can be computed and accessed in $\widetilde{O}(1)$-time.*

▶ **Theorem 2** (Theorem 10.13, [15]). *Let G be a graph, and $\mathbf{d} \in \mathbb{R}^V$ be a demand vector. Given a collection of computationally efficient cost functions on edges $\{c_e(\cdot)\}_e$ and their barriers $\{\psi_e(\cdot)\}_e$ (Assumption 1), there is an algorithm that runs in $m^{1+o(1)}$ time and outputs a flow $\mathbf{f} \in \mathbb{R}^E$ that routes $\mathbf{d}$ and for any fixed constant $C > 0$,*

$$c(\mathbf{f}) \le \min_{\mathbf{B}^\top \mathbf{f}^* = \mathbf{d}} c(\mathbf{f}^*) + \exp(-\log^C m),$$

where $c(\mathbf{f}) \stackrel{\text{def}}{=} \sum_{e \in E} c_e(f_e)$.

2.3 Iterative Refinement

At a high level, the iterative refinement framework introduced by [2] approximates the Bregman Divergence of the function $|x|^p$ with something simpler.

▶ **Definition 3** (Bregman divergence). *Given a differentiable convex function $g(\cdot)$ and any two points $\mathbf{x}, \mathbf{y}$ in its domain, we define its* Bregman divergence *as*

$$D_g(\mathbf{y}, \mathbf{x}) \stackrel{\text{def}}{=} g(\mathbf{y}) - g(\mathbf{x}) - \langle \nabla g(\mathbf{x}), \boldsymbol{\Delta}\rangle = \int_0^1 \int_0^t \langle \boldsymbol{\Delta}, \nabla^2 g(\mathbf{x} + u\boldsymbol{\Delta})\boldsymbol{\Delta}\rangle \mathrm{d}u\mathrm{d}t,$$

where $\boldsymbol{\Delta} \stackrel{\text{def}}{=} \mathbf{y} - \mathbf{x}$.

For any $p > 1$, [2] shows that the Bregman Divergence of $|x + \delta|^p$ can be locally approximated by an error term $\gamma_p(\delta; |x|)$, which behaves quadratically in δ when $|\delta| \le |x|$ and as $|\delta|^p$ otherwise.

▶ **Definition 4** ([14]). *For $x \in \mathbb{R}$, $f > 0$, and $p > 1$, we define*

$$\gamma_p(x, f) \stackrel{\text{def}}{=} \begin{cases} \frac{p}{2} f^{p-2} x^2 & |x| \leq f, \\ |x|^p - \left(1 - \frac{p}{2}\right) f^p & |x| > f. \end{cases}$$

For $1 < q \leq 2$, [3] approximates the Bregman divergence of $|x|^q$ using the γ_q function we just defined.

▶ **Lemma 5** (Lemma 2.14, [3]). *For $q \in (1, 2]$ and $f, x \in \mathbb{R}$, it holds that*

$$\frac{q-1}{q 2^q} \cdot \gamma_q(x, |f|) \leq |f + x|^q - |f|^q - q|f|^{q-2} fx \leq 2^q \cdot \gamma_q(x, |f|).$$

For $p \geq 2$, the Bregman divergence of $|x|^p$ can be approximated by an x^2 and an $|x|^p$ term.

▶ **Lemma 6** (Lemma 2.5, [3]). *For $p \geq 2$ and $f, x \in \mathbb{R}$, it holds that*

$$\frac{p}{8}|f|^{p-2}x^2 + \frac{1}{2^{p+1}}|x|^p \leq |f + x|^p - |f|^p - p|f|^{p-2} fx \leq 2p^2|f|^{p-2}x^2 + p^p|x|^p.$$

Here we present some facts about γ_q functions that are helpful.

▶ **Lemma 7** (Lemma 3.3, [2]). *For $q \in (1, 2]$, $f, x \in \mathbb{R}$, and $t \geq 1$, it holds that*

$$t^q \cdot \gamma_q(x, |f|) \leq \gamma_q(tx, |f|) \leq t^2 \cdot \gamma_q(x, |f|).$$

3 Iterative Refinement Algorithm

In this section, we present the $\ell_{q,p}$-norm k-commodity flow algorithm based on iterative refinement and prove Theorem 1.

▶ **Theorem 1.** *Given any $1 < q \leq 2 \leq p$ with $p = \widetilde{O}(1)$ and $\frac{1}{q-1} = O(1)$ and an error parameter $\varepsilon > \exp(-\widetilde{O}(1))$, let* OPT *be the optimal value to Problem* (1)*. There is a randomized algorithm that computes a feasible flow $\mathbf{F}$ to Problem* (1) *such that*

$$\|\mathbf{WF}\|_{q,p}^{pq} \leq (1 + \varepsilon)\,\mathrm{OPT} + \varepsilon.$$

The algorithm runs in time

$$O\left(p^2 \cdot \left(\frac{1}{q-1}\right)^{\frac{1}{q-1}} m^{1+o(1)} \cdot k^2 \cdot \log \frac{1}{\varepsilon}\right)$$

with high probability.

In the rest of the paper, we use $\mathcal{E}(\mathbf{F})$ to denote the objective of Problem (1), that is, $\mathcal{E}(\mathbf{F}) = \|\mathbf{WF}\|_{q,p}^{pq}$.

Our iterative refinement algorithm is based on an approximation to the Bregman divergence of the objective $\|\mathbf{WF}\|_{q,p}^{pq}$. Since the objective can be decomposed into a summation of m seperate terms, i.e., $\sum_{e \in E} w_e^{pq} \|\mathbf{f}^e\|_q^{pq}$, we approximate the Bregman divergence for each edge separately. Consequently, we present the following lemma that approximates $\|\mathbf{f}^e + \mathbf{x}^e\|_q^{pq}$ for each edge e. This is the key technical lemma of this paper and its proof can be found in the full version.

▶ **Lemma 8.** *[$\ell_{q,p}$-Norm Iterative Refinement] Given $1 < q \le 2 \le p$, and any $\mathbf{f}, \mathbf{x} \in \mathbb{R}^k$, we have*

$$\|\mathbf{f}+\mathbf{x}\|_q^{pq} - \|\mathbf{f}\|_q^{pq} - pq\|\mathbf{f}\|_q^{q(p-1)}\langle|\mathbf{f}|^{q-2}\cdot\mathbf{f},\mathbf{x}\rangle \ge \frac{p(q-1)}{16}\|\mathbf{f}\|_q^{q(p-1)}\cdot\gamma_q(\mathbf{x},|\mathbf{f}|) + \frac{q-1}{pq-1}\frac{1}{2^{pq+2}}\|\mathbf{x}\|_{pq}^{pq}, \tag{4}$$

$$\|\mathbf{f}+\mathbf{x}\|_q^{pq} - \|\mathbf{f}\|_q^{pq} - pq\|\mathbf{f}\|_q^{q(p-1)}\langle|\mathbf{f}|^{q-2}\cdot\mathbf{f},\mathbf{x}\rangle \le \frac{7}{k}\|\mathbf{f}\|_q^{q(p-1)}\cdot\gamma_q(6kp\mathbf{x},|\mathbf{f}|) + \frac{3(6pk)^{pq}}{k}\|\mathbf{x}\|_{pq}^{pq}, \tag{5}$$

where we write $\gamma_q(\mathbf{x},\mathbf{y}) \stackrel{\text{def}}{=} \sum_j \gamma_q(x_j,y_j)$ for vectors $\mathbf{x},\mathbf{y} \in \mathbb{R}^k$.

Using Lemma 8, we can define the *residual function* $\mathcal{R}(\mathbf{x};\mathbf{f})$ that upper bounds the difference in the objective, i.e., $\mathcal{R}(\mathbf{x};\mathbf{f}) \ge \|\mathbf{f}+\mathbf{x}\|_q^{pq} - \|\mathbf{f}\|_q^{pq}$.

▶ **Definition 9** (Residual Problem)**.** *Given two vectors $\mathbf{f},\mathbf{x} \in \mathbb{R}^k$, we define $\mathcal{R}(\mathbf{x};\mathbf{f})$ as*

$$\mathcal{R}(\mathbf{x};\mathbf{f}) \stackrel{\text{def}}{=} pq\|\mathbf{f}\|_q^{q(p-1)}\langle|\mathbf{f}|^{q-2}\cdot\mathbf{f},\mathbf{x}\rangle + \frac{7}{k}\|\mathbf{f}\|_q^{q(p-1)}\cdot\gamma_q(6kp\mathbf{x},|\mathbf{f}|) + \frac{3(6pk)^{pq}}{k}\|\mathbf{x}\|_{pq}^{pq}.$$

In the setting of Problem 1, given a feasible flow $\mathbf{F} \in \mathbb{R}^{E\times k}$, we define the residual problem *w.r.t. $\mathbf{F}$ as follows*

$$\min_{\mathbf{X}\in\mathbb{R}^{E\times k}} \mathcal{R}(\mathbf{X};\mathbf{F}) \stackrel{\text{def}}{=} \sum_{e\in E} w_e^{pq}\mathcal{R}(\mathbf{x}^e;\mathbf{f}^e) \quad \text{s.t. } \mathbf{B}^\top\mathbf{X} = \mathbf{0}. \tag{6}$$

Note that in the residual problem, the objective is decomposable for each coordinate (e,j). The decomposability allows us to use the almost-linear time convex flow solver (Theorem 2) to solve the residual problem to high accuracy. The following lemma summarizes the algorithm and the proof is deferred to Section 4.

▶ **Lemma 10.** *Given any feasible flow $\mathbf{F} \in \mathbb{R}^{E\times k}$ to Problem (1), there is a randomized algorithm that runs in time $km^{1+o(1)}$ and outputs, for any $C > 0$, a k-commodity circulation $\mathbf{X}$ such that*

$$\mathcal{R}(\mathbf{X};\mathbf{F}) \le \min_{\mathbf{B}^\top\mathbf{X}^*=\mathbf{0}} \mathcal{R}(\mathbf{X}^*;\mathbf{F}) + \exp\left(-\log^C m\right).$$

Now, we are ready to prove Theorem 1 with the following Algorithm 1. The algorithm starts with some initial flow and runs in T iterations. Each iteration, the algorithm updates the flow $\mathbf{F}^{(t+1)} \leftarrow \mathbf{F}^{(t)} + \mathbf{X}^{(t)}$ with a near-optimal solution to the residual problem. In other words, given a current flow $\mathbf{F}$, the algorithm updates the flow by solving a simpler residual problem which is an upper bound to the change in objective value.

To analyze Algorithm 1 and prove Theorem 1, we first relate the value of $\mathcal{R}(\mathbf{X};\mathbf{F})$ to the change in objective value when updating $\mathbf{F}$ with $\mathbf{X}$.

▶ **Lemma 11.** *For any $\mathbf{F},\mathbf{X} \in \mathbb{R}^{E\times k}$, we have*

$$\mathcal{E}(\mathbf{F}+\mathbf{X}) - \mathcal{E}(\mathbf{F}) \le \mathcal{R}(\mathbf{X};\mathbf{F}) \text{ and} \tag{7}$$

$$\mathcal{E}(\mathbf{F}+\lambda\mathbf{X}) - \mathcal{E}(\mathbf{F}) \ge \lambda\mathcal{R}(\mathbf{X};\mathbf{F}), \text{ where } \lambda \stackrel{\text{def}}{=} O\left(kp\left(\frac{4032}{q-1}\right)^{\frac{1}{q-1}}\right). \tag{8}$$

Algorithm 1 High-Accuracy $\ell_{q,p}$-norm Multicommodity Flow.

procedure *LqpNormFlow*$(G, \mathbf{w}, \mathbf{D}, q, p)$
  Initialize the flow $\mathbf{F}^{(0)} \in \mathbb{R}^{E\times k}$ such that $\mathbf{B}^\top \mathbf{F}^{(0)} = \mathbf{D}$ via Lemma 13.
  $T \leftarrow O(p\lambda \log(m/\varepsilon))$, where λ comes from Lemma 11
  for $t = 0$ **to** $T-1$ **do**
    Solve the residual problem (6) w.r.t. $\mathbf{F}^{(t)}$ via Lemma 10 and obtain the solution $\mathbf{X}^{(t)}$.
    $\mathbf{F}^{(t+1)} \leftarrow \mathbf{F}^{(t)} + \mathbf{X}^{(t)}$
  end
  return $\mathbf{F}^{(T)}$

Proof. By the definition of $\mathcal{R}(\mathbf{x})$ and Lemma 8, the Inequality (7) holds trivially. We now focus on proving Inequality (8). In particular, we show that for any vector $\mathbf{f}, \mathbf{x} \in \mathbb{R}^k$, the following

$$\|\mathbf{f}+\lambda\mathbf{x}\|_q^{pq} - \|\mathbf{f}\|_q^{pq} \geq \lambda\mathcal{R}(\mathbf{f};\mathbf{x}). \tag{9}$$

Inequality (9) implies Inequality (8) by taking the summation over all edges.

Lemma 8 gives

$$\begin{aligned}&\|\mathbf{f}+\lambda\mathbf{x}\|_q^{pq} - \|\mathbf{f}\|_q^{pq}\\ &\geq pq\|\mathbf{f}\|_q^{(p-1)q}\langle|\mathbf{f}|^{q-2}\cdot\mathbf{f}, \lambda\mathbf{x}\rangle + \frac{p(q-1)}{16}\|\mathbf{f}\|_q^{(p-1)q}\cdot\gamma_q(\lambda\mathbf{x}, |\mathbf{f}|) + \frac{q-1}{pq-1}\frac{1}{2^{pq+2}}\|\lambda\mathbf{x}\|_{pq}^{pq}.\end{aligned}$$

In addition, we have

$$\lambda\mathcal{R}(\mathbf{x}) = \lambda pq\|\mathbf{f}\|_q^{(p-1)q}\langle|\mathbf{f}|^{q-2}\cdot\mathbf{f}, \mathbf{x}\rangle + \frac{7\lambda}{k}\|\mathbf{f}\|_q^{(p-1)q}\cdot\gamma_q(6kp\mathbf{x}, |\mathbf{f}|) + \frac{3\lambda(6pk)^{pq}}{k}\|\mathbf{x}\|_{pq}^{pq}.$$

In order to prove (9), it suffices to ensure that

$$\begin{aligned}\frac{p(q-1)}{16}\|\mathbf{f}\|_q^{(p-1)q}\cdot\gamma_q(\lambda\mathbf{x}, |\mathbf{f}|) &\geq \frac{7\lambda}{k}\|\mathbf{f}\|_q^{(p-1)q}\cdot\gamma_q(6kp\mathbf{x}, |\mathbf{f}|),\\ \frac{q-1}{pq-1}\frac{1}{2^{pq+2}}\|\lambda\mathbf{x}\|_{pq}^{pq} &\geq \frac{3\lambda(6pk)^{pq}}{k}\|\mathbf{x}\|_{pq}^{pq}.\end{aligned}$$

We can consider each entry separately and (9) follows if for any $f, x \in \mathbb{R}$, we have

$$\frac{p(q-1)}{16}\cdot\gamma_q(\lambda x, |f|) \geq \frac{7\lambda}{k}\cdot\gamma_q(6kpx, |f|), \tag{10}$$

$$\frac{q-1}{pq-1}\frac{1}{2^{pq+2}}|\lambda x|^{pq} \geq \frac{3\lambda(6pk)^{pq}}{k}|x|^{pq}. \tag{11}$$

Inequality (10) follows from Lemma 7

$$\frac{p(q-1)}{16}\cdot\gamma_q(\lambda x, |f|) \geq \frac{p(q-1)}{16}\left(\frac{\lambda}{6kp}\right)^q\cdot\gamma_q(6kpx, |f|) \geq \frac{7\lambda}{k}\cdot\gamma_q(6kpx, |f|),$$

if we set

$$\lambda \geq kp\left(\frac{4032}{q-1}\right)^{\frac{1}{q-1}} \geq 6kp. \tag{12}$$

For Inequality (11) to hold, we need to set

$$\lambda \geq 1728k \left(\frac{pq-1}{q-1}\right)^{\frac{1}{pq-1}} p^{\frac{pq}{pq-1}}. \tag{13}$$

Observe that

$$\left(\frac{pq-1}{q-1}\right)^{\frac{1}{pq-1}} = (pq-1)^{\frac{1}{pq-1}} \left(\frac{1}{q-1}\right)^{\frac{1}{pq-1}} \leq e \left(\frac{1}{q-1}\right)^{\frac{1}{q-1}}, \text{ and}$$
$$p^{\frac{pq}{pq-1}} = p^{1+\frac{1}{pq-1}} \leq p^{1+\frac{1}{p-1}} \leq 2p.$$

Combining the observation along with (12) and (13), Inequality (9) follows if we set

$$\lambda = O\left(kp\left(\frac{4032}{q-1}\right)^{\frac{1}{q-1}}\right).$$

This completes the proof. ◀

Using Lemma 11, we now show that each iteration decreases the objective exponentially. This is summarized by the following lemma

▶ **Lemma 12** (Convergence Rate). *Let $\mathbf{F}^*$ be the optimal solution to Problem (1). At any iteration t of Algorithm 1, we have*

$$\mathcal{E}(\mathbf{F}^{(t+1)}) - \mathcal{E}(\mathbf{F}^*) \leq \left(1 - \frac{1}{\lambda}\right)\left(\mathcal{E}(\mathbf{F}^{(t)}) - \mathcal{E}(\mathbf{F}^*)\right) + \exp(-\log^C m).$$

Proof. Recall that $\mathbf{F}^{(t+1)} = \mathbf{F}^{(t)} + \mathbf{X}^{(t)}$ and $\mathbf{X}^{(t)}$ is a high-accuracy solution to the residual problem w.r.t. $\mathbf{F}^{(t)}$. Lemma 11 and the optimality of $\mathbf{X}^{(t)}$ yields

$$\begin{aligned}\mathcal{E}(\mathbf{F}^{(t+1)}) - \mathcal{E}(\mathbf{F}^{(t)}) &\leq \mathcal{R}(\mathbf{X}^{(t)}; \mathbf{F}^{(t)}) \\ &\leq \mathcal{R}\left(\lambda^{-1}\left(\mathbf{F}^* - \mathbf{F}^{(t)}\right); \mathbf{F}^{(t)}\right) + \exp(-\log^C m) \\ &\leq \frac{1}{\lambda}\left(\mathcal{E}(\mathbf{F}^*) - \mathcal{E}(\mathbf{F}^{(t)})\right) + \exp(-\log^C m).\end{aligned} \tag{14}$$

We can conclude the lemma as follows:

$$\begin{aligned}\mathcal{E}(\mathbf{F}^{(t+1)}) - \mathcal{E}(\mathbf{F}^*) &= \mathcal{E}(\mathbf{F}^{(t+1)}) - \mathcal{E}(\mathbf{F}^{(t)}) + \mathcal{E}(\mathbf{F}^{(t)}) - \mathcal{E}(\mathbf{F}^*) \\ &\leq \frac{1}{\lambda}\left(\mathcal{E}(\mathbf{F}^*) - \mathcal{E}(\mathbf{F}^{(t)})\right) + \exp(-\log^C m) + \mathcal{E}(\mathbf{F}^{(t)}) - \mathcal{E}(\mathbf{F}^*) \\ &= \left(1 - \frac{1}{\lambda}\right)\left(\mathcal{E}(\mathbf{F}^{(t)}) - \mathcal{E}(\mathbf{F}^*)\right) + \exp(-\log^C m).\end{aligned}$$ ◀

Then, we show how to find an initial solution efficiently.

▶ **Lemma 13** (Initial Flow). *Given an instance of Problem (1), there is an algorithm that runs in $\widetilde{O}(pmk)$ time and finds a feasible flow $\mathbf{F}^{(0)} \in \mathbb{R}^{E\times k}$ such that $\mathcal{E}(\mathbf{F}^{(0)}) \leq 4m^{p+1}\mathcal{E}(\mathbf{F}^*)$, where $\mathbf{F}^*$ is the optimal solution.*

Proof. Let flow $\mathbf{F}^{(0)}$ be a $(1+1/pq)$-approximate maximum concurrent flow on $(G, \mathbf{w})$ that routes the demand $\mathbf{D}$. That is, $\mathbf{F}^{(0)}$ is a $(1+1/pq)$-approximate solution to the following problem

$$\min_{\mathbf{B}^\top \mathbf{F} = \mathbf{D}} \max_{e\in E} w_e \sum_{j=1}^{k} |F_{ej}|.$$

Moreover, $\mathbf{F}^{(0)}$ can be computed in $\widetilde{O}(pmk)$ time using the algorithm from [66]. Set $\mathbf{F} = \mathbf{F}^{(0)}$ and let $\mathbf{G} = \mathbf{F}^*$ be the optimal solution to Problem (1). We can view $\mathbf{G}$ as a collection of k single commodity flows and the approximation guarantee of $\mathbf{F}$ yields

$$\max_{e\in E} w_e \left\|\mathbf{f}^e\right\|_1 \leq \left(1+\frac{1}{pq}\right) \max_{e\in E} w_e \left\|\mathbf{g}^e\right\|_1 . \tag{15}$$

We now analyze the approximation ratio of $\mathbf{F}$. Recall the fact that for any vector $\mathbf{x} \in \mathbb{R}^k$, we have $\|\mathbf{x}\|_1 \leq m^{1-1/q} \|\mathbf{x}\|_q$. Combining the observation with Inequality (15), we have

$$\begin{aligned}
\mathcal{E}(\mathbf{G}) \leq \mathcal{E}(\mathbf{F}) &= \sum_{e\in E} w_e^{pq} \left\|\mathbf{f}^e\right\|_q^{pq} \\
&\leq \sum_{e\in E} w_e^{pq} \left\|\mathbf{f}^e\right\|_1^{pq} \leq m \left(\max_{e\in E} w_e \left\|\mathbf{f}^e\right\|_1\right)^{pq} \\
&\leq m\left(1+\frac{1}{pq}\right)^{pq} \left(\max_{e\in E} w_e \left\|\mathbf{g}^e\right\|_1\right)^{pq} \\
&\leq 4m \sum_{e\in E} w_e^{pq} \left\|\mathbf{g}^e\right\|_1^{pq} \leq 4m^{1+pq-p} \sum_{e\in E} w_e^{pq} \left\|\mathbf{g}^e\right\|_q^{pq} \\
&\leq 4m^{p+1}\mathcal{E}(\mathbf{G}).
\end{aligned}$$

◀

We use Lemma 12 to analyze the correctness of the algorithm and prove Theorem 1.

Proof of Theorem 1. After $T = O(p\lambda \log(m/\varepsilon))$ iterations, we use Lemma 12 to bound the objective of the final flow $\mathbf{F}^{(T)}$ output by Algorithm 1 as follows:

$$\begin{aligned}
\mathcal{E}(\mathbf{F}^{(T)}) - \mathcal{E}(\mathbf{F}^*) &\leq \left(1-\frac{1}{\lambda}\right)^T \left(\mathcal{E}(\mathbf{F}^{(0)}) - \mathcal{E}(\mathbf{F}^*)\right) + \exp(-\log^C m) \cdot \sum_{t=0}^{T-1} \left(1-\frac{1}{\lambda}\right)^t \\
&\leq \exp\left(-\frac{T}{\lambda}\right) \left(\mathcal{E}(\mathbf{F}^{(0)}) - \mathcal{E}(\mathbf{F}^*)\right) + \lambda \cdot \exp(-\log^C m) \\
&\leq \varepsilon \mathcal{E}(\mathbf{F}^*) + \varepsilon,
\end{aligned}$$

where the last inequality comes from $\mathcal{E}(\mathbf{F}^{(0)}) - \mathcal{E}(\mathbf{F}^*) \leq 4m^{p+1}\mathcal{E}(\mathbf{F}^*)$ and the sufficiently small constant C in Lemma 10. Rearrangement yields that $\mathcal{E}(\mathbf{F}^{(T)})$ is at most $(1+\varepsilon)\mathcal{E}(\mathbf{F}^*) + \varepsilon$.

We now analyze the runtime. Initialization of $\mathbf{F}^{(0)}$ takes $\widetilde{O}(pmk)$ time by Lemma 13. Each iteration takes $km^{1+o(1)}$ time due to Lemma 10 and there are $T = \widetilde{O}(p\lambda \log(1/\varepsilon))$ iterations. Then the runtime bound follows. ◀

4 Solving the Residual Problem

In this section, we prove Lemma 10.

▶ **Lemma 10.** *Given any feasible flow $\mathbf{F} \in \mathbb{R}^{E\times k}$ to Problem (1), there is a randomized algorithm that runs in time $km^{1+o(1)}$ and outputs, for any $C > 0$, a k-commodity circulation $\mathbf{X}$ such that*

$$\mathcal{R}(\mathbf{X};\mathbf{F}) \leq \min_{\mathbf{B}^\top \mathbf{X}^* = \mathbf{0}} \mathcal{R}(\mathbf{X}^*;\mathbf{F}) + \exp\left(-\log^C m\right).$$

At a high level, we will show that solving the residual problem is equivalent to solving k instances of single commodity convex flow problems. Each of them can be solved in $m^{1+o(1)}$ time via Theorem 2. In particular, we need to construct computationally efficient barriers for the edge cost functions.

Proof of Lemma 10. Recall the residual problem

$$\begin{aligned} &\min_{\mathbf{X}\in\mathbb{R}^{E\times k}} \mathcal{R}(\mathbf{X};\mathbf{F}) \\ &\quad \text{s.t. } \mathbf{B}^\top\mathbf{X} = \mathbf{0}. \end{aligned} \tag{16}$$

From Definition 9, we know

$$\mathcal{R}(\mathbf{X};\mathbf{F}) = \sum_{e\in E}\sum_{j=1}^{k} w_e^{pq}\cdot\left(pq\|\mathbf{f}^e\|_q^{q(p-1)}|F_{ej}|^{q-2}F_{ej}X_{ej} + \frac{7}{k}\|\mathbf{f}^e\|_q^{q(p-1)}\gamma_q(6kpX_{ej},|F_{ej}|) + \frac{3(6pk)^{pq}}{k}|X_{ej}|^{pq}\right).$$

For each commodity $j\in[k]$, we write $\mathbf{x}_j$ and $\mathbf{f}_j$ to be the j-th column of $\mathbf{X}$ and $\mathbf{F}$ respectively, i.e., the flow that routes the commodity j. The constraint $\mathbf{B}^\top\mathbf{X}=\mathbf{0}$ is equivalent to $\mathbf{B}^\top\mathbf{x}_j=\mathbf{0}$ for each j. Thus, (16) is equivalent to solving, for each commodity j, the following single commodity flow problem:

$$\begin{aligned} &\min_{\mathbf{x}\in\mathbb{R}^{E}} \sum_{e\in E} w_e^{pq}\left(pq\|\mathbf{f}^e\|_q^{q(p-1)}|F_{ej}|^{q-2}F_{ej}x_e + \frac{7}{k}\|\mathbf{f}^e\|_q^{q(p-1)}\gamma_q(6kpx_e,|F_{ej}|) + \frac{3(6pk)^{pq}}{k}|x_e|^{pq}\right) \\ &\quad \text{s.t. } \mathbf{B}^\top\mathbf{x} = \mathbf{0}. \end{aligned} \tag{17}$$

To use Theorem 2 to solve (17), we need to show that the objective is a sum of convex edge costs with efficient barriers. For each edge e and commodity j, we define the cost $c_{ej}(x)$ to be

$$\begin{aligned} &c_{ej}(x) = A_{ej}x + B_{ej}\gamma_q(6kpx,|F_{ej}|) + C_{ej}|x|^{pq}, \text{ where} \\ &\quad A_{ej} \stackrel{\text{def}}{=} w_e^{pq}\cdot pq\|\mathbf{f}^e\|_q^{q(p-1)}|F_{ej}|^{q-2}F_{ej}, \\ &\quad B_{ej} \stackrel{\text{def}}{=} w_e^{pq}\cdot\frac{7}{k}\|\mathbf{f}^e\|_q^{q(p-1)}, \\ &\quad C_{ej} \stackrel{\text{def}}{=} w_e^{pq}\cdot\frac{3(6pk)^{pq}}{k}. \end{aligned}$$

Clearly $c_{ej}(x)$ is a convex function and the objective of (17) is exactly $\sum_e c_{ej}(x_e)$.

We now present computationally efficient barriers for each $c_{ej}(x)$ and show that $c_{ej}(x)$ satisfies Assumption 1. For clarity, we ignore both subscripts e and j and use f to denote $|F_{ej}|$. That is, we will show that the following function satisfies Assumption 1 for any positive $A,B,C,f>0$,

$$c(x) = A\cdot x + B\cdot\gamma_q(6kpx;f) + C\cdot|x|^{pq}.$$

Item 1 holds because $p=\widetilde{O}(1)$.

We now show Item 2 using Theorem 9.1.1 from [55]. It says that the function $\psi_c(x,y) = -\ln(y-c(x))$ is a 1-self-concordance barrier for the epigraph $\mathcal{D}_c \stackrel{\text{def}}{=} \{(x,y)|c(x)\le y\}$ if there is some $\beta>0$ such that $|c'''(x)|\le 3\beta|c''(x)/x|$ holds for all $x\in\mathbb{R}$. The derivatives of $c(x)$ have different forms depending on the value of x due to the γ_q function.

- If $|6kpx|\le f$, we know $\gamma_q(6kpx;f) = \frac{q}{2}f^{q-2}(6kp)^2x^2$ and

$$\begin{aligned} c'(x) &= A + Bqf^{q-2}(6kp)^2x + Cpq|x|^{pq-1}\mathrm{sgn}(x), \\ c''(x) &= Bqf^{q-2}(6kp)^2 + Cpq(pq-1)|x|^{pq-2}, \\ c'''(x) &= Cpq(pq-1)(pq-2)|x|^{pq-3}\mathrm{sgn}(x). \end{aligned}$$

In this case, we have

$$\left|\frac{c''(x)}{x}\right| = \frac{Bqf^{q-2}(6kp)^2}{|x|} + Cpq(pq-1)|x|^{pq-3} \geq \frac{1}{pq-2}|c'''(x)|.$$

It suffices to set $\beta \geq (pq-2)/3$.

- Otherwise, $|6kpx| > f$. We know $\gamma_q(6kpx; f) = |6kpx|^q - (1-\frac{q}{2})f^q$, and

$$\begin{aligned}
c'(x) &= A + B(6kp)^q q|x|^{q-1}\mathrm{sgn}(x) + Cpq|x|^{pq-1}\mathrm{sgn}(x),\\
c''(x) &= B(6kp)^q q(q-1)|x|^{q-2} + Cpq(pq-1)|x|^{pq-2},\\
c'''(x) &= B(6kp)^q q(q-1)(q-2)|x|^{q-3}\mathrm{sgn}(x) + Cpq(pq-1)(pq-2)|x|^{pq-3}\mathrm{sgn}(x).
\end{aligned}$$

In this case, notice that $q-2<0$ and we have

$$\begin{aligned}
\left|\frac{c''(x)}{x}\right| &= B(6kp)^q q(q-1)|x|^{q-3} + Cpq(pq-1)|x|^{pq-3}, \text{ and}\\
|c'''(x)| &= \left|B(6kp)^q q(q-1)(q-2)|x|^{q-3} + Cpq(pq-1)(pq-2)|x|^{pq-3}\right|\\
&\leq B(6kp)^q q(q-1)(2-q)|x|^{q-3} + Cpq(pq-1)(pq-2)|x|^{pq-3}.
\end{aligned}$$

Setting $\beta \geq \max\{2-q, pq-2\}/3$ yields that

$$3\beta\left|\frac{c''(x)}{x}\right| \geq B(6kp)^q q(q-1)(2-q)|x|^{q-3} + Cpq(pq-1)(pq-2)|x|^{pq-3} \geq |c'''(x)|.$$

We conclude Item 2 with the barrier function $\psi_c(y,x) = -\ln(y-c(x))$. Item 3 follows directly from Item 1, and Item 4 follows using the explicit formula for $c(x), c'(x)$, and $c''(x)$.

Now we can apply Theorem 2 to compute, for each j, a flow $\mathbf{x}_j$ in time $m^{1+o(1)}$ such that

$$c(\mathbf{x}_j) \leq \min_{\mathbf{B}^\top \mathbf{x}^* = \mathbf{0}} c(\mathbf{x}^*) + \exp(-\log^C m).$$

Let $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_k]$, then we have $\mathbf{B}^\top \mathbf{X} = \mathbf{0}$ and $\mathbf{X}$ is optimal to (16) up to a $k\exp(-\log^C m)$-additive error, i.e.,

$$\mathcal{R}(\mathbf{X}; \mathbf{F}) \leq \min_{\mathbf{B}^\top \mathbf{X}^* = \mathbf{0}} \mathcal{R}(\mathbf{X}^*; \mathbf{F}) + k\exp(-\log^C m).$$

The total runtime is $k \cdot m^{1+o(1)}$ since we compute $\mathbf{x}_j$ for each $j \in [k]$. ◀

Abstract

In this paper we study the problem of finding (ϵ, ϕ)-expander decompositions of a graph in the streaming model, in particular for dynamic streams of edge insertions and deletions. The goal is to partition the vertex set so that every component induces a ϕ-expander, while the number of inter-cluster edges is only an ϵ fraction of the total volume. It was recently shown that there exists a simple algorithm to construct a $(O(\phi \log n), \phi)$-expander decomposition of an n-vertex graph using $\widetilde{O}(n/\phi^2)$ bits of space [Filtser, Kapralov, Makarov, ITCS'23]. This result calls for understanding the extent to which a dependence in space on the sparsity parameter ϕ is inherent. We move towards answering this question on two fronts.

We prove that a $(O(\phi \log n), \phi)$-expander decomposition can be found using $\widetilde{O}(n)$ space, for every ϕ. At the core of our result is the first streaming algorithm for computing boundary-linked expander decompositions, a recently introduced strengthening of the classical notion [Goranci et al., SODA'21]. The key advantage is that a classical sparsifier [Fung et al., STOC'11], with size independent of ϕ, preserves the cuts inside the clusters of a boundary-linked expander decomposition within a multiplicative error.

Notable algorithmic applications use sequences of expander decompositions, in particular one often repeatedly computes a decomposition of the subgraph induced by the inter-cluster edges (e.g., the seminal work of Spielman and Teng on spectral sparsifiers [Spielman, Teng, SIAM Journal of Computing 40(4)], or the recent maximum flow breakthrough [Chen et al., FOCS'22], among others). We prove that any streaming algorithm that computes a sequence of $(O(\phi \log n), \phi)$-expander decompositions requires $\widetilde{\Omega}(n/\phi)$ bits of space, even in insertion only streams.

1 Introduction

Expander graphs are known to represent a class of easier instances for many problems. Therefore, breaking down the input into disjoint expanders can allow to conveniently solve the task on each of them separately, before combining the partial results into a global solution. This approach is enabled by (ϵ, ϕ)-expander decompositions (for short, (ϵ, ϕ)-

ED). For an undirected graph $G = (V, E)$, this is a partition $\mathcal{U}$ of the vertex set V, such that there are at most $\epsilon|E|$ inter-cluster edges, while every cluster $U \in \mathcal{U}$ induces a ϕ-expander. The list of successful applications of this framework is long, including Laplacian system solvers [31], deterministic algorithms for minimum cut [28], graph and hyper-graph sparsification [2, 14, 23, 32], dynamic algorithms for cut and connectivity problems [18, 19], fast max flow algorithms [11], distributed triangle enumeration [9], polynomial time algorithms for semirandom planted CSPs [20], and many more.

We refer to ϵ and ϕ as the *sparsity* parameters: the former controls how sparsely connected the clusters need to be, and the latter determines how expanding (i.e. non-sparse) the cuts within clusters are. The reason for using the same term for both is that they are in fact very closely related. One can show that any n-vertex graph has an (ϵ, ϕ)-ED with $\epsilon = O(\phi \log n)$. To see this, consider the following constructive argument: if the graph has no ϕ-sparse cut then $\{V\}$ is a valid ED of G, otherwise recurse on the two sides $(S, V \setminus S)$ of a ϕ-sparse cut and union the results to get an ED for G. Every cluster in this decomposition is then an expander, and a charging argument allows to bound the number of inter-cluster edges by $O(\phi|E| \log n)$ [30]. One can also observe that no better asymptotic trade-off between ϵ and ϕ is possible in general [6]. Therefore, this sets the benchmark for algorithmic constructions of EDs.

At a high level, many ED algorithms follow the approach suggested by the existential argument. As a naive implementation would take exponential time, the crux often lies in efficient algorithms that either certify that a large portion of the input is an expander, or find a balanced sparse cut. This would result in a small depth recursion, thanks to balancedness, where each level requires little computational resources. There are several successful examples of this approach. In the sequential setting, a recent algorithm constructs a $(O(\phi \log^3 n), \phi)$-ED in $\widetilde{O}(|E|)$ time [29], based on the previous best algorithm which runs in $\widetilde{O}(|E|/\phi)$ time [30]. There is also a deterministic counterpart, which outputs a $(\phi \cdot n^{o(1)}, \phi)$-ED in almost linear time [15]. For the CONGEST model of distributed computing, it is possible to obtain, for instance, a $(\phi^{1/\sqrt{\log n}} \cdot n^{o(1)}, \phi)$-ED in $n^{o(1)}/\phi$ rounds [9]. It is also possible to maintain a $(\phi \cdot n^{o(1)}, \phi)$-ED for a graph undergoing edge updates in $n^{o(1)}/\phi^2$ amortized update time [19, 21].

1.1 Previous Work

In the streaming setting, the problem of finding EDs was open until the recent work of [16]. They obtain a dynamic stream algorithm which outputs a $(O(\phi \log n), \phi)$-ED and takes $\widetilde{O}(n/\phi^2)$ space. While being optimal in the quality of the decomposition, decoding the sketch to actually output an ED takes exponential time. The authors also give a polynomial time version: one can produce a $(\phi \cdot n^{o(1)}, \phi)$-ED using space $\widetilde{O}(n/\phi^2) + n^{1+o(1)}/\phi^{1-o(1)}$, with a post-processing that takes $\text{poly}(n)$ time (where the $o(1)$'s can be tuned, allowing for a quality-space trade-off).

These streaming algorithms also adopt the recursive approach based on finding balanced ϕ-sparse cuts, but the streaming model poses a challenge that we now illustrate. Sparsification for graph streams has been extensively studied [3, 4, 5, 24, 25], so a natural attempt would consist of maintaining a cut sparsifier as the stream comes and later run the recursive partitioning on it. However, it must be noted that these cuts are to be found in the subgraphs induced by the two sides of a previously made cut. This is not a problem in a classical computational setting, but it actually constitutes the main obstacle for the streaming model: at sketching time, the algorithm does not know which subgraphs it will need to access. Unfortunately, it is impossible to preserve cut sizes in arbitrary subgraphs with multiplicative

precision. The natural work-around is to introduce an additive error term: in [16], the authors introduce the concept of power-cut sparsifiers. For any given partition $\mathcal{U}$ of V, these sparsifiers preserve the cuts $|E(S, U \setminus S)|$ of each cluster $U \in \mathcal{U}$ in the partition up to an error of $\delta \cdot |E(S, U \setminus S)| + \psi \cdot \mathrm{vol}(S)$. They further show that maintaining $\widetilde{O}(n/\delta\psi)$ random linear measurements of the incidence matrix of the input graph is enough to obtain such sparsifiers. One can see that setting $\delta \ll 1$ and $\psi \approx \phi$ preserves the sparsity of cuts to within an additive error of roughly ϕ, using $\widetilde{O}(n/\phi)$ linear measurements. This is enough to find a balanced ϕ-sparse cut in every subgraph induced by a given partition of the vertex set. There is another caveat, though: power-cut sparsifiers give a high probability guarantee for any fixed partition, but we cannot expect them to work for all partitions simultaneously. Therefore, in order not to use the sparsifiers adaptively, we need one power-cut sparsifier for every recursion level. The authors show that the depth of the procedure cannot exceed $\widetilde{O}(1/\epsilon) = \widetilde{O}(1/\phi)$, thus obtaining the space complexity stated before. A few more details are involved in the polynomial time algorithm, but the underlying framework is the same.

1.2 Our Contribution

The work of [16] initiated the study of expander decompositions in the streaming setting, and consequently raised the question of whether a dependence in space on the sparsity parameter ϕ is inherent. In this paper, we move towards settling the streaming complexity of expander decompositions by attacking the problem on two fronts: (1) we give a nearly optimal algorithm for "one-level" expander decomposition that avoids the sparsity dependence, and (2) we show that computing a "repeated" expander decomposition, commonly used in applications, cannot avoid such dependence.

Upper Bound

We give an $\widetilde{O}(n)$ space algorithm for computing a $(O(\phi \log n), \phi)$-ED in dynamic streams. Specifically, we show that a "universal" sketch consisting of $\widetilde{O}(n)$ random linear measurements of the incidence matrix can be decoded into a $(O(\phi \log n), \phi)$-ED for any ϕ: the sketch is independent of the sparsity ϕ.

▶ **Theorem 1** (ED algorithm – exponential time decoding). *Let $G = (V, E)$ be a graph given in a dynamic stream. Then, there is an algorithm that maintains a linear sketch of G in $\widetilde{O}(n)$ space. For any $\phi \in (0, 1)$, the algorithm decodes the sketch to compute a $(O(\phi \log n), \phi)$-ED of G with high probability, in $\widetilde{O}(n)$ space and $2^{O(n)}$ time.*

We note that at least $\Omega(n \log n)$ space is needed for any small enough ϕ: for example, if the input graph is a matching of size $n/10$, say, its ED gives a $1 - O(\phi \log n)$ fraction of the matching edges.

The decoding time of our sketch can be made polynomial, at the expense of some loss in the quality of the expander decomposition (similarly to [16]), but keeping the space independent of the sparsity ϕ.

▶ **Theorem 2** (ED algorithm – polynomial time decoding). *Let $G = (V, E)$ be a graph given in a dynamic stream. Then, there is an algorithm that maintains a linear sketch of G in $n^{1+o(1)}$ space. For any $\phi \in (0, 1)$, the algorithm decodes the sketch to compute a $(\phi \cdot n^{o(1)}, \phi)$-ED of G with high probability, in $n^{1+o(1)}$ space and $\mathrm{poly}(n)$ time.*

In this case we are off by subpolynomial factors in both quality and space complexity as compared to the optimal ones. The actual theorem that we prove allows one to trade-off the loss in quality and increase in space.

Lower Bound

Most algorithmic applications of EDs, including the ones mentioned above, do not use just one ED of the input graph. Rather, they use an ED sequence obtained by repeatedly computing an ED of the inter-cluster edges from the previous level. This can be done in two natural ways: by contracting the clusters of an ED (we call this variant CED, for "contraction"), or by removing the intra-cluster edges without changing the vertex set (we call this variant RED, for "removal", see Section 1.3). These approaches lead to different results and are used for different applications (e.g., [19, 28] contract the clusters, and [32, 11] recurse on inter-cluster edges). In the sequential setting, both CEDs and REDs can be obtained straightforwardly given an ED algorithm. However, this is not so obvious in the streaming model.

One the one hand, one should be able get a sparsity-independent algorithm for computing CEDs in dynamic streams via Theorem 1 or Theorem 2: observe that contracting the vertices of a sparsifier of the input graph G gives a sparsifier of the graph obtained by contracting vertices in G, so the idea would be to maintain an independent copy of our algorithm for each of the $O(\log n)$ levels and contracting vertices in the sparsifier based on the decomposition of the previous level. On the other hand, we show a space lower bound for computing REDs, even in insertion only streams, showing that a dependence on $1/\phi$ is necessary.

▶ **Theorem 3** (RED lower bound). *Let $\epsilon, \phi \in (0,1)$ such that $1/n \ll \phi \ll 1/\operatorname{polylog} n$ and $\epsilon = \widetilde{O}(\phi)$. Any streaming algorithm that with constant probability computes at least two levels of an (ϵ, ϕ)-RED requires $\widetilde{\Omega}(n/\phi)$ bits of space.*

The result seems to challenge the intuition that EDs become weaker as ϕ and ϵ decrease (note that when ϕ is, say, $1/n^2$, an ED can simply consist of connected components). The questions of (1) whether this bound can be improved, (2) how it scales with the number of levels of RED we compute, and (3) whether there are algorithms matching such bounds, remain open.

1.3 Preliminaries

Graph Streaming

In this paper, we will be mostly working in the dynamic graph streaming model, where we know the vertex set $V = [n]$, and we receive a stream of insertions and deletions for undirected edges over V. In insertion-only graph streams, the only difference is that previously inserted edges cannot be deleted. At the end of the stream, the graph $G = (V, E)$ consists of the edges that have been inserted and not deleted, and we say that G is given in a (dynamic) stream. When we consider a graph given in a (dynamic) stream, we are implicitly assuming it to have n vertices, without introducing the parameter n explicitly. Also, when we refer to G and n without reintroducing them we are implicitly considering the graph resulting from the input stream and its number of vertices.

A powerful tool for dynamic graph streams is linear sketching, introduced in the seminal work of Ahn, Guha, and McGregor [4]. The idea is to left-multiply the $\binom{n}{2} \times n$ incidence matrix of the graph by a random $k \times \binom{n}{2}$ matrix for $k \ll \binom{n}{2}$. Since the sketch consists of linear measurements, it automatically handles the case of dynamic streams. We will not be using sketching techniques directly, but rather employ existing algorithms that do. In this paper we restrain ourselves to unweighted edge streams. One may study the same problem in general turnstile graph streams [13], but we do not do this here.

Cuts, Volumes, and Expanders

Given an unweighted graph $G = (V, E)$, possibly with multiple self-loops on the vertices, we will operate with weighted graphs that approximate G in an appropriate sense. We write $G' = (V', E', w)$ to denote a weighted graph, possibly with multiple weighted self-loops on the vertices. We describe next some notation for such weighted graph G'. The same notation carries over to the unweighted graph G by implicitly setting w to assign a weight of 1 to all edges and self-loops.

For any $A, B \subseteq V'$ we denote by $E'(A, B)$ the edges in E' with one endpoint in A and one in B, and by $w(A, B)$ the total weight of edges in $E'(A, B)$. The volume of a cut $S \subseteq V'$ is the sum of the (weighted) degrees, including self-loops, of its vertices. We denote it by $\mathrm{vol}_{G'}(S)$. The sparsity of a cut $\emptyset \neq S \subsetneq V'$ is defined as

$$\Phi_{G'}(S) = \frac{w(S, V' \setminus S)}{\min\{\mathrm{vol}_{G'}(S), \mathrm{vol}_{G'}(V' \setminus S)\}} .$$

For $\psi \in (0, 1)$, we make a distinction between cuts having sparsity less than ψ, which we call ψ-sparse, and cuts having sparsity at least ψ, which we call ψ-expanding. The sparsity of G' is then defined as

$$\Phi_{G'} = \min_{\emptyset \neq S \subsetneq V'} \Phi_{G'}(S) ,$$

and we call G' a ψ-expander if all its cuts are ψ-expanding, i.e. $\Phi_{G'} \geq \psi$.

Expander Decomposition

As we will treat expander decompositions for the input graph G only, we conveniently use the following additional notation. For a cluster $U \subseteq V$, i.e. a subset of the vertices, and a cut $S \subseteq U$, which is also a subset of the vertices, we denote the number of edges crossing S in U by $\partial_U S$, i.e. $\partial_U S = |E(S, U \setminus S)|$. This is the *local* cut of S in U. If $U = V$, we use a shorthand notation $\partial S = \partial_V S$. We call such a cut the *global* cut of S, since for $S \subseteq U$ we will be interested in both $\partial_U S$ and ∂S. Moreover, we drop the subscript from the volume and simply write $\mathrm{vol}(\cdot)$ instead of $\mathrm{vol}_G(\cdot)$. Then, EDs can be defined as follow.

▶ **Definition 4** (Expander decomposition). *Let $G = (V, E)$ and let $\epsilon, \phi \in (0, 1)$. A partition $\mathcal{U}$ of V is an (ϵ, ϕ)-expander decomposition (for short, (ϵ, ϕ)-ED) of G if*

1. $\frac{1}{2} \sum_{U \in \mathcal{U}} \partial U \leq \epsilon |E|$, *and*
2. *for every $U \in \mathcal{U}$, one has that $G[U]$ is a ϕ-expander.*

Boundary-Linked Expander Decomposition

A boundary-linked ED [19] is the same as a classical ED except that Property 2 of Definition 4 is strengthened. For a cut S in a cluster U, the boundary $\mathrm{bnd}_U(S)$ of S with respect to U is the number of edges that go from S to the outside of U, i.e. $\mathrm{bnd}_U(S) = |E(S, V \setminus U)|$. For $U \subseteq V$ and $\tau \geq 0$, the τ-boundary linked subgraph of G on U, denoted by $G[U]^\tau$, is the subgraph of G induced by U with additional $\tau \cdot \mathrm{bnd}_U(\{u\})$ self-loops attached to every $u \in U$. Then a boundary-linked ED can be defined as follows.

▶ **Definition 5** (Boundary-linked expander decomposition [19]). *Let $G = (V, E)$, let $b, \epsilon, \phi \in (0, 1)$ be parameters such that $b \geq \phi$, and let $\gamma \geq 1$ be an error parameter. A partition $\mathcal{U}$ of V is a $(b, \epsilon, \phi, \gamma)$-boundary-linked expander decomposition (for short, $(b, \epsilon, \phi, \gamma)$-BLD) of G if*

1. $\frac{1}{2} \sum_{U \in \mathcal{U}} \partial U \leq \epsilon |E|$, *and*
2. *for every $U \in \mathcal{U}$, $G[U]^{b/\phi}$ is a ϕ/γ-expander.*

Algorithm 1 DECOMPOSE: recursive procedure for computing a $(O(\phi \log n), \phi)$-ED of G.

```
// G = (V, E) is the input graph
// φ ∈ (0, 1) is the sparsity parameter
procedure DECOMPOSE(G):
    if G is a φ-expander then
        return {V}
    else
        S ← a φ-sparse cut of G
        return DECOMPOSE(G[S]) ∪ DECOMPOSE(G[V \ S])
    end
```

Expander Decomposition Sequence

For a partition $\mathcal{U}$ of V (think of $\mathcal{U}$ as an ED of G), we denote by $E \setminus \mathcal{U}$ the set of inter-cluster (or crossing) edges with respect to $\mathcal{U}$, i.e.

$$E \setminus \mathcal{U} = E \setminus \bigcup_{U \in \mathcal{U}} \binom{U}{2}.$$

Analogously, we let $G \setminus \mathcal{U} = (V, E \setminus \mathcal{U})$ be the subgraph of G obtained by removing the intra-cluster edges in $\mathcal{U}$. For a sequence of partitions $\mathcal{U}_1, \ldots, \mathcal{U}_\ell$ of V and $i \in [\ell]$, we define $G_1^{\mathrm{R}} = G$ and denote by $G_{i+1}^{\mathrm{R}} = G_i^{\mathrm{R}} \setminus \mathcal{U}_i$ the subgraph of G obtained by removing the intra-cluster edges of the first i partitions.

▶ **Definition 6** (Removal-based ED sequence). *Let $G = (V, E)$, let $\epsilon, \phi \in (0, 1)$, let $\ell \geq 1$, and let $\mathcal{U}_1, \ldots, \mathcal{U}_\ell$ be a sequence of partitions of V. The sequence $\mathcal{U}_1, \ldots, \mathcal{U}_\ell$ is an ℓ-level removal-based (ϵ, ϕ)-ED sequence (for short, ℓ-level (ϵ, ϕ)-RED or (ϵ, ϕ, ℓ)-RED) of G if, for all $i \in [\ell]$, $\mathcal{U}_i$ is an (ϵ, ϕ)-ED of the graph G_i^{R}.*

2 Sparsity-Independent One-Level Expander Decomposition

Given a graph $G = (V, E)$ in a dynamic stream, and a parameter $\phi \in (0, 1)$, we consider the problem of computing an (ϵ, ϕ)-ED of G for $\epsilon = O(\phi \log n)$. We show that one can do this in $\widetilde{O}(n)$ bits of space, without any dependence on ϕ. In this section, we sketch our approach.

Let us begin by recalling the standard recursive framework for constructing expander decompositions [22, 32, 33], concisely summarized in Algorithm 1. For any parameter $\phi \leq 10^{-1}/\log n$, this algorithm produces a $(O(\phi \log n), \phi)$-ED by recursively partitioning G along ϕ-sparse cuts until no more such cuts are found.

Many algorithmic constructions of EDs are essentially efficient implementations of Algorithm 1. Adapting Algorithm 1 to dynamic streams comes with its own set of challenges. When the input is given in a dynamic stream, one can only afford to store a limited amount of information about the input graph. Since Algorithm 1 only needs to measure the sparsity of cuts, it seems enough to have access to cut sizes and volumes. Both these quantities are preserved by cut sparsifiers. According to the classical definition [7], a δ-cut sparsifier is a weighted subgraph $H = (V, E', w)$ of the input $G = (V, E)$, where for every cut $S \subseteq V$ one has

$$(1 - \delta) \cdot \partial S \leq \partial^w S \leq (1 + \delta) \cdot \partial S.$$

It is known that such a sparsifier can be constructed in dynamic streams using $\widetilde{O}(n/\delta^2)$ bits of space [5]. With the same space requirement we can also measure the sparsity of cuts up to a $(1 \pm \delta)$ multiplicative error. Having this in mind, it is natural to consider the following algorithm: first, read the stream and construct a cut sparsifier, then run Algorithm 1 on it and output the resulting clustering as the expander decomposition. However, this approach does not work as is. As it turns out, more information is needed about the graph than what is captured by the regular notion of a cut sparsifier.

The problem with this approach becomes immediately apparent when one considers the second recursion level. As the process recurses on the two sides of a sparse cut S, it will repeat the procedure on the subgraphs $G[S]$ and $G[V \setminus S]$. Unfortunately, the cut preservation property of the sparsifier does not carry over to those subgraphs, making it inadequate for estimating the sparsity of the cuts in those graphs. In fact, the notion of expander decomposition itself already operates on the subgraphs, as it is required that each cut in each cluster of the decomposition is expanding.

2.1 Testing Expansion of Subgraphs

The reasoning from above gives rise to the following sketching problem: produce a sparsifier that can be used to check that any subgraph is a ϕ-expander. To solve it, the authors of [16] introduced the concept of a (δ, ψ)-power-cut sparsifier. Its property is that, for any cluster $U \subseteq V$, with high probability all cuts $S \subseteq U$ are preserved within an additive-multiplicative error. Recall that $\partial_U S$ is equal to the size of the cut S inside the induced subgraph $G[U]$. When talking about sparsifiers in this section, we will slightly abuse notation by assuming that there is some instance $H = (V, E', w)$ of it and denote by $\partial_U^w S$ the size of the cut S in the subgraph $H[U]$ of this sparsifier H. Then we can write the guarantee of a (δ, ψ)-power-cut sparsifier as follows[1]:

$$\forall\, S \subseteq U, \quad (1-\delta) \cdot \partial_U S - \psi \cdot \mathrm{vol}(S) \leq \partial_U^w S \leq (1+\delta) \cdot \partial_U S + \psi \cdot \mathrm{vol}(S)\,.$$

The authors also give a dynamic stream construction, which uses $\widetilde{O}(n/\delta\psi)$ bits of space by sampling edges proportionally to the degrees of their endpoints.

To check the ϕ-expansion of subgraphs up to a small constant multiplicative error, it is enough to set δ to be a small constant. However, the multiplicative error parameter ψ must be $\lesssim \phi$. This is a significant downside of this construction, as it was shown in [16] that a (δ, ϕ)-power-cut sparsifier must have at least $\Omega(n/\phi)$ edges. In fact, their lower bound is more general, and holds for general subgraphs[2]. In other words, $\Omega(n/\phi)$ space is necessary in order to test ϕ-expansion of general subgraphs. Consequently, new tools must be used to have any hope of getting an algorithm independent of $1/\phi$.

Our Contribution: Sparsification of Boundary-Linked Subgraphs

As it turns out, solving the expansion testing problem, as it was stated, is not necessary. Recently, in the breakthrough work of [19], it was shown that one could demand additional properties from the expander decomposition, and it will still exist at the price of increasing the number of inter-cluster edges by a small multiplicative factor.

[1] A similar sparsifier construction was proposed by [1]. Their construction has an additive error of $\psi|S|$, so the dependence is on the number of vertices instead of the volume.

[2] The lower bound instance is a $1/\phi$-regular graph. There, each edge by itself forms a ϕ-expander, while any pair of vertices without an edge between them is not. Being able to test the ϕ-expansion of the majority of those small subgraphs would imply being able to recover the majority of edges in the graph.

More formally, let $U \subseteq V$ and $\tau > 0$. Note that if the τ-boundary-linked subgraph $G[U]^\tau$ (see Section 1.3 for the definition) is a ϕ-expander, then so necessarily is $G[U]$, but not the other way around. Then it is possible, for a given ϕ, and $\epsilon = \widetilde{O}(\phi)$, $\tau \approx 1/\phi$, to construct an (ϵ, ϕ)-expander decomposition $\mathcal{U}$ where for each cluster $U \in \mathcal{U}$, $G[U]^\tau$ is a $\widetilde{\Omega}(\phi)$-expander [19]. Such a decomposition is called a boundary-linked expander decomposition.

A key observation is that if in our algorithm we were aiming to construct a boundary-linked expander decomposition, the testing problem would only involve checking that any given boundary-linked subgraph is ϕ-expanding. Indeed, this problem is much easier than the original one and can be solved in space $\widetilde{O}(n)$. We will show how to do it in two steps: first, we will discuss how to strengthen the power-cut sparsifier, and then prove that this strengthening is enough to resolve the problem.

Achieving Additive Error in the Global Cut

As was noted in [16], the idea behind constructing a power-cut sparsifier was to reanalyse the guarantee given by the construction of [32] for sparsifying expanders. In other words, a power-cut sparsifier results from a more rigorous analysis of an existing sparsifier. The problem with this approach is that the sparsifier of [32] is relatively weak to begin with: it only preserves cuts in expanders, while other constructions can preserve them in all graphs [7, 17]. To strengthen the guarantee, one can give the same treatment to the construction of [17] (see the full version of this paper). For the sake of simplicity and to gain an intuition for why this kind of sparsification is at all possible, we discuss here how to do that with the classical construction of [27] by closely following the original proof.

We show that, given a graph $G = (V, E)$ with a minimum cut of size k, it is possible to construct a sparsifier H of G such that every cut inside any given subgraph $G[U]$ of G is preserved with high probability with the following guarantee:

$$\forall\, S \subseteq U, \quad \partial_U S - \delta \cdot \partial S \leq \partial_U^w S \leq \partial_U S + \delta \cdot \partial S\,. \tag{1}$$

In this paper, a sparsifier with the property of Equation (1) is called a cluster sparsifier. To achieve the guarantee of Equation (1), consider using the same process as in [27]: sample each edge with the same probability $p \approx \delta^{-2}/k$.

To see why this works, fix a subgraph $U \subseteq V$, and consider any cut S in U. We wish to show that the size of the cut S inside U concentrates well after sampling. In the original proof, this is done by simply applying a Chernoff bound. In our case, this bound would look like this:

$$\Pr[|\partial_U^w S - \partial_U S| \geq \delta \cdot \partial_U S] \leq \exp\left(-\frac{1}{3}\delta^2 p \cdot \partial_U S\right)\,.$$

However, this is insufficient, as the probability depends on the cut size inside $G[U]$. As we have no lower bound on its size, unlike with the sizes of global cuts, the second part of the argument of [27] cannot be applied. Instead, we apply an additive-multiplicative version of the Chernoff bound (see for example [16]), that allows us to compare the approximation error with a bigger value than its expectation. This gives us

$$\Pr[|\partial_U^w S - \partial_U S| \geq \delta \cdot \partial S] \leq 2\exp\left(-\frac{1}{100}\delta^2 p \cdot \partial S\right)\,.$$

Expressing the probability in terms of the global cut allows us to use the cut counting lemma [26], which bounds the number of global cuts of size at most αk by $n^{2\alpha}$, for $\alpha \geq 1$. The proof is concluded by associating each global cut with a local cut in $G[U]$ and taking the union bound over them.

In order to get the guarantee of Equation (1) for all graphs, not only those with a minimum cut of size k, one can sample edges proportionally to the inverse of their edge connectivity (as in the work of [17]) as opposed to uniformly. Moreover, one can implement such sampling scheme in dynamic streams, using the approach of Ahn, Guha, and McGregor [5]. We defer the details of these reanalyses to the full version of this paper, where we show how to construct cluster sparsifiers with the property of Equation (1) in dynamic streams.

Benefits of Boundary-Linked Subgraphs

To see why the cluster sparsifier is enough to solve the boundary-linked ϕ-expansion testing problem, consider the following reasoning. Set the self-loop parameter τ equal to b/ϕ, for some $b \gg \phi$ and $b \ll 1$. Fix a cluster U, for which $G[U]^{b/\phi}$ is an $\widetilde{\Omega}(\phi)$-expander. The crucial fact is that the size of any cut inside $G[U]^{b/\phi}$ is lower bounded by its size in the global graph up to a small polylogarithmic factor in the following way:

$$\partial_U S \geq \widetilde{\Omega}(b) \cdot \partial S \,. \tag{2}$$

We will now explain the derivation of the above equation in detail. For a cut $\emptyset \neq S \subsetneq U$, recall that $\mathrm{bnd}_U(S)$ is the number of edges going from S to $V \setminus U$. Note that by the definition of $G[U]^{b/\phi}$, the volume of any cut S inside of it is equal to

$$\mathrm{vol}_{G[U]^{b/\phi}}(S) = \mathrm{vol}(S) + \left(\frac{b}{\phi} - 1\right) \mathrm{bnd}_U(S) \,.$$

First, because we assume that $G[U]^{b/\phi}$ is an $\widetilde{\Omega}(\phi)$-expander, we have

$$\partial_U S \geq \widetilde{\Omega}(\phi) \cdot \mathrm{vol}_{G[U]^{b/\phi}}(S) \,.$$

Then, applying the aforementioned formula for $\mathrm{vol}_{G[U]^{b/\phi}}(S)$, we have

$$\partial_U S \geq \widetilde{\Omega}(\phi)\,\mathrm{vol}(S) + \widetilde{\Omega}(\phi)\left(\frac{b}{\phi} - 1\right) \mathrm{bnd}_U(S) \,.$$

Since $b \gg \phi$ and dropping the first summand, the above simplifies to

$$\partial_U S \geq \widetilde{\Omega}(b)\,\mathrm{bnd}_U(S) \,.$$

Finally, applying $\partial_U S + \mathrm{bnd}_U(S) = \partial S$ and $b \ll 1$, we arrive back at Equation (2).

A consequence of Equation (2) is that setting $\delta \approx 1/b$ in the cluster sparsifier produces the following guarantee for $\widetilde{\Omega}(\phi)$-expander subgraphs $G[U]^{b/\phi}$:

$$\forall\, S \subseteq U, \quad \partial_U S - O(1) \cdot \partial_U S \leq \partial_U^w S \leq \partial_U S + O(1) \cdot \partial_U S \,,$$

where the $O(1)$ can be made arbitrarily small. In other words, we achieve a multiplicative approximation guarantee on subgraphs of interest, which is enough to solve the testing problem. Since b can be set to be $1/\operatorname{polylog} n$, the final sparsifier size does not depend on $1/\phi$. In this sense, such sparsifier can be thought of as a "universal" sketch of the graph that allows to solve the testing problem for all ϕ simultaneously.

Even though we now know how to solve the testing problem, an implementation of Algorithm 1 would need to actually find a sparse cut when the test fails (and in particular, it needs to find a *balanced* sparse cut, see the next section). In the full version of this paper, we show that cluster sparsifiers enable to solve this harder task too: consider an offline algorithm that either correctly determines a graph to be a boundary-linked expander or finds

a (balanced) sparse cut; one can prove that we can run such algorithm on a subgraph of the sparsifier as a black box and obtain essentially the same result as if the algorithm was run on the corresponding subgraph of the original graph. In this sense, cluster sparsifiers serve as small error proxies to the original graph for expander-vs-sparse-cut type of queries on vertex-induced subgraphs.

2.2 Low Depth Recursion

Another problem that arises when using the recursive approach is that the subgraph sparsification guarantee of both power-cut sparsifiers and cluster sparsifiers is only probabilistic, and it can be shown that it cannot be made deterministic [16]. This means that after finding a sparse cut S in a subgraph $G[U]^{b/\phi}$ of a sparsifier, we cannot claim that the same sparsifier would preserve the cuts inside the new graph $G[S]^{b/\phi}$ with high probability, as it is dependent on another cut that we have already found inside the sparsifier. This means we cannot use the same sparsifier for two different calls to Algorithm 1 inside the same execution path. However, we can share a sparsifier among all the calls at the same recursion level since these will operate on independent portions of G. Therefore, we want to have a separate sparsifier for every recursion level. This means that in order to minimize space requirements, it is crucial to have a small recursion depth.

To have small recursion depth, the algorithmic approach of [8, 9, 16] enforces the sparse cut S from line 5 of Algorithm 1 to be balanced, i.e. none of S and $V \setminus S$ is much larger than the other. In particular, they only recurse on the two sides of a cut if $\mathrm{vol}(S) \gtrsim \epsilon \,\mathrm{vol}(V \setminus S)$. When there is no balanced sparse cut and yet the input is not an expander, a lemma of Spielman and Teng [32] suggests there should be an $\Omega(\phi)$-expander $G[S']$ that accounts for a $(1 - O(\epsilon))$-fraction of the total volume. An algorithmic version of this structural result allows us to iteratively trim off a small piece of the graph until such S' is found. At this point, the algorithm of [16] can simply return $\{S'\} \cup (\cup_{u \in V \setminus S'} \{u\})$ as an ED, with at most $O(\epsilon|E|)$ inter-cluster edges between singletons. As the volume of the cluster multiplicatively decreases by $1 - O(\epsilon)$ after each call, this gives recursion depth at most $\widetilde{O}(1/\epsilon) \approx \widetilde{O}(1/\phi)$.

Our Contribution: Adaptation of Trimming

We show that a simple refinement of this approach allows us to adapt the framework of [30], which leads to an algorithm with recursion depth independent of ϕ. We run the same algorithm, but instead of separating each vertex in $V \setminus S'$ into its own singleton cluster, we recurse with Algorithm 1 on the whole set $V \setminus S'$. Conceptually, this implements an analogue of the trimming step of [30].

This means that at the end, fewer edges in $V \setminus S$ become inter-cluster edges. Because of that, we can strengthen the balancedness requirement: we recurse on the two sides of a sparse cut only if $\mathrm{vol}(S) \gtrsim \frac{1}{C} \mathrm{vol}(V \setminus S)$ for a large constant C. This allows us to trim more vertices each time, resulting in $\widetilde{O}(1)$ depth of the trimming step. On the other hand, because in each call to Algorithm 1 the volume of clusters passed to recursive calls is decreased by at least a constant factor, the total recursion depth becomes at most $\widetilde{O}(1)$.

Other than the refinement discussed above, our space efficient implementation of Algorithm 1, as well as the iterative procedure to find the large expander S', are almost the same as the ones of [16] (which in turn are inspired by the one of [9]). The details of the algorithms are given in the full version of this paper.

2.3 Putting It All Together

Combining the ideas illustrated in the two sections above, neither the sparsifier's size nor the recursion depth depend on ϕ, thus giving a sparsity-independent space algorithm for boundary-linked expander decomposition (BLD for short). This result is stated in terms of parameters $b, \epsilon, \phi \in (0,1)$, $\gamma \geq 1$: a (b,ϵ,ϕ,γ)-BLD is a partition $\mathcal{U}$ with at most an ϵ fraction of crossing edges and every $U \in \mathcal{U}$ induces a ϕ/γ-expander $G[U]^{b/\phi}$ (see Section 1.3). Using this terminology, we obtain the following result.

▶ **Theorem 7** (Exponential time decoding BLD). *Let $G = (V,E)$ be a graph given in a dynamic stream, and let $b \in (0,1)$ be a parameter such that $b \leq 1/\log^2 n$. Then, there is an algorithm that maintains a linear sketch of G in $\widetilde{O}(n/b^3)$ space. For any $\epsilon \in [n^{-2}, b\log n]$, the algorithm decodes the sketch to compute, with high probability and in $\widetilde{O}(n/b^3)$ space and $2^{O(n)}$ time, a (b,ϵ,ϕ,γ)-BLD of G for*

$$\phi = \Omega\left(\frac{\epsilon}{\log n}\right) \quad \text{and} \quad \gamma = O(1)\,.$$

From this, one can easily conclude our main result.

▶ **Theorem 8** (See Theorem 1). *Let $G = (V,E)$ be a graph given in a dynamic stream. Then, there is an algorithm that maintains a linear sketch of G in $\widetilde{O}(n)$ space. For any $\phi \in (0,1)$ such that $\phi \leq c/\log^2 n$ for a small enough constant $c > 0$, the algorithm decodes the sketch to compute a $(O(\phi \log n), \phi)$-ED of G with high probability, in $\widetilde{O}(n)$ space and $2^{O(n)}$ time.*

We remark that for $\phi \geq \Omega(1/\log^2 n)$, one can use the algorithm of [16] to still have an $\widetilde{O}(n)$ space construction of a $(O(\phi \log n), \phi)$-ED.

Proof. First note that without loss of generality we can assume $\phi \geq 1/n^2$, otherwise an ED can simply consist of the connected components of G (which can be computed in dynamic streams in $\widetilde{O}(n)$ space [4]). Then, we note that since c is small enough and $\phi \leq c/\log^2 n$, one can always define $\epsilon = C \cdot \phi \cdot \log n$ for an appropriate constant $C > 0$ while ensuring $1/n^2 \leq \epsilon \leq 1/\log n$. We can thus prove the theorem by equivalently showing that there is an algorithm that maintains a linear sketch of G in $\widetilde{O}(n)$ space, and that for all $\epsilon \in [1/n^2, 1/\log n]$ decodes the sketch to compute, with high probability, an $(\epsilon, \Omega(\epsilon/\log n)))$-ED of G in $\widetilde{O}(n)$ space and $2^{O(n)}$ time.

Let then $\epsilon \in [1/n^2, 1/\log n]$. We use the algorithm from Theorem 7 with parameter ϵ and a parameter b of our choice. We need to meet two preconditions: $b \leq 1/\log^2 n$ and $\epsilon \leq b \log n$. Since we assume $\epsilon \leq 1/\log n$, we can set $b = 1/\log^2 n$, and all the prerequisites are fulfilled. Then the algorithm from Theorem 7 runs in $2^{O(n)}$ time and takes $\widetilde{O}(n/b^3) = \widetilde{O}(n)$ bits of space. The output $\mathcal{U}$ is a (b,ϵ,ϕ,γ)-BLD of G with high probability, where $\phi = \Omega(\epsilon/\log n)$ and $\gamma = O(1)$. Since a (b,ϵ,ϕ,γ)-BLD of G is an $(\epsilon,\phi/\gamma)$-ED of G, we have obtained an $(\epsilon, \Omega(\epsilon/\log n))$-ED of G with high probability. ◀

The exponential time in the decoding is due to the subtask of finding a balanced sparse cut. As we show, one can make the decoding time polynomial by resorting to known offline approximation algorithms [29, 30]. However, we only have $\log^{\Omega(1)} n$-approximations for finding a balanced sparse cut, and in particular, we do not expect (under NP-hardness and the Unique Games Conjecture) there to be a polynomial time $O(1)$-approximation [10]. Such super-constant factor error incurs some loss in the quality of decomposition and space requirement, which, nevertheless, remains independent of the sparsity.

▶ **Theorem 9** (Polynomial time decoding BLD). *Let $G = (V, E)$ be a graph given in a dynamic stream, and let $b \in (0, 1)$ be a parameter such that $b \leq 1/\log^5 n$. Then, there is an algorithm that maintains a linear sketch of G in $n/b^3 \cdot \log^{O(\log n/\log \frac{1}{b})} n$ space. For any $\epsilon \in [n^{-2}, b \log n]$, the algorithm decodes the sketch to compute, with high probability and in $n/b^3 \cdot \log^{O(\log n/\log \frac{1}{b})} n$ space and $\mathrm{poly}(n)$ time, a $(b, \epsilon, \phi, \gamma)$-BLD of G for*

$$\phi = \Omega\left(\frac{\epsilon}{\log^4 n}\right) \quad \text{and} \quad \gamma = \log^{O\left(\frac{\log n}{\log 1/b}\right)} n\,.$$

A polynomial time version of Theorem 8 then follows from Theorem 9.

▶ **Theorem 10** (See Theorem 2). *Let $G = (V, E)$ be a graph given in a dynamic stream, and let $b \in (0, 1)$ be a parameter such that $b \leq 1/\log^5 n$. Then, there is an algorithm that maintains a linear sketch of G in $n/b^3 \cdot \log^{O(\log n/\log \frac{1}{b})} n$ space. For any $\phi \in (0, 1)$ such that $\phi \leq b/\log^{C \cdot \log n/\log \frac{1}{b}} n$ for a large enough constant $C > 0$, the algorithm decodes the sketch to compute a $(\phi \cdot \log^{O(\log n/\log \frac{1}{b})} n, \phi)$-ED of G with high probability, in $n/b^3 \cdot \log^{O(\log n/\log \frac{1}{b})} n$ space and $\mathrm{poly}(n)$ time.*

We remark that setting, say, $b = 2^{-\sqrt{\log n}}$ in the above result gives a $n^{1+o(1)}$ space algorithm for computing a $(\phi \cdot n^{o(1)}, \phi)$-ED for any $\phi \leq 2^{-2C \log\log n\sqrt{\log n}}$. For larger values of ϕ, one can use the polynomial time algorithm of [16] to still get a $n^{1+o(1)}$ space construction for a $(\phi \cdot n^{o(1)}, \phi)$-ED.

Proof. As in the proof of Theorem 8, we can assume $\phi \geq 1/n^2$. Also, by virtue of C being a large enough constant and $\phi \leq b/\log^{C \cdot \log n/\log \frac{1}{b}} n$, one can always define ϵ to be $\epsilon = \phi \cdot \log^{C \cdot \log n/\log \frac{1}{b}} n$ while ensuring $n^{-2} \leq \epsilon \leq b \log n$. Then, we equivalently prove that for any $b \in (0, 1)$ with $b \leq 1/\log^5 n$ there is an algorithm that maintains a linear sketch of G in $n/b^3 \cdot \log^{O(\log n/\log \frac{1}{b})} n$ space, and that for any $\epsilon \in (0, 1)$ such that $n^{-2} \leq \epsilon \leq b \log n$ decodes the sketch to compute, with high probability, an $(\epsilon, \epsilon/\log^{O(\log n/\log \frac{1}{b})} n)$-ED of G in $n/b^3 \cdot \log^{O(\log n/\log \frac{1}{b})} n$ space and $\mathrm{poly}(n)$ time.

Let then $b, \epsilon \in (0, 1)$ with $b \leq 1/\log^5 n$ and $n^{-2} \leq \epsilon \leq b \log n$. We use the algorithm from Theorem 9 with the same parameters b and ϵ, since every admissible pair of parameters b and ϵ fulfils the conditions of Theorem 9. The space complexity is also the same, and the running time is $\mathrm{poly}(n)$. Again, observe that a $(b, \epsilon, \phi, \gamma)$-BLD of G is an $(\epsilon, \phi/\gamma)$-ED of G. Hence the claim, since Theorem 9 gives

$$\frac{\phi}{\gamma} = \Omega\left(\frac{\epsilon}{\log^4 n}\right) \cdot \frac{1}{\log^{O\left(\frac{\log n}{\log 1/b}\right)} n} = \frac{\epsilon}{\log^{O\left(\frac{\log n}{\log 1/b}\right)} n}\,. \qquad \blacktriangleleft$$

The proofs of Theorem 7 and Theorem 9 can be found in the full version of this paper.

3 Two-Level Expander Decomposition Incurs a Sparsity Dependence

Given a graph $G = (V, E)$ in a stream and parameters $\epsilon, \phi \in (0, 1)$, we consider the problem of computing a two-level (ϵ, ϕ)-RED of G (see Section 1.3). In other words, we study the problem of computing an (ϵ, ϕ)-ED $\mathcal{U}$ of G and an (ϵ, ϕ)-ED $\mathcal{U}'$ of the graph $G' = (V, E \setminus \mathcal{U})$, where $E \setminus \mathcal{U}$ denotes the set of inter-cluster edges of $\mathcal{U}$, i.e. the edges of E that are not entirely contained in a cluster $U \in \mathcal{U}$. We remark that we wish to do so in a single pass over the stream.

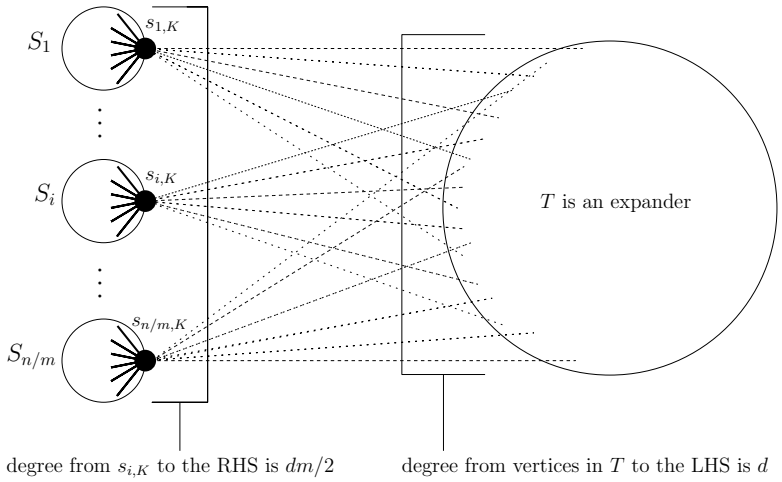

Figure 1 Illustration of the graph we use for proving the lower bound. Thick bullets represent important vertices, thick lines represent important edges, dotted lines represent edges connecting the important vertices to T.

A Natural Algorithmic Approach and Why It Fails

A naive attempt to solve this problem would be that of sketching the graph twice, for example by using our algorithm from Theorem 1. One can use the first sketch to construct the first level ED $\mathcal{U}$. After, the hope is that one can send updates to the second sketch so as to remove the intra-cluster edges and then decode this sketch into an ED of $G' = (V, E \setminus \mathcal{U})$ using again Theorem 1. However, this hope is readily dashed. Indeed, sketching algorithms break down if we send a removal update for an edge that was not there in the first place, and we do not have knowledge of which of the pairs $\binom{U}{2}$ are in E and which are not.

Our Contribution: Space Lower Bound

We show that, in sharp contrast to our algorithm for constructing a one-level expander decomposition, this problem requires $\widetilde{\Omega}(n/\phi)$ space, i.e. a dependence on $1/\phi$ is unavoidable. Formally, we obtain the following result.

▶ **Theorem 11** (See Theorem 3). *Let $\ell \geq 2$ and let $\epsilon, \phi \in (0,1)$ such that $\epsilon = 1 - \Omega(1)$, $\phi \leq \epsilon$, and $\phi \geq C \cdot \max\{\epsilon^2, 1/n\}$ for a large enough constant $C > 0$. Any streaming algorithm that with probability at least $9/10$ computes an ℓ-level (ϵ, ϕ)-RED requires $\Omega(n/\epsilon)$ bits of space.*

The above theorem gives an $\widetilde{\Omega}(n/\phi)$ space lower bound for algorithms that compute a RED with near-optimal parameters, i.e. algorithms that achieve $\epsilon = \widetilde{O}(\phi)$ for any $1/n \ll \phi \ll 1/\log n$.

Setup and Hard Instances

Throughout this section, the symbols $\ll$ and $\gg$ mean smaller or larger by a large constant factor. Let us fix the RED parameters $\epsilon, \phi \in (0,1)$, and let us restrain ourselves to the regime $\phi \gg \epsilon^2$ (and of course $\phi \ll \epsilon$). We prove the lower bound by giving a distribution over hard instances $G = (V, E)$. This distribution is parametrised by integers d and m such that $1 \ll d \ll m \ll n$, $m \gg 1/\phi$, $m \ll 1/\epsilon^2$, and $d \ll \frac{1}{\epsilon}$. With these parameters fixed, our hard distribution $\mathcal{G}$ is defined below in Definition 12. An illustration is given in Figure 1.

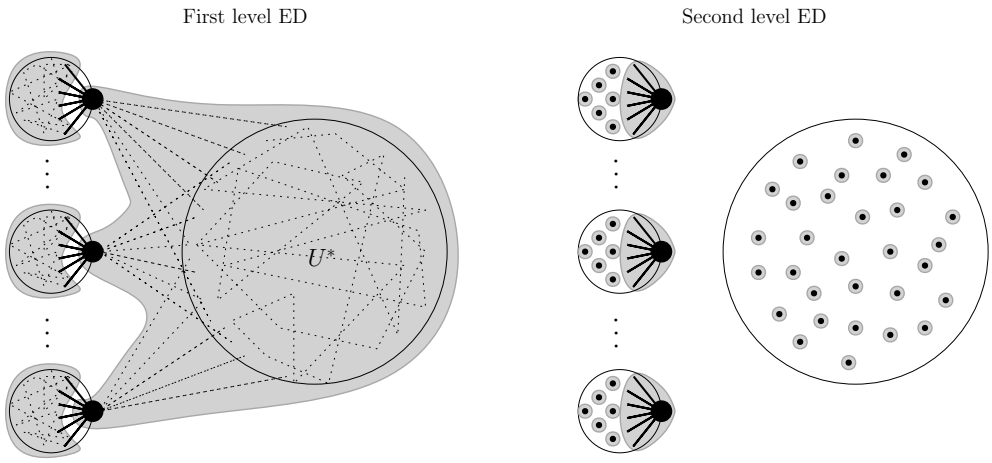

Figure 2 Illustration of the ideal expander decomposition of the graph. Thick bullets represent important vertices, smaller bullets represent ordinary vertices, thick lines represent important edges, dotted lines represent the rest of the edges. Grey areas represent the clusters in the decomposition.

▶ **Definition 12** (Distributions $\mathcal{G}$ and $\mathcal{G}'$ – Informal). *We partition V arbitrarily into two sets S and T with $n/2$ vertices each, and further partition S into n/m sets $S_1, \ldots, S_{n/m}$ with $m/2$ vertices each. The edge set of the graph $G = (V, E) \sim \mathcal{G}$ is defined as follows.*

1. *For each $i \in [n/m]$, the induced subgraph $G[S_i]$ is an Erdős-Rényi random graph with $m/2$ vertices and degree $\approx d$. We denote by $\mathcal{G}'$ the distribution of the subgraph $G[S]$.*
2. *The induced subgraph $G[T]$ is a* fixed *d-regular $\Omega(1)$-expander.*
3. *We fix for convenience an arbitrary labelling $s_{i,1}, \ldots, s_{i,m/2}$ of the vertices in each S_i, and we sample an index K uniformly from $[m/2]$. Then, for every $i \in [n/m]$, we add $dm/2$ edges from $s_{i,K}$ to T so that each $t \in T$ has d incident edges connecting to S.*

Roughly speaking, our hard instances should be composed of n/m regular expanders that are densely connected to T, which is also an expander, through a selection of "special" vertices. We will show that the hardness arises from recovering information about certain important vertices and edges, defined below and also illustrated in Figure 1.

▶ **Definition 13** (Important vertices and edges – Informal). *Let $G = (V, E) \sim \mathcal{G}$. We define the set of important vertices $V^* = \{s_{i,K} : i \in [n/m]\}$ to be the set of vertices of S that are connected to T, and define the set of important edges $E^* = \{\{s_{i,K}, v\} : i \in [n/m], v \in S\}$ to be the set of edges in the induced subgraph $G[S]$ that are incident on V^*.*

The lower bound proof has two steps: we first prove that a two-level RED leaks a non-trivial amount of information about the graph $G \sim \mathcal{G}$; then we prove that, in order to obtain such amount of information, the algorithm must use a lot of space.

3.1 Two-Level Expander Decomposition of the Hard Instance

In this section, we show that any valid two-level RED reveals a lot of informations about the important edges. The following lemma shows that a non-trivial amount of important edges are inter-cluster edges in the first level decomposition. An ideal decomposition is illustrated in Figure 2.

▶ **Lemma 14** (Informal). *Let $G = (V, E) \in \mathrm{supp}(\mathcal{G})$. Then, any (ϵ, ϕ)-ED $\mathcal{U}$ of G satisfies*

$$|E^* \setminus \mathcal{U}| \geq \frac{4}{5} \cdot |E^*| \ .$$

Proof sketch. By definition of the graph, there are $\Theta(dn)$ edges in the graph. Since there is at most an ϵ fraction of crossing edges, there are only $O(\epsilon dn)$ crossing edges. Note that there are $\Theta(dn)$ edges in $G[T]$, so only an $O(\epsilon)$ fraction of the edges in $G[T]$ are crossing edges. Furthermore, $G[T]$ is a regular expander: this implies that there is a large cluster $U^* \in \mathcal{U}$ comprising a $1 - O(\epsilon)$ fraction of T, together with a $1 - O(\epsilon)$ fraction of important vertices. The latter is true since the edges between S and T make up a constant fraction of the total volume and only a small fraction of the edges can be crossing. We refer the reader to the full version of this paper for more details.

The edges in the subgraph $G[S]$ also account for a constant fraction of the total volume. Together with the fact that each S_i induces a regular expander, for many of the S_i's we will have a cluster in $\mathcal{U}$ that contains most of S_i. Now consider a set S_i such that the important vertex of S_i is in U^* and most of the vertices in S_i are all in the same cluster. If most of the vertices in S_i are also inside U^*, then consider the cut from $(U^* \cap S_i) \setminus \{s_{i,K}\}$ to $(U^* \setminus S_i) \cup \{s_{i,K}\}$. The cut size is at most the number of important edges in S_i, which is $O(d)$. On the other hand, the volume of the cut is $\Theta(dm)$ since most of the vertices of S_i are in the cluster. Recalling that $m \gg \frac{1}{\phi}$, one concludes that the cut is sparse. Therefore, we ruled out the possibility of having many vertices of S_i in U^*. See the full version of this paper for a detailed discussion.

In summary, as illustrated in Figure 2, in any valid expander decomposition, most of the vertices in T and most of the important vertices are inside a giant cluster U^*, and for most of the S_i's, there is a cluster other than U^* that contains most of the vertices in S_i. For any such S_i, most of the important edges inside it are then crossing edges. ◀

The second level expander decomposition, i.e. an expander decomposition of the inter-cluster edges from the first level, is also quite structured, as illustrated in the ideal RED of Figure 2.

▶ **Lemma 15** (Informal). *Let $G = (V, E) \in \mathrm{supp}(\mathcal{G})$, and let $\mathcal{U}_1, \mathcal{U}_2$ be any 2-level (ϵ, ϕ)-RED of G. Then, there are at most $n/10$ vertices in S that are non-isolated vertices[3] in $\mathcal{U}_2$. Moreover, at least a $2/3$ fraction of important edges are not in $E \setminus \mathcal{U}_2$, i.e. a $2/3$ fraction of important edges are inside clusters of $\mathcal{U}_2$.*

Proof sketch. The number of crossing edges in the first level decomposition is $O(\epsilon dn)$, which is much less than n since $d \ll \frac{1}{\epsilon}$. This means that most of the vertices are isolated vertices in the second level. Moreover, by Lemma 14, most of the important edges are crossing edges in the first level decomposition. Among these $\Theta(dn/m)$ edges, at most $O(\epsilon^2 dn)$ edges can be crossing edges in the second level decomposition. Recalling that $m \ll \frac{1}{\epsilon^2}$, we see that most of the important edges are not crossing edges in the second level decomposition. ◀

3.2 Lower Bound via Communication Complexity

Our streaming lower bound will be proven in the two-player one-way communication model. In this setting, Alice gets the edges in $G[S]$ and $G[T]$, and Bob gets the edges between S and T. We prove that in order to give a two-level RED, Alice needs to send $\Omega(dn)$ bits of information to Bob.

The high level idea is the following. Note that the identity of the important vertices can be only revealed by edges given to Bob. Thus, given Alice's input, every vertex in S has the same probability to be an important vertex, which means that every edge in S has the same

[3] We call a vertex v non-isolated in a decomposition $\mathcal{U}$ if $\mathcal{U}$ puts v in a cluster with other vertices, i.e. v does not constitute a singleton cluster in $\mathcal{U}$.

probability to be an important edge. Therefore, in order to make sure that Bob recovers most of the important edges (which is morally equivalent to computing a two-level RED, as suggested by Figure 2), Alice needs to send most of the edges in S to Bob, which is $\Omega(dn)$.

To make the above idea concrete, we consider a communication problem where Alice is given a graph, and Bob is asked to output a not too large set of pairs that contains a good fraction of the edges of Alice's input. We first reduce this new problem to the two-level RED problem. Then, we will prove a communication complexity lower bound for this problem.

▶ **Definition 16** (Informal). *In the communication problem* RECOVER*, Alice's input is a graph $G' = (S, E')$ where $|S| = n/2$, and Bob's output is a set of pairs of vertices $F \subseteq \binom{S}{2}$ that must satisfy $|F| \leq nm/10$ and $|F \cap E'| \geq \Omega(|E'|)$, i.e. at least a constant fraction of the edges in G' are in F.*

Now, the idea is to plant Alice's input for RECOVER into our instance from Definition 12. The input distribution for RECOVER is sampled from the distribution $\mathcal{G}'$. In other words, the distribution of Alice's input is the same as the left-hand side part of $G \sim \mathcal{G}$ (i.e. the subgraph $G[S]$). Then, in the reduction, Alice gets the edges of $G[S]$ and $G[T]$ while Bob gets the edges between S and T. By virtue of the discussion in the previous section, we expect a RED of G to allow Bob to recover many important edges in $G[S]$. Hence, Bob could simulate the RED algorithm for all the $m/2$ possible choices of the random index $K \sim [m/2]$ that defines the important edges (see Definition 12): in this way, the k-th RED should reveal information about Alice's edges that are incident on the vertices $\{s_{i,k}\}_i$. Therefore, by varying k over $[m/2]$, Bob should obtain information about all the edges in Alice's graph. More precisely, the reduction is the following.

▶ Reduction (Informal). Let $\mathcal{A}$ be a deterministic streaming algorithm for computing a 2-level (ϵ, ϕ)-RED. Alice, given her input graph $G' = (S, E')$ generated by $\mathcal{G}'$, feeds her edges E' to $\mathcal{A}$, together with the fixed edges of $G[T]$. Then, she sends the memory state of $\mathcal{A}$ to Bob. Upon receiving the message, Bob makes $m/2$ copies of $\mathcal{A}$ and initialises them to the memory state he received from Alice. Call these copies $\mathcal{A}_1, \ldots, \mathcal{A}_{m/2}$. Next, for each $k \in [m/2]$, call $G_k = (V, E_k)$ the graph we obtain from $\mathcal{G}$ when $K = k$ and the left-hand side $G_k[S]$ is exactly Alice's input G' (so that the vertices $\{s_{i,k}\}_i$ are the important vertices in G_k, see Definition 12 and Definition 13). Then, Bob feeds the edges $E_k(S, T)$ to $\mathcal{A}_k$. Let then $\mathcal{U}_1^k, \mathcal{U}_2^k$ be the RED output by $\mathcal{A}_k$. Bob finally constructs his output set F as follows: for each $k \in [m/2]$, add the pair $\{s, s_{i,k}\}$ to F for every $i \in [n/m]$ and every vertex $s \in S_i$ that is not isolated in $\mathcal{U}_2^k$. ⌟

By Lemma 15, the number of non-isolated vertices in the second-level decomposition is at most $n/10$. Hence, the total number of pairs added to F is at most $nm/10$, thus satisfying the first requirement of Definition 16. Moreover, by Lemma 15, at least a $2/3$ fraction of the important edges are not crossing edges in the second level. This means that for each k, at least a $2/3$ fraction of the edges that are incident on $s_{i,k}$ is added to F. In turn, this implies that F contains at least a constant fraction of the edges in E', thus satisfying the second requirement of Definition 16. More precisely, one can prove the following.

▶ **Lemma 17** (Informal). *If there is a deterministic L-bit space streaming algorithm $\mathcal{A}$ that computes a 2-level (ϵ, ϕ)-RED with constant probability over inputs $G \sim \mathcal{G}$, then there is a deterministic protocol $\mathcal{R}$ that solves* RECOVER *with constant probability over inputs $G' \sim \mathcal{G}'$. The communication complexity of $\mathcal{R}$ is at most L.*

The final component of the proof is the communication complexity lower bound for RECOVER.

▶ **Lemma 18** (Informal). *The one-way communication complexity of solving* RECOVER *with constant probability over inputs sampled from* $\mathcal{G}'$ *is* $\Omega(dn)$.

Proof sketch. Roughly speaking, we show that the posterior distribution of the input conditioned on the output is shifted away from its prior distribution.

Recall that when the input $G' = (S, E')$ is sampled from $\mathcal{G}'$, the graph is a disjoint union of n/m random graphs with $m/2$ vertices each and degree $\approx d$. There are roughly

$$\left(\binom{m/2}{d}^{m/2}\right)^{n/m} \approx \left(\frac{m}{2d}\right)^{dn/2}$$

possible inputs in total and the information complexity is $\Omega(dn)$. Conditioning on the the output F of a correct protocol for RECOVER, the number of possible inputs is greatly decreased. In particular, to determine the input E', we need to select a constant fraction, say $2/3$ for example, of the pairs from F, and select the rest of the edges (a $1/3$ fraction, in our example) arbitrarily. Since $|F|$ is at most $nm/10$, $|E'| = \Theta(dn)$, and $\binom{S}{2} \approx nm/2$, the total number of possible inputs is then roughly

$$\binom{nm/10}{2/3 \cdot dn} \cdot \binom{nm/2}{1/3 \cdot dn} \approx \left(\frac{3m}{20d}\right)^{1/3 \cdot dn} \cdot \left(\frac{3m}{2d}\right)^{1/6 \cdot dn} < \left(\frac{m}{3d}\right)^{dn/2}.$$

This means the information complexity of the input is decreased by a constant factor, which means that the protocol needs to communicate $\Omega(dn)$ bits of information. ◀

Finally, one can conclude the main result Theorem 11 combining Lemma 17 and Lemma 18. The formal proofs and definitions are deferred to the full version of this paper.

Lower Bounds on 0-Extension with Steiner Nodes

Yu Chen

Rutgers University, Piscataway, NJ, USA

Abstract

In the 0-*Extension problem*, we are given an edge-weighted graph $G = (V, E, c)$, a set $T \subseteq V$ of its vertices called terminals, and a semi-metric D over T, and the goal is to find an assignment f of each non-terminal vertex to a terminal, minimizing the sum, over all edges $(u, v) \in E$, the product of the edge weight $c(u, v)$ and the distance $D(f(u), f(v))$ between the terminals that u, v are mapped to. Current best approximation algorithms on 0-Extension are based on rounding a linear programming relaxation called the *semi-metric LP relaxation*. The integrality gap of this LP, is upper bounded by $O(\log |T|/ \log \log |T|)$ and lower bounded by $\Omega((\log |T|)^{2/3})$, has been shown to be closely related to the quality of cut and flow vertex sparsifiers.

We study a variant of the 0-Extension problem where Steiner vertices are allowed. Specifically, we focus on the integrality gap of the same semi-metric LP relaxation to this new problem. Following from previous work, this new integrality gap turns out to be closely related to the quality achievable by cut/flow vertex sparsifiers with Steiner nodes, a major open problem in graph compression. We show that the new integrality gap stays superconstant $\Omega(\log \log |T|)$ even if we allow a super-linear $O(|T| \log^{1-\varepsilon} |T|)$ number of Steiner nodes.

1 Introduction

In the 0-*Extension* problem (0-Ext), we are given an undirected edge-weighted graph $G = (V, E, c)$, a set $T \subseteq V$ of its vertices called *terminals*, and a metric D on terminals, and the goal is to find a mapping $f : V \to T$ that maps each vertex to a terminal in T, such that each terminal is mapped to itself (i.e., $f(t) = t$ for all $t \in T$), and the sum $\sum_{(u,v)\in E} c(u, v) \cdot D(f(u), f(v))$ is minimized.

The 0-Ext problem was first introduced by Karzanov [22]. It is a generalization of the *multi-way cut* problem (by setting $D(t, t') = 1$ for all pairs $t, t' \in T$) [15, 7, 17, 5, 2, 6, 4], and a special case of the *metric labeling* problem [23, 10, 3, 20, 14]. Călinescu, Karloff and Rabani [8] gave the first approximation algorithm for 0-Ext, achieving a ratio of $O(\log |T|)$, by rounding the solution of a *semi-metric LP relaxation* (LP-Metric), which is presented below.

$$\text{(LP-Metric)} \qquad \begin{aligned} \text{minimize} \quad & \textstyle\sum_{(u,v)\in E} c(u,v)\cdot\delta(u,v) \\ s.t. \quad & (V,\delta) \text{ is a semi-metric space} \\ & \delta(t,t') = D(t,t'), \quad \forall t,t' \in T \end{aligned}$$

Fakcharoenphol, Harrelson, Rao and Talwar [16] later gave a modified rounding algorithm on the same LP, improving the ratio to $O(\log|T|/\log\log|T|)$, which is the current best-known approximation. On the other hand, this LP was shown to have integrality gap $\Omega(\sqrt{\log|T|})$ [8], and this was recently improved to $\Omega((\log|T|)^{2/3})$ by Schwartz and Tur [31]. Another LP relaxation called *earthmover distance relaxation* (LP-EMD) was considered by Chekuri, Khanna, Naor and Zosin [10] and utilized to obtain an $O(\log|T|)$-approximation of the metric labeling problem (and therefore also the 0-Ext problem). It has been shown [21] by Karloff, Khot, Mehta and Rabani that this LP relaxation has an integrality gap $\Omega(\sqrt{\log|T|})$. Manokaran, Naor, Raghavendra and Schwartz [28] showed that the integrality gap of this LP relaxation leads to a hardness of approximation result, assuming the Unique Game Conjecture.

In addition to being an important problem on its own, the 0-Ext problem and its two LP relaxations are also closely related to the construction of *cut/flow vertex sparsifiers*, a central problem in the paradigm of graph compression. Given a graph G and a set $T \subseteq V(G)$ of terminals, a cut sparsifier of G with respect to T is a graph H with $V(H) = T$, such that for every partition (T_1, T_2) of T, the size of the minimum cut separating T_1 from T_2 in G and the size of the minimum cut separating T_1 from T_2 in H, are within some small factor q, which is also called the *quality* of the sparsifier[1]. Moitra [29] first showed that every graph with k terminals admits a cut sparsifier with quality bounded by the *integrality gap* of its LP-Metric (hence $O(\log k/\log\log k)$). Later on, Leighton and Moitra [26], and Makarychev and Makarychev [27] concurrently obtained the same results for flow sparsifiers, and then Charikar, Leighton, Li and Moitra [9] showed that the best flow sparsifiers can be computed by solving an LP similar to LP-EMD. On the lower bound side, it was shown after a line of work [26, 9, 27] that there exist graphs with k terminals whose best flow sparsifier has quality $\tilde{\Omega}(\sqrt{\log k})$.

A major open question on vertex sparsifiers is:

Q1. Can better quality sparsifiers be achieved by allowing a small number of Steiner vertices?

In other words, what if we no longer require that the sparsifier H only contain terminals, but just require that H contain all terminals and its size be bounded by some function f on the number of terminals (for example, $f(k) = 2k, k^2$ or even 2^k)? Chuzhoy [13] constructed $O(1)$-quality cut/flow sparsifiers with size dependent on the number of terminal-incident edges in G. Andoni, Gupta and Krauthgamer [1] showed the construction for $(1+\varepsilon)$-quality flow sparsifiers for quasi-bipartite graphs. For general graphs, they constructed a sketch of size $f(k,\varepsilon)$ that stores all feasible multicommodity flows up to a factor of $(1+\varepsilon)$, raising the hope for a special type of $(1+\varepsilon)$-quality flow sparsifier, called contraction-based flow sparsifiers, of size $f(k,\varepsilon)$ for general graphs, which was recently invalidated by Chen and Tan [12], who showed that contraction-based flow sparsifiers whose size are bounded by any function $f(k)$ must have quality $1+\Omega(1)$. But it is still possible for such flow sparsifiers with constant quality and finite size to exist. Prior to this work, Krauthgamer and Mosenzon [24] showed that there exist 6-terminal graphs G whose quality-1 flow sparsifiers must have an arbitrarily large size.

[1] flow sparsifiers has a slightly more technical definition, which can be found in [19, 26, 13, 1].

Given the concrete connection between the 0-Ext problem and cut/flow sparsifiers, it is natural to ask a similar question for 0-Ext:

Q2. Can better approximation of 0-Ext *be achieved by allowing a small number of Steiner vertices?*

In this paper, we formulate and study the following variant of the 0-Ext problem, which we call the *0-Extension with Steiner Nodes* problem (0EwSN). (We note that a similar variant was mentioned in [1], and we provide a comparison between them in more detail in Appendix A.) We are also given a function $f : \mathbb{Z} \to \mathbb{Z}$ with $f(k) \geq k$ for all $k \in \mathbb{Z}$, this should be the total number of Steiner vertices.

0-Extension with Steiner Nodes

In an instance of 0EwSN(f), the input consists of an edge-weighted graph $G = (V, E, c)$, a subset $T \subseteq V$ of k vertices, that we call *terminals*, and a metric D on terminals in T, which is exactly the same as 0-Ext. A solution to the instance (G, T, D) consists of

- a partition $\mathcal{F}$ of V with $|\mathcal{F}| \leq f(k)$, such that distinct terminals of T belong to different sets in $\mathcal{F}$; we call sets in $\mathcal{F}$ *clusters*, and for each vertex $u \in V$, we denote by $F(u)$ the cluster in $\mathcal{F}$ that contains it;
- a semi-metric δ on the clusters in $\mathcal{F}$, such that for each pair $t, t' \in T$, $\delta(F(t), F(t')) = D(t, t')$.

We define the *cost* of a solution $(\mathcal{F}, \delta)$ as $\mathsf{cost}(\mathcal{F}, \delta) = \sum_{(u,v)\in E} c(u, v) \cdot \delta(F(u), F(v))$, and its *size* as $|\mathcal{F}|$. The goal is to compute a solution $(\mathcal{F}, \delta)$ with size at most $f(k)$ and minimum cost.

The difference between 0EwSN(f) and 0-Ext is that, instead of enforcing every vertex to be mapped to a terminal, in 0EwSN(f) we allow vertices to be mapped to $(f(k) - k)$ non-terminals (or Steiner nodes), which are the clusters in $\mathcal{F}$ that do not contain terminals. We are also allowed to manipulate the distances between these non-terminals, conditioned on not destroying the induced metric D on terminals. Clearly, when $f(k) = k$, the 0EwSN(f) problem degenerates to the 0-Ext problem.

It is easy to see that (LP-Metric) is still an LP relaxation for 0EwSN(f), as each solution $(\mathcal{F}, \delta)$ to 0EwSN naturally corresponds to a semi-metric δ' on V (where we can set $\delta'(u, u') = \delta(F(u), F(u'))$ for all pairs $u, u' \in V$). Denote by $\mathsf{IG}_f(k)$ the worst integrality gap for (LP-Metric) to any 0EwSN(f) instance with at most k terminals. In fact, similar to the connection between the integrality gap of (LP-Metric) and the quality achievable by flow sparsifiers [29, 26], it was recently shown by Chen and Tan [12] that the value of $\mathsf{IG}_f(k)$ is also closely related to the quality achievable by flow sparsifiers with Steiner nodes. Specifically, for any function f, every graph G with k terminals has a quality-$\big((1 + \varepsilon) \cdot \mathsf{IG}_f(k)\big)$ flow sparsifier with size bounded by $(f(k))^{(\log k/\varepsilon)^{k^2}}$. This means that any positive answer to question Q2 (by proving that $\mathsf{IG}_f(k) = o(\log k/ \log\log k)$ for some f) also gives a positive answer to question Q1.

This makes it tempting to study the 0EwSN problem. Specifically, can we prove any better-than-$O(\log k/ \log\log k)$ upper bound for $\mathsf{IG}_f(k)$, for any function f? To the best of our knowledge, no such bound is known for any f, leaving the problem wide open. In fact, no non-trivial lower bound on $\mathsf{IG}_f(k)$ is known for even very small function like $f(k) = O(k)$.

1.1 Our Results

In this paper, we make a first step in investigating the value of $\mathsf{IG}_f(k)$, by giving a superconstant lower bound on $\mathsf{IG}_f(k)$ for near-linear functions f. Our main result is summarized in the following theorem.

▶ **Theorem 1.** *For any $0 < \varepsilon < 1$ and any size function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ with $f(k) = O(k \log^{1-\varepsilon} k)$, the integrality gap of the LP-relaxation (*LP-Metric*) is $\mathsf{IG}_f(k) = \Omega(\varepsilon \log \log k)$.*

We remark that our lower bound for the integrality gap of $\mathsf{0EwSN}(f)$ does not imply a size lower bound for $O(\log \log k)$-quality flow sparsifiers. However, if the same lower bound can be proved for a slightly generalized version of $\mathsf{0EwSN}(f)$, that was proposed in [1] and analyzed in [12], then it will imply an $\Omega(k \log^{1-\varepsilon} k)$ size lower bound for $O(\log \log k)$-quality flow sparsifiers. We provide a detailed discussion in Appendix A.

1.2 Technical Overview

We now discuss some high-level ideas in the proof of Theorem 1. Given any k, we will construct an unweighted graph G on n vertices (where $n \approx k \log k$) and k terminals, and show that any solution of the 0EwSN problem with size $O(k \log^{1-\varepsilon} k)$ has cost lower bounded by $\Omega(\log \log k)$ times the number of edges in G.

Our hard instance is a constant degree expander (with an arbitrary set of its k vertices as terminals). There are two main reasons to choose such a graph. First, in previous work [8] for proving the $\Omega(\sqrt{\log k})$ integrality gap lower bound for the 0-Extension problem, a graph called "expander with tails" was used. Though the tails in their construction appear useless for our purpose, as we allow a super-linear number of Steiner vertices which easily accomodate a single-edge tail for each terminal, the expander graph turns out to still be the core structure that is hard to compress. Second, it has been shown [3] that 0-Extension problem on minor-free graphs has integrality gap $O(1)$, so our hard example has to contain large cliques as minor, which makes expanders, a favorable choice. For technical reasons, we need some additional properties like Hamiltonicity and high girth. See Section 3.1 for more details.

Next we want to lower bound the cost of an 0EwSN solution of size $O(k \log^{1-\varepsilon} k)$. We first consider a special type of solutions where each cluster is mapped to a vertex on the graph. Recall that a solution consists of a partition $\mathcal{F}$ of $V(G)$ into clusters and a metric δ on clusters in $\mathcal{F}$. Specifically, in this special type of solutions, we require that each cluster $F \in \mathcal{F}$ corresponds to a distinct vertex v_F (called its *center*) in G, and for all pairs F, F' the metric $\delta(F, F')$ coincides with the shortest-path distance between $v_F, v_{F'}$ in G. We show that all special solutions have cost $\Omega(n \cdot \varepsilon \log \log k)$. Intuitively, as the graph is a constant degree expander, every center v_F is within distance $(\varepsilon/100) \cdot \log \log k$ to at most $(\log k)^{\varepsilon/10}$ other centers, but its cluster F contains $(\log k)^{\varepsilon}$ vertices on average and so it has $\Omega((\log k)^{\varepsilon})$ inter-cluster edges. As we measure the distance between clusters using their centers, only a small fraction of the inter-cluster edges will cost less than $(\varepsilon/100) \cdot \log \log k$, making the total new edge length $\Omega(n \cdot \varepsilon \log \log k)$ (as the number of inter-cluster edges in a balanced expander partition is $\Omega(n)$). Careful calculations are needed to turn these informal arguments into a rigorous proof. See Section 3.2 for more details.

Afterwards, we show that general solutions can actually be reduced to the special type of solutions considered in the first step, losing only an $O(1)$ factor in its cost. In fact, it has been recently shown [12] that, to analyze the cost of any 0EwSN instance, it suffices to consider 0EwSN solutions whose metric δ is embeddable into a geodesic structure of the

terminal-induced shortest path distance metric called *tight span*. Our main contribution here, on a conceptual level, is showing that *for a graph with high girth, its tight span structure locally coincides with the graph structure itself*. In this sense, we can compare any solution to some special solution considered in Step 1. On a global level, in such a comparison it turns out that we will lose a factor which is approximately the *diameter-girth ratio*, which we can manage to get to $O(1)$ with an additional short-cycle-removing step in the construction of the expander. We believe this diameter-girth ratio quantifies how "local" a graph structure is, and should be of independent interest to other graph problems on shortest-path distances. To carry out the technical steps, we employ a notion called *continuiazation* of a graph recently studied in [11]. See Section 3.3 for more details.

2 Preliminaries

By default, all logarithms are to the base of 2.

Let $G = (V, E, \ell)$ be an edge-weighted graph, where each edge $e \in E$ has weight (or *length*) ℓ_e. For a vertex $v \in V$, we denote by $\deg_G(v)$ the degree of v in G. For each pair $S, T \subseteq V$ of disjoint subsets, we denote by $E_G(S, T)$ the set of edges in G with one endpoint in S the other endpoint in T. For a pair v, v' of vertices in G, we denote by $\mathsf{dist}_G(v, v')$ (or $\mathsf{dist}_\ell(v, v')$) the shortest-path distance between v and v' in G. We define the *diameter* of G as $\mathsf{diam}(G) = \max_{v,v' \in V} \{\mathsf{dist}_G(v, v')\}$, and we define the *girth* of G, denoted by $\mathsf{girth}(G)$, as the minimum weight of any cycle in G. We may omit the subscript G in the above notations when the graph is clear from the context.

Given a graph G, its *conductance* is defined as

$$\Phi(G) = \min_{S \subseteq V, S \neq \emptyset, S \neq V} \left\{ \frac{|E_G(S, V \setminus S)|}{\min\left\{\sum_{v \in S} \deg_G(v), \sum_{v \notin S} \deg_G(v)\right\}} \right\}.$$

We say that G is a *ϕ-expander* iff $\Phi(G) \geq \phi$.

3 Proof of Theorem 1

In this section we prove the main result Theorem 1, which shows that, when we only have $O(k \log^{1-\varepsilon} k)$ Steiner nodes, the best ratio we can get is $\Omega(\varepsilon \log \log k)$. We begin by describing the hard instance in Section 3.1, which is essentially a high-girth expander with a subset of vertices designated as terminals. Then in Section 3.2 we show that a special type of solutions may not have small cost. Finally, in Section 3.3 we generalize the arguments in Section 3.2 to analyze an arbitrary solution, completing the proof of Theorem 1. Some technical details in Section 3.3 are deferred to Section 3.4.

3.1 The Hard Instance

Let k be a sufficiently large integer. Let $n > k$ be an integer such that $k = \left\lceil \frac{n \log \log n}{\log n} \right\rceil$. Let V be a set of n vertices. Let Σ be the set of all permutations on V. For a permutation $\sigma \in \Sigma$, we define its corresponding edge set $E_\sigma = \{(v, \sigma(v)) \mid v \in V\}$.

We now define the hard instance (G, T, D). Graph G is constructed in two steps. In the first step, we construct an auxiliary graph G'. Its vertex set is V. Its edge set is obtained as follows. We sample three permutations $\sigma_1, \sigma_2, \sigma_3$ uniformly at random from Σ, and then let $E(G') = E_{\sigma_1} \cup E_{\sigma_2} \cup E_{\sigma_3}$. In the second step, we remove all short cycles in G' to obtain G. Specifically, we first compute a breath-first-search tree τ starting from an arbitrary vertex

of G'. We then iteratively modify G' as follows. While G' contains a cycle C of length at most $(\log n)/100$, we find an edge of $C \setminus \tau$ (note that such an edge must exist, as τ is a tree), and remove it from G'. We continue until G' no longer contains cycles of length at most $(\log n)/100$. We denote by G the resulting graph. The terminal set T is an arbitrary subset of V with size k. For each edge $e \in E(G)$, its weight $c(e)$ is defined to be 1, and its *length* ℓ_e is also defined to be 1. The metric D on the set T of terminals is simply defined to be the shortest-path distance (in G) metric on T induced by edge length $\{\ell_e\}_{e \in E(G)}$.

We next show some basic properties of the graphs G' and G. We start with the following observations and propositions.

▶ **Observation 2.** *G' is a 6-regular graph, so $|E(G)| \leq |E(G')| \leq 3n$.*

▶ **Observation 3.** $\mathsf{girth}(G) \geq (\log n)/100$.

▶ **Proposition 4.** *The probability that $|E(G') \setminus E(G)| \geq n^{0.3}$ is at most $O(n^{-0.2})$.*

Proof. Let $v_1, \ldots, v_L$ be a sequence of $L \leq (\log n)/100$ distinct vertices of V. We now show that the probability that the cycle $(v_1, \ldots, v_L, v_1)$ exists in $E(G')$ is at most $\big(6/(n-L)\big)^L$. Indeed, to realize the cycle edge (v_i, v_{i+1}), for some $\ell \in \{1,2,3\}$, $\sigma_\ell(v_i) = v_{i+1}$ or $\sigma_\ell(v_{i+1} = v_i$, where for convenience we say $v_{L+1} = v_1$. There are 6 possible events. In order to form the cycle, we need to form L edges, and each edge has 6 possible events, which means there are at most 6^L ways to form the cycle in total. Consider any possible way, we have $\ell_1 \ldots, \ell_L \in \{1,2,3\}$ and $j_1, \ldots, j_L \in \{0,1\}$ such that for any index $1 \leq i \leq L$, we have $\sigma_{\ell_i}(v_{i+j_i}) = v_{i+1-j_i}$. Let $\mathcal{E}_i$ denote this event, we have $\Pr[\mathcal{E}_i | \mathcal{E}_1, \ldots, \mathcal{E}_{i-1}] \leq 1/(n-i)$. Thus the probability that all events $\mathcal{E}_i$ happen is at most $1/(n-L)^L$. Applying union bound on all the ways to form the cycle, the probability that the cycle exists in $E(G')$ is at most $\big(6/(n-L)\big)^L$.

Therefore, the expected number of cycles in G' with length at most $(\log n)/100$ is at most

$$\sum_{3 \leq L \leq (\log n)/100} \frac{n(n-1)\cdots(n-L+1)}{2L \cdot \left(\frac{n-L}{6}\right)^L} \leq \sum_{3 \leq L \leq (\log n)/100} \frac{6^L}{2L} \cdot \left(1 + \frac{L}{n-L}\right)^L$$
$$\leq \sum_{3 \leq L \leq (\log n)/100} 6^L \leq n^{0.1}.$$

Therefore, from Markov Bound, with probability $n^{-0.2}$, the number of cycles in G' with length at most $(\log n)/100$ is at most $n^{0.3}$. Note that we delete at most one edge per each cycle, so $|E(G') \setminus E(G)|$ is less than the number of cycles in G' with length at most $(\log n)/100$, the proposition follows. ◀

We use the following previous results on the conductance and the Hamiltonicity of G'.

▶ **Lemma 5** ([30])**.** *With probability $1 - o(1)$, $\Phi(G') = \Omega(1)$.*

▶ **Corollary 6.** *With probability $1 - o(1)$, the diameter of G is at most $O(\log n)$.*

Proof. From the construction of G, G contains a BFS tree of G', so the diameter of G is at most twice the diameter of G'. Therefore, it suffices to show that, if $\Phi(G') \geq \Omega(1)$, then the diameter of graph G' is at most $O(\log n)$, which we do next.

Let v be an arbitrary vertex of G'. For each integer t, we define the set $B_t = \{v' \mid \mathsf{dist}(v, v') \leq t\}$, and $\alpha_t = \sum_{v' : \mathsf{dist}_{G'}(v,v') \leq t} \deg(v')$, namely the sum of degrees of all vertices in B_t.

Denote $t^* = \max\{t \mid \alpha_t \leq |E(G')|\}$. Note that, for each $1 \leq t \leq t^*$, as $\Phi(G') \geq \Omega(1)$, $|E(B_t, V \setminus B_t)| \geq \Omega(\alpha_t)$. Therefore,

$$\alpha_{t+1} \geq \alpha_t + \sum_{v' \in B_{t+1} \setminus B_t} \deg(v) \geq \alpha_t + |E(B_t, V \setminus B_t)| \geq \alpha_t \cdot (1 + \Omega(1)).$$

It follows that $t^* \leq O(\log n)$. Therefore, for any pair $v, v' \in V$, the set of vertices that are at distance at most $t^* + 1$ from v must intersect the set of vertices that are at distance at most $t^* + 1$ from v', as otherwise the sum of degrees in all vertices in these two sets is greater than $2|E(G')|$, a contradiction. Consequently, the diameter of G' is at most $2t^* + 2 \leq O(\log n)$. ◀

▶ **Lemma 7** ([18]). *With probability $1 - o(1)$, the subgraph of G' induced by edges of $E_{\sigma_1} \cup E_{\sigma_2}$ is Hamiltonian.*

Now if we consider the semi-metric LP relaxation (LP-Metric) of this instance (G, T, D), then clearly the graph itself gives a solution δ to (LP-Metric). Specifically, $\delta(u, u') = \mathsf{dist}_\ell(u, u')$, where $\mathsf{dist}_\ell(\cdot, \cdot)$ the shortest-path (in G) distance metric on V induced by the lengths $\{\ell_e\}_{e \in E(G)}$. Such a solution has cost $|E(G)| = O(n)$ (as all edges have weight $c(e) = 1$). Therefore, in order to prove Theorem 1, it suffices to show that any solution $(\mathcal{F}, \delta)$ with size $O(k \log^{1-\varepsilon} k)$ has cost at least $\Omega(\varepsilon n \log\log n) = \Omega(\varepsilon n \log\log k)$.

Observe that, the graph G constructed above is essentially a bounded-degree high-girth expander, which is similar to the hard instance used in [26] for proving the $\Omega(\log\log k)$ quality lower bound for flow vertex sparsifier (without Steiner nodes). However, our proof in the following subsections takes a completely different approach from the approach in [26].

3.2 Proof of Theorem 1 for Canonical Solutions

In this subsection, we prove the cost lower bound for a special type of solutions to the 0EwSN(f) instance (G, T, D) which we call canonical. Specifically, a solution is canonical $(\mathcal{F}, \delta)$ if

- each cluster $F \in \mathcal{F}$ corresponds to a distinct vertex of V, we call this vertex the *center* of F, denote as $v(F)$ (note however that $v(F)$ does not necessarily lie in F). For each terminal $t \in T$, the unique cluster $F \in \mathcal{F}$ that contains t, $v(F) = t$; and
- for each pair F, F' of clusters in $\mathcal{F}$, $\delta(F, F') = \mathsf{dist}_G(v(F), v(F'))$.

In this subsection, we show that, with high probability, any canonical solution of size $o(n/\log^\varepsilon n)$ has cost $\Omega(\varepsilon n \log\log n)$.

Consider now a canonical solution $(\mathcal{F}, \delta)$ to the instance. We say that $F \in \mathcal{F}$ is *large* iff $|F| \geq n^{0.1}$, otherwise we say it is *small*. We distinguish between the following cases, depending on the total size of large clusters.

Recall that $\mathsf{cost}(\mathcal{F}, \delta) = \sum_{(u,u') \in E(G)} \delta(F(u), F(u'))$, where $F(u)$ ($F(u')$, resp.) is the unique cluster in $\mathcal{F}$ that contains u (u', resp.). We call $\delta(F(u), F(u'))$ the *contribution* of edge (u, u') to the cost $\mathsf{cost}(\mathcal{F}, \delta)$.

Case 1: The total size of large clusters is at most $0.1n$

As the solution $(\mathcal{F}, \delta)$ is canonical,

$$\delta(F(u), F(u')) = \mathsf{dist}_G(v(F(u)), v(F(u')) \geq \mathsf{dist}_{G'}(v(F(u)), v(F(u')),$$

as G is obtained from G' by only deleting edges. We say that a pair F, F' of clusters are *friends* (denoted as $F \sim F'$), iff $\mathsf{dist}_{G'}(v(F), v(F')) \leq \varepsilon \log\log n/30$. We say that an edge

(u, u') is *unfriendly*, iff the pair of clusters that contain u and u' are not friends. Therefore, in order to show $\mathsf{cost}(\mathcal{F}, \delta) = \Omega(\varepsilon n \log\log n)$, it suffices to show that there are $\Omega(n)$ unfriendly edges in G'. In particular, since graph G is obtained from G' by deleting at most $n^{0.3}$ edges, there are $\Omega(n)$ edges contributing at least $\varepsilon \log\log n$ each to $\mathsf{cost}(\mathcal{F}, \delta)$. Note that, as G is a 6-regular graph, each cluster is a friend to at most $6^{\varepsilon \log\log n/30} < \log^{\varepsilon/10} n$ clusters in $\mathcal{F}$.

The following lemma shows that there with high probability, const fraction of the edges in G' are unfriendly edges whose lengths are $\Omega(\varepsilon \log\log n)$. This lemma completes the proof in this case.

▶ **Lemma 8.** *With probability* $1-o(1)$*, the random graph* G' *satisfies that, for any partition* $\mathcal{F}$ *of* V *into* $|\mathcal{F}| \le O(n/\log^{\varepsilon} n)$ *clusters such that* $\sum_{|F|\ge n^{0.1}} |F| \le 0.1n$*, and for any friendship relation on* $\mathcal{F}$ *in which each cluster* F *is a friend to at most* $\log^{0.1\varepsilon} n$ *other clusters,* G' *contains at least* $n/10$ *unfriendly edges, i.e.,* $\sum_{F \not\sim F'} |E_{G'}(F, F')| \ge n/10$.

Proof. Recall that G' is obtained by sampling three random permutations $\sigma_1, \sigma_2, \sigma_3$ from Σ and taking the union of their corresponding edge sets $E_{\sigma_1}, E_{\sigma_2}, E_{\sigma_3}$. We alternatively view G' as constructed in two steps. In the first step, we obtain a graph $\hat{G}$ by sampling two random permutations σ_1, σ_2 from Σ and letting $\hat{G} = (V, E_{\sigma_1} \cup E_{\sigma_2})$. In the second step, we sample a third permutation σ_3 from Σ and let $G' = (V, E(\hat{G}) \cup E_{\sigma_3})$. From Lemma 7, with high probability, $\hat{G}$ contains a Hamiltonian cycle on V.

For convenience, we denote by $(\mathcal{F}, \sim)$ a pair of clustering $\mathcal{F}$ and the friendship relation on clusters of $\mathcal{F}$. We say that the pair $(\mathcal{F}, \sim)$ is *valid*, iff $|\mathcal{F}| \le O(n/\log^{\varepsilon} n)$, $\sum_{|F|\ge n^{0.1}} |F| \le 0.1n$, and each cluster F is a friend to at most $\log^{\varepsilon/10} n$ other clusters.

▷ Claim 9. For any Hamiltonian cycle C on V, there are at most $n^{n/4}$ valid pairs $(\mathcal{F}, \sim)$ satisfying that $\sum_{F \not\sim F'} |E_C(F, F')| < n/10$.

Proof. Denote by $L = c^* n/\log^{\varepsilon} n$ the number of clusters of $\mathcal{F}$, and let $\mathcal{F} = \{F_1, \ldots, F_L\}$.

First, the number of possible friendship relations on $\mathcal{F}$ such that each cluster of $\mathcal{F}$ is a friend to at most $\log^{0.1\varepsilon} n$ other clusters is at most

$$\binom{L}{\log^{0.1\varepsilon} n}^{L} \le \binom{\frac{c^* n}{\log^{\varepsilon} n}}{\log^{0.1\varepsilon} n}^{\frac{c^* n}{\log^{\varepsilon} n}} \le \left(\frac{c^* n}{\log^{\varepsilon} n}\right)^{\frac{c^* n}{\log^{\varepsilon} n} \cdot \log^{0.1\varepsilon} n} < n^{c^* n \log^{-0.05\varepsilon} n}.$$

Assume now that we have a fixed friendship relation $\sim$ on the clusters in $\mathcal{F}$. We now count the number of clusterings $\mathcal{F}$ with $\sum_{F \not\sim F'} |E_C(F, F')| < n/10$. Denote $C = (v_1, v_2, \ldots, v_n, v_1)$. First, the number of possible unfriendly edge set (which is a subset of $E(C)$ of size at most $0.1n$) is at most

$$\sum_{i=0}^{n/10} \binom{n}{i} \le n \cdot \binom{n}{n/10} < n \cdot \left(\frac{en}{n/10}\right)^{n/10} < n^{n \log^{-0.5} n}.$$

We now count the number of clusterings $\mathcal{F}$ that, together with the fixed friendship relation $\sim$, realizes a specific unfriendly edge set. We will sequentially pick, for each i from 1 to n, a set among $\{F_1, \ldots, F_L\}$ to add the vertex v_i to. The first vertex v_1 has L choices. Consider now some index $1 \le i \le n-1$ and assume that we have picked sets for $v_1, \ldots, v_i$. If (v_i, v_{i+1}) is an unfriendly edge, then vertex v_{i+1} has L choices; if (v_i, v_{i+1}) is not an unfriendly edge, this means that v_{i+1} must go to some cluster that is a friend of the cluster we have picked for v_i (or v_{i+1} can go to the same cluster as v_i), so v_{i+1} has at most $\log^{0.1\varepsilon} n + 1$ choices. As there are no more than $0.1n$ unfriendly edges, the number of possible clusterings $\mathcal{F}$ is at most

$$n \cdot (\log^{0.1\varepsilon} n)^n \cdot \left(\frac{n}{\log^{\varepsilon} n}\right)^{0.1n} < n^{n/5}.$$

Altogether, the number of valid pairs $(\mathcal{F}, \sim)$ satisfying that $\sum_{F \not\sim F'} |E_C(F, F')| \geq n/10$ is at most

$$n^{c^* n \log^{-0.05\varepsilon} n} \cdot n^{n \log^{-0.5} n} \cdot n^{n/5} < n^{n/4}.$$ ◁

▷ Claim 10. For every valid pair $(\mathcal{F}, \sim)$, the probability that the edge set E_{σ_3} of a random permutation σ_3 contains at most $n/10$ unfriendly edges is at most $n^{-n/3}$.

Proof. We say that a cluster $F \in \mathcal{F}$ is *bad* if it does not have a friend cluster of size at least $n^{0.4}$, otherwise we say it is *good*. We first prove the following observation that most vertices lie in a bad cluster.

▶ **Observation 11.** $\sum_{F:bad} |F| \geq 0.8n$.

Proof. As the pair $(\mathcal{F}, \sim)$ is valid, $\sum_{|F| \geq n^{0.1}} |F| \leq 0.1n$, so $\mathcal{F}$ contains at most $0.1 \cdot n^{0.6}$ clusters with size at least $n^{0.4}$. As each cluster is a friend to at most $\log^{0.1\varepsilon} n$ other clusters, $\mathcal{F}$ contains at most $\left(0.1 \cdot n^{0.6} \cdot \log^{0.1\varepsilon} n\right)$ good sets. Therefore, the total size of all good clusters is at most $0.1n + n^{0.1} \cdot 0.1 \cdot n^{0.6} \cdot \log^{0.1\varepsilon} n < 0.2n$. The observation now follows. ◀

We alternatively construct the random permutation σ_3 as follows. We arrange the vertices in V into a sequence $(v_1, \ldots, v_n)$, such that each of the first half $v_1, \ldots, v_{n/2}$ lies in some bad set. Now sequentially for each $1, 2, \ldots, n$, we sample a vertex u_i (without replacement) from V and designate it as $\sigma_3(v_i)$. It is easy to observe that the permutation σ_3 constructed in this way is a random permutation from Σ.

The following observation completes the proof of Claim 10.

▶ **Observation 12.** *The probability that the number of unfriendly edges in* $\{(v_i, \sigma_3(v_i)) \mid 1 \leq i \leq 9n/10\}$ *is less than* $0.1n$ *is at most* $n^{-n/3}$.

Proof. For any v in a bad cluster, the number of vertices in its friend clusters is at most $n^{0.4} \log^{0.1} n$. For each $1 \leq i \leq 9n/10$, when we pick $\sigma_3(v_i)$, we have at least $n/10$ choices from the remaining element in V, and as v_i is in a bad set, at most $n^{0.4} \log^{0.1} n$ of them will not create an unfriendly edge. Therefore, the probability that the edge we sample is not a bad edge is at most $\frac{1}{\sqrt{n}}$. Let X_i be the indicator random variable such that $X_i = 1$ if $(v_i, \sigma_3(v_i))$ is not a bad edge. By Azuma's Inequality (Chernoff Bounds on martingales, see e.g., [25]),

$$\Pr\left[\sum_{i=1}^{2n/3} X_i > 4n/5\right] < \left(\frac{5}{4\sqrt{n}}\right)^{4n/5} < n^{-n/3}.$$

Thus, with probability at least $1 - n^{-n/3}$, the set $\{(v_i, \sigma_3(v_i)) | 1 \leq i \leq 9n/10\}$ contains at least $9n/10 - 4n/5 = n/10$ bad edges. ◀

◁

Combining Claim 9 and Claim 10, we get that, over the randomness in the construction of G', the probability that there exists a pair $(\mathcal{F}, \sim)$ in which each cluster F is a friend to at most $\log^{0.1\varepsilon} n$ other clusters, such that G' contains less than $n/10$ unfriendly edges, is at most $n^{-n/3} \cdot n^{n/4} = n^{-n/12}$. This completes the proof of Lemma 8. ◀

Case 2: The total size of large clusters is greater than $0.1n$

We denote by V' the union of all large clusters in $\mathcal{F}$. We start by proving the following claim.

