In SNDP, given a graph $G=(V,E)$ with a weight function $w: E\to\{0,1,\ldots,W\}$ together with a *connectivity requirement* $r\colon V\times V\to\mathbb{Z}_{\geq 0}$, the goal is to find a minimum weight subgraph $H\subseteq G$ so that for every $s,t\in V$, H contains $r(st)$ edge-disjoint paths connecting s and t. A parameter of interest in SNDP is the maximum connectivity requirement $k=\max_{st} r(st)$. SNDP is a classic problem in combinatorial optimization and generalizes several well-studied problems such as MST, Steiner tree, k-edge connected spanning subgraph (k-ECSS), and k-CAP.

The fourth row of Table 1 shows our results for SNDP in edge arrival streams. In fact, our streaming algorithm works even for the more general problem of covering proper functions of the form $f: 2^V\to\{0,1,\ldots,k\}$ using the edges of G (see Section B.2 for more details). k-ECSS, which itself is a basic problem in discrete optimization, is a variant of SNDP in which for every $s,t\in V$, $r(st)=k$. As a straightforward application of our algorithm for k-CAP in link arrival streams, we get a k-pass, $O(\log k)$-approximation for k-ECSS using $O(kn\log n)$ words of space. (See last row of Table 1).

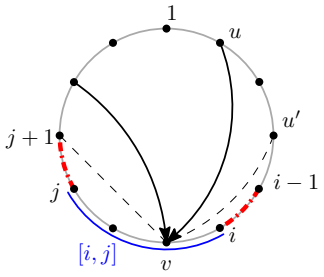
Unweighted variant. We remark that while we get tight algorithms for weighted k-CAP in both link arrival and fully streaming models, our lower bounds for link arrival does not hold for unweighted graphs. By a reduction from bipartite matching and invoking the result of [30], we observe a weaker lower bound that no streaming algorithm with $n\text{polylog}n$ space can achieve an approximation factor better than 1.409. Therefore, it remains an interesting open question to close the gap between 1.409 and 2 for unweighted k-CAP. Again, given that this lower bound is for tree augmentation, and the best known algorithm for (offline) TAP in unweighted graphs achieves an approximation factor of 1.326 [24], this again shows a gap between the two models for the problem in the unweighted variant.

1.3 Our Techniques

Given a streaming algorithm for the unweighted variants of both k-CAP and the spanner problems, an easy generalization to the weighted graphs is by partitioning the set of weights into $\log_{1+\epsilon} W$ number of classes and roughly running the unweighted sparsification on each class, resulting in $\epsilon^{-1} \log W$ blow up in the space usage. To remove the dependency on $\log W$ from the number of words, we follow an *even-odd bucketing* approach. More precisely, we partition the weights into much larger classes (i.e., *buckets*), such that the minimum and maximum weight in each class differ by $\text{poly}(n)/\epsilon$. This ensures that first, inside each class one can perform the weight-based partitioning to solve the problem while having only $\log n$ dependence in the space. Second, even picking all the edges from the $(i-2)$-th class E_{i-2} is cheaper than picking any edge in the i-th class E_i (i.e., it only introduces an extra $(1+\epsilon)$ multiplicative factor). This assumption allows us to infer additional properties about the graph once we are processing the edges in the class E_i, and shrink the problem significantly from each level E_{i-2} to E_i. Thus our algorithm proceeds by separating the sparsification for the even-indexed buckets E_{2i} and the odd-indexed buckets E_{2i-1}, and processes the buckets from smallest to largest weights.

Spanner. First, consider the spanner problem, and let $\mathcal{C} = \{C_1, \ldots, C_r\}$ be the set of connected components created by the edges from the classes upto E_{i-2}. The even-odd bucketing ensures that we only need to consider the edges from E_i that are between two different components of $\mathcal{C}$. Thus, we shrink each connected component into a super-node and use the standard spanner algorithm with weight-based partitioning on this reduced graph. Note that the space usage of the algorithm is proportional to the number of *super-nodes with non-zero degree*. However, all such super-nodes will merge into bigger components for the next bucket E_{i+2}. Therefore the space usage of the algorithm for processing E_i can be charged to the reduction in the number of super-nodes. Since the number of super-nodes starts from n and goes down to 1, the total space usage of the algorithm can be bounded as a function of n. Finally, we need to perform the above process in a streaming setting: As we receive more edges in the stream, the components in $\mathcal{C}_i$ change but it is easy to maintain all required information in a streaming fashion.

Link arrival k-CAP. Our algorithm for k-CAP is more involved. First, by standard results in the literature, the problem reduces to cycle augmentation: given a cycle C, the goal is to augment it with a subset of edges from L such that the resulting graph becomes 3-edge-connected. Let the nodes on the cycle be indexed 1 to n in this order with vertex 1 being called the *root*. Now every cut of size 2 corresponds to two edges on the cycle. We specify such a cut with the interval $[i, j]$ with $1 < i \leq j \leq n$ that does not include the root. The goal is to cover all such cuts specified by these intervals.



First, using known ideas from [35, 36], we present a simple streaming algorithm for the unweighted variant of the problem as follows. We replace every link uv by two directed links $\vec{uv}$ and $\vec{vu}$, (this is where the factor 2 in the approximation comes from), and we say that $\vec{uv}$ covers a cut $[i, j]$ if $v \in [i, j]$ and $u \notin [i, j]$. Now one can show that for $1 \leq u < u' < v$, it is always better to keep the edge $\vec{uv}$ than $\vec{u'v}$. Similarly, for $v < u' < u \leq n$, it is always better to keep the edge $\vec{uv}$ than $\vec{u'v}$. As a result, for each vertex, we keep at most two incoming edges. Therefore, the total space usage of the algorithm is only $O(n)$ in this case. Again this algorithm can be generalized to the weighted graphs using a weight-based partitioning, introducing a factor $\log W$.

To remove the dependency on $\log W$, again we consider the even-odd bucketing. This time, for each weight class E_i, we consider the 3-edge-connected components $C_1, \ldots, C_r$ formed by the edges in buckets upto E_{i-2}. Again using the even-odd bucketing plus the fact that the cycle is already 2-edge-connected, we can show that shrinking each of the 3-connected components into a super-node still works. The main challenge is that as opposed to the spanner setting, the problem on the super-node does not reduce to the same problem of cycle augmentation. This is because a single super-node does not necessarily span a consecutive set of vertices on the cycle. However, we note that in this case, the min-cuts on the cycle that do not fully include or fully exclude the vertices in a single super-node do not need to be considered. This allows us to reduce the space usage of the algorithm again to be proportional to the number of super-nodes and thus bound the total space usage of the algorithm as a function of n.

Fully streaming k-CAP. Our algorithm in this setting maintains two sketches. First, it keeps a k-connectivity certificate on the set of edges E using a folklore streaming algorithm that keeps k disjoint forests, which contains the information of all min-cuts of E that need to be augmented in k-CAP. Second, employing our results on weighted spanners, the algorithm maintains a spanner for the set of (weighted) links. This means that every link ℓ of weight/length w that we miss, can be replaced with a path of weight at most $O(t) \cdot w$, thus covering all the min-cuts originally covered by ℓ. We show that this is a near-optimal algorithm one can get in this setting.

Lower bounds. Most of our lower bounds are via simple reductions from the INDEX problem in a two-party communication model, where we embed the bit-string held by Alice into edges of a graph, where by asking augmentation queries, Bob is able to tell whether edge (u, v) exists in Alice's graph for any pair of vertices u, v. The most interesting one of our lower bounds (Theorem 12) shows that, in the fully streaming model, the space complexity for storing a spanner is essentially necessary. In the proof we let Alice hold a subgraph of a high-girth graph, and Bob wants to estimate the distance in this graph between u, v (which is sufficient for telling whether (u, v) is an edge, due to the high girth). Our proof reduces

this problem of estimating the distance between u, v to the problem of augmenting a chain with end points u, v into a 2-edge-connected graph. However, we also need rule out potential augmentation solutions that do not correspond to a uv-path.

Applications. Our algorithms for streaming connectivity augmentation also imply streaming algorithms for problems such as STAP, k-ECSS and SNDP. In particular, our one-pass algorithm for SNDP works by running k instances of our streaming spanner algorithm in parallel, which store k disjoint sparse subgraphs of the input graph that satisfy certain approximation guarantee. In particular, we show these k disjoint "spanner-like" objects forms a coreset for SNDP instances with maximum connectivity requirement at most k.[3] Our approach follows the augmentation framework of [51, 26] to show the existence of an approximately good solution using edges from these k sparse subgraphs.

1.4 Organization

In Section 2, we present our $(2+\epsilon)$-approximate algorithms for k-CAP in the link arrival model, and present a lower bound showing our approximation ratio is close to optimal. In Section 3, we study k-CAP in the fully streaming model, and present matching space lower bounds and upper bounds assuming our weighted spanner result. In Appendix A, we present our weighed spanner algorithm in the streaming model with better $\log W$ dependence. Finally in Appendix B we present further applications to other network design problems such as k-ECSS and SNDP. All missing proofs are deferred to the full version of the paper.

2 Connectivity Augmentation in Link Arrival Streams

In this section, we consider k-CAP, the problem of augmenting the connectivity of a given graph $G = (V, E)$ from $k-1$ to k using a subset of weighted links $L \subseteq \binom{V}{2}$ in link arrival streams. To recall, in the link arrival model, a cactus representation of the graph G, which is of size $O(n)$ (see Definition 2 for the formal definition of cactus), is given to us in advance and the set L arrives in the stream (see Section 1.1).

▶ **Theorem 1.** *The k-connectivity augmentation problem (k-CAP) on $(G = (V, E), L)$ in the link arrival model admits a one-pass $(2+\epsilon)$-approximation algorithm with total memory space $O(\frac{n}{\epsilon} \log \min(n, W))$ words, where $W = \max_{e \in E} w(e)$.*

Note that the augmentation set itself may have size $\Omega(n)$[4], so any algorithm that explicitly stores a solution must consume $\Omega(n)$ space. Moreover, we will show that just approximating the optimal total weight of the augmentation solution to any factor already requires $\Omega(n)$ bits of space. Hence, the space of our algorithm is tight up to a poly-logarithmic factor.

2.1 Preliminaries

Cactus representation of min-cuts. To increase the edge-connectivity of a $(k-1)$-connected graph G to k, we need to add links to *cover* all min-cuts of size $k-1$. That is, for each cut S of size $k-1$ (i.e., $|\delta_G(S)| = k-1$), we must add a link $e \in L$ such that $e \in \delta(S)$. Dinits, Karzanov, and Lomonosov [14] showed there is a compact representation of all min-cuts of an undirected graph by a *cactus graph*.

[3] In fact, the coreset guarantee holds even for the more general covering proper functions of the form $f : 2^V \to \{0, 1, \ldots, k\}$.

[4] As an example, consider a graph $G = (V, E)$ where $V = \{0, 1, \ldots, n-1\}$ and $E = \{(i, j) : j - i \in \{1, 2, \ldots, k\}\}$ (where indices are modulo n), which has edge connectivity $2k$. If the link set is $L = \{(i, i+1) : i \in [n]\}$, then at least $\lceil n/2 \rceil$ links are necessary to increase the edge connectivity by one.

▶ **Definition 2** (Cactus Graph). *A cactus graph is a 2-edge-connected graph $C = (V_C, E_C)$ where each edge in E_C belongs to exactly one simple cycle. Note that we allow cycles of length 1 or 2 too.*

▶ **Lemma 3** ([14]). *Let $G = (V, E)$ be an undirected graph. There is a loopless cactus $C = (V_C, E_C)$ of size at most $2n - 1$ and a mapping $\varphi : V \to V_C$ so that a subset $S \in V$ is a min-cut of G if and only if $\varphi(S)$ is a min-cut of C.*

Moreover, when the min-cut size of G is an odd integer, the cactus representation of G is a spanning tree (we may still treat it as a cactus by duplicating each tree edge).

The cactus representation is particularly useful for connectivity augmentation problems:

▶ **Corollary 4.** *Let $G = (V, E)$ be an undirected graph. Let C denote the cactus representation of min-cuts in G. Then a link $(u, v) \in E \setminus E_H$ crosses a min-cut S in G if and only if the corresponding link $(\varphi(u), \varphi(v))$ crosses $\varphi(S)$ in C.*

▶ Remark 5. We remark that there is a simple streaming algorithm for constructing the cactus representation with space complexity $\tilde{O}(kn)$: First, construct a k-connectivity certificate H of G (recall that a k-connectivity certificate for a graph G is a subgraph H of G that contains all edges crossing cuts of size k or less in G, and at least k edges from each cut of size more than k) with $O(kn)$ edges with space complexity $O(kn)$ words in polynomial time, using a simple algorithm by [41]. Then, we apply the algorithm of [34] for computing the cactus representation of the subgraph H in $\tilde{O}(|E(H)|) = \tilde{O}(kn)$ time and space. It is straightforward to verify that the constructed cactus is a cactus representation of G, given G is a $(k-1)$-connected graph.

We then get the following as a corollary of Theorem 1: If the algorithm receives a k-connectivity certificate as a representation of G or the edges of G arrive in the stream before any link arrives, we can construct a cactus representation of G in $O(kn)$ space first and then run our algorithm in this section for cactus augmentation and the overall space complexity will be $O(nk + \frac{n}{\epsilon} \log n)$.

Transforming cactus to cycle. In the (weighted) *cactus augmentation* problem, without loss of generality, we can assume the cactus is a single cycle. The latter problem is known as weighted *cycle augmentation*. To reduce an instance on a general cactus to the single cycle case (without losing approximation factor), we apply the technique observed in [23, 50]: Unfold the cactus into its Eulerian circuit, then add additional zero-weight edges (which we can use to augment at no cost) to connect the nodes corresponding to the same junction node in the cactus. See Section 3 in [50] for a detailed description.

▶ **Lemma 6** (Theorem 3 in [23]; see also Lemma 2.2 in [50]). *Let $\alpha > 1$. If there is an α-approximation algorithm for the weighted cycle augmentation problem, then the weighted cactus augmentation problem admits an α-approximation.*

Note that this reduction only produces $O(n)$ extra zero-weight edges, so it does not affect the space complexity of the streaming algorithm. We can apply the unfolding technique in the preprocessing step and in the rest of this section, we assume that the cactus is a single cycle.

2.2 Main Step: Cycle Augmentation in Link Arrival Streams

We arbitrarily assign a root node on the cycle, and let its index be 0. Then let the vertices of the cycle be $V = \{0, 1, \ldots, n-1\}$, with edges $C = \{e_1, e_2, \ldots, e_n\}$ where $e_i = (i-1, i)$ (with indices modulo n). We first describe a 2-approximation for the unweighted case, using an idea from [35, 36].

▶ **Theorem 7.** *There exists a one-pass 2-approximation algorithm for the cycle augmentation problem on unweighted graphs with total memory space $O(n)$ edges.*

Proof. Following [35, 36], we consider a directed version of the problem defined as follows: given a set E of *directed* edges, augment a minimum size subset $E' \subseteq E$ to the cycle, such that for every 2-cut $(L, V \setminus L)$ of the cycle where $0 \in V \setminus L$ (i.e., $L = \{l, l+1, \ldots, r\}$ for some $1 \leq l \leq r \leq n-1$), there exists $x\vec{y} \in E'$ with $y \in L$ and $x \in V \setminus L$ (we say $x\vec{y}$ covers L in this case). To reduce the original (undirected) cycle augmentation instance to this directed problem, simply replace each input edge (u, v) by two arcs $u\vec{v}, v\vec{u}$, incurring a 2-factor approximation: any directed solution $\{x\vec{y}\}$ implies an undirected solution $\{(x, y)\}$ of the same cost, and any undirected solution $\{(x, y)\}$ implies a directed solution $\{x\vec{y}\} \cup \{y\vec{x}\}$ of twice the cost.

Now we solve the directed instance exactly by an $O(n)$-space streaming algorithm. For each $v \in V$, we only need to keep the input arc $u\vec{v}$ with minimum indexed u, and keep the input arc $u\vec{v}$ with maximum indexed u. In this way we store only $O(n)$ arcs in total, and finally we run an offline exact algorithm (e.g., [22], which was also used by [36]) for the directed problem on these stored arcs. This does not affect optimality, because when $0 \leq u < u' < v$, any 2-cut, $U = \{l, l+1, \ldots, r\}$ covered by $u'\vec{v}$ is also covered by $u\vec{v}$, so we can discard $u'\vec{v}$ if we already have $u\vec{v}$ (a similar argument applies to the $v < u' < u \leq n-1$ case). ◀

By a simple scaling, this algorithm can be modified into a $(2+\epsilon)$-approximate algorithm for the weighted case with total space $O(\frac{n}{\epsilon} \log W)$ edges. Now we improve this $\log W$ dependency.

▶ **Theorem 8.** *The cycle augmentation problem on weighted graphs admits a one-pass $(2+\varepsilon)$-approximation streaming algorithm with total memory space $O(\frac{n}{\epsilon} \log \min(W, n))$ edges.*

Proof. We assume $\epsilon > 1/n$; otherwise use the trivial $O(n^2)$-space algorithm that stores the cheapest edge between every pair of vertices.

Define weight intervals $I_k = [(n/\epsilon)^k, (n/\epsilon)^{k+1})$. Let E_k be the set of input edges e that have arrived so far with weights $w(e) \in I_k$. Note that[5]

$$\frac{\min_{e \in E_{k+2}} w(e)}{\max_{e \in E_k} w(e)} > n/\epsilon. \tag{1}$$

These weight intervals do not contain zero, so we separately use a zero-weight class E_{-1} to hold edges of zero weight. But for notational simplicity, we will not specially mention this zero weight class in later description. One can check that this does not affect the correctness of the algorithm.

Recall C is the base cycle of length n. For each $k \in \{0, 1, \ldots, \lceil \log_{n/\epsilon} W \rceil\}$, define graph

$$G_k := C \cup \bigcup_{i \geq 0} E_{k-2i}. \tag{2}$$

Let Q_k denote the collection of 3-edge-connected components of G_k, which form a partition of the n vertices. See Figure 1 for an illustration. Let $1 \leq |Q_k| \leq n$ denote the number of components. Since $G_k \subseteq G_{k+2}$, Q_k refines Q_{k+2}, and $|Q_k| \geq |Q_{k+2}|$.

[5] This inequality is meaningful only if both E_k and E_{k+2} are nonempty. This issue does not affect our overall argument since our algorithm can simply ignore the empty weight classes.

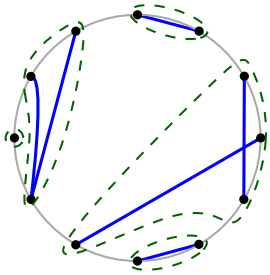


Figure 1 An example of 3-edge-connected components Q_k of the graph G_k. Thin black edges denote the base cycle, and thick blue edges denote the links from the set $\bigcup_{i\geq 0} E_{k-2i}$; together they form G_k. The dashed green lines describe the 3-edge-connected components of graph G_k.

Algorithm description. At any point, our streaming algorithm always stores a subset of the input edges $E = \bigcup_k E_k$, which includes the following:

1. **Undirected edges F_k:** We store edge subsets $F_k \subseteq E_k$, such that for all k the subgraph $C \cup \bigcup_{i\geq 0} F_{k-2i} \subseteq G_k$ has the same 3-edge-connected components as Q_k.
2. **Directed arcs S_k:** For each k and 3-edge-connected component $U \in Q_k$, and every weight interval $J_i = [(1+\epsilon)^i, (1+\epsilon)^{i+1}) \subseteq I_{k+2}$, we store the arc $x\vec{y}$ with minimum (and maximum) indexed x where $(x, y) \in E_{k+2}$, $y \in U, x \notin U$, and $w(x, y) \in J_i$. The set of these arcs is denoted by S_k.

Now we describe how to maintain this information when a new edge $(u, v) \in E_{k'}$ arrives.

- **Maintain Item 1:** Note that adding this edge could potentially cause the components in $Q_{k'+2i}$ $(i = 0, 1, 2, \dots)$ to merge. To maintain Item 1 (and hence the knowledge of all Q_k), we insert (u, v) into the current $F_{k'}$, and then run a clean up procedure to remove redundant edges: Start from the graph $H \leftarrow C \cup \bigcup_{j\geq 1} F_{k'-2j}$ which encodes the 3-connectivity information of the graph formed using edges prior to $E_{k'}$, and iterate over the edges $e \in F_{k'+2i}$ (in increasing order of $i = 0, 1, 2, \dots$). If adding e to H does not change the 3-edge-connected components of H, then remove e from $F_{k'+2i}$. Otherwise add e to H. It is clear that this clean up procedure preserves all the 3-connectivity information, since we start from the base graph C which is already 2-edge-connected.
- **Maintain Item 2:** To maintain Item 2, we simply use arcs $u\vec{v}$ and $v\vec{u}$ to replace the existing ones that become dominated. When two 3-edge-connected components $U, U' \in Q_k$ merge, we also merge the stored information for U, U' (compare the best arcs stored for these two components and keep the better one).
- **Offline step:** In the end, we run an offline exact algorithm (such as [22]) that solves the directed problem (see proof of Theorem 7) on the stored arcs in Item 2 and directed versions of the stored edges in Item 1.

Space complexity. For Item 1 the total space is $\sum_k |F_k| = \sum_j |F_{2j}| + \sum_j |F_{2j+1}|$ edges. We bound both terms separately. Due to our clean up procedure, there should be no redundant edges in $F_{\text{even}} = \bigcup_j F_{2j}$: starting from the base cycle $H \leftarrow C$, we can iterate over the edges $e \in F_{\text{even}}$ in certain order so that adding edge e to H always strictly decreases the number of 3-edge-connected components of H. Hence $|F_{\text{even}}| \leq n - 1$, and similarly $|F_{\text{odd}}| \leq n - 1$, so

$$\sum_k |F_k| \leq 2(n-1). \tag{3}$$

Define c_{k+2} to be the number of 3-edge-connected components $U \in Q_k$ for which there exists $(u,v) \in E_{k+2}$ with $u \in U$ and $v \notin U$. Then the space for Item 2 is $\sum_k 2c_{k+2} \cdot \log_{1+\epsilon} \frac{\max_{e\in E_{k+2}} w(e)}{\min_{e\in E_{k+2}} w(e)} \leq \sum_k c_{k+2} \cdot O(\log(n/\epsilon)/\epsilon) \leq \sum_k c_{k+2} \cdot O(\log(n)/\epsilon)$ edges. We need the following lemma.

▶ **Lemma 9.** $c_{k+2} \leq 2(|Q_k| - |Q_{k+2}|)$.

Using this lemma, the space complexity for Item 2 is

$$\begin{aligned} O(\frac{\log n}{\epsilon}) \sum_k c_{k+2} &\leq O(\frac{\log n}{\epsilon}) \sum_k (|Q_k| - |Q_{k+2}|) \\ &\leq O(\frac{\log n}{\epsilon}) \cdot 2(n-1) \\ &\leq O(\frac{n \log n}{\epsilon}) \qquad \triangleright \text{ by summing over even and odd } k \text{ separately} \end{aligned}$$

So the total space complexity is $O(\epsilon^{-1} n \log n)$ edges.

Proof of Lemma 9. We first shrink the graph $G_k = C \cup \bigcup_{i\geq 0} E_{k-2i}$ into graph H_k. Let each node of H_k represent a 3-edge-connected component $U \in Q_k$, and for every $(u,v) \in C$ (recall C is the set of edges on the base cycle) with $u \in U \in Q_k$ and $v \in V \in Q_k$, we connect U, V in H_k by an edge (allowing self-loops and parallel edges). As a standard fact, H_k is a cactus (allowing self loops), and C corresponds to an Eulerian circuit of H_k.

Let $\mathcal{C}_k$ denote the collection of simple cycles (cycles with distinct vertices; we view a self loop as a simple cycle as well) of the cactus H_k. Then $\mathcal{C}_k$ can be viewed as a partition of the n edges on the base cycle C, where $e, e' \in C$ belong to the same partition if and only if $\{e, e'\}$ is a 2-cut of G_k. Observe that $|\mathcal{C}_k| = n + 1 - |Q_k|$.[6] Hence, in the following it suffices to prove $c_{k+2} \leq 2 \cdot (|\mathcal{C}_{k+2}| - |\mathcal{C}_k|)$. Note that $\mathcal{C}_{k+2}$ is a finer partition of C than $\mathcal{C}_k$.

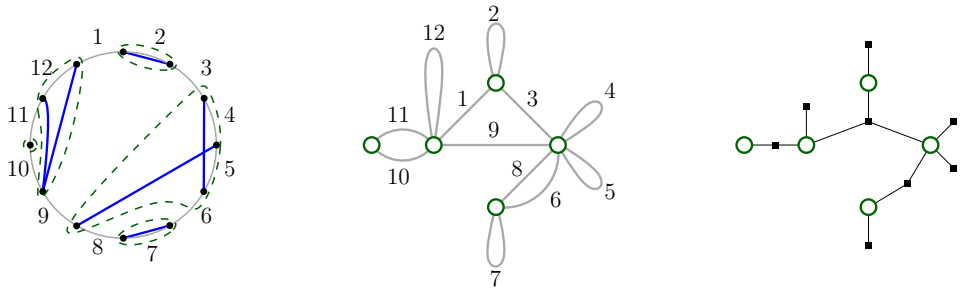

Figure 2 A picture of the cactus H_k (middle) produced by shrinking G_k (left). The tree T_k (right) is produced from cactus H_k.

We now consider how adding edges E_{k+2} into G_k can refine $\mathcal{C}_k$. Convert the cactus H_k into a tree T_k as follows. Let T_k be a bipartite graph with vertex bipartition $(\mathcal{C}_k, Q_k)$, in which $D \in \mathcal{C}_k$ is connected to every $U \in Q_k$ that lies on the simple cycle D in cactus H_k. Observe this bipartite graph T_k is indeed a tree. For each $(u,v) \in E_{k+2}$, let $u \in U \in Q_k$ and $v \in V \in Q_k$, and we mark all the tree-edges on the unique path connecting U and V in T_k.

[6] To see this equality, consider removing one arbitrary edge from each simple cycle of the cactus, and the remaining edges should form a tree. As there are $|Q_k|$ vertices, the number of edges in the remaining tree is $|Q_k| - 1$, so the number of edges n in the original cactus equals $|Q_k| - 1 + |\mathcal{C}_k|$, since we removed $|\mathcal{C}_k|$ edges in the removal step.

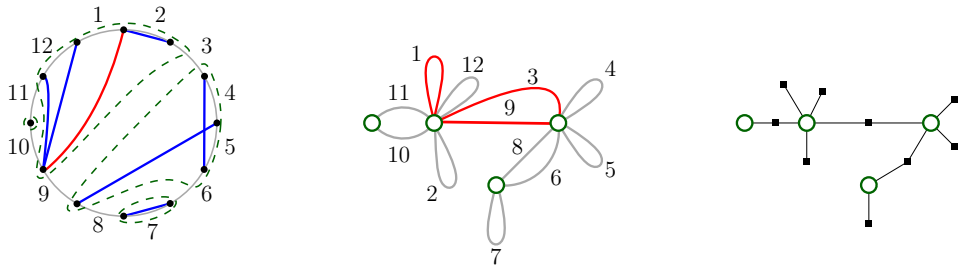

Figure 3 After adding an edge from E_{k+2} (depicted in red), the partition $\mathcal{C}_{k+2}$ refines the old partition $\mathcal{C}_k$: $\{1,3,9\}$ breaks into $\{1\}$ and $\{3,9\}$.

For each $D \in \mathcal{C}_k$, let $d(D)$ denote the number of marked tree-edges incident to the tree-node D in T_k. Then, observe that $d(D) \in \{0\} \cup \{2,3,4,\dots\}$, and $D \in \mathcal{C}_k$ (viewed as a subset of C) breaks into $\max\{d(D),1\}$ subsets in the partition $\mathcal{C}_{k+2}$.

By assumption, there are at least c_{k+2} many tree-nodes $U \in Q_k$ that are incident to at least one marked tree-edge in T_k, so T_k contains at least c_{k+2} marked tree-edges. Hence,

$$\begin{aligned}|\mathcal{C}_{k+2}| = \sum_{D\in\mathcal{C}_k} \max\{d(D),1\} &\geq \sum_{D\in\mathcal{C}_k} (1+d(D)/2) \quad \triangleright \text{since } d(D) \in \{0\}\cup\{2,3,4,\dots\} \\ &= |\mathcal{C}_k| + \frac{1}{2}\sum_{D\in\mathcal{C}_k} d(D) \geq |\mathcal{C}_k| + \frac{1}{2}c_{k+2},\end{aligned}$$

which completes the proof. ◀

Approximation factor. Let $\mathrm{OPT} \subseteq E = \bigcup_{k=-\infty}^{+\infty} E_k$ denote the optimal solution for the (undirected) cycle augmentation problem. Let k^* be the maximum k^* such that $\mathrm{OPT} \cap E_{k^*} \neq \varnothing$. Then by (1) we have

$$w(\mathrm{OPT}) > (n/\epsilon) \cdot \max_{e\in E_{k^*-2}} w(e). \tag{4}$$

Bidirecting OPT gives a solution OPT' for the directed problem with total cost $w(\mathrm{OPT}') = 2w(\mathrm{OPT})$. In the following we convert OPT' into a solution SOL for the directed problem that only uses arcs stored by the streaming algorithm, with total cost $w(\mathrm{SOL}) \leq (1 + O(\epsilon))w(\mathrm{OPT}') \leq (2 + O(\epsilon))w(\mathrm{OPT})$. This establishes that our streaming algorithm achieves $2 + O(\epsilon)$ approximation ratio for the (undirected) cycle augmentation problem.