▷ Claim 13. There exists a collection of $k/4$ edge-disjoint paths in G, such that each path connects a distinct terminal to a distinct vertex of V'.

Proof. We construct a graph $\hat{G}$ as follows. We start from graph G', and add two vertices s, t to it. We then connect s to each terminal in T by an edge, and connect each vertex in V' to t by an edge. All edges in $\hat{G}$ has unit capacity. We claim that there exists a collection $\mathcal{P}$ of $k/3$ edge-disjoint paths in $\hat{G}$, such that each path connects a distinct terminal to a distinct vertex of V'. Note that this implies Claim 13. This is because the number of edges in $E(G') \setminus E(G)$ is at most $n^{0.3} < k/12$, and each such edge is contained in at most one path in $\mathcal{P}$ (since the paths in $\mathcal{P}$ are edge-disjoint), so at least $k/3 - k/12 \geq k/4$ paths in $\mathcal{P}$ are entirely contained in G. We now prove the claim. From the max-flow min-cut theorem, it suffices to show that the minimum s-t cut in $\hat{G}$ contains at least $k/3$ edges.

Consider any s-t cut $(S \cup \{s\}, (V \setminus S) \cup \{t\})$ in $\hat{G}$ and denote by E' the set of edges in this cut. We distinguish between the following cases.

Case 1: $|S| \leq |V|/2$. Recall that G is a 6-regular graph, so $\sum_{v \in S} \deg(v) \leq \sum_{v \notin S} \deg(v)$. Then from Lemma 5, $|E'| \geq \sum_{v \in S} \deg(v)/2 \geq |S|/2$. If $|S| \geq 2k/3$, then $|E'| \geq k/3$. If $|S| < 2k/3$, then at least $k/3$ terminals lie in $V \setminus S$. As there is an edge connecting s to each terminal, $|E'| \geq k/3$.

Case 2: $|S| > |V|/2$. Via similar arguments, we can show that $|E'| \geq |V'|/3 \geq 0.1n/3 > k/3$. ◁

We denote by $\mathcal{P}$ the collection of paths given by Claim 13. We now use these paths to complete the proof. Consider such a path $P = (u_1, \ldots, u_r)$. Denote by F_i the cluster that contains u_i, then the contribution of P to the cost $\mathsf{cost}(\mathcal{F}, \delta)$ is

$$\sum_{(u_i, u_{i+1}) \in E(P)} \delta(F_i, F_{i+1}) = \sum_{1 \leq i \leq r-1} \mathsf{dist}_G(v(F_i), v(F_{i+1})) \geq \mathsf{dist}_G(v(F_1), v(F_r)) \geq \mathsf{dist}_{G'}(v(F_1), v(F_r)).$$

(We have used the property that for every pair $v, v' \in V$, $\mathsf{dist}_G(v, v') \geq \mathsf{dist}_{G'}(v, v')$, as G is obtained from G' by only deleting edges.)

Recall P connects a terminal to a vertex in V'. Recall that each large cluster has size at least $n^{0.1}$, so there are at most $n^{0.9}$ of them. Therefore, if we denote by V'' the subset of vertices that large clusters corresponds to, then $|V''| \leq n^{0.9}$. For each path $P \in \mathcal{P}$, we denote by t_P the terminal endpoint of P (that is, $u_1 = v(F_1) = t_P$), and by v''_P the vertex that the cluster containing u_r corresponds to (that is, $v''_P = v(F_r)$), then $\sum_{(u_i, u_{i+1}) \in E(P)} \delta(F_i, F_{i+1}) \geq \mathsf{dist}_\ell(t_P, v''_P)$. As the paths in $\mathcal{P}$ are edge-disjoint, their contribution to $\mathsf{cost}(\mathcal{F}, \delta)$ can be added up, i.e.,

$$\mathsf{cost}(\mathcal{F}, \delta) \geq \sum_{P \in \mathcal{P}} \mathsf{dist}_\ell(t_P, v''_P). \tag{1}$$

On the one hand, as graph G' is 6-regular, for each $v'' \in V''$, the number of vertices at distance at most $\log n/100$ to v'' is at most $6^{\log n/100} \leq n^{1/30}$. Therefore, there are at most $n^{1/30} \cdot n^{0.9} = n^{14/15}$ terms on the RHS of Equation (1) that at most $\leq \log n/100$. On the other hand, there are at least $k/4 = \Omega(\frac{n \log \log n}{\log n})$ terms on the RHS of Equation (1), so at least $k/4 - n^{14/15} \geq k/5$ terms has value at least $\log n/100$. Consequently, $\mathsf{cost}(\mathcal{F}, \delta) \geq (k/5) \cdot (\log n/100) = \Omega(k \log n) = \Omega(n \log \log n)$.

3.3 Completing the Proof of Theorem 1

We have shown in Section 3.2 all canonical solutions with size $O(k \log^{1-\varepsilon} n)$ have cost $\Omega(\varepsilon n \log \log n)$. In this subsection, we complete the proof of Theorem 1 by showing that, intuitively, an arbitrary solution $(\mathcal{F}, \delta)$ to the instance (G, T, D) can be "embedded" into a canonical solution, without increasing its cost by too much.

We start by introducing the notion of *continuization*.

Continuization of a graph

Let $G = (V, E, \ell)$ be an edge-weighted graph. Its *continuization* is a metric space $(V^{\mathsf{con}}, \ell^{\mathsf{con}})$, that is defined as follows. Each edge $(u, v) \in E$ is viewed as a continuous line segment $\mathsf{con}(u, v)$ of length $\ell_{(u,v)}$ connecting u, v, and the point set V^{con} is the union of the points on all lines $\{\mathsf{con}(u, v)\}_{(u,v)\in E}$. Specifically, for each edge $(u, v) \in E$, the line $\mathsf{con}(u, v)$ is defined as

$$\mathsf{con}(u, v) = \left\{(u, \alpha) \mid 0 \le \alpha \le \ell_{(u,v)}\right\} = \left\{(v, \beta) \mid 0 \le \beta \le \ell_{(u,v)}\right\},$$

where (u, α) refers to the unique point on the line that is at distance α from u, and (v, β) refers to the unique point on the line that is at distance β from v, so $(u, \alpha) = (v, \ell_{(u,v)} - \alpha)$.

The metric ℓ^{con} on V^{con} is naturally induced by the shortest-path distance metric $\mathsf{dist}_\ell(\cdot, \cdot)$ on V as follows. For a pair p, p' of points in V^{con},

- if p, p' lie on the same line (u, v), say $p = (u, \alpha)$ and $p' = (u, \alpha')$, then $\ell^{\mathsf{con}}(p, p') = |\alpha - \alpha'|$;
- if p lies on the line (u, v) with $p = (u, \alpha)$ and p' lies on the line (u', v') with $p' = (u', \alpha')$, then

$$\begin{aligned}\ell^{\mathsf{con}}(p, p') = \min\{&\mathsf{dist}_\ell(u, u') + \alpha + \alpha', \quad \mathsf{dist}_\ell(u, v') + \alpha + (\ell_{(u',v')} - \alpha'),\\ &\mathsf{dist}_\ell(v, u') + (\ell_{(u,v)} - \alpha) + \alpha', \quad \mathsf{dist}_\ell(v, v') + (\ell_{(u,v)} - \alpha) + (\ell_{(u',v')} - \alpha')\}.\end{aligned}$$

Clearly, every vertex $u \in V$ also belongs to V^{con}, and for every pair $u, u' \in V$, $\mathsf{dist}_\ell(u, u') = \ell^{\mathsf{con}}(u, u')$. For a path P in G connecting u to u', it naturally corresponds to a set P^{con} of points in V^{con}, which is the union of all lines corresponding to edges in $E(P)$. The set P^{con} naturally inherits the metric ℓ^{con} restricted on P^{con}. We will also call P^{con} a path in the continuization $(V^{\mathsf{con}}, \ell^{\mathsf{con}})$.

We show that, for each graph G with a set T of terminals, then any other metric w on a set of points containing T, such that w restricted on T is identical to dist_G restricted on T, can be "embedded" into the continuation of G, with expected stretch bounded by some structural measure that only depends on G. Specifically, we prove the following main technical lemma.

▶ **Lemma 14.** *Let (G, T, ℓ) be any instance of* 0EwSN *such that G is not a tree (so $\mathsf{girth}(G) < +\infty$), and let $(\mathcal{F}, \delta)$ be any solution to it. Let $(V^{\mathsf{con}}, \ell^{\mathsf{con}})$ be the continuization of graph G. Then there exists a random mapping $\phi : \mathcal{F} \to V^{\mathsf{con}}$, such that*

- *for each terminal $t \in T$, if F is the (unique) cluster in $\mathcal{F}$ that contains t, then $\phi(F) = t$; and*
- *for every pair $F, F' \in \mathcal{F}$,*

$$\mathbb{E}\left[\ell^{\mathsf{con}}(\phi(F), \phi(F'))\right] \le O\left(\frac{\mathsf{diam}(G)}{\mathsf{girth}(G)}\right) \cdot \delta(F, F').$$

Before we prove Lemma 14 in Section 3.4, we provide the proof of Theorem 1 using it.

Proof of Theorem 1. Consider any solution $(\mathcal{F}, \delta)$ to the instance (G, T, ℓ) constructed in Section 3.1 with size $|\mathcal{F}| \leq o(k \cdot \log^{1-\varepsilon} k)$. From Observation 3 and Corollary 6, $\frac{\mathsf{diam}(G)}{\mathsf{girth}(G)} \leq \frac{O(\log n)}{(\log n)/100} = O(1)$. From Lemma 14, there exists a random mapping $\phi : \mathcal{F} \to V^{\mathsf{con}}$, such that for every pair $F, F' \in \mathcal{F}$, $\mathbb{E}\left[\ell^{\mathsf{con}}(\phi(F), \phi(F'))\right] \leq O(1) \cdot \delta(F, F')$.

Fix such a mapping ϕ, we define a canonical solution $(\mathcal{F}, \hat{\delta})$ based on $(\mathcal{F}, \delta)$ as follows. The collection of clusters is identical to the collection $\mathcal{F}$. For each $F \in \mathcal{F}$, recall that $\phi(F)$ is a point in V^{con}. Assume the point $\phi(F)$ lies on the line (u, v) and is closer to u than to v (i.e., $\ell^{\mathsf{con}}(\phi(F), u) \leq \ell^{\mathsf{con}}(\phi(F), v)$), then we let u be the vertex in V that it corresponds to. For each pair $F, F' \in \mathcal{F}$, with F corresponding to u_F and and F' corresponding to $u_{F'}$, we define $\hat{\delta}(F, F') = \mathsf{dist}_\ell(u_F, u_{F'})$. As graph G in the instance (G, T, δ) constructed in Section 3.1 is an unweighted graph, it is easy to see that

$$\hat{\delta}(F, F') = \mathsf{dist}_\ell(u_F, u_{F'}) \leq \ell^{\mathsf{con}}(\phi(F), \phi(F')) + 2.$$

As the mapping ϕ is random, $\hat{\delta}$ is also random, and so $\mathbb{E}\left[\hat{\delta}(F, F')\right] \leq O(1) \cdot \delta(F, F') + 2$.

From the properties of mapping ϕ in Lemma 14, we are guaranteed that such a solution $(\mathcal{F}, \hat{\delta})$ is a canonical solution. Moreover, from linearity of expectation,

$$\begin{aligned}\mathbb{E}\left[\mathsf{cost}(\mathcal{F}, \hat{\delta})\right] = \mathbb{E}\left[\sum_{(u,v)\in E} \hat{\delta}(F(u), F(v))\right] &= \sum_{(u,v)\in E} O\Big(\delta(F(u), F(v))\Big) + 2 \\ &= O\Big(\mathsf{cost}(\mathcal{F}, \delta)\Big) + O(n).\end{aligned}$$

Therefore, it follows that there exists a canonical solution $(\mathcal{F}, \hat{\delta})$, such that $\mathsf{cost}(\mathcal{F}, \hat{\delta}) \leq O(\mathsf{cost}(\mathcal{F}, \delta) + n)$. As we have shown in Section 3.2 that any canonical solution $(\mathcal{F}, \hat{\delta})$ with $|\mathcal{F}| \leq o(k \log^{1-\varepsilon} k)$ satisfies that $\mathsf{cost}(\mathcal{F}, \hat{\delta}) = \Omega(\varepsilon n \log\log n)$, it follows that $\mathsf{cost}(\mathcal{F}, \delta) = \Omega(\varepsilon n \log\log n)$. This implies that the integrality gap of (LP-Metric) is at least $\Omega(\varepsilon \log\log n)$. ◀

3.4 Proof of Lemma 14

In this subsection, we provide the proof of Lemma 14. We first consider the special case where G is a tree, and then prove Lemma 14 for the general case.

▶ **Lemma 15.** *Let (G, T, ℓ) be an instance of* 0EwSN *where G is a tree. Let $(\mathcal{F}, \delta)$ be an solution to it. Let $(V^{\mathsf{con}}, \ell^{\mathsf{con}})$ be the continuization of G. Then there exists a mapping $\phi : \mathcal{F} \to V^{\mathsf{con}}$, such that*

- *for each terminal $t \in T$, if F is the (unique) cluster in $\mathcal{F}$ that contains t, then $\phi(F) = t$; and*
- *for every pair $F, F' \in \mathcal{F}$, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq \delta(F, F')$.*

Proof. For each terminal $t \in T$, we denote by F_t the cluster in $\mathcal{F}$ that contains it, and set $\phi(F_t) = t$. For each cluster $F \in \mathcal{F}$ that does not contain any terminals, we define

$$\nu(F) = \min\left\{\frac{1}{2} \cdot \big(\delta(F, F_t) + \delta(F, F_{t'}) - \delta(F_t, F_{t'})\big) \mid t, t' \in T\right\}.$$

Denote by t_1, t_2 the pair of terminals (t, t') that minimizes $(\delta(F, F_t) + \delta(F, F_{t'}) - \delta(F_t, F_{t'}))/2$. As G is a tree, there is a unique shortest path connecting t_1 to t_2 in G, and therefore there exists a unique point p in V^{con} (that lies on the t_1-t_2 shortest path in V^{con}) with $\ell^{\mathsf{con}}(p, t_1) = \delta(F, F_{t_1}) - \nu(F)$ and $\ell^{\mathsf{con}}(p, t_2) = \delta(F, F_{t_2}) - \nu(F)$. We set $\phi(F) = p$.

▷ Claim 16. For every cluster $F \in \mathcal{F}$ and every terminal $t \in T$, $\ell^{\mathsf{con}}(\phi(F), t) \leq \delta(F, F_t) - \nu(F)$.

Proof. Note that the point $\phi(F)$ lies on the (unique) shortest path between a pair t_1, t_2 of terminals. For $t \in \{t_1, t_2\}$, clearly the claim holds. Consider any other terminal t. Clearly $\phi(F)$ lies on either the path connecting t to t_1 or the path connecting t to t_2. Assume without lose of generality that $\phi(F)$ is on the path connecting t_1 and t. Since G is a tree, $\ell^{\mathsf{con}}(\phi(F), t_1) + \ell^{\mathsf{con}}(\phi(F), t) = \ell^{\mathsf{con}}(t_1, t) = \mathsf{dist}_\ell(t_1, t)$. On the other hand, by definition of $\nu(F)$ and $\phi(F)$, $\delta(F, F_{t_1}) + \delta(F, F_t) \geq \delta(F_{t_1}, F_t) + 2 \cdot \nu(F)$ holds, and $\ell^{\mathsf{con}}(\phi(F), t_1) = \delta(F, F_{t_1}) - \nu(F)$. Therefore, $\delta(F, F_t) \geq \ell^{\mathsf{con}}(\phi(F), t) + \nu(F)$. ◁

We now show that, for every pair $F, F' \in \mathcal{F}$, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq \delta(F, F')$. Denote by t_1, t_2 the pair of terminals whose shortest path contains $\phi(F)$, and by t_1', t_2' the pair of terminals whose shortest path contains $\phi(F')$. Assume without lose of generality that $\phi(F)$ is on the tree path between $\phi(F')$ and t_1, so $\ell^{\mathsf{con}}(\phi(F'), \phi(F)) + \ell^{\mathsf{con}}(\phi(F), t_1) = \ell^{\mathsf{con}}(\phi(F'), t_1)$. On the other hand, from the definition of $\phi(F)$ and Claim 16, $\ell^{\mathsf{con}}(\phi(F), t_1) = \delta(F, F_{t_1}) - \nu(F)$ and $\ell^{\mathsf{con}}(\phi(F'), t_1) \leq \delta(F', F_{t_1}) - \nu(F')$. Therefore,

$$\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq \delta(F', F_{t_1}) - \delta(F, F_{t_1}) - \nu(F') + \nu(F) \leq \delta(F, F') + \nu(F) - \nu(F').$$

Similarly, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq \delta(F, F') + \nu(F') - \nu(F)$. Altogether, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq \delta(F, F')$. ◀

In the remainder of this subsection, we complete the proof of Lemma 14. Denote $g = \mathsf{girth}(G)$. Let r be a real number chosen uniformly at random from the interval $[g/60, g/30]$, so $r \leq g/30$ always holds. For each terminal $t \in T$, we denote by F_t the cluster in $\mathcal{F}$ that contains it, and set $\phi(F_t) = t$, so the first condition in Lemma 14 is satisfied.

For each cluster $F \in \mathcal{F}$, we define $A_F = \min\{\delta(F, F_t) \mid t \in T\}$. We first determine the image $\phi(F)$ for all clusters F with $A_F \leq r$, in a similar way as Lemma 15 as follows.

Define

$$\nu(F) = \min\left\{\frac{1}{2} \cdot \left(\delta(F, F_t) + \delta(F, F_{t'}) - \frac{\delta(F_t, F_{t'})}{2}\right) \mid t, t' \in T\right\}.$$

Denote by t_1, t_2 the pair (t, t') that minimizes the above formula. We prove the following claim.

▷ Claim 17. $\delta(F, F_{t_1}) + \delta(F, F_{t_2}) \leq 4 \cdot A_F \leq 4r$.

Proof. Let t be the terminal such that $\delta(F, F_t) = A_F$. By definition of $\nu(F)$,

$$\nu(F) \leq \frac{\delta(F, F_t) + \delta(F, F_t) - \frac{1}{2} \cdot \delta(F_t, F_t)}{2} = A_F.$$

On the other hand, from triangle inequality,

$$\nu(F) = \frac{\delta(F, F_{t_1}) + \delta(F, F_{t_2}) - \frac{1}{2} \cdot \delta(F_{t_1}, F_{t_2})}{2} \geq \frac{\delta(F, F_{t_1}) + \delta(F, F_{t_2})}{4}.$$

Altogether, $\delta(F, F_{t_1}) + \delta(F, F_{t_2}) \leq 4 \cdot A_F$. ◁

From Claim 17, $\delta(F_{t_1}, F_{t_2}) \leq \delta(F, F_{t_1}) + \delta(F, F_{t_2}) \leq 4r < g/3$. Therefore, there is a unique shortest path connecting t_1 to t_2 in G, as otherwise G must contain a cycle of length at most $2g/3$, contradicting the fact that $\mathsf{girth}(G) = g$.

We then set $\phi(F)$ to be the point in V^{con} that lies in the t_1-t_2 shortest path, such that $\ell^{\mathsf{con}}(\phi(F), t_1) = 2 \cdot (\delta(F, F_{t_1}) - \nu(F))$ and $\ell^{\mathsf{con}}(\phi(F), t_2) = 2 \cdot (\delta(F, F_{t_2}) - \nu(F))$. Note that, by definition of t_1, t_2,

$$\ell^{\mathsf{con}}(\phi(F), t_1) + \ell^{\mathsf{con}}(\phi(F), t_2) = 2 \cdot \delta(F, F_{t_1}) + 2 \cdot \delta(F, F_{t_2}) - 4 \cdot \nu(F) = \delta(F_{t_1}, F_{t_2}).$$

We prove the following claim, that is similar to Claim 16.

▷ Claim 18. For every terminal t with $\delta(F, F_t) \leq 6r$, $\ell^{\mathsf{con}}(\phi(F), t) \leq 2 \cdot (\delta(F, F_t) - \nu(F))$.

Proof. From Claim 17,

$$\begin{aligned}\delta(F_t, F_{t_1}) + \delta(F_t, F_{t_2}) + \delta(F_{t_1}, F_{t_2}) &\leq \Big(2 \cdot \delta(F, F_t) + \delta(F, F_{t_1}) + \delta(F, F_{t_2})\Big) + \delta(F_{t_1}, F_{t_2}) \\ &\leq 12r + 4r + 4r + 4r < g.\end{aligned}$$

Therefore, the point $\phi(F)$ must lie on either the t-t_1 shortest path or the t-t_2 shortest path in V^{con}, as otherwise the union of t-t_1 shortest path, t-t_2 shortest path, and t_1-t_2 shortest path contains a cycle of length less than g, a contradiction.

Assume without loss of generality that $\phi(F)$ lies on the t-t_1 shortest path, so

$$\ell^{\mathsf{con}}(\phi(F), t) = \delta(F_t, F_{t_1}) - \ell^{\mathsf{con}}(\phi(F), t_1) = \delta(F_t, F_{t_1}) - 2(\delta(F, F_{t_1}) - \nu(F)).$$

By definition of $\nu(F)$, $\delta(F_t, F_{t_1}) \leq 2 \cdot (\delta(F, F_t) + \delta(F, F_{t_1}) - 2 \cdot \nu(F))$. Therefore,

$$\ell^{\mathsf{con}}(\phi(F), t) \leq 2\Big(\delta(F, t) + \delta(F, F_{t_1}) - 2\nu(F) - \big(\nu(F, F_{t_1}) - \nu(F)\big)\Big) = 2(\delta(F, F_t) - \nu(F)).$$

◁

We now show in the next claim that the second condition in Lemma 14 holds for pairs of clusters that are close in δ.

▷ Claim 19. For every pair $F, F' \in \mathcal{F}$ with $A_F, A_{F'}, \delta(F, F') \leq r$, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq 2 \cdot \delta(F, F')$.

Proof. Since $\delta(F, F') < r$, from triangle inequality and Claim 17,

$$\delta(F', F_{t_1}) \leq \delta(F', F) + \delta(F, F_{t_1}) \leq r + 4r \leq 5r.$$

Similarly, $\delta(F', F_{t_2}) \leq 5r$. Then from Claim 18,

$$\ell^{\mathsf{con}}(\phi(F'), t_1) \leq 2 \cdot (\delta(F', F_{t_1}) - \nu(F')) \leq 2 \cdot \delta(F', F_{t_1}) \leq 10r,$$

and symmetrically, $\ell^{\mathsf{con}}(\phi(F'), t_2) < 10r$. Therefore,

$$\ell^{\mathsf{con}}(\phi(F'), t_1) + \ell^{\mathsf{con}}(\phi(F'), t_2) + \ell^{\mathsf{con}}(t_1, t_2) < 20r + 4r < g.$$

Therefore, the point $\phi(F)$ must lie either on the $\phi(F')$-t_1 shortest path or the $\phi(F')$-t_2 shortest path in V^{con}, as otherwise the union of $\phi(F')$-t_1 shortest path, $\phi(F')$-t_2 shortest path, and t_1-t_2 shortest path in V^{con} contains a cycle of length less than g, a contradiction.

Assume without loss of generality that $\phi(F)$ lies on the $\phi(F')$-t_1 shortest path. Then

$$\begin{aligned}\ell^{\mathsf{con}}(\phi(F), \phi(F')) &= \ell^{\mathsf{con}}(\phi(F'), t_1(F)) - \ell^{\mathsf{con}}(\phi(F), t_1(F)) \\ &\leq 2\Big(\delta(F', t_1(F)) - \nu(F')\Big) - 2\Big(\delta(F, t_1(F)) - \nu(F)\Big) \\ &\leq 2\Big(\delta(F, F') + \nu(F) - \nu(F')\Big).\end{aligned}$$

Similarly, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq 2\big(\delta(F, F') + \nu(F') - \nu(F)\big)$. Altogether, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq 2\delta(F, F')$. ◁

We now complete the construction of the mapping ϕ, by specifying the images of all clusters $F \in \mathcal{F}$ with $A_F > r$. Let t^* be an arbitrarily chosen terminal in T. For all clusters $F \in \mathcal{F}$ with $A_F > r$, we simply set $\phi(F) = t^*$.

It remains to show that the second condition in Lemma 14 holds for all pairs $F, F' \in \mathcal{F}$. Consider a pair F, F'. Assume first that $\delta(F, F') > g/60$. Then

$$\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq \mathsf{diam}(G) \leq \frac{60 \cdot \mathsf{diam}(G)}{\mathsf{girth}(G)} \cdot \delta(F, F').$$

Assume now that $\delta(F, F') \leq g/60$, and without loss of generality that $A_F \leq A_{F'}$. Note that, from triangle inequality, for every terminal $t \in T$, $\delta(F', F_t) \leq \delta(F, F_t) - \delta(F, F')$. This implies that $A_{F'} - A_F \leq \delta(F, F')$. Therefore, the probability that the random number r takes value from the interval $[A_F, A_{F'}]$ is at most $\frac{\delta(F,F')}{g/60}$. Note that, if $r \leq A_F$, then $\phi(F) = \phi(F') = t^*$ and $\ell^{\mathsf{con}}(\phi(F), \phi(F')) = 0$. And if $r \geq A_{F'}$, then from Claim 19, $\ell^{\mathsf{con}}(\phi(F), \phi(F')) \leq 2\delta(F, F')$. Altogether,

$$\mathbb{E}\left[\ell^{\mathsf{con}}(\phi(F), \phi(F'))\right] \leq \frac{60 \cdot \mathsf{diam}(G)}{\mathsf{girth}(G)} \cdot \delta(F, F') + 2\delta(F, F') \leq O\left(\frac{\mathsf{diam}(G)}{\mathsf{girth}(G)}\right) \cdot \delta(F, F').$$

A Comparison between 0EwSN and the variant in [1]

The Steiner node variant of 0-Ext in [1]

In [1], the following problem (referred to as $\mathsf{0EwSN}_{\mathsf{AGK}}$) was proposed.

The input consists of

- an edge-capacitated graph $G = (V, E, c)$, with length $\{\ell_e\}_{e\in E}$ on its edges;
- a set $T \subseteq V$ of k terminals; and
- a *demand* $\mathcal{D} : T \times T \to \mathbb{R}^+$ on terminals.

A solution consists of

- a partition $\mathcal{F}$ of V with $|\mathcal{F}|$, such that distinct terminals of T belong to different sets in $\mathcal{F}$; for each vertex $u \in V$, we denote by $F(u)$ the cluster in $\mathcal{F}$ that contains it;
- a semi-metric δ on the clusters in $\mathcal{F}$, such that: $\sum_{t,t'} \mathcal{D}(t,t') \cdot \delta(F(t), F(t')) \geq \sum_{t,t'} \mathcal{D}(t,t') \cdot \mathsf{dist}_\ell(t,t')$, where $\mathsf{dist}_\ell(\cdot,\cdot)$ is the shortest-path distance (in G) metric induced by edge length $\{\ell_e\}_{e\in E(G)}$.

The cost of a solution $(\mathcal{F}, \delta)$ is $\mathsf{cost}(\mathcal{F}, \delta) = \sum_{(u,v)\in E} c(u,v) \cdot \delta(F(u), F(v))$, and its *size* is $|\mathcal{F}|$.

From (LP1) and Proposition 4.2 in [1], it is proved that:

▶ **Proposition 20.** *Given a graph G and a subset T of its terminals, and a function f, if for every length $\{\ell_e\}_{e\in E(G)}$ and every demand D, the instance $(G, T, \ell, \mathcal{D})$ of $\mathsf{0EwSN}_{AGK}$ has a solution $(\mathcal{F}, \delta)$ with size $|\mathcal{F}| \leq f(k)$ and cost*

$$\sum_{(u,v)\in E} c(u,v) \cdot \delta(F(u), F(v)) \leq q \cdot \sum_{(u,v)\in E} c(u,v) \cdot \mathsf{dist}_\ell(u,v),$$

then there is a quality-$(1+\varepsilon)q$ flow sparsifier H for G w.r.t T with $|V(H)| \leq (f(k))^{(\log k/\varepsilon)^{k^2}}$.

The 0EwSN problem

In studying the integrality gap of (LP-Metric), we are essentially considering the following problem.

The input consists of

- an edge-capacitated graph $G = (V, E, c)$, with length $\{\ell_e\}_{e\in E}$ on its edges; and
- a set $T \subseteq V$ of k terminals.

A solution consists of

- a partition $\mathcal{F}$ of V with $|\mathcal{F}|$, such that distinct terminals of T belong to different sets in $\mathcal{F}$; for each vertex $u \in V$, we denote by $F(u)$ the cluster in $\mathcal{F}$ that contains it;
- a semi-metric δ on the clusters in $\mathcal{F}$, such that for all pairs $t, t' \in T$, $\delta(F(t), F(t')) = \mathsf{dist}_\ell(t,t')$, where $\mathsf{dist}_\ell(\cdot,\cdot)$ is the shortest-path distance (in G) metric induced by edge length $\{\ell_e\}_{e\in E(G)}$.

The cost and the size of a solution is defined in the same way as $\mathsf{0EwSN}_{\mathsf{AGK}}$.

The difference between two problems are underlined. Specifically, in $\mathsf{0EwSN}_{\mathsf{AGK}}$ it is only required that some "average terminal distance" does not decrease, while in our problem it is required that all pairwise distances between terminals are preserved. Clearly, our requirement for a solution is stronger, which implies that any valid solution to our instance is also a valid solution to the same $\mathsf{0EwSN}_{\mathsf{AGK}}$ instance (with arbitrary $\mathcal{D}$). Therefore, we have the following corollary.

▶ **Corollary 21.** *Given a graph G and a subset T of its terminals, and a function f, if for every length $\{\ell_e\}_{e\in E(G)}$, the instance (G,T,ℓ) of* 0EwSN *has a solution $(\mathcal{F},\delta)$ with size $|\mathcal{F}| \le f(k)$ and cost*

$$\sum_{(u,v)\in E} c(u,v)\cdot\delta(F(u),F(v)) \le q\cdot\sum_{(u,v)\in E} c(u,v)\cdot \mathsf{dist}_\ell(u,v),$$

then there is a quality-$(1+\varepsilon)q$ flow sparsifier H for G w.r.t T with $|V(H)| \le (f(k))^{(\log k/\varepsilon)^{k^2}}$.

On the other hand, the main result of our paper is a lower bound for the 0EwSN problem. As 0EwSN has stronger requirement (for solutions) than $\mathsf{0EwSN}_{\mathsf{AGK}}$, our lower bound does not immediately imply a lower bound for $\mathsf{0EwSN}_{\mathsf{AGK}}$ or for the flow sparsifier. However, if we can show that, for some function f, there exists a graph G, a terminal set T with size k, and a demand $\mathcal{D}$ on T, such that any solution $(\mathcal{F},\delta)$ with size $|\mathcal{F}| \le f(k)$ has cost at least

$$\sum_{(u,v)\in E} c(u,v)\cdot\delta(F(u),F(v)) \ge q\cdot\sum_{(u,v)\in E} c(u,v)\cdot \mathsf{dist}_\ell(u,v),$$

then this, from the (LP1) and the discussion in [1], implies that any quality-$o(q)$ contraction-based flow sparsifier for G has size at least $f(k)$.

Solving Woeginger's Hiking Problem: Wonderful Partitions in Anonymous Hedonic Games

Abstract

A decade ago, Gerhard Woeginger posed an open problem that became well-known as "Woeginger's Hiking Problem": Consider a group of n people that want to go hiking; everyone expresses preferences over the size of their hiking group in the form of an interval between 1 and n. Is it possible to efficiently assign the n people to a set of hiking subgroups so that every person approves the size of their assigned subgroup? The problem is also known as efficiently deciding if an instance of an anonymous Hedonic Game with interval approval preferences admits a wonderful partition.

We resolve the open problem in the affirmative by presenting an $O(n^5)$ time algorithm for Woeginger's Hiking Problem. Our solution is based on employing a dynamic programming approach for a specific rectangle stabbing problem from computational geometry. Moreover, we propose natural, more demanding extensions of the problem, e.g., maximizing the number of satisfied participants and variants with single-peaked preferences, and show that they are also efficiently solvable. Last but not least, we employ our solution to efficiently compute a partition that maximizes the egalitarian welfare for anonymous single-peaked Hedonic Games.

1 Introduction

Suppose there are n attendees of a workshop, who aim to go for a joint hike during a break. Keeping the whole group together is logistically challenging, so typically the attendees split into smaller subgroups that will do the hike together. It is natural that different attendees might have different preferences for the sizes of the subgroups they will eventually join. In particular, each attendee i reports an interval $[\ell_i, r_i]$ signifying that they will be content if they are in a group of size $s \in [\ell_i, r_i]$. The organizers of the hike now face the following problem: Is there a polynomial time algorithm that determines whether there is a partition of the attendees into subgroups such that they are all content with the sizes of their subgroups?

In 2013, Gerhard Woeginger famously phrased this problem underlying an anonymous hedonic game to explain an open question stemming from his work [29]. It is one of the very nice problems that he used to share at various occurrences, e.g., at the coffee machine, while waiting in a seminar room, or even during a joint walk.[2] As this is one of the problems he explained to many people, it became known as Woeginger's *Hiking Problem*.

In this work we answer Woeginger's question in the affirmative by exploiting a tight connection to a variant of the rectangle stabbing problem from computational geometry that can be solved in polynomial time via elegant dynamic programming.

Using Woeginger's motivation of the problem, many natural extensions arise that we introduce in this paper. If the sought partition does not exist, then what is the maximum number of attendees that can be satisfied with their group sizes, or what is the minimum number of attendees to exclude such that the remaining ones can be partitioned to all become satisfied? Moreover, we also consider a version where the hikers have single-peaked preferences over the group sizes and a partition is sought that minimizes the utilitarian or egalitarian cost, where cost is defined as a function of the assigned and the ideal group size. We show that these more demanding problems can also be solved efficiently. Finally, we discuss the relationship between the hiking problem and the problem of maximizing the egalitarian welfare in (general) anonymous Hedonic Games.

1.1 Related Work

Hedonic Games (HGs), introduced by Dreze and Greenberg in [19], model multi-agent systems where selfish agents have to be partitioned into coalitions and have preferences over the possible outcomes. Such games are called hedonic as agents' preferences only depend on the coalition they belong to but not on how the other agents are grouped. HGs have been widely studied (see [7] for a survey) and numerous prominent subclasses have been identified based on properties of the agents' preferences or other possible constraints: [8, 14, 1, 26, 21, 2]. Simple examples of such classes are anonymous HGs [9], where the preferences of the agents depend only on the size of their coalition and not on the individual participants, or HGs with approval-based (Boolean) preferences [6], where agents have binary values for the coalitions. Woeginger's Hiking Problem resides in the intersection of these classes.

The HGs literature has typically focused on the existence and computation of stable or optimal solutions, see, e.g., [14]. The most desirable, ideal partition is the one where every agent is assigned to one of her best coalitions – called *perfect* (or *wonderful*) *partition* [3].

[2] Gerhard's ability to explain open research questions in an easily accessible way has been extraordinarily motivating. In particular, this work would not have started without Gerhard meeting one of the authors for lunch and explaining the problem exactly in this way. With this work we contribute to the recent line of publications celebrating the life and work of Gerhard Woeginger, see [25].

Unfortunately, such a solution rarely exists and the related decision or computational problem is usually hard [3, 27]. Even in simple cases such as anonymous approval-based HGs, it is NP-complete to determine the existence of a wonderful partition [18, 29]. Such a result holds true even if the number of approved coalition sizes of each agent is at most 2 [18]. The problem of finding a wonderful partition in Hedonic Games is related to the one of maximizing the utilitarian welfare, i.e. the sum of agents' utilities, for Boolean utilities. An overall picture of the complexity of finding wonderful partitions in Boolean Hedonic Games, including anonymous ones, is given in [27]. For general utility functions, the problem of maximizing the utilitarian or egalitarian social welfare has been studied in various settings, e.g., in fractional [5] and additively separable Hedonic Games [4]. To the best of our knowledge, these objectives have not been considered in the context of anonymous Hedonic Games.

In our paper, we show the tractability of computing a wonderful partition for instances with interval approvals as formulated by Woeginger [29]. To this aim, we provide a dynamic program that relies on the approach used in [22] to solve a capacitated rectangle stabbing problem from computational geometry. Here, the goal is to stab a set of rectangles with a minimum subset of a given set of lines, each intersecting (i.e., potentially *stabbing*) some of the rectangles. Each line has a maximum number of rectangles it can stab, and to stab all rectangles, one is allowed to use multiple copies of each line.

We also consider variants with single-peaked cost functions of the agents. Single-peaked preferences date back to Black [12]. Such preferences are a common theme in the Economics and Game Theory literature. In particular, they play a prominent role in different fields such as Hedonic Diversity Games [16, 13], Schelling Games [11, 23], and in various works on voting and social choice [28, 30, 10, 20, 15].

1.2 Model

The hiking problem as formulated by Gerhard Woeginger is a special case of anonymous Hedonic Games with approval-based preferences. In an anonymous Hedonic Game with approval-based preferences we are given a set N of n agents to be partitioned into coalitions. Each agent $i \in N$ reports an approval set $S_i \subseteq [n]$ representing the approved group sizes for agent i. In particular, agent i wants to be in some group of size s such that $s \in S_i$. An approval set S_i is said to be an *interval* if $S_i = \{\ell_i, \ell_i + 1, \dots, r_i\}$, for some $1 \leq \ell_i \leq r_i \leq n$. The agents have to be partitioned into coalitions, i.e., subsets of the agent set. This induces a *partition* π of the set of agents N. We denote by $\pi(i)$ the coalition agent i belongs to in the partition π. We follow the notation in Woeginger's survey paper [29] and call a partition π *wonderful* if each agent approves of the size of its coalition in π, i.e., for each agent i, $|\pi(i)| \in S_i$. This leads to the following natural computational problem called Wonderful-Partition.

Wonderful-Partition
Input: A set N of agents and size approval sets $(S_i)_{i \in N}$.
Problem: Decide whether there exists a wonderful partition of the agents. If yes, compute one.

Woeginger's Hiking Problem is Wonderful-Partition with interval approval sets, which we formally define as follows.

Wonderful-Partition-Intervals (Hiking)
Input: A set N of agents and for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \ldots, r_i\}$.
Problem: Decide whether there exists a wonderful partition of the agents. If yes, compute one.

We also consider natural extensions of the hiking problem, to be introduced later.

1.3 Our Contribution

We solve Woeginger's Hiking Problem in the affirmative by giving an $O(n^5)$-algorithm that computes a wonderful partition for an instance with n agents that each have interval approval sets (see Figure 1 (a)), if such a partition exists. For this we use a dynamic programming approach for a rectangle stabbing problem from computational geometry. Moreover, we extend this approach to achieve an $O(n^5)$-algorithm for computing the minimum set of hikers that have to be excluded from the hike, in order for a wonderful partition to become possible. We also give an $O(n^7)$-algorithm for deciding if a wonderful partition exists if exactly x hikers are excluded. This is then used to derive an $O(n^7 \log n)$-algorithm for finding a partition that maximizes the number of hikers that approve of their assigned group size. These approaches can also be extended to a setting where hikers have weights.

All these positive results hold for the case where the agents have interval approval sets (Figure 1 (a)). The special case where every hiker only approves of one group size, i.e., approval intervals of size 1, can be solved efficiently by checking if for all i the number of agents approving only of size i is divisible by i. In contrast to this, it was already known that the problem is NP-hard even if each attendee has at most two different approved group sizes that need not form an interval [18] (see Figure 1 (b)). We extend the original proof slightly by establishing a connection to a graph orientation problem. For the sake of completeness and to improve readability, it can be found in the full version [17].

We complete the picture by considering agents with single-peaked preferences over group sizes. In this setting an agent has a cost that is a function of its assigned group size and its ideal group size. If all agents incur a cost that is given by a fixed function that depends on their peak (but different peak values are allowed, see Figure 1 (c)) and if this function satisfies a mild technical condition, we compute a partition that minimizes the social cost in time $O(n^2(\alpha + 1))$, if at most α agents can be excluded from the hike. This holds for the utilitarian setting, i.e., minimizing the sum of the agents' costs, and also for the egalitarian setting, where the maximum agent cost is to be minimized. Finally, we prove polynomial time

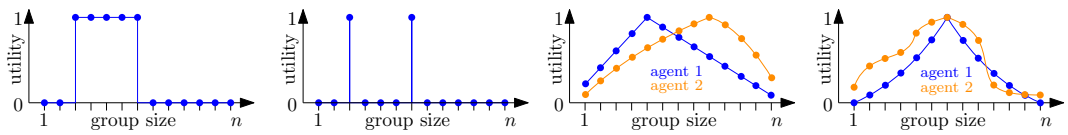

Figure 1 Examples of utility functions considered in this paper. (a) interval approval sets, (b) non-interval approval sets with two approved group sizes, (c) utility functions are single-peaked and all agents with the same peak have the same utility function (under some additional mild technical assumptions), (d) individual single-peaked utility functions for all agents (as shown, the functions may differ even if they have the same peak).

equivalence of the wonderful partition problem and the problem of minimizing the egalitarian social cost in (general) anonymous Hedonic Games. We use this result to show that even for the setting where each agent has its own single-peaked cost function (see Figure 1 (d)), a partition that minimizes the egalitarian social cost can be computed in $O(n^5 \log n)$.

All omitted details can be found in the full version [17].

2 Efficient Algorithm for Woeginger's Hiking Problem, and Extensions

We prove that Wonderful-Partition-Intervals can be solved in polynomial time by casting the problem as a version of capacitated rectangle stabbing, which can be efficiently solved via an elegant dynamic programming approach introduced by Even, Levi, Rawitz, Schieber, Shahar, and Srividenko [22]. In the capacitated rectangle stabbing problem, we are given axis parallel rectangles and a set of lines. The goal is to find a minimum number of lines that intersect and stab all rectangles. Each line has a maximum number of intersecting rectangles it can stab, and to stab all rectangles, one is allowed to use multiple copies of each line. Woeginger's Hiking Problem can be seen as a special case of the capacitated rectangle stabbing problem in one dimension, where the agents' intervals correspond to 1-dimensional rectangles and stabbing rectangles at some integer position i corresponds to creating a partition of size i where the respective agents belonging to the stabbed rectangles are included. Using this relationship, we give a simpler and faster $\mathcal{O}(n^5)$ dynamic program that is specifically tailored to our needs. Note that this reduction from our partition problem to a version of rectangle stabbing draws a powerful new connection between the problem types that is not limited to our specific problem version, but is possible in more generality; e.g., it can be adapted to the variant where there can be at most one group of each size.

In the following, we use the central observations of Even, Levi, Rawitz, Schieber, Shahar, and Srividenko [22] to derive a dynamic programming solution to Woeginger's Hiking problem, i.e., to Wonderful-Partition-Intervals. The definition and analysis of which will then also power our results on the more demanding problem variants discussed in the introduction.

2.1 Dynamic Program for Woeginger's Hiking Problem

Consider an instance of Wonderful-Partition-Intervals, i.e., a set N of n agents, without loss of generality $N = [n]$, and n pairs $(\ell_i, r_i)_{i \in N}$ such that agent $i \in [n]$ approves of sizes $S_i = \{\ell_i, \dots, r_i\}$. We are interested in checking whether there exists a wonderful partition of the agents; i.e., one where every agent approves of their coalition size. For consistent tie-breaking reasons, throughout this section we write $i \prec j$ for two distinct agents $i, j \in [n]$ if either $r_i < r_j$, or $r_i = r_j$ and $i < j$. Note that $\prec$ is a well-defined strict linear order and, without loss of generality, assume that agents are ordered so that $1 \prec \dots \prec n$.

As the main technical ingredient of our approach, given a subset $N' \subseteq N$ of agents, we say that a wonderful partition π of N' is *earliest-due-date* if for any two agents $i \prec j$ it does not hold that $\ell_i \leq |\pi(j)| < |\pi(i)|$. This terminology is borrowed from the scheduling literature, and based on the following well-known observation: let us view the agents' allowed intervals of coalition sizes on an axis labeled with the natural numbers $1, \dots, n$, and consider an arbitrary collection of coalition sizes we might decide on using, in non-decreasing order of coalition size. Then, going in this order, it is always safe to include those agents first whose right interval endpoints are the smallest: in said order of coalitions, they are the ones that stop being servable first, making an earliest-due-date approach impose the least restrictions on later assignments. In other words, whenever a wonderful partition into the given coalition sizes exists, there also exists one that is earliest-due-date. We prove this formally below for completeness. Note that, to make the process well-defined, instead of comparing agents by right endpoints, we compare them by $\prec$.

▶ **Lemma 1.** *If a subset $N' \subseteq N$ of agents admits a wonderful partition, then it admits an earliest-due-date wonderful partition.*

Proof. Consider a wonderful partition π of N'. If it satisfies the required property, then we are done, otherwise, consider $i, j \in N'$ such that $i \prec j$ and $\ell_i \leq |\pi(j)| < |\pi(i)|$. These conditions imply that $|\pi(j)| \in [\ell_i, r_i]$ and $|\pi(i)| \in [\ell_j, r_j]$. Hence, one can construct a new wonderful partition π' from π by exchanging the groups of agents i and j; i.e., $\pi'(i) = (\pi(j) \setminus \{j\}) \cup \{i\}$ and $\pi'(j) = (\pi(i) \setminus \{i\}) \cup \{j\}$. Subsequently, set $\pi \leftarrow \pi'$ and repeat the same procedure until the required condition is satisfied. To complete the proof, we need to show that this is eventually the case. To do so, since $1 \prec \ldots \prec n$, each exchange strictly increases the sequence $(|\pi(n)|, \ldots, |\pi(1)|)$ lexicographically. Because this sequence is bounded from above by $(n, \ldots, n)$, the process eventually ends. ◀

Hence, from now on, we will only seek earliest-due-date wonderful partitions. This crucial restriction, which we have shown to be without loss of generality, will allow us to bootstrap a dynamic programming algorithm that determines a wonderful partition if one exists.

To construct our algorithm, we first show that earliest-due-date partitions admit an attractive recursive decomposition. Consider an earliest-due-date wonderful partition π of the agents (if any exist), and consider the size of the coalition that agent n is a part of; i.e., $|\pi(n)|$. Moreover, consider an arbitrary agent $i \neq n$. Agent i is part of a coalition of size $|\pi(i)|$. Because π is earliest-due-date, by definition it can not be the case that $\ell_i \leq |\pi(n)| < |\pi(i)|$, so either $|\pi(n)| < \ell_i$ or $|\pi(i)| \leq |\pi(n)|$ holds.

▶ **Lemma 2.** *Consider an earliest-due-date wonderful partition π of N. Partition the agents as $N = N_- \cup N_+ \cup \{n\}$, where $N_- = \{i \in N \setminus \{n\} \mid \ell_i \leq |\pi(n)|\}$ and $N_+ = \{i \in N \setminus \{n\} \mid \ell_i > |\pi(n)|\}$, then it holds that:*

1. *For all $i \in N_-$ we have $|\pi(i)| \leq |\pi(n)|$;*
2. *For all $i \in N_+$ we have $|\pi(i)| > |\pi(n)|$.*

Proof. For (2) note that any $i \in N_+$ by definition satisfies $\ell_i > |\pi(n)|$. Since we have the requirement that $|\pi(i)| \in [\ell_i, r_i]$, this means that $|\pi(i)| \geq \ell_i > |\pi(n)|$, as desired.

For (1), consider some $i \in N_-$. By definition, we have that $\ell_i \leq |\pi(n)|$. Assume for a contradiction that $|\pi(i)| > |\pi(n)|$. This implies that $\ell_i \leq |\pi(n)| < |\pi(i)|$. Since $r_i \leq r_n$ and by the sorting criterion we also have $i \prec n$, which contradicts that π is earliest-due-date. ◀

Notably, the same result holds true if we work with a subset of the agents $N' \subsetneq N$ and n is replaced with the agent $a \in N'$ with maximum r_a.

Armed as such, to build intuition, Lemma 2 tells us that no two agents $a_- \in N_-$ and $a_+ \in N_+$ can go into the same group, so a first attempt at a recursive algorithm looking for a wonderful partition of N, to be later optimized by memorization/dynamic programming, would proceed as follows: start with $N' = N$; at each step, identify the agent $a \in N'$ maximizing r_a and exhaust over all possibilities for $|\pi(a)|$; for each one, write $N' = N'_- \cup N'_+ \cup \{a\}$ as defined in Lemma 2 and recurse with N'_- and N'_+. We will specify the details of the process such that, if the recursive calls yield wonderful partitions of N'_- and N'_+, a wonderful partition of N can also be constructed by incorporating agent a into them. Of course, the last step of reasoning is incorrect, since one needs to make sure that a group of size $|\pi(a)|$ with one space available indeed exists, and this information needs to be somehow propagated across recursive calls. Moreover, it is unclear what the number of sets N' reachable by the recursion is. This has to be polynomially bounded so that memorization/dynamic programming leads to a polynomial-time algorithm.

Let us first address the second issue outlined above, namely the size of the state space. This turns out to be relatively simple: define $N(x_1, x_2, i) = \{j \in N \mid j \leq i \text{ and } \ell_j \in [x_1, x_2]\}$. Then, we can adapt the recursive approach: instead of storing N' explicitly, start with $x_1 = 1$ and $x_2 = n$, as well as $i = n$, from which implicitly $N' = N(x_1, x_2, i)$. At each step we will first check whether i, which by the sorting criterion is the largest agent maximizing r_i, is in $N' = N(x_1, x_2, i)$; i.e., whether $\ell_i \in [x_1, x_2]$. If not, then $N(x_1, x_2, i) = N(x_1, x_2, i-1)$ and we simply recurse with the same x_1, x_2 and $i' = i - 1$. Otherwise, i is the largest agent in N' maximizing r_i, so we can exhaust as before over all possible values for $|\pi(i)|$ and perform two recursive calls in each case: one with $(x_1', x_2', i') = (x_1, |\pi(i)|, i-1)$ and one with $(x_1', x_2', i') = (|\pi(i)| + 1, x_2, i - 1)$. We have yet to solve the correctness issue, but we have made progress: the state space now consists of triples (x_1, x_2, i) such that $1 \leq x_1 \leq x_2 \leq n$ and $1 \leq i \leq n$, which there are $O(n^3)$ of.

Let us now turn our attention to ensuring correctness. To do so, we need to investigate more closely how to ensure that the group of size $|\pi(i)|$ of agent i (recall that we only exhaust over its size, not over which agents are in it) exists and is used to its full capacity in the solution constructed by the recursion. There is one crucial guarantee given by Lemma 2 that we have so far not exploited. Namely, the recursive call with $(x_1, |\pi(i)|, i-1)$ should only use groups of sizes $s \in [x_1, |\pi(i)|]$ and the one with $(x_1', x_2', i') = (|\pi(i)| + 1, x_2, i - 1)$ should only use groups of sizes $s \in [|\pi(i)| + 1, x_2]$. In general, state (x_1, x_2, i) should only consider groups of sizes $s \in [x_1, x_2]$. This can be ensured by requiring that the exhausted value for $|\pi(i)|$ additionally satisfies $x_1 \leq |\pi(i)| \leq x_2$. This small, seemingly inconsequential, refinement of the approach will ultimately allow us to propagate information about incomplete groups across states in the recursion. Before describing how this is done in general, to build more intuition, let us consider the first level of the recursion, namely $(x_1, x_2, i) = (1, n, n)$. At this level, the algorithm exhausts over the possible values for $|\pi(n)| \in [\ell_n, r_n]$. For each possibility, in the ensuing recursive call with $(x_1', x_2', i') = (|\pi(n)| + 1, n, n - 1)$ all used groups will be of size at least $|\pi(n)| + 1 > |\pi(n)|$ so nothing special needs to be done in this case since those agents can not be part of agent n's group. However, in the other call, having $(x_1', x_2', i') = (1, |\pi(n)|, n - 1)$ some $|\pi(n)| - 1$ other agents will need to share a group of size $|\pi(n)|$ with agent n, and this is not yet modeled by our approach. To model this effect across recursive calls, we introduce a fourth variable $0 \leq k < x_2$ to the state of our recursive algorithm; i.e., each state is now of the form (x_1, x_2, i, k). This variable intuitively signifies that there exists (from upward in the recursion) an incomplete group, currently of size k, whose final size should be x_2. With this setup, the starting top-level call will now be with $(x_1, x_2, i, k) = (1, n, n, 0)$. For each value of $|\pi(n)|$, the two resultant recursive calls will be with $(x_1', x_2', i', k') = (1, |\pi(n)|, n - 1, 1)$[3] and $(x_1', x_2', i', k') = (|\pi(n)| + 1, n, n - 1, 0)$. Note how the former call has $k' = 1$, signifying that we just "opened a new (incomplete) group of size one, whose final size should be $x_2' = |\pi(n)|$" The fundamental reason why such an approach can work is that in any node of the recursion tree, there is at most a single incomplete group to keep track of. Note that this fact crucially depends on each call (x_1, x_2, i, k) only considering partitions into groups of sizes between x_1 and x_2. We still need to describe the transitions for general calls (x_1, x_2, i, k) given the newly added parameter k. The formal details will following below, but in rough lines, the call for N_- creates a new group; i.e., $k' = 1$; while the call for N_+ keeps the currently open one; i.e., $k' = k$; the exception comes when $|\pi(i)| = x_2$, in which case the call for N_- adds to the same group, possibly closing the group; i.e., $k' = (k + 1) \pmod{x_2}$; and no call for N_+ is generated.

[3] Strictly speaking, this should be $(x_1', x_2', i', k') = (1, |\pi(n)|, n - 1, 1 \bmod |\pi(n)|)$. We omit this detail from the higher-level exposition to improve readability.

▶ **Theorem 3.** *Deciding whether a wonderful partition exists and computing one if so can be achieved in $O(n^5)$ time.*

Proof. We show how to solve the decision version. Constructing a wonderful partition for yes-instances can be subsequently achieved by standard techniques. We proceed by dynamic programming (DP). Define the Boolean DP array $dp[x_1, x_2, i, k]$ for $1 \leq x_1 \leq x_2 \leq n$, $0 \leq i \leq n$ and $0 \leq k < x_2$, with the meaning $dp[x_1, x_2, i, k] = 1$ if and only if there exists a wonderful partition of agents in $N(x_1, x_2, i)$ using only groups of sizes in $[x_1, x_2]$ and assuming that we start with an incomplete group of current size k which has to have final size x_2. Naturally, if $k = 0$ this means starting with no partially filled group. The final answer will be available at the end in $dp[1, n, n, 0]$. To compute the DP table, we use the following recurrence relations and base cases (using a hyphen as stand-in for any group size):

1. $dp[-, -, 0, 0] = 1$;
2. $dp[-, -, 0, k] = 0$ if $k \neq 0$;
3. $dp[x_1, x_2, i, k] = dp[x_1, x_2, i-1, k]$ if $\ell_i \notin [x_1, x_2]$;
4. $dp[x_1, x_2, i, k] = \bigvee_{x=\ell_i}^{\min(x_2, r_i)} F_x$ if $\ell_i \in [x_1, x_2]$, where

$$F_x := \begin{cases} dp[x_1, x_2, i-1, (k+1) \bmod x_2] & x = x_2 \\ dp[x_1, x, i-1, 1 \bmod x] \wedge dp[x+1, x_2, i-1, k] & x < x_2. \end{cases}$$

The first three cases are immediate from the definition of the DP. For the last case, we iterate over $x \in [\ell_i, \max(x_2, r_i)]$ which is agent i's group size. There are two cases: if $x = x_2$, then we put i into the group of current size k and final size x_2 that we assumed to have at our disposal; this increases the size of the group by one, or completes it if $k = x_2 - 1$; otherwise, $x < x_2$, and we recurse into partitioning agents in $N(x_1, x, i-1)$ into groups of sizes between x_1 and x, and $N(x+1, x_2, i-1)$ into groups of sizes between $x+1$ and x_2. For the first call, this generates a new group of size 1 (unless $x = 1$), while for the latter, this keeps the previously open group of current size k and final size x_2 that we assumed to have.

To compute the DP table in an acyclic fashion, it suffices to iterate through i in ascending order. The complexity of the approach is $O(n^5)$ because there are $O(n^4)$ states and computing the value for states of type (4) requires iterating through $O(n)$ values of x. ◀

2.2 Extensions

Using a similar DP approach, we can solve the following natural extension.

Hiking-Min-Delete
Input: A set N of agents and for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \ldots, r_i\}$.
Problem: Compute a set $N' \subseteq N$ of minimum size such that $N \setminus N'$ has a wonderful partition. Output N' and a wonderful partition of $N \setminus N'$.

The approach relies on essentially the same recursive reasoning as before, except that we now also consider the possibility of "ignoring" an agent i and hence recursing with $(x_1', x_2', i', k') = (x_1, x_2, i-1, k)$. Moreover, instead of making the recursion return whether a wonderful partition is possible or not, we make it return the minimum number of agents that need to be removed so that this is possible. In light of this, the "ignore i" recursive call incurs a cost of 1 removed agent. The details are formalized in the following.

▶ **Theorem 4.** *Hiking-Min-Delete is solvable in $O(n^5)$ time.*

Proof. We use a similar approach as in the proof of Theorem 3. As before, it suffices to show how to compute the minimum size of N', as computing such a set N' and a corresponding wonderful partition for $N \setminus N'$ follow by standard techniques. Define the integer-valued DP array $dp[x_1, x_2, i, k]$ for $1 \leq x_1 \leq x_2 \leq n$, $0 \leq i \leq n$ and $0 \leq k < x_2$, with the meaning that $dp[x_1, x_2, i, k]$ contains the minimum number of agents which need to be removed from $N(x_1, x_2, i)$ so that the remaining agents admit a wonderful partition into groups of sizes in $[x_1, x_2]$ assuming that we start with an incomplete group of current size k which has to have final size x_2. Note that, in contrast to the previous DP, the value 0 corresponds to removing no agents, which is the best possible outcome, while previously it corresponded to the need for removing at least one agent. The final answer will be available at the end in $dp[1, n, n, 0]$. To compute the DP table, we use the following recurrence relations and base cases:

1. $dp[-, -, 0, 0] = 0$;
2. $dp[-, -, 0, k] = \infty$ if $k \neq 0$;
3. $dp[x_1, x_2, i, k] = dp[x_1, x_2, i-1, k]$ if $\ell_i \notin [x_1, x_2]$;
4. $dp[x_1, x_2, i, k] = \min\{1 + dp[x_1, x_2, i-1, k], X\}$ if $\ell_i \in [x_1, x_2]$, where

$$X := \min\{F_x \mid \ell_i \leq x \leq \min(x_2, r_i)\}$$

and

$$F_x := \begin{cases} dp[x_1, x_2, i-1, (k+1) \bmod x_2] & x = x_2 \\ dp[x_1, x, i-1, 1 \bmod x] + dp[x+1, x_2, i-1, k] & x < x_2. \end{cases}$$

The reasoning stays largely the same as before, with the only difference being the new $1 + dp[x_1, x_2, i-1, k]$ term, which accounts for discarding agent i and incurring a cost of 1 corresponding to removing an agent. ◀

Another subtly distinct natural variant of Woeginger's Hiking Problem is the following:

Hiking-Max-Satisfied
Input: A set N of agents and for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \ldots, r_i\}$.
Problem: Compute a partition π of N maximizing the number of agents approving of their coalition sizes.

Indeed, Hiking-Max-Satisfied and Hiking-Min-Delete are related, in that if N' is a minimum-size set of agents such that $N \setminus N'$ has a wonderful partition, then it is also possible to satisfy at least $n - |N'|$ agents in a partition of N. This is because agents in N' can be put together in a group in tandem to a wonderful partition of $N \setminus N'$ to get a partition of N with at least $n - |N'|$ satisfied agents. However, it might be possible to satisfy more than $n - |N'|$ agents if unsatisfied agents do not all go into the same group.

Hence, solving this variant of the problem introduces new challenges that require further insight. Let us fix a number k and ask whether it is possible to satisfy at least $|N| - k$ agents. If the answer is affirmative, we also want a partition achieving this. To solve Hiking-Max-Satisfied, we will binary search for the smallest $0 \leq k \leq |N|$ for which the answer is affirmative, call it k^*, and then recover a partition for k^*. It remains to show how to solve the problem for a fixed value of k. To do so, we need to adjust the angle from which we look at the problem. In particular, instead of looking for a partition satisfying at least k agents, we will look for a size-k subset $N' \subseteq N$ (corresponding to k agents which we do not

require to be satisfied) such that $(N \setminus N') \cup D_k$ admits a wonderful partition, where D_k is a set of k dummy agents happy with any group size. Intuitively, k agents are replaced with dummies not minding their group size. Because it is always no worse to remove agents from N in contrast to removing agents from D_k, it is enough to ask to remove exactly k agents from $N \cup D_k$ such that the remaining agents admit a wonderful partition. Checking whether this is possible and finding a corresponding wonderful partition reduces to the following more general problem, which we will show can be solved in polynomial time.

Hiking-x-Delete
Input: A set N of agents, for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \dots, r_i\}$, and also a number $0 \leq x \leq |N|$.
Problem: Compute a set $N' \subseteq N$ of size x such that $N \setminus N'$ has a wonderful partition (or report impossibility). Output N' and a wonderful partition of $N \setminus N'$.

We now show how to solve Hiking-x-Delete in polynomial time. We can once again try to attack the problem recursively with our usual state (x_1, x_2, i, k). Just like we did for Hiking-Min-Delete, we will have recursive calls for ignoring an agent; i.e., adding it to the set N' of removed agents.[4] In order to ensure that exactly x agents are removed, we add another variable r to the state of the recursion: (x_1, x_2, i, k, r), where r is how many agents we want to remove. The top-level call will be invoked with $r = x$. The recursive approach for Hiking-Min-Delete now translates relatively swiftly to the new setting. The main difference is the case where a state of the form $(x_1, x_2, i, k, -)$ with $\ell_i \in [x_1, x_2]$ performs two recursive calls to $(x_1, x, i-1, 1, -)$ and $(x+1, x_2, i-1, k, -)$. In particular, say the state is (x_1, x_2, i, k, r), then what should be the values r' and r'' for the two recursive calls? Intuitively, there is no fixed answer, since it could be that we remove more agents in the first or in the second call. In fact, we have full freedom over how to split the r removals across the two calls as long as $r' + r'' = r$. Hence, we will iterate over all options $0 \leq r' \leq r$ and set $r'' = r - r'$, and in each case call recursively with $(x_1, x, i-1, 1, r')$ and $(x+1, x_2, i-1, k, r'')$.

▶ **Theorem 5.** *Hiking-x-Delete is solvable in $O(n^7)$ time.*

Proof. As before, it suffices to check feasibility, a solution can then be recovered using standard techniques. Define the Boolean DP array $dp[x_1, x_2, i, k, r]$ for $1 \leq x_1 \leq x_2 \leq n$, $0 \leq i \leq n$, $0 \leq k < x_2$, and $0 \leq r \leq x$ with the meaning that $dp[x_1, x_2, i, k, r] = 1$ if and only if there exist r agents that can be removed from $N(x_1, x_2, i)$ such that the remaining agents admit a wonderful partition into groups of sizes in $[x_1, x_2]$ assuming that we start with an incomplete group of current size k which has to have final size x_2. At the end, $dp[1, n, n, 0, x]$ will be 1 if and only if it is possible to remove x agents from N such that the remaining agents admit a wonderful partition. To compute the DP table, we use the following:

1. $dp[-, -, 0, 0, 0] = 1$;
2. $dp[-, -, 0, k, r] = 0$ if $k \neq 0$ or $r \neq 0$;
3. $dp[x_1, x_2, i, k, r] = dp[x_1, x_2, i-1, k, r]$ if $\ell_i \notin [x_1, x_2]$;
4. $dp[x_1, x_2, i, k, r] = dp[x_1, x_2, i-1, k, r-1, d] \vee X$[5] if $\ell_i \in [x_1, x_2]$, where $X := \bigvee_{x=\ell_i}^{\min(x_2, r_i)} F_x$ and

$$F_x := \begin{cases} dp[x_1, x_2, i-1, (k+1) \bmod x_2, r] & x = x_2 \\ \bigvee_{r'=0}^{r} \left(dp[x_1, x, i-1, 1 \bmod x, r'] \wedge dp[x+1, x_2, i-1, k, r-r'] \right) & x < x_2. \end{cases}$$

[4] Note that previously we used N' to denote $N(x_1, x_2, i)$ when discussing the recursive algorithm for the original hiking problem. We do not keep this notation here.
[5] Only X for $r = 0$ as otherwise we would be referring to the invalid value $r = -1$.

We explain the four cases separately: for cases (1) and (2) we have $i = 0$; i.e., the set of yet-to-be-considered agents is empty, so $k = r = 0$ is necessary and sufficient for the table to store a 1, signifying feasibility. As before, case (3) straightforwardly ignores an agent that is not part of the current set of active agents.

The more interesting case is case (4). First, the $dp[x_1, x_2, i-1, k, r-1]$ term corresponds to removing an agent, and it only applies to $r \geq 1$, as in the footnote. This decreases r by 1 since we have just removed an agent. The $X := \bigvee_{x=\ell_i}^{\min(x_2,r_i)} F_x$ term is more involved. The selection of $\ell_i \leq x \leq \min(x_2, r_i)$ corresponds to selecting the size of the group that agent i will be part of. For $x = x_2$, the analysis is similar to our previous DPs. For $x < x_2$, on the other hand, we moreover split the r agent removals into r' removals for the first recursive call and $r'' = r - r'$ for the second. Whether both calls are successful is represented by the expression $dp[x_1, x, i-1, 1 \bmod x, r'] \wedge dp[x+1, x_2, i-1, k, r'']$.

As before, to compute the DP table in an acyclic fashion, it suffices to iterate through i in ascending order. The complexity is $O(n^7)$ because there are $O(n^5)$ states and computing the value for states of type (4) requires iterating through $O(n^2)$ values for (x, r). ◀

Using the above binary search approach we get a solution for Hiking-Max-Satisfied that runs only a $O(\log n)$ factor slower than the runtime for Hiking-x-Delete.

▶ **Theorem 6.** *Hiking-Max-Satisfied is solvable in $O(n^7 \log n)$ time.*

2.3 Further Weighted Extensions

If not all agents can be satisfied, Hiking-Min-Delete and Hiking-Max-Satisfied provide two ways of implementing a compromise. However, both treat unsatisfied/deleted agents equally. In certain settings, it might be more desirable to take into account the different *entitlements* of the agents; i.e., one agent might have been dissatisfied with their group size during the previous edition of the workshop, or another agent might be the senior invited speaker. One modelling option is to assign a weight w_i to each agent $i \in N$ and weigh the dissatisfied/deleted agents accordingly leading to the following variants:

Hiking-Min-Delete-Weighted
Input: A set N of agents and for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \dots, r_i\}$. Moreover, for each agent $i \in N$, a number $w_i \in \mathbb{R}_{\geq 0}$.
Problem: Compute a set $N' \subseteq N$ minimizing $\sum_{i \in N'} w_i$ such that $N \setminus N'$ has a wonderful partition. Output N' and a wonderful partition of $N \setminus N'$.

Hiking-Max-Satisfied-Weighted
Input: A set N of agents and for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \dots, r_i\}$. Moreover, for each agent $i \in N$, a number $w_i \in \mathbb{R}_{\geq 0}$.
Problem: Compute a partition π of the agents such that if N_π is the set of agents approving of their coalition sizes in π, then $\sum_{i \in N_\pi} w_i$ is maximized.

Our dynamic programs, with minor modifications which we sketch next, can also be used to solve the weighted variants. We begin with Hiking-Min-Delete-Weighted.

▶ **Theorem 7.** *Hiking-Min-Delete-Weighted is solvable in $O(n^5)$ time.*

Proof Sketch. In the proof of Theorem 4, we defined the DP as follows: "$dp[x_1, x_2, i, k]$ contains the minimum number of agents which need to be removed from $N(x_1, x_2, i)$ so that the remaining agents admit a wonderful partition into groups of sizes in $[x_1, x_2]$ assuming

that we start with an incomplete group of current size k which has to have final size x_2". To handle weights, this is replaced by "$dp[x_1, x_2, i, k]$ contains the minimum total weight of agents which need to be removed from $N(x_1, x_2, i)$ so that the remaining agents admit a wonderful partition into groups of sizes in $[x_1, x_2]$ assuming that we start with an incomplete group of current size k which has to have final size x_2". The rest of the proof stays the same, with the minor adaptation that the fourth recurrence relation accordingly becomes $dp[x_1, x_2, i, k] = \min\{w_i + dp[x_1, x_2, i-1, k], X\}$, where previously $w_i = 1$ has been used. ◀

To get a similar result for Hiking-Max-Satisfied-Weighted following our previous proof outline, we first define a weighted analogue of Hiking-x-Delete, as follows.

Hiking-x-Delete-Min-Weight
Input: A set N of agents, for each agent $i \in N$ two numbers $\ell_i \leq r_i$ such that $S_i = \{\ell_i, \ldots, r_i\}$, and also a number $0 \leq x \leq |N|$. Moreover, for each agent $i \in N$, a number $w_i \in \mathbb{R}_{\geq 0}$.
Problem: Compute a set $N' \subseteq N$ of size x minimizing $\sum_{i \in N'} w_i$ such that $N \setminus N'$ has a wonderful partition (or report impossibility). Output N' and a wonderful partition of $N \setminus N'$.

▶ **Theorem 8.** *Hiking-x-Delete-Min-Weight is solvable in $O(n^7)$ time.*

Proof Sketch. In the proof of Theorem 5 for the unweighted version, we defined a boolean DP as follows: "$dp[x_1, x_2, i, k, r] = 1$ if and only if there exist r agents that can be removed from $N(x_1, x_2, i)$ such that the remaining agents admit a wonderful partition into groups of sizes in $[x_1, x_2]$ assuming that we start with an incomplete group of current size k which has to have final size x_2". For the current problem, we want the states to signal not only possibility/impossibility but also what is the minimum total weight of those r removed agents. Hence, we replace this definition by "$dp[x_1, x_2, i, k, r]$ is the minimum total weight of r agents that can be removed from $N(x_1, x_2, i)$ such that [...] (or ∞ if impossible)". The rest of the reasoning stays analogous with minor changes: the values $0, 1$ in the base cases become $\infty, 0$, disjunctions ($\vee$) are replaced by "min" and conjunctions ($\wedge$) by $+$. Finally, the fourth recurrence relation becomes $dp[x_1, x_2, i, k, r] = \min\{w_i + dp[x_1, x_2, i-1, k, r-1, d], X\}$. ◀

We make use of Theorem 8 to show the following.

▶ **Theorem 9.** *Hiking-Max-Satisfied-Weighted is solvable in $O(n^8)$ time.*

Proof Sketch. In the proof of Theorem 6 for the unweighted case, we were looking for the largest k such that there exists a size-k subset $N' \subseteq N$ (corresponding to k agents which we do not require to be satisfied) such that $(N \setminus N') \cup D_k$ admits a wonderful partition, where D_k was a set of k dummy agents happy with any group size. We then argued that we could relax to asking for a size-k subset $N' \subseteq (N \cup D_k)$ such that $(N \cup D_k) \setminus N'$ admits a wonderful partition, which can be done using our polynomial-time algorithm for Hiking-x-Delete-Min in Theorem 5. This time, we follow a similar approach, except without binary search: we will try out all values $0 \leq k \leq n$ and ask for a size-k subset $N' \subseteq (N \cup D_k)$ such that $(N \cup D_k) \setminus N'$ admits a wonderful partition. For a fixed k, out of all abiding N', we want one minimizing $\sum_{i \in N'} w_i$. Such an N' can be computed using our $O(n^7)$ algorithm for Hiking-x-Delete-Min-Weight in Theorem 8. We do this for all values $0 \leq k \leq n$ and take the minimum-weight solution, adding an extra $O(n)$ factor, so the overall complexity is $O(n^8)$. ◀

3 Single-Peaked Preferences over Group Sizes

We extend the binary version of the hiking problem by considering single-peaked preferences over group sizes. We assume that each agent i has an ideal group size s_i and the cost of agent i if placed in a group of size s is given by a cost function dependent on s_i and s.

Given these ingredients, minimizing the social cost can be done in two variants: a utilitarian variant and an egalitarian variant. In the utilitarian variant, the goal is to minimize the total cost of the agents, while in the egalitarian version we want the cost of the agent having the highest cost to be as low as possible, i.e., we replace summation with maximum. We are also interested in a variation of the problem where the hike organizers consider it reasonable to exclude at most α of the agents from the hike, the goal becoming to select the agents to remove and then to organize a hike with best social cost among the remaining agents.[6] Note that we assume that each excluded agent has a cost of 0. This is different from assuming that excluded agents have to hike alone, which is covered by the case $\alpha = 0$.

More formally, we assume that each agent $i \in N$ announces an ideal coalition size s_i; i.e., agent i would be most happy when belonging to a coalition of size s_i. Moreover, given some cost function $cost : N^2 \to \mathbb{R}$ agent i incurs a cost of $cost(s_i, s)$ if placed in a coalition of size $s \in [n]$ and a cost equal to 0 if not participating in the hike. We assume c to be monotone, i.e., $cost(s_i, s) \leq cost(s_i, s')$ if $s_i \leq s \leq s'$ or $s' \leq s \leq s_i$. Notice that since agent i incurs a disutility equal to $cost(s_i, s)$, where s_i is the most preferred size of i, the monotonicity condition on $cost(\cdot, \cdot)$ implies that the preferences of agents are single-peaked w.r.t. the natural ordering. We refer to the next section for a formal definition. Given a partition π, we recall that $\pi(i)$ denotes the coalition of agent i; if i is not participating in the hike we write $\pi(i) = \perp$. Furthermore, by slight abuse of notation, for an agent i we write $i \in \pi$ to indicate that agent i takes part in the hike; i.e., $\pi(i) \neq \perp$.

The utilitarian social cost of a partition π is given by $cost(\pi) = \sum_{i \in \pi} cost(s_i, |\pi(i)|)$ while the egalitarian social cost is given by $cost(\pi) = \max_{i \in \pi} cost(s_i, |\pi(i)|)$. The goal is, therefore, to find a partition minimizing the social cost under the constraint $|\{i \mid \pi(i) = \perp\}| \leq \alpha$, or equivalently, $|\{i \mid i \in \pi\}| \geq n - \alpha$, where α is the maximum number of agents that are allowed to not participate in the hike. Without loss of generality, we assume that $s_1 \leq \ldots \leq s_n$.

We begin by proving two structural properties of optimal solutions that will allow us to greatly reduce the space of solutions that have to be considered, hence enabling us later to give efficient dynamic programming algorithms computing optimal partitions for both the utilitarian and the egalitarian settings. For the utilitarian social cost we need a mild assumption on the cost function *cost*.

▶ **Definition 10.** *A function* $cost : N^2 \to \mathbb{R}$ *fulfills the* quadrangle inequality *if and only if*

$$cost(a, c) + cost(b, d) \leq cost(a, d) + cost(b, c) \text{ for all } a \leq b \leq c \leq d.$$

Analogously, it fulfills the reverse quadrangle inequality *if and only if*

$$cost(a, c) + cost(b, d) \leq cost(a, d) + cost(b, c) \text{ for all } a \geq b \geq c \geq d.$$

Note that quadrangle inequality and reverse quadrangle inequality are equivalent if *cost* is symmetric, i.e. $cost(a, b) = cost(b, a)$. Moreover, notice that if $cost(\cdot, \cdot)$ is the Euclidean distance on $\mathbb{R}$ or $cost(a, b) = |b - a|^k$ for any $k \geq 1$, then it satisfies both the aforementioned quadrangle inequalities. The first observation that our approach will hinge upon is that it is enough to consider *size-monotonic* partitions.

[6] The original problem can be seen to be the $\alpha = 0$ case.

▶ **Definition 11** (Size-Monotonicity). *A partition π is* size-monotonic *if for any two agents $i, j \in \pi$, with $i < j$, it holds that $|\pi(i)| \leq |\pi(j)|$.*

Roughly speaking, there are optimal solutions where all participating agents with lower preferred coalition sizes belong to smaller coalitions than agents with higher preferred sizes. We prove this fact in the following.

▶ **Lemma 12.** *The following properties hold.*

(a) *In the utilitarian setting, if $cost(\cdot, \cdot)$ is monotone and fulfills quadrangle inequality and reverse quadrangle inequality, then there exists a size-monotonic optimal solution.*

(b) *In the egalitarian setting, if $cost(\cdot, \cdot)$ is monotone, then there exists a size-monotonic optimal solution.*

Finally, we will show that it is enough to consider size-monotonic partitions which additionally are *compact*. The latter is defined as follows:

▶ **Definition 13** (Compactness). *A coalition C is* compact *if it is of the form $C = \{i, i + 1, \ldots, j\}$ for some $i \leq j$. A solution π is* compact *if all coalitions $C \in \pi$ are compact.*

We now prove that we can modify any optimal size-monotonic partition so that it is size-monotonic and compact.

▶ **Lemma 14.** *There exists an optimal partition which is size-monotonic and compact.*

With the above observations, we now know that it is enough to give an efficient algorithm to compute the best size-monotonic and compact solution. We do so in the following. In fact, our algorithm will only directly leverage compactness.[7] To begin, for any two agents $i \leq j$ define $c(i, j)$ to be the social cost induced by agents $i, i + 1, \ldots, j$ when forming the coalition $\{i, i + 1, \ldots, j\}$. In particular, $c(i, j) = \sum_{k=i}^{j} cost(s_k, j - i + 1)$ in the utilitarian case, and similarly with summation replaced by maximum in the egalitarian case. With this definition in place, note that selecting the best compact solution π with at most α agents not taking part in the hike amounts to selecting compact non-intersecting coalitions $C_1, \ldots, C_\ell$ where $C_k = \{a_k, a_k + 1, \ldots, b_k - 1, b_k\}$, such that $\sum_{k=1}^{\ell}(b_k - a_k + 1) \geq n - \alpha$, and the sum/maximum of $c(a_1, b_1), \ldots, c(a_\ell, b_\ell)$ is minimized. Without loss of generality we can assume that $b_1 < a_2$, $b_2 < a_3$, $\ldots$, $b_{\ell-1} < a_\ell$, i.e., we assume that the coalitions are sorted by index in increasing order. Before giving the actual algorithm, we note that, to get the best efficiency possible, we will need that the values $c(i, j)$, for all pairs (i, j) with $i \leq j$, can be computed in total time $O(n^2)$ as a preprocessing step. We show this now.

▶ **Lemma 15.** *All values $c(i, j)$ for $i \leq j$ can be computed in total time $O(n^2)$.*

Proof. We will compute the values separately for each value of $j - i$. In particular, for each $0 \leq \ell < n$ we will compute all values $c(i, i + \ell)$ for $1 \leq i \leq n - \ell$ in linear time. To do this, for a fixed ℓ, note the contribution of agent k to the c-values that it counts into is precisely $cost(s_k, \ell + 1)$. Therefore, the values $[c(i, i + \ell)]_{1 \leq i \leq n-\ell}$ that we want to compute are aggregate queries over a sliding window of length $\ell + 1$ over the sequence $[cost(s_k, \ell + 1)]_{1 \leq k \leq n}$. Depending on the utilitarian/egalitarian goal, the aggregate can be either summation or maximum, but in either case, all the $n - \ell$ aggregates can be computed in linear time using standard sliding window techniques. ◀

[7] However, size-monotonicity is crucial in showing that considering compact solutions is enough.

We are now ready to present our algorithm. We construct a weighted directed acyclic graph $\mathcal{G}$ corresponding to the problem instance, as follows. We are given a source node $s = (0, 0)$ and a target node $t = (n + 1, *)$. For the remaining vertices, we have one vertex for each pair (i, j) with $1 \leq i \leq n+1$ and $0 \leq j \leq \alpha$. Intuitively, vertex (i, j) has the meaning "agent $1 \leq i \leq n+1$ is the next one to consider[8] and so far we have excluded $0 \leq j \leq \alpha$ agents from the hike. The source s is connected with a directed edge towards $(1, 0)$ and such an edge has weight 0, while t is reachable from the node $(n + 1, j)$, for each $0 \leq j \leq \alpha$, via an edge of weight 0. For the remaining edges, we add the following two types:

- We add a weighted edge $(i, j) \xrightarrow{0} (i+1, j+1)$ for all $1 \leq i \leq n$ and $0 \leq j < \alpha$. Intuitively, these correspond to excluding agent i from the hike.
- We add a weighted edge $(i, j) \xrightarrow{c(i,k)} (k + 1, j)$ for all $1 \leq i \leq k \leq n$ and $0 \leq j \leq \alpha$,. Intuitively, these correspond to adding a new coalition $C = \{i, i + 1, \ldots, k\}$ to the hike, incurring a cost of $c(i, k)$.

The next lemma establishes how paths in $\mathcal{G}$ correspond to compact solutions to our problem and its statement immediately follows by the construction of $\mathcal{G}$.

▶ **Lemma 16.** *There is a bijection from compact solutions to s-t paths in $\mathcal{G}$. Moreover, the social cost of a compact solution is the cost of the associated path, defined as either the sum or the maximum of the costs of its constituent edges.*

As a result, computing an optimal compact solution amounts to finding a minimum cost s-t path in $\mathcal{G}$; this gives us a polynomial time algorithm for computing an optimal solution.

▶ **Theorem 17.** *A hike with minimum social cost can be computed in time $O(n^2(\alpha + 1))$.*

Proof. By Lemma 14 it is enough to compute the best hike among compact solutions. To do so, we construct the graph $\mathcal{G}$ corresponding to the problem instance. Subsequently, we compute an s-t path in $\mathcal{G}$ of minimum cost. This can be done in time linear in the size of the graph, as the graph is acyclic. Correctness is assured by Lemma 16. For the time bound, note that the number of vertices in the graph is $O(n(\alpha + 1))$ and the number of edges is $O(n^2(\alpha + 1))$. Moreover, edge costs can be computed in constant time after $O(n^2)$ total precomputation by Lemma 15. Overall, we get a time complexity of $O(n^2(\alpha + 1))$. ◀

4 Wonderful Partitions versus Minimum Egalitarian Partitions

So far we assumed each agent has an ideal group size, a peak, and there exists a cost function $cost(x, y)$ which expresses the cost that any agent having ideal group size x incurs if placed in a coalition of size y. More broadly, agents may express their disutility with any cost function, that is, for each agent i there is a mapping $cost_i : N \to \mathbb{R}$ simply expressing the cost agent i incurs when assigned to a coalition of a certain size.

In this section, we are interested in finding the minimum egalitarian cost achievable by any partition and we denote by Min-Eg the problem of computing this value. In Section 3, we have already shown that whenever $cost_i(s) = cost(s_i, s)$, Min-Eg can be computed in $O(n^2)$. In what follows, we exploit the connection between Wonderful-Partition and Min-Eg delineating the tractability of the latter with respect to the properties of the cost functions. First, we show a general connection between Wonderful-Partition and Min-Eg.

▶ **Proposition 18.** *Wonderful-Partition and Min-Eg are polynomial time equivalent.*

[8] Indeed, there is a "dummy" agent $n + 1$ signifying that there are no more agents to consider.

Proof. A Wonderful-Partition instance can be transformed into a Min-Eg instance by setting for each agent a cost function $cost_i$ where $cost_i(j) = 1$ if agent i does not approve coalition size j and $cost_i(j) = 0$, otherwise. Hence, the Wonderful-Partition instance is a yes instance if Min-Eg is 0 and it is a no instance, otherwise.

If we have a Min-Eg instance, there are at most n^2 distinct values $cost_i(j)$. Assume there are k distinct such values and let us sort them from the lowest to the highest, namely, $c_1 < \ldots < c_k$. For each value c_h, we can define a Wonderful-Partition instance where a coalition of size $j \in [n]$ is approved by agent i if and only if $cost_i(j) \leq c_h$. We can therefore determine if there exists a partition having egalitarian welfare of at most c_h by solving Wonderful-Partition on the just described instance. Clearly, if there exists a partition having an egalitarian cost of at most c then there exists a partition having an egalitarian cost of value at most c' for each $c \leq c'$. Conversely, if there is no partition having an egalitarian welfare of at most c then there is no partition having an egalitarian cost of at most c'', for each $0 \leq c'' \leq c$. Therefore, we can use binary search among the possible values $c_1, \ldots, c_k$ to find the minimum value c such that a partition having an egalitarian welfare of at most c exists. This solves Min-Eg. ◀

▶ **Corollary 19.** *If Wonderful-Partition can be decided in time $T(n)$, then Min-Eg can be solved in $O((n^2 + T(n)) \cdot \log_2 n)$.*

Given the polynomial time equivalence between these two problems, it follows that solving Min-Eg is in general computationally intractable because Wonderful-Partition is NP-hard as soon as the approval sets are not intervals [18].

Nevertheless, there exists a special class of costs that can be solved using our dynamic programming approach for Wonderful-Partition described in Section 2.1. Such a class is a generalization of what we discussed in Section 3: Namely, each agent has an ideal group size s_i, and the closer the coalition size is to s_i the lower the cost. We align to the Hedonic Games literature calling this property *naturally single-peakedness*.[9]

▶ **Definition 20.** *A cost function $cost : \mathbb{N} \to \mathbb{R}_{\geq 0}$ is said to be* naturally single-peaked *if there exists an ideal group size, a* peak*, $p \in [n]$ such that $h < k \leq p$ or $h > k \geq p$ imply that $cost(k) < cost(h)$ holds.*

We observe that the reduction from Min-Eg to Wonderful-Partition described in Proposition 18 produces an interval instance in the case of naturally single-peaked cost functions. With this, we obtain the following theorem.

▶ **Theorem 21.** *Min-Eg for naturally single-peaked costs can be found in time $O(n^5 \log_2 n)$.*

Proof. We can use a similar idea as in the polynomial time reduction from Min-Eg to Wonderful-Partition, as described in Proposition 18. In Min-Eg we are looking for a partition that minimizes the cost of the agent having the highest disutility. Here, since we consider naturally single-peaked preferences, the disutility of an agent i is decreased the closer the size of their assigned group $|\pi(i)|$ is to their ideal group size s_i (the peak value of agent i). We can now fix, for a value c, some distances Δ, Δ' such that $cost_i(s) \leq c$ for each $s \in [s_i - \Delta, s_i + \Delta']$. Therefore, we define that any agent i approves their assigned group size if it is in the interval $[s_i - \Delta, s_i + \Delta']$; this defines the instance of Wonderful-Partition-Intervals to be solved for determining if there exists a partition of having an egalitarian cost of at most c.

Now, applying Corollary 19 and Theorem 3, the statement follows. ◀

[9] We say *naturally* as general single-peakedness may be defined w.r.t. any fixed ordering of coalition sizes. In our setting we consider cost functions that are single-peaked w.r.t. the natural ordering $1, \ldots, n$.

Notice that the computational complexity guaranteed by Theorem 17 is way more efficient than the one of Theorem 21. However, the former holds true for very specific naturally single-peaked costs, while the latter establishes the tractability of Min-Eg whenever agents have naturally single-peaked costs.

5 Conclusions

We resolved an open problem posed a decade ago by Gerhard Woeginger by giving a polynomial-time algorithm via establishing a connection to a version of rectangle stabbing, and investigated several interesting variants. We give a complete picture on the tractability of the Hiking Problem itself and show that maximizing the number of satisfied participants or deleting the minimal number such that the remaining participants admit a wonderful partition is polynomial time solvable. The tractability of both the original decision-, and the according optimization problems is crucially enabled by the existence of optimal solutions that exhibit simple and intuitive structural properties, fueling the algorithmic solutions based on Dynamic Programming. Last but not least, we employ our solution to efficiently compute a partition that maximizes the egalitarian welfare for anonymous naturally single-peaked Hedonic Games. We note that our approach also works for general interval instances, that is, for a given permutation σ of numbers $1, \dots, n$, intervals are defined over the numbers in order of the permutation, i.e., $\sigma(1), \dots, \sigma(n)$. This extends our results from naturally single-peaked to general single-peaked cost functions. The problem of minimizing utilitarian cost for general single-peaked cost functions remains open.

An Optimal Sparsification Lemma for Low-Crossing Matchings and Its Applications to Discrepancy and Approximations

Mónika Csikós

Abstract

Matchings with low crossing numbers were originally introduced in the late 1980s in the seminal works of Welzl [35, 36] and Chazelle-Welzl [11]. They have since become fundamental structures in combinatorics, computational geometry, and algorithms.

In this paper, we study matchings with low crossing numbers and their relation to random samples. In particular, our main technical result states that, given a set system $(X, \mathcal{S})$ with dual VC-dimension d and a parameter $\alpha \in (0, 1]$, a random set of $\tilde{\Theta}\left(n^{1+\alpha}\right)$ edges of $\binom{X}{2}$ contains a linear-sized matching with crossing number $O\left(n^{1-\alpha/d}\right)$.

Furthermore, we show that this bound is optimal up to a logarithmic factor.

By incorporating the above sampling step to existing algorithms, we obtain improved running times, by a factor of $\tilde{\Theta}(n)$, for computing matchings with low crossing numbers. This immediately implies new bounds for a number of well-studied problems, such as combinatorial discrepancy, ε-approximations and their applications.

To the best of our knowledge, these are the first near-linear time algorithms for general, non-geometric set systems, for a) matchings with *sub-linear* crossing numbers, and b) discrepancy beating the standard deviation bound. As an immediate consequence we get fast algorithms for computing $o(1/\varepsilon^2)$-sized ε-approximations.

1 Introduction

A perfect matching of a set X is a partition of X into $|X|/2$ disjoint pairs[1]. Given a set system $(X, \mathcal{S})$, we say that a set $S \in \mathcal{S}$ *crosses* a pair $\{x, y\} \subseteq X$ iff $|S \cap \{x, y\}| = 1$. Then for a perfect matching M of X, the *crossing number* of M with respect to $\mathcal{S}$ is defined to be the maximum number of edges of M crossed by any $S \in \mathcal{S}$.

Matchings with low crossing numbers were originally introduced by Welzl [35, 36] for the special case where X is a set of points in $\mathbb{R}^d$ and $\mathcal{S}$ is induced on X by half-spaces. His result was then improved and generalized by Chazelle and Welzl [11] to a broader class of set systems using the notion of the *dual shatter function* $\pi^*_{\mathcal{S}}$ of $(X, \mathcal{S})$, which is defined as follows:

[1] If $|X|$ is odd, then we partition X into $\lfloor |X|/2 \rfloor$ disjoint pairs plus a singleton set.

> For any $k \leq |\mathcal{S}|$, $\pi^*_{\mathcal{S}}(k)$ denotes the maximum number of equivalence classes on X defined by a k-element subfamily $\mathcal{R} \subseteq \mathcal{S}$, where $x, y \in X$ are equivalent w.r.t. $\mathcal{R}$ iff x belongs to the same sets of $\mathcal{R}$ as y. The number of such equivalence classes, for a given $\mathcal{R} \subseteq \mathcal{S}$, is essentially the number of non-empty cells, w.r.t. X, in the Venn diagram of the sets of $\mathcal{R}$.

The family of set systems with polynomially bounded dual-shatter function includes set systems with bounded dual VC-dimension and most of the commonly-studied geometric cases – e.g., the primal and dual set systems induced by half-spaces, balls, intersections/unions of bounded complexity geometric objects and more generally, algebraic varieties [26].

The following theorem on the existence of matchings with low crossing number is a celebrated and fundamental result in computational geometry.

▶ **Theorem A** ([11, 20]). *Let $(X, \mathcal{S})$ be a set system with $n = |X|$, and dual shatter function $\pi^*_{\mathcal{S}}(k) = O(k^d)$. Then there exists a perfect matching on X with crossing number $O\left(n^{1-1/d} + \ln |\mathcal{S}|\right)$.*

Theorem A has had numerous applications, including range searching, extremal results for hypergraphs with bounded VC dimension, low-discrepancy colorings in geometric hypergraphs, near-optimal sized epsilon-approximations, to name a few. We refer the reader to these books [10, 25, 29] for more information.

The power of Theorem A, as well as the difficulty in efficiently computing such matchings, come from the same source: a vanishingly small proportion of matchings are low-crossing matchings. Indeed, it is not difficult to see that a random matching will have crossing number $\Omega(n)$. For example, any set containing $n/2$ elements of X will cross, in expectation, a linear number of edges of such a matching.

This contrasts sharply with the case for the related structures of ε-nets and ε-approximations: a large-enough random sample is an ε-net/ε-approximation with high probability and thus a constant fraction of all subsets of X are ε-nets and ε-approximations. The use of randomness fails in our case since these ε-net/ε-approximation bounds rely on the fact that each set in the set system has *large* measure – at least ε-th measure – and the behavior of the random sample can be analyzed independently for each set, which are all known in advance.

Thus the ingenious proof of Theorem A takes a different route: it constructs a matching in $n/2$ iterations, where each iteration considers all remaining edges and picks one minimizing a certain function. This is computationally expensive, and consequently, all old and recent – with one exception – algorithms for building matchings with crossing numbers $o(n)$ in general set systems have $\Omega\left(n^2\right)$ running times, even when $|\mathcal{S}| = O(n)$ [11, 13, 18, 19].

The one exception is the algorithm proposed by Ducoffe *et al.* [16], designed specifically to get below the quadratic (in $|X| + |\mathcal{S}|$) running time barrier: they show that there is a universal constant $c > 2$ such that for any set system $(X, \mathcal{S})$ with VC-dimension D and dual VC-dimension d, one can compute a spanning path with crossing number $\tilde{O}\left(n^{1-1/(c \cdot D \cdot d)}\right)$ in time $\tilde{O}\left(|\mathcal{S}| + n^{2-1/(c \cdot D \cdot d)}\right)$.

2 Our Results

Motivated by the above considerations, we revisit the key question, of independent interest, of the utility of random sampling for constructing matchings with low crossing numbers. Our main technical result is that although a random perfect matching is very far from a low-crossing matching, a slightly larger random sample of edges contains a linear-sized matching that is close to a low-crossing matching. More precisely:

▶ **Lemma 1** (Main lemma; Proof in Section 4). *Let $(X, \mathcal{S})$, $n = |X|$, be a set system with dual shatter function $\pi^*(k) = O(k^d)$, and let $\alpha \in (0, 1]$, $\delta \in (0, 1)$ be two given parameters. Let E be a uniform random sample from $\binom{X}{2}$, where each edge is picked i.i.d. with probability*

$$p = \min\left\{\frac{2\ln n}{n^{1-\alpha}} + \frac{4\ln(2/\delta)}{n^{2-\alpha}},\ 1\right\}.$$

Then with probability at least $1 - \delta$, E contains a matching of size $n/4$ of crossing number

$$O\left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right).$$

Moreover, we show that the above is near-optimal.

▶ **Lemma 2** (Optimality; Proof in Section 5). *For any $d \geq 2$, $c \geq 2$, $\alpha > 0$, and $n_0 \in \mathbb{N}$, there is a set system $(X, \mathcal{S})$ with $|X| = n \geq n_0$, and dual shatter function $\pi^*_{\mathcal{S}}(k) = O(k^d)$, such that the following holds:*

> *let E be a random edge-set obtained by selecting each edge in $\binom{X}{2}$ i.i.d. with probability $p(n) = o\left(n^{\alpha-1}\right)$. Then with probability at least $1/2$, every matching in E of size n/c has crossing number $\omega\left(n^{1-\alpha/d}\right)$ with respect to $\mathcal{S}$, where the constants in the asymptotic notation depend on d and c.*

▶ Remark. The same asymptotic results hold for low-crossing spanning paths and spanning trees.

We find Lemma 1 surprising for the following reason: the classical proof of Theorem A assigns exponentially-increasing weights to the sets of $\mathcal{S}$, which then dictate the choice of the edge picked at each iteration. Thus a different choice of the edge at iteration i could result in a changing of the weight distribution, which then influences the sequence of edges picked for all later iterations. At first glance, a random sample chosen once, and uniformly from $\binom{X}{2}$ cannot simply assure that it will contain many edges from all possible *exponentially* many paths possibly chosen by the algorithm.

In particular, if we fix an initial uniform sample of edges, and build the matching using this sample (by always choosing a light edge from the sample, as in previous algorithms), it introduces a bias (as the set of uncovered points depend on the initial sample of edges) and we cannot assume anymore that among the uncovered points, every edge is picked i.i.d. with a fixed probability. Indeed, with later iterations, the possible paths to be taken care of increase exponentially and the initial random sample has low probability of containing a good perfect matching.

Therefore, we take a different, more subtle, approach in the analysis, similar in spirit to the technique of quasi-uniform sampling of Varadarajan [34] and Chan et al.[9]:

1. instead of a perfect matching, we aim for a *linear-sized* partial matching with crossing number $O\left(n^{1-\alpha/d}\right)$. As we will prove, this requirement is weak-enough for a single sample to work, but strong-enough so that to compute a perfect matching, $O(\log n)$ adaptive uniform samples are sufficient.
2. instead of the classical algorithm, we propose a new randomized version where an edge from our initial, fixed, random sample of edges is picked in each iteration with a carefully chosen probability distribution that *does* depend on the changing weights in each iteration.

While Lemma 1 only guarantees the existence of a low-crossing *partial* matching, it can be used to speed up the fastest existing algorithms, by computing a linear sized matching and recursing on the uncovered points. This leads to the following result that improves the running times of previous-best algorithm of Csikós and Mustafa [13] by nearly a factor of $\Theta(n)$, at the cost of a higher, but still sub-linear crossing number.

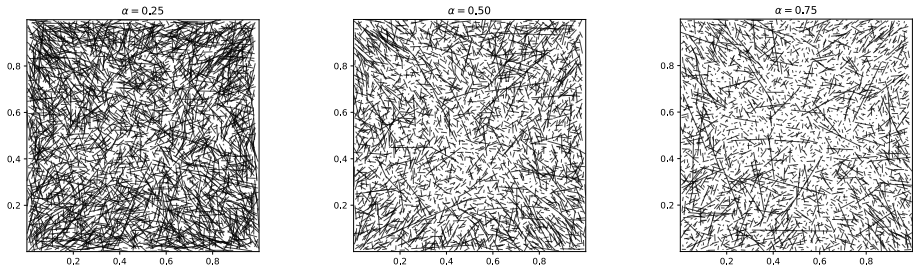
Table 1 $(X, \mathcal{S})$ has dual-shatter function $\pi^*(k) = O(k^d)$, $n = |X|$, $m = |\mathcal{S}|$.

Problem	Our Method		Previous-best	
	Guarantee	Time	Guarantee	Time
matching with low crossing number	$O\left(n^{1-\alpha/d} + \ln m \ln n\right)$	$\tilde{O}\left(n^{(1+\alpha)+\frac{2\alpha}{d}} + m \cdot n^{\frac{2\alpha}{d}}\right)$	$O\left(n^{1-1/d} + \ln m \ln n\right)$	$\tilde{O}\left(n^{2+\frac{2}{d}} + m \cdot n^{\frac{2}{d}}\right)$ [13]
			$O\left(n^{1-1/O(d \cdot 2^d)} + \ln m \ln n\right)$	$\tilde{O}\left(m + n^{2-1/O(d \cdot 2^d)}\right)$ [16]
combinatorial discrepancy	$O\left(\sqrt{n^{1-\alpha/d} \ln m + \ln^2 m \ln n}\right)$	$\tilde{O}\left(n^{(1+\alpha)+\frac{2\alpha}{d}} + m \cdot n^{\frac{2\alpha}{d}}\right)$	$O\left(\sqrt{n^{1-1/d} \ln m}\right)$	$\tilde{O}\left(n^{2+\frac{2}{d}} + m \cdot n^{\frac{2}{d}}\right)$ [13]

▶ **Corollary 3** (Proof in Appendix A.1). *Let $(X, \mathcal{S})$ be a set system with dual shatter function $\pi^*_{\mathcal{S}}(k) = O(k^d)$, $n = |X|$ and $\alpha \in (0, 1]$. Then there is a randomized algorithm which returns a perfect matching of expected crossing number $O\left(n^{1-\alpha/d} + \ln |\mathcal{S}| \ln n\right)$ in expected time $\tilde{O}\left(n^{1+\alpha+\frac{2\alpha}{d}} + |\mathcal{S}| \cdot n^{\frac{2\alpha}{d}}\right)$.*

▶ Remark. The algorithm of Corollary 3 can easily be modified to create a spanning path with the same crossing number guarantee.

Figure 1 The matchings output by the algorithm of Corollary 3 on the set system induced by half-spaces in $\mathbb{R}^2$ are shown below, for $\alpha = 0.25, 0.5$ and 0.75.



Algorithmic Consequences

Besides a new trade-off between quality and speed of computation, Corollary 3 has several algorithmic applications.

1. A better sub-quadratic time (in $|X| + |\mathcal{S}|$) algorithm. Setting a low value for the parameter $\alpha \in (0, 1]$ allows us to get a running time that is close to linear, at the expense of the crossing number. At the other end of the spectrum, we can get below the quadratic running time barrier without sacrificing too much in the crossing number. This improves the result of Ducoffe *et al.* [16] – who computed a spanning path with crossing number $\tilde{O}\left(n^{1-1/(c \cdot D \cdot d)}\right)$ in time $\tilde{O}\left(m + n^{2-1/(c \cdot D \cdot d)}\right)$, where $D = \text{VCdim}(X, \mathcal{S})$ – by letting $\alpha = d/(d+3)$. Besides improving the crossing number, the new algorithm also does not depend on the primal VC dimension.

▶ **Corollary 4.** *Let $(X, \mathcal{S})$ be a set system with dual shatter function $\pi^*_{\mathcal{S}}(k) = O(k^d)$, $n = |X|$. Then there is a randomized algorithm which returns a perfect matching of expected crossing number $O\left(n^{1-1/(d+3)} + \ln |\mathcal{S}| \ln n\right)$ in expected time $\tilde{O}\left(n^{2-\frac{1}{d+3}} + |\mathcal{S}| \cdot n^{\frac{2}{d+3}}\right)$.*

▶ Remark. In the work of Ducoffe *et al.* [16], spanning paths were used as a key algorithmic tool for computing the diameter of graphs. Their main result is a $\tilde{O}\left(k\, n^{2-1/O(d\cdot 2^d)}\right)$ time algorithm to decide whether the diameter of a graph G with distance VC-dimension d is at most k. Using Corollary 4 in their algorithmic framework ([16, Lemma 6]), we get an algorithm that decides whether G has diameter at most k, in time $O\left(k\, n^{2-1/(d+3)}\right)$.

2. Discrepancy. Using Corollary 3 in a standard iterative halving scheme [27] gives us faster approximation algorithms for combinatorial discrepancy, again improving the previous-best algorithms by nearly a factor of $\tilde{\Theta}(n)$, at the cost of a slightly higher discrepancy.

▶ **Corollary 5** (Proof in Appendix A.2). *Let $(X,\mathcal{S})$, $n=|X|$, $m=|\mathcal{S}|$, be a set system and d be a constant such that $\pi^*_{\mathcal{S}}(k)=O\left(k^d\right)$. For any $0<\alpha\le 1$, there is a randomized algorithm which constructs a coloring χ of X with expected discrepancy $O\left(\sqrt{n^{1-\alpha/d}\ln m+\ln^2 m\log n}\right)$, in expected time $\tilde{O}\left(n^{1+\alpha+\frac{2\alpha}{d}}+m\cdot n^{\frac{2\alpha}{d}}\right)$.*

This allows us to get the first near-linear time algorithm, for general non-geometric set systems, that beats the standard deviation discrepancy bound:

▶ **Corollary 6.** *Let $(X,\mathcal{S})$, $n=|X|$, $m=|\mathcal{S}|$, be a set system and d be a constant such that $\pi^*_{\mathcal{S}}(k)=O\left(k^d\right)$. For any $0<\varepsilon\le 1$, there is a randomized algorithm which constructs a coloring χ of X with expected discrepancy $O\left(\sqrt{n^{1-\frac{\varepsilon}{d+2}}\ln m+\ln^2 m\log n}\right)$, in expected time $\tilde{O}\left(n^{1+\varepsilon}+m^{1+\varepsilon}\right)$.*

3. ε-Approximations. The iterative application of Corollary 5 implies the following faster algorithm for computing ε-approximations [10, 29, 32, 24, 14].

▶ **Corollary 7.** *Let $\varepsilon\in(0,1)$, $(X,\mathcal{S})$ be a set system and c,d,D be constants such that $\pi^*_{\mathcal{S}}(k)\le ck^d$ and $\mathrm{VCdim}(X,\mathcal{S})\le D$. Then for any $\alpha\in(0,1)$, there is a randomized algorithm which returns an ε-approximation $A\subset X$ of size*

$$O\left(\left(\frac{1}{\varepsilon^2}\log\frac{1}{\varepsilon}\right)^{\frac{d}{d+\alpha}}\right)$$

in expected time

$$\tilde{O}\left(\left(\frac{D}{\varepsilon^2}\right)^{1+\alpha+\frac{2\alpha}{d}}+\left(\frac{D}{\varepsilon^2}\right)^{D+\frac{2\alpha}{d}}\right).$$

3 Previous Results

Matchings with low crossing numbers

The study of perfect matchings (along with spanning paths and spanning trees) with low crossing number was originally introduced for geometric range searching [35, 11]. Since then, they have found applications in various fields, for instance, discrepancy theory [27], learning theory [3], or algorithmic graph theory [16].

The proof of Theorem A is constructive, using the Multiplicative Weights Update (**MWU**) technique. Moreover it works for any (abstract) set system $(X,\mathcal{S})$ with polynomially bounded dual-shatter function. It builds a low-crossing matching iteratively, guided by a weight

Algorithm 1 MatchingMWU$\big((X,\mathcal{S})\big)$.

$\omega_1(S) \leftarrow 1$ for all $S \in \mathcal{S}$
$X_1 \leftarrow X$
for $i = 1, \ldots, n/2$ **do**
  $e_i \leftarrow$ the lightest edge in $\binom{X_i}{2}$ w.r.t. ω_i
  Obtain ω_{i+1} from ω_i by doubling the weights of each set crossing e_i
  $X_{i+1} \leftarrow X_i \setminus \text{endpoints}(e_i)$
return $\{e_1, \ldots, e_{n/2}\}$

function ω on $\mathcal{S}$, with initial weights set to 1. At each iteration, the algorithm adds the "lightest" edge to the matching – that is, the edge that is crossed by sets of minimum total weight. At the end of an iteration, it updates ω by doubling the weight of each set crossing the picked edge. See Algorithm 1. The algorithmic bottleneck is in finding such an edge: for an abstract set system without additional structure, this takes $O(n^2m)$ time for each of the $n/2$ iterations, giving a total running time of $O\left(n^3m\right)$, where $n = |X|$ and $m = |\mathcal{S}|$. Using MWU together with ideas from linear programming duality have led to the current-best running time for computing matchings with crossing number $O\left(n^{1-1/d}\right)$ in time $\tilde{O}\left(n^{2+2/d} + mn^{2/d}\right)$ [13].

A different approach was proposed by Har-Peled [19] (see also [17]). His result implies that if $(X,\mathcal{S})$ has a spanning tree with crossing number $\kappa = \Theta(n^\gamma)$ for some $\gamma \in [1/\log n, 1]$, then a spanning tree of crossing number $O(\kappa/\gamma)$ can be found by solving an LP on $\binom{n}{2}$ variables and $m + n$ constraints, see also [18]. Another result for general set systems having spanning trees with crossing number κ, is based on rounding fractional solutions of minimax integer programs with matroid constraints. This method gives a randomized algorithm that constructs a spanning tree with expected crossing number at most $\kappa + O(\sqrt{\kappa \log m})$ in time $\tilde{O}(mn^4 + n^8)$ [12].

For the geometric case, where X is a set of points in $\mathbb{R}^d$ and $\mathcal{S}$ is induced by half-spaces, Chan [8] gave a $O\left(n \log n\right)$ time algorithm to compute a matching with crossing number $O\left(n^{1-1/d}\right)$ using hierarchical cuttings. More generally, spatial partitioning by polynomials has also been extensively studied in the last decade [1, 2].

Discrepancy

Spencer [31] showed that for any set system (X, S), there exists a coloring of X with discrepancy $O\left(\sqrt{n \ln(m/n)}\right)$, which is tight and improves the general bound for $m = O\left(n\right)$. A series of algorithms for its construction started with the breakthrough work of Bansal [5], who gave the first polynomial-time randomized algorithm (using SDP rounding) to compute a coloring with discrepancy $O\left(\sqrt{n}\ln(m/n)\right)$, which matches the bound of Spencer for $m = O(n)$. Later Lovett and Meka [23] gave a combinatorial randomized algorithm for constructing colorings with discrepancy $O\left(\sqrt{n \ln(m/n)}\right)$ and improved the expected running time to $\tilde{O}\left(n^3 + m^3\right)$; see also [30] for a different proof. The algorithm of Bansal was de-randomized [7] (but still used a non-constructive method to prove the feasability of an underlying SDP), and later, Levy et al.[22] used the multiplicative weights update technique to give a deterministic $O\left(n^4m\right)$-time algorithm to compute a two-coloring with discrepancy $O\left(\sqrt{n \ln(m/n)}\right)$ for an arbitrary set system. See also [6] for a random-walk algorithm for Banaszczyk's discrepancy bound, with running time $O\left(n^{3.3728..} + nm^{2.3728..}\right)$. Most recently, Larsen proposed an

$O(n^2 m \ln(2 + m/n) + n^3)$ time algorithm with hereditary discrepancy guarantees [21]. The discrepancy guarantees of [21] can also be achieved with an $\tilde{O}(\mathrm{nnz}(A) + n^3)$ time algorithm [15], where A is the membership matrix of $(X, \mathcal{S})$. We note that many of these algorithms can be applied in more general settings (e.g. for real-valued matrices), however none of them provide a sub-quadratic time algorithm for the combinatorial discepancy problem in structured set systems.

4 Proof of the Main Lemma

In this section, we prove Lemma 1. Given a weight function $\omega\colon \mathcal{S} \to \mathbb{R}^+$, for $e \in \binom{X}{2}$, set

$$\mathrm{weight}(e, \omega) := \sum_{\substack{S \in \mathcal{S}: \\ e \text{ crosses } S}} \omega(S).$$

Then for any integer $k > 0$, by *"the k lightest edges of $\binom{X}{2}$ w.r.t. ω"*, we refer to the k edges with the smallest values of $\mathrm{weight}(\cdot, \omega)$ (ties broken arbitrarily).

We show the required property of the random sample E via the analysis of the randomized algorithm RelaxedMWU presented in Algorithm 2. In particular, Lemma 1 immediately follows from these two properties.

▶ **Lemma 8.** *Let $(X, \mathcal{S})$ be a set system with dual shatter function $\pi^*_{\mathcal{S}}(k) = O\left(k^d\right)$, $\alpha \in (0, 1]$ and $E \subseteq \binom{X}{2}$. For any halting iteration $T = t$, the set of edges returned by RelaxedMWU$\left((X, \mathcal{S}), \alpha, E\right)$ have crossing number $O\left(t^{1-\alpha/d} + \ln|\mathcal{S}|\right)$.*

▶ **Lemma 9.** *If $E \subseteq \binom{X}{2}$ is an i.i.d. sample where each edge is picked with probability*

$$p = \min\left\{\frac{2\ln n}{n^{1-\alpha}} + \frac{4\ln(2/\delta)}{n^{2-\alpha}},\ 1\right\},$$

then RelaxedMWU$((X, \mathcal{S}), \alpha, E)$ returns at least $n/4$ edges with probability at least $1 - \delta$.

▶ Remark. Lemma 8 does not use the fact that E is chosen randomly, or the randomness used in the algorithm; these are only used by Lemma 9.

Algorithm 2 RelaxedMWU$\left((X, \mathcal{S}), \alpha, E\right)$.

```
1  ω_1(S) ← 1 for all S ∈ S
2  X_1 ← X
3  for iteration i = 1, ..., n/2 do
4      E_i ← the |X_i|^{2−α} lightest edges in (X_i choose 2) w.r.t. ω_i
5      if E ∩ E_i = ∅ then
6          return {e_1, ..., e_{i−1}} and set T = i − 1
7      else
8          Pick an edge e_i from E ∩ E_i uniformly at random
9          Compute ω_{i+1} from ω_i by doubling the weight of each set crossing e_i
10         X_{i+1} ← X_i \ endpoints(e_i)
11 return {e_1, ..., e_{n/2}} and set T = n/2
```

▶ Remark. The precise definition of $\mathcal{E}_i$ (line 4 of Algorithm 2) should consider the $\lfloor |X_i|^{2-\alpha} \rfloor$ lightest edges. For the simplicity of presentation, we replace $\lfloor |X_i|^{2-\alpha} \rfloor$ with $|X_i|^{2-\alpha}$ throughout the proof.

We now prove the two key properties of RelaxedMWU separately.

4.1 Proof of Lemma 8

For any function $f : \mathcal{S} \to \mathbb{R}$, define $f(\mathcal{S}) := \sum_{S \in \mathcal{S}} f(S)$.

We will use the following key lemma; its proof will be presented later.

▶ **Lemma 10.** *Let $(X, \mathcal{S})$ be a set system with dual shatter function $\pi^*_{\mathcal{S}}(k) \le c_1 \cdot k^d$. Then given any $Y \subset X$, a weight function $w : \mathcal{S} \to \mathbb{Z}^+$, and an integer $\ell \in \left[|Y|, \binom{|Y|}{2}\right]$, there are at least ℓ distinct edges in $\binom{Y}{2}$ such that the total weight of the sets of $\mathcal{S}$ crossing each edge is at most*

$$(10c_1)^{1/d} \cdot \frac{w(\mathcal{S}) \cdot \ell^{1/d}}{|Y|^{2/d}}.$$

Let $\{e_1, \ldots, e_t\}$ be the output of RelaxedMWU and for each $i \in [1, t]$, set $\eta_i = \text{weight}(e_i, \omega_i)$.

At the start of iteration i, we have $|X_i| = n - 2i + 2$ and we pick one of the $|\mathcal{E}_i| = |X_i|^{2-\alpha}$ lightest edges of $\binom{X_i}{2}$ w.r.t. ω_i. Applying Lemma 10 with $Y = X_i$, $\omega = \omega_i$ and $\ell = |\mathcal{E}_i|$, gives an upper bound on the weight of each edge in $\mathcal{E}_i$ w.r.t. ω_i. In particular, as $e_i \in \mathcal{E}_i$, we have

$$\eta_i \le (10c_1)^{1/d} \cdot \frac{\omega_i(\mathcal{S}) \cdot |X_i|^{(2-\alpha)/d}}{|X_i|^{2/d}} = (10c_1)^{1/d} \cdot \frac{\omega_i(\mathcal{S})}{|X_i|^{\alpha/d}} = \frac{(10c_1)^{1/d}\omega_i(\mathcal{S})}{(n-2i+2)^{\alpha/d}}. \tag{1}$$

Let κ_t denote the maximum number of edges in $\{e_1, \ldots, e_t\}$ that are crossed by a set in $\mathcal{S}$. By the weight-update rule of the algorithm, we have

$$\omega_{t+1}(\mathcal{S}) \ge \max_{S \in \mathcal{S}} \omega_{t+1}(S) = 2^{\kappa_t},$$

and for any $j \in [1, t]$

$$\omega_{j+1}(\mathcal{S}) = \omega_j(\mathcal{S}) + \eta_j = \omega_j(\mathcal{S}) \left(1 + \frac{\eta_j}{\omega_j(\mathcal{S})}\right).$$

Applying the above equality for $j = t, \ldots, 1$ iteratively and using $\omega_1(\mathcal{S}) = |\mathcal{S}|$, we obtain

$$\omega_{t+1}(\mathcal{S}) = \omega_t(\mathcal{S}) \left(1 + \frac{\eta_t}{\omega_t(\mathcal{S})}\right) = \cdots = |\mathcal{S}| \cdot \prod_{j=1}^{t} \left(1 + \frac{\eta_j}{\omega_j(\mathcal{S})}\right) \le |\mathcal{S}| \cdot \exp\left(\sum_{j=1}^{t} \frac{\eta_j}{\omega_j(\mathcal{S})}\right).$$

Combining the upper and lower bounds for $\omega_{t+1}(\mathcal{S})$, we get

$$2^{\kappa_t} \le \omega_{t+1}(\mathcal{S}) \le |\mathcal{S}| \cdot \exp\left(\sum_{j=1}^{t} \frac{\eta_j}{\omega_j(\mathcal{S})}\right) \quad \Longrightarrow \quad \kappa_t \le \frac{1}{\ln 2}\left(\ln|\mathcal{S}| + \sum_{j=1}^{t} \frac{\eta_j}{\omega_j(\mathcal{S})}\right). \tag{2}$$

Using the upper-bound on η_j from Equation (1), we conclude that for any stopping time $t \in [1, n/2]$, the matching $\{e_1, \ldots, e_t\}$ returned by RelaxedMWU has crossing number at most

$$\begin{aligned}
\frac{1}{\ln 2}\left(\ln|\mathcal{S}| + \sum_{j=1}^{t} \frac{(10c_1)^{1/d}}{(n-2j+2)^{\alpha/d}}\right) &\le \frac{1}{\ln 2}\left(\ln|\mathcal{S}| + \sum_{j=1}^{t} \frac{(10c_1)^{1/d}}{(2t-2j+2)^{\alpha/d}}\right) \quad \left(\textit{since } t \le \frac{n}{2}\right) \\
&\le \frac{1}{\ln 2}\left(\ln|\mathcal{S}| + \sum_{j=1}^{t} \frac{(10c_1)^{1/d}}{(t-j+1)^{\alpha/d}}\right) \\
&= \frac{1}{\ln 2}\left(\ln|\mathcal{S}| + \sum_{j=1}^{t} \frac{(10c_1)^{1/d}}{j^{\alpha/d}}\right) \\
&= \frac{\ln|\mathcal{S}|}{\ln 2} + O\left(t^{1-\alpha/d}\right) = O\left(t^{1-\alpha/d} + \ln|\mathcal{S}|\right).
\end{aligned}$$

This concludes the proof of Lemma 8 assuming Lemma 10. We now return to the proof of Lemma 10, for which we need the following two statements.

▶ **Theorem 11** (Turán's Theorem [33]). *Let $G = (V, E)$ be a graph with no clique of size $r + 1$. Then*

$$|E| \leq \left(1 - \frac{1}{r}\right) \frac{n^2}{2}.$$

▶ **Lemma 12** (Packing Lemma [20, 28, 29]). *Let $(X, \mathcal{S})$ be a set system with shatter function $\pi_{\mathcal{S}}(k) \leq c_1 \cdot k^d$ and let $\delta \in (1, |X|)$ be a parameter. Furthermore, let $\mathcal{P} \subset \mathcal{S}$ be a δ-separated set; that is, $|S_1 \Delta S_2| \geq \delta$ for all $S_1, S_2 \in \mathcal{P}$ (where $S_1 \Delta S_2$ denotes the symmetric difference of S_1 and S_2). Then*

$$|\mathcal{P}| \leq 2c_1 \left(\frac{|X|}{\delta}\right)^d.$$

Proof of Lemma 10. Let $(\mathcal{S}_w, \mathcal{R}_Y)$ denote the set system dual to $(Y, \mathcal{S})$ with multiplicities given by $w(\cdot)$. That is, the base set $\mathcal{S}_w$ consists of sets of $\mathcal{S}$, where each $S \in \mathcal{S}$ has $w(S)$ copies in $\mathcal{S}_w$. And $\mathcal{R}_Y$ consists of $|Y|$ sets, one for each element of Y:

$$\mathcal{R}_Y = \{R_y : y \in Y\}, \quad \text{where} \quad R_y = \{S \in \mathcal{S}_w : y \in S\}.$$

Observe that

- for any $x, y \in Y$, the set $R_x \Delta R_y$ contains precisely the sets in $\mathcal{S}_w$ that cross the edge xy,
- $|\mathcal{S}_w| = w(\mathcal{S})$, and
- the shatter function of $(\mathcal{S}_w, \mathcal{R}_Y)$ is the dual shatter function of $(Y, \mathcal{S})$.

Consider a graph G on Y, where there is an edge between two elements $x, y \in Y$ if and only if xy is crossed by more than δ_ℓ sets in $\mathcal{S}_w$, where we set

$$\delta_\ell = \left(10c_1 \cdot \frac{w(\mathcal{S})^d \ell}{|Y|^2}\right)^{1/d}.$$

Now the **Packing Lemma** implies that any δ_ℓ-separated subset of sets in $\mathcal{R}_Y$ has cardinality at most

$$C_\ell = 2c_1 \left(\frac{w(\mathcal{S})}{\delta_\ell}\right)^d = 2c_1 \frac{w(\mathcal{S})^d}{10c_1 \cdot \frac{w(\mathcal{S})^d \ell}{|Y|^2}} = \frac{|Y|^2}{5\ell}.$$

This implies that G does not contain a clique on $C_\ell + 1$ vertices, and so by **Turán's Theorem**, the number of pairs that are *not* edges in G is at least

$$\binom{|Y|}{2} - \left(1 - \frac{1}{C_\ell}\right) \frac{|Y|^2}{2} = \frac{|Y|^2}{2C_\ell} - \frac{|Y|}{2} = \frac{5\ell}{2} - \frac{|Y|}{2} \geq \ell,$$

where we used that $|Y| \leq \ell$. Thus, we have shown that there are at least ℓ edges which cross sets of total weight at most δ_ℓ. This concludes the proof of Lemma 10 and thus the proof of Lemma 8. ◀

4.2 Proof of Lemma 9

Our goal is to prove that if $E \subseteq \binom{X}{2}$ is a random set of edges, where each edge from $\binom{X}{2}$ is picked i.i.d. with probability

$$p = \min\left\{\frac{2\ln n}{n^{1-\alpha}} + \frac{4\ln(2/\delta)}{n^{2-\alpha}},\ 1\right\},$$

then the random halting time T of $\textsc{RelaxedMWU}\big((X,\mathcal{S}),\alpha,E\big)$ satisfies

$$\mathbb{P}\left[\ T \le n/4\ \right] \le \delta.$$

If $p = 1$, then the statement is trivially true, therefore assume that $p < 1$.

Note that we have two different sources of randomness: we run the algorithm on an initial sample E of edges and at each iteration, if $E \cap \mathcal{E}_i \neq \emptyset$, we sample an edge $e_i \in E \cap \mathcal{E}_i$ uniformly at random. The notation $\mathbb{P}[A]$ denotes the probability of event A under both randomness sources.

We will upper bound the probabilities $\mathbb{P}\left[\ T = i\ \right]$ for each $i = 0, \ldots, n/4$. For the case $i = 0$, since E is an i.i.d. uniform random sample of $\binom{X}{2}$, we have

$$\mathbb{P}\left[\ T = 0\ \right] = \mathbb{P}\left[\ E \cap \mathcal{E}_1 = \emptyset\ \right] = (1-p)^{|\mathcal{E}_1|} = (1-p)^{n^{2-\alpha}}.$$

Now consider the case $i \ge 1$. Observe that the edge-set $\mathcal{E}_i$ depends on the edges chosen in earlier iterations $j < i$. To signify this, for any sequence of $i-1$ edges $(e^1, \ldots, e^{i-1})$, let $\mathcal{E}_i(e^1, \ldots, e^{i-1})$ denote the set of $(n - 2(i-1))^{2-\alpha}$ lightest edges *assuming* that $e^1, \ldots, e^{i-1}$ were added to the matching and the weights of the sets of $\mathcal{S}$ were adjusted multiplicatively accordingly.

We say that a sequence $(e^1, \ldots, e^i)$ is *feasible* if $e^1 \in \mathcal{E}_1$, $e^2 \in \mathcal{E}_2(e^1)$, $\ldots$, $e^i \in \mathcal{E}_i(e^1, \ldots, e^{i-1})$. We denote the set of all feasible sequences of length i by $\mathcal{C}^i$.

For a $\mathbf{c} \in \mathcal{C}^i$, we use the notation $\mathbf{c}^0 = \emptyset$, and $\mathbf{c}^j = (e^1, \ldots, e^j)$ for all $j \in [1, i]$; note that $\mathbf{c}^i = \mathbf{c}$. Let $\mathbf{e}_i = (e_1, \ldots, e_i)$ denote the sequence of *random variables* representing the edges actually chosen at each step by the algorithm up to iteration i, with $\mathbf{e}_0 = \emptyset$ and $\mathbf{e}_j = (e_1, \ldots, e_j)$ for all $j \in [1, i]$.

In the analysis, we will apply the law of total probability over the events that the algorithm picks the edges given by a certain feasible sequence $\mathbf{c} \in \mathcal{C}^i$, that is, $\mathbf{e}_i = \mathbf{c}^i$.

We break the analysis into three steps.

1. Unfolding the probability $\mathbb{P}\left[\ T = i\ \right]$

Given the above notation, we have

$$\begin{aligned}
&\mathbb{P}\left[\ T = i\ \right] = \mathbb{P}\left[\ E \cap \mathcal{E}_1 \neq \emptyset,\ \ldots,\ E \cap \mathcal{E}_i \neq \emptyset,\ E \cap \mathcal{E}_{i+1} = \emptyset\ \right] \\
&= \sum_{\mathbf{c} \in \mathcal{C}^i} \mathbb{P}\left[\ E \cap \mathcal{E}_1(\mathbf{c}^0) \neq \emptyset,\ \ldots,\ E \cap \mathcal{E}_i(\mathbf{c}^{i-1}) \neq \emptyset,\ E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \ \middle|\ \mathbf{e}_i = \mathbf{c}^i\ \right] \cdot \mathbb{P}\left[\ \mathbf{e}_i = \mathbf{c}^i\ \right] \\
&\le \sum_{\mathbf{c} \in \mathcal{C}^i} \mathbb{P}\left[\ E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \ \middle|\ \mathbf{e}_i = \mathbf{c}^i\ \right] \cdot \mathbb{P}\left[\ \mathbf{e}_i = \mathbf{c}^i\ \right].
\end{aligned}$$

Note that $\mathcal{E}_{i+1}(\mathbf{c}^i)$ is a fixed set once we are given $\mathbf{c}^i = (e^1, \ldots, e^i)$. Using Bayes' theorem, we can express the conditional probabilities on the R.H.S. of the above inequality as

$$\mathbb{P}\left[\ E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \ \middle|\ \mathbf{e}_i = \mathbf{c}^i\ \right] = \frac{\mathbb{P}\left[\ \mathbf{e}_i = \mathbf{c}^i \ \middle|\ E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset\ \right] \cdot \mathbb{P}\left[\ E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset\ \right]}{\mathbb{P}\left[\ \mathbf{e}_i = \mathbf{c}^i\ \right]}.$$

Thus, we get

$$\mathbb{P}\left[\, T = i \,\right] \leq \sum_{\mathbf{c}\in\mathcal{C}^i} \mathbb{P}\left[\, \mathbf{e}_i = \mathbf{c}^i \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \,\right] \cdot \mathbb{P}\left[\, E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \,\right].$$

Fixing $\mathbf{e}_i = \mathbf{c}^i$ completely determines the set of edges in $\mathcal{E}_{i+1}(\mathbf{c}^i)$, and so

$$= \sum_{\mathbf{c}\in\mathcal{C}^i} \mathbb{P}\left[\, \mathbf{e}_i = \mathbf{c}^i \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \,\right] \cdot (1-p)^{|\mathcal{E}_{i+1}(\mathbf{c}^i)|}.$$

We now proceed by bounding the probability $\mathbb{P}\left[\, \mathbf{e}_i = \mathbf{c}^i \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \,\right]$, iteration by iteration:

$$\begin{aligned}
&\mathbb{P}\left[\, \mathbf{e}_i = \mathbf{c}^i \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \,\right] \\
&= \mathbb{P}\left[\, e_i = e^i \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{i-1} = \mathbf{c}^{i-1} \,\right] \cdot \mathbb{P}\left[\, \mathbf{e}_{i-1} = \mathbf{c}^{i-1} \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset \,\right] \\
&= \ldots = \prod_{j=1}^{i} \mathbb{P}\left[\, e_j = e^j \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset, \mathbf{e}_{j-1} = \mathbf{c}^{j-1} \,\right],
\end{aligned}$$

recalling that $\mathbf{e}_0 = \mathbf{c}^0 = \emptyset$. We conclude that

$$\mathbb{P}\left[\, T = i \,\right] \leq \sum_{\mathbf{c}\in\mathcal{C}^i} (1-p)^{|\mathcal{E}_{i+1}(\mathbf{c}^i)|} \cdot \prod_{j=1}^{i} \mathbb{P}\left[\, e_j = e^j \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset, \mathbf{e}_{j-1} = \mathbf{c}^{j-1} \,\right]. \tag{3}$$

2. Bounding the probabilities $\mathbb{P}[\, e_j = e^j \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1} \,],\ j \in [1, i]$

Note that the condition $\mathbf{e}_{j-1} = \mathbf{c}^{j-1}$ fixes the set $\mathcal{E}_j(\mathbf{c}^{j-1})$. As e_j was picked uniformly from $E \cap \mathcal{E}_j(\mathbf{c}^{j-1})$, we further condition on all possible choices of $E \cap \mathcal{E}_j(\mathbf{c}^{j-1})$, with the constraint that $E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset$:

$$\begin{aligned}
&\mathbb{P}\left[\, e_j = e^j \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1} \,\right] \\
&= \sum_{S' \subseteq \mathcal{E}_j(\mathbf{c}^{j-1})} \left(\mathbb{P}\left[\, e_j = e^j \;\middle|\; E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1},\ E \cap \mathcal{E}_j(\mathbf{c}^{j-1}) = S' \,\right] \right) \\
&\qquad\qquad \cdot \left(\mathbb{P}\left[\, E \cap \mathcal{E}_j(\mathbf{c}^{j-1}) = S' \;\middle|\; E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1} \,\right] \right)
\end{aligned}$$

Note that if S' is such that $e^j \notin S'$, then the first probability in the above product is 0. Similarly, if $S' \cap \mathcal{E}_{i+1}(\mathbf{c}^i) \neq \emptyset$, then the second probability is equal to 0. Continuing,

$$\begin{aligned}
&= \sum_{\substack{S' \subseteq \mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i): \\ e^j \in S'}} \left(\mathbb{P}\left[\, e_j = e^j \;\middle|\; E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1},\ E \cap \mathcal{E}_j(\mathbf{c}^{j-1}) = S' \,\right] \right) \\
&\qquad\qquad \cdot \left(\mathbb{P}\left[\, E \cap \mathcal{E}_j(\mathbf{c}^{j-1}) = S' \;\middle|\; E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1} \,\right] \right) \\
&= \sum_{\substack{S' \subseteq \mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i): \\ e^j \in S'}} \left(\frac{1}{|S'|} \right) \cdot \left(p^{|S'|} \cdot (1-p)^{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)| - |S'|} \right).
\end{aligned}$$

Rearranging the sum by the sizes of the S''s containing e^j:

$$= \sum_{\ell=1}^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|} \binom{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)| - 1}{\ell - 1} \cdot \frac{1}{\ell} \cdot p^\ell \cdot (1-p)^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|-\ell}$$

$$= \sum_{\ell=1}^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|} \frac{\ell}{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|} \binom{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|}{\ell} \cdot \frac{1}{\ell} \cdot p^\ell \cdot (1-p)^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|-\ell}$$

$$= \frac{1}{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|} \sum_{\ell=1}^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|} \binom{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|}{\ell} \cdot p^\ell \cdot (1-p)^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|-\ell}.$$

Using the Binomial theorem, and adjusting for the case $\ell = 0$,

$$= \frac{1}{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|} \left((p + (1-p))^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|} - (1-p)^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|} \right)$$

$$= \frac{1}{|\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|} \left(1 - (1-p)^{|\mathcal{E}_j(\mathbf{c}^{j-1})\setminus\mathcal{E}_{i+1}(\mathbf{c}^i)|} \right).$$

We can thus conclude that, setting $a = |\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)|$,

$$\mathbb{P}\left[\ e_j = e^j \mid E \cap \mathcal{E}_{i+1}(\mathbf{c}^i) = \emptyset,\ \mathbf{e}_{j-1} = \mathbf{c}^{j-1}\ \right] = \frac{1}{a}\left(1 - (1-p)^a\right) \leq p, \tag{4}$$

where the last bound follows from Bernoulli's inequality $(1+x)^r \geq 1 + rx$ for $x \geq -1$ and $r \geq 1$, which holds in our case since $x = -p \geq -1$ and $r = |\mathcal{E}_j(\mathbf{c}^{j-1}) \setminus \mathcal{E}_{i+1}(\mathbf{c}^i)| \geq 1$.