In SOL we first include both directed versions of all $(u,v) \in \bigcup_{k\leq k^*-2} F_k$, with total cost at most

$$\begin{aligned}\sum_{k\leq k^*-2} 2|F_k| \cdot \max_{e\in F_k} w(e) &\leq \sum_k 2|F_k| \cdot \max_{e\in E_{k^*-2}} w(e) \\ &\leq 4(n-1)\cdot\frac{\epsilon}{n} w(\mathrm{OPT}) \qquad \triangleright \text{by (3) and (4)} \\ &\leq 4\epsilon w(\mathrm{OPT}).\end{aligned}$$

Then, for every arc $x\vec{y} \in \mathrm{OPT}'$ with weight $w(x\vec{y}) \in I_k$ where $k \in \{k^*-1, k^*\}$, we will find a replacement arc $x'\vec{y}' \in S_k$ stored by Item 2: Let $y \in U \in Q_k$. If $x \notin U$, then by Item 2 we can pick a stored arc $x'\vec{y}' \in S_k$ with $y' \in U$ and $w(x'\vec{y}') < (1+\epsilon)w(x\vec{y})$, such that $x' \leq x$ (if $x < y$) or $x' \geq x$ (if $x > y$). We include $x'\vec{y}'$ in SOL. (in the case of $x \in U$ we do not need to do anything)

By definition we immediately have $w(\text{SOL}) \leq 4\epsilon w(\text{OPT}) + (1+\epsilon)w(\text{OPT}') = (2 + 6\epsilon)w(\text{OPT})$. To show SOL is a feasible solution for the directed problem, we verify that each 2-cut $L = \{l, l+1, \ldots, r\}$ (where $1 \leq l \leq r \leq n-1$) is covered. There are three cases:

- **Case 1: $(L, V \setminus L)$ is not a 2-cut of G_{k^*-2}.** By Item 1, G_{k^*-2} and $C \cup \bigcup_{i \geq 0} F_{k^*-2-2i}$ have the same 3-edge-connected components, and hence have the same 2-cuts, so $(L, V \setminus L)$ is also not a 2-cut of $C \cup \bigcup_{i \geq 0} F_{k^*-2-2i}$. Hence, there exists $(u', v') \in \bigcup_{i \geq 0} F_{k^*-2-2i}$ such that $u' \in V \setminus L, v' \in L$. Then, $\vec{u'v'}$ covers L, and by construction we have $\vec{u'v'} \in \text{SOL}$.
- **Case 2: $(L, V \setminus L)$ is not a 2-cut of G_{k^*-3}.** This case is similar to case 1.
- **Case 3: Otherwise.** In this case, $(L, V \setminus L)$ is a 2-cut of both G_{k^*-2} and G_{k^*-3}. From the feasibility of OPT, we know there must exist arc $\vec{xy} \in \text{OPT}'$ that covers L (i.e., $y \in L, x \in V \setminus L$) with weight $w(\vec{xy}) \in I_k$ where $k \in \{k^*-1, k^*\}$. Let $y \in U \in Q_{k-2}$. Since $(L, V \setminus L)$ is a 2-cut of G_{k-2}, we know x, y cannot be in the same 3-edge-connected component of G_{k-2}, so $x \notin U$. Now let $\vec{x'y'} \in \text{SOL}$ be the replacement arc we found for $\vec{xy}$. By definition, $y' \in U$. We consider the case of $x < y$ (the other case $y < x$ is similar), and hence $x' \leq x$. In this case we must have $x < l \leq y \leq r$, so $x' < l$ and hence $x' \notin L$. Suppose for contradiction that $\vec{x'y'}$ does not cover L. Then we must have $y' \notin L$. But this would mean $(L, V \setminus L)$ is a 2-cut in G_{k-2} separating y and y', contradicting the assumption that $y, y' \in U$ belong to the same 3-edge-connected component of G_{k-2}. This proves that the replacement arc $\vec{x'y'} \in \text{SOL}$ indeed covers L. ◀

The following shows that the approximation factor of our algorithm is close to optimal.

▶ **Theorem 10.** *Any streaming algorithm that solves the weighted TAP in the link arrival model with better than 2-approximation needs $\Omega(n^2)$ bits of space.*

3 Connectivity Augmentation in the Fully Streaming Setting

In this section, we first prove a space lower bound for k-CAP in the fully streaming model. Then, we show a streaming algorithm with nearly matching space complexity.

3.1 Lowerbound for Estimating Connectivity Augmentation Cost

Our main lower bound statement is the following.

▶ **Theorem 11.** *For any constant integer $t \geq 1$, the (unweighted) k-CAP (even when k is known) in the fully streaming model requires space complexity $\Omega(kn + n^{1+1/t})$ bits (assuming the Erdős's girth conjecture) to approximate the solution size to a factor better than $2t+1$.*

It follows from combining two lower bound results Theorem 12 and Theorem 13.

Lower bound in terms of approximation factor (t). We first describe the space lower bound in terms of the approximation factor. As is standard in the spanner literature, the proof is based on high-girth graphs, but here we need to be more careful to make the connection between tree-augmentation and shortest paths.

▶ **Theorem 12.** *Consider the (unweighted) TAP where E is the base tree and L is the set of edges to augment, and $E \cup L$ arrive as a stream in an arbitrary order.*

For any constant integer $t \geq 1$, any (randomized) streaming algorithm $\mathcal{A}$ that can output the size of a better than $(2t+1)$-approximate solution requires $\Omega(\gamma(n, 2t+1))$ bits of space, where $\gamma(n, 2t+1)$ denotes the maximum possible number of edges in an n–vertex graph with girth $> 2t+1$.

We remark that the same lower bound of Theorem 12 also generalizes to k-CAP for higher values of $k > 2$, provided that we allow the base graph E to have parallel edges.

Lower bound in terms of connectivity parameter (k). Zelke [53] gave a simple proof that computing the size of the minimum cut of an (unweighted) undirected graph requires $\Omega(n^2)$ bits of space for any one-pass streaming algorithm. In Zelke's construction the input graph has minimum cut size as large as $\Theta(n)$. Here we observe that Zelke's proof can be adapted to graphs with minimum cut size $\Theta(k)$, and show lower bounds for the connectivity augmentation problem.

We remark that [47] also obtained an $\Omega(kn)$-bit randomized lower bound and an $\Omega(kn \log n)$-bit deterministic lower bound for the k-CAP using a different proof.

▶ **Theorem 13.** *The k-CAP (where k is known) in the fully streaming model (with unweighted links) requires $\Omega(nk)$ bits of space to approximate to any finite factor.*

▶ Remark 14. We remark that the same $\Omega(nk)$ lower bound also holds for the task of constructing a cactus representation of a graph (Lemma 3), even assuming the edge connectivity value k is known. This is because the cactus representation immediately allows to distinguish between the cases of having two minimum cuts C_1, C_2 or one minimum cut C_2, and thus the proof above still applies.

3.2 Tight Algorithm

The main result of this section, whose details are deferred to the full version of the paper, is a single-pass algorithm that outputs a $(2t-1+\epsilon)$-approximate solution in $O(nk+\epsilon^{-1}n^{1+1/t}\log n)$ space, nearly matching the lower bounds of Theorem 12 and 13.

▶ **Theorem 15.** *The k-CAP in the fully-streaming model can be solved by a single-pass streaming algorithm with approximation ratio $(2t-1+\epsilon)$ in $O(nk+\epsilon^{-1}n^{1+1/t}\log n)$ space.*

A Streaming Algorithm for Spanners on Weighted Graphs

In this section, we prove the following theorem on computing spanners for weighted graphs in the streaming model.

▶ **Theorem 16.** *For any integer $t \geq 1$, there is a one-pass streaming algorithm for computing a $(2t-1+\epsilon)$-spanner of size $O(\epsilon^{-1}n^{1+1/t}\log n)$ of a weighted graph, with space complexity $O(\epsilon^{-1}n^{1+1/t}\log n)$ words.*

Let $G=(V,E)$ be a weighted graph. We denote the weight function by $w : E \to \mathbb{R}^+$. Moreover, We normalize the weights so that $w(e) \in \{0\} \cup [1, W]$. For each $j \in [0, \lceil \log_{1+\epsilon} W \rceil]$, our algorithm stores E_j, a subset of edges of G that have weights in $[(1+\epsilon)^j, (1+\epsilon)^{j+1})$. (These intervals do not contain zero, so we separately use a zero-weight class E_{-1} to hold edges of zero weight. For notational simplicity, we will not mention this zero weight class in later description. One can check that this does not affect the correctness of the algorithm.)

Our algorithm is as follows (see Algorithm 2). As an edge e arrives, round its weight to the nearest power of $(1+\epsilon)$ and place it in the corresponding weight class E_j. As usual, we keep the edge e iff it does not close a cycle of length at most $2t$ in E_j, for some given parameter t. After processing the edge, we run the Sparsify subroutine described below in Algorithm 1.

Sparsify subroutine. Let $C > 0$ be a sufficiently large constant. Define intervals $I_k = [k \cdot (C/\epsilon)\log n, (k+1)\cdot(C/\epsilon)\log n]$. For all k let $\tilde{E}_k := \bigcup_{j \in I_k} E_j$. For each k let $E^{\text{even}}_{\leq k} = \bigcup_{j=-\infty}^{k} \tilde{E}_{2j}$ and $E^{\text{odd}}_{\leq k} = \bigcup_{j=-\infty}^{k} \tilde{E}_{2j+1}$. Let $E^{\text{even}} = \bigcup_j \tilde{E}_{2j}$, and we define E^{odd} similarly. Our Sparsify procedure operates independently on these two sets. We will ensure that each set contains $O(\epsilon^{-1}n^{1+1/t}\log n)$ edges, independent of the weight bound W. We now describe how Sparsify operates on E^{even} (the operations are the same for E^{odd}).

▷ Claim 17. Let the constant C in the definition of the sets $\tilde{E}_k$ be chosen sufficiently large. Let k be an integer. Let $H = (V, E^{\text{even}}_{\leq k-1})$. Then for any edge $e=(u,v) \in \tilde{E}_{2k}$ such that u and v belong to the same connected component in H, one has $w_e \geq \text{dist}_H(u,v)$.

Our procedure Sparsify(k) performs the following step for each k from $k_{\max}$ down to $k_{\min}$. Collapse the connected components induced by $E^{\text{even}}_{\leq k-1}$ into supernodes, and consider the multigraph with edges $\tilde{E}_{2k}$ on this set of supernodes. We convert this multigraph into a simple graph in the following natural way. For each edge $e=(u,v) \in \tilde{E}_{2k}$,

- delete e if it is a self loop in this graph (i.e. u, v belong to the same connected component)
- delete e if there is a shorter edge that is parallel to e.

This is summarized in Algorithm 1. The algorithm is summarized in Algorithm 2.

▶ **Lemma 18.** *The edges stored by Algorithm 2 form a $(2t-1)\cdot(1+\epsilon)$-spanner of G.*

▶ **Lemma 19.** *Throughout the algorithm, the total number of edges stored by Algorithm 2 is always at most $O(\epsilon^{-1}n^{1+1/t}\log n)$.*

B Further Applications of Streaming Connectivity Augmentation

In this section, we show applications of our streaming algorithms for k-CAP for following well-studied *network design* problems: STAP, SNDP and k-ECSS.

B.1 Steiner Tree Augmentation Problem (STAP) in Streaming

In STAP, we are given a set of vertices V partitioned into *terminal* nodes (R) and *Steiner* nodes ($V \setminus R$), and a Steiner tree T spanning the terminal set R. Then given a set of weighted links $L \subseteq \binom{V}{2}$, the goal is to find a minimum weight set of links $S \subseteq L$ such that $H = (V, E(T) \cup S)$ has 2 edge-disjoint paths between any pair of terminals. The problem is a special case of SNDP and can be approximate within a factor of 2 by iterative rounding method of Jain [29]. In light of recent developments for approximating tree augmentation and connectivity augmentation problems [49], Ravi, Zhang, and Zlatin [45] provided a $(1.5 + \epsilon)$-approximation for Steiner tree augmentation problem in polynomial time.

Algorithm in fully streaming setting. First, we observe that our results imply an algorithm for STAP in the fully streaming setting.

▶ **Corollary 20.** *STAP in the fully streaming model can be solved by a single-pass streaming algorithm with approximation ratio $(2t-1+\epsilon)$ and space complexity $O(\epsilon^{-1}n^{1+1/t}\log n)$ words.*

Note that the same fully streaming algorithm from Corollary 20 can also be used to solve STAP in the easier link arrival streams.

Lower bound in link arrival streams. Now we show that STAP has a lower bound nearly matching Corollary 20 *even in link arrival streams*. This shows a separation of STAP from the easier TAP: the latter problem has a better streaming algorithm in link arrival streams than in the fully streaming setting, whereas the former problem does not.

▶ **Corollary 21.** *For any constant integer $t \geq 1$, weighted STAP in link arrival streams requires space complexity $\Omega(n^{1+1/t})$ bits (assuming the Erdős's girth conjecture) to approximate the solution cost to a factor better than $2t+1$.*

B.2 SNDP in Edge Arrival Streams

In this section, using our results and techniques from k-CAP and weighted spanners, we present a streaming algorithm for the general SNDP problem in edge arrival streams. We remark that our result in this section provide coresets for *covering functions* defined on cuts.

▶ **Lemma 22.** *Consider a weighted graph $G = (V, E)$ in an edge arrival stream. For integer $k \geq 1$ there is a one-pass streaming algorithm that computes k disjoint edge subsets $S_1 \uplus S_2 \uplus \cdots \uplus S_k \subseteq E$ each of size $|S_i| \leq O(\epsilon^{-1} n^{1+1/t} \log n)$, in total space $O(k\epsilon^{-1} n^{1+1/t} \log n)$ words such that, for every $i \in [k]$ and every $e = (u, v) \in E \setminus (S_1 \cup S_2 \cup \cdots \cup S_i)$, there is be a path $P \subseteq S_i$ connecting u, v with total length $w(P) \leq (2t - 1 + \epsilon)w(e)$.*

One of the main algorithmic approaches for SNDP is the augmentation framework pioneered by [51]. In this approach, the solution is constructed in k phases and by the end of the phase ℓ, the connectivity of every pair u, v in the so-far-constructed solution is at least $\min\{\ell, r(st)\}$. So, the optimization problem of each phase is to increase connectivity of subset of pairs by one. More precisely, in each phase ℓ, we need to pick a minimum-weight subgraph H to cover a function $f_\ell : 2^V \to \{0, 1\}$. We say that a subgraph H covers f iff for every $U \subset V$, $\delta_H(U) \geq f(s)$. In the case of SNDP, for every $\ell \leq k$, f_ℓ is a skew-supermodular function and admits a 2-approximation via a primal-dual algorithm [51].

Next, We use Lemma 22 to show a coreset for covering $\{0, 1\}$ functions $f : 2^V \to \{0, 1\}$:

▶ **Definition 23.** *Given a weighted graph $G = (V, E)$, and a function $f : 2^V \to \{0, 1, \ldots, k\}$, find an edge subset $H \subseteq E$ with minimum total weight such that for all $U \subseteq V$ it holds that $|\delta_H(U)| \geq f(U)$. Throughout this section, we consider the functions f arising from an instance of SNDP on G with connectivity requirement function r with maximum requirement k. Then, for every $U \subset V$, $f(U) := \max_{s \in U, t \in V \setminus U} r(st)$.*[7]

▶ **Lemma 24.** *Given a weighted graph $G = (V, E)$, let $S = S_1 \cup \cdots \cup S_k$ be the set of edges returned by the algorithm of Lemma 22. Then, the optimal solution for covering a function $f : 2^V \to \{0, 1, \cdots, k\}$ (arising from a SNDP instance on G) on graph $G' = (V, S)$ is an $O(t \log k)$-approximation of the optimal solution for covering f on $G = (V, E)$.*

▶ **Theorem 25.** *SNDP with maximum connectivity requirement k on a weighted graph $G = (V, E)$ admits a single-pass streaming algorithm with space complexity $O(kn^{1+1/t})$ words and approximation ratio $O(t \log k)$.*

Note that SNDP generalizes STAP, so the same lower bound for STAP from Corollary 21 also applies to SNDP. Specifically, for any constant integer $t \geq 1$, weighted SNDP requires space complexity $\Omega(n^{1+1/t})$ bits (assuming the Erdős's girth conjecture) to approximate the solution cost to a factor better than $2t + 1$.

[7] All results hold for a more general class of *proper* functions too. The function f is called proper if $f(V) = 0$, $f(U) = f(V \setminus U)$ for every $U \subset V$ (symmetry), and $f(U_1 \cup U_2) \leq \max\{f(U_1), f(U_2)\}$ whenever U_1 and U_2 are disjoint (maximality).

Min-Weight k-ECSS. As a corollary of Theorem 1 for CAP in link arrival streams, we have the following guarantee for the problem of finding minimum-weight k-edge-connected spanning subgraph (k-ECSS), where given a graph $G = (V, E)$ with a weight function $w : E \to \mathbb{R}_{\geq 0}$, the goal is to find a minimum-weight k-edge-connected subgraph $H \subseteq G$.

▶ **Corollary 26.** *There exists a k-pass $O(\log k)$-approximation algorithm for minimum-weight k-ECSS with total memory space $O(nk + n \log \min(n, W))$ where $W = \max_{e \in E} w(e)$.*

C Related Work

Approximation algorithms of k-CAP. The edge-connectivity of a graph plays a central role in a wide range of network design problems, spanning both classical and modern problems. While the celebrated iterative rounding technique of [29] provides a 2-approximation for most of these problems, any better than 2-approximation for them are among main open problems within the field of approximation algorithms.

Significant progress has been made in achieving better than a 2-approximation for specific instances of the weighted k-CAP.Notably, extensive research focusing on the well-studied unweighted TAP has led to breakthroughs [40, 16, 38, 27, 9], culminating in an approximation factor of 1.326 [24]. Remarkably, this same factor has also been achieved for the unweighted k-CAP [9], a problem that recently saw significant advancements surpassing the 2-approximation barrier [8]. Moreover, in a recent development, the weighted TAP and k-CAP have witnessed breakthroughs with approximation factors below 2 [48, 49, 50]. It is noteworthy that these advancements in the weighted variants are relatively recent in the research landscape.

The Steiner tree augmentation problem, in which given a Steiner tree $T \subset G = (V, E)$ over terminals $R \subset V$ the goal is to find a minimum weight set of edges $H \subseteq G \setminus T$ that increases the connectivity of the set R to 2, has also been studied and recently [45] provides $(1.5 + \epsilon)$-approximation generalizing some of the techniques in [49].

SNDP. Similarly to k-ECSS, the augmentation variant of SNDP has been extensively studied and is significant in the development of approximation algorithms for different variations of SNDP. Notably, the augmentation variant of SNDP generalizes well-studied problems such as TAP, STAP and k-CAP. The augmentation variant of SNDP was originally studied to analyze the primal-dual methods for SNDP, leading to k and $\log k$ approximations [51, 26], and compared to the state-of-the-art 2-approximation iterative rounding technique of [29] has the advantage of applicability to other variants of SNDP such as node-weighted SNDP [44, 11, 10] or vertex-connectivity SNDP [37, 17, 12].

Spanners and sparsifiers. Graph spanners are important tools for graph compression in which the distances between the nodes are preserved. See [1] for a survey on graph spanners in general. Spanners have also been studied extensively in the streaming setting, see e.g., [7, 2, 15, 33, 21]. For other notions of graph sparsifiers in the streaming model, see e.g., [31, 32].

A Faster Algorithm for Pigeonhole Equal Sums

Ce Jin

Abstract

An important area of research in exact algorithms is to solve Subset-Sum-type problems faster than meet-in-middle. In this paper we study *Pigeonhole Equal Sums*, a total search problem proposed by Papadimitriou (1994): given n positive integers $w_1, \ldots, w_n$ of total sum $\sum_{i=1}^{n} w_i < 2^n - 1$, the task is to find two distinct subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i = \sum_{i \in B} w_i$.

Similar to the status of the Subset Sum problem, the best known algorithm for Pigeonhole Equal Sums runs in $O^*(2^{n/2})$ time, via either meet-in-middle or dynamic programming (Allcock, Hamoudi, Joux, Klingelhöfer, and Santha, 2022).

Our main result is an improved algorithm for Pigeonhole Equal Sums in $O^*(2^{0.4n})$ time. We also give a polynomial-space algorithm in $O^*(2^{0.75n})$ time. Unlike many previous works in this area, our approach does not use the representation method, but rather exploits a simple structural characterization of input instances with few solutions.

1 Introduction

The Subset Sum problem is an important NP-hard problem in computer science: given positive integers $w_1, w_2, \ldots, w_n$ and a target integer t, find a subset $A \subseteq [n]$ such that $\sum_{i \in A} w_i = t$. Subset Sum can be solved in $O(2^{n/2})$ time by a simple meet-in-middle algorithm [14], and an important open problem is to improve it to $O(2^{(1/2-\varepsilon)n})$. A long line of research attempts to solve Subset Sum faster using the representation method [15] and connections to uniquely decodable code pairs [3, 4, 22], but these techniques have so far only succeeded on average-case inputs [15, 8, 9] or restricted classes of inputs [2, 3]. Nevertheless, significant progress has been made for other variants of Subset Sum, including Equal Sums [17], 2-Subset Sum and Shifted Sums [1] and more general subset balancing problems [12], as well as Subset Sum in other computational settings such as Merlin–Arthur protocols [18], low-space algorithms [6, 19], quantum algorithms [1], and algorithms with lower-order run time improvements [13]. The general hope is that the tools developed for solving these variant problems might one day help solve the original Subset Sum problem.

In this paper we study an interesting variant of Subset Sum called *Pigeonhole Equal Sums*:

> PIGEONHOLE EQUAL SUMS [20]
> **Input:** positive integers $w_1, w_2, \ldots, w_n$, with promise $\sum_{i=1}^{n} w_i < 2^n - 1$.
> **Output:** two different subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i = \sum_{i \in B} w_i$.

Since there are 2^n subsets $S \subseteq [n]$ with only $2^n - 1$ possible subset sums $\sum_{i \in S} w_i \in \{0, 1, \ldots, 2^n - 2\}$ due to the promise, the pigeonhole principle guarantees that there exists a pair of subsets with the same subset sum.

Pigeonhole Equal Sums was introduced by Papadimitriou [20] as a natural example problem in the total search complexity class PPP. This problem has received attention in the TFNP literature [5, 21], and is conjectured to be PPP-complete [20].

From the algorithmic point of view, the current status of Pigeonhole Equal Sums is quite similar to that of the Subset Sum problem: a simple binary search with meet-in-middle solves Pigeonhole Equal Sums in $O^*(2^{n/2})$ time (see Section 2).[1] Allcock, Hamoudi, Joux, Klingelhöfer, and Santha [1, Theorem 6.2] gave another $O^*(2^{n/2})$-time algorithm based on dynamic programming (which is analogous to the alternative $O^*(2^{n/2})$-time Subset Sum algorithm from [3][2]). It remains open whether $O(2^{(1/2-\varepsilon)n})$ time is possible for Pigeonhole Equal Sums. Improvement of such type was achieved for the Equal Sums problem (without the pigeonhole promise) by Mucha, Nederlof, Pawlewicz, and Węgrzycki [17] via the representation method with $O(3^{(1/2-\varepsilon)n})$ run time for some $\varepsilon > 0.01$, but this result has no direct implications for Pigeonhole Equal Sums (for which the known $O^*(2^{n/2})$ time bound is already much better than $O(3^{n/2})$).

1.1 Our results

We give an algorithm that solves Pigeonhole Equal Sums faster than the previous $O^*(2^{n/2})$ running time [1].

▶ **Theorem 1** (Main). *Pigeonhole Equal Sums can be solved by a randomized algorithm in $O^*(2^{0.4n})$ time.*

Surprisingly, unlike previous works on other variants of Subset Sum, our algorithm does not use the representation method [15] or tools from coding theory [3, 4, 22]. Instead, our main insight is a simple structural characterization of Pigeonhole Equal Sums instances with few solutions.

Our techniques also yield a fast polynomial-space algorithm for Pigeonhole Equal Sums, in an analogous way to the previous $O(3^{(1-\varepsilon)n})$-time polynomial-space algorithm for Equal Sums [17].

▶ **Theorem 2.** *Pigeonhole Equal Sums can be solved by a randomized algorithm in $O^*(2^{0.75n})$ time and $\mathrm{poly}(n)$ space.*

For comparison, a straightforward algorithm based on binary search solves Pigeonhole Equal Sums in $\mathrm{poly}(n)$ space and $O^*(2^n)$ time (see the beginning of Section 4).

Theorem 1 and Theorem 2 will be proved in Section 3 and Section 4 respectively.

---

[1] We use $O^*(\cdot)$ to hide $\mathrm{poly}(n)$ factors.
[2] See also `https://youtu.be/cHimhXXIwcg?t=454`.

2 Preliminaries

Denote $[n] = \{1, \dots, n\}$. Let $O^*(\cdot), \Omega^*(\cdot)$ hide $\mathrm{poly}(n)$ factors, where n is the number of input integers in the Pigeonhole Equal Sums problem.

Denote $w(A) = \sum_{i \in A} w_i$ for $A \subseteq [n]$. The pigeonhole promise states $w([n]) < 2^n - 1$.

For a predicate p we define $\mathbf{1}[p] = 1$ if p is true and $\mathbf{1}[p] = 0$ if p is false.

We need the following well-known lemma.

▶ **Lemma 3** (Counting subset sums via meet-in-middle [14]). *Given integers $w_1, \dots, w_n$ and t, we can compute $\#\{S \subseteq [n] : w(S) \le t\}$ in $O^*(2^{n/2})$ time. Moreover, we can list $S \subseteq [n]$ such that $w(S) \le t$ in $O^*(1)$ additional time per S.*

Proof. Divide $[n]$ into $S_1 = \{1, \dots, \lfloor n/2 \rfloor\}$ and $S_2 = [n] \setminus S_1$, and every subset $S \subseteq [n]$ can be represented as $X \uplus Y, X \subseteq S_1, Y \subseteq S_2$. Compute and sort the two lists $A = \{w(X)\}_{X \subseteq S_1}$ and $B = \{w(Y)\}_{Y \subseteq S_2}$ of length $O(2^{n/2})$ each. Then for each $w(X) \in A$ we accumulate $|B \cap (-\infty, t - w(X)]|$ to the answer. It is easy to augment this algorithm to support listing. ◀

Pigeonhole Equal Sums via binary search

The following simple binary-search algorithm (described in [1, Remark 6.9 of arXiv version] and attributed to an anonymous referee) solves Pigeonhole Equal Sums in $O^*(2^{n/2})$ time: Maintain an interval $\{\ell, \ell+1, \dots, r\}$ (initialized to $\ell = 0, r = 2^n - 2$) that satisfies the pigeonhole invariant $r - \ell + 1 < \#\{S \subseteq [n] : \ell \le w(S) \le r\}$. Initially this invariant is satisfied due to $w([n]) \le 2^n - 2$. While $r > \ell$, pick the middle point $m = \lfloor \frac{\ell + r}{2} \rfloor$, and use meet-in-middle (Lemma 3) to compute $c_1 = \#\{S \subseteq [n] : \ell \le w(S) \le m\}$ and $c_2 = \#\{S \subseteq [n] : m+1 \le w(S) \le r\}$ in $O^*(2^{n/2})$ time. Then we shrink the interval to $\{\ell, \dots, m\}$ if $m - \ell + 1 < c_1$, or to $\{m+1, \dots, r\}$ if $r - m < c_2$ (the invariant guarantees that at least one holds). After $\lceil \log_2(2^n - 1) \rceil = n$ iterations we shrink to a singleton interval $\ell = r$. By the invariant, there exist two different $S_1, S_2 \subseteq [n]$ such that $w(S_1) = w(S_2) = \ell$, and we can report such S_1, S_2 using meet-in-middle (Lemma 3).

This binary-search strategy will be used in our improved algorithms as well.

3 The improved algorithm

Let the n input integers be sorted as $0 < w_1 < w_2 < \cdots < w_n$ (assuming no trivial solution $w_i = w_j$ exists).