3. Putting everything together

Let $k_i = \left|\mathcal{E}_i(\mathbf{c}^{i-1})\right| = |X_i|^{2-\alpha} = (n - 2(i-1))^{2-\alpha}$.

Continuing Equation (3) together with the bound from Equation (4), we get

$$\mathbb{P}\left[\ T = i\ \right] \leq (1-p)^{k_{i+1}} \cdot \sum_{\mathbf{c}\in\mathcal{C}^i} \prod_{j=1}^{i} p \ = \ (1-p)^{k_{i+1}} \cdot k_1 \cdot k_2 \cdots k_i \cdot p^i.$$

Summing the above over all iterations,

$$\mathbb{P}\left[\ T \leq i\ \right] \leq (1-p)^{k_1} + \sum_{\ell=1}^{i} (1-p)^{k_{\ell+1}} \cdot k_1 \cdot k_2 \cdots k_\ell \cdot p^\ell$$

Using that $k_1 \geq k_2 \geq \cdots \geq k_{i+1}$,

$$\mathbb{P}\left[\ T \leq i\ \right] \leq (1-p)^{k_{i+1}} + \sum_{\ell=1}^{i} (1-p)^{k_{i+1}} \cdot k_1^\ell \cdot p^\ell = (1-p)^{k_{i+1}} \cdot \sum_{\ell=0}^{i} (k_1 \cdot p)^\ell.$$

Thus, for $i = n/4$, using that $pk_1 = pn^{2-\alpha} \geq 2n \ln n \geq 2$, we obtain

$$\begin{aligned}
\mathbb{P}\left[\ T \leq n/4\ \right] &\leq (1-p)^{k_{n/4+1}} \sum_{\ell=0}^{n/4} (pk_1)^\ell \\
&= (1-p)^{k_{n/4+1}} \frac{(pk_1)^{n/4+1} - 1}{pk_1 - 1} < (1-p)^{k_{n/4+1}} \frac{(pk_1)^{n/4+1}}{pk_1 - 1} \\
&= (1-p)^{k_{n/4+1}} \cdot \frac{(pk_1)}{pk_1 - 1} \cdot (pk_1)^{n/4} \leq (1-p)^{k_{n/4+1}} \cdot 2 \cdot (pk_1)^{n/4} \quad \left(pk_1 > 2\right) \\
&\leq \exp(-pk_{n/4+1}) \cdot 2 \cdot k_1^{n/4}.
\end{aligned}$$

Substituting $k_1 = n^{2-\alpha}$, $k_{n/4+1} = (n/2)^{2-\alpha} \geq n^{2-\alpha}/4$ and $p = \frac{2\ln n}{n^{1-\alpha}} + \frac{4\ln(2/\delta)}{n^{2-\alpha}}$, we conclude

$$\mathbb{P}[\, T \leq n/4 \,] \leq 2\exp\left(-\frac{n\ln n}{2} - \ln\frac{2}{\delta}\right)\cdot\left(n^{2-\alpha}\right)^{n/4} = 2\cdot\frac{1}{n^{n/2}}\cdot\frac{\delta}{2}\cdot n^{n/2-\alpha n/4}$$
$$= n^{-\alpha n/4}\cdot\delta \leq \delta.$$

Therefore, with probability at least $1-\delta$, RelaxedMWU returns a matching of size at least $n/4$, which concludes the proof of Lemma 9. ◀

▶ Remark. In the last equation, to get failure probability at most δ, we crucially need the fact that at the final iteration i, we still have $k_i \geq n^{2-\alpha}/4$, which limits the range of i. This is the technical reason why we can only guarantee that E contains a good partial matching, but the analysis breaks for perfect matchings.

5 Proof of Optimality

In this section we present the proof of Lemma 2. Let X be the set of $n = \left\lfloor n_0^{1/d}\right\rfloor^d$ points defined as $\left[\,1, \left\lfloor n_0^{1/d}\right\rfloor\,\right] \times \cdots \times \left[\,1, \left\lfloor n_0^{1/d}\right\rfloor\,\right] \subset \mathbb{Z}^d$, and let $\mathcal{S}$ consist of the $d\cdot\left\lfloor n_0^{1/d}\right\rfloor$ subsets of X induced by half-spaces of the form

$$H_{i,j} = \left\{x \in \mathbb{R}^d \;:\; x_i \leq j + 1/2\right\}, \quad i = 1,\ldots,d,\ j = 1,\ldots\left\lfloor n_0^{1/d}\right\rfloor.$$

Observe that for any edge $\{x,y\} \in \binom{X}{2}$, the number of sets in $\mathcal{S}$ that crosses $\{x,y\}$ is precisely the ℓ_1-distance[2] of x and y. Using this observation, it is easy to see that for any $k \in \mathbb{N}^+$ and $x \in X$, the number of edges $\{x,y\}$ that are crossed by at most k sets from $\mathcal{S}$ is $O(k^d)$. Thus, there is an absolute constant c_0 (depending on d) such that the total number of edges in $\binom{X}{2}$ crossed by at most k sets from $\mathcal{S}$ is at most $c_0\cdot nk^d$. We refer to these edges as *k-good* and denote their set with $\mathcal{G}_k$.

Let $p(n) = o(n^{\alpha-1})$ and E be a uniform random sample of edges, where each edge of $\binom{X}{2}$ is picked with probability $p(n)$. Setting $k_{p,c}(n) = \left(\frac{1}{4c\cdot c_0 p(n)}\right)^{1/d}$, the expected number of $k_{p,c}(n)$-good edges in E is

$$\mathbb{E}\left[\,|E\cap\mathcal{G}_{k_{p,c}(n)}|\,\right] \leq c_0 n\left(k_{p,c}(n)\right)^d\cdot p(n) = \frac{n}{4c}.$$

Thus, by Markov's inequality, we have $|E\cap\mathcal{G}_{k_{p,c}(n)}| \leq \frac{n}{2c}$ with probability at least $1/2$. Assume that $|E\cap\mathcal{G}_{k_{p,c}(n)}| \leq \frac{n}{2c}$ holds and let $M \subset E$ be any subset of size $\frac{n}{c}$. Then M contains at least $\frac{n}{2c}$ edges which are not $k_{p,c}(n)$-good. Therefore, the number of crossings between the edges of M and the sets of $\mathcal{S}$ is at least

$$\frac{n}{2c}\cdot\left(\frac{1}{4c\cdot c_0\cdot p(n)}\right)^{1/d}.$$

Recall that $|\mathcal{S}| = d\cdot\left\lfloor n_0^{1/d}\right\rfloor \leq dn^{1/d}$ and so by the pigeonhole principle, we get that there is a set in $\mathcal{S}$ that crosses at least

[2] The ℓ_1-distance of x and y is defined as $\ell_1(x,y) = \sum_{i=1}^d |x_i - y_i|$, where x_i is the i-th coordinate of x.

$$\frac{\frac{n}{2c}\cdot\left(\frac{1}{4c\cdot c_0 p(n)}\right)^{1/d}}{|\mathcal{S}|} \geq \frac{\frac{n}{2c}\cdot\left(\frac{1}{4c\cdot c_0 p(n)}\right)^{1/d}}{dn^{1/d}} = \frac{1}{2c\cdot d\cdot(4c\cdot c_0)^{1/d}}\cdot n^{1-1/d}\underbrace{\left(\frac{1}{p(n)}\right)^{1/d}}_{\omega\left(n^{(1-\alpha)/d}\right)}$$

$$= \omega_{d,c}\cdot\left(n^{1-\alpha/d}\right)$$

edges of M. This concludes the proof of Lemma 2. ◀

A Appendix

A.1 Proof of Corollary 3

The algorithm achieving the guarantees of Corollary 3 is presented in MatchingPresampled. It is essentially the algorithm presented in [13] run on an initial random sample of edges with a small modification: to incorporate the pre-sampling step in the analysis, we need to recurse slightly more often (after $n/16$ steps instead of $n/4$).

We use the following key lemma for PartialMatching.

▶ **Lemma 13** ([13]). *Let $\tilde{E} \subset E$ denote the set of edges that have non-zero weight when* PartialMatching$\big((X,\mathcal{S}),E,\kappa\big)$ *terminates. Then*

$$\mathbb{E}\left[\max_{S\in\mathcal{S}}\sum_{i=1}^{n/16}\mathrm{I}\left(e_i,S\right)\right]\leq 2\cdot\mathbb{E}\left[\min_{e\in\tilde{E}}\sum_{i=1}^{n/16}\mathrm{I}\left(e,S_i\right)\right]+O\left(\kappa+\ln|E|+\ln|\mathcal{S}|\right). \tag{5}$$

Algorithm 3 MatchingPresampled$\big((X,\mathcal{S}),d,\alpha\big)$.

$M \leftarrow \emptyset$
while $|X| > 16$ **do**
  $n \leftarrow |X|$
  $E \leftarrow$ sample of $O(n^{1+\alpha}\ln n)$ edges from $\binom{X}{2}$
  $\{e_1,\ldots,e_{n/16}\} \leftarrow$ PartialMatching$\big((X,\mathcal{S}),E,(n/16)^{1-\alpha/d}\big)$
  $M \leftarrow M \cup \{e_1,\ldots,e_{n/16}\}$
  $X \leftarrow X \setminus \text{endpoints}(M)$
match the remaining elements of X randomly and add the edges to M
return M

Algorithm 4 PartialMatching$\big((X,\mathcal{S}),E,\kappa\big)$.

$\omega_1(e) \leftarrow 1, \quad \pi_1(S) \leftarrow 1 \qquad \forall e \in E,\ S \in \mathcal{S}$
$\mathbf{p} \leftarrow \min\{106\cdot|X|/\kappa^2\cdot\ln(|E|\cdot|X|/16),\,1\}$
$\mathbf{q} \leftarrow \min\{39\cdot|X|/\kappa^2\cdot\ln(|\mathcal{S}|\cdot|X|/16),\,1\}$
for $i = 1,\ldots,|X|/16$ **do**
  $\omega_i(E) \leftarrow \sum_{e\in E}\omega_i(e)$
  $\pi_i(\mathcal{S}) \leftarrow \sum_{S\in\mathcal{S}}\pi_i(S)$
  choose $e_i \sim \omega_i$; // $\mathbb{P}[e_i = e] = \frac{\omega_i(e)}{\omega_i(E)} \quad \forall e \in E$
  choose $S_i \sim \pi_i$; // $\mathbb{P}[S_i = S] = \frac{\pi_i(S)}{\pi_i(\mathcal{S})} \quad \forall S \in \mathcal{S}$
  $E_i \leftarrow$ sample from E with probability $\mathbf{p}$; // $\mathbb{P}[e \in E_i] = \mathbf{p} \quad \forall e \in E$
  $\mathcal{S}_i \leftarrow$ sample from $\mathcal{S}$ with probability $\mathbf{q}$; // $\mathbb{P}[S \in \mathcal{S}_i] = \mathbf{q} \quad \forall S \in \mathcal{S}$
  ; // $\mathrm{I}(e,S) = 1$ if e crosses S, $\mathrm{I}(e,S) = 0$ otherwise
  for $e \in E_i$ **do**
    $\omega_{i+1}(e) \leftarrow \omega_i(e)\big(1 - \frac{1}{2}\mathrm{I}(e,S_i)\big)$; // halve weight if S_i crosses e
  for $S \in \mathcal{S}_i$ **do**
    $\pi_{i+1}(S) \leftarrow \pi_i(S)\big(1 + \mathrm{I}(e_i,S)\big)$; // double weight if S crosses e_i
  set the weight in ω_{i+1} of e_i and of each edge adjacent to e_i to zero
return $\{e_1,\ldots,e_{|X|/16}\}$

In MatchingPresampled, the subroutine PartialMatching is called with the parameter $\kappa = (n/16)^{1-\alpha/d}$, thus we get the following bound on the expected crossing number of $\{e_1,\ldots,e_{n/16}\}$:

$$\mathbb{E}\left[\max_{S\in\mathcal{S}}\sum_{i=1}^{n/16}\mathrm{I}(e_i,S)\right] \le \frac{1}{2}\cdot\mathbb{E}\left[\min_{e\in\tilde{E}}\sum_{i=1}^{n/16}\mathrm{I}(e,S_i)\right] + O\left(n^{1-\alpha/d}\right). \tag{6}$$

The left-hand side of Equation (5) is precisely the expected crossing number of the edges returned by PartialMatching. It remains to bound the expectation on the right-hand side of Equation (6). By Lemma 1, with probability at least $1-\frac{1}{n}$, the initial sample E contains a matching M_0 of size $\lceil n/4\rceil$ with crossing number

$$c_0\cdot\left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right)$$

for some fixed constant c_0. Assume that it happens, then clearly $M_0 \cap \tilde{E}$ also has crossing number at most $c_0\cdot\left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right)$ with respect to $\mathcal{S}$. Moreover, since we only zeroed the weights of edges adjacent to $2\cdot n/16$ distinct vertices of X, there are at least $n/8$ edges of

M_0 with positive weight when PartialMatching terminates. That is, $\left|M_0 \cap \tilde{E}\right| \geq n/8$ and $n/8 > 0$ since $n > 16$ at each call of PartialMatching . By the pigeonhole principle, there is an edge in $M_0 \cap \tilde{E}$ which is crossed by at most

$$\frac{c_0 \cdot \left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right) \cdot n/16}{n/8} = O\left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right)$$

sets from $S_1, \ldots, S_{n/16}$. Therefore, we have

$$\mathbb{E}\left[\max_{S\in\mathcal{S}} \sum_{i=1}^{n/16} \mathrm{I}(e_i, S)\right] \leq \frac{1}{2} \cdot \mathbb{E}\left[\min_{e\in\tilde{E}} \sum_{i=1}^{n/16} \mathrm{I}(e, S_i)\right] + O\left(n^{1-\alpha/d}\right) = O\left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right),$$

where the last bound holds with with probability at least $1 - \frac{1}{n}$. Since the crossing number of any matching of X is at most $n/2$, the expected crossing number of the matching returned by the subroutine PartialMatching$\left((X,\mathcal{S}), E, (n/16)^{1-\alpha/d}\right)$ is $O\left(n^{1-\alpha/d} + \ln|\mathcal{S}|\right)$.

The bottleneck algorithmic step in PartialMatching is to update the weights of edges and sets belonging to E_i and $\mathcal{S}_i$ at each iteration $i = 1, \ldots, n/16$.

For any i, we have $\mathbb{E}[\,|E_i| + |\mathcal{S}_i|\,] = \tilde{O}\left(n^{1+\alpha}\mathbf{p} + m\mathbf{q}\right)$, thus in expectation, the total running time is $O\left(n\left(n^{1+\alpha} \cdot \min\{n/\kappa^2 \ln n,\, 1\} + m \cdot \min\{n/\kappa^2 \ln m,\, 1\}\right)\right) = \tilde{O}\left(n^{1+\alpha+\frac{2\alpha}{d}} + mn^{\frac{2\alpha}{d}}\right)$.

The algorithm MatchingPresampled makes $\log n$ calls to PartialMatching with exponentially decreasing input sizes. It can easily be deduced that MatchingPresampled returns a matching with expected crossing number $O\left(n^{1-\alpha/d} + \ln|\mathcal{S}| \ln n\right)$ in expected time $\tilde{O}\left(n^{1+\alpha+\frac{2\alpha}{d}} + mn^{\frac{2\alpha}{d}}\right)$. This concludes the proof of Corollary 3. ◀

A.2 Proof of Corollary 5

Now we deduce how Corollary 3 implies Corollary 5. The randomized algorithm that achieves the guarantees of Corollary 5 is presented in Algorithm 5.

Algorithm 5 LowDiscColorPresampled$\left((X,\mathcal{S}), d, \alpha\right)$.

$n \leftarrow |X|$
$\{e_1, \ldots, e_{\lceil n/2\rceil}\} \leftarrow$ MatchingPresampled$\left((X,\mathcal{S}), d, \alpha\right)$
for $i = 1, \ldots, \lceil n/2\rceil$ **do**
  $\{x_i, y_i\} \leftarrow$ endpoints (e_i)
  $\chi(x_i) = \begin{cases} 1 & \text{with probability } 1/2 \\ -1 & \text{with probability } 1/2 \end{cases}$
  $\chi(y_i) = -\chi(x_i)$; // we skip this step if $y_i = x_i$
return χ

▶ **Lemma 14.** *Let $(X,\mathcal{S})$ be a set system, $n = |X|$, $m = |\mathcal{S}| \geq 34$, and let M be a perfect matching of X with crossing number κ with respect to $\mathcal{S}$ and for each edge $\{x, y\} \in M$ define*

$$\chi_M(x) = \begin{cases} 1 & \textit{with probability } 1/2 \\ -1 & \textit{with probability } 1/2 \end{cases}$$

and $\chi_M(y) = -\chi_M(x)$. Then the expected discrepancy of χ_M is at most $\sqrt{3\kappa \ln m}$.

▶ Remark. A "high probability version" of Lemma 14 is well-known [27, Lemma 2.5] and implies the above bound.

Corollary 3 and Lemma 14 immediately imply that the algorithm LowDiscColorPresampled constructs a coloring with expected discrepancy $O\left(\sqrt{n^{1-\alpha/d}\ln m + \ln^2 m \log n}\right)$, in time $\tilde{O}\left(n^{1+\alpha+2\alpha/d} + |\mathcal{S}| \cdot n^{2\alpha/d}\right)$. This concludes the proof of Corollary 5. ◀

Proof of Lemma 14. Let $S \in \mathcal{S}$ be a fixed range. We express the sum $\chi_M(S)$ of colors over elements of S as

$$\chi_M(S) = \sum_{\{x,y\}\in M; x,y\in S} (\chi_M(x) + \chi_M(y)) + \sum_{x\in \mathrm{cr}(S,M)} \chi_M(x) = \sum_{x\in \mathrm{cr}(S,M)} \chi_M(x) \ ,$$

where $\mathrm{cr}(S,M) = \{x \in S : \{x,y\} \in M, y \notin S\}$. Since $\mathrm{cr}(S,M) \le \kappa$ for any $S \in \mathcal{S}$, $\mathrm{disc}(S,\chi_M)$ is a sum of at most κ *independent* random variables. We use the following concentration bound from [4].

▷ Claim 15 (Theorem A.1.1 from [4]). Let $X_1, \ldots, X_k$ be independent $\{-1,1\}$-valued random variables with $\mathbb{P}[X_i = -1] = \mathbb{P}[X_i = 1] = 1/2$. Then for any $\alpha \ge 0$

$$\mathbb{P}\left[\ \left|\sum_{i=1}^{k} X_i\right| > \alpha\ \right] \le 2e^{-\alpha^2/2k}.$$

Applying Claim 15, we get that for any fixed $S \in \mathcal{S}$ and $\alpha > 0$,

$$\mathbb{P}\left[\ |\chi_M(S)| > \alpha\ \right] \le 2e^{-\alpha^2/2\kappa}.$$

By the union bound, we get

$$\mathbb{P}\left[\ \mathrm{disc}_{\mathcal{S}}(\chi_M) > \alpha\ \right] = \mathbb{P}\left[\ \max_{S\in\mathcal{S}} |\chi_M(S)| > \alpha\ \right] \le m \cdot 2e^{-\alpha^2/2\kappa}.$$

Finally, we bound the expected discrepancy by applying Fubini's theorem

$$\mathbb{E}\left[\ \mathrm{disc}_{\mathcal{S}}(\chi_M)\ \right] \stackrel{\mathrm{def}}{=} \int_0^\infty \mathbb{P}\left[\ \mathrm{disc}_{\mathcal{S}}(\chi_M) > \alpha\ \right] d\alpha \le \int_0^\infty \min\left\{2m \cdot e^{-\alpha^2/2\kappa},\ 1\right\} d\alpha$$

$$= \int_0^{\sqrt{2\kappa\ln(2m)}} 1 d\alpha + \int_{\sqrt{2\kappa\ln(2m)}}^\infty 2m \cdot e^{-\alpha^2/2\kappa} d\alpha = \sqrt{2\kappa\ln(2m)} + 2m\sqrt{2\kappa} \int_{\sqrt{\ln(2m)}}^\infty e^{-t^2}\ dt$$

$$= \sqrt{2\kappa\ln(2m)} + 2m\sqrt{2\kappa} \int_{\sqrt{\ln(2m)}}^\infty \frac{t}{t} \cdot e^{-t^2}\ dt \le \sqrt{2\kappa\ln(2m)} + 2m\sqrt{\frac{2\kappa}{\ln(2m)}} \int_{\sqrt{\ln(2m)}}^\infty te^{-t^2}\ dt$$

$$= \sqrt{2\kappa\ln(2m)} + 2m\sqrt{\frac{2\kappa}{\ln(2m)}} \left[\ -\frac{e^{-t^2}}{2}\ \right]_{\sqrt{\ln(2m)}}^\infty = \sqrt{2\kappa\ln(2m)} + \sqrt{\frac{\kappa}{2\ln(2m)}} \le \sqrt{3\kappa\ln m},$$

if $m \ge 34$. This concludes the proof of Lemma 14. ◀

Fully-Scalable MPC Algorithms for Clustering in High Dimension

Abstract

We design new parallel algorithms for clustering in high-dimensional Euclidean spaces. These algorithms run in the Massively Parallel Computation (MPC) model, and are *fully scalable*, meaning that the local memory in each machine may be n^σ for arbitrarily small fixed $\sigma > 0$. Importantly, the local memory may be substantially smaller than the number of clusters k, yet all our algorithms are fast, i.e., run in $O(1)$ rounds.

We first devise a fast MPC algorithm for $O(1)$-approximation of uniform Facility Location. This is the first fully-scalable MPC algorithm that achieves $O(1)$-approximation for any clustering problem in general geometric setting; previous algorithms only provide $\mathrm{poly}(\log n)$-approximation or apply to restricted inputs, like low dimension or small number of clusters k; e.g. [Bhaskara and Wijewardena, ICML'18; Cohen-Addad et al., NeurIPS'21; Cohen-Addad et al., ICML'22]. We then build on this Facility Location result and devise a fast MPC algorithm that achieves $O(1)$-bicriteria approximation for k-Median and for k-Means, namely, it computes $(1+\varepsilon)k$ clusters of cost within $O(1/\varepsilon^2)$-factor of the optimum for k clusters.

A primary technical tool that we introduce, and may be of independent interest, is a new MPC primitive for geometric aggregation, namely, computing for every data point a statistic of its approximate neighborhood, for statistics like range counting and nearest-neighbor search. Our implementation of this primitive works in high dimension, and is based on consistent hashing (aka sparse partition), a technique that was recently used for streaming algorithms [Czumaj et al., FOCS'22].

1 Introduction

Clustering large data sets is a fundamental computational task that has been studied extensively due to its wide applicability in data science, including, e.g., unsupervised learning, classification, data mining. Two highly popular and extremely basic problems are k-Median and k-Means. In the geometric (Euclidean) setting, the k-Median problem asks, given as input an integer k and a set $P \subseteq \mathbb{R}^d$ of n data points, to compute a set $C \subset \mathbb{R}^d$ of k center points, so as to minimize the sum of distances from each point in P to its nearest center. The k-Means problem is similar except that instead of the sum of distances, one minimizes the sum of squares of distances. A closely related problem is (uniform) Facility Location, which can be viewed as a Lagrangian relaxation of k-Median, where the number of centers can vary but it adds a penalty to the objective, namely, each center (called open facility) incurs a given cost $\mathfrak{f} > 0$. Other variants include a similar relaxation of k-Means, or generalizing the squaring each distance to raising it to power $z \geq 1$ (see Section 2 for formal definitions), and there is a vast literature on these computational problems.

Clustering is often performed on massive datasets, and it is therefore important to study clustering in the framework of distributed and parallel computations. We consider fundamental clustering problems in the theoretical model of *Massively Parallel Computation (MPC)*, which captures key aspects of modern large-scale computation systems, such as MapReduce, Hadoop, Dryad, or Spark. The MPC model was introduced over a decade ago by Karloff, Suri, and Vassilvitskii [55], and over time has become the standard theoretical model to study data-intensive parallel algorithms (see, e.g., [11, 41, 47]). At a high level, the MPC model consists of many machines that communicate with each other synchronously in a constrained manner, in order to solve a desired task in a few rounds. In more detail, an MPC system has m *machines*, each with a *local memory* of s words, hence the system's *total memory* is the product $m \cdot s$. Computation takes place in synchronous rounds, where machines perform arbitrary computations on their local memory and then exchange messages with other machines. Every machine is constrained to send and receive at most s words in every round, and every message must be destined to a single machine (not a broadcast). At each round, every machine processes its incoming messages to generate its outgoing messages, usually without any computational restrictions on this processing (e.g., running time). At the end of the computation, the machines collectively output the solution. The efficiency of an algorithm is measured by the *number of rounds* and by the local-memory size s. The total space should be low as well, but this is typically of secondary importance.

The local-memory size s is a key parameter and should be sublinear in the input size N (for if $s \geq N$ then any sequential algorithm can be executed locally by a single machine in one round). We focus on the more challenging regime, called *fully-scalable MPC*, where the local-memory size is an arbitrarily small polynomial, i.e., $s = N^\sigma$ for any fixed $\sigma \in (0, 1)$. This regime is highly desirable because in practice, the local memory of the machines is limited by the hardware available at hand, and the parameter σ can be used to model this limitation. The total memory should obviously be large enough to fit the input, i.e., $m \cdot s \geq N$, and ideally not much larger.

Modern research on MPC algorithms aims to solve fundamental problems in as few rounds as possible, ideally in $O(1)$ rounds, even in the fully-scalable regime, and so far there have been some successes in designing fast (i.e., $O(1)$-rounds) algorithms for fixed $\sigma < 1$; see e.g., [4, 12, 41]. In contrast, many graph problems, including fundamental ones such as connectivity or even distinguishing between 1 and 2 cycles, seem to require super-constant number of rounds (at the same time, proving a super-constant lower bound would yield a breakthrough in circuit complexity [62]). One can also consider smaller local space s, i.e., $\sigma = o(1)$, and in fact many algorithms work as long as $s \geq \text{polylog}(N)$. In this regime, the best one can hope for is usually not $O(1)$ but rather $O(\log_s N)$ rounds, because even broadcasting a single number to all machines requires $\Omega(\log_s N)$ rounds; see [62] for further discussion.

Clustering of massive datasets has received significant attention recently, with numerous algorithms that span multiple computational models, such as streaming [18, 63] or distributed and parallel models [16, 35, 15, 8, 9, 60, 6, 21, 12, 34]. However, this advance is facing a barrier, first identified by Bhaskara and Wijewardena [13]: State-of-the-art methods for k-clustering (i.e., when the number k of clusters is specified in the input) typically fail to yield fully-scalable MPC algorithms, because when implemented in the MPC model, these methods usually require local-memory size $s \geq \Omega(k)$. For example, many streaming algorithms for k-clustering problems are based on a linear sketch and thus readily applicable to the MPC model; however, all known streaming algorithms require $\Omega(k)$ space, and in fact there are lower bounds to this effect [23] even in low dimension. Another example is coresets [43], an extremely effective method to decrease the size of the dataset, even in high dimension; see [29, 17, 26] for the latest in this long line of research. Coresets can often be merged and/or applied repeatedly via the so-called "merge-and-reduce" framework [43], and can thus be applied successfully in many different settings, including the parallel setting. However, this method suffers from the drawback (which so far seems inherent) that each coreset must be stored in its entirety in a single machine, and it is easy to see that a coreset for k-clustering must be of size at least k; see also [26].

These shortcomings have led to a surge of interest in MPC algorithms for clustering, with emphasis on fully-scalable and fast algorithms (i.e., taking $O(1)$ rounds even for large k) that work in high dimension d. The first such result for k-clustering was by Bhaskara and Wijewardena [13]; their $O(1)$-round fully-scalable MPC algorithm achieves polylogarithmic bicriteria approximation for k-Means, i.e., it outputs $k \cdot \text{polylog}(n)$ centers (or clusters) whose cost is within $\text{polylog}(n)$-factor of the optimum for k centers. Recent work by Cohen-Addad et al. [27] achieves for k-Median a true $\text{polylog}(n)$-approximation (i.e., without violating the bound k on number of centers); their algorithm actually computes a hierarchical clustering, that is, a single hierarchical structure of centers that induces an approximate solution for k-Median for every k. These were the best fully-scalable $O(1)$-round MPC algorithms known for k-Median and k-Means prior to our work, and it remained open to achieve better than $O(\log n)$-approximation, even as a bicriteria approximation.

Not surprisingly, previous work on MPC algorithms has focused also on achieving improved approximation for restricted inputs. In particular, $(1+\varepsilon)$-approximation is achieved in [28] for k-Means and k-Median on inputs that are *perturbation-resilient* [14], meaning that perturbing pairwise distances by (bounded) multiplicative factors does not change the optimal clusters; unfortunately, results for such special cases rarely generalize to all inputs. There are also known fully-scalable MPC algorithms for k-center [10, 30], but they are applicable only in low dimension d and thus less relevant to our focus.

Despite these many advances on fully-scalable MPC algorithms, we are not aware of $O(1)$-approximation *for any clustering problem* in high dimension.[1] From a technical perspective, the primary difficulty is to distribute the data points across machines, so that points arriving to the same machine are from the same cluster. This task seems to require knowing the clustering, which is actually the desired output, so we run into a chicken-and-egg problem! Fortunately, powerful algorithmic tools can spot points that are close together, even in high-dimensional geometry. Namely, locality sensitive hashing (LSH) is employed in [13] and tree embedding is used in [27], but as mentioned above, these previous results do not achieve $O(1)$-approximation. We rely instead on the framework of *consistent hashing*, which was first employed for streaming algorithms in [33], although it was originally proposed in [53]; see Section 1.2 for details.

1.1 Our Results

We devise fully-scalable $O(1)$-round MPC algorithms for a range of clustering problems in $\mathbb{R}^d$, most notably Facility Location, k-Median, and k-Means. We first devise an $O(1)$-approximation algorithm for Facility Location and then exploit the connection between the problems to solve k-clustering.

By convention, we express memory bounds in machine words, where each word can store a counter in the range $[\mathrm{poly}(n)]$, i.e., $O(\log n)$ bits, and/or a coordinate of a point from $\mathbb{R}^d$ with restricted precision (comparable to that of a point from P). For example, the input $P \subset \mathbb{R}^d, |P| = n$ fits in nd words. Throughout, the notation $O_\varepsilon(\cdot)$ hides factors that depend on ε. We stress that in the next theorem, the memory bounds are polynomial in the dimension d (and not exponential); this is crucial because the most important case is $d = O(\log n)$, as explained in Remark 1.2f below.

▶ **Theorem 1.1** (Simplified version)**.** *Let $\varepsilon, \sigma \in (0,1)$ be fixed. There is a randomized fully-scalable MPC algorithm that, given a multiset $P \subset \mathbb{R}^d$ of n points distributed across machines with local memory of size $s \geq n^\sigma \cdot \mathrm{poly}(d)$, computes in $O_\sigma(1)$ rounds an $O_\varepsilon(1)$-approximation for uniform Facility Location. The algorithm uses $O(n^{1+\varepsilon}) \cdot \mathrm{poly}(d)$ total space.*

▶ Remark 1.2. This simplified statement omits standard technical details:

a) We consider here fixed σ, but the algorithm works for any local-memory size $s \geq \mathrm{poly}(d \log n)$, and in that case the number of rounds becomes $O(\log_s n)$.

b) Similarly, ε can be part of the input, and the approximation factor is in fact $(1/\varepsilon)^{O(1)}$.

c) The algorithm succeeds with high probability $1 - 1/\mathrm{poly}(n)$.

d) The input P can be a multiset, in contrast to streaming algorithms for such problems [49, 33], where data points must be distinct.

e) The algorithm outputs a feasible solution, i.e., a set of facilities $F \subset \mathbb{R}^d$ and an assignment of the input points to facilities. In fact, in all our algorithms $F \subseteq P$. We focus throughout on computing F, since our methods can easily compute a near-optimal assignment given F.

f) We state here the dependence on d explicitly for sake of completeness, but our result works whenever $s \geq \mathrm{polylog}(dn)$, which is preferable when $d \gg \log n$. This is achieved by reducing to the case $d = O(\log n)$, using a standard dimension reduction, as discussed in Remark 2.4.

[1] Having said that, $(3+\varepsilon)$-approximation is known for (non-geometric) correlation clustering [12].

Our full result (in the full version) is more general in two respects. First, it addresses a generalization of Facility Location where distances are raised to power $z \geq 1$ (see Section 2 for definitions). Second, it assumes access to consistent hashing with parameters Γ and Λ, and here we plugged in a known construction [33] that achieves a tradeoff $\Gamma = O(1/\varepsilon)$ and $\Lambda = n^{\varepsilon}$ for any desired $\varepsilon \in (0,1)$; see Lemma 2.3 and Remark 2.4. The description of the hash function should be included in our MPC algorithm, but it takes only $\mathrm{poly}(d)$ bits, which is easily absorbed in our bounds.

Previously, no fully-scalable MPC algorithm was known for Facility Location, although one can apply the algorithm for k-Median from [27] to obtain an $O(\mathrm{polylog}(n))$-approximation in $O(\log_s n)$ rounds. Another previous result that one could use is a streaming algorithm that achieves $O(1)$-approximation [33]. Although many streaming algorithms, including this one, can be implemented in the MPC model, they approximate the optimal value without reporting a solution; see Section 1.3 for details. Thus, from a technical perspective, our chief contribution is to compute an approximately optimal solution, which is a set of facilities F, in the fully-scalable regime.

k-Clustering. Our second result presents MPC algorithms for k-Median and k-Means that achieve an $(O(\mu^{-2}), 1+\mu)$-bicriteria approximation, for any desired $\mu \in (0,1)$. As usual, (α,β)-*bicriteria approximation* means that for every input, the algorithm outputs at most βk centers whose cost is at most α-factor larger than the optimum cost for k centers. By letting $\mu > 0$ be arbitrarily small but fixed, our algorithm gets arbitrarily close (multiplicatively) to k centers, while still approximating the optimal cost within $O(1)$-factor; in both respects, this is far stronger than the previous bicriteria approximation for k-Means [13]. Our result is incomparable to the previous bound for k-Median, which is a true $O(\mathrm{polylog}(n))$-approximation [27]. Nevertheless, our bicriteria approximation breaks a fundamental technical barrier in their tree-embedding approach, which cannot go below $O(\log n)$ ratio, due to known distortion lower bounds, and moreover does not generalize to k-Means, because it fails to preserve the squared distance.

Our approach is to tackle k-Median and k-Means via Lagrangian relaxation and rely on our algorithm for Facility Location. This approach can inherently handle large k, because our core algorithms for Facility Location can even output n clusters. The Lagrangian technique was initiated by Jain and Vazirani [51], who achieved a true $O(1)$-approximation for k-Median by leveraging special properties of their algorithm for Facility Location (see Section 1.2). However, their primal-dual approach for Facility Location seems challenging to implement in fully-scalable MPC. We thus develop an alternative approach that is inherently more parallel, albeit achieves only bicriteria approximation for k-clustering.

▶ **Theorem 1.3** (Simplified version). *Let $\varepsilon, \sigma \in (0,1)$ be fixed. There is a randomized fully-scalable MPC algorithm that, given $\mu \in (0,1)$, $k \geq 1$, and a multiset $P \subset \mathbb{R}^d$ of n points distributed across machines of memory $s \geq n^{\sigma} \cdot \mathrm{poly}(d)$, computes in $O_\sigma(1)$ rounds an $(O_\varepsilon(\mu^{-2}), 1+\mu)$-bicriteria approximation for k-Median, or alternatively k-Means. The algorithm uses $O(n^{1+\varepsilon}) \cdot d^{O(1)}$ total space.*

This simplified statement omits the same standard details as in Theorem 1.1, and Remark 1.2 applies here as well. In addition, it is known for k-Median and k-Means (but not known for Facility Location) that any (true) finite approximation requires $\Omega(\log_s n)$ rounds [13].

1.2 Technical Overview

We overview the main components in our algorithms, and highlight technical ideas that may find more applications in the future. We focus in this overview on Facility Location and k-Median, noting that our algorithm for k-Means (and other powers $z \geq 1$) is essentially the same. We further assume that $s = n^\sigma \cdot \text{poly}(d)$ for a fixed $\sigma \in (0, 1)$, and we aim to achieve round complexity $O(\log_s n) = O_\sigma(1)$.

Facility Location. Several different algorithmic approaches have been used in the past to achieve $O(1)$-approximation for Facility Location, including LP-rounding [19, 56], primal-dual [51], greedy [50], and local search [5]. Some of these sequential algorithms were adapted to the PRAM model [16], i.e., to run in polylogarithmic parallel time (RNC algorithms). These algorithms can be implemented in the MPC model, but as some logarithmic factors in the time complexity seem inherent, these fall short of $O(1)$ rounds in the fully-scalable regime. Our starting point is the Mettu-Plaxton (MP) algorithm [61], which is a combinatorial algorithm inspired by [51], that has been previously used to achieve $O(1)$-approximation in a few related models, particularly streaming, congested clique, and sublinear-time computation [7, 38, 33]. At a high level, this MP algorithm has two steps, it first computes a "radius" $r_p > 0$ for every $p \in P$, and then uses these r_p values to determine which facilities to open. However, implementing these steps in MPC is technically challenging:

- Computing r_p (approximately) can be reduced to counting the number of points in P within a certain distance from p [7], which is non-trivial to compute in $O(1)$ rounds, because many geometric techniques are ineffective in high dimension, for instance quadtrees/tree embeddings incur large approximation error and grids/nets require large memory. We overcome this issue by devising a new MPC primitive for geometric aggregation (in high dimension), that can handle a wide range of statistics, including the counting mentioned above.
- The MP algorithm determines which facilities to open by scanning the points in P in order of non-decreasing r_p value and deciding greedily whether to open each point as a facility. We design a new algorithm that avoids any sequential decision-making and decides whether to open each facility locally and in parallel. Our new algorithm may thus be useful also in other models.

Let us discuss these two new ideas in more detail.

MPC Primitive for Geometric Aggregation in High Dimension. We propose a new MPC primitive for aggregation tasks in high-dimensional Euclidean spaces (see Theorem 3.1 for details). Given a radius $r > 0$, this primitive outputs, for every data point $p \in P$, a certain statistic of the ball $B_P(p, r) := P \cap \{y \in \mathbb{R}^d : \text{dist}(x, y) \leq r\}$. Our implementation can handle any statistic that is defined by a *composable* function f, which means that $f(\cup_i S_i)$ for disjoint sets $S_i \subset \mathbb{R}^d$ can be evaluated from the values $\{f(S_i)\}_i$. Composable functions include counting the number of points, or finding the smallest label (when data points are labeled). In fact, this primitive can even be used for approximate nearest-neighbor search in parallel for all points (see Section 3.1). This natural aggregation tool plays a central role in all our MPC algorithms, and we expect it to be useful for other MPC algorithms in high dimension.

Technically, exact computation of such statistics may be difficult, and our algorithm estimates the statistic by evaluating it (exactly) on a set $A_P(p, r)$ that approximates the ball $B_P(p, r)$ in the sense that it is sandwiched between $B_P(p, r)$ and $B_P(p, \beta r)$ for some error parameter $\beta \geq 1$. To implement this algorithm in MPC, a natural idea is to "collect" all

data points in the ball $B_P(p,r)$ at a single machine, however this set might be too large to fit in one or even few machines. A standard technique to resolve this issue in low dimension is to impose a grid of fine resolution, say εr, and move each data point to its nearest grid point, which provides a decent approximation (e.g., $\beta = 1 + \sqrt{d}\varepsilon$). However, a ball $B_P(p,r)$ might contain $\varepsilon^{-\Theta(d)}$ grid points, which for high dimension might still not fit in one machine.

Our approach is to use *consistent hashing* (see Definition 2.2), which was first introduced in [53] under the name sparse partition, and was recently employed in the streaming setting for Facility Location in high dimension [33]. Roughly speaking, consistent hashing is a partition of the space $\mathbb{R}^d$, such that each part has diameter bounded by βr, and every ball $B_P(p,r)$ intersects at most $n^{1/\beta}$ parts.[2] Our algorithm moves each data point $p \in P$ to a fixed representative point inside its own part, then computes the desired statistic on each part (namely, on the data points moved to the same representative), and finally aggregates, for each $p \in P$, the $n^{1/\beta}$ statistics of the parts that intersect $B_P(p,r)$. This algorithm can be implemented in $O(\log_s n)$ rounds on MPC, albeit with slightly bigger total space $n^{1+1/\beta}$. An interesting feature of this algorithm is that its core is deterministic and hence leads to new *deterministic* MPC algorithms, including for approximate nearest-neighbor search; see Section 3.1.

Computing A Solution for Facility Location. Our algorithm is based on the MP algorithm, where a key notion is the "radius" $r_p > 0$ defined for each data point $p \in P$. Formally, it takes the value r such that serving all points in the ball $B(p,r)$ by p, i.e., opening a facility at p and assigning points to p, incurs a cost of $|B_P(p,r)| \cdot r$. This value r always exists and is unique. It is known that a constant-factor approximation $\hat{r}_p$ of r_p satisfies that $|B_P(p,\hat{r}_p)| \approx 1/\hat{r}_p$, hence computing $|B_P(p,r)|$ for $O(\operatorname{poly}\log n)$ different values of r suffices to compute an $O(1)$-approximation of r_p [7, Lemma 1]. However, it is not easy to estimate $|B_P(p,r)|$ in MPC (simultaneously for all p and r), and the abovementioned geometric aggregation only estimates $|A_P(p,r)|$ for some $A_P(p,r)$ that is sandwiched between $B(p,r)$ and $B(p,\beta r)$. Nonetheless, we show this weaker estimate suffices for approximating r_p within $O(\beta)$ factor. Thus, our aggregation primitive yields an $O(1)$-approximation for all the r_p values in $O(1)$ rounds.

An $O(1)$-factor estimate of the optimal cost OPT can be computed from an $O(1)$-approximation of the r_p values for all $p \in P$, because $\sum_{p\in P} r_p = \Theta(\mathrm{OPT})$ [7, 38]. Moreover, the r_p values can be used to compute an $O(1)$-approximate *solution* for Facility Location. Specifically, the MP algorithm [61] scans the points in P in order of non-decreasing r_p value, and opens a facility at each point p if so far no facility was opened within distance $2r_p$ from p. The sequential nature of this algorithm makes it inadequate for MPC, and we therefore design a new algorithm that makes decisions in parallel. It has two separate rules to decide whether to open a facility at each point $p \in P$:

(P1) open a facility at p with probability $\Theta(r_p)$, independently of other points; and

(P2) open a facility at p if it has the smallest label among $B_P(p,r_p)$, where each point $q \in P$ is assigned independently a random label $h(q) \in [0,1]$.

Let us give some intuition for these rules. Rule (P1) is a straightforward way to use the r_p values so that the expected opening cost is $O(\sum_p r_p) = O(\mathrm{OPT})$, but it is not sufficient by itself because the connection cost might be too large. Indeed, if a cluster of points is very far from all other points, say, a cluster of t points all with the same $r_p = 1/t$, then with constant

[2] This tradeoff between βr and $n^{1/\beta}$ is just one specific choice of known parameters. Our theorem works with any possible parameters of consistent hashing, see Lemma 2.3 and Remark 2.4.

probability, (P1) does not open any facility inside this cluster, and the closest open facility is prohibitively far. However, (P2) guarantees that at least one facility is opened inside this cluster, at the point that has the smallest label. Rule (P2) is not sufficient by itself as well. Indeed, let $x_1 \in P$ be the minimizer from the viewpoint of p, i.e., have the smallest label in $B_P(p, r_p)$. Then it may happen that there is no facility at x_1 because $B_P(x_1, r_{x_1})$ has another point x_2 with an even smaller label. The same may happen also to x_2, and we may potentially get a long "assignment" sequence $(p = x_0, x_1, x_2, x_3, \ldots, x_t)$, where each x_{i+1} is the minimizer from the viewpoint of x_i and only the last point x_t is an open facility. In this case, the connection cost of p can be as large as $\sum_{i=0}^{t-1} r_{x_i}$ (i.e., matching the bound obtained by the triangle inequality), which might be unbounded relative to r_p. This might happen not only for one point p but actually for many points, and the total connection cost would be prohibitive.

We deal with this assignment issue using rule (P1), and in effect use both rules together. Given such an assignment sequence, we prove that for every $i \geq 0$, either (i) $B_P(x_i, r_{x_i})$ contains an open facility with constant probability, or (ii) $r_{x_{i+1}} \leq r_{x_i}/2$, i.e., the r_p value drops significantly in the next step. Property (i) means that the sequence stops at x_i with constant probability and thus, unless (ii) occurs, the expected length of the assignment sequence is $O(1)$. Property (ii) implies that the connection cost of the next step drops significantly as it is proportional to its r_p value, and hence, we just sum up a subsequence of geometrically decreasing r_p values. Combining the two properties, we obtain that the expected connection cost for every point p is $O(r_p)$. Hence, the expected total connection cost is $O(\sum_p r_p) = O(\mathrm{OPT})$.

The main technical challenge is to show property (i) when (ii) does not occur. Specifically, we need to show that, given a partial reassignment sequence $(p = x_0, \ldots, x_{i-1})$, the probability that the sequence does not terminate at x_i is bounded by a small constant. This event can be broken into two sub-events: (a) rule (P1) does not open any facility at the "new" points of $B_P(x_i, r_{x_i})$, where a point is considered new if it is not in $\cup_{j<i} B_P(x_j, r_{x_j})$; and (b) the smallest label appears at a new point (and thus rule (P2) does not open a facility at x_i). Let $t \in [0, 1]$ be the fraction of points that are new in $B_P(x_i, r_{x_i})$. Then the probability of (a) is roughly $(1 - r_{x_i})^{\Omega(t/r_{x_i})} \approx e^{-\Omega(t)}$, where this calculation crucially uses that (ii) does not occur, which means all new points have a similar r_p value as x_i, and that for every point x, the ball $B_P(x, r_x)$ roughly contains $\Omega(1/r_x)$ points. Since the two events are independent and since (b) happens with probability t by symmetry, we conclude that the probability we need to bound is at most $\exp(-O(t)) \cdot t \leq O(1)$. Here, one can observe that (P1) and (P2) are "complementing" each other to make the said probability small: when t is large, the probability $\exp(-O(t))$ of (a), which comes from rule (P1), is small; otherwise, the probability t of (b), which comes from rule (P2), is small.

The idea of opening facilities using random labels and analyzing the cost by constructing an assignment sequence was previously used in [3]. The context there is of a dynamically changing input, and this technique is used to limit changes in the solution over time, while our goal is to have a fast parallel implementation. Although the high level idea is similar, the setup is quite different, as their algorithm needs a solution to a linear-programming (LP) relaxation for Facility Location, while ours only needs the r_p values; and consequently also the analysis is different, as their analysis uses the LP constraints and bounds the cost relative to LP value, while our analysis crucially uses basic properties of the r_p values.

It remains to bound the opening cost which is the easy part. We show that the number of open facilities is $O(\sum_p r_p)$ in expectation. Indeed, for points selected by rule (P1) this is clear. For rule (P2), since $B_P(p, r_p)$ contains at least $1/r_p$ points, the probability that p has the smallest label in $B_P(p, r_p)$ is at most r_p.

When implementing our algorithm in the MPC model, the only non-trivial part (except for estimating the r_p values) is to check that p has the minimum label in the ball $B(p, r_p)$. Nevertheless, it is sufficient to look for the minimum label in a larger set that approximates the ball, such as a set sandwiched between this ball and a ball whose radius is larger by $O(1)$-factor. Therefore, the MPC primitive for geometric aggregation is sufficient to execute rule (P2).

Overall, these rules compute a set of open facilities. To compute also an assignment of each point $p \in P$ to an open facility, we use our approximate nearest-neighbor search algorithm, to find for each point $p \in P$ its $O(1)$-approximately closest facility (see Section 3.1). Notice that the assignment algorithm searches for the closest facility, but the analysis is still based on the assignment sequence as above, even though the connection cost of this sequence may substantially exceed the distance to the closest facility.

k-Clustering. Our algorithm for k-Median follows the Lagrangian-relaxation framework established by Jain and Vazirani [51] (and used implicitly earlier by Garg [37]). They managed to obtain a true $O(1)$-approximation for k-Median by leveraging a special property guaranteed by their algorithm for Facility Location, namely, its output solution has opening cost cost_O and connection cost cost_C that satisfy $\alpha \cdot \text{cost}_O + \text{cost}_C \leq \alpha \cdot \text{OPT}$ for a certain $\alpha = O(1)$. Unfortunately, this stronger property is obtained via a highly sequential primal-dual approach, and seems difficult to implement efficiently in MPC, particularly because it is too sensitive for the known toolkit for high dimension, like locality sensitive hashing (LSH) and our geometric aggregation via consistent hashing.

We therefore take another approach of relying on a *generic* γ-approximation algorithm for Facility Location, and using it in a black-box manner to obtain bicriteria approximation for k-Median. Our algorithm can output $(1+\mu)k$ centers whose cost is at most $O(1/\mu^2)$-factor larger than the optimum cost for k centers, for any desired $0 < \mu < 1$. This type of tradeoff, where the number of centers is arbitrarily close to k, was relatively less understood, as previous work has focused mostly on a smaller $O(1)$-factor in the cost, but using significantly more than k centers [57, 58, 1, 64, 46]. The result of [59] does give $(1+\mu)k$ centers, and is thus the closest to ours in terms of bicriteria bounds, however it relies explicitly on LP rounding, which seems difficult to implement in MPC. To the best of our knowledge, obtaining $(1+\mu)k$ centers for k-clustering by a black-box reduction to Facility Location was not known before. We believe this new reduction, and the smooth tradeoff it offers, may be of independent interest.

In more detail, the black-box reduction from k-Median to Facility Location goes as follows: Assume momentarily that we know (an approximation of) the optimal clustering cost OPT, and consider the clustering instance as an input for Facility Location with opening cost $\mathfrak{f} := \text{OPT}/k$. The optimal cost of this instance is at most $k \cdot \mathfrak{f} + \text{OPT} = 2\,\text{OPT}$ as the optimal k-Median solution is also a feasible solution for Facility Location with at most k facilities; note that the choice of $\mathfrak{f}$ balances the opening and connection costs in this solution. We then run (any) γ-approximation algorithm for Facility Location, and it will find a solution whose cost is at most $\gamma \cdot 2\,\text{OPT}$. The choice of $\mathfrak{f}$ implies that the number of open facilities in this solution is at most $\gamma \cdot 2\,\text{OPT}/\mathfrak{f} = 2\gamma \cdot k$. Hence, we obtain a $(2\gamma, 2\gamma)$-bicriteria approximation of k-Median. Finally, we remove the assumption of knowing OPT by running this procedure in parallel for a logarithmic number of guesses for OPT, and taking the cheapest solution that uses at most $O(\gamma \cdot k)$ centers. Using our MPC algorithm for Facility Location, this gives an efficient MPC algorithm for clustering with $(O(\gamma), O(\gamma))$-bicriteria approximation guarantees.

In this approach, the number of centers (in the solution) might exceed k by a large constant factor. We now use a different method to reduce it to be arbitrarily close to k. First, we observe that the $(O(\gamma), O(\gamma))$-approximate solution can be used to get a *weak coreset*, namely, a weighted set of at most $O(\gamma \cdot k)$ distinct points, such that any α-approximate set of centers for the coreset is also an $O(\alpha \cdot \gamma)$-approximate solution for the original instance. To obtain the coreset, we just move every point to its approximately nearest facility in the approximate solution, which is a standard step in the clustering literature (see e.g. [42]). Then, weight $w(p)$ of a point p is the number of original points rounded to p. We note that the problem becomes trivial if the coreset fits in one machine, and thus the interesting case is when k is very large.

Given this weak coreset, we find an approximate solution with at most, say, $2k$ centers and cost increased by another factor of $O(\gamma)$, using the following simple but sequential algorithm: Process the coreset points in order of non-increasing weights $w(\cdot)$, and open a center at point p if so far there is no center within distance $\mathrm{OPT}/(k \cdot w(p))$ from p; here we again need a guess for OPT. In a nutshell, the analysis of this algorithm is based on averaging arguments; intuitively, only few points in the weak coreset can have a relatively large connection cost in the optimal solution.

We then convert this sequential algorithm into a parallel one using similar ideas as for Facility Location. That is, for every point in parallel, we add it to the set of centers using two separate rules: (i) independently with probability $1/\gamma$; or (ii) if there is no point with larger weight within distance $\mathrm{OPT}/(k \cdot w(p))$. To implement (ii) in MPC, we need to ensure a consistent tie-breaking, for which a small random perturbation of the weights is sufficient. Finally, to efficiently find the point of maximum (perturbed) weight in the neighborhood of every point, we again employ our MPC primitive for geometric aggregation.

1.3 Related Work

Parallel and Distributed Algorithms. A more general metric setting of Facility Location has been studied earlier in the distributed Congest and CongestedClique models (see, e.g., [38, 44, 45]), and these results immediately transfer into MPC algorithms with $O(n)$ local memory and $O(n^2)$ total space. In particular, in combination with the recent result in [20], these results yield an $O(1)$-round MPC algorithm for metric Facility Location. In this general-metric setting of Facility Location, instances have size $O(n^2)$, which makes the problem significantly different from our geometric setting, e.g., instances in $\mathbb{R}^d$ are trivial if the local memory is $O(n)$. Furthermore, those results for general metrics rely on computing $O(1)$-ruling sets, and by the conditional lower bounds in [40, 31], this seems to require $\omega(1)$ rounds on a fully-scalable MPC. Our algorithms bypass the obstacle of ruling sets by leveraging the geometric structure in $\mathbb{R}^d$ and one can view our high-level contribution as proposing a setting avoiding that obstacle.

Clustering problems (e.g., Facility Location, k-Means, k-Median) have been also studied in the PRAM model of parallel computation [16, 15]. These algorithms can be implemented in the MPC model, but the logarithmic factors in the running time or the approximation ratio seem inherent, and they fall short of achieving $O(1)$ rounds in the fully-scalable regime.

Connections to Streaming. A closely related model is the streaming model, which mainly focuses on sequential processing of large datasets by a single machine with a limited (sublinear) memory. In general, if a streaming algorithm is storing only a linear sketch and uses space $O(s^{1-\varepsilon})$ for a fixed $\varepsilon > 0$, then it can be simulated on MPC in $O(\log_s N)$ rounds (recall

s is the local memory per machine and N is the input size); this was also observed and mentioned in, e.g., [24]. Thus, the various recent results on streaming algorithms in high dimension can be readily applied in MPC, and we briefly discuss the most relevant ones in the following. We note that streaming algorithms typically assume the input is discrete, i.e., $P \subseteq [\Delta]^d$ with $\Delta = \mathrm{poly}(n)$.

For both k-Median [18] and k-Means [63], it is possible to find $(1+\varepsilon)$-approximate solution with k centers using space $\mathrm{poly}(\varepsilon^{-1}kd\log\Delta)$. However, these algorithms are not directly applicable in our setting, since to simulate these algorithms it requires local memory size $s = \Omega(k)$ which is not fully scalable. For Facility Location, [49] gave $O(d\log\Delta)$-approximation (along with several other problems including minimum spanning tree and matching), using space $\mathrm{poly}(d\log\Delta)$. Later on, an $O(d/\log d)$-approximation for Facility Location was obtained using similar space $\mathrm{poly}(d\log\Delta)$, and alternatively $O(1/\varepsilon)$-approximation using space $O(n^\varepsilon)$ [33]. However, these results for Facility Location can only estimate the optimal cost, as storing the solution requires linear space (which is too costly since streaming algorithms aim to use sublinear space). Hence, simulating these results only leads to estimating the optimal cost in MPC, while our result for Facility Location can indeed find an approximate solution.

MPC Algorithms for MST. A similar issue of cost estimation versus finding approximate solutions is present also for the minimum spanning tree (MST) problem. The classical streaming algorithm of [49] was recently improved to an $O(\log n)$-approximation using the same space regime $\mathrm{poly}(d\log\Delta)$ [25] and to an $O(1/\varepsilon^2)$-approximation for the n^ε space regime [24]. However, these results are for estimating the optimal MST cost, and it is still open to find an $O(1)$-approximate solution for high-dimensional MST in $O(\log_s n)$ rounds of MPC. Indeed, the currently best MPC algorithm finds an $O(1)$-approximate MST in $\tilde{O}(\log\log n)$ rounds [52] (using local space polynomial in n), while in $O(\log_s n)$ rounds, one can only find an $O(1)$-approximation in a low dimension [4] (see also [22] for an exact MST algorithm for $d=2$) or a $\mathrm{poly}(\log n)$-approximation in a high dimension [2]. For a related problem of single-linkage clustering in a low dimension, there is a $(1+\varepsilon)$-approximation on MPC in $O(\log n)$ rounds [65].

2 Preliminaries

For integer n, let $[n] \coloneqq \{1,2,\ldots,n\}$. For a function $\varphi : X \to Y$, the image of a subset $S \subseteq X$ is defined $\varphi(S) \coloneqq \{\varphi(x) : x \in S\}$, and the preimage of $y \in Y$ is defined as $\varphi^{-1}(y) \coloneqq \{x \in X : \varphi(x) = y\}$. A Euclidean ball centered at $x \in \mathbb{R}^d$ with radius $r \geq 0$ is defined as $B(x,r) \coloneqq \{y \in \mathbb{R}^d : \mathrm{dist}(x,y) \leq r\}$, where $\mathrm{dist}(x,y) \coloneqq \|x-y\|_2$ refers throughout to Euclidean distance. For a set $P \subset \mathbb{R}^d$, we define $B_P(x,r) \coloneqq B(x,r) \cap P$, which is also a metric ball inside P. Let $\mathrm{diam}(S)$ denote the diameter of $S \subseteq \mathbb{R}^d$. For two sequences S, T, denote their concatenation by $S \circ T$. The aspect ratio of a point set $S \subset \mathbb{R}^d$ is the ratio between the maximum and minimum inter-point distance of S, i.e., $\frac{\max_{x,y\in S}\mathrm{dist}(x,y)}{\min_{x\neq y\in S}\mathrm{dist}(x,y)}$.

▶ **Fact 2.1** (Generalized triangle inequality). *Let (V,ρ) be a metric space, and let $z \geq 1$. Then*

$$\forall x, x', y \in V, \qquad \rho^z(x,y) \leq 2^{z-1}(\rho^z(x,x') + \rho^z(x',y)).$$

Power-z (Uniform) Facility Location. Given a set of data points $P \subset \mathbb{R}^d$, a (uniform) opening cost $\mathfrak{f} > 0$ and some $z \geq 1$, the objective function of Power-z (Uniform) Facility Location for a set of facilities $F \subset \mathbb{R}^d$ is defined as

$$\mathrm{fl}_z(P,F) \coloneqq |F| \cdot \mathfrak{f} + \sum_{p\in P} \mathrm{dist}^z(p,F),$$

where again $\mathrm{dist}(x,y) \coloneqq \|x-y\|_2$ and $\mathrm{dist}(x,S) \coloneqq \min_{y\in S}\mathrm{dist}(x,y)$. From now on, we omit "uniform" from the name of the problem, and simply use Power-z Facility Location. We denote the minimum value of a solution for Power-z Facility Location by $\mathrm{OPT}^{\mathrm{fl}}_z(P) \coloneqq \min_{F\subseteq\mathbb{R}^d} \mathrm{fl}_z(P,F)$; we omit P if it is clear from the context.

(k,z)-Clustering. Given a set of data points $P\subset\mathbb{R}^d$, an integer $k\geq 1$ and some $z\geq 1$, the objective function of (k,z)-Clustering for a center set $C\subset\mathbb{R}^d$ with $|C|\leq k$ is defined as

$$\mathrm{cl}_z(P,C) \coloneqq \sum_{p\in P}\mathrm{dist}^z(p,C).$$

Notice that the special cases $z=1$ and $z=2$ are called k-Median and k-Means, respectively. We denote the minimum value of a solution for (k,z)-Clustering by $\mathrm{OPT}^{\mathrm{cl}}_z(P) \coloneqq \min_{C\subseteq\mathbb{R}^d:|C|\leq k}\mathrm{cl}_z(P,C)$; we again omit P when it is clear from the context.

Consistent Hashing. As mentioned above, our MPC primitive for geometric aggregation relies on *consistent hashing*. We define it below, and then state the best known bounds for its parameters, which are near-optimal [36].

▶ **Definition 2.2** ([33, Definition 1.6]). *A mapping $\varphi:\mathbb{R}^d\to\mathbb{R}^d$ is called a* Γ-gap Λ-consistent hash *with diameter bound $\ell>0$, or simply (Γ,Λ)-hash,*[3] *if it satisfies:*

1. *Diameter: for every image $z\in\varphi(\mathbb{R}^d)$, we have $\mathrm{diam}(\varphi^{-1}(z))\leq\ell$; and*
2. *Consistency: for every $S\subseteq\mathbb{R}^d$ with $\mathrm{diam}(S)\leq\ell/\Gamma$, we have $|\varphi(S)|\leq\Lambda$.*

▶ **Lemma 2.3** ([33, Theorem 5.1]). *For every $\Gamma\in[8,2d]$, there exists a (deterministic) (Γ,Λ)-hash $\varphi:\mathbb{R}^d\to\mathbb{R}^d$ where $\Lambda=\exp(8d/\Gamma)\cdot O(d\log d)$. Furthermore, φ can be described using $O(d^2\log^2 d)$ bits and one can evaluate $\varphi(x)$ for any point $x\in\mathbb{R}^d$ in space $O(d^2\log^2 d)$.*

▶ Remark 2.4. Our main results also hold under the assumption that $s\geq\mathrm{polylog}(dn)$, which is preferable when $d\gg\log n$. It follows by the well-known idea of applying a JL transform π (named after Johnson and Lindenstrauss [54]) with target dimension $O(\log n)$ as a preprocessing of the input $P\subset\mathbb{R}^d$, i.e., running our algorithm on $\pi(P)$ instead of P. Then, with probability $1-1/\mathrm{poly}(n)$, all the guarantees in our results would suffer only an $O(1)$ factor. To implement this preprocessing in MPC using $\mathrm{polylog}(dn)$ words of local memory, we use a bounded-space version of the JL transform [48], that requires only $\mathrm{polylog}(dn)$ words to specify π (in comparison, a naive implementation of π requires $O(d\log n)$ words). One machine can randomly generate this specification of π and broadcast it, and then all machines can apply π locally in parallel. This requires additional $O(\mathrm{polylog}(dn))$ local memory and $O(\log_s n)$ rounds, and these additional costs are easily absorbed in our bounds. Hence, in all our results we can assume without loss of generality that P is replaced by $\pi(P)$. Furthermore, after this preprocessing, we can use $d=O(\log n)$ also in the consistent hashing bounds in Lemma 2.3 to obtain a tradeoff $\Gamma=O(1/\varepsilon)$ and $\Lambda=O(n^\varepsilon)$, for any desired fixed $\varepsilon\in(0,1)$, and also the hash can be described using $\mathrm{polylog}(n)$ bits.

3 MPC Primitive for Geometric Aggregation in High Dimension

In our MPC algorithms, we often face a scenario where we want to compute something for each input point $p\in P$. That computation is a relatively simple problem, like computing the number of points in the ball $B_P(p,r)$ for some global value $r>0$. A more general

[3] Note that this definition is scale invariant with respect to ℓ, i.e., a scaling of $\mathbb{R}^d$ will scale ℓ but not affect the parameters Γ and Λ. Thus, upper and lower bounds can restrict attention to the case $\ell=1$.

version is to allow different radii r (local for each p); another generalization is to compute some function f over the points in $B_P(p,r)$, like finding the point with smallest identifier or smallest distance to p. A naive approach is to collect (copies of) all the points in $B_P(p,r)$ to the same machine, say the one holding p, and then compute f there. This is very challenging and our solution is to approximate these balls by generating sets $A_P(p,r) \approx B_P(p,r)$, and evaluate f on these sets instead of on the balls. The approximation here just means that the set $A_P(p,r)$ is sandwiched between a ball of radius r and one of larger radius, see (1). Informally, we thus compute $f(A_P(p,r)) \approx f(B_P(p,r))$, but of course the approximation here need not be multiplicative.

Our MPC algorithm derives these sets $A_P(p,r)$ from consistent hashing (see Definition 2.2), and thus our description below requires access to such a hash function φ, and moreover the final guarantees depend on the parameters Γ and Λ of the consistent hashing. The theorem below is stated in general, i.e., for any (Γ,Λ)-hash, but we eventually employ known constructions with $\Gamma = O(1/\varepsilon)$ and $\Lambda = n^{\varepsilon}$, for any desired $\varepsilon > 0$ (see Remark 2.4 and Lemma 2.3 for details). Obviously, running this algorithm in MPC requires an implementation of consistent hashing, which might require additional memory; but this memory requirement is typically much smaller than $\sqrt{s}$, and thus the hash function can be easily stored in each machine.

Yet another challenge is that the entire set $A_P(p,r)$ might not fit in a single machine, and we thus impose on f another requirement. We say that a function f is *composable* if for every disjoint $S_1,\dots,S_t \subseteq \mathbb{R}^d$, one can evaluate $f(S_1 \cup \dots \cup S_t)$ from the values of $f(S_1),\dots,f(S_t)$.[4] In our context, f maps finite subsets of $\mathbb{R}^d$ to $\mathbb{R}$. For instance, $f(S) = |S|$ is clearly composable. For a few more interesting examples, suppose every $x \in \mathbb{R}^d$ is associated with a value $h(x) \in \mathbb{R}$. Now if $h(x)$ represents the weight of x, then $f(S) = \sum_{x\in S} h(x)$ is the total weight of S; and if $h(x)$ represents an identifier (perhaps chosen at random), then $f(S) = \min_{x\in S} h(x)$ is the smallest identifier in S.

▶ **Theorem 3.1** (Geometric Aggregation in MPC). *There is a deterministic fully-scalable MPC algorithm with the following guarantees. Suppose that*

- *the input is $r \geq 0$ and a multiset $P \subset \mathbb{R}^d$ of n points distributed across machines with local memory $s \geq \mathrm{poly}(d \log n)$; and*
- *the algorithm has access to a composable function f (mapping finite subsets of $\mathbb{R}^d$ to $\mathbb{R}$) and to a (Γ,Λ)-hash $\varphi : \mathbb{R}^d \to \mathbb{R}^d$.*

Then the algorithm uses $O(\log_s n)$ rounds and $O(\Lambda \cdot \mathrm{poly}(d)) \cdot \tilde{O}(n)$ total space, and computes for each $p \in P$ a value $f(A_P(p,r))$, where $A_P(p,r)$ is an arbitrary set that satisfies

$$B_P(p,r) \subseteq A_P(p,r) \subseteq B_P(p, 3\Gamma \cdot r). \tag{1}$$

(In fact, the set $A_P(p,r)$ is determined by φ.)

Proof. Our algorithm makes use of the following standard subroutines in MPC, and we note that they are deterministic. In the broadcast procedure, to send a message of length at most $\sqrt{s}$ from some machine $\mathcal{M}_0$ to every other ones, one can build an $\sqrt{s}$-ary broadcasting tree whose nodes are the machines (with $\mathcal{M}_0$ as the root), and send/replicate the message level-by-level through the tree (starting from the root). Observe that the height of the tree is $O(\log_s n)$ and hence the entire process runs in $O(\log_s n)$ rounds. The reversed procedure defined on the same broadcast tree, sometimes called converge-cast [39], can be used to

[4] We use general t here because of our intended application, but obviously it follows from the special case $t = 2$.

aggregate messages with size at most $\sqrt{s}$ distributed across machines to some root machine $\mathcal{M}_0$ (for instance, to aggregate the sum of vectors of length $\sqrt{s}$ distributed across machines), in $O(\log_s n)$ rounds. In particular, it can be used to evaluate the composable function f on a (distributed) set S, where each machine $\mathcal{M}$ evaluates $f(S_{\mathcal{M}})$ for its own part $S_{\mathcal{M}} \subseteq S$, and aggregate using converge-cast.

▶ **Lemma 3.2** (Sorting in MPC [41]). *There is a deterministic MPC algorithm that given a set X of N comparable items distributed across machines with local memory s, sorts X such that each $x \in X$ knows its rank and $\forall x < y \in X$, it holds that the machine that holds x has an ID no larger than that of y. The algorithm uses $O(\log_s N)$ rounds and total space of $O(N)$ words.*

We give an outline of our algorithm in Algorithm 1; the implementation details in MPC are discussed below. The algorithm starts with "partitioning" $\mathbb{R}^d$ into buckets with respect to the (Γ, Λ)-hash φ, and approximates each ball $B(p, r)$ by the union of buckets that this ball intersects. This distorts the radius by at most an $O(\Gamma)$-factor. Then, we evaluate the f value on each bucket, and the approximation to $f(B_P(p, r))$ is obtained by "aggregating" the f value for the intersecting buckets of $B(p, r)$, where the composability of f is crucially used.

Implementation Details. Here we discuss how each step of Algorithm 1 is implemented efficiently in MPC. In line 3, since after the sorting, for each $u \in \varphi(P)$ the points in P_u, i.e., the set of points p such that $u = \varphi(p)$, span a (partial) segment of machines with contiguous IDs, one can use a converge-cast in parallel in each segment to aggregate $f(P_u)$. In line 4, although the total space is sufficient to hold all tuples, we may not have enough space to store the $O(\Lambda)$ tuples for a point p in a single machine. Instead, we allocate for every point p a (partial) segment of machines whose total space is $O(\Lambda)$ (which can be figured out via sorting), replicate p's to them (via broadcast), and generate $\varphi(B(p, r))$ in parallel on those machines. Specifically, each machine in the segment is responsible for generating a part of $\varphi(B(p, r))$, and a part can be generated locally without further communication since every machine holds the same deterministic φ. Line 6 and line 7 can be implemented similarly by broadcast and converge-cast, respectively, in parallel on each segment of machines.

Algorithm 1 MPC algorithm for evaluating $f(A_P(p, r))$ for $p \in P$, for given $P \subset \mathbb{R}^d, r > 0$.

1: each machine imposes the same (Γ, Λ)-hash $\varphi : \mathbb{R}^d \to \mathbb{R}^d$ with diameter bound $\ell := 2\Gamma r$
▷ notice that φ is deterministic, hence no communication is required
2: sort P with respect to $\varphi(p)$ for $p \in P$ (using Lemma 3.2)
3: for $u \in \varphi(P)$, evaluate and store $f(P_u)$ where $P_u := \varphi^{-1}(u) \cap P$
4: for each $p \in P$ and $u \in \varphi(B(p, r))$, create and store a tuple (p, u)
▷ as $|\varphi(B(p, r))| = O(\Lambda)$ by Definition 2.2, the total space is enough to hold all tuples
5: sort the tuples with respect to u (using Lemma 3.2)
6: let $\mathcal{T}_u = \{(\cdot, u)\}$, append $f(P_u)$ to all tuples in $\mathcal{T}_u$
▷ $f(P_u)$ is already evaluated and stored, as in line 3
7: sort the tuples with respect to p, and evaluate $f(A_P(p, r))$ for each p, where

$$A_P(p, r) := \bigcup_{u \in \varphi(B(p,r))} P_u$$

Round Complexity and Total Space. The round complexity is dominated by the sorting, broadcast and converge-cast procedures, which all take $O(\log_s n)$ rounds to finish and are invoked $O(1)$ times in total. Therefore, the algorithm runs in $O(\log_s n)$ rounds. The total space is asymptotically dominated by $\text{poly}(d \log n)$ times the total number of tuples, which is $O(\Lambda) \cdot n$ by Definition 2.2.

Correctness. Observe that the algorithm is deterministic, and hence there is no failure probability. It remains to show that $A_P(p,r)$ satisfies that $B_P(p,r) \subseteq A_P(p,r) \subseteq B_P(p,3\Gamma r)$. Recall that $P_u = \varphi^{-1}(u) \cap P$ as defined in line 3, and that $A_P(p,r) = \bigcup_{u \in \varphi(B(p,r))} P_u$ as in line 7. Hence, we have

$$A_P(p,r) = P \cap \varphi^{-1}(\varphi(B(p,r))).$$

Therefore, the first inequality is straightforward as $B_P(p,r) \subseteq \varphi^{-1}(\varphi(B(p,r))) \cap P = A_P(p,r)$ for any mapping φ.

To prove the second inequality, fix some $p \in P$. For a point $q \in A_P(p,r)$, by definition there is a $u_q \in \varphi(B_P(p,r))$ such that $q \in \varphi^{-1}(u_q)$. Then by Definition 2.2, we have $\text{diam}(\varphi^{-1}(u_q)) \leq \ell = 2\Gamma r$ which implies that any point $x \in \varphi^{-1}(u_q)$ satisfies $\text{dist}(x,q) \leq 2\Gamma r$. Now, pick a point $x \in B_P(p,r)$ such that $\varphi(x) = u_q$; such a point exists as $u_q \in \varphi(B_P(p,r))$. Then by definition, $x \in B_P(p,r) \cap \varphi^{-1}(u_q)$ and $\text{dist}(p,x) \leq r$. Hence, by triangle inequality, we have that $\text{dist}(p,q) \leq \text{dist}(p,x) + \text{dist}(x,q) \leq r + 2\Gamma r \leq 3\Gamma r$, which implies that $A_P(p,r) \subseteq B_P(p,3\Gamma r)$. This finishes the proof. ◀

3.1 Application to Nearest Neighbor Search

Given a set $X \subseteq \mathbb{R}^d$ of *terminals* and a set $P \subseteq \mathbb{R}^d$ of data points, the ρ-approximate nearest neighbor search problem asks to find for every $p \in P$ a terminal $x \in X$, such that $\text{dist}(p,x) \leq \rho \cdot \text{dist}(p,X)$. This process is useful in clustering and facility location problems, since one can find an assignment of every data point to its approximately nearest center/facility. We show how to solve this problem using Theorem 3.1, provided the knowledge of the *aspect ratio* Δ of $X \cup P$.

Pick an arbitrary point $x \in X \cup P$, compute in $O(\log_s n)$ rounds the maximum distance $M := \max_{y \in X \cup P} \text{dist}(x,y)$ from x to every other point (via broadcast and converge-cast). Since M is a 2-approximation to $\text{diam}(X \cup P)$, we conclude that for every $x \neq y \in X \cup P$, $M/\Delta \leq \text{dist}(x,y) \leq 2M$. Rescale the instance by dividing M/Δ, then the distances are between 1 and $O(\Delta)$. Then, let $Z := \{2^i : 1 \leq 2^i \leq O(\Delta)\}$. We apply Theorem 3.1 in parallel for $r \in Z$ and f such that $f(Y)$ for $Y \subseteq X$ finds the terminal with the smallest ID in Y (where the ID of a point can be defined arbitrarily as long as it is consistent), and f returns $\perp$ if $Y = \emptyset$. This f is clearly composable. After we obtain the result of Theorem 3.1, i.e., $f(A_X(p,r))$ for $p \in P$ and $r \in Z$, we find in parallel for each $p \in P$ the smallest $r \in Z$ such that $f(A_X(p,r)) \neq \perp$. This way, we explicitly get for each point p an approximately nearest facility in X. This algorithm has approximation factor $\rho = O(\Gamma)$, using total space by an $O(\log \Delta)$-factor larger than that of Theorem 3.1, while the round complexity remains $O(\log_s n)$.

We remark that techniques based on locality sensitive hashing (LSH) can also be applied in MPC to solve the approximate nearest neighbor problem [13, 28]. LSH in fact achieves a slightly better tradeoff, namely, an $O(c)$-approximation using total space $n^{1/c^2} \cdot \tilde{O}(n)$, while our approach requires total space $n^{1/c} \cdot \tilde{O}(n)$, by plugging in Lemma 2.3 and assuming the dimension reduction in Remark 2.4 is performed. Alternatively, if $d \leq O(\log n)$, one can

obtain the same $n^{1/c} \cdot \tilde{O}(n)$ bound without applying the randomized dimension reduction in Remark 2.4, which leads to a deterministic algorithm, whereas approaches based on LSH are inherently randomized.

Abstract

The independence number of a tree decomposition is the maximum of the independence numbers of the subgraphs induced by its bags. The tree-independence number of a graph is the minimum independence number of a tree decomposition of it. Several NP-hard graph problems, like maximum weight independent set, can be solved in time $n^{\mathcal{O}(k)}$ if the input n-vertex graph is given together with a tree decomposition of independence number k. Yolov in [SODA 2018] gave an algorithm that given an n-vertex graph G and an integer k, in time $n^{\mathcal{O}(k^3)}$ either constructs a tree decomposition of G whose independence number is $\mathcal{O}(k^3)$ or correctly reports that the tree-independence number of G is larger than k.

In this paper, we first give an algorithm for computing the tree-independence number with a better approximation ratio and running time and then prove that our algorithm is, in some sense, the best one can hope for. More precisely, our algorithm runs in time $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$ and either outputs a tree decomposition of G with independence number at most $8k$, or determines that the tree-independence number of G is larger than k. This implies $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$-time algorithms for various problems, like maximum weight independent set, parameterized by the tree-independence number k without needing the decomposition as an input. Assuming Gap-ETH, an $n^{\Omega(k)}$ factor in the running time is unavoidable for any approximation algorithm for the tree-independence number.

Our second result is that the exact computation of the tree-independence number is para-NP-hard: We show that for every constant $k \geq 4$ it is NP-hard to decide if a given graph has the tree-independence number at most k.

1 Introduction

Tree decompositions are among the most popular tools in graph algorithms. The crucial property of tree decompositions exploited in the majority of dynamic programming algorithms is that each bag of the decomposition can interact with an optimal solution only in a bounded number of vertices. The common measure of a tree decomposition is the width, that is, the maximum size of a bag in the decomposition (minus 1). The corresponding graph parameter is the treewidth of a graph. Many problems that are intractable on general graphs can be solved efficiently when the treewidth of a graph is bounded.

However, it is not always the size of a bag that matters. For example, suppose that every bag of the decomposition is a clique, that is, the graph is chordal. Since every independent set intersects each of the clique-bags in at most one vertex, dynamic programming still computes maximum weight independent sets in such graphs in polynomial time even if the bags could be arbitrarily large. An elegant approach to capturing such properties of tree decompositions is the notion of the tree-independence number of a graph. The *independence number* of a tree decomposition is the maximum of the independence numbers (that is, the maximum size of an independent set) of the subgraphs induced by its bags. The *tree-independence number* of a graph G, denoted by $\mathsf{tree}\text{-}\alpha(G)$, is the minimum independence number of a tree decomposition of G. In particular, the tree-independence number of a chordal graph is at most one, and for any graph G, the value $\mathsf{tree}\text{-}\alpha(G)$ does not exceed the treewidth of G (plus 1) or the independence number $\alpha(G)$ of G.

The family of graph classes with bounded tree-independence number forms a significant generalization of graph classes with bounded treewidth. It also contains dense graphs classes, including graph classes with bounded independence number; classes of intersection graphs of connected subgraphs of graphs with bounded treewidth, studied by Bodlaender, Gustedt, and Telle [6], which in particular include classes of *H-graphs*, that is, intersection graphs of connected subgraphs of a subdivision of a fixed multigraph H, introduced in 1992 by Bíró, Hujter, and Tuza [4] and studied more recently in a number of papers [8, 9, 22]; classes of graphs in which all minimal separators have bounded size, studied by Skodinis in 1999 [38]; and, more generally, classes of graphs in which all minimal separators induce subgraphs with bounded independence number, studied by Dallard, Milanič, and Štorgel [15].

Our results. Yolov [40] gave an algorithm that for a given n-vertex graph G and integer k, in time $n^{\mathcal{O}(k^3)}$ either constructs a tree decomposition of G whose independence number is $\mathcal{O}(k^3)$ or correctly reports that the tree-independence number of G is larger than k. Our first main result is the following improvement over Yolov's algorithm.

▶ **Theorem 1.** *There is an algorithm that, given an n-vertex graph G and an integer k, in time $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$ either outputs a tree decomposition of G with independence number at most $8k$, or concludes that the tree-independence number of G is larger than k.*

The performance of the algorithm from Theorem 1 (the running time and the need of approximation) are in some sense optimal, for the following reasons. First, by a simple reduction that given an n-vertex graph G produces a $2n$-vertex graph G' with $\mathsf{tree}\text{-}\alpha(G') = \alpha(G)$ hardness results for the independence number (or clique) translate into hardness results for the tree-independence number. In particular, from the result of Lin [30] it follows that a constant-factor approximation of the tree-independence number is W[1]-hard, and from the result of Chalermsook, Cygan, Kortsarz, Laekhanukit, Manurangsi, Nanongkai,

and Trevisan [7] it follows that assuming Gap-ETH[1], there is no $f(k) \cdot n^{o(k)}$-time $g(k)$-approximation algorithm for the tree-independence number for any computable functions f and g. In particular, the time complexity obtained in Theorem 1 is optimal in the sense that an $n^{\Omega(k)}$ factor is unavoidable assuming Gap-ETH, even if the approximation ratio would be drastically weakened.

The above arguments do not exclude the possibility of *exact* computation of the tree-independence number in time $n^{f(k)}$ for some function f. The computational complexity of recognizing graphs with the tree-independence numbers at most k for a fixed integer $k \geq 2$ was asked as an open problem by Dallard, Milanič, and Štorgel [15, Question 8.3][2]. While for values $k = 2$ and $k = 3$ the question remains open, our next result resolves it for any constant $k \geq 4$.[3]

▶ **Theorem 2** (⋆). *For every constant $k \geq 4$, it is NP-complete to decide whether* tree-$\alpha(G) \leq k$ *for a given graph G.*

Let us observe that Theorem 2 implies also that, assuming P ≠ NP, there is no $n^{f(k)}$-time approximation algorithm for the tree-independence number with approximation ratio less than 5/4.

We supplement our main results with a second NP-completeness proof for a problem closely related to computing the tree-independence number and the algorithm of Theorem 1. We consider the problem where we are given a graph G, two non-adjacent vertices u and v, and an integer k, and the task is to decide if u and v can be separated by removing a set of vertices that induces a subgraph with independence number at most k. We show in Theorem 14 that this problem is NP-complete for any fixed integer $k \geq 3$. This hardness result is motivated by the fact that the algorithm of Theorem 1 finds separators with bounded independence number as a subroutine. While for the algorithm of Theorem 1 we design a $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$-time 2-approximation algorithm for a generalization of this problem, assuming that a tree decomposition of independence number $\mathcal{O}(k)$ is given, this proof shows that this step of the algorithm cannot be turned into an exact algorithm (in our reduction, we can construct along the graph G also a tree decomposition of independence number $\mathcal{O}(k)$ of G).

Previous work and applications of Theorem 1. The notion of the tree-independence number is very natural and it is not surprising that it was introduced independently by several researchers [15, 40]. Yolov in [40] introduced a new width measure called *minor-matching hypertree-width*, tree-μ.[4] He proved that a number of problems including Maximum Independent Set, k-Colouring, and Graph Homomorphism permit polynomial-time solutions for graphs with bounded minor-matching hypertree width. Furthermore, Yolov showed that the minor-matching hypertree-width of a graph is equal to the tree-independence number of the square of its line graph, that is, tree-$\mu(G)$ = tree-$\alpha(L(G)^2)$ holds for all graphs G, where $L(G)^2$ is the graph whose vertices are the edges of G, with two distinct edges adjacent if and only if they have nonempty intersection or there is a third edge

[1] Gap-ETH states that for some constant $\epsilon > 0$, distinguishing between a satisfiable 3-SAT formula and one that is not even $(1-\epsilon)$-satisfiable requires exponential time (see [20, 32]).

[2] There is a linear-time algorithm for deciding if a given graph has the tree-independence number at most 1, because such graphs are exactly the chordal graphs, see, e.g., [25].

[3] The proofs of the statements marked (⋆) are omitted due to space constraints and can be found in the full version of the paper [13].

[4] Minor-matching hypertree-width is defined for hypergraphs, but algorithms for computing decompositions for it are only known for graphs.

intersecting both. Moreover, a tree decomposition of $L(G)^2$ with independence number at most k can be turned into a tree decomposition of G with minor-matching hypertree-width at most k. Then, Yolov gave an $n^{\mathcal{O}(k^3)}$-time $\mathcal{O}(k^2)$-approximation algorithm computing the tree-independence number of an n-vertex graph, implying also the same bounds for computing the minor-matching hypertree-width of a graph. Theorem 1 improves the running time and approximation ratio of Yolov's algorithm. Pipelined with Yolov's reduction, Theorem 1 also implies an 8-approximation of minor-matching hypertree-width of graphs in time $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$.

Theorem 2 implies also the NP-hardness of deciding whether $\mathsf{tree}\text{-}\mu(G) \leq k$ for every constant $k \geq 4$ because a simple reduction that attaches a pendant vertex to every vertex of a graph G produces a graph G' such that $\mathsf{tree}\text{-}\mu(G') = \mathsf{tree}\text{-}\alpha(G)$ (see [40]).

The tree-independence number of a graph was introduced independently by Yolov [40] and Dallard et al. [15].[5] The original motivation for Dallard et al. [15] stems from structural graph theory. In 2020, Dallard, Milanič, and Štorgel [14, 17] initiated a systematic study of (tw, ω)-bounded graph classes, that is, hereditary graph classes in which the treewidth can only be large due to the presence of a large clique. While (tw, ω)-bounded graph classes are known to possess some good algorithmic properties related to clique and coloring problems (see [9, 10, 14, 15, 17]), the extent to which this property has useful algorithmic implications for problems related to independent sets is an open problem. The connection with the tree-independence number follows from Ramsey's theorem, which implies that graph classes with bounded tree-independence number are (tw, ω)-bounded with a polynomial binding function (see [15]). Dallard, Milanič, and Štorgel [16] conjecture the converse, namely, that every (tw, ω)-bounded graph class has bounded tree-independence number. A related research direction in structural graph theory is the study of induced obstructions to bounded treewidth and tree-independence number; see for example the recent work of Abrishami, Alecu, Chudnovsky, Hajebi, Spirkl, and Vušković [1].

In our opinion, the most interesting application of Theorem 1 lies in the area of graph algorithms for NP-hard optimization problems. Dallard et al. [15] and Yolov in [40] have shown that certain NP-hard optimization problems like Maximum Independent Set, Graph Homomorphism, or Maximum Induced Matching problems can be solved in time $n^{\mathcal{O}(k)}$ if the input graph is given with a tree decomposition of independence number at most k. Lima et al. [29] extended this idea to generic packing problems in which any two of the chosen subgraphs have to be at pairwise distance at least d, for even d. They also obtained an algorithmic metatheorem for the problem of finding a maximum-weight sparse (bounded chromatic number) induced subgraph satisfying an arbitrary but fixed property expressible in counting monadic second-order logic (CMSO_2). In particular, the metatheorem implies polynomial-time solvability of several classical problems like finding the largest induced forest (which is equivalent to Minimum Feedback Vertex Set), finding the largest induced bipartite subgraph (which is equivalent to Minimum Odd Cycle Transversal), finding the maximum number of pairwise disjoint and non-adjacent cycles (Maximum Induced Cycle Packing), and finding the largest induced planar subgraph (which is equivalent to Planarization).

However, the weak spot in all these algorithmic approaches is the requirement that a tree decomposition with bounded independence number is given with the input. Theorem 1 fills this gap by constructing a decomposition of bounded independence number in time that asymptotically matches or improves the time required to solve all these optimization problems.

[5] Yolov called it *α-treewidth* in [40].

Theorem 1 appears to be a handy tool in the subarea of computational geometry concerning optimization problems on geometric graphs. Treewidth plays a fundamental role in the design of exact and approximation algorithms on planar graphs (and more generally, H-minor-free graphs) [3, 19, 26]. The main property of such graphs is that they enjoy the bounded local treewidth property. In other words, any planar graph of a small diameter has a small treewidth. A natural research direction is to extend such methods to intersection graphs of geometric objects [23, 31]. However, even for very "simple" objects like unit disks, the corresponding intersection graphs do not have locally bounded treewidth. On the other hand, in many scenarios, the treewidth-based methods on such graphs could be replaced by tree decompositions of bounded independence number. In particular, de Berg, Bodlaender, Kisfaludi-Bak, Marx, and van der Zanden use tree decompositions whose bags are covered by a small number of cliques, and thus of small independence number, to design subexponential-time algorithms on geometric graph classes [18]. Galby, Munaro, and Yang [24] use Theorem 1 for obtaining polynomial-time approximation schemes for several packing problems on geometric graphs. It is interesting to note that algorithms on geometric graphs often require geometric representation of a graph. Sometimes, like for unit disk graphs, finding such a representation is a challenging computational task [27]. On the contrary, Theorem 1 does not need the geometric properties of objects or their geometric representations and thus could be used for developing so-called robust algorithms [35] on geometric graphs [11].

In parameterized algorithms, Fomin and Golovach [21] and Jacob, Panolan, Raman, and Sahlot [28] used tree decompositions where each bag is obtained from a clique by deleting at most k edges or adding at most k vertices, respectively. These type of decompositions are special types of tree decompositions with bounded independence numbers.

The rest of this paper is organized as follows. In Section 2, we overview the proof of our main algorithmic result Theorem 1. In Section 3 we recall definitions. Section 4 is devoted to the proof of Theorem 1. In Section 5, we survey our computational lower bounds. Due to space constraints, the proofs of the hardness results are omitted and are available in the full version of the paper [13]. We conclude in Section 6 with final remarks and open problems.

2 Overview

In this section we sketch the proof of Theorem 1. For simplicity, we sketch here a version with approximation ratio 11 instead of 8. The difference between the 11-approximation and 8-approximation is that for 11-approximation it is sufficient to use 2-way separators, while for 8-approximation we use 3-way separators.

On a high level, our algorithm follows the classical technique of constructing a tree decomposition by repeatedly finding balanced separators. This technique was introduced by Robertson and Seymour in Graph Minors XIII [37], was used for example in [5, 18, 28], and an exposition of it was given in [12, Section 7.6.2] and in [34].

The challenge in applying this technique is the need to compute separators that are both balanced and small with respect to the independence numbers of the involved vertex sets. Our main technical contribution is an approximation algorithm for finding such separators. In what follows, we will sketch an algorithm that given a graph G, a parameter k, and a set of vertices $W \subseteq V(G)$ with independence number $\alpha(W) = 9k$ either finds a partition (S, C_1, C_2) of $V(G)$ such that each S, C_1, and C_2 are nonempty, S separates C_1 from C_2, $\alpha(S) \leq 2k$, and $\alpha(W \cap C_i) \leq 7k$ for both $i = 1, 2$, or determines that the tree-independence number of G is larger than k. (For $S \subseteq V(G)$ we use $\alpha(S)$ to denote the independence

number of the induced subgraph $G[S]$.) Our algorithm for finding such balanced separators works in two parts. First, we reduce finding balanced separators to finding separators, and then we give a 2-approximation algorithm for finding separators.

At first glance, it is not even clear that small tree-independence number guarantees the existence of such balanced separators. To prove the existence of balanced separators and to reduce the finding of balanced separators to finding separators between specified sets of vertices, instead of directly enforcing that both sides of the separation have a small independence number, we enforce that both sides of the separation have sufficiently large independence number. More precisely, we pick an arbitrary independent set $I \subseteq W$ of size $|I| = 9k$. By making use of the properties of tree decompositions, it is possible to show that there exists a separation (S, C_1, C_2) with $|I \cap C_i| \leq 6k$ for $i \in \{1, 2\}$ and $\alpha(S) \leq k$. Hence $|I \cap C_i| \geq 2k$ for $i \in \{1, 2\}$. By enforcing the condition $|I \cap C_i| \geq 2k$ for both $i \in \{1, 2\}$, we will have that $\alpha(W \cap C_i) \leq 7k$ for both $i \in \{1, 2\}$. (Note that $\alpha(W \cap C_1) + \alpha(W \cap C_2) \leq \alpha(W)$.) Therefore, to find a balanced separator for W or to conclude that the tree-independence number of G is larger than k, it is sufficient to select an arbitrary independent set $I \subseteq W$ with $|I| = 9k$, do $2^{\mathcal{O}(k)}$ guesses for sets $I \cap C_1$ and $I \cap C_2$, and for each of the guesses search for a separator between the sets $I \cap C_1$ and $I \cap C_2$.

In the separator finding algorithm the input includes two sets $V_1 = I \cap C_1$ and $V_2 = I \cap C_2$, and the task is to find a set of vertices S disjoint from both V_1 and V_2 separating V_1 from V_2 with $\alpha(S) \leq 2k$ or to conclude that no such separator S with $\alpha(S) \leq k$ exists. Our algorithm works by first using multiple stages of different branching steps, and then arriving at a special case which is solved by rounding a linear program. We explain some details in what follows.

First, by using iterative compression around the whole algorithm, we can assume that we have a tree decomposition with independence number $\mathcal{O}(k)$ available. We show that any set $S \subseteq V(G)$ with $\alpha(S) \leq k$ can be covered by $\mathcal{O}(k)$ bags of the tree decomposition. This implies that by first guessing the covering bags, we reduce the problem to the case where we search for a separator $S \subseteq R$ for some set $R \subseteq V(G)$ with independence number $\alpha(R) = \mathcal{O}(k^2)$.

Then, we use a branching procedure to reduce the problem to the case where $R \subseteq N[V_1 \cup V_2]$. In the branching, we select a vertex $v \in R \setminus N[V_1 \cup V_2]$, and branch into three subproblems, corresponding to including v into V_1, into V_2, or into a partially constructed solution S. The key observation here is that if we branch on vertices $v \in R \setminus N[V_1 \cup V_2]$, then the branches where v is included in V_1 or in V_2 reduce the value $\alpha(R \setminus N[V_1 \cup V_2])$. By first handling the case with $\alpha(R \setminus N[V_1 \cup V_2]) \geq 2k$ by branching on $2k$ vertices at the same time and then branching on single vertices, this branching results in $2^{\mathcal{O}(\alpha(R))} n^{\mathcal{O}(k)} = 2^{\mathcal{O}(k^2)} n^{\mathcal{O}(k)}$ instances where $R \subseteq N[V_1 \cup V_2]$.

Finally, when we arrive at the subproblem where $R \subseteq N[V_1 \cup V_2]$, we design a 2-approximation algorithm by rounding a linear program. For $v \in R$, let us have variables x_v with $x_v = 1$ indicating that $v \in S$ and $x_v = 0$ indicating that $v \notin S$. Because $R \subseteq N[V_1 \cup V_2]$, the fact that $S \subseteq R$ separates V_1 from V_2 can be encoded by only using inequalities of form $x_v + x_u \geq 1$. To bound the independence number of S, for every independent set I of size $|I| = 2k+1$ we add a constraint that $\sum_{v \in I} x_v \leq k$. Now, a separator S with $\alpha(S) \leq k$ corresponds to an integer solution. We then find a fractional solution and round x_v to 1 if $x_v \geq 1/2$ and to 0 otherwise. Note that this satisfies the $x_v + x_u \geq 1$ constraints, so the rounded solution corresponds to a separator. To bound the independence number of the rounded solution, note that $\sum_{v \in I} x_v \leq 2k$ for independent sets I of size $|I| = 2k + 1$, therefore implying that $\alpha(S) \leq 2k$.

3 Preliminaries

We denote the vertex set and the edge set of a graph $G = (V, E)$ by $V(G)$ and $E(G)$, respectively. The *neighborhood* of a vertex v in G is the set $N_G(v)$ of vertices adjacent to v in G, and the *closed neighborhood* of v is the set $N_G[v] = N_G(v) \cup \{v\}$. These concepts are extended to sets $X \subseteq V(G)$ so that $N_G[X]$ is defined as the union of all closed neighborhoods of vertices in X, and $N_G(X)$ is defined as the set $N_G[X] \setminus X$. The *degree* of v, denoted by $d_G(v)$, is the cardinality of the set $N_G(v)$. When there is no ambiguity, we may omit the subscript G in the notations of the degree, and open and closed neighborhoods, and thus simply write $d(v)$, $N(v)$, and $N[v]$, respectively.

Given a set $X \subseteq V(G)$, we denote by $G[X]$ the subgraph of G induced by X. We also write $G \setminus X = G[V(G) \setminus X]$. Similarly, given a vertex $v \in V(G)$, we denote by $G \setminus v$ the graph obtained from G by deleting v. A graph G is *chordal* if it has no induced cycles of length at least four.

A *clique* (resp. *independent set*) in a graph G is a set of pairwise adjacent (resp. non-adjacent) vertices. The *independence number* of G, denoted by $\alpha(G)$, is the maximum size of an independent set in G. For a set of vertices $X \subseteq V(G)$, the independence number of X is $\alpha(X) = \alpha(G[X])$.

Let $(V_1, V_2, \ldots, V_t)$ be a tuple of disjoint subsets of $V(G)$. A $(V_1, V_2, \ldots, V_t)$-*separator* is a set $S \subseteq V(G)$ such that $S \cap V_i = \emptyset$ for each $i \in [t]$, and in the graph $G \setminus S$ there is no path from V_i to V_j for all pairs $i \neq j$. Such a separator is sometimes called a t-way separator. Note that if V_i is adjacent to V_j for some $i \neq j$, then no $(V_1, V_2, \ldots, V_t)$-separator exists.

A *tree decomposition* of a graph G is a pair $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$ where T is a tree and every node t of T is assigned a vertex subset $X_t \subseteq V(G)$ called a bag such that the following conditions are satisfied: (1) every vertex of G is in at least one bag, (2) for every edge $uv \in E(G)$ there exists a node $t \in V(T)$ such that X_t contains both u and v, and (3) for every vertex $u \in V(G)$ the subgraph T_u of T induced by the set $\{t \in V(T) : u \in X_t\}$ is connected (that is, a tree). The *independence number* of a tree decomposition $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$ of a graph G, denoted by $\alpha(\mathcal{T})$, is defined as follows:

$$\alpha(\mathcal{T}) = \max_{t \in V(T)} \alpha(X_t)\,.$$

The *tree-independence number* of G, denoted by $\mathsf{tree}\text{-}\alpha(G)$, is the minimum independence number among all tree decompositions of G.

4 An 8-approximation algorithm for tree-independence number

In this section we prove Theorem 1, that is, we give a $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$-time algorithm for either computing tree decompositions with independence number at most $8k$ or deciding that the tree-independence number of the graph is more than k. Our algorithm consists of three parts. First, we give a $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$-time 2-approximation algorithm for finding 3-way separators with independence number at most k, with the assumption that a tree decomposition with independence number $\mathcal{O}(k)$ is given with the input. Then, we apply this separator finding algorithm to find balanced separators, and then apply balanced separators in the fashion of the Robertson-Seymour treewidth approximation algorithm [37] to construct a tree decomposition with independence number at most $8k$. The requirement for having a tree decomposition with independence number $\mathcal{O}(k)$ as an input in the separator algorithm is satisfied by iterative compression (see, e.g., [12]), as we explain at the end of Section 4.3.

The presentation of the algorithm in this section is in reverse order compared to the presentation we gave in Section 2.

4.1 Finding approximate separators

In this subsection, we show the following theorem.

▶ **Theorem 3.** *There is an algorithm, that given a graph G, an integer k, a tree decomposition $\mathcal{T}$ of G with independence number $\alpha(\mathcal{T}) = \mathcal{O}(k)$, and three disjoint sets of vertices $V_1, V_2, V_3 \subseteq V(G)$, in time $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$ either reports that no (V_1, V_2, V_3)-separator with independence number at most k exists, or returns a (V_1, V_2, V_3)-separator with independence number at most $2k$.*

To prove Theorem 3, we define a more general problem that we call PARTIAL 3-WAY α-SEPARATOR, which is the same as the problem of Theorem 3 except that two sets S_0 and R are given with the input, and we are only looking for separators S with $S_0 \subseteq S \subseteq S_0 \cup R$.

▶ **Definition 4** (PARTIAL 3-WAY α-SEPARATOR)**.** *An instance of PARTIAL 3-WAY α-SEPARATOR is a 5-tuple $(G, (V_1, V_2, V_3), S_0, R, k)$, where G is a graph, V_1, V_2, V_3, S_0, and R are disjoint subsets of $V(G)$, and k is an integer. A solution to PARTIAL 3-WAY α-SEPARATOR is a (V_1, V_2, V_3)-separator S such that $S_0 \subseteq S \subseteq S_0 \cup R$. A 2-approximation algorithm for PARTIAL 3-WAY α-SEPARATOR either returns a solution S with $\alpha(S) \leq 2k$ or determines that there is no solution S with $\alpha(S) \leq k$.*

We give a 2-approximation algorithm for PARTIAL 3-WAY α-SEPARATOR. Then Theorem 3 will follow by setting $S_0 = \emptyset$ and $R = V(G) \setminus (V_1 \cup V_2 \cup V_3)$.

We give our 2-approximation algorithm by giving 2-approximation algorithms for increasingly more general cases of PARTIAL 3-WAY α-SEPARATOR. First, we give a linear programming based 2-approximation algorithm for the special case when $R \subseteq N(V_1 \cup V_2 \cup V_3)$. Then, we use branching and the first algorithm to give a 2-approximation algorithm for the case when $\alpha(R) = \mathcal{O}(k^2)$. Then, we use the input tree decomposition to reduce the general case to the case where $\alpha(R) = \mathcal{O}(k^2)$.

Let us make some observations about trivial instances of PARTIAL 3-WAY α-SEPARATOR. First, we can assume that $\alpha(S_0) \leq k$, as otherwise any solution S has $\alpha(S) > k$ and we can return no immediately. All our algorithms include an $n^{\mathcal{O}(k)}$ factor in the time complexity, so it can be assumed that this condition is always tested. Then, we can also always return no if V_i is adjacent to V_j, where $i \neq j$. This can be checked in polynomial time, so we can assume that this condition is always tested. Note that testing this condition implies that $N(V_1 \cup V_2 \cup V_3) = N(V_1) \cup N(V_2) \cup N(V_3)$. For simplicity, we write $N(V_1 \cup V_2 \cup V_3)$ as it is shorter.

We start with the linear programming based 2-approximation algorithm for the case when $R \subseteq N(V_1 \cup V_2 \cup V_3)$.

▶ **Lemma 5.** *There is an $n^{\mathcal{O}(k)}$-time 2-approximation algorithm for PARTIAL 3-WAY α-SEPARATOR when $R \subseteq N(V_1 \cup V_2 \cup V_3)$.*

Proof. First, note that we may assume that for all $i, j \in \{1, 2, 3\}$, $i \neq j$, there is no path in the graph $G \setminus (R \cup S_0)$ between a vertex of V_i and a vertex of V_j, since otherwise the given instance has no solution at all. Furthermore, under this assumption, we can safely replace each set V_i with the set of vertices reachable from a vertex in V_i in the graph $G \setminus (R \cup S_0)$. We thus arrive at an instance such that $R \subseteq N(V_1 \cup V_2 \cup V_3) \subseteq R \cup S_0$. We then make an integer programming formulation of the problem (with $n^{\mathcal{O}(k)}$ constraints) and show that it gives a 2-approximation by rounding a fractional solution.

For every vertex $v \in R \cup S_0$ we introduce a variable x_v, with the interpretation that $x_v = 1$ if $v \in S$ and $x_v = 0$ otherwise. We force S_0 to be in the solution by adding constraints $x_v = 1$ for all $v \in S_0$. Then, we say that a pair (v_i, v_j) of vertices with $v_i \in N(V_i)$, $v_j \in N(V_j)$,

$i \neq j$, is *connected* if there is a v_i, v_j-path in the graph $G \setminus ((S_0 \cup R) \setminus \{v_i, v_j\})$. For any pair (v_i, v_j) of connected vertices we introduce a constraint $x_{v_i} + x_{v_j} \geq 1$ indicating that v_i or v_j should be selected to the solution. Note that here it can happen that $v_i = v_j$, corresponding to the case when $v_i \in N(V_i) \cap N(V_j)$, resulting in a constraint forcing v_i to be in the solution. Finally, for every independent set $I \subseteq R \cup S_0$ of size $|I| = 2k + 1$, we introduce a constraint $\sum_{v \in I} x_v \leq k$.

We observe that any solution S with $\alpha(S) \leq k$ corresponds to a solution to the integer program. In particular, any (V_1, V_2, V_3)-separator S must satisfy the $x_{v_i} + x_{v_j} \geq 1$ constraints for connected pairs (v_i, v_j), as otherwise there would be a V_i,V_j-path in $G \setminus S$, and a separator with $\alpha(S) \leq k$ satisfies the independent set constraints as otherwise it would contain an independent set larger than k.

Then, we show that any integral solution that satisfies the $x_{v_i} + x_{v_j} \geq 1$ constraints for connected pairs (v_i, v_j) and the constraints $x_v = 1$ for $v \in S_0$ corresponds to a (V_1, V_2, V_3)-separator. Suppose that all such constraints are satisfied by an integral solution corresponding to a set S, but there is a path from V_i to V_j with $i \neq j$ in $G \setminus S$. Take a shortest path connecting $N(V_i) \setminus S$ to $N(V_j) \setminus S$ in $G \setminus S$ for any $i \neq j$, and note that the intermediate vertices of such path do not intersect $N(V_1 \cup V_2 \cup V_3)$, as otherwise we could get a shorter path, and therefore do not intersect R. By $S_0 \subseteq S$, we have that the intermediate vertices do not intersect $R \cup S_0$, so this path is in fact a path in the graph $G \setminus ((S_0 \cup R) \setminus \{v_i, v_j\})$, where $v_i \in N(V_i) \setminus S$ is the first vertex and $v_j \in N(V_j) \setminus S$ is the last vertex. However, in this case (v_i, v_j) is a connected pair and we have a constraint $x_{v_i} + x_{v_j} \geq 1$, which would be violated by such an integral solution, so we get a contradiction.

We solve the linear program in polynomial time (which is $n^{\mathcal{O}(k)}$ as the number of variables is $\mathcal{O}(n)$ and the number of constraints is $n^{\mathcal{O}(k)}$), and round the solution by rounding x_v to 1 if $x_v \geq 1/2$ and otherwise to 0. This rounding will satisfy the $x_{v_i} + x_{v_j} \geq 1$ constraints for connected pairs, so the resulting solution corresponds to a separator. Then, by the constraints $\sum_{v \in I} x_v \leq k$ for independent sets I of size $2k + 1$, the rounded solution will satisfy $\sum_{v \in I} x_v \leq 2k$ for independent sets I of size $2k+1$. Therefore, there are no independent sets of size $2k + 1$ in the resulting solution, so its independence number is at most $2k$. ◀

We will pipeline Lemma 5 with branching to obtain a 2-approximation algorithm for PARTIAL 3-WAY α-SEPARATOR in a setting where $\alpha(R)$ is small. In our final algorithm, $\alpha(R)$ will be bounded by $\mathcal{O}(k^2)$, and this is the part that causes the $2^{\mathcal{O}(k^2)}$ factor in the time complexity.

Let us observe that we can naturally branch on vertices in R in instances of PARTIAL 3-WAY α-SEPARATOR.

▶ **Lemma 6** (Branching). *Let $\mathcal{I} = (G, (V_1, V_2, V_3), S_0, R, k)$ be an instance of* PARTIAL 3-WAY α-SEPARATOR*, and let $v \in R$. If S is a solution of $\mathcal{I}$, then S is also a solution of at least one of*

1. $(G, (V_1 \cup \{v\}, V_2, V_3), S_0, R \setminus \{v\}, k)$,
2. $(G, (V_1, V_2 \cup \{v\}, V_3), S_0, R \setminus \{v\}, k)$,
3. $(G, (V_1, V_2, V_3 \cup \{v\}), S_0, R \setminus \{v\}, k)$, *or*
4. $(G, (V_1, V_2, V_3), S_0 \cup \{v\}, R \setminus \{v\}, k)$.

Moreover, any solution of any of the instances 1-4 is also a solution of $\mathcal{I}$.

Proof. If S is a solution of $\mathcal{I}$, we can partition $V(G) \setminus S$ to parts $V_1' \supseteq V_1$, $V_2' \supseteq V_2$, and $V_3' \supseteq V_3$ by including the vertices in any connected component of $G \setminus S$ containing vertices of V_i into V_i' for all $i \in \{1, 2, 3\}$, and including the vertices in connected components containing

no vertices of V_1, V_2, V_3 into V_1', resulting in a partition (V_1', V_2', V_3') of $V(G) \setminus S$ such that S is a (V_1', V_2', V_3')-separator. Therefore, the first branch corresponds to when $v \in V_1'$, the second when $v \in V_2'$, the third when $v \in V_3'$, and the fourth when $v \in S$.

The direction that any solution of any of the instances 1-4 is also a solution of the original instance is immediate from the fact that we do not remove vertices from any V_i or S_0. ◀

Lemma 6 allows to branch into four subproblems, corresponding to the situation whether a vertex from R goes to V_1, V_2, V_3, or to S_0. Now, our goal is to branch until we derive an instance with $R \subseteq N(V_1 \cup V_2 \cup V_3)$, which can be solved by Lemma 5. In particular, we would like to branch on vertices $v \in R \setminus N(V_1 \cup V_2 \cup V_3)$. The following lemma shows that we can use $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$ as a measure of progress in the branching.

▶ **Lemma 7.** *For any vertex $v \in R \setminus N(V_1 \cup V_2 \cup V_3)$ it holds that $\alpha(R \setminus (N[v] \cup N(V_1 \cup V_2 \cup V_3))) < \alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$.*

Proof. If $\alpha(R \setminus (N[v] \cup N(V_1 \cup V_2 \cup V_3))) \geq \alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$, then we could take an independent set $I \subseteq R \setminus (N[v] \cup N(V_1 \cup V_2 \cup V_3))$ such that $|I| = \alpha(R \setminus N(V_1 \cup V_2 \cup V_3)$ and construct an independent set $I \cup \{v\} \subseteq R \setminus N(V_1 \cup V_2 \cup V_3)$ of size $|I \cup \{v\}| > \alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$, which is a contradiction. ◀

Lemma 7 implies that when branching on a vertex $v \in R \setminus N(V_1 \cup V_2 \cup V_3)$, the branches where v is moved to V_1, V_2, or V_3 decrease $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$. This will be the main idea of our algorithm for the case when $\alpha(R)$ is bounded, which we give next.

▶ **Lemma 8.** *There is a $2^{\mathcal{O}(\alpha(R))}n^{\mathcal{O}(k)}$-time 2-approximation algorithm for* PARTIAL 3-WAY α-SEPARATOR.

Proof. We give a branching algorithm, whose base case is the case when $R \subseteq N(V_1 \cup V_2 \cup V_3)$, which is solved by Lemma 5. The main idea is to analyze the branching by the parameter $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$, in particular with $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3)) = 0$ corresponding to the base case. The branching itself will be "exact" in the sense that all four cases of Lemma 6 are always included, in particular, the 2-approximation is caused only by the application of Lemma 5.

First, while $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3)) \geq 2k$, which can be checked in $n^{\mathcal{O}(k)}$ time, we branch as follows. We select an independent set $I \subseteq R \setminus N(V_1 \cup V_2 \cup V_3)$ of size $|I| = 2k$, and for all of its vertices we branch on whether to move it into V_1, V_2, V_3, or S_0, i.e., according to Lemma 6. Because I is an independent set, at most k of the vertices can go to S_0, so at least k go to V_1, V_2, or V_3. Also for the reason that I is an independent set, Lemma 7 can be successively applied for all of the vertices that go to V_1, V_2, or V_3. Therefore, this decreases $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$ by at least k, so the depth of this recursion is at most $\alpha(R)/k$, so the total number of nodes in this branching tree is at most $(4^{2k})^{\alpha(R)/k} = 2^{\mathcal{O}(\alpha(R))}$.

Then, we can assume that $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3)) < 2k$. We continue with a similar branching, this time branching on single vertices. In particular, as long as $R \setminus N(V_1 \cup V_2 \cup V_3)$ is nonempty, we select a vertex in it and branch on whether to move it into V_1, V_2, V_3, or S_0. To analyze the size of this branching tree, note that by Lemma 7, when moving a vertex into V_1, V_2, or V_3, the value of $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3))$ decreases by at least one. Therefore, as initially $\alpha(R \setminus N(V_1 \cup V_2 \cup V_3)) < 2k$, any root-to-leaf path of the branching tree contains less than $2k$ edges that correspond to such branches, and therefore any root-leaf path can be characterized by specifying the $< 2k$ indices corresponding to such edges, and then for these indices whether they correspond to V_1, V_2, or V_3. The length of any root-leaf path is at most n because $|R \setminus N(V_1 \cup V_2 \cup V_3)|$ decreases in every branch, and therefore the number of different root-to-leaf paths is at most $n^{2k}3^{2k} = n^{\mathcal{O}(k)}$, and therefore the total number of nodes in this branching tree is $n^{\mathcal{O}(k)}$.

Therefore, the total size of both of the branching trees put together is $2^{\mathcal{O}(\alpha(R))}n^{\mathcal{O}(k)}$, so our algorithm works by $2^{\mathcal{O}(\alpha(R))}n^{\mathcal{O}(k)}$ applications of Lemma 5, resulting in a $2^{\mathcal{O}(\alpha(R))}n^{\mathcal{O}(k)}$-time algorithm. ◀

Finally, what is left is to reduce the general case to the case where $\alpha(R) = \mathcal{O}(k^2)$. We do not know if this can be done in general, but we manage to do it by using a tree decomposition with independence number $\mathcal{O}(k)$. To this end, we show the following lemma. Given a graph G, a tree decomposition $\mathcal{T}$ of G, and a set $W \subseteq V(G)$, we say that W is *covered* by a set $\mathcal{B}$ of bags of $\mathcal{T}$ if every vertex in W is contained in at least one of the bags in $\mathcal{B}$. The lemma generalizes the well-known fact that any clique W of G, that is, a set with $\alpha(W) = 1$, is covered by a single bag of the tree decomposition.

▶ **Lemma 9.** *Let G be a graph, $\mathcal{T}$ a tree decomposition of G, and W a nonempty set of vertices of G. Then W is covered by a set of at most $2\alpha(W) - 1$ bags of $\mathcal{T}$.*

Proof. We denote $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$. Every edge $ab \in E(T)$ corresponds to a partition $(X_a \cap X_b, C_a, C_b)$ of $V(G)$, where C_a is the set of vertices of $G \setminus (X_a \cap X_b)$ in the bags of $\mathcal{T}$ that are closer to a than b, C_b is the set of vertices of $G \setminus (X_a \cap X_b)$ in the bags of $\mathcal{T}$ that are closer to b than a, and $X_a \cap X_b$ is a (C_a, C_b)-separator.

First, assume that for every edge ab either $C_a \cap W = \emptyset$ or $C_b \cap W = \emptyset$. If both $C_a \cap W = C_b \cap W = \emptyset$, then $W \subseteq X_a \cap X_b$, and we cover W by a single bag X_a (or X_b). Thus we may assume that for every edge exactly one of the sets $C_a \cap W$ and $C_b \cap W$ is nonempty. We orient the edge ab from a towards b if $C_b \cap W \neq \emptyset$, and from b to a if $C_a \cap W \neq \emptyset$. Because T is a tree, there exists a node $t \in V(T)$ such that all edges incident with t are oriented towards t. This implies that X_t covers W because otherwise some edge would be oriented away from t.

Note that if $\alpha(W) = 1$, then W is a clique and indeed for every edge ab either $C_a \cap W = \emptyset$ or $C_b \cap W = \emptyset$. The remaining case is that $\alpha(W) \geq 2$ and that there exists an edge ab such that both $|C_a \cap W| \geq 1$ and $|C_b \cap W| \geq 1$ hold. In this case, we use induction on $\alpha(W)$. Since $X_a \cap X_b$ is a (C_a, C_b)-separator, we have that $\alpha(C_a \cap W) + \alpha(C_b \cap W) \leq \alpha(W)$. Therefore we can take the union of a smallest set of bags covering $C_a \cap W$, a smallest set of bags covering $C_b \cap W$, and the bag X_a. By induction, this set of bags covering W contains at most $2\alpha(W \cap C_a) - 1 + 2\alpha(W \cap C_b) - 1 + 1 \leq 2\alpha(W) - 1$ bags. ◀

With Lemma 9, we can use a tree decomposition $\mathcal{T}$ with independence number $\alpha(\mathcal{T}) = \mathcal{O}(k)$ to 2-approximate the general case of PARTIAL 3-WAY α-SEPARATOR as follows. By Lemma 9, any solution S with $\alpha(S) \leq k$ is covered by at most $2k - 1$ bags of $\mathcal{T}$. Therefore, with $\mathcal{T}$ available (and having $n^{\mathcal{O}(1)}$ bags by standard arguments), we can guess a set of at most $2k - 1$ bags of $\mathcal{T}$ that covers S, and intersect R by the union of these bags, resulting in $\alpha(R) \leq \alpha(\mathcal{T})(2k - 1) = \mathcal{O}(k^2)$. Therefore, we solve the general case by $n^{\mathcal{O}(k)}$ applications of Lemma 8 with $\alpha(R) = \mathcal{O}(k^2)$, resulting in a total time complexity of $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$. This completes the proof of Theorem 3.

4.2 From separators to balanced separators

In this subsection we show that Theorem 3 can be used to either find certain balanced separators for sets $W \subseteq V(G)$ or to show that the tree-independence number of the graph is large.

To enforce the "balance" condition, we cannot directly enforce that the separator separates a given set W into sets of small independence numbers. (This would result in time complexity exponential in $|W|$ instead of $\alpha(W)$.) Instead, we fix a maximum independent set in W,

and enforce that this independent set is separated in a balanced manner. As long as the independent set is large enough, this will enforce that the separator is balanced also with respect to α. The following lemma, which is an adaptation of a well-known lemma given in Graph Minors II [36] is the starting point of this approach.

▶ **Lemma 10.** *Let G be a graph with the tree-independence number at most k and $I \subseteq V(G)$ an independent set. Then there exists a partition (S, C_1, C_2, C_3) of $V(G)$ (where some C_i can be empty) such that S is a (C_1, C_2, C_3)-separator, $\alpha(S) \leq k$, and $|I \cap (C_i \cup C_j)| \geq |I|/2 - k$ for any pair $i, j \in \{1, 2, 3\}$ with $i \neq j$.*

Proof. Let $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$ be a tree decomposition of G with $\alpha(\mathcal{T}) \leq k$. As in Lemma 9, we introduce the following notation. Every edge $ab \in E(T)$ of T corresponds to a partition $(X_a \cap X_b, C_a, C_b)$ of $V(G)$, where C_a is the set of vertices of $G \setminus (X_a \cap X_b)$ in the bags of $\mathcal{T}$ that are closer to a than b, C_b is the set of vertices of $G \setminus (X_a \cap X_b)$ in the bags of $\mathcal{T}$ that are closer to b than a, and $X_a \cap X_b$ is a (C_a, C_b)-separator. We orient the edge ab from a to b if $|C_b \cap I| > |I|/2$, from b to a if $|C_a \cap I| > |I|/2$, and otherwise arbitrarily. Now, because T is a tree, there exists a node $t \in V(T)$ such that all of its incident edges are oriented towards it. Therefore, for all connected components C of $G \setminus X_t$, we see that $|V(C) \cap I| \leq |I|/2$, as otherwise some edge would be oriented out of t.

As long as the number of such connected components C is at least 4, we can take two of them with the smallest values of $|V(C) \cap I|$ and merge them, in the end arriving at a partition (X_t, C_1, C_2, C_3) of $V(G)$ such that X_t is a (C_1, C_2, C_3)-separator, $\alpha(X_t) \leq k$, and $|I \cap C_i| \leq |I|/2$ for all $i \in \{1, 2, 3\}$. Then, because $|I \cap C_i| \leq |I|/2$, we have that $|I \cap (V(G) \setminus C_i)| \geq |I|/2$. Therefore, since $|I \cap X_t| \leq k$, it follows that $|I \cap (C_j \cup C_\ell)| \geq |I|/2 - k$, where (i, j, ℓ) is any permutation of the set $\{1, 2, 3\}$. ◀

Next we use Lemma 10 together with the separator algorithm of Theorem 3 to design an algorithm for finding α-balanced separators of sets W with $\alpha(W) = 6k$.

▶ **Lemma 11.** *There is an algorithm that for a given graph G, an integer k, a tree decomposition of G with independence number $\mathcal{O}(k)$, and a set $W \subseteq V(G)$ with $\alpha(W) = 6k$, in time $2^{\mathcal{O}(k^2)} n^{\mathcal{O}(k)}$ either concludes that the tree-independence number of G is larger than k, or finds a partition (S, C_1, C_2, C_3) of $V(G)$ such that S is a (C_1, C_2, C_3)-separator, $\alpha(S) \leq 2k$, at most one of C_1, C_2, and C_3 is empty, and $\alpha(W \cap C_i) \leq 4k$ for each $i \in \{1, 2, 3\}$.*

Proof. First, we take an arbitrary independent set $I \subseteq W$ of size $|I| = 6k$, which can be found in $n^{\mathcal{O}(k)}$ time. If the tree-independence number of G is at most k, then, by Lemma 10, there exists a partition (S, C_1, C_2, C_3) of $V(G)$ such that S is a (C_1, C_2, C_3)-separator, $\alpha(S) \leq k$, and $|I \cap (C_i \cup C_j)| \geq |I|/2 - k \geq 2k$ for any pair $i, j \in \{1, 2, 3\}$ with $i \neq j$. We guess the intersection of such a partition with I, in particular we guess the partition $(S \cap I, C_1 \cap I, C_2 \cap I, C_3 \cap I)$, immediately enforcing that it satisfies the constraints $|I \cap (C_i \cup C_j)| \geq 2k$ for $i \neq j$.

For each such guess, we use Theorem 3 to either find a $(C_1 \cap I, C_2 \cap I, C_3 \cap I)$-separator with independence number at most $2k$ or to decide that no such separator with independence number at most k exists. The set S of the partition guaranteed by Lemma 10 is indeed a $(C_1 \cap I, C_2 \cap I, C_3 \cap I)$-separator with independence number at most k, so if the algorithm reports for every guess that no such separator exists, we return that G has the independence number larger than k.

Otherwise, for some guess a $(C_1 \cap I, C_2 \cap I, C_3 \cap I)$-separator S' with $\alpha(S') \leq 2k$ is found, and we return the partition (S', C'_1, C'_2, C'_3), where C'_i is the union of the vertex sets of components of $G \setminus S'$ that contain a vertex of $C_i \cap I$, for all $i \in \{1, 2, 3\}$. Because

$|I \cap (C_i \cup C_j)| \geq 2k$ for $i \neq j$, we see that $\alpha(W \cap C_\ell) \leq \alpha(W) - 2k \leq 4k$, where (i, j, ℓ) is an arbitrary permutation of the set $\{1, 2, 3\}$, because otherwise we could use the union of $I \cap (C_i \cup C_j)$ and a maximum independent set in $W \cap C_\ell$ to construct an independent set in W of size larger than $\alpha(W)$. Also, because $|I \cap (C_i \cup C_j)| \geq 2k$ for any pair $i \neq j$, the set C_i cannot be empty for more than one i.

The algorithm works by first finding an independent set of size $6k$ and then using the algorithm of Theorem 3 at most 4^{6k} times, so the total time complexity is $\mathcal{O}(n^{6k}) + 4^{6k} \cdot 2^{\mathcal{O}(k^2)} n^{\mathcal{O}(k)} = 2^{\mathcal{O}(k^2)} n^{\mathcal{O}(k)}$. ◀

4.3 Constructing the decomposition

Everything is prepared for the final step of the proof – the algorithm constructing a tree decomposition with independence number at most $8k$ by using the balanced separator algorithm of Lemma 11. Our algorithm constructs a tree decomposition from root to the leaves by maintaining an "interface" W and breaking it with balanced separators. This is a common strategy used for various algorithms for constructing tree decompositions and branch decompositions. In our case, perhaps the largest hurdle in the proof is the analysis that the size of the recursion tree and the constructed decomposition is polynomial in n.

A rooted tree decomposition is a tree decomposition where one node is designated as the root.

▶ **Lemma 12.** *There is an algorithm that for a given graph G, an integer k, a tree decomposition of G with independence number $\mathcal{O}(k)$, and a set $W \subseteq V(G)$ with $\alpha(W) \leq 6k$, in time $2^{\mathcal{O}(k^2)} n^{\mathcal{O}(k)}$ either determines that the tree-independence number of G is larger than k or returns a rooted tree decomposition $\mathcal{T}$ of G with independence number at most $8k$ such that W is contained in the root bag of $\mathcal{T}$.*

Proof. The algorithm will be based on recursively constructing the decomposition, using W as the interface in the recursion. First, if $\alpha(G) \leq 6k$, we return the trivial tree decomposition with only one bag $V(G)$. Otherwise, we start by inserting arbitrary vertices of G into W until the condition $\alpha(W) = 6k$ holds.

Then, we apply the algorithm of Lemma 11 to find a partition (S, C_1, C_2, C_3) of $V(G)$ such that S is a (C_1, C_2, C_3)-separator, $\alpha(S) \leq 2k$, $\alpha(W \cap C_i) \leq 4k$ for each $i \in \{1, 2, 3\}$, and at most one of C_1, C_2, C_3 is empty, or to determine that the tree-independence number of G is larger than k, in this case returning no immediately. Then, we construct the tree decomposition recursively as follows: for each $i \in \{1, 2, 3\}$, we recursively use the algorithm with the graph $G_i = G[C_i \cup S]$ and the set $W_i = (C_i \cap W) \cup S$. Let $\mathcal{T}_1$, $\mathcal{T}_2$, $\mathcal{T}_3$ be the obtained tree decompositions and let r_1, r_2, r_3 be their root nodes. We create a new root node r with a bag $X_r = S \cup W$, and connect r_1, r_2, and r_3 as children of r.

Lemma 11 guarantees that $\alpha(C_i \cap W) \leq 4k$ and $\alpha(S) \leq 2k$, and therefore $\alpha(W_i) \leq 6k$. Also, $\alpha(S \cup W) \leq 8k$ because $\alpha(W) \leq 6k$ and $\alpha(S) \leq 2k$. Therefore, the independence number of the constructed tree decomposition is at most $8k$. The constructed tree decomposition satisfies all conditions of tree decompositions: Because S is a separator between C_1, C_2, and C_3, when recursing into the graphs $G_i = G[C_i \cup S]$ for $i \in \{1, 2, 3\}$, the union of the graphs G_1, G_2, and G_3 includes all vertices and edges of G. Therefore, by induction, every vertex and edge will be contained in some bag of the constructed tree decomposition (the base case is $\alpha(G) \leq 6k$). By induction, the decomposition satisfies also the connectivity condition: if a vertex occurs in G_i and G_j for $i \neq j$, then it is in S and therefore in the bag X_r and also in the sets W_i and W_j and therefore in the root bags X_{r_i} and X_{r_j} of $\mathcal{T}_i$ and $\mathcal{T}_j$.

It remains to argue that the size of the recursion tree (and equivalently the size of the decomposition constructed) is $n^{\mathcal{O}(1)}$. First, by the guarantee of Lemma 11 that C_i is empty for at most one $i \in \{1,2,3\}$, we have that each G_i has strictly fewer vertices than G, and therefore the constructed tree has height at most n. We say that a constructed node t is a forget node if its bag contains a vertex v so that its parent's bag does not contain v. The number of forget nodes is at most n because a vertex can be forgotten only once in a tree decomposition.

Recall that in the start of each recursive call, on a graph G_i and a subset W_i, we either recognize that $\alpha(G_i) \leq 6k$, creating a leaf node in this case, or add vertices to W_i until $\alpha(W_i) = 6k$. In the latter case, as these added vertices were not initially in W_i, they are not in the bag of the parent node, and therefore the node constructed in such a call will be a forget node if any such vertices are added. Therefore, the new node constructed can be a non-forget non-leaf node only if $\alpha(W_i) = 6k$ already for the initial input W_i. Then, we observe that $\alpha(W_i) = 6k$ can hold for the initial input W_i only if $\alpha(C_i \cap W) = 4k$ did hold for the corresponding component C_i of the parent and the corresponding set W. Therefore, as $\alpha(C_i \cap W) = 4k$ can hold for at most one $i \in \{1,2,3\}$, we have that any node can have at most one non-forget non-leaf child node.

It follows that non-forget non-leaf nodes can be decomposed into maximal paths going between a node and its ancestor, and these paths have a length at most n by the height of the tree. Each such path either starts at the root or its highest node is a child of a forget node. Thus, the number of maximal paths of non-forget non-leaf nodes is at most n, and therefore the number of non-forget non-leaf nodes is at most n^2. The number of leaf nodes is at most three times the number of non-leaf nodes, so the total number of nodes is $\mathcal{O}(n^2)$.

Therefore, the algorithm works by $\mathcal{O}(n^2)$ applications of the algorithm of Lemma 11, and therefore its time complexity is $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$. ◀

It remains to observe that by using iterative compression, we can satisfy the requirement of Lemma 12 to have a tree decomposition with independence number $\mathcal{O}(k)$ as an input (in particular, here the independence number will be at most $8k+1$), and therefore Lemma 12 implies Theorem 1.

In more detail, we order the vertices of G as $v_1, \ldots, v_n$, and iteratively compute tree decompositions with independence number at most $8k$ for induced subgraphs $G[\{v_1, \ldots, v_i\}]$, for increasing values of i. The iterative computation guarantees that when computing the tree decomposition for $G[\{v_1, \ldots, v_i\}]$, we have the tree decomposition for $G[\{v_1, \ldots, v_{i-1}\}]$ with independence number at most $8k$ available, which can be used to obtain a tree decomposition with independence number at most $8k+1$ of $G[\{v_1, \ldots, v_i\}]$ by adding v_i to each bag to be used as the input tree decomposition. More precisely, we use Lemma 12 to either determine in time $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$ that the tree-independence number of $G[\{v_1, \ldots, v_i\}]$ is larger than k or obtain a rooted tree decomposition $\mathcal{T}$ of $G[\{v_1, \ldots, v_i\}]$ with independence number at most $8k$. As the tree-independence number does not increase when taking induced subgraphs, if for some induced subgraph we conclude that the tree-independence number is larger than k, we can conclude the same holds also for G. Otherwise, after n steps we will have a rooted tree decomposition $\mathcal{T}$ of G with independence number at most $8k$.

5 Hardness of computing tree-independence number

In this section, we complement our main algorithmic result by complexity lower bounds. First, we use the W[1]-hardness of independent set approximation by Lin [30] and the Gap-ETH result of Chalermsook et al. [7] to prove the following theorem.

▶ **Theorem 13** (⋆). *For any constant $c \geq 1$, there is no algorithm running in $f(k) \cdot n^{\mathcal{O}(1)}$ time for a computable function $f(k)$ that, given an n-vertex graph and a positive integer k, can distinguish between the cases* tree-$\alpha(G) \leq k$ *and* tree-$\alpha(G) > ck$, *unless FPT = W[1]. Moreover, assuming* Gap-ETH, *for any computable function $g(k) \geq k$, there is no algorithm running in $f(k) \cdot n^{o(k)}$ time for a computable function $f(k)$ that, given an n-vertex graph and a positive integer k, can distinguish between the cases* tree-$\alpha(G) \leq k$ *and* tree-$\alpha(G) > g(k)$.

Theorem 13 implies that it is W[1]-hard to decide whether tree-$\alpha(G) \leq k$ for the parameterization by k. However, the problem is, in fact, harder. We prove that it is NP-complete to decide whether tree-$\alpha(G) \leq 4$.

▶ **Theorem 2** (⋆). *For every constant $k \geq 4$, it is NP-complete to decide whether* tree-$\alpha(G) \leq k$ *for a given graph G.*

Finally, we show that, for every fixed integer $k \geq 3$, deciding if two given vertices of a graph can be separated by removing a set of vertices that induces a graph with independence number at most k is NP-complete. To put this result in perspective, note that the case with $k = 1$ is polynomial since we can compute all clique cutsets in polynomial time using Tarjan's algorithm [39]. We leave open the case with $k = 2$.

▶ **Theorem 14** (⋆). *For every integer $k \geq 3$, it is NP-complete to decide, given a graph H and two distinct vertices $u, v \in V(H)$, if there exists a u,v-separator S such that $\alpha(H[S]) \leq k$.*

6 Conclusion

The main result of our paper is an algorithm that, given an n-vertex graph G and an integer k, in time $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$ either outputs a tree decomposition of G with independence number at most $8k$, or concludes that the tree-independence number of G is larger than k. This yields also the same result for computing the minor-matching hypertree-width of a graph [40]. Our results allow to solve in $2^{\mathcal{O}(k^2)}n^{\mathcal{O}(k)}$ time a plethora of problems when the inputs are restricted to graphs of tree-independence number k or minor-matching hypertree-width k [15, 29, 40]. We now show that this result is tight in several aspects.

First, one could ask what is the most general width-parameter defined by a min-max formula over the bags of a tree decomposition (see, e.g. [2, 33]) that allows to solve problems like Maximum Independent Set in polynomial time when bounded? For parameters where the width of a bag depends only on the induced subgraph of the bag, this turns out to be tree-α. In particular, we recall that Maximum Independent Set is NP-hard on graphs with each edge subdivided twice, but such graphs admit a tree decomposition where one bag is a large independent set, and the induced subgraphs of the other bags are isomorphic to 4-vertex paths. It follows that if the width-measure of a bag is monotone, i.e., it does not increase when taking induced subgraphs, it must be unbounded whenever α is unbounded. In other words, if there would be a width parameter tree-λ defined as the minimum, over all tree decomposition, of the maximum of $\lambda(G[X_t])$ over the bags X_t of the tree decomposition, where λ is a monotone graph invariant, then either Maximum Independent Set is already NP-hard when λ is a constant, or the parameterization by tree-α is more general than the parameterization by tree-λ.

The width parameter tree-μ, the minor-matching hypertree-width, escapes this argument because it does not only depend on the subgraphs induced by the bags, but also on the neighborhoods of the bags. In particular, for tree-μ the width of a bag X_t is defined as the maximum cardinality of an induced matching in G whose every edge intersects X_t. A

similar example shows that this type of parameters where the width of a bag X_t depends on $G[N[X_t]]$ cannot be generalized much more: If we start from Maximum Independent Set on cubic graphs and subdivide each edge four times, we obtain graphs where Maximum Independent Set is NP-hard, but that admit tree decompositions that contain one large bag X_t such that every connected component of $G[N[X_t]]$ is a 3-vertex path, while for all other bags X_t their closed neighborhood $N[X_t]$ has bounded size.

Further, we remind that our main result is computationally tight. In particular, in Theorem 13, we proved that it is unlikely that there is a $g(k)$-approximation algorithm for the tree-independence number with running time $f(k)n^{o(k)}$, for any computable function g. This shows that the $n^{\Omega(k)}$-factor in the running time is unavoidable up to some reasonable complexity assumptions. For exact computation of the tree-independence number, we proved in Theorem 2 that it is NP-complete to decide whether tree-$\alpha(G) \leq k$ for every constant $k \geq 4$. Since tree-$\alpha(G) = 1$ if and only if G is a chordal graph, Theorem 2 leads to the question about the complexity of deciding whether the tree-independence number is at most k for $k = 2$ and 3. In Theorem 14, we demonstrated that for every fixed integer $k \geq 3$, deciding if two given vertices of a graph can be separated by removing a set of vertices that induces a graph with independence number at most k is NP-complete. This result indicates that it may be already NP-complete to decide whether tree-$\alpha(G) \leq 3$. We hesitate to state any conjecture for the case $k = 2$.

The final question is about the place of computing the tree-independence number in the polynomial hierarchy. For a fixed k, deciding whether tree-$\alpha(G) \leq k$ is in NP. However, when k is a part of the input, the problem is naturally placed in the class Σ_2^P on the second level of the polynomial hierarchy. Is the problem Σ_2^P-complete?

Abstract

This paper considers correlation clustering on unweighted complete graphs. We give a combinatorial algorithm that returns a *single* clustering solution that is *simultaneously* $O(1)$-approximate for all ℓ_p-norms of the disagreement vector; in other words, a combinatorial $O(1)$-approximation of the *all-norms* objective for correlation clustering. This is the first proof that minimal sacrifice is needed in order to optimize different norms of the disagreement vector. In addition, our algorithm is the first combinatorial approximation algorithm for the ℓ_2-norm objective, and more generally the first combinatorial algorithm for the ℓ_p-norm objective when $1 < p < \infty$. It is also faster than all previous algorithms that minimize the ℓ_p-norm of the disagreement vector, with run-time $O(n^\omega)$, where $O(n^\omega)$ is the time for matrix multiplication on $n \times n$ matrices. When the maximum positive degree in the graph is at most Δ, this can be improved to a run-time of $O(n\Delta^2 \log n)$.

1 Introduction

Correlation clustering is one of the most prominent problems in clustering, as it cleanly models community detection problems [38, 36] and provides a way to decompose complex network structures [39, 32]. The input to the unweighted correlation clustering problem is a complete graph $G = (V, E)$, where $|V| = n$ and each edge $e \in E$ is labeled positive $(+)$ or negative $(-)$. If the edge (u, v) is positive, this indicates that u and v are similar, and analogously if the edge (u, v) is negative, this indicates that u and v are dissimilar. The output of the problem is a partition of the vertex set into parts $C_1, C_2, \ldots$, where each part represents a cluster.

The output should cluster similar vertices together and separate dissimilar vertices. Specifically, for a fixed clustering (i.e., partition of the vertices), a positive edge (u, v) is a *disagreement* with respect to the clustering if u and v are in different clusters and an *agreement* if u and v are in the same cluster. Similarly, a negative edge (u, v) is a disagreement with respect to the clustering if u and v are in the same cluster and an agreement if u and v are in different clusters. The goal is to find a clustering that minimizes some objective that is a function of the disagreements.[1] For example, the most commonly studied objective minimizes the total number of disagreements.

As an easy example to illustrate the problem, consider a social network. Every pair of people has an edge between them, and the edge is positive if the two people have ever met before, and negative otherwise. The goal of correlation clustering translates to partitioning all the people into clusters so that people are in the same cluster as their friends/acquaintances and in different clusters than strangers. The difficulty in constructing a clustering is that the labels may not be consistent, making disagreements unavoidable. Consider in the social network what happens when there is one person with two friends who have never met each other (u, v, w with (u, v) and (u, w) positive but (v, w) negative). The choice of objective matters in determining the best clustering.

For a given clustering $\mathcal{C}$, let $y_{\mathcal{C}}(u)$ denote the number of edges incident to u that are disagreements with respect to $\mathcal{C}$ (we drop $\mathcal{C}$ and write y when it is clear from context). The most commonly considered objectives are $\|y_{\mathcal{C}}\|_p = \sqrt[p]{\sum_{u \in V} y_{\mathcal{C}}(u)^p}$ for $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$, the ℓ_p-norms of the *disagreement vector* y. Note that the optimal objective values may drastically vary for different norms too. (For instance, in the example in Appendix A of [35], $V = A \sqcup B$[2], where $|A| = |B| = n/2$, and all edges are positive except for a negative matching between A and B. The optimal ℓ_∞-norm objective value is 1 whereas the optimal for ℓ_1 is $\Theta(n)$.) When $p = 1$, this objective minimizes the total number of disagreements. Setting $p = \infty$ minimizes the maximum number of disagreements incident to any node, ensuring a type of worst-case fairness.[3] Balancing these two extremes – average welfare on one hand and fairness on the other – is the ℓ_2-norm, which minimizes the variance of the disagreements at each node.

Correlation clustering was proposed by Bansal, Blum, and Chawla [7] with the objective of minimizing the ℓ_1-norm of the disagreement vector. The problem is NP-hard and several approximation algorithms have been proposed [7, 4, 16, 18]. Puleo and Milenkovic [35] proposed studying ℓ_p-norms of the disagreement vector for $p > 1$, and they give a 48-approximation for any fixed p. Charikar, Gupta, and Schwartz [15] introduced an improved 7-approximation, which Kalhan, Makarychev, and Zhou [29] further improved to a 5-approximation. When $p > 1$, up until recently, the only strategies were LP or SDP rounding, and it has been of interest to develop fast combinatorial algorithms [37]. Davies, Moseley, and Newman [19] introduced a combinatorial $O(1)$-approximation algorithm for $p = \infty$ (see also [25] for a different combinatorial algorithm), and leave open the question of discovering a combinatorial $O(1)$-approximation algorithm for $1 < p < \infty$.

In all prior work, solutions obtained for ℓ_p-norms are tailored to each norm (i.e., p is part of the input to the algorithm), and it was not well-understood what the trade-offs were between solutions that optimize different norms. Solutions naively optimizing one norm can be arbitrarily bad for other norms (see Figure 1). A natural question is whether this loss from using a solution to one objective for another is avoidable. More specifically:

[1] Note that the sizes and number of clusters are unspecified.

[2] $\sqcup$ denotes disjoint union.

[3] In the social network example, minimizing the ℓ_1-norm corresponds to finding a clustering that minimizes the total number of friends who are separated plus the total number of strangers who are in the same cluster. The ℓ_∞-norm corresponds to finding a clustering minimizing the number of friends any person is separated from plus the number of strangers in that person's same cluster.

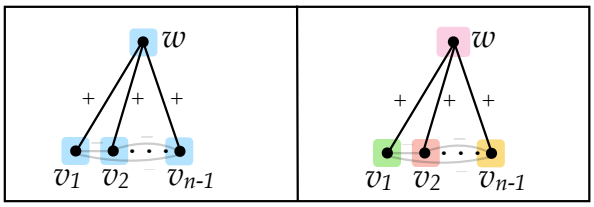

Figure 1 Two clusterings of the star graph, which has one node (w) with positive edges to all nodes, and the rest of the edges negative. **Left:** Clustering assigns all nodes to one (blue) cluster, and is (almost) optimal for the ℓ_∞-norm with cost $\Theta(n)$. **Right:** Clustering assigns all nodes to different clusters and is (almost) optimal for the ℓ_1-norm with cost $\Theta(n)$. The left solution is terrible for the ℓ_1-norm, as the negative clique has $\Theta(n^2)$ edges that are disagreements.

For any graph input to unweighted, complete correlation clustering, does there exist a partition (clustering) that is ***simultaneously*** $O(1)$*-approximate for all* ℓ_p*-norm objectives?*

Phrased another way, does there exist a *universal algorithm* for ℓ_p-norm correlation clustering – one which is guaranteed to produce a solution that well-approximates many objectives at once? When the goal is to simultaneously optimize every ℓ_p-norm, this is known as the *all-norms* objective.[4] Universal algorithms and the all-norms objective are well-studied in combinatorial optimization problems, such as load balancing and set cover (see Section 1.2 for more discussion). In the context of correlation clustering, such an algorithm outputs a partition that has good global performance (i.e. ℓ_1-norm) and also has no individual node with too many adjacent disagreements (i.e. ℓ_∞-norm). Universal algorithms exist for some problems and are provably impossible for others. The question looms, what can be said about universal algorithms for correlation clustering?

As far as we are aware, there are no known results for the all-norms objective in other clustering problems. In fact, for the popular k-median and k-center problems, it is actually *impossible* to $O(1)$-approximate (or even $o(\sqrt{n})$-approximate) these two objectives simultaneously [5].

1.1 Results

This paper is focused on optimizing all ℓ_p-norms ($p \geq 1$) for correlation clustering at the same time. The main result of the paper answers the previous question positively: perhaps surprisingly, there is a single clustering that simultaneously $O(1)$-approximates the optimal for all ℓ_p-norms. Further, it can be found through an *efficient combinatorial algorithm*. This is also the first known combinatorial approximation algorithm for the ℓ_2-norm objective and more generally ℓ_p-norm objective for fixed $2 \leq p < \infty$.

In what follows, let $O(n^\omega)$ denote the run-time of $n \times n$ matrix multiplication.

▶ **Theorem 1.** *Let $G = (V, E)$ be an instance of unweighted, complete correlation clustering on $|V| = n$ nodes. There exists a combinatorial algorithm returning a single clustering that is simultaneously an $O(1)$-approximation[5] for all ℓ_p-norm objectives, for all $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$, and its run-time is $O(n^\omega)$.*

[4] In some of the literature, for instance that of Golovin et al. [24], it is called the *all-ℓ_p-norms* objective.
[5] Note this is independent of p.

The algorithm gives the *fastest run-time* of any $O(1)$-approximation algorithm for the ℓ_p-norm objective when $p \in \mathbb{R}_{>1}$. Further, the run-time can be improved when the positive degree of the graph is bounded, as shown in the following corollary.

▶ **Corollary 2.** *Let Δ denote the maximum positive degree in an instance $G = (V, E)$ of unweighted, complete correlation clustering on $|V| = n$ nodes. Suppose G is given as an adjacency list representation of its positive edges. There exists a combinatorial algorithm returning a single clustering that is simultaneously an $O(1)$-approximation for all ℓ_p-norm objectives, for all $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$, and its run-time is $O(n\Delta^2 \log n)$.*

The run-time of the algorithm matches the fastest known algorithm for the ℓ_∞-norm objective [19], in both the general case and when the maximum positive degree is bounded. The best-known algorithm before our work relied on solving a convex relaxation on $|V|^2$ variables and $|V|^3$ constraints. We improve the run-time by avoiding this bottleneck.

In the setting when the positive edges form a regular graph, the interested reader may also find a clean proof (which is much simpler than that of Theorem 1) in Section 3 showing there is a solution that is simultaneously $O(1)$-approximate for the ℓ_1-norm and ℓ_∞-norm objectives.

1.2 Related work

Correlation clustering was introduced by Bansal, Blum, and Chawla [7]. The version they introduced also studies the problem on unweighted, complete graphs, but is concerned with minimizing the ℓ_1-norm of the disagreement vector. For this problem, Ailon, Charikar, and Newman [4] designed the Pivot algorithm, which is a randomized algorithm that in expectation obtains a 3-approximation. While we know algorithms with better approximations for ℓ_1 correlation clustering than Pivot [16, 18], the algorithm remains a baseline in correlation clustering due to its simplicity. (However, Pivot can perform arbitrarily badly – i.e., give $\Omega(n)$ approximation ratios – for other ℓ_p-norms; see again the example in Appendix A of [35].) It is an active area of research to develop algorithms for the ℓ_1-norm that focus on practical scalability [11, 17, 33, 36, 14]. Correlation clustering has also been studied on non-complete, weighted graphs [15, 29], with conditions on the cluster sizes [34], and with asymmetric errors [26]. In fact, in recent work Veldt [37] highlighted the need for deterministic techniques in correlation clustering that do not use linear programming. Much interest in correlation clustering stems from its connections to applications, including community detection, natural language processing, location area planning, and gene expression [38, 36, 39, 32, 9, 21].

Puleo and Milenkovic [35] introduced correlation clustering with the goal of minimizing the ℓ_p-norm of the disagreement vector. They show that even for minimizing the ℓ_∞-norm on complete, unweighted graphs, the problem is NP-hard (Appendix C in [35]). Several groups found $O(1)$-approximation algorithms for minimizing the ℓ_p-norm on complete, unweighted graphs [35, 15, 29], the best of which is currently the 5-approximation of Kalhan, Makarychev, and Zhou [29]. Many other interesting objectives for correlation clustering focus on finding solutions that are (in some sense) fair or locally desirable [3, 8, 1, 22, 27, 2]. All of these previous works that study general ℓ_p-norms or other notions of fairness or locality rely on solving a convex relaxation. This has two downsides: (1) the run-time of the algorithms are bottle-necked by the time it takes to solve the relaxation with at least $\Omega(n^2)$ many variables and $\Omega(n^3)$ constraints; in fact, it is time-consuming to even enumerate the $\Omega(n^2)$ variables and $\Omega(n^3)$ constraints; and (2) the solution is only guaranteed to be good for one particular value of p.

Several problems have been studied with the goal of finding a solution that is a good approximation for several objectives simultaneously. The all-norms objective was introduced by Azar et al. [6], where the goal is to design a ρ-approximation algorithm for all ℓ_p-norm objectives of a problem. They originally introduced the objective for the restricted assignment load balancing problem and showed an all-norms 2-approximation. Further follow-up on the all-norms objective has been done for load balancing [30, 10, 31], and for set cover [24]. The term "universal" algorithm has also been used for Steiner tree [12, 13], TSP [28], and clustering [23], though in these settings the goal is different, namely, to find a solution that is good for any potential *input*; e.g., in Universal Steiner Tree, the goal is to find a spanning tree where for any set of terminals, the sub-tree connecting the root to the terminals is a good approximation of the optimal.

2 Preliminaries

We will introduce notation, and then we will discuss two relevant works – the papers by Kalhan, Makarychev, and Zhou [29] and Davies, Moseley, and Newman [19].

2.1 Notation

Recall our input to the correlation clustering problem is $G = (V, E)$, an unweighted, complete graph on n vertices, and every edge is assigned a label of either positive $(+)$ or negative $(-)$. Let the set of positive edges be denoted E^+ and the set of negative edges E^-. Then, we can define the *positive neighborhood* and *negative neighborhood* of a vertex u as $N_u^+ = \{v \in V \mid (u, v) \in E^+\}$ and $N_u^- = \{v \in V \mid (u, v) \in E^-\}$, respectively. We further assume without loss of generality that every vertex has a positive self-loop to itself.

A *clustering* $\mathcal{C}$ is a partition of V into *clusters* $C_1, \ldots, C_k$ (but recall that k is *not* pre-specified). Let $C(u)$ denote the cluster that vertex u is in, i.e., if $\mathcal{C}$ has k clusters, there exists exactly one $i \in [k]$ such that $C(u) = C_i$. It is also helpful to consider the vertices in a different cluster than u, and so we let $\overline{C(u)} = V \setminus C(u)$ denote this. We say that a positive edge $e = (u, v) \in E^+$ is a *disagreement* with respect to $\mathcal{C}$ if $v \in \overline{C(u)}$. On the other hand, we say that a negative edge $e = (u, v) \in E^-$ is a disagreement with respect to $\mathcal{C}$ if $v \in C(u)$. For a fixed clustering $\mathcal{C}$, we denote the *disagreement vector* of $\mathcal{C}$ as $y_{\mathcal{C}} \in \mathbb{Z}^n_{\geq 0}$, where for $u \in V$, $y_{\mathcal{C}}(u)$ is the number of edges incident to u that are disagreements with respect to $\mathcal{C}$. We omit the subscript throughout the proofs when a clustering is clear.

Throughout, we let OPT be the optimal objective value, and the ℓ_p-norm to which it corresponds will be clear from context. The next fact follows from the definitions seen so far (recalling also the positive self-loops).

▶ **Fact 3.** *For any $u, v \in V$, $n = |N_u^+ \cap N_v^+| + |N_u^- \cap N_v^-| + |N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|$.*

2.2 Summary of work by Kalhan, Makarychev, and Zhou

The standard linear program relaxation for correlation clustering is given in (P) below.[6] In the *integer* LP, the variable x_{uv} indicates whether vertices u and v will be in the same cluster (0 for yes, 1 for no), and the disagreement vector is y; the optimal solution to the integer LP has value OPT, while the optimal solution to the relaxation gives a lower bound on OPT. Note the triangle inequality is enforced on all triples of vertices, inducing a semi-metric space

[6] Technically this is a convex program as the objective is convex; we say LP as the constraints are linear.

on V. Throughout this paper, as in [19], we refer to the algorithm by Kalhan, Makarychev, and Zhou as the KMZ algorithm. The *KMZ algorithm* has two phases: it solves (P), and then uses the *KMZ rounding algorithm* to obtain an integral assignment of vertices to clusters. At a high-level, the KMZ rounding algorithm is an iterative, ball-growing algorithm that uses the semi-metric to guide its choices. Their algorithm is a 5-approximation, and produces different clusterings for different p, since the optimal solution x^* to (P) depends on p.

$$\begin{aligned} &\min \|y\|_p \\ \text{s.t. } y_u &= \sum_{v \in N_u^+} x_{uv} + \sum_{v \in N_u^-} (1 - x_{uv}) && \forall u \in V \\ x_{uv} &\leq x_{uw} + x_{vw} && \forall u, v, w \in V \\ 0 &\leq x_{uv} \leq 1 && \forall u, v \in V. \end{aligned} \tag{P}$$

▶ **Definition 4.** *Let f be a semi-metric on V, i.e., taking $x = f$ gives a feasible solution to (P). The* fractional cost of f in the ℓ_p-norm objective *is the value of (P) that results from setting $x = f$. When p is clear from context, we will simply call this the fractional cost of f.*

2.3 Summary of work by Davies, Moseley, and Newman

The main take-away from the work of Kalhan, Makarychev, and Zhou [29] is that one only requires a semi-metric on the set of vertices, whose cost is comparable to the cost of an optimal solution, as input to the KMZ rounding algorithm. Thus, the insight of Davies, Moseley, and Newman [19] for the ℓ_∞-norm objective is that one can combinatorially construct such a semi-metric without solving an LP, and at small loss in the quality of the fractional solution. They do this by introducing the *correlation metric*.

▶ **Definition 5** ([19])**.** *For all $u, v \in V$, the correlation metric defines the distance between u and v as*

$$d_{uv} = 1 - \frac{|N_u^+ \cap N_v^+|}{|N_u^+ \cup N_v^+|} = \frac{|N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|}{|N_u^+ \cap N_v^+| + |N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|}.$$

Note that the rewrite in the second equality is apparent from Fact 3.

The correlation metric captures useful information succinctly. Intuitively, if u and v have relatively large positive intersection, i.e., $N_u^+ \cap N_v^+$ is large compared to their other relevant joint neighborhoods $(N_u^+ \cap N_v^-) \cup (N_u^- \cap N_v^+)$, then from the perspective of u and v, fewer disagreements are incurred by putting u and v in the same cluster than by putting them in different clusters. This is because if u and v are in the same cluster, then they have disagreements on edges (u, w) and (v, w) for $w \in (N_u^+ \cap N_v^-) \cup (N_u^- \cap N_v^+)$, but if they are in different clusters, then u and v have disagreements on edges (u, w) and (v, w) for $w \in N_u^+ \cap N_v^+$. For more on intuition behind the correlation metric, see Section 2 in [19].

Davies, Moseley, and Newman [19] prove that the correlation metric d can be used as input to the KMZ rounding algorithm by showing that (1) d satisfies the triangle inequality and (2) the fractional cost of d in the ℓ_∞-norm (recall Definition 4) is no more than 8 times the value of the optimal integral solution (OPT). Since the KMZ rounding algorithm loses a factor of at most 5, inputting d to that algorithm returns a 40-approximation algorithm. A benefit of the correlation metric is that it can be computed in time $O(n^\omega)$, and even faster when the subgraph on positive edges is sparse.

2.4 Technical overview

It is not hard to see that the correlation metric cannot be used as input to the KMZ algorithm for ℓ_p-norms other than $p = \infty$, as one cannot bound the fractional cost of the correlation metric against the optimal with only an $O(1)$-factor loss. To see why, consider the star again, as in Figure 1. Here, for all $u, v \in \{v_1, \ldots, v_{n-1}\}$, $d_{uv} = 1 - 1/(n - (n-3)) = 2/3$, but for the ℓ_1-norm, we need the semi-metric to have the value $1 - d_{uv}$ be close to 0, i.e. $O(1/n)$, for such u, v, in order for the fractional cost to be comparable to the value of OPT for $p = 1$.

There are several possible fixes one could try to make to the correlation metric. One idea is that since one can interpret the correlation metric as a coarse approximation of the probability the Pivot algorithm[7] separates u and v, one could try to adapt the correlation metric to more accurately approximate this probability.[8] Another idea, inspired by an observation below, is that one could define a semi-metric for edges in E^+ and another semi-metric for edges in E^-, but then there is the difficulty of showing the triangle inequality holds when positive and negative edges are mixed. Both of these ideas were, for us, unsuccessful.

Instead, the following two observations of how the correlation metric works with respect to the ℓ_1-norm led us to an effective adaptation:

1. One can bound the fractional cost, *restricted to positive edges*, of the correlation metric in the ℓ_1-norm by an $O(1)$-factor times the optimal solution's cost (see Claim 1 in Appendix C of the full version [20]). Negative edges still pose a challenge.
2. If the subgraph of positive edges is regular, then we can actually bound the fractional cost of the correlation metric in the ℓ_1-norm on negative edges as well.[9] See Section 3.

These observations led us to ask whether some adjustments to the correlation metric might yield a semi-metric with bounded fractional cost in the ℓ_1-norm or even the ℓ_p-norm more generally (while still remaining bounded in the ℓ_∞-norm). Moreover, since the KMZ rounding algorithm does not depend on p (whereas in the KMZ algorithm, the solution to the LP *does* depend on p), inputting the same semi-metric to the rounding algorithm produces the same clustering for all ℓ_p-norms!

We are ready to define the *adjusted correlation metric*. Let Δ_u denote the positive degree of u (the degree of u in the subgraph of positive edges).

▶ **Definition 6.** *Define the* adjusted correlation metric $f : E \to [0, 1]$ *as follows:*

1. *For d the correlation metric, i.e., $d_{uv} = 1 - \frac{|N_u^+ \cap N_v^+|}{|N_u^+ \cup N_v^+|}$, initially set $f = d$.*
2. *If $e \in E^-$ and $d_e > 0.7$, set $f_e = 1$ (round up).*
3. *For $u \in V$ such that $|N_u^- \cap \{v : d_{uv} \leq 0.7\}| \geq \frac{10}{3}\Delta_u$, set $f_{uv} = 1$ for all $v \in V \setminus \{u\}$.*

The idea in Step 3 is that if the fractional cost of negative edges incident to u is sufficiently large, we instead trade this for the cost of positive disagreements, as the rounding algorithm will now put u in its own cluster. For the ℓ_∞-norm, this trade-off is innocuous. For ℓ_p-norms in general, a refined charging argument is needed to show that post-processing d in this way sufficiently curbs the (too large) fractional cost of d.

In Section 3, we start with a warm-up exercise and show that if the graph on positive edges is regular, then the (original) correlation metric d has $O(1)$-approximate fractional cost. Note this section is not necessary to understanding the rest of the paper, but we

[7] Pivot operates as follows: Choose a random unclustered $u \in V$. Take u and all its unclustered positive neighbors and let this be the newest cluster. Continue until all vertices in V are clustered.

[8] If in (P), x_{uv} is set exactly to the probability that u and v are separated by Pivot, then x will be a feasible solution with cost at most $3\mathsf{OPT}$. However, this probability seems difficult to express in closed form, even approximately.

[9] In contrast, one cannot bound the fractional cost of the correlation metric on the star (Figure 1).

include it in the main body because we find the proof here is clean and lends insight into the challenges for the irregular case. The main technical result of the paper is Section 4, where we prove Theorem 1 by showing that the adjusted correlation metric can be input to the KMZ rounding algorithm. Namely, we will first show (quite easily) that the adjusted correlation metric satisfies an approximate triangle inequality. Then, it remains to upper bound the fractional cost of the adjusted correlation metric against OPT. We tackle this with a combinatorial charging argument. This argument leverages a somewhat different approach from that used in [19] and is simpler than their proof for only the ℓ_∞-norm. The *constant* approximation factor obtained from inputting the adjusted correlation metric to the KMZ rounding algorithm is bounded above (and below) by universal constants for all p (this is the worst case and one can get better constants for each p).

3 A Special Case: Regular Graphs

In general, the original correlation metric d (Definition 5) does not necessarily have bounded fractional cost for the ℓ_1-norm objective (or more generally for ℓ_p-norm objectives). So, we use the adjusted correlation metric f (Definition 6) as input to the KMZ rounding algorithm. In this section, we show that *if the subgraph of positive edges is regular*, then the correlation metric d can be used as is (i.e., without the adjustments in Steps 2 and 3 of Definition 6) to yield a clustering that is constant approximate for the ℓ_1-norm and ℓ_∞-norm simultaneously:

▶ **Theorem 7.** *Let $G = (V, E)$ be an instance of unweighted, complete correlation clustering, and let E^+ denote the set of positive edges. Suppose that the subgraph induced by E^+ is regular. The fractional cost of d in the ℓ_1-norm objective is within a constant factor of OPT:*

$$\sum_{u\in V}\sum_{v\in N_u^+} d_{uv} + \sum_{u\in V}\sum_{v\in N_u^-}(1-d_{uv}) = O(OPT).$$

Therefore, the clustering produced by inputting d to the KMZ rounding algorithm is a constant-factor approximation simultaneously for the ℓ_1-norm and ℓ_∞-norm objectives.

Proof. Let Δ be the (common) degree of the positive subgraph. To show that the fractional cost of d in the ℓ_1-norm objective is $O(\mathsf{OPT})$ for regular graphs, we will use a dual fitting argument. The LP relaxation we consider is from [4], which uses a dual fitting argument to show constant approximation guarantees for Pivot (although the proof here does not otherwise resemble the proof for Pivot). The primal is given by

$$\min\Big\{\sum_{e\in E} x_e \mid x_{ij}+x_{jk}+x_{ki}\geq 1, \forall ijk\in\mathcal{T}, x\geq 0\Big\} \tag{P'}$$

where $\mathcal{T}$ is the set of bad triangles (i.e. triangles with exactly two positive edges and one negative edge). For $x\in\{0,1\}^{|E|}$, x corresponds to disagreements in a clustering: we set $x_e = 1$ if e is a disagreement and $x_e = 0$ otherwise. The constraints state that every clustering must make a disagreement on every bad triangle. Thus, (P') is a relaxation for the ℓ_1-norm objective. In fact, we will prove the stronger statement that the fractional cost is $O(\mathsf{OPT}_{P'})$, where $\mathsf{OPT}_{P'}$ is the optimal objective value of (P').

The dual is given by

$$\max\Big\{\sum_{T\in\mathcal{T}} y_T \mid \sum_{T\in\mathcal{T}:T\ni e} y_T \leq 1, \forall e\in E, y\geq 0\Big\}. \tag{D'}$$

We show that by setting $y_T = \frac{1}{2\Delta}$ for all $T \in \mathcal{T}$, y satisfies the following properties:

1. y is feasible in (D').
2. The fractional cost of d is at most $6 \cdot \sum_{T \in \mathcal{T}} y_T$.

Letting $\mathsf{OPT}_{D'}$ be the optimal objective value of (D'), we have $6 \cdot \sum_{T \in \mathcal{T}} y_T \leq 6 \cdot \mathsf{OPT}_{D'} = 6 \cdot \mathsf{OPT}_{P'} \leq 6 \cdot \mathsf{OPT}$, which will conclude the proof.

To prove feasibility, we case on whether e is positive or negative.

If $e \in E^-$, then $|\{T \in \mathcal{T} : T \ni e\}| = |N_u^+ \cap N_v^+| \leq \Delta$, where equality is by the definition of a bad triangle. So $\sum_{T \in \mathcal{T}: T \ni e} y_T \leq \frac{\Delta}{2\Delta} \leq 1$.

If $e \in E^+$, then $|\{T : T \ni e\}| = |(N_u^+ \cap N_v^-) \cup (N_u^- \cap N_v^+)| \leq 2\Delta$. We conclude y is feasible, since $\sum_{T \in \mathcal{T}: T \ni e} y_T \leq \frac{2\Delta}{2\Delta} = 1$.

Now we need to show that the fractional cost of d is bounded in terms of the objective value of (D'). First we bound the fractional cost of the negative edges:

$$\sum_{(u,v) \in E^-} (1 - d_{uv}) \leq \sum_{(u,v) \in E^-} |N_u^+ \cap N_v^+| / \Delta = \sum_{e \in E^-} \sum_{T \in \mathcal{T}: T \ni e} 1/\Delta = \sum_{e \in E^-} \sum_{T \in \mathcal{T}: T \ni e} 2y_T,$$

where in the first inequality we have used that $|N_u^+ \cup N_v^+| \geq \Delta$. Next we bound the fractional cost of the positive edges:

$$\sum_{(u,v) \in E^+} d_{uv} \leq \sum_{(u,v) \in E^+} (|N_u^+ \cap N_v^-| + |N_u^- \cap N_v^+|)/\Delta = \sum_{e \in E^+} \sum_{T \in \mathcal{T}: T \ni e} 1/\Delta = \sum_{e \in E^+} \sum_{T \in \mathcal{T}: T \ni e} 2y_T.$$

So the total fractional cost is bounded by $\sum_{e \in E} \sum_{T \in \mathcal{T}: T \ni e} 2y_T = 6 \cdot \sum_{T \in \mathcal{T}} y_T$, since each triangle contains three edges. This is what we sought to show. Since the fractional cost of d is bounded for the ℓ_1-norm objective (and the ℓ_∞-norm objective by [19]), using d as input to KMZ rounding algorithm produces a clustering that is simultaneously $O(1)$-approximate for the ℓ_1- and ℓ_∞-norm objectives. ◀

4 Proof of Theorem 1

The goal of this section is to prove Theorem 1 and the subsequent Corollary 2. We begin by outlining that the adjusted correlation metric satisfies an approximate triangle inequality in Subsection 4.1. Then in Subsection 4.2, we prove the fractional cost of the adjusted correlation metric in any ℓ_p-norm objective is an $O(1)$ factor away from the optimal solution's value. We tie it all together to prove Theorem 1 and Corollary 2 in Subsection 4.3.

We start with an easy but key proposition. Loosely, it states that if two vertices are close to each other according to d, then they have a large shared positive neighborhood.

▶ **Proposition 8.** *Fix vertices $u, v \in V$ and a clustering $\mathcal{C}$ on V such that $d_{uv} \leq 0.7$ and $|N_u^+ \cap C(u)| \,/\, |N_u^+| \geq 0.85$. Then $|N_u^+ \cap N_v^+ \cap C(u)| \geq 0.15 \cdot |N_u^+|$.*

4.1 Triangle inequality

Recall that the correlation metric d satisfies the triangle inequality (see Section 4.2 in [19]). We will show that the adjusted correlation metric f satisfies an approximate triangle inequality, which is sufficient for the KMZ rounding algorithm. Formally, we say that a function g is a *δ-semi-metric* on some set S if it is a semi-metric on S, except instead of satisfying the triangle inequality, g satisfies $g(u, v) \leq \delta \cdot (g(u, w) + g(v, w))$ for all $u, v, w \in S$.

▶ **Lemma 9** (Triangle Inequality). *The adjusted correlation metric f is a $\frac{10}{7}$-semi-metric.*

The proof of Lemma 9 is straightforward given that d satisfies the triangle inequality.

Lemma 3 in [19] proves that one can input a semi-metric that satisfies an approximate triangle inequality (instead of the exact triangle inequality) to the KMZ rounding algorithm (with some loss in the approximation factor). We summarize the main take-away below.

▶ **Lemma 10** ([19]). *If g is a δ-semi-metric on the set V, instead of a true semi-metric (i.e., 1-semi-metric), then the KMZ algorithm loses a factor of $1+\delta+\delta^2+\delta^3+\delta^4$.*[10]

Since we show in Lemma 9 that f is a $\frac{10}{7}$-semi-metric, we lose a factor of 12 in inputting f to the KMZ algorithm (along with the factor loss from the fractional cost).

4.2 Bounding the fractional cost of ℓ_p-norms

This section bounds the fractional cost of the adjusted correlation metric for the ℓ_p-norms. The following lemma considers the case where $p=\infty$. The general case is handled after.

▶ **Lemma 11.** *The fractional cost of the adjusted correlation metric f in the ℓ_∞-norm objective is at most $56 \cdot \mathsf{OPT}$, where OPT is the cost of the optimal integral solution.*

The lemma follows from the fact that the fractional cost of the correlation metric d in the ℓ_∞-norm is known to be bounded by [19], and that it only decreases when d is replaced by f due to Definition 6. See Appendix B in the full version [20] for a proof.

We use two primary lemmas – one for the positive edge fractional cost and one for the negative edge fractional cost – to show that the adjusted correlation metric well approximates the optimal for general ℓ_p-norms.

▶ **Lemma 12.** *The fractional cost of the adjusted correlation metric f in the ℓ_p-norm objective is a constant factor (independent of p) away from the cost of the optimal integral ℓ_p solution.*

Proof. Let y be the disagreement vector for an optimal clustering $\mathcal{C}$ in the ℓ_p-norm, for any $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$. When $p=\infty$, see Lemma 11. For $p \in \mathbb{R}_{\geq 1}$, by definition $\mathsf{OPT}^p = \sum_{w\in V}(y(w))^p$, and the pth power of the fractional cost of f is given by

$$cost(f)^p = \sum_{u\in V}\left[\sum_{v\in N_u^+} f_{uv} + \sum_{v\in N_u^-}(1-f_{uv})\right]^p.$$

Observe that $$cost(f)^p \leq 2^p \underbrace{\sum_{u\in V}\Big(\sum_{v\in N_u^+} f_{uv}\Big)^p}_{(S^+)^p} + 2^p \underbrace{\sum_{u\in V}\Big(\sum_{v\in N_u^-}(1-f_{uv})\Big)^p}_{(S^-)^p}.$$

We refer to bounding $(S^+)^p$ as bounding the fractional cost of the positive edges, and likewise $(S^-)^p$ for the negative edges. The first sum, $(S^+)^p$, is bounded in Lemma 13 and the second sum, $(S^-)^p$, is bounded in Lemma 16. Using those two bounds, together we have $cost(f) \leq [2^p((S^+)^p + (S^-)^p)]^{1/p} \leq 529$, for $p \in [1,\infty)$. Specifically, the middle term is maximized at $p=1$, giving the bound of 529, and tends to below 214 as $p\to\infty$. (A more tailored analysis gives a constant of 74 for $p=1$; see Appendix C in the full version [20].) ◀

We note that, as our main interest is determining whether a simultaneous constant approximation is even possible (and a combinatorial one, at that), we did not pay particular attention to optimizing constants, but suspect these could be greatly reduced.

[10] When $\delta=1$, this factor equals 5, which is the loss in the KMZ algorithm.

4.2.1 Fractional cost of positive edges in ℓ_p-norms

We first bound the fractional cost of the positive edges.

▶ **Lemma 13.** *For $p \in \mathbb{R}_{\geq 1}$, the fractional cost of the adjusted correlation metric f in the ℓ_p-norm objective for the set of positive edges is a constant factor approximation to the optimal, i.e.,*

$$(S^+)^p = \sum_{u \in V} \Big(\sum_{v \in N_u^+} f_{uv} \Big)^p \leq 2^p \cdot [(8^p/2+1)((20/3)^p + 2 + 2 \cdot 4^p) + 8^p + 1] \cdot \mathit{OPT}^p.$$

One of the challenges in bounding the cost of f is that disagreements in the ℓ_p-norm objective for $p \neq 1$ are asymmetric, in that a disagreeing edge charges $y(u)$ and $y(v)$ (whereas for $p = 1$ we can just sum the number of disagreeing edges). Step 3 rounds up the edges incident to u when the tradeoff is good *from u's perspective*. However, an edge (u, v) may be rounded up to 1 when this tradeoff is good from v's perspective, but not from u's perspective. The high-level idea for why this is fine is that if u and v are close under d, their positive neighborhoods overlap significantly and, in some average sense, u can charge to v. Proving this requires a double counting argument using a bipartite auxiliary graph. If u and v are far under d, on the other hand, we can charge to the cost of the correlation metric, which will be bounded on an appropriate subgraph. The second challenge is showing that the ℓ_p-norm of the disagreement vector, restricted to vertices u that are made singletons in Step 3, is bounded. This again requires a double counting argument.

Proof. Fix an optimal clustering $\mathcal{C}$. We partition vertices based on membership in $C(u)$ or $\overline{C(u)}$ (as defined in Subsection 2.1). Let y denote the disagreement vector of $\mathcal{C}$. We have

$$(S^+)^p = \sum_{u \in V} \Big(\sum_{v \in N_u^+} f_{uv} \Big)^p \leq 2^p \underbrace{\sum_{u \in V} \Big(\sum_{v \in N_u^+ \cap C(u)} f_{uv} \Big)^p}_{S_1^+} + 2^p \underbrace{\sum_{u \in V} \Big(\sum_{v \in N_u^+ \cap \overline{C(u)}} f_{uv} \Big)^p}_{S_2^+}.$$

It is easy to bound S_2^+ by using the trivial upper bound $f_{uv} \leq 1$:

$$\boxed{S_2^+ = \sum_{u \in V} \Big(\sum_{v \in N_u^+ \cap \overline{C(u)}} f_{uv} \Big)^p \leq \sum_{u \in V} \Big(\sum_{v \in N_u^+ \cap \overline{C(u)}} 1 \Big)^p \leq \sum_{u \in V} (y(u))^p = \mathsf{OPT}^p,}$$

where we used that every edge $(u, v) \in E^+$ with $v \notin C(u)$ is a disagreement incident to u.

Next, we bound S_1^+. Let R_1 be the set of u for which Step 3 of Definition 6 applies. For these u, we have $f_{uv} = 1$ for all $v \in V \setminus \{u\}$. Let $R_2 = V \setminus R_1$. For $u \in R_2$ and $v \in N_u^+$, we have that either $v \in R_2$, in which case $f_{uv} = d_{uv}$; or $v \in R_1$, in which case $f_{uv} = 1$. (Note that V is the disjoint union of R_1 and R_2.) So

$$S_1^+ = \underbrace{\sum_{u \in R_1} \Big(\sum_{v \in N_u^+ \cap C(u), v \neq u} 1 \Big)^p}_{S_{11}^+} + \underbrace{\sum_{u \in R_2} \Big(\sum_{v \in N_u^+ \cap C(u)} f_{uv} \Big)^p}_{S_{12}^+},$$

and in particular

$$\begin{aligned}
S_{12}^+ &= \sum_{u\in R_2}\Big(\sum_{\substack{v\in N_u^+\cap C(u)\cap R_1}} 1 + \sum_{v\in N_u^+\cap C(u)\cap R_2} d_{uv}\Big)^p \\
&= \sum_{u\in R_2}\Big(\sum_{\substack{v\in N_u^+\cap C(u)\cap R_1\\ d_{uv}\le 1/4}} 1 + \sum_{\substack{v\in N_u^+\cap C(u)\cap R_1\\ d_{uv}\ge 1/4}} 1 + \sum_{v\in N_u^+\cap C(u)\cap R_2} d_{uv}\Big)^p \\
&\le \sum_{u\in R_2}\Big(\sum_{\substack{v\in N_u^+\cap C(u)\cap R_1\\ d_{uv}\le 1/4}} 1 + \sum_{\substack{v\in N_u^+\cap C(u)\cap R_1\\ d_{uv}\ge 1/4}} 4\cdot d_{uv} + \sum_{v\in N_u^+\cap C(u)\cap R_2} d_{uv}\Big)^p \\
&\le \sum_{u\in R_2}\Big(\sum_{\substack{v\in N_u^+\cap C(u)\cap R_1\\ d_{uv}\le 1/4}} 1 + \sum_{v\in N_u^+\cap C(u)} 4\cdot d_{uv}\Big)^p \\
&\le \underbrace{2^p\sum_{u\in R_2}\Big(\sum_{\substack{v\in N_u^+\cap R_1\\ d_{uv}\le 1/4}} 1\Big)^p}_{S_{13}^+} + \underbrace{8^p\cdot\sum_{u\in R_2}\Big(\sum_{v\in N_u^+\cap C(u)} d_{uv}\Big)^p}_{S_{14}^+}.
\end{aligned}$$

First we bound S_{13}^+. We will strongly use that $d_{uv}\le 1/4$ in the inner sum. Observe:

▶ **Proposition 14.** *Let d be the correlation metric, and $d_{uv}\le 1/4$. Then $|N_u^+|\le \frac{7}{3}\cdot|N_v^+|$.*

Next, we will need to create a bipartite auxiliary graph $H=(R_2,R_1,F)$ with R_2 and R_1 being the sides of the partition, and F being the edge set. We will then use a double counting argument. Place an edge between $u\in R_2$ and $v\in R_1$ if $uv\in E^+$ and $d_{uv}\le 1/4$. Then we have precisely that $S_{13}^+=\sum_{u\in R_2}\deg_H(u)^p$. We will show that

$$\boxed{S_{13}^+ = \sum_{u\in R_2}\deg_H(u)^p \le 4^{p-1}\cdot\sum_{v\in R_1}|N_v^+|^p \le 4^{p-1}\cdot((20/3)^p+2+2\cdot 4^p)\cdot\mathsf{OPT}^p} \tag{1}$$

where the last bound follows from Proposition 15, which we establish separately below. We will bound via double counting the quantity L, defined below. Let $N_H(\cdot)$ denote the neighborhoods in H of the vertices.

$$\begin{aligned}
L &:= \sum_{f=uv\in F}(\deg_H(u)+\deg_H(v))^{p-1} \le \sum_{v\in R_1}\sum_{u\in N_H(v)}(\deg_H(v)+\deg_H(u))^{p-1} \\
&\le \sum_{v\in R_1}\sum_{u\in N_H(v)}\big(|N_v^+|+|N_u^+|\big)^{p-1} \le \sum_{v\in R_1}\sum_{u\in N_H(v)} 4^{p-1}\cdot|N_v^+|^{p-1} \qquad (2)\\
&\le 4^{p-1}\cdot\sum_{v\in R_1}|N_v^+|\cdot|N_v^+|^{p-1} = 4^{p-1}\cdot\sum_{v\in R_1}|N_v^+|^p
\end{aligned}$$

where in (2) we've used Proposition 14. Note that L is upper bounded by the right-hand side in (1). Now it just remains to show that L is lower bounded by the left-hand side in (1).

$$\begin{aligned}
L &= \sum_{f=uv\in F}(\deg_H(u)+\deg_H(v))^{p-1} = \sum_{u\in R_2}\sum_{v\in N_H(u)}(\deg_H(u)+\deg_H(v))^{p-1} \\
&\ge \sum_{u\in R_2}\sum_{v\in N_H(u)}\deg_H(u)^{p-1} = \sum_{u\in R_2}\deg_H(u)\cdot\deg_H(u)^{p-1} = \sum_{u\in R_2}\deg_H(u)^p,
\end{aligned}$$

which is what we sought to show. Now we bound S_{14}^+.

$$\begin{aligned} S_{14}^+ &\le \sum_{u\in V}\left(\sum_{v\in N_u^+\cap C(u)} \frac{|N_u^+\cap N_v^-| + |N_u^-\cap N_v^+|}{|N_u^+\cup N_v^+|}\right)^p \\ &\le \sum_{u\in V}\left(\sum_{v\in N_u^+}\frac{y(u)+y(v)}{|N_u^+\cup N_v^+|}\right)^p \le \sum_{u\in V}|N_u^+|^{p-1}\sum_{v\in N_u^+}\frac{(y(u)+y(v))^p}{|N_u^+\cup N_v^+|^p} \\ &\le 2^p\sum_{u\in V}\sum_{v\in N_u^+}|N_u^+|^{p-1}\cdot\frac{y(u)^p}{|N_u^+\cup N_v^+|^p} + 2^p\sum_{u\in V}\sum_{v\in N_u^+}|N_u^+|^{p-1}\cdot\frac{y(v)^p}{|N_u^+\cup N_v^+|^p}. \end{aligned}$$

In the second line, the first inequality uses the fact that for $w\in(N_u^+\cap N_v^-)\cup(N_u^-\cap N_v^+)$, then at least one of $(u,w),(v,w)$ is a disagreement, since $v\in C(u)$ in the inner summation of the first line. The second inequality in the second line uses Jensen's inequality.

To bound the first double sum above, we use an averaging argument:

$$\sum_{u\in V}\sum_{v\in N_u^+}|N_u^+|^{p-1}\cdot\frac{y(u)^p}{|N_u^+\cup N_v^+|^p} \le \sum_{u\in V}\sum_{v\in N_u^+}\frac{y(u)^p}{|N_u^+|} = \sum_{u\in V}y(u)^p = \mathsf{OPT}^p.$$

To bound the second double sum, we first have to flip it:

$$\begin{aligned} \sum_{u\in V}\sum_{v\in N_u^+}|N_u^+|^{p-1}\cdot\frac{y(v)^p}{|N_u^+\cup N_v^+|^p} &= \sum_{v\in V}\sum_{u\in N_v^+}|N_u^+|^{p-1}\cdot\frac{y(v)^p}{|N_u^+\cup N_v^+|^p} \\ &\le \sum_{v\in V}\sum_{u\in N_v^+}|N_u^+|^{p-1}\frac{y(v)^p}{|N_u^+|^{p-1}\cdot|N_v^+|} = \sum_{v\in V}y(v)^p = \mathsf{OPT}^p. \end{aligned}$$

In total, we have

$$\boxed{S_{14}^+ \le 2\cdot 2^p\cdot\mathsf{OPT}^p = 2^{p+1}\cdot\mathsf{OPT}^p}$$

and $$\boxed{S_{12}^+ \le 2^p\cdot S_{13}^+ + 8^p\cdot S_{14}^+ \le 2^p\cdot 4^{p-1}\cdot((20/3)^p+2+2\cdot 4^p)\cdot\mathsf{OPT}^p + 8^p\cdot\mathsf{OPT}^p.}$$

Next we turn to bounding S_{11}^+. Recall that $R_1 = \{u : |N_u^-\cap\{v : d_{uv}\le 0.7\}| \ge \frac{10}{3}\cdot\Delta_u\}$ and

$$S_{11}^+ \le \sum_{u\in R_1}|N_u^+\cap C(u)|^p \le \sum_{u\in R_1}|N_u^+|^p.$$

So it suffices to bound the right-hand side, which we do in the following proposition.

▶ **Proposition 15.** *Let R_1 be the set of u for which Step 3 of Definition 6 applies. Then*

$$\sum_{u\in R_1}|N_u^+|^p \le ((20/3)^p+2+2\cdot 4^p)\cdot\mathit{OPT}^p.$$

Proof of Proposition 15. For $u\in R_1$, define $R_1(u) = N_u^-\cap\{v : d_{uv}\le 0.7\}$, so in particular $|R_1(u)|\ge\frac{10}{3}\cdot\Delta_u$. Fix a vertex $u\in R_1$. We consider a few cases. The crux is Case 2a(ii).

Case 1. *At least a 0.15 fraction of N_u^+ is in clusters other than $C(u)$.*
Let $u\in V^1$ be the vertices in this case. This means that $0.15\cdot|N_u^+|\le y(u)$, so

$$\boxed{\sum_{u\in V^1}|N_u^+|^p \le \sum_{u\in V^1}\frac{1}{0.15^p}y(u)^p \le (20/3)^p\cdot\mathsf{OPT}^p.}$$

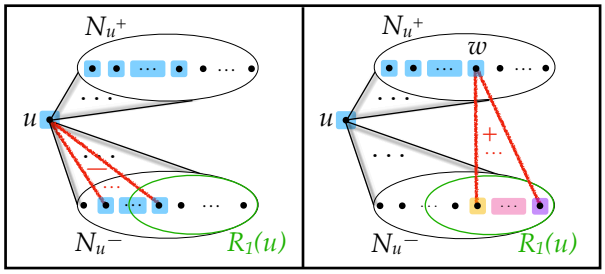

Figure 2 Left: Case 2a(i). For $v \in |N_u^- \cap C(u)|$, (u, v) is a disagreement. **Right:** Case 2a(ii). For $w \in |N_u^+ \cap C(u)|$ and $v \in N_w^+ \cap R_1'(u)$, (w, v) is a disagreement.

Case 2. *At least a 0.85 fraction of N_u^+ is in $C(u)$.*
We further partition the cases based on how much $R_1(u)$ intersects $C(u)$.

Case 2a: *At least half of $R_1(u)$ is in clusters other than $C(u)$.*
We partition into cases (just one more time!) based on the size of $N_u^- \cap C(u)$. See Figure 2.

Case 2a(i): *At least half of $R_1(u)$ is in clusters other than $C(u)$ and $|N_u^- \cap C(u)| \geq \Delta_u$.*
Let $u \in V^{2a(i)}$ be the vertices in this case. Note that $y(u) \geq |N_u^- \cap C(u)|$. Then

$$\sum_{u \in V^{2ai}} |N_u^+|^p = \sum_{u \in V^{2ai}} \Delta_u^p \leq \sum_{u \in V^{2ai}} |N_u^- \cap C(u)|^p \leq \sum_{u \in V^{2ai}} y(u)^p \leq \mathsf{OPT}^p.$$

Case 2a(ii): *At least half of $R_1(u)$ is in clusters other than $C(u)$ and $|N_u^- \cap C(u)| \leq \Delta_u$.*

Let $u \in V^{2a(ii)}$ be the vertices in this case. Denote the vertices in $R_1(u)$ that are in clusters other than $C(u)$ by $R_1'(u)$. By definition of Case 2a(ii), $|R_1'(u)| \geq \frac{5}{3} \cdot \Delta_u$. A key fact we will use is that $|C(u)| \leq 2 \cdot \Delta_u$:

$$|C(u)| = |N_u^- \cap C(u)| + |N_u^+ \cap C(u)| \leq \Delta_u + \Delta_u = 2 \cdot \Delta_u.$$

For $u \in V^{2a(ii)}$ and $w \in N_u^+ \cap C(u)$, define $\varphi(u, w) = |R_1'(u) \cap N_w^+|$.
Each $w \in N_u^+ \cap C(u)$ dispenses $\varphi(u, w)^p / |C(u)|$ charge to u. Also, observe that for $v \in R_1'(u)$, we have that $d_{uv} \leq 0.7$, so we know by Proposition 8 that $|N_u^+ \cap N_v^+ \cap C(u)| \geq 0.15 \cdot |N_u^+|$. This implies that

$$\begin{aligned}
\sum_{w \in N_u^+ \cap C(u)} |R_1'(u) \cap N_w^+| &= \sum_{w \in N_u^+ \cap C(u)} \sum_{v \in R_1'(u) \cap N_w^+} 1 = \sum_{v \in R_1'(u)} \sum_{\substack{w \in \cap N_v^+ \\ \cap C(u) \cap N_u^+}} 1 \\
&= \sum_{v \in R_1'(u)} |C(u) \cap N_u^+ \cap N_v^+| \geq \sum_{v \in R_1'(u)} 0.15 \cdot |N_u^+| \\
&= 0.15 \cdot |N_u^+| \cdot |R_1'(u)| \geq 0.15 \cdot \Delta_u \cdot \frac{5}{3} \Delta_u = 0.25 \cdot \Delta_u^2.
\end{aligned}$$

By Jensen's inequality, the amount of charge each u satisfying Case 2a(ii) receives is at least

$$\begin{aligned}
\frac{1}{|C(u)|} \sum_{w \in N_u^+ \cap C(u)} \varphi(u, w)^p &\geq \frac{1}{|C(u)|} \cdot \frac{1}{|N_u^+ \cap C(u)|^{p-1}} \cdot \Big(\sum_{w \in N_u^+ \cap C(u)} \varphi(u, w) \Big)^p \\
&\geq \frac{1}{2\Delta_u} \cdot \frac{1}{\Delta_u^{p-1}} \cdot \left(0.25 \cdot \Delta_u^2\right)^p \geq \frac{1}{2} \cdot 0.25^p \cdot |N_u^+|^p,
\end{aligned}$$

Next we need to upper bound the amount of charge dispensed in total to *all* u satisfying Case 2a(ii). Note by definition that $\varphi(u,w) \le y(w)$. Each vertex $w \in V$ dispenses at most $y(w)^p/|C(u)| = y(w)^p/|C(w)|$ charge to each $u \in C(w) \cap N_w^+$. So in total each w dispenses at most $|C(w)| \cdot y(w)^p/|C(w)| = y(w)^p$ charge to all u satisfying Case 2a(ii). Now we put together the lower and upper bounds on the total charge dispensed:

$$\sum_{w\in V} y(w)^p \ge \text{charge dispensed} \ge \sum_{u\in V^{2a(ii)}} \frac{1}{|C(u)|} \sum_{w\in N_u^+\cap C(u)} \varphi(u,w)^p$$
$$\ge \sum_{u\in V^{2a(ii)}} \frac{1}{2}\cdot 0.25^p \cdot |N_u^+|^p.$$

In all, $$\boxed{\sum_{u\in V^{2a(ii)}} |N_u^+|^p \le 2\cdot 4^p \cdot \sum_{w\in V} y(w)^p \le 2\cdot 4^p \cdot \mathsf{OPT}^p.}$$

Case 2b: *At least half of $R_1(u)$ is in $C(u)$.*

Let $u \in V^{2b}$ be the vertices in this case. Denote the vertices in $R_1(u)$ that are in $C(u)$ by $R_1''(u)$. By definition of Case 2b, $|R_1''(u)| \ge \frac{5}{3}\cdot\Delta_u$. Since every vertex in $R''(u)$ is in N_u^-, there are at least $|R''(u)|$ disagreements incident to u. So $y(u) \ge |R''(u)| \ge \frac{5}{3}\cdot\Delta_u$, giving

$$\boxed{\sum_{u\in V^{2b}} |N_u^+|^p = \sum_{u\in V^{2b}} \Delta_u^p \le \sum_{u\in V^{2b}} y(u)^p \le \mathsf{OPT}^p.}$$

Adding the terms in the boxed expressions across all cases, the proposition follows. ◀

So we have $$\boxed{S_{11}^+ \le \sum_{u\in R_1} |N_u^+|^p \le ((20/3)^p + 2 + 2\cdot 4^p)\cdot \mathsf{OPT}^p.}$$

Adding together all the cases, we conclude that

$$(S^+)^p \le 2^p\cdot(S_1^+ + S_2^+) \le 2^p\cdot(S_{11}^+ S_{12^+} + S_2^+) \le 2^p\cdot[(8^p/2+1)((20/3)^p+2+2\cdot 4^p)+8^p+1]\cdot\mathsf{OPT}^p.$$

◀

4.2.2 Fractional cost of negative edges in ℓ_p-norms

This section bounds the cost of negative edges. The meanings of $\mathcal{C}$, $C(\cdot)$, and y are as before.

▶ **Lemma 16.** *For $p \in \mathbb{R}_{\ge 1}$, the fractional cost of the adjusted correlation metric f in the ℓ_p-norm objective for the set of negative edges is a constant factor away from optimal:*

$$(S^-)^p = \sum_{u\in V}\Big(\sum_{v\in N_u^-}(1-f_{uv})\Big)^p \le 2^p((200/9)^p + 1 + (10/3)^p + 2\cdot(20/3)^p)\cdot \mathit{OPT}^p.$$

Proof. We have

$$(S^-)^p = \sum_{u\in V}\Big(\sum_{v\in N_u^-}(1-f_{uv})\Big)^p \le 2^p \underbrace{\sum_{u\in V}\Big(\sum_{v\in N_u^-\cap C(u)}(1-f_{uv})\Big)^p}_{S_1^-}$$
$$+ 2^p \underbrace{\sum_{u\in V}\Big(\sum_{v\in N_u^-\cap \overline{C(u)}}(1-f_{uv})\Big)^p}_{S_2^-}.$$

It is easy to bound S_1^- by using the trivial upper bound $1 - f_{uv} \le 1$:

$$\boxed{S_1^- = \sum_{u\in V}\Big(\sum_{v\in N_u^-\cap C(u)}(1-f_{uv})\Big)^p \le \sum_{u\in V}\Big(\sum_{v\in N_u^-\cap C(u)}1\Big)^p \le \sum_{u\in V} y(u)^p = \mathsf{OPT}^p,}$$

where we have used that every edge $(u, v) \in E^-$ with $v \in C(u)$ is a disagreement incident to u. Next, we bound S_2^-. Let R_1 and R_2 be as in the previous subsection: $R_1 = \{u : |N_u^- \cap \{v : d_{uv} \le 0.7\}| \ge \frac{10}{3}\cdot\Delta_u\}$ and $R_2 = V \setminus R_1$. For $u \in R_2$, define

$$V_u = \{v : v \in N_u^- \cap \overline{C(u)}, d_{uv} \le 0.7\}.$$

Note that the definition of V_u is the same as $R_1'(u)$ in the previous subsection, but here V_u is only defined for $u \in R_2$, while $R_1'(u)$ was defined for $u \in R_1$. For $u \in R_1$, we have $1 - f_{uv} = 0$ for every $v \in V \setminus \{u\}$. So the outer sum in S_2^- only need be taken over $u \in R_2$:

$$S_2^- = \sum_{u\in R_2}\Big(\sum_{v\in N_u^-\cap\overline{C(u)}}(1-f_{uv})\Big)^p \le \sum_{u\in R_2}\Big(\sum_{\substack{v:v\in N_u^-\cap\overline{C(u)},\\ d_{uv}\le 0.7}}(1-d_{uv})\Big)^p \le \sum_{u\in R_2}|V_u|^p$$

In the second equality, we have used that if $u \in R_2$ and $v \in N_u^-$, then $f_{uv} = d_{uv}$, unless f_{uv} was rounded up to 1 in Step 2 of Definition 6 (which happens when $d_{uv} > 0.7$), or f_{uv} was rounded up to 1 in Step 3 (in which case $1 - f_{uv} = 0 \le 1 - d_{uv}$).

A key observation is that since $u \in R_2$, it is the case that $|V_u| \le \frac{10}{3}\cdot\Delta_u$.

Fix a vertex $u \in R_2$. We consider a few cases.

Case 1. *At least a 0.15 fraction of N_u^+ is in clusters other than $C(u)$.*
Define V^1 to be the set of $u \in R_2$ satisfying Case 1. Then for $u \in V^1$, $0.15\cdot|N_u^+| \le y(u)$, and

$$|V_u| \le \frac{10}{3}\Delta_u \le \frac{1}{0.15}\cdot\frac{10}{3}y(u) = \frac{200}{9}y(u).$$

so $$\boxed{\sum_{u\in V^1}|V_u|^p \le (200/9)^p\cdot\sum_{u\in V^1}y(u)^p \le (200/9)^p\cdot\mathsf{OPT}^p.}$$

Case 2. *At least a 0.85 fraction of N_u^+ is in $C(u)$.*
Define V^2 to be the set of $u \in R_2$ that satisfy Case 2. Fix $u \in V^2$ and $v \in V_u$. Define $N_{u,v} = N_u^+ \cap N_v^+ \cap C(u)$. Since $d_{uv} \le 0.7$ and by the assumption of this case, using Proposition 8 we have

$$|N_{u,v}| = |N_u^+ \cap N_v^+ \cap C(u)| \ge 0.15\cdot\Delta_u.$$

Observe that since $v \notin C(u)$ for $v \in V_u$, (v, w) is a (positive) disagreement for all $w \in N_{u,v}$.
Case 2a: $|N_u^- \cap C(u)| \ge \Delta_u$.
Define V^{2a} to be the set of $u \in V^2$ that satisfy Case 2a. Since all edges (u, v) with $v \in N_u^- \cap C(u)$ are disagreements, we have $y(u) \ge \Delta_u$. Recalling that $|V_u| \le \frac{10}{3}\cdot\Delta_u$ for $u \in R_2$, we have

$$\boxed{\sum_{u\in V^{2a}}|V_u|^p \le \sum_{u\in V^{2a}}(10/3\cdot\Delta_u)^p \le (10/3)^p\cdot\sum_{u\in V^{2a}}y(u)^p \le (10/3)^p\cdot\mathsf{OPT}^p.}$$

Case 2b: $|C(u)| \leq 2\Delta_u$.

Define V^{2b} to be the $u \in V^2$ satisfying Case 2b. Fix $w \in N_u^+ \cap C(u)$ and $u \in V^{2b}$. Define

$$\varphi(u,w) = |V_u \cap N_w^+|,$$

i.e. $\varphi(u,w)$ is the number of $v \in V_u$ with $w \in N_{u,v}$. Each $w \in N_u^+ \cap C(u)$ dispenses $\frac{\varphi(u,w)^p}{|C(u)|}$ charge to u. Also,

$$\begin{aligned}\sum_{w \in N_u^+ \cap C(u)} \varphi(u,w) &= \sum_{w \in N_u^+ \cap C(u)} |V_u \cap N_w^+| = \sum_{w \in N_u^+ \cap C(u)} \sum_{v \in V_u \cap N_w^+} 1 \\ &= \sum_{v \in V_u} \sum_{w \in N_{u,v}} 1 = \sum_{v \in V_u} |N_{u,v}| \geq |V_u| \cdot 0.15 \cdot \Delta_u.\end{aligned}$$

By Jensen's inequality, the amount of charge each u satisfying Case 2b receives is at least

$$\begin{aligned}\frac{1}{|C(u)|} \sum_{w \in N_u^+ \cap C(u)} \varphi(u,w)^p &\geq \frac{1}{|C(u)|} \cdot \frac{1}{|N_u^+ \cap C(u)|^{p-1}} \Big(\sum_{w \in N_u^+ \cap C(u)} \varphi(u,w) \Big)^p \\ &\geq \frac{1}{2\Delta_u} \cdot \frac{1}{\Delta_u^{p-1}} \left(|V_u| \cdot 0.15 \cdot \Delta_u\right)^p = \frac{1}{2} \cdot 0.15^p \cdot |V_u|^p,\end{aligned}$$

To upper bound the amount of charge dispensed in total to *all* u satisfying Case 2b, first note that $\varphi(u,w) \leq y(w)$. Also, each vertex $w \in V$ only distributes charge to $u \in C(w) \cap N_w^+$, and the amount of charge distributed to each such u is

$$\frac{\varphi(u,w)^p}{|C(u)|} = \frac{\varphi(u,w)^p}{|C(w)|} \leq \frac{y(w)^p}{|C(w)|},$$

so that in total each w dispenses at most $\frac{y(w)^p}{|C(w)|} \cdot |C(w)| \leq y(w)^p$ charge. Putting together the lower and upper bounds on the amount of charge dispensed:

$$\begin{aligned}\sum_{w \in V} y(w)^p \geq \text{total charge dispensed} &\geq \sum_{u \in V^{2b}} \frac{1}{|C(u)|} \sum_{w \in N_u^+ \cap C(u)} \varphi(u,w)^p \\ &\geq \sum_{u \in V^{2b}} \frac{1}{2} \cdot 0.15^p \cdot |V_u|^p.\end{aligned}$$

In all, $\boxed{\sum_{u \in V^{2b}} |V_u|^p \leq 2 \cdot (20/3)^p \cdot \sum_{w \in V} y(w)^p = 2 \cdot (20/3)^p \cdot \mathsf{OPT}^p.}$

Combining the cases, we see that $(S^-)^p \leq 2^p((200/9)^p + 1 + (10/3)^p + 2 \cdot (20/3)^p) \cdot \mathsf{OPT}^p$. ◀

4.3 Proofs of Theorem 1 and Corollary 2

Here we show that Theorem 1 follows directly from the preceding lemmas. We defer the proof of Corollary 2 to the full version [20].

Proof of Theorem 1. First we show that Lemma 12 implies that the clustering resulting from inputting f into the KMZ rounding algorithm is $O(1)$-approximate in any ℓ_p-norm. Since the rounding algorithm does not depend on p, the clustering will be the same for all p. Let $\mathcal{C}^*$ be the clustering produced by running the KMZ rounding algorithm with the adjusted correlation metric f as input. Let $\mathsf{ALG}(u)$ be the number of edges incident to u that are disagreements with respect to $\mathcal{C}^*$. From [29] and Lemmas 9 and 10, we have that

for every $u \in V$, $\mathsf{ALG}(u) \leq 12 \cdot y_u$ where y_u is as in LP P when taking $x = f$. So $||y||_p$ is the fractional cost of f in the ℓ_p-norm. In what follows, $||\mathsf{ALG}||_p$ is the objective value of $\mathcal{C}^*$ in the ℓ_p-norm and $\mathsf{OPT}(p)$ is the optimal objective value in the ℓ_p-norm. Thus using Lemma 12 in the last inequality, we have

$$||\mathsf{ALG}||_p \leq 12 \cdot ||y||_p \leq 12 \cdot 529 \cdot \mathsf{OPT}(p) = 6348 \cdot \mathsf{OPT}(p).$$

The overall run-time is $O(n^\omega)$. From the analysis in [19], computing the correlation metric takes time $O(n^\omega)$, and the KMZ rounding algorithm takes time $O(n^2)$. We just have to show the post-processing of d in Steps 2 and 3 of Definition 6 that were done in order to obtain the adjusted correlation metric f can be done quickly. Indeed, Step 2 takes $O(n^2)$ time as it simply iterates through the edges. Step 3 also takes $O(n^2)$ time, since it visits each vertex and iterates through the neighbors. Thus, the run-time remains $O(n^\omega)$. ◀

5 Conclusion

This paper considered correlation clustering on unweighted, complete graphs, a problem that arises in many settings including community detection and the study of large networks. All previous works that study minimizing the ℓ_p-norm (for $p \in \mathbb{R}_{>1}$) of the disagreement vector rely on solving a large, convex relaxation (which is costly to the algorithm's run-time) and produce a solution that is only $O(1)$-approximate for one specific value of p. We innovate upon this rich line of work by (1) giving the first combinatorial algorithm for the ℓ_p-norms for $p \in \mathbb{R}_{>1}$, (2) designing scalable algorithms for this practical problem, and (3) obtaining solutions that are $O(1)$-approximate for all ℓ_p-norms (for $p \in \mathbb{R}_{\geq 1} \cup \{\infty\}$) simultaneously. We emphasize this last point, as such solutions are good in both global and local senses, and thus may be more desirable than typical optimal or approximate solutions. The existence of these solutions reveals a surprising structural property of correlation clustering.

One question is whether there is a simpler existential (not necessarily algorithmic) proof that there exists an $O(1)$-approximation for the all-norm objective for correlation clustering.

It is also of interest to implement the KMZ algorithm with the adjusted correlation metric as input, and empirically gain an understanding of how good the adjusted correlation metric is for different ℓ_p-norms. We suspect that our analysis is lossy (we did not focus on optimizing constants), and that the approximation obtained would be of much better quality.

Abstract

We study the parameterized complexity of a generalization of the coordinated motion planning problem on graphs, where the goal is to route a specified subset of a given set of k robots to their destinations with the aim of minimizing the total energy (i.e., the total length traveled). We develop novel techniques to push beyond previously-established results that were restricted to solid grids.

We design a fixed-parameter additive approximation algorithm for this problem parameterized by k alone. This result, which is of independent interest, allows us to prove the following two results pertaining to well-studied coordinated motion planning problems: (1) A fixed-parameter algorithm, parameterized by k, for routing a single robot to its destination while avoiding the other robots, which is related to the famous Rush-Hour Puzzle; and (2) a fixed-parameter algorithm, parameterized by k plus the treewidth of the input graph, for the standard Coordinated Motion Planning (CMP) problem in which we need to route all the k robots to their destinations. The latter of these results implies, among others, the fixed-parameter tractability of CMP parameterized by k on graphs of bounded outerplanarity, which include bounded-height subgrids.

We complement the above results with a lower bound which rules out the fixed-parameter tractability for CMP when parameterized by the total energy. This contrasts the recently-obtained tractability of the problem on solid grids under the same parameterization. As our final result, we strengthen the aforementioned fixed-parameter tractability to hold not only on solid grids but all graphs of bounded local treewidth – a class including, among others, all graphs of bounded genus.

1 Introduction

The task of routing a set of robots (or agents) from their initial positions to specified destinations while avoiding collisions is of great importance in a multitude of different settings. Indeed, there is an extensive body of works dedicated to algorithms solving this task, especially in the computational geometry [1,24–26,30,32–34,37], artificial intelligence [6,35,38] and robotics [3, 23, 36] research communities. Such algorithms typically aim at providing a schedule for the robots which is not only safe (in the sense of avoiding collisions), but which also optimizes a certain measure of the schedule – typically its makespan or energy (i.e., the total distance traveled by all robots). In this article, we focus solely on the task of optimizing the latter of these two measures.

A common formalization of our task of interest is given by the Coordinated Motion Planning problem (also known as Multiagent Pathfinding). In the context of energy minimization, the problem can be stated as follows: Given a graph G, a budget ℓ and a set $\mathcal{M}$ of robots, each equipped with an initial vertex and destination vertex in G, compute a schedule which delivers all the robots to their destinations while ensuring that the combined length traveled of all the robots is at most ℓ. Here, a schedule can be seen as a sequence of commands to the robots, where at every time step each of the robots can move to an adjacent vertex as long as no vertex or edge is used by more than a single robot at that time step. Coordinated Motion Planning, which generalizes the famous NP-hard (n^2-1)-puzzle [11, 29], has been extensively studied – both in the discrete setting considered here as well as in various continuous settings [4, 6, 10, 14, 23, 28, 32–36, 38–40] – and has also been the target of specific computing challenges [17]. In other variants of the problem, there is no requirement to route *all* the robots to their destinations – sometimes the majority (or all but 1) of the robots are simply movable obstacles that do not have destinations of their own. This is captured, e.g., by the closely-related and well-studied Rush Hour puzzle/problem [7, 19] and by Graph Motion Planning with 1 Robot (GCMP1) [27], which both feature a single robot with a designated destination.

Both Coordinated Motion Planning and GCMP1 are known to be NP-hard [11, 29, 39]. While several works have already studied Coordinated Motion Planning in the context of approximation and classical complexity theory, a more fine-grained investigation of the difficulty of finding optimal schedules through the lens of *parameterized complexity* [9, 13] was only carried out recently [15, 18]. The work in [15] established the fixed-parameter tractability[1] of Coordinated Motion Planning parameterized by either the number k of robots or the budget ℓ (as well as the makespan variant when parameterized by k), but only on solid grids; a *solid* grid is a standard rectangular $p \times q$ grid (i.e., with no holes), for some $p, q \in \mathbb{N}$. The more recent work in [18] showed the W[1]-hardness of the makespan variant of Coordinated Motion Planning w.r.t. the number of robots. The paper [18] also showed the NP-hardness of the makespan problem-variant on trees, and presented parameterized complexity results with respect to several combinations of parameters. In this article, we focus our attention on GCMP [27], which generalizes both Coordinated Motion Planning and GCMP1 by allowing an arbitrary partitioning of the robots into those with destinations and those which act merely as movable obstacles[2].

[1] A problem is *fixed-parameter tractable* w.r.t. a parameter k if it can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$, where n is the input size and f is a computable function.

[2] While previous hardness results for GCMP considers serial motion of robots (e.g., [27]), the hardness applies to parallel motion as well. Here we obtain algorithms for the coordinated motion variant with parallel movement, but note that the results can be directly translated to the serial version.

Contribution. The aim of this article is to push our understanding of the parameterized complexity of finding energy-optimal schedules beyond the class of solid grids. While this aim was already highlighted in the aforementioned paper on solid grids [15, Section 5], the techniques used there are highly specific to that setting and it is entirely unclear how one could generalize them even to the setting of subgrids; a *subgrid* is a subgraph of a solid grid and we define its *height* to be the minimum of its two dimensions.

As our two main contributions, we provide novel fixed-parameter algorithms (1) for GCMP1 parameterized by the number of robots alone (Theorem 1), and (2) for GCMP parameterized by the number of robots plus the treewidth of the graph (Theorem 2). Theorem 2 implies, as a corollary, the fixed-parameter tractability of GCMP parameterized by k plus the minimum dimension of the subgrid.

▶ **Theorem 1.** GCMP1 *is* FPT *parameterized by the number k of robots.*

▶ **Theorem 2.** GCMP *is* FPT *parameterized by the number of robots and the treewidth of the input graph.*

The main technical tool we use to obtain both of these results is a novel fixed-parameter approximation algorithm for Generalized Coordinated Motion Planning parameterized by k alone, where the approximation error is only *additive* in k. We believe this result – summarized in Theorem 3 below – to be of independent interest.

▶ **Theorem 3.** *There is an* FPT *approximation algorithm for* GCMP *parameterized by the number k of robots which guarantees an additive error of $\mathcal{O}(k^5)$.*

The proof of Theorem 1 builds upon Theorem 3. For the proof of Theorem 2, we need to combine the approximation algorithm with novel insights concerning the "decomposability" of schedules along small separators in order to design a treewidth-based dynamic programming algorithm for the problem. A brief summary of the ideas used in this proof is provided at the beginning of Section 3.

We complement our positive results which use k as a parameter with an algorithmic lower bound showing that Coordinated Motion Planning is W[1]-hard (and hence not fixed-parameter tractable under well-established complexity-theoretic assumptions) when parameterized by the energy budget ℓ. This result (Theorem 4 below) contrasts the fixed-parameter tractability of the problem under the same parameterization when restricted to solid grids [15, Theorem 19].

▶ **Theorem 4.** GCMP *is* W[1]*-hard when parameterized by ℓ.*

While Theorem 4 establishes the intractability of the problem when parameterized by the energy on general graphs, one can in fact show that GCMP is fixed-parameter tractable under the same parameterization when the graphs are "well-structured" in the sense of having bounded *local treewidth* [16, 22]. This implies fixed-parameter tractability, e.g., on graphs of bounded genus and generalizes the aforementioned result on grids [15, Theorem 19].

▶ **Theorem 5.** GCMP *is* FPT *parameterized by ℓ on graph classes of bounded local treewidth.*

Further Related Work. As surveyed above, the computational complexity of GCMP has received significant attention, particularly by researchers in the fields of computational geometry, AI/Robotics, and theoretical computer science. The problem has been shown to remain NP-hard under a broad set of restrictions, including on graphs where only a single

vertex is not occupied [21], on grids [3], and bounded-height subgrids [20]. On the other hand, a feasibility check for the existence of a schedule can be carried out in polynomial time [41]. The recent AAMAS blue sky paper [31] also highlighted the need of understanding the hardness of the problem and asked for a deeper investigation of its parameterized complexity.

2 Terminology and Problem Definition

The graphs considered in this paper are undirected simple graphs. We assume familiarity with the standard graph-theoretic concepts and terminology [12]. For a subgraph H of a graph G and two vertices $u, v \in V(H)$, we denote by $\text{dist}_H(u, v)$ the length of a shortest path in H between u and v. We write $[n]$, where $n \in \mathbb{N}$, for $\{1, \ldots, n\}$.

We also assume basic familiarity with parameterized complexity theory, including *fixed-parameter tractability*, *parameterized reductions*, and the class W[1] [9, 13].

Treewidth. Treewidth is a structural parameter that provides a way of expressing the resemblance of a graph to a forest. Formally, the treewidth of a graph is defined via the notion of tree decompositions as follows.

▶ **Definition 6** (Tree decomposition)**.** A *tree decomposition* of a graph G is a pair (T, β) of a tree T and $\beta : V(T) \to 2^{V(G)}$, such that:

- $\bigcup_{t \in V(T)} \beta(t) = V(G)$,
- for any edge $e \in E(G)$, there exists a node $t \in V(T)$ such that both endpoints of e belong to $\beta(t)$, and
- for any vertex $v \in V(G)$, the subgraph of T induced by the set $T_v = \{t \in V(T) : v \in \beta(t)\}$ is a tree.

The *width* of (T, β) is $\max_{v \in V(T)}\{|\beta(v)|\} - 1$. The *treewidth* of G is the minimum width of a tree decomposition of G.

Let (T, β) be a tree decomposition of a graph G. We refer to the vertices of the tree T as *nodes*. We always assume that T is a rooted tree and hence, we have a natural parent-child and ancestor-descendant relationship among nodes in T. A *leaf* node nor a *leaf* of T is a node with degree exactly one in T which is different from the root node. All the nodes of T which are neither the root node or a leaf are called *non-leaf* nodes. The set $\beta(t)$ is called the *bag* at t. For two nodes $u, t \in T$, we say that u is a *descendant* of t, denoted $u \preceq t$, if t lies on the unique path connecting u to the root. Note that every node is its own descendant. If $u \preceq t$ and $u \neq t$, then we write $u \prec t$. For a tree decomposition (T, β) we also have a mapping $\gamma : V(T) \to 2^{V(G)}$ defined as $\gamma(t) = \bigcup_{u \preceq t} \beta(u)$.

We use the following structured tree decomposition in our algorithm.

▶ **Definition 7** (Nice tree decomposition)**.** Let (T, β) be a tree decomposition of a graph G, where r is the root of T. The tree decomposition (T, β) is called a *nice tree decomposition* if the following conditions are satisfied.

1. $\beta(r) = \emptyset$ and $\beta(\ell) = \emptyset$ for every leaf node ℓ of T; and
2. every non-leaf node (including the root node) t of T is of one of the following types:
   - **Introduce node:** The node t has exactly one child t' in T and $\beta(t) = \beta(t') \cup \{v\}$, where $v \notin \beta(t')$.
   - **Forget node:** The node t has exactly one child t' in T and $\beta(t) = \beta(t') \setminus \{v\}$, where $v \in \beta(t')$.
   - **Join node:** The node t has exactly two children t_1 and t_2 in T and $\beta(t) = \beta(t_1) = \beta(t_2)$.

A graph class closed under vertex and edge deletion is said to have *bounded local treewidth* [16,22] if the treewidth of each graph in the class is upper-bounded by a function of its diameter. Examples of classes of bounded local treewidth include, e.g., graphs of bounded genus [5].

Problem Definition. In our problems of interest, we are given an undirected graph G and a set $\mathcal{R} = \{R_1, R_2, \ldots, R_k\}$ of k robots where $\mathcal{R}$ is partitioned into two sets $\mathcal{M}$ and $\mathcal{F}$. Each $R_i \in \mathcal{M}$ has a starting vertex s_i and a destination vertex t_i in $V(G)$ and each $R_i \in \mathcal{F}$ is associated only with a starting vertex $s_i \in V(G)$. We refer to the elements in the set $\{s_i \mid i \in [k]\} \cup \{t_i \mid R_i \in \mathcal{M}\}$ as *terminals*. The set $\mathcal{M}$ contains robots that have specific destinations they must reach, whereas $\mathcal{F}$ is the set of remaining "free" robots. We assume that all the s_i are pairwise distinct and that all the t_i are pairwise distinct. At each time step, a robot may either move to an adjacent vertex, or stay at its current vertex, and robots may move simultaneously. We use a discrete time frame $[0, t]$, $t \in \mathbb{N}$, to reference the sequence of moves of the robots and in each time step $x \in [0, t]$ every robot remains stationary or moves.

A *route* for robot R_i is a tuple $W_i = (u_0, \ldots, u_t)$ of vertices in G such that (i) $u_0 = s_i$ and $u_t = t_i$ if $R_i \in \mathcal{M}$ and (ii) $\forall j \in [t]$, either $u_{j-1} = u_j$ or $u_{j-1}u_j \in E(G)$. Put simply, W_i corresponds to a "walk" in G, with the exception that consecutive vertices in W_i may be identical (representing waiting time steps), in which R_i begins at its starting vertex at time step 0, and if $R_i \in \mathcal{M}$ then R_i reaches its destination vertex at time step t. Two routes $W_i = (u_0, \ldots, u_t)$ and $W_j = (v_0, \ldots, v_t)$, where $i \neq j \in [k]$, are *non-conflicting* if (i) $\forall r \in \{0, \ldots, t\}$, $u_r \neq v_r$, and (ii) $\nexists r \in \{0, \ldots, t-1\}$ such that $v_{r+1} = u_r$ and $u_{r+1} = v_r$. Otherwise, we say that W_i and W_j *conflict*. Intuitively, two routes conflict if the corresponding robots are at the same vertex at the end of a time step, or go through the same edge (in opposite directions) during the same time step.

A *schedule* S for $\mathcal{R}$ is a set of pairwise non-conflicting routes $W_i, i \in [k]$, during a time interval $[0, t]$. The (*traveled*) *length* of a route (or its associated robot) within S is the number of time steps j such that $u_j \neq u_{j+1}$. The *total traveled length* of a schedule is the sum of the lengths of its routes; this value is often called the *energy* in the literature (e.g., see [17]).

Using the introduced terminology, we formalize the Generalized Coordinated Motion Planning with Energy Minimization (GCMP) problem below.

GCMP

Input: A tuple $(G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$, where G is a graph, $\mathcal{R} = \{R_i \mid i \in [k]\}$ is a set of robots partitioned into sets $\mathcal{M}$ and $\mathcal{F}$, where each robot in $\mathcal{M}$ is given as a pair of vertices (s_i, t_i) and each robot in $\mathcal{F}$ as a single vertex s_i, and $k, \ell \in \mathbb{N}$.

Problem: Is there a schedule for $\mathcal{R}$ of total traveled length at most ℓ?

By observing that the feasibility check of Yu and Rus [41] transfers seamlessly to the case where some robots do not have destinations, we obtain the following.

▶ **Proposition 8** ([41]). *The existence of a schedule for an instance of* GCMP *can be decided in linear time. Moreover, if such a schedule exists, then a schedule with total length traveled of $\mathcal{O}(|V(G)|^3)$ can be computed in $\mathcal{O}(|V(G)|^3)$ time.*

Proposition 8 implies inclusion in NP, and allows us to assume henceforth that every instance of GCMP is feasible (otherwise, in linear time we can reject the instance). We denote by GCMP1 the restriction of GCMP to instances where $|\mathcal{M}| = 1$. We remark that even though GCMP is stated as as a decision problem, all the algorithms provided in this paper are constructive and can output a corresponding schedule (when it exists) as a witness.

3 An Additive FPT Approximation for GCMP

In this section, we give an FPT approximation algorithm for GCMP with an additive error that is a function of the number k of robots.

We start by providing a high-level, low-rigor intuition for the main result of this section. Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of GCMP. Ideally, we would like to route the robots in $\mathcal{M}$ along shortest paths to their destinations, while having the other robots move away only a "little" ($\epsilon(k)$-many steps) to unblock the shortest paths for the robots in $\mathcal{M}$. Unfortunately, this might not be possible as it is easy to observe that a free robot might have to travel a long distance in order to unblock the shortest paths of other robots. (For instance, think about the situation where a free robot is positioned in the middle of a long path of degree-2 vertices that the shortest paths traverse.) However, we will show that such a situation could only happen if the blocking robots are positioned in simple graph structures containing a long path of degree-2 vertices.

We then exploit these simple structures to "guess" in FPT-time, for each robot, a location which it visits in an optimal solution and which is in the vicinity of a safe location, called a "haven"; this haven is centered around a "nice" vertex of degree at least 3, and allows the robot to avoid any passing robot within $\epsilon(k)$ moves. We show how to navigate the robots to these havens optimally in the case of GCMP1, and with an $\epsilon(k)$ overhead in the case of GCMP. Moreover, this navigation is well-structured and can be leveraged to show that no robot in an optimal solution will visit the same vertex many times. A similar navigation takes place at the end, during the routing of the robots from their havens to their destinations.

Once we obtain such a reduced instance in which all starting positions and destinations of the robots are in havens, we can use our intended strategy to navigate each robot in $\mathcal{M}$ along a shortest path, with only an $\epsilon(k)$ overhead, which immediately gives us the approximation result and the property that no robot visits any vertex more than $\epsilon(k)$ times in an optimal solution. This latter property about the optimal solution is crucial, as we exploit it later in Section 5 to design an intricate dynamic programming algorithm over a tree decomposition of the input graph.

In addition, each free robot moves at most $\epsilon(k)$ times in the considered solution for the reduced instance. This, together with the equivalence between $\mathcal{I}$ and the reduced instance in the case of GCMP1, allow us to restrict the movement of the free robots in an optimal solution to only $\epsilon(k)$-many locations, which we use in Section 4 to obtain the FPT algorithm for GCMP1.

We start by defining the notion of a nice vertex and its haven.

▶ **Definition 9** (Nice Vertex). A vertex $w \in V(G)$ is *nice* if there exist three connected subgraphs C_1, C_2, C_3 of G such that: (i) the pairwise intersection of the vertex sets of any pair of these subgraphs is exactly w, and (ii) $|V(C_1)| \geq k+1$, $|V(C_2)| \geq k+1$, and $|V(C_3)| \geq 2$. If w is nice, let $x \in V(C_3)$ be a neighbor of w, and define the *haven* H_w of w to be the subgraph of G induced by the vertices in $\{x\} \cup V(C_1) \cup V(C_2)$ whose distance from w in H_w (i.e., $\text{dist}_{H_v}(w, u)$, for $u \in V(C_1) \cup V(C_2)$) is at most k.

For a set $S \subseteq \mathcal{R}$ of robots and a subgraph H, a *configuration* of S w.r.t. H is an injection $\iota : S \longrightarrow V(H)$. The following lemma shows that we can take the robots in a haven from any configuration to any other configuration in the haven, while incurring a total of $\mathcal{O}(k^3)$ travel (in the haven) length.

▶ **Lemma 10.** *Let w be a nice vertex, let C_1, C_2, C_3 be three subgraphs satisfying conditions (i) and (ii) of Definition 9, and let H_w be a haven for w. Then for any set of robots $S \subseteq \mathcal{R}$ in H_w with current configuration $\iota(S)$, any configuration $\iota'(S)$ with respect to H_w can be obtained from $\iota(S)$ via a sequence of $\mathcal{O}(k^3)$ moves that take place in H_w.*

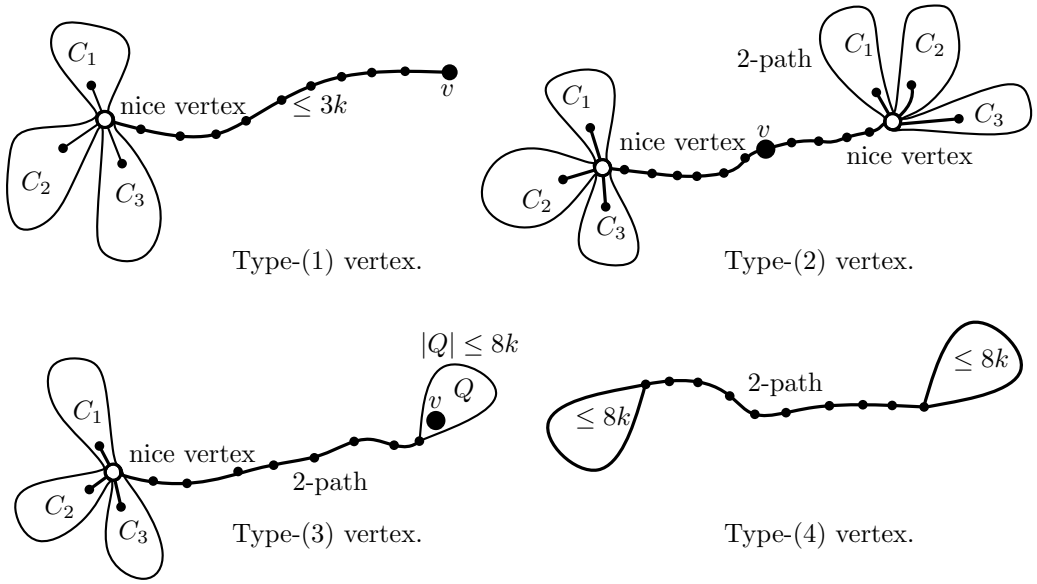

Figure 1 Illustration of the four types for a vertex v that is not nice.

Call a path P in G a *2-path* if P is an induced path of degree-2 vertices in G. The next lemma is used to characterize the possible graph structures around a vertex that is not nice; an illustration for the four cases handled by the lemma is provided in Figure 1.

▶ **Lemma 11.** *For every vertex v that is not nice, one of the following holds:*

(1) *There is a nice vertex at distance at most $3k$ from v; or*

(2) *vertex v is on a 2-path whose both endpoints are nice vertices; or*

(3) *there is a 2-path P such that one of its endpoints is nice and the other is contained in a connected subgraph Q of size at most $8k$ that P cuts from the nice vertex and such that v is in $P \cup Q$; or*

(4) *Either $|V(G)| \leq 8k$, or G consists of a 2-path P, each of whose endpoints is contained in a subgraph of size at most $8k$, such that P cuts the two subgraphs from one another.*

▶ **Definition 12** (Vertex Types)**.** Let v be a vertex in G that is not nice. We say that v is a *type-(i) vertex*, where $i \in \{1, \ldots, 4\}$, if v satisfies Statement (i) in Lemma 11 but does not satisfy any Statement (j), where $j < i$ (if Statement (j) exists). Note that, by Lemma 11, every vertex v that is not nice must be a type-(i) vertex for some $i \in \{1, \ldots, 4\}$.

The following lemma shows that we can restrict our attention to the case where there is no type-(4) vertex in G.

▶ **Lemma 13.** *Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of* GCMP*. If there exists a type-(4) vertex $v \in V(G)$ then $\mathcal{I}$ can be solved in time $\mathcal{O}^*((4k^2 + 16k)^{2k})$ and hence is* FPT*.*

Before we are ready to prove the main theorem for this section, we first need the following lemma, which will allow us to restrict the movement of the free robots.

▶ **Lemma 14.** *Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of* GCMP*. For every $R_i \in \mathcal{F}$ that is within distance λ_i from a nice vertex, there is a set $B(R_i, \lambda_i)$ of vertices of cardinality $k^{\mathcal{O}(\lambda_i \cdot k + k^4)}$ such that, for any optimal solution $opt(\mathcal{I})$, there exists an optimal solution $opt'(\mathcal{I})$ satisfying that, in $opt'(\mathcal{I})$ R_i moves only on vertices in $B(R_i, \lambda_i)$ and all the remaining robots move exactly the same in $opt(\mathcal{I})$ and $opt'(\mathcal{I})$. Moreover, $B(R_i, \lambda_i)$ is computable in $\mathcal{O}(|V(G)| + |E(G)|)$ time.*

▶ **Theorem 15.** *Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of* GCMP. *In* FPT*-time, we can reduce $\mathcal{I}$ to $p = g(k)$-many instances (for some computable function $g(k)$) $\mathcal{I}_1, \ldots, \mathcal{I}_p$ such that there exists $j \in [p]$ satisfying:*

1. *If $\mathcal{M} = \{R_1\}$ then $\mathcal{I}_j = (G_j, \mathcal{R}_j = (\mathcal{M}_j, \emptyset), k_j, \ell_j)$, where $k_j \leq k$ and $\ell_j \leq \ell$, is a yes-instance of* GCMP *if and only if $\mathcal{I}$ is a yes-instance. Moreover, in this case there is an optimal solution $opt(\mathcal{I}_j)$ such that $|opt(\mathcal{I}_j)| = \mathrm{dist}_{G_j}(s_1, t_1) + \mathcal{O}(k^5)$, and for every robot $R_i \in \mathcal{M}_j \setminus \{R_1\}$, the moves of R_i in $opt(\mathcal{I}_j)$ are restricted to a vertex set of cardinality at most $k^{\mathcal{O}(k^4)}$ that is computable in linear time.*
2. *In polynomial time we can compute a schedule for $\mathcal{I}_j$ with total traveled length at most $\sum_{R_i \in \mathcal{M}_j} \mathrm{dist}(s_i, t_i) + \mathcal{O}(k^5)$, and given such a schedule for $\mathcal{I}_j$, in polynomial time we can compute a schedule for $\mathcal{I}$ of cost at most $|opt(\mathcal{I})| + \mathcal{O}(k^5)$.*

Furthermore, every optimal schedule for $\mathcal{I}$ satisfies the property that every vertex in G is visited at most $\mathcal{O}(k^5)$ many times in the schedule.

Proof Sketch. Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of GCMP, and let $opt(\mathcal{I})$ denote an optimal schedule for $\mathcal{I}$. We give a nondeterministic reduction that produces a single instance $\mathcal{I}_j = (G_j, R_j = (\mathcal{M}_j, \emptyset), k_j, \ell_j)$, which can be made deterministic in FPT-time.

To construct $\mathcal{I}_j$, we will be making guesses about the initial and final segments of the robots' routes in $opt(\mathcal{I})$, which may lead to redefining the starting and final positions for some of them, with the purpose of getting them close to havens – as explained at the beginning of this section. The guessing is based on the types of the starting and final positions of the robots (see Lemma 11). We set $\ell_j = \ell$.

Case I. If the starting or the final position of a robot is at distance at most $11k$ from a nice vertex, we do not change it.

Case II. If the starting or the final position of a robot is a type-(2) vertex on a path P that connects two nice vertices, then we look separately at all the robots that start on P and all the robots that end on P (guessing for each free robot whether it ends on P). Let us first consider the robots that start on P. We make a guess, for each of these robots, about whether it ever leaves P, and if it does, from which endpoint of P it leaves for the first time. This splits the robots on P into three sets S_{Left}, S_{Mid}, S_{Right}. Observe that these three sets have to be "consecutive" on P (i.e., their robots respect the order of the sets), and we push the starting points of the robots in S_{Left} and in S_{Right} to distance at most k from the nice vertex they leave from for the first time. Similarly, we split the robots that end on P into the sets T_{Left}, T_{Mid}, T_{Right}. We redefine the destinations of the robots in T_{Left} and T_{Right} to vertices at distance at most k from their respective nice vertices through which they enter P, and we compute the additional travel length incurred by moving them directly from these positions at distance at most k from nice vertices to their destinations and subtract this number from ℓ_j. Recall that, according to our guess, S_{Mid} and T_{Mid} each contains precisely the robots that never leave P, and hence $S_{\mathrm{Mid}} = T_{\mathrm{Mid}}$. We show that for most of the robots in S_{Mid}, any optimal solution takes them directly from their starting positions to their destinations, except for those that start and end at distance at most k from the same nice vertex. For those that do not start and end at distance at most k from the same nice vertex, we compute the travel length incurred by taking them directly to their destinations, subtract it from ℓ_j, and delete these robots from $\mathcal{R}$. Finally, if $S_{\mathrm{Mid}} \neq \emptyset$, then no robot can use P to move between its two endpoints. Moreover, if a robot is on P, then it does not need to go beyond the k-closest vertices on P to a nice vertex. Hence, if $S_{\mathrm{Mid}} \neq \emptyset$, then we delete all the vertices on P that are at distance at least $k + 1$ from a nice vertex.

Case III. If the starting or the final position of a robot is a type-(3) vertex, which consists of a nice vertex n_R joined by a 2-path P to a vertex u in a connected subgraph C of size at most $8k$, then we start by treating this situation the same as that of a type-(2) vertex, with the role of the second nice vertex replaced by u. In particular, we guess the sets S_{Left}, S_{Mid}, S_{Right}, T_{Left}, T_{Mid}, T_{Right}, where S_{Right} (resp. T_{Right}) are the robots that start their routing by going from a vertex on P to u, or from u to a vertex on P. We also change the starting and ending positions for the robots that are not in S_{Mid} to vertices that are at distance at most k from either n_R or u; we compute the routing that reflects this change, and subtract its travel length from ℓ_j.

If $S_{\text{Mid}} \neq \emptyset$, then the vertices on which the robots in S_{Mid} are positioned separate the robots that are in $S_{\text{Right}} \cup T_{\text{Right}}$ plus the robots that start or end in C, from the rest of the graph. Note that at this point, there is no interaction between the robots in $S_{\text{Right}} \cup T_{\text{Right}} \cup S_{\text{Mid}}$ and the other robots in $\mathcal{R}$. Therefore, we can treat C and the part of P containing the robots in $S_{\text{Right}} \cup T_{\text{Right}} \cup S_{\text{Mid}}$ as a separate instance, which has the same structure as that of a type-(4) vertex. We solve this instance optimally using Lemma 13, and keep on $V(P)$ only the k-closest vertices to n_R. On the other hand, if $S_{\text{Mid}} = \emptyset$ then some robots that start (resp. end) in S_{Right} (resp. T_{Right}) or in C might also visit n_R. We show that, in the case of GCMP1, this happens only in a very restricted setting where the single robot in $\mathcal{M}$ starts or ends in C, which can be dealt with easily with the help of Lemma 13. On the other hand, if $|\mathcal{M}| \geq 2$, then this is no longer the case. We now further guess which of the robots that start (resp. end) in S_{Right} (resp. T_{Right}) or in C also visit n_R on the other end of P. Using Proposition 8, we can show that we can always route these robots at the beginning (resp. at the end) to (resp. from) a position at distance at most k from n_R with overhead at most $\mathcal{O}(k^3)$ over an optimal routing. Afterwards, we keep in G only the vertices on P at distance at most k from n_R, and remove the rest of $V(C) \cup V(P)$.

This concludes the reduction to obtain the instance $\mathcal{I}_j$ from $\mathcal{I}$.

Let us now prove Statement 1. Observe that all the free robots can now be either at distance at most $11k$ from a nice vertex and we can use Lemma 14 to compute the set $B(R_i, 11k)$ where they can move; or alternatively, they can be at distance at most k from a connected subgraph of size at most $8k$ associated with a type-(3) vertex and they will stay there, and hence, their movement in this case is restricted to $9k$ vertices.

We now show how to compute a schedule for $\mathcal{I}_j$ with total traveled length at most $\text{dist}(s_1, t_1) + \mathcal{O}(k^5)$. To do so, we first move all the robots that are at distance at most $11k$ from a nice vertex v to a haven H_v of v. We then compute a shortest path P between s_1 and t_1. We note that P can only interact with a connected subgraph C of a type-(3) vertex at the beginning or at the end. In both cases, we can use Lemma 13 to compute an optimal routing of R_1 from C (resp. to) to the first (resp. from the last) haven P intersects. Afterwards, all free robots on P are in havens. We let R_1 follow P. Whenever P interacts with a haven H that contains a free robot, we replace the subpath of P between the first interaction of R_1 with H and the last interaction of R_1 with H with a schedule computed by Lemma 10 that reconfigures H taking R_1 between its two interaction positions. Each interaction with a haven increases the length of P by $\mathcal{O}(k^3)$ and there are at most k havens that contain a free robot. Finally, we move the free robots at the end to their guessed destinations in $\mathcal{I}_j$. We can show that this incurs a travel length of $\mathcal{O}(k^5)$.

For Statement 2, if $|\mathcal{M}| = 1$ then Statement 2 follows from Statement 1. Otherwise, all starting positions and destinations are at distance at most $11k$ from nice vertices. Due to this, we can show that we can start by incurring an $\mathcal{O}(k^2)$ travel length to route each robot to a nearest haven, and finish by incurring $\mathcal{O}(k^4)$ travel length to route all the robots from

havens at distance at most $11k$ from their destinations to their destinations. We can then route the robots one-by-one from a "starting" haven to a "destination" haven along a shortest path in the same manner we routed the robot R_1 in the case of GCMP1. The routing of each robot incurs an overhead of $\mathcal{O}(k^4)$ above its shortest path length, and hence the total overhead for routing all the robots between havens is $\mathcal{O}(k^5)$ and Statement 2 follows. ◀

The approximation algorithm claimed in the introduction (restated below) follows directly from Statement 2 of Theorem 15.

▶ **Theorem 3.** *There is an* FPT *approximation algorithm for* GCMP *parameterized by the number k of robots which guarantees an additive error of $\mathcal{O}(k^5)$.*

4 An FPT Algorithm for GCMP1 Parameterized by k

The aim of this section is to establish Theorem 1 by using Theorem 15.

▶ **Theorem 1.** GCMP1 *is* FPT *parameterized by the number k of robots.*

Proof Sketch. Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of GCMP1. By Statement 1 of Theorem 15, in FPT-time we can compute an equivalent instance $\mathcal{I}_j = (G_j, \mathcal{R}_j = (\mathcal{M}_j, \emptyset), k_j, \ell_j)$ to $\mathcal{I}$ satisfying that $k_j \leq k$ and $|opt(\mathcal{I}_j)| = \text{dist}_{G_j}(s_1, t_1) + \mathcal{O}(k^5)$, where $\mathcal{M} = \{R_1\}$. Moreover, for every robot $R_i \in \mathcal{M}_j \setminus \{R_1\}$, the moves of R_i in $opt(\mathcal{I}_j)$ are restricted to the vertices of a vertex-set $B(R_i)$ of cardinality at most $k^{\mathcal{O}(k^4)}$ that is computable in linear time.

Define a state graph $\mathcal{Q}$ whose vertices are k-tuples with coordinates defined as follows. The first coordinate of a k_j-tuple corresponds to R_1 and can be any of the at most n vertices in $V(G_j)$; the i-th coordinate of a tuple, where $i \in \{2, \ldots, k_j\}$, encodes the possible location of R_i and is confined to the vertices in $B(R_i)$. We purge any tuple in which a vertex in $V(G_j)$ appears in more than one coordinate of the tuple (i.e., is occupied by more than one robot in the same time step). Since $|B(R_i)| = k^{\mathcal{O}(k^4)}$, for $i \in \{2, \ldots, k_j\}$, it follows that the number of vertices in $\mathcal{Q}$ is at most $\mathcal{O}(n \cdot k^{\mathcal{O}(k^5)})$. Two vertices/states S and S' in $\mathcal{Q}$ are adjacent if there is a valid (i.e., causing no collision) single (parallel) move for the robots from their locations in S to their locations in S'; the weight of an edge (S, S') in $\mathcal{Q}$ is the number of robots in S that have moved (i.e., their positions have changed).

Define the starting configuration S_{start} in $\mathcal{Q}$ to be the k_j-tuple whose coordinates correspond to the starting positions of the robots in $\mathcal{I}_j$. Define S_{final} to be the k_j-tuple whose coordinates correspond to the destinations of the robots in $\mathcal{I}_j$. Now compute a shortest (weighted) path from S_{start} to S_{final} in $\mathcal{Q}$ (e.g., using Dijkstra's algorithm) and accept the instance $\mathcal{I}$ if and only if the weight of the computed shortest path is at most ℓ_j. The running time of the algorithm is $\mathcal{O}(|V(\mathcal{Q})|^2) = \mathcal{O}(n^2 \cdot k^{\mathcal{O}(k^5)})$, and it is clear that the above algorithm decides the instance correctly. It follows that GCMP1 is FPT parameterized by k. ◀

5 An FPT Algorithm Parameterized by Treewidth and k

In this section, we present an FPT algorithm for GCMP parameterized by the number of robots and the treewidth of the input graph combined. This result implies that the problem is FPT on certain graph classes such as graphs of bounded outerplanarity, which include subgrids of bounded height. In this sense, the result can be seen as complementary to the recently established NP-hardness of the problem on bounded-height subgrids [20].

▶ **Definition 16** (Semi-routes). A *semi-route* for R_i is a tuple $W_i = (u_0^i, \ldots, u_t^i)$ such that each u_j^i is either a vertex of G or the symbol $\perp$, and such that (i) $u_0^i = s_i$ and moreover, if $R_i \in \mathcal{M}$, then $u_t^i = t_i$, and (ii) $\forall j \in [t]$, either $u_{j-1}^i = u_j^i$ or $u_{j-1}^i u_j^i \in E(G)$ or one out of u_{j-1}^i and u_j^i is the symbol $\perp$. The notion of two conflicting semi-routes is identical to that for routes, except that we only consider time steps where neither semi-routes has $\perp$.

Intuitively, the above definition gives us a notion of partial routes, where the robots can be thought of as having become "invisible" (but still potentially in motion) for some time steps during a route (assume only a small part of the graph is visible to us). These time steps where a robot disappears from view are represented by the symbol $\perp$. Note that a robot can "reappear" at a different vertex than the one it "disappeared" at. A *semi-schedule* for $\mathcal{R}$ is a set of semi-routes during a time interval $[0, t]$ that are pairwise non-conflicting. The *length* of a semi-route and a semi-schedule is naturally defined as the number of time steps in which the robot moves from one vertex to a different vertex, and the *total traveled length* of a semi-schedule is the sum of the lengths of its semi-routes.

A *boundaried graph* [9] is a graph G with a set $X \subseteq V(G)$ of distinguished vertices called *boundary vertices*; the set X is called the *boundary* of G. A boundaried graph (G, X) is called a *p-boundaried* graph if $|X| \leq p$. A *p-boundaried subgraph* of a graph G is a p-boundaried graph (H, Z) such that (i) H is a vertex-induced subgraph of G and (ii) Z separates $V(H) \setminus Z$ from $V(G) \setminus V(H)$.

In what follows, let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of GCMP. Let (H, Z) be a p-boundaried subgraph of G with boundary Z containing all the terminals. Let S be a schedule for this instance with routes $W_i, i \in [k]$.

▶ **Definition 17** (Signatures of Schedules). Call the tuples in the set $(Z \cup \{\uparrow, \downarrow\})^k$, *configuration tuples* for (H, Z). We define the *signature* of the schedule S with respect to (H, Z) as a sequence of tuples $\tau_0, \ldots, \tau_t$, where each τ_i is a configuration tuple defined as follows: the j^{th} coordinate of τ_i signifies whether at the end of time step i

- R_j is on a vertex $v \in Z$, in which case this value is v; or
- whether it is inside H but not on the boundary, in which case this value is $\downarrow$; or
- whether it is disjoint from H, in which case this value is $\uparrow$.

The tuple τ_i is called the *signature of the schedule S with respect to (H, Z) at time step i*. The tuple τ_0 and τ_t are called *starting* and *ending* configuration tuples.

▶ **Definition 18** (Checkpoints of Schedules). We say that the schedule S:

- *externally affects* (H, Z) *at time steps* i and $i+1$ if some robot moves from a vertex outside H to a vertex in Z during time step $i+1$, or if some robot moves from some vertex of Z to a vertex outside H during time step $i+1$. That is, for some robot R_j, we either have that $u_i^j \notin V(H)$ and $u_{i+1}^j \in Z$, or we have $u_i^j \in Z$ and $u_{i+1}^j \notin V(H)$.
- *internally affects* (H, Z) at time steps i and $i+1$ if some robot moves from a vertex of H to a vertex of Z during time step $i+1$, or if some robot moves from some vertex of Z to a vertex in H during time step $i+1$. That is, for some robot R_j, we have $u_i^j \neq u_{i+1}^j$ and moreover, we either have that $u_i^j \in V(H)$ and $u_{i+1}^j \in Z$ or we have $u_i^j \in Z$ and $u_{i+1}^j \in V(H)$.
- *affects* (H, Z) at time steps i and $i+1$ if it internally or externally affects (H, Z) at time steps i and $i+1$.

The pairs of consecutive time steps at which the schedule affects (H, Z) are called *checkpoints of the schedule with respect to* (H, Z). We drop the explicit reference to (H, Z) whenever it is clear from the context. Two checkpoints $(x, x+1)$ and $(y, y+1)$ are said to be *consecutive* if $x < y$ and there is no checkpoint $(z, z+1)$ such that $x < z < y$.

Roughly speaking, the checkpoints are the time steps at which the schedule interacts in some way with the separator Z. The interaction involves a robot either moving to or from a vertex of Z. As a result, the notion of checkpoints enables one to "decompose" a solution along the vertices of Z between consecutive checkpoints. We will argue that whenever Z is sufficiently small, the number of possible checkpoints will also be small.

▶ **Definition 19** (Semi-schedules). A *semi-schedule with respect to* (H, Z) is a semi-schedule where every vertex on every semi-route is contained in $V(H)$ and for every subtuple $(u, \perp, \ldots, \perp, v)$ in a semi-route, where $u, v \in V(H)$, it must be the case that $u, v \in Z$.

The intuition here is that whenever the robot "vanishes" or "reappears", it happens at the boundary Z. This allows us to analyze how a schedule interacts with the subgraph H since every movement between H and the rest of G must happen through the boundary Z.

▶ **Definition 20** (Signatures of Semi-schedules). The *signature* $\tau_0, \ldots, \tau_t$ of a semi-schedule with respect to (H, Z) is defined similarly to that of a schedule after making the assumption that $\perp$ denotes a vertex outside H, that is, we have the symbol $\uparrow$ in the j^{th} coordinate of tuple τ_i if and only if the robot R_j has $u_i^j = \perp$. A semi-schedule *externally affects* (H, Z) at time steps i and $i+1$ if some robot "moves" from $\perp$ to Z during time step $i+1$ or it "moves" from Z to $\perp$ during time step $i+1$. That is, for some robot R_j, we have $u_i^j = \perp$ and $u_{i+1}^j \in Z$ or we have $u_i^j \in Z$ and $u_{i+1}^j = \perp$. The notions of internally affecting (H, Z), affecting (H, Z), checkpoints with respect to (H, Z) are defined exactly as for schedules.

▶ **Definition 21** (Checkpoint Tuples). *Checkpoint tuples* of a schedule or semi-schedule S with respect to (H, Z) are defined as those configuration tuples for (H, Z) that appear in the signature of S at the time steps participating in checkpoints of S with respect to (H, Z). The *checkpoint tuple sequence* of S with respect to (H, Z) is the set of checkpoint tuples ordered according to their respective time steps.

Our dynamic programming algorithm will make use of the following observation about signatures of schedules and semi-schedules to narrow down the search space.

▶ **Observation 22.** *Let $\tau_0, \ldots, \tau_t$ be the signature of a schedule or semi-schedule with respect to (H, Z). Then, the following properties hold:*

1. *$\tau_0 = (s_1, \ldots, s_k)$. Moreover, the coordinates of τ_t that correspond to the robots in $\mathcal{M}$ are fixed, that is, $\tau_t = (t_1, \ldots, t_{|\mathcal{M}|}, v_1, \ldots, v_{k-|\mathcal{M}|})$ for some vertices $v_1, \ldots, v_{k-|\mathcal{M}|}$ distinct from $\{t_1, \ldots, t_{|\mathcal{M}|}\}$.*
2. *The first two and last two tuples in the signature are at checkpoints. That is, $(0, 1)$ and $(t-1, t)$ are checkpoints.*
3. *Let $(x, x+1), (y, y+1)$ be consecutive checkpoints such that $x+1 < y$. Then, the tuples $\tau_{x+2}, \ldots, \tau_{y-1}$ are identical.*
4. *Let $(x, x+1)$ be a checkpoint. There is a coordinate j such that $\tau_x[j] \neq \tau_{x+1}[j]$ and at least one of $\tau_x[j]$ or $\tau_{x+1}[j]$ is a vertex of Z.*
5. *Let $(x, x+1)$ be a checkpoint. There is no coordinate j such that $\tau_x[j] = \uparrow$ and $\tau_{x+1}[j] = \downarrow$ or $\tau_x[j] = \downarrow$ and $\tau_{x+1}[j] = \uparrow$.*
6. *For every time step x, τ_x contains at most one occurrence of any vertex of Z.*
7. *Let $(x, x+1)$ be a checkpoint and suppose that $\tau_x[j] \neq v \in Z$ and $\tau_{x+1}[j] = v$. Then, either there is no j' such that $\tau_x[j'] = v$ or it must be the case that $\tau_{x+1}[j'] \neq v$.*
8. *Parallel movements between vertices of the boundary Z in a single time step must happen along edges that exist and moreover, no edge can be used by two robots.*

Proof. The first two statements follow from the fact that the terminals are contained in Z. The third, fourth and fifth statements follow from the definition of checkpoints and the fact that the boundary is a separator between $V(H) \setminus Z$ and $V(G) \setminus V(H)$. The sixth and seventh statements are due to the fact that no vertex can be occupied by two robots at the same time. The eighth statement is due to the fact that a schedule or semi-schedule must be comprised of pairwise non-conflicting routes or semi-routes. ◀

▶ **Observation 23.** *Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of* GCMP. *Let (H, Z) be a p-boundaried subgraph of G with boundary Z containing all the terminals. If there is a schedule S for $\mathcal{I}$ in which each vertex is entered by any robot at most $\nu(k)$ times, then the following hold.*

1. *The number of checkpoints of S with respect to (H, Z) is bounded by $\mathcal{O}(pk \cdot \nu(k))$.*
2. *The number of possible checkpoint tuple sequences of S with respect to (H, Z) is bounded by $g(k, p) = p^{\mathcal{O}(pk \cdot \nu(k))}$.*

We now proceed by defining the partial solutions which play a central role in our algorithm.

▶ **Definition 24** (Partial Solutions)**.** Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of GCMP. Let (H, Z) be a p-boundaried subgraph of G with boundary Z containing all the terminals. Given an ordered set of configuration tuples $\gamma_1, \ldots, \gamma_q$ for (H, Z) where q is even, γ_1 is a starting configuration tuple and γ_q is an ending configuration tuple, a *partial solution corresponding to the sequence* $(\gamma_1, \gamma_2), \ldots, (\gamma_{q-1}, \gamma_q)$ is a semi-schedule S with respect to (H, Z) such that the checkpoint tuple sequence of S with respect to (H, Z) is exactly these tuples in this order. That is, the checkpoints of S with respect to (H, Z) are $(x_1, x_2), \ldots, (x_{q-1}, x_q)$ and $\tau_{x_i} = \gamma_i$ for each $i \in [q]$.

▶ **Theorem 2.** GCMP *is* FPT *parameterized by the number of robots and the treewidth of the input graph.*

Proof Sketch. Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be the given instance of GCMP. We start with a tree decomposition (T, β) of G of optimal width and add the terminals to every bag. Call the resulting tree decomposition (T, β') and let its width be w. By invoking Theorem 3 and setting $\nu(k) = \mathcal{O}(k^5)$ in Observation 23, we infer that the length of the checkpoint tuple sequence of S with respect to each boundaried graph $(G^{\downarrow}_{x,T}, \beta'(x))$ where $x \in V(T)$, is at most twice the number of checkpoints in this sequence. Hence, the length of this checkpoint tuple sequence is bounded by $\lambda(k, w) = \mathcal{O}(wk^6)$. Here, $G^{\downarrow}_{x,T}$ denotes the graph induced by the vertices that lie either in the bag $\beta'(x)$ or below it. Moreover, by the same observation, the number of possible checkpoint tuple sequences of S with respect to each boundaried graph $(G^{\downarrow}_{x,T}, \beta'(x))$ is at most $g(k, w+1) = w^{\mathcal{O}(wk^6)}$.

Based on this fact, our goal is to use dynamic programming to compute, for every $x \in V(T)$ and boundaried graph $(G^{\downarrow}_{x,T}, \beta'(x))$, and for every possible checkpoint tuple sequence of length at most $\lambda(k, w)$ with respect to this boundaried graph, the length of the best partial solution corresponding to this checkpoint tuple sequence within the boundaried graph. When x is the root node, $G^{\downarrow}_{x,T}$ is exactly the input graph G. Hence, the solution is given by the minimum entry in the table computed at the root node. Note that we only describe an algorithm to compute the length of an optimal solution. However, it is straightforward to see that an optimal schedule can also be produced in the same running time. ◀

6 Using the Total Energy as the Parameter

In the final part of our paper, we consider the complexity of GCMP in settings where we are dealing with many robots but the energy budget ℓ is small. While intuitively this may seem like an "easier" case due to the fact that ℓ immediately bounds the number of robots

that will end up moving in a hypothetical schedule, we show that the problem (and even its restriction to the often-studied case where all robots have destinations) is unlikely to be fixed-parameter tractable when parameterized by ℓ.

▶ **Theorem 4.** GCMP *is* W[1]*-hard when parameterized by* ℓ.

Proof. We provide a parameterized reduction from the well-known W[1]-complete Multicolored Clique problem [9, 13]: decide whether a given κ-partite graph $(V_1, \ldots, V_\kappa, E)$ contains a clique of size κ. To avoid any confusion, we explicitly remark that in this proof we use κ to denote the parameter of the initial instance of Multicolored Clique and not the number of robots in the resulting instance of GCMP.

Our reduction takes an instance $(V_1, \ldots, V_\kappa, E)$ of Multicolored Clique and constructs an instance $(G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), \kappa', \ell)$ of GCMP as follows. To obtain G, we:

1. subdivide each edge $e \in E$ κ^3 many times;
2. attach a single new pendant vertex v' to each vertex $v \in V_1 \cup \cdots \cup V_\kappa$ in the original graph; and
3. for each pair of integers i, j such that $1 \leq i < j \leq \kappa$, construct a new vertex $s_{i,j}$ and make it adjacent to every vertex in V_i, and construct a new vertex $t_{i,j}$ and make it adjacent to every vertex in V_j.

For $\mathcal{R} = (\mathcal{M}, \mathcal{F})$, we set $\mathcal{F} = \emptyset$ and add two sets of robots into $\mathcal{M}$. First, for each vertex v in $V_1 \cup \cdots \cup V_\kappa$, we construct a *blocking* robot r^v and set v as its starting point as well as its destination. Second, for each of the newly constructed $s_{i,j} \in V(G)$, we construct a *clique* robot $r^{i,j}$, set $s_{i,j}$ as its starting point and $t_{i,j}$ as its destination. Finally, we set $\ell := 2\kappa + \binom{\kappa}{2} \cdot (\kappa^3 + 3)$ and $\kappa' := |\mathcal{R}|$. This completes the description of our reduction.

Towards proving correctness, we first observe that a hypothetical schedule for $(G, \mathcal{R}, \kappa', \ell)$ can never use less than $\ell := 2\kappa + \binom{\kappa}{2} \cdot (\kappa^3 + 3)$ travel length. Indeed, there are $\binom{\kappa}{2}$ many clique robots, and the shortest path between their starting and destination points has length $\kappa^3 + 3$. Moreover, every schedule must route each clique robot $r^{i,j}$ through at least one vertex in V_i and at least one vertex in V_j, and hence a hypothetical solution must spend a length of at least 2 to move at least one of the blocking robots in each V_p, $p \in [\kappa]$, out of the way and then back to its initial position (which is also its destination).

Now, assume that $(G, \mathcal{R}, \kappa', \ell)$ is a yes-instance. By the argument above, this implies that there is a schedule which moves precisely one of the blocking robots in each V_p, $p \in [\kappa]$; let us denote by w_p the starting vertex of the unique blocking robot which is moved from V_p. Since $(G, \mathcal{R}, \kappa', \ell)$ is a yes-instance, E must contain an edge between each w_i and w_j, $1 \leq i < j \leq \kappa$; in particular, these vertices induce a clique in $(V_1, \ldots, V_\kappa, E)$.

For the converse, assume that $(V_1, \ldots, V_\kappa, E)$ contains a κ-clique $w_1, \ldots, w_\kappa$. We construct a solution for $(G, \mathcal{R}, \kappa', \ell)$ as follows. First, for each robot starting at w_i, $i \in [\kappa]$, we spend a length of 1 to move it to the pendant vertex w_i'. Next, we route each robot $r^{i,j}$ from $s_{i,j}$ to w_i, through the $(\kappa^3 + 1)$-length path to w_j (whereas the existence of this path is guaranteed by the existence of the edge $w_i w_j \in E$), and then to its destination $t_{i,j}$. Finally, we route each blocking robot which originally started at w_i back to w_i from w_i'. The travelled length of this schedule is precisely $2\kappa + \binom{\kappa}{2} \cdot (\kappa^3 + 3)$, as desired. ◀

As mentioned in the introduction, we complement Theorem 4 with a fixed-parameter algorithm on graph classes of bounded local treewidth.

Before proceeding to the proof, we recall the syntax of Monadic Second Order Logic (MSO) of graphs. It contains the logical connectives $\vee$, $\wedge$, $\neg$, $\Leftrightarrow$, $\Rightarrow$, variables for vertices, edges, sets of vertices and sets of edges, and the quantifiers $\forall$ and $\exists$, which can be applied to these variables. It also contains the following binary relations: (i) $u \in U$, where u is a vertex

variable and U is a vertex set variable; (ii) $d \in D$, where d is an edge variable and D is an edge set variable; (iii) $\mathbf{inc}(d, u)$, where d is an edge variable, u is a vertex variable, with the interpretation that the edge d is incident to u; (iv) equality of variables representing vertices, edges, vertex sets and edge sets.

The well-known Courcelle's theorem [2, 8] states that checking whether a given graph G models a given MSO formula ϕ can be done in FPT time parameterized by the treewidth of G and the size of ϕ. Morover, this result holds even if some vertices of G are given labels or colors (i.e., we allow a fixed number of additional unary relations over $V(G)$). This is because one can produce an equivalent graph G' such that G has bounded treewidth if and only if G' does, plus an alternate MSO formula ϕ' such that G models ϕ if and only if G' models ϕ'.