An assumption on prefix sums

If any proper prefix $\{w_1, \dots, w_i\}$ $(i \le n-1)$ already satisfies the pigeonhole promise $w([i]) < 2^i - 1$, then we can instead solve the smaller Pigeonhole Equal Sums instance $\{w_1, \dots, w_i\}$ and obtain $A, B \subseteq [i], A \ne B$ with $w(A) = w(B)$. Hence, without loss of generality we assume such prefix does not exist, i.e.,

$$w([i]) \ge 2^i - 1 \text{ for all } i \in [n-1]. \tag{1}$$

Frequencies f_t and parameter d

The *frequency* (also called bin size) of $t \in \mathbb{N}$ is the number of input subsets achieving sum t, denoted as $f_t = \#\{S \subseteq [n] : w(S) = t\}$. Since $w([n]) < 2^n - 1$, we know $f_t = 0$ for all $t \ge 2^n - 1$, and

$$\sum_{0 \le t < 2^n} f_t = 2^n. \tag{2}$$

Two different subsets achieving equal subset sum t imply $f_t > 1$. This motivates the following parameter,

$$d = \sum_{0 \le t < 2^n} \max\{0, f_t - 1\}, \tag{3}$$

which counts the (non-trivial) equality relations among all the 2^n subset sums. Using Equation (2), we can rewrite Equation (3) as $d = \sum_{0 \le t < 2^n} (f_t - \mathbf{1}[f_t \ge 1]) = 2^n - \sum_{0 \le t < 2^n} \mathbf{1}[f_t \ge 1]$, and thus obtain

$$d = \#\{0 \le t < 2^n : f_t = 0\}, \tag{4}$$

which counts the non-subset-sums in $\{0, 1, \ldots, 2^n - 1\}$. In particular, $d < 2^n$.

The equivalence between Equation (3) and Equation (4) is powerful. In the following we will give two different algorithms for Pigeonhole Equal Sums. The first one works for small d by analyzing the structure of input instances with few non-subset-sums (by Equation (4)). The second one works when d is large and hence there are many solutions (by Equation (3)) which allow a subsampling approach. These two algorithms are summarized as follows:

▶ **Lemma 4.** *Given parameter $\Delta \le 2^n/(3n^2)$, Pigeonhole Equal Sums with $d \le \Delta$ can be solved deterministically in $O^*(\sqrt{\Delta})$ time.*

▶ **Lemma 5.** *Given parameter $2^{n/2} \le \Delta < 2^n$, Pigeonhole Equal Sums with $d \ge \Delta$ can be solved in $O^*((2^{2n}/\Delta)^{1/3})$ time by a randomized algorithm.*

Combining these two lemmas implies our main result:

Proof of Theorem 1. Set $\Delta = 2^{0.8n}$ so that the two time bounds in Lemma 4 and Lemma 5 are balanced to $O^*(2^{0.4n})$. Given an instance of Pigeonhole Equal Sums (with unknown d), we run both algorithms in parallel, and return the answer of whichever terminates first. ◀

3.1 Small d case via structural characterization

In this section we prove Lemma 4. Assume $d \le \Delta \le 2^n/(3n^2)$ and Δ is known.

Since $f_t = 0$ for all $w([n]) < t < 2^n$, from Equation (4) we know $d \ge 2^n - 1 - w([n])$, and hence $w([n]) \ge 2^n - 1 - d \ge 2^n - 1 - \Delta$. Combined with Equation (1) for $i \in [n-1]$, we get the following lower bound

$$w([i]) \ge 2^i - 1 - \Delta \text{ for all } i \in [n]. \tag{5}$$

The key step is to complement Equation (5) with a nearly matching upper bound:

▶ **Lemma 6.** *For all $i \in [n]$,*

$$w_i \le 2^{i-1} + \Delta. \tag{6}$$

Summing Equation (6) over i gives

$$w([i]) \le 2^i - 1 + i\Delta \tag{7}$$

for all $i \in [n]$.

Proof. Fix $i \in [n]$. Let M be the number of subsets $S \subseteq [n]$ with $w(S) < w_i$. Since $w_i < w_{i+1} < \cdots < w_n$, any such S must be contained in $[i-1]$, and thus $M \le 2^{i-1}$. On the other hand, $M = \sum_{t=0}^{w_i - 1} f_t \ge w_i - \#\{0 \le t < w_i : f_t = 0\} \ge w_i - d$ by Equation (4). Hence, $w_i \le M + d \le 2^{i-1} + \Delta$. ◀

Comparing Equation (5) with Equation (7) gives the lower bound

$$w_i = w([i]) - w([i-1]) \geq (2^i - 1 - \Delta) - (2^{i-1} - 1 + (i-1)\Delta) = 2^{i-1} - i\Delta,$$

which is very close to the upper bound from Equation (6). Together we get

$$w_i - 2^{i-1} \in [-i\Delta, \Delta] \tag{8}$$

for all $i \in [n]$.

Equation (8) gives a very rigid structure of the large input numbers. In the next lemma we exploit this structure to improve the naive meet-in-middle subset sum counting algorithm from Lemma 3.

▶ **Lemma 7.** *For any given $T < 2^n$, we can compute $\sum_{t=0}^{T} f_t$ in $O^*(\sqrt{\Delta})$ time.*

Proof. Let i^* be the minimum $i^* \in [n]$ such that $2^{i^*} \geq 3n^2\Delta$, which exists by our assumption $\Delta \leq 2^n/(3n^2)$. Let $A = \{1, 2, \ldots, i^*\}$ and $B = \{i^* + 1, \ldots, n\}$.

By Equation (7), $w(A) < 2^{i^*} + n\Delta$.

For every $B' \subseteq B$, by Equation (8) we have

$$\left|w(B') - \sum_{j \in B'} 2^{j-1}\right| \leq \sum_{j \in B'} |w_j - 2^{j-1}| \leq \sum_{j \in B'} j\Delta \leq n^2\Delta.$$

In other words, the subset sums of $\{w_j\}_{j \in B}$ are $n^2\Delta$-additively approximated by the subset sums of $\{2^{j-1}\}_{j \in B}$. The subset sums of the latter set form an arithmetic progression $\{k \cdot 2^{i^*} : 0 \leq k < 2^{n-i^*}\}$, namely all n-bit binary numbers whose lowest i^* bits are zeros. Notably, this arithmetic progression is very sparse: its difference 2^{i^*} is large enough compared to $w(A) < 2^{i^*} + n\Delta$.

Given query T, we want to count the number of pairs (A', B') $(A' \subseteq A, B' \subseteq B)$ such that $w(A') + w(B') \leq T$. To do this, we enumerate $B' \subseteq B$, and consider three cases (the non-trivial case is Case 3, where $w(B')$ and $\sum_{j \in B'} 2^{j-1}$ are close to T):

- **Case 1:** $\sum_{j \in B'} 2^{j-1} \leq T - 2^{i^*} - (n + n^2)\Delta$.
  Then, for all $A' \subseteq A$, we have $w(A') + w(B') \leq w(A) + w(B') \leq (2^{i^*} + n\Delta) + (n^2\Delta + \sum_{j \in B'} 2^{j-1}) \leq T$. Hence B' contributes $2^{|A|}$ many pairs (A', B').
- **Case 2:** $\sum_{j \in B'} 2^{j-1} > T + n^2\Delta$.
  Then, for all $A' \subseteq A$, we have $w(A') + w(B') \geq w(B') \geq \sum_{j \in B'} 2^{j-1} - n^2\Delta > T$. Hence B' does not contribute any pairs (A', B').
- **Case 3:** otherwise, $\sum_{j \in B'} 2^{j-1} \in (T - 2^{i^*} - (n + n^2)\Delta, T + n^2\Delta]$.
  This interval has length $2^{i^*} + (n + n^2)\Delta + n^2\Delta \leq 2 \cdot 2^{i^*}$ by our choice of i^*. Since $\sum_{j \in B'} 2^{j-1}$ is a multiple of 2^{i^*} in this interval, it has at most two possibilities, namely $2^{i^*} \cdot \lfloor \frac{T-(n+n^2)\Delta}{2^{i^*}} \rfloor$ and $2^{i^*} \cdot \left(\lfloor \frac{T-(n+n^2)\Delta}{2^{i^*}} \rfloor + 1\right)$, and then B' is uniquely determined by the binary decomposition of $\sum_{j \in B'} 2^{j-1}$. For each possible B', we count the number of $A' \subseteq A$ such that $w(A') \leq T - w(B')$ using meet-in-middle (Lemma 3) with time complexity $O^*(2^{|A|/2}) = O^*(2^{i^*/2}) = O^*(\sqrt{\Delta})$ by the definition of i^*.

Note that in $O^*(1)$ time we can easily find the (at most two) subsets B' satisfying Case 3, and also count the total contribution of Case 1. Hence the overall time complexity is $O^*(\sqrt{\Delta})$. ◀

Using Lemma 7 we can solve Pigeonhole Equal Sums using binary search, in the same way as described in the last paragraph of Section 2. The running time is $O^*(\sqrt{\Delta})$. This finishes the proof of Lemma 4.

3.2 Large d case via subsampling

In this section we prove Lemma 5. Assume $2^{n/2} \le \Delta \le d < 2^n$, and Δ is known. We first use $d = \sum_{0 \le t < 2^n} \max\{0, f_t - 1\}$ (Equation (3)) to show that many subset sums t have large f_t, which then allows us to use subsampling to speed up the modular dynamic programming approach of [1, 3].

▶ **Lemma 8.** *There exists a $j \in \{0, 1, \ldots, n-1\}$ such that $\#\{t : f_t > 2^j\} > \frac{\Delta}{2^{j+1}n}$.*

Proof. By definition of d in Equation (3),

$$\Delta \le d = \sum_{t : f_t > 1} (f_t - 1) \le \sum_{0 \le j < n} \#\{t : 2^j < f_t \le 2^{j+1}\} \cdot (2^{j+1} - 1). \tag{9}$$

If the claimed inequality fails for all j, then

$$[\text{RHS of Equation (9)}] \le \sum_{0 \le j < n} \frac{\Delta}{2^{j+1}n} \cdot (2^{j+1} - 1) < \Delta,$$

a contradiction. ◀

Our algorithm enumerates all $j \in \{0, 1, \ldots, n-1\}$ (increasing the time complexity by a factor of $n = O^*(1)$), and from now on we assume j satisfies the inequality in Lemma 8. Define

$$h := 2^j + 1 \ge 2, \quad m := \left\lceil \frac{\Delta}{2^{j+1}n} \right\rceil > \frac{\Delta}{2hn}, \quad \text{and } X := \{t \in [2^n] : f_t \ge h\}. \tag{10}$$

Here we defined the set X of frequent subset sums only for the sake of analysis. By Lemma 8,

$$|X| \ge m. \tag{11}$$

Readers are encouraged to focus on the case of $h = 2$ and $m \ge \Omega^*(\Delta)$ (which is the hardest case for our algorithm) at first read.

We first describe the behavior of our algorithm: Let $p \in [P, 2P]$ be a uniformly random prime (for some parameter $2 \le P \le 2m$ to be determined later in the "Time complexity" paragraph). For each $r \in \mathbb{Z}_p$, define bin $B_r := \{S \subseteq [n] : w(S) \equiv r \pmod p\}$. The algorithm picks a random bin index $r^* \in \mathbb{Z}_p$, and subsamples $C \subseteq B_{r^*}$ by keeping each $S \in B_{r^*}$ with probability α independently (for some $0 < \alpha \le \frac{1}{2h}$ to be determined later in the "Success probability" paragraph). Finally, a pair of distinct $S, S' \in C$ with $w(S) = w(S')$ is reported (if exists).

Now we explain how to implement the algorithm above via dynamic programming (DP) similarly to [1, 3]. Build the DP table $D_{i,r} = \#\{S \subseteq [i] : w(S) \equiv r \pmod p\}$ (where $0 \le i \le n$ and $r \in \mathbb{Z}_p$) in $O^*(p)$ overall time via the transition $D_{i,r} = D_{i-1,r} + D_{i-1,(r-w_i) \bmod p}$ with initial values $D_{0,r} = \mathbf{1}[r = 0]$. This DP computes the size of every bin $|B_r| = D_{n,r}$. Furthermore, for any bin B_r and integer $k \in [|B_r|]$, we can report the rank-k set S in B_r (in lexicographical order, where larger indices are compared first) by backtracing in the DP table in $O^*(1)$ time. Then, in order to subsample a collection of sets $C \subseteq B_{r^*}$ at rate α, we can first subsample their ranks in $[|B_{r^*}|]$ (in near-linear time in the output size, see e.g., [10]), and then recover the actual sets by backtracing.

Success probability

We study how the frequent subset sums, $X = \{t : f_t \geq h\}$, are distributed to the bins modulo a random prime p, using an argument similar to [3]. Setting

$$k := \lceil \frac{m}{4P} \rceil, \tag{12}$$

the following lemma shows that the bin B_{r^*} receives at least k frequent subset sums, with $\Omega^*(1)$ probability.

▶ **Lemma 9.** *With at least $\Omega(1/n)$ probability over the choice of prime $p \in [P, 2P]$ and $r^* \in \mathbb{Z}_p$, there are at least k integers $t \in \mathbb{N}$ such that $\#\{S \in B_{r^*} : w(S) = t\} \geq h$.*

Proof. Since $|X| \geq m$ by Equation (11), we arbitrarily pick $X' \subseteq X$ with $|X'| = m$ for the sake of analysis. Let $c_{r,p} := \{t \in X' : t \equiv r \pmod p\}$. Then,

$$\begin{aligned}
\mathop{\mathbf{E}}_{p\in[P,2P]}\Big[\sum_{r\in\mathbb{Z}_p} c_{r,p}^2\Big] &= \sum_{x\in X', y\in X'} \mathop{\mathbf{Pr}}_{p\in[P,2P]}[p \mid x-y] \\
&\leq m + m^2 \cdot \frac{\log_P 2^n}{\Omega(P/\ln P)} \qquad \text{(by } |x-y| \leq 2^n \text{ and the density of primes)} \\
&\leq O(n \cdot m^2/P). \qquad \text{(by the assumption that } P \leq 2m)
\end{aligned}$$

Then by Markov's inequality, with 0.9 success probability over the choice of p, we have $\sum_{r\in\mathbb{Z}_p} c_{r,p}^2 \leq O(n \cdot m^2/P)$. Conditioned on this happening, by Cauchy–Schwarz inequality we have

$$\begin{aligned}
\sum_{r\in\mathbb{Z}_p} \mathbf{1}[c_{r,p} \geq \tfrac{m}{2p}] &\geq \frac{\left(\sum_{r\in\mathbb{Z}_p} \mathbf{1}[c_{r,p} \geq \frac{m}{2p}] \cdot c_{r,p}\right)^2}{\sum_{r\in\mathbb{Z}_p} c_{r,p}^2} \\
&\geq \frac{\left((\sum_{r\in\mathbb{Z}_p} c_{r,p}) - p \cdot \frac{m}{2p}\right)^2}{O(n \cdot m^2/P)} = \frac{(|X'| - m/2)^2}{O(n \cdot m^2/P)} = \frac{(m/2)^2}{O(n \cdot m^2/P)} = \Omega(P/n),
\end{aligned}$$

and hence, by our choice of $k = \lceil \frac{m}{4P} \rceil \leq \lceil \frac{m}{2p} \rceil$,

$$\mathop{\mathbf{Pr}}_{r^*\in\mathbb{Z}_p}[c_{r^*,p} \geq k] \geq \mathop{\mathbf{Pr}}_{r^*\in\mathbb{Z}_p}[c_{r^*,p} \geq \tfrac{m}{2p}] \geq \frac{\Omega(P/n)}{p} = \Omega(1/n).$$

Conditioned on $c_{r^*,p} \geq k$ happening, we have at least k integers $t \in X' \subseteq X$ such that $t \equiv r^* \pmod p$. By definitions of B_{r^*} and X, this implies that there are at least k integers $t \in \mathbb{N}$ such that $\#\{S \in B_{r^*} : w(S) = t\} \geq h$, with overall success probability at least $0.9 \cdot \Omega(1/n) = \Omega(1/n)$ over the choice of p and r^*. ◀

Recall our algorithm subsamples $C \subseteq B_{r^*}$ at rate $\alpha \in (0, \frac{1}{2h}]$, and fails iff $w(S)$ are distinct for all $S \in C$. The failure probability of this step can be derived from the following lemma:

▶ **Lemma 10.** *Let B' be a collection of kh colored balls ($h \geq 2, k \geq 1$), with exactly h balls of color i for each color $i \in [k]$. Let $C' \subseteq B'$ be an i.i.d. subsample at rate $\alpha \in [0, \frac{1}{2h}]$. Then C' contains distinct colors with at most $\exp(-kh(h-1)\alpha^2/4)$ probability.*

Proof. For each color $i \in [k]$, by Bernoulli's inequality, the probability that C' includes exactly two balls of color i is $\binom{h}{2}\alpha^2(1-\alpha)^{h-2} \geq \binom{h}{2}\alpha^2(1-(h-2)\alpha) \geq \binom{h}{2}\alpha^2/2$. Hence, the probability that C' includes at most one ball of every color $i \in [k]$ is at most $\left(1-\binom{h}{2}\alpha^2/2\right)^k \leq \exp\left(-k\binom{h}{2}\alpha^2/2\right) = \exp(-kh(h-1)\alpha^2/4)$. ◀

We think of each set $S \in B_{r^*}$ as a ball of color $w(S)$, and apply Lemma 10 to the k integers (colors) $t \in \mathbb{N}$ ensured by Lemma 9, each having at least h sets (balls) $S \in B_{r^*}$ with $w(S) = t$. We set the sample rate to be

$$\alpha := \frac{1}{2h\sqrt{k}} \le \frac{1}{2h}. \tag{13}$$

Then the failure probability of the subsampling step is at most

$$\exp(-kh(h-1)\alpha^2/4) = \exp(-\tfrac{h-1}{16h}) \le \exp(-1/32).$$

Overall, the probability that the algorithm successfully finds a solution is at least $\Omega(1/n) \cdot (1 - \exp(-1/32)) \ge \Omega(n^{-1})$.

Time complexity

The mod-p DP runs in $O^*(p) \le O^*(P)$ time. Since the bins have total size $\sum_{r\in\mathbb{Z}_p} |B_r| = 2^n$, the chosen bin B_{r^*} has expected size $\mathbf{E}_{r^*\in\mathbb{Z}_p}[|B_{r^*}|] = 2^n/p \le 2^n/P$, and hence the subsample $C \subseteq B_{r^*}$ has expected size $\mathbf{E}[|C|] \le \alpha 2^n/P$. To detect a solution $S, S' \in C$ with $w(S) = w(S')$, we simply sort C in near-linear time. Hence the total expected running time is $O^*(P + \alpha 2^n/P)$. By Markov's inequality, with probability at least $1 - n^{-10}$, the algorithm terminates in $O^*(P + \alpha 2^n/P)$ time. By a union bound, the algorithm successfully finds a solution in time $O^*(P + \alpha 2^n/P)$ with probability at least $\Omega(n^{-1}) - n^{-10} \ge \Omega(n^{-1})$. This success probability can be boosted to 0.99 by repeating the algorithm $O(n)$ times.

Recall from Equations (12) and (13) that $\alpha = \frac{1}{2h\sqrt{k}} = \frac{1}{2h\sqrt{\lceil m/4P\rceil}} \le \frac{\sqrt{P}}{h\sqrt{m}}$, so the run time is (ignoring poly(n) factors)

$$P + \alpha 2^n/P \le P + \frac{2^n}{h\sqrt{mP}}.$$

Recall $h = 2^j + 1$ (where $0 \le j \le n-1$) and $m = \lceil \frac{\Delta}{2^{j+1}n} \rceil$, and hence $hm < h(1 + \frac{\Delta}{2^{j+1}n}) \le h + \frac{\Delta}{n} < (2^{n-1}+1) + \frac{2^n}{n} \le 2^n$ (assuming $n \ge 3$). Now we set

$$P := 2m \cdot \min\left\{1, \left(\frac{2^n}{hm^2}\right)^{2/3}\right\},$$

and we first need to verify the requirement $2 \le P \le 2m$ introduced earlier: The upper bound is obvious. To see the lower bound, note that $2m \ge 2$ and $2m \cdot \left(\frac{2^n}{hm^2}\right)^{2/3} = 2\left(\frac{2^{2n}}{h^2 m}\right)^{1/3} \ge 2\left(\frac{2^{2n}}{(hm)^2}\right)^{1/3} \ge 2$ (using the inequality $hm \le 2^n$ we just showed).

Hence, the overall running time is at most (ignoring poly(n) factors)

$$\begin{aligned}
P + \frac{2^n}{h\sqrt{mP}} &\le 2m\left(\frac{2^n}{hm^2}\right)^{2/3} + \frac{2^n}{h\sqrt{m\cdot 2m}} \cdot \max\left\{1, \left(\frac{hm^2}{2^n}\right)^{1/3}\right\} \\
&= 2\cdot\frac{2^{2n/3}}{h^{2/3}m^{1/3}} + \frac{1}{\sqrt{2}}\max\left\{\frac{2^n}{hm}, \frac{2^{2n/3}}{h^{2/3}m^{1/3}}\right\} \\
&\le O\left(\frac{2^{2n/3}}{h^{2/3}m^{1/3}} + \frac{2^n}{hm}\right) \\
&\le O^*\left(\frac{2^{2n/3}}{h^{1/3}\Delta^{1/3}} + \frac{2^n}{\Delta}\right) && \text{(by } hm > \tfrac{\Delta}{2n} \text{ from Equation (10))} \\
&\le O^*\left(\frac{2^{2n/3}}{\Delta^{1/3}}\right). && \text{(by } h > 1 \text{ and the assumption that } \Delta \ge 2^{n/2})
\end{aligned}$$

This finishes the proof of Lemma 5.

4 A polynomial-space algorithm

We now consider poly(n)-space algorithms for Pigeonhole Equal Sums. The straightforward binary search approach (described at the end of Section 2) can be adapted to run in $O^*(2^n)$ time and poly(n) space: instead of using meet-in-middle (Lemma 3, which requires large space), we count the number of valid subsets $S \subseteq [n]$ by brute force in $O^*(2^n)$ time and only poly(n) space.

We improve this $O^*(2^n)$ running time using the ideas from earlier sections. Again, consider two cases depending on whether parameter d from Equation (3) is small or large.

▶ **Lemma 11.** *Given parameter $\Delta \le 2^n/(3n^2)$, Pigeonhole Equal Sums with $d \le \Delta$ can be solved deterministically in* poly(n) *space and $O^*(\Delta)$ time.*

Proof Sketch. The proof is almost the same as Lemma 4 (see Section 3.1), with the only difference in Case 3 from the proof of Lemma 7: instead of using meet-in-middle, here we count the valid subsets $A' \subseteq A$ by brute force in $O^*(2^{|A|}) = O^*(2^{i^*}) = O^*(\Delta)$ time and only poly(n) space. ◀

To solve the large d case, we need the low-space element distinctness algorithm by Beame, Clifford, and Machmouchi [7] (generalized in [6], and with a non-standard assumption removed by [11, 16]). This algorithm was also previously used for Subset Sum [6] and Equal Sums [17]. The following statement can be inferred from [11, Section 4.2 (proof of Theorem 1.1)].

▶ **Theorem 12** (Low-space Element Distinctness, [7, 6, 11])**.** *Given random access to an integer list $a_1, \dots, a_N$ (where $a_i \in [\text{poly}(N)]$) that contains at least one pair $(i, j) \in [N] \times [N]$ with $a_i = a_j, i \ne j$, there is a randomized algorithm that reports such a pair using* poly log N *working memory and*

$$O\left(\frac{N\sqrt{F_2}}{F_2 - N} \cdot \text{poly}\log N\right)$$

time, where $F_2 = \sum_{i=1}^{N} \sum_{j=1}^{N} \mathbf{1}[a_i = a_j] \in [N + 2, N^2]$.[3]

▶ **Lemma 13.** *Given parameter $1 \le \Delta \le 2^n$, Pigeonhole Equal Sums with $d \ge \Delta$ can be solved in $O^*(2^{1.5n}/\Delta)$ time and* poly(n) *space by a randomized algorithm.*

Proof. Apply Theorem 12 to the list $\{w(A)\}_{A \subseteq [n]}$ of length $N = 2^n$ and we obtain a pair of distinct $A, A' \subseteq [n]$ with $w(A) = w(A')$ as desired. The space complexity is poly log$(2^n) =$ poly(n). To analyze the time complexity, note that

$$F_2 - 2^n = \sum_{A \subseteq [n]} \sum_{\substack{B \subseteq [n] \\ B \ne A}} \mathbf{1}[w(A) = w(B)] = \sum_{0 \le t < 2^n} f_t(f_t - 1) \ge \sum_{0 \le t < 2^n} \max\{0, f_t - 1\} \overset{\text{Eq. (3)}}{=} d \ge \Delta,$$

so the time bound is (ignoring poly(n) factors)

$$\frac{2^n\sqrt{F_2}}{F_2 - 2^n} < \frac{2^{0.5n}F_2}{F_2 - 2^n} = 2^{0.5n}\left(1 + \frac{2^n}{F_2 - 2^n}\right) \le 2^{0.5n}\left(1 + \frac{2^n}{\Delta}\right) \le \frac{2 \cdot 2^{1.5n}}{\Delta}$$

as claimed. ◀

[3] We have $F_2 \ge N + 2$ due to the following $(N + 2)$ pairs: $(1, 1), (2, 2), \dots, (N, N)$ and $(i, j), (j, i)$, where $a_i = a_j$ $(i \ne j)$.

Combining the two lemmas gives the desired result.

Proof of Theorem 2. Set $\Delta = 2^{0.75n}$ so that the two time bounds in Lemma 11 and Lemma 13 are balanced to $O^*(2^{0.75n})$. Given an instance of Pigeonhole Equal Sums (with unknown d), we run both algorithms in parallel, and return the answer of whichever terminates first. ◀

5 Open problems

Allcock et al. [1] proposed a modular variant of the Pigeonhole Equal Sums problem: given integers $w_1, \ldots, w_n$ and a modulus $m \leq 2^n - 1$, find two distinct subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i \equiv \sum_{i \in B} w_i \pmod{m}$. They obtained a $O^*(2^{n/2})$-time algorithm for this problem. Can this result be improved as well?

Can we obtain faster algorithms for other problems in PPP (e.g., [5, 21])?

Fully Dynamic Strongly Connected Components in Planar Digraphs

Adam Karczmarz

University of Warsaw, Poland

Abstract

In this paper we consider maintaining strongly connected components (SCCs) of a directed planar graph subject to edge insertions and deletions. We show a data structure maintaining an implicit representation of the SCCs within $\widetilde{O}(n^{6/7})$ worst-case time per update. The data structure supports, in $O(\log^2 n)$ time, reporting vertices of any specified SCC (with constant overhead per reported vertex) and aggregating vertex information (e.g., computing the maximum label) over all the vertices of that SCC. Furthermore, it can maintain global information about the structure of SCCs, such as the number of SCCs, or the size of the largest SCC.

To the best of our knowledge, no fully dynamic SCCs data structures with sublinear update time have been previously known for any major subclass of digraphs. Our result should be contrasted with the $n^{1-o(1)}$ amortized update time lower bound conditional on SETH, which holds even for dynamically maintaining whether a general digraph has more than two SCCs.

1 Introduction

Two vertices of a directed graph $G = (V, E)$ are called strongly connected if they can reach each other using paths in G. Pairwise strong connectivity is an equivalence relation and the strongly connected components (SCCs) of G are its equivalence classes. Computing the SCCs is among the most classical and fundamental algorithmic problems on digraphs and there exists a number of linear-time algorithms for that [14, 33, 35]. Therefore, it is no surprise that *maintaining* SCCs has been one of the most actively studied problems on *dynamic directed graphs* [1, 2, 3, 4, 5, 7, 8, 18, 23, 25, 30, 31].

When maintaining the strongly connected components, the information we care about may vary. First, we could be interested in efficiently answering *pairwise* strong connectivity queries: given $u, v \in V$, decide whether u and v are strongly connected. Pairwise strong connectivity queries, however, cannot easily provide any information about the *global* structure of SCCs (such as the number of SCCs, the size of the largest SCC). Neither they enable, e.g., listing the vertices strongly connected to some $u \in V$. This is why, in the following, we distinguish between *dynamic pairwise strong connectivity* and *dynamic SCCs* data structures which

provide a more global view. In particular, all the data about the SCCs can be easily accessed if the SCCs are maintained *explicitly*, e.g., if the SCC identifier of every vertex is stored at all times and explicitly updated.

1.1 Previous work

In the following, let $n = |V|$ and $m = |E|$. Dynamic graph data structures are traditionally studies in *incremental*, *decremental* or *fully dynamic* settings, which permit the graph to evolve by either only edge insertions, only deletions, or both, respectively. A decremental data structure maintaining SCCs with near-optimal total update time is known [5]. Very recently, a deterministic data structure with $m^{1+o(1)}$ total update time has been obtained also for the incremental setting [8]. Both these state-of-the art data structures maintain the SCCs explicitly.