▶ **Theorem 5.** GCMP *is* FPT *parameterized by* ℓ *on graph classes of bounded local treewidth.*

Proof. Let $\mathcal{I} = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be the given instance of GCMP where G belongs to a graph class that is closed under taking subgraphs and in which the treewidth of a graph of diameter d is bounded by $f(d)$ for some function f. Let $\mathcal{M}'$ denote the set of those robots in $\mathcal{M}$ whose final position is distinct from the starting position. Since each of the robots in $\mathcal{M}'$ must move at least one step, it follows that if $|\mathcal{M}'| > \ell$, then the instance is a no-instance. So, assume that $|\mathcal{M}'| \leq \ell$. Let U denote the set of starting points of the robots in $\mathcal{M}'$.

Consider an optimal schedule S. We say that an edge e appears in a route $W = (u_0, \ldots, u_t)$ in S if the endpoints of e are the vertices u_{j-1} and u_j for some $j \in [t]$. We say that e appears in S if it appears in some route in S. Let E_S denote the set of edges of G that appear in S. We observe that every connected component of the subgraph of G induced by E_S (call it G_S) contains a vertex of U. If this were not the case and there is a connected component of G_S disjoint from U, then we can delete all the routes whose edges appear in this connected component and still have a feasible schedule for the given instance, contradicting the optimality of S. Moreover, since S has total energy at most ℓ, it follows that at most ℓ edges can appear in S. Hence, it follows that S is contained in the subgraph H defined as the union of the subgraphs induced by the ℓ-balls centered at the starting positions of the robots in $\mathcal{M}'$.

Notice that since H is obtained by taking the union of at most ℓ graphs, each of diameter at most 2ℓ, it follows that H has diameter at most $2\ell^2$ and so, the treewidth of H is upper bounded by $f(2\ell^2)$. It remains to argue that GCMP is FPT parameterized by the energy and treewidth of the input graph. We do this by making some guesses, obtaining a bounded number of MSO formulas such that input is a yes-instance if and only if at least one of these formulas is true on the graph H with a label function (with constant number of labels) and then invoking Courcelle's theorem [2, 8]. Let $\mathcal{M}''$ denote the subset of $\mathcal{M} \setminus \mathcal{M}'$ contained in H and let $\mathcal{R}' = \mathcal{R} \cap V(H)$.

Suppose that $\alpha \leq \ell$ robots move in S and let the routes in S be $\{W_i = (v_1^i, \ldots, v_{d_i}^i) \mid i \in [\alpha]\}$. Assume that the first $|\mathcal{M}'|$ routes, $W_1, \ldots, W_{|\mathcal{M}'|}$, correspond to the robots in $\mathcal{M}'$. We guess α and $d_1, \ldots, d_\alpha$ as these are all at most ℓ. Moreover, we guess, for every pair of vertices v_j^i and v_q^p whether they are equal. Let this be expressed by a function $\mu(v_j^i, v_q^p)$ that evaluates to 1 if and only if these vertices are guessed to be equal. Thus, even though we do not know the actual vertices in the solution (except for the starting and endpoint positions of the robots in $\mathcal{M}'$), this guess gives us the "structure" of the entire solution. Notice that the number of guesses is bounded by a function of ℓ. Now, we consider the labeled graph H where the starting points of all robots in $\mathcal{R}' \setminus \mathcal{M}''$ are labeled red and the starting points of the robots in $\mathcal{M}''$ are labeled blue. Fix a guess of α, the numbers $d_1, \ldots, d_\alpha$ and a guess of the function μ and express the following as an MSO formula.

There are ordered vertex sets $\{W_i = (v^i_1, \ldots, v^i_{d_i}) \mid i \in [\alpha]\}$ such that the following hold:

1. Each W_i is a walk in H.
2. For every i, j, p, q, v^i_j and v^p_q are equal if and only if $\mu(v^i_j, v^p_q)$ is 1.
3. The walks W_i are pairwise non-conflicting routes.
4. For each of the first $|\mathcal{M}'|$ walks $W_1, \ldots, W_{|\mathcal{M}'|}$, the initial and final vertices are precisely the starting and ending points, respectively, of some robot in $\mathcal{M}'$.
5. For each labeled vertex appearing on any walk W_i, this vertex must be the first vertex of some walk W_i.
6. For each walk W_i starting at a blue vertex, it must terminate at the same blue vertex.

Expressing the above in MSO is straightforward to do, so we do not go in to lower level details of the MSO formula.

We next argue that the input is a yes-instance if and only if there is a guess of α, the numbers $d_1, \ldots, d_\alpha$ and a guess of the function μ such that the resulting MSO formula is true on H. Consider the forward direction. An optimal schedule S with routes $W_1, \ldots, W_\alpha$ naturally gives us a "correct" guess of α, $d_1, \ldots, d_\alpha$ and the function μ. Moreover notice that Properties 1-4 are clearly satisfied. For Property 5, notice that only the starting points of robots that never move can be disjoint from the set of initial vertices of the routes $\{W_i \mid i \in [\alpha]\}$ in the optimal schedule S. Since these robots do not move, they also cannot appear on any route W_i or they would obstruct a robot that moves. Finally, Property 6 is satisfied since every robot in $\mathcal{M}''$ that moves also ends up returning to its starting point. The converse is trivial. ◀

7 Conclusion

In this paper, we presented parameterized algorithms for fundamental coordinated motion planning problems on graphs. In particular, we proved that GCMP1 is fixed-parameter tractable parameterized by the number of robots, and that GCMP is fixed-parameter tractable parameterized by the number k of robots and the treewidth of the input graph combined. This latter result implies that GCMP is fixed-parameter tractable in several graph classes which may be of interest w.r.t. application domains, including graphs of bounded outerplanarity.

We conclude by highlighting three directions that may be pursued in future works:

1. Is GCMP FPT parameterized by k (alone) on planar graphs, or even on general graphs?
2. What is the complexity of GCMP on trees? While GCMP1 is known to be in P on trees, the complexity of the general problem on trees remains unresolved.
3. The focus of this paper was on minimizing the travel length/energy, which is one of the most-studied optimization objectives. Nevertheless, there are other important objectives, most notably that of minimizing the makespan. It seems that at least in the settings considered here, optimizing the makespan may be a computationally more challenging problem. In particular, the question of whether Coordinated Motion Planning on trees is FPT parameterized by k remains open.

Abstract

Consider a query model of computation in which an n-vertex k-hypergraph can be accessed only via its independence oracle or via its colourful independence oracle, and each oracle query may incur a cost depending on the size of the query. Several recent results (Dell and Lapinskas, STOC 2018; Dell, Lapinskas, and Meeks, SODA 2020) give efficient algorithms to approximately count the hypergraph's edges in the colourful setting. These algorithms immediately imply fine-grained reductions from approximate counting to decision, with overhead only $\log^{\Theta(k)} n$ over the running time n^{α} of the original decision algorithm, for many well-studied problems including k-Orthogonal Vectors, k-SUM, subgraph isomorphism problems including k-Clique and colourful-H, graph motifs, and k-variable first-order model checking.

We explore the limits of what is achievable in this setting, obtaining unconditional lower bounds on the oracle cost of algorithms to approximately count the hypergraph's edges in both the colourful and uncoloured settings. In both settings, we also obtain algorithms which essentially match these lower bounds; in the colourful setting, this requires significant changes to the algorithm of Dell, Lapinskas, and Meeks (SODA 2020) and reduces the total overhead to $\log^{\Theta(k-\alpha)} n$. Our lower bound for the uncoloured setting shows that there is no fine-grained reduction from approximate counting to the corresponding uncoloured decision problem (except in the case $\alpha \geq k-1$): without an algorithm for the colourful decision problem, we cannot hope to avoid the much larger overhead of roughly $n^{(k-\alpha)^2/4}$. The uncoloured setting has previously been studied for the special case $k = 2$ (Peled, Ramamoorthy, Rashtchian, Sinha, ITCS 2018; Chen, Levi, and Waingarten, SODA 2020), and our work generalises the existing algorithms and lower bounds for this special case to $k > 2$ and to oracles with cost.

1 Introduction

Many decision problems in computer science, particularly those in NP, can naturally be expressed in terms of determining the existence of a witness. For example, solving SAT requires determining the existence of a satisfying assignment to a CNF formula. All such problems Π naturally give rise to a counting version #Π, in which we ask for the number of

witnesses. It is well-known that #Π is often significantly harder than Π; for example, Toda's theorem implies that it is impossible to solve #P-complete counting problems in polynomial time with access to an NP-oracle unless the polynomial hierarchy collapses. However, the same is not true for *approximately* counting witnesses (to within a factor of two, say). For example, it is known that: if Π is a problem in NP, then there is an FPRAS for #Π using an NP-oracle [30]; if Π is a problem in $W[i]$, then there is an FPTRAS for #Π using a $W[i]$-oracle [25]; and that the Exponential Time Hypothesis is equivalent to the statement that there is no subexponential-time approximation algorithm for #3-SAT [12].

In this paper we are concerned with analogous results in the fine-grained setting, which considers exact running times rather than coarse-grained classifications such as polynomial, FPT, or subexponential; such results turn out to be inextricably bound to graph oracle results of independent interest.

Past work in this area has focused on the family of *uniform witness problems* [13]. Roughly speaking, these are problems which can be expressed as counting edges in a k-hypergraph G in which the edges correspond to witnesses and induced subgraphs correspond to sub-problems. (See Section 3 for a detailed definition.) Many of the most important problems in fine-grained and parameterised complexity can be expressed as uniform witness problems including k-SUM, k-OV, k-Clique, Hamming weight-k solutions to CNFs, Size-k Graph Motif, most subgraph detection problems (including weighted problems such as Zero-Weight k-Clique and Negative-Weight Triangle), and first-order model-checking [13], in addition to certain database queries [16] and patterns in graphs [9]. Here k may be either a constant, as in the case of k-SUM, or a parameter, as in the case of k-Clique. In this setting, invoking a decision algorithm on a sub-problem of the original problem corresponds to invoking an oracle to test, given a set of vertices S, whether the induced subgraph $G[S]$ contains any edges; this oracle is called an *independence oracle* for G and is well-studied in its own right (see Section 4 for an overview).

Surprisingly, there is a partial analogue of the above reductions from approximate counting to decision in this setting. If the vertices of G are coloured, given a set $S \subseteq V(G)$, a *colourful independence oracle* tests whether $G[S]$ contains any edges with one vertex of each colour. This typically corresponds to a natural colourful variant of the original decision problem – for example, for k-Clique, it corresponds to deciding whether a k-coloured graph contains a size-k clique with one vertex of each colour. These oracles are again well-studied in their own right (see Section 4), and for many but not all uniform witness problems they can be efficiently simulated using the independence oracle. Given access to a colourful independence oracle for a graph G, we can count G's edges to within a factor of $1 \pm \varepsilon$ using $\varepsilon^{-2}k^{\mathcal{O}(k)} \log^{\Theta(k)} n$ oracle queries [13]. (See [4] for an improvement to the log factor.) In fact, we can say more – if we can simulate the colourful independence oracle in time n^{α_k} with $\alpha_k \geq 1$, then these queries dominate the running time and we obtain an approximate counting algorithm with running time $n^{\alpha_k} \cdot \varepsilon^{-2}k^{\mathcal{O}(k)} \log^{\Theta(k)} n$ in the usual word-RAM model. Translating back out of the oracle setting, this means that if we simulate the oracle by running an algorithm for the colourful decision problem, then for constant k and ε, we obtain an approximate counting algorithm with only polylogarithmic overhead over that decision algorithm. This result has led to several improved approximate counting algorithms – see [13] for applications to k-OV over finite fields and graph motifs, [16] for applications to database queries, and [9] for applications to patterns in graphs.

We are left with two major open problems of concern to researchers in fine-grained complexity, parameterised complexity and graph oracles, and we expect our paper to be of interest to all three communities. First, can the result of [13] be generalised from colourful

independence oracles to independence oracles? This would imply, for example, a fine-grained reduction from approximate induced sub-hypergraph counting to induced sub-hypergraph detection. In this setting, efficiently simulating the colourful independence oracle using the independence oracle requires solving a long-standing open problem – see Section 3 – so the result of [13] does not straightforwardly apply. Second, in the parameterised setting, the factor of $\log^{\Theta(k)} n$ is not truly polylogarithmic, but equivalent to a factor of $k^{\mathcal{O}(k)}n^{o(1)}$. Can it be improved to $\log^{\mathcal{O}(1)} n$?

In this paper, we answer both questions, and in the process substantially generalise recent graph oracle results for the $k = 2$ case [11]. In both the colourful and uncoloured settings, we pin down the optimal oracle algorithm almost exactly. In both cases this algorithm improves on the current state of the art, and it allows for the desired fine-grained reductions if and only if the cost of calling the oracle on an x-vertex set (corresponding to the run-time of a decision algorithm on an x-element instance) is close to x^k. Moreover, our lower bounds are unconditional – they do not rely on conjectures such as SETH or FPT $\neq$ W[1].

In a little more detail, suppose for the moment that $\varepsilon = 1/2$, and that the cost of calling the oracle on an x-vertex set is x^{α_k} for some $\alpha_k \in [0, k]$. In the uncoloured setting, we define a function $g(k, \alpha_k) \approx (k - \alpha)^2/(4k)$ (see (2.1.1)) and show that an overhead of $2^{\mathcal{O}(k)}n^{g(k,\alpha_k)\pm o(1)}$ is both achievable and required; we have $g(k, \alpha_k) = 0$ when $\alpha_k \geq k - 1$, so in this regime we obtain a fine-grained reduction. In the colourful setting, we show that the $\log^{\Theta(k)} n$ overhead of [13, 4] can be improved to $\log^{\Theta(k-\alpha_k)} n$, but no further; thus polylogarithmic overhead is possible if and only if $k - \alpha_k \in \mathcal{O}(1)$ as $k \to \infty$. For general values of ε, both of our upper bounds have an additional multiplicative overhead of $\mathcal{O}(\varepsilon^{-2})$, which is common in approximate counting algorithms.

In the rest of the paper, we state our results for graph oracles more formally in Section 2, followed by their (immediate) corollaries for uniform witness problems in Section 3. We then give an overview of related work in Section 4, followed by a brief description of our proof techniques in Section 5 and a generalisation to non-polynomial running times in Section 6. A full version of the paper is available as [14].

2 Oracle results

Our results are focused on two graph oracle models on k-hypergraphs: independence oracles and colourful independence oracles. Both oracles are well-studied in their own right from a theoretical perspective, as they are both natural generalisations of group testing from unary relations to k-ary relations, and the apparent separation between them in power is already a source of substantial interest. They also provide a point of comparison for a rich history of sublinear-time algorithms for oracles which provide more local information, such as degree oracles. See the introduction of [11] for a more detailed overview of the full motivation, and Section 4 for a survey of past results.

In both the colourful and uncoloured case, while formally the oracles are bitstrings and a query takes $\mathcal{O}(1)$ time, in order to obtain reductions from approximate counting problems to decision problems in Section 3 we will simulate oracle queries using a decision algorithm. As such, rather than focusing on the *number* of queries as a computational resource, we define a more general *cost function* which will correspond to the running time of the algorithm used to simulate the query; thus the cost of a query will scale with its size. In our application, this allows for more efficient reductions by exploiting cheap queries, while also substantially strengthening our lower bounds. Indeed, simulating an oracle query typically requires between $\text{poly}(k)$ and $\text{poly}(n)$ time, so a lower bound on the total number of queries required would tell us very little; meanwhile, setting the cost of all queries to 1 in our results yields tight bounds for the number of queries required.

We are also concerned with the *running times* of our oracle algorithms, again due to our applications in Section 3. We work in the standard RAM-model of computation with $\Theta(\log n)$ bits per word and access to the usual $\mathcal{O}(1)$-time arithmetic and logical operations on these words; in addition, oracle algorithms can perform oracle queries, which are considered to take $\mathcal{O}(1)$ time.

As shorthand, for all real $x, y > 0$ and $\varepsilon \in (0,1)$, we say that x is an *ε-approximation* to y if $|x - y| < \varepsilon y$. We define an *ε-approximate counting algorithm* to be an oracle algorithm that is given n and k as explicit input, is given access to an oracle representing an n-vertex k-hypergraph G, and outputs an ε-approximation to the number of edges of G, denoted by $e(G)$. We allow ε to be part of the input (for upper bounds) or fixed (for lower bounds).

2.1 Our results for the uncoloured independence oracle

Given a k-hypergraph G with vertex set $[n]$, the *(uncoloured) independence oracle* is the bitstring $\texttt{IND}(G)$ such that for all sets $S \subseteq [n]$, $\texttt{IND}(G)_S = 1$ if $G[S]$ contains no edges and 0 otherwise. Thus a query to $\texttt{IND}(G)_S$ allows us to test whether or not the induced subgraph $G[S]$ contains an edge. We define the *cost* of an oracle call $\texttt{IND}(G)_S$ to be a polynomial function of the form $\mathrm{cost}_k(S) = |S|^{\alpha_k}$, where the map $k \mapsto \alpha_k$ satisfies $\alpha_k \in [0, k]$ but is otherwise arbitrary. (This upper bound is motivated by the fact that we can trivially enumerate all edges of G by using $\mathcal{O}(n^k)$ queries to all size-k subsets of $[n]$, incurring oracle cost at most $n^k \cdot k^{\alpha_k}$.)

It is not too hard to show that the naive $\mathcal{O}(n^k)$-cost exact edge-counting algorithm of querying every possible edge and the naive $\mathcal{O}(n^{\alpha_k})$-cost algorithm to decide whether any edge is present by querying $[n]$ are both essentially optimal. For approximate counting we prove the following, where for all real numbers x we write $\lfloor x \rceil \coloneqq \lfloor x + 1/2 \rfloor$ for the value of x rounded to the nearest integer, rounding up in case of a tie.

▶ **Theorem 1** (Uncoloured independence oracle, polynomial cost function)**.** *Let $\alpha_k \in [0, k]$ for all $k \geq 2$, let $\mathrm{cost}_k(x) = x^{\alpha_k}$, and let*

$$g(k, \beta) \coloneqq \frac{1}{k} \cdot \left\lfloor \frac{k-\beta}{2} \right\rceil \cdot \left(k - \beta - \left\lfloor \frac{k-\beta}{2} \right\rceil \right). \tag{2.1.1}$$

There is a randomised ε-approximate counting algorithm $\texttt{Uncol}(\texttt{IND}(G), \varepsilon, \delta)$ with failure probability at most δ, worst-case running time

$$\mathcal{O}\Big(\log(1/\delta) \big(k^{5k} + \varepsilon^{-2} 2^{5k} \log^5 n \cdot n^{g(k,1)} \cdot n \big) \Big),$$

and worst-case oracle cost

$$\mathcal{O}\Big(\log(1/\delta) \big(k^{7k} + \varepsilon^{-2} 2^{5k} \log^5 n \cdot n^{g(k,\alpha_k)} \cdot n^{\alpha_k} \big) \Big)$$

under cost_k. Moreover, every randomised $(1/2)$-approximate edge-counting $\texttt{IND}$-oracle algorithm with failure probability at most $1/10$ has $\Omega((n^{g(k,\alpha_k)}/k^{3k}) \cdot n^{\alpha_k})$ worst-case expected oracle cost under cost_k.

Observe that the polynomial overhead $n^{g(k,\alpha_k)}$ of approximate counting over decision is roughly equal to $n^{(k-\alpha_k)^2/(4k)}$. If $\alpha_k = 0$, then the worst-case oracle cost of an algorithm is simply the worst-case number of queries that it makes. Thus Theorem 1 generalises known matching upper and lower bounds of $\widetilde{\Theta}(\sqrt{n})$ queries in the graph case [11], both by allowing $k > 2$ and by allowing $\alpha_k > 0$. (See Section 4 for more details.) Moreover, if $\alpha_k \geq k - 1$,

then $g(k, \alpha_k) = 0$; thus in this case, Theorem 1 shows that approximate counting requires the same oracle cost as decision, up to a polylogarithmic factor. Taking $k = 2$ and $\alpha_k = 1$, this implies that whenever we can simulate an edge-detection oracle for a graph in linear time, then we can also obtain a linear-time approximate edge-counting algorithm (up to polylogarithmic factors). Analogous upper bounds on the running time and oracle cost of `Uncol` also hold for any "reasonable" cost function of the form $\text{cost}_k(n) = n^{\alpha_k + o(1)}$; for details, see Section 6 and Theorem 10.

2.2 Our results for the colourful independence oracle

Given a k-hypergraph G with vertex set $[n]$, the *colourful independence oracle* is the bitstring $\texttt{cIND}(G)$ such that for all disjoint sets $S_1, \dots, S_k \subseteq [n]$, $\texttt{cIND}(G)_{S_1,\dots,S_k} = 1$ if G contains no edge $e \in E(G)$ with $|S_i \cap e| = 1$ for all i, and 0 otherwise. We view $S_1, \dots, S_k$ as colour classes in a partial colouring of $[n]$; thus a query to $\texttt{cIND}(G)_{S_1,\dots,S_k}$ allows us to test whether or not G contains an edge with one vertex of each colour. (Note that we do not require $S_1 \cup \dots \cup S_k = [n]$.) Analogously to the uncoloured case, we define the *cost* of an oracle call $\texttt{cIND}(G)_{S_1,\dots,S_k}$ to be a polynomial function of the form $\text{cost}_k(S_1, \dots, S_k) = \text{cost}_k(|S_1| + \dots + |S_k|) = (|S_1| + \dots + |S_k|)^{\alpha_k}$, where the map $k \mapsto \alpha_k$ satisfies $\alpha_k \in [0, k]$ but is otherwise arbitrary.

It is not too hard to show that the naive $\mathcal{O}(n^k)$-cost exact edge-counting algorithm of querying every possible edge and the naive $\mathcal{O}((k^k/k!)n^{\alpha_k})$-cost algorithm to decide whether any edge is present by randomly colouring the vertices are both essentially optimal, and indeed we prove as Proposition 65 of the full version that any such decision algorithm requires cost $\Omega(n^{\alpha_k})$. For approximate counting, we prove the following.

▶ **Theorem 2** (Colourful independence oracle, polynomial cost function). *Let $\alpha_k \in [0, k]$ for all $k \geq 2$, let $\text{cost}_k(x) = x^{\alpha_k}$, and let $T := \log(1/\delta)\varepsilon^{-2}k^{27k}\log^{4(k-\lceil\alpha_k\rceil)+18} n$. There is a randomised ε-approximate edge counting algorithm $\texttt{Count}(\texttt{cIND}(G), \varepsilon, \delta)$ with worst-case running time $\mathcal{O}(T \cdot n^{\max(1,\alpha_k)})$, worst-case oracle cost $\mathcal{O}(T \cdot n^{\alpha_k})$ under cost_k, and failure probability at most δ. Moreover, every randomised $(1/2)$-approximate edge counting $\texttt{cIND}$-oracle algorithm with failure probability at most $1/10$ has worst-case oracle cost*

$$\Omega\left(k^{-9k}\left(\frac{\log n}{\log\log n}\right)^{k-\lfloor\alpha_k\rfloor-3} \cdot n^{\alpha_k}\right)$$

under cost_k.

The upper bound replaces a $\log^{\Theta(k)} n$ term in the query count of the previous best-known algorithm ([5] for $\alpha_k = 0$) by a $\log^{\Theta(k-\alpha_k)} n$ term in the multiplicative overhead over decision, giving polylogarithmic overhead over decision when $k - \alpha_k = \mathcal{O}(1)$. The lower bound shows that this term is necessary and cannot be reduced to $\log^{\mathcal{O}(1)} n$; this is a new result even for $\alpha_k = 0$. (See Section 4 for more details.) Analogous upper bounds on the running time and oracle cost of `Count` also hold for any "reasonable" cost function of the form $\text{cost}_k(n) = n^{\alpha_k + o(1)}$; for details, see Section 6 and Theorem 10.

2.3 Approximate sampling results

There is a known fine-grained reduction from approximate sampling to approximate counting [13]. Strictly speaking this, reduction is proved for $\alpha_k = 1$ with a colourful independence oracle, but the only actual use of the oracle in the reduction is to enumerate all edges in a set X with $\mathcal{O}(|X|^k)$ size-k queries, so it transfers immediately to our setting. The upper bounds of Theorems 1 and 2 therefore also yield approximate sampling algorithms with overhead $2^{\mathcal{O}(k)}\log^{\mathcal{O}(1)} n$ over approximate counting.

2.4 A parameterised complexity motivation for our lower bound results

To understand an important motivation for the lower bounds in our results, consider as an example the longest path problem: Given (G, k), does there exist a simple path of length k? A long sequence of works in parameterised complexity led to a spectacular algorithm [7] for this problem in undirected graphs that runs in time $1.66^k \cdot \text{poly}(n)$. There is a somewhat shorter sequence of works for the corresponding approximate counting version of the problem, which culminated in a $4^k \text{poly}(n)$-time algorithm [8, 20].

Instead of designing ever-more sophisticated algorithms for approximately counting k-paths in order to get closer to the running time of the decision problem, our dream result would instead be a subexponential-time approximate-counting-to-decision reduction that uses the decision problem in a black-box fashion and causes only a factor $2^{o(k)} \text{poly}(n)$ overhead in the running time. This way, any improvements to the decision algorithm would automatically carry over. One way to formalise what the black-box can do is captured by defining the k-hypergraph whose edges are the k-paths of the underlying graphs; using an algorithm for the k-path decision problem, it is trivial to simulate the independence oracle and easy to simulate the colourful independence oracle for this hypergraph.

Theorem 2 implies that any decision algorithm for k-path can be turned into an approximate counting algorithm by paying a $\log^{\mathcal{O}(k)} n$-factor overhead in the running time. While this is still a fixed-parameter tractable running time, it leads to a useless algorithm, since the running time is much worse than $c^k \text{poly}(n)$. The main consequence of Theorem 2 for k-path stems not from this meaningless upper bound, but from the lower bound, which is new even for $\alpha_k = 0$: Our results imply that if the decision algorithm for k-path is formalized using the colourful independence oracle, then the overhead of the approximate-counting-to-decision reduction must be $\log^{\Omega(k)} n$, and so a subexponential-time reduction cannot exist. Conversely, if a useful approximate-counting-to-decision reduction exists, it cannot merely be based on the hypergraph whose edges consist of all k-paths; instead, the reduction would have to have access to and exploit the underlying structure of the original graph. We believe that this is a useful insight for the design of future algorithms for approximate counting.

3 Reductions from approximate counting to decision

Theorems 1 and 2 can easily be applied to obtain reductions from approximate counting to decision for many important problems in fine-grained and parameterised complexity. The following definition is taken from [13]; recall that a counting problem is a function $\#\Pi\colon \{0,1\}^* \to \mathbb{N}$ and its corresponding decision problem is defined via $\Pi = \{x \in \{0,1\}^* \colon \#\Pi(x) > 0\}$.

▶ **Definition 3.** *The decision problem* Π *is a* uniform witness problem *if there is a function that maps instances* $x \in \{0,1\}^*$ *to uniform hypergraphs* G_x *such that the following statements hold:*

- **(i)** $\#\Pi(x)$ *is equal to the number* $e(G_x)$ *of edges in* G_x*;*
- **(ii)** $V(G_x)$ *and the size* $k(G_x)$ *of edges in* $E(G_x)$ *can be computed from* x *in time* $\widetilde{\mathcal{O}}(|x|)$*;*
- **(iii)** *there exists an algorithm which, given* x *and* $S \subseteq V(G_x)$*, in time* $\widetilde{\mathcal{O}}(|x|)$ *prepares an instance* $I_x(S) \in \{0,1\}^*$ *such that* $G_{I_x(S)} = G_x[S]$ *and* $|I_x(S)| \in \mathcal{O}(|x|)$*.*

The set $E(G_x)$ *is the set of* witnesses *of the instance* x*.*

Intuitively, we can think of a uniform witness problem as a problem of counting witnesses in an instance x that can be naturally expressed as edges in a hypergraph G_x, in such a way that induced subgraphs of G_x correspond to sub-instances of x. This allows us to simulate a query to $\texttt{IND}(G_x)_S$ by running a decision algorithm for Π on the instance $I_x(S)$, and if

our decision algorithm runs on an instance y in time $T(|y|)$ then this simulation will require time $\widetilde{\mathcal{O}}(T(|S|))$. Typically there is only one natural map $x \mapsto G_x$, and so we consider it to be a part of the problem statement. Simulating the independence oracle in this way, the statement of Theorem 1 yields the following.

▶ **Theorem 4.** *Suppose $\alpha_k \in [1, k]$ for all $k \geq 2$. Let Π be a uniform witness problem. Suppose that given an instance x of Π, writing $n = |V(G_x)|$ and $k = k(G_x)$, there is an algorithm to solve Π on x with error probability at most $1/3$ in time $\widetilde{\mathcal{O}}(n^{\alpha_k})$. Then there is an ε-approximation algorithm for $\#\Pi(x)$ with error probability at most $1/3$ and running time*

$$k^{\mathcal{O}(k)} + \varepsilon^{-2} n^{\alpha_k} \cdot 2^{\mathcal{O}(k)} n^{g(k,\alpha_k)}.$$

Note that the running time of the algorithm for $\#\Pi$ is the sum of the oracle cost and the running time of the algorithm of Theorem 1; by requiring $\alpha_k \geq 1$, we ensure this is dominated by the oracle cost. (Indeed, for most uniform witness problems it is very easy to prove that every decision algorithm must read a constant proportion of the input, and so we will always have $\alpha_k \geq 1$.) The lower bound of Theorem 1 implies that the $n^{\alpha_k + g(k,\alpha_k)}$ term in the running time cannot be substantially improved with any argument that relativises; thus in simple terms, there is a generic fine-grained reduction from approximate counting to decision if and only if the decision algorithm runs in time $\Omega(n^{k-1})$.

It is instructive to consider an example. Take Π to be the problem Induced-H of deciding whether a given input graph G contains an induced copy of a fixed graph H. In this case, the hypergraph corresponding to an instance G will have vertex set $V(G)$ and edge set $\{X \subseteq V(G) \colon G[X] \simeq H\}$; thus the witnesses are vertex sets which induce copies of H in G. The requirements of Definition 3(i) and (ii) are immediately satisfied, and Definition 3(iii) is satisfied since deleting vertices from the hypergraph corresponds to deleting vertices of G. Thus writing $k = |V(H)|$, Theorem 4 gives us a reduction from approximate #Induced-H to Induced-H with overhead $\varepsilon^{-2} 2^{\mathcal{O}(k)} n^{g(k,\alpha_k)}$ over the cost of the decision algorithm. Moreover, on applying the fine-grained reduction from approximate sampling to counting in [13] we also obtain an approximate uniform sampling algorithm with overhead $\varepsilon^{-2} 2^{\mathcal{O}(k)} n^{g(k,\alpha_k)}$. Many more examples of uniform witness problems to which Theorem 4 applies can be found in the introduction of [13].

We now describe the corresponding result in the colourful oracle setting, which we now set out – again, the following definition is taken from [13].

▶ **Definition 5.** *Suppose Π is a uniform witness problem. Colourful-Π is defined as the problem of, given an instance $x \in \{0,1\}^*$ of Π and a partition of $V(G_x)$ into disjoint sets $S_1, \dots, S_k$, deciding whether $\texttt{cIND}_{G_x}(S_1, \dots, S_k) = 0$ holds.*

Continuing our previous example, in Colourful-Induced-H, we are given a (perhaps improper) vertex colouring of our input graph G, and we wish to decide whether G contains an induced copy of H with exactly one vertex from each colour. Simulating an oracle call to $\texttt{cIND}(G_x)_{S_1,\dots,S_k}$ corresponds to running a decision algorithm for Colourful-Π on the instance $I_x(S_1 \cup \dots \cup S_k)$ with colour classes $S_1, \dots, S_k$, and if this decision algorithm runs on an instance y in time $T(|y|)$ then this simulation will require time $\widetilde{\mathcal{O}}(T(|S_1| + \dots + |S_k|))$. Simulating the colourful independence oracle in this way, the statement of Theorem 2 yields the following.

▶ **Theorem 6.** *Suppose $\alpha_k \in [1, k]$ for all $k \geq 2$. Let Π be a uniform witness problem. Suppose that given an instance x of Π, writing $n = |V(G_x)|$ and $k = k(G_x)$, there is an algorithm to solve Colourful-Π on x with error probability at most $1/3$ in time $\mathcal{O}(n^{\alpha_k})$. Then there is an ε-approximation algorithm for $\#\Pi(x)$ with error probability at most $1/3$ and running time $\varepsilon^{-2} n^{\alpha_k} \cdot k^{\mathcal{O}(k)} (\log n)^{\mathcal{O}(k - \alpha_k)}$.*

As in the uncoloured case, the requirement $\alpha_k \geq 1$ ensures that the dominant term in the running time is the time required to simulate the required oracle queries, and the lower bound of Theorem 2 implies that the $\log^{\mathcal{O}(k-\alpha_k)} n$ term in the running time cannot be substantially improved with any argument that relativises. Again writing $k = |V(H)|$, Theorem 6 gives us a reduction from approximate #Induced-H to Colourful-Induced-H with overhead $\varepsilon^{-2}k^{\mathcal{O}(k)}(\log n)^{\mathcal{O}(k-\alpha_k)}$ over the cost of the decision algorithm. This result improves on the reduction of [13, Theorem 1.7] by a factor of $\log^{\Omega(\alpha_k)} n$, and using the fine-grained reduction from approximate sampling to counting in [13] it can immediately be turned into an approximate uniform sampling algorithm.

Observe that in most cases, there is far less overhead over decision in applying Theorem 6 to reduce #Induced-H to Colourful-Induced-H than there is in applying Theorem 4 to reduce #Induced-H to Induced-H. In some cases, such as the case where H is a k-clique, there are simple fine-grained reductions from Colourful-Induced-H to Induced-H, and in this case Theorem 6 is an improvement. However, it is not known whether the same is true of all choices of H, and indeed even an FPT reduction from Colourful-Induced-H to Induced-H would imply the long-standing dichotomy conjecture for the embedding problem introduced in [18]. More generally, but still within the setting of uniform witness problems, the problem of detecting whether a graph contains a size-k set which either spans a clique or spans an independent set is in FPT by Ramsey's theorem, but its colourful version is W[1]-complete [22].

While the distinction between colourful problems and uncoloured problems is already well-studied in subgraph problems, these results strongly suggest that it is worth studying in many other contexts in fine-grained complexity as well. Indeed, it is easy to simulate $\texttt{IND}(G)$ from $\texttt{cIND}(G)$ with random colouring; thus the lower bound of Theorem 1 and the upper bound of Theorem 2 imply that there is a fine-grained reduction from uncoloured approximate counting to colourful decision, but not to uncoloured decision. By studying the relationship between colourful problems and their uncoloured counterparts, we may therefore hope to shed light on the relationship between approximate counting and decision.

Finally, we observe that the set of running times allowed by Theorems 4 and 6 may not be sufficiently fine-grained to derive meaningful results for some problems. In fine-grained complexity, even a subpolynomial improvement to a polynomial-time algorithm may be of significant interest – the classic example is the Negative-Weight-Triangle algorithm of [31], which runs in $n^3/e^{\Omega(\sqrt{\log n})}$ time on an n-vertex instance, compared to the naive $\mathcal{O}(n^3)$-time algorithm. In order to "lift" such improvements from decision problems to approximate counting, we must generalise the upper bounds of Theorems 1 and 2 to cost functions of the form $\text{cost}_k(x) = x^{\alpha_k \pm o(1)}$ while maintaining low overhead. We do so in Theorem 10 for all "reasonable" cost functions, including any function of the form $\text{cost}_k(x) = n^{\alpha_k}\log^{\beta_k} n$ and any function of the form $\text{cost}_k(x) = n^{\alpha_k}e^{\pm(\log n)^{\gamma_k}}$ where $\gamma_k < 1$. A full list of technical requirements is given in Section 6, but the most important one is regular variation – this is a standard notion from probability theory for "almost polynomial" functions, and requiring it avoids pathological cases where (for example) we may have $\text{cost}_k(x) = \mathcal{O}(x)$ as $x \to \infty$, but $\text{cost}_k(2x_i) = \omega(\text{cost}_k(x_i))$ as $i \to \infty$ along some sequence $(x_i : i \geq 1)$.

4 Discussion of related work

In order to compare algorithms without excessive re-definition of notation, throughout this subsection we consider the problem of ε-approximating the number of edges in an m-edge, n-vertex k-hypergraph.

Colourful and uncoloured independence oracles were introduced in [3] in the graph setting, then first generalised to hypergraphs in [6]. Edge estimation using these oracles was first studied in the graph setting (i.e. for $k = 2$) in [3], which gave an $\varepsilon^{-4}\log^{\mathcal{O}(1)} n$-query algorithm for colourful independence oracles and an $(\varepsilon^{-4} + \varepsilon^{-2}\min\{\sqrt{m}, n^2/m\})\log^{\mathcal{O}(1)} n = (\varepsilon^{-4} + \varepsilon^{-2}n^{2/3})\log^{\mathcal{O}(1)} n$-query algorithm for uncoloured independence oracles. The connection to approximate counting in fine-grained and parameterised complexity was first studied in [12].

For colourful independence oracles in the graph setting, [12] (independently from [3]) gave an algorithm using $\varepsilon^{-2}\log^{\mathcal{O}(1)} n$ `cIND` queries and $\varepsilon^{-2}n\log^{\mathcal{O}(1)} n$ adjacency queries. [1] subsequently gave a *non-adaptive* algorithm using $\varepsilon^{-6}\log^{\mathcal{O}(1)} n$ `cIND` queries.

The case of edge estimation in k-hypergraphs (i.e. for arbitrary $k \geq 2$) was first considered independently by [13, 4]; [13] gave an algorithm using $\varepsilon^{-2}k^{\mathcal{O}(k)}\log^{4k+\mathcal{O}(1)} n$ queries, while [4] gave an $\varepsilon^{-4}k^{\mathcal{O}(k)}\log^{4k+\mathcal{O}(1)}$-query algorithm. [13] also introduced a reduction from approximate sampling to approximate counting in this setting (which also applies in the uncoloured setting) with overhead $k^{\mathcal{O}(k)}\log^{\mathcal{O}(1)} n$. [5] then improved the query count further to $\varepsilon^{-2}k^{\mathcal{O}(k)}\log^{3k+\mathcal{O}(1)} n$.

In this paper, we give an algorithm with total query cost $\varepsilon^{-2}k^{\mathcal{O}(k)}\log^{4(k-\alpha_k)+\mathcal{O}(1)} n$ under $\mathrm{cost}_k(x) = x^{\alpha_k}$, giving polylogarithmic overhead when $\alpha_k \approx k$. We also give a lower bound which shows that a $\log^{\Theta(k-\alpha_k)}$ term is necessary; no lower bounds were previously known even for $\alpha_k = 0$ (i.e. the case where the total query cost equals the number of queries).

For uncoloured independence oracles of graphs, [11] improved the algorithm of [3] to use

$$\varepsilon^{-\Theta(1)}\min\{\sqrt{m}, n/\sqrt{m}\}\operatorname{polylog} n = \varepsilon^{-\Theta(1)}\sqrt{n}\operatorname{polylog} n \tag{4.0.1}$$

queries and gave a matching lower bound. (It is difficult to tell the exact value of the $\Theta(1)$ term from the proof, but it is at least 9 – see the definition of N in the proof of Lemma 3.9 on p. 15.) It is worth noting that the bound in (4.0.1) is stated as a function of both n and m. We believe that our results can be stated in such a way as well, but we defer doing so to the journal version of this paper.

To the best of our knowledge, no results on uncoloured edge estimation for $\alpha_k > 0$ or $k > 2$ have previously appeared in the literature. However, we believe it would be easy to partially generalise the proof of [3] to this setting. Very roughly speaking, their argument works by running a naive sampling algorithm and a more subtle branch-and-bound approximation algorithm in parallel, with the sampling algorithm running quickly on dense graphs and the branch-and-bound algorithm running quickly on sparse graphs. The main obstacle to generalising this approach would be the branch-and-bound approximation algorithm; however, by replacing it with a slower branch-and-bound *enumeration* algorithm for k-hypergraphs such as [23], we believe we would obtain worst-case oracle cost $k^{\mathcal{O}(k)} + \varepsilon^{-2}2^{\mathcal{O}(k)}n^{\alpha_k+(k-\alpha_k)/2}$ under $\mathrm{cost}_k(x) = x^{\alpha_k}$; this technique is well-known in the literature and also appears in e.g. [29]. By comparison (see Figure 1), the algorithm of Theorem 1 achieves a much smaller worst-case oracle cost of $k^{\mathcal{O}(k)} + \varepsilon^{-2}2^{\mathcal{O}(k)}n^{\alpha_k+g(k,\alpha_k)}$, where $g(k,\alpha_k) \approx (k-\alpha_k)^2/(4k) < (k-\alpha_k)/2$ and where $g(k,\alpha_k) = 0$ for $\alpha_k \geq k-1$. This substantially improves on the algorithm implicit in [3], and indeed is optimal up to a factor of $\varepsilon^{\Theta(1)}k^{\Theta(k)}$. Also, our algorithm has a better dependence on ε compared with [11] when $k = 2$; however, we bound the cost only in terms of n and not in terms of m.

Although a full survey is beyond the scope of this paper, there are natural generalisations of (colourful and uncoloured) independence oracles [27], and edge estimation problems are studied for other oracle models including neighbourhood access [28]. Other types of oracle are also regularly applied to fine-grained complexity in other models, notably including cut oracles [24, 2]. Perhaps surprisingly, we were unable to find any previous examples in the

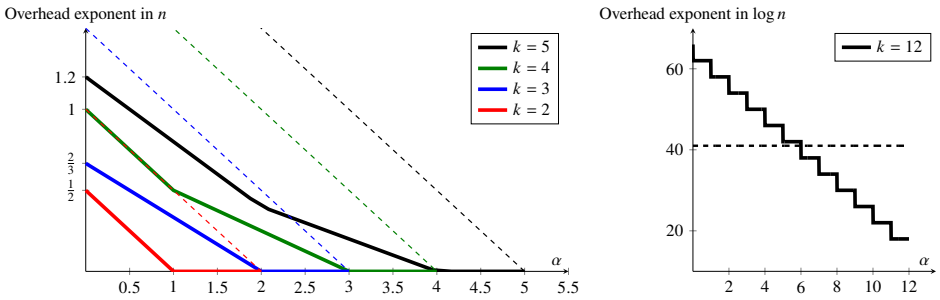

Figure 1 *Left:* If each IND-query of size x has cost x^{α_k}, then up to $k^{\mathcal{O}(k)} \log^{\mathcal{O}(1)} n$ factors, we show in Theorem 1 that $n^{g(k,\alpha_k)+\alpha_k}$ is the smallest possible IND-oracle cost to $(1/2)$-approximate the number of edges. Plotted here in *thick lines* is the overhead $\alpha \mapsto g(k,\alpha)$ in the exponent of n for $k \in \{2,3,4,5\}$, and in *dashed lines* is the larger overhead exponent $\alpha \mapsto (k-\alpha)/2$ obtained from a naive generalisation of the techniques of [3]. *Right:* If each cIND-query of size x has cost x^{α_k}, then up to $k^{\mathcal{O}(k)}(\log n)^{\mathcal{O}(1)}(\log\log n)^{\mathcal{O}(k-\alpha_k)}$ factors, we show in Theorem 2 that $n^{\alpha_k} \log^{4(k-\lceil\alpha_k\rceil)+18} n$ is the smallest possible cIND-oracle cost to $(1/2)$-approximate the number of edges. Plotted in *thick lines* is the overhead $\alpha \mapsto 4(k-\lceil\alpha\rceil)+18$ in the exponent of $\log n$ for $k = 12$, and the *dashed line* depicts the overhead $\alpha \mapsto 3k+5$ obtained by using the bound on the number of queries by [5]; our bound is better if $\lceil\alpha_k\rceil \geq k/4 + \Theta(1)$.

literature of unconditional oracle lower bounds relative to a general query cost function, and so our definitions and methods are novel in that sense. Of course, many existing works prove unconditional lower bounds in terms of query count [28], or consider algorithmic construction of graph oracles with bounded query times [19], or provide oracle algorithms with fast running times in addition to low query counts [26]. In our setting, however, a lower bound in terms of query cost is absolutely necessary. Recall that for us, query cost is the running time of an algorithm for the decision problem we are reducing to, and the algorithmic results of Theorems 4 and 6 all rely on smaller queries running faster; thus to prove they are "best possible" in any meaningful sense, we absolutely require the formal notion of query cost set out in Section 2.

Outside the oracle setting, it was recently proved [21] that any decision algorithm built around the representative family technique of [17] can be turned into an approximate counting algorithm with substantially lower overheads in k than those of [13]. More recently, several important decision problems in the fine-grained setting with $k = 3$ have been discovered to be "equivalent" to their *exact* counting versions [10]. This work is not directly comparable to ours, as they work in a substantially stronger setting and use a correspondingly weaker notion of equivalence. Their equivalence is in the sense of equivalence of conjectures – for example, they prove that if there is an $O(n^{2-\varepsilon})$-time algorithm for 3-SUM, then there exists $0 < \varepsilon' < \varepsilon$ such that there is an $O(n^{2-\varepsilon'})$-time algorithm for #3-SUM. We stress that for exact counting problems as studied in [10], such equivalence results are genuinely deep and surprising. However, for the approximate counting problems we study, analogous results are typically quite easy to prove via the standard combination of sampling and branch-and-bound approaches discussed above, and so we instead study the stronger notion of fine-grained reductions from approximate counting to decision. Where no such reductions exist, we aim to nail down the exact value of ε'. (Recall also that there are uniform witness problems whose decision versions are in FPT but whose exact counting versions are W[1]-hard [22], so we cannot hope to extend our results to exact counting in this setting.)

5 Proof techniques

5.1 Colourful upper bound

We first discuss the proof of the upper bound of Theorem 2, our cIND-oracle algorithm for edge estimation using the colourful independence oracle of an n-vertex k-hypergraph G. In [13], it is implicitly proved that a cIND-oracle algorithm that computes a "coarse approximation" to $e(G)$, which is accurate up to multiplicative error b, can be bootstrapped into a full ε-approximation algorithm with overhead $\varepsilon^{-2}2^{\mathcal{O}(k)}\log^{\mathcal{O}(1)} n \cdot b^2$. (See Theorem 49 of the full version for details.) It therefore suffices to improve the coarse approximation algorithm of [13] from $k^{\mathcal{O}(k)}\log^{\Theta(k)} n$ queries and $k^{\mathcal{O}(k)}\log^{\Theta(k)} n$ multiplicative error to $k^{\mathcal{O}(k)}\log^{\Theta(k-\alpha_k)} n$ query cost and $k^{\mathcal{O}(k)}\log^{\Theta(k-\alpha_k)} n$ multiplicative error. Moreover, by a standard colour-coding argument, it suffices to make this improvement when G is k-partite with vertex classes $V_1,\dots,V_k$ known to the algorithm.

Oversimplifying a little, and assuming n is a power of two, the algorithm of [13] works by guessing a probability vector $(Q_1,\dots,Q_k)\in\{1,1/2,1/4,\dots,1/n\}^k$. It then deletes vertices from $V_1,\dots,V_k$ independently at random to form sets $\mathcal{X}_1,\dots,\mathcal{X}_k$, so that for all $v\in V_j$ we have $\mathbb{P}(v\in\mathcal{X}_j)=Q_j$. After doing so, in expectation, $Q_1Q_2\dots Q_k$ proportion of the edges of G remain in the induced k-partite subgraph $G[\mathcal{X}_1,\dots,\mathcal{X}_k]$. If $e(G)\ll 1/(Q_1\dots Q_k)$, it is easy to show with a union bound that no edges are likely to remain. What is more surprising is that there exist $q_1,\dots,q_k$ with $q_1\dots q_k\approx 1/e(G)$ such that if $\vec{Q}=\vec{q}$, then at least one edge is likely to remain in $G[\mathcal{X}_1,\dots,\mathcal{X}_k]$. Thus the algorithm of [13] iterates over all $\log^{\Theta(k)} n$ possible values of $\vec{Q}$, querying $\texttt{cIND}(G)$ on $\mathcal{X}_1,\dots,\mathcal{X}_k$ for each, and then outputs the least value m such that $e(G[\mathcal{X}_1,\dots,\mathcal{X}_k])>0$ for some $Q_1,\dots,Q_k$ with $1/(Q_1\dots Q_k)=m$.

Our algorithm improves on this idea as follows. First, [13] does not actually prove the existence of the vector $\vec{q}$ described above – it relies on a coupling between the different guesses of $\vec{Q}$. We require not only the existence of $\vec{q}$ but also a structural result which may be of independent interest. For all $I\subseteq[k]$ and all $\zeta\in(0,1]$, we define an (I,ζ)-*core* to be an induced subgraph $H=G[Y_1,\dots,Y_k]$ of G such that:

- **(i)** H contains at least $k^{-\mathcal{O}(k)}$ proportion of the edges of G.
- **(ii)** For all $i\in I$, the set Y_i is very small, containing at most $2/\zeta$ vertices.
- **(iii)** For all $i\notin I$, every vertex of Y_i is contained in at most ζ proportion of edges in H.

As an example, the most extreme core is the *rooted star*: It consists of some vertices $r_i\in Y_i$ for all $i\in I$ and *all* k-partite edges e with $e\supseteq\{r_i:i\in I\}$. We prove in Lemma 56 of the full version that, for all $\zeta\in(0,1]$, there is some $I\subseteq[k]$ such that G contains an (I,ζ)-core H.

Suppose for the moment that we are given the value of I, but not $Y_1,\dots,Y_k$. By property (i), it would then suffice to approximate $e(H)$ using $k^{\mathcal{O}(k)}\log^{\mathcal{O}(k-\alpha_k)} n$ query cost. If $|I|\geq\alpha_k$, then we can adapt the idea of the algorithm of [13], but taking $Q_j=1$ for all $i\notin I$ to use only $\log^{\mathcal{O}(k-\alpha_k)} n$ queries in total; intuitively, this is possible due to property (ii), which implies that this is the "correct" setting. We set this algorithm out as CoarseLargeCore in Section 4.1.3 of the full version.

If instead $|I|\leq\alpha_k$, then we will exploit the fact that query cost decreases polynomially with instance size by breaking H into smaller instances. For all $i\notin I$, we randomly delete vertices from V_i with a carefully-chosen probability p. Property (iii), together with a martingale bound (see Lemma 59 of the full version), guarantees that the number of edges in the resulting hypergraph G' will be concentrated around its expectation of $p^k e(G)$. If we had access to $Y_1,\dots,Y_k$, we could then intersect V_i with Y_i for all $i\in I$ to obtain a substantially smaller instance, whose edges we could count with cheap queries; we could then divide the result by p^k to obtain an estimate for $e(G)$. Unfortunately we do not have

access to $Y_1, \dots, Y_k$, but we can still break G' into smaller sub-hypergraphs by applying colour-coding to the vertex sets V_i with $i \in I$, and as long as $|I| \leq \alpha_k$ this still gives enough of a saving in query cost to prove the result. We set this algorithm out as `CoarseSmallCore` in Section 4.1.2 of the full version.

Now, we are not in fact given the value of I in the (I, ζ)-core of G. But both `CoarseLargeCore` and `CoarseSmallCore` fail gracefully if they are given an incorrect value of I, returning an underestimate of $e(G)$ rather than an overestimate. We can therefore simply iterate over all 2^k possible values of I, applying `CoarseLargeCore` or `CoarseSmallCore` as appropriate, and return the maximum resulting estimate of $e(G)$. This proves the result.

5.2 Colourful lower bound

We now discuss the proof of the lower bound of Theorem 2. Using the minimax principle, to prove the bound for randomised algorithms, it is enough to give a pair of random graphs G_1 and G_2 with $e(G_2) \gg e(G_1)$ and prove that no *deterministic* algorithm A can distinguish between G_1 and G_2 with constant probability and worst-case oracle cost as in the bound. We base these random graphs on the main bottleneck in the algorithm described in the previous section: the need to check all possible values of $\mathcal{Q}$ in a k-partite k-hypergraph with an (I, ζ)-core where $|I| \approx k - \alpha_k$.

We take G_1 to be an Erdős-Rényi k-partite k-hypergraph with edge density $p := t^{-(k-\lfloor \alpha_k \rfloor - 2)/2}$. We take the vertex classes $V_1, \dots, V_k$ of G_1 to have equal size t, so that $t = n/k$. We then define a random complete k-partite graph H as follows. We first define a random vector $\vec{\mathcal{Q}}$ of probabilities, then take binomially random subsets $\mathcal{X}_1, \dots, \mathcal{X}_{k-\lfloor \alpha_k \rfloor - 2}$ of $V_1, \dots, V_{k-\lfloor \alpha_k \rfloor - 2}$, with $\mathbb{P}(v \in \mathcal{X}_j) = \mathcal{Q}_j$ for all $v \in V_j$. For $j \geq k - \lfloor \alpha_k \rfloor - 1$, we take $\mathcal{X}_j \subseteq V_j$ to contain a single uniformly random vertex. We then define H to be the complete k-partite graph with vertex classes $\mathcal{X}_1, \dots, \mathcal{X}_k$, and form $G_2 = G_1 \cup H$ by adding the edges of H to G_1. We choose $\mathcal{Q}$ in such a way that $\mathcal{Q}_1 \cdot \ldots \cdot \mathcal{Q}_{k-\lfloor \alpha_k \rfloor - 2}$ is guaranteed to be a bit larger than $pt^{\lfloor \alpha_k \rfloor + 2}$, so that $\mathbb{E}(e(H)) \gg \mathbb{E}(e(G_1))$. Intuitively, this corresponds to the situation of a randomly planted (I, ζ)-core where $I = \{k - \lfloor \alpha_k \rfloor - 1, \dots, k\}$ – we will show that the algorithm A needs to essentially guess the value of $\mathcal{Q}$ using expensive queries.

To show that a low-cost deterministic algorithm A cannot distinguish G_1 from G_2, suppose for simplicity that A is *non-adaptive*, so that its future oracle queries cannot depend on the oracle's past responses. In this setting, it suffices to bound the probability of a fixed query $S = (S_1, \dots, S_k)$ distinguishing G_1 from G_2.

It is not hard to show that without loss of generality we can assume $S_i \subseteq V_i$ for all $i \in [k]$. If $|S_j| \ll t$ for some $j \geq k - \lfloor \alpha_k \rfloor - 1$, then with high probability S_j will not contain the single "root" vertex of $\mathcal{X}_j$, so $H[S_1, \dots, S_k]$ will contain no edges and S will not distinguish G_1 from G_2. With some effort (a simple union bound does not suffice), this idea allows us to essentially restrict our attention to large, expensive queries S. However, if $|S_1| \dots |S_k|$ is large, then with high probability $G_1[S_1, \dots, S_k]$ will contain an edge, so again S will not distinguish G_1 from $G_2 = G_1 \cup H$. With some more effort, this allows us to essentially restrict our attention to queries where for some possible value $\vec{q}$ of $\vec{\mathcal{Q}}$ we have $|S_j| \approx 1/q_j$ for all $j \leq k - \lfloor \alpha \rfloor - 2$; we choose these possible values to be far enough apart that such a query is only likely to distinguish G_1 from G_2 if $\vec{\mathcal{Q}} = \vec{q}$. There are roughly $((\log n)/\log\log n)^{k-\lfloor \alpha_k \rfloor - 2}$ possible values of $\mathcal{Q}_j$, so the result follows.

Of course, in our setting A may be adaptive, and this breaks the argument above. Since the query A makes depends on the results of past queries, we cannot bound the probability of a fixed query distinguishing G_1 from G_2 in isolation – we must condition on the results of past queries. This is not a small technical point – it is equivalent to allowing A to be

adaptive in the first place. The most damaging implication is that we could have a query $S = (S_1, \dots, S_k)$ with $|S_1| \dots |S_k|$ very large but such that $G_1[S_1, \dots, S_k]$ contains no edges, because most of the potential edges have already been exposed as not existing in past queries. We are able to deal with this while preserving the spirit of the argument above, by arguing based on the number of unexposed edges rather than $|S_1| \dots |S_k|$, but it requires significantly more effort and a great deal of care.

5.3 Uncoloured upper bound

We now discuss the proof of the upper bound of Theorem 1. We adapt a classic framework for approximate counting algorithms that originated in [30], and that was previously applied to edge counting in [12]. We first observe that by using an algorithm from [23], we can enumerate the edges in an n-vertex k-hypergraph G with $2^{\mathcal{O}(k)} \log^{\mathcal{O}(1)} n \cdot e(G)$ queries to an independence oracle. Suppose we form an induced subgraph G_i of G by deleting vertices independently at random, keeping each vertex with probability 2^{-i}; then in expectation, we have $e(G_i) = 2^{-ki} e(G)$. If $e(G_i)$ is small, and $e(G_i) \approx \mathbb{E}(e(G_i))$, then we can efficiently count the edges of G_i using [23] and then multiply by 2^{ki} to obtain an estimate of $e(G)$. We can then simply iterate over all i from 0 to $\log n$ and return an estimate based on the first i such that $e(G_i)$ is small enough for [23] to return a value quickly.

Of course in general we do not have $e(G_i) \approx \mathbb{E}(e(G_i))$! One issue arises if, for some $r \in [k-1]$, every edge of G contains a common size-r set R – a "root". Then with probability $1 - 2^{-ri}$, at least one vertex in R will be deleted and G_i will contain no edges. We address this issue in the simplest way possible: by taking more samples. Roughly speaking, suppose we are given i, and that we already know (based on the failure of previous values of i to return a result) that $e(G) > n^{k-r-1}$ for some $0 \leq r \leq k-1$. This implies that G cannot have any "roots" of size greater than r. Rather than taking a single random subgraph G_i, we take $t_i \approx 2^{ri}$ independent copies of G_i and sum their edge counts using [23]; thus if G does contain a size-r root, we are likely to include it in the vertex set of at least one sample. Writing Σ_i for the sum of their edge counts, we then return $\Sigma_i / (t_i 2^{-ik})$ if the enumeration succeeds.

The exact expression we use for t_i is more complicated than 2^{ri}, due to the possibility of multiple roots – see Section 3.2.2 of the full version for a more detailed discussion – but the idea is the same. The proof that Σ_i is concentrated around its expectation is an (admittedly somewhat involved) application of Chebyshev's inequality, in which the rooted "worst cases" correspond to terms in the variance of Σ_i. We consider it surprising and interesting that such a conceptually simple approach yields an optimal upper bound, and indeed gives us a strong hint as to how we should prove the lower bound of Theorem 1.

5.4 Uncoloured lower bound

We finally discuss the proof of the lower bound of Theorem 1. As in the colourful case, we apply the minimax principle, so we wish to define random k-hypergraphs G_1 and G_2 with $e(G_2) \gg e(G_1)$ which cannot be distinguished by a low-cost deterministic algorithm A.

Our construction of G_1 and G_2 is natural from the above discussion, and the special case with $k = 2$ and $\alpha_k = 0$ is very similar to the construction used in [11]. We take G_1 to be an Erdős-Rényi k-hypergraph with edge probability roughly $k!/n^r$. We choose a random collection of size-r sets in $V(G_1)$ to be "roots", with a large constant number of roots present in expectation, and we define a k-hypergraph H to include every possible edge containing at least one of these roots as a subset. We then define $G_2 := G_1 \cup H$.

Similarly to the colourful lower bound, in the non-adaptive setting, any fixed query S_i with $|S_i|$ large is likely to contain an edge of G_1, and any fixed query with $|S_i|$ small is unlikely to contain a root and therefore unlikely to contain any edges of H; in either case, the query does not distinguish G_1 from G_2. Also as in the colourful case, generalising this argument from the non-adaptive setting to the adaptive setting requires a significant amount of care and effort.

6 More general cost functions for upper bounds

In our previous theorem statements we focused on polynomial cost functions of the form $\text{cost}_k(S) = |S|^{\alpha_k}$ for some $\alpha_k \in [0, k]$, and these functions are easy to work with. However, even subpolynomial improvements to an algorithm's running time can be of interest and by considering more general cost functions we can lift these improvements from decision algorithms to approximate counting algorithms. To take a well-known example, in the negative-weight triangle problem, we are given an n-vertex edge-weighted graph G and asked to determine whether it contains a triangle of negative total weight; this problem is equivalent to a set of other problems under subcubic reductions, including APSP [32]. The naive $\Theta(n^3)$-time algorithm can be improved by a subpolynomial factor of $e^{\Theta(\sqrt{\log n})}$ [31], but as stated in the introduction our result would not lift this improvement from decision to approximate counting – we would need to take $k = 3$ and $\text{cost}(n) = n^3/e^{\Theta(\sqrt{\log n})}$. (For clarity, in this specific case the problem is equivalent to its colourful version and a fine-grained reduction is already known [12, 13].)

While we cannot hope to say anything meaningful in the algorithmic setting with a fully general cost function, our results do extend to all cost functions which might reasonably arise as running times. A natural first attempt to formalise what we mean by "reasonable" would be to consider cost functions of the form $\text{cost}_k(n) = n^{\alpha_k + o(1)}$ as $n \to \infty$. Unfortunately, such cost functions can still have a pathological property which makes a fine-grained reduction almost impossible: the $o(1)$ term might vary wildly between different values of n. For example, if we take $\text{cost}_k(n) = n^{\alpha_k + \sin(\pi n/2)/\sqrt{\log(n)}}$, then we have $\text{cost}_k(n) = n^{\alpha_k + o(1)}$, but $\text{cost}_k(2n)/\text{cost}_k(n)$ could be $\omega(\text{polylog}(n))$, $\Theta(1)$ or $o(1/\text{polylog}(n))$ depending on whether n is congruent to 3, 2 or 1 modulo 4 (respectively). It is even possible to construct a similar example which is monotonically increasing. We will need to be able to approximate $f(Ax)$ by $A^{\alpha_k} f(x)$ and so we require something slightly stronger, borrowing a standard notion from the probability literature for distributions which are "almost power laws".

▶ **Definition 7.** *A function* $f\colon (0,\infty) \to \mathbb{R}$ *is* regularly-varying *if, for all fixed* $A > 0$,

$$\lim_{x\to\infty} |f(Ax)/f(x)| \in (0,\infty).$$

We say f *is* slowly-varying *if this limit is always* 1.

Observe that any cost function likely to arise as a running time is regularly-varying. While Definition 7 may look overly general for our purposes, in fact it gives us exactly what we need – regularly-varying functions are all of the form $f(x) = x^{\alpha + o(1)}$ as $x \to \infty$, are eventually increasing whenever $\alpha > 0$, and satisfy very strict bounds on $f(Ax)/f(x)$ as $x \to \infty$ as detailed in the following lemma. (These properties are all well-known, see e.g. Feller [15].) With these properties in hand, the extra generality of Definition 7 adds very little overhead to our existing arguments.

▶ **Lemma 8.** *Let $f\colon (0,\infty)\to\mathbb{R}$ be a function. Then f is regularly-varying if and only if there exists a unique $\alpha\in\mathbb{R}$, called the* index *of f, and a unique slowly-varying function $\sigma\colon(0,\infty)\to\mathbb{R}$, called the* slowly-varying component *of f, such that $f(x)=x^{\alpha}\sigma(x)$. Moreover, any regularly-varying function f and slowly-varying function σ satisfy the following properties.*

- **(i)** *$\sigma(x)=x^{o(1)}$ as $x\to\infty$.*
- **(ii)** *For all fixed $A>0$, $\lim_{x\to\infty}(\sigma(Ax)/\sigma(x))=1$. Moreover, for all closed intervals $I\subseteq\mathbb{R}$, this limit is uniform over all $A\in I$.*
- **(iii)** *For all $\delta>0$, there exists x_0 such that for all $x\geq x_0$ and all $A_x\geq 1$,*

$$A_x^{-\delta}\leq\sigma(A_x x)/\sigma(x)\leq A_x^{\delta}.$$

- **(iv)** *If f has positive index, then there exists x_0 such that f is strictly increasing on $[x_0,\infty)$.*

Our cost function will be a function of both the parameter k and the number n of vertices in the instance, and we will only require regular variation in n. We are now ready to state the technical requirements on our cost functions.

▶ **Definition 9.** *For each $k\geq 2$, let $\mathrm{cost}_k\colon(0,\infty)\to(0,\infty)$. We say that $\mathrm{cost}=\{\mathrm{cost}_k\colon k\geq 2\}$ is a* regularly-varying parameterised cost function *if $\mathrm{cost}_k(x)\leq x^k$ for all k and x, and there exists a slowly-varying function $\sigma\colon(0,\infty)\to(0,\infty)$ and a map $k\mapsto\alpha_k$ satisfying the following properties:*

- **(i)** *for all k and x, $\mathrm{cost}_k(x)=x^{\alpha_k}\sigma(x)$;*
- **(ii)** *for all k, $\alpha_k\in[0,k]$;*
- **(iii)** *for all k and x, $\mathrm{cost}_k(x)\leq x^k$;*
- **(iv)** *either $\liminf_{k\to\infty}\alpha_k>0$ or there exists x_0 such that for all k, cost_k is non-decreasing on (x_0,∞);*
- **(v)** *there is an algorithm to compute $\lfloor\alpha_k\rfloor$ in time $\mathcal{O}(k^{9k})$.*

We say that k is the parameter *of* cost*, α is the* index *of* cost*, and σ is the* slowly-varying component *of* cost*.*

Point (i) is the main restriction, and the one we have been discussing until now. Points (ii) and (iii) have already been discussed in the introduction. In the colourful case we will need to compute $\lfloor\alpha_k\rfloor$, so point (v) avoids an additive term in the running time; the precise choice of k^{9k} is purely for technical convenience. Finally, the purpose of point (iv) is to guarantee monotonicity (together with point (i) and Lemma 8(iv)). Requiring point (iv) is unlikely to affect applications of our results – typically such applications would satisfy either $\alpha_k=0$ (for tracking total query count) or $\alpha_k\geq 1$ (for tracking total running time, where query cost is the running time of a decision algorithm which needs to read its entire input).

▶ **Theorem 10.** *Theorems 1 and 2 remain valid when the cost function $\mathrm{cost}_k(x)=x^{\alpha_k}$ is replaced by an arbitrary regularly-varying parameterised cost function. Likewise, Theorems 4 and 6 remain valid when the the running time $\tilde{O}(n^{\alpha_k})$ of the decision algorithm is replaced by an arbitrary regularly-varying parameterised cost function.*

Abstract

Temporal graphs are dynamic graphs where the edge set can change in each time step, while the vertex set stays the same. Exploration of temporal graphs whose snapshot in each time step is a connected graph, called connected temporal graphs, has been widely studied. In this paper, we extend the concept of graph automorphisms from static graphs to temporal graphs and show for the first time that symmetries enable faster exploration: We prove that a connected temporal graph with n vertices and orbit number r (i.e., r is the number of automorphism orbits) can be explored in $O(rn^{1+\epsilon})$ time steps, for any fixed $\epsilon > 0$. For $r = O(n^c)$ for constant $c < 1$, this is a significant improvement over the known tight worst-case bound of $\Theta(n^2)$ time steps for arbitrary connected temporal graphs. We also give two lower bounds for temporal exploration, showing that $\Omega(n \log n)$ time steps are required for some inputs with $r = O(1)$ and that $\Omega(rn)$ time steps are required for some inputs for any r with $1 \leq r \leq n$.

Moreover, we show that the techniques we develop for fast exploration can be used to derive the following result for rendezvous: Two agents with different programs and without communication ability are placed by an adversary at arbitrary vertices and given full information about the connected temporal graph, except that they do not have consistent vertex labels. Then the two agents can meet at a common vertex after $O(n^{1+\epsilon})$ time steps, for any constant $\epsilon > 0$. For some connected temporal graphs with the orbit number being a constant, we also present a complementary lower bound of $\Omega(n \log n)$ time steps.

1 Introduction

For many decades, graph theory has been a tool used to model and study many real world problems and phenomena [15]. A usual assumption for many of these problems is that the graphs have a fixed structure. However, there are quite a number of cases where the structure of a system changes over time. For example, consider the problem of routing in transportation networks (roads, rails) where specific connections can become unavailable (due to a disaster) or they are active during specific times (due to safety). Such scenarios can be modeled using temporal graphs, a sequence of graphs over the same vertex set where the edges possibly change in each time step. The temporal graph setting has received significant interest from the research community in the recent past as seen in recent surveys [19, 48].

In this paper, we study two problems on temporal graphs. The first is the *temporal exploration problem* (TEXP), which has been studied, e.g., by Michail and Spirakis [49, 50] and by Ilcinkas et al. [37]. It requires an agent to explore all vertices of the temporal graph as quickly as possible. The second is the *temporal rendezvous problem* (TRP), which we formulate for the first time in this paper. It requires two heterogeneous agents (in terms of the programs they run) to rendezvous on a temporal graph when they cannot communicate with one another. For both problems, we assume that each agent has complete knowledge of the temporal graph in advance (a common assumption [3, 14, 27, 28, 30, 31, 37, 49, 50, 62]). However, in the case of TRP the agents may have different names for the same vertices, i.e., the local labels of the vertices may be different.

The problem of exploration has been well studied in the static setting since it was introduced in 1951 by Shannon [59]. It has also been intensively studied in the temporal graph setting since 2014 (see all references from the previous paragraph). On an application-oriented note, the problem captures the setting where a person is trying to visit various parts of a city using public transportation. For example, train schedules involve multiple train stations (vertices) with trains running between them at different times (i.e., repeatedly changing edges). Thus, planning a visit to multiple destinations over a given day using railways is an example of solving TEXP.

The rendezvous problem can be broadly categorized into two types: symmetric and asymmetric rendezvous. The version where agents have the same strategy (symmetric rendezvous) was introduced by Alpern [10]. The version where agents can have distinct strategies (asymmetric rendezvous) was introduced by Alpern [7] and is the focus of research in this paper. TRP is a natural extension of the asymmetric rendezvous problem to the dynamic setting. As a real world example, consider a pair of tourists who want to explore a city together and have to agree on a strategy to meet up in case they are separated and their cell phones die. In this scenario, they may use public transportation (dynamically changing network) to meet and agree in advance to use different strategies that guarantee that they meet quickly.

In this paper, we present results that extend the literature in two ways. Firstly, we formalize the TRP problem in the setting where agents have complete knowledge of the temporal graph a priori and develop good upper and lower bounds for it. Secondly, we utilize interesting structural properties (namely automorphisms of a graph and associated orbits of vertices) in order to analyze bounds on the number of time steps required by temporal walks that solve certain problems. In particular, we develop upper and lower bounds for both TEXP and TRP that leverage the aforementioned graph properties. To the best of our knowledge, this is the first work that takes advantage of these graph properties to study problems in temporal graphs.

1.1 Our Contributions

We present results for two problems: first, the TEMPORAL EXPLORATION PROBLEM (TEXP) which, for a given temporal graph $\mathcal{G}$, asks for a temporal walk that visits all vertices of $\mathcal{G}$, and secondly, the TEMPORAL RENDEZVOUS PROBLEM (TRP), which considers two agents that try to meet in the given temporal graph, meaning they must be stationed at the same vertex in the same time step.

One of our primary contributions is formalizing the problem of TRP in Section 2, and in doing so extending the problem of asymmetric rendezvous to the temporal graph setting where agents have complete knowledge of the temporal graph in advance. Another significant contribution is that we show how to leverage the use of a structural graph property, namely the automorphism group of a temporal graph and the associated notion of orbits, to bound the number of time steps required by algorithms we devise for these problems. To the best of our knowledge, this work is the first instance of leveraging such properties to study any problem on temporal graphs apart from a practical implementation of a generator for listing all non-isosomorphic simple temporal graphs [18]. Intuitively, an automorphism of a graph is a mapping from the set of vertices of the graph to the same set of vertices that preserves the neighborhood relation between the vertices. The set of automorphisms of a temporal graph consists of the *intersection* of the sets of automorphisms of the graph at each time step. The set of automorphisms of the temporal graph, along with function composition as group operation, forms the automorphism group of the temporal graph. An orbit of the automorphism group of a temporal graph is a maximal set of vertices such that each vertex can be mapped to any other vertex in the set via an automorphism of the group. Intuitively, the vertices in an orbit look indistinguishable to an agent that has full information about the temporal graph but without meaningful vertex labels. As the agents are able to compute a consistent numbering of the orbits (Lemma 13), they can agree to meet in some specific orbit, but not at a specific vertex. Therefore, temporal graphs where all orbits are large (or that even have a single orbit containing all vertices) appear to be the most challenging graphs for solving TRP. Our result providing fast exploration schedules in temporal graphs with few orbits is therefore a crucial ingredient for enabling our solution to TRP to handle all possible temporal graphs (including those with a single orbit).

We give precise definitions and present further preliminaries in Section 2. Then, we introduce some useful utilities related to automorphisms in Section 3. These will be used in later sections, where we present the following results.

Upper bounds. In Section 4, we develop a deterministic algorithm to solve TEXP in $O(rn^{1+\epsilon})$ time steps for any fixed $\epsilon > 0$ (see Corollary 12), where n is the number of vertices in the temporal graph and r is the number of orbits of the automorphism group of the temporal graph. Note that r can range in value from 1 to n. Thus, for $r = O(n^c)$ for constant $c < 1$, this is a significant improvement over the known tight worst-case bound of $\Theta(n^2)$ time steps for arbitrary connected temporal graphs [27]. In Section 5, we leverage this algorithm for TEXP to develop a deterministic solution for TRP using $O(n^{1+\epsilon})$ time steps for any fixed $\epsilon > 0$ (see Theorem 14). Our focus is on bounding the time steps of the temporal walks required to solve TEXP and TRP, and not on optimizing the running time of the respective algorithms to compute such walks.

Lower bounds. We complement our algorithms with lower bounds for both TEXP and TRP in Section 6. In particular, we design an instance of TRP such that any solution for it requires $\Omega(n \log n)$ time steps (see Theorem 16). We then show how this translates to a

lower bound of $\Omega(n \log n)$ time steps for some instances of TEXP where the temporal graph at hand has an orbit number $r = O(1)$ (see Corollary 17). By revisiting the lower bound of [27] for TEXP, which focused on arbitrary temporal graphs, and studying it through the lens of automorphisms and orbits, we can obtain a more fine-grained lower bound of $\Omega(rn)$ time steps (see Lemma 15) for some temporal graphs with orbit number $1 \leq r \leq n$. Notice that the multiplicative gap between our upper and lower bounds for both problems is only a factor of $O(n^\epsilon)$.

Relevance of the orbit number. It is well known in graph theory that almost all (static) graphs are *rigid* [12], meaning that the automorphism group contains only the trivial identity function. This is in contrast to observations in practice. Many real-world graphs have non-trivial automorphisms. A recent analysis of real-world graphs in the popular database `https://networkrepository.com` showed that over 70% of the analyzed graphs had non-trivial automorphisms [12]. One may reasonably expect that real-world temporal graphs have similar properties. Symmetries are also abundant in graphs arising in chemistry [11], which have been studied in temporal settings as well [57]. We believe that these observations provide a strong motivation for studying temporal graph problems for temporal graphs with fewer than n orbits, e.g., with algorithms parameterized via the number of orbits. Furthermore, we emphasize that our results for TRP hold for all temporal graphs, independent of the orbit number parameter, even though they utilize techniques we develop for TEXP parameterized by the orbit number. Roughly speaking, for orbit number r, the penalty factor r in the number of time steps to solve TEXP is saved when solving TRP by focusing only on a smallest orbit of size at most n/r.

1.2 Technical Overview and Challenges

Firstly, we give an intuitive overview of our upper bound results. The concepts used in this section are more precisely defined in the next sections.

For TEXP, we first consider the problem of visiting all the vertices of one orbit S. One key insight is that, if we have a temporal walk W that visits k vertices of S, we can use the automorphisms of the temporal graph to transform W into other walks that visit different sets of k vertices of S (Lemma 3). Therefore, even if the k vertices visited by W have already been explored earlier, we can transform W into a temporal walk W' that visits a "good" number of previously unexplored vertices of S. The number of previously unexplored vertices of S that W' is guaranteed to visit increases with the number of possible start vertices in S that we allow for W', but the larger that set X of possible start vertices is, the longer it may take the agent to reach the best start vertex in that set. A challenge is to analyze this tradeoff. By carefully relating the size of X to the guaranteed number of unexplored vertices that a walk W' starting at a vertex in X can visit (Corollary 4), we manage to balance the number of time steps needed to move to the start vertex of W' and the number of previously unexplored vertices that W' visits. To show that vertices of X can be reached quickly, we study the structure of edges that connect vertices in different orbits (Lemma 5) and use it to analyze reachability between orbits (Lemmas 6 and 7).

We then employ a recursive construction: We recursively construct a temporal walk W_1 that visits k vertices of S, concatenate W_1 with a temporal walk that moves quickly from the endpoint of W_1 to a good start vertex in S for what follows, and then use a second recursively constructed walk (transformed via an automorphism to a "good" temporal walk W_2 starting in a vertex of S) to visit "nearly" k further vertices of S. A careful analysis then shows that in this way we can visit a constant fraction of the vertices of S in $O(r|S|^{1+\epsilon})$ steps

(Lemma 9 and Corollary 10). We then show that the concatenation of $O(\log |S|)$ such walks (each one again transformed via an automorphism to maximize the number of newly explored vertices) suffices to visit all vertices of S in $O(r|S|^{1+\epsilon} + n \log |S|)$ time steps (Theorem 11), which can be bounded by $O(rn^{1+\epsilon'})$ time steps). By visiting the r orbits one after another, we can finally show that the whole temporal graph can be explored in $O(rn^{1+\epsilon'})$ time steps (Corollary 12).

For TRP, a simple and fast solution one first thinks of is to have the agents simply meet at a vertex with a specific label. However, this is not feasible in the model we consider. In particular, we assume that the agents cannot communicate and, while both agents have complete information about the temporal graph, they do not have access to consistent vertex labels. As such, the agents are unable to agree upon the same vertex based on the vertex label. We rely, instead, on structural graph properties and let the agents meet at a vertex in a smallest orbit: One agent moves to any vertex in that orbit, and the other searches all vertices in that orbit. The first challenge is for the agents to independently identify the same orbit in which to meet. We show that this can be done by letting each agent enumerate all temporal graphs, together with colorings of their orbits, until it encounters for the first time a temporal graph that is isomorphic to the input graph in which TRP is to be solved. In this way both agents obtain the same colored temporal graph and can independently select, among all orbits of smallest size, the one with smallest color (Lemma 13). Then one agent moves to a vertex in that orbit S, while the other searches all vertices of S. The challenge here is to deal with orbits that are large, because previously known techniques would require $\Theta(n^2)$ time steps to explore an orbit of size $\Omega(n)$. Fortunately, this is where our above-mentioned results for exploration of (orbits of) temporal graphs come to the rescue: As $|S| \leq n/r$, we have $O(r|S|^{1+\epsilon} + n \log |S|) = O(n^{1+\epsilon'})$, and hence S can be explored (and TRP solved) in $O(n^{1+\epsilon'})$ time steps (Theorem 14).

Now we turn to our lower bounds. For TEXP, we first observe that the existing lower bound construction that shows that $\Omega(n^2)$ time steps are necessary for exploration on some temporal graphs uses temporal graphs with $\frac{n}{2}+1$ orbits. By slightly varying the construction, we can show for any r in the range from 1 to n that there are temporal graphs with r orbits that require $\Omega(rn)$ time steps for exploration (Lemma 15). Our main lower bound result is the lower bound of $\Omega(n \log n)$ for TRP in temporal graphs with a single orbit (Theorem 16). The temporal graph is a cycle on $n = 2^m - 1$ vertices in every step, and the edges change every $\lfloor n/16 \rfloor$ time steps. Each period of $\lfloor n/16 \rfloor$ time steps in which the edges do not change is called a *phase*. We number the vertices of the cycle from 0 to $n-1$ and consider the binary representation of the vertex labels. In phase 1, each vertex j is adjacent to $j+1$ and $j-1$, while in any phase $i > 1$, it is adjacent to $j + 2^{2i}$ and $j - 2^{2i}$ (with all computations done modulo n). As all vertices are indistinguishable to the agents, we can force each agent to make the same movements no matter where we place it initially. By fixing the five highest-order bits of the agents' start positions in a certain way, we can ensure that the agents do not meet in the first phase, no matter how the remaining bits of their start positions are chosen. Depending on the positions where the agents end up at the end of each phase (relative to their start position in that phase), we fix a certain number of bits of the binary representations of the start positions of the agents: After the first phase, we fix the lowest four bits, and after each further phase, we fix the next-higher two bits. We can show that this is sufficient to ensure that the agents start the next phase at vertices that are sufficiently far from each other in the cycle of that phase. This process can be repeated $\Omega(\log n)$ times, showing that it takes $\Omega(n \log n)$ time steps for the agents to meet. This lower bound for TRP implies also that exploration of the constructed temporal graph requires $\Omega(n \log n)$ steps (Corollary 17).

1.3 Related Work

There is a divide in the research on temporal graphs with respect to the amount of knowledge known in advance by the agents on the graph. When complete knowledge of the temporal graph is known in advance to the agents, as is assumed in this paper, the setting is sometimes referred to as the *post-mortem* setting (see, e.g., Santoro [58]). Since we consider scenarios where agents plan temporal walks using advance knowledge of future time steps, we refer to the post-mortem setting as the *clairvoyant* setting in the remainder of this section.

The clairvoyant setting is in contrast to the *live* setting where agents only have partial knowledge of the temporal graph, and the solutions to problems in these different settings are of a different nature. The reader can refer to the survey by Di Luna [22] for more information on problems and solutions in the live setting. We restrict the rest of this related work section to work in the clairvoyant setting.

Exploration. We trace the progress of solving instances of TEXP, first by identifying which assumptions are required for the problem to even be solvable, and then by identifying properties that were leveraged to give faster and faster solutions.

Michail and Spirakis [49, 50] showed that it is **NP**-complete to decide whether a given temporal graph with a given *lifetime*, i.e., the number of time steps it exists, is explorable when no assumptions are made on the input graph. This holds even if the graph is connected in every time step, termed *connected* (and sometimes called *always-connected* in the literature). Even when a restriction is placed on the *underlying graph*, i.e., the union of the graphs at each time step, such that the underlying graph has pathwidth at most 2, Bodlaender and van der Zanden [14] showed that TEXP is **NP**-complete.

However, the exploration is always possible when the lifetime of the graph is sufficiently large. In particular, Michail and Spirakis [50] showed that a connected graph with n vertices may be explored in $O(n^2)$ time steps. For the rest of the related work on TEXP, we focus on the case of connected temporal graphs with a sufficiently large lifetime. Erlebach et al. [27] showed that exploration on arbitrary temporal graphs takes $\Omega(n^2)$ time steps. By restricting their study of temporal graphs to those where the underlying graph belongs to a special graph class, however, they showed that TEXP can be solved in $o(n^2)$ time steps in several such cases. In particular, when the underlying graph is planar, has bounded treewidth k, or is a $2 \times n$ grid, they showed that TEXP can be solved in $O(n^{1.8} \log n)$ time steps, $O(n^{1.5} k^{1.5} \log n)$ time steps, and $O(n \log^3 n)$ time steps, respectively. They also showed a lower bound of $\Omega(n \log n)$ when the underlying graph is a planar graph of degree at most 4.

The study of TEXP when the temporal graph is restricted continued in several papers. Taghian Alamouti [62] showed that TEXP can be solved in $O(k^2(k!)(2e)^k n)$ time steps when the underlying graph is a cycle with k chords. Adamson et al. [3] improved this to $O(kn)$ time steps. They also improved the upper bounds on TEXP for underlying graphs that have bounded treewidth k or are planar to $O(kn^{1.5} \log n)$ and $O(n^{1.75} \log n)$, respectively. In addition, they strengthened the lower bound for underlying planar graphs by showing that even if the degree is at most 3, the lower bound is $\Omega(n \log n)$. Erlebach et al. [28] further improved work on bounded degree underlying graphs by showing that TEXP can be solved in $O(n^{1.75})$ time steps for such temporal graphs. Ilcinkas et al. [37] showed that when the underlying graph is a cactus, the exploration time is $2^{\Theta(\sqrt{\log n})} n$ time steps.

Other variants of TEXP have been studied where the problem is slightly different, or the edges of the temporal graph vary in some particular way (e.g., periodically, T-interval connected, k-edge deficient), or multiple agents explore the graph [1, 2, 5, 17, 30, 31, 38].

Rendezvous. Symmetric rendezvous [10] and asymmetric rendezvous [7] have received much interest over the years, resulting in numerous surveys [8, 9, 32, 40, 41, 54, 55] being written on the problems covering different settings. In this work, we are the first to extend asymmetric rendezvous to temporal graphs in the clairvoyant setting. Note that there has been previous work [16, 21, 23, 51, 53, 60, 61] that has studied multi-agent rendezvous (also called gathering) in a dynamic graph setting, but that was in the live setting. For an overview of rendezvous in static graphs we refer the reader to [9, 41]. Rendezvous has been studied in deterministic settings [13, 56] and asynchronous settings [24, 43], and has been shown to be solvable in logarithmic space [20].

Other Related Work. Other problems have also been studied in the temporal graph setting, e.g., matchings [46], separators [34, 63], vertex covers [6, 36], containments of epidemics [26], Eulerian tours [17, 44], graph coloring [45, 47], network flow [4], treewidth [33] and cops and robbers [29, 52]. See the survey by Michail [48] for more information.

2 Preliminaries

Basic terminology. We use standard graph terminology. All static graphs are assumed to be simple and undirected. We write $[x] = \{1, \dots, x\}$ for any integer x.

A *temporal graph* $\mathcal{G} = (G_1, \dots, G_\ell)$ is a sequence of static graphs, all with the same vertex set V. For a temporal graph $\mathcal{G}$, the graph $G = (V, \bigcup_{t\in[\ell]} E(G_t))$ is the *underlying graph of* $\mathcal{G}$. We call $\mathcal{G}$ connected if each G_t for $t \in [\ell]$ is connected. We use n to refer to the number of vertices of the (temporal) graph under consideration. A *temporal walk* W is a walk in a temporal graph $\mathcal{G}$ that is time respecting, i.e., traverses edges in strictly increasing time steps. For a temporal walk W starting at time step t we write $W = (u_1, u_2, u_3, \dots)$ to mean the temporal walk starts at vertex u_1 in time step t, is at vertex u_2 at the beginning of time step $t + 1$, and so forth. Note that subsequent vertices in the temporal walk can be the same vertex, i.e., we can wait for an arbitrary number of time steps at a vertex. We say that a temporal walk *spans* x time steps if it starts at some time step t and ends at some time step t' with $t' - t = x$. We assume that the lifetime ℓ is large enough such that a desired temporal walk can be constructed. For all our results it is enough to assume $\ell \geq n^2$, as n^2 time steps suffice for TEXP [27] and therefore also for TRP. For any function $f : X \to X$ for a universe X we write $f^i(x)$ when we mean applying the function i-times iteratively for any $x \in X$ and integer i, e.g., $f^2(x) = f(f(x))$. We use $\circ$ to denote function composition, i.e., for two functions $f : X \to X$ and $g : X \to X$, we denote with $f \circ g$ the function that maps $x \in X$ to $f(g(x))$.

Isomorphisms and automorphisms. Two static graphs G and H are *isomorphic* exactly if a bijection $\theta : V(G) \to V(H)$ (called an *isomorphism*) exists with the following property: two vertices u, v are adjacent in G exactly if $\theta(u)$ is adjacent to $\theta(v)$ in H. We write $G \cong H$ if G is isomorphic to H. An *automorphism* is an isomorphism from a graph G to itself. The set of all automorphisms of a graph G forms a group $\mathrm{Aut}(G)$, with $\circ$ as group operation. Refer to [35, 39, 42] for further reading on the topic of isomorphisms and automorphisms of graphs.

For a temporal graph $\mathcal{G}$ with lifetime ℓ we denote with $\mathrm{Aut}(\mathcal{G})$ the set of all functions σ such that σ is an automorphism of each graph G_t at every time step $t \in [\ell]$ (and hence also an automorphism of the underlying graph G). $\mathrm{Aut}(\mathcal{G})$ with $\circ$ as group operation is the automorphism group of the temporal graph $\mathcal{G}$. We remark that the automorphism group of the temporal graph $\mathcal{G}$ is the intersection of the automorphism groups of the graphs G_t for

$t \in [\ell]$ and that the automorphism group of $\mathcal{G}$ can be viewed as the automorphism group of the underlying graph G of $\mathcal{G}$ with edge labels such that each edge is labeled with the set of time steps in which it occurs.

The *orbit* of a vertex u in a temporal graph $\mathcal{G}$ with respect to $\mathrm{Aut}(\mathcal{G})$ is the set $V' \subseteq V$ of all vertices that u can be mapped to by automorphisms in $\mathrm{Aut}(\mathcal{G})$. Note that, if V' is the orbit of u, then the orbit of every vertex in V' is also V': For any two vertices v, v' in V', the automorphisms σ and σ' that map u to v and v', respectively, can be composed to the automorphism $\sigma' \circ \sigma^{-1}$ that maps v to v'. Furthermore, there cannot be an automorphism ρ that maps v to a vertex outside V' because $\rho \circ \sigma$ would then be an automorphism that maps u to a vertex outside V'; a contradiction to the definition of the orbit V' of u. We denote by $\mathcal{G}/\mathrm{Aut}(\mathcal{G})$ the set of all orbits of the vertices of $\mathcal{G}$. Note that this set forms a partition of V. We call $|\mathcal{G}/\mathrm{Aut}(\mathcal{G})|$ the *orbit number* of $\mathcal{G}$. We call an edge $\{u, v\} \in E(G_t)$ for $t \in [\ell]$ an *orbit boundary edge* if u and v are in different orbits, and *inner orbit edge* otherwise. Two orbits connected by an orbit boundary edge in time step t are called *adjacent (in time step t)*.

We use automorphisms to transform temporal walks, as outlined in the following. For a temporal graph $\mathcal{G}$ with lifetime ℓ and any automorphism $\sigma \in \mathrm{Aut}(\mathcal{G})$ and any temporal walk $W = (u_t, u_{t+1}, \ldots, u_{t'})$ that starts at time t and ends at time t' with $t, t' \in [\ell]$, we say we *apply σ to W* when we construct the temporal walk $W' = (\sigma(u_t), \sigma(u_{t+1}), \ldots, \sigma(u_{t'}))$.

Temporal Exploration Problem. The TEMPORAL EXPLORATION PROBLEM (TEXP) is defined for a given temporal graph $\mathcal{G}$ with vertex set V and lifetime ℓ and asks for the existence of a temporal walk W such that W starts at a given vertex $u \in V$ and visits all vertices of V. In connected temporal graphs with sufficiently large lifetime such a walk always exists, and this is the setting we consider throughout this work. As such, the question of existence is no longer of interest, and instead we focus on the time span of temporal walks that start at u at time step 1 and visit all (or a certain set of) vertices.

The following is an adaptation of a result of Erlebach et al. [27], slightly modified to fit our notation and use case. Intuitively speaking, the lemma states that with every extra time step at least one additional vertex becomes reachable. Thus, starting from any vertex at any time step, we can reach any particular other vertex in $n - 1$ steps. Consequently, there is always a temporal walk that visits all vertices of $\mathcal{G}$ within n^2 time steps.

▶ **Lemma 1** (Reachability, [27]). *Let $\mathcal{G}$ be a connected temporal graph with vertex set V and lifetime ℓ. Denote by $R_{t,t'}(u)$ the set of vertices reachable by some temporal walk starting at vertex $u \in V$ at time step $t \in [\ell]$ and ending at time step $t' \in [\ell]$ with $t' \geq t$. If $R_{t,t'}(u) \neq V$ and $t' < \ell$, then $R_{t,t'}(u) \subsetneq R_{t,t'+1}(u)$.*

Temporal Rendezvous Problem. We consider a problem we call TEMPORAL RENDEZVOUS PROBLEM (TRP) defined as follows. Let $\mathcal{G}$ be a temporal graph with vertex set V and lifetime ℓ. Two agents a_1, a_2 are placed at arbitrary vertices $u_1, u_2 \in V$ (respectively) in G_1 of $\mathcal{G}$. They compute respective temporal walks W_1 and W_2 such that the agents meet at the same vertex in the same time step at least once during these walks. The agents have the full information of $\mathcal{G}$ available, but they cannot communicate with each other. Furthermore, they do not know the location of the other agent, and the vertex labels that one agent sees can be arbitrarily different from the vertex labels that the other agent sees. The lack of consistent labels prohibits trivial solutions such as the two agents agreeing to meet at a vertex with a specific label, e.g., the lowest labeled vertex. We call such agents *label-oblivious*. A solution to TRP is a pair of possibly different programs p_1 and p_2 for agents a_1 and a_2, respectively, that the agents use to compute and execute their temporal walks. The respective start

positions $u_1, u_2 \in V$ of the agents (and the vertex labels that each agent sees) are chosen by an all-knowing adversary once a solution (p_1, p_2) is provided. As we assume that $\ell \geq n^2$, there is always a solution that ensures that the agents meet: Agent a_1 simply waits at its start vertex, while agent a_2 explores the whole graph and visits every vertex, which is always possible within n^2 time steps as mentioned above. Therefore, we are interested in solutions that enable the agents to meet as early as possible and aim to obtain worst-case bounds significantly better than n^2 on the number of steps that are required for TRP.

3 Automorphism Utilities

We now introduce some helpful utilities regarding automorphisms that we use in the following sections. Intuitively, we build up to a framework that allows us to transform a temporal walk W into a temporal walk W' that visits more vertices that are desirable (with respect to the exploration goal) than W does, by applying a well-chosen automorphism to W. The following is needed to give specific guarantees that the transformed temporal walks must uphold. Throughout this section we use and extend techniques of the field of algebraic graph theory [35, 39, 42], adapted to our specific use cases.

For this, we begin with some definitions. Let $\mathcal{G}$ be a temporal graph with vertex set V and let $S \in \mathcal{G}/\mathrm{Aut}(\mathcal{G})$ be any orbit. For any $X \subseteq S$ and any $u \in S$ denote with $\mathrm{Aut}(\mathcal{G})[u, X]$ the set of all automorphisms $\sigma \in \mathrm{Aut}(\mathcal{G})$ that map u to any vertex $v \in X$. We use the shorthand $\mathrm{Aut}(\mathcal{G})[u, x]$ for $\mathrm{Aut}(\mathcal{G})[u, \{x\}]$. We can then show the following.

▶ **Lemma 2.** *Let $S \in \mathcal{G}/Aut(\mathcal{G})$ be any orbit. Then $|Aut(\mathcal{G})[u, x_1]| = |Aut(\mathcal{G})[u, x_2]|$ for any $u, x_1, x_2 \in S$.*

Let $S \in \mathcal{G}/\mathrm{Aut}(\mathcal{G})$. We now consider a special 2-dimensional *automorphism matrix* $\mathcal{M}_{u,Y,X}$ for any $u \in S$, $Y \subseteq S$, and $X \subseteq S$. It has columns $C_1, C_2, \ldots, C_{|Y|+1}$, and a row for each $\sigma \in \mathrm{Aut}(\mathcal{G})[u, X]$. We refer to the row for some σ simply as row σ. The entry in row σ of column C_1 is $\sigma(u)$. Each vertex $y \in Y$ is assigned a unique column among $C_2, \ldots C_{|Y|+1}$ in an arbitrary way. The entry in row σ of the column to which y is assigned is $\sigma(y)$. We now give some intuition about the application of an automorphism matrix. Assume that we are constructing a temporal walk W that has already visited a set $T \subsetneq S$ and we want to extend it to visit the vertices of $S \setminus T$ (with S an arbitrary orbit). To facilitate this extension we first construct a temporal walk W' that visits at least a certain number of vertices of S, but that is not guaranteed to visit vertices of $S \setminus T$. This walk W' cannot be used to extend W in a meaningful way. Instead, using the automorphism matrix we show that there always exists an automorphism $\sigma \in \mathrm{Aut}(\mathcal{G})$ that we can apply to W' to obtain a temporal walk W_σ that visits a guaranteed fraction of vertices of $S \setminus T$. We can then use W_σ as our desired extension. Figure 2 visualizes this concept. In later sections we will show how repeated application of such extensions leads to temporal walks that visit all vertices of an orbit S. Note that the value p in the following lemma represents the fraction of vertices that we still need to visit compared to all vertices in the orbit under consideration. While T is a set of already visited vertices in the application sketched above, the following lemma and Corollary 4 are formulated more generally for arbitrary sets $T \subseteq S$.

▶ **Lemma 3.** *Let $\mathcal{G}$ be a connected temporal graph with lifetime ℓ and let $S \in \mathcal{G}/Aut(\mathcal{G})$ be any orbit. Let $T \subseteq S$ with $p = (|S| - |T|)/|S|$ and $W = (u_1, u_2, \ldots, u_x)$ a temporal walk starting at time step t and ending at t' with $t, t' \in [\ell]$ and $u_1 \in S$ such that W visits k vertices of S. Then there exists a temporal walk W' starting at a vertex $u' \in S$ in time step t and ending at time step t' that visits at least pk vertices of $S \setminus T$.*

When restricting the possible start vertices where the temporal walk W' of Lemma 3 is allowed to start, we obtain the following corollary. In detail, we are given a set $X \subset S$ such that the walk W' is only allowed to begin at a vertex $u' \in X$. In Lemma 3, W' was allowed to start at any vertex of S. Our use case for the following corollary is that X is a set of vertices that can be reached faster, making them better candidates for start vertices when extending walks in the way sketched above Lemma 3.

▶ **Corollary 4.** *Let $\mathcal{G}$ be a connected temporal graph with lifetime ℓ and let $S \in \mathcal{G}/Aut(\mathcal{G})$ be any orbit. Let $T \subsetneq S$ and W a temporal walk starting at time step t and ending at t' with $t, t' \in [\ell]$ such that the first vertex of W is in S and such that W visits k different vertices of S. For any $X \subseteq S$ with $|X| > |T|$ there exists a temporal walk W' starting at a vertex $u' \in X$ at time step t and ending at time step t' that visits at least $(c-1)/c \cdot k$ vertices of $S \setminus T$, with $c = |X|/|T|$.*

4 Upper Bounds for TEXP

A common approach to build a temporal walk for TEXP is to use Lemma 1, i.e., to construct a (large) set X of reachable vertices so that an unseen vertex v of the current walk is in the set X and the walk can then be extended by v. We are interested in exploring the vertices of one orbit quickly, as this will be useful for TRP in Section 5 where the agents try to meet in one orbit, and for TEXP because we can explore a temporal graph orbit by orbit. Therefore, we want to find walks visiting many vertices of one orbit. Our approach is similar to the common approach mentioned above, and so we want to construct a (large) set X of reachable vertices, but now with the property that X is a subset of the orbit under consideration. To construct X, we show in Lemma 6 a kind of "reachability between orbits."

To describe this in more detail, we need the concept of so-called lanes. Intuitively, lanes are defined for a set of vertices that are all contained in some single orbit, and give us knowledge about the vertices that are quickly reachable while only using orbit boundary edges in each time step. Using this concept of lanes we derive a first result for exploring a single large orbit with a temporal walk that spans $O((n^{5/3}+rn)\log n)$ time steps (Theorem 8). In the proof of that lemma we build the final temporal walk iteratively, by concatenating multiple smaller temporal walks. To make sure each new such small temporal walk visits a desired number of vertices not yet visited, we use Lemma 3, which – informally – lets us transform temporal walks that visit too many previously visited vertices into temporal walks that visit many previously unvisited vertices.

We follow this up with a more refined technique that considers the size of the orbit S one wants to explore as a parameter, but also uses the concept of lanes and walk transformations sketched above. It gives us an upper bound of $O(|S|^{1+\epsilon} + n\log|S|)$, for any constant $\epsilon > 0$. This result is formulated in Theorem 11. Finally, we use a repeated application of Theorem 11 to achieve an upper bound for TEXP of $O(rn^{1+\epsilon})$. We start with an auxiliary lemma that focuses on the orbit boundary edges between two orbits.

▶ **Lemma 5.** *Let G_t be the graph at time step t in a connected temporal graph $\mathcal{G}$ and $S, S' \in \mathcal{G}/Aut(\mathcal{G})$, and let G' be the subgraph of G_t that contains only orbit boundary edges. Then all vertices in S have the same degree in the bipartite graph $G'[S \cup S']$.*

To describe reachability between orbits, we have to introduce some extra notation. Let $\mathcal{G}$ be a temporal graph with lifetime ℓ and vertex set V and $S \in \mathcal{G}/\mathrm{Aut}(\mathcal{G})$ be an orbit. We call a *lane* $L_{t,t'}(X)$ with $X \subseteq S$ and $t, t' \in [\ell]$ the set of all vertices reachable from any $u \in X$ in G by any temporal walk W that only uses orbit boundary edges and starts in time step t and ends in time step at most t'. We write $L_{t,t'}(u)$ instead of $L_{t,t'}(\{u\})$. See Fig. 1 for some intuition.

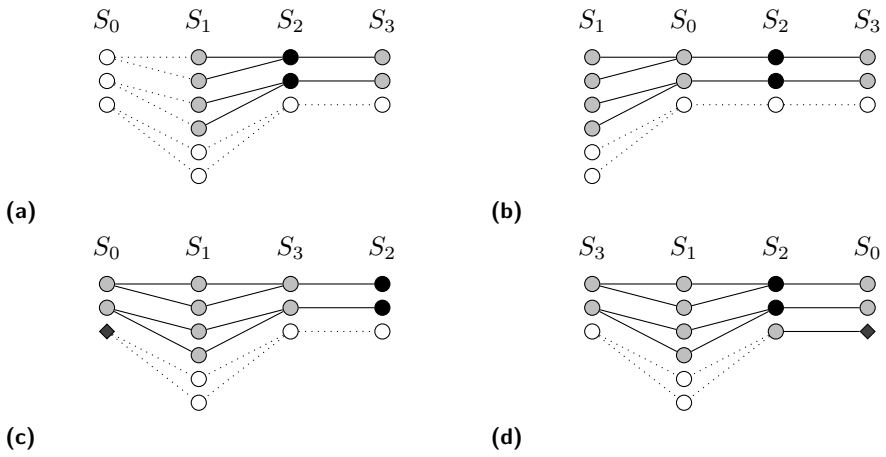

Figure 1 Visualization of the properties of a lane $L_{t,t+r}(X)$. Each vertex in the set X is colored black, and the set of reachable vertices in each time step is colored gray. Each figure represents one additional time step. In the second time step (Figure b) all vertices of the lane are reachable. In the third time step (Figure c) one vertex outside the lane must be reachable, for example the diamond shaped vertex. This is due to the fact that the temporal graph at hand is connected, and thus at least one additional vertex is reachable with every next time step. Here, one additional time step then suffices to reach a vertex of $S_2 \setminus X$ (Figure d).

The next lemma gives us a lower bound on the number of vertices of an orbit S' that can be reached from a subset X of the vertices of an orbit S within r time steps. Intuitively speaking, we show a lower bound on the number of vertices *reachable from orbit S in another orbit S'*. A simple consequence of the following lemma is that, from any start vertex in the temporal graph, at least one vertex in every orbit is reachable within r time steps.

▶ **Lemma 6** (Reachability between Orbits). *Let $\mathcal{G}$ be a connected temporal graph with lifetime ℓ and $S \in \mathcal{G}/Aut(\mathcal{G})$. For any $X \subseteq S$ and $S' \in \mathcal{G}/Aut(\mathcal{G})$ it holds that $|L_{t,t'}(X) \cap S'| \geq \lceil |X| \cdot |S'|/|S| \rceil$ for any $t \in [\ell]$ and $t' = t + r$, where $r = |\mathcal{G}/Aut(\mathcal{G})|$ is the orbit number.*

By using Lemma 1 and Lemma 6, we now bound the number of time steps needed to reach a set of h vertices within an orbit S.

▶ **Lemma 7.** *Let $\mathcal{G}$ be a connected temporal graph with lifetime ℓ and vertex set V. Let $S \in \mathcal{G}/Aut(\mathcal{G})$ and let $r = |\mathcal{G}/Aut(\mathcal{G})|$ be the orbit number. For any $h \leq |S|$, start vertex $u \in S$ and start time t, there exists a set $X \subset S$ with $|X| = h$ such that we can reach any vertex in X in at most $O(\min\{h \cdot n/|S|, hr\} + r)$ time steps. That is, for every vertex u' of X, we have a temporal walk starting at u at time step t and ending at u' at time step t' with $t' - t = O(\min\{h \cdot n/|S|, hr\} + r)$.*

Next we present Theorem 8, which states an upper bound for visiting all vertices of a given orbit S. The rough idea used in the proof is that we iteratively build the final temporal walk W by concatenating smaller temporal walks. In each step of the iteration, a small temporal walk W' is first constructed via Lemma 7 to visit a subset of the vertices of S, which are not necessarily unvisited, but such that the size of the subset is at least a certain threshold value. Using Lemma 3 we find an automorphism σ that we apply to W' to obtain a temporal walk W_σ that visits many unvisited vertices of S. We then extend W via this transformed walk W_σ (see Fig. 2 for a sketch of the proof idea). In this way we can explore all vertices of a large orbit S faster than by repeated application of Lemma 1. The key to obtain a good bound on the number of time steps required is to find a good value for the number of vertices of S visited by each small temporal walk.

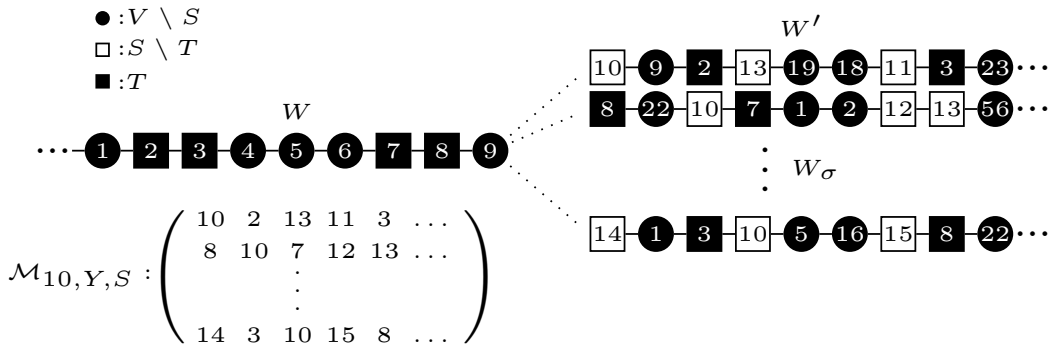

Figure 2 The construction scheme of Theorem 8. W is the temporal walk constructed so far. We aim to extend the walk with a walk W_σ that visits many vertices of $S \setminus T$, where T is the set of vertices of orbit S that we have already visited. To find W_σ, we construct W' and the automorphism matrix (bottom left) for the vertex with label 10 (the start vertex of W'), the set Y of vertices of S visited by W', and the entire orbit S as the set of possible start vertices of W_σ. One of the rows in the matrix then gives us an automorphism σ that, when applied to W', yields the desired walk W_σ.

▶ **Theorem 8.** *Let $\mathcal{G}$ be a temporal graph with lifetime ℓ and vertex set V. Take $S \in \mathcal{G}/Aut(\mathcal{G})$ and $r = |\mathcal{G}/Aut(\mathcal{G})|$ the orbit number. For any $t \in [\ell]$ there exists a temporal walk W starting at time step t that visits all vertices of S and ends at time step t' with $t' - t = O((n^{5/3} + rn) \log n)$.*

The following lemma is concerned with visiting a fraction $1/c$ of the vertices of a given orbit S with a temporal walk. One significant contribution to the number of time steps required by the temporal walk constructed in Theorem 8 is the use of Lemma 3. Roughly speaking, Lemma 3 provides a temporal walk that visits a large number of unvisited vertices, but with the caveat that every vertex of S can potentially be the start vertex of this transformed walk (instead of restricting the potential start vertices for the walk to a smaller subset, which might be reachable more quickly). The consequence of this is that for each such transformation we require, we must plan a "buffer" of n time steps to ensure that all vertices of S are reachable by the time step in which the transformed walk starts (Lemma 1). Corollary 4 provides a "trade-off" for this: a decrease in the set of possible start vertices of the transformed walk W_σ decreases the number of previously unvisited vertices W_σ visits, but also decreases the number of time steps required to reach the first vertex of W_σ. Using this property we construct a recursive algorithm that visits a fraction of the vertices of S quickly instead of applying the iterative construction of Theorem 8. In our recursive construction, the walks we concatenate shrink with each recursive call. If we were to use Lemma 3 during this, we would have an additional n time steps with each recursive call. Instead, Corollary 4 lets us reduce the number of possible start vertices dramatically. The time span required by this walk is then not dependent on n, but dependent on $|S|$ and r (the orbit number), and thus is especially useful for exploring smaller orbits. This can then be used iteratively to construct a temporal walk that visits all vertices of S, which we in turn use to visit all vertices V by visiting all orbits one after the other.

▶ **Lemma 9.** *Let $\mathcal{G}$ be a connected temporal graph with lifetime ℓ and vertex set V. Let $S \in \mathcal{G}/Aut(\mathcal{G})$ and let $r = |\mathcal{G}/Aut(\mathcal{G})|$ be the orbit number. For any $t \in [\ell]$ and any $u \in S$ there exists a temporal walk W that starts at vertex u in time step t and visits a fraction $1/c$ (for any $1 < c < |S|$) of the vertices of S such that W spans $O(rc(|S|/c)^{\phi(c)} \log |S|)$ time steps, with $\phi(c) = 1/(\log f(c))$ and $f(c) = (1 + (c-1)/c)$.*

▶ **Corollary 10.** *Let $\mathcal{G}$ be a temporal graph with lifetime ℓ and vertex set V. Let $S \in \mathcal{G}/Aut(\mathcal{G})$ and $r = |\mathcal{G}/Aut(\mathcal{G})|$ be the orbit number. For any $t \in [\ell]$, any $u \in S$, and any fixed $\epsilon > 0$, there exists a temporal walk W that starts at vertex u in time step t and visits some constant fraction $\alpha < 1$ of the vertices of S such that W spans $O(r|S|^{1+\epsilon})$ time steps.*

We now present an improved version of Theorem 8 for exploring a whole orbit.

▶ **Theorem 11.** *Let $\mathcal{G}$ be a temporal graph with lifetime ℓ and vertex set V. Let $S \in \mathcal{G}/Aut(\mathcal{G})$ and $r = |\mathcal{G}/Aut(\mathcal{G})|$ be the orbit number. For any $t \in [\ell]$, any $u \in V$, and any fixed $\epsilon > 0$, there exists a temporal walk W that starts at vertex u in time step t and visits all vertices of S such that W spans $O(r|S|^{1+\epsilon} + n \log |S|)$ time steps.*

By using the theorem above repeatedly for each orbit, we get a temporal walk for the whole temporal graph.

▶ **Corollary 12.** *Let $\mathcal{G}$ be a temporal graph with lifetime ℓ and vertex set V. For any fixed $\epsilon > 0$, there exists a temporal walk W that spans $O(rn^{1+\epsilon})$ time steps and visits all vertices of V, where $r = |\mathcal{G}/Aut(\mathcal{G})|$ is the orbit number.*

5 Upper Bound for TRP

Using Theorem 11 we show that TRP can be solved by constructing a walk that spans (asymptotically) the same number of steps as a walk for exploring an arbitrary single orbit. The idea is that the two agents identify an orbit in which they meet, and then the first agent moves to this orbit, and after n time steps the second agent starts exploring this orbit. For this the agents must be able to independently identify the same orbit, for which we introduce some additional notation. We extend the definition of isomorphism to temporal graphs as follows. Let $\mathcal{G}, \mathcal{H}$ be two temporal graphs with lifetime ℓ and vertex sets $V_\mathcal{G}$ and $V_\mathcal{H}$, respectively. We call a bijection $\theta : V_\mathcal{G} \to V_\mathcal{H}$ a *temporal isomorphism* if θ is an isomorphism from G_t to H_t for each $t \in [\ell]$ (and thus also an isomorphism from G to H, which denote the underlying graphs of $\mathcal{G}$ and $\mathcal{H}$, respectively). If clear from the context, we say *isomorphism* instead of *temporal isomorphism*.

We define an *integer coloring* as a coloring of the vertices in the vertex set V of a temporal graph $\mathcal{G}$ (with the colors being integer values). The assigned colors induce a partial order $\prec_\mathcal{P}$ on the vertex set V such that, for all vertices $u, v \in V$ that are assigned colors c_u and c_v, respectively, with $c_u \neq c_v$ it holds that $u \prec_\mathcal{P} v$ if $c_u < c_v$. The idea is now that the two agents compute the same integer coloring of the given temporal graph $\mathcal{G}$ with the property that two vertices $u, v \in V$ are assigned the same color c if and only if $u, v \in S$, with S some orbit of $\mathcal{G}/\mathrm{Aut}(\mathcal{G})$. The agents then meet at the smallest orbit, breaking ties via the coloring.

Note that, since the agents do not have access to consistent labels of the vertices in V, they are unable to distinguish between two vertices $u, v \in S$ with S being an orbit. Intuitively, the two agents a_1 and a_2 view $\mathcal{G}$ as different temporal graphs $\mathcal{G}_1$ and $\mathcal{G}_2$, respectively, such that $\mathcal{G}_1 \cong \mathcal{G} \cong \mathcal{G}_2$. A natural idea is for the agents to pick a smallest orbit for their meeting, but the challenge is how to ensure that the agents pick the same orbit if there are multiple equal-size orbits that all have the smallest size. Therefore, in the proof of the following lemma we let the agents iterate over all possible temporal graphs until they find a graph $\mathcal{H}$ with $\mathcal{G}_1 \cong \mathcal{H} \cong \mathcal{G}_2$. Then both agents compute an integer coloring for $\mathcal{H}$ as outlined in the previous paragraph. This coloring is translated to a coloring of $\mathcal{G}_1$ by agent a_1 and to a coloring of $\mathcal{G}_2$ by agent a_2 via isomorphism functions, which are independently computed by the agents.

▶ **Lemma 13.** *Let $\mathcal{G}$ be a temporal graph with vertex set V and lifetime ℓ and let a_1, a_2 be two label-oblivious agents. There exists a pair of programs (p_1, p_2) assigned to a_1 and a_2, respectively, such that each agent computes the same integer coloring of V and such that two vertices $u, v \in V$ have the same color exactly if u, v are in the same orbit of $\mathcal{G}/Aut(\mathcal{G})$.*

We can now easily construct an algorithm for TRP. The agents simply meet in a smallest orbit, breaking ties via the integer coloring (Lemma 13). The first agent moves to said orbit, then the second agent searches the orbit for the first agent. Note that the smallest orbit has size at most n/r, where r is the orbit number. Thus, the bound on the number of time steps provided by Theorem 11 becomes $O(r(n/r)^{1+\epsilon} + n\log(n/r)) = O(n^{1+\epsilon})$, and we obtain the following upper bound for TRP.

▶ **Theorem 14.** *Let $\mathcal{G}$ be a temporal graph with lifetime ℓ and a_1, a_2 two label-oblivious agents. For any fixed $\epsilon > 0$, there exists a pair of programs (p_1, p_2) assigned to a_1, a_2, respectively, such that the two agents are guaranteed to meet after $O(n^{1+\epsilon})$ time steps.*

6 Lower Bounds for TEXP and TRP

We start this section with a simple lower bound for TEXP, which is a fairly straightforward adaptation of the known lower bound of $\Omega(n^2)$ time steps [27]. Following that, we give a lower bound of $\Omega(n \log n)$ time steps for TRP. For this we describe the construction of a temporal graph that is connected and has only a single orbit. We then show how an adversary can choose the starting positions of the two agents that want to meet in order to delay their meeting. Intuitively, the graph we create is a cycle that changes repeatedly after some number of steps. By our construction, the adversary can make sure that after every change of the graph, the two agents are placed far away from each other. In the end, we also show that the resulting lower bound for TRP yields a corresponding lower bound for TEXP.

▶ **Lemma 15.** *For any $1 \leq r \leq n$, there exist n-vertex instances of TEXP with orbit number r that require $\Omega(rn)$ time steps to be explored.*

▶ **Theorem 16.** *For any two agents a_1 and a_2 with arbitrary deterministic programs, there exist instances of TRP where the agents require $\Omega(n \log n)$ time steps to meet.*

▶ **Corollary 17.** *There exist connected temporal graphs $\mathcal{G}$ with vertex set V, lifetime ℓ and a single orbit such that all temporal walks W require $\Omega(n \log n)$ time steps to visit all vertices of V.*

The lower bounds of Theorem 16 and Corollary 17 can be adapted to temporal graphs with r orbits for any constant r as follows: Use the construction from the proof of Theorem 16, but instead of letting the graph G_t in each time step be a single cycle C_i, let G_t contain $2r-1$ copies of C_i, and for each vertex u of C_i connect all copies of u by a path P_u (starting with the vertex u in the first copy of C_i and ending with the vertex u in the $(2r-1)$-th copy of C_i). The resulting temporal graph has r orbits: The vertices of the "middle" copy of C_i form one orbit, and the vertices in the two copies of C_i that have distance k from the middle copy, for $1 \leq k \leq r-1$, also form an orbit. Let $n' = n/r$ denote the number of vertices in one copy of C_i. By the arguments in the proof of Theorem 16, it takes $\Omega(n' \log n')$ time steps for the two agents to reach a location in the same path P_u, and thus TRP requires $\Omega(n' \log n')$ time steps. As $n' = n/r$ and r is a constant, this gives a lower bound of $\Omega(n \log n)$ for TRP. The lower bound of $\Omega(n \log n)$ time steps for exploration of temporal graphs with orbit number r for any constant r then follows as in the proof of Corollary 17.

7 Conclusions & Future Work

In this work, we looked at temporal graphs where agents know the complete information of the temporal graph ahead of time. In this clairvoyant setting, we studied the temporal exploration problem (TEXP) and showed how to bound the exploration time of a temporal graph using the structural graph property of the number of orbits of the automorphism group of the temporal graph. Additionally, we formalized the problem of asymmetric rendezvous in this setting as the temporal rendezvous problem (TRP) and showed how to adapt our ideas for TEXP to solve TRP quickly. For both TEXP and TRP we provided lower bounds such that the gap between upper and lower bounds is $O(n^{\epsilon})$ for any fixed $\epsilon > 0$. There are several ways in which our work can be extended. One line of research for both problems is to reduce the gap between the lower and upper bounds by improving either of them. A second line of work is to study the symmetric variant of rendezvous in the given setting and see if something can be said about it. Another interesting situation to explore is when multiple agents are used to explore the temporal graph (and also if multiple agents need to perform temporal rendezvous) and how much faster solutions in these scenarios might be. Lastly, a possible avenue of research is to study the structural properties provided by automorphism groups and how they can be used to tackle other problems that concern temporal graphs.

Abstract

We study a family of *matroid optimization problems with a linear constraint* (MOL). In these problems, we seek a subset of elements which optimizes (i.e., maximizes or minimizes) a linear objective function subject to (i) a matroid independent set, or a matroid basis constraint, (ii) additional linear constraint. A notable member in this family is BUDGETED MATROID INDEPENDENT SET (BM), which can be viewed as classic 0/1-KNAPSACK with a matroid constraint. While special cases of BM, such as KNAPSACK WITH CARDINALITY CONSTRAINT and MULTIPLE-CHOICE KNAPSACK, admit a *fully polynomial-time approximation scheme* (Fully PTAS), the best known result for BM on a general matroid is an *Efficient* PTAS. Prior to this work, the existence of a Fully PTAS for BM, and more generally, for any problem in the family of MOL problems, has been open.

In this paper, we answer this question negatively by showing that none of the (non-trivial) problems in this family admits a Fully PTAS. This resolves the complexity status of several well studied problems. Our main result is obtained by showing first that EXACT WEIGHT MATROID BASIS (EMB) does not admit a pseudo-polynomial time algorithm. This distinguishes EMB from the special cases of k-SUBSET SUM and EMB on a linear matroid, which are solvable in pseudo-polynomial time. We then obtain unconditional hardness results for the family of MOL problems in the oracle model (even if randomization is allowed), and show that the same results hold when the matroids are encoded as part of the input, assuming P $\neq$ NP. For the hardness proof of EMB, we introduce the Π-*matroid* family. This intricate subclass of matroids, which exploits the interaction between a weight function and the matroid constraint, may find use in tackling other matroid optimization problems.

1 Introduction

Matroids are simple combinatorial structures, providing a unified abstraction for independence systems such as linear independence in a vector space, or cycle-free subsets of edges in a given graph. A *matroid* is a set system $(E, \mathcal{I})$, where E is a finite set and $\mathcal{I} \subseteq 2^E$ are the *independent sets (IS)* such that (i) $\emptyset \in \mathcal{I}$, (ii) for all $A \in \mathcal{I}$ and $B \subseteq A$ it holds that $B \in \mathcal{I}$, and (iii) for all $A, B \in \mathcal{I}$ where $|A| > |B|$, there is $e \in A \setminus B$ such that $B \cup \{e\} \in \mathcal{I}$.[1]

[1] Properties (ii) and (iii) are known, respectively, as *hereditary property*, and *exchange property*.

While serving as a generic abstraction for numerous applications, matroids possess useful combinatorial properties that allow the development of efficient algorithms. These algorithms include such canonical results as the classic greedy approach for finding a maximum weight independent set of a matroid (see, e.g., [13]), Edmond's algorithm for matroid partitioning [21], and Lawler's algorithm for matroid intersection [31]. In all of the above, polynomial running time is enabled due to the structure of the problem − a single objective function with a matroid constraint. However, in many natural applications, there is an added *linear* constraint.

Consider, for example, the problem of finding a maximum independent set in a matroid subject to a budget constraint. Formally, we are given a set of elements E, a membership oracle for a collection of independent sets $\mathcal{I} \subseteq 2^E$ of a matroid $(E, \mathcal{I})$, a budget $L > 0$, a weight function $w : E \to \mathbb{R}_{\geq 0}$, and a value function $v : E \to \mathbb{R}_{\geq 0}$. A *solution* for the problem is an independent set $S \in \mathcal{I}$ of total weight at most L, i.e., $w(S) \leq L$.[2] The *value* of a solution S is given by $v(S)$, and the objective is to find a solution of maximum value. This problem, known as BUDGETED MATROID INDEPENDENT SET (BM), is a generalization of the classic 0/1-KNAPSACK, which is NP-hard and therefore unlikely to admit an exact polynomial-time algorithm. Thus, obtaining efficient approximations has been a main focus in the study of BM.

For an instance I of an optimization problem $\mathcal{G}$, let $\mathrm{OPT}_{\mathcal{G}}(I)$ be the value of an optimal solution for I. For some $\rho \geq 1$, a *ρ-approximate solution* S for I is a solution of value $v \geq \frac{\mathrm{OPT}_{\mathcal{G}}(I)}{\rho}$ ($v \leq \rho \cdot \mathrm{OPT}_{\mathcal{G}}(I)$) if $\mathcal{G}$ is a maximization (minimization) problem. We say that $\mathcal{A}$ is a *randomized ρ-approximation algorithm* for $\mathcal{G}$ if given an instance I of $\mathcal{G}$ $\mathcal{A}$ returns with probability at least $\frac{1}{2}$ a ρ-approximate solution for I − if a solution exists. If no solution exists − $\mathcal{A}$ returns that I does not have a solution.

Let $|I|$ be the encoding size of an instance I of a problem $\mathcal{G}$. A (randomized) *polynomial-time approximation scheme* (PTAS) for $\mathcal{G}$ is a family of algorithms $(A_\varepsilon)_{\varepsilon>0}$ such that, for any $\varepsilon > 0$, A_ε is a (randomized) polynomial-time $(1+\varepsilon)$-approximation algorithm for $\mathcal{G}$. A (randomized) *Efficient PTAS* (EPTAS) is a (randomized) PTAS $(A_\varepsilon)_{\varepsilon>0}$ with running time of the form $f\left(\frac{1}{\varepsilon}\right) \cdot |I|^{O(1)}$, where f is an arbitrary computable function. The strong dependence of run-times on the error parameter, $\varepsilon > 0$, often renders the above schemes highly impractical. This led to the study of the following more desirable class of schemes. A (randomized) approximation scheme $(A_\varepsilon)_{\varepsilon>0}$ is a (randomized) *Fully PTAS* (FPTAS) if the running time of A_ε is of the form $\left(\frac{|I|}{\varepsilon}\right)^{O(1)}$.[3]

In the past decades, BM was shown to admit a PTAS [2, 12, 25], and more recently an Efficient PTAS [18, 17]. As the special case of 0/1-KNAPSACK admits a Fully PTAS, it is natural to explore the existence of a Fully PTAS for BM. There are known Fully PTASs for BM on restricted families of matroids. This includes KNAPSACK WITH A CARDINALITY CONSTRAINT [7], MULTIPLE-CHOICE KNAPSACK [32], and BM WITH LAMINAR MATROID CONSTRAINT [19]. However, the question whether BM admits a Fully PTAS on general matroids remained open.

In this paper, we resolve this question negatively for BM and other fundamental matroid optimization problems with a linear constraint.

---

[2] For every set X, a function $f : X \to \mathbb{R}_{\geq 0}$ and $Y \subseteq X$ we define $f(Y) = \sum_{e \in Y} f(e)$.

[3] To better distinguish between EPTAS and FPTAS, we use throughout the paper Efficient PTAS and Fully PTAS.

1.1 Our Results

For a matroid $\mathcal{M} = (E, \mathcal{I})$ we define $\text{IS}(\mathcal{M}) = \mathcal{I}$ and $\text{bases}(\mathcal{M}) = \{S \in \mathcal{I} \mid |S| = \mathsf{rank}(\mathcal{M})\}$, where $\mathsf{rank}(\mathcal{M}) = \max_{T \in \mathcal{I}} |T|$ is the *rank* of $\mathcal{M}$, i.e., the maximum cardinality of an independent set. We study a family of *matroid optimization problems with a linear constraint* (MOL). Problems in this family are characterized by three parameters:

(i) The optimization objective opt $-$ either the operator "max" or "min".

(ii) A *matroid feasibility constraint* $\mathcal{F}$ $-$ either the independent sets of a matroid, or the set of *bases* of a matroid. The feasibility constraint is $\mathcal{F} \in \{\text{IS}, \text{bases}\}$.

(iii) A relation $\triangleleft$ $-$ realized by one of the relations "$\geq$" or "$\leq$".

Let $\mathcal{P} = \{\max, \min\} \times \{\text{bases}, \text{IS}\} \times \{\leq, \geq\}$ be the set of *parameters* for MOL problems. Based on the set of parameters $\mathcal{P}$, we define for every triplet a problem in the MOL family. For $P \in \mathcal{P}$ where $P = (\text{opt}, \mathcal{F}, \triangleleft)$, define the P-MATROID OPTIMIZATION WITH A LINEAR CONSTRAINT (P-MOL) problem as follows. An instance is a tuple $I = (E, \mathcal{I}, v, w, L)$ such that $\mathcal{M} = (E, \mathcal{I})$ is a matroid, $v : E \to \mathbb{R}_{\geq 0}$ is the objective function, $w : E \to \mathbb{R}_{\geq 0}$ is a weight function, and $L \in \mathbb{R}_{\geq 0}$ is a *bound* for the linear constraint. A *solution* of I is $S \subseteq E$ which satisfies the matroid feasibility constraint $S \in \mathcal{F}(\mathcal{M})$ and the linear constraint $w(S) \triangleleft L$. The goal is to optimize (i.e., maximize or minimize) the value $v(S)$. Thus, we can formulate a P-MOL optimization problem as

$$\text{opt } v(S) \text{ s.t. } S \in \mathcal{F}(\mathcal{M}),\ w(S) \triangleleft L. \tag{1}$$

Observe that $(\max, \text{IS}, \leq)$-MOL is the BM problem. That is, given a BM instance (equivalently, $(\max, \text{IS}, \leq)$-MOL instance) $I = (E, \mathcal{I}, v, w, L)$, the goal is to find an independent set $S \in \mathcal{I}$ of maximum total value $v(S)$ such that $w(S) \leq L$. Other notable examples for MOL problems are CONSTRAINED MINIMUM BASIS OF A MATROID (CMB) [26], which can be cast as $(\min, \text{bases}, \leq)$-MOL, and KNAPSACK COVER WITH MATROID CONSTRAINT (KCM) [8] formalized by $(\min, \text{IS}, \geq)$-MOL.[4]

We note that (1) does not refer to the *representation* of the instance I. We consider two possible representations. For any $P \in \mathcal{P}$, in an instance $(E, \mathcal{I}, v, w, L)$ of *oracle* P-MOL, the arguments E, v, w, L are given as the input, and the independent sets $\mathcal{I}$ are accessed via a *membership oracle*, which determines whether a given set $S \subseteq E$ belongs to $\mathcal{I}$ in a single query. Thus, the independent sets are not considered in the encoding size of the instance. The term *running time* for problems involving oracles refers to the sum of the number of queries to the oracle and the number of basic operations. Previous works on MOL problems often consider membership oracles [12, 2, 8, 18, 17]. As hardness with oracles does not necessarily imply hardness in non-oracle models (see, e.g., [6, 9]), in Section 4 we show lower bounds for variants of MOL problems in which the independent sets are encoded as part of the input.

Clearly, the problem $(\min, \text{IS}, \leq)$-MOL is trivial since the empty set achieves the optimal objective value. However, for any other $P \in \mathcal{P}$, solving the P-MOL problem is challenging. The *non-trivial* MOL problems are all the MOL problems excluding $(\min, \text{IS}, \leq)$-MOL. That is, P-MOL is non-trivial if $P \in \mathcal{Q}$ where $\mathcal{Q} = \mathcal{P} \setminus \{(\min, \text{IS}, \leq)\}$. Observe that non-trivial MOL problems are NP-hard (e.g., 0/1-KNAPSACK is a special case of $(\max, \text{IS}, \leq)$-MOL); however, all previously studied MOL problems admit approximation schemes.