The *fully dynamic* variant – which is our focus in this paper – although the most natural, has been studied the least. First of all, there is strong evidence that a non-trivial dynamic SCCs data structure for sparse graphs cannot exist. If the SCCs have to be maintained explicitly, then a single update can cause a rather dramatic $\Omega(n)$-sized amortized change in the set of SCCs[1]. As a result, an explicit update may be asymptotically as costly as recomputing SCCs from scratch. This argument – applicable also for maintaining *connected components* of an undirected graph – does not exclude the possibility of maintaining an *implicit* representation of the SCCs in sublinear time, though. After all, there exist very efficient fully dynamic connectivity data structures, e.g., [20, 21, 38], typically maintaining also an explicit spanning forest which allows retrieving any "global" component-wise information one can think of rather easily. However, Abboud and Vassilevska Williams [1] showed that even for maintaining a single-bit information whether G has *more than two SCCs*, a data structure with $O(n^{1-\epsilon})$ amortized time is unlikely, as it would break the Orthogonal Vectors conjecture implied by the SETH [22, 37].[2] This considerably limits the possible global information about the SCCs that can be maintained within sublinear time per update.

For denser graphs, Abboud and Vassilevska Williams [1] also proved that maintaining essentially any (even pairwise) information about SCCs dynamically within truly subquadratic update time has to rely on fast matrix multiplication. And indeed, that pairwise strong connectivity can be maintained this way follows easily from the dynamic matrix inverse-based dynamic *st*-reachability data structures [36, 32]. More recently, we [25] showed that in fact SCCs can be maintained explicitly in $O(n^{1.529})$ worst-case time per update. They also proved that maintaining whether G has just a single SCC (*dynamic SC*) is easier[3] and can be achieved within $O(n^{1.406})$ worst-case time per update. Both these bounds are tight conditional on the appropriate variants [36] of the OMv conjecture [19].

In summary, the complexity of maintaining SCCs in general directed graphs is rather well-understood now. In partially dynamic settings, the known bounds are near optimal unconditionally, whereas in the fully dynamic setting, the picture appears complete unless some popular hardness conjectures are proven wrong. In particular, for general sparse digraphs, no (asymptotically) non-trivial fully dynamic SCCs data structure can exist.

---

[1] Consider a directed cycle and switching its arbitrary single edge on and off.

[2] In [1], a conditional lower bound of the same strength is also derived for the dynamic #SSR problem where the goal is to dynamically count vertices reachable from a source $s \in V$.

[3] Interestingly, the SETH-based lower bound of [1] does not apply to the dynamic SC problem.

Planar graphs. It is thus natural to ask whether non-trivial dynamic SCCs data structures are possible if we limit our attention to some significant class of sparse digraphs. And indeed, this question has been partially addressed for *planar digraphs* in the past. Since pairwise s,t-strong connectivity queries reduce to two s,t-reachability queries, the known planar dynamic reachability data structures [9, 34] imply that sublinear ($\widetilde{O}(n^{2/3})$ or $\widetilde{O}(\sqrt{n})$-time, depending on whether embedding-respecting insertions are required) updates/queries are possible for *pairwise* strong connectivity. Another trade-off for dynamic pairwise strong connectivity has been showed by Charalampopoulos and Karczmarz [6]. Namely, they showed a fully dynamic data structure for planar graphs with $\widetilde{O}(n^{4/5})$ worst-case update time that can produce an identifier s_v of an SCC of a given query vertex v in $O(\log^2 n)$ time. Whereas this is slightly more general[4], it still not powerful enough to enable efficiently maintaining any of the global data about the SCCs of a dynamic planar digraph such as the SCCs count.

To the best of our knowledge, the question whether a more robust – that is, giving a more "global" perspective on the SCCs beyond only supporting pairwise queries – fully dynamic SCCs data structure for planar digraphs (or digraphs from any other interesting class) with sublinear update time is possible has not been addressed before.

1.2 Our results

In this paper, we address the posed question in the case of planar directed graphs. Specifically, our main result is a dynamic SCCs data structure summarized by the following theorem.

▶ **Theorem 1.** *Let G be a planar digraph subject to planarity-preserving edge insertions and deletions. There exists a data structure maintaining the strongly connected components of G implicitly in $\widetilde{O}(n^{6/7})$ worst-case time per update. Specifically:*

- *The data structure maintains the number of SCCs and the size of the largest SCC in G.*
- *For any query vertex v, in $O(\log^2 n)$ time the data structure can compute the size of the SCC of v, and enable reporting the elements of the SCC of v in $O(1)$ worst-case time per element.*

In particular, Theorem 1 constitutes the first known fully dynamic SCCs data structure with sublinear update time for any significant class of sparse digraphs. It also shows that the conditional lower bound of [1] does not hold in planar digraphs.

The data structure of Theorem 1 is deterministic and does not require the edge insertions to respect any fixed embedding of the graph (this also applies to side results discussed below). Obtaining more efficient data structures for fully dynamic embedding-respecting updates is an interesting direction (see, e.g., [9]) that is beyond the scope of this paper.

Related problems. Motivated by the discrepancies between the known bounds for dynamic SCCs and dynamic SC in general digraphs (both from the lower- [1] and upper bounds [25] perspective), we also complement Theorem 1 with a significantly simpler and faster data structure suggesting that the dynamic SC might be easier (than dynamic SCCs) in planar digraphs as well.[5]

[4] Than answering pairwise strong connectivity queries. Using the SCC-identifiers, one can, e.g., partition any k vertices of G into strongly connected classes in $\widetilde{O}(k)$ time, whereas using pairwise queries this requires $\Theta(k^2)$ queries.

[5] Clearly, one could use Theorem 1 for dynamic SC as well.

▶ **Lemma 2.** *Let G be a planar digraph subject to planarity-preserving edge insertions and deletions. One can maintain whether G has a single SCC in $\widetilde{O}(n^{2/3})$ worst-case time per update.*

Similarly, one could ask how *dynamic #SSR* (i.e., counting vertices reachable from a single source) relates to dynamic SCCs in planar digraphs. Especially since:

(1) in general directed graphs, dynamic SCCs and dynamic #SSR currently have matching lower- [1, 36] and upper bounds [25, 32] (up to polylogarithmic factors);

(2) the former problem is at least as hard as the latter in the sense that dynamic #SSR reduces to dynamic SCCs in general graphs easily[6], whereas an opposite reduction is not known.

Unfortunately, the aforementioned reduction of dynamic #SSR to dynamic SCCs breaks planarity rather badly. Interestingly, the *path net* technique we develop to obtain Theorem 1 does not seem to work for counting "asymmetric" reachabilities from a single source.

Nevertheless, the Voronoi diagram machinery developed for computing the diameter of a planar graph [15] almost immediately yields a more efficient data structure for dynamic #SSR in planar digraphs with $\widetilde{O}(n^{4/5})$ update time. We provide the details of that construction in the full version of this extended abstract.

It is worth noting that Voronoi diagrams-based techniques (as developed for distance oracles [16]) have been used in the pairwise strong connectivity data structure [6]. However, as we discuss later on, it is not clear how to apply those for the dynamic SCCs problem. This is why Theorem 1 relies on a completely different path net approach developed in this paper.

1.3 Organization

We review some standard planar graph tools in Section 2. Then, as a warm-up, we show the data structure for dynamic SC in Section 3. In Section 4 we define a path net data structure and show how it can be used to obtain a dynamic SCCs data structure. Finally, in Section 5 we describe the path net data structure. Due to space limit, some details and proofs are deferred to the full version.

2 Preliminaries

In this paper we deal with *directed* graphs. We write $V(G)$ and $E(G)$ to denote the sets of vertices and edges of G, respectively. We omit G when the graph in consideration is clear from the context. A graph H is a *subgraph* of G, which we denote by $H \subseteq G$, iff $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. We write $e = uv \in E(G)$ when referring to edges of G. By G^{R} we denote G with edges reversed.

A sequence of vertices $P = v_1 \dots v_k$, where $k \geq 1$, is called an $s \to t$ path in G if $s = v_1$, $v_k = t$ and there is an edge $v_i v_{i+1}$ in G for each $i = 1, \dots, k-1$. We sometimes view a path P as a subgraph of G with vertices $\{v_1, \dots, v_k\}$ and (possibly zero) edges $\{v_1v_2, \dots, v_{k-1}v_k\}$. For convenience, we sometimes consider a single edge uv a path. If P_1 is a $u \to v$ path and P_2 is a $v \to w$ path, we denote by $P_1 \cdot P_2$ (or simply P_1P_2) a path obtained by concatenating P_1 with P_2. A vertex $t \in V(G)$ is *reachable* from $s \in V(G)$ if there is an $s \to t$ path in G.

[6] Consider the graph G' obtained from G by adding a supersink t with a single outgoing edge ts and incoming edges vt for all $v \in V$. Then $v \in V$ is reachable from s in G iff s and v are strongly connected in G'. See also [36].

Planar graph toolbox. An *r-division* [13] $\mathcal{R}$ of a planar graph, for $r \in [1, n]$, is a decomposition of the graph into a union of $O(n/r)$ pieces P, each of size $O(r)$ and with $O(\sqrt{r})$ boundary vertices (denoted ∂P), i.e., vertices shared with some other piece of $\mathcal{R}$. We denote by $\partial\mathcal{R}$ the set $\bigcup_{P\in\mathcal{R}} \partial P$. If additionally G is plane-embedded, all pieces are connected, and the boundary vertices of each piece P of the r-division $\mathcal{R}$ are distributed among $O(1)$ faces of P that contain the vertices from ∂P *exclusively* (also called holes of P), we call $\mathcal{R}$ an *r-division with few holes*. Klein [27] showed that an r-division with few holes of a triangulated graph can be computed in linear time.

Fully dynamic r-divisions. Many dynamic algorithms for planar graphs maintain r-divisions and useful piecewise auxiliary data structures under dynamic updates. Let us slightly generalize the definition of an r-division with few holes to non-planar graphs by dropping the requirement that G as a whole is planar but retaining all the other requirements (in particular, the individual pieces are plane-embedded).

▶ **Theorem 3** ([6, 28, 34]). *Let $G = (V, E)$ be a weighted planar graph that undergoes edge deletions and edge insertions (assumed to preserve the planarity of G). Let $r \in [1, n]$.*

There is a data structure maintaining an r-division with few holes $\mathcal{R}$ of some G^+, where G^+ can be obtained from G by adding edges[7]*, such that each piece $P \in \mathcal{R}$ is accompanied with some auxiliary data structures that can be constructed in $T(r)$ time given P and use $S(r)$ space.*

The data structure uses $O\left(n + \frac{n}{r} \cdot S(r)\right)$ space and can be initialized in $O\left(n + \frac{n}{r} \cdot T(r)\right)$ time. After each edge insertion/deletion, it can be updated in $O(r + T(r))$ worst-case *time.*

3 Fully dynamic SC data structure

To illustrate the general approach and introduce some of the concepts used for obtaining Theorem 1, in this section we first prove Lemma 2. That is, we show that the information whether a planar graph G is strongly connected can be maintained in $\widetilde{O}(n^{2/3})$ time per update.

We build upon the following general template used previously for designing fully dynamic data structures supporting reachability, strong connectivity, and shortest paths queries in planar graphs, e.g., [34, 28, 11, 6, 24]. As a base, we will maintain dynamically an r-division with few holes $\mathcal{R}$ of G using Theorem 3 with auxiliary piecewise data structures to be fixed later. Intuitively, as long as the piecewise data structures are powerful enough to allow recomputing the requested graph property (e.g., strong connectivity, shortest path between a fixed source/target pair) while spending $r^{1-\epsilon}$ time per piece, for some choice of r we get a sublinear update bound of $\widetilde{O}(n/r^{\epsilon} + r + T(r))$. For example, if $T(r) = O(r^{9.9})$ and $\epsilon = 0.1$, for $r = n^{0.1}$ we get $\widetilde{O}(n^{0.99})$ worst-case update time bound.

Reachability certificates. Subramanian [34] described *reachability certificates* that sparsify reachability between a subset of vertices lying on $O(1)$ faces of a plane digraph G into a (non-necessarily planar) digraph of size near-linear in the size of the subset in question. Formally, we have the following.

[7] Note that G^+ need not be planar.

▶ **Lemma 4** ([34]). *Let H be a plane digraph with a distinguished set $\partial H \subseteq V(H)$ lying on some $O(1)$ faces of H. There exists a directed graph X_H, where $\partial H \subseteq V(X_H)$, of size $\widetilde{O}(|\partial H|)$ satisfying the following property: for any $u, v \in \partial H$, a path $u \to v$ exists in H if and only if there exists a $u \to v$ path in X_H. The graph X_H can be computed in $\widetilde{O}(|H|)$ time.*

▶ Remark 5. For Lemma 4 to hold, it is enough that ∂H lies on $O(1)$ Jordan curves in the plane, each of them having the embedding of H entirely (but not strictly) on one side of the curve. In particular, it is enough that ∂H lies on $O(1)$ faces of some plane supergraph H' with $H \subseteq H'$.

Roughly speaking, Subramanian [34] uses reachability certificates as auxiliary data structures in Theorem 3 in order to obtain a fully dynamic reachability data structure. Crucially, the union of the piecewise certificates preserves pairwise reachability between the boundary vertices $\partial\mathcal{R}$, or more formally (see e.g. [6] for a proof):

▶ **Lemma 6.** *For any $u, v \in \partial\mathcal{R}$, u can reach v in G if and only if u can reach v in $X = \bigcup_{P\in\mathcal{R}} X_P$.*

Strong connectivity data structure. The union of certificates X preserves reachability, and thus strong connectivity between the vertices $\partial\mathcal{R} := \bigcup_{P\in\mathcal{R}} \partial P$. As a result, if G is strongly connected, then so is $\partial\mathcal{R}$ in X. But the reverse implication might not hold. It turns out that for connected graphs, to have an equivalence, it is enough to additionally maintain, for each piece P, whether P is strongly connected conditioned on whether ∂P is strongly connected in G.

In the following, we give a formal description of the data structure. As already said, the data structure maintains a dynamic r-division $\mathcal{R}^+$ of a supergraph G^+ of G (i.e., the input graph), as given by Theorem 3. Since $G \subseteq G^+$, the pieces $\{P^+ \cap G : P^+ \in \mathcal{R}^+\}$ induce an r-division $\mathcal{R}$ of G; however, the boundary ∂P of a piece $P \in \mathcal{R}$ does not necessarily lie on $O(1)$ faces of P, so $\mathcal{R}$ is not technically an r-division with few holes. Nevertheless, ∂P still lies on $O(1)$ faces of a plane supergraph P^+ of P that do not contain vertices outside ∂P. Consequently, by Remark 5, we can still use Lemma 4 to construct a sparse reachability certificate for the piece $P \in \mathcal{R}$. For obtaining Lemma 2, we do not require anything besides beyond that, so for simplicity and wlog. we can assume we work with $\mathcal{R}$ instead of $\mathcal{R}^+$.

While $\mathcal{R}$ evolves, each piece P is accompanied with a reachability certificate X_P of Lemma 4. Note that since $|\partial P| = O(\sqrt{r})$, X_P has size $\widetilde{O}(\sqrt{r})$ and can be constructed in $\widetilde{O}(r)$ time. Moreover, for each P, let $C_{\partial P}$ be a directed simple cycle on the vertices ∂P. We additionally store the (1-bit) information whether the graph $P \cup C_{\partial P}$ is strongly connected. Clearly, this can be computed in $O(|P|) = O(r)$ time. All the accompanying data structures of a piece $P \in \mathcal{R}$ can be thus constructed in $\widetilde{O}(r)$ time. Therefore, by Theorem 3, they are maintained in $\widetilde{O}(r)$ time per update.

Finally, in a separate data structure, we maintain whether G is connected (in the undirected sense). This can be maintained within $n^{o(1)}$ worst-case update time deterministically even in general graphs [17]; in our case, also a less involved data structure such as [12] would suffice.

After $\mathcal{R}$ and the accompanying data structures are updated, strong connectivity of G can be verified as follows. First of all, the union X of all X_P, $P \in \mathcal{R}$, is formed. Note that we can test whether the vertices $\partial\mathcal{R}$ are strongly connected in X in $O(|X|) = \widetilde{O}(n/\sqrt{r})$ time by computing the strongly connected components $\mathcal{S}_X$ of X using any classical linear time algorithm. If G is not connected, or $\partial\mathcal{R}$ is not strongly connected in X, we declare G not strongly connected. If, on the other hand, $\partial\mathcal{R}$ is strongly connected in X, we simply

check whether $P \cup C_{\partial P}$ is strongly connected for each $P \in \mathcal{R}$ and if so, declare G strongly connected. This takes $O(n/r)$ time. Thus, testing strong connectivity takes $\widetilde{O}(n/\sqrt{r})$ time. The following lemma establishes the correctness.

▶ **Lemma 7.** *G is strongly connected if and only if G is connected, the vertices $\partial\mathcal{R}$ are strongly connected in X, and for all $P \in \mathcal{R}$, $P \cup C_{\partial P}$ is strongly connected.*

Proof. First suppose that G is strongly connected. Then, G is clearly connected. Moreover, by Lemma 6, $\partial\mathcal{R}$ is strongly connected in X. For contradiction, suppose that for some $P \in \mathcal{R}$ and $u, v \in V(P)$, u cannot reach v in $P \cup C_{\partial P}$. By strong connectivity of G, there exists some path $Q = u \to v$ in G. Since u cannot reach v in P, Q is not fully contained in P. As a result, Q can be expressed as $Q_1 \cdot R \cdot Q_2$, where $Q_1 = u \to a, Q_2 = b \to v$ are fully contained in P, and $a, b \in \partial P$. But there is a path $Z = a \to b$ in $C_{\partial P}$, so there is a $u \to v$ path $Q_1 \cdot Z \cdot Q_2$ in $P \cup C_{\partial P}$, a contradiction.

Now consider the " $\Longleftarrow$ " direction. Suppose G is connected, the vertices $\partial\mathcal{R}$ are strongly connected in X, and for all $P \in \mathcal{R}$, $P \cup C_{\partial P}$ is strongly connected. By Lemma 6, $\partial\mathcal{R}$ is strongly connected in G. Consider any $P \in \mathcal{R}$ and let $x, y \in V(P)$. We first prove that there exists a path $x \to y$ in G. Indeed, if an $x \to y$ path exists in P, it also exists in G. Otherwise, since $P \cup C_{\partial P}$ is strongly connected, there exists a path $Q = x \to y$ in $P \cup C_{\partial P}$ that can be expressed as $Q_1 \cdot R \cdot Q_2$, where $Q_1 = x \to a$ and $Q_2 = b \to y$ are fully contained in P and $a, b \in \partial P$. But since $a, b \in \partial\mathcal{R}$, by strong connectivity of $\partial\mathcal{R}$, there exists a path $R' = a \to b$ in G. Since $Q_1, Q_2 \subseteq G$, $Q_1 \cdot R' \cdot Q_2$ is an $x \to y$ path in G.

Now take arbitrary $u, v \in V(G)$. If there exists a piece in $\mathcal{R}$ containing both u and v, then we have already proved that there exists a path $u \to v$ in G. Otherwise, let P_u, P_v, $P_u \neq P_v$, be some pieces of $\mathcal{R}$ containing u, v, respectively. We have $P_u \neq G$ and $P_v \neq G$. Since G is connected, P_u has at least one boundary vertex $a \in \partial P_u$. Similarly, P_v has at least one boundary vertex $b \in \partial P_v$. We have proved that there exist paths $u \to a$ and $b \to v$ in G. But also $a, b \in \partial\mathcal{R}$, by the strong connectivity of $\partial\mathcal{R}$, there exists a path $a \to b$ in G as well. We conclude that there exists a path $u \to v$ in G. Since u, v were arbitrary, G is indeed strongly connected. ◀

The worst-case update time of the data structure is $\widetilde{O}(r + n/\sqrt{r}) + n^{o(1)}$. By setting $r = n^{2/3}$, we obtain Lemma 2.

4 Dynamic strongly connected components

The approach we take for maintaining strong connectivity in planar graphs does not easily generalize even to dynamic SCCs counting. This is the case for the following reason. Even if the piece P is fixed (static), there can be possibly an exponential number of different assignments of the vertices ∂P to the SCCs in G (when the other pieces are subject to changes), whereas for dynamic SC, a non-trivial situation arises only when all of ∂P lies within a single SCC. In order to achieve sublinear update time, for any assignment we need to be able to count the SCCs fully contained in P in time sublinear in r after preprocessing P in only *polynomial* (and not exponential) time.

The following notion will be crucial for all our developments.

▶ **Definition 8.** *Let $P \in \mathcal{R}$, and let $A \subseteq \partial P$. A* path net $\Pi_P(A)$ *induced by A is the set of vertices of P that lie on some directed path in P connecting some two elements of A.*

In other words, the path net $\Pi_P(A)$ contains vertices $v \in V(P)$ such that v can reach A and can be reached from A in P. We call a path net $\Pi_P(A)$ *closed* if $A = \Pi_P(A) \cap \partial P$, that is, there are no boundary vertices of P outside A that can reach and can be reached from A.

The following key lemma relates a piece's path net to the SCCs of G.

▶ **Lemma 9.** *Let S be an SCC of G containing at least one boundary vertex of P, i.e., $S \cap \partial P \neq \emptyset$. Then the path net $\Pi_P(S \cap \partial P)$ is closed and equals $S \cap V(P)$.*

Proof. Let us first argue that $\Pi_P(S \cap \partial P)$ is closed. If it was not, there would exist $b \in \partial P \setminus S$ such that there exist paths $b \to (S \cap \partial P)$ and $(S \cap \partial P) \to b$ in P. It follows that b can reach and be reached from S in G, i.e., b is strongly connected with S. Hence, $b \in S$, a contradiction.

Let $v \in \Pi_P(S \cap \partial P)$. Since v can reach and can be reached from $S \cap \partial P$ in P, then it is indeed strongly connected with S in G, since the vertices S are strongly connected in G. So $v \in S \cap V(P)$.

Now let $v \in S \cap V(P)$. Pick any $b \in S \cap \partial P$ (possibly $b = v$ if $v \in \partial P$). There exists paths $R = v \to b$ and $Q = b \to v$ in G. Note that R has some prefix $R_1 = v \to a$ that is fully contained in P and $a \in \partial P$. Similarly, Q has a suffix $Q_1 = c \to v$ that is fully contained in P and $c \in \partial P$. Since there exists paths $v \to a$, $a \to b$, $b \to c$, $c \to v$ in G, vertices a, b, c are strongly connected in G. So $a, c \in S \cap \partial P$. The paths R_1, Q_1 certify that v can be reached from and can reach $S \cap \partial P$ in P. Therefore, $v \in \Pi_P(S \cap \partial P)$ as desired. ◀

If an SCC S is as in Lemma 9, then since the vertices ∂P might be shared with other pieces of $\mathcal{R}$, $\Pi_P(S \cap \partial P) \setminus \partial P$ constitutes the vertices of S contained *exclusively in the piece P*. As there are only $\widetilde{O}(n/\sqrt{r})$ boundary vertices through all pieces, their affiliation to the SCCs of G can be derived from the (SCCs of the) certificate graph $X = \bigcup_{P \in \mathcal{R}} X_P$ (defined and maintained as in Section 3), i.e., they may be handled efficiently separately. Consequently, being able to efficiently aggregate labels, or report the elements, of the sets of the form $\Pi_P(A) \setminus \partial P$ (where $\Pi_P(A)$ is closed) is the key to obtaining an efficient implicit representation of the SCCs of G, as claimed in Theorem 1. Our main technical contribution (Theorem 10) is a *path net data structure* enabling precisely that. The data structure requires a rather large $\widetilde{O}(r^3)$ preprocessing time but achieves the goal by supporting queries about $A \subseteq \partial P$ in near-optimal $\widetilde{O}(|A|)$ time. Formally, we show:

▶ **Theorem 10.** *Let $P \in \mathcal{R}$ and let $\alpha : V(P) \to \mathbb{R}$ be a weight function. In $\widetilde{O}(r^3)$ time one can construct a data structure supporting the following queries. Given a subset $A \subseteq \partial P$, such that $\Pi_P(A)$ is closed, in $\widetilde{O}(|A|)$ time one can:*

- *create an* iterator *that enables listing elements of $\Pi_P(A) \setminus \partial P$ in $O(1)$ time per element,*
- *aggregate weights over $\Pi_P(A) \setminus \partial P$, i.e., compute $\sum_{v \in \Pi_P(A) \setminus \partial P} \alpha(v)$.*

▶ Remark 11. We do not require using subtractions to compute the aggregate weights. In fact, the data structure of Theorem 10 can be easily modified to aggregate weights coming from any semigroup, e.g., one can compute the max/min weight in $\Pi_P(A) \setminus \partial P$ within these bounds.

Our high-level strategy is to maintain the certificates and path net data structures accompanying individual pieces along with the r-division. Roughly speaking, to obtain the information about the SCCs of G beyond how the partition of $\partial\mathcal{R}$ into SCCs looks like, we will query the path net data structures for each piece P with the sets A equal to the SCCs of X having non-empty intersection with ∂P. We prove Theorem 10 later on, in Section 5.

In the remaining part of the section, we explain in detail how, equipped with Theorem 10, a dynamic (implicit) strongly connected components data structure can be obtained. As in Section 3, we maintain an r-division $\mathcal{R}$ dynamically, and maintain sparse reachability certificates X_P, along with the set $\mathcal{S}_X$ of SCCs of $X = \bigcup_{P \in \mathcal{R}} X_P$. Moreover, for each P

we store the strongly connected components $\mathcal{S}_P$ of P. Let $\mathcal{S}_{\partial P}$ be the elements of $\mathcal{S}_P$ that contain a boundary vertex, and $\mathcal{S}_{P\setminus\partial P}$ the elements of $\mathcal{S}_P$ that do not. Clearly, we have $\mathcal{S}_P = \mathcal{S}_{\partial P} \cup \mathcal{S}_{P\setminus\partial P}$ and $(\bigcup \mathcal{S}_P) \cap \left(\bigcup \mathcal{S}_{P\setminus\partial P}\right) = \emptyset$.

For each piece $P \in \mathcal{R}$, we additionally store a path net data structure $\mathcal{D}_P$ of Theorem 10 with an appropriately defined weight function (to be picked depending on the application later). Note that for a piece P, all the auxiliary data structures accompanying P that we have defined can be computed in $\widetilde{O}(r^3)$ time. We now consider the specific goals that can be achieved this way.

Finding the largest SCC. Denote by S^* the largest SCC of G. To be able to identify S^*, and e.g., compute its size, we additionally store and maintain the following. For each piece P, we also maintain the largest SCC S^*_P of P. The sizes of all the SCCs of P, in particular the size of S^*_P, can be easily found and stored after computing $\mathcal{S}_P$.

Note that if the largest SCC S^* of G is not contained entirely in any individual piece P (and thus is larger than $\max_{P\in\mathcal{R}} |S^*_P|$), it has to intersect $\partial\mathcal{R}$. More specifically, in this case for each piece P such that $S^* \cap V(P) \neq \emptyset$, we have $S^* \cap \partial P \neq \emptyset$.

Recall that by Lemma 6, $X = \bigcup_{P\in\mathcal{R}} X_P$ preserves the strong connectivity relation on the vertices $\partial\mathcal{R}$. Therefore, if S^* intersects $\partial\mathcal{R}$, it has to contain $B \cap \partial\mathcal{R}$ for some SCC B of X. For any such B, we can compute the size of the SCC S_B of G satisfying $B \cap \partial\mathcal{R} \subseteq S_B$ as follows. First of all, $|S_B \cap \partial\mathcal{R}| = |B \cap \partial\mathcal{R}|$ since B is an SCC of X. It is thus enough to compute, for all $P \in \mathcal{R}$, $|S_B \cap (V(P) \setminus \partial P)|$. Since the sets $V(P) \setminus \partial P$ are pairwise disjoint across the pieces, by adding these values, we will get the desired size $|S_B|$.

We have already argued that if $B \cap \partial P = \emptyset$, then $S_B \cap V(P) = \emptyset$. If, on the other hand, $B \cap \partial P$ is non-empty, by Lemma 9, if we use the weight function $\alpha(v) \equiv 1$ in the piecewise data structures $\mathcal{D}_P$ of Theorem 10, we can compute $|S_B \cap (V(P) \setminus \partial P)| = \sum_{v\in\Pi_P(B\cap\partial P)\setminus\partial P} \alpha(v)$ in $\widetilde{O}(|B \cap \partial P|)$ time using the input set $A := B \cap \partial P$. We conclude that the sizes S_B for all $B \in \mathcal{S}_X$ can be computed in time

$$\widetilde{O}\left(\sum_{B\in\mathcal{S}_X} \sum_{\substack{P\in\mathcal{R}\\ B\cap\partial P\neq\emptyset}} |B \cap \partial P|\right) = \widetilde{O}\left(\sum_{P\in\mathcal{R}} \sum_{\substack{B\in\mathcal{S}_X\\ B\cap\partial P\neq\emptyset}} |B \cap \partial P|\right) = \widetilde{O}\left(\sum_{P\in\mathcal{R}} |\partial P|\right) = \widetilde{O}(n/\sqrt{r}). \tag{1}$$

Finally, S^* is either equal to the largest S_B for $B \in \mathcal{S}_X$, or the largest S^*_P (through $P \in \mathcal{R}$). The latter is the case if $\max_{B\in\mathcal{S}_X} |S_B| < \max_{P\in\mathcal{R}} |S^*_P|$. Which case we fall into is easily decided once all the $O(n/\sqrt{r})$ sizes $|S_B|$ are computed.

Accessing the SCC of a specified vertex. Suppose first that we know the SCC S_v of G containing a query vertex v, and additionally whether S_v intersects $\partial\mathcal{R}$. If $S_v \cap \partial\mathcal{R} = \emptyset$, then v is a vertex of a unique piece P, and $S_v \in \mathcal{S}_{P\setminus\partial P}$. In this case, we can clearly compute the size of S_v and report the elements of S_v in $O(1)$ time since $S_v \in \mathcal{S}_P$ is stored explicitly.

Otherwise, if $S_v \cap \partial\mathcal{R} \neq \emptyset$, we reuse the information that we have computed for finding the largest SCC. We have already described how to compute the sizes of all the SCCs S of G intersecting $\partial\mathcal{R}$ (in particular S_v) along with these respective intersections in $\widetilde{O}(n/\sqrt{r})$ time upon update. Moreover, for all $P \in \mathcal{R}$ we have computed $|S \cap (V(P) \setminus \partial P)|$ using the data structure $\mathcal{D}_P$ of Theorem 10. As a result, we can store, for each such S, a subset $L(S) \subseteq \mathcal{R}$ of pieces P such that $S \cap (V(P) \setminus \partial P) \neq \emptyset$. Recall that for all $P \in L(S)$, we can also use $\mathcal{D}_P$ to create an iterator for reporting the elements of $S \cap (V(P) \setminus \partial P)$ in $O(1)$ time per

element. So, in order to efficiently report elements of any such S, we first report the vertices of $S \cap \partial\mathcal{R}$, and then the elements of each $S \cap (V(P) \setminus \partial P)$ for subsequent pieces $P \in L(S)$. Indeed, one needs only $O(1)$ worst-case time to find each subsequent vertex of S.

Finally, we are left with the task of of finding the SCC S_v of a query vertex $v \in V$. It is not clear how to leverage path net data structures for that in the case when S_v intersects $\partial\mathcal{R}$. Instead, we use the data structure of [6] in a black-box way. That data structure handles fully dynamic edge updates in $\widetilde{O}(n^{4/5})$ worst-case time, and provides $O(\log^2 n)$ worst-case time access to consistent (for queries issued between any two subsequent updates) SCC identifiers of individual vertices[8]. Using [6], after every update we find the identifiers I of the SCCs of vertices $\partial\mathcal{R}$ in G in $\widetilde{O}(n/\sqrt{r})$ time. Now, to find the SCC of v upon query, we find the identifier i_v of the SCC containing v in $O(\log^2 n)$ time. If $i_v \in I$ (which can be tested in $O(\log n)$ time), we obtain that v is in an SCC of G intersecting $\partial\mathcal{R}$ and some vertex b_v from the intersection. b_v can be in turn used to access $L(S_v)$ and thus enable reporting the elements of S_v. Otherwise, if $i_v \notin I$, $S \cap \partial\mathcal{R} = \emptyset$ and thus S equals the unique SCC from $S_{P \setminus \partial P}$ containing v in the unique piece P containing v.

Counting strongly connected components. Let us separately count SCCs $\mathcal{S}_{\partial\mathcal{R}}$ that intersect $\partial\mathcal{R}$ and those that do not. The former can be counted in $\widetilde{O}(n/\sqrt{r})$ time by counting the SCCs of X that intersect $\partial\mathcal{R}$ (that we maintain). The latter can be computed as follows. Consider the sum $\Phi = \sum_{P \in \mathcal{R}} |\mathcal{S}_{P \setminus \partial P}|$. If we wanted the sum Φ to count the SCCs not intersecting $\partial\mathcal{R}$, then an SCC $S \in \mathcal{S}_{P \setminus \partial P}$ contributes to the sum unnecessarily precisely when S is not an SCC of G. To see that, note that if an SCC S of P is not an SCC of G, it has to be a part of another SCC S' of G that also contains vertices of other pieces, i.e., S' intersects $\partial\mathcal{R}$. From Lemma 9, we conclude:

▶ **Corollary 12.** *An SCC $S \in \mathcal{S}_{P \setminus \partial P}$ is not an SCC of G iff there exists (precisely one) SCC B of X such that $S \subseteq \Pi_P(B \cap \partial P)$ (or equivalently, such that $S \cap \Pi_P(B \cap \partial P) \neq \emptyset$).*

As a result, we can count the number of SCCs in G that do not intersect $\partial\mathcal{R}$ by subtracting from Φ, for each $P \in \mathcal{R}$, and each $B \in \mathcal{S}_X$ the number $c_{P,B}$ of SCCs in $\mathcal{S}_{P \setminus \partial P}$ that intersect $\Pi_P(B \cap \partial P)$. To this end, we can use the data structure $\mathcal{D}_P$ of Theorem 10 built upon P (and maintained as described before) with a weight function α on $V(P)$ assigning 1 to an arbitrary single vertex v_S of each SCC $S \in \mathcal{S}_{P \setminus \partial P}$, and 0 to all other vertices. By Corollary 12, with such a weight function, $c_{P,B} = \sum_{v \in \Pi_P(B \cap \partial P) \setminus \partial P} \alpha(v)$ can be computed in $\widetilde{O}(|B \cap \partial P|)$ time using $\mathcal{D}_P$. Consequently, similarly as in (1), over all $B \in \mathcal{S}_X$, and $P \in \mathcal{R}$, computing all the values $c_{P,B}$ will take $\widetilde{O}(n/\sqrt{r})$ time. As mentioned before, the SCC count is obtained by subtracting those from Φ and adding the result to the count of $\mathcal{S}_{\partial\mathcal{R}}$.

Depending on the application, the worst-case update time of the data structure is $\widetilde{O}(n/\sqrt{r} + r^3)$ or $\widetilde{O}(n/\sqrt{r} + r^3 + n^{4/5})$. The bound is optimized for $r = n^{2/7}$ and this yields Theorem 1.

5 The path net data structure

This section is devoted to describing the below key component of our dynamic SCCs data structure.

[8] The query time of that data structure can be easily reduced to $O(\log n \cdot \log\log n)$ without affecting the $\widetilde{O}(n^{4/5})$ update bound if one simply replaces the classical MSSP data structure [26] used internally for performing point location queries in additively weighted Voronoi diagrams [16] with the MSSP data structure of [29].

▶ **Theorem 10.** *Let $P \in \mathcal{R}$ and let $\alpha : V(P) \to \mathbb{R}$ be a weight function. In $\widetilde{O}(r^3)$ time one can construct a data structure supporting the following queries. Given a subset $A \subseteq \partial P$, such that $\Pi_P(A)$ is closed, in $\widetilde{O}(|A|)$ time one can:*

- *create an* iterator *that enables listing elements of $\Pi_P(A) \setminus \partial P$ in $O(1)$ time per element,*
- *aggregate weights over $\Pi_P(A) \setminus \partial P$, i.e., compute $\sum_{v \in \Pi_P(A) \setminus \partial P} \alpha(v)$.*

5.1 Overview

Charalampopoulos and Karczmarz [6] showed that for any SCC S of G, $V(P) \cap S$ forms an intersection of two cells coming from two carefully prepared additively weighted Voronoi diagrams on P with sites ∂P. As a result, they could use Voronoi diagram point location mechanism [16, 29] for testing in $O(\operatorname{polylog} n)$ time whether a query vertex lies in such an intersection. If we tried to follow this approach, we would need to be able to aggregate/report vertices in such intersections of cells coming from two seemingly unrelated Voronoi diagrams. This is very different from just testing membership, and it is not clear whether this can be done efficiently.

Instead, in order to prove Theorem 10, we take a more direct approach. As is done typically, we first consider the situation when A lies on a single face of P. In the single-hole case, the first step is to reduce to the case when the input piece P is acyclic; note that if a vertex lies in the path net $\Pi_P(A)$, its entire SCC in P does. Acyclicity and appropriate perturbation [10] allows us to pick a collection of paths $\pi_{u,v}$, for all $u, v \in \partial P$, such that every two paths in the collection are either disjoint or their intersection forms a single subpath of both. This property makes the paths $\pi_{u,v}$ particularly convenient to use for cutting the piece P into smaller non-overlapping parts.

More specifically, the paths $\pi_{u,v}$ are used to partition – using a polygon triangulation-like procedure – a queried net $\Pi_P(A)$ into regions in the plane with vertices $B \subseteq A$ bounded by either fragments of the face of P containing ∂P or some paths $\pi_{u,v}$ for $u, v \in B$ (so-called *base instances*). A base instance has a very special structure guaranteeing that for a given vertex $v \in V(P) \setminus \partial P$, there are *only* $O(1)$ *pairs* $s, t \in B$ such that an $s \to v \to t$ path exists in P. At the end, this crucial property can be used to reduce a base instance query B even further to looking up $\widetilde{O}(|B|)$ preprocessed answers for base instances with at most 5 vertices from ∂P, of which there are at most $\widetilde{O}(|\partial P|^5) = \widetilde{O}(r^{5/2})$. The precomputation of small base instances can be done in $\widetilde{O}(r^3)$ time.

For efficiently implementing the polygon triangulation-like partition procedure – which repeatedly cuts off base instances from the "core" part of the problem – we develop a dynamic data structure for existential reachability queries on a single face of a plane digraph (Lemma 15). To this end, we leverage the single-face reachability characterization of [23].

As the final step, we show a reduction from the case when A can lie on k faces on P, to the case when A lies on $k-1$ faces. The reduction – which eventually reduces the problem to the single-hole case – can blow up the piece's size by a constant factor. However, since there are only $O(1)$ holes initially, the general case can still be solved only constant factor slower than the single-hole case.

5.2 Reducing to the acyclic case

Recall that P is a piece of an r-division with few holes $\mathcal{R}$ and thus has size $O(r)$. Moreover, ∂P lies on $O(1)$ faces (*holes*) of some supergraph P^+ of P and $|\partial P| = O(\sqrt{r})$. For simplicity we will not differentiate between the faces/holes of P and P^+. Whenever we refer to a hole h of P, we mean a closed curve h in the plane such that whole embedding of P lies weakly on a single side of h, and only vertices ∂P may lie on the curve h.

First of all, we compute the strongly connected components $\mathcal{S}_P$ of P. Observe that from the point of view of supported queries, all vertices of a single SCC $S \in \mathcal{S}_P$ are treated exactly the same: when a single vertex $v \in S \setminus \partial P$ is reported (or its weight $\alpha(v)$ is aggregated), all other vertices from $S \setminus \partial P$ are as well. For each $S \in \mathcal{S}_P$ we precompute the aggregate weight $\alpha(S) = \sum_{v \in S \setminus \partial P} \alpha(v)$ in $O(r)$ time. We then contract each strongly connected component $S \in \mathcal{S}_P$ into a single vertex v_S. Crucially, since each subgraph $P[S]$ is connected in the undirected sense, contractions can be performed in an embedding preserving way (via a sequence of single-edge contractions), so that:

- The obtained graph P' is acyclic.
- The vertices $\partial P' := \{v_S : S \in \mathcal{S}_P, S \cap \partial P \neq \emptyset\}$ lie on $O(1)$ faces of (a supergraph of) P'.

Indeed, to see the latter property, label each $b \in \partial P$ initially each with hole that b lies on and make non-boundary vertices unlabeled. When the vertices merge, label the resulting vertex using one of the involved vertices' labels, if any of them has one. At the end there will be still $O(1)$ labels, each vertex of $\partial P'$ will have one of these labels, and for each label, all the vertices holding that label will be incident to a single face of P'. Clearly, $|P'| = O(r)$ and $|\partial P'| = O(\sqrt{r})$.

The proof of the below lemma can be found in the full version.

▶ **Lemma 13.** *Suppose a data structure $\mathcal{D}'$ of Theorem 10 is built for the acyclic graph P' with the weight function $\alpha'(v_S) := \alpha(S) = \sum_{v \in S \setminus \partial P} \alpha(v)$. Then, a query $A \subseteq \partial P$ from Theorem 10 can be reduced, in $O(|A|)$ time, to a query about $A' = \{v_S : S \in \mathcal{S}_P, S \cap A \neq \emptyset\}$ issued to $\mathcal{D}'$.*

In the following we will assume that P is an acyclic graph. We will no longer need the assumption $\Pi_P(A) \cap \partial P = A$; this was only needed for the efficient reduction to the acyclic case. Consequently, we will design a data structure with query time $\widetilde{O}(|A|)$ even if $A \subsetneq \Pi_P(A) \cap \partial P$.

The single-hole assumption. In the remaining part of this section, we assume we only want to handle queries where the query set A lies on a *single hole* h of an acyclic piece P. Due to space constraints, we present the reduction of the general case to the single-hole case in the full version. Our strategy for the single-hole case will be to efficiently break the problem into subproblems for which we have the answer precomputed.

5.3 Picking non-crossing paths

We first fix, for any $u, v \in V(P)$ such that u can reach v, one particular $u \to v$ path $\pi_{u,v} \subseteq P$. We apply the perturbation scheme of [10] to P, so that the shortest paths in P become unique. For any $u, v \in V(P)$ such that u can reach v in P, we define $\pi_{u,v}$ to be the unique shortest $u \to v$ path in P. Note that each $\pi_{u,v}$ is a simple path in P. We have the following crucial property.

▶ **Lemma 14.** *Let $u, v, x, y \in V(P)$ be such that u can reach v and x can reach y in P. If $V(\pi_{u,v}) \cap V(\pi_{x,y}) \neq \emptyset$, then $\pi_{u,v}$ and $\pi_{x,y}$ share a single (possibly zero-edge) subpath.*

Proof. Let a (b) be the first (last, resp.) vertex on $\pi_{u,v}$ that is also a vertex of $\pi_{x,y}$. $\pi_{u,v}$ can be expressed as $Q_1 \cdot T \cdot Q_2$, where $T = a \to b$. Moreover, $V(\pi_{u,v}) \cap V(\pi_{x,y}) \subseteq V(T)$. If $a \neq b$, the vertex b cannot appear before a on $\pi_{x,y}$, because then a and b would lie on a cycle in P, contradicting acyclicity of P. As a result, $\pi_{x,y}$ has an $a \to b$ subpath as well. Since shortest paths in P are unique and shortest paths have optimal substructure, the $a \to b$ subpath of $\pi_{x,y}$ equals T. So, $\pi_{x,y}$ can be expressed as $R_1 \cdot T \cdot R_2$. Since $\pi_{x,y}$ is simple, and $V(\pi_{u,v}) \cap V(\pi_{x,y}) \subseteq V(T)$, we indeed have $\pi_{u,v} \cap \pi_{x,y} = T$. ◀

Observe that since P is a DAG, for $u, v \in V(P)$, $u \neq v$, $\pi_{u,v}$ and $\pi_{v,u}$ cannot both exist. When one of them exists, we will sometimes write $\pi_{\{u,v\}}$ to denote the one that exists.

5.4 Generalization

Before we proceed, we need to state our problem in a more general way that will enable decomposition into smaller subproblems of similar kind. Let us first fix a counterclockwise order of $V(h)$, as follows. Let $u_1, e_1, u_2, e_2, \ldots, u_r, e_r$ be the sequence of vertices and edges on a counterclockwise bounding walk of h with an arbitrary starting point. The encountered vertices u_i might not be all distinct since h can be a non-simple face in general. The order $\prec_h$ of $V(h)$ that we use is obtained by removing duplicate vertices from the sequence in an arbitrary way, i.e., for each $v \in V(h)$ we pick one index i_v such that $u_{i_v} = v$. If $x, y \in V(h)$ and $i_x < i_y$, then we define $C_{x,y}$ to be the curve $e_{i_x} e_{i_x+1} \ldots e_{i_y-1}$. Otherwise, if $i_x > i_y$, then $C_{x,y} = e_{i_x} e_{i_x+1} \ldots e_r e_1 e_2 \ldots e_{i_y-1}$. If h is simple, then $C_{x,y}$ is a simple curve. However, in general, $C_{x,y}$ can be self-touching but it does not cross itself.

Suppose $B \subseteq \partial P \cap V(h)$ is given in the counterclockwise order on h. Moreover, for each pair of neighboring (i.e., appearing consecutively in the *cyclic* order of B given by $\prec_h$) vertices x, y of B, a curve $\Phi_{x,y}$ connecting x to y is given. The curve $\Phi_{x,y}$ equals either $\pi_{\{x,y\}}$ or $C_{x,y}$. Let Φ be the closed curve formed by concatenating the subsequent curves $\Phi_{x,y}$ for all neighboring $x, y \in B$. For brevity, we also extend the notation $\Phi_{a,b}$ to non-neighboring vertices a, b of B, and define $\Phi_{a,b}$ to be a concatenation of the curves $\Phi_{x,y}$ for all neighboring pairs (x, y) between a and b on Φ. We don't require Φ to be a simple (Jordan) curve; parts of it may be overlapping. Whereas Φ is allowed to be self-touching, it does not cross itself, like e.g., the cycle bounding a non-simple face of a plane graph. Let $P[\Phi]$ denote the region of P that lies *weakly* inside the curve Φ.

The objective of the problem (B, Φ) is to aggregate weights of (or report) the vertices of $\Pi_P(B) \setminus \partial P$ that lie *strictly inside* Φ. More formally, we want to aggregate vertices v that lie, at the same time, strictly on the left side of each of the curves $\Phi_{x,y}$ (seen as a curve directed from x to y) where $x, y \in B$ are neighboring in the counterclockwise order on h.[9] Note that with such a defined problem, the original goal of the query procedure can be rephrased as (A, h) since all the vertices of $\Pi_P(A) \setminus \partial P$ indeed lie strictly inside h.

5.5 Preprocessing

Preprocessing for small instances and subproblems.

- For any tuple $B = (b_1, \ldots, b_q)$ of at most 4 vertices of ∂P appearing in that order on in $\prec_h$, and any out of at most $2^q = O(1)$ possible curves Φ that might constitute the problem (B, Φ), we precompute the aggregate weight and the list of vertices in $\Pi_P(B) \setminus \partial P$ that lie strictly inside Φ. This can clearly be done in $\widetilde{O}(|\partial P|^4 \cdot |P|) = \widetilde{O}(r^3)$ time.
- For any 5-tuple $\tau = (b_0, \ldots, b_4)$ ordered by $\prec_h$, and any out of at most 2^4 possible curves $\Phi_{b_i,b_{i+1}} \in \{\pi_{\{b_i,b_{i+1}\}}, C_{b_i,b_{i+1}}\}$, where $i \in \{0, \ldots, 3\}$, we precompute and store the set X_τ of vertices $x \in V(P) \setminus \partial P$ such that:
  1. x lies on some path connecting b_1 and b_2 in P,
  2. x *does not* lie on any path connecting b_0 and b_1 in P,
  3. x lies strictly to the left of each $\Phi_{b_i,b_{i+1}}$ for $i = \{0, \ldots, 3\}$.

[9] Even more formally, assuming P is embedded in such a way that h is the infinite face of a supergraph of P, we are interested in the vertices lying in the intersection of the regions strictly inside closed curves $\Phi_{x,y} \cdot C_{y,x}$ for all neighboring x, y in B.

We also store the aggregate weight $w(X_\tau)$. This preprocessing can be performed in a brute-force way in $\widetilde{O}(|\partial P|^5 \cdot |P|) = \widetilde{O}(r^{7/2})$ time. It can be also optimized fairly easily to $\widetilde{O}(r^3)$ time and space, as shown in the full version.

- For any $u, v \in \partial P$, we store the path $\pi_{\{u,v\}}$ itself, along with aggregate weights of all its subpaths. This data can be computed in $\widetilde{O}(|\partial P|^2 \cdot |P|^2) = \widetilde{O}(r^3)$ time in a brute-force way.
- Finally, for any two pairs $(u, v), (x, y) \in \partial P \times \partial P$, we compute the intersection of the paths $\pi_{\{u,v\}}$ and $\pi_{\{x,y\}}$. By Lemma 14, that intersection is either empty or is a subpath of both these paths. Hence, it is enough to store the two endpoints of the intersection subpath only. The desired intersections can be found in $\widetilde{O}(|\partial P|^4 \cdot |P|) = \widetilde{O}(r^3)$ time in a brute-force way.

Existential reachability data structure. We also build data structures $\mathcal{L}, \mathcal{L}^R$ of the following lemma for P and P^R, respectively.

▶ **Lemma 15.** *In $\widetilde{O}(r)$ time one can construct a data structure maintaining an (initially empty) set $Z \subseteq \partial P \cap V(h)$ and supporting the following operations in $O(\operatorname{polylog} n)$ time:*

- *insert or delete a single $b \in \partial P \cap V(h)$ either to or from Z.*
- *for any query vertex $v \in (\partial P \cap V(h)) \setminus Z$, find any $z \in Z$ (if exists) that v can reach in P.*

Due to space constraints, the proof of Lemma 15 is deferred to the full version.

5.6 Answering queries

We now proceed with the description of our algorithm solving the general problem (B, Φ).

Base case. Let the elements of $B = \{b_1, \ldots, b_k\}$ be sorted according to their order $\prec_h$ on Φ. For convenience, identify b_{k+l} with b_l for any integer l.

We first consider the easier *base case*, with the following additional requirement:

For any $1 \leq i < j \leq k$, if b_i can reach b_j or can be reached from b_j in P, then either $j = i + 1$ or $(i, j) = (1, k)$.

If $k \leq 4$, we will simply return the precomputed aggregate weight, or an iterator to a list of vertices in $\Pi_P(B) \setminus \partial P$ strictly inside Φ. So suppose $k \geq 5$. We start with the following lemma.

▶ **Lemma 16.** *Let $v \in \Pi_P(B) \setminus \partial P$ lie strictly inside Φ. Then:*

- *There exists such i that v lies on some $b_i \to b_{i+1}$ or on some $b_{i+1} \to b_i$ path in P.*
- *Moreover, there is at most one more pair $\{x, y\} \subseteq B$, $\{x, y\} \neq \{b_i, b_{i+1}\}$ such that v lies on some $x \to y$ or $y \to x$ path in P, and either $\{x, y\} = \{b_{i-1}, b_i\}$, or $\{x, y\} = \{b_{i+1}, b_{i+2}\}$.*

Proof. Item (1) follows easily by the additional requirement of the base case. Let v lie on some $b_j \to c$ path in P, where $c \in B$. Since P is acyclic, we have that $b_j \neq c$ and thus $c \in \{b_{j-1}, b_{j+1}\}$. If $c = b_{j+1}$, we put $i = j$ and if $c = b_{j-1}$, we put $i = j - 1$.

For item (2), consider the case when v lies on some $b_i \to b_{i+1}$; the case when v lies on a $b_{i+1} \to b_i$ path is symmetric. Suppose v also lies on some $x \to y$ path in P, where $x, y \in B$, $x \neq y$, $\{x, y\} \neq \{b_i, b_{i+1}\}$. Since b_i can reach y through v, $y \in \{b_{i-1}, b_{i+1}\}$ by the base case requirement. Similarly, since x can reach b_{i+1} through v, $x \in \{b_i, b_{i+2}\}$. We cannot have $x = b_{i+2}$ and $y = b_{i-1}$ since b_{i+2} reaching b_{i-1} is a contradiction with the first base case requirement for $k \geq 5$. As a result, $(x, y) \neq (b_i, b_{i+1})$ implies $(x, y) = (b_i, b_{i-1})$

or $(x, y) = (b_{i+2}, b_{i+1})$. Moreover, v cannot lie on both some $b_i \to b_{i-1}$ path and some $b_{i+2} \to b_{i+1}$ path, since then b_{i+2} could reach b_{i-1}, which is again a contradiction for $k \geq 5$. ◀

By Lemma 16, each $v \in \Pi_P(B) \setminus \partial P$ falls into exactly one of the k sets Y_i, for $i = 1, \ldots, k$, such that Y_i contains those v in $V(P) \setminus \partial P$ that lie on a path in P connecting b_i and b_{i+1} (in any direction), but at the same time *do not* lie on any path connecting b_{i-1} and b_i in P (in any direction). Indeed, if v appears only on paths connecting b_i and b_{i+1}, it will be included in Y_i. On the other hand, if v appears both on paths connecting b_i and b_{i+1} and on paths connecting b_{i+1} and b_{i+2}, it will be included only in Y_i, but not in Y_{i+1}.

▶ **Lemma 17.** *Suppose $v \in Y_i$. Then v lies strictly inside Φ if and only if v lies strictly on the left side of Φ_{b_{i-1},b_i}, $\Phi_{b_i,b_{i+1}}$, $\Phi_{b_{i+1},b_{i+2}}$, and $\Phi_{b_{i+2},b_{i+3}}$.*

Proof. Since strictly inside Φ means strictly to the left of all $\Phi_{b_j,b_{j+1}}$, the " $\Longrightarrow$ " direction is trivial.

Consider the " $\Longleftarrow$ " direction. For contradiction, suppose v does not lie strictly inside Φ. Then, for some $j \notin \{i-1, i, i+1, i+2\}$, v lies weakly to the right of $\Phi_{b_j,b_{j+1}}$. Since $v \in V(P) \setminus \partial P$ and the hole h contains only vertices of ∂P, this means that $\Phi_{b_j,b_{j+1}} = \pi_{\{b_j,b_{j+1}\}}$. Since b_j and b_{j+1} are consecutive in B, and $i \notin \{j, j+1\}$, b_i lies weakly to the left of $\pi_{\{b_j,b_{j+1}\}}$.

By $v \in Y_i$, the vertex v lies on a path Q connecting b_i and b_{i+1} in P. Since v and b_i lie weakly on different sides of $\pi_{\{b_j,b_{j+1}\}}$, the path Q has to cross $\pi_{\{b_j,b_{j+1}\}}$ at a vertex w appearing not later than v on Q (possibly $v = w$). If $Q = b_i \to b_{i+1}$, the existence of w implies that there exists an $s \to b_{i+1}$ path in P going through v such that $s \in \{b_j, b_{j+1}\}$. By $v \in Y_i$, this implies $s \in \{b_i, b_{i+2}\}$. As a result, $j \in \{i-1, i, i+1, i+2\}$, a contradiction. Similarly, if $Q = b_{i+1} \to b_i$, there exists an $s \to b_i$ path in P going through v such that $s \in \{b_j, b_{j+1}\}$. But on the other hand by $v \in Y_i$ we have $s = b_{i+1}$ so $j \in \{i, i+1\}$, a contradiction. ◀

As a result, we can equivalently aggregate vertices v in each Y_i under a (seemingly) weaker requirement that v lies strictly on the left side of Φ_{b_{i-1},b_i}, $\Phi_{b_i,b_{i+1}}$, $\Phi_{b_{i+1},b_{i+2}}$, and $\Phi_{b_{i+2},b_{i+3}}$. But this is, again, part of the precomputed data for the tuple $(b_{i-1}, b_i, b_{i+1}, b_{i+2}, b_{i+3})$.

Consequently, there are k disjoint sets Y_i to consider. We can thus aggregate weights or construct a list for reporting vertices from $v \in \Pi_P(B) \setminus \partial P$ strictly inside Φ in $O(k)$ time. We thus obtain:

▶ **Lemma 18.** *The base case can be handled in $O(|B|)$ time.*

General case. To solve the general case, we reduce it to a number of base case instances. To this end, we maintain a partition of $B = S \cup T$ such that S precedes T on Φ. Let $S = \{s_1, \ldots, s_p\}$ and $T = \{t_1, \ldots, t_q\}$. We will gradually simplify the problem while maintaining the following invariants:

(1) For any $u, v \in B$, if u can reach v in P, then $\pi_{u,v} \subseteq P[\Phi]$.
(2) For any $1 \leq i < j \leq p$, if s_i can reach s_j or can be reached from s_j, then $j = i + 1$.
(3) If $x, y \in B$ are neighbors in the counterclockwise order $\prec_h$ on Φ and $\Phi_{x,y} = \pi_{\{x,y\}}$, then $x, y \in S$.
(4) In the data structures $\mathcal{L}, \mathcal{L}^R$ of Lemma 15, the set Z satisfies $Z = S \setminus \{s_p\}$.

The algorithm will gradually modify B, S, T, Φ until we have $S = B$ and $T = \emptyset$. Note that when $T = \emptyset$, $(B, \Phi) = (S, \Phi)$ satisfies the requirement of the base case and can be solved in $\widetilde{O}(|B|)$ time.

Initially we put $\Phi = h$, $S = \{b_1, b_2\}$, and insert b_1 to Z to satisfy the invariants.

The main loop of the procedure runs while $T \neq \emptyset$ and does the following. Using $\mathcal{L}$ and $\mathcal{L}^R$, in $O(\text{polylog}\, n)$ time we test whether t_1 can reach Z or can be reached from Z in P. If this is not the case, we simply move t_1 to the end of S, an update Z accordingly. Note that $|T|$ decreases then.