[4] CMB, KCM, and other MOL problems may not have a solution; however, we can decide in polynomial time if a solution exists, and our definition of approximation algorithms captures instances with no solution.

For certain special cases of MOL problems, e.g., BM with simple matroid constraints, the existence of a Fully PTAS is known for decades [38, 7]. However, for MOL problems with arbitrary matroid constraints, the best known results are Efficient PTAS. While matroids form an important generalization of well known basic constraints, the complexity of the corresponding MOL problems remained open. Specifically, prior to this work, the existence of a MOL problem which does not admit a Fully PTAS was open.

Our main result is that none of the (non-trivial) oracle matroid optimization problem with a linear constraint admits a Fully PTAS, even if randomization is allowed. This unconditioned hardness result is established by deriving a lower bound on the minimum number of queries to the membership oracle.

▶ **Theorem 1.** *For every $P \in \mathcal{Q}$ there is no randomized* Fully PTAS *for oracle P-*MOL.

Table 1 Implications of our results for previously studied MOL problems. All of our bounds hold for randomized algorithms.

Problem	Previous Results	This Paper
Budgeted Matroid Independent Set	Efficient PTAS [18]	**No Fully PTAS**
Budgeted Matroid Intersection	Efficient PTAS [17]	**No Fully PTAS**
Constrained Minimum Basis of Matroid	Efficient PTAS [26]	**No Fully PTAS**
Knapsack Cover with a Matroid	PTAS [8]	**No Fully PTAS**

Theorem 1 conclusively distinguishes MOL problems with arbitrary matroids, such as BM, from special cases with simpler matroid constraints. Furthermore, it shows that existing Efficient PTAS [26, 18, 17] for MOL problems on general matroids are the best possible. Notable implications of our results are given in Table 1, and consequences of our lower bounds for a set of previously studied problems [5, 26, 2, 12, 25, 8, 18, 17, 16] are given in Section 1.3. By resolving the complexity status of MOL problems on general matroids, our results promote future research to design (or rule out) Fully PTAS for MOL problems on restricted matroid classes (see Section 5).

To prove Theorem 1, we turn our attention to the following problem.

▶ **Definition 2.** *An instance of* Exact Matroid Basis (EMB) *is $I = (E, \mathcal{I}, c, T)$, where $(E, \mathcal{I})$ is a matroid, $c : E \to \mathbb{N}$ is a weight function, and $T \in \mathbb{N}$ is a target value. A* solution *is a basis S of $(E, \mathcal{I})$ such that $c(S) = T$. The goal is to decide if there is a solution.*

Similar to MOL problems, EMB does not specify the input. In an instance $(E, \mathcal{I}, c, T)$ of oracle-EMB, E, c, T are explicitly given, and the independent sets $\mathcal{I}$ are accessed via a membership oracle. An instance I of a decision problem $\mathcal{D}$ is a "yes"-instance if the correct answer for I is "yes"; otherwise, I is a "no"-instance. We say that $\mathcal{A}$ is a *randomized algorithm* for a decision problem $\mathcal{D}$ if, given a "yes"-instance I of $\mathcal{D}$, $\mathcal{A}$ returns "yes" with probability at least $\frac{1}{2}$; for a "no"-instance, $\mathcal{A}$ returns "no" with probability 1. The next result rules out a pseudo-polynomial time algorithm for oracle-EMB, thus distinguishing the problem from the special cases of k-subset sum and EMB on linear matroids, which admit a pseudo-polynomial time algorithm [5].

▶ **Theorem 3.** *For any* oracle-EMB *instance $I = (E, \mathcal{I}, c, T)$, there is no randomized algorithm for* oracle-EMB *that runs in time $(n \cdot (T+2) \cdot m)^{O(1)}$, where $n = |E| + 1$ and $m = c(E) + 1$.*

1.2 Technical Contribution

We derive our results by introducing Π-*matroids*. This new family of *paving* matroids carefully exploits a simple weight function to define a matroid that successfully *hides* a specific property Π within its independent sets (see Section 2).[5] Using Π-matroids, we define oracle-EMB instances whose solutions must satisfy the property Π. This shows the unconditional hardness of oracle-EMB, as Π can be discovered only via an exponential number of queries to the membership oracle. Our hardness results for MOL problems (as stated in Theorem 1) are derived via reduction from oracle-EMB.

Despite the abundance of lower bounds for matroid problems [33, 28, 29, 39], as well as for knapsack problems [10, 30, 14, 3], we are not aware of lower bounds that leverage the interaction between the matroid constraint and the additional linear constraint required for deriving our new lower bound for EMB, and consequently for MOL problems. Indeed, if the matroid constraint is removed from (1) (equivalently, $\mathcal{F}(\mathcal{M}) = 2^E$), MOL problems become variants of classic 0/1-KNAPSACK, which admits a Fully PTAS. Alternatively, if the linear constraint imposed by w, L is removed, then we have the polynomially solvable maximum/minimum weight matroid independent set problem. This distinguishes our construction from existing lower bounds for matroid problems, as even previous constructions of *paving* matroids (e.g., [28]) cannot be easily adapted to tackle both the knapsack constraint along with the matroid constraint. Π-matroids may be useful for deriving lower bounds for other problems (see Section 5).

Our unconditional lower bounds apply in the *oracle* model, where the independent sets of the given matroid can be accessed only via a membership oracle. One may question the validity of the bounds for variants of the problems where the matroid is encoded as part of the input. Indeed, in some scenarios, the use of oracles makes problems harder [6, 9]. Thus, we complement our results by showing that the same lower bounds hold under the standard complexity assumption P $\neq$ NP, even if the matroid is encoded as part of the instance and membership can be decided in polynomial time. We accomplish this by designing the family of SAT-*matroids* – a counterpart of the Π-matroid family whose members can be efficiently encoded. This construction can be used to obtain hardness results for other matroid problems in non-oracle models, based on existing analogous lower bounds in the oracle model (e.g., [28]). We elaborate on that in Section 4.

1.3 Implications of Our Results and Prior Work

Below we describe in further detail the implications of our results, and discuss previous work on MOL problems. In the following problems, general matroids are assumed to be accessed via membership oracles.

Exact Matroid Basis (EMB). This is a generalization of the k-SUBSET SUM problem (where $(E, \mathcal{I})$ is a uniform matroid).[6] Thus, EMB is unlikely to be solvable in polynomial time. Instead, we seek a pseudo-polynomial time algorithm whose running time has polynomial dependence on the encoding size of the instance and the target value T. Indeed, the special case of EMB in which the matroid is *representable* (or, linear) admits such a pseudo-polynomial time algorithm [5]. Since the 1990s, it has been an open question whether the result of Camerini et al. [5] can be extended to general matroids. Theorem 3 resolves this question, ruling out the existence of a pseudo-polynomial time algorithm for EMB.

[5] We note that paving matroids have been used in earlier work, e.g., to show intractability of the matroid matching problem in the oracle model [33, 28].
[6] In a uniform matroid, $\mathcal{I} = \{S \subseteq E \mid |S| \leq k\}$.

Budgeted Matroid Independent Set (BM). This problem is cast as $(\max, \mathrm{IS}, \leq)$-MOL. BM is a natural generalization of the classic 0/1-KNAPSACK problem, for which a Fully PTAS has been known since the 1970s [32]. As mentioned above, a Fully PTAS is known also for other special cases of BM. A PTAS for BM was first given in [2] as a special case of BUDGETED MATROID INTERSECTION (BMI). In this generalization of BM, we are given *two* matroids $(E, \mathcal{I}_1)$ and $(E, \mathcal{I}_2)$, and a solution has to be an independent set of *both* matroids. A PTAS for BM also follows from the results of [25, 12] which present PTASs for multi-budgeted variants of BM. An Efficient PTAS for BM was recently given in [18] and for BMI in [17]. The existence of a Fully PTAS for BM was posed as a central open question in [2, 18, 17]. We answer this question negatively, as formalized in Theorem 1, giving a tight lower bound for BM and BMI.

Constrained Minimum Basis of a Matroid (CMB). This problem can be cast as the matroid optimization problem $(\min, \mathrm{bases}, \leq)$-MOL. The CONSTRAINED MINIMUM SPANNING TREE (CST) problem is the special case of CMB in which the matroid $(E, \mathcal{I})$ is graphical [36, 1, 26, 27], namely, there is a graph $G = (V, E)$ such that the independent sets $\mathcal{I}$ are cycle-free subsets of edges in G. A PTAS for CST was given by Ravi and Goemans [36]. This result was improved to an Efficient PTAS by Hassin and Levin [26]. A *bicriteria* FPTAS, which violates the budget constraint by a factor of $(1+\varepsilon)$, was presented in [27]. The authors of [26] mention that their result actually gives an Efficient PTAS for CMB. The existence of a Fully PTAS for CMB remained an open question. Theorem 1 shows that the Efficient PTAS for CMB cannot be improved.

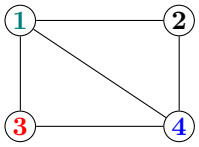
Knapsack Cover with a Matroid (KCM). As a final implication, Theorem 1 rules out the existence of a Fully PTAS for a *coverage* variant of 0/1-KNAPSACK, formulated as $(\min, \mathrm{IS}, \geq)$-MOL. In [8], Chakaravarthy et al. presented a PTAS for KCM using integrality properties of a linear programming formulation of KCM. Moreover, for the special case of KCM with a *partition matroid*, they give a Fully PTAS based on dynamic programming. The existence of a Fully PTAS for KCM on a general matroid was posed in [8] as an open question. Theorem 1 answers this question negatively. Our initial study indicates that an Efficient PTAS for KCM can potentially be obtained by adapting the approach of Hassin and Levin [26] to the setting of KCM. This suggests that our lower bound cannot be strengthened.

1.4 Organization

In Section 2 we introduce the Π-matroid family and give the proof of Theorem 3. In Section 3 we prove Theorem 1, and in Section 4 we show that similar lower bounds hold in the standard computational model. We conclude in Section 5 with a summary and directions for future work. Due to space constraints, some of the proofs are given in the full version of the paper [20].

2 The Hardness of ORACLE EXACT MATROID BASIS

In this section, we prove Theorem 3. We use in the proof the family of Π-*matroids*. For any $m \in \mathbb{N}$, let $[m] = \{1, \ldots, m\}$. A member in the Π-matroid family is given by four arguments: $n, k, \alpha \in \mathbb{N}_{>0}$, and $\Pi \subseteq 2^{[n]}$. The first argument, $n \in \mathbb{N}_{>0}$, is the number of elements, and the ground set is $[n]$. The second argument, $k \in [n]$, is the rank of the matroid. The third argument, $\alpha \in \mathbb{N}_{>0}$, is a target value, that is usually equal to $\mathsf{sum}(S)$ for some $S \subseteq [n]$, where $\mathsf{sum}(S) = \sum_{i \in S} i$. The last argument is a family of subsets $\Pi \subseteq 2^{[n]}$.



$\mathcal{J}_{4,2} = \{\emptyset, \{1\}, \{2\}, \{3\}, \{4\}\}$, $\mathcal{K}_{4,2,5} = \{\{2,4\}, \{2,1\}, \{4,3\}, \{3,1\}\}$, $\mathcal{L}_{4,2,5}(\Pi) = \{\{2,3\}\}$

Figure 1 The independent sets of the Π-matroid $M_{n,k,\alpha}(\Pi)$, with parameters $n = 4$, $k = 2$, and $\alpha = 5$. The secret family Π contains all independent sets in the graph G, where $\{2, 3\}$ is the only independent set in G with k elements.

The set Π is called the *secret family* because finding $S \in \Pi$ is possible only via repeated queries to the membership oracle of the matroid. Since Π can have an arbitrary structure, this may require exhaustive enumeration.

▶ **Definition 4.** *Let $n, k, \alpha \in \mathbb{N}_{>0}$. For some $\Pi \subseteq 2^{[n]}$, define the* **Π-matroid** *on n, k, and α as $M_{n,k,\alpha}(\Pi) = ([n], \mathcal{I}_{n,k,\alpha}(\Pi))$, where*

$$\mathcal{I}_{n,k,\alpha}(\Pi) = \mathcal{J}_{n,k} \cup \mathcal{K}_{n,k,\alpha} \cup \mathcal{L}_{n,k,\alpha}(\Pi)$$

and $\mathcal{J}_{n,k}, \mathcal{K}_{n,k,\alpha}, \mathcal{L}_{n,k,\alpha}(\Pi)$ are defined as follows.

$$\begin{aligned} \mathcal{J}_{n,k} &= \{S \subseteq [n] \mid |S| < k\} \\ \mathcal{K}_{n,k,\alpha} &= \{S \subseteq [n] \mid |S| = k, \mathsf{sum}(S) \neq \alpha\} \\ \mathcal{L}_{n,k,\alpha}(\Pi) &= \{S \subseteq [n] \mid |S| = k, \mathsf{sum}(S) = \alpha, S \in \Pi\}. \end{aligned} \tag{2}$$

In words, $\mathcal{J}_{n,k}$ contains all subsets of strictly less than k elements; $\mathcal{K}_{n,k,\alpha}$ contains all subsets of cardinality k whose total sum is not α. Finally, $\mathcal{L}_{n,k,\alpha}(\Pi)$ contains all subsets of cardinality k and total sum α which also belong to Π. See Figure 1 for an example of a member of the Π-matroid family. Using a simple argument, we show that the set system in Definition 4 is indeed a matroid. For the sets $\mathcal{I}_{n,k,\alpha}(\Pi)$, $\mathcal{J}_{n,k}$, $\mathcal{K}_{n,k,\alpha}$ and $\mathcal{L}_{n,k,\alpha}(\Pi)$ defined in Definition 4, we often omit the subscripts n, k, α and n, k when the values of n, k, α are known by context. For simplicity, for any set A and an element a, let $A + a$, $A - a$ be $A \cup \{a\}$ and $A \setminus \{a\}$, respectively.

▶ **Lemma 5.** *For every $n, k, \alpha \in \mathbb{N}_{>0}$, and $\Pi \subseteq 2^{[n]}$ it holds that $M_{n,k,\alpha}(\Pi)$ is a matroid.*[7]

Proof. We first note that $\emptyset \in \mathcal{J}$ since $0 < k$; therefore, $\emptyset \in \mathcal{I}(\Pi)$. For the hereditary property, let $A \in \mathcal{I}(\Pi)$. For all $B \subset A$ it holds that $|B| < k$; thus, $B \in \mathcal{J}$ and it follows that $B \in \mathcal{I}(\Pi)$. For the exchange property, let $A, B \in \mathcal{I}(\Pi)$ such that $|A| > |B|$. We consider the following cases.

1. $|B| < k - 1$. Then, for all $e \in A \setminus B$ it holds that $|B + e| < k - 1 + 1 = k$. Hence, $B + e \in \mathcal{J}$ and it follows that $B + e \in \mathcal{I}(\Pi)$. Note that there is such $e \in A \setminus B$ because $|A| > |B|$.
2. $|B| = k - 1$ and $|A| = k$. We consider two subcases.
   a. $B \subseteq A$. Then, as $|A| > |B|$ there is $e \in A \setminus B$. Hence, $B + e = A$ (because $|B| = k - 1$ and $|A| = k$). As $A \in \mathcal{I}(\Pi)$, it follows that $B + e \in \mathcal{I}(\Pi)$.

[7] We remark that the lemma can be proved using Theorem 5.3.5 in [23]. We give the proof for completeness.

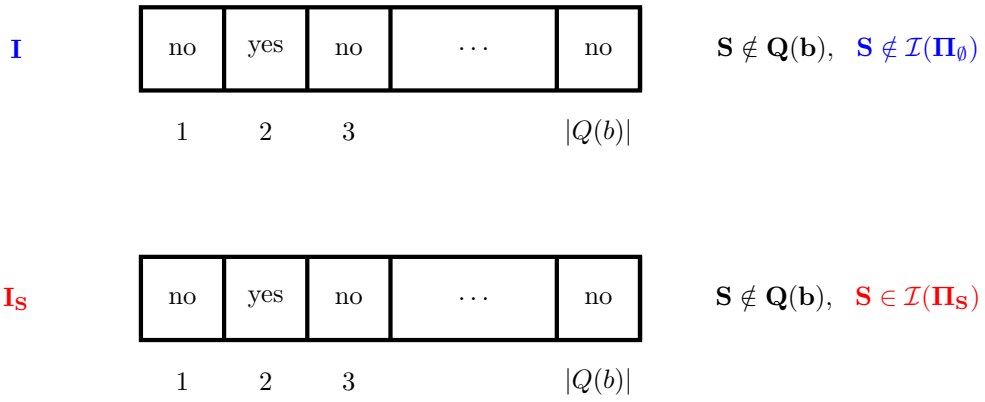


Figure 2 An illustration of the proof of Theorem 3. The figure presents the sequences of queries to the membership oracles by the algorithm on the instances I and I_S for a string of bits b, such that $S \notin Q(b)$. The label "yes" ("no") indicates that the queried set is (not) independent in the matroid. The only query that distinguishes between I and I_S is on the set S, which is not queried; thus, the algorithm returns the same output for I and I_S.

b. $B \not\subseteq A$. Then, as $|B| = k-1$ and $|A| = k$ it follows that $|B \cap A| < |B| = k-1$. Thus, $|A \setminus B| = |A| - |A \cap B| > k - (k-1) = 1$. Hence, there are $e, f \in A \setminus B$ such that $e \neq f$. It follows that there is $g \in \{e, f\}$ such that $\mathsf{sum}(B+g) = \mathsf{sum}(B) + g \neq \alpha$. We conclude from (2) that $B + g \in \mathcal{K}$, implying that $B + g \in \mathcal{I}(\Pi)$. ◀

Observe that $\mathcal{K}_{n,k,\alpha} \cup \mathcal{L}_{n,k,\alpha}(\Pi)$ is the set of bases of the matroid. Moreover, for any arguments n, k, α and Π, the cardinality of every dependent set $S \in 2^{[n]} \setminus \mathcal{I}_{n,k,\alpha}(\Pi)$ is at least the rank of the Π-matroid $M_{n,k,\alpha}(\Pi) = ([n], \mathcal{I}_{n,k,\alpha}(\Pi))$. Such matroids are known as *paving matroids* (see, e.g., [34, 35]). Using Π-matroids, we define the following collection of oracle-EMB instances. In these instances, the matroid is a Π-matroid, where Π is some unknown fixed family of subsets of the ground set.

▶ **Definition 6.** *For every $n, k, \alpha \in \mathbb{N}_{>0}$, and $\Pi \subseteq 2^{[n]}$ define the* induced *oracle*-EMB *instance of n, k, α, Π, denoted $I_{n,k,\alpha}(\Pi)$, as follows. Let $\mathsf{id}_n : [n] \to [n]$, where $\mathsf{id}_n(i) = i$ $\forall i \in [n]$. Then, $I_{n,k,\alpha}(\Pi) = ([n], \mathcal{I}_{n,k,\alpha}(\Pi), \mathsf{id}_n, \alpha)$.*

Observe that the above is indeed an oracle-EMB instance if the independent sets of the given matroid are accessible via a membership oracle. The following is an easy consequence of Definition 6.

▶ **Observation 7.** *For every $n, k, \alpha \in \mathbb{N}_{>0}$ and $\Pi \subseteq 2^{[n]}$, it holds that $I_{n,k,\alpha}(\Pi)$ is an* oracle-EMB *"yes"-instance if and only if there is $S \in \Pi$ such that $|S| = k$ and $\mathsf{sum}(S) = \mathsf{id}_n(S) = \alpha$.*

By Observation 7, an algorithm that finds an independent set of $\mathcal{M}_{n,k,\alpha}(\Pi)$ satisfying $|S| = k$ and $\mathsf{sum}(S) = \alpha$, in fact outputs a subset $S \in \Pi$. As the input for an induced oracle-EMB instance $I_{n,k,\alpha}(\Pi)$ does not contain an explicit encoding of Π, finding $S \in \Pi$ requires a sequence of queries to the membership oracle of $M_{n,k,\alpha}(\Pi)$. Roughly speaking, to decide $I_{n,k,\alpha}(\Pi)$, an algorithm for oracle-EMB must iterate over all (exponentially many) subsets $S \subseteq [n]$ such that $|S| = k$ and $\mathsf{sum}(S) = \alpha$. This is the intuition behind the proof of the next result.

▶ **Theorem 3.** *For any* oracle-EMB *instance $I = (E, \mathcal{I}, c, T)$, there is no randomized algorithm for* ORACLE-EMB *that runs in time $(n \cdot (T+2) \cdot m)^{O(1)}$, where $n = |E| + 1$ and $m = c(E) + 1$.*

Proof. Assume towards contradiction that there exist a constant $d \in \mathbb{N}$ and a randomized algorithm $\mathcal{A}$ that decides every oracle-EMB instance $(E, \mathcal{I}, c, T)$ in time $((T+2) \cdot n \cdot m)^d$, where $n = |E| + 1$ and $m = c(E) + 1$. For every $n, k, \alpha \in \mathbb{N}_{>0}$, consider the set of all subsets of $[n]$ with cardinality k and sum α, i.e.,

$$\mathcal{F}_{n,k,\alpha} = \left\{ S \subseteq [n] \;\middle|\; |S| = k, \mathsf{sum}(S) = \alpha \right\}.$$

To reach a contradiction, we construct an induced oracle-EMB instance on which $\mathcal{A}$ does not compute the proper output with sufficiently high probability. The parameters of the instance are extracted from the following combinatorial claim.

▷ Claim 8. There are $\tilde{n} \in \mathbb{N}_{>0}$, $\tilde{k} \in [\tilde{n}]$, and $\tilde{\alpha} \in \left[\tilde{n}^2\right]$ such that $|\mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}| > 2 \cdot \left(12 \cdot \tilde{n}^5\right)^d$.

Proof. Since d is a constant, there is $\tilde{n} \in \mathbb{N}_{>0}$ such that

$$\left(12 \cdot \tilde{n}^5\right)^d < \frac{2^{\tilde{n}} - 1}{2 \cdot \tilde{n}^3}. \tag{3}$$

Fix $\tilde{n} \in \mathbb{N}_{>0}$ satisfying (3). Recall that $\sum_{k \in \{0,1,\ldots,\tilde{n}\}} \binom{\tilde{n}}{k} = 2^{\tilde{n}}$ from a basic property of the Pascal triangle; therefore, $\sum_{k \in \{1,\ldots,\tilde{n}\}} \binom{\tilde{n}}{k} = 2^{\tilde{n}} - 1$. Thus, there is $\tilde{k} \in \{1, \ldots, \tilde{n}\}$, such that

$$\binom{\tilde{n}}{\tilde{k}} \geq \frac{2^{\tilde{n}} - 1}{\tilde{n}}. \tag{4}$$

Fix $\tilde{k} \in [\tilde{n}]$ satisfying (4). Observe that for each $S \in 2^{[\tilde{n}]}$ satisfying $|S| = \tilde{k} > 0$, it holds that $1 \leq \mathsf{sum}(S) \leq |S| \cdot \max_{i \in [\tilde{n}]} i = \tilde{n}^2$. Thus, there are $\tilde{n}^2$ possibilities for $\alpha \in \left[\tilde{n}^2\right]$ satisfying $\alpha = \mathsf{sum}(S)$, for some $S \in 2^{[\tilde{n}]}$ such that $|S| = \tilde{k}$. Moreover, there are $\binom{\tilde{n}}{\tilde{k}}$ subsets of $[\tilde{n}]$ of cardinality $\tilde{k}$. By the pigeonhole principle, there is $\tilde{\alpha} \in \left[\tilde{n}^2\right]$ such that $|\mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}| \geq \frac{\binom{\tilde{n}}{\tilde{k}}}{\tilde{n}^2}$. Thus,

$$|\mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}| \geq \frac{\binom{\tilde{n}}{\tilde{k}}}{\tilde{n}^2} \geq \frac{2^{\tilde{n}} - 1}{\tilde{n} \cdot \tilde{n}^2} > 2 \cdot \left(12 \cdot \tilde{n}^5\right)^d.$$

The second inequality follows from (4), and the third inequality holds by (3). ◁

Let $\tilde{n} \in \mathbb{N}_{>0}$, $\tilde{k} \in [\tilde{n}]$, and $\tilde{\alpha} \in \left[\tilde{n}^2\right]$ satisfying the conditions of Claim 8. Define t to be the maximum running time of $\mathcal{A}$ on an induced EMB instance $I_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi)$ over all $\Pi \in 2^{[\tilde{n}]}$.

▷ Claim 9. $t \leq \left(12 \cdot \tilde{n}^5\right)^d$.

Proof. Let $T = \tilde{\alpha}$, $n = \tilde{n} + 1$, and $m = \mathsf{id}_{\tilde{n}}([\tilde{n}]) + 1$. By the running time guarantee of $\mathcal{A}$, it follows that $t \leq (n \cdot (T+2) \cdot m)^d$. It remains to bound $n \cdot (T+2) \cdot m$. Since $\mathsf{id}_{\tilde{n}}([\tilde{n}]) = \mathsf{sum}([\tilde{n}])$ and $\tilde{\alpha} \leq \tilde{n}^2$,

$$n \cdot (T+2) \cdot m \leq (\tilde{n}+1) \cdot \left(\tilde{n}^2 + 2\right) \left(\mathsf{sum}([\tilde{n}]) + 1\right) \leq 2\tilde{n} \cdot 3\tilde{n}^2 \cdot \left(\frac{\tilde{n} \cdot (\tilde{n}+1)}{2} + 1\right) \leq 12 \cdot \tilde{n}^5.$$

The second inequality follows from the sum of the terms of an arithmetic sequence. By the above and the running time guarantee of $\mathcal{A}$, it follows that $t \leq (n \cdot (T+2) \cdot m)^d \leq \left(12 \cdot \tilde{n}^5\right)^d$. ◁

Given an induced oracle-EMB instance $I_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi)$, for some $\Pi \subseteq [\tilde{n}]$, the randomized algorithm $\mathcal{A}$ generates a random string of bits $\bar{b} \in \{0,1\}^t$ and performs a sequence of queries to the membership oracle of $M_{\tilde{n},\tilde{k},\tilde{\alpha}}$, based on $\bar{b}, \tilde{n}, \tilde{k}, \tilde{\alpha}$, and the results of the previous queries. Then, the algorithm decides the given instance based on the queries.

Let $\Pi_\emptyset = \emptyset$, and consider the induced oracle-EMB instance $I = I_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi_0)$. Given a string of bits $b \in \{0,1\}^t$, let $Q(b) \subseteq 2^{[\tilde{n}]}$ be the set of all subsets $S \subseteq [\tilde{n}]$ queried by $\mathcal{A}$ on the instance I and the bit-string b (on the membership oracle of $M_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi_\emptyset)$). For clarity, we use $\bar{b}$ for a random string, and b for a realization of $\bar{b}$ to a specific string. Note that $Q(b)$ is a set, since the algorithm is deterministic for every $b \in \{0,1\}^t$; conversely, $Q(\bar{b})$ is a random set for a random string $\bar{b} \in \{0,1\}^t$. As the running time of $\mathcal{A}$ on I is bounded by t, it holds that $|Q(b)| \leq t$ for every $b \in \{0,1\}^t$. Let

$$R(I) = \left\{ S \in \mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}} \;\middle|\; \Pr\left(S \in Q(\bar{b})\right) \geq \frac{1}{2} \right\}$$

be all sets in $\mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}$ that are queried by $\mathcal{A}$ with probability at least $\frac{1}{2}$.

▷ Claim 10. $|R(I)| < |\mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}|$.

Proof. By the definition of $R(I)$, it holds that

$$\begin{aligned} |R(I)| &= \left| \left\{ S \in \mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}} \;\middle|\; \Pr\left(S \in Q(\bar{b})\right) \geq \frac{1}{2} \right\} \right| \\ &\leq 2 \cdot \sum_{S \in \mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}} \Pr\left(S \in Q(\bar{b})\right) \\ &= 2 \cdot \sum_{S \in \mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}} \sum_{b \in \{0,1\}^t} \Pr\left(S \in Q(b)\right) \cdot \Pr(\bar{b} = b). \end{aligned}$$

Thus, by changing the order of summation, we have

$$|R(I)| \leq 2 \cdot \sum_{b \in \{0,1\}^t} \Pr(\bar{b} = b) \cdot \sum_{S \in \mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}} \Pr\left(S \in Q(b)\right) \leq 2 \cdot \sum_{b \in \{0,1\}^t} \Pr(\bar{b} = b) \cdot |Q(b)|.$$

Since $|Q(b)| \leq t$ for all $b \in \{0,1\}^t$, by the above we have

$$|R(I)| \leq 2t \cdot \sum_{b \in \{0,1\}^t} \Pr(\bar{b} = b) = 2 \cdot t \leq 2 \cdot \left(12 \cdot \tilde{n}^5\right)^d < |\mathcal{F}_{\tilde{n},\tilde{k},\tilde{\alpha}}|.$$

The second inequality follows from Claim 9. The last inequality holds by Claim 8. ◁

By Claim 10, there exists $S \in F_{\tilde{n},\tilde{k},\tilde{\alpha}} \setminus R(I)$. Consider the induced oracle-EMB instance $I_S = I_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi_S)$ where $\Pi_S = \{S\}$, and let $B = \{b \in \{0,1\}^t \mid S \notin Q(b)\}$ be all strings for which S is not queried by $\mathcal{A}$ on the instance I. Observe that for all $b \in B$ it holds that the answers to all queries for $T \in Q(b)$ are the same for both oracles (of $M_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi_\emptyset)$ and $M_{\tilde{n},\tilde{k},\tilde{\alpha}}(\Pi_S)$). Moreover, the decision on which set to query next depends only on $b, \tilde{n}, \tilde{k}, \tilde{\alpha}$, and the answers to previous queries.

Hence, for all $b \in B$, the executions of $\mathcal{A}$ on the instances I and I_S are identical. Since $\Pi_\emptyset = \emptyset$, by Observation 7, I is a "no"-instance for oracle-EMB; thus, $\mathcal{A}$ returns that I_S is a "no"-instance for every $b \in B$. However, since $\mathsf{id}_n(S) = \mathsf{sum}(S) = \alpha$, $|S| = k$, and $S \in \Pi_S$, it follows that I_S is a "yes"-instance by Observation 7. Therefore, $\mathcal{A}$ does not decide I_S correctly for all $b \in B$. We give an illustration in Figure 2. Since $S \notin R(I)$, it holds that $\Pr\left(\bar{b} \in B\right) = \Pr\left(S \notin Q(\bar{b})\right) > \frac{1}{2}$; thus, with probability greater than $\frac{1}{2}$, $\mathcal{A}$ does not decide correctly the instance I_S. A contradiction to the correctness of $\mathcal{A}$ as a randomized algorithm for oracle-EMB. The statement of the theorem follows. ◀

3 Hardness of Matroid Optimization with a Linear Constraint

In this section we use Theorem 3 to prove Theorem 1. We apply the following reductions from EMB to MOL problems. Recall that $\mathcal{Q} = \mathcal{P} \setminus \{(\min, \text{IS}, \leq)\}$ is the set of parameters for non-trivial MOL problems. Given a P-MOL problem for some $P \in \mathcal{Q}$, and an EMB instance I, the reduction returns an instance $R_P(I)$ of the P-MOL problem. Note that the reduction is purely mathematical, and does not specify the encoding of the instance. This will be useful for obtaining our hardness results in non-oracle computational models (see Section 4).

Given $(\text{opt}, \mathcal{F}, \triangleleft), (\text{opt}', \mathcal{F}', \triangleleft') \in \mathcal{Q}$, we use the notation $(\text{opt is opt}')$, $(\mathcal{F}$ is $\mathcal{F}')$, $(\triangleleft$ is $\triangleleft')$ to denote the boolean expressions of equality between parameters of a MOL problem. For example, $(\text{opt is opt}')$ is *true* if and only if either opt, opt' are both max, or opt, opt' are both min.

▶ **Definition 11.** *Given an* EMB *instance* $I = (E, \mathcal{I}, c, T)$ *and* $P \in \mathcal{Q}$ *where* $P = (\text{opt}, \mathcal{F}, \triangleleft)$, *define the* reduced P-MOL instance *of* I, *denoted by* $R_P(I) = (E, \mathcal{I}, v_I, w_{I,P}, L_{I,P})$, *as follows.*

1. *Define the auxiliary variable*

$$d(P) = \begin{cases} 0 & \text{if } \Big((\text{opt is max}) \text{ and } (\triangleleft \text{ is } \leq)\Big) \text{ or } \Big((\text{opt is min}) \text{ and } (\triangleleft \text{ is } \geq)\Big) \\ 1 & \text{otherwise.} \end{cases}$$

   For example, if $P = (\max, \text{IS}, \leq)$ *then* $d(P) = 0$, *and if* $P' = (\max, \text{IS}, \geq)$ *then* $d(P') = 1$.
2. *Let* $H_I = 2 \cdot \max\{1, c(E)\}$.
3. *For all* $e \in E$ *let* $v_I(e) = H_I + c(e)$.
4. *For all* $e \in E$ *let* $w_{I,P}(e) = H_I + c(e) \cdot (-1)^{d(P)}$.
5. *Let* $k_I = \max_{S \in \mathcal{I}} |S|$ *be the rank of* $(E, \mathcal{I})$.
6. *Define* $L_{I,P} = k_I \cdot H_I + T \cdot (-1)^{d(P)}$.

Now, for every EMB instance $I = (E, \mathcal{I}, c, T)$, define the *error parameter* of I as

$$\varepsilon_I = \frac{1}{8 \cdot (|E| + 1) \cdot (T + 1) \cdot (c(E) + 1)}. \tag{5}$$

Indeed, since the value selected for of the error parameter is sufficiently small, we can use a $(1 + \varepsilon_I)$-approximation for $R_P(I)$ to decide an EMB instance I.

▶ **Theorem 12.** *Given an instance* $I = (E, \mathcal{I}, c, T)$ *of* EMB, *and* $P \in \mathcal{Q}$ *with* $P = (\text{opt}, \mathcal{F}, \triangleleft)$, *the following holds.*

1. *If there is a solution* S *for* $R_P(I)$ *such that* $v_I(S) = k_I \cdot H_I + T$, *then* I *is a "yes"-instance.*
2. *If* I *is a "yes"-instance then: (i)* $R_P(I)$ *has a solution, and (ii) every* $(1+\varepsilon_I)$*-approximate solution* S *for* $R_P(I)$ *satisfies* $v_I(S) = k_I \cdot H_I + T$.

Using Theorem 12 and an assumed randomized Fully PTAS for the P-MOL problem, we can decide EMB in time which contradicts Theorem 3. This gives the proof of Theorem 1. We first prove Theorem 1, and later give the proof of Theorem 12.

▶ **Theorem 1.** *For every* $P \in \mathcal{Q}$ *there is no randomized* Fully PTAS *for oracle* P-MOL.

Proof. Assume towards a contradiction that there is a randomized Fully PTAS $\mathcal{A}$ for oracle P-MOL. We use $\mathcal{A}$ to decide oracle-EMB. Let $I = (E, \mathcal{I}, c, T)$ be an oracle-EMB instance, and consider the following randomized algorithm $\mathcal{B}$ that decides I.

1. Construct the oracle P-MOL instance $R_P(I)$ with the membership oracle of $(E, \mathcal{I})$.
2. Execute $\mathcal{A}$ with the input $R_P(I)$ and ε_I.
3. If $\mathcal{A}$ returns that $R_P(I)$ does not have a solution − Return "no" on I.
4. Otherwise, let $S \leftarrow \mathcal{A}(R_P(I), \varepsilon_I)$ be the solution returned by $\mathcal{A}$.
5. Return "yes" on I if and only if $v_I(S) = H_I \cdot k_I + T$.

Let $n = |E| + 1$ and $m = c(E) + 1$. Note that $R_P(I)$ can be naively constructed from I in time $(n \cdot (T+2) \cdot m)^{O(1)}$ using Definition 11. As $\mathcal{A}$ is a randomized Fully PTAS for oracle P-MOL, and by the selection of the error parameter (5), the running time of $\mathcal{B}$ on I is $(n \cdot (T+2) \cdot m)^{O(1)}$. We now show correctness.

- If $\mathcal{B}$ returns "yes" on I, then Step 4 of the algorithm computes a solution S for $R_p(I)$ satisfying $v_I(S) = H_I \cdot k_I + T$. Thus, by Theorem 12, I is a "yes" instance.
- If I is a "yes" instance then $R_P(I)$ has a solution by Theorem 12. As $\mathcal{A}$ is a randomized Fully PTAS, with probability at least $\frac{1}{2}$ $\mathcal{A}$ returns a $(1+\varepsilon_I)$-approximate solution S for $R_P(I)$ in Step 4. By Theorem 12, $v_I(S) = H_I \cdot k_I + T$ (with probability at least $\frac{1}{2}$). Thus, $\mathcal{B}$ returns "yes" on I with probability at least $\frac{1}{2}$.

Hence, $\mathcal{B}$ is a randomized algorithm which decides the oracle-EMB instance I in time $(n \cdot (T+2) \cdot m)^{O(1)}$. This is a contradiction to Theorem 3. ◀

In the remainder of this section we prove Theorem 12. We start with some basic properties of the reduction outlined in Definition 11.

▶ **Lemma 13.** *Given an instance $I = (E, \mathcal{I}, c, T)$ of* EMB*, let $P \in \mathcal{Q}$ and consider a solution S for $R_P(I)$ satisfying $v_I(S) = k_I \cdot H_I + T$. Then, S is a solution for I.*

Proof. Let $\mathcal{M} = (E, \mathcal{I})$. As S is a solution for $R_P(I)$, it holds that $S \in \mathrm{IS}(\mathcal{M})$; thus, $|S| \leq k_I$. Assume towards contradiction that $|S| < k_I$. Then,

$$v_I(S) = |S| \cdot H_I + c(S) \leq (k_I - 1) \cdot H_I + c(S) \leq (k_I - 1) \cdot H_I + c(E) < k_I \cdot H_I \leq k_I \cdot H_I + T.$$

We reach a contradiction since $v_I(S) = k_I \cdot H_I + T$; thus, $|S| = k_I$, and

$$k_I \cdot H_I + T = v_I(S) = |S| \cdot H_I + c(S) = k_I \cdot H_I + c(S). \tag{6}$$

As $|S| = k_I$, we have that S is a basis of $\mathcal{M}$, and by (6), $c(S) = T$. Hence, S is a solution for I. ◀

The next result is the converse of the statement in Lemma 13.

▶ **Lemma 14.** *Let S be a solution for a given* EMB *instance $I = (E, \mathcal{I}, c, T)$, and let $P \in \mathcal{Q}$ where $P = (\mathrm{opt}, \mathcal{F}, \triangleleft)$. Then, S is a solution for $R_P(I)$ of value $v_I(S) = k_I \cdot H_I + T$.*

Proof. Let $\mathcal{M} = (E, \mathcal{I})$. Since S is a solution for I we have $S \in \mathrm{bases}(\mathcal{M})$; thus, $S \in \mathcal{F}(\mathcal{M})$. Then,

$$w_{I,P}(S) = |S| \cdot H_I + c(S) \cdot (-1)^{d(P)} = k_I \cdot H_I + T \cdot (-1)^{d(P)} = L_{I,P}.$$

The second equality holds since S is a solution for I; thus, $|S| = k_I$ (as S is a basis of $\mathcal{M}$), and $c(S) = T$. We conclude that S is a solution for $R_P(I)$. Finally, note that S satisfies

$$v_I(S) = |S| \cdot H_I + c(S) = k_I \cdot H_I + T$$ ◀

The next claim gives an upper bound on the optimal value for maximization MOL problems. We then derive an analogous lower bound for minimization (non-trivial) MOL problems.

▶ **Lemma 15.** *Let $I = (E, \mathcal{I}, c, T)$ be an* EMB *instance and $P \in \mathcal{Q}$, where $P = (\text{opt}, \mathcal{F}, \triangleleft)$ and* (opt is max)*. Then, for every solution S of $R_P(I)$ it holds that $v_I(S) \leq k_I \cdot H_I + T$.*

Proof. Let S be an optimal solution for $R_P(I)$. Thus, $|S| \leq k_I$ as $S \in \mathcal{I}$. If $|S| < k_I$ then

$$v_I(S) \leq (k_I - 1) \cdot H_I + c(S) \leq (k_I - 1) \cdot H_I + c(E) < k_I \cdot H_I \leq k_I \cdot H_I + T.$$

Otherwise, $|S| = k_I$. Consider the two cases for $\triangleleft$.

1. ($\triangleleft$ is $\leq$). Then, $d(P) = 0$ (see Definition 11); thus, since S is a solution for $R_P(I)$:

$$v_I(S) = w_{I,P}(S) \leq L_{I,P} = k_I \cdot H_I + T.$$

2. ($\triangleleft$ is $\geq$). Then, $d(P) = 1$. As S is a solution for $R_P(I)$,

$$k_I \cdot H_I - c(S) = |S| \cdot H_I - c(S) = w_{I,P}(S) \geq L_{I,P} = k_I \cdot H_I - T. \tag{7}$$

By (7), it follows that $c(S) \leq T$; thus, $v_I(S) = k_I \cdot H_I + c(S) \leq k_I \cdot H_I + T$.

In all the above cases, we have that $v_I(S) \leq k_I \cdot H_I + T$, implying the statement of the lemma. ◀

Now, for minimization problems we have the next result.

▶ **Lemma 16.** *Let $I = (E, \mathcal{I}, c, T)$ be an* EMB *instance, and $P \in \mathcal{Q}$, where $P = (\text{opt}, \mathcal{F}, \triangleleft)$ and* (opt is min)*. Then, for every solution S of $R_P(I)$, it holds that $v_I(S) \geq k_I \cdot H_I + T$.*

Using Lemmas 13–16, we can now prove Theorem 12.

▶ **Theorem 12.** *Given an instance $I = (E, \mathcal{I}, c, T)$ of* EMB*, and $P \in \mathcal{Q}$ with $P = (\text{opt}, \mathcal{F}, \triangleleft)$, the following holds.*

1. *If there is a solution S for $R_P(I)$ such that $v_I(S) = k_I \cdot H_I + T$, then I is a "yes"-instance.*
2. *If I is a "yes"-instance then: (i) $R_P(I)$ has a solution, and (ii) every $(1+\varepsilon_I)$-approximate solution S for $R_P(I)$ satisfies $v_I(S) = k_I \cdot H_I + T$.*

Proof. We note that Property 1 follows directly from Lemma 13. For Property 2, assume that I is a "yes"-instance, then by Lemma 14, there is a solution D for $R_P(I)$ such that $v_I(D) = H_I \cdot k_I + T$. It remains to show Property 2. (ii). Let S be a $(1 + \varepsilon_I)$-approximate solution for $R_P(I)$. We distinguish between two cases.

1. (opt is max). Then, by Lemma 15,

$$0 \leq H_I \cdot k_I + T - v_I(S).$$

Moreover, since S is a $(1 + \varepsilon_I)$-approximate solution for $R_P(I)$, and D is a solution for $R_P(I)$,

$$H_I \cdot k_I + T - v_I(S) \leq H_I \cdot k_I + T - \frac{v_I(D)}{(1 + \varepsilon_I)} = \frac{\varepsilon_I \cdot (H_I \cdot k_I + T)}{(1 + \varepsilon_I)} \leq \varepsilon_I \cdot (H_I \cdot k_I + T).$$

By the above, it follows that

$$|v_I(S) - (H_I \cdot k_I + T)| \leq \varepsilon_I \cdot (H_I \cdot k_I + T).$$

2. (opt is min). This case is analogous to the above. By Lemma 16,

$$0 \leq v_I(S) - (H_I \cdot k_I + T)\,.$$

Since S is a $(1+\varepsilon_I)$-approximate solution for $R_P(I)$, and D is a solution for $R_P(I)$,

$$v_I(S) - (H_I \cdot k_I + T) \leq (1+\varepsilon_I) \cdot v_I(D) - (H_I \cdot k_I + T) = \varepsilon_I \cdot (H_I \cdot k_I + T)\,.$$

By the above,

$$|v_I(S) - (H_I \cdot k_I + T)| \leq \varepsilon_I \cdot (H_I \cdot k_I + T)\,.$$

Thus in both cases it holds that,

$$|v_I(S) - (H_I \cdot k_I + T)| \leq \varepsilon_I \cdot (H_I \cdot k_I + T)\,. \tag{8}$$

Let $n = |E| + 1$ and $m = c(E) + 1$. Then, by the selection of ε_I in (5),

$$\varepsilon_I \cdot (H_I \cdot k_I + T) = \frac{H_I \cdot k_I + T}{8 \cdot n \cdot (T+1) \cdot m} \leq \frac{2 \cdot m \cdot n + T}{8 \cdot n \cdot (T+1) \cdot m} < \frac{4 \cdot m \cdot n \cdot (T+1)}{8 \cdot n \cdot (T+1) \cdot m} = \frac{1}{2}. \tag{9}$$

The first inequality holds since $k_I \leq |E|$ and $H_I \leq 2 \cdot m$. Therefore, by (8) and (9),

$$|v_I(S) - (H_I \cdot k_I + T)| \leq \varepsilon_I \cdot (H_I \cdot k_I + T) < \frac{1}{2}. \tag{10}$$

Since $v_I(S) \in \mathbb{N}$ by Definition 11, it follows from (10) that $v_I(S) = H_I \cdot k_I + T$. This gives the statement of the theorem. ◀

4 Lower Bounds in the Standard Computational Model

Our hardness result in Section 2 shows that oracle Exact Matroid Basis (EMB) is hard, leading to the unconditional lower bounds for all non-trivial oracle MOL problems in Section 3. Nonetheless, these hardness results consider matroids with general membership oracles, and do not give a lower bound for matroids that can be efficiently encoded. This is particularly important, as in some settings oracle models differ from non-oracle models w.r.t complexity [6, 9]. Moreover, some matroids show up in problems that can be encoded efficiently. This includes partition matroids, graphic matroids, linear matroids, etc (see, e.g., [37] for a survey on various families of matroids). Next, we formally define an efficient encoding of matroids.

▶ **Definition 17.** *A function $f : \{0,1\}^* \to 2^{\mathbb{N}} \times 2^{2^{\mathbb{N}}}$ is called* matroid decoder *if for every $I \in \{0,1\}^*$ it holds that $f(I) = \left(E_{f(I)}, \mathcal{I}_{f(I)}\right)$ is a matroid, and the following holds.*

1. *There is an algorithm that given $I \in \{0,1\}^*$ returns $E_{f(I)}$ in time $|I|^{O(1)}$.*
2. *There is an algorithm that given $I \in \{0,1\}^*$ and $S \subseteq E_{f(I)}$ decides if $S \in \mathcal{I}_{f(I)}$ in time $|I|^{O(1)}$.*

There is a simple matroid decoder that can decode every matroid $(E, \mathcal{I})$ (such that $E \subseteq \mathbb{N}$), in which the encoding I explicitly lists $\mathcal{I}$. However, using such a matroid decoder, the encoding size of a matroid might be very large, up to $|I| = \Omega\left(2^{|E|}\right)$, while we often seek algorithms with running times polynomial in $|E|$. One way to overcome this difficulty is via the oracle model considered in previous sections. However, our results in this model may suggest that the hardness of EMB and MOL problems is due to the intrinsic hardness of the oracle model. Yet, there are families of matroids with very efficient encoding. For

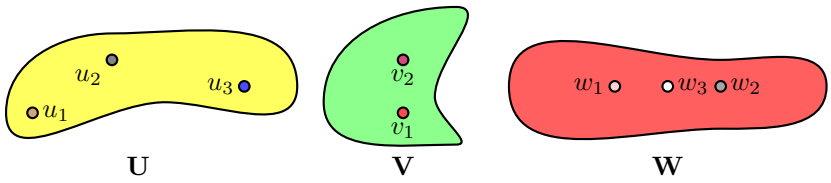

Figure 3 An example of a *partition matroid* $(E, \mathcal{I})$, which can be efficiently encoded. The ground set is $E = \{u_1, u_2, u_3, v_1, v_2, w_1, w_2, w_3\}$, partitioned into three sets: U, V, W. The independent sets are all subsets of E containing at most one element from U, V, and W; that is, $\mathcal{I} = \{S \subseteq E \mid \forall X \in \{U, V, W\} : |S \cap X| \leq 1\}$. A simple efficient encoding of $(E, \mathcal{I})$ is $I = (E, U, V, W)$. Membership can be decided efficiently given I, by checking the feasibility of a given set S w.r.t. U, V and W.

example, a *uniform matroid* $(E, \mathcal{I})$, where $\mathcal{I} = \{S \subseteq E \mid |S| \leq k\}$, can be efficiently encoded using $I = (E, k) \in \{0,1\}^*$. Clearly, the time to decide membership of a given subset $S \subseteq E$ depends only on $|S|$ and k. Another example is given in Figure 3.

We start with a definition of an encoded variant of EMB. We technically define a different problem for every decoder f. The definition of the problem is analogous to the versions of EMB considered earlier in the paper, besides that the matroid is given via an arbitrary bit-string $I \in \{0,1\}^*$, that a matroid decoder f decodes into a matroid $f(I)$.

f-DECODED EXACT MATROID BASIS **(f-decoded EMB)**
Decoder $f : \{0,1\}^* \to 2^{\mathbb{N}} \times 2^{2^{\mathbb{N}}}$ is a matroid decoder.
Instance (I, c, T), where $I \in \{0,1\}^*$, $c : E_{f(I)} \to \mathbb{N}$, $T \in \mathbb{N}$.
Solution A basis S of the matroid $f(I)$ such that $c(S) = T$.
Objective Decide if there is a solution.

▶ **Definition 18.** *The* f-DECODED EXACT MATROID BASIS *(f-decoded EMB) problem is defined as follows.*

- ***Decoder:*** *$f : \{0,1\}^* \to 2^{\mathbb{N}} \times 2^{2^{\mathbb{N}}}$ is a matroid decoder.*
- ***Instance:*** *(I, c, T), where $I \in \{0,1\}^*$, $c : E_{f(I)} \to \mathbb{N}$, $T \in \mathbb{N}$.*
- ***Solution:*** *A basis S of the matroid $f(I)$ such that $c(S) = T$.*
- ***Objective:*** *Decide if there is a solution.*

As a simple example, consider the f_{u}-decoded EMB problem, for a specific matroid decoder f_{u} that decodes uniform matroids. The matroid decoder f_{u} interprets every $I \in \{0,1\}^*$ as $I = (E, k)$ where E is a set (of numbers) and $k \in \mathbb{N}$, and returns the uniform matroid $f_{\mathsf{u}}(I) = (E, \mathcal{I})$ such that $\mathcal{I} = \{S \subseteq E \mid |S| \leq k\}$; clearly, f_{u} is a matroid decoder. Thus, an instance of f_{u}-decoded EMB is a tuple $U = ((E, k), c, T)$ and a solution of U is $S \subseteq E$ such that $|S| = k$ and $c(S) = T$; the goal, as before, is to decide if there is a solution. This problem is commonly known as the k-SUBSET SUM.

Recall that Theorem 3 asserts that oracle-EMB does not admit a pseudo-polynomial time algorithm. However, this does not rule out that hypothetically, for every matroid decoder f there is a pseudo-polynomial time algorithm for f-decoded EMB. The next result excludes this option.

▶ **Theorem 19.** *Assuming* P $\neq$ NP*, there is a matroid decoder f such that there is no algorithm for f-*decoded EMB *that for any f-*decoded EMB *instance $U = (I, c, T)$, where $n = |E_{f(I)}| + 1$ and $m = c(E_{f(I)}) + 1$, runs in time $(n \cdot (T+2) \cdot m)^{O(1)}$.*

The proof of Theorem 19 is given towards the end of this section. Analogously to our hardness result for oracle MOL problems, we use Theorem 19 to give a hardness result for an encoded version of MOL problems. For every matroid decoder f and every $P \in \mathcal{P}$, we define a variant of the P-MATROID OPTIMIZATION WITH A LINEAR CONSTRAINT (P-MOL) problem in which the matroid is given via an arbitrary bit-string which a matroid decoder f decodes into a matroid. Formally, let $P \in \mathcal{P}$, where $P = (\text{opt}, \mathcal{F}, \triangleleft)$, be the parameters of the P-MOL problem. For a matroid decoder f, we define the f-decoded P-MOL problem as follows.

▶ **Definition 20.** *The f-*DECODED *P-*MATROID OPTIMIZATION WITH A LINEAR CONSTRAINT *(f-decoded P-MOL) problem is defined as follows.*

- ***Decoder:*** $f : \{0,1\}^* \to 2^{\mathbb{N}} \times 2^{2^{\mathbb{N}}}$ *is a matroid decoder.*
- ***Instance:*** (I, v, w, L)*, where* $I \in \{0,1\}^*$*,* $v : E_{f(I)} \to \mathbb{R}_{\geq 0}$*,* $w : E_{f(I)} \to \mathbb{R}_{\geq 0}$*,* $L \in \mathbb{R}_{\geq 0}$*.*
- ***Solution:*** *A basis* S *of the matroid* $f(I)$ *such that* $c(S) = T$*.*
- ***Objective:*** opt $v(S)$ *s.t.* $S \in \mathcal{F}\left(f(I)\right),\ w(S) \triangleleft L$*.*

For example, consider the encoded version of the P-MOL for $P = (\max, \text{IS}, \leq)$ with the matroid decoder f_{u} that decodes uniform matroids. An instance of the f_{u}-decoded P-MOL problem is a tuple $U = (I, v, w, L)$ where $I = (E, k)$ is a bit-string used for extracting the uniform matroid $f_{\mathsf{u}}(I) = (E, \mathcal{I})$ such that $\mathcal{I} = \{S \subseteq E \mid |S| \leq k\}$, v is the value function, w is the weight function, and L is the bound. A *solution* of U is $S \subseteq E$ such that $|S| \leq k$ and $w(S) \leq L$; the goal is to find a solution S of maximum value $v(S)$. This problem is widely known as KNAPSACK WITH CARDINALITY CONSTRAINT.

Recall that $\mathcal{Q} = \mathcal{P} \setminus \{(\min, \text{IS}, \leq)\}$ is the set of parameters for non-trivial MOL problems. Using the hardness of f-decoded, for some matroid decoder f (details on f are given towards the end of the section), we show the hardness of the f-decoded variant of all non-trivial MOL problems.

▶ **Theorem 21.** *Assuming* P $\neq$ NP*, for any $P \in \mathcal{Q}$ there is a matroid decoder f such that there is no* Fully PTAS *for f-*decoded *P-*MOL*.*

In the remainder of this section, we prove Theorem 19 and Theorem 21. The matroid decoder used in our proofs decodes a subclass of the Π-matroid family (see Section 2), in which the secret family Π consists of the solutions for a BOOLEAN SATISFIABILITY PROBLEM (SAT) instance.

In a SAT instance $A = (V, \bar{V}, \mathcal{C})$ with $n \in \mathbb{N}$ variables (in a slightly simplified notation), we are given a set $V = \{v_1, \ldots, v_n\}$ of variables, their negations $\bar{V} = \{\bar{v}_1, \ldots, \bar{v}_n\}$, and a set $\mathcal{C} \subseteq 2^{V \cup \bar{V}}$ of clauses. The goal is to decide if there is a set $S \subseteq [n]$ satisfying that for all $C \in \mathcal{C}$ there is $i \in [n]$ such that one of the following holds.

- $v_i \in C$ and $i \in S$.
- $\bar{v}_i \in C$ and $i \notin S$.

Such a set S is called a *solution* of A; let $\mathcal{S}(A)$ be the set of solutions of a SAT instance A. In addition, let $n(A) = n$ be the number of variables in the instance A. The family of SAT-matroids is the subfamily of Π-matroids where $\Pi = \mathcal{S}(A)$ for some SAT instance A (for the notation and definition of Π-matroids, see Definition 4). Specifically,

▶ **Definition 22.** *Let A be a* SAT *instance, $k \in [n(A)]$, and $\alpha \in \left[n(A)^2\right]$. Define the* **SAT-matroid** *on A, k, α as $M_{n(A),k,\alpha}(\mathcal{S}(A)) = \left([n(A)], \mathcal{I}_{n(A),k,\alpha}(\mathcal{S}(A))\right)$.*

We show below that SAT-matroids can be encoded efficiently. For every $I \in \{0,1\}^*$, we interpret I as $I = (A, k, \alpha)$, where A is a SAT instance, $k \in [n(A)]$, and $\alpha \in \left[n(A)^2\right]$; w.l.o.g., we may assume that every $I = (A, k, \alpha) \in \{0,1\}^*$ can be interpreted in that manner; moreover, we can assume that $n(A) \leq |A|$, where $|A|$ is the encoding size of A. The following definition defines a matroid decoder that decodes SAT-matroids from a bit-string.

▶ **Definition 23.** *Define the* SAT-decoder *as the function* $f_{\text{SAT}} : \{0,1\}^* \to 2^{\mathbb{N}} \times 2^{2^{\mathbb{N}}}$ *such that for all* $I = (A, k, \alpha) \in \{0,1\}^*$ *it holds that* $f_{\text{SAT}}(I) = M_{n(A),k,\alpha}(\mathcal{S}(A))$.

In the next result, we show that the SAT-decoder f_{SAT} is indeed a matroid decoder.

▶ **Lemma 24.** f_{SAT} *is a matroid decoder such that* $|I| = |A|^{O(1)}$ *for every* $I = (A, k, \alpha) \in \{0,1\}^*$.

Recall the sets $\mathcal{J}_{n,k}$, $\mathcal{K}_{n,k,\alpha}$, $\mathcal{L}_{n,k,\alpha}(\Pi)$ and $\mathcal{I}_{n,k,\alpha}(\Pi)$ were defined in Definition 4. We will use an algorithm for f-decoded EMB to obtain an algorithm for SAT. To this end, consider the following family of *structured* f_{SAT}-decoded EMB instances.

▶ **Definition 25.** *An* f_{SAT}-DECODED EMB *instance* (I, c, T)*, where* $I = (A, k, \alpha)$ *is called* structured *if* $\alpha \in \left[n(A)^2\right]$*,* $T = \alpha$*, and* $c : [n(A)] \to \mathbb{N}$ *such that for all* $i \in [n(A)]$ *it holds that* $c(i) = i$

The next observation immediately follows from the definition of structured f_{SAT}-decoded EMB instances and SAT-matroids.

▶ **Observation 26.** *for any structured* f_{SAT}-DECODED EMB *instance* $U = (I, c, T)$*, where* $I = (A, k, \alpha)$*, and* $S \subseteq [n(A)]$*, it holds that:* S *is a solution for* U *if and only if* $S \in \mathcal{S}(A)$*,* $|S| = k$*, and* $\mathsf{sum}(S) = c(S) = \alpha$.

We show that given a polynomial algorithm that decides structured f_{SAT}-decoded EMB instances, we can decide SAT. This result easily imply Theorem 19 as shown afterwards.

▶ **Lemma 27.** *Assuming* P $\neq$ NP*, there no algorithm that decides every* f_{SAT}*-decoded* EMB *structured instance* (I, c, T) *in time* $|I|^{O(1)}$.

From the above result, the hardness of the more general f_{SAT}-decoded EMB easily follows. As an immediate corollary, Theorem 28 gives the proof of Theorem 19.

▶ **Theorem 28.** *Assuming* P $\neq$ NP*, there is no algorithm for* f_{SAT}*-decoded* EMB *that runs in time* $(n \cdot (T+2) \cdot m)^{O(1)}$*, for any* f_{SAT}*-decoded* EMB *instance* $U = (I, c, T)$ *where* $n = \left|E_{f_{\text{SAT}}(I)}\right| + 1$ *and* $m = c\left(E_{f_{\text{SAT}}(I)}\right) + 1$.

Finally, we show that the variants of non-trivial matroid optimization with a linear constraint (MOL) problems, in which the decoding is performed by the SAT-decoder f_{SAT}, do not admit Fully PTAS under the standard assumption P $\neq$ NP. The proof is similar to the proof of Theorem 1 in Section 3. Lemma 29 directly gives the proof of Theorem 21.

▶ **Lemma 29.** *Assuming* P $\neq$ NP*, for any* $P \in \mathcal{Q}$ *there is no* Fully PTAS *for* f_{SAT}-decoded P-MOL.

5 Discussion

In this paper, we derive lower bounds for a family of matroid optimization problems with a linear constraint. We show that none of the (non-trivial) members of this family admits a Fully PTAS. In particular, this rules out a Fully PTAS for well studied problems such as BUDGETED MATROID INDEPENDENT SET, CONSTRAINED MINIMUM BASIS OF A MATROID, and KNAPSACK COVER WITH A MATROID. As BM and CMB admit an Efficient PTAS, our lower bounds resolve the complexity status of these problems, which has been open also for the generalization of BUDGETED MATROID INTERSECTION [12, 2, 17]. Our preliminary study shows that using the techniques of [26], we may be able to derive Efficient PTAS for *all* MOL problems. This would imply that Theorem 1 gives a tight lower bound for the entire MOL family. We leave the details for future work.

A key result of this paper is that EXACT MATROID BASIS (EMB) does not admit a pseudo-polynomial time algorithm, unlike the known special cases of k-SUBSET SUM and EMB on a linear matroid. Our proofs can be used to obtain lower bounds for other problems. For example, the hardness result for EMB can be adapted to yield lower bounds for related *parameterized* problems [22, 16]. Moreover, the proof of Theorem 1 can be modified to show that an Efficient PTAS for a non-trivial MOL problem with running time $f\left(\frac{1}{\varepsilon}\right)\cdot\text{poly}(n)$ must satisfy $f\left(\frac{1}{\varepsilon}\right)=\Omega\left(2^{\varepsilon^{-\frac{1}{4}}}\right)$. We leave these generalizations of our results to a later version of this paper.

Our results build on the Π-matroid family introduced in this paper. Such matroids exploit the interaction between a weight function and the underlying matroid constraint of the given problem. Aside from the implications of our results for previously studied problems, the new subclass of Π-matroids may enable to derive lower bounds for other problems. For example, consider the generalization of BM where the objective function is submodular and monotone. This is known as monotone submodular maximization with a knapsack and a matroid constraint [11]. Indeed, if the knapsack constraint is removed, there is a tight $\left(1-\frac{1}{e}\right)$-approximation for the problem [4]. The same bound holds if we relax the matroid constraint [40]. However, the best known approximation for the problem with a knapsack and a matroid constraint is $\left(1-\frac{1}{e}-\varepsilon\right)$ [11]. This setting resembles the status of MOL problems prior to our work, where removing either the linear or the matroid constraint induces a substantially easier problem. The potential use of Π-matroid variants to rule out a $\left(1-\frac{1}{e}\right)$-approximation for the above problem remains an interesting open question.

In the context of solving *configuration* LPs for packing problems with a matroid constraint (e.g., [24, 15]), our lower bound implies that an FPTAS for an LP in this class cannot be obtained using the standard ellipsoid method.

We show unconditional hardness results in the oracle model (even if randomization is allowed), and give analogous lower bounds where the matroids are encoded as part of the input, assuming P $\neq$ NP. Our construction in Section 4 can be used to derive hardness results for other matroid problems in non-oracle models. Specifically, we can obtain in the standard computational model hardness results analogous to those in the oracle model of [28]. This includes a proof that it is NP-hard to decide if a given matroid is uniform, analogous to the unconditional hardness result in the oracle model of [28]. We leave these results for future work.

Our lower bounds for MOL problems on general matroids call for a more comprehensive study of these problems on restricted classes of matroids. We note the existence of Fully PTASs for MOL problems on some restricted matroid classes, e.g., BM on a laminar matroid or KCM on a partition matroid. The question whether (non-trivial) MOL problems admit

Fully PTAS on broader matroid classes, such as graphical matroids or linear matroids, remains open. In particular, it would be interesting to obtain a Fully PTAS for CONSTRAINED MINIMUM SPANNING TREE [26] and BM on a linear matroid − or show that one does not exist.

Non-Linear Paging

Ilan Doron-Arad

Computer Science Department, Technion, Haifa, Israel

Abstract

We formulate and study *non-linear paging* - a broad model of online paging where the size of subsets of pages is determined by a monotone non-linear set function of the pages. This model captures the well-studied classic weighted paging and generalized paging problems, and also *submodular* and *supermodular* paging, studied here for the first time, that have a range of applications from virtual memory to machine learning.

Unlike classic paging, the cache threshold parameter k does not yield good competitive ratios for non-linear paging. Instead, we introduce a novel parameter ℓ that generalizes the notion of cache size to the non-linear setting. We obtain a tight deterministic ℓ-competitive algorithm for general non-linear paging and a $o\left(\log^2(\ell)\right)$-competitive lower bound for randomized algorithms. Our algorithm is based on a new generic LP for the problem that captures both submodular and supermodular paging, in contrast to LPs used for submodular cover settings. We finally focus on the supermodular paging problem, which is a variant of online set cover and online submodular cover, where sets are repeatedly requested to be removed from the cover. We obtain polylogarithmic lower and upper bounds and an offline approximation algorithm.

1 Introduction

In the well studied *paging* problem, we are given a collection of n pages and a cache that can contain up to k pages simultaneously, where $k < n$. At each time step, one of the pages is requested. If the requested page is already in the cache, the request is immediately served. Otherwise, there is a *cache miss* and the requested page is fetched to the cache; to ensure that the cache contains at most k pages, some other page is potentially evicted. In the most fundamental model, the goal is to minimize the number of cache misses (or equivalently, number of evictions).

In more general models, pages may have different sizes and costs (see, e.g., [1, 5]) and then the sum of the sizes of the pages in cache cannot exceed its capacity. However, a linear function over page sizes that defines cache feasibility fails to capture scenarios with more involved relations between subsets of pages that can reside together in cache. Consider a system in which pages share parts of their memory and then only the missing memory parts of a requested page can contribute to the increase in cache size. This setting can be modeled using a *submodular* function that defines cache feasibility. Another example is a setting in

which items stored in cache have dependencies yielding additional overhead in their mutual storage demand. The *rule caching* problem is one such setting and it has been well studied in networking [12, 46, 37, 21, 25, 39, 24, 17, 9, 35, 26, 16, 45, 34, 33, 47, 13].

Our focus in this paper will be on settings where such non-linear behavior exists. We will further motivate our model in detail in Section 1.2.

1.1 Our Model

Before presenting our model, we give some required preliminary definitions. Let $\mathcal{P}$ be a set and let $f : 2^{\mathcal{P}} \to \mathbb{N}$ be a set function of $\mathcal{P}$. The function f is called *monotone* if for every $S \subseteq \mathcal{P}$ and $S' \subseteq S$ it holds that $f(S') \leq S$. In addition, f is called *submodular* if for every $S, S' \subseteq \mathcal{P}$ it holds that $f(S) + f(S') \geq f(S \cup S') + f(S \cap S')$. Conversely, f is called *supermodular* if for every $S, S' \subseteq \mathcal{P}$ it holds that $f(S) + f(S') \leq f(S \cup S') + f(S \cap S')$.

In this work, we introduce a very general model of paging with an arbitrary function defining cache feasibility. In the *non-linear paging* problem, we are given a collection $\mathcal{P}$ of n pages where each page $p \in \mathcal{P}$ has a fixed eviction cost $c(p)$. We are also given a monotone *feasibility* function $f : 2^{\mathcal{P}} \to \mathbb{N}$ that assigns a value to every subset of pages, indicating their size. Finally, we are given a cache threshold k. As in standard paging, in each time step t there is a request p_t for one of the pages. If p_t is already in cache, the request is immediately served. Otherwise, p_t is fetched to the cache and possibly some subset of pages is evicted to ensure that the set of pages in the cache, denoted by S_t, is feasible, i.e., $f(S_t) \leq k$. The goal is to minimize the total cost incurred from page evictions. The classic paging problem is obtained by setting $f(S) = |S|$ for all $S \subseteq \mathcal{P}$. Other interesting applications of our model are described below.

- *Generalized Paging* [5, 1]. Here the feasibility function is linear; that is, for every $S \subseteq \mathcal{P}$ it holds that $f(S) = \sum_{p \in S} f(p)$, where $f(p)$ is the size of page $p \in \mathcal{P}$.
- *Submodular Paging.* The feasibility function is *submodular*. A natural application of this variant is to settings where pages share memory items (see Section 1.2).
- *Supermodular Paging.* The feasibility function is *supermodular*, implying a submodular cover function for pages remaining out of the cache. This setting effectively captures online submodular covering problems [2, 23, 20]. Supermodular paging will be the main focus of our paper.

Supermodular paging is a variant of *online set cover* [2] and *online submodular cover* [20]. In online set cover, we are given a ground set X and a family $\mathcal{S}$ of subsets of X. Requests for elements of X arrive online; if a requested element is not already covered by a previously chosen set, a set $S \in \mathcal{S}$ containing it is chosen, paying a cost $c(S)$. The goal is to minimize the cost of the selected sets. Online submodular cover generalizes online set cover - the goal is to cover a general (monotone) submodular function with an increasing cover demand over time. In supermodular paging (submodular cover), the cover demand does not change over time, as the same page (a set $S \in \mathcal{S}$ in online set cover) may be requested (removed from the cover) multiple times. We show in the full version of the paper (see [14]) that supermodular paging is even more challenging than (online) submodular cover.

1.2 Motivation

Non-linear paging generalizes several fundamental caching problems, capturing many real world applications. Besides known applications of the classic paging models with linear feasibility functions [38, 15, 4, 5, 1], there are many scenarios in which the interaction between

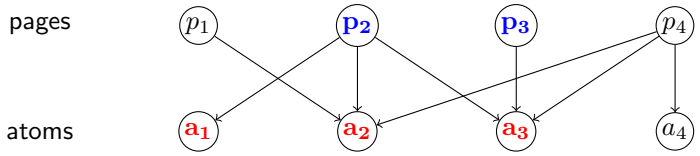

Figure 1 An illustration of a shared memory systems with four pages and four shared memory units ("atoms"). The cache is of size $k = 3$ and contains pages p_2, p_3 (in blue) whose shared memory is of size 3 - the three red atoms. Observe that either fetching p_1 or evicting it will not change the number of atoms stored in cache, however, fetching p_4 requires evicting p_2.

pages is non-linear, requiring the more general non-linear paging model. As already indicated, supermodular paging roughly generalizes online set cover and therefore has both theoretical and practical importance [20, 2]. We describe below several interesting applications of non-linear paging.

A major motivation for the study of non-linear paging is caching in shared memory systems (e.g., [28, 7, 43, 40]). Each process in a multi-process memory system is associated with a *virtual memory* [11], providing the illusion that it has a much larger memory. In some shared memory systems, caching policies are defined over entire processes, that is, the entire virtual address space of a process can be taken to the cache. Since the virtual memory of two processes typically overlaps in physical memory, the increase in (physical) memory in cache is larger if the cache is empty, as the entire memory of a process is loaded to the cache. In contrast, if the cache is nearly full, and a process is loaded to the cache, the increase in total size is smaller, as most of the virtual memory addresses are already in cache. In a similar vein, when caching hot data at the network edge, to avoid serving requests from a remote cloud, space efficiency of similar files is achieved through *deduplication* (e.g. [27]), which is very similar to the way overlaps are handled in virtual memory.

Thus, caching in shared memory systems is a special case of submodular paging. More formally, consider a cache that can store up to k *atoms* from a larger set $A = \{a_1, \ldots, a_n\}$ spanning the physical memory. Each page (process) p contains a subset of atoms $a(p) \subseteq A$ corresponding to the physical memory to which process p is mapped. The feasibility function f ensures that a collection S of pages contains jointly at most k atoms. Thus, $f(S) = \left|\bigcup_{p \in S} a(p)\right|$, and it is a submodular function. See Figure 1 for an illustration.

Paging with a supermodular feasibility function arises in common settings where the storage demand grows rapidly as a function of the number of "pages" stored in cache. In these scenarios, there is a large set of n *entities* (corresponding to vertices), and among subsets of entities certain interactions exist (represented by hyperedges). This data structure, known as a hypergraph, is ubiquitous in applications such as recommendation systems [19, 41] (where vertices represent individuals and hyperedges represent communities), image retrieval [29](vertices represent images and hyperedges represent correlations), and bioinformatics [32] (vertices represent substances and hyperedges stand for biochemical interactions). Other applications arise in machine learning [42, 18, 49] and databases [6].

In various practical settings, the hypergraph is very large (e.g., [36, 31, 22]). Therefore, a natural approach is to store frequently accessed vertices in a cache. However, caching is effective only if all interactions (i.e., hyperedges) among subsets of vertices in cache are also stored therein. As a set of x vertices may have up to 2^x induced hyperedges, the storage demand for hyperedges tends to be significantly larger compared to the number of vertices. Caching hypergraphs in the non-linear paging framework can be formally defined as follows:

consider a set $\mathcal{P}$ of vertices and define a feasibility function f over $\mathcal{P}$, such that for a subset of vertices $S \subseteq \mathcal{P}$, the storage demand $f(S)$ is the number of induced hyperedges in S plus the cardinality of S. Function f is a supermodular function.

For example, a real-world problem related to supermodular paging is caching in device-to-device (D2D) communication networks, with social ties among users and common interests that are used as key factors in determining the caching policy and are modeled via a hypergraph [3]. Here, the number of hyperedges (describing roughly interferences among users of the network, content, transmission rate, etc.) grows in a supermodular manner with respect to the number of users placed in cache. In addition, our reduction from online set cover (similarly, online submodular cover) to supermodular paging implies that applications of online set cover are also applications of supermodular paging.

1.3 Our Results and Techniques

We now present our results and elaborate on the techniques used. We start with general non-linear paging and then proceed to the special case of supermodular paging.

1.3.1 General Non-Linear Paging

In classic paging models, competitive ratios are typically given as a function of k, the cache size. However, non-linear paging is more difficult. Even for non-linear paging instances with $k = 0$ the competitive ratio can be very high. For example, consider a (classic) paging instance I' with cache threshold k'; define a non-linear paging instance I with a (non-linear) feasibility function f for which $f(S) = 0$ if S is feasible for I' and $f(S) = 1$ otherwise. In addition, we set $k = 0$ as the cache threshold of I. Clearly, a solution for I implies a solution for I'. Hence, by the hardness of paging [38, 15] the best competitive ratio of non-linear paging is arbitrarily large as a function of k (we give the remaining details in [14]). Thus, instead of k, we look for a parameter that better captures the competitiveness of general non-linear paging. This parameter turns out to be the maximum cardinality of a *minimally infeasible* set, i.e., an infeasible set where every proper subset of it is feasible[1]. Formally,

▶ **Definition 1.** *A set $S \subseteq \mathcal{P}$ is called* feasible *if $f(S) \leq k$ and is* infeasible *otherwise. Additionally, S is* minimally infeasible *if S is infeasible and every $S' \subset S$ is feasible, and let $\mathcal{M} = \{S \subseteq \mathcal{P} \mid f(S) > k \text{ and } f(S') \leq k \ \forall S' \subset S\}$ be all minimally infeasible sets. Finally, let the* width *of f be*

$$\ell(f) = \max_{S \in \mathcal{M}} (|S| - 1) .$$

We simply let $\ell = \ell(f)$ when it is clear from context. Clearly, for paging (or weighted paging) the width ℓ equals k. Hence, the width accurately captures the optimal performance of paging algorithms: there is a tight ℓ-competitive deterministic algorithm [38] and a tight $\Theta(\log(\ell))$-competitive randomized algorithm [15]. However, the width behaves quite differently in other scenarios. For example, in the setting of submodular paging described in Section 1.2, the instance can have a fixed width $\ell = O(1)$, but the number of pages in cache can be unbounded (e.g., all pages use the same atom). Interestingly, we show that the width gives a tight competitive ratio also for general non-linear paging via a new LP for the problem (see Sections 2 and 2.1).

[1] Technically, we subtract one so that the definition coincides with the parameter k in paging.

▶ **Theorem 2.** *There is a deterministic ℓ-competitive algorithm for* non-linear paging. *Moreover, every deterministic algorithm for* non-linear paging *is at least ℓ-competitive.*

The algorithm achieving Theorem 2 is based on a new LP relaxation, designed for the general setting of non-linear paging. We now explain why previous techniques for classic paging are not sufficient for obtaining a competitive online algorithm for this setting.

Previous work on generalized paging [5, 1] and on other online covering problems [20, 10] use *knapsack cover* constraints. This powerful technique, originated by Wolsey [44], is very useful for relaxing submodular cover constraints using linear inequalities. Indeed, paging problems are often studied from the viewpoint of a *covering* problem (e.g., [4]), where the complement of the cache (i.e., pages outside the cache) needs to be covered. In classic paging, at any point of time at least $n - k$ pages are not in the cache.

Consider the *covering* function $g : 2^{\mathcal{P}} \to \mathbb{N}$ of a feasibility function f defined to be the (non-linear) size requirement *outside* of the cache: $g(S) = f(\mathcal{P}) - f(\mathcal{P} \setminus S)$ for every $S \subseteq \mathcal{P}$. Observe that for classic paging it holds that $g(S) = n - (n - |S|) = |S|$ and the feasibility constraint translates to $g(S) \geq n - k$ at all times. If f is submodular (i.e., submodular paging) then g is supermodular, and vice versa. Knapsack cover constraints yield a relaxation of the covering problem when the cover function g is submodular [20], as is the case in classic paging problems.

However, for submodular paging, the covering function g is supermodular and knapsack cover constraints do not even provide a relaxation of the problem. For example, let $g(S) = 1$ for $S = \mathcal{P}$ and $g(S) = 0$ otherwise. Then, the knapsack constraints are not satisfied by the unique solution that covers a demand of $k = 1$ (the entire set $\mathcal{P}$). Specifically, $\mathcal{P}$ does not satisfy the knapsack constraint for $S = \emptyset$, i.e., $\sum_{p \in \mathcal{P}} x_p \cdot g_{\emptyset}(\{p\}) = 0$, but $g_{\emptyset}(\mathcal{P}) = 1$.

To circumvent the limits of knapsack cover constraints for submodular paging, we formulate a new set of covering constraints that are valid for any feasibility functions f and g. Specifically, the constraints require removing at least one page from every infeasible set. Then, using the online primal-dual approach applied to this set of constraints, we obtain a tight ℓ-competitive deterministic algorithm for non-linear paging. Specifically, upon arrival of a page that induces an infeasible set of pages in cache, our algorithm identifies a minimally infeasible set of pages and continuously increases their corresponding dual variable in the LP, evicting *tight* pages.

Interestingly, as a special case, Theorem 2 gives a simple k-competitive deterministic algorithm for generalized paging; to the best of our knowledge, there are only $(k + 1)$-competitive deterministic algorithms [8, 48] for generalized paging. Thus, our bound is tight for this problem.

▶ **Corollary 3.** *There is a deterministic k-competitive algorithm for* generalized paging.

We emphasize that the lower bound of Theorem 2 can be obtained for *any* function f with a minimally infeasible set of cardinality ℓ (regardless of whether f is linear, submodular, supermodular, or any other function). This shows the robustness of the parameter ℓ as an indicator for the competitiveness of non-linear paging. Thus, it is natural to ask whether the parameter ℓ for non-linear paging is analogous to the parameter k for classic paging when allowing randomization. We answer this question in the negative by showing that in contrast to paging, that admits an $O(\log(\ell))$-competitive randomized algorithm [15], non-linear paging is substantially harder w.r.t. the parameter ℓ.

▶ **Theorem 4.** *Unless* NP $\subseteq$ BPP*, there is no polynomial-time randomized $o(\log^2(\ell))$-competitive algorithm for* non-linear paging.

A very intriguing open question is whether there exists a randomized polylog(ℓ)-competitive algorithm for general non-linear paging. Unfortunately, we show that the LP used for obtaining Theorem 2 has an integrality gap of ℓ, and thus would need to be strengthened to achieve this end (see Section 2.3). Hence, obtaining a polylog(ℓ) competitive factor would require a new set of techniques. As we have already discussed earlier, existing techniques for obtaining randomized online algorithms for paging problems and related variants focus on solving covering linear programs (LP) online, and they break down in the presence of general non-linear paging constraints.

To overcome the integrality gap of our LP, we formulate a stronger LP for non-linear paging (see Section 2.3). Obtaining even a fractional polylog(ℓ)-competitive algorithm for this LP seems a hard task. Thus, we consider another parameter which allows us to get a better competitive ratio. The parameter is the maximum number of pages that fit together in the cache. Formally, define

$$\mu = \max_{S \subseteq \mathcal{P} \text{ s.t. } f(S) \leq k} |S| \tag{1}$$

as the maximum cardinality of a feasible set in cache. Observe that $\mu = k$ for e.g., generalized paging, hence it is a natural parameter to also consider in our setting. We also remark that in many practical settings, such as classic paging, it holds that $n \gg \mu$ and obtaining a competitive ratio that depends on μ (rather than n) is much more desirable.

Clearly, $\mu \geq \ell$. The following example illustrates a scenario demonstrating a scenario where $\mu \gg \ell$. Consider a non-linear paging instance on a set P of pages which is partitioned into disjoint sets X, Y, where $|X| = n$, $|Y| = k+1$, and $n \gg k$. Define a feasibility function f such that for all subsets S of P, $f(S) = |Y \cap S|$. Define the cache threshold as k. Therefore, the only minimally infeasible set is Y; thus, $\ell = k$. On the other hand, the maximum cardinality of a set that fits into cache is the cardinality of all pages in X and any k pages from Y; thus, $\mu = n + k$. Since $n \gg k$ (i.e., n can be chosen to be arbitrarily large with respect to k) it follows that $\mu \gg \ell$.

We give the following fractional algorithm for solving the strengthened LP online.

▶ **Theorem 5.** *There is an $O(\log \mu)$-competitive algorithm for obtaining a fractional solution for the strengthened* LP*.*

It as an interesting open question if a randomized polylog(μ)-competitive algorithm for non-linear paging can be designed by rounding the fractional solution obtained in Theorem 5.

1.3.2 Supermodular Paging

We now discuss our results and techniques for supermodular paging. Our main result is a polylogarithmic randomized competitive algorithm for supermodular paging, i.e., submodular cover paging. As we show later on, our upper bound turns out to be quite close to the lower bound we prove.

▶ **Theorem 6.** *There is an $O\left(\log^2 \mu \cdot \log\left(\frac{c_{\max}}{c_{\min}} \cdot f(\mathcal{P})\right)\right)$-competitive randomized algorithm for* supermodular paging (submodular cover paging)*, where $c_{\max}, c_{\min}$ are the maximum and minimum costs of pages, respectively.*

In particular, for unweighted supermodular paging (where $c_p = 1 \; \forall p \in \mathcal{P}$), the above theorem implies an $O\left(\log^2(\mu) \cdot \log\left(f(\mathcal{P})\right)\right)$-competitive algorithm.

Our algorithm relies on a different LP relaxation than the one described in Section 1.3.1. As we aim to solve supermodular paging, which implies a submodular cover function g, we design an LP relaxation inspired by the submodular cover relaxation of Wolsey [44] (see

also [20]). We solve this LP in the case that the constraints arrive online to obtain a fractional $O(\log(\mu))$-competitive (deterministic) algorithm, while maintaining the property that the entries are either integral or multiples of $\frac{1}{k}$.

To obtain an integral solution, one is tempted to maintain online a set of feasible *cache states* respecting (even approximately) the marginal probabilities induced by the fractional solution, similarly to previous works on weighted paging and generalized paging [4, 5, 1]. However, techniques for online cache state maintenance of [4, 5, 1] seem to break down in the presence of submodular cover constraints. Instead, we augment the fractional solution by an additional polylogarithmic *boosting factor* and perform randomized rounding, with possible corrections to ensure feasibility. The probability of a page to be evicted at some point in time is shown to be proportional to the page's fractional increase normalized by the probability that the page is in cache.

We also give lower bounds for online supermodular paging. Surprisingly, even though online set cover seems starkly different from supermodular paging, in particular since the cover constraints change over time for online set cover, we can show that supermodular paging is in a sense harder to solve online.

▶ **Theorem 7.** *For any $\rho \geq 1$, if there is a ρ-competitive algorithm for* supermodular paging*, then there is a ρ-competitive algorithm for* online set cover *having the same running time up to polynomial factors.*

By Theorem 7 and the results of [2, 23], we give a lower bound on the competitiveness of supermodular paging, indicating the necessity of the factor $\log \mu \cdot \log(\mathcal{P})$.

▶ **Corollary 8.** *Unless* NP $\subseteq$ BPP*, there is no polynomial $o(\log \mu \cdot \log(f(\mathcal{P})))$-competitive algorithm for* supermodular paging*. Moreover, there is no deterministic $o\left(\frac{\log \mu \cdot \log(f(\mathcal{P}))}{\log\log \mu + \log\log(f(\mathcal{P}))}\right)$-competitive algorithm for* supermodular paging *of any running time.*

We remark that some of our results from Section 1.3.1 can be stated using the parameter μ as well. However, as we showed earlier, there are non-linear paging instances in which the parameter $\mu \gg \ell$ and it grows artificially apart from the true hardness of the instance – in terms of competitive analysis. In contrast, every minimally infeasible set of cardinality $\ell + 1$ can be used to obtain the lower bounds for classic paging [38, 15] (i.e., ℓ- deterministic and $O(\log \ell)$-randomized lower bounds). Thus, in an informal sense, an increase in ℓ always incurs an increase in the difficulty of the problem, unlike an increase in μ. For this reason, we believe that searching for competitive algorithms and lower bounds in terms of ℓ, rather than μ, may be of greater interest in the non-linear paging setting.

Finally, we also aim at obtaining an offline approximation algorithms for supermodular paging (i.e., where all requests are known in advance). A first attempt would be to reduce the problem to offline submodular cover, as follows. Define a covering function G on the domain containing all pairs (p, j), for every page p and the j-th time it is requested. Define the value of G on a subset of pairs S as $G(S) = \sum_{t \in T} g(S_t)$, where g is the covering function of the instance (see Section 1.3.1), and S_t is the set of all pages p, where (p, j) belongs to S and the time interval between requests j and $(j + 1)$ for p intersects t. Clearly, the total cover demand, even with a unit demand per-time slot, is a function of T; thus, applying an offline set cover algorithm in a black box manner gives only an $\Omega(\log(T))$-approximation [30]. As T may be very large, a different technique is in place.

Combined with the strong *round-or-separate* algorithm of [20], our techniques yield an approximation algorithm for supermodular paging independently of T (see Section 3). We defer the details to the full version of the paper.

▶ **Theorem 9.** *There is an offline* $O\left(\log\left(\frac{c_{\max}}{c_{\min}} \cdot f(\mathcal{P})\right)\right)$*-approximation algorithm for* supermodular paging.

Due to space constraints, some of the proofs (including our lower bounds) are given only in the full version of the paper [14].

2 Deterministic Algorithm for Non-Linear Paging

In this section, we present a deterministic algorithm for non-linear paging and show that it gives a tight competitive ratio for the problem, thus providing proofs for Theorem 2 and Corollary 3. Our algorithmic results are based on a new LP relaxation for the problem which we introduce here.

2.1 LP Relaxation for Non-Linear Paging

Consider a non-linear paging instance with a set of pages $\mathcal{P}$, a feasibility function f, cache threshold k, a set of time points T, and a page request $p_t \in \mathcal{P}$ for every time $t \in T$. To simplify notation, for a set S and an element p we use $S + p = S \cup \{p\}$ and $S - p = S \setminus \{p\}$. The LP is as follows.

The variables of the LP are $x_p(j)$ for every page $p \in \mathcal{P}$ and the j-th time that p is requested. Intuitively, the value of the variable $x_p(j)$ indicates to what extent page p is evicted between its j-th and $(j+1)$-th requests. The constraints state that for every infeasible set S containing the requested page p_t, for time point t, we must "break" this set - i.e., evicting at least one page from $S - p_t$. If this constraint is satisfied for every such infeasible set by an integral solution, then it induces a feasible set of pages in the cache at all times. See Figure 2 for a visualization of these constraints.

We use n_p to denote the number of requests for page p during the request sequence. Also, we use $r(p,t)$ to denote the number of requests for page p until time t. We assume that $x_p(0)$ is a variable always set to 0, for all $p \in \mathcal{P}$. To simplify notation, for every $t \in T$, let $\mathcal{S}(t) = \{S \subseteq \mathcal{P} \mid p_t \in S \text{ and } f(S) > k\}$ denote the infeasible sets containing p_t. For any $w \in \mathbb{N}$, let $[w] = \{1, 2, \ldots, w\}$. Our LP relaxation is as follows.

$$\begin{aligned} \min \quad & \sum_{p \in \mathcal{P}} \sum_{j \in [n_p]} x_p(j) \cdot c(p) \\ & \text{s.t.} \\ & \sum_{p \in S - p_t} x_p(r(p,t)) \geq 1, && \forall t \in T \ \forall S \in \mathcal{S}(t) \\ & x_p(j) \geq 0 && \forall p \in \mathcal{P} \ \forall j \in [n_p] \end{aligned} \tag{2}$$

We now define the dual LP. For page $p \in \mathcal{P}$ and $j \in [n_p]$ let $I(p,j) = \{t \in T \mid j = r(p,t)\}$ be the *interval* of all time points between the j-th request to p till the last time point before the $(j+1)$-st request for page p. The *dual* of (2) is the following.

$$\begin{aligned} \max \quad & \sum_{t \in T} \sum_{S \in \mathcal{S}(t)} y_t(S) \\ & \text{s.t.} \\ & \sum_{t \in I(p,j)} \sum_{S \in \mathcal{S}(t) \mid p \in S - p_t} y_t(S) \leq c(p), && \forall p \in \mathcal{P} \ \forall j \in [n_p] \end{aligned} \tag{3}$$

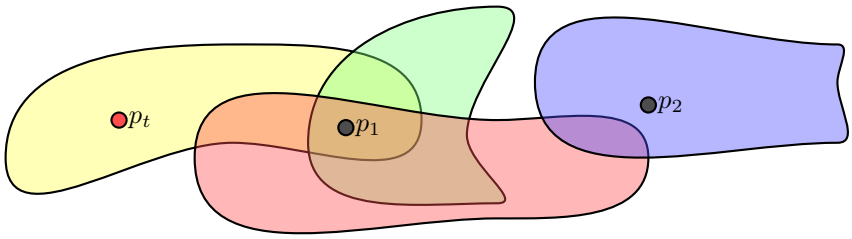

Figure 2 An illustration of the LP constraints. Each colored shape represents a minimally infeasible set of pages upon the arrival of a page p_t. Removing pages p_1 and p_2 ensures cache feasibility.

We use Primal-LP and Dual-LP to denote the values of the optimal solutions for the primal and dual programs, respectively, and by OPT the offline (integral) optimum. The next result follows from weak duality and since our LP is a relaxation of non-linear paging.

▶ **Lemma 10.** Dual-LP $\leq$ Primal-LP $\leq$ OPT.

Proof. The first inequality follows from weak duality, since (3) is the dual program of (2). For the second inequality, we show that (2) is a relaxation of non-linear paging. Consider an integral feasible solution M to our instance; define a solution x for (2) such that $x_p(j) = 1$ if and only if page p is removed from the cache during the interval $I(p, j)$ in M, for every $p \in \mathcal{P}$ and $j \in [n_p]$. Then, for every time $t \in T$ and $S \in \mathcal{S}(t)$, S cannot be fully contained in the cache at time t, since M is a feasible solution, and there is at least one $p \in S - p_t$ which is not in the cache at this time. Therefore, the primal constraint corresponding to t and S is satisfied. We conclude that x is feasible for (2); consequently, (2) is indeed a relaxation of non-linear paging, implying the second inequality. ◀

2.2 A Deterministic Algorithm for Non-Linear Paging

In this section, we give a primal-dual algorithm, based on the LP relaxation of non-linear paging presented in Section 2.1. For brevity, we denote the left handside of the dual constraint corresponding to page p and $j \in [n_p]$ as

$$Y_p(j) = \sum_{t \in I(p,j)} \sum_{S \in \mathcal{S}(t) \mid p \in S - p_t} y_t(S). \tag{4}$$

We call a page p *tight* at time t if $Y_p(j) = c(p)$.

The algorithm initializes an infeasible primal solution and a feasible dual solution as vectors of zeros $\bar{0}$. In every time step t, if the set of pages currently in cache, denoted by Cache_t, is infeasible, then our algorithm finds a subset of pages Q in the cache such that: first, Q is infeasible; second, Q contains the requested page p_t, i.e., $Q \in \mathcal{S}(t)$; third, Q has minimum cardinality amongst all such sets. we increase the variable $y_t(Q)$ continuously. Once one of the pages becomes tight, we remove it from cache. If the cache is feasible, the algorithm proceeds to time $t + 1$; otherwise, we repeat this process with a new set Q' from the current cache. The pseudocode is given in Algorithm 1.

We start by showing the feasibility of the algorithm.

Algorithm 1 Deterministic.

```
Initialize (infeasible) primal and (feasible) dual solutions x ← 0̄ and y ← 0̄.
for time t ∈ T do
    Let Cache_t = {p ∈ P | r(p,t) ≥ 1 and x_p(r(p,t)) = 0} be the pages currently in cache.
    while f(Cache_t) > k do
        Find Q ⊆ Cache_t such that Q ∈ S(t) of minimum cardinality.
        while Y_p(r(p,t)) < c(p) ∀p ∈ Q − p_t do
            Increase y_t(Q) continously.
        end
        for p ∈ Q − p_t such that Y_p(r(p,t)) = c(p) do
            Remove p from cache: x_p(r(p,t)) ← 1,  Cache_t ← Cache_t − p.
        end
    end
end
Return the (primal) solution x and the (dual) solution y.
```

▶ **Lemma 11.** *Algorithm 1 returns primal and dual feasible solutions of* (2).

Proof. By Algorithm 1, the algorithm keeps evicting pages until reaching a feasible set of pages in the cache. By the monotonicity of the feasibility function f, we eventually reach a feasible set in cache: every page p is considered to be feasible alone in the cache, i.e., $f(\{p\}) \leq k$; thus, in the worst case, the content of the cache at the end of time step t is p_t. The above shows that the primal solution x is feasible, being a relaxation of the integer problem. In addition, the dual y is feasible since for all $p \in \mathcal{P}$ and $j \in [n_p]$ it holds that $Y_p(j) \leq c(p)$ by Algorithm 1. ◀

In the following we bound the competitive ratio of the algorithm. Let $c(x)$ be the cost of our (integral) solution x and let $v(y)$ be the value of the dual solution y obtained by Algorithm 1. Using the selection of minimal sets for Q in Algorithm 1 we have the following result. Recall the width parameter ℓ defined in Definition 1.

▶ **Lemma 12.** $c(x) \leq \ell \cdot v(y)$

Proof. By LP (2),

$$\begin{aligned} c(x) &= \sum_{p\in\mathcal{P}} \sum_{j\in[n_p]} x_p(j)\cdot c(p) \leq \sum_{p\in\mathcal{P}} \sum_{j\in[n_p]} x_p(j)\cdot Y_p(j) \\ &= \sum_{p\in\mathcal{P}} \sum_{j\in[n_p]} x_p(j)\cdot \left(\sum_{t\in I(p,j)} \sum_{S\in\mathcal{S}(t)\,\middle|\, p\in S-p_t} y_t(S) \right). \end{aligned} \tag{5}$$

The inequality holds since we only evict tight pages. By changing summation order in (5),

$$c(x) \leq \sum_{t\in T} \sum_{S\in\mathcal{S}(t)} y_t(S)\cdot \sum_{p\in S-p_t} x_p(r(p,t)) \leq \sum_{t\in T} \sum_{S\in\mathcal{S}(t)} y_t(S)\cdot \ell = \ell\cdot v(y).$$

The second inequality holds since in Algorithm 1 we always choose a minimally infeasible set of cardinality at most $\ell+1$; hence, $y_t(S) \neq 0$ only if $|S| \leq \ell+1$. ◀

We are now ready to give the proof of our main theorem.

Proof of Theorem 2. By Lemma 11, the returned solution x is a feasible solution. Combined with Lemma 10 and Lemma 12, $c(x) \leq \ell \cdot v(y) \leq \ell \cdot \text{OPT}$. Along with the tight lower bound from the special case of paging [38], the statement of the theorem follows.

We remark that for any ℓ and function f such that $\ell(f) = \ell$, there is a minimally infeasible set S of cardinality ℓ; as a result, the lower bound for deterministic algorithms of paging [38] can be obtained from the set S. Namely, given a deterministic algorithm $\mathcal{A}$ for unweighted non-linear paging, construct a sequence of requests for pages in S that always requests the page missing in cache by algorithm $\mathcal{A}$; clearly, $\mathcal{A}$ pays a cost of one at each time step, since S is minimally infeasible. Conversely, the offline optimum would evict the page that is requested latest in the future, missing only once in ℓ requests, giving the lower bound of ℓ. ◀

2.3 Integrality Gap

In this section, we show the limitations of the LP. Specifically, we show that the integrality gap of the LP defined in (2) is at least ℓ; together with our algorithmic upper bound the integrality gap is exactly ℓ. We then discuss a stronger LP formulation based on (2).

▶ **Lemma 13.** *The integrality gap of* LP (2) *is* ℓ.

Proof. For some $n \geq 1$, consider an instance with n pages $\mathcal{P} = \{p_1, \ldots, p_n\}$ with uniform costs $c(p) = 1 \; \forall p \in \mathcal{P}$ and a uniform feasibility function f as in classic paging, i.e., $f(S) = |S|$ for all $S \subseteq \mathcal{P}$, and some cache capacity k. Thus, all minimally infeasible sets are of cardinality $k+1$ and it follows that $\ell(f) = k$. Define the sequence of requests $p_1, \ldots, p_n$. That is, each page is requested exactly once. Observe that each request results in a page fault. Hence, any integral solution, in particular the optimal integral solution, evicts at least $n - k$ pages. On the other hand, define a fractional solution such that $x_p(1) = \frac{1}{k}$ for all $p \in \mathcal{P}$, i.e., each page is evicted after its first request with fraction $\frac{1}{k}$ (note that each page is requested exactly once). Consider some infeasible set $S \subseteq \mathcal{P}$ such that $|S| > k$. It holds that

$$\sum_{p \in S} x_p(1) = |S| \cdot \frac{1}{k} \geq \frac{k+1}{k} \geq 1.$$

Thus, x satisfies the constraints of (2). The cost paid by the fractional solution x is $\frac{n}{k}$. Therefore, as n and k can be chosen arbitrarily, the integrality gap of the LP is at least

$$\lim_{n \to \infty} \frac{n-k}{\frac{n}{k}} = \lim_{n \to \infty} \left(k - \frac{k^2}{n} \right) = k = \ell(f).$$

Therefore, in general, the integrality gap cannot be smaller than ℓ. ◀

2.3.1 Discussion: a Stronger LP

The integrality gap example shows that LP (2) is not sufficient for obtaining a randomized polylog(ℓ)-competitive algorithm for general non-linear paging. Instead, we describe a stronger version of our LP (2), in which we require removing from each infeasible set S a set of pages S', so that the complement of S' in S, $S \setminus S'$, will be feasible in the cache (i.e., $f(S \setminus S') \leq k$). The strengthened LP and our fractional algorithm for solving the LP online are presented in [14], giving the proof of Theorem 5.

3 A Randomized Algorithm for Supermodular Paging

We provide here an $O(\log \mu)$-competitive algorithm for a fractional version of supermodular paging. Then, we design randomized online and offline algorithms for supermodular paging.

3.1 LP for Supermodular Paging

The starting point of our fractional algorithm is earlier work on submodular cover LP [44, 20, 10]. Consider a supermodular paging instance with a set of pages $\mathcal{P}$, a feasibility function f inducing the submodular cover function g (recall that $g(S) = f(\mathcal{P}) - f(\mathcal{P} \setminus S)$ for every $S \subseteq \mathcal{P}$), cache threshold k, a set of time points T, and a page request $p_t \in \mathcal{P}$ for every time $t \in T$. We use the following LP relaxation of supermodular paging. As in the LP introduced in Section 2.1, the variables of the LP are $x_p(j)$ for every page $p \in \mathcal{P}$ and the j-th time that p is requested. We will use the same notation as in the LP of (2). Recall that for some $S \subseteq P$ and $p \in \mathcal{P}$ we use $g_S(p) = g_S(\{p\}) = g(S+p) - g(S)$. Let $N = f(\mathcal{P}) - k$ be our *cover demand*; at any point of time, the (non-linear) total size outside of the cache must be at least N.

Our LP relaxation goes as follows; the constraints of the LP require that for every time t and subset of pages S (assumed to already be outside of the cache) we must evict from the cache (fractionally) a total size of at least $N - g(S) = f(\mathcal{P} \setminus S) - k$, since we cannot have more than a total size of k in cache. This constraint is very natural in the linear case (i.e., classic paging), but more involved in the submodular cover setting.

$$\begin{aligned} \min \sum_{p \in \mathcal{P}} \sum_{j \in [n_p]} & x_p(j) \cdot c(p) \\ \text{s.t.} & \\ \sum_{p \in \mathcal{P} - p_t} & x_p(r(p,t)) \cdot g_S(p) \geq N - g(S), && \forall t \in T \ \forall S \subseteq \mathcal{P} \\ & x_p(j) \geq 0 && \forall p \in \mathcal{P} \ \forall j \in [n_p] \end{aligned} \tag{6}$$

In the following we define the *dual* LP of (6).

$$\begin{aligned} \max \sum_{t \in T} \sum_{S \subseteq \mathcal{P}} & y_t(S) \cdot (N - g(S)) \\ \text{s.t.} & \\ \sum_{t \in I(p,j)} \sum_{S \subseteq \mathcal{P} \,\middle|\, p \in S - p_t} & y_t(S) \leq c(p), && \forall p \in \mathcal{P} \ \forall j \in [n_p] \\ & y_t(S) \geq 0 && \forall t \in T \ \forall S \subseteq \mathcal{P}. \end{aligned} \tag{7}$$

We use Primal-LP and Dual-LP to denote the values of the optimal solutions for the primal and dual programs, respectively, and by OPT the offline (integral) optimum.

Before we describe our fractional algorithm, we show that it is sufficient to satisfy only *minimal constraints* rather than all constraints of the LP. Formally, a primal constraint of (6) corresponding to $t \in T$ and $S \subseteq \mathcal{P}$ is called *minimal* for some solution x' if for all $p \in \mathcal{P}$ where $x'_p(r(p,t)) = 1$ it holds that $p \in S$.

▶ **Lemma 14.** *If x' satisfies all minimal constraints of (6), then x' is feasible for (6).*

Our fractional algorithm initializes the (infeasible) primal solution x and the (feasible) dual solution y both as vectors of zeros $\bar{0}$. When the requested page p_t at time t arrives, we do the following til x satisfies all LP constraints (6) up to time t.

At time t, the algorithm considers a *minimally violating set* of pages $Q \subseteq \mathcal{P}$. This set is a minimal set for our solution x violating the primal constraint in (6) corresponding to t and Q. We increase variable $y_t(\mathcal{P} \setminus Q)$ continuously and at the same time increase variables $x_p(r(p,t))$ for all pages in $(\mathcal{P} - p_t) \setminus Q$ except p_t. The increasing rate is a function of $Y_p(r(p,t))$, where

$$Y_p(j) = \sum_{t \in I(p,j)} \sum_{S \subseteq \mathcal{P} \mid p \in S - p_t} y_t(S) \tag{8}$$

is the left hand side of the corresponding dual constraint of p and $j = r(p,t)$ in (6) (analogously to (4)). This growth function has an exponential dependence on $Y_p(r(p,t))$ scaled by the cost of the page $c(p)$ and the number of pages possible in cache - the parameter μ. The growth of the variable $x_p(j)$ stops once it reaches $\frac{1}{2}$.

Algorithm 2 Fractional.

Initialize (infeasible) primal solutions $x, z \leftarrow \bar{0}$
Initialize (feasible) dual solution $y \leftarrow \bar{0}$.
for $t \in T$ **do**
  while x *is not feasible for* t **do**
    Find a minimal set $Q \subseteq \mathcal{P}$ for x such that $\sum_{p \in \mathcal{P} - p_t} x_p(r(p,t)) \cdot g_Q(p) < N - g(Q)$.
    while $\sum_{p \in \mathcal{P} - p_t} x_p(r(p,t)) \cdot g_Q(p) < N - g(Q)$ and Q is minimal for x **do**
      Increase $y_t(\mathcal{P} \setminus Q)$ continously.
      forall $p \in (\mathcal{P} - p_t) \setminus Q$ **do**
        increase $x_p(r(p,t))$ according to

$$x_p(r(p,t)) \leftarrow \frac{1}{\mu} \cdot \left(\exp\left(\frac{\ln(\mu+1)}{c(p)} \cdot Y_p(r(p,t)) \right) - 1 \right).$$

        if $x_p(r(p,t)) - \frac{z_p(r(p,t))}{2} \geq \frac{1}{4 \cdot N \cdot \mu}$ **then**
          $z_p(r(p,t)) \leftarrow 2 \cdot x_p(r(p,t))$.
        end
        if $x_p(r(p,t)) \geq \frac{1}{2}$ **then**
          $z_p(r(p,t)), x_p(r(p,t)) \leftarrow 1$.
        end
      end
    end
  end
end
Return the (primal) solution x and the (dual) solution y.

Once the primal constraint corresponding to t, Q is satisfied, or Q is no longer minimal for x (a page $p \in \mathcal{P} \setminus Q$ reaches 1), there are two cases. If x is feasible, the algorithm proceeds to the next time step. Otherwise, the algorithm repeats the above process with a new minimal violating set Q'. An additional property that will be useful in the analysis is that all non-zero entries of the obtained solution will be larger than $\Omega\left(\frac{1}{N \cdot \mu}\right)$ and there will be no fractional

entries larger than $\frac{1}{2}$. Thus, we update through the algorithm another primal solution z; we update an entry $z_p(j)$ to be the value of $2 \cdot x_p(j)$ whenever the difference $x_p(j) - z_p(j)$ becomes larger than $\Omega\left(\frac{1}{N \cdot \mu}\right)$. Moreover, we increase $z_p(j)$ immediately to 1 once $x_p(j)$ reaches $\frac{1}{2}$. The pseudocode of the algorithm is given in Algorithm 2.

3.2 Analysis of Algorithm 2

We now analyze the competitive ratio of the fractional algorithm. We start by claiming the feasibility of the solutions obtained throughout the execution of the algorithm.

▶ **Lemma 15.** *The primal solution x defined by Algorithm 2 is feasible for the* LP (6).

▶ **Lemma 16.** *The solution z returned by Algorithm 2 is feasible for* (6).

▶ **Lemma 17.** *Algorithm 2 returns a feasible dual solution to the* LP (6).

It remains to prove that the algorithm is $O(\log(\mu))$-competitive. To do so, we bound the increase in the primal x by a $O(\log \mu)$ factor of the dual increase, at any time.

▶ **Lemma 18.** *The cost of x is bounded by $O(\log(\mu))$ times the value of the dual y.*

Proof. Consider an infinitesimal increase in the value of the dual solution y. Specifically, assume that the algorithm chooses a minimal set Q in Algorithm 2 for time step t and that the dual variable $y_t(\mathcal{P} \setminus Q)$ increases infinitesimally by $dy_t(\mathcal{P} \setminus Q)$. Let dx and dy denote the infinitesimal change in the objective value of x and y, respectively. We bound the increase dx in x as a function of the increase dy.

$$\begin{aligned} dx &= \sum_{p \in \mathcal{P} - p_t} dx_p(r(p,t)) \cdot c(p) \\ &= \sum_{p \in (\mathcal{P} - p_t) \setminus Q} \frac{dx_p(r(p,t)) \cdot c(p) \cdot dy_t(\mathcal{P} \setminus Q)}{dy_t(\mathcal{P} \setminus Q)} \\ &= \sum_{p \in (\mathcal{P} - p_t) \setminus Q} \ln(\mu + 1) \cdot \left(x_p(r(p,t)) + \frac{1}{\mu} \right) \cdot dy_t(\mathcal{P} \setminus Q). \end{aligned} \tag{9}$$

The first equality holds since the increase in $y_t(\mathcal{P} \setminus Q)$ induces an increase only on the primal variables corresponding to pages in $(\mathcal{P} - p_t) \setminus Q$ by (6). The last equality follows from the growth rate of a variable $x_p(r(p,t))$, for some $p \in (\mathcal{P} - p_t) \setminus Q$, as a result of the growth in $y_t(\mathcal{P} \setminus Q)$. We separately analyze two of the expressions in (9). First, since y changes as a result of the increase in the variable $y_t(\mathcal{P} \setminus Q)$, by Algorithm 2 it implies that

$$\sum_{p \in (\mathcal{P} - p_t) \setminus Q} x_p(r(p,t)) \cdot g_Q(p) \leq \sum_{p \in \mathcal{P} - p_t} x_p(r(p,t)) \cdot g_Q(p) < N - g(Q). \tag{10}$$

For the second expression, let $S' \in (\mathcal{P} - p_t) \setminus Q$ such that (i) $g_Q(S') \geq N - g(Q)$ and (ii) S' is of minimum cardinality of all such sets. Clearly, there is such S' as $S'' = (\mathcal{P} - p_t) \setminus Q$ satisfies the first condition (p_t is feasible alone in cache). Since S' satisfies the cover constraints it holds that $f(\mathcal{P} \setminus (S' \cup Q) \leq k$; thus, by the definition of μ it holds that $|\mathcal{P} \setminus (S' \cup Q| \leq \mu$.

Therefore,

$$\begin{aligned}\sum_{p\in(\mathcal{P}-p_t)\setminus Q}\frac{1}{\mu} &= \frac{|(\mathcal{P}-p_t)\setminus Q|-1}{\mu}\\ &= \frac{|S'|+|\mathcal{P}\setminus(S'\cup Q)|-1}{\mu}\\ &\leq \frac{N-g(Q)+\mu-1}{\mu}\\ &\leq N-g(Q)+1\leq 2\cdot(N-g(Q))\,.\end{aligned} \tag{11}$$

The first inequality holds since $|S'|\leq N-g(Q)$, as S' is the minimum cardinality set that covers the demand of $N-g(Q)$; thus, the marginal contribution of any page in S' to the cover is at least 1 implying the inequality. The first inequality also uses $|\mathcal{P}\setminus(S'\cup Q|\leq\mu$ as explained above. For the last inequality, note that $N-g(Q)\geq 1$ since we assume that $y_t(\mathcal{P}\setminus Q)$ increases at this time, implying that the corresponding constraint of t and S is not trivially satisfied. Therefore, by (9), (10), and (11),

$$\begin{aligned}dx &\leq \ln(\mu+1)\cdot dy_t(\mathcal{P}\setminus Q)\cdot\left(\sum_{p\in(\mathcal{P}-p_t)\setminus Q}x_p(r(p,t))+\sum_{p\in(\mathcal{P}-p_t)\setminus Q}\frac{1}{\mu}\right)\\ &= \ln(\mu+1)\cdot dy_t(\mathcal{P}\setminus Q)\cdot 3\cdot(N-g(Q))\\ &= O(\log(\mu))\cdot dy.\end{aligned} \tag{12}$$

Thus, by (12), every increase in y incurs an increase of at most a factor $O(\log(\mu))$ in x. Finally, note that if $x_p(j)\geq\frac{1}{2}$ then we immediately increase $x_p(j)$ to 1; this increase the total cost of x by a factor of 2 w.r.t. the value of y. ◀

To conclude, by Algorithm 2 and Algorithm 2 we can trivially bound the cost of z by a constant factor of the cost of x.

▶ **Observation 19.** *The cost of z is bounded by 4 times the cost of x.*

Finally, using the above we summarize the properties of z.

▶ **Lemma 20.** *Algorithm 2 returns a feasible primal solution z to (6) such that the following holds.*

1. *For all $p\in\mathcal{P}$ and $j\in[n_p]$ it holds that either $z_p(j)\in\{0,1\}$ or that $z_p(j)\in\left[\frac{1}{4\cdot N\cdot\mu},\frac{1}{2}\right]$.*
2. *The cost of z is bounded by $O(\log(\mu))$ times the cost of* OPT.

3.3 Randomized Rounding

In this section, we construct a randomized algorithm for supermodular paging based on an online rounding scheme of the solution z to the LP (6) obtained by Algorithm 2. Let

$$C=\max_{p,q\in\mathcal{P}}\frac{c(p)}{c(q)}$$

be the maximum ratio of costs taken over all pairs pages; we assume without the loss of generality that all costs are strictly positive. As a scaling factor for our algorithm, let $\alpha=\log\left(4\cdot C\cdot N^2\cdot\mu^2\right)$ and let z' be the solution obtained by augmenting z by a factor of α. That is, for all $p\in\mathcal{P}$ and $j\in[n_p]$ define $z'_p(j)=\min(1,\alpha\cdot z_p)$.

Our algorithm computes z' in an online fashion. At every time t, after updating z', the algorithm evicts each page $p \in \mathcal{P}$ from the cache with probability chosen carefully so that the total probability that p is missing from cache after this moment is exactly $z'_p(r(p,t))$. If the cache is not feasible after this randomized rounding procedure, we evict pages that increase the total cover until we reach feasibility. The pseudocode of the algorithm is given in Algorithm 3.

Algorithm 3 Randomized Rounding.

for $t \in T$ **do**
  If p_t is missing from cache: fetch p_t.
  Initialize $\Delta_{p_t} \leftarrow 0$.
  Update the solution z according to Algorithm 2.
  Define $z'_p(r(p,t)) \leftarrow \min(1, \alpha \cdot z_p)$ for all $p \in \mathcal{P}$.
  for $p \in \mathcal{P}$ **do**
    Evict p from cache with probability $\frac{z'_p(r(p,t)) - \Delta_p}{1 - \Delta_p}$.
    Update $\Delta_p = z'_p(r(p,t))$.
  end
  Let $\mathcal{F}$ be the pages outside of the cache (part of the cover).
  while $g(\mathcal{F}) < N$ **do**
    Evict a page $p \in \mathcal{P} \setminus \mathcal{F}$ such that $g_{\mathcal{F}}(p) > 0$.
  end
end
Return the integral solution.

Observe that we evict a page p at time t with probability $\frac{z'_p(r(p,t)) - \Delta_p}{\Delta_p}$, conditioned on the event that p is still in the cache. Thus, the probability that p belongs to the cache at the beginning of time t is Δ_p, and is $z'_p(r(p,t))$ after Algorithm 3. Thus, we have the following observation.

▶ **Observation 21.** *For all $p \in \mathcal{P}$ and $t \in T$ the probability that p is missing from the cache at time t is at least $z'_p(r(p,t))$.*

To analyze the performance of the algorithm, we use the following lemma. The proof follows from Lemma 2.5 in [20] combined with Observation 21.

▶ **Lemma 22.** *Let $\mathcal{F}$ be the set of pages outside cache at Algorithm 3 at time t. Then,*

$$\mathbb{E}[g(\mathcal{F})] \geq N - e^{-\alpha} \cdot N \geq N - \frac{1}{2 \cdot \mu^2 \cdot C \cdot N}.$$

Using Lemma 22, we bound the expected cost of the algorithm.

▶ **Lemma 23.** *Algorithm 3 returns a feasible integral solution for* supermodular paging *with expected cost $O(\log(\mu) \cdot \alpha) \cdot \mathrm{OPT} = O\left(\log^2(\mu) \cdot \log(C \cdot N)\right) \cdot \mathrm{OPT}$.*

The proof of Theorem 6 follows from Lemma 23. Moreover, the proof of Theorem 9 follows using the "round-or-separate" approach of [20].

Abstract

We provide new tradeoffs between approximation and running time for the decremental all-pairs shortest paths (APSP) problem. For undirected graphs with m edges and n nodes undergoing edge deletions, we provide four new approximate decremental APSP algorithms, two for weighted and two for unweighted graphs. Our first result is $(2+\epsilon)$-APSP with total update time $\tilde{O}(m^{1/2}n^{3/2})$ (when $m = n^{1+c}$ for any constant $0 < c < 1$). Prior to our work the fastest algorithm for weighted graphs with approximation at most 3 had total $\tilde{O}(mn)$ update time for $(1+\epsilon)$-APSP [Bernstein, SICOMP 2016]. Our second result is $(2+\epsilon, W_{u,v})$-APSP with total update time $\tilde{O}(nm^{3/4})$, where the second term is an additive stretch with respect to $W_{u,v}$, the maximum weight on the shortest path from u to v.

Our third result is $(2+\epsilon)$-APSP for unweighted graphs in $\tilde{O}(m^{7/4})$ update time, which for sparse graphs ($m = o(n^{8/7})$) is the first subquadratic $(2+\epsilon)$-approximation. Our last result for unweighted graphs is $(1+\epsilon, 2(k-1))$-APSP, for $k \geq 2$, with $\tilde{O}(n^{2-1/k}m^{1/k})$ total update time (when $m = n^{1+c}$ for any constant $c > 0$). For comparison, in the special case of $(1+\epsilon, 2)$-approximation, this improves over the state-of-the-art algorithm by [Henzinger, Krinninger, Nanongkai, SICOMP 2016] with total update time of $\tilde{O}(n^{2.5})$. All of our results are randomized, work against an oblivious adversary, and have constant query time.

1 Introduction

The dynamic algorithms paradigm is becoming increasingly popular for studying algorithmic questions in the presence of gradually changing inputs. A natural goal in this area is to design algorithms that process each change to the input as fast as possible to adapt the algorithm's output (or a data structure for querying the output) to the current state of the input. The time spent after an update to perform these computations is called the *update time* of the algorithm. In many cases, bounds on the update time are obtained in an *amortized* sense as an average over a long enough sequence of updates. Among dynamic graph problems, the question of maintaining exact or approximate shortest paths has received considerable attention in the past two decades. The main focus usually lies on maintaining a distance oracle that answers queries for the distance between a pair of nodes. For this problem, we call an algorithm *fully dynamic* if it supports both insertions and deletions of edges, and *partially dynamic* if it supports only one type of updates; in particular we call it *decremental* if it only supports edge deletions (which is the focus of this paper), and *incremental* if it only supports edge insertions.

The running times of partially dynamic algorithms are usually characterized by their bounds on the *total update time*, which is the accumulated time for processing all updates in a sequence of at most m deletions (where m is the maximum number of edges ever contained the graph). A typical design choice, which we also impose in this paper, is small (say polylogarithmic) query time. In particular, our algorithms will have constant query time. While fully dynamic algorithms are more general, the restriction to only one type of updates in partially dynamic algorithms often admits much faster update times. In particular, some partially dynamic algorithms have a total update time that almost matches the running time of the fastest static algorithm, i.e., computing *all* updates does not take significantly more time than processing the graph once.

Decremental shortest paths

For the decremental single-source shortest paths problem, conditional lower bounds [58, 48] suggest that *exact* decremental algorithms have an $\Omega(mn)$ bottleneck in their total update time (up to subpolynomial factors). On the other hand, this problem admits a $(1+\epsilon)$-approximation (also called *stretch*) with total update time $m^{1+o(1)}$ in weighted, undirected graphs [22, 47, 20, 19, 21], which exceeds the running time of the state-of-the art static algorithm by only a subpolynomial factor. Hence for the single-source shortest paths problem on undirected graphs we can fully characterize for which multiplicative stretches the total update time of the fastest decremental algorithm matches (up to subpolynomial factors) the running time of the fastest static algorithm.

Obtaining a similar characterization for the decremental all-pairs shortest paths (APSP) problem is an intriguing open question. Conditional lower bounds [32, 48] suggest an $\Omega(mn)$ bottleneck in the total update time of decremental APSP algorithms with (a) any finite stretch on *directed* graphs and (b) with any stretch guarantee with a multiplicative term of $\alpha \geq 1$ and an additive term of $\beta \geq 0$ with $2\alpha + \beta < 4$ on *undirected* graphs. This motivates the study of decremental (α, β)-approximate APSP algorithms such that $2\alpha + \beta \geq 4$, i.e., with multiplicative stretch $\alpha \geq 2$ or additive stretch $\beta \geq 2$.

Apart from two notable exceptions [46, 5], all known decremental APSP algorithms fall into one of two categories. They either (a) maintain exact distances or have a relatively small multiplicative stretch of $(1+\epsilon)$ or (b) they have a stretch of at least 3. The space in between is largely unexplored in the decremental setting. This stands in sharp contrast to the static

setting where for undirected graphs approximations guarantees different from multiplicative $(1+\epsilon)$ or "3 and above" have been the focus of a large body of works [7, 32, 28, 14, 16, 51, 11, 55, 61, 52, 8, 9]. The aforementioned exceptions in dynamic algorithms [46, 5], concern unweighted undirected graphs and maintain $(1+\epsilon, 2)$-approximations that simultaneously have a multiplicative error of $1+\epsilon$ and an additive error of 2, which implies a purely multiplicative $(2+\epsilon)$-approximation. The algorithms run in $\tilde{O}(n^{5/2})$[1] and $n^{5/2+o(1)}$ total update time respectively. In the next section, we will detail how our algorithms improve over this total update time and generalize to weighted graphs.

Concerning the fully dynamic setting, Bernstein [17] provided an algorithm for $(2+\epsilon)$-APSP which takes $m^{1+o(1)}$ time per update. Although we are not aware of any lower bounds, it seems to be hard to beat this: no improvements have been made since. The lack of progress in the fully-dynamic setting motivates the study in a partially dynamic setting, where we obtain improvements for the decremental case.

1.1 Our Results

In this paper, we provide novel decremental APSP algorithms with approximation guarantees that previously were mostly unexplored in the decremental setting. Our algorithms are randomized and we assume an oblivious adversary. For each pair of nodes, we can not only provide the distance estimate, but we can also report a shortest path π of this length in $\tilde{O}(|\pi|)$ time using standard techniques, see e.g. [43].

$(2+\epsilon)$-APSP for weighted graphs

Our first contribution is an algorithm for maintaining a $(2+\epsilon)$-approximation in weighted, undirected graphs.

▶ **Theorem 1.** *Given a weighted graph G and a constant $0 < \epsilon < 1$, there is a decremental data structure that maintains a $(2+\epsilon)$-approximation of APSP. The algorithm has constant query time and the total update time is w.h.p.*

- $\tilde{O}(m^{1/2}n^{3/2}\log^2(nW))$ *if $m = n^{1+\Omega(1)}$ and $m \leq n^{2-\rho}$ for an arbitrary small constant ρ,*
- $\tilde{O}(m^{1/2}n^{3/2+\rho}\log^2(nW))$ *if $m \geq n^{2-\rho}$ for any constant ρ,*
- $\tilde{O}(m^{1/2}n^{3/2+o(1)}\log^2(nW))$ *otherwise,*

where W is the ratio between the maximum and minimum weight.

The fastest known algorithm with an approximation ratio at least as good as ours is the $(1+\epsilon)$-approximate decremental APSP algorithm by Bernstein [18] with total update time $\tilde{O}(mn)$. With our $(2+\epsilon)$-approximation, we improve upon this total update time when $m = n^{1+\eta}$, for any $\eta > 0$. Furthermore, the fastest known algorithm with a larger approximation ratio than our algorithm is the $(3+\epsilon)$-approximate decremental distance oracle by Łącki and Nazari [53] with total update time $\tilde{O}(m\sqrt{n})$. Our result also has to be compared to the *fully dynamic* algorithm of Bernstein [17] for maintaining a $(2+\epsilon)$-approximation that takes amortized time $m^{1+o(1)}$ per update. Note that in *unweighted* graphs, $(2+\epsilon)$-approximate decremental APSP algorithm can be maintained with total update time $\tilde{O}(n^{2.5})$ (which is implied by the results of Abraham and Chechik [5] and Henzinger, Krinninger, and Nanongkai [46]). Our approach improves upon this bound for most densities, and matches it for $m = n^2$.

[1] In the introduction, we make two simplifying assumptions: (a) ϵ is a constant and (b) the ratio W between the maximum and minimum weight is polynomial in n. Unless otherwise noted, the cited algorithms have constant or polylogarithmic query time. Throughout we use $\tilde{O}(\cdot)$ notation to omit factors that are polylogarithmic in n.

$(2+\epsilon, 1)$-APSP for unweighted and $(2+\epsilon, W_{u,v})$-APSP for weighted graphs

Our second contribution is a faster algorithm with an additional additive error term of 1 for unweighted graphs, which in turn can be used to obtain our unweighted $(2+\epsilon)$-APSP result. The corresponding generalization to weighted graphs can be formulated as follows.

▶ **Theorem 2.** *Given a weighted graph G and a constant $0 < \epsilon < 1$, there is a decremental data structure that maintains a $(2+\epsilon, W_{u,v})$-approximation for APSP, where $W_{u,v}$ is the maximum weight on a shortest path from u to v. The algorithm has constant query time and the total update time is w.h.p. $\tilde{O}(nm^{3/4}\log^2(nW))$ if $m = n^{1+\Omega(1)}$, and $\tilde{O}(n^{1+o(1)}m^{3/4}\log^2(nW))$ otherwise, where W is the ratio between the maximum and minimum weight.*

$(2+\epsilon)$-APSP for unweighted graphs

We obtain this result by a general reduction from mixed approximations to purely multiplicative approximations, which might be of independent interest beyond the dynamic setting. See Theorem 5 for the statement. We can then combine this with Theorem 2 to obtain a fast algorithm for non-dense unweighted graphs.

▶ **Theorem 3.** *Given an undirected unweighted graph G, there is a decremental data structure that maintains a $(2+\epsilon)$-approximation for APSP with constant query time. W.h.p. the total update time is bounded by $\tilde{O}(m^{7/4})$ if $m = n^{1+\Omega(1)}$, and $\tilde{O}(m^{7/4+o(1)})$ otherwise.*

Note that for $m = o(n^{8/7})$ this gives the first subquadratic decremental $(2+\epsilon)$-approximate APSP algorithm. For $m \leq n^{6/5}$, this approach is faster than our weighted result, Theorem 1, which was already beating the unweighted state-of-the-art [5, 46].

$(1+\epsilon, 2(k-1))$-APSP for unweighted graphs

Our fourth contribution is an algorithm for unweighted, undirected graphs that maintains, for any $k \geq 2$, a $(1+\epsilon, 2(k-1))$-approximation, i.e., a distance estimate that has a multiplicative error of $1+\epsilon$ and an additive error of $2(k-1)$.

▶ **Theorem 4.** *Given an undirected unweighted graph G, a constant $0 < \epsilon < 1$ and an integer $2 \leq k \leq \log n$, there is a decremental data structure that maintains $(1+\epsilon, 2(k-1))$-approximation for APSP with constant query time. The expected total update time is bounded by $\min\{O(n^{2-1/k+o(1)}m^{1/k}), \tilde{O}((n^{2-1/k}m^{1/k})O(1/\epsilon)^{k/\rho})\}$ where $m = n^{1+\rho}$.*

Note that for small values of k and if $m = n^{1+\rho}$ for a constant $\rho > 0$, we get total update time of $\tilde{O}(n^{2-1/k}m^{1/k})$, and otherwise we have an extra $n^{o(1)}$ factor. In addition, in the special case of $k = \log n$, we get a near-quadratic update time of $O(n^{2+o(1)})$. The state-of-the-art for a purely multiplicative $(1+\epsilon)$-approximation is the algorithm of Roditty and Zwick with total update time $\tilde{O}(mn)$.[2] It was shown independently by Abraham and Chechik [5] and by Henzinger, Krinninger, and Nanongkai [46] how to improve upon this total update time bound at the cost of an additional small additive error term: a $(1+\epsilon, 2)$-approximation can be maintained with total update time $\tilde{O}(n^{2.5})$. This has been generalized by Henzinger, Krinninger, and Nanongkai [45] to an additive error term of $2(1+\frac{2}{\epsilon})^{k-2}$ and total update time $\tilde{O}(n^{2+1/k}O(\frac{1}{\epsilon})^{k-1})$. We improve upon this tradeoff in two ways: (1) our additive term is independent of $1/\epsilon$ and *linear* in k and (2) our algorithm profits from graphs being sparse.

[2] Note that the algorithms of Roditty and Zwick [59] for unweighted, undirected graphs precedes the more general algorithm of Bernstein [18] for weighted, directed graphs.

Static follow-up work

Interestingly, our techniques inspired a new algorithm for a static 2-approximate distance oracle [33], giving the first such distance oracle algorithm with subquadratic construction time for sparse graphs. Moreover, for $m = n$ they match conditional lower bounds [56, 3].

1.2 Related Work

Static algorithms

The baseline for the static APSP problem are the exact textbook algorithms with running times of $O(n^3)$ and $\tilde{O}(mn)$, respectively. There are several works obtaining improvements upon these running times by either shaving subpolynomial factors or by employing fast matrix multiplication, which sometimes comes at the cost of a $(1+\epsilon)$-approximation instead of an exact result. See [67] and [66], and the references therein, for details on these approaches. For the regime of stretch 3 and more in undirected graphs, a multitude of algorithms has been developed with the distance oracle of Thorup and Zwick [64] arguably being the most well-known constructions. In the following, we focus on summarizing the state of affairs for approximate APSP with stretch between $1+\epsilon$ and 3.