Otherwise, we can find all vertices $X = \{x_1, \ldots, x_l\} \subseteq Z$ that t_1 can reach or can be reached from in $\widetilde{O}(|X|)$ by repeatedly extracting them from the data structures $\mathcal{L}, \mathcal{L}^R$. Additionally we sort X so that the order $x_1, \ldots, x_l$ matches the order of S on Φ. Let π_i denote the path $\pi_{\{t_1, x_i\}}$ possibly reversed to go from t_1 to x_i, and π_i^R denote the reverse π_i going from x_i to t_1. The vertices X are used to "cut off" l base case instances, as follows. For $i = 0, \ldots, l$, let S_i denote the vertices of S between x_i and x_{i+1} on Φ (inclusive), where we set $x_{l+1} := s_p$, $x_0 := s_1$. We split the problem (B, Φ) into the following subproblems (see Figure 1 for better understanding):

1. For each $i = 1, \ldots, l-1$, an instance $(S_i \cup \{t_1\}, \Phi_{x_i, x_{i+1}} \cdot \pi_{i+1}^R \cdot \pi_i)$.
2. An instance $(S_l \cup \{t_1\}, \Phi_{x_l, t_1} \cdot \pi_l)$.
3. An instance $(S_0 \cup T, \Phi_{s_1, x_1} \cdot \pi_1^R \cdot \Phi_{t_1, s_1})$.

▶ **Lemma 19.** *For each of the above subproblems (B', Φ'), and $u, v \in B'$, if u can reach v in P, then $\pi_{u,v} \subseteq P[\Phi']$.*

Proof. Note that (B', Φ') is obtained from (B, Φ) by cutting it out of (B, Φ) with at most two paths $\pi_{\{t_1, a\}}, \pi_{\{t_1, b\}}$, for some $t_1, a, b \in B' \subseteq B$. By our assumption, $\pi_{u,v} \subseteq P[\Phi]$. As a result, if $\pi_{u,v}$ was not contained in $P[\Phi']$, then $\pi_{u,v}$ would need to cross either $\pi_{\{t_1,a\}}$ or $\pi_{\{t_1,b\}}$. However, this is impossible by Lemma 14 and since $u, v \in V(P[\Phi'])$. ◀

▶ **Lemma 20.** *The obtained instances of types 1 and 2 above fall into the base case.*

Proof. To see that the base case requirement is satisfied, recall that by the invariant posed on S, if two elements of S_i, where $i \in \{1, \ldots, l\}$, are related (wrt. reachability in P), they are neighboring in S_i. By construction, t_1 can be only related to the first and the last element of S_i. ◀

Since the cutting is performed using non-crossing paths in P, the regions $P[\Phi']$ for the obtained subproblems can only share their boundaries, that is, if some v is strictly inside one of the curves Φ', then it it is not strictly inside another obtained curve Φ''. Therefore, if we proceeded with the above subproblems recursively, we would not aggregate or report any vertex of $v \in \Pi_P(B) \setminus \partial P$ twice. However, we still need to report/aggregate vertices that lie on paths $\pi_1, \ldots, \pi_l$ strictly inside the curve Φ. We now discuss how this strategy is implemented. Let us first consider solving the subproblems recursively. We handle all the obtained base case instance of types 1 and 2 as explained before. If $x_1 = s_g$, then by Lemma 18, the total time required for this is $O\left(\sum_{i=1}^{l}(|S_i| + 1)\right) = O((p-g) + l)$. But note that $l \leq p - g$, so in fact the bound is $O(p - g)$.

To handle the instance $(S_0 \cup T, \Phi_{s_1, x_1} \cdot \pi_1^R \cdot \Phi_{t_1, s_1})$, we simply replace (B, Φ) with it and proceed with solving it using the algorithm for the general case. To this end, we set $S := S_0 \cup \{t_1\}$, $T := \{t_2, \ldots, t_q\}$ and update Z in the data structures $\mathcal{L}, \mathcal{L}^R$ to S_0 by removing elements. Then, invariant (1) is satisfied by Lemma 19, and invariants (2), (3) and (4) are satisfied by construction. This way, in $\widetilde{O}(\Delta)$ time we reduce the instance (B, Φ) by $\Delta = |S| - |S_0| = p - g$ vertices. Recall that $Z = S \setminus \{s_p\}$ implies that $g < p$. Thus, $\Delta \geq 1$ and the sizes of B and T strictly decrease.

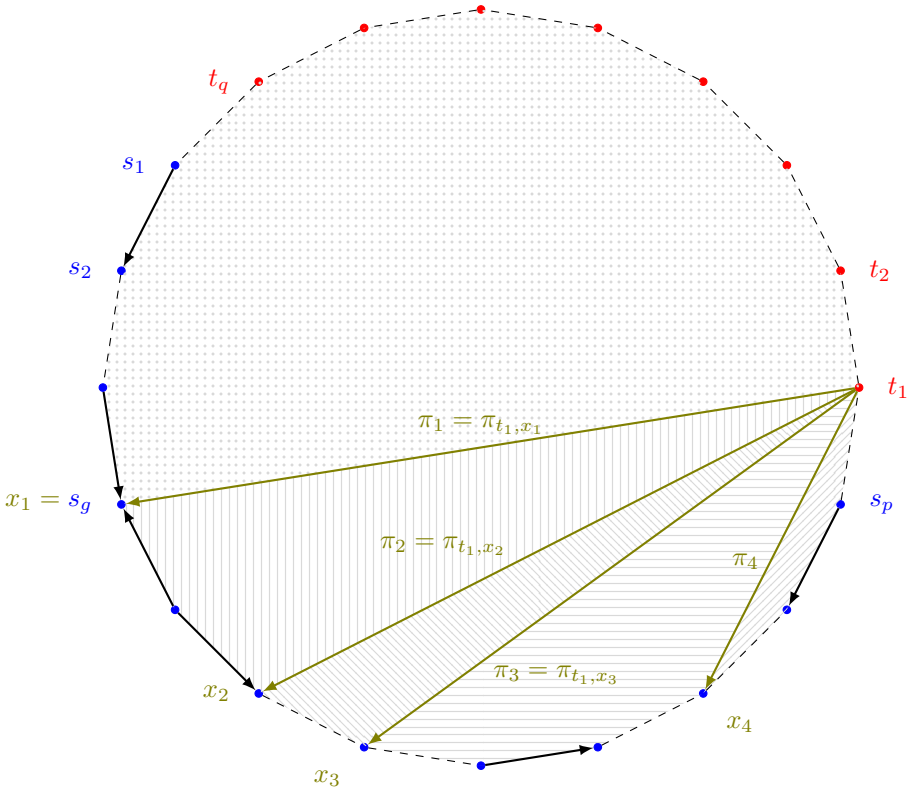

Figure 1 Splitting the instance (B, Φ), where $B = S \cup T$, into 5 smaller instances with paths $\pi_1, \ldots, \pi_l$ (either originating or ending in t_1) for $l = 4$. The vertices $S = \{s_1, \ldots, s_p\}$ are shown in blue, whereas the vertices $T = \{t_1, \ldots, t_q\}$ in red. The black arrows and dashed lines represent the individual parts of the curve Φ: paths of the form $\pi_{u,v}$ or parts of the curve h, respectively. Note that the black arrows appear only on the Φ_{s_1,s_p} part of Φ. The vertices $x_1, \ldots, x_4$, marked green, are precisely all the vertices of $S \setminus \{s_p\}$ that t_1 can reach or can be reached from. The obtained smaller instances are marked with distinct patterns. The instances marked with line patterns (types 1 or 2) are base instances. The instance marked using a dotted pattern (type 3) might constitute the only obtained instance that is not a base instance (for which the algorithm continues).

Let us now discuss how to aggregate/report the vertices of $\Pi_P(B) \setminus \partial P$ that lie on any of the paths $\pi_1, \ldots, \pi_l$ (that are not handled in any of the subproblems), but at the same time lie strictly inside Φ (before altering (B, Φ)). Since Φ is formed of either the edges of the hole h, or from the paths $\pi_{\{u,v\}}$, and each π_i is contained in $P[\Phi]$, equivalently we need to aggregate the vertices of $\Pi_P(B) \setminus \partial P$ on the paths $\pi_1, \ldots, \pi_l$ that do not lie on Φ.

Observe that since $x_1, \ldots, x_l$ lie on Φ in that order, and the paths $\pi_1, \ldots, \pi_l$ all lie in $P[\Phi]$ and are non-crossing by Lemma 14, for any three $i < j < k$, we have $V(\pi_i) \cap V(\pi_k) \subseteq V(\pi_j)$. As a result, any vertex on these paths is included in precisely one of the sets $V(\pi_i) \setminus V(\pi_{i-1})$, for $i = 1, \ldots, l$ and $V(\pi_0) := \emptyset$. Moreover, in Lemma 21 we will show that each π_i can possibly have a non-empty intersection with $O(1)$ parts (between neighboring elements of B) of Φ, that we can also identify in $O(1)$ time. Since, by Lemma 14, for every path $\pi_{\{u,v\}}$, the intersection of $\pi_{\{u,v\}}$ with π_i is either empty or forms a subpath of π_i, aggregating or reporting the required vertices of π_i boils down to aggregating or reporting the vertices of $V(P) \setminus \partial P$ on some $O(1)$ subpaths of π_i that form what remains from π_i after removing $O(1)$ of its intersections with other paths $\pi_{u,v}$.

▶ **Lemma 21.** *Consider the moment when the split into subproblems happens. Suppose $x_i = s_j$. Let $u, v \in B$ be neighboring on Φ, so that u comes before v in the counterclockwise order $\prec_h$ on Φ. Then $(V(\pi_i) \cap V(\Phi_{u,v})) \setminus \partial P \neq \emptyset$ implies that $u = s_{j'}$ for some $j' \in \{1, \ldots, p\}$ such that $|j - j'| \leq 2$.*

Proof. Recall that the curve is π_i is either the path $\pi_{\{x_i,t_1\}}$ or its reverse. Let us only consider the case when $\pi_{\{x_i,t_1\}} = \pi_{x_i,t_1}$; the case when $\pi_{\{x_i,t_1\}} = \pi_{t_1,x_i}$ is analogous.

By invariant (3), we have that $u, v \in S$ since otherwise $\Phi_{u,v}$ is a part of the curve h and therefore does not contain any vertices from outside $V(h)$. So $\{u, v\} = \{s_{j'}, s_{j'+1}\}$ for some $j' \in \{1, \ldots, p-1\}$. Let $z \in (V(\pi_i) \cap V(\Phi_{u,v})) \setminus \partial P$. If $\Phi_{u,v} = \pi_{s_{j'},s_{j'+1}}$, then the $z \to v$ subpath of $\Phi_{u,v}$ and the $x_i \to z$ subpath of π_i together form an $s_j \to s_{j'+1}$ path in P, which by invariant (2) implies $j' + 1 \in \{j-1, j, j+1\}$, and thus $j' \in [j-2, j]$. If $\Phi_{u,v} = \pi_{s_{j'+1},s_{j'}}$, then, analogously, there exists an $s_j \to s_{j'}$ path in P, so $j' \in [j-1, j+1]$. ◀

By Lemma 21, for each π_i, we need to report all vertices of π_i from outside ∂P, except those on the union of at most 6 subpaths of π_i. Since the subpaths are always intersections of some two paths $\pi_{u,v}$, we can identify these subpaths using precomputed data in $O(1)$ time. Aggregating vertex weights not on at most 6 subpaths of π_i is the same as aggregating weights on at most 7 disjoint subpaths of π_i. Recall that we have precomputed the aggregate weights for all the subpaths of all the possible $\pi_{u,v}$. As a result, aggregating or reporting vertices $\Pi_P(B) \setminus \partial P$ that lie on any of the paths $\pi_1, \ldots, \pi_l$ takes $O(l) = O(p - g)$ time.

▶ **Lemma 22.** *The general case can be handled in $\widetilde{O}(|B|)$ time.*

Proof. Recall that when $T = \emptyset$, we have a base instance that can be solved in $O(|B|)$ time.

Every iteration of the main loop that does not involve changing B takes $O(\text{polylog}\, n)$ time and reduces the size of T by one. But the set T can shrink at most $|B|$ times, so such iterations cost $\widetilde{O}(|B|)$ time in total. Every other iteration of the main loop involves reducing the size of B by some $\Delta > 0$ in $\widetilde{O}(\Delta)$ time. Such iterations clearly cost $\widetilde{O}(|B|)$ time in total as well. ◀

Minimizing Symmetric Convex Functions over Hybrid of Continuous and Discrete Convex Sets

Abstract

We study the problem of minimizing a given symmetric strictly convex function over the Minkowski sum of an integral base-polyhedron and an M-convex set. This problem has a hybrid of continuous and discrete structures. This emerges from the problem of allocating mixed goods, consisting of both divisible and indivisible goods, to agents with binary valuations so that the fairness measure, such as the Nash welfare, is maximized. It is known that both an integral base-polyhedron and an M-convex set have similar and nice properties, and the non-hybrid case can be solved in polynomial time. While the hybrid case lacks some of these properties, we show the structure of an optimal solution. Moreover, we exploit a proximity inherent in the problem. Through our findings, we demonstrate that our problem is NP-hard even in the fair allocation setting where all indivisible goods are identical. Moreover, we provide a polynomial-time algorithm for the fair allocation problem when all divisible goods are identical.

1 Introduction

In this paper, we study the hybrid problem of discrete and continuous structures. We are given a finite set N, a symmetric strictly convex function $\Phi\colon \mathbb{R}^N \to \mathbb{R}$ and two supermodular functions $f_C, f_M\colon 2^N \to \mathbb{Z}_+$. We assume that function values can be accessed by an oracle. For a supermodular function f, we call

$$\overline{\mathbf{B}} = \left\{x \in \mathbb{R}^N : x(N) = f(N) \quad \text{and} \quad x(X) \geq f(X) \ \ (\forall X \subseteq N)\right\}$$

the *integral base-polyhedron* of f, and $\ddot{\mathbf{B}} = \overline{\mathbf{B}} \cap \mathbb{Z}^N$ the *M-convex* set. Let $\overline{\mathbf{B}}_C$, $\overline{\mathbf{B}}_M$ be the integral base-polyhedra of f_C, f_M, respectively, and let $\ddot{\mathbf{B}}_M = \overline{\mathbf{B}}_M \cap \mathbb{Z}^N$. In addition, let

$\mathbf{B}_E$ be the Minkowski sum of $\ddot{\mathbf{B}}_M$ and $\overline{\mathbf{B}}_C$, i.e., $\mathbf{B}_E = \{x + y : x \in \ddot{\mathbf{B}}_M,\ y \in \overline{\mathbf{B}}_C\}$. The goal of the problem is to find a vector z that attains

$$\min_{z \in \mathbf{B}_E} \Phi(z)\ (= \min_{x \in \ddot{\mathbf{B}}_M} \min_{y \in \overline{\mathbf{B}}_C} \Phi(x + y)). \tag{1}$$

An optimal solution of this problem is called Φ-*minimizer* (on $\mathbf{B}_E$).

When $f_M = 0$ (i.e., $\mathbf{B}_E = \overline{\mathbf{B}}_C$), it is known that an integral base-polyhedron has a common unique minimizer independent of Φ, and the minimizer can be characterized by a structure called the *principal partition* [18, 34] (see Section 2.2 for the definition and details). By this structure, the problem (1) can be solved in polynomial time [38]. When $f_C = 0$, it is known that a Φ-minimizer on an M-convex set can be characterized by the *canonical partition* [15], which is an aggregation of the principal partition. Additionally, the set of Φ-minimizers does not depend on Φ [15] and a Φ-minimizer can be found in polynomial time [16]. Furthermore, a *proximity theorem* has been established [17]. This theorem states that a Φ-minimizer in an M-convex set lies within a unit hypercube that contains the Φ-minimizer in the corresponding integral base-polyhedron.

The hybrid problem (1) appears in the fair allocation of a mix of divisible and indivisible goods, which has recently been attracting attention [5,7,10,31,32,33,40]. Let $N = \{1, 2, \ldots, n\}$ be the set of agents. Let C and M be the sets of divisible and indivisible goods, respectively, and let also $E = C \cup M$. Each agent i has a binary valuation $v_{ie} \in \{0, 1\}$ for each good e. An allocation is a matrix $\pi \in [0, 1]^{N \times E}$ such that $\pi_{ie} \in \{0, 1\}$ for all $i \in N$ and $e \in M$. The entry π_{ie} means the allocated amount of good e to agent i. Throughout this paper, we only consider utilitarian optimum allocations, that is, $\pi_{ie} > 0$ only if $v_{ie} = 1$. Agents have additive utility, and the utility of agent i in allocation π is $\pi_i(E) = \sum_{e \in E} v_{ie}\pi_{ie}$. For an allocation π, a vector $z = (\pi_1(E), \ldots, \pi_n(E))$ is called a utility vector of π.

The problem of finding a utility vector with the maximum *Nash welfare* (MNW), which is a prominent fairness measure, can be reduced to our problem (1). Roughly speaking, the set of possible utility vectors by divisible goods C forms an integral base-polyhedron $\overline{\mathbf{B}}_C$, and the set by indivisible goods M forms an *M-convex set* $\ddot{\mathbf{B}}_M$, which is the set of integral vectors in an integral base-polyhedron. Maximizing the Nash welfare corresponds to minimizing a symmetric strictly convex function $\Phi(z) = -\sum_{i \in N} \log(z_i + \varepsilon)$ for sufficiently small $\varepsilon > 0$ (depending on the instance). Another standard fairness measure called *egalitarian social welfare* (max-min fairness) also can be represented by a symmetric strictly convex function. For a given symmetric strictly convex function Φ, we call an allocation π Φ-*fair* if its utility vector $z = (\pi_1(E), \ldots, \pi_n(E))$ is a Φ-minimizer. We will detail these in Section 2.

Unfortunately, the hybrid case does not inherit nice properties of continuous or discrete cases even in the fair allocation case. The set $\mathbf{B}_E$ is not necessarily an integral base-polyhedron or an M-convex set. It also does not work to find allocations of divisible and indivisible goods separately and combine them. We can observe these from the following example.

▶ **Example 1.** Suppose that there are one indivisible good g, one divisible good c, and three agents who desire both goods. Let $\Phi(z) = -z_1 \cdot z_2 \cdot z_3$. In this case, allocating c equally to the three agents minimizes Φ when considering only c. However, allocating g to agent 1 and c to agents 2 and 3 equally minimizes Φ for mixed goods. In addition, the set of possible utility vectors is not an M-convex set since it contains fractional utility vectors and not an integral base-polyhedron since it is not convex (see Figure 1).

In addition, we will see that the uniqueness of a Φ-minimizer set no longer holds (Example 7). Therefore, existing results are not applicable to our problem.

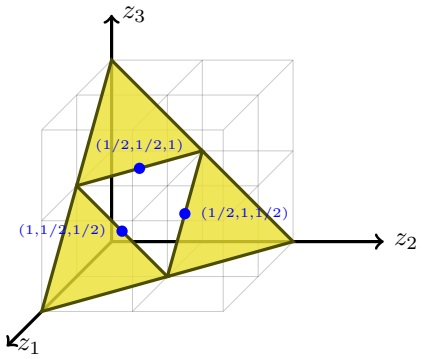

Figure 1 The set of possible utility vectors in Example 1. The blue points are minimizers of Φ.

1.1 Our contribution

First, we investigate the structure of the problem (1). Fortunately, we show that the hybrid problem still retains a structure of the canonical partition (Lemma 28), which is originally defined for the discrete case [15]. Namely, there exists integers $\beta_1 > \cdots > \beta_q$ and a partition $N_1, \ldots, N_q$ of N such that $\beta_j - 1 \leq z_i^* \leq \beta_j$ for any Φ-minimizer z^*, each $j = 1, \ldots, q$ and $i \in N_j$. The proof is based on exchanging element values of a solution. Since existing exchange properties in the discrete case are insufficient to deal with the hybrid problem, we need to introduce new exchange properties. Moreover, we discuss an optimality criterion in terms of an exchange graph, and unlike the discrete case, elaborate analysis of the graph is required. By this result, we can see that an optimal integral solution (i.e., $\arg\min_{z \in \ddot{\mathbf{B}}_M + \ddot{\mathbf{B}}_C} \Phi(z)$) is a good approximation solution for (1) in the sense that the ℓ_∞ distance from the optimal solution is at most 1. We remark that the canonical partition together can be found in polynomial time, and an optimal integral solution can be easily obtained from it.

In addition, by using the canonical partition, we can demonstrate a proximity theorem (Theorem 2). Namely, Φ-minimizer on $\mathbf{B}_E$ lies within a unit box containing the Φ-minimizer on an integral base-polyhedron $\overline{\mathbf{B}}_E$ of $f_E = f_M + f_C$. This generalizes a proximity theorem for the discrete case [17].

▶ **Theorem 2.** *Let Φ be a symmetric strictly convex function. For any $z^* \in \arg\min_{z \in \mathbf{B}_E} \Phi(z)$ and $\bar{z} \in \arg\min_{z \in \overline{\mathbf{B}}_E} \Phi(z)$, we have $\lfloor \bar{z}_i \rfloor \leq z_i^* \leq \lceil \bar{z}_i \rceil$ for all $i \in N$.*

Second, by applying the above results, we analyze the computational complexity of the problem (1) where $\overline{\mathbf{B}}_C$ and $\ddot{\mathbf{B}}_M$ arise from fair allocation. As a negative result, we show that the problem is NP-hard even when indivisible goods are *identical*, i.e., for each agent i, either $v_{ie} = 1$ $(\forall e \in M)$ or $v_{ie} = 0$ $(\forall e \in M)$.

▶ **Theorem 3.** *For any fixed symmetric strictly convex function Φ, finding a Φ-fair allocation is NP-hard even when indivisible goods are identical.*

We also prove that computing an MNW allocation and an optimal egalitarian allocation are both NP-hard. These results highlight the difficulty of the mixed goods case because the problems can be solved in polynomial time when there are only divisible goods or only indivisible goods.

As a positive result, we show the following tractability when divisible goods are identical. This class includes the case when the divisible goods are money.

▶ **Theorem 4.** *Let Φ be a symmetric strictly convex function. There exists a polynomial-time algorithm that finds a Φ-fair allocation if all the divisible goods are identical.*

This result may be interesting, because in fact, finding an allocation that attains a given utility vector is NP-hard (see Appendix B in the full version [29]). Nevertheless, Theorem 4 says that we can obtain not only a Φ-minimizer (utility vector) but also an allocation that attains the utility vector.

A key tool to construct our algorithm is the canonical partition for the mixed goods. By applying it, we can partition goods as $E_1, \dots, E_q$ and agents as $N_1, \dots, N_q$ so that goods in E_j are allocated to agents in N_j in a Φ-fair allocation (Theorem 29). Thanks to this structure, a Φ-minimizer can be found by independently solving the subproblems of assigning E_j to N_j for $j = 1, 2, \dots, q$. In each subproblem, the utility of every agent is almost the same. However, unlike the continuous or discrete case, an optimal allocation depends on Φ (see Examples 6 and 7). Thus, it is not easy to obtain a full characterization of minimizers.

Due to the space limitation, some proofs are omitted. They can be found in the full version [29].

1.2 Related work

The (integral) base-polyhedron has been studied in the theory of matroids and submodular functions [19]. The concept of M-convex sets [36] is defined as a set of integral vectors satisfying certain exchange axioms. *Discrete convex analysis* [37] is a framework of convex analysis in discrete settings, including M-convexity.

The concepts of continuous/discrete hybrid convexity have been proposed previously [35, 44]. In particular, an optimality criterion for an integral polyhedral hybrid M-convex function minimization is known [35]. However, the functions treated in the present paper are hybrid M-convex functions that are not necessarily integral polyhedral.

For the fair allocation of divisible homogeneous goods with additive valuations (not restricted to binary), an MNW allocation corresponds to a market equilibrium of a special case of the Fisher's market model (see, e.g., [39]). Moreover, an MNW allocation is *envy-free* (EF) [43, 45], that is, no agent envies any other agent. It is known that this problem can be solved in strongly polynomial time [41, 46].

For the fair allocation of indivisible goods with additive valuations, Caragiannis et al. [10] proved that an MNW allocation is *envy-free up to one good* (EF1), that is, each agent i does not envy another agent j if some indivisible good is removed from the bundle of agent j. Since computing an MNW allocation is hard in general [30], there is a series of research to design an approximation algorithm [1, 11, 12, 13, 22]. Benabbou et al. [6] proved that the set of MNW allocations coincides with that of minimizers of any symmetric strictly convex function, even when the utility of each agent is represented by a matroid rank function.[1] Harvey et al. [26] proposed efficient algorithms for computing an allocation that minimizes a certain symmetric strictly convex function. When agents have binary additive valuations, an MNW allocation can be computed in polynomial time [4, 14]. Truthful mechanisms to find an MNW allocation are also proposed [2, 24].

Fair allocation with a mixture of divisible and indivisible goods has recently gained attention. Bei et al. [5] introduced a fairness notion called *envy-freeness for mixed goods* (EFM) as a generalization of EF and EF1 notions. Very recently, Li et al. [31] proposed a truthful mechanism that outputs an EFM allocation for the case where agents have binary

[1] Note that Theorem 2 is an extension of this result. Specifically, we construct an "augmenting" path of [6, Section 3.2] for a hybrid situation.

additive valuations on indivisible goods and a common valuation on a single divisible good (e.g., money). They also showed that their mechanism runs in polynomial time, and its output achieves MNW. We remark that their algorithm does not work in our problem even when divisible goods are identical because we allow some agents to have value 0 on them. In addition, fair allocation of indivisible goods with subsidy [3, 8, 9, 23, 25, 28] is related to the problem since subsidy could be viewed as a divisible good. For more details, see a survey paper by Liu et al. [32].

2 Preliminaries

In this section, we explain the relationship between fair allocation of mixed goods and the hybrid problem (1). Then we introduce the canonical partition for the discrete case.

For $k \in \mathbb{N}$, we denote $[k] = \{1, 2, \ldots, k\}$. Let $N = [n]$ be a finite set. A set function f over N is called *supermodular* if

$$f(X) + f(Y) \leq f(X \cup Y) + f(X \cap Y) \quad (\forall X, Y \subseteq N)$$

and *submodular* if $-f$ is supermodular. For a subset $X \subseteq N$ and a vector $x \in \mathbb{R}^N$, we denote $x(X) = \sum_{i \in X} x_i$. For an integer-valued supermodular set function f on N for which $f(\emptyset) = 0$ (normalized), the *integral base-polyhedron* $\overline{\mathbf{B}}$ of f is defined as

$$\overline{\mathbf{B}} = \left\{ x \in \mathbb{R}^N : x(N) = f(N) \text{ and } x(X) \geq f(X) \ (\forall X \subseteq N) \right\}.$$

In addition, we call the set $\ddot{\mathbf{B}}$ of the integer vectors in an integral base-polyhedron $\overline{\mathbf{B}}$ an *M-convex set*. Note that an M-convex set $\ddot{\mathbf{B}}$ induces an integral base-polyhedron $\overline{\mathbf{B}}$ as its convex hull.

We say that a function $\Phi \colon \mathbb{R}^N \to \mathbb{R}$ is *symmetric* if

$$\Phi(z_1, z_2, \ldots, z_n) = \Phi(z_{\sigma(1)}, z_{\sigma(2)}, \ldots, z_{\sigma(n)})$$

for all permutations σ over $[n]$. We say that a function $\Phi \colon \mathbb{R}^N \to \mathbb{R}$ is strictly *convex* if

$$\lambda \Phi(z) + (1 - \lambda)\Phi(z') > \Phi(\lambda z + (1 - \lambda)z')$$

for all $z, z' \in \mathbb{R}^N$ and $\lambda \in (0, 1)$. A typical example of symmetric strictly convex functions is the square-sum $\Phi(z) = \sum_{i \in N} z_i^2$.

In general, for $z \in \mathbb{R}^N$ and $i, j \in N$ with $z_i > z_j$, we have $\Phi(z - \varepsilon(\chi_i - \chi_j)) < \Phi(z)$ for any $\varepsilon \in (0, z_i - z_j)$ because

$$\begin{aligned} \Phi(z) &= \lambda \Phi(z - (z_i - z_j)(\chi_i - \chi_j)) + (1 - \lambda)\Phi(z) \\ &> \Phi(\lambda(z - (z_i - z_j)(\chi_i - \chi_j)) + (1 - \lambda)z) = \Phi(z - \lambda(z_i - z_j)(\chi_i - \chi_j)) \end{aligned} \tag{2}$$

for any $\lambda \in (0, 1)$. Here, χ_i represents a unit vector where only the ith component is equal to 1, while all other components are equal to 0.

2.1 Relationship to fair allocation

Let $N = [n]$ represent the set of n agents. We have two types of goods: $M = \{g_1, g_2, \ldots, g_m\}$ represents the set of indivisible goods, and $C = \{c_1, c_2, \ldots, c_r\}$ denotes the set of homogeneous divisible goods, that is, the valuation for a piece of a good is proportional to its fraction. The set of all goods is denoted by $E = M \cup C$. Let v_{ie} be the valuation of good $e \in E$ for

agent $i \in N$. We assume that agents have binary valuations, that is, the valuation v_{ie} for the whole of good e is either 0 or 1 for all $i \in N$ and $e \in E$. An instance of the fair allocation we deal with in this paper is described as (N, M, C, v). Without loss of generality, we assume that, for any $e \in E$, there exists $i \in N$ such that $v_{ie} = 1$.

A *relaxed allocation* is defined as a matrix $\pi \in [0,1]^{N \times E}$ that satisfies (i) $\sum_{i \in N} \pi_{ie} = 1$ for all $e \in E$ and (ii) $\pi_{ie} = 0$ for any $i \in N$ and $e \in E$ with $v_{ie} = 0$. In a relaxed allocation π, each agent i receives each good e in the proportion of π_{ie}. Relaxed allocations treat indivisible goods as divisible. A relaxed allocation π is an *allocation* if it additionally satisfies $\pi_{ie} \in \{0,1\}$ for all $i \in N$ and $e \in M$. A relaxed allocation π is an *integral allocation* if it additionally satisfies $\pi_{ie} \in \{0,1\}$ for all $i \in N$ and $e \in E$. For an allocation π, an agent $i \in N$, and a subset of goods $E' \subseteq E$, let $\pi_i(E') = \sum_{e \in E'} \pi_{ie}$, which is the valuation of agent i's bundle from E'. For an allocation π, the utility of agent $i \in N$ is defined as $\pi_i(E)$. For an allocation π, let $\pi(E)$ be the utility vector $(\pi_1(E), \ldots, \pi_n(E))$.

Here we rewrite the set of possible utility vectors in terms of an integral base-polyhedron. We define $f_M, f_C, f_E \colon 2^N \to \mathbb{Z}_+$ as follows: for a subset $X \subseteq N$ of agents,

- $f_M(X) = |\{g \in M : v_{ig} = 0 \ (\forall i \notin X)\}|$ is the number of indivisible goods that must be allocated to agents in X,
- $f_C(X) = |\{c \in C : v_{ic} = 0 \ (\forall i \notin X)\}|$ is the number of divisible goods that must be allocated to agents in X, and
- $f_E(X) = f_M(X) + f_C(X)$ is the number of goods that must be allocated to agents in X.

It is not difficult to see that the functions f_M, f_C, f_E are normalized integer-valued supermodular.[2] Let $\ddot{\mathbf{B}}_M$ and $\overline{\mathbf{B}}_C$ be the M-convex set of f_M and the integral base-polyhedron of f_C, respectively. In addition, let $\mathbf{B}_E$ be the Minkowski sum of $\ddot{\mathbf{B}}_M$ and $\overline{\mathbf{B}}_C$, i.e., $\mathbf{B}_E = \{x + y : x \in \ddot{\mathbf{B}}_M, \ y \in \overline{B}_C\}$. Then, $\mathbf{B}_E$ is the set of possible utility vectors.

Recall that $\overline{\mathbf{B}}_M = \mathrm{conv}(\ddot{\mathbf{B}}_M)$ and $\ddot{\mathbf{B}}_C = \overline{B}_C \cap \mathbb{Z}^N$. We denote $\overline{\mathbf{B}}_E = \mathrm{conv}(\mathbf{B}_E)$, and $\ddot{\mathbf{B}}_E = \mathbf{B}_E \cap \mathbb{Z}^N$. Note that $\mathbf{B}_E$ is not necessarily an M-convex set or an integral base-polyhedron as we have seen in Example 1.

For a symmetric strictly convex function Φ, an allocation π is called Φ-*fair* if the utility vector $(\pi_1(E), \ldots, \pi_n(E))$ minimizes Φ among allocations.

Some prominent fairness notions are naturally represented as Φ-fairness for some Φ. An allocation π is said to achieve the *maximum Nash welfare* (MNW) if the number of agents with positive utilities is maximized, and subject to that, the Nash welfare $(\prod_{i \in N : \pi_i(E) > 0} \pi_i(E))^{1/n}$ is maximized. Finding a utility vector of an MNW allocation is equivalent to minimizing $-\prod_{i \in N : z_i > 0}(z_i + \varepsilon)$ for some sufficiently small $\varepsilon > 0$ (see Appendix A in the full version [29]). The egalitarian social welfare is defined by the smallest utility among agents. Maximizing the egalitarian social welfare is a weaker notion of *increasingly maximal* (*inc-max*, for short) allocations; an allocation is inc-max if its smallest utility is as large as possible, within this, its second smallest utility is as large as possible, and so on. Similarly, we say that an allocation is *decreasingly minimal* (*dec-min*, for short) if its largest utility is as small as possible, within this, its second largest utility is as small as possible, and so on. We show that a certain symmetric strictly convex function Φ induces the dec-min and inc-max solution as a Φ-fair allocation.

[2] Most of our results can be extended to the case when each agent evaluates indivisible goods with a matroid rank function and divisible goods with the concave closure of a matroid rank function because the functions f_M, f_C, f_E continue to be normalized integer-valued supermodular in this scenario.

▶ **Proposition 5.** *Let (N, M, C, v) be a fair allocation instance. There exists a symmetric strictly convex function Φ such that a dec-min allocation is Φ-fair. In addition, there exists a symmetric strictly convex function Φ' such that an inc-max allocation is Φ'-fair.*

Then for a symmetric strictly convex function $\Phi\colon \mathbb{R}^N \to \mathbb{R}$, we can rewrite finding a utility vector z^* of a Φ-fair allocation as the hybrid problem (1). If $M = \emptyset$ or $C = \emptyset$, the problem (1) can be solved in polynomial time [15, 16, 17, 18, 34].

When there are only divisible goods or only indivisible goods, once we obtain a Φ-mimizer z^* of (1), a Φ-fair allocation π is obtained by using the maximum flow problem. Since we can find an integral maximum flow in the indivisible goods case, π can be an integral allocation. However, when both types of goods exist, it is not straightforward to construct an allocation from a given utility vector. Indeed, given a vector u (not necessarily in $\mathbf{B}_E$), checking the existence of an allocation whose utility vector is u is NP-hard (see Appendix B in the full version [29]).

As mentioned in Introduction, when $\mathbf{B}_E = \overline{\mathbf{B}}_C$ (continuous case) or $\mathbf{B}_E = \ddot{\mathbf{B}}_M$ (discrete case), the set of Φ-minimizers is independent of Φ. However, this is not the case in general even in fair allocation with both types of goods (i.e., $M \neq \emptyset$ and $C \neq \emptyset$). Thus, our problem is challenging.

▶ **Example 6.** Consider an instance with five agents $N = \{1, 2, 3, 4, 5\}$, five indivisible goods $M = \{g_1, g_2, g_3, g_4, g_5\}$, and three divisible goods $C = \{c_1, c_2, c_3\}$. Suppose that agents 1, 2, 3, and 4 desire all the goods, but agent 5 desires only the indivisible goods (see Table 1). Then, an allocation π with $\pi(E) = (7/4, 7/4, 7/4, 7/4, 1)$ is dec-min. However, an allocation ρ with $\rho(E) = (6/4, 6/4, 6/4, 6/4, 2)$ is inc-max and square-sum minimizer. Indeed, $\sum_{i\in N} \pi_i(E)^2 = 13.25$ and $\sum_{i\in N} \rho_i(E)^2 = 13$.

▶ **Example 7.** Consider an instance with five agents $N = \{1, 2, 3, 4, 5\}$, five indivisible goods $M = \{g_1, g_2, g_3, g_4, g_5\}$, and *two* divisible goods $C = \{c_1, c_2\}$. Suppose that agents 1, 2, 3, and 4 desire all the goods, but agent 5 desires only the indivisible goods. Then, an allocation π with $\pi(E) = (\frac{6}{4}, \frac{6}{4}, \frac{6}{4}, \frac{6}{4}, 1)$ is dec-min and square-sum minimizer. However, an allocation ρ with $\rho(E) = (\frac{5}{4}, \frac{5}{4}, \frac{5}{4}, \frac{5}{4}, 2)$ is inc-max. Indeed, $\sum_{i\in N} \pi_i(E)^2 = 10$ and $\sum_{i\in N} \rho_i(E)^2 = 10.25$.

2.2 Principal Partition and Canonical Partition

Consider the integral base-polyhedron $\overline{\mathbf{B}}$ and the M-convex set $\ddot{\mathbf{B}}$ of a supermodular function $f\colon 2^N \to \mathbb{Z}_+$. For any real number λ, let $\mathcal{L}(\lambda)$ be the set of all maximizers of $f(X) - \lambda|X|$, i.e., $\mathcal{L}(\lambda) = \arg\max_{X\subseteq N}(f(X) - \lambda|X|)$. Note that $\mathcal{L}$ has a lattice structure, i.e., $\mathcal{L}$ is closed under union and intersection. Let $\mathrm{L}(\lambda)$ be the smallest member in $\mathcal{L}(\lambda)$. It is known that $\mathrm{L}(\lambda) \subseteq \mathrm{L}(\lambda')$ for any $\lambda > \lambda'$ (see, e.g., [17, Proposition 3.1]).

Fujishige [18] characterized the optimal utility vectors by the *principal partition* of N. There are at most $|N|$ number of λ for which $|\mathcal{L}(\lambda)| \geq 2$. Let us denote such numbers as $\lambda_1 > \lambda_2 > \cdots > \lambda_r$, which are called the *critical values*. The principal partition $\hat{N}_1, \hat{N}_2, \ldots, \hat{N}_r$ is a partition of N defined by

$$\hat{N}_j = \mathrm{L}(\lambda'_j) - \mathrm{L}(\lambda_j) \quad (j = 1, 2, \ldots, r),$$

where λ'_j is an arbitrary real satisfying $\lambda_j > \lambda'_j > \lambda_{j+1}$ (assuming that $\lambda_{r+1} = -\infty$).

▶ **Theorem 8** (Fujishige [18] and Maruyama [34]). *The unique minimizer x^* of $\min_{x \in \overline{\mathbf{B}}} \Phi(x)$ satisfies $x^*_i = \lambda_j$ for each $i \in \hat{N}_j$ and $j \in [r]$.*

The principal partition and critical values can be found in strongly polynomial time by using the submodular function minimization [27, 42]; see also [38]. For more details of the principal partition, see a book and a survey of Fujishige [19, 20].

Frank and Murota [15] characterized the optimal utility vectors of $\min_{y \in \ddot{\mathbf{B}}} \Phi(y)$ by the *canonical partition* of N. There are at most $|N|$ number of $\beta \in \mathbb{Z}$ for which $\mathrm{L}(\beta) \neq \mathrm{L}(\beta - 1)$. Let us denote such numbers as $\beta_1 > \beta_2 > \cdots > \beta_q$, which are called the *essential values*. The canonical partition $N_1, N_2, \ldots, N_q$ is a partition of N defined by

$$N_i = \mathrm{L}(\beta_i - 1) - \mathrm{L}(\beta_i) \quad (i = 1, 2, \ldots, q).$$

Alternatively, the canonical partition and the essential values can be obtained by the following procedure [17, Section 3]: for $j = 1, 2, \ldots, q$, define

$$\beta_j = \max_{\emptyset \neq X \subseteq N \setminus \bigcup_{j'=1}^{j-1} N_{j'}} \left\lceil (f(X \cup \textstyle\bigcup_{j'=1}^{j-1} N_{j'}) - f(\bigcup_{j'=1}^{j-1} N_{j'}))/|X| \right\rceil, \tag{3}$$

$$h_j(X) = f(X \cup \textstyle\bigcup_{j'=1}^{j-1} N_{j'}) - (\beta_j - 1)|X| - f(\bigcup_{j'=1}^{j-1} N_{j'}) \quad (\forall X \subseteq N \setminus \textstyle\bigcup_{j'=1}^{j-1} N_{j'}),$$

$$N_j = \text{smallest subset of } N \setminus \textstyle\bigcup_{j'=1}^{j-1} N_{j'} \text{ maximizing } h_j.$$

They provided a strongly polynomial-time algorithm to compute the canonical partition and the essential values by using this structure and a strongly polynomial-time algorithm for the submodular function minimization [27, 42].

▶ **Theorem 9** (Frank and Murota [15, 16, 17]). *The essential values $\beta_1 > \beta_2 > \cdots > \beta_q$ are obtained from the critical values $\lambda_1 > \lambda_2 > \cdots > \lambda_r$ as the distinct members of the rounded-up integers $\lceil \lambda_1 \rceil \geq \lceil \lambda_2 \rceil \geq \cdots \geq \lceil \lambda_r \rceil$. Moreover, the canonical partition is an aggregation of the principal partition as $N_i = \bigcup_{j: \lceil \lambda_j \rceil = \beta_i} \hat{N}_j$ for each $i \in [q]$. Any minimizer y^* of $\min_{y \in \ddot{\mathbf{B}}} \Phi(y)$ satisfies $\beta_j - 1 \leq y^*_i \leq \beta_j$ for each $i \in N_j$ and $j \in [q]$. The minimizer y^*, the canonical partition, and essential values can be found in strongly polynomial time with respect to $|N|$.*

3 Exchange properties of integral base-polyhedra and M-convex sets

In this section, we review exchange properties of an integral base-polyhedron and an M-convex set. We also add new exchange properties for our hybrid case.

Let $f \colon 2^N \to \mathbb{Z}$ be a supermodular function. Let $\overline{\mathbf{B}}$ be an integral base-polyhedra and let $\ddot{\mathbf{B}}$ be an M-convex set defined by f. It is known that the M-convex set $\ddot{\mathbf{B}}$ and the integral base-polyhedron $\overline{\mathbf{B}}$ satisfy the *exchange properties*, respectively. For a vector $z \in \mathbb{R}^N$, define $\mathrm{supp}^+(z) \coloneqq \{i \in N : z_i > 0\}$ and $\mathrm{supp}^-(z) \coloneqq \{i \in N : z_i < 0\}$.

▶ **Proposition 10** ([37]). *For any $x, y \in \ddot{\mathbf{B}}$ and $i \in \mathrm{supp}^+(x - y)$, there exists some $j \in \mathrm{supp}^-(x - y)$ such that $x - \chi_i + \chi_j \in \ddot{\mathbf{B}}$ and $y + \chi_i - \chi_j \in \ddot{\mathbf{B}}$.*

▶ **Proposition 11** ([37]). *For any $x, y \in \overline{\mathbf{B}}$ and $i \in \mathrm{supp}^+(x - y)$, there exists some $j \in \mathrm{supp}^-(x - y)$ and a positive real α_0 such that $x - \alpha(\chi_i - \chi_j) \in \overline{\mathbf{B}}$ and $y + \alpha(\chi_i - \chi_j) \in \overline{\mathbf{B}}$ for all $\alpha \in [0, \alpha_0]$.*

In addition, we show the following variants of exchange properties.

▶ **Proposition 12.** *For any $x, y \in \ddot{\mathbf{B}}$ and $X \subseteq N$ with $x(X) > y(X)$, there exist $i \in X$ and $j \in N \setminus X$ such that $x - \chi_i + \chi_j \in \ddot{\mathbf{B}}$. Moreover, if $x(X) > f(X)$, there exist $i \in X$ and $j \in N \setminus X$ such that $x - \chi_i + \chi_j \in \ddot{\mathbf{B}}$.*

▶ **Proposition 13.** *For any $x, y \in \overline{\mathbf{B}}$ and $X \subseteq N$ with $x(X) > y(X)$, there exist $i \in X$, $j \in N \setminus X$, and $\varepsilon > 0$ such that $x - \varepsilon(\chi_i - \chi_j) \in \overline{\mathbf{B}}$. Moreover, if $x(X) > f(X)$, there exist $i \in X$, $j \in N \setminus X$, and $\varepsilon > 0$ such that $x - \varepsilon(\chi_i - \chi_j) \in \overline{\mathbf{B}}$.*

▶ **Proposition 14.** *For any $x \in \ddot{\mathbf{B}}$ and disjoint subsets $I, J \subseteq N$ such that $x(J) < f(I \cup J) - f(I)$, there exist $i \in I$ and $j \in J$ such that $x - \chi_i + \chi_j \in \ddot{\mathbf{B}}$.*

Then we show an exchange property for the hybrid situation.

▶ **Proposition 15.** *For any $x \in \ddot{\mathbf{B}}$ and $y \in \overline{\mathbf{B}}$, and $i \in \operatorname{supp}^+(x - y)$, there exists $j \in \operatorname{supp}^-(x-y)$ such that $x-\chi_i+\chi_j \in \ddot{\mathbf{B}}$. Also, for any $x \in \ddot{\mathbf{B}}$ and $y \in \overline{\mathbf{B}}$, and $i \in \operatorname{supp}^-(x-y)$, there exists $j \in \operatorname{supp}^+(x - y)$ such that $x + \chi_i - \chi_j \in \ddot{\mathbf{B}}$.*

Proof. We only provide a proof for the former part, as the latter part can be demonstrated in a similar manner. By Proposition 11, there exists some $j \in \operatorname{supp}^-(x - y)$ and a positive real α_0 such that $x' \coloneqq x - \alpha_0(\chi_i - \chi_j) \in \overline{\mathbf{B}}$. For any $X \subseteq N$ with $i \in X$ and $j \notin X$, we have $x'(X) = x(X) - \alpha_0 \geq f(X)$, and hence $x(X) - 1 \geq f(X)$ since $x(X)$ and $f(X)$ are integers. Therefore, $x - \chi_i + \chi_j \in \ddot{B}$ holds. ◀

4 Structure of Φ-minimizers

In this section, we prove a proximity theorem (Theorem 2) by using the structure (Lemma 28) based on the canonical partition. Moreover, in the case of fair allocation, we also show that the problem has a canonical partition of goods (Theorem 29).

Let f_M and f_C be two supermodular functions over M and C, respectively. Let also $f_E = f_M + f_C$. Recall that $\ddot{\mathbf{B}}_M$ and $\overline{\mathbf{B}}_C$ are a corresponding M-convex set and integral base-polyhedron, respectively. In addition, $\mathbf{B}_E$ is the Minkowski sum of $\ddot{\mathbf{B}}_M$ and $\overline{\mathbf{B}}_C$.

It should be noted that, for the integral base-polyhedron $\overline{\mathbf{B}}$ and the M-convex set $\ddot{\mathbf{B}}$ of a common supermodular function, the following proximity theorem has been shown by Frank and Murota [17].

▶ **Theorem 16** ([17, Theorem 4.1])**.** *Let Φ be a symmetric strictly convex function. For any $x^* \in \arg\min_{x \in \ddot{\mathbf{B}}} \Phi(x)$ and $y^* \in \arg\min_{y \in \overline{\mathbf{B}}} \Phi(y)$, we have $\lfloor y_i^* \rfloor \leq x_i^* \leq \lceil y_i^* \rceil$ for all $i \in N$.*

Note that this is a special case of our Theorem 2 when $f_C(X) = 0$ ($\forall X \subseteq N$). We prove Theorem 2 following the same approach as for Theorem 16. However, we need to conduct a more detailed analysis to handle $\overline{\mathbf{B}}_C$.

Throughout this section, we fix a symmetric strictly convex function $\Phi\colon \mathbb{R}^N \to \mathbb{R}$ and its minimizer $z^* \in \arg\min_{z \in \mathbf{B}_E} \Phi(z)$. By definition, z^* can be represented as $x^* + y^*$ by $x^* \in \ddot{\mathbf{B}}_M$ and $y^* \in \overline{\mathbf{B}}_C$. Moreover, let $N_1, \ldots, N_q$ and $\beta_1, \ldots, \beta_q$ be the canonical partition and the essential values of the M-convex set $\ddot{\mathbf{B}}_E$.

In subsequent subsections, we prove Theorem 2 through the following steps. First, in Section 4.1, we demonstrate that z_i^* lies within the interval $[\beta_1 - 1, \beta_1]$ for $i \in N_1$. Then, in Section 4.2, we decompose the problem of finding z^* into two independent problems on N_1 and $N \setminus N_1$. By iteratively applying the same procedure, we obtain the desired structure. In Section 4.3, we show an additional result when $\mathbf{B}_E$ emerges from the fair allocation.

4.1 The peak-set N_1

In this subsection, we prove that $\beta_1 - 1 \leq z^*_i \leq \beta_1$ $(\forall i \in N_1)$ and $z^*(N_1) = f_E(N_1)$. The main idea to prove these is to transfer some amounts from elements with high value to those with low value, which improves the objective value. Here, we need to be careful about the constraint.

We first introduce the basic properties for an M-convex set $\ddot{\mathbf{B}}$ and an integral base-polyhedron $\overline{\mathbf{B}}$.

▶ **Proposition 17.** *For any $x \in \ddot{\mathbf{B}}$, if $x - \chi_i + \chi_j \in \ddot{\mathbf{B}}$ and $x - \chi_j + \chi_k \in \ddot{\mathbf{B}}$, then it holds that $x - \chi_i + \chi_k \in \ddot{\mathbf{B}}$.*

▶ **Proposition 18** ([19, Lemma 4.5])**.** *Let $x \in \ddot{\mathbf{B}}$. Suppose that there exist a sequence $i_1, j_1, \ldots, i_r, j_r$ of $2r$ distinct elements in N such that $x - \chi_{i_h} + \chi_{j_k} \in \ddot{\mathbf{B}}$ if $h = k$ and $x - \chi_{i_h} + \chi_{j_k} \notin \ddot{\mathbf{B}}$ if $h > k$ for $h, k \in [r]$. Then, it holds that $x - \sum_{k\in[r]}(\chi_{i_k} - \chi_{j_k}) \in \ddot{\mathbf{B}}$.*

▶ **Proposition 19** ([37])**.** *For any $x \in \overline{\mathbf{B}}$, we have $x \in \mathrm{conv}(\overline{\mathbf{B}} \cap \{y \in \mathbb{Z}^N : \|x - y\|_\infty < 1\})$.*

▶ **Lemma 20.** *If $y^* + \varepsilon(\chi_i - \chi_j) \in \overline{\mathbf{B}}_C$ for some $i, j \in N$ and $\varepsilon > 0$, then $z^*_i = x^*_i + y^*_i \geq x^*_j + y^*_j = z^*_j$. In addition, for any $\beta \in \mathbb{R}$, it holds that $y^*(N') = f_C(N')$ with $N' = \{i \in N : z^*_i \geq \beta\}$.*

Proof. For the former statement, suppose to the contrary that $y^* + \varepsilon(\chi_i - \chi_j) \in \overline{\mathbf{B}}_C$ for some $i, j \in N$ such that $x^*_i + y^*_i < x^*_j + y^*_j$ and $\varepsilon > 0$. Then, $y = y^* + \min\{\varepsilon, (y^*_j - y^*_i)/2\} \cdot (\chi_i - \chi_j) \in \overline{\mathbf{B}}_C$ and $\Phi(x^* + y) < \Phi(x^* + y^*)$ by (2). This contradicts the assumption that $z^* = x^* + y^*$ is a Φ-minimizer.

For the latter statement, suppose that $y^*(N') > f_C(N')$ for some $N' = \{i \in N : z^*_i \geq \beta\}$ with $\beta \in \mathbb{R}$. Then, by Proposition 13, there exist $i \in N'$, $j \in N \setminus N'$, and $\varepsilon > 0$ such that $y^* + \varepsilon(\chi_j - \chi_i) \in \overline{\mathbf{B}}_C$. By the former statement, this implies $z^*_j \geq z^*_i$, contradicting $j \notin N'$. ◀

We define a graph whose edge represents that transferring a unit amount of elements does not violate the constraints. Then we show that transferring a unit amount along a path will improve the objective value.

▶ **Lemma 21.** *Let β be an integer and $N' \subseteq N$. Define $N^> = \{i \in N : z^*_i > \beta\}$, $N^= = \{i \in N : z^*_i = \beta\}$, and $N^< = \{i \in N : z^*_i < \beta\}$. Construct a graph*

$$G = \big(N', \big\{(i,j) \in N' \times N' : x^* - \chi_i + \chi_j \in \ddot{\mathbf{B}}_M \text{ or } y^* - \chi_i + \chi_j \in \overline{\mathbf{B}}_C\big\}\big).$$

If G has a path from some $i \in N' \cap N^>$ to some $j \in N' \cap N^>$ with $i \neq j$, then there exists a vector z'' such that $\Phi(z'') < \Phi(z^*)$.

Proof. We first observe that Lemma 20 implies $y^*(N^>) = f_C(N^>)$ and $y^*(N^> \cup N^=) = f_C(N^> \cup N^=)$.

Let $P = (i_1, i_2, \ldots, i_k)$ be a shortest path from some $i_1 \in N' \cap N^>$ to some $i_k \in N' \cap N^<$. Then we have $i_1 \in N^>$, $i_2, \ldots, i_{k-1} \in N^=$, and $i_k \in N^<$. Since $z^*_{i_2} < z^*_{i_1}$, Lemma 20 implies that $y^* - \chi_{i_1} + \chi_{i_2} \notin \overline{\mathbf{B}}_C$, and thus $x^* - \chi_{i_1} + \chi_{i_2} \in \ddot{\mathbf{B}}_M$. If $x^* - \chi_{i_2} + \chi_{i_3} \in \ddot{\mathbf{B}}_M$, then $x^* - \chi_{i_1} + \chi_{i_3} \in \ddot{\mathbf{B}}_M$ by Proposition 17, which leads to a shortcut of P. Thus, we have $x^* - \chi_{i_2} + \chi_{i_3} \notin \ddot{\mathbf{B}}_M$ and instead, $y^* - \chi_{i_2} + \chi_{i_3} \in \overline{\mathbf{B}}_C$ holds. Next, let us assume that $y^* - \chi_{i_3} + \chi_{i_4} \in \overline{\mathbf{B}}_C$ and $i_4 \in N^=$, and derive a contradiction. Consider

$$\overline{\mathbf{B}}^= = \left\{ \tilde{y} \in \mathbb{R}^{N^=} : \begin{array}{l} \tilde{y}(N^=) = f_C(N^= \cup N^>) - f_C(N^>), \\ \tilde{y}(X) \geq f_C(X \cup N^>) - f_C(N^>) \ (\forall X \subseteq N^=) \end{array} \right\},$$

which is also an integral base-polyhedron of a supermodular function. Since β is an integer, $y^*_{N^=}$ is also integral. Thus, the vectors $y^*_{N^=} - \chi_{i_2} + \chi_{i_3}$ and $y^*_{N^=} - \chi_{i_3} + \chi_{i_4}$ are contained in $\ddot{\mathbf{B}}^=$, since $y^*(N^>) = f_C(N^>)$ and $i_2, i_3, i_4 \in N^=$. Then $y^*_{N^=} - \chi_{i_2} + \chi_{i_4} \in \ddot{\mathbf{B}}^=$ follows from Proposition 17, which means that $y^* - \chi_{i_2} + \chi_{i_4} \in \overline{\mathbf{B}}_C$[3]. However, this implies a shortcut of P. Therefore, if $i_4 \in N^=$, then $y^* - \chi_{i_3} + \chi_{i_4} \notin \overline{\mathbf{B}}_C$, and hence $x^* - \chi_{i_3} + \chi_{i_4} \in \ddot{\mathbf{B}}_M$. By the same argument, we have $x^* - \chi_{i_\ell} + \chi_{i_{\ell+1}} \in \ddot{\mathbf{B}}_M$ if ℓ is an odd number and $i_{\ell+1} \in N^=$, and $y^* - \chi_{i_\ell} + \chi_{i_{\ell+1}} \in \overline{\mathbf{B}}_C$ if ℓ is an even number. Note that k must be an even number, because $y^* - \chi_{i_{k-1}} + \chi_{i_k} \notin \overline{\mathbf{B}}_C$ follows from Lemma 20 and $z^*_{i_k} < z^*_{i_{k-1}}$. Moreover, for any integers ℓ and h with $\ell \geq h+2$, we have $x^* - \chi_{i_\ell} + \chi_{i_h} \notin \ddot{\mathbf{B}}_M$ and $y^* - \chi_{i_\ell} + \chi_{i_h} \notin \overline{\mathbf{B}}_C$. Let $x' = x^* - \sum_{\ell:\,\mathrm{odd}}(\chi_{i_\ell} - \chi_{i_{\ell+1}})$, $y' = y^* - \sum_{\ell:\,\mathrm{even}}(\chi_{i_\ell} - \chi_{i_{\ell+1}})$, and $z' = x' + y'$. By Proposition 18, we have $x' \in \ddot{\mathbf{B}}_M$, $y' \in \overline{\mathbf{B}}_C$, and $z' \in \mathbf{B}_E$. Note that $z' = z^* - \chi_{i_1} + \chi_{i_k}$, $y'(N^>) = y^*(N^>)$ $(= f_C(N^>))$ and $y'(N^> \cup N^=) = y^*(N^> \cup N^=)$ $(= f_C(N^> \cup N^=))$ by the construction. For notational convenience, we denote $i^* = i_1$ and $j^* = i_k$ in the following.