In *weighted*, undirected graphs, Cohen and Zwick [28] obtained a 2-approximation with running time $\tilde{O}(m^{1/2}n^{3/2})$. This running time has been improved to $\tilde{O}(m\sqrt{n}+n^2)$ by Baswana and Kavitha [14] and, employing fast matrix multiplication, to $\tilde{O}(n^{2.25})$ by Kavitha [51]. For $(2+\epsilon)$-APSP, Dory et al. [33] provide two algorithms, for dense graphs: $O(n^{2.214})$ and sparse graphs: $\tilde{O}(mn^{2/3})$. In addition, efficient approximation algorithms for stretches of $\frac{7}{3}$ [28] and $\frac{5}{2}$ [51] have been obtained. These results have recently been generalized by Akav and Roditty [9] who presented an algorithm with stretch $2+\frac{k-2}{k}$ and running time $\tilde{O}(m^{2/k}n^{2-3/k}+n^2)$ for any $k \geq 2$.

In *unweighted*, undirected graphs, a $(1,2)$-approximation algorithm with running time $\tilde{O}(n^{2.5})$ has been presented by Aingworth, Chekuri, Indyk and Motwani [7]. This has been improved by Dor, Halperin, and Zwick [32] that showed a $(1,2)$-approximation with running time $\tilde{O}(\min\{n^{3/2}m^{1/2}, n^{7/3}\})$. They also show a generalized version of the algorithm that gives stretch $(1,k)$ and running time $\tilde{O}(\min\{n^{2-2/(k+2)}m^{2/(k+2)}, n^{2+2/(3k-2)}\})$ for every even $k > 2$. Recently faster $(1,2)$-approximation algorithms based on fast matrix multiplication techniques were developed [31, 36], the fastest of them runs in $O(n^{2.260})$ time [36]. This was extended to a $(1+\epsilon,2)$-approximation in $O(n^{2.152})$ [33]. In addition, recently Roditty [57] extended the approach of [32] to obtain a combinatorial $(2,0)$-approximation for APSP in $\tilde{O}(n^{2.25})$ time in unweighted undirected graphs. Using fast matrix multiplication, this running time was improved to $O(n^{2.032})$ [33, 60].

Berman and Kasiviswanathan [16] showed how to compute a $(2,1)$-approximation in time $\tilde{O}(n^2)$. Subsequent works [11, 14, 55, 61, 52] have improved the polylogarithmic factors in the running time and the space requirements for such nearly 2-approximations. Recently, slightly subquadratic algorithms have been given: an algorithm with stretch $(2(1+\epsilon),5)$ by Akav and Roditty [8], and an algorithm with stretch $(2,3)$ by Chechik and Zang [25].

Decremental algorithms

The fastest algorithms for maintaining exact APSP under edge deletions have total update time $\tilde{O}(n^3)$ [30, 13, 39]. There are several algorithms that are more efficient at the cost of returning only an approximate solution. In particular, a $(1+\epsilon)$-approximation can be maintained in total time $\tilde{O}(mn)$ [59, 18, 49]. If additionally, an additive error of 2 is tolerable,

then a $(1+\epsilon, 2)$-approximation can be maintained in total time $\tilde{O}(n^{2.5})$ in unweighted, undirected graphs [46, 5]. Note that such a $(1+\epsilon, 2)$-approximation directly implies a $(2+\epsilon)$-approximation because the only paths of length 1 are edges between neighboring nodes. All of these decremental approximation algorithms are randomized and assume an oblivious adversary. Deterministic algorithms with stretch $1+\epsilon$ exist for unweighted, undirected graphs with running time $\tilde{O}(mn)$ [46], for weighted, undirected graphs with running time $\tilde{O}(mn^{1+o(1)})$ [21] and for weighted, directed graphs with running time $\tilde{O}(n^3)$ [50].

Decremental approximate APSP algorithms of larger stretch, namely at least 3, have first been studied by Baswana, Hariharan, and Sen [12]. After a series of improvements [59, 22, 6, 47], the state-of-the-art algorithms of [24, 53] maintain $(2k-1)(1+\epsilon)$-approximate all-pairs shortest paths for any integer $k \geq 2$ and $0 < \epsilon \leq 1$ in total update time $\tilde{O}((m+n^{1+o(1)})n^{1/k})$ with query time $O(\log\log(nW))$ and $O(k)$ respectively. All of these "larger stretch" algorithms are randomized and assume an oblivious adversary.

Recently, deterministic algorithms have been developed by Chuzhoy and Saranurak [27] and by Chuzhoy [26]. One tradeoff in the algorithm of Chuzhoy [26] for example provides total update time $\tilde{O}(m^{1+\mu})$ for any constant μ and polylogarithmic stretch. As observed by Mądry [54], decremental approximate APSP algorithms that are deterministic – or more generally work against an adaptive adversary – can lead to fast static approximation algorithms for the maximum multicommodity flow problem via the Garg-Könemann-Fleischer framework [44, 41]. The above upper bounds for decremental APSP have recently been contrasted by conditional lower bounds [4] stating that constant stretch cannot be achieved with subpolynomial update and query time under certain hardness assumptions on 3SUM or (static) APSP.

Fully dynamic algorithms

The reference point in fully dynamic APSP with subpolynomial query time is the *exact* algorithm of Demetrescu and Italiano [29] with update time $\tilde{O}(n^2)$ (with log-factor improvements by Thorup [62]). For undirected graphs, several fully dynamic distance oracles have been developed. In particular, Bernstein [17] developed a distance oracle of stretch $2+\epsilon$ (for any given constant $0 < \epsilon \leq 1$) and update time $O(m^{1+o(1)})$. In the regime of stretch at least 3, tradeoffs between stretch and update time have been developed by Abraham, Chechik, and Talwar [6], and by Forster, Goranci, and Henzinger [42]. Finally, most fully dynamic algorithm with update time sensitive to the edge density can be combined with a fully dynamic spanner algorithm leading to faster update time at the cost of a multiplicative increase in the stretch, see [15] for the seminal work on fully dynamic spanners.

2 High-Level Overview

In this section we provide a high-level overview of our algorithms, for the complete algorithms and their proof we refer to the full version. First we describe our $(2+\epsilon)$-APSP algorithms for weighted graphs, by giving a simpler static version first. Then we describe our $(2+\epsilon, W_{u,v})$-APSP algorithm, where we introduce a notion of *bunch overlap threshold* to overcome the challenge of dynamically maintaining a well-known static adaptive sampling technique [63] (see Section 2.2). We give a reduction from mixed approximations to purely multiplicative approximations, which together with the previous result gives our $(2+\epsilon)$-APSP algorithm for unweighted graphs. Finally, we describe our $(1+\epsilon, 2(k-1))$-APSP algorithm for any $k \geq 2$ in unweighted graphs.

2.1 $(2+\epsilon)$-APSP for Weighted Graphs

We first present a warm-up static algorithm, that we later turn into a dynamic algorithm.

2.1.1 Static 2-APSP

We start by reviewing the concepts of bunch and cluster as defined in the seminal distance oracle construction of [64].

Let $0 < p < 1$ be a parameter and A a set of nodes sampled with probability p. For each node u, the pivot $p(u)$ is the closest node in A to u. The *bunch* $B(v)$ of a node v is the set $B(v) := \{u \in V : d(u,v) < d(v,p(v))\}$ and the *clusters* are $C(u) := \{v \in V : d(u,v) < d(v,p(v))\} = \{v \in V : u \in B(v)\}$. Hence bunches and clusters are reverse of each other: $u \in B(v)$ if any only if $v \in C(u)$.

These structures have been widely used in various settings, including the decremental model (e.g. [46, 58, 53, 24]). We can use these existing decremental algorithms to maintain bunches and clusters, but will need to develop new decremental tools to get our desired tradeoffs that we will describe in Section 2.1.2.

Using the well-known distance oracles of [64], we know that by storing the clusters and bunches and the corresponding distances inside them, we can query 3-approximate distances for any pair. At a high-level, for querying distance between a pair u, v we either have $u \in B(v)$ or $v \in B(u)$ and so we explicitly have stored their distance, or we can get a 3-approximate estimate by computing $\min\{d(u,p(u)) + d(p(u),v), d(v,p(v)) + d(p(v),u)\}$. In the following we explain that in some special cases we can use these estimates to a obtain 2-approximation for a pair u, v, and in other cases by storing more information depending on how $B(u)$ and $B(v)$ overlap we can also obtain a 2-approximation to $d(u,v)$.

Let us assume that for all nodes v we have computed $B(v)$ and have access to all the distances from v to each node $u \in B(v)$. Also assume that we have computed the distances from the set A to all nodes. We now describe how using this information we can get a 2-approximate estimate of *any* pair of nodes u, v in one case. In another case we will discuss what other estimates we need to precompute. Let π be the shortest path between u and v. We consider two cases depending on how the bunches $B(u)$ and $B(v)$ interact with π. A similar case analysis was used in [23, 35] in distributed approximate shortest paths algorithms.

1. There exists $w \in \pi$ such that $w \notin B(u) \cup B(v)$ (left case in Figure 1): Since w is on the shortest path, we either have $d(w,u) \leq d(u,v)/2$ or $d(v,w) \leq d(u,v)/2$. Suppose $d(w,u) \leq d(u,v)/2$. We observe that by definition $d(u,p(u)) \leq d(u,w)$, hence we obtain $d(u,p(u))+d(p(u),v) \leq d(u,p(u))+d(u,p(u))+d(u,v) \leq 2d(u,v)$. The case that $d(v,w) \leq d(u,v)/2$ is analogous, and hence by computing $\min\{d(u,p(u)) + d(p(u),v), d(v,p(v)) + d(p(v),u)\}$ we get a 2-approximation.
2. There exists no $w \in \pi$ such that $w \notin B(u) \cup B(v)$. In other words, $B(u) \cap B(v) \cap \pi = \emptyset$ and there exists at least one edge $\{u', v'\}$ on π where $u' \in B(u)$ and $v' \in B(v)$ (right case in Figure 1[3]): in this case we can find the minimum over estimates obtained through all such pairs u', v', i.e. by computing $d(u,u') + w(u',v') + d(v',v)$.

If we had access to all the above distances for the bunches and the pivots, we could then use them to query 2-approximate distances between any pair $u, v \in V$. As we will see, in our algorithms we only have *approximate bunches and pivots* which lead to $(2+\epsilon)$-approximate queries.

[3] Although the picture implies $B(u)$ and $B(v)$ are disjoint, this also includes the case where they overlap, or even where $u \in B(v)$ or $v \in B(u)$.

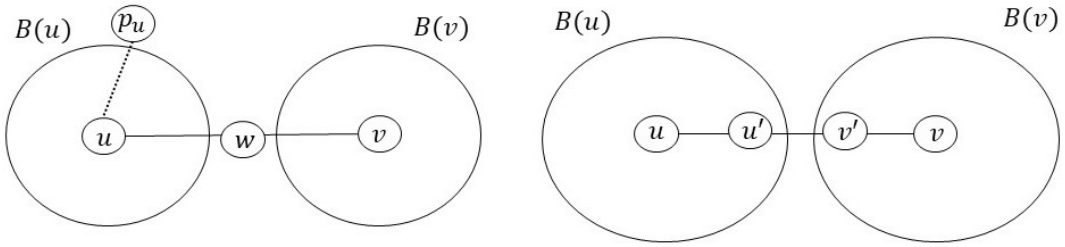

Figure 1 Possible scenarios for the overlap between the bunches $B(u)$, $B(v)$ and the shortest path π from u to v.

Running time

We can compute bunches and clusters in $\tilde{O}(\frac{m}{p})$ time [64]. We need to compute shortest paths from A for the estimates in Case 1. This takes $O(|A|m) = \tilde{O}(pnm)$ time using Dijkstra's algorithm. Finally, we consider Case 2. A straight-forward approach is to consider each pair of vertices u, v, and all $u' \in B(u)$ and $v' \in B(v)$. This takes $O(\frac{n^2}{p^2})$ time.

We use a sophisticated intermediate step that computes the distance between u' and v if there is an edge $\{u', v'\} \in E$ such that $v' \in B(v)$. For each node $v \in V$, we consider all $v' \in B(v)$, for which we consider all neighbors $u' \in N(v')$ and compute the estimate $w(u', v') + d(v', v)$ (and replace current $u' - v$ minimum if it is smaller). Since $|B(v)| = \tilde{O}(\frac{1}{p})$, we can compute these estimates for $d(u', v)$ in $\tilde{O}(\frac{n^2}{p})$ time.

Next, for each pair $u, v \in V$, we take the minimum over the distances $d(u, u') + d(u', v)$ for all u' in the bunch $B(u)$ using the precomputed distances from the previous step in time $\tilde{O}(n^2/p)$, by iterating over all pairs $u, v \in V$, and all $u' \in B(u)$. So in total the adjacent case takes time $\tilde{O}(\frac{n^2}{p})$. Hence the total running time of the algorithm will be $\tilde{O}(pnm + m/p + n^2/p) = \tilde{O}(pnm + n^2/p)$. By setting $p = \sqrt{\frac{n}{m}}$ we obtain the total update time $\tilde{O}(m^{1/2}n^{3/2})$ as stated in Theorem 1.

There are several subtleties that make it more difficult to maintain these estimates in decremental settings since the bunches and which bunches are adjacent keep on changing over the updates. We next discuss how these can be handled. We obtain a total update time that matches the stated static running time (up to subpolynomial factors).

2.1.2 Dynamic Challenges

Maintaining bunches and pivots

First, we need to dynamically maintain bunches efficiently as nodes may join and leave a bunch throughout the updates using an adaptation of prior work. One option would be maintaining the clusters and bunches using the [59] framework, however using this directly is slow for our purposes. Hence we maintain *approximate* clusters and bunches using hopsets of [53]. This algorithm also maintains approximate pivots, i.e. pivots that are within $(1 + \epsilon)$-approximate distance of the true closest sampled node. These estimates let us handle the first case (up to $(1 + \epsilon)$ approximation). One subtlety is that the type of approximate bunches used in [53] is slightly different with the type of approximate bunches we need for other parts of our algorithm. Specifically we need to bound the number of times nodes in a bunch can change. Roughly speaking, we can show this since the graph is decremental and the estimates obtained from the algorithm of [53] are monotone. Hence we perform *lazy bunch updates*, where we only let a bunch grow if the distance to the pivot grows by at least a factor $1 + \epsilon$. This means a bunch grows at most $O(\log_{1+\epsilon}(nW))$ times. In addition, these approximate bunches need to be taken into account into our stretch analysis.

We note that $(1+\epsilon)$-approximate decremental SSSP takes $\tilde{O}(m^{1+o(1)})$ total update time. However, we use the multi-source shortest path result from [53], where the $n^{o(1)}$-term vanishes when applied with polynomially many sources, giving us a total update time of $\tilde{O}(|A|m)$.

Maintaining estimates for Case 2

When we are in Case 2, we need more tools to keep track of estimates going through these nodes since both the bunches and the distances involved are changing. In particular, we explain how by using heaps in different parts of our algorithm we get efficient update and query times. Moreover, note that we have an additional complication: there are two data structures in this step, where one impacts the other. We need to ensure that an update in the original graph does not lead to many changes in the first data structure, which all need to be processed for the second data structure.

To be precise, we need intermediate data structures $Q_{u',v}$ that store approximate distances for u' and v of the form $w(u',v') + \delta(v',v)$ for each $v' \in B(v)$ such that $\{u',v'\} \in E$, as explained for the static algorithm[4]. As opposed to the static algorithm, we do not only keep the minimum, but instead maintain a min-heap, from which the minimum is easily extracted.

However, this approach has a problem: $\delta(v',v)$ might change many times, and for each such change we need to update at most $|N(v')| \leq n$ heaps. To overcome this problem, we use another notion of *lazy distance update*: we only update a bunch if the estimate of a node changes by at least a factor $1+\epsilon$. Combining this with the fact that, due to the lazy *bunch* update, nodes only join a cluster at most $O(\log_{1+\epsilon}(nW))$ times, and thus there is only an $O(\log_{1+\epsilon}(nW)\log(nW))$ overhead in maintaining these min-heaps $Q_{u',v}$ dynamically due to bunch updates.

Similarly, $w(u',v')$ might change many times, which has an impact for every $v \in C(v')$. Since this can be many nodes, we need to use an additional trick so an adversary cannot increase our update time to mn. Again the solution is a lazy update scheme: instead of $w(u',v')$ we use $\tilde{w}(u',v') = (1+\epsilon)^{\lceil \log_{1+\epsilon} w(u',v') \rceil}$, which can only change $\log_{1+\epsilon} W$ times. This comes at the cost of a $(1+\epsilon)$ approximation factor.

We note that our bunches are approximate bunches in three different ways. We have one notion of approximation due to the fact that we are using hopsets (that implicitly maintain bunches on scaled graphs). We have a second notion of approximation due to our lazy bunch update, which only lets nodes join a bunch a bounded number of times. We have a third notion of approximation due to the lazy distance update, which only propagates distance changes $O(\log(nW))$ times. We need to carefully consider how these different notions of approximate bunch interact with each other and with the stretch of the algorithm.

Next, we want to use the min-heaps $Q_{u',v}$ to maintain the distance estimates for $u,v \in V$ (see again the right case in Figure 1). We construct min-heaps $Q'_{u,v}$, with for each pair u,v entries $\delta(u,u') + \delta(u',v)$ for $u' \in B(u)$. Here $\delta(u',v)$ is the minimum from the intermediate data structure $Q_{u',v}$.

An entry $\delta(u,u') + \delta(u',v)$ in $Q'_{u,v}$ has to be updated when either $\delta(u,u')$ or $\delta(u',v)$ change. We have to make sure we do not have to update these entries too often. For the first part of each entry, we bound updates to the distance estimates $\delta(u,u')$ by the lazy distance updates. One challenge here is that when the distance estimates in a bunch change we need to update all the impacted heaps i.e. if $\delta(u,u')$ inside a bunch $B(u)$ changes, we must update all the heaps $Q'_{u,v}$ such that there exists $\{u',v'\} \in E$ with $v' \in B(v)$. For this purpose one

[4] In this section, $\delta(\cdot,\cdot)$ denotes $(1+\epsilon)$-approximate distances in our dynamic data structures.

approach is the following: for each $u \in V, u' \in B(u)$ we keep an additional data structure $\text{Set}_{u,u'}$ that stores for which $v \in V$ we have $v' \in B(v)$ with $\{u', v'\} \in E$. This means that given a change in $\delta(u, u')$, we can update each of the heaps in logarithmic time.

For the second part of the entry, which is the distance estimate $\delta(u', v)$ from the first data structure, this is more complicated. Another subtlety for our decremental data structures is the fact that $\delta(u', v)$ may also decrease due to a new node being added to $B(v)$. However, our lazy bunch update ensures that $\delta(u', v)$ can only decrease $O(\log_{1+\epsilon}(nW))$ times. Further, we use lazy distance increases *in between* such decreases. Hence in total we propagate changes to $\delta(u', v)$ at most $O(\log_{1+\epsilon}(nW)\log(nW))$ times, and thus our decremental algorithm has $\tilde{O}(\log_{1+\epsilon}(nW)\log(nW))$ overhead compared to the static algorithm.

2.2 $(2+\epsilon, W_{u,v})$-APSP for Weighted Graphs

For a moment, let us go back to the first static algorithm. It turns out, that if instead of computing an estimate for two "adjacent" bunches, we keep an estimate for bunches that overlap in at least one node, we obtain a $(2, W_{u,v})$-approximation, where $W_{u,v}$ is the maximum weight on the shortest path from u to v.

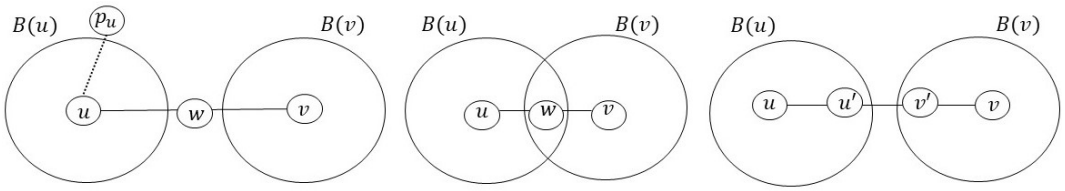

Figure 2 Possible scenarios for the overlap between the bunches $B(u)$ and $B(v)$ and the shortest path π from u to v.

The stretch analysis comes down to the following cases:

- There exists no $w \in \pi \cap B(u) \cap B(v)$ (the left and right case in Figure 2).
- There exists $w \in \pi$ such that $w \in B(u) \cap B(v)$ (the middle case in Figure 2).

The crucial observation here is that the distance estimate via the pivot (Case 1 in the previous section) already gives a $(2, W_{u,v})$-approximation for the adjacent case (the right case in Figure 2). So if we maintain an estimate for $d(u, v)$ if there exists $w \in \pi$ such that $w \in B(u) \cap B(v)$ (the "overlap case"), then we obtain a $(2, W_{u,v})$-approximation in total.

Here we need to create a min-heap for the overlap case, later we show we can maintain in $\tilde{O}(nC_{\max}/p)$ time. First we focus on the challenge of bounding $C_{\max}$.

Efficiency challenge

While the bunches are small, there is no bound on the size of the clusters. To overcome this issue in the static case, Thorup and Zwick developed an alternative way to build the bunches and clusters, that guarantees that the clusters are also small [63]. At a high-level, their approach is to adaptively change (grow) A by sampling big clusters into smaller clusters using a sampling rate proportional to the cluster size and adding these nodes to the set of pivots A. In total, in $\tilde{O}(m/p)$ time we obtain bunches and clusters, *both* of size $\tilde{O}(1/p)$. This idea was developed in the context of obtaining compact routing schemes, and later found numerous applications in static algorithms for approximating shortest paths and distances (see e.g., [14, 8, 10, 9]).

Using this trick, the static algorithm has running time $\tilde{O}(\frac{m}{p} + pnm + \frac{n}{p^2}) = \tilde{O}(nm^{3/4} + m^{4/3})$, for $p = m^{-1/3}$ or $\tilde{O}(mn^{1/2} + n^2)$ for $p = n^{-1/2}$.

However, the adaptive sampling procedure does not seem to be well-suited to a dynamic setting. The reason is that the sampling procedure is adaptive in such a way that when the bunches/clusters change, the set of sampled nodes can also change. Although (a dynamic adaptation of) the algorithm can guarantee that the set of sampled nodes is small at any particular moment, there is no guarantee on the *monotonicity* of the set A of sources that we need to maintain distances from. This would add a significant amount of computation necessary to propagate these changes to other parts of the algorithm. A possible solution is to enforce monotonicity by never letting nodes leave A. This would require us to bound the *total* number of nodes that would ever be sampled, which seems impossible with the current approach. To overcome this, we next suggest a new approach that gives us the monotonicity needed for our dynamic algorithm. For simplicity, we first present this in a static setting.

Introducing bunch overlap thresholds

Our proposed approach is to divide the nodes into two types depending on the number of bunches they appear in. In particular, we consider a threshold parameter τ and we define a node to be a *heavy node* if it is in more than τ bunches (equivalently its cluster contains more than τ nodes), and otherwise we call it a *light node*. In other words, for the set of light nodes we have $C_{\max} \leq \tau$. This threshold introduces a second type of pivot for each node u, which we denote by $q(u)$ that is defined to be the closest heavy node to u. In particular, instead of computing all distance estimates going through nodes $w \in B(u) \cap B(v)$, we only compute them for the case that w is light, and otherwise it is enough to compute the minimum estimates going through the heavy pivots, i.e. $\min\{d(u, q(u)) + d(q(u), v), d(v, q(v)) + d(q(v), u)\}$. We emphasize that these heavy pivots are *not a subset* of our original pivots $p(v), v \in V$, and they have a different behavior in bounding the running time than the *bunch pivots*. As we will see later, introducing these thresholds is crucial in efficiently obtaining the estimates required for Case 2.2 as we can handle the light and heavy case separately.

Stretch of the algorithm with bunch overlap thresholds

As discussed above, the stretch analysis was divided into two cases. In the new variant of the algorithm we add a third case, where we look at the distance estimates going through heavy pivots, i.e. $\min\{d(u, q(u)) + d(q(u), v), d(v, q(v)) + d(q(v), u)\}$. The main idea is that now we only need to consider the difficult case, Case 2.2, if the relevant node is light, which allows us to implement the algorithm efficiently.

If the relevant node $w \in B(u) \cap B(v)$ in Case 2 is heavy, we obtain a 2-approximation through the heavy pivot: we get that the $\min\{d(u, w), d(v, w)\} \leq d(u, v)/2$, since $d(u, v) = d(u, w) + d(w, v)$. W.l.o.g. say $d(u, w) \leq d(u, v)/2$. Then $d(u, q(u)) \leq d(u, w) \leq d(u, v)/2$, hence $d(u, q(u)) + d(q(u), v) \leq d(u, q(u)) + d(q(u), u) + d(u, v) \leq 2d(u, v)$.

Maintaining estimates through heavy nodes

For the stretch analysis above, we need to maintain a shortest path tree from each heavy node. We ensure a bunch grows at most $O(\log_{1+\epsilon}(nW))$ times. Hence by a total load argument we get that the *total* number of nodes in all bunches over all updates is at most $O(\frac{n}{p} \log_{1+\epsilon}(nW))$. This implies there cannot be too many heavy nodes in total, hence we can enforce monotonicity by keeping in V_{heavy} all nodes that were once heavy. As a consequence, we can maintain multi-source approximate distances from all heavy nodes efficiently: we can compute shortest paths from this set to all other nodes in $O(|V_{\text{heavy}}|m) = O(\frac{nm}{p\tau})$ time.

Running time of the algorithm with bunch overlap thresholds

Summarizing, we compute bunches and clusters in $O(m/p)$ time, compute distances from A to V in $O(|A|m) = \tilde{O}(pnm)$ time, and we can compute shortest paths from ththe heavy nodes in $O(|V_{\text{heavy}}|m) = O(\frac{nm}{p\tau})$ time.

Finally, we consider Case 2.2. For each node $u \in V$, we consider every light node $w \in B(u)$, and then all nodes $v \in C(W)$. Since w is light, we have $|C(w)| \leq \tau$, so this takes time $\tilde{O}(n \cdot \frac{1}{p} \cdot \tau)$.

Hence, in the total update time, we obtain $\tilde{O}((pnm + \frac{nm}{p\tau} + n\tau/p)\log^2(nW))$. Setting $p = m^{-1/4}$ and $\tau = m^{1/2}$ gives a total update time of $\tilde{O}(nm^{3/4}\log(nW))$.

Again for a decremental algorithm, we need to combine this new idea with the subtleties we had in the previous section: the bunches, their overlaps, and the heavy nodes keep on changing over the updates. We obtain a total update time that matches the stated static running time (up to subpolynomial factors) for the algorithm using bunch overlap thresholds.

2.2.1 $(2+\epsilon)$-APSP for Unweighted Graphs

We observe that in unweighted graphs mixed approximation can always be turned into a multiplicative approximation – at the cost of a blow-up in the number of vertices. More precisely, we prove the following reduction.

▶ **Theorem 5.** *Let $\mathcal{A}$ be an algorithm that provides a $(a+\epsilon, k)$-approximation for APSP in $\tau_{\mathcal{A}}(n', m')$ time, for any unweighted n'-node m'-edge graph G', and any constants $a, k \in \mathbb{N}_{\geq 1}$ and $\epsilon \in [0, 1)$. Given an unweighted graph $G = (V, E)$ on n nodes and m vertices, we can compute $(a + (k+2)\epsilon, 0)$-APSP in $\tau_{\mathcal{A}}(n + km, (k+1)m)$ time.*

If $\mathcal{A}$ is a dynamic algorithm, then each update takes $(k+1) \cdot$ [update time of $\mathcal{A}$] time. The query time remains the same (up to a constant factor).

The result is obtained by splitting every edge into k edges, by introducing new nodes on the edge. Now a path corresponding to a $+k$ approximation cannot take a non-trivial detour.

We combine this result with Theorem 2 to obtain a $(2+\epsilon)$-approximation for unweighted graphs in $\tilde{O}(m^{7/4})$ total update time.

2.3 $(1+\epsilon, 2(k-1))$-APSP for Unweighted Graphs

In this section, we describe our near-additive APSP algorithm. Our work is inspired by a classic result of Dor, Halperin, and Zwick [32], that presented a static algorithm that computes purely additive $+2(k-1)$ approximation for APSP in $\tilde{O}(n^{2-1/k}m^{1/k})$ time in unweighted graphs. Our goal is to obtain similar results dynamically. More concretely, we obtain decremental $(1+\epsilon, 2(k-1))$-approximate APSP in $O(n^{2-1/k+o(1)}m^{1/k})$ total update time in unweighted graphs.

2.3.1 $(1+\epsilon, 2)$-APSP

To explain the high-level idea of the algorithm, we first focus on the special case that $k = 2$, and that we only want to approximate the distances between pairs of nodes at distance at most d from each other, for a parameter d. In this case, we obtain a $+2$-additive approximation in $\tilde{O}(n^{3/2}m^{1/2}d)$ time. This case already allows to present many of the high-level ideas of the algorithm. Later we explain how to extend the results to the more general case. We start by describing the static algorithm from [32], and then explain the dynamic version. The static version of the data structure is as follows:

- Let $s_1 = (\frac{m}{n})^{1/2}$. Let V_1 be the set of *dense nodes*: $V_1 := \{v \in V : \deg(v) \geq s_1\}$. Also let E_2 be the set of *sparse edges*, i.e. edges with at least one endpoint with degree less than s_1.
- **Node set D_1.** Construct a hitting set D_1 of nodes in V_1. This means that every node $v \in V_1$ has a neighbor in D_1. The size of D_1 is $O(n \log n/s_1)$.
- **Edge set E^*.** Let E^* be a set of size $O(n)$ such that for each $v \in V_1$, there exists $u \in D_1 \cap N(v)$ such that $\{u, v\} \in E^*$.
- **Computing distances from D_1.** Store distances $D_1 \times V$ by running a BFS from each $u \in D_1$ on the input graph G.
- **Computing distances from $V \setminus D_1$.** For each $u \in V \setminus D_1$ store a shortest path tree, denoted by T_u rooted at u by running Dijkstra on $(V, E_2 \cup E^* \cup E_u^{D_1})$, where $E_u^{D_1}$ is the set of weighted edges corresponding to distances in $(\{u\} \times D_1)$ computed in the previous step.

Dynamic data structure

The static algorithm computes distances in two steps. First, it computes distances from D_1 by computing BFS trees in the graph G. This step can be maintained dynamically by using *Even-Shiloach trees (ES-trees)* [40], a data structure that maintains distances in a decremental graph. Maintaining the distances up to distance $O(d)$ takes $O(|D_1|md)$ time. The more challenging part is computing distances from $V \setminus D_1$. Here the static algorithm computes distances in the graphs $H_u = (V, E_2 \cup E^* \cup E_u^{D_1})$. Note that the graphs H_u change dynamically in several ways. First, in the static algorithm, the set E_2 is the set of light edges. To keep the correctness of the dynamic algorithm, every time that a node v no longer has a neighbor in D_1, we should add all its adjacent edges to E_2. Second, when an edge in E^* is deleted from G, we should replace it by an alternative edge if such an edge exists. Finally, the weights of the edges in $E_u^{D_1}$ can change over time, when the estimates change. This means that other than deletions of edges, we can also add new edges to the graphs H_u or change the weights of their edges. Because of these edge insertions we can no longer use the standard ES-tree data structure to maintain the distances, because that only works in a decremental setting.

To overcome this, we use *monotone ES-trees*, a generalization of ES-trees proposed by [46, 45]. In this data structure, to keep the algorithm efficient, when new edges are inserted, the distance estimates do not change. In particular, when edges are inserted, some distances may decrease, however, in such cases the data structure keeps an old larger estimate of the distance. The main challenge in using this data structure is to show that the stretch analysis still holds. In particular, in our case, the stretch analysis of the static algorithm was based on the fact the distances from the nodes $V \setminus D_1$ are computed in the graphs H_u, where in the dynamic setting, we do not have this guarantee anymore.

Stretch analysis

The high-level idea of the stretch analysis uses the special structure of the graphs H_u. To prove that the distance estimate between u and v is at most $d(u, v) + 2$, we distinguish between two cases. First, we maintain the property that as long as v has a neighbor $x \in D_1$, then an edge of the form $\{v, x\}$ is in E^* for $x \in D_1 \cap N(v)$, and since we maintain correctly the distances from D_1, we can prove that we get an additive stretch of at most 2 in this case.

In the second case, all the edges adjacent to v are in $E_2 \subseteq H_u$, and here we can use an inductive argument on the length of the path to prove that we get an additive stretch of at most 2. Note that the estimate that we get can be larger compared to the distance between u and v in the graph H_u, but we can still show that the additive approximation is at most 2 as needed.

Update time

Our update time depends on the size of the graphs H_u. While in the static setting it is easy to bound the number of edges in E_2 and E^*, in the decremental setting, as new edges are added to these sets, we need a more careful analysis. For example, in the static setting $|E^*| = O(n)$, as any node only adds one adjacent edge to the set E^*, where in the decremental setting, we may need to add many different edges to this set because the previous ones got deleted. However, we can still prove that even if a node needs to add to E^* edges to all its adjacent neighbors in D_1 during the algorithm, the size of H_u is small enough as needed. In the full version we show that the total update time is $\tilde{O}(m^{1/2}n^{3/2}d)$ in expectation, this matches the static complexity up to the factor d.

Handling large distances

The algorithm described above is efficient if d is small, to obtain an efficient algorithm for the general case, we combine our approach with a decremental near-additive APSP algorithm. More concretely, we use an algorithm from [45] that allows to compute $(1+\epsilon, \beta)$-approximation for APSP in $O(n^{2+o(1)})$ total update time, for $\beta = n^{o(1)}$. Now we set $d = \Theta(\beta/\epsilon)$, and distinguish between two cases. For pairs of nodes at distance at most d from each other, we get a $+2$-additive approximation as discussed above, in $O(m^{1/2}n^{3/2+o(1)})$ time. For pairs of nodes at distance larger than d, the near-additive approximation is already a $(1 + O(\epsilon))$-approximation by the choice of the parameter d. For such pairs, the additive β term becomes negligible, as their distance is $\Omega(\beta/\epsilon)$. Overall, we get a $(1+\epsilon, 2)$-approximation for APSP in $O(m^{1/2}n^{3/2+o(1)})$ time. In fact, if the graph is dense enough ($m = n^{1+\Omega(1)}$), the $n^{o(1)}$ term is replaced by a poly-logarithmic term.

2.3.2 General k

We can extend the algorithm to obtain a $(1 + \epsilon, 2(k - 1))$-approximate APSP in $O(n^{2-1/k+o(1)}m^{1/k})$ total update time, by adapting the general algorithm of [32] to the dynamic setting. At a high-level, instead of having one hitting set D_1, we have a series of hitting sets $D_1, D_2, ..., D_k$, such that the set D_i hits nodes of degree s_i. We compute distances from D_i in appropriate graphs H_u^i, that are sparser when the set D_i is larger. Balancing the parameters of the algorithm leads to the desired total update time.

2.3.3 Limitations of previous approaches

We next explain why approaches used in previous decremental algorithms cannot be generalized to obtain our near-additive results. First, the unweighted $(1 + \epsilon, 2)$-approximate APSP algorithm that takes $\tilde{O}(n^{5/2}/\epsilon)$ time [46], is inspired by static algorithms for $+2$-additive emulators, sparse graphs that preserve the distances up to a $+2$-additive stretch. The main idea is to maintain a sparse emulator of size $\tilde{O}(n^{3/2})$, and exploit its sparsity to obtain a fast algorithm. This construction however is specific for the $+2$ case, and cannot be generalized to a general k. Note that the update time of the algorithm crucially depends on the size of the

emulator, and to obtain a better algorithm for a general k, we need to be able to construct a sparser emulator for a general k. However, a beautiful lower bound result by Abboud and Bodwin [1] shows that for any constant k, a purely additive $+k$ emulator should have $\Omega(n^{4/3-\epsilon})$ edges. This implies that dynamic algorithms that are based on purely additive emulators seem to require $\Omega(n^{7/3-\epsilon})$ time, and we cannot get running time arbitrarily close to $O(n^2)$. An alternative approach is to build a *near-additive* emulator. This is done in [45], where the authors show a $(1+\epsilon, 2(1+2/\epsilon)^{k-2})$-approximation algorithm for decremental APSP with expected total update time of $\tilde{O}(n^{2+1/k}(37/\epsilon)^{k-1})$. Here the running time indeed gets closer to $O(n^2)$, but this comes at a price of a much worse additive term of $2(1+2/\epsilon)^{k-2}$. While in the static setting there are also other bounds obtained for near-additive emulators, such as $O(1+\epsilon, O(k/\epsilon)^{k-1})$ emulators of size $O(kn^{1+\frac{1}{2^{k+1}-1}})$ [38, 65, 2, 37], in all of the constructions the additive term depends on ϵ, and the dependence on ϵ is known to be nearly tight for small k by lower bounds from [2]. Hence this approach cannot lead to small constant additive terms that do not depend on ϵ.

Decremental Matching in General Weighted Graphs

Aditi Dudeja ✉
University of Salzburg, Austria

Abstract

In this paper, we consider the problem of maintaining a $(1-\varepsilon)$-approximate *maximum weight matching* in a dynamic graph G, while the adversary makes changes to the edges of the graph. In the fully dynamic setting, where both edge insertions and deletions are allowed, Gupta and Peng [20] gave an algorithm for this problem with an update time of $\tilde{O}_\varepsilon(\sqrt{m})$. We study a natural relaxation of this problem, namely the decremental model, where the adversary is only allowed to delete edges. For the unweighted version of this problem in general (possibly, non-bipartite) graphs, [3] gave a decremental algorithm with update time $O_\varepsilon(\text{poly}(\log n))$. However, beating $\tilde{O}_\varepsilon(\sqrt{m})$ update time remained an open problem for the *weighted* version in *general graphs*. In this paper, we bridge the gap between unweighted and weighted general graphs for the decremental setting. We give a $O_\varepsilon(\text{poly}(\log n))$ update time algorithm that maintains a $(1-\varepsilon)$ approximate maximum weight matching under adversarial deletions. Like the decremental algorithm of [3], our algorithm is randomized, but works against an adaptive adversary. It also matches the time bound for the unweighted version upto dependencies on ε and a $\log R$ factor, where R is the ratio between the maximum and minimum edge weight in G.

1 Introduction

In a dynamic graph G with vertex set V, an adversary makes updates to the edge set E of the graph, and the algorithm is required to adjust to these changes and maintain a key property of the graph. An algorithm is called *decremental* if it can only cope with edge deletions, *incremental* if it can only cope with edge insertions, and *fully dynamic* if it can cope with both edge insertions and deletions. Typically, the algorithm has to optimize the update time, which is the time taken to adapt to a single edge update. For incremental (respectively, decremental) algorithms, one seeks to optimize the amortized update time, which is the average time taken over m edge insertions (respectively, deletions).

In this paper, we consider the problem of maintaining a $(1-\varepsilon)$-approximate matching in a dynamic graph. For the general fully dynamic setting, where we have an unweighted graph undergoing updates, the best known algorithms for this problem due to Bhattacharya, Kiss, Saranurak [11] and Assadi, Behnezhad, Khanna, Li [2] have update times of $O(m^{0.5-\Omega_\varepsilon(1)})$ and $O(n/\log^* n)$, respectively. Improving these bounds to $O_\varepsilon(\text{poly}(\log n))$ is a fundamental

Table 1 A Comparison of Weighted and Unweighted Dynamic Matching in General Graphs.

Setting	Approximation	Time (Unweighted)	Time (Weighted)
Fully Dynamic	$(1-\varepsilon)$	$O(m^{0.5-\Omega_\varepsilon(1)})$ [11]	$\tilde{O}_\varepsilon(\sqrt{m})$ [20]
Fully Dynamic	$(2-\sqrt{2})$	$\tilde{O}_\varepsilon(1)$ [5]	$\tilde{O}_\varepsilon(\sqrt{m})$ [20]
Fully Dynamic	0.609	$\tilde{O}(\min\{\Delta^{1/3}, m^{1/6}\})$ [7]	$\tilde{O}_\varepsilon(\sqrt{m})$ [20]
Incremental	$(1-\varepsilon)$	$O_\varepsilon(1)$ [18]	$\tilde{O}_\varepsilon(\sqrt{m})$ [20]
Decremental	$(1-\varepsilon)$	$\tilde{O}_\varepsilon(1)$ [3]	$\tilde{O}_\varepsilon(1)$ (new)

open problem, and conditional lower bounds of $\Omega(\sqrt{m})$ (see [21] and [23]) for the exact case, seem to suggest that this problem is quite challenging. This has motivated the study of more relaxed versions of this problem. For example, one line of research has focussed on obtaining considerably faster update times, but at the cost of worse approximation ratios [6, 12]. Another research direction has been to study this problem in partially dynamic settings. In the *incremental setting*, there has been steady progress over the years. Several results [19, 18, 11, 14] culminated in a $O_\varepsilon(1)$ update time algorithm for maintaining $(1-\varepsilon)$-approximate matching in incremental graphs. On the *decremental* side, [9] and [22] gave $O_\varepsilon(\text{poly}(\log n))$ update time algorithms for maintaining $(1-\varepsilon)$-approximate matching in bipartite graphs. Subsequently, [3] extended these results to the case of general graphs by giving a $O_\varepsilon(\text{poly}(\log n))$ update time algorithm for the same approximation ratio.

For the case of weighted graphs, the picture is less clear. A general reduction of Stubbs and Williams [25] shows that any α-approximation unweighted matching algorithm can be converted to a $(0.5-\varepsilon)\cdot\alpha$-approximation weighted matching algorithm with nearly the same update time. Subsequently, [8] showed that one can avoid this factor 2 loss in the approximation ratio for the specific case of **bipartite** graphs. However, for the case of general graphs (possibly, non-bipartite), there is a significant gap between the best known weighted and unweighted dynamic algorithms, as illustrated in Table 1. The main contribution of our paper is to close this gap between weighted and unweighted matching for general graphs in the decremental setting:

▶ **Result 1** (Formalized in Theorem 4). *Given a decremental weighted graph G, there is a randomized algorithm that with high probability maintains a $(1-\varepsilon)$-approximation to the maximum weight matching in G in total time $\tilde{O}_\varepsilon(m)$.*

Concurrent Work. Independent of this work, Chen, Sidford, and Tu also [15] gave a $O_\varepsilon(\text{poly}(\log n))$ update time algorithm for maintaining $(1-\varepsilon)$-maximum weight matching in decremental graphs. Their techniques are very different from ours, and extend the entropy regularization approach of [22], who originally gave this framework for bipartite unweighted graphs. Both approaches are of independent interest, since they use vastly different technical frameworks: [15] use insights from concave optimization, whereas our approach is combinatorial. Our approach also has a better dependence on $\log n$[1], and additionally uses simple algorithmic paradigms such as independent sampling or the static approximate matching algorithms of [16]. In contrast, their approach has better dependence on ε (in particular, their update time has a dependence of $(1/\varepsilon)^{O(1/\varepsilon)}$), but uses more involved algorithmic subroutines such as computing k-partial Gomory-Hu trees.

[1] while they don't state it explicitly, we determined that their algorithm has an update time of $O_\varepsilon(\log^{11} n)$.

2 High-Level Overview

Our high-level approach is to follow the congestion balancing framework of [9], who maintain a fractional matching that is robust to deletions. In order to do this, they hope to compute a fractional matching which "spreads out" its flow. Therefore, they impose a capacity function on the edges. These capacities are initially small, and are increased gradually. In particular, they repeatedly invoke a subroutine M-OR-E*() that does one of the following in $O_\varepsilon(m \cdot \log n)$ time (here $\mu(G)$ refers to the size of the maximum cardinality matching):

1. Either output a fractional matching $\vec{x}$, with $x(e) \leqslant \kappa(e)$ for all $e \in E$, and $\sum_{e \in E} x(e) \geqslant (1-\varepsilon) \cdot \mu(G)$, or,
2. Output a set of bottleneck edges E^*, along which we can increase capacities:
   a. We have, $\kappa(E^*) = O(\mu(G) \cdot \log n)$.
   b. Every large matching M has at least $\varepsilon \cdot \mu(G)$ edges in E^*.

Property 2 ensures that we increase capacities carefully: Property 2a ensures the capacity increase is small, and Property 2b ensures that we only increase capacity along important edges. The subroutine M-OR-E*() can be used as a black-box to get a decremental matching algorithm: if M-OR-E*() outputs a fractional matching, then we can round it to an integral matching (see [26, 10, 13]). Otherwise, the capacity obeying maximum fractional matching is too small, and the algorithm outputs a set of bottleneck edges E^*. Thus, we increase capacity along it. Property 2 ensures the matching obtained is "robust" to deletions since it ensures the capacities are small on average.

The authors of [9] also use an outer subroutine which repeatedly invokes M-OR-E*() to get a decremental matching algorithm. Similar to the case of [3], this subroutine carries over with some impediments for the case of **general weighted graphs** as well. But, M-OR-E*() is far more challenging to implement, and this will be the focus of this extended abstract.

2.1 M-or-E*() for General Weighted Graphs

We first explicate what the impediments for implementing M-OR-E*() in general graphs is. For bipartite graphs, M-OR-E*() is much easier to implement, since approximate fractional matchings obeying capacity constraints can be computed using approximate max flows. Similarly, the set of bottleneck edges E^* correspond to the minimum cut. However, in *general graphs*, we don't have such a natural correspondence to max-flow/min-cut due to the integrality gap. More specifically, we mean that not every fractional matching has a large integral matching in its support. On the other hand, while fractional matchings which satisfy odd set constraints do have large integral matchings in their support, this characterization doesn't seem computationally useful at first. [3], in the context of unweighted graphs defined a fractional matching that is both computationally easy to compute, and also avoids the integrality gap. In particular, their candidate fractional matching either puts flow 1 on an edge or a flow of at most ε. By a folklore lemma, one can show that such fractional matchings satisfy small odd set constraints, and therefore have an integrality gap of $1-\varepsilon$. This is sufficient for us, since we focus on only approximation algorithms.

In this work on weighted decremental graphs, we also focus on finding the fractional matchings mentioned above, since even in weighted graphs they are known to have a small integrality gap. Towards this, we show the following structural lemmas. We note that [3] also prove unweighted versions of these structural lemmas, but as we will state later, their proofs are tailored towards unweighted graphs. Consequently, to prove these lemmas for weighted graphs, we come up with significantly different proof strategies. In what follows, we will use $\mathsf{mwm}(G)$ to denote the maximum weight matching of G.

1. First, given a weighted graph G with capacities κ on the edges of the graph, we want to check if the maximum weight fractional matching obeying odd set constraints (denoted $\mathsf{mwm}(G,\kappa)$) is at least $(1-\varepsilon)\cdot\mathsf{mwm}(G)$. As mentioned before, we can't use approximate min-cost flow to find such a fractional matching. First, such an algorithm is computationally expensive. Secondly, the fractional matching returned by it may not obey odd set constraints. Therefore, akin to [3] we prove a sampling theorem: sample every edge e of G independently, with a probability $p(e) \propto \kappa(e)$ to construct an uncapacitated graph G_s. Then, we show, with high probability, $\mathsf{mwm}(G_s) \geqslant \mathsf{mwm}(G,\kappa) - \varepsilon\cdot n$. Thus, we can now use G_s as a substitute for (G,κ): more concretely, we can compute $(1-\varepsilon)\cdot\mathsf{mwm}(G_s)$ using efficient algorithms such as the one by [16], and thus, get an estimate on $\mathsf{mwm}(G,\kappa)$. The authors in [3] proved the unweighted version of this lemma. However, their proof strategy was to use the Tutte-Berge theorem. The Tutte-Berge theorem is the non-bipartite counterpart of the Hall's theorem. In Hall's theorem, deficiency is defined as $\max_{T\subseteq L}\{|T| - |N(T)|\}$, where L is the left vertex set and is equal to $n-\mu(G)$. In the Tutte-Berge theorem, deficiency is analogously defined. The authors in [3] showed that in G_s, with high probability, the deficiency is at most $n-(\mu(G,\kappa)+\varepsilon\cdot n)$, and consequently, $\mu(G_s) \geqslant \mu(G,\kappa) - \varepsilon\cdot n$. However, since Tutte-Berge theorem is specific to unweighted graphs, our proof deviates from this.
2. Suppose the sampling procedure tells us that $\mathsf{mwm}(G,\kappa) \geqslant (1-\varepsilon)\cdot\mathsf{mwm}(G)$. In this case, we would like to compute a fractional matching $\vec{x}$ such that $\sum_{e\in E} w(e)\cdot x(e) \geqslant \mathsf{mwm}(G,\kappa)$. Akin to [3], we consider any M such that $w(M) \geqslant (1-\varepsilon)\cdot\mathsf{mwm}(G_s)$, and we split up M into two parts $M_H \subseteq M$, which are edges with high capacity, and $M_L \subseteq M$ which are edges with low capacity, and $V_H = V(M_H)$ and $V_L = V(M_L)$. Let E_L be the low capacity edges of G. Then, we can show that with high probability, $|M_H| + \mathsf{mwm}(G[V_L]\cap E_L,\kappa) \geqslant \mathsf{mwm}(G_s) - \varepsilon\cdot n$. Since congestion balancing allows us to round capacities of M_H to 1, we only need to compute $(1-\varepsilon)$-approximation to $\mathsf{mwm}(G[V_L]\cap E_L,\kappa)$, and we would have the required fractional matching. There are a few impediments to showing this theorem, and to computing $\mathsf{mwm}(G[V_L]\cap E_L,\kappa)$.
   a. First, the unweighted analog of this theorem by [3], showed the opposite of the structural theorem in 1: it shows that deficiency of G_s can not reduce by too much either. To do this, they consider the bipartite double cover of G_s and (G,κ) and use Hall's theorem to derive this conclusion. As mentioned before, for weighted graphs, we don't have this tool at our disposal, and therefore, have to make other arguments. We look at the dual linear programs of G_s and (G,κ), and use facts about these to draw our conclusions. We believe our arguments can be seen as a generalization of the approach of [3]. Looking at the proof in this light also simplifies the proof considerably.
   b. The second challenge is the computational aspect. We would like to compute a $(1-\varepsilon)$-approximate maximum weight fractional matching in $G[V_L]\cap E_L$ that obeys κ. The authors in [3] observe that since $G[V_L]\cap E_L$ only consists of low capacity edges, we can transform this into a bipartite graph, and then use an approximate flow algorithm. However, for us that would mean computing an approximate min-cost flow, which is computationally expensive. Another way to do this is to use LP-solvers (see [1]). However, these incur additional $\log n$ factors, which we believe in the context of dynamic graph algorithms can be huge. Therefore, we give a simple scaling based algorithm that repeatedly uses maximal flow as a subroutine to obtain a $(1-\varepsilon)$ approximation to $\mathsf{mwm}(G[V_L]\cap E_L,\kappa)$, while avoiding these $\log n$ factors.

There are other peripheral challenges as well, such as computing the set E^*. [9] showed that these edges E^* corresponded to the min-cut, and [3] showed that one can use the duals of G_s to determine these edges. We extend the proof of [3] to weighted graphs. Secondly, the

congestion balancing framework, as shown in [3] and [9] only applies to unweighted graphs, we are able to show that it extends to weighted graphs as well. Finally, the known rounding schemes of [26, 10, 13] as stated only apply to unweighted graphs. We extend [26] to handle the weighted fractional matching we construct.

▶ Remark 2. The structural theorems stated in Item 1 and Item 2a incur an additive error of $\varepsilon \cdot n$. In order to account for this, we use the vertex sparsification technique of [4], which allows us to construct $O(R \cdot \log n)$ multigraphs H_i such that $|V(H_i)| \leqslant O(^{R \cdot \mathsf{mwm}(G)}/_{\varepsilon})$ and each matching of G is preserved in one of the H_i. Here, R is the ratio of the max-weight edge and min-weight edge in G. As is evident, this reduction will cause our algorithms to have a large dependence on R. However, we can reduce this dependence by using a reduction of [20] (see Lemma 3), which has been used similarly in other prior works (see [8, 15]). We refer the reader to Appendix C of [8] for a proof.

▶ **Lemma 3** ([20]). *Let G be a weighted graph with arbitrary weights with R being the ratio between maximum and minimum edge weights. Let $\varepsilon \in (0, 0.5)$ and let $\gamma_\varepsilon = (^1/_\varepsilon)^{O(1/\varepsilon)}$. If there is an algorithm $\mathcal{A}$ that maintains an α-approximate maximum weight matching in a graph whose weights are $\{1, 2, 3, \cdots, W\}$ with update time $T(n, m, \alpha, W)$, then there is an algorithm $\mathcal{A}'$ that maintains a $(1-\varepsilon) \cdot \alpha$-approximate maximum weight matching in G in update time $O(T(n, m, \alpha, \gamma_\varepsilon) \cdot \log R)$.*

In the rest of the paper we will assume that $\mathsf{mwm}(G) = \Omega(\log n)$. This is because the graph is undergoing deletions, and soon as $\mathsf{mwm}(G)$ drops below this value, we can switch to a different decremental algorithm which we describe in the full version of our paper. Additionally, from Remark 2 we can also assume that $\mathsf{mwm}(G) = \Omega(^{\varepsilon \cdot n}/_W)$. Finally, from Lemma 3 we can assume that our graphs are integer-weighted with weights in $\{1, 2, \cdots, W\}$. All our structural theorems will be proven using these assumptions in mind. We will justify these assumption in the full version of this paper.

3 Preliminaries

Throughout the paper, we will use G to refer to the current version of the graph, and let V and E be the vertex set and edge set of G, respectively. The graphs we deal with are weighted, and we use R to denote the ratio between the max-weight and min-weight edge. Additionally use $\mathsf{mwm}(G)$ to denote the weight of the maximum weight matching of G. During the course of the algorithm, we will maintain a fractional matching, which corresponds to a non-negative vector $\vec{x} \in [0,1]^m$ satisfying the following constraints : $\sum_{v \ni e} x(e) \leqslant 1$. For a set $S \subseteq E$, we let $x(S) = \sum_{e \in S} x(e)$. Given a capacity function κ on the edges of the graph, we say that $\vec{x}$ obeys κ if $x(e) \leqslant \kappa(e)$ for all $e \in E$. For a vector $\vec{x}$, we use $\mathrm{supp}(\vec{x})$ to denote the set of edges that are in the support of $\vec{x}$. For a fractional matching $\vec{x}$, we say that it satisfies odd set constraints if for all odd-sized sets $B \subseteq V$, we have, $\sum_{e \in G[B]} x(e) \leqslant \frac{|B|-1}{2}$. We use $\mathsf{mwm}(G, \kappa)$ to denote the size of the maximum weight fractional matching obeying the odd set constraints and the capacity function κ. Additionally, we will use $\gamma_\varepsilon = (^1/_\varepsilon)^{O(1/\varepsilon)}$, $\alpha_\varepsilon = 2^{^{W^2}/_{\varepsilon^3}} \cdot \log n$ and $\rho_\varepsilon = 2^{^{W^2}/_{\varepsilon^2}} \cdot \log n$. We also use V_{odd} to denote the set of all odd-sized subsets $B \subseteq V$. Our main result is a decremental algorithm for maintaining $(1-\varepsilon)$-approximate maximum weight matching in general graphs. In particular, we formally state our main theorem.

▶ **Theorem 4.** *Let G be a weighted graph with weight function w on the edges of the graph and let $\varepsilon \in (0, 1/2)$. There is a decremental algorithm with total update time $O_\varepsilon(m \cdot \log^7 n \cdot \log R)$ (amortized $\tilde{O}_\varepsilon(1)$) that maintains an integral matching M with $w(M) \geqslant (1-\varepsilon) \cdot \mathsf{mwm}(G)$, with high probability, where G refers to the current version of the graph. The algorithm is randomized but works against an adaptive adversary. The dependence on ε is $2^{(^1/_\varepsilon)^{O(1/\varepsilon)}}$.*

Roadmap for Extended Abstract. As mentioned in the overview, our main contribution is to give an algorithm M-OR-E*() for *weighted general graphs* (we call this subroutine WEIGHTEDM-OR-E*()). Thus, rest of this paper is dedicated to setting this up. We postpone the proof of Theorem 4 to the full version of this paper.

4 Properties of WeightedM-or-E*()

As mentioned in the overview, we will focus our attention on implementing M-OR-E*() in general **weighted** graphs. We will call this subroutine WEIGHTEDM-OR-E*() We additionally mentioned that we will be working with multigraphs, so this will motivate some definitions. After giving these definitions, we state the properties of WEIGHTEDM-OR-E*() that we need. Finally, we show that we are indeed able to implement WEIGHTEDM-OR-E*(). Recall, that is sufficient to design WEIGHTEDM-OR-E*() for the case of graph that have integer weights in $\{1, 2, \cdots, W\}$ by Section 2.1.

▶ **Definition 5.** *Let G be a multigraph. For a pair of vertices $u, v \in V$, we define $D_i(u, v)$ to be the edges e between u and v that have weight i. Additionally, we also have $D(u, v) = \cup_{i=1}^{W} D_i(u, v)$. Since we assume integral weights, these sets are well-defined. If e is an edge between $u, v \in V$, then $D_i(e) \coloneqq D_i(u, v)$ and $D(e) \coloneqq D(u, v)$.*

▶ **Definition 6.** *Let G be a weighted multigraph, with n vertices and m edges. Let κ be the capacity function on the edges of the graph, and let $\vec{x}$ be a fractional matching. We define $\vec{x}^C$ to be a vector, with support size $\min\left\{W \cdot \binom{n}{2}, m\right\}$, where for vertices $u, v \in V$, $x_i^C(u, v) = \sum_{e \in D_i(u,v)} x(e)$. That is, $\vec{x}^C$ is obtained by "collapsing" all edges of the same weight between a pair of vertices together. We now describe the opposite operation: the "distribution" operation. Similarly, suppose $\vec{y}$ is a vector with $|supp(\vec{y})| \leqslant \binom{n}{2} \cdot W$, where, $y_i(u, v)$ is the entry corresponding to the edge of weight i between u and v. Then, we define $\vec{y}^D$ to be an m length vector such that for every $e \in E$ between u, v with $w(e) = i$, $y^D(e) \coloneqq \frac{y_i(u,v) \cdot \kappa(e)}{\kappa(D_i(u,v))}$. Intuitively, $\vec{y}^D$ is a multigraph obtained by distributing the $y_i(u, v)$ among all edges of the same weight.*

We will next, state two folklore observations (proved in the full version of the paper), which motivates the main lemma which we want to prove.

▶ **Observation 7.** *Let $\vec{f}$ be a fractional matching on a multigraph, that puts flow 1 or, at most ε between every pair of vertices $u, v \in V$. Then, $\vec{f}$ satisfies odd set constraints of sets of size at most $1/\varepsilon$.*

▶ **Observation 8.** *Suppose $\vec{x}$ is a fractional matching that satisfies odd set constraints for all odd sets of size smaller than $3/\varepsilon + 1$, then the fractional matching $\vec{z} = \frac{\vec{x}}{(1+\varepsilon)}$ satisfies odd set constraints for all odd sets, and therefore, $\mathsf{mwm}(supp(\vec{x})) \geqslant (1 - \varepsilon) \cdot \sum_{e \in E} w(e) \cdot x(e)$.*

We now state the main lemma, which we focus on proving in the extended abstract.

▶ **Lemma 9.** *Let G be a multigraph with edge weights in $\{1, 2, \cdots, W\}$. Then, there is an algorithm WEIGHTEDM-OR-E*() that takes as input $G, \kappa, \varepsilon \in (0, 0.5)$, and a parameter $\mu \geqslant \mathsf{mwm}(G) \cdot (1 - \varepsilon)$, and in time $O(m \cdot W \cdot \log n/\varepsilon)$ returns one of the following.*

1. *A fractional matching $\vec{x}$ such that $\sum_{e \in E} w(e) \cdot x(e) \geqslant (1 - 2\varepsilon) \cdot \mathsf{mwm}(G)$, with the following properties.*
   - **a.** *Let $e \in D_i(u, v)$ such that $e \in supp(\vec{x})$, with $\kappa(D_i(u, v)) \geqslant 1/\alpha_\varepsilon^2$, then $x(D_i(u, v)) = 1$, and we have, $x(e) = \frac{\kappa(e)}{\kappa(D_i(u,v))}$. Moreover, since $\vec{x}$ is a fractional matching, we have $x(D_j(u, v)) = 0$ for all $j \neq i$.*

   b. *Consider any* $e \in D_i(u,v)$ *such that* $e \in supp(\vec{x})$*, with* $\kappa(D_i(u,v)) \leqslant 1/\alpha_\varepsilon^2$*, then* $x(D_i(u,v)) \leqslant \kappa(D_i(u,v)) \cdot \alpha_\varepsilon$*, and* $x(e) \leqslant \kappa(e) \cdot \alpha_\varepsilon$*. Moreover, for any* $e \in D_j(u,v)$ *with* $\kappa(D_j(u,v)) > 1/\alpha_\varepsilon^2$*, we have* $x(e) = 0$*.*
2. *A set of edges* E^* *such that* $\sum_{e \in E^*} w(e) \cdot \kappa(e) = O(\mathsf{mwm}(G) \cdot \log n)$*, and for any integral matching* M *with* $w(M) \geqslant (1-2\varepsilon) \cdot \mathsf{mwm}(G)$*, we have* $w(M \cap E^*) \geqslant \varepsilon \cdot \mathsf{mwm}(G)$*. Additionally, for all* $e \in E^*$*, we have* $\kappa(e) < 1$*.*

We give some intuition about why $\vec{x}$ avoids the integrality gap. Consider the situation in which the algorithm WeightedM-or-E*() returns a fractional matching $\vec{x}$. For any pair of vertices u, v consider $\sum_{i=1}^{W} x_i^C(u,v)$, then this is either 1 or at most ε by Lemma 9(1). Thus, it satisfies odd set constraints for all odd sets of size at most $1/\varepsilon$ by Observation 7. By Observation 8 , we can then argue that $\vec{x}$ contains an integral matching of weight at least $(1+\varepsilon)^{-1} \cdot \sum_{u \neq v} \sum_{i=1}^{W} x_i^C(u,v) \cdot i$ in its support.

We will use WeightedM-or-E*() as a subroutine in our decremental matching algorithm, and we will get a matching $\vec{x}$ with the following properties. We mention these properties since they will help us visualize the fractional matching better. These properties are evident once we state the algorithm WeightedM-or-E*().

▶ **Property 10.** *The set* E^* *returned WeightedM-or-E*() has the following properties.*
1. *Each time WeightedM-or-E*() returns* E^**, we will increase capacity along* E^* *by multiplying existing capacities by the same factor.*
2. *Consider* $u, v \in V$*, and let* e, e' *be two edges between* u *and* v *such that* $w(e) = w(e')$*, then* $\kappa(e) = \kappa(e')$ *at all times during the run of the algorithm.*

The next property follows directly as a consequence of Lemma 9(1).

▶ **Property 11.** *Let* $\vec{x}$ *be a matching output by Lemma 9, then* $x(e) \leqslant \kappa(e) \cdot \alpha_\varepsilon^2$ *for all* $e \in E$*. This is evident from Lemma 9(1).*

▶ **Definition 12.** *Let* G *be a multigraph, and let* $\vec{x}$ *be a fractional matching of* G*. Then, we split* $supp(\vec{x})$ *into two parts:* $\vec{x}^i$ *and* $\vec{x}^f$*, where,* $\vec{x} = \vec{x}^i + \vec{x}^f$*, and* $supp(\vec{x}^i) = \{e \mid x(D_j(e)) > 1/\alpha_\varepsilon^2 \text{ and } w(e) = j\}$ *and* $supp(\vec{x}^f) = \{e \mid x(D_j(e)) \leqslant 1/\alpha_\varepsilon^2 \text{ and } w(e) = j\}$*. When* $\vec{x}$ *is the output of WeightedM-or-E*(), then these correspond to the integral and fractional parts of* $\vec{x}$*.*

▶ **Property 13.** *Let* G *be any multigraph, and let* $\vec{x}$ *be a fractional matching of* G *that is returned by WeightedM-or-E*(). Then, for any pair of vertices,* u, v*, we have the following properties, which are a consequence of Lemma 9(1a) and Lemma 9(1b):*
1. *Either* $D(u,v) \cap supp(\vec{x}^i) \neq \emptyset$ *or* $D(u,v) \cap supp(\vec{x}^f) \neq \emptyset$*, but not both.*
2. *For any* u, v, j *such that* $D_j(u,v) \cap supp(\vec{x}) \neq \emptyset$*, we have* $D_j(u,v) \subseteq supp(\vec{x})$*.*

Thus, the supports of $\vec{x}^i$ *and* $\vec{x}^f$ *are vertex disjoint.*

▶ **Property 14.** *Let* $\vec{x}$ *be a fractional matching returned by WeightedM-or-E*(), consider* $\vec{z} = \vec{x}^i$*. Then,* $\vec{z}^C$ *is an integral matching. This is implied by Lemma 9(1).*

5 Building Blocks for WeightedM-or-E*()

In this section, we focus on stating the building blocks we need for Lemma 9. The algorithm WeightedM-or-E*() will proceed in phases. In Phase 1, we would like to determine if a given graph G, with weight function w and capacity function κ on the edges, has the

property that $\mathsf{mwm}(G,\kappa) \geqslant (1-\varepsilon)\cdot\mathsf{mwm}(G)$. We give the structural theorem related to this in Section 5.1. If it is indeed the case that $\mathsf{mwm}(G,\kappa) \geqslant (1-\varepsilon)\cdot\mathsf{mwm}(G)$, then the algorithm proceeds to Phase 2, and in this phase we want to find such a fractional matching. We describe the main structural theorem of this phase in Section 5.2. In Phase 2, there is an additional computational question, that of finding a $(1-\varepsilon)$-approximate maximum weight fractional matching efficiently. We give an algorithm for this in Section 5.4. Finally, if in Phase 1 we know that $\mathsf{mwm}(G,\kappa) < (1-\varepsilon)\cdot\mathsf{mwm}(G)$, then we increase capacities along E^*. In Section 5.3, we give a characterization of these edges. We start with stating some probabilistic tools that we will need, for example the Chernoff Bound:

▶ **Lemma 15** ([17]). *Let $X_1, X_2, \cdots, X_k$ be k negatively associated random variables with $0 \leqslant |X_i| \leqslant M$, and let $X = \sum_{i=1}^{k} X_i$. Suppose $\mu = \mathbb{E}[X]$, and $\mu_{min} \leqslant \mu \leqslant \mu_{max}$. Then, we have, for $\delta > 0$,*

$$\Pr\left(X \geqslant (1+\delta)\cdot\mu_{max}\right) \leqslant \left(\frac{e^{\delta}}{(1+\delta)^{(1+\delta)}}\right)^{\frac{\mu_{max}}{M}}$$

$$\Pr\left(X < (1-\delta)\cdot\mu_{min}\right) \leqslant \exp\left(-\frac{\delta^2\cdot\mu_{min}}{(2+\delta)\cdot M}\right)$$

Additionally, we will also need Bernstein's inequality.

▶ **Lemma 16.** *Let X be the sum of negatively associated random variables $X_1, \cdots, X_k$ with $X_i \in [0, M]$ for each $i \in [k]$. Then, for $\sigma^2 = \sum_{i=1}^{k} \mathrm{Var}[X_i]$ and all $a > 0$,*

$$\Pr\left(X > \mathbb{E}[X] + a\right) \leqslant \exp\left(\frac{-a^2}{2\left(\sigma^2 + {}^{a\cdot M}/_{3}\right)}\right)$$

5.1 Phase 1 of WeightedM-or-E*()

Recall that we used $\mathsf{mwm}(G,\kappa)$ to denote the weight of the maximum weight fractional matching of G obeying κ as well as the odd set constraints. As in the congestion balancing step, we want to estimate $\mathsf{mwm}(G,\kappa)$. In the bipartite case, because of the correspondence between flows and fractional matchings, one could do this relatively easily. But in non-bipartite graphs, we don't have this correspondence.

In this section, we show the following structural lemma: if in a weighted graph G, we sample every edge with probability $p(e) = \min\{1, \kappa(e)\cdot\rho_\varepsilon\}$ to create a graph G_s, then $\mathsf{mwm}(G_s) \geqslant \mathsf{mwm}(G,\kappa) - \varepsilon\cdot\mathsf{mwm}(G)$. Thus, now we can estimate $\mathsf{mwm}(G_s)$ (and consequently, $\mathsf{mwm}(G,\kappa)$) by using existing results (such [16]). We remark that [3] proved the unweighted version of this lemma, but their proof strategy relied on showing that with high probability, G_s does not contain a Tutte set causing a high deficiency (see Lemma 28 in [3]).

▶ **Lemma 17.** *Let G be an integer weighted multigraph with weights in $\{1, 2, \cdots, W\}$, and with $\mathsf{mwm}(G) \geqslant \max\{{}^{\varepsilon\cdot n}/_{16\cdot W}, {}^{\log n}/_{\varepsilon^4}\}$, where $\varepsilon \in (0, {}^1/_2)$. Let κ be a capacity function on the edges of the graph, and let G_s be obtained by sampling every edge e independently with probability $p(e) = \min\{1, \kappa(e)\cdot\rho_\varepsilon\}$. Then, with high probability, $\mathsf{mwm}(G_s) \geqslant \mathsf{mwm}(G,\kappa) - \varepsilon\cdot\mathsf{mwm}(G)$.*

Proof. Let $\vec{x}$ denote the fractional matching that realizes $\mathsf{mwm}(G,\kappa)$. In order to prove the statement, we will construct a vector $\vec{z}$ in the support of G_s. This vector $\vec{z}$ will have the following properties: it will satisfy the fractional matching constraints and small blossom constraints with high probability. It will also have the property that $\sum_{e\in E)} w(e)\cdot z(e) \geqslant (1-\varepsilon)\cdot\sum_{e\in E} w(e)\cdot x(e) \geqslant \mathsf{mwm}(G,\kappa) - \varepsilon\cdot\mathsf{mwm}(G)$ with high probability as well.

Since with high probability G_s, contains a fractional matching $\vec{z}$ satisfying the above properties, there is an integral matching M in support of G_s with $w(M) \geqslant (1-\varepsilon)\cdot\sum_{e\in E} w(e)\cdot z(e) \geqslant \mathsf{mwm}(G,\kappa) - \varepsilon\cdot\mathsf{mwm}(G)$ (see Observation 8).

Let X_e denote the indicator random variable of the event $e \in G_s$. We define $\vec{z}$ as follows:

$$z(e) = X_e \cdot \frac{x(e)}{\min\{1, \kappa(e)\cdot\rho_\varepsilon\}}\cdot(1-\varepsilon)$$

Note that $\{z(e)\}_{e\in E}$ are independent random variables, and, $\mathbb{E}\left[\sum_{e\in E} z(e)\cdot w(e)\right] = (1-\varepsilon)\cdot\sum_{e\in E} w(e)\cdot x(e)$. Further, consider any e with $\kappa(e) \geqslant \frac{1}{\rho_\varepsilon}$, then $w(e)\cdot z(e) = w(e)\cdot x(e)$ always. Thus, we focus on e with $\kappa(e) < 1/\rho_\varepsilon$. We first have the following observation.

▶ **Observation 18.** *Note that,* $\sum_{e\in E:\kappa(e)<1/\rho_\varepsilon} w(e)\cdot x(e) \geqslant \varepsilon\cdot\mathsf{mwm}(G)$. *Otherwise,* $\sum_{e\in E} z(e)\cdot w(e) \geqslant (1-\varepsilon)\cdot\sum_{e\in E} x(e)\cdot w(e) - \varepsilon\cdot\mathsf{mwm}(G)$ *with probability* 1.

Using Chernoff bound with $M = \frac{W}{\rho_\varepsilon}$ and $\mu_{\min} = \varepsilon\cdot\mathsf{mwm}(G)$ (see Lemma 15), we have,

$$\Pr\left(\sum_{e\in E:\kappa(e)<1/\rho_\varepsilon} z(e)\cdot w(e) \leqslant \sum_{e\in E:\kappa(e)<1/\rho_\varepsilon} w(e)\cdot x(e) - 2\cdot\varepsilon^2\cdot\mathsf{mwm}(G)\right) = \exp\left(\frac{-\varepsilon^4\cdot\mathsf{mwm}(G)\cdot\rho_\varepsilon}{2\cdot W}\right)$$

By assumption, $\mathsf{mwm}(G) \geqslant 100\cdot\log n/\varepsilon^4$, we have that the above claim holds with probability at least $1 - O(1/n^{1/\varepsilon})$. We will now show that it obeys fractional matching constraints with high probability as well. Consider an edge e with $\kappa(e) > 1/\rho_\varepsilon$, we know that $e \in G_s$. Consequently, we have $\mathrm{Var}[z(e)] = 0$ for such an edge, since $z(e) = x(e)$ always. For any edge with $\kappa(e) < 1/\rho_e$, we have, $\mathrm{Var}[z(e)] \leqslant (1-2\varepsilon)\cdot\frac{x(e)}{\rho_\varepsilon}$. Since $z(e)$ are independent random variables, we have $\mathrm{Var}\left[\sum_{v\ni e} z(e)\right] = \sum_{v\ni e}\mathrm{Var}[z(e)] \leqslant (1-2\varepsilon)\cdot\rho_\varepsilon^{-1}$. Moreover, we know that $\mathbb{E}\left[\sum_{e\ni v} z(e)\right] \leqslant (1-\varepsilon)$. Thus, we want to compute the probability of the event that $\sum_{e\ni v} z(e) \geqslant 1$. Note that, in order to do this, it is sufficient to consider the edges e for which $\kappa(e) < \rho_\varepsilon^{-1}$, since for edges other than this, $z(e) = x(e)$. Thus, by Lemma 16, with $a = \varepsilon$, $M = \rho_\varepsilon^{-1}$, $\Pr\left(\sum_{e\ni v} z(e) > 1\right) = O\left(\frac{1}{n^{1/\varepsilon}}\right)$. ◀

Taking a union bound over all vertices in the graph, we have our claim. Next, we want to compute the probability that $\vec{z}$ also satisfies small odd set constraints. To see this, consider any odd set B such that $|B| \leqslant 1/\varepsilon$. We know that by definition of $\vec{x}$, we have, $\mathbb{E}\left[\sum_{e\in G[B]} z(e)\right] \leqslant (1-\varepsilon)\cdot\frac{|B|-1}{2}$. We can bound variance as well, $\mathrm{Var}\left[\sum_{e\in G[B]} z(e)\right] \leqslant (1-\varepsilon)\cdot\frac{|B|-1}{2}\cdot\frac{1}{\rho_\varepsilon}$. Consider the following subclaim.

▶ **Observation 19.** *Let* B *be any odd set with* $3 \leqslant |B| \leqslant 1/\varepsilon$. *Then,* $\frac{|B|-1}{2} \geqslant (1-\varepsilon)\cdot\frac{|B|-1}{2} + \varepsilon$.

Let $\mathcal{E}_B$ be the event that $\sum_{e\in G[B]} z(e) \geqslant \frac{|B|-1}{2}$, then from the above observation, and Lemma 16, $\Pr(\mathcal{E}_B) = O\left(\frac{1}{n^{1/\varepsilon^2}}\right)$. The second equality follows from the fact that we are considering small blossoms, that is, $|B| \leqslant 1/\varepsilon$. Taking a union bound over all small blossoms, we have our claim.

5.2 Phase 2 of WeightedM-or-E*()

The algorithm WeightedM-or-E*() proceeds to Phase 2 only if in Phase 1, if $\mathsf{mwm}(G,\kappa) \geqslant (1-\varepsilon)\cdot\mathsf{mwm}(G)$ (Lemma 17). In Phase 2, we now want to construct a good fractional matching: it should be close to $\mathsf{mwm}(G,\kappa)$ and also satisfy odd set constraints. The fractional

matching will be inspired by Observation 7 and is constructed as follows: Suppose M is a matching in G_s with weight at least $(1-\varepsilon)\cdot \mathsf{mwm}(G_s)$. Then, we will split up M into high-capacity part, M_H, and low capacity part M_L. We can introduce some slack in the congestion balancing framework, and round up the capacities of M_H. We will then compute a $(1-\varepsilon)$-approximate maximum weight fractional matching $\vec{f}$ on the low-capacity edges of $G[V(M_L)]$. Since these capacities are small, we can accomplish by computing a fractional matching in the bipartite double cover of $G[V(M_L)]$. For now, in this section, we will show that: $w(M_H) + \sum_{e\in E} f(e)\cdot w(e) \geqslant \mathsf{mwm}(G_s) - \varepsilon\cdot \mathsf{mwm}(G)$.

▶ **Definition 20.** *Let G be a multigraph, we define $E_L = \{e \in E \mid e \in D_i(u,v), \kappa(D_i(u,v)) \leqslant 1/\alpha_\varepsilon^2\}$. Intuitively, these correspond to the low capacity edges. Similarly, we define $\kappa^+(e) = \kappa(e)\cdot\alpha_\varepsilon$.*

[3] proved an unweighted version of this lemma, but their proof strategy was based on considering the bipartite double cover of G_s an (G,κ), and analysing the size of the Hall set in G_s. We take a different approach based on the dual programs of $\mathsf{mwm}(G_s)$ and $\mathsf{mwm}(G,\kappa)$. We believe our proof is arguably simpler.

▶ **Lemma 21.** *Let G be a weighted multigraph with maximum edge weight W. Suppose $\mathsf{mwm}(G) \geqslant \max\{\varepsilon\cdot n/16\cdot W, \log n/\varepsilon^4\}$ Then, with high probability, for all $X \subseteq V$, we have*

$$\mathsf{mwm}(G_s[X]) \leqslant \mathsf{mwm}(G[X]\cap E_L, \kappa^+) + \varepsilon\cdot\mathsf{mwm}(G)$$

Proof. Consider a fixed X, and from now on, we use $H \coloneqq G[X]\cap E_L$ and $H_s \coloneqq G_s[X]\cap E_L$. To prove this, we will make use of a primal-dual argument. We state the linear program for $\mathsf{mwm}(H,\kappa^+)$, and its dual.

$$\begin{aligned}
&\text{maximize} && \sum_{e\in E(H)} w(e)\cdot x(e) && \\
&\text{subject to} && && \\
&\sum_{e\ni v, e\in E(H)} x(e) && \leqslant 1 && \forall v \in X \\
&\sum_{e\in G[B]\cap E(H)} x(e) && \leqslant \tfrac{|B|-1}{2} && \forall B \in X_{\text{odd}} \\
&x(e) && \leqslant \kappa^+(e) && \forall e \in E(H)
\end{aligned}$$

The corresponding dual program is,

$$\begin{aligned}
&\text{minimize} && f(y,z,r) = \sum_{u\in V} y(u) + \sum_{B\subseteq X_{\text{odd}}} r(B)\cdot\left(\frac{|B|-1}{2}\right) + \sum_{e\in E(H)} z(e)\cdot\kappa^+(e) && \\
&\text{subject to} && && \\
& && y(u)+y(v)+z(e)+\sum_{B\in X_{\text{odd}}:(u,v)\in G[B]} r(B) \geqslant w(e) && \\
& && && \forall e\in E(H) \text{ between } u,v, \forall u,v\in X
\end{aligned}$$

By strong duality, we know that $\mathsf{mwm}(H,\kappa^+) = f(y,z,r)$ for optimal $\vec{y},\vec{z},\vec{r}$. Similarly, for the uncapacitated graph H_s we have the same primal and dual programs, except we don't have the third constraint in the primal program, and in the dual program we omit the z variables.

$$\begin{aligned}
&\text{maximize} && \sum_{e\in E(H_s)} w(e)\cdot x'(e) && \\
&\text{subject to} && && \\
&\sum_{e\ni v, e\in H_s} x'(e) && \leqslant 1 && \forall v\in X \\
&\sum_{e\in G[B]\cap E(H_s)} x'(e) && \leqslant \tfrac{|B|-1}{2} && \forall B\in X_{\text{odd}}
\end{aligned}$$

The corresponding dual program is as follows:

$$\begin{aligned}
&\text{minimize} && \sum_{u\in V} y'(u) + \sum_{B\subseteq X_{\text{odd}}} r'(B)\cdot\left(\frac{|B|-1}{2}\right) && \\
&\text{subject to} && && \\
&y'(u)+y'(v)+ && \sum_{B\in X_{\text{odd}}:(u,v)\in G[B]} r'(B) \geqslant w(e) && \forall e\in E(H_s) \text{ between } u,v, \forall u,v\in X
\end{aligned}$$

Let $g(y',r')$ denote the optimal for dual program corresponding to H_s. Note that this is a random variable, since H_s is a random graph. We will show that with high probability,

$$g(y',r') \leqslant f(y,r,z) + \varepsilon\cdot \mathsf{mwm}(G)$$

By duality, we have, $\mathsf{mwm}(H_s)\leqslant g(y',r')$, and $f(y,z,r)=\mathsf{mwm}(H,\kappa^+)$. This will show our claim for a fixed H, and then we take a union bound over all H.

We will use $\left\{\{y(u)\}_{u\in X}, \{r(B)\}_{B\in X_{\text{odd}}}\right\}$ to get a solution for the dual program for H_s. We will refer to this set of dual variables as an attempted cover. Let $E'=\{e \mid z(e)>0\}$. Observe that the edges left uncovered by attempted cover of H_s are precisely a subset of E'. We now modify the cover as follows.

$$\Delta y(u) = \sum_{e\ni v, e\in H_s} z(e), \text{ and, } y'(u) = y(u)+\Delta y(u)$$

Note that $\left\{\{y'(u)\}_{u\in X}, \{r(B)\}_{B\in X_{\text{odd}}}\right\}$ is a valid cover of H_s. To see this, consider edge $e\in H_s$ and let u,v be the endpoints of H_s. Suppose $e\notin E'$, then, $w(e)\leqslant y'(u)+y'(v)+\sum_{e\in G[B]} r(B)$. Similarly, for an edge $e\in E'$, we have, $w(e)\leqslant y'(u)+y'(v)+\sum_{e\in G[B]} r(B)$. Moreover, $g(y',r')=f(y,r,z)+\sum_{u\in X}\Delta y(u)$. Thus, it is sufficient to bound $\sum_{u\in X}\Delta y(u) = 2\cdot\sum_{e\in E'} z(e)\cdot X_e$, where X_e is the indicator variable that takes value 1 if $e\in H_s$, and 0 otherwise. Note that $\mathbb{E}\left[\sum_{e\in E'} z(e)\cdot X_e\right] \leqslant \mathsf{mwm}(H,\kappa^+)\cdot 2^{-W^2/\varepsilon^3}$. Using Chernoff and choosing $\delta = \frac{\varepsilon\cdot\mathsf{mwm}(G)\cdot 2^{W^2/\varepsilon^3}}{\mathsf{mwm}(H,\kappa^+)}$ and noting that $M=W$, we have,

$$\Pr\left(\sum_{e\in E'} z(e)\cdot X_e \geqslant 2\cdot\varepsilon\cdot\mathsf{mwm}(G)\right) \leqslant \exp\left(-\varepsilon\cdot\mathsf{mwm}(G)\cdot\frac{W}{\varepsilon^2}\right)$$

By assumption, $n\leqslant \frac{\mathsf{mwm}(G)\cdot W}{\varepsilon}$, thus taking a union bound over all subsets, we have our theorem. ◀

5.3 Phase 3: Finding Set E*

The algorithm WeightedM-or-E*() proceeds to Phase 3, if $\mathsf{mwm}(G, \kappa)$ is not large enough (see Lemma 17). At this point we have to increase capacity along some edges in the graph. Recall Lemma 9(2), the properties required of such edges. Phase 3 finds such edges E^*, and makes sure it has that this set has the property that $\sum_{e \in E^*} w(e) \cdot \kappa(e) = O(\mathsf{mwm}(G) \log n)$, and moreover, every good matching in G has significant weight going through E^*.

Similar to the case of [3], we will use the dual variables of G_s to describe E^*. We will first start with describing the dual program corresponding to the general matching LP:

$$\begin{aligned} \text{minimize} \quad & \sum_{u \in V} y(u) + \sum_{B \subseteq V_{\text{odd}}} r(B) \cdot \left(\frac{|B| - 1}{2} \right) \\ \text{subject to} \quad & y(u) + y(v) + \sum_{B : (u,v) \in G[B]} r(B) \geqslant w(u,v) \quad \forall (u,v) \in E \end{aligned}$$

Additionally, we define $yr(e)$ to be the dual constraint corresponding to the edge e, and$f(y, r)$ to be the value of the objective function. We now describe some properties of Static-Weighted-Match(H, ε). This is the algorithm whose properties we use to describe E^*. We state these properties without proof for now and postpone the proof to the full version.

▶ **Lemma 22** ([16]). *There is an $O(m/\varepsilon \cdot \log 1/\varepsilon)$ time algorithm Static-Weighted-Match() that takes as input, a weighted graph G, and a parameter $\varepsilon > 0$, and outputs an integral matching M, and dual vectors $\vec{y}$ and $\vec{r}$ with the following properties.*

1. *It returns an integral matching M such that $w(M) \geqslant (1 - \varepsilon) \cdot \mathsf{mwm}(G)$*
2. *A set Ω of laminar odd-sized sets such that $\{B \in V_{odd} \mid r(B) > 0\} \subseteq \Omega$.*
3. *For all odd-sized sets B such that $|B| \geqslant 1/\varepsilon + 1$, $r(B) = 0$.*
4. *For all $v \in V$, $y(v)$ is an integral multiple of ε, and for all $B \in V_{odd}$, $r(B)$ is an integral multiple of ε.*
5. *For each edge $e \in E$, we have $yr(e) \geqslant (1 - \varepsilon) \cdot w(e)$, that is e is* approximately covered *by $\vec{y}$ and $\vec{r}$.*
6. *The value of the dual objective, $f(y, r)$ is at most $(1 + \varepsilon) \cdot \mathsf{mwm}(G)$.*

We now state our first claim, which in Section 6 will help us show that when $\mathsf{mwm}(G, \kappa) < (1 - 2\varepsilon) \cdot \mathsf{mwm}(G)$, then every large matching in G has a lot of weight in E^*.

▷ Claim 23. Suppose $H \subseteq G$, and $\vec{y}, \vec{r}$ are the dual vectors returned by Static-Weighted-Match(H, ε). Let $E_H = \{e \in E \mid yr(e) \geqslant (1 - \varepsilon) \cdot w(e)\}$. Let M be any matching of G, then $w(M \cap E \setminus E_H) \geqslant w(M) - (1 + \varepsilon)^2 \cdot \mathsf{mwm}(H)$.

Proof. Observe that if we scale up the dual variables $\vec{y}$ and $\vec{r}$ by $(1 + \varepsilon)$, then $\vec{y}$ and $\vec{r}$ is a feasible solution for the dual matching problem for the graph E_H. Thus, by weak duality and Lemma 22(6), we have $\mathsf{mwm}(E_H) \leqslant (1 + \varepsilon) \cdot f(y, r) \leqslant (1 + \varepsilon)^2 \cdot \mathsf{mwm}(H)$. Thus, we have: $w(M) \leqslant (1 + \varepsilon)^2 \cdot \mathsf{mwm}(H) + w(M \cap E \setminus E_H)$. ◁

We now describe the set E^*, and show that $w(\kappa(E^*)) = O(\mathsf{mwm}(G) \cdot \log n)$ with high probability.

▶ **Lemma 24.** *Let G be a multigraph such that $\mathsf{mwm}(G) \geqslant \varepsilon n / W$, and let κ be the capacity function on the edges of the graph. Suppose G_s is the graph obtained by sampling edge e with probability $p(e) = \min\{1, \rho_\varepsilon \cdot \kappa(e)\}$. Let $\vec{y}, \vec{r}$ be the duals returned by Static-Weighted-Match(G_s, ε). Let $E^* = \{e \mid yr(e) < (1 - \varepsilon) \cdot w(e)\}$, then with high probability, $w(\kappa(E^*)) = O(\mathsf{mwm}(G) \cdot \log n)$.*

Proof. We consider the set $\mathcal{D}$ of duals $\vec{y}, \vec{r}$ that satisfy the following properties.

1. For all $v \in V$, $y(v)$ is a multiple of ε, and for all $B \in V_{\text{odd}}$, $r(B)$ is a multiple of ε.
2. Let $\Omega = \{B \mid r(B) > 0\}$, then Ω is laminar.
3. If $r(B) > 0$ for some B, then $|B| \leqslant 1/\varepsilon$.

Observe that $\mathcal{D}$ contains all possible duals that could be returned by Static-Weighted-Match(). Now, we bound $|\mathcal{D}|$.

$$|\mathcal{D}| \leqslant \sum_{i=0}^{2n} \binom{n^{1/\varepsilon}}{i} \cdot \left(\frac{W}{\varepsilon}\right)^{n} \cdot \left(\frac{W}{\varepsilon}\right)^{2n} \leqslant 2^{10/\varepsilon^3 \cdot n \cdot \log W} \leqslant 2^{10/\varepsilon^3 \cdot \frac{\mathsf{mwm}(G)}{W} \cdot \log W}$$

This follows from the following argument. Since Ω is laminar (due to 2), there are at most $2n$ sets contained in Ω, and from 3, we can conclude that these laminar sets are chosen from among $n^{1/\varepsilon}$ sets. Similarly, 1 suggests that each $y(v)$ and chosen $r(B)$ can be assigned W/ε values, thus for a given choice of Ω, there are at most $\left(\frac{W}{\varepsilon}\right)^{n} \cdot \left(\frac{W}{\varepsilon}\right)^{2n}$ choices for $\vec{y}$ and $\vec{r}$. We can derive the last set of equations by the premise of our lemma: that $\mathsf{mwm}(G) \geqslant \varepsilon n/W$. Additionally, observe that $\mathcal{D}$ includes the set of duals that can be returned by G, and therefore $|\mathcal{D}|$ is an upper bound on the set of possible duals returned by Static-Weighted-Match().

Now, consider any $\vec{y}, \vec{r} \in \mathcal{D}$ and let $E_{y,r} = \{e \mid yr(e) < (1-\varepsilon) \cdot w(e)\}$. Observe that for all $e \in E_{y,r}$, we have $\kappa(e) < 1/\rho_\varepsilon$, since otherwise $\kappa(e) = 1$, and e would be included in G_s with probability 1 and be approximately covered by $\vec{y}, \vec{r}$ (by Lemma 22(5)). Thus, for all $e \in E_{y,r}$, we have $\kappa(e) < 1/\rho_\varepsilon$. Now, $\vec{y}, \vec{r}$ are such that $w(\kappa(E_{y,r})) > \mathsf{mwm}(G) \cdot \log n$, then none of the edges in $E_{y,r}$ were sampled. Note that in this case, $\kappa(E_{y,r}) \geqslant \mathsf{mwm}(G) \cdot \log n \cdot W^{-1}$. Let $\mathcal{E}_{y,r}$ denote the event that $\vec{y}, \vec{r}$ is returned by Static-Weighted-Match(G_s, ε) and $\mathcal{E}_2$ be the event that $E_{y,r}$ is not sampled into G_s. Then, observe that in this case,

$$\Pr(\mathcal{E}_{y,r}) \leqslant \Pr(\mathcal{E}_2) \leqslant \prod_{e \in E_{y,r}} (1 - p(e)) \leqslant \exp\left(-\sum_{e \in E_{y,r}} \kappa(e) \cdot \rho_\varepsilon\right) \leqslant \exp\left(-\frac{\mathsf{mwm}(G)}{W} \cdot \rho_\varepsilon\right)$$

Now, we want to upper bound the probability that Static-Weighted-Match(G_s, ε) outputs $\vec{y}, \vec{r}$ such that $w(\kappa(E_{y,r})) \geqslant \mathsf{mwm}(G) \cdot \log n$. To do this, we take a union bound over all $|\mathcal{D}|$ many possible duals. From the previous discussion we know that $|\mathcal{D}| \leqslant \exp\left(\frac{10}{\varepsilon^2} \cdot \frac{\mathsf{mwm}(G)}{W} \cdot \log W\right)$. This concludes the proof. ◀

5.4 Weighted Fractional Matching in Bipartite Graphs

The final ingredient we need for WeightedM-or-E*() is the following lemma, which computes a fractional matching on low capacity edges in bipartite graphs. We will show in Section 6 how to use this as a subroutine to do the same in general graphs.

▶ **Lemma 25.** *Consider a weighted bipartite multigraph G with the following property: for any $u, v \in V$ with $e \neq e'$ between u, v, then $w(e) \neq w(e')$. Suppose κ is the capacity function on the edges of the graph, and suppose the edge weights are in $\{1, 2, \cdots, W\}$. There is an algorithm that in $O(m \cdot W \cdot \log n \cdot 1/\varepsilon)$ time finds a fractional matching $\vec{x}$ obeying the capacity function κ such that $\sum_{e \in E} w(e) \cdot x(e) \geqslant (1-\varepsilon) \cdot \mathsf{mwm}(G, \kappa)$.*

Note that there are algorithms in the literature, which can compute weighted fractional matchings in bipartite graphs: such the one by [1]. However, like many LP solvers, one incurs additional $\log n$ factors in the time bound. In contrast, our algorithm incurs a W factor, but since we use Lemma 3, in the final algorithm, we will only incur a $\log W$ factor for the entire decremental algorithm. In contrast, using LP solvers, we will incur additional

$\log n$ factors for implementing WeightedM-or-E*() alone. In order to come up with the algorithm for Lemma 25, we first recall the maximum weight capacitated fractional matching linear program for **bipartite graphs**, and its corresponding dual.

$$\begin{aligned} &\text{maximize} \sum_{e\in E} w(e)\cdot x(e) \\ &\text{subject to} \\ &\quad x(e) \leqslant \kappa(e) && \forall e \in E \\ &\quad \sum_{e\ni v} x(e) \leqslant 1 && \forall v \in V \end{aligned}$$

$$\begin{aligned} &\text{minimize} \sum_{v\in L} y(v) + \sum_{u\in R} y(u) + \sum_{e\in E} z(e)\cdot\kappa(e) \\ &\text{subject to} \\ &\quad y(u)+y(v)+z(e) \geqslant w(e) && \forall e \in E \end{aligned}$$

Here, $yz(e) = y(u) + y(v) + z(e)$, where u, v are the two endpoints of e.

Our algorithm will be a scaling algorithm, which essentially reduces the problem of finding $(1-\varepsilon)$-approximate **maximum weight fractional matching** to the problem of finding a maximal fractional matching, which can be easily accomplished using known subroutines (see [24, 9, 3]). Before stating our algorithm, we give some definitions.

▶ **Definition 26** (Residual Graph)**.** *Given a bipartite graph $G = (L, R, E)$, with a capacity function κ on the edges of the graph. Let $\vec{x}$ be a fractional matching obeying κ. We define G_x to be the residual graph with respect to $\vec{x}$. In particular, this is a directed graph, where corresponding to each undirected edge $e \in G$, there are two directed edges, e_f (forward edges, directed from L to R), and e_b (backward edge, directed from R to L). Moreover, e_f has a residual capacity of $\kappa(e) - x(e)$, and e_b has a capacity of $x(e)$. Thus, if an edge e is saturated, that is $x(e) = \kappa(e)$, then e_f is not in G_x. Similarly, if $x(e) = 0$, then e_b is not in G_x.*

▶ **Definition 27** (Free Vertices)**.** *Given a graph G, and a fractional matching $\vec{x}$, we say that a vertex v is free with respect to $\vec{x}$ if $\sum_{e\ni v} x(e) < 1$.*

▶ **Definition 28.** *An augmenting path in G_x, will refer to a path starting and ending in a free vertex, and all the intermediate vertices on this path will be saturated.*

Before stating our algorithm, we will state the invariants that the algorithm will maintain. Subsequently, we will show that maintaining these invariants throughout implies that the algorithm will output a matching satisfying the approximation guarantees of Lemma 25 and in the desired runtime.

▶ Remark 29. We round down ε so that $1/\varepsilon$ is an integer.

▶ **Property 30.** *Our algorithm will at all times maintain, a fractional matching $\vec{x}$, and the dual variables $y(u)$ for all $u \in V$, and $z(e)$, for all $e \in E$ with the following properties.*

1. ***Granularity:*** *At all times, $y(u)$ for all $u \in V$, and $z(e)$ for all $e \in E$, are integral multiples of ε.*
2. ***Domination:*** *For all directed edges e_f and e_b in G_x, we have $yz(e) \geqslant w(e) - \varepsilon$.*
3. ***Tightness:*** *For all backward edges $e_b \in G_x$, we additionally have the property that $yz(e) \leqslant w(e) + \varepsilon$.*
4. ***Free Duals:*** *The $y(u)$ for free vertices $u \in L$ are equal, and are at most $y(v)$ for $v \in L \setminus Z$. The free vertex duals in R are always 0. The algorithm terminates when the free vertex duals in L are all 0.*
5. ***Complementary Slackness:*** *If $z(e) > 0$ for some $e \in E$, then $x(e) = \kappa(e)$.*

▶ **Definition 31** (Eligible Edges)**.** *Let $\vec{x}$ be the current fractional matching maintained by the graph, and let G_x denote the residual graph with respect to $\vec{x}$. A forward edge e_f is eligible if $yz(e) = w(e) - \varepsilon$, and backward edge e_b is said to be eligible if $yz(e) = w(e) + \varepsilon$. We use G_x^t to denote the eligible subgraph of G_x.*

▶ **Lemma 32.** *The fractional matching $\vec{x}$ returned by the algorithm mentioned in Property 30 has $\sum_{e\in E} w(e)\cdot x(e) \geqslant (1-\varepsilon)\cdot \mathit{mwm}(G)$.*

Proof. In order to see this, consider the dual variables returned by the algorithm. Note that if we increase each of the duals by a factor of $(1+\varepsilon)$, then the dual solutions $\vec{y}, \vec{z}$ maintained by the algorithm are feasible dual solutions to the dual program (this is by Property 30(2)). Thus, by weak duality, we have, $\sum_{u\in V} y(u) + \sum_{e\in E} z(e)\cdot\kappa(e) \geqslant (1-\varepsilon)\cdot \mathsf{mwm}(G)$. Due to complementary slackness, (Property 30(5)), we have, $\sum_{u\in V} y(u) + \sum_{e\in E} x(e)\cdot z(e) \geqslant (1-\varepsilon)\cdot \mathsf{mwm}(G)$. Due to the fact that free vertex duals, at the end of the algorithm are zero (Property 30(4)), we have, $\sum_{u\in V}\sum_{e\ni u} x(e)\cdot y(u) + \sum_{e\in E} z(e)\cdot x(e) \geqslant (1-\varepsilon)\cdot \mathsf{mwm}(G)$. Simplifying the above expression, and using Property 30(3), that is, tightness, we have, $\sum_{e\in E}(1+4\varepsilon)\cdot w(e)\cdot x(e) \geqslant (1-\varepsilon)\cdot \mathsf{mwm}(G)$.This shows the claim. ◀

The precise algorithm is stated in Algorithm 2. We now show that Algorithm 2 proves Property 30. Later, we will show runtime guarantees of Algorithm 2. Towards this, we start with the following observation.

▶ **Observation 33.** *Let $e\in E(G)$, then e_f and e_b cannot simultaneously appear in G_x^t.*

▶ **Definition 34.** *Let H and G be directed, capacitated graphs with capacity functions c_h and c_g respectively. Then, we say $E(H)\subseteq_c E(G)$ if $e\in H$ implies $e\in G$, and $c_h(e)\leqslant c_g(e)$.*

▷ Claim 35. After Line 13, there are no augmenting paths in the graph G_x^t.

Proof. Let $\vec{y}$ denote the fractional matching after the augmentation step. Then, in order to show the claim, it is sufficient to show $E(G_y^t)\subseteq_c E(G_x^t)$. Consider any forward edge $e_f\in E(G_x^t)$, observe that $e_b\notin E(G_x^t)$ due to Observation 33. Since we don't change the duals, $e_b\notin E(G_y^t)$ as well. Finally, e_f can either be augmented along or not, in either case, we have, $\kappa(e)-x(e)\geqslant\kappa(e)-y(e)$. Such an argument applies for any edge e_b as well. From this, we can conclude that any augmenting path that is present in G_y^t is in G_x^t as well, and this contradicts the fact that we found a maximal set of augmenting paths $\mathcal{P}$. The subsequent claims follow from induction, and we prove them in the full version. ◁

▷ Claim 36 (Granularity). Throughout the algorithm, Property 30(1) holds.

▷ Claim 37 (Domination). Throughout the algorithm, Property 30(2) holds.

▷ Claim 38 (Tightness). Throughout the algorithm, Property 30(3) property holds.

▷ Claim 39 (Free Duals). Throughout the algorithm, Property 30(4) holds.

▷ Claim 40 (Complementary Slackness). Throughout the algorithm, Property 30(5) holds.

5.5 Runtime

Before proving the runtime of Algorithm 2, we start with the following structural lemma.

▶ **Observation 41.** *In G_x^t, after dual adjustment step, there are only forward edges between $L\cap Z$ and $R\setminus Z$, and backward edges between $R\cap Z$ and $L\setminus Z$ i.e. all directed edges between Z and $V\setminus Z$ go from Z to $V\setminus Z$.*

Proof. Suppose there is a backward edge e_b between $L\cap Z$ and $R\setminus Z$ after the dual adjustment step. This implies, that after the dual adjustment step, $yz(e_b)=w(e)+\varepsilon$. Thus, prior to the dual adjustment step, we had that $yz(e_b)=w(e)+2\varepsilon$. However, this would contradict the

tightness property (see Property 30(3)). Similarly, suppose there is a forward edge e_f between $R \cap Z$ and $L \setminus Z$ after the dual adjustment step. This would imply that $yz(e_f) = w(e) - \varepsilon$ after the dual adjustment step. Thus, before the dual adjustment step, $yz(e_f) = w(e) - 2\varepsilon$, which would contradict the domination property (see Property 30(2)). ◀

▶ **Lemma 42.** *The graph G_x^t that is fed into* AUGMENTATION *procedure is acyclic.*

Proof. We will show this by induction. Observe that at the beginning of the algorithm, there are no back edges, so the graph is acyclic. We now show that if no cycles are present in the graph, then dual adjustment and augmentation procedures cannot create cycles.

1. First consider 8, observe that if $e_b \in G_x^t$ is subjected to this, then $x(e) = \kappa(e)$ due to complementary slackness. Thus e_f does not exist, and cannot be added to G_x^t due to this modification. Moreover, Line 8 does not affect any other e. Thus, if the graph G_x^t was acyclic before, then it remains acyclic after Line 8.
2. Let $\vec{y}$ be the fractional matching after augmentation step. As we saw in Claim 35, $E(G_y^t) \subseteq_c E(G_x^t)$. Thus, if G_x^t is acyclic, then G_y^t is acyclic as well.
3. Now consider Line 17. By induction hypothesis, there are no cycles in G_x^t before Line 17 was executed. Suppose a cycle C exists in G_x^t after this step, then C contains either e_f or e_b, where e is an edge subjected to Line 17. However, for e_b, $\kappa(e) = x(e)$, and therefore, e_f cannot exist in G_x^t. Moreover, $e_b \notin G_x^t$ since before the dual modification $yz(e) = w(e) - \varepsilon$, and after dual adjustment, $yz(e) = w(e)$.
4. By induction hypothesis, there are no cycles in G_x^t before Line 18 and Line 19. These steps preserve eligibility and ineligibility status of any edge between $L \cap Z$ and $R \cap Z$ and those between $L \setminus Z$ and $R \setminus Z$. Thus, if a new cycle is created after Line 18 and Line 19, then it must contain a directed edge from Z to $V \setminus Z$, and from $V \setminus Z$ to Z. However, Observation 41 suggests that after this step, the latter are not in G_x^t. ◀

▶ **Observation 43.** *Property 30(4) holds. By Line 18, at the end of each iteration of the while loop, the free duals in $L \cap Z$ drops by ε. Therefore, total number of iterations is $O(\frac{W}{\varepsilon})$.*

▶ **Lemma 44** ([24])**.** *For G_x^t acyclic, maximal augmenting paths can be found in time $O(m \log n)$.*

▶ **Lemma 45.** *The total runtime of the algorithm is $O(m/\varepsilon \cdot W \cdot \log n)$.*

Proof. In a particular iteration of a while loop, we see how each of the steps contribute to the runtime. Consider step Line 8, this takes time $O(m)$ and similarly, the subsequent step of updating G_x^t takes time $O(m)$ as well. Since G_x^t is acyclic (by Lemma 42), we can use Lemma 44 to find the maximal set of augmenting paths in time $O(m \cdot \log n)$. Finally, the dual adjustment steps can also be accomplished in time $O(m)$. From Observation 43 implies the total runtime is $O(m/\varepsilon \cdot W \cdot \log n)$. ◀

6 Algorithm WeightedM-or-E*()

In this section, we now put everything together and describe the algorithm WEIGHTEDM-OR-E*(). Then, we describe how to use WEIGHTED-FRAC-MATCH() to get fractional matchings obeying capacity, and odd set constraints in general graphs.

▶ **Definition 46.** *Given a matching M, define $E_L^M(G, \kappa) = E_L(G, \kappa) \cap M$, and V_L^M to be the set of vertices that are the endpoints of $E_L^M(G, \kappa)$.*

▶ **Definition 47.** *Given a multigraph G with weight function w and capacity function κ on the edges of G, we define the bipartite double cover of G, denoted $\text{BC}(G)$, with capacity function κ_{BC} and weight function w_{BC} as follows:*

1. *For every vertex $v \in V(G)$, make two copies v and v' in $V(\text{BC}(G))$.*
2. *If e is an edge between u, v, then we add an edge e' between u and v' and an edge e'' between u' and v. Moreover, $w_{BC}(e') = w_{BC}(e'') = w(e)$ and $\kappa_{BC}(e') = \kappa_{BC}(e'') = \kappa(e)$.*

▶ **Observation 48.** *For weighted graph G, with capacity κ, $\mathsf{mwm}(\text{BC}(G), \kappa_{BC}) \geqslant 2 \cdot \mathsf{mwm}(G, \kappa)$.*

▶ **Lemma 49.** *Given a weighted multigraph G (possibly non-bipartite) with capacity function κ, $\varepsilon \in (0, 1)$, with edge weights from $\{1, 2, \cdots, W\}$, and with the property that for all $i \in [W]$, and for all vertices $u, v \in V$ we have, $\kappa(D_i((u, v))) \leqslant 1/\alpha_\varepsilon$, then there is an algorithm Weighted-Frac-Match-General() that takes as input $G, \kappa, w, \varepsilon$ and outputs a fractional matching $\vec{x}$ such that $\sum_{e \in E} w(e) \cdot x(e) \geqslant (1 - \varepsilon) \cdot \mathsf{mwm}(G, \kappa)$, and further $\vec{x}$ obeys the capacities and the odd set constraints.*

Proof. In the previous section, we saw the algorithm Weighted-Frac-Match() that solved this problem for bipartite graphs. For the case of general graphs, we proceed as follows. We collapse edges of $\text{BC}(G)$ as in Definition 6, and run Weighted-Frac-Match$(\text{BC}(G), \kappa_{\text{BC}}, w_{\text{BC}}, \varepsilon)$, and obtain a fractional matching $\vec{y}$. We let $\vec{z} = \vec{y}^C$. To translate this into a valid fractional matching $\vec{x}$ in G, do the following: for each $e \in G$, consider $e', e'' \in \text{BC}(G)$, and let $x(e) = \frac{z(e') + z(e'')}{2}$. Note that $\vec{z}$ is a fractional matching, since $\vec{x}$ is and moreover since $\vec{x}$ satisfies capacity constraints since $\vec{z}$ does. Applying Observation 48, we know that $\sum_{e \in E} w(e) \cdot x(e) \geqslant (1 - \varepsilon) \cdot \mathsf{mwm}(G, \kappa)$. Moreover, $\frac{\vec{x}}{1+\varepsilon}$ satisfies all odd set constraints since it satisfies the premise of Observation 8. ◀

We show how Algorithm 1 satisfies the conditions of Lemma 9.

Proof. (Lemma 9) We first show the runtime of the algorithm. First note that G_s can be computed in $O(m)$ time since this only involves sampling edges independently. Moreover, by Lemma 22, we know that the runtime of Static-Weighted-Match(G, ε) is $O(m/\varepsilon \cdot \log 1/\varepsilon)$. Additionally, from Lemma 24, we can conclude that we can obtain set E^* using the output of Static-Weighted-Match(G_s, ε) and the time taken to do this is $O(m)$. Finally, from Lemma 49, we can conclude that we can run Line 7 in time $O(m/\varepsilon \cdot \log 1/\varepsilon \cdot W \cdot \log n)$.

Now, we turn to show Lemma 9(1). In this case, first note that V_L^M and $V(M_I)$ are disjoint. This follows from Algorithm 1 and Definition 46. Thus, since $\vec{y}, \vec{x}$ are fractional matchings, we can conclude that $\vec{z}$ is also a fractional matching. Note that we land in Lemma 9(1) if $w(M) \geqslant (1-\varepsilon) \cdot \mathsf{mwm}(G)$. From Lemma 21 we can conclude that for $H = E_L(G, \kappa) \cap G[V_L^M]$ and $H_s = E_L(G, \kappa) \cap G_s[V_L^M]$, we have that $\mathsf{mwm}(H_s) \leqslant \mathsf{mwm}(H, \kappa^+) + \varepsilon \cdot \mathsf{mwm}(G)$. Thus, we have, $\sum_{e \in E} y(e) \cdot w(e) + \sum_{e \in E} x(e) \cdot w(e) \geqslant (1 - \varepsilon) \cdot \mathsf{mwm}(G) - 2\varepsilon \cdot \mathsf{mwm}(G)$.

We now proceed to proof Lemma 9(1a) and (1b). Consider any edge $e \in \text{supp}(\vec{z})$ with $w(e) = i$ and $\kappa(D_i(e)) \leqslant 1/\alpha_\varepsilon^2$. Thus, we know that $e \in \text{supp}(\vec{x})$, and so by Lemma 49, we have that $z(e) = x(e) \leqslant \kappa^+(e) \leqslant \kappa(e) \cdot \alpha_\varepsilon$ and $z(D_i(e)) = x(D_i(e)) \leqslant \kappa^+(D_i(e)) \leqslant \kappa(D_i(e)) \cdot \alpha_\varepsilon$. Similarly, for any $e \in \text{supp}(\vec{z})$ with $w(e) = i$, and $\kappa(D_i(e)) > 1/\alpha_\varepsilon^2$. We know that $e \in \mathsf{supp}(\vec{y})$. By definition of $\vec{y}$, we have $z(e) = y(e) = \kappa(e)/\kappa(D_i(e))$, and $z(D_i(e)) = 1$. Finally, we prove Lemma 9(2). First consider Lemma 24, this lemma implies that $\sum_{e \in E^*} \kappa(e) \cdot w(e) = O(\mathsf{mwm}(G) \cdot \log n)$. Finally, by Claim 23, we have, $\sum_{e \in M \cap E^*} w(e) \geqslant w(M) - (1+\varepsilon)^2 \cdot \mathsf{mwm}(G_s)$, thus, for any M with $w(M) \geqslant (1-\varepsilon) \cdot \mathsf{mwm}(G)$, we have $\sum_{e \in M \cap E^*} w(e) \geqslant \varepsilon \cdot \mathsf{mwm}(G)$. This is implied by the fact that the algorithm returns E^* when $\mathsf{mwm}(G_s) \leqslant (1 - 5\varepsilon) \cdot \mathsf{mwm}(G)$. Finally, for all edges in E^*, $\kappa(e) < 1$, otherwise they'd be sampled into G_s. ◀

Testing C_k-Freeness in Bounded-Arboricity Graphs

Talya Eden
Department of Computer Science, Bar-Ilan University, Ramat-Gan, Israel

Reut Levi
Efi Arazi School of Computer Science, Reichman University, Herzliya, Israel

Dana Ron
School of Electrical Engineering, Tel Aviv University, Israel

Abstract

We study the problem of testing C_k-freeness (k-cycle-freeness) for fixed constant $k > 3$ in graphs with bounded arboricity (but unbounded degrees). In particular, we are interested in one-sided error algorithms, so that they must detect a copy of C_k with high constant probability when the graph is ϵ-far from C_k-free.

We next state our results for constant arboricity and constant ϵ with a focus on the dependence on the number of graph vertices, n. The query complexity of all our algorithms grows polynomially with $1/\epsilon$.

1. As opposed to the case of $k = 3$, where the complexity of testing C_3-freeness grows with the arboricity of the graph but not with the size of the graph (*Levi, ICALP 2021*)[1] this is no longer the case already for $k = 4$. We show that $\Omega(n^{1/4})$ queries are necessary for testing C_4-freeness, and that $\widetilde{O}(n^{1/4})$ are sufficient. The same bounds hold for C_5.
2. For every fixed $k \geq 6$, any one-sided error algorithm for testing C_k-freeness must perform $\Omega(n^{1/3})$ queries.
3. For $k = 6$ we give a testing algorithm whose query complexity is $\widetilde{O}(n^{1/2})$.
4. For any fixed k, the query complexity of testing C_k-freeness is upper bounded by $O(n^{1-1/\lfloor k/2 \rfloor})$.

The last upper bound builds on another result in which we show that for any fixed subgraph F, the query complexity of testing F-freeness is upper bounded by $O(n^{1-1/\ell(F)})$, where $\ell(F)$ is a parameter of F that is always upper bounded by the number of vertices in F (and in particular is $k/2$ in C_k for even k).

We extend some of our results to bounded (non-constant) arboricity, where in particular, we obtain sublinear upper bounds for all k.

Our $\Omega(n^{1/4})$ lower bound for testing C_4-freeness in constant arboricity graphs provides a negative answer to an open problem posed by (Goldreich, 2021).

1 Introduction

Detecting small subgraphs with specific structures (referred to as *finding network motifs*) is a basic algorithmic task, with a variety of applications in biology, sociology and network science (see e.g. [21, 8, 31, 11, 7, 28, 5, 18, 6, 32, 23]). Of special interest is the natural case of subgraphs that are cycles of a fixed size k, which we denote by C_k. When the algorithm receives the entire graph as input, then by the well known result of Alon, Yuster and Zwick [4], this task can be solved in time $\widetilde{O}(n^\omega)$ where n is the number of graph vertices and ω is the exponent of matrix multiplication.[2] But what if we seek a sublinear-time (randomized) algorithm that does not read the entire graph? Namely, the algorithm is given query access to the graph[3] and should find a C_k when the graph is not C_k-free. This is clearly not possible if the graph contains only a single copy of C_k. However, is it possible to detect such a copy in sublinear-time when the graph is relatively far from being C_k-free? By "relatively far" we mean that it is necessary to remove a non-negligible fraction, denoted ϵ, of its edges in order to obtain an C_k-free graph. A closely related formulation of the question is whether we can design a one-sided error algorithm for testing C_k-freeness.[4]

If the maximum degree in the graph is upper bounded by a parameter $d_{\max}$, then the C_k-freeness testing problem can easily be solved by performing a number of queries that grows polynomially with $d_{\max}$ and exponentially with $\Theta(k)$ [20]. In particular, when $d_{\max} = O(1)$, then there is no dependence on the size of the graph G. We are however interested in considering graphs with varying degrees, so that, in particular, the maximum degree may be much larger than the average degree, and possibly as large as $\Theta(n)$.

For the special and interesting case where $k = 3$, i.e., the cycle is a triangle, Alon, Kaufman, Krivelevich and Ron [3] gave several upper and lower bounds on the query complexity of testing triangle-freeness as a function of the average degree d of the graph (in addition to the dependence on n and ϵ). While the upper and lower bounds are not tight in general, they are tight for $d = O(1)$, where the complexity is $\Theta(\sqrt{n})$ (for constant ϵ). The lower bound in this case is essentially based on "hiding" a small clique.

Since the aforementioned lower bound relies on the existence of a small dense subgraph, a natural question, studied by Levi [26], is whether it is possible to obtain improved (and possibly tight) results when the arboricity of the graph, denoted $arb(G)$, is bounded.[5] Focusing on the result under the assumption that $m \geq n$ (i.e., $d = \Omega(1)$) Levi showed that $\widetilde{O}(arb(G))$ queries are sufficient for testing triangle-freeness (the dependence on $1/\epsilon$ is polynomial), and that $\Omega(arb(G))$ queries are necessary.[6] In particular, when $arb(G)$ is a constant, the complexity is polynomial in $1/\epsilon$ and does not depend on the size of the graph.

In this work we seek to understand the complexity of testing C_k-freeness, in particular with one-sided error, for fixed $k > 3$. Our main focus is on constant arboricity graphs and some of our results extend to bounded arboricity graphs, as well as to F-freeness for any

---

[2] The dependence on k is exponential, but k is considered a constant.

[3] The types of queries typically considered are neighbor queries ("what is the ith neighbor of a vertex v?"), degree queries ("what is the degree of a vertex v?"), and pair queries ("is there an edge between a pair of vertices v and u?").

[4] The problems are equivalent if the algorithm is not given access to degree queries, otherwise the algorithm might find evidence to the existence of a C_k without actually detecting one. We note that all our algorithms do detect copies of C_k when they reject.

[5] The arboricity of a graph G is the minimum number of forests required to cover its edges, and is equal (up to a factor of 2) to the maximum average degree of any subgraph of G.

[6] To be precise, this lower bound holds for $m \geq (arb(G))^3$ – if $m < (\arg(G))^3$ then the lower bound is $\Omega(m^{1/3})$. See also Footnote 1 regarding the upper bound.

general subgraph F (of constant size). We note that the problem of testing cycle-freeness without requiring the cycle to be of specific length, is different from our problem. We further discuss this in Section 1.3. In the next subsection we state our findings.

1.1 Our results

Since our main focus is on graphs with constant arboricity, we first state our results in this setting, and later discuss our extensions to graphs with non-constant arboricity. Throughout this paper we assume that $m = \Omega(n)$ since even obtaining a single edge in the graph requires $\Omega(n/m)$ queries. Our algorithms use degree and neighbor queries and our lower bounds also allow pair queries (see Footnote 3). For simplicity, we state our results for constant ϵ. All our algorithms have a polynomial dependence on $1/\epsilon$.

Our first finding is that, as opposed to the case of $k = 3$, where the complexity of testing C_3-freeness grows with the arboricity of the graph but not with the size of the graph,[7] this is no longer the case for $k = 4$ (and larger k). In particular:

▶ **Theorem 1.** *The query complexity of one-sided error testing of C_4-freeness in constant-arboricity graphs over n vertices is $\widetilde{\Theta}(n^{1/4})$. The same bound holds for testing C_5-freeness.*

Theorem 1 (together with the upper bound in [20]) answers negatively the following open problem raised by Goldreich.

Open problem (number 3.2 in [19]): From bounded degree to bounded arboricity.
Suppose that property Π is testable within complexity $Q(n, \epsilon)$ in the bounded-degree graph model. Provide an upper bound on the complexity of testing Π in the general graph model under the promise that the tested graph has constant arboricity. For example, can the latter complexity be linear in $Q(n, \epsilon)$ while permitting extra $poly(\log n)$ or $1/\epsilon$ factors?

The $\Omega(n^{1/4})$ lower bound for testing C_4-freeness, answers this question negatively. Indeed, testing C_4-freeness in d-bounded degree graphs can be done with $poly(d, \epsilon)$ queries [20], while our lower bound suggest that even in constant arboricity graphs, a polynomial dependence on n is necessary.

When $k \geq 6$, we show that it is no longer possible to obtain a complexity of $\widetilde{O}(n^{1/4})$ as is the case for $k = 4, 5$.

▶ **Theorem 2.** *Let $k \geq 6$. Any one-sided error tester for the property of C_k-freeness in graphs of constant arboricity over n vertices must perform $\Omega(n^{1/3})$ queries.*

While for C_6 we were not able to match the lower bound of $\Omega(n^{1/3})$, we were able to obtain a sublinear-time algorithm, as stated next.

▶ **Theorem 3.** *There exists a one-sided error algorithm for testing C_6-freeness in graphs of constant arboricity over n vertices whose query complexity is $\widetilde{O}(n^{1/2})$.*

For general (fixed) k we prove the following upper bound.

▶ **Theorem 4.** *There exists a one-sided error algorithm for testing C_k-freeness in graphs of constant arboricity over n vertices whose query complexity is $O(n^{1-1/\lfloor k/2 \rfloor})$.*

We also prove a more general result for testing F-freeness for any constant size subgraph F. Below, $\ell(F)$ is as defined in Definition 10, and is always upper bounded by the number of vertices in F.

[7] We note that this is true also for other k-cliques for $k > 3$.

▶ **Theorem 5.** *There exists a one-sided error algorithm for testing F-freeness in graphs of constant arboricity over n vertices whose query complexity is $O(n^{1-1/\ell(F)})$.*

1.1.1 Extensions for general arboricity

We state our results for general arboricity graphs assuming that the algorithm is given an upper bound α on the arboricity of the graph (in the lower bounds the algorithm may be assumed to know the arboricity). Alternatively, if the algorithm receives as an input the number of edges, m, (as in previous results for C_k-freeness [3, 26]) instead of an upper bound on the arboricity, then we can estimate a notion known [26] as the "effective arboricity" of the graph, and depend on it instead of α. This is potentially beneficial since the effective arboricity can be much smaller than the actual arboricity of the graph, and it does not affect the asymptotic running times of our algorithms in terms of the dependence on the size of the graph and α. For further details see Section 2.

For C_4-freeness we give both an upper bound and a lower bound for general arboricity graphs. In particular, we show that a linear dependence on α is sufficient and a $\sqrt{\alpha}$-dependence is necessary (both for one-sided error algorithms) as stated next.

▶ **Theorem 6.** *There exists a one-sided error algorithm for testing C_4-freeness in graphs of arboricity at most α over n vertices whose query complexity is $\tilde{O}\left(\min\{n^{1/4}\alpha, \alpha + n^{3/4}\}\right)$.*[8]

▶ **Theorem 7.** *Testing C_4-freeness with one-sided error in graphs over n vertices with arboricity $c_1 \log n < \alpha < n^{1/2}/c_1'$ for sufficiently large constants c_1 and c_1' requires $\Omega(n^{1/4}\alpha^{1/2})$ queries.*[9]

For general constant size subgraphs F (and in particular C_k) our upper bound also has at most a linear dependence on α (recall that $\ell(F)$ is defined in Definition 10).

▶ **Theorem 8.** *There exists a one-sided error tester for F-freeness whose query complexity is $O\left(k^{2+1/\ell(F)} \cdot m^{1-1/\ell(F)} \cdot \alpha^{1/\ell(F)}\right)$.*

▶ **Corollary 9.** *There exists a one-sided error tester for C_k-freeness whose query complexity for even k is $O\left(k^{2+(2/k))} \cdot m^{1-2/k} \cdot \alpha^{2/k}\right)$, and for odd k is $O\left(k^{2+2/(k+1)} \cdot m^{1-2/(k+1)} \cdot \alpha^{2/(k+1)}\right)$.*

We comment that our lower bound of $\Omega(n^{1/3})$ for one-sided error algorithms, $k \geq 6$ and constant arboricity (stated in Theorem 2) also applies to graphs with non-constant arboricity (by adding a C_k-free subgraph with higher arboricity).[10]

We also note that it is possible to extend our algorithms for C_5 and C_6 freeness so as to get a polynomial (but not linear) dependence on α. However, these extensions do not introduce new techniques (and are most probably not optimal), so we do not present them here.

---

[8] More precisely, for values $\alpha < \log n$, the complexity is $O(n^{1/4}\alpha^{1/2}\log^{1/2} n/\epsilon^3)$, for values $\log n < \alpha < \sqrt{n}$, the complexity is $O(n^{1/4}\alpha/\epsilon^3)$, and for values $\alpha > n^{1/2}$, it is $O((\alpha + n^{3/4})/\epsilon^3)$.

[9] Note that the two-sided error lower bound of $\Omega(n^{1/4})$ for constant arboricity graphs (as stated in Theorem 1) also holds for graphs with higher arboricity α, and in particular, $\alpha = O(\log n)$. This is the case since we can simply add a small subgraph with arboricity α and no C_4s to the lower bound construction.

[10] For an odd k, it suffices to add a dense bipartite graph, and for even k, by the Erdős girth conjecture [16], one can add a subgraph with arboricity $n^{2/k}$.

1.2 A high-level discussion of our algorithms and lower bounds

Before discussing each of our results in more detail, we highlight some common themes. The starting point of all our algorithms is that if a graph is ϵ-far from being C_k-free (for a constant k), then it contains $\Omega(\epsilon m)$ edge-disjoint cycles.[11] We next use the bounded arboricity of the graph. Specifically, if a graph has arboricity at most α, then the number of edges between pairs of vertices that both have degree greater than $\theta_0 = \Theta(\alpha/\epsilon)$, is at most $O(\epsilon m)$.

Hence, there is a set of edge-disjoint C_ks, which we denote by $\mathcal{C}$, such that $|\mathcal{C}| = \Omega(\epsilon m)$, and no C_k in $\mathcal{C}$ contains any edge between two vertices with degree greater than θ_0. In other words, for every k-cycle ρ in $\mathcal{C}$, and for every vertex v with degree greater than θ_0 in ρ, the two neighbors of v in ρ have degree at most θ_0. In particular, when α is a constant, the two neighbors have degree $O(1/\epsilon)$.

At this point our algorithms diverge, but there are two common aspects when $k = 4, 5, 6$, which we would like to highlight. The first is that for the sake of "catching" one of the C_ks in $\mathcal{C}$, it will be useful to consider a subset, $\mathcal{C}'$, in which every vertex v that participates in one of the edge-disjoint C_ks in $\mathcal{C}'$ actually participate in $\Omega(\epsilon \cdot d(v))$ C_ks in $\mathcal{C}'$. The existence of such a subset follows by applying (as a mental experiment) a simple iterative process that removes C_ks with vertices that do not obey this constraint.

To illustrate why it is useful to have such a set $\mathcal{C}'$, consider the case of $k = 4$, and assume that a relatively large fraction of the C_4s in $\mathcal{C}'$ contain, in addition to the two vertices of degree at most $\theta_0 = O(\alpha/\epsilon)$, at least one other vertex that has degree at most $\theta_1 = O(n^{1/2}/\epsilon)$. In this case we can obtain such a vertex v with high probability (as discussed below), and then sample roughly $\sqrt{d(v)/\epsilon} = O(\sqrt{\theta_1/\epsilon}) = O(n^{1/4}/\epsilon)$ of its neighbors, so that the following holds. By (a slight variant of) the birthday paradox, with high constant probability we hit two of its neighbors, u and u', that reside on the same C_4 in $\mathcal{C}'$ (and hence have degree at most θ_0). By querying all the neighbors of u and u', we obtain this C_4.

However, what if for most of the C_4's in $\mathcal{C}'$ there are two vertices with degree significantly larger than $\sqrt{n}$ (that are "one opposite the other" on the C_4s)? Roughly speaking, in this case we exploit the fact that the number of such high-degree vertices is bounded, and we show how to detect a C_4 by performing random walks of length 2. A related issue arises in the case of $k = 6$, when there are three very high degree vertices on most C_6s in $\mathcal{C}'$. In this case we show how to essentially reduce the problem to testing triangle-freeness in a certain auxiliary graph. More precisely, the auxiliary graph is a multi-graph to which we have access only to certain types of queries, so that we cannot apply the algorithm of [3]. However, we can still show how to obtain a triangle in this graph, and hence a C_6 in the original graph. Interestingly, our general lower bound of $\Omega(n^{1/3})$ for C_k-freeness, $k \geq 6$ builds on the lower bound for testing triangle-freeness of [3].

In the following subsections we assume for the sake of the exposition that ϵ is a constant.

1.2.1 The results for C_4-freeness (and C_5-freeness)

We discuss our results for C_4-freeness in graphs with general arboricity. The results for C_5-freeness in constant arboricity graphs are obtained using very similar techniques.

[11] To verify this, let G be a graph that is ϵ-far from being C_k-free for a fixed constant k. Consider any maximal set S of edge-disjoint k-cycles. Since by removing all $k \cdot |S|$ edges on these cycles, the graph can be made cycle-free, $|S| \geq \epsilon m/k = \Omega(\epsilon m)$.

The algorithm

Our algorithm for testing C_4-freeness, Test-C_4-freeness, which has query complexity $\widetilde{O}(n^{1/4}\alpha)$, is governed by two thresholds: $\theta_0 = \Theta(\alpha)$, and $\theta_1 = \Theta(n^{1/2})$. For the sake of the current high-level presentation, we assume that[12] $\alpha \leq n^{1/2}$, so that $\theta_0 \leq \theta_1$.

The algorithm first samples $O(1)$ edges approximately uniformly by invoking a procedure Select-an-Edge,[13] and then randomly selects one of their endpoints. For each vertex v selected, it queries its degree, $d(v)$. If $d(v) \leq \theta_1$, then the algorithm selects $O(\sqrt{d(v)})$ random neighbors of v, and for each selected neighbor u such that $d(u) \leq \theta_0$, it queries all the neighbors of u. If $d(v) > \theta_1$, then the algorithm performs $\widetilde{O}(n^{1/4}\alpha^{1/2})$ random walks of length two from v. If a C_4 is observed in any one of these steps, then the algorithm rejects, otherwise it accepts.

The analysis of the algorithm

By the above description, the algorithm will only reject a graph if it detects a C_4, implying that it never errs on C_4-free graphs. Hence, consider a graph G that is far from being C_4-free. As discussed at the start of Section 1.2, the setting of $\theta_0 = \Theta(\alpha)$ (together with the fact that G is $\Omega(1)$-far from being C_4-free) implies the following. There exists a set, denoted $\mathcal{C}$, of $\Omega(m)$ *edge-disjoint* C_4s in G, such that no C_4 in $\mathcal{C}$ contains an edge between two vertices that both have degree greater than θ_0. Thus, for each C_4 in $\mathcal{C}$, there are at most two vertices with degree greater than θ_0, and they do not neighbor each other.

Considering the second aforementioned degree threshold θ_1 (and recalling that $\theta_1 \geq \theta_0$), we partition $\mathcal{C}$ into two subsets. The first, $\mathcal{C}_1$, consists of those C_4s in $\mathcal{C}$ that contain at most one vertex with degree greater than θ_1, and the second, $\mathcal{C}_2$, of the remaining C_4s in $\mathcal{C}$, which contain exactly two vertices with degree greater than θ_1. Since $\mathcal{C} = \mathcal{C}_1 \uplus \mathcal{C}_2$, at least one of these subsets is of size $\Omega(m)$.

***C_4*s with at most one high-degree vertex.** Suppose first that $|\mathcal{C}_1| = \Omega(m)$. Observe that since each 4-cycle $\rho \in \mathcal{C}_1$ contains at least two vertices with degree at most θ_0 and at most one vertex with degree greater than θ_1, it must contain at least one vertex, with degree at most θ_1 whose neighbors on the C_4 both have degree at most θ_0. For an illustration, see the LHS of Figure 1. Furthermore, we show that there exists a subset of $\mathcal{C}_1$, which we denote by $\mathcal{C}'_1$, such that $|\mathcal{C}'_1| = \Omega(m)$, and every vertex v that participates in one of the C_4s in $\mathcal{C}'_1$, actually participates in $\Omega(d(v))$ edges-disjoint C_4s in $\mathcal{C}_1$. It follows that in this case, when the algorithm selects a random edge (almost uniformly), with high constant probability it will obtain an edge with (at least) one endpoint v having the above properties. Conditioned on the selection of such a vertex v, the algorithm selects $\Theta(\sqrt{d(v)})$ random neighbors of v. By the birthday paradox, with high constant probability, among these neighbors there will be a pair of vertices that reside, together with v, on a common C_4 in $\mathcal{C}'_1$. Once their (at most θ_0) neighbors are queried, this C_4 is revealed.

***C_4*s with two high-degree vertex.** We now turn to the case in which $|\mathcal{C}_2| = \Omega(m)$. Here too we can show that there exists a subset of $\mathcal{C}_2$, denoted $\mathcal{C}'_2$, such that $|\mathcal{C}'_2| = \Omega(m)$, and every vertex v that participates in one of the C_4s in $\mathcal{C}'_2$ actually participates in $\Omega(d(v))$ edges-disjoint C_4s in $\mathcal{C}_2$.

[12] Indeed, graphs with arboricity greater than $n^{1/2}$ necessarily contain at least one C_4, but since we are interested in a one-sided error algorithm, and α is only known to be an upper bound on α, the algorithm cannot reject if it is provided with $\alpha > n^{1/2}$.

[13] This is a fairly standard and simple procedure, where we use the fact that graph has bounded arboricity, so that most of its edges have at least one endpoint with degree θ_0.

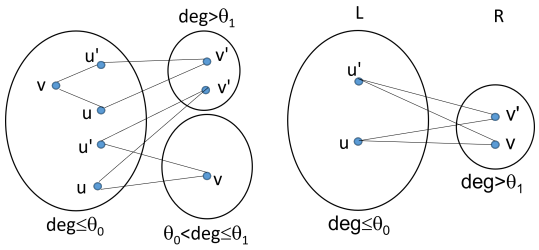

Figure 1 An illustration for some of the cases considered in the analysis of the algorithm for C_4-freeness. On the left side are two examples in which there is a single vertex v' with degree greater than θ_1, so that there is a vertex v with degree at most θ_1 with two neighbors whose degree is at most θ_0. On the right is an illustration when there are two such vertices with degree greater than θ_1.

Recall that by the definitions of $\mathcal{C}$ and $\mathcal{C}_2$ and since $\mathcal{C}'_2 \subseteq \mathcal{C}_2 \subseteq \mathcal{C}$, the following holds. For each 4-cycle ρ in $\mathcal{C}'_2$, since it is in $\mathcal{C}_2$, there are two vertices whose degree is greater than θ_1. Therefore, by the definition of $\mathcal{C}$, they are both adjacent on ρ to two vertices whose degree is at most θ_0. Hence, if we consider the subgraph induced by the vertices and edges of the C_4s in $\mathcal{C}'_2$, it is a bipartite graph, where on one side, denoted L, all vertices have degree at most θ_0, and on the other side, denoted R, all vertices have degree greater than θ_1. Furthermore, by the definition of $\mathcal{C}'_2$, for each vertex in R, a constant fraction of its neighbors (in the original graph G) belong to L, and for each vertex in L, a constant fraction of its neighbors belong to R. For an illustration, see the RHS of Figure 1.

Hence, if we select an edge almost uniformly and pick one of its endpoints with equal probability, with high constant probability we obtain a vertex $v \in R$. Conditioned on this event, since $d(v) > \theta_1$, the algorithm will perform $\widetilde{O}(n^{1/4}\alpha^{1/2})$ random walks of length two from v, and with high constant probability, a constant fraction of these walks will be of the form (v, u, v') where $u \in L$ and $v' \in R$. If for some v' we get two walks, (v, u, v') and (v, u', v') for $u \neq u'$, then a C_4 is detected.

Observe that since all vertices in R have degree greater than $\theta_1 = \Theta(n^{1/2})$, we have that $|R| \leq 2m/\theta_1 = O(n^{1/2}\alpha)$. This can be used to show that the expected number of pairs of walks that induce a C_4 is greater than 1. In order to show that we actually get such a pair with high constant probability, we perform a more careful analysis to bound the variance.

A (two-sided error) lower bound for testing C_4-freeness in constant arboricity graphs

To obtain this lower bound of $\Omega(n^{1/4})$, we define two distributions over graphs. In the support of the first distribution, $\mathcal{D}_0$, all graphs are C_4-free, and in the support of the second distribution, $\mathcal{D}_1$, all graphs are $\Omega(1)$-far from being C_4-free. Furthermore, $\mathcal{D}_0$ is uniform over all graphs isomorphic to a specific graph G_0, and $\mathcal{D}_1$ is uniform over all graphs isomorphic to a specific graph G_1.

We next describe a slightly simplified version of the two graphs (which cannot be used to prove the lower bound, but gives the essence of the proof). Both graphs are bipartite graphs, where one side, Y, contains $\Theta(\sqrt{n})$ vertices, and the other side, X, contains $\Theta(n)$ vertices, In G_0, each vertex in X has a unique pair of neighbors in Y (so there are no C_4s). On the other hand, in G_1, each vertex x in X has a "twin", x', where x and x' have the same pair of neighbors in Y (thus creating $\Omega(n)$ edge-disjoint C_4. See Figure 2. Observe that the arboricity of both graphs is 2 as for any subset of vertices S, the number of edges within S is at most $|S \cap X| \cdot 2$ so the average degree in the subgraph induced by S is at most 2.

In order to prove that no (possibly adaptive) algorithm can distinguish between a graph selected according to $\mathcal{D}_0$ and a graph selected according to $\mathcal{D}_1$, we define two processes, $\mathcal{P}_0$ and $\mathcal{P}_1$, which answer the queries of a testing algorithm while selecting a graph from $\mathcal{D}_0$ (respectively, $\mathcal{D}_1$) "on the fly". The lower bound of $\Omega(n^{1/4})$ follows from the fact that when performing fewer than $n^{1/4}/c$ queries (where c is a sufficiently large constant), for both distributions, with high constant probability, each new neighbor query is answered by a uniformly selected vertex id.

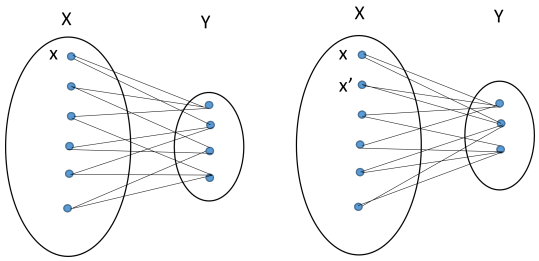

Figure 2 An illustration for the lower bound construction. The graph on the left is C_4-free while the graph on the right contains $\Omega(m)$ edge-disjoint C_4s and is hence $\Omega(1)$-far from being C_4-free.

A one-sided error lower bound for testing C_4-freeness in graphs with arboricity α

We next discuss the lower bound of $\Omega(n^{1/4}\alpha^{1/2})$ for graphs with arboricity $\alpha = \Omega(\log n)$ and one-sided error algorithms.

Here we define a single distribution $\mathcal{D}$ which is uniform over a family of graphs with arboricity α such that almost all graphs in this family are $\Omega(1)$-far from C_4-free.

Roughly speaking, the graphs in the support of $\mathcal{D}$ are random bipartite graphs, where one side, Y, is of size $\Theta(\sqrt{n}\alpha)$ and the other side, X, is of size $\Theta(n)$. Every vertex in X has α neighbors in Y, and every vertex in Y has $\Theta(\sqrt{n})$ neighbors in X. We need to show that if we select such a graph randomly, then on one hand it will be $\Omega(1)$-far from C_4-free, and on the other hand, in order to detect a C_4, any algorithm must perform $\Omega(n^{1/4}\alpha^{1/2})$ queries.

We next discuss the high-level idea as to why the resulting graphs are (with high constant probability) far from being C_4-free. Consider a fixed edge (x, y) in the bipartite graph, where $x \in X, y \in Y$. The number of C_4s this edge participates in is determined by the number of edges between the sets of neighbors of x and y, respectively $\Gamma(x)$ and $\Gamma(y)$. Recall that x has $\Theta(\alpha)$ neighbors and y has $\Theta(\sqrt{n})$ neighbors. Since overall there are $|X| \cdot |Y| = \Theta(n^{3/2}\alpha)$ potential pairs in the bipartite graph, and $\Theta(n\alpha)$ edges, each pair in $X \times Y$ is an edge with probability $\Theta(1/\sqrt{n})$. Hence, the expected number of edges between $\Gamma(x)$ and $\Gamma(y)$ is $|\Gamma(x)| \cdot |\Gamma(y)| \cdot (1/\sqrt{n}) = \Theta(\alpha)$. By analyzing the variance between pairs of edges, we furthermore show that with high constant probability, most edges do not participate in too many C_4s. Combining the two insights, it follows that with high constant probability, the graph is indeed far form being C_4-free.

In order to prove that any algorithm that performs at most $n^{1/4}\alpha^{1/2}/c$ queries (for a sufficiently large constant c), will not detect a C_4 with high constant probability, we actually prove that it will not detect *any* cycle. Roughly speaking, we show that by the randomness of the construction, since $|Y| = \Theta(\sqrt{n}\alpha)$, and the algorithm performs $O(\sqrt{|Y|})$ queries, each new neighbor query is answered by a uniformly distributed vertex that has not yet been observed. Therefore, the algorithm essentially views a forest.

A central challenge that we need to overcome is that we do not want to allow parallel edges, where the above construction might lead to their existence. One possibility is to first define the distribution over graphs with parallel edges and then to remove them. The benefit is that due to the higher degree of independence in the construction, it is somewhat easier to formally prove that the graphs obtained (with parallel edges) are with high probability $\Omega(1)$-far from C_4-free, and this remains the case when we remove parallel edges.

However, this creates a difficulty when we turn to argue that no (one-sided error) algorithm can detect a C_4 unless it makes $\Omega(n^{1/4}\alpha^{1/2})$ queries. The difficulty is due to the fact that in the formal proof we need to deal with dependencies that arise due to varying degrees (which occur because parallel edges are removed). While intuitively, varying degree should not actually "help" the algorithm, this intuition is difficult to formalize. Hence, we have chosen to define the distribution, from the start, over graphs that do not have parallel edges. This choice creates some technical challenges of its own (in particular in the argument that the graphs obtained are $\Omega(1)$-far from C_4-free), but we are able to overcome them. For more details see the full version.

1.2.2 The algorithm for C_6-freeness

Recall that for C_6 we have a (one-sided error) testing algorithm whose query complexity is $\widetilde{O}(n^{1/2})$. In addition to assuming (for the sake of the exposition) that ϵ is a constant, we also ignore polylogarithmic factors in n. Similarly to the algorithm for testing C_4-freeness, the algorithm for testing C_6-freeness in constant arboricity graphs is governed by two thresholds. The first, θ_0, is of the order of the arboricity, so that it is a constant (recall that we assume that ϵ is a constant). The second, θ_2, is of the order of $\sqrt{n}$.

The algorithm repeats the following process several times. It selects a vertex v uniformly at random, and if $d(v) \leq \theta_0$, it performs a *restricted* BFS starting from v to depth 4. Specifically:

1. Whenever a vertex u is reached such that $d(u) \leq \theta_0$, all its neighbors are queried.
2. Whenever a vertex u is reached such that $d(u) > \theta_0$ and u is reached from a vertex u' such that $d(u') \leq \theta_0$, there are two sub-cases. If $d(u) \leq \theta_1$, then all of u's neighbors are queried. Otherwise, θ_1 neighbors of u are selected uniformly at random.
3. Whenever a vertex u is reached from a vertex u' such that both $d(u) > \theta_0$ and $d(u') > \theta_0$, the BFS does not continue from u.

The algorithm rejects if and only if it observes a C_6.

Consider a graph that is far from being C_6-free, so that it contains a set of $\Omega(m) = \Omega(n)$ edge-disjoint C_6s. Furthermore, it contains such a set, denoted $\mathcal{C}$ for which every C_6 in $\mathcal{C}$ contains at most three vertices with degree greater than θ_0, and furthermore, these vertices are *not* adjacent on the C_6. We partition $\mathcal{C}$ into three subsets: $\mathcal{C}_1$, $\mathcal{C}_2$, and $\mathcal{C}_3$, depending on the number of vertices with degree greater than θ_0 that it contains.

If either $|\mathcal{C}_1| = \Omega(m)$, or $|\mathcal{C}_2| = \Omega(m)$, then it is not hard to show that the algorithm will detect a C_6 with high constant probability. The more interesting part of the proof is handling the case in which only $|\mathcal{C}_3| = \Omega(m)$.

In this case we define an auxiliary multi-graph, denoted G', over the set of vertices that participate in C_6s belonging to $\mathcal{C}_3$, and have degree greater than θ_0 (in G). We denote this set of vertices by M, and the set of vertices with degree at most θ_0 that participate in these C_6s, by L.

Assume for simplicity that each vertex in L has degree exactly 2 (i.e., it participates in a single C_6). For each pair of vertices in M, we put in G' a set of parallel edges, whose size equals the number of length-2 paths between them in G that pass through vertices in L. Hence, for each C_6 in $\mathcal{C}$, we have a triangle in G', where these triangles are edge-disjoint, and we denote their set by $\mathcal{T}$. See Figure 3.

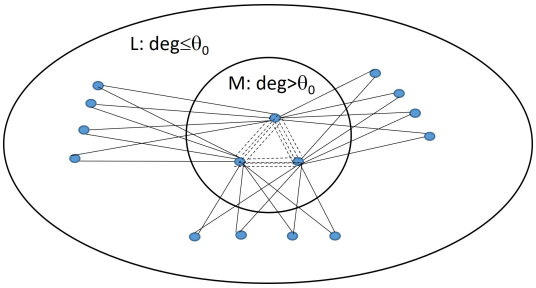

Figure 3 An illustration of the auxiliary (multi-)graph G' in the C_6-freeness testing algorithm. The dashed lines represent edges in G', each one corresponding to a length-2 path in G that passes through a vertex with degree at most θ_0.

Observe that selecting a vertex uniformly at random from L and querying its two neighbors in M corresponds to selecting an edge uniformly at random in G'. If we add an additional simplifying assumption by which (in G), vertices belonging to M only neighbor vertices belonging to L, then our algorithm on G essentially translates to picking a random edge in G'. Then depending on the degree of the endpoints, either querying all their neighbors in G' or θ_1 random neighbors.

Let H denote the subset of vertices in M whose degree in G is greater than θ_1. If relatively many triangles in $\mathcal{T}$ contain at most one vertex in H, then we are done, since these triangles contain an edge for which both endpoints have degree at most θ_1. Hence, it remains to address the case in which almost all triangles in $\mathcal{T}$ have two or three vertices in H.

Roughly speaking, in this case we show that the existence of many edge-disjoint, but not vertex-disjoint, triangles in G' that contain such high-degree vertices implies the existence of "many more" triangles that may be caught by our algorithm. As an illustrative extreme (but easy) special case, assume that in G' there are only three vertices. Then the existence of some number t of edge-disjoint triangles between them, actually implies the existence of t^3 (non edge-disjoint) triangles.

1.2.3 The general lower bound for C_k-freeness, $k \geq 6$

We establish our general lower bound of $\Omega(n^{1/3})$ for one-sided error testing of C_k-freeness when $k \geq 6$ by building on a lower bound for testing triangle-freeness that appears in [3, Lemma 2]. This lower bound for testing triangle-freeness is based on the difficulty of detecting a triangle in graphs selected uniformly from a family $\mathcal{G}_{n'}$ of graphs in which almost all graphs are $\Omega(1)$-far from being triangle-free. All graphs in the family are d-regular tri-partite graphs over n' vertices and the lower bound on the number of queries necessary to detect a triangle (with constant probability), is $\Omega(\min\{d, n'/d\})$. By setting $d = \sqrt{n'}$, the lower bound is $\Omega(\sqrt{n'})$.

We show that, for any constant $k \geq 6$, if we had a one-sided error testing algorithm $\mathcal{A}$ for C_k-freeness of graphs with n vertices and constant arboricity using at most $n^{1/3}/c$ queries (for a constant c), then we would be able to detect triangles in graphs selected uniformly from $\mathcal{G}_{n'}$ using at most $\sqrt{n'}/c'$ queries (for a constant c').

To this end we define an algorithm $\mathcal{A}$ that, given query access to a graph $G' \in \mathcal{G}_{n'}$, implicitly defines a graph G for which the following holds. First, the number of vertices in G is $n = \Theta((n')^{3/2})$, and the number of edges is $m = \Theta(m')$, where m' is the number of edges in G' (so that $m' = \Theta((n')^{3/2})$). Second, G has arboricity 2. Third, the distance of G to C_k-freeness is of the same order as the distance of G' to triangle-freeness. Fourth, there is a one-to-one correspondence between triangles in G' and C_ks in G. The basic idea is to replace edges in the tri-partite graph G' with paths of length $k/3$. See Figure 4

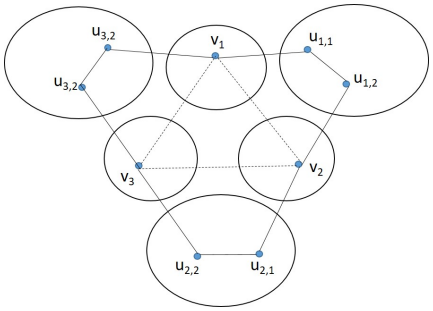

Figure 4 An illustration for the lower bound construction for C_k-freeness in constant arboricity graphs when $k = 9$. The three circles in the middle and the dashed lines represent a graph $G' \in \mathcal{G}_{n'}$. The outer circles represent the additional vertices in G. Since $k = 9$ in this example, each edge in G' is replaced by a path of length 3 in G.

Assuming there existed a testing algorithm $\mathcal{A}$ as stated above, the algorithm $\mathcal{A}'$ would use it to try and find a C_k in G (and hence a triangle in G'). In order to be able to run $\mathcal{A}$ on G, the algorithm $\mathcal{A}'$ must be able to answer queries of $\mathcal{A}$ to G by performing queries to G'. We show how this can be done with a constant multiplicative overhead. Hence, the lower bound of $\Omega(\sqrt{n'})$ for testing triangle-freeness (when the degree is $\Theta(\sqrt{n'})$) translated into a lower bound of $\Omega(n^{1/3})$ for testing C_k-freeness.

1.2.4 The general upper bound for C_k-freeness

Recall that our starting point is that if G is $\Omega(1)$-far from being C_k-free, then it contains a set $\mathcal{C}$ of $\Omega(m)$ edge-disjoint C_k's that do not contain any edge between vertices that both have degree greater than $\theta_0 = \Theta(\alpha)$. We refer to vertices with degree at most θ_0 as *light* vertices, and to those with degree greater than θ_0 as *heavy*. Hence, each C_k in $\mathcal{C}$ has at least $\lceil k/2 \rceil$ light vertices, and each heavy vertex on it neighbors two light vertices.

We present two different algorithms, where each of them is suitable for a different setting. The basic idea of both algorithms is to take a large enough sample of vertices and edges so that the subgraph determined by the sampled light vertices and their incident edges, as well as the sampled edges, contains a copy of C_k. The query complexity of each algorithm is stated following its high-level description.

The first algorithm

Our first algorithm simply samples vertices uniformly, independently at random, and then performs queries that reveal the neighbors of all light vertices in the sample. To analyze what is the sufficient sample size for this algorithm, consider the following generalization of the birthday paradox for k-way collisions. Assume we sample elements under the uniform distribution over $[n]$. Then we obtain a k-way collision after taking $\Theta(n^{1-1/k})$ samples.

Similarly, suppose we sample vertices uniformly from a graph that is composed only of n/k vertex-disjoint copies of C_k. Then, after sampling $\Theta(n^{1-1/k})$ vertices, we will hit all the vertices of at least one of the copies (with high constant probability). Conditioned on this event, if we reveal the neighborhood of all the vertices in the sample, then we obtain a C_k.

The next observation is that, in fact, we only need to hit a *vertex cover* of a copy of a C_k (as opposed to all its vertices). In particular we would like to hit such a cover that contains only light vertices, which we refer to as a *light vertex cover*. For constant α, this yields an improved dependence on k in the exponent, i.e., $O(n^{1-1/\lfloor k/2 \rfloor})$ sampled vertices suffice.

When taking into account the dependence on α (so that it is not necessarily true that $m = O(n)$) and incorporating this in the analysis, we prove that the query complexity is upper bounded by $O(m \cdot (\alpha/m)^{2/k})$ for even k and $O(m \cdot (\alpha/m)^{2/(k+1)})$ for odd k (up to a polynomial dependence on k). Since $\alpha \leq \sqrt{m}$ it follows that the above bounds are at most $O(m^{1-1/k})$ and $O(m^{1-1/(k+1)})$, respectively.

The second algorithm

Our second algorithm is designed for the case in which k is odd and $m = \Omega(\alpha^{(k+3)/2})$. In particular it is preferable when α is constant. We observe that when k is odd, for each C_k in $\mathcal{C}$, there is an edge in which both endpoints are light vertices. Therefore, if we sample edges (almost) uniformly from the graph (using a variant of the procedure Select-an-Edge), then we are likely to hit one of these edges. This additional step reduces the number of vertices we need to hit in each copy by 2, which results in improved complexity for some range of the parameters. In particular, the query complexity of this algorithm is $O(m \cdot (\alpha^2/m)^{2/(k-1)})$. Specifically, when α is a constant, the query complexity of this algorithm (which works for odd k) is $O(m^{1-2/(k-1)})$ (instead of $O(m^{1-2/(k+1)})$).

General subgraph F

Our first algorithm also works for any constant-size subgraph, F, where the upper bound on the sample size is of the form $m^{1-1/\ell(F)}$ where $\ell(F)$ depends on the structure of F, as defined next.

▶ **Definition 10.** *For a graph $F = (V_F, E_F)$ let $\mathcal{VC}(F)$ denote the set of all vertex covers of F. For a vertex cover Z of F we denote by $\mathcal{VC}'(Z)$ the set of vertex covers of F that are subsets of Z. We define $\ell(F) = \max_{Z \in \mathcal{VC}(F)} \left\{ min_{B \in \mathcal{VC}'(Z)} (|B|) \right\}$.*

Observe that by Definition 10, we have that $\ell(F)$ is lower bounded by the size of a minimum vertex cover of F and is upper bounded by $k = |V_F|$.

The high-level idea is that if we want to find a copy of F, it suffices to hit a light vertex cover of this copy and then query all neighbors of the sampled light vertices.

1.3 Related work

In this subsection we shortly discuss several related works, in addition to the two aforementioned works regarding testing C_3-freeness [3, 26].

Testing subgraph-freeness for fixed, constant size subgraphs in the dense-graphs model can be done using a number of queries that depends only on $1/\epsilon$ (where the dependence is a tower of height poly$(1/\epsilon)$), as shown by Alon, Fischer, Krivelevich and Szegedy [2]. Alon [1] proved that a super polynomial dependence on $1/\epsilon$ is necessary, unless the subgraph F is bipartite. Goldreich and Ron addressed the problem in the bounded-degree model [20], and gave a simple algorithm that depends polynomially on $1/\epsilon$ and the maximum degree in the graph, and exponentially on the diameter of F.

A special case of graphs that have bounded arboricity is the family of graphs that exclude a fixed minor (a.k.a. minor-free graphs). Newman and Sohler [29] showed that for this family of graphs, in the bounded-degree model, all properties can be tested with no dependence on the size of the graph G. Moreover, it was recently shown [25, 27] that any property which is monotone and additive[14] (and in particular F-freeness where F is a connected graph) can be tested using a number of queries that is only polynomial in $1/\epsilon$ and d, where d is the degree bound (and $O(d^{\rho(\epsilon)})$ in general $(\epsilon, \rho(\epsilon))$-hyperfinite graphs[15]). For minor-free graphs with unbounded degrees, Czumaj and Sohler [10] showed that a property is testable with one sided error and a number of queries that does not depend on the size of the graph if and only if it can be reduced to testing for a finite family of finite forbidden subgraphs.[16] The correctness of their algorithm relies on the fact that the arboricity of minor-free graphs remains constant even after contractions of edges (which is not the case for general constant-arboricity graphs).

In general graphs, it was shown that k-path freeness [22] and more generally T-freeness where T is a tree of order k [17], can be tested with time and query complexity that depend only on k, assuming the edges of the graph can be accessed uniformly at random. Testing cycle-freeness (where a no instance is a graph that is far from being a forest) was studied in the bounded-degree model in [20], where a two-sided error algorithm was given whose query complexity is polynomial in $1/\epsilon$ and the degree bound. Czumaj et. al [9] showed that the complexity of this problem for one-sided error algorithms in the bounded-degree model is $\widetilde{\Theta}(\sqrt{n})$ (for constant ϵ – their algorithm has a polynomial dependence on $1/\epsilon$), and the algorithm can be adapted to the general-graphs model.

Other sublinear-time graph algorithms for counting and sampling (rather than detecting) subgraphs that give improved results when the graph G has bounded arboricity include [14, 12, 15, 13].

1.4 Organization

We start in Section 2 with some preliminaries. In Section 3 we give the upper bound for testing C_4-freeness. All missing details and proofs appear in the full version of the paper.

2 Preliminaries

Unless stated explicitly otherwise, the graphs we consider are simple, so that in particular they do not contain any parallel edges. We denote the number of vertices in the graph by n and the number of edges by m. Every vertex v in the graph has a unique id, denoted $id(v)$, and its degree is denoted by $d(v)$.

We work in what is known as the *general graph model* [30, 24]. In particular, under this model, the *distance* of a graph G to C_k-freeness, denoted $dist(G, C_k\text{-free})$, is the minimum fraction of edges that should be removed from G in order to obtain a C_k-free graph. As for the allowed queries, a neighbor query to the ith neighbor of a vertex v is denoted by $nbr(v, i)$, and to its degree by $deg(v)$. A pair query between two vertices v_1 and v_2 is denoted by $pair(v_1, v_2)$. Given query access to a graph G and a parameter ϵ, a one-sided error testing

[14] A property is monotone if it closed under removal of edges and vertices. A property is additive if it is closed under the disjoint union of graphs.

[15] Let ρ be a function from $\mathbb{R}_+$ to $\mathbb{R}_+$. A graph $G = (V, E)$ is $(\epsilon, \rho(\epsilon))$-hyperfinite if for every $\epsilon > 0$ it is possible to remove $\epsilon|V|$ edges of the graph such that the remaining graph has connected components of size at most $\rho(\epsilon)$.

[16] They consider a model in which they can perform only random neighbor queries.

algorithm for C_k-freeness should accept G if it is C_k-free, and should reject G with probability at least $2/3$ if $dist(G, C_k\text{-free}) > \epsilon$. If the algorithm may also reject C_k-free graphs with probability at most $1/3$, then it has two-sided error.

As noted in the introduction, we assume our algorithms for graphs whose arboricity is not promised to be constant, are given an upper bound α on the arboricity $arb(G)$ of the tested graph G, and their complexity depends on this upper bound. Alternatively, if the algorithm is provided with the number of edges, m, then it may run a procedure from [26] to obtain a value α^* that with high constant probability satisfies the following: (1) $\alpha^* \leq 2arb(G)$; (2) The number of edges between vertices whose degree is at least $\alpha^*/(c\epsilon)$ for a constant c is at most $(1-\epsilon/c')m$ (for another, sufficiently large, constant c'). Up to polylogarithmic factors in n, the query complexity and running time of the procedure are $O(arb(G)/\epsilon^3)$ with high probability (assuming the average degree is $\Omega(1)$).

Throughout this work we assume, whenever needed, that ϵ is upper bounded by some sufficiently small constant (or else it can be set to that constant).

We also make use of the following claim – whose proof is given in the full version.

▷ Claim 11. For an integer s let $\{\chi_{i,j}\}_{(i,j)\in\Phi(s)}$ be Bernoulli random variables where $\Pr[\chi_{i,j}=1]=\mu$ for every $(i,j)\in\Phi(s)$. Suppose that the following conditions hold for some $c_1>0$ and $c_2>4$.

1. For every $(i_1,j_1)\in\Phi(s)$ and $(i_2,j_2)\in\Phi(s)$ such that the four indices are distinct, χ_{i_1,j_1} and χ_{i_2,j_2} are independent.
2. For every $(i_1,j_1)\in\Phi(s)$ and $(i_2,j_2)\in\Phi(s)$ such that exactly two of the four indices are the same, $\Pr[\chi_{i_1,j_1}=\chi_{i_2,j_2}=1]\leq c_1\cdot\mu^{3/2}$.
3. $s\geq c_2/\sqrt{\mu}$.

Then $\Pr\left[\sum_{(i,j)\in\Phi(s)}\chi_{i,j}=0\right]\leq\frac{1+c_1}{c_2}$.

3 An upper bound of $\widetilde{O}(n^{1/4}\alpha)$ for testing C_4-freeness

In this section we prove the more general (arboricity-dependent) form of the upper bound for testing C_4-freeness which is stated as Theorem 6 in the introduction.

Recall that the assumption on α is that it is an upper bound on the arboricity $arb(G)$. While it is known that for graphs with $arb(G)>\sqrt{n}$ there exists a C_4, we cannot simply reject if we get $\alpha>n^{1/2}$ since it might be that $arb(G)<\sqrt{n}$ (and we want one-sided error). However, in the case that $\alpha>n^{1/2}$, the $n^{1/4}\alpha$ term is replaced by $n^{3/4}$ (and the additive α term is due to the edge sampling).

The algorithm referred to in Theorem 6 is described next.

Algorithm 1 Test-C_4-freeness(n,ϵ,α).

1. Let $\theta_0=4\alpha/\epsilon$, $\theta_1=c_1\cdot\sqrt{n}/\epsilon$ (where c_1 will be determined subsequently) and $\theta_{min}=\min\{\theta_0,\theta_1\}$ (it is useful to read the algorithm while having in mind that $\theta_0\leq\theta_1$ (i.e., $\alpha=O(\sqrt{n})$) so that $\theta_{min}=\theta_0$).
2. Repeat the following $t=\Theta(1/\epsilon)$ times:
   a. Select an edge e by calling the procedure Select-an-Edge(α,ϵ), which appears below. If it does not return an edge, then continue to the next iteration.
   b. Select an endpoint v of e by flipping a fair coin.
   c. If $d(v)\leq\theta_1$, then select $s_1=\Theta(\sqrt{d(v)/\epsilon})$ $(=O(n^{1/4}/\epsilon))$ random neighbors of v, and for each neighbor u such that $d(u)\leq\theta_{min}$ query all the neighbors of u.
   d. Otherwise $(d(v)>\theta_1)$, perform $s_2=\Theta(\sqrt{(n\alpha/\theta_1)\log n/\epsilon^2})$ $(=\tilde{O}(n^{1/4}\alpha^{1/2}/\epsilon^2))$ random walks of length 2 starting from v.
   e. If a C_4 is detected, then return it, "Reject" and terminate.
3. Return "Accept".

We note that the algorithm can be unified/simplified so that it only performs random walks of length-2, where the number of walks is $\Theta(n^{1/4}\alpha/\epsilon^2)$, but then the analysis becomes slightly more complicated.

Algorithm 2 Select-an-edge(ϵ, α).

1. Repeat the following $\Theta(\alpha/\epsilon)$ times:
   a. Select a vertex u uniformly at random.
   b. If $d(u) \leq \theta_0$ for $\theta_0 = 4\alpha/\epsilon$, then with probability $d(u)/\theta_0$ select an edge incident to u uniformly at random and return it.
2. If no edge was selected, then return "Fail".

We start by stating a claim concerning the procedure Select-an-Edge where its proof is deferred to the full version.We then state and prove two additional claims that will be used in the proof of Theorem 6.

▷ Claim 12. With probability at least 2/3 the procedure Select-an-Edge returns an edge. Conditioned on it returning an edge, each edge incident to a vertex with degree at most θ_0 is returned with probability at least $1/(2m')$ and at most $1/m'$, where m' is the number of edges incident to vertices with degree at most θ_0.

▷ Claim 13. Let v be a vertex and let $C(v, \theta_{min})$ be a set of edge-disjoint C_4's containing v such that the neighbors of v on these C_4s all have degree at most θ_{min}, where θ_{min} is as defined in the algorithm.[17] Suppose that $|C(v, \theta_{min})| \geq 1$ and let $\epsilon' = |C(v, \theta_{min})|/d(v)$. If we select $s = 16\sqrt{d(v)/\epsilon'}$ random neighbors of v, and for each selected neighbor u such that $d(u) \leq \theta_{min}$ we query all the neighbors of u, then the probability that we obtain a C_4 is at least 9/10.

Proof. Let $E'(v)$ denote the set of edges incident to v that participate in the set $C(v, \theta_{min})$. By the premise of the claim, $|E'(v)|/d(v) = 2|C(v, \theta_{min})|/d(v) = 2\epsilon'$. Let s' be the number of neighbors of v that are incident to edges in $E'(v)$ among the s selected random neighbors of v. It holds that $\mathbb{E}[s'] = 2\epsilon' \cdot s$, and by the multiplicative Chernoff bound, $s' \geq \epsilon' \cdot s$ with probability at least $1 - e^{-\epsilon' \cdot s/4}$. We first show that this probability is at least 19/20, and then condition on this event. By the setting of $s = 16\sqrt{d(v)/\epsilon'}$, it holds that $\epsilon' \cdot s = 16\sqrt{\epsilon' \cdot d(v)}$, and by the setting of $\epsilon' = |C(v, \theta)|/d(v)$, we get $\epsilon' \cdot s \geq 16\sqrt{|C(v, \theta_{min})|} \geq 16$. Therefore, with probability at least 19/20, $s' > \epsilon' \cdot s = 16\sqrt{\epsilon' \cdot d(v)}$. We condition on this event and consider only those s' selected neighbors of v that are endpoints of $E'(v)$.

For each 4-cycle $\rho \in C(v, \theta_{min})$, let $u_1(\rho)$ and $u_2(\rho)$ be the two neighbors of v on this C_4 (so that they are endpoints of edges in $E'(v)$). Since the C_4s in $C(v, \theta_{min})$ are edge-disjoint, these vertices are distinct. Observe that the s' selected neighbors of v are uniformly distributed in $\bigcup_{\rho \in C(v, \theta_{min})} \{u_1(\rho), u_2(\rho)\}$, and that $s' \geq 16 \cdot \sqrt{|C(v, \theta_{min})|}$. Hence, by the "birthday paradox", with high constant probability, the sample of neighbors of v contains two vertices, $u_1(\rho)$, and $u_2(\rho)$ for some $\rho \in C(v, \theta_{min})$. Conditioned on this event, once the (at most θ_{min}) neighbors of $u_1(\rho)$ and $u_2(\rho)$ are queried, the four-cycle ρ is observed. ◁

▷ Claim 14. Let G be a graph over n vertices and m edges, and let $\theta_1, \epsilon', \epsilon''$ be parameters. Suppose that G contains a bipartite subgraph $G' = (L, R, E(G'))$ such that every vertex in R has degree at least θ_1 in G. Let v be a vertex in R such that v has at least $\epsilon' \cdot d(v)$

[17] Actually, we do not rely on the setting of θ_{min}, so this claim holds for any threshold value.

neighbors in L where each of these neighbors, u, has at least $\epsilon'' \cdot \max\{d(u), \frac{m}{n}\}$ neighbors in R. If $\theta_1 \geq 2\sqrt{n/(\epsilon' \cdot \epsilon'')}$ and we take $s_2 \geq \frac{32}{\epsilon' \cdot \epsilon''} \cdot \sqrt{2 \log n \cdot |R|}$ random walks of length 2 from v for a sufficiently large constant c', then with probability at least 9/10 we shall detect a C_4 in G.

Proof. For a pair of vertices v and $v' \neq v$ in R, let $\ell_2(v, v')$ be the number of length-2 paths between v and v', and let $\ell_2(v, R) = \sum_{v' \in R} \ell_2(v, v')$. Consider taking two random length-2 walks from v, and let $\mathcal{E}_1$ be the event that both of them end at vertices in R. Let $\mathcal{E}_2$ be the event that these two paths are distinct and end at the same vertex. Then for each single vertex $v' \in R$, conditioned on $\mathcal{E}_1$, the probability that the two walks end at v' is exactly $\frac{\ell_2(v,v')}{\ell_2(v,R)} \cdot \frac{\ell_2(v,v')-1}{\ell_2(v,R)}$. Therefore,

$$\Pr[\mathcal{E}_2 \,|\, \mathcal{E}_1] = \sum_{v' \in R} \frac{\ell_2(v, v')}{\ell_2(v, R)} \cdot \frac{\ell_2(v, v') - 1}{\ell_2(v, R)} = \frac{1}{(\ell_2(v, R))^2} \cdot \sum_{v' \in R} (\ell_2(v, v'))^2 - \frac{1}{\ell_2(v, R)} \,. \quad (1)$$

We would like to lower bound the above probability. For the first term on the right-hand-side, by applying the Cauchy-Schwartz inequality we get that

$$\frac{1}{(\ell_2(v, R))^2} \cdot \sum_{v' \in R} (\ell_2(v, v'))^2 \geq \frac{1}{(\ell_2(v, R))^2} \cdot |R| \cdot \left(\frac{\ell_2(v, R))}{|R|} \right)^2 = \frac{1}{|R|} \,. \quad (2)$$

By combining Equations (1) and (2) we get that $\Pr[\mathcal{E}_2 \,|\, \mathcal{E}_1] \geq \frac{1}{|R|} - \frac{1}{\ell_2(v,R)}$. Since each vertex in R has degree at least θ_1, we have that $|R| \leq \frac{2m}{\theta_1}$. By the premise of the claim regarding v and its neighbors, v has $\epsilon' d(v) \geq \epsilon' \cdot \theta_1$ neighbors in L, and each of them has at least $\epsilon'' \cdot (m/n)$ neighbors in R. Therefore,

$$\ell_2(v, R) \geq \epsilon' \cdot \theta_1 \cdot \epsilon'' \cdot \frac{m}{n} \geq \frac{\epsilon' \cdot \epsilon'' \cdot \theta_1^2 \cdot |R|}{2n} \geq 2|R|, \quad (3)$$

where the last inequality is by the premise $\theta_1 \geq 2\sqrt{n/(\epsilon' \cdot \epsilon'')}$. Therefore, $\Pr[\mathcal{E}_2 \,|\, \mathcal{E}_1] \geq \frac{1}{2|R|}$. So far we have shown that when taking two distinct random walks from v, and conditioned on them both ending at R (the event $\mathcal{E}_1$), the two paths collide on the end vertex (and hence result in a C_4) with probability at least $1/2|R|$. We shall now prove, that when taking s length-2 random walks from v, sufficiently many of them indeed end at R, and that with high probability, at least two of them collide, resulting in a C_4.

Consider first the event $\mathcal{E}_1$. By the premise of the claim, v has at least $\epsilon' \cdot d(v)$ neighbors in L, and each u of them has at least $\epsilon'' \max\{d(u), m/n\} \geq \epsilon'' d(u)$ neighbors in R. Therefore, the probability that a single random walk from v ends at R is at least $\epsilon' \cdot \epsilon''$. Hence, if we take $s \geq \frac{32}{\epsilon' \cdot \epsilon''} \sqrt{2 \log n \cdot |R|}$ length-2 random walks from v, and let s' denote the number of walks that end at a vertex in R, we have that $\mathbb{E}[s'] = 32 \cdot \sqrt{2 \log n \cdot |R|}$, and that with probability at least 9/10, we have $s' \geq 16 \cdot \sqrt{2 \log n \cdot |R|}$. We henceforth condition on this event.

Let $\chi'_{i,j}$ denote the event that the ith and jth random walks among the ones that end at R collide on the ending vertex (and thus result in a C_4). By the above discussion, we have that for a specific pair $i \neq j$, $\Pr[\chi'_{i,j} = 1] \geq 1/2|R|$. We now lower bound the probability that at least one pair of random walks from the s' that end in R detects a C_4, i.e. lower bound $\sum_{i,j \in [s']} \chi_{i,j}$, using Claim 11. For that end we also need to upper bound the variance of the sum.

Partition the vertices in R according to $\ell_2(v, v')$, where $R_x(v) = \{v' : 2^{x-1} < \ell_2(v, v') \leq 2^x\}$ for $x = 0, \ldots \log L \leq \log n$. Since $\sum_{v' \in R} \frac{\ell_2(v,v')}{\ell_2(v,R)} \cdot \frac{\ell_2(v,v')-1}{\ell_2(v,R)} > \frac{1}{2|R|}$, there exists at least one setting of x for which $\sum_{v' \in R_x} \frac{\ell_2(v,v')}{\ell_2(v,R)} \cdot \frac{\ell_2(v,v')-1}{\ell_2(v,R)} \geq \frac{1}{2|R| \log n}$. We denote this setting by x^* and observe that $x^* > 0$ (since for every $v' \in R_0$, $\ell_2(v, v') - 1 = 0$).

For every $i, j \in [s']$, $i < j$, we define a Bernoulli random variable $\chi_{i,j}$ that is 1 if and only if the ith and the jth random walks from v (among the s' considered) end at the same $v' \in R_{x^*}$ and pass through a different vertex in L. We next show that we can apply Claim 11 (with s in that claim set to s') to get an upper bound on the probability that $\sum_{i,j \in [s'], i<j} \chi_{i,j} = 0$ (which is an upper bound on the probability that we do not detect a C_4).

By the definition of the random variables, for every $i_1 \neq i_2, j_1 \neq j_2$, it holds that $\chi_{i_1,j_1}, \chi_{i_2,j_2}$ are independent, so that the first condition in Claim 11 is satisfied. Next, for any pair $i, j \in [s']$, $i < j$ we have that

$$\mu = \Pr[\chi_{i,j} = 1] = \sum_{v' \in R_{x^*}} \frac{\ell_2(v,v')}{\ell_2(v,R)} \cdot \frac{\ell_2(v,v') - 1}{\ell_2(v,R)} \geq \frac{1}{2|R| \log n} \,. \tag{4}$$

Therefore, we have that $s' \geq 16 \cdot \sqrt{2|R| \log n} = 16/\sqrt{\mu}$, and so the third condition in Claim 11 is satisfied (for $c_2 = 16$, where s' serves as the parameter s in the claim).

It remains to verify that the second condition holds. For any four indices $i_1, j_1, i_2, j_2 \in [s']$, $i_1 < j_1$, $i_2 < j_2$ such that exactly two of the four indices are the same,

$$\Pr[\chi_{i_1,j_1} = \chi_{i_2,j_2} = 1] = \sum_{v' \in R_{x^*}} \frac{\ell_2(v,v')}{\ell_2(v,R)} \cdot \left(\frac{\ell_2(v,v') - 1}{\ell_2(v,R)} \right)^2 \leq \mu \cdot \frac{2^{x^*} - 1}{\ell_2(v,R)} \,. \tag{5}$$

Since by Equation (4), $\mu = \sum_{v' \in R_{x^*}} \frac{\ell_2(v,v')}{\ell_2(v,R)} \cdot \frac{\ell_2(v,v')-1}{\ell_2(v,R)} \geq \frac{2^{2(x^*-1)}}{2(\ell_2(v,R))^2}$ (as $\ell_2(v,v') \geq 2^{x^*-1}$ for every $v' \in R_{x^*}$ and $\ell_2(v,v') - 1 \geq \ell_2(v,v')/2$), we get that $\Pr[\chi_{i_1,j_1} = \chi_{i_2,j_2} = 1] < \sqrt{2} \cdot \mu^{3/2}$, and so the second condition in Claim 11 holds as well (for $c_1 = \sqrt{2}$). Thus, the current claim follows. ◁

We are now ready to prove Theorem 6.

Proof of Theorem 6. Since the algorithm only rejects a graph G if it detects a C_4, it will always accept graphs that are C_4-free. Hence, we focus on the case that G is ϵ-far from being C_4-free.

Recall that $\theta_0 = 4\alpha/\epsilon$ and let $E_{>\theta_0}$ be the subset of edges in G where both endpoints have degree greater than θ_0. Since the arboricity of G is at most α, there are at most $2m/\theta_0$ vertices with degree greater than θ_0, so that $|E_{>\theta_0}| \leq (2m/\theta_0) \cdot \alpha = \epsilon m/2$ edges.

Since G is ϵ-far from C_4-free, if we remove all edges in $E_{>\theta_0}$, then we get a graph that is at least $(\epsilon/2)$-far from C_4-free. It follows that there exists a set of edge-disjoint C_4s, denoted $\mathcal{C}$, such that no C_4 in $\mathcal{C}$ contains an edge in $E_{>\theta_0}$, and $|\mathcal{C}| \geq \epsilon m/8$.

We next partition $\mathcal{C}$ into two disjoint subsets: $\mathcal{C}_1$ contains those C_4s that have at most one vertex with degree at least θ_1 in them, and $\mathcal{C}_2$ contains those that have at least two such vertices (where in the case $\theta_0 \leq \theta_1$ there will be exactly two). Since $\mathcal{C} = \mathcal{C}_1 \cup \mathcal{C}_2$, either $|\mathcal{C}_1| \geq \epsilon m/16$ or $|\mathcal{C}_2| \geq \epsilon m/16$ (possibly both).

The case $|\mathcal{C}_1| \geq \epsilon m/16$. Consider first the case that $|\mathcal{C}_1| \geq \epsilon m/16$. In order to analyze this case, we apply a process of "coloring" vertices and edges. Initially, all vertices and edges that participate in C_4s that belong to $\mathcal{C}_1$ are colored *green*, and all other vertices and edges are colored *red*. We next apply the following iterative process. As long as there is a green vertex v whose number of incident green edges is less than $\epsilon d(v)/64$, color v and its green incident edges by red. Observe that the total number of edges colored red by this process is at most $\epsilon m/32$. Furthermore, at the end of this process, every green vertex v has at least

$\epsilon d(v)/64$ incident green edges (and if a vertex is red, then all its incident edges are red). Let $\mathcal{C}_1'$ be the subset of $\mathcal{C}_1$ that consists of those C_4s in $\mathcal{C}_1$ whose edges all remain green after the process (and hence they are green), so that $|\mathcal{C}_1'| \geq \epsilon m/32$.

By the definition of $\mathcal{C}_1$, and hence also $\mathcal{C}_1'$, in each C_4 in $\mathcal{C}_1'$ there is at most one vertex with degree greater than θ_1, and no edges such that both endpoints have degree greater than θ_0. Assume without loss of generality that for each four-cycle $\rho \in \mathcal{C}_1'$, where $\rho = (v_0(\rho), v_1(\rho), v_2(\rho), v_3(\rho))$, $v_2(\rho)$ is the highest degree vertex (where $d(v_2(\rho))$ could be any value between 1 to n). Let $V_0(\mathcal{C}_1') = \bigcup_{\rho \in \mathcal{C}_1'} \{v_0(\rho)\}$ denote this set of vertices (i.e., the ones that are across from the highest degree vertex in a (green) four-cycle in $\mathcal{C}_1'$).

Observation. *For every $\rho \in \mathcal{C}_1'$,*

1. *$d(v_0(\rho)) \leq \theta_1$, and*
2. *$v_1(\rho)$ and $v_3(\rho)$ are of degree at most $\theta_{min} = \min\{\theta_0, \theta_1\}$.*

To verify this observation, note that by the definition of $\mathcal{C}_1'$, for every $\rho \in \mathcal{C}_1'$, there is at most one vertex with degree greater than θ_1, and since $v_2(\rho)$ is the highest degree vertex in ρ, it follows that all three other vertices in ρ are of degree at most θ_1.

We now show that $d(v_1(\rho)) \leq \theta_0$, and the proof for $v_3(\rho)$ is identical. If $d(v_2(\rho)) > \theta_0$, then it must be the case that $d(v_1(\rho)) < \theta_0$, as otherwise both have degree greater than θ_0 and so they cannot be connected, which is a contradiction to them both being incident on the four-cycle ρ. If $d(v_2(\rho)) \leq \theta_0$, then since $v_2(\rho)$ is the highest degree vertex in ρ, $d(v_1(\rho)) \leq d(v_2(\rho)) \leq \theta_0$.

Therefore, for every $v \in V_0(\mathcal{C}_1')$, it has at least $\epsilon d(v)/64$ neighbors u such that (v, u) is green and $d(u) \leq \theta_{min}$. Hence, overall in the graph, the set of vertices $V_0(\mathcal{C}_1')$ has at least $\epsilon m/32$ green edges that are incident to it and their second endpoint is of degree at most $\theta_{min} \leq \theta_0$. It follows that conditioned on an edge being returned by procedure Select-an-Edge, by Claim 12, it returns an edge incident to a vertex $v \in V_0(\mathcal{C}_1')$ with probability at least $(\epsilon m/32)/2m' > \epsilon/128$ (since $m' > \frac{1}{2}m$). So the probability that in some iteration of Test-C_4-freeness a vertex $v_0 \in V_0(\mathcal{C}_1')$ is selected, is at least $1 - (1 - \frac{\epsilon}{128})^t > 9/10$ (recall that $t = \Theta(1/\epsilon)$ so that it suffices to set $t = 500/\epsilon$).

Conditioning on this event, we apply Claim 13. Specifically:

- $\theta_0 = 4\alpha/\epsilon$ (as defined in Step 1 in Algorithm Test-C_4-freeness);
- $C(v_0, \theta_{min})$ is the set of C_4s in $\mathcal{C}_1'$ that are incident to v_0;
- $\epsilon' = |C(v_0, \theta_{min})|/d(v) \geq \epsilon/128$ (since v_0 has at least $\epsilon d(v)/64$ incident green edges, and they can be partitioned into pairs such that each pair belongs to exactly one C_4 in $C(v_0, \theta_{min})$);
- $d(v_0) \leq \theta_1$ (by the above observation);

In order to apply the claim, we must ensure that $s > 16\sqrt{d(v_0)/\epsilon'}$. By the above, it is sufficient to set s_1 in Step 2c, to be $s_1 = 512\sqrt{d(v_0)/\epsilon}$.

Hence, by Claim 13, if Step 2c is applied to v_0, then a C_4 is observed with probability at least 9/10.

The analysis for the case that $|\mathcal{C}_2| \geq \epsilon m/16$ is similar, and due to space constraints, it is deferred to the full version.

We next turn to analyze the query complexity. By the settings of θ_0, θ_1, t, s_1 and s_2 in the algorithm, the query complexity of the algorithm is upper bounded as follows.

$$O\left(\frac{1}{\epsilon} \cdot \left(\frac{\alpha}{\epsilon} + \max\{s_1, s_2\}\right)\right) = O\left(\frac{1}{\epsilon}\left(\frac{\alpha}{\epsilon} + \max\left\{\sqrt{\frac{\theta_1}{\epsilon}} \cdot \theta_{min}, \frac{1}{\epsilon^2} \cdot \sqrt{\frac{n\alpha}{\theta_1} \cdot \log n}\right\}\right)\right) \quad (6)$$

For the case that $\alpha \leq (c_1/4)\sqrt{n}$, we have that $\theta_{min} = \theta_0 = \Theta(\alpha/\epsilon)$ and that $\theta_1 = \Theta(\sqrt{n}/\epsilon)$, and so we get a complexity of

$$O\left(\epsilon^{-3} \cdot n^{1/4}\alpha^{1/2} \cdot \max\{\alpha^{1/2}, \log^{1/2} n\}\right) = O(\epsilon^{-3} \cdot n^{1/4}\alpha) \ , \tag{7}$$

where the last inequality is for $\alpha > \log n$, and otherwise the complexity is $O(\epsilon^{-3} \cdot n^{1/4}\alpha^{1/2}\log^{1/2} n)$.

For the case that $\alpha > (c_1/4)\sqrt{n}$, we have that $\theta_{min} = \theta_1 = \Theta(\sqrt{n}/\epsilon)$. Therefore, the complexity is

$$O(\epsilon^{-3} \cdot (\alpha + n^{3/4})) \ . \tag{8}$$

Thus, the proof is complete. ◀

Parameterized Algorithms for Steiner Forest in Bounded Width Graphs

Andreas Emil Feldmann

Abstract

In this paper we reassess the parameterized complexity and approximability of the well-studied Steiner Forest problem in several graph classes of bounded width. The problem takes an edge-weighted graph and pairs of vertices as input, and the aim is to find a minimum cost subgraph in which each given vertex pair lies in the same connected component. It is known that this problem is APX-hard in general, and NP-hard on graphs of treewidth 3, treedepth 4, and feedback vertex set size 2. However, Bateni, Hajiaghayi and Marx [JACM, 2011] gave an approximation scheme with a runtime of $n^{O(k^2/\varepsilon)}$ on graphs of treewidth k. Our main result is a much faster *efficient parameterized approximation scheme (EPAS)* with a runtime of $2^{O(\frac{k^2}{\varepsilon}\log\frac{k}{\varepsilon})} \cdot n^{O(1)}$. If k instead is the vertex cover number of the input graph, we show how to compute the optimum solution in $2^{O(k \log k)} \cdot n^{O(1)}$ time, and we also prove that this runtime dependence on k is asymptotically best possible, under ETH. Furthermore, if k is the size of a feedback edge set, then we obtain a faster $2^{O(k)} \cdot n^{O(1)}$ time algorithm, which again cannot be improved under ETH.

1 Introduction

The Steiner Forest problem is one of the most well-studied problems in network design [16, 23, 24, 28]. In this problem the input consists of a graph $G = (V, E)$ with positive edge weights, a set of *terminals* $R \subseteq V$, and a set of *demands* $D \subseteq \binom{R}{2}$. The objective is to select a subgraph $F \subseteq G$, minimizing the total cost of selected edges, while ensuring that for every demand pair $\{s, t\} \in D$, s and t are in the same connected component of F. Since edge weights are positive, it is easy to see that the optimal solution is always a forest. The Steiner Forest problem finds many applications (see surveys [11, 28, 32, 33]), for example in telecommunication networks (cf. [33]).

Our goal in this paper is to reassess the complexity of this fundamental problem from the point of view of parameterized complexity and approximation algorithms.[1] In order to recall the context, it is helpful to compare Steiner Forest to the even more well-studied Steiner

[1] We assume the reader is familiar with the basics of parameterized complexity and approximation algorithms, such as the classes FPT and APX and the definition of treewidth, as given in standard textbooks [14, 19, 34]. We give full definitions of all parameters in Section 2.

Tree problem, which is the special case of Steiner Forest where all terminals are required to be connected, i.e., $D = \binom{R}{2}$, and an optimal solution is a tree. Steiner Tree was already included in Karp's seminal list [25] of NP-hard problems from the 1970s. From the approximation point of view, Steiner Tree (and therefore Steiner Forest) is known to be APX-hard [13], but both problems admit constant factor approximations in polynomial time for general input graphs, where the best approximation factors known are $\ln(4)+\varepsilon < 1.39$ [10] and 2 [1, 31], respectively. Despite this similarity, when considering graph width parameters the problems exhibit wildly divergent behaviors from the parameterized complexity point of view: whereas Steiner Tree is FPT parameterized by standard structural parameters such as treewidth and can in fact even be solved in single exponential $2^{O(k)}n^{O(1)}$ time [6] when k is the treewidth, Steiner Forest is NP-hard on graphs of treewidth 3, as shown independently by Gassner [21] and Bateni, Hajiaghayi, and Marx [4].

Steiner Forest is therefore a problem that presents a dramatic jump in complexity in this context, compared to Steiner Tree, as the hardness result on graphs of treewidth 3 rules out even an XP algorithm for parameter treewidth. One of the main positive contributions of Bateni, Hajiaghayi, and Marx [4] was an algorithm attempting to bridge this gap using approximation. In particular, they showed that Steiner Forest admits an approximation scheme for graphs of treewidth k, which computes a $(1+\varepsilon)$-approximation in $n^{O(k^2/\varepsilon)}$ time for any $\varepsilon > 0$. Hence, if we allow slightly sub-optimal solutions, we can at least place the problem in XP parameterized by treewidth. In their paper, Bateni, Hajiaghayi, and Marx [4] remark that because the exponent of the polynomial of this runtime depends on k and ε, "it remains an interesting question for future research whether this dependence can be removed", that is, whether a $(1+\varepsilon)$-approximation can be obtained in FPT time.

The main result of our paper is a positive resolution of the question of [4]: we show that Steiner Forest admits an *efficient parameterized approximation scheme (EPAS)* for treewidth, that is, a $(1+\varepsilon)$-approximation algorithm with a runtime of the form $f(k,\varepsilon)n^{O(1)}$. In other words, we show that their algorithm can be improved in a way that makes the running time FPT not only in the treewidth, but also in $1/\varepsilon$. More precisely, we show the following:

▶ **Theorem 1.** *The Steiner Forest problem admits an EPAS parameterized by the treewidth k with a runtime of $2^{O(\frac{k^2}{\varepsilon}\log\frac{k}{\varepsilon})} \cdot n^{O(1)}$.*

Moving on from treewidth, we ask what the most general parameter is for which we may hope to obtain an FPT *exact* algorithm for Steiner Forest. We observe that the NP-hardness result of [4, 21] for Steiner Forest on graphs of treewidth 3 actually has some further implications for some even more restricted parameters: the graphs constructed in their reductions also have constant *treedepth* and *feedback vertex set* size, implying that the problem remains hard for both of these parameters (which are incomparable in general). More precisely, known reductions imply the following:

▶ **Theorem 2** ([4, 21])**.** *The Steiner Forest problem is NP-hard on graphs of treewidth* 3*, treedepth* 4*, and feedback vertex set of size* 2*.*

This leads us to consider even more restricted parameters, such as the size of a *vertex cover* and *feedback edge set*, which are not bounded in this reduction. Indeed, not only do we prove that Steiner Forest is FPT for both of these parameters, but we are also able to determine the correct parameter dependence, under the Exponential Time Hypothesis (ETH). For feedback edge set the optimal dependence is single exponential:

▶ **Theorem 3.** *The* Steiner Forest *problem is FPT parameterized by the size k of a feedback edge set and can be solved in $2^{O(k)}n^{O(1)}$ time. Furthermore, no $2^{o(k)}n^{O(1)}$ time algorithm exists, under ETH.*

For the parameterization by the vertex cover size, we obtain a slower runtime for our FPT algorithm. Interestingly, we are also able to prove that this is best possible, under ETH. Our lower bound for Steiner Forest is in contrast to the Steiner Tree problem, for which a faster $2^{O(k)}n^{O(1)}$ time algorithm exists, even if k is the treewidth [6].

▶ **Theorem 4.** *The* Steiner Forest *problem is FPT parameterized by the size k of a vertex cover and can be solved in $2^{O(k \log k)}n^{O(1)}$ time. Furthermore, no $2^{o(k \log k)}n^{O(1)}$ time algorithm exists, under ETH.*

We remark that Bodlaender et al. [8] recently independently showed that Steiner Forest admits a $2^{O(k \log k)}n^{O(1)}$ time algorithm for the size k of a vertex cover (improving an algorithm for the unweighted version of the problem given in [22]). While they develop their own dynamic program to solve this problem, we rely on an existing algorithm by [4] (see Theorem 5). Accordingly our description of the algorithm is very short compared to [8]. The more interesting part of Theorem 4 however is the proof of the lower bound.

1.1 Overview of Techniques

Let us briefly sketch the high level ideas of our results given by Theorems 1, 3, and 4.

EPAS for treewidth. Our algorithm extends the work of [4], so let us briefly recall some key ideas. Given a rooted tree decomposition, a terminal t is called *active* for a bag B if there is a demand $\{s, t\} \in D$ such that t lies in the sub-tree rooted at B while s does not (see Section 2 for formal definitions). It is a standard property of tree decompositions that every bag is a separator. Hence the component of any feasible solution that contains an active terminal must intersect B. The hardness of the problem now inherently stems from the fact that we have to decide for all active terminals of a bag, how the corresponding component intersects the bag, and therefore how the active terminals (whose number is unbounded by k) are partitioned into connected components. Suppose, however, that someone supplied us with this information, that is, suppose that for each bag B we are given a set of partitions Π_B of its active terminals and we are promised that the optimal solution *conforms* to all Π_B. By this we mean that if we look at how the optimal solution partitions the active terminals of B into connected components and call this partition π, then $\pi \in \Pi_B$, that is, the optimal partition is always one of the supplied options. In this case, using this extra information, the problem does become tractable, as shown in [4]:

▶ **Theorem 5** ([4])**.** *For an input graph G on n vertices, let a rooted nice tree decomposition of width k be given, such that all terminals lie in bags of leaf nodes of the decomposition. Also, let a set Π_B of partitions of the active terminals of each bag B of the decomposition be given. If $p = \sum_B |\Pi_B|$ is the total number of partitions, then a minimum cost* Steiner Forest *solution conforming to all Π_B can be computed in $2^{O(k \log k)} \cdot (pn)^{O(1)}$ time.*

The above theorem does not seem immediately helpful, since one would still need to find a small collection of partitions Π_B in order to obtain an efficient algorithm. Note however, that the partition sets may conform to an approximate solution as well, which would let the algorithm compute a solution that is at least as good. The strategy of [4] therefore is to construct a collection of partitions that has size polynomial in n (when k, ε are fixed

constants) by stipulating that when two active terminals are "close" to each other, they should belong in the same set of the partition of some near-optimal solution. In order to bound the resulting approximation ratio, they need to provide a charging scheme: starting from an optimal solution, they merge components which are "close", to obtain a solution that conforms to the Π_B used by the algorithm. They then show that the resulting solution is still near-optimal by charging the extra cost incurred by a merging operation to one of the two merged components.

A blocking point in the above is that we need to make sure we do not "overcharge" any component. This is accomplished in [4] via a partial ordering of the components: we order the components according to the highest bag of the rooted tree decomposition they intersect, and whenever two components are merged we charge this to the *lower* component. As shown in [4], this ensures that no component is charged for more than k merges. Unfortunately, this also implies that the merging procedure is not symmetric, which severely diminishes the contexts in which we can apply it.

Let us now describe how our approach improves upon this algorithm. A key ingredient will be a more sophisticated charging scheme, which will allow us to obtain a better (smaller) collection of partitions Π_B, without sacrificing solution quality. Counter-intuitively, we will achieve this by introducing a *second* parameter: the height h of the tree decomposition. Informally, we will now construct a near-optimal solution by merging two components whenever the connection cost is low compared to the cost of (a part of) *either* component (as opposed to the lower component). As in [4], this runs the risk of charging many merging operations to a higher component, but by performing an accounting by tree decomposition level and using the fact that the decomposition only has h levels, we are able to show that our solution is still near-optimal even though we merge components much more aggressively than [4]. In this way, for each bag we construct one partition of its active terminals into a number of sets that is polynomial in $k + h + \frac{1}{\varepsilon} + \log n$, in a way that guarantees that this partition is a *refinement* of a near-optimal solution. That is, whenever we decide to place two terminals together in our partition, the near-optimal solution does the same. However, this solution does not necessarily conform to the resulting partitions, as two terminals of the same component might end up in different sets of the partition for a bag.

At this point an astute reader may be wondering that since we consider both the width k and the height h of the decomposition as parameters, we are effectively parameterizing by treedepth, rather than treewidth. This is correct, but we then go on to invoke a result of [7] which states that any tree decomposition can be rebalanced to have height $O(\log n)$ without severely increasing its width. Hence, the family of partitions we now have has size polynomial in $k + \frac{1}{\varepsilon} + \log n$. However, we are not done yet, since at this point we can only guarantee that our partitions are refinements of a near-optimal solution. To complete the algorithm, we work from this family of partitions to obtain a collection of partitions *conforming* to our near-optimal solutions using δ-nets (this is similar to the approach of [4]). This leads to a running time of the form $(\log n)^{O(\frac{k^2}{\varepsilon})} n^{O(1)}$, which by standard arguments of parameterized complexity is in fact FPT and can be upper-bounded by a function of the form $2^{O(\frac{k^2}{\varepsilon} \log \frac{k}{\varepsilon})} \cdot n^{O(1)}$. To summarize, our high-level strategy is to show that the approach of [4] can be significantly improved when the input decomposition has small width and height, but then we observe that our new scheme is efficient enough in the height that even if we replace h by a bound that can be obtained for *any* graph, we still have an algorithm with an FPT running time, that is, significantly faster than that of [4].

Vertex Cover. For the parameterization by the vertex cover size, as mentioned we obtain an FPT exact algorithm with dependence $2^{O(k \log k)}$. A similar algorithm was recently independently obtained by [8] via dynamic programming. However, our algorithm is significantly simpler, because our strategy is to show how to construct a tree decomposition and a collection of partitions Π_B such that we only need *one* partition of the active terminals for each bag. As a consequence, $p = O(n)$ and Theorem 5 implies the algorithm of Theorem 4, without the need to formulate a new dynamic program.

Our main result for this parameter is that under ETH the runtime dependence is asymptotically optimal. Note that this also implies that the runtime of the dynamic program given by Theorem 5 cannot be improved with regards to the dependence on the treewidth. To show this, we present a reduction from 3-SAT, where the goal is to compress an n-variable formula into a Steiner Forest instance such that the graph has vertex cover size $O(n/\log n)$. The intuition on why it is possible to achieve such a compression is the following: suppose we have an instance with vertex cover of size k and a demand between two vertices of the independent set. Then the simplest way to satisfy such a demand is to connect both vertices to a common neighbor in the vertex cover. This encodes a choice among k vertices, and hence it is sufficient to encode the assignment for $\log k$ binary variables. The strategy of our reduction is to set up some choice gadgets which allow us to encode the assignments to the original formula taking advantage of the fact that each choice can represent a logarithmic number of variables. Hence we can obtain a construction of slightly sub-linear ($O(n/\log n)$) size. We then of course need to add some verification gadgets, representing the clauses, to check that the formula is indeed satisfied. But even though the number of such gadgets is linear in n, we make sure that they form an independent set, and hence the total vertex cover size remains sufficiently small to obtain our lower bound. We note that this compression strategy is similar to techniques recently used to obtain slightly super-exponential lower bounds for vertex cover for other problems [26, 27], but the constructions we use are new and tailored to Steiner Forest.

Feedback Edge Set. For the parameterization by the size k of a feedback edge set, instead of relying on the dynamic program given by Theorem 5 we go an entirely different route in order to obtain the faster $2^{O(k)}n^{O(1)}$ time FPT algorithm of Theorem 3. First off, it is not hard to reduce the Steiner Forest problem to an instance in which all vertices have degree at least 2. We then consider paths with internal vertices of degree 2, with endpoints that are vertices incident to the feedback edge set or vertices of degree at least 3. We call these paths *topo-edges* and argue that there are only $O(k)$ of these. We then guess for which topo-edges the two endpoints lie in different components of the optimal Steiner Forest solution, which can be done in $2^{O(k)}$ time. If a topo-edge has both its endpoints in the same component of the optimum, we show that it can be easily handled. For the remaining topo-edges, we can decide which edges along the path do not belong to the optimal solution by a reduction to the polynomial-time solvable Min Cut problem.

1.2 Related work

Bateni, Hajiaghayi, and Marx [4] show that one of the consequences of their XP approximation scheme is a PTAS for Steiner Forest on planar graphs, by using the common technique pioneered by Baker [2] of reducing this problem to graphs for which the treewidth is bounded as a function of ε. Because their algorithm is not FPT, their PTAS has a running time of the form $n^{f(\varepsilon)}$. By using our algorithm from Theorem 1 we can improve this runtime to $f(\varepsilon)n^{O(1)}$, i.e., we obtain on EPTAS for planar graphs. However, [18] already showed that

a $(1+\varepsilon)$-approximation algorithm with a runtime of $O(f(\varepsilon) \cdot n \log^3 n)$ exists for Steiner Forest on planar graphs. While they build on the work of [4], and in particular also reduce to graphs of treewidth bounded as a function of ε, interestingly they do not obtain an EPAS parameterized by treewidth. Instead they use a different route and show that given a graph H of treewidth k, in $O(f(k,\varepsilon) \cdot n \log^2 n)$ time it is possible to compute a Steiner Forest solution in H whose cost is at most $\text{cost}(F^\star) + \varepsilon \,\text{cost}(H)$, i.e., there is an additive error that depends on the cost of H compared to the optimum solution $F^\star$. If the input graph G is planar, then a result by [9] implies that from G a so-called *banyan* [3, 30] can be computed, which is a subgraph of G with cost bounded by $O(g(\varepsilon)\,\text{cost}(F^\star))$, and which contains a near-optimal approximation of every Steiner forest (cf. [18, Lemma 2.1]). By applying the framework of [4] on the banyan instead of the input graph, it is then possible to obtain a graph H of treewidth bounded by a function of ε, for which the algorithm of [18] computes a $(1+O(\varepsilon))$-approximation for the input.

If it would be possible to compute a banyan for bounded treewidth graphs, then the algorithm of [18] would also imply an EPAS for treewidth. However, to the best of our knowledge, and as explicitly stated by [3], banyans are only known for planar graphs [9, 18], Euclidean metrics [30], and doubling metrics [3] (in fact, the latter are so-called *forest banyans*, which have weaker properties). Thus it is unclear how to obtain an EPAS for Steiner Forest parameterized by the treewidth via the algorithm of [18]. We leave open whether a banyan exists for bounded treewidth graphs, which could give an alternative algorithm to the one given in Theorem 1. However, a further remark is that the cost of the banyan for planar graphs obtained by [9] has exponential dependence on $1/\varepsilon$, which implies a double exponential runtime dependence on $1/\varepsilon$ for the EPTAS for planar graphs. If a banyan can be obtained for bounded treewidth graphs by generalizing the techniques of [9] to minor-free graphs, then the resulting EPAS parameterized by treewidth would also have double exponential runtime in $1/\varepsilon$. In this case however, our EPAS given by Theorem 1 would be exponentially faster.

A different parameter that is often studied in the context of Steiner problems is the number $p = |R|$ of terminals. The classic result of [15] presents an FPT algorithm for Steiner Tree with a runtime of $3^p n^{O(1)}$. For unweighted graphs, this was improved [5, 29] to $2^p n^{O(1)}$, while the fastest known algorithm for weighted graphs can compute the optimum in $(2+\varepsilon)^p n^{O(\sqrt{\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}})}$ time [20] for any $\varepsilon > 0$. The algorithm of [15] can be generalized to solve Steiner Forest in $2^{O(p)} n^{O(1)}$ time (cf. [12]). A somewhat dual parameter to the number of terminals is the number q of non-terminals (so-called *Steiner vertices*) in the optimum solution. For this parameter, a folklore result states that Steiner Tree (and thus also Steiner Forest) is W[2]-hard (cf. [14, 17]). However, an EPAS with a runtime of $2^{O(q^2/\varepsilon^4)} n^{O(1)}$ was shown to exist for Steiner Tree [17]. For Steiner Forest it is not hard to see that such an EPAS parameterized by q cannot exist unless P=NP (cf. [17]), but if c denotes the number of components of the optimum solution, there is an EPAS with a runtime of $(2c)^{O((q+c)^2/\varepsilon^4)} n^{O(1)}$ [17]. Similar results have been found for related Steiner problems in directed graphs [12]. For further results in the area of parameterized approximations, we refer to the survey in [19].

2 Preliminaries

As mentioned, we assume the reader is familiar with the basics of parameterized complexity, such as the class FPT [14], and approximation algorithms such as a PTAS [34]. A *parameterized approximation scheme (PAS)* is an algorithm that computes a $(1+\varepsilon)$-approximation

for a problem in $f(k,\varepsilon)n^{g(\varepsilon)}$ time for some functions f and g, while an an *efficient parameterized approximation scheme (EPAS)* is a $(1+\varepsilon)$-approximation algorithm running in time $f(k,\varepsilon)n^{O(1)}$ (that is, the running time is FPT in $k+\frac{1}{\varepsilon}$). The distinction between a PAS and an EPAS is similar to the one between a PTAS and an EPTAS.

By $w : E \to \mathbb{R}^+$ we denote an edge-weight function, so that the cost of a solution F to the Steiner Forest problem is $\text{cost}(F) = \sum_{e\in E(F)} w(e)$. We will use $F^\star$ to denote an optimal solution, and for $\alpha \geq 1$ we will say that a solution F is α-approximate if $\text{cost}(F) \leq \alpha\,\text{cost}(F^\star)$. For $u, v \in V$ we use $\text{dist}(u,v)$ to denote the shortest-path distance from u to v in G according to the weight function w.

▶ **Definition 6.** *Given a graph $G = (V,E)$, a* tree decomposition *is a pair $(T, \{B_i\}_{i\in V(T)})$, where T is a tree and each node $i \in V(T)$ of the tree is associated with a* bag *$B_i \subseteq V$, with the following properties:*

1. *$\bigcup_{i\in V(T)} B_i = V$, i.e., all vertices of G are covered by the bags,*
2. *for every edge $uv \in E$ of G there exists a node $i \in V(T)$ of the tree for which $u, v \in B_i$, and*
3. *for every vertex $v \in V$ of G the nodes $\{i \in V(T) \mid v \in B_i\}$ of the tree for which the bags contain v induce a (connected) subtree of T.*

The width *of the tree decomposition is $\max_{i\in V(T)}\{|B_i| - 1\}$ and the* treewidth *of G is the minimum width over all its tree decompositions.*

A rooted tree decomposition is nice *if for every $i \in V(T)$ we have one of the following:*

1. *i has no children*[2] *(i is a* leaf node*),*
2. *i has exactly two children i_1 and i_2 such that $B_i = B_{i_1} = B_{i_2}$ (i is a* join node*),*
3. *i has a single child i' where $B_i = B_{i'} \cup \{v\}$ for some $v \in V$ (i is an* introduce node*), or*
4. *i has a single child i' where $B_i = B_{i'} \setminus \{v\}$ for some $v \in V$ (i is a* forget node*).*

Given a rooted tree decomposition T of a graph G, for a node u of T let B be the bag associated with it. Then V_B is the set of vertices of all bags in the subtree rooted at u. The set $A_B \subseteq R$ denotes the *active terminals* of the bag B: for any demand pair $\{s,t\} \in D$, if $s \in V_B$ and $t \notin V_B$ then $s \in A_B$. For any Steiner Forest solution F, if a connected component C of F contains an active terminal, then we say that C is an *active component* for B. For a fixed solution F, we denote the set of all active components for B by $\mathcal{C}_B$. Note that every active component must intersect the bag B.

If for every bag B a set of partitions Π_B of A_B is given, a Steiner Forest solution F is *conforming* to all Π_B, if for each bag B there exists a partition $\pi \in \Pi_B$ such that any two active terminals in A_B are in the same set $S \in \pi$ if and only if they are part of the same active component C of F, i.e., $S \subseteq V(C)$ and $S' \cap V(C) = \emptyset$ for any $S' \in \pi$ with $S' \neq S$ (note that this implies $|\pi| \leq |B|$). One technicality of Theorem 5 is that the algorithm needs a nice tree decomposition as input, for which the terminals only appear in bags that are leaf nodes of the decomposition. Given any tree decomposition, these conditions are not hard to meet (cf. [4, Lemma 6]). However, for our algorithms we are going to rely on tree decompositions with certain additional properties. Hence we will need to revisit the conditions needed for the algorithm of Theorem 5 when using it for our purposes.

We will also consider the following parameters: The *treedepth* of a graph G can be defined recursively as follows: (i) the treedepth of K_1 is 1 (ii) the treedepth of a disconnected graph is the maximum of the treedepth of any of its components (iii) the treedepth of a connected graph G is $1 + \min_{v\in V(G)} \text{td}(G - v)$. A *feedback vertex set* is a set of vertices whose removal

[2] here we do not demand the leaf nodes to be empty, as is often assumed for this definition.

leaves a forest. A *vertex cover* is a set of vertices such that its removal leaves an edge-less graph. A *feedback edge set* is a set of edges whose removal leaves a forest. In a connected graph with n vertices and m edges the minimum feedback edge set always has size $m - n + 1$.

As part of our approximation algorithm we will use the notion of δ-nets, defined as follows. A well-known fact is that a δ-net exists for any metric and any $\delta \geq 0$, and it can be constructed greedily in polynomial time.

▶ **Definition 7.** *Given a metric* (X, dist)*, a* δ-net *is a subset* $N \subseteq X$ *of points, such that*
1. *any two net points* $u, v \in N$ *are far from one another, i.e.,* $\mathrm{dist}(u, v) > \delta$*, and*
2. *for any node* $u \in X$ *there is some net point* $v \in N$ *close by, i.e.,* $\mathrm{dist}(u, v) \leq \delta$*.*

3 An efficient parameterized approximation scheme for treewidth

In this section we describe the main result of this paper which is an EPAS for Steiner Forest parameterized by treewidth. We begin by giving two preliminary tools (Lemma 8 and Lemma 9) which facilitate the algorithm by ensuring that the given tree decomposition has logarithmic height and that the instance has aspect ratio (ratio of the weights of the heaviest over the lightest edge) bounded by a polynomial in n.

We then go on to Subsection 3.1 where we introduce a second parameter, the height h of the decomposition. Our goal is to fix an almost-optimal solution F_ε and describe an algorithm that produces a partition ζ_B of the active terminals for each bag B of the decomposition, where ζ_B is *a refinement* of the partition implied by F_ε (Lemma 10). In other words, we seek a partition ζ_B of A_B such that if two terminals t_1, t_2 are in the same set of ζ_B, then they are also in the same component of F_ε. Of course, it is trivial to achieve this by giving a ζ_B where each active terminal is in its own set, so the interesting part here is how we group terminals together in a way that in the end allows us to bound $|\zeta_B|$ by a polynomial of $k + h + \frac{1}{\varepsilon} + \log n$, while still ensuring that F_ε is almost optimal.

The partition ζ_B of Lemma 10 is not yet conforming, because two terminals which are in distinct sets of ζ_B may still be in the same component of F_ε, and thus we cannot apply Theorem 5 at this point. Therefore in Subsection 3.2, given ζ_B we focus on how to obtain every possible partition of the set of active terminals, which could be conforming with an almost-optimal solution. By an appropriate use of δ-nets, similar to [4], we are able to "guess" (that is, brute-force) a choice of a small number of net points per active component. Since the number of choices for each point is at most $|\zeta_B|$ and we choose roughly $O(k^2/\epsilon)$ points in total, the total number of produced partitions (and hence the running time given by Theorem 5) is of the form $(\log n + k + \frac{1}{\epsilon})^{O(k^2/\epsilon)} n^{O(1)}$, which is FPT.

Let us now recall a result of Bodlaender and Hagerup [7] which states that a tree decomposition of logarithmic height can always be obtained.

▶ **Lemma 8** ([7])**.** *Given a tree decomposition of width* k *of a graph* G *on* n *vertices, there is a polynomial time algorithm computing a nice tree decomposition of* G *of width* $O(k)$ *and height* $O(k \log n)$*.*

We also need to reduce the aspect ratio of the given graph to a polynomial. This can be done using a standard technique, where however we need to make sure that the treewidth of the given graph remains bounded. Note that the aspect ratio of the resulting graph G' in the following lemma is polynomially bounded in the size of the original graph, but not necessarily in the size of G' (because G' may have significantly fewer vertices).

▶ **Lemma 9.** *Given* $\varepsilon > 0$*, an instance of* Steiner Forest *on a graph* G *with* n *vertices, and a (nice) tree decomposition* T *of width* k *and height* h *for* G*, in polynomial time we can compute an instance on a graph* G' *with at most* n *vertices and a (nice) tree decomposition* T'

of width at most k and height h for G', such that the ratio of the longest to the shortest edge in G' is at most $2n/\varepsilon$, and any α-approximation for G' can be converted into an $(\alpha+\varepsilon)$-approximation for G.

For simplicity, in the following we will scale the edge lengths of any given graph so that the shortest edge has length 1. In particular, after applying Lemma 9, the longest edge has length at most $2n/\varepsilon$.

3.1 Tree decompositions with bounded height

In this section we informally assume that the height h of the given tree decomposition is bounded as well as the width k. Our aim is to prove the following statement, where we restrict ourselves to input graphs of polynomial aspect ratio, which we may do according to Lemma 9 (keeping in mind that n is the number of vertices of the original input graph).

▶ **Lemma 10.** *Let an instance of* Steiner Forest *on a graph G with at most n vertices be given together with a tree decomposition T of width k and height h for G. For any $\varepsilon > 0$, if the ratio between the longest and shortest edge of G is at most $2n/\varepsilon$, then there exists a $(1+\varepsilon)$-approximation F_ε with the following properties. There exists a polynomial time algorithm, which for every bag B of T outputs a partition ζ_B of the active terminals A_B, such that each set of ζ_B belongs to the same component of F_ε and $|\zeta_B| = O(\frac{k^4h^2}{\varepsilon^2}\log\frac{n}{\varepsilon})$.*

To prove Lemma 10 we first identify the solution F_ε, after which we will show how to compute the partitions ζ_B.

3.1.1 A near-optimal solution

The high-level idea to obtain a $(1+\varepsilon)$-approximate solution F_ε is to connect components of the optimum solution $F^\star$ that lie very close to each other. In particular, if the distance between two components C and C' of $F^\star$ is of the form $f(k,h,\varepsilon)\,\mathrm{cost}(C)$ for some small enough function f, then we may hope to add a shortest path between C and C' and charge this additional cost to C, in order to obtain a $(1+\varepsilon)$-approximation. Unfortunately, this approach is not viable, since the number of components that are very close to C may be very large, meaning that the function f in the distance bound would have to linearly depend on the number of vertices in order to result in a $(1+\varepsilon)$-approximation. This in turn would mean that the size of the partition ζ_B would depend polynomially on the number of vertices, making it unsuitable for an FPT time algorithm. This issue lies at the heart of the problem and is the reason for why it is non-trivial to obtain an approximation scheme parameterized by the treewidth. To get around this issue we will measure the distance between components using a modified cost function, which we define next.

Given a bag B of the rooted tree decomposition T, we denote by T_B the subtree of T rooted at the node associated with B, and by $G_B = G[V_B]$ the graph induced by the vertices V_B lying in bags of T_B. We also define the graph $G_B^\downarrow \subseteq G_B$ as the graph spanned by all edges of G_B, except those induced by B, i.e., the edge set of $G_B^\downarrow$ is

$$E(G_B^\downarrow) = \{uv \in E(G_B) \mid u \notin B \vee v \notin B\}.$$

The cost of a component C of some Steiner Forest solution restricted to $G_B^\downarrow$ only counts the edge weights of C in $G_B^\downarrow$, and is denoted by

$$\mathrm{cost}_B^\downarrow(C) = \sum_{e \in E(C) \cap E(G_B^\downarrow)} w(e).$$

Based on these definitions, we fix an optimal solution $F^\star$ and construct a solution F_ε by initially setting $F_\varepsilon = F^\star$, and then connecting components by exhaustively applying the following rule, where we say that two components C and C' *share* a bag B if $V(C) \cap B \neq \emptyset$ and $V(C') \cap B \neq \emptyset$:

▶ **Rule 1.** *If C, C' are components of $F^\star$ sharing a bag B with $\operatorname{dist}(C, C') \leq \frac{\varepsilon}{kh} \cdot \operatorname{cost}^\downarrow_B(C)$ but C and C' are in different components of F_ε, then add a shortest path of length $\operatorname{dist}(C, C')$ between C and C' to the solution F_ε.*

▶ **Lemma 11.** *The cost of the solution F_ε obtained by Rule 1 from $F^\star$ is at most $(1+\varepsilon)\operatorname{cost}(F^\star)$.*

Proof. It suffices to prove that the cost of all paths added to $F^\star$ in order to obtain F_ε according to Rule 1 is at most $\varepsilon \cdot \operatorname{cost}(F^\star)$. For this we use a charging scheme that charges new paths to components of $F^\star$. In particular, we charge a path of length $\operatorname{dist}(C, C') \leq \frac{\varepsilon}{kh} \cdot \operatorname{cost}^\downarrow_B(C)$ to component C.

Fix a component C of $F^\star$ and a bag B with $V(C) \cap B \neq \emptyset$. We define $\operatorname{charge}(C, B)$ to be the cost we charge to C for operations involving other components of $F^\star$ that share B. It is not hard to see that $\operatorname{charge}(C, B) \leq \frac{\varepsilon}{h} \cdot \operatorname{cost}^\downarrow_B(C)$, because there are at most k other components of $F^\star$ that share B.

For $\ell \in \{0, \ldots, h-1\}$, let $\mathcal{B}_\ell$ be the set of bags of the tree decomposition that appear at distance exactly ℓ from the root, i.e., they lie on level ℓ of the tree. We now observe that

$$\sum_{B \in \mathcal{B}_\ell} \operatorname{charge}(C, B) \leq \sum_{B \in \mathcal{B}_\ell} \frac{\varepsilon}{h} \cdot \operatorname{cost}^\downarrow_B(C) \leq \frac{\varepsilon}{h} \operatorname{cost}(C),$$

where the last inequality follows because if we have two bags $B, B' \in \mathcal{B}_\ell$, then $E(G^\downarrow_B) \cap E(G^\downarrow_{B'}) = \emptyset$: note that every edge of $E(G^\downarrow_B)$ must be incident on a vertex v that appears in a descendant of B, but not in B. By the properties of tree decompositions, notably by the fact that B is a separator of G, v cannot appear in B' or any of its descendants. Therefore none of its incident edges are contained in $E(G^\downarrow_{B'})$. Because $\sum_{B \in \mathcal{B}_\ell} \operatorname{cost}^\downarrow_B(C)$ is the sum of costs of C over disjoint sets of edges, the sum is a lower bound on the total cost of C.

To conclude, we observe that the total charge of C is

$$\operatorname{charge}(C) \leq \sum_{\ell=0}^{h-1} \sum_{B \in \mathcal{B}_\ell} \operatorname{charge}(C, B) \leq \varepsilon \operatorname{cost}(C).$$

Therefore, summing over all components of $F^\star$, the total cost of the edges we have added according to Rule 1 is at most $\varepsilon \cdot \operatorname{cost}(F^\star)$. ◀

3.1.2 Partitioning active terminals

We are now ready to prove Lemma 10 for the near-optimal solution F_ε constructed above, for which we will compute the partitions ζ_B for all bags B. We will use the following two claims for the active terminals A_B of the given bag B.

▷ Claim 12. If there exist $t_1, t_2 \in A_B$ such that $\operatorname{dist}(t_1, t_2) \leq \frac{\varepsilon}{kh} \operatorname{dist}(t_1, B)$, then t_1, t_2 are in the same component of F_ε.

▷ Claim 13. Let $A \subseteq A_B$ and $d \geq 0$ be such that (i) there exists $b \in B$ such that for all $t \in A$ we have $\operatorname{dist}(t, B) = \operatorname{dist}(t, b)$ and $d \leq \operatorname{dist}(t, B) \leq 2d$ (ii) for all distinct $t, t' \in A$ we have $\operatorname{dist}(t, t') > \frac{\varepsilon}{kh} d$ (iii) $|A| \geq \frac{8k^2(k+1)h^2}{\varepsilon^2}$. Then, there exists a component of F_ε that contains all terminals of A.

Intuitively, Claim 12 allows us to place terminals of A which are very close to each other into the same set of the partition ζ_B, as placing one terminal in a component forces the placement of the other. Thanks to this claim we can work with an appropriate net. If we find a large collection of such net points which also are roughly the same distance from the bag and closest to the same vertex of the bag, Claim 13 allows us to group them all together in the partition ζ_B. Armed with these tools, we can now prove the main lemma.

Proof of Lemma 10. To compute the partition ζ_B in polynomial time, we first partition the active terminals $A_B \cap B$ contained in the bag B. For this we simply add a set $\{t\}$ for each $t \in A_B \cap B$ to ζ_B, which adds at most $|B| \leq k+1$ sets to ζ_B. Let now $A = A_B \setminus B$ be the remaining active terminals.

To partition A, let $d = \min_{t \in A_B \setminus B} \operatorname{dist}(t, B)$ and $D = \max_{t \in A_B \setminus B} \operatorname{dist}(t, B)$ be the minimum and maximum distances of these active terminals from the bag B. Then partition $A_B \setminus B$ into $|B| \leq k+1$ sets $A_1, A_2, \ldots, A_{|B|}$, depending on the vertex of B that is closest to each $t \in A$ (breaking ties arbitrarily). That is, for each A_i there exists $b \in B$ such that for all $t \in A_i$ we have $\operatorname{dist}(t, B) = \operatorname{dist}(t, b)$. Consider now a set A_i and further partition it into $r = \lceil \log_2 \frac{D}{d} \rceil$ sets $A_{i,0}, A_{i,1}, \ldots, A_{i,r-1}$, where $A_{i,j}$ contains all $t \in A_i$ such that $\operatorname{dist}(t, B) \in [2^j d, 2^{j+1} d)$. Now (greedily) compute an $(\frac{\varepsilon}{kh} 2^j d)$-net $N_{i,j}$ of $A_{i,j}$. We observe that $N_{i,j}$ satisfies the first two conditions of Claim 13 for $2^j d$, so if $|N_{i,j}| \geq \frac{8k^2(k+1)h^2}{\varepsilon^2}$, then we add $A_{i,j}$ as a set of our partition ζ_B, remove the terminals of $N_{i,j}$ from A and continue the algorithm for the remaining terminals. Repeat the previous step for all i, j for which $N_{i,j}$ is sufficiently large. This contributes at most $(k+1)\lceil \log \frac{D}{d} \rceil$ sets to ζ_B. To partition A, let $d = \min_{t \in A_B \setminus B} \operatorname{dist}(t, B)$ and $D = \max_{t \in A_B \setminus B} \operatorname{dist}(t, B)$ be the minimum and maximum distances of these active terminals from the bag B. Then partition $A_B \setminus B$ into $|B| \leq k+1$ sets $A_1, A_2, \ldots, A_{|B|}$, depending on the vertex of B that is closest to each $t \in A$ (breaking ties arbitrarily). That is, for each A_i there exists $b \in B$ such that for all $t \in A_i$ we have $\operatorname{dist}(t, B) = \operatorname{dist}(t, b)$. Consider now a set A_i and further partition it into $r = \lceil \log_2 \frac{D}{d} \rceil$ sets $A_{i,0}, A_{i,1}, \ldots, A_{i,r-1}$, where $A_{i,j}$ contains all $t \in A_i$ such that $\operatorname{dist}(t, B) \in [2^j d, 2^{j+1} d)$. Now (greedily) compute an $(\frac{\varepsilon}{kh} 2^j d)$-net $N_{i,j}$ of $A_{i,j}$. We observe that $N_{i,j}$ satisfies the first two conditions of Claim 13 for $2^j d$, so if $|N_{i,j}| \geq \frac{8k^2(k+1)h^2}{\varepsilon^2}$, then we add $A_{i,j}$ as a set of our partition ζ_B, remove the terminals of $A_{i,j}$ from A and continue the algorithm for the remaining terminals. Repeat the previous step for all i, j for which $N_{i,j}$ is sufficiently large. This contributes at most $(k+1)\lceil \log \frac{D}{d} \rceil$ sets to ζ_B.

Suppose now that we are left with a set of terminals A such that the procedure above fails to construct a sufficiently large net $N_{i,j}$ to apply Claim 13. For every index pair i, j, each remaining terminal $t \in A_{i,j}$ is close enough to some net point $t' \in N_{i,j}$ such that we can apply Claim 12. We therefore create a set in the partition ζ_B for each $t' \in N_{i,j}$, placing into such a set those terminals of $A_{i,j}$ that are closest to t' (breaking ties arbitrarily). Since we cannot apply Claim 13 to the remaining sets $A_{i,j}$, each of the at most $(k+1)\lceil \log \frac{D}{d} \rceil$ nets $N_{i,j}$ has size less than $\frac{8k^2(k+1)h^2}{\varepsilon^2}$, which implies $|\zeta_B| \leq O(\frac{k^4 h^2}{\varepsilon^2} \log \frac{D}{d})$.

Clearly the above procedure can be implemented in polynomial time, and the fact that every set of ζ_B is contained in the same component of F_ε follows from Claim 12 and Claim 13. Finally, any path in a graph with at most n vertices has less than n edges, so that $\frac{D}{d} < 2n^2/\varepsilon$, given that the ratio of the longest to the shortest edge is $2n/\varepsilon$ (note that $d > 0$ by definition). Hence the claimed bound of $|\zeta_B| \leq O(\frac{k^4 h^2}{\varepsilon^2} \log \frac{n}{\varepsilon})$ follows. ◀

3.2 Tree decompositions with logarithmic height

Given a tree decomposition T of logarithmic height, using Lemma 10 we are ready to compute a set of partitions Π_B of FPT size for each bag B, such that a near-optimal solution conforms to Π_B. In particular, by Lemma 8 we may assume that the height of T is $h = O(k \log n)$, which means that the bound on ζ_B in Lemma 10 translates to $O(\frac{k^6}{\varepsilon^2} \log^3 \frac{n}{\varepsilon})$. As in the previous section, we need to apply Lemma 9 in order to bound the aspect ratio of the graph, so that n denotes the number of vertices of the original input graph, while now the graph G has at most n vertices but the ratio between the longest and shortest edge is at most $2n/\varepsilon$. We begin by describing how to obtain the near-optimal solution, after which we will identify the partition sets Π_B.

3.2.1 A near-optimal solution

Bateni, Hajiaghayi, and Marx [4] construct a near-optimal solution by modifying the optimum. We will use similar techniques to obtain our near-optimal solution, but we construct it by instead modifying the $(1+\varepsilon)$-approximate solution F_ε given by Lemma 10. In particular, we construct a near-optimal $(1+\varepsilon)^2$-approximation $\widetilde{F}_\varepsilon$ from F_ε. The main idea to obtain $\widetilde{F}_\varepsilon$ is to connect components of F_ε if they are very close to one another. As before however, doing this naively would incur too much cost for the additional connections.

To make sure that the cost incurred by connecting components of F_ε is not too large, [4] introduced a partial order on the components based on the structure of a given rooted tree decomposition T. Let C_1, C_2 be two components of F_ε that share a bag B of T, i.e., $V(C_1) \cap B \neq \emptyset$ and $V(C_2) \cap B \neq \emptyset$. Since C_1 and C_2 are connected subgraphs of the input graph, a basic property of tree decompositions implies that there are (connected) subtrees T_1 and T_2 of T induced by the respective bags containing vertices of C_1 and C_2. Because these components both contain vertices of B, the node associated with B is part of both T_1 and T_2, and therefore the roots of both subtrees lie on the path from this node to the root of T. This defines an order on C_1 and C_2, and we write $C_1 \leq C_2$ if the root of T_1 is farther from the root of T than the root of T_2 is. This order is defined for any two components of F_ε that share a bag, and thus we obtain a partial order on the components of F_ε, where any components that do not share a bag are incomparable.

Using the defined order, [4] connect components of the optimum solution that are very close to each other. In order to obtain smaller partition sets, we modify the distance bound used in this procedure compared to [4]. In particular, for any value $x > 0$, let $\lfloor x \rfloor_2 = 2^{\lfloor \log_2 x \rfloor}$ denote the largest power of 2 that is at most x. Now, starting with $\widetilde{F}_\varepsilon = F_\varepsilon$ we connect components by exhaustively applying the following rule:

▶ **Rule 2.** *If C, C' are components of F_ε with $C \leq C'$ and $\operatorname{dist}(C, C') \leq \frac{\varepsilon}{k} \lfloor \operatorname{cost}(C) \rfloor_2$ but C and C' lie in different components of $\widetilde{F}_\varepsilon$, then add a shortest path of length $\operatorname{dist}(C, C')$ between C and C' to the solution $\widetilde{F}_\varepsilon$.*

A crucial but subtle observation is that for a component C of F_ε there can be many components $C' \leq C$ at distance at most $\frac{\varepsilon}{k} \lfloor \operatorname{cost}(C) \rfloor_2$ to C, which however are not connected to C in the resulting solution $\widetilde{F}_\varepsilon$ according to Rule 2. This makes it non-trivial to find small partition sets Π_B. Contrary to this however, an important property of the order on the components is that for any component C of F_ε, there are at most k other components C' for which $C \leq C'$, as we will argue for the following lemma to bound the cost of $\widetilde{F}_\varepsilon$. In particular, the lemma implies that $\widetilde{F}_\varepsilon$ is a near-optimal $(1+\varepsilon)^2$-approximation, given that F_ε is a $(1+\varepsilon)$-approximation.

▶ **Lemma 14.** *The cost of the solution $\widetilde{F}_\varepsilon$ obtained by Rule 2 from F_ε is at most $(1+\varepsilon) \operatorname{cost}(F_\varepsilon)$.*

3.2.2 Partitioning active terminals

Given the construction of the $(1+\varepsilon)^2$-approximate solution $\widetilde{F}_\varepsilon$ above, the next step is to find a set of partitions Π_B of the active terminals A_B for each bag B, such that $\widetilde{F}_\varepsilon$ conforms with all sets Π_B. In the following, fix a bag B of the given tree decomposition T. The technique used by [4] is to guess a small net for each active component of bag B,[3] so that every terminal of A_B close to a net point must be part of the same component in the approximate solution, after taking the order on the active components as defined previously into account. Next we choose a net on the terminals of each active component and bound its size.

▶ **Lemma 15.** *Let $N \subseteq A_B \cap C$ be an $\frac{\varepsilon}{k}\lfloor \mathrm{cost}(C)\rfloor_2$-net of the metric induced by the active terminals of some active component C. The size of the net can be bounded by $|N| \leq \lfloor 4k/\varepsilon \rfloor$.*[4]

Following the algorithm of [4], the next step would be to guess such an $\frac{\varepsilon}{k}\lfloor \mathrm{cost}(C)\rfloor_2$-net for each of the at most $k+1$ active components C of the bag B. By Lemma 15, the total number of net points for these at most $k+1$ nets is at most $\lfloor 4k/\varepsilon \rfloor (k+1) = O(k^2/\varepsilon)$. Since however there may be up to n active terminals, guessing these nets for all active components can result in $n^{O(k^2/\varepsilon)}$ many possible choices, which leads to an XP time algorithm. To circumvent this, we instead consider the partition ζ_B of the active terminals as given by Lemma 10, and guess which of the sets of ζ_B contains a net point. We will argue that since the size of ζ_B is $O(\frac{k^6}{\varepsilon^2}\log^3\frac{n}{\varepsilon})$ there are only $(\frac{k}{\varepsilon}\log\frac{n}{\varepsilon})^{O(k^2/\varepsilon)}$ possibilities, leading to a faster algorithm.

More concretely, to compute a set of partitions Π_B that $\widetilde{F}_\varepsilon$ conforms to, our algorithm considers every sequence $((S_1,\delta_1),(S_2,\delta_2),\ldots,(S_\ell,\delta_\ell),\rho)$ of at most $k+1$ pairs (S_j,δ_j) and partitions ρ of the index set $\{1,\ldots,\ell\}$, where each S_j is a subset of the parts of ζ_B such that $|S_j| \leq \lfloor 4k/\varepsilon \rfloor$, and $\delta_j \in \{2^q \mid q \in \mathbb{N}_0 \wedge 0 \leq q \leq \log_2(2n^2/\varepsilon)\}$ is an integer power of 2 between 1 and $2n^2/\varepsilon$, where n is the number of vertices of the original input graph in accordance with Lemma 9. From every such sequence, the algorithm attempts to construct a partition of the active terminals, and if it succeeds adds it to the set Π_B. As we will show, in this process the algorithm will successfully construct one partition π of A_B that $\widetilde{F}_\varepsilon$ conforms to.

Before describing how a partition of the active terminals arises from such a sequence, we bound the number of these sequences, which determines the running time. By Lemma 10, $|\zeta_B| = O(\frac{k^6}{\varepsilon^2}\log^3\frac{n}{\varepsilon})$ if the tree decomposition T has logarithmic height, so that there are at most $\binom{|\zeta_B|}{\lfloor 4k/\varepsilon \rfloor} = (\frac{k}{\varepsilon}\log\frac{n}{\varepsilon})^{O(k/\varepsilon)}$ possible choices for each S_j. Clearly there are $O(\log\frac{n}{\varepsilon})$ choices for each δ_j, and $\ell^\ell = k^{O(k)}$ possible partitions ρ, given that $\ell \leq k+1$. Since a sequence contains ℓ sets S_j, the total number of sequences is bounded by $(\frac{k}{\varepsilon}\log\frac{n}{\varepsilon})^{O(k^2/\varepsilon)}$.

Each sequence may give rise to a partition $\pi \in \Pi_B$ of the active terminals as follows. First, let $\pi = \{Y_1,\ldots,Y_{|\rho|}\}$, i.e., π has the same number of sets as the partition ρ. Let $U_j = \bigcup_{U\in S_j} U$ denote the set of active terminals in S_j, and let $\rho(j)$ be the part of ρ containing j. We distinguish between active terminals $t \in A_B$ that lie in some set U_j and those that do not:

- if $t \in U_j$ for some $j \in [\ell]$ then $t \in Y_{\rho(j)}$ (i.e., $U_j \subseteq Y_{\rho(j)}$), and
- otherwise, if $p_t \in \{1,\ldots,\ell\}$ denotes the smallest index for which $\mathrm{dist}(t,U_{p_t}) \leq \frac{\varepsilon}{k}\delta_{p_t}$, then $t \in Y_{\rho(p_t)}$.

If this π is a partition of A_B we add π to Π_B, and otherwise we dismiss the current sequence. Clearly π can be constructed in polynomial time, given a sequence.

[3] [4] refers to these nets as *groups*.
[4] A slightly worse bound follows from [4, Lemma 19].

▶ **Lemma 16.** *The $(1+\varepsilon)^2$-approximate solution $\widetilde{F}_\varepsilon$ conforms to the set Π_B of partitions constructed above.*

Proof. Consider the $(1+\varepsilon)$-approximate solution F_ε of Lemma 10 from which $\widetilde{F}_\varepsilon$ is constructed according to Rule 2, and the partition ζ_B of A_B as given by Lemma 10. Let the active components of F_ε be $C_1, \ldots, C_\ell$ indexed according to their order, i.e., $C_j \leq C_{j'}$ if and only if $j \leq j'$. For each active component C_j we fix an $\frac{\varepsilon}{k}\lfloor \mathrm{cost}(C_j)\rfloor_2$-net N_j of size at most $\lfloor 4k/\varepsilon \rfloor$ according to Lemma 15. Now, consider the sequence $((S_1,\delta_1),(S_2,\delta_2),\ldots,(S_\ell,\delta_\ell),\rho)$, where

- S_j contains exactly those sets of ζ_B that contain at least one net point of N_j,
- $\delta_j = \lfloor \mathrm{cost}(C_j)\rfloor_2$, and
- ρ is the partition of the index set corresponding to the components of $\widetilde{F}_\varepsilon$, i.e., $\rho(j) = \rho(j')$ if and only if C_j and $C_{j'}$ lie in the same component in $\widetilde{F}_\varepsilon$.

Recall that after applying Lemma 9 to the input, the ratio between the shortest and longest edge is at most $2n/\varepsilon$, where n is the number of vertices of the original input graph. Since we assume that the length of the shortest edge is 1, the cost of any component lies between 1 and $2n^2/\varepsilon$, given that a component is a tree with less than n edges. Therefore $\lfloor \mathrm{cost}(C_j)\rfloor_2 \in \{2^q \mid q \in \mathbb{N}_0 \wedge 0 \leq q \leq \log_2(2n^2/\varepsilon)\}$, which means that the algorithm will consider the above sequence in some iteration.

We now turn to $\pi = \{Y_1, \ldots, Y_{|\rho|}\}$ constructed for this sequence, and show that it is a partition of A_B and that $\widetilde{F}_\varepsilon$ conforms to it. For this, note that no set of ζ_B contains net points of several active components of F_ε, since by Lemma 10 all active terminals in the same set of ζ_B also belong to the same component of F_ε. Thus the sets S_j as defined above (and also the corresponding sets U_j) are pairwise disjoint. This means that, due to the definition of ρ, any two terminals $t \in U_j$ and $t' \in U_{j'}$ end up in the same set of π if and only if t and t' belong to the same component of $\widetilde{F}_\varepsilon$ (as $U_j \subseteq Y_{\rho(j)}$).

Now consider a terminal $t \in A_B$, which does not lie in any U_j, and let q be the index of the active component C_q of F_ε containing t. As $\delta_q = \lfloor \mathrm{cost}(C_q)\rfloor_2$, N_q is an $\frac{\varepsilon}{k}\delta_q$-net of $C_q \cap A_B$. Also, we chose S_q so that $N_q \subseteq U_q$. Hence we get $\mathrm{dist}(t, U_q) \leq \mathrm{dist}(t, N_q) \leq \frac{\varepsilon}{k}\delta_q$, and the definition of p_t implies $p_t \leq q$. Now C_{p_t} is either equal to C_q, or C_q is connected to the component C_{p_t} in the approximate solution $\widetilde{F}_\varepsilon$ according to Rule 2: on one hand we have $C_{p_t} \leq C_q$ due to the order of the indices, and at the same time by Lemma 10 we have $U_{p_t} \subseteq V(C_{p_t}) \cap A_B$, which implies

$$\mathrm{dist}(C_q, C_{p_t}) \leq \mathrm{dist}(t, C_{p_t}) \leq \mathrm{dist}(t, U_{p_t}) \leq \frac{\varepsilon}{k}\delta_{p_t} = \frac{\varepsilon}{k}\lfloor \mathrm{cost}(C_{p_t})\rfloor_2.$$

Hence we can conclude that t lies in the same component as C_{p_t} in $\widetilde{F}_\varepsilon$.

In conclusion, adding U_j to $Y_{\rho(j)}$ and t to $Y_{\rho(p_t)}$ for each terminal t not lying in any U_j, partitions the terminals according to the components of $\widetilde{F}_\varepsilon$. Hence π is a partition of the active terminals A_B that is added to Π_B, and $\widetilde{F}_\varepsilon$ conforms to it. ◀

Using all of the above, we can finally prove our main theorem, stating that there is an EPAS for Steiner Forest parameterized by the treewidth.

Proof of Theorem 1. The first steps of our algorithm are to preprocess the given tree decomposition using Lemma 8 so that it is nice and its height is $O(k \log n)$, and the input graph using Lemma 9 so that the aspect ratio is bounded (which means that n denotes the number of vertices in the original input graph). We then compute the partition sets Π_B for all bags B using the above procedure, resulting in partition sets of size $(\frac{k}{\varepsilon}\log\frac{n}{\varepsilon})^{O(k^2/\varepsilon)} = 2^{O(\frac{k^2}{\varepsilon}\log\frac{k}{\varepsilon})} \cdot n^{o(1)}$. Here, we are using a well-known Win/Win argument: if $k^2/\varepsilon < \sqrt{\log n}$, then $(\log n)^{k^2/\varepsilon} = n^{o(1)}$; otherwise, $\log n \leq k^4/\varepsilon^2$, therefore $(\frac{k}{\varepsilon}\log\frac{n}{\varepsilon})^{O(k^2/\varepsilon)} = (\frac{k}{\varepsilon})^{O(\frac{k^2}{\varepsilon})}$.

Since each partition of a set Π_B can be computed in polynomial time, and the number of bags of the nice tree decomposition is $O(kn)$, this takes $2^{O(\frac{k^2}{\varepsilon}\log\frac{k}{\varepsilon})} \cdot n^{O(1)}$ time. Next we apply Theorem 5 to compute a solution that is at least as good as $\widetilde{F}_\varepsilon$ conforming to all Π_B, in $2^{O(\frac{k^2}{\varepsilon}\log\frac{k}{\varepsilon})} \cdot n^{O(1)}$ time. Hence we obtain a $(1+\varepsilon)^2$-approximation F. According to Lemma 9, F can be converted into a $((1+\varepsilon)^2+\varepsilon)$-approximation to the original input graph. Since for any $\varepsilon' > 0$ we may choose $\varepsilon = \Theta(\varepsilon')$ so that $((1+\varepsilon)^2+\varepsilon) \leq 1+\varepsilon'$, we obtain an EPAS as claimed. ◀

4 Vertex cover

In this section we consider the parameterization by the size of a *vertex cover*, which is a set $S \subseteq V$ of vertices such that every edge is incident on at least one of the vertices of S. In the full version of this paper we present an easy FPT algorithm based on Theorem 5.

Our goal here is to present a reduction showing that the algorithm we have given for Steiner Forest parameterized by vertex cover is essentially optimal, assuming the ETH. Recall that the ETH is the hypothesis that 3-SAT on instances with n variables cannot be solved in time $2^{o(n)}$. We will give a reduction that given a 3-SAT instance ϕ, produces an equivalent Steiner Forest instance with vertex cover at most $O(n/\log n)$. We stress that our reduction works even for unweighted instances.

▶ **Theorem 17.** *If there exists an algorithm which, given an unweighted Steiner Forest instance on n vertices with vertex cover k, finds an optimal solution in time $2^{o(k\log k)}n^{O(1)}$, then the ETH is false.*

Proof. We present a reduction from 3-SAT. Before we proceed, we would like to add to our formula the requirement that the variable set comes partitioned into three sets in a way that each clause contains at most one variable from each set. It is not hard to show that this does not affect the complexity of the instance much, as we demonstrate in the following claim.

▷ Claim 18. Suppose that there exists an algorithm that takes as input a 3-SAT instance ϕ on n variables and a partition of the variables into three sets of equal size, such that each clause contains at most one variable from each set, and decides if ϕ is satisfiable in time $2^{o(n)}$. Then, the ETH is false.

In the remainder we will then assume that we are given a formula ϕ on $3n$ variables which are partitioned into three sets of size n as specified by the previous claim. Without loss of generality, suppose that n is a power of 4 (this can be achieved by adding dummy variables). Note that this ensures that $\frac{\log n}{2}$ and $\sqrt{n}$ are both integers.

We construct an equivalent instance of Steiner Forest as follows. Let $L = \lceil \frac{n}{\log^2 n} \rceil$. We begin by constructing i choice gadgets, i.e., for $i \in \{1, \ldots, 3\log n\}$ we make:

- $2L$ left vertices, labeled ℓ^i_j, for $j \in \{0, \ldots, 2L-1\}$.
- $2L$ right vertices, labeled r^i_j, for $j \in \{0, \ldots, 2L-1\}$.
- $\sqrt{n}$ middle vertices, labeled m^i_j, for $j \in \{0, \ldots, \sqrt{n}-1\}$.
- We connect all middle vertices to all left and right vertices, that is, for all $j \in \{0, \ldots, 2L-1\}$ and $j' \in \{0, \sqrt{n}-1\}$ we connect ℓ^i_j and r^i_j to $m^i_{j'}$.
- For each $j \in \{0, \ldots, 2L-1\}$ we add a demand from ℓ^i_j to r^i_j.

Notice that the graph we have constructed so far contains $3\log n$ choice gadgets, each of which has $4L + \sqrt{n} = O(n/\log^2 n)$ vertices, so the graph at the moment contains $O(n/\log n)$ vertices in total.

Before we proceed, let $X = X_a \cup X_b \cup X_c$ be the set of $3n$ variables of ϕ that was given to us partitioned into three sets of size n. We partition X into $3\log n$ groups $X_1, \ldots, X_{3\log n}$ in a way that (i) $|X_i| \leq \lceil n/\log n \rceil$ for all $i \in \{1, \ldots, \log n\}$ and (ii) for all $i \in \{1, \ldots, \log n\}$ we have X_i is contained in one of X_a, X_b, X_c. This can be done by taking the n variables of X_a and partitioning them arbitrarily into groups $X_1, \ldots, X_{\log n}$ of size as equal as possible (therefore at most $\lceil n/\log n \rceil$), and we proceed similarly for X_b, X_c. Rename the variables of ϕ so that for each i we have that $X_i = \{x_{(i,0)}, \ldots, x_{(i,\lceil n/\log n \rceil - 1)}\}$.

To give some intuition, we will now say that, for $i \in \{1, \ldots, 3\log n\}$, the choice gadget i represents the variables of the set X_i. In particular, for each $j \in \{0, \ldots 2L-1\}$, we will say that the way that the demand $\ell_j^i \to r_j^i$ was satisfied encodes the assignment to the $\frac{\log n}{2}$ variables $\{x_{(i,\frac{j\log n}{2})}, \ldots, x_{(i,\frac{(j+1)\log n}{2}-1)}\}$. More precisely, in our intended solution the demand $\ell_j^i \to r_j^i$ is satisfied by connecting both terminals to a common middle vertex $m_{j'}^i$. We can infer the assignment to the $\frac{\log n}{2}$ variables this represents simply by writing down the binary representation of j', which is a number between 0 and $\sqrt{n}-1$, hence a number with $\frac{\log n}{2}$ bits. Note that this way we represent $2L \cdot \frac{\log n}{2} \geq \lceil \frac{n}{\log n} \rceil$ variables, that is, we can represent the assignment to all the variables of the group.

Armed with this intuition, we can now complete our construction. For each clause c we construct two new vertices, c_1, c_2 and add a demand from c_1 to c_2. For each literal contained in c, suppose that the literal involves the variable $x_{(i,\frac{j\log n}{2}+\alpha)}$ for $i \in \{1, \ldots, 3\log n\}$, $j \in \{0, \ldots, 2L-1\}$, $\alpha \in \{0, \ldots, \frac{\log n}{2} - 1\}$. We then connect c_1 to ℓ_j^i. Furthermore, if $x_{(i,\frac{j\log n}{2}+\alpha)}$ appears positive in c, we connect c_2 to all $m_{j'}^i$ such that the binary representation of j' has a 1 in position α. If on the other hand $x_{(i,\frac{j\log n}{2}+\alpha)}$ appears negative in c, we connect c_2 to all $m_{j'}^i$ such that the binary representation of j' has a 0 in position α. In other words, we connect c_2 to all the middle vertices to which ℓ_j^i could be connected and are consistent with an assignment that satisfies c using the current literal. After repeating the above for all literals of each clause the construction is complete. We set the target cost to be $B = 2m + 12L\log n$.

Before we argue about the correctness of the reduction, let us observe that if the reduction preserves the satisfiability of ϕ, then we obtain the theorem, because the instance we constructed has vertex cover $k = O(n/\log n)$ and size polynomial in the size of ϕ. Indeed, as we argued the choice gadgets have $O(n/\log n)$ vertices in total, and all further edges we added have an endpoint in a choice gadget. If there was an algorithm solving the new instance in time $k^{o(k)}n^{O(1)}$, this would give a $2^{o(n)}$ algorithm to decide ϕ.

Regarding correctness, let us first observe that if ϕ is satisfiable, we can obtain a valid solution using the intuitive translation from assignments to choice gadget solutions we gave above. In particular, for each $i \in \{1, \ldots, 3\log n\}$ and $j \in \{0, \ldots, 2L-1\}$, we consider the assignment to variables $\{x_{(i,\frac{j\log n}{2})}, \ldots, x_{(i,\frac{(j+1)\log n}{2}-1)}\}$ as a binary number, which must have a value j' between 0 and $\sqrt{n}-1$. We then connect both ℓ_j^i, r_j^i to $m_{j'}^i$. Repeating this satisfies all demands internal to choice gadgets and uses $3\log n \cdot 4L = 12L\log n$ edges. Consider now a clause c and the demand from c_1 to c_2. Since we started with a satisfying assignment, c must contain a true literal, say involving the variable $x_{(i,\frac{j\log n}{2}+\alpha)}$. We select the edge from c_1 to ℓ_j^i. Furthermore, we observe that c_2 must be a neighbor of all vertices $m_{j'}^i$ such that the bit in position α of the binary representation of j' agrees with the value of $x_{(i,\frac{j\log n}{2}+\alpha)}$. Since ℓ_j^i is already connected to such a $m_{j'}^i$, we select the edge from that vertex to c_2 to satisfy the demand for this clause. We have therefore spent $2m$ further edges for the clause demands and have used a budget of exactly B.

For the converse direction, suppose we have a solution of cost B. We first observe that each vertex r^i_j must be connected to a middle vertex $m^i_{j'}$, since all right vertices are terminals, but such vertices only have edges connecting them to middle vertices. Recall that, for each i, j, the left vertex ℓ^i_j must be in the same component of the solution as r^i_j, since there is a demand between these two vertices. Hence, each ℓ^i_j is in the same component of the solution as some $m^i_{j'}$. We now slightly edit the solution as follows: suppose there exists a vertex ℓ^i_j which is not directly connected in the solution to any middle vertex $m^i_{j'}$. Since this vertex is in the same component as one such vertex $m^i_{j'}$, we add to the solution the edge connecting them, and since this creates a cycle, remove from the solution another edge incident on ℓ^i_j. Doing this repeatedly ensures that each ℓ^i_j is connected to a middle vertex $m^i_{j'}$ in the solution without increasing the total cost.

We now observe that since each ℓ^i_j and each r^i_j is connected to at least one middle vertex $m^i_{j'}$ in the solution, this already uses a cost of $3 \log n \cdot 4L = 12L \log n$. Furthermore, for each clause we have constructed two terminals, each of which must use at least one of its incident edges, giving an extra cost of $2m$. Since our budget is exactly $2m + 12L \log n$, we conclude that each terminal constructed for a clause is incident on exactly one edge, and each ℓ^i_j and each r^i_j is connected to exactly one middle vertex. Crucially, these observations imply the following fact: if for some i, j, j' we have that ℓ^i_j and $m^i_{j'}$ are in the same component of the solution, then the edge connecting ℓ^i_j and $m^i_{j'}$ is part of the solution. To see this, observe that any path connecting ℓ^i_j and $m^i_{j'}$ that is not a direct edge would need to have length at least 3. However, no clause terminal can be an internal vertex of such a path, since clause terminals have degree 1 in the solution. Furthermore, if we remove clause terminals from the graph, left and right vertices also have degree 1 in the remaining solution, so such vertices also cannot be internal in the path. Finally, middle vertices are an independent set, so it is impossible for all internal vertices of a path of length at least 3 to be middle vertices.

Armed with the observation that ℓ^i_j and $m^i_{j'}$ are in the same connected component of the solution if and only if they are directly connected, we are ready to extract a satisfying assignment from the Steiner forest. For each i, j, if ℓ^i_j is connected to $m^i_{j'}$ we write j' in binary and assign to variable $x_{(i, \frac{j \log n}{2} + \alpha)}$, for $\alpha \in \{0, \ldots, \frac{logn}{2} - 1\}$ the value in position α of the binary representation of j'. We claim that this assignment must be satisfying. Indeed, consider the clause c, and the terminals c_1, c_2 which represent it. Since these terminals have a demand, they must be in the same component. Because c_1 has at most three neighbors which are in different choice gadgets (as each clause contains variables from distinct groups), we can see that c_1 must be connected to some ℓ^i_j and c_2 to some $m^i_{j'}$ in the solution, such that ℓ^i_j and $m^i_{j'}$ are in the same component, and are therefore directly connected. But if ℓ^i_j is directly connected to $m^i_{j'}$ this means that the assignment we extracted from ℓ^i_j gives a value to a variable $x_{(i, \frac{j \log n}{2} + \alpha)}$ which satisfies the clause c, hence we have a satisfying assignment. ◀

5 Feedback Edge Set

A *feedback edge set* of a graph is a set of edges that when removed renders the graph acyclic. It is well-known that if G is a connected undirected graph on n vertices and m edges, then all minimal feedback edge sets of G have size $k = m - n + 1$. Indeed, such a set can be constructed in polynomial time by repeatedly locating a cycle in the graph and selecting an arbitrary edge of the cycle to insert into the feedback edge set.

In this section we will consider Steiner Forest parameterized by the feedback edge set of the input graph, which we will denote by k. Unlike the vertex cover section, here our main result is positive: we show that Steiner Forest can be solved optimally in time

$2^{O(k)}n^{O(1)}$, that is, in time single-exponential in the parameter. Since we are able to achieve a single-exponential dependence, it is straightforward to see that this is optimal under the ETH.

▶ **Theorem 19.** *If there is an algorithm solving* Steiner Tree *in time* $2^{o(k)}n^{O(1)}$*, where* k *is the feedback edge set of the input, then the ETH is false.*

Let us now proceed to the detailed presentation of the algorithm. Suppose that we are given a budget b and we want to decide if there exists a Steiner Forest solution F such that $\text{cost}(F) \leq b$. We start by applying a simple reduction rule.

▶ **Rule 3.** *Suppose we have a* Steiner Forest *instance on graph* G *with weight function* w *and budget* b*, such that a vertex* $u \in V$ *has degree* 1*. If* $u \notin R$*, then delete* u*. If* $u \in R$*, let* v *be the unique neighbor of* u*. Then set* $b' := b - w(uv)$*, delete* u *from the graph and the demand* $\{u, v\}$ *from* D *if it exists, and replace, for each* $x \in V \setminus \{u, v\}$ *such that* $\{u, x\} \in D$ *the demand* $\{u, x\}$ *with the demand* $\{v, x\}$*.*

▶ **Lemma 20.** *Rule 3 is safe.*

Observe that if we apply Rule 3 exhaustively, then the minimum degree of the graph is 2. As we show next, relatively few vertices can have higher degree.

▶ **Lemma 21.** *Suppose we have a* Steiner Forest *instance with feedback edge set of size* k *and minimum degree at least* 2*. Then* G *contains at most* $2k$ *vertices of degree at least* 3*.*

In the remainder we will assume that we have a Steiner Forest instance $G = (V, E)$ with a feedback edge set $H \subseteq E$ of size k, to which 3 can no longer be applied. We will say that a vertex v is *special* if v is incident on an edge of H or v has degree at least 3. By Lemma 21 we know that G contains at most $4k$ special vertices.

We define a *topological edge* (topo-edge for short) as follows: a path P in G is a topological edge if the two endpoints of P are special vertices and all internal vertices of P are non-special. Note that by this definition, all edges of H form topo-edges, since the endpoints of such edges are special. We observe the following:

▶ **Lemma 22.** *Suppose we have a graph* G *with feedback edge set of size* k *and minimum degree at least* 2*. Then* G *contains at most* $5k$ *topological edges.*

We are now ready to state the main algorithmic result of this section.

▶ **Theorem 23.** *There is an algorithm that solves* Steiner Forest *on instances with* n *vertices and a feedback edge set of size* k *in* $2^{O(k)}n^{O(1)}$ *time.*

An FPRAS for Two Terminal Reliability in Directed Acyclic Graphs

Weiming Feng
Institute for Theoretical Studies, ETH Zürich, Switzerland

Heng Guo
School of Informatics, University of Edinburgh, UK

Abstract

We give a fully polynomial-time randomized approximation scheme (FPRAS) for two terminal reliability in directed acyclic graphs (DAGs). In contrast, we also show the complementing problem of approximating two terminal unreliability in DAGs is #**BIS**-hard.

Funding This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 947778). Weiming Feng acknowledges support of Dr. Max Rössler, the Walter Haefner Foundation and the ETH Zürich Foundation.

Acknowledgements We thank Kuldeep S. Meel for bringing the problem to our attention, Antoine Amarilli for explaining their method to us, and Marcelo Arenas for insightful discussions. We also thank Zongchen Chen for suggesting a better presentation of Theorem 1, and Mark Jerrum for some useful insights. This work was done in part while Weiming Feng was visiting the Simons Institute for the Theory of Computing.

1 Introduction

Network reliability is one of the first problems studied in counting complexity. Indeed, $s-t$ reliability is listed as one of the first thirteen complete problems when Valiant [29] introduced the counting complexity class #**P**. The general setting is that given a (directed or undirected) graph G, each edge e of G fails independently with probability q_e. The problem of $s-t$ reliability is then asking the probability that in the remaining graph, the source vertex s can reach the sink t. There are also other variants, where one may ask the probability of various kinds of connectivity properties of the remaining graph. These problems have been extensively studied, and apparently most variants are #**P**-complete [6, 19, 8, 28, 7, 11].

While the exact complexity of reliability problems is quite well understood, their approximation complexity is not. Indeed, the approximation complexity of the first studied $s-t$ reliability is still open in either directed or undirected graphs. One main exception is the *all-terminal* version (where one is interested in the remaining graph being connected or disconnected). A famous result by Karger [21] gives the first fully polynomial-time randomized approximation scheme (FPRAS) for all-terminal *unreliability*, while about two decades later, Guo and Jerrum [16] give the first FPRAS for all-terminal *reliability*. The latter algorithm is under the partial rejection sampling framework [17], and the Markov chain Monte Carlo

(MCMC) method is also shown to be efficient shortly after [3, 12]. See [18, 22, 9], [15], and [4, 10] for more recent results and improved running times along the three lines above for the all-terminal version respectively.

The success of these methods implies that the solution space of all-terminal reliability is well-connected via local moves. However, this is not the case for the two-terminal version (namely the $s-t$ version). Instead, the natural local-move Markov chain for $s-t$ reliability is torpidly mixing. Here the solution space consists of all spanning subgraphs (namely a subset of edges) in which s can reach t. Consider a (directed or undirected) graph composed of two paths of equal length connecting s and t. Suppose we start from one path and leave the other path empty. Then before the other path is all included in the current state, we cannot remove any edge of the initial path. This creates an exponential bottleneck for local-move Markov chains, and it suggests that a different approach is required.

In this paper, we give an FPRAS for the $s-t$ reliability in directed acyclic graphs. Note that the exact version of this problem is #**P**-complete [28, Sec 3], even restricted to planar DAGs where the vertex degrees are at most 3 [27, Theorem 3]. Our result positively resolves an open problem by Zenklusen and Laumanns [30]. Without loss of generality, in the theorem below we assume that any vertex other than s has at least one incoming edge, and thus $|E| \geq |V| - 1$ for the input $G = (V, E)$.

▶ **Theorem 1.** *Let $G = (V, E)$ be a directed acyclic graph (DAG), failure probabilities $\mathbf{q} = (q_e)_{e \in E} \in [0, 1]^E$, two vertices $s, t \in V$, and $\varepsilon > 0$. There is a randomized algorithm that takes $(G, \mathbf{q}, s, t, \varepsilon)$ as inputs and outputs a $(1 \pm \varepsilon)$-approximation to the $s-t$ reliability with probability at least $3/4$ in time $\widetilde{O}(n^6 m^4 \max\{m^4, \varepsilon^{-4}\})$ where $n = |V|$, $m = |E|$, and $\widetilde{O}$ hides polylog(n/ϵ) factors.*

The running time of Theorem 1 is $\widetilde{O}(n^6 m^8)$ when $\varepsilon > 1/m$, and is $\widetilde{O}(n^6 m^4/\varepsilon^4)$ when $\varepsilon < 1/m$. The reason behind this running time is that our algorithm always outputs at least a $(1 \pm 1/m)$-approximation. Thus, when $\varepsilon > 1/m$, it does not matter what ε actually is for the running time. This high level of precision is required for the correctness of the algorithm.

As hinted earlier, our method is a significant departure from the techniques for the all-terminal versions. Indeed, a classical result by Karp and Luby [23, 25] has shown how to efficiently estimate the size of a union of sets. A direct application of this method to $s-t$ reliability is efficient only for certain special cases [24, 30]. Our main observation is to use the Karp-Luby method as a subroutine in dynamic programming using the structure of DAGs. Let $s = v_1, \ldots, v_n = t$ be a topological ordering of the DAG G. (Note that we can ignore vertices before s and after t.) Let R_u be the $u-t$ reliability so that our goal is to estimate R_s. We inductively estimate R_{v_i} from $i = n$ to $i = 1$. For each vertex u, our algorithm maintains an estimator of R_u and a set S_u of samples of subgraphs in which u can reach t. In the induction step, we use the Karp-Luby method to generate the next estimator, and use a self-reduction similar to the Jerrum-Valiant-Vazirani sampling to counting reduction [20] to generate samples. Both tasks can be done efficiently using only what have been computed for previous vertices. Moreover, a naive implementation of this outline would require exponentially many samples. To avoid this, we reuse generated samples and carefully analyze the impact of doing so on the overall error bound. A more detailed overview is given in Section 1.1.

Our technique is inspired by an FPRAS for the number of accepting strings of non-deterministic finite automata (#NFA), found by Arenas, Croquevielle, Jayaram, and Riveros [5], which in turn used some techniques from a quasi-polynomial-time algorithm for sampling words from context-free languages by Gore, Jerrum, Kannan, Sweedyk, and