If $z^*_{i^*} > z^*_{j^*} + 1$, then $\Phi(z') < \Phi(z^*)$. Thus, suppose that $z^*_{i^*} \leq z^*_{j^*} + 1$ $(< \beta + 1)$. In this case, $\beta - 1 < z'_{i^*} < \beta$ and $\beta < z'_{j^*} < \beta + 1$. By Proposition 19, y' can be represented by a convex combination of its integral neighbors in $\overline{\mathbf{B}}_C$. Let $y' = \sum_{t=1}^r \lambda^{(t)} \cdot y^{(t)}$, where $y^{(t)} \in \ddot{\mathbf{B}}_C \cap \{y \in \mathbb{Z}^N : \|y - y'\| < 1\}$ $(\forall t \in [r])$, $\sum_{t=1}^r \lambda^{(t)} = 1$, and $\lambda^{(t)} \geq 0$ $(\forall t \in [r])$. Define $z^{(t)} = x' + y^{(t)}$ for each t. Thus, we also obtain $z' = \sum_{t=1}^r \lambda^{(t)} \cdot z^{(t)}$. Note that $z^{(t)}_{i^*} \in \{\beta - 1, \beta\}$ and $z^{(t)}_{j^*} \in \{\beta, \beta + 1\}$ for each t. In addition, for each t, it holds that $y^{(t)}(N^>) = f_C(N^>)$ because $\sum_{t=1}^r \lambda^{(t)} \cdot y^{(t)}(N^>) = y'(N^>) = y^*(N^>) = f_C(N^>)$ and $y^{(t)}(N^>) \geq f_C(N^>)$. Similarly, we can see that $y^{(t)}(N^> \cup N^=) = f_C(N^> \cup N^=)$ for each t.

Let us choose an arbitrary t with $z^{(t)}_{i^*} = \beta - 1$. Let

$$\overline{\mathbf{B}}^> = \{\tilde{y} \in \mathbb{R}^{N^>} : \tilde{y}(N^>) = f_C(N^>) \text{ and } \tilde{y}(X) \geq f_C(X)\ (\forall X \subseteq N^>)\}$$

(the restriction of $\overline{\mathbf{B}}_C$ to $N^>$), and $\ddot{\mathbf{B}}^>$ be the M-convex set induced from $\overline{\mathbf{B}}^>$. Then it holds that $y^{(t)}_{N^>} \in \ddot{\mathbf{B}}^>$, $y'_{N^>} \in \overline{\mathbf{B}}^>$ and $i^* \in \mathrm{supp}^-(y^{(t)}_{N^>} - y'_{N^>})$. We apply Proposition 15 to them. Then we can choose an index $i^{(t)} \in \mathrm{supp}^+(y^{(t)}_{N^>} - y'_{N^>})$ such that $y^{(t)}_{N^>} + \chi_{i^*} - \chi_{i^{(t)}} \in \overline{\mathbf{B}}^>$. We show that this implies $\hat{y}^{(t)} := y^{(t)} + \chi_{i^*} - \chi_{i^{(t)}} \in \overline{\mathbf{B}}_C$. Indeed, for any X with $i^* \notin X$ and $i^{(t)} \in X$ (the other cases are trivial), since $y^{(t)}(X \cap N^>) - 1 \geq f_C(X \cap N^>)$, we have

$$\begin{aligned} y^{(t)}(X) &= y^{(t)}(X \cap N^>) + y^{(t)}(X \cup N^>) - y^{(t)}(N^>) \\ &> f_C(X \cap N^>) + f_C(X \cup N^>) - f_C(N^>) \geq f_C(X), \end{aligned}$$

which implies that $\hat{y}^{(t)}(X) \geq f_C(X)$. In addition, we observe that $z^{(t)}_{i^{(t)}} = y^{(t)}_{i^{(t)}} + x'_{i^{(t)}} > y'_{i^{(t)}} + x'_{i^{(t)}} = z'_{i^{(t)}} = z_{i^{(t)}} > \beta$. Thus, since $z^{(t)}_{i^{(t)}}$ is an integer,

$$\hat{y}^{(t)}_{i^{(t)}} + x'_{i^{(t)}} = z^{(t)}_{i^{(t)}} - 1 \geq \beta. \tag{4}$$

On the other hand, for each t with $z^{(t)}_{i^*} = \beta$, we denote $\hat{y}^{(t)} = y^{(t)}$. We also remark that $\hat{y}^{(t)}(N^> \cup N^=) = y^{(t)}(N^> \cup N^=)$ and $\hat{y}^{(t)}_i = y^{(t)}_i$ for each t and $i \in N \setminus N^>$.

We will do similar operations for indices in $N^<$. Let us choose an arbitrary t with $z^{(t)}_{j^*} = \beta_1 + 1$. We show that we can choose $j^{(t)} \in N^<$ with $z^{(t)}_{j^{(t)}} \leq \beta_1 - 1$ such that $\hat{y}^{(t)} - \chi_{j^*} + \chi_{j^{(t)}} \in \overline{\mathbf{B}}_C$ by applying Proposition 15. We denote $N^\geq = N^> \cup N^=$. Let also

$$\overline{\mathbf{B}}^< = \left\{ \tilde{y} \in \mathbb{R}^{N^<} : \begin{array}{l} \tilde{y}(N^<) = f_C(N) - f_C(N^\geq), \\ \tilde{y}(X) \geq f_C(X \cup N^\geq) - f_C(N^\geq)\ (\forall X \subseteq N^<) \end{array} \right\}.$$

[3] We need to check for each X such that $i_2 \in X$ but $i_4 \notin X$. The case when $X \supseteq \{i_2, i_3\}$ follows by $y^* - \chi_{i_3} + \chi_{i_4} \in \overline{\mathbf{B}}_C$, and the case when $i_2 \in X$ but $i_3 \notin X$ follows by $y^* - \chi_{i_2} + \chi_{i_3} \in \overline{\mathbf{B}}_C$.

(the contraction of $\overline{\mathbf{B}}_C$ by $N^{\geq}$), and $\ddot{\mathbf{B}}^{<}$ be the M-convex set induced from $\overline{\mathbf{B}}^{<}$. Then it holds that $\hat{y}^{(t)}_{N^{<}} \in \ddot{\mathbf{B}}^{<}$, $y'_{N^{<}} \in \overline{\mathbf{B}}^{<}$ and $j^* \in \mathrm{supp}^+(\hat{y}^{(t)}_{N^{<}} - y'_{N^{<}})$. We apply Proposition 15 to them. Then we can choose an index $j^{(t)} \in \mathrm{supp}^-(\hat{y}^{(t)}_{N^{<}} - y'_{N^{<}})$ such that $\hat{y}^{(t)}_{N^{<}} - \chi_{j^*} + \chi_{j^{(t)}} \in \overline{\mathbf{B}}^{<}$. Then we can observe that $\hat{y}^{(t)} - \chi_{j^*} + \chi_{j^{(t)}} \in \overline{\mathbf{B}}_C$. Indeed, for any X with $j^* \in X$ and $j^{(t)} \notin X$, since $y^{(t)}(X \cap N^{<}) - 1 \geq f_C((X \cap N^{<}) \cup N^{\geq}) - f_C(N^{\geq})$ and $y^{(t)}(X \cap N^{\geq}) \geq f_C(X \cap N^{\geq})$, we have

$$\begin{aligned} y^{(t)}(X) &= y^{(t)}(X \cap N^{<}) + y^{(t)}(X \cap N^{\geq}) \\ &> f_C(X \cap N^{<}) - f_C(N^{\geq}) + f_C(X \cup N^{\geq}) \geq f_C(X). \end{aligned}$$

Moreover, $z^{(t)}_{j^{(t)}} < y'_{j^{(t)}} + x'_{j^{(t)}} = z'_{j^{(t)}} = z_{j^{(t)}} < \beta$, which implies that

$$\hat{y}^{(t)}_{j^{(t)}} + 1 + x'_{j^{(t)}} = z^{(t)}_{j^{(t)}} + 1 \leq \beta. \tag{5}$$

For simplicity, let $j^{(t)} = j^*$ for each t with $z^{(t)}_{j^*} = \beta$. Then, $y'' \coloneqq \sum_{t=1}^{r} \lambda^{(t)} \cdot (\hat{y}^{(t)} - \chi_{j^*} + \chi_{j^{(t)}}) \in \overline{\mathbf{B}}_C$.

Let $z'' = x' + y''$. Note that this operation to produce z'' first reduces the value of elements more than β while keeping them at least β by (4), and then increases the value of elements less than β while keeping them at most β by (5). In other words, $\beta_1 \leq z''_i \leq z^*_i$ for $i \in N^{>}$, $z''_i = z^*_i$ for $i \in N^{=}$, and $z^*_i \leq z''_i \leq \beta_1$ for $i \in N^{<}$. Therefore, $\Phi(z'') < \Phi(z^*)$ holds. This contradicts to the optimality of z^*. ◀

To prove $\beta_1 - 1 \leq z^*_i \leq \beta_1$, we find a path on the graph by supposing the contrary. While it is easy for the continuous or discrete case, elaborate analysis is required in the hybrid case. Recall that $\beta_1 = \max\{\lceil f_E(X)/|X| \rceil : \emptyset \neq X \subseteq N\}$ by (3).

▶ **Lemma 22.** *$z^*_i \leq \beta_1$ for all $i \in N$.*

Proof. Define the sets $N^{>} = \{i \in N : z^*_i > \beta_1\}$, $N^{=} = \{i \in N : z^*_i = \beta_1\}$, and $N^{<} = \{i \in N : z^*_i < \beta_1\}$. By Lemma 20, $y^*(N^{>}) = f_C(N^{>})$ and $y^*(N^{>} \cup N^{=}) = f_C(N^{>} \cup N^{=})$.

Suppose to the contrary that $N^{>}$ is nonempty. We construct a graph

$$G = \big(N, \big\{(i,j) \in N^2 : x^* - \chi_i + \chi_j \in \ddot{\mathbf{B}}_M \text{ or } y^* - \chi_i + \chi_j \in \overline{\mathbf{B}}_C\big\}\big).$$

We observe that for any Z with $N^{>} \subseteq Z \subseteq N^{>} \cup N^{=}$, it holds that

$$z^*(Z) > f_E(Z) \tag{6}$$

because $f_M(Z) + f_C(Z) = x^*(Z) + y^*(Z) = z^*(Z) > \beta_1 \cdot |Z| \geq f_E(Z) = f_M(Z) + f_C(Z)$, where the last inequality holds by the definition of β_1. This implies the following claim.

▷ Claim 23. For any Z satisfying (6), there exists an edge $(i,j) \in Z \times (N \setminus Z)$.

▷ Claim 24. There exist paths in G from some vertex in $N^{>}$ to some vertex in $N^{<}$.

By the above claim and Lemma 21 with $N' = N$ and $\beta = \beta_1$, there exists a vector z with $\Phi(z) < \phi(z^*)$, which contradicts to the optimality of z^*. This completes the proof of Lemma 22. ◀

We then prove that z^*_i is at least $\beta_1 - 1$ for all $i \in N_1$ by a similar technique to Lemma 22. Recall that N_1 is the smallest subset of N maximizing $f_E(X) - (\beta_1 - 1)|X|$.

▶ **Lemma 25.** *$z^*_i \geq \beta_1 - 1$ for all $i \in N_1$.*

We then show that we cannot decrease the values of elements in N_1 (which have high values) anymore. In the words of fair allocation, this means that goods not required to be assigned to N_1 are not assigned to N_1.

▶ **Lemma 26.** *$x^*(N_1) = f_M(N_1)$, $y^*(N_1) = f_C(N_1)$, and $z^*(N_1) = f_E(N_1)$.*

Proof. It is sufficient to prove that $z^*(N_1) = f_E(N_1)$. Let $N^> := \{i \in N : z^*_i > \beta_1 - 1\}$, $N^= := \{i \in N : z^*_i = \beta_1 - 1\}$, and $N^< := \{i \in N : z^*_i < \beta_1 - 1\}$.

Suppose to the contrary that $z^*(N_1) > f_E(N_1)$. We construct a graph

$$G = \big(N, \{(i,j) \in N \times N : x^* - \chi_i + \chi_j \in \ddot{\mathbf{B}}_M \text{ or } y^* - \chi_i + \chi_j \in \overline{\mathbf{B}}_C\}\big).$$

Since $N_1 \in \arg\max_{S \subseteq N} f_E(S) - (\beta_1 - 1)|S|$, we have $f_E(N_1) - (\beta_1 - 1)|N_1| \geq f_E(X) - (\beta_1 - 1)|X|$ for any $X \subseteq N$. For any X with $N^> \subseteq X \subseteq N^> \cup N^=$, it holds that

$$\begin{aligned}
z^*(X) &= z^*(N^>) + z^*(X \setminus N^>) = z^*(N^>) + (\beta_1 - 1) \cdot (|X| - |N^>|) \\
&\geq z^*(N^> \cap N_1) + (\beta_1 - 1) \cdot (|X| - |N^> \cap N_1|) \\
&= z^*(N_1) - (\beta_1 - 1) \cdot (|N_1| - |N^> \cap N_1|) + (\beta_1 - 1) \cdot (|X| - |N^> \cap N_1|) \\
&\qquad\qquad \text{(by Lemma 25)} \\
&= z^*(N_1) - (\beta_1 - 1)|N_1| + (\beta_1 - 1)|X| \\
&> f_E(N_1) - (\beta_1 - 1)|N_1| + (\beta_1 - 1)|X| \qquad \text{(by assumption)} \\
&\geq f_E(X) - (\beta_1 - 1)|X| + (\beta_1 - 1)|X| = f_E(X).
\end{aligned}$$

Hence, by the same proofs of Claims 23 and 24, there exist paths in G from an agent in $N^>$ to an agent in $N^<$. Then, by applying Lemma 21 with $N' = N$ and $\beta = \beta_1 - 1$, we can decrease the value of Φ, which is a contradiction. Hence, we obtain $z^*(N_1) = f_E(N_1)$. This implies that $x^*(N_1) = f_M(N_1)$ and $y^*(N_1) = f_C(N_1)$. ◀

4.2 Decomposition

We describe that we can derive a similar result for $N_2, \ldots, N_q$.

Let $N'_1 = N \setminus N_1$. For a supermodular function f, we denote $f^{(1)} \colon 2^{N'_1} \to \mathbb{Z}$ to be the supermodular function obtained from f by contracting N_1, i.e., $f^{(1)}(X) = f(X \cup N_1) - f(N_1)$ for each $X \subseteq N'_1$. We consider the M-convex set $\ddot{\mathbf{B}}^{(1)}_M$ of $f^{(1)}_M$, integral base-polyhedra $\overline{\mathbf{B}}^{(1)}_C$ of $f^{(1)}_C$, and $\mathbf{B}^{(1)}_E = \ddot{\mathbf{B}}^{(1)}_M + \overline{\mathbf{B}}^{(1)}_C$.

By Lemma 26, we have $z^*_{N'_1} \in \mathbf{B}^{(1)}_E$. In addition, for any $z_{N'_1} \in \mathbf{B}^{(1)}_E$, an extended vector $z = (z^*_{N_1}, z_{N'_1})$ is contained in $\mathbf{B}_E$ because $z(X) \geq f_E(X \cap N_1) + f^{(1)}_E(X \cap N'_1) = f_E(X \cap N_1) + f_E(X \cup N_1) - f(N_1) \geq f_E(X)$ for all $X \subseteq N$ by the supermodularity of f_E. Hence, we obtain the following lemma. Let $\Phi' \colon \mathbb{R}^{N'_1} \to \mathbb{R}$ be the symmetric strictly convex function such that $\Phi'(z_{N'_1}) = \Phi(z^*_{N_1}, z_{N'_1})$.

▶ **Lemma 27.** *For any $z_{N'_1} \in \mathbf{B}^{(1)}_E$, a vector $z = (z^*_{N_1}, z_{N'_1})$ is a Φ-minimizer of $\mathbf{B}_E$ if and only if $z_{N'_1}$ is a Φ'-minimizer of $\mathbf{B}^{(1)}_E$.*

Therefore, we can apply the results in Section 4.1 to N'_1, $f^{(1)}_M$, $f^{(1)}_C$ and $f^{(1)}_E$, and repeat the same procedure. By the definition of the canonical partition and the essential values, we obtain the following lemma.

▶ **Lemma 28.** *For each $j = 1, \ldots, q$, it holds that $\beta_j - 1 \leq z^*_i \leq \beta_j$ for every $i \in N_j$.*

We can prove Theorem 2 by using Theorem 9 and Lemma 28, and basic results for the integral base-polyhedra.

Proof of Theorem 2. Recall that the partition $N_1, \dots, N_q$ is the canonical partition of $\ddot{\mathbf{B}}_E$, and $\beta_1, \dots, \beta_q$ are the corresponding essential values. Let $\hat{N}_1, \dots, \hat{N}_r$ be the principal partition of $\overline{\mathbf{B}}_E$, and let $\lambda_1, \dots, \lambda_r$ be the critical values. We fix $i \in N$ arbitrarily. Let $j \in [q]$ and $k \in [r]$ be the unique indices such that $i \in N_j$ and $i \in \hat{N}_k$. By invoking Theorem 9, we have $\beta_j = \lceil \lambda_k \rceil$. Consequently, by Theorem 8 and Lemma 28, we obtain $z^*_i \leq \beta_j = \lceil \lambda_k \rceil = \lceil \bar{z}_i \rceil$.

To show the other inequality, let $\Phi' \colon \mathbb{R}^N \to \mathbb{R}$ be a symmetric strictly convex function such that $\Phi'(z) = \Phi(-z)$ for $z \in \mathbb{R}^N$. Let $\mathbf{B}'_E = -\mathbf{B}_E$ and $\overline{\mathbf{B}}'_E = -\overline{\mathbf{B}}_E$. Then, $-z^*$ and $-\bar{z}$ are Φ'-minimizers of $\mathbf{B}'_E$ and $\overline{\mathbf{B}}'_E$, respectively. By applying the same argument as above, we obtain $-z^*_i \leq \lceil -\bar{z}_i \rceil$, which is equivalent to $z^*_i \geq \lfloor \bar{z}_i \rfloor$. ◀

4.3 Structures in Fair Allocation

We establish the structure in the case of fair allocations. We partition the goods according to the canonical partition as follows. Let M_1 and C_1 denote the subset of indivisible goods M and divisible goods C, respectively, that must be allocated to agents in N_1. We iteratively define M_j and C_j as the subset of $M \setminus \bigcup_{j'=1}^{j-1} M_{j'}$ and $C \setminus \bigcup_{j'=1}^{j-1} C_{j'}$, respectively, that must be allocated to agents in $\bigcup_{j'=1}^{j} N_{j'}$. In other words, M_j and C_j $(j = 1, \dots, q)$ is defined as

$$M_j = \left\{ g \in M \setminus \textstyle\bigcup_{j'=1}^{j-1} M_{j'} : v_{ig} = 0 \ (\forall i \in N \setminus \bigcup_{j'=1}^{j} N_{j'}) \right\}, \tag{7}$$

$$C_j = \left\{ c \in C \setminus \textstyle\bigcup_{j'=1}^{j-1} C_{j'} : v_{ic} = 0 \ (\forall i \in N \setminus \bigcup_{j'=1}^{j} N_{j'}) \right\}. \tag{8}$$

We refer $M_1, \dots, M_q$ and $C_1, \dots, C_q$ as the canonical partitions of the indivisible goods and the divisible goods, respectively. By Lemmas 26 and 27, we show the following.

▶ **Theorem 29.** *For any allocation π^* whose utility vector is a Φ-minimizer over $\mathbf{B}_E$, it holds that $\sum_{i \in N_j} \pi^*_{ie} = 1$ for every good $e \in M_j \cup C_j$ and $j = 1, 2, \dots, q$.*

Proof. Let z^* be the utility vector of π^*. Let x^* and y^* be the utility vectors for indivisible and divisible goods in π^*, respectively. Thus, $z^* = x^* + y^*$.

First, since $f_M(N_1) = |M_1|$ and $f_C(N_1) = |C_1|$, we have $z^*(N_1) = |M_1 \cup C_1|$ by Lemma 26. Next, let $N'_j = N \setminus \bigcup_{j'=1}^{j} N_{j'}$ for $j = 1, \dots, q-1$. By Lemma 27, $z^*_{N'_1}$ is a Φ'-minimizer, where $\Phi'(z) = \phi(z^*_{N_1}, z)$. Thus by the definition of N_2 and Lemma 26 again, $x^*_{N'_1}(N_2) = f^{(1)}_M(N_2) = f_M(N_1 \cup N_2) - f_M(N_1) = |M_2|$ and $y^*_{N'_1}(N_2) = f^{(1)}_C(N_2) = |C_2|$. By iteratively applying this argument, we observe that $z^*(N_j) = |M_j \cup C_j|$ for $j = 2, \dots, q$.

Because agents in N_q want only the goods in $M_q \cup C_q$, these goods are allocated to the agents in N_q. Then, for each $j = q-1, \dots, 1$, since agents in N_j want only the goods in $\bigcup_{j'=j}^{q} (M_{j'} \cup C_{j'})$ but the goods in $\bigcup_{j'=j+1}^{q} (M_{j'} \cup C_{j'})$ are allocated to agents in $N_{j+1} \cup \cdots \cup N_q$, the goods in $M_j \cup C_j$ are allocated to agents in N_j. Therefore, the theorem holds. ◀

5 Tractability for Identical Divisible Goods

In this section, we focus on the setting where all the divisible goods are identical, i.e., $v_{ic} = v_{ic'}$ for any $c, c' \in C$ and $i \in N$. Let Φ be a symmetric strictly convex function. The main result of this section is Theorem 4, i.e., a polynomial-time algorithm to find a Φ-fair allocation. As a corollary, an MNW allocation for mixed goods can be found in polynomial time when the divisible goods are identical.

Our algorithm utilizes structures discussed in the previous section. Namely, we seek allocations whose utility vectors satisfy the statements in Lemma 28 and Theorem 29, which are necessary conditions to be optimal. The high-level idea of our algorithm is described as follows.

First, we find a discrete Φ-minimizer $\ddot{z}^* \in \arg\min_{z \in \ddot{\mathbf{B}}_E} \Phi(z)$, the canonical partition $N_1, \ldots, N_q$, and the essential values $\beta_1, \ldots, \beta_q$ of $\ddot{\mathbf{B}}_E$. These can be found in polynomial time by Theorem 9. Note that $\ddot{z}^*$ is an optimal utility vector if every good is assumed to be indivisible. We also compute the canonical partition of the indivisible goods $M_1, \ldots, M_q$ and that of the divisible ones $C_1, \ldots, C_q$ by (7) and (8). Since all divisible goods are identical, only one of $C_1, \ldots, C_q$ can be non-empty. Let j^* be the index such that $C_{j^*} = C$.

Next, we decide on an allocation for agents in N_j for each $j \neq j^*$. Let us fix $j \neq j^*$. Theorem 29 implies that in an optimal allocation, the agents in N_j receive only the indivisible goods in M_j. Moreover, by Lemma 28, some agents in N_j must receive β_j goods and the others must receive $\beta_j - 1$. Because $\beta_j - 1 \leq \ddot{z}^*_i \leq \beta_j$ holds by Theorem 9, we allocate goods in M_j so that each agent $i \in N \setminus N_{j^*}$ receives $\ddot{z}^*_i$ goods. Such an allocation can be computed by solving a bipartite matching problem.[4] For agents in N_j, the utility vector of this allocation is the same as an optimal one up to arrangement of elements. Thus, we have found an optimal allocation for agents in N_j.

The remaining task is to determine the allocation of $M_{j^*} \cup C$ to agents N_{j^*}. Since the optimal allocation of $M_{j^*} \cup C$ depends on Φ, we conduct an enumeration-based approach rather than performing a full characterization.

Let π^* be an optimal allocation. Let $N^+_{j^*}$ be the set of agents in N_{j^*} who desire the divisible goods, i.e., $N^+_{j^*} = \{i \in N_{j^*} : v_i(c) = 1 \ (\forall c \in C)\}$. Let $N^-_{j^*} = N_{j^*} \setminus N^+_{j^*}$. The following lemma indicates that there are a finite number of candidates for a Φ-minimizer.

▶ **Lemma 30.** *All the agents receiving divisible goods (i.e., $\pi^*_i(C) > 0$) have the same utility.*

Let k be the number of agents in $N^+_{j^*}$ who receive β_{j^*} indivisible goods and let ℓ be the total number of indivisible goods received by agents in $N^+_{j^*}$. Note that $k < |N^+_{j^*}|$. The key observation is the following lemma.

▶ **Lemma 31.** *The following properties hold:*

1. $|N^+_{j^*}| \cdot (\beta_{j^*} - 1) + k \leq \ell + |C| \leq |N^+_{j^*}| \cdot \beta_{j^*}$;
2. *there exist $X \subseteq N^+_{j^*}$ such that $|X| = k$ and*
   a. *for each $i \in X$: $\pi^*_i(M_{j^*}) = \beta_{j^*}$ and $\pi^*_i(C) = 0$;*
   b. *for each $i \in N^+_{j^*} \setminus X$: $\pi^*_i(M_{j^*}) \leq \beta_{j^*} - 1$ and $\pi^*_i(E) = \beta_{j^*} - (|N^+_{j^*}| \cdot \beta_{j^*} - \ell - |C|)/(|N^+_{j^*}| - k)$;*
3. *$\pi^*_i(M_{j^*}) \in \{\beta_{j^*}, \beta_{j^*} - 1\}$ and $\pi^*_i(C) = 0$ for each $i \in N^-_{j^*}$.*

Since Lemma 31 specifies the utility vector (i.e., $\pi^*_i(E)$ for each $i \in N_{j^*}$) of an optimal allocation up to arrangement, it suffices to find an allocation whose utility vector satisfies the statement in Lemma 31. In fact, if we are given ℓ, an optimal allocation can be computed as follows. For each $k = 0, \ldots, |N^+_{j^*}|$ such that property 1 in Lemma 31 is satisfied,

1. find an allocation $\pi^{k,\ell} \in \{0,1\}^{N_{j^*} \times M_{j^*}}$ of indivisible goods in M_{j^*} such that (a) $|\{i \in N^+_{j^*} : \pi_i(M_{j^*}) = \beta_{j^*}\}| \leq k$, (b) $\pi_i(M_{j^*}) \leq \beta_{j^*}$ for each $i \in N^+_{j^*}$, (c) $\sum_{i \in N^+_{j^*}} \pi_i(M_{j^*}) = \ell$, (d) $\pi_i(M_{j^*}) \in \{\beta_{j^*}, \beta_{j^*} - 1\}$ for each $i \in N^-_{j^*}$;

[4] It can also be calculated directly with a method of Harvey et al. [26].

2. if $\pi^{k,\ell}$ exists, let $\hat{\pi}^{k,\ell}$ be the allocation by allocating indivisible goods according to $\pi^{k,\ell}$, and allocating divisible goods by a water-filling policy so that

$$\hat{\pi}_i^{k,\ell}(c) = \frac{1}{|C|} \cdot \left(\beta_{j^*} - \frac{|N_{j^*}^+| \cdot \beta_{j^*} - \ell - |C|}{|N_{j^*}^+| - k} - \pi_i^{k,\ell}(M) \right)$$

for each $i \in N_{j^*}^+$ such that $\pi_i^{k,\ell}(M) < \beta_{j^*}$ and $c \in C$.

Let us see that this indeed works. Since $\Phi(\hat{\pi}^{k,\ell}) \leq \Phi(\hat{\pi}^{k+1,\ell})$ holds (if $\pi^{k,\ell}$ exists), the smallest k such that $\pi^{k,\ell}$ exists is the number in Lemma 31. For such an integer k, we have $|\{i \in N_{j^*}^+ : \pi_i(M_{j^*}) = \beta_{j^*}\}| = k$, and the properties in Lemma 31 are satisfied except the allocation of divisible goods. Once we have decided on an allocation of indivisible goods, an optimal allocation of divisible goods is found by the water-filling policy.

Now, we explain how to find an allocation $\pi^{k,\ell}$ at step 1 in polynomial time. We reduce this problem to the submodular flow problem. Let $G = (V, A)$ be a directed graph constructed as follows. The set of vertices V is $M_{j^*} \cup N_{j^*} \cup N'_{j^*}$ where N'_{j^*} is a set of copy i' of each $i \in N_{j^*}$. The set of edges A is $A_1 \cup A_2 \cup A_3$ where $A_1 = \{(g, i') \in M_{j^*} \times N'_{j^*} : v_i(g) = 1\}$, $A_2 = \{(i', i) : i \in N_{j^*}^+\}$, and $A_3 = \{(i', i) : i \in N_{j^*}^-\}$. We define $\underline{c}, \bar{c} \colon A \to \mathbb{Z}$ as $\underline{c}(a) = 0$ and $\bar{c}(a) = 1$ for each $a \in A_1$; $\underline{c}(a) = 0$ and $\bar{c}(a) = \beta_{j^*}$ for each $a \in A_2$; $\underline{c}(a) = \beta_{j^*} - 1$ and $\bar{c}(a) = \beta_{j^*}$ for each $a \in A_3$. In addition, let $f_{k,\ell} \colon 2^V \to \mathbb{Z}$ be a function such that

$$f_{k,\ell}(X) = \varphi_{k,\ell}(|X \cap N_{j^*}^+|) + (|M_{j^*}| - \ell)\mathbf{1}_{X \cap N_{j^*}^- \neq \emptyset} - |X \cap M_{j^*}| \quad (\forall X \subseteq V), \tag{9}$$

where $\varphi_{k,\ell}(h) = \min\{\beta_{j^*} h,\ (\beta_{j^*} - 1)h + k,\ \ell\}$, and $\mathbf{1}_{X \cap N_{j^*}^- \neq \emptyset}$ takes the value 1 if $X \cap N_{j^*}^- \neq \emptyset$ and 0 otherwise. We remark that $f_{k,\ell}$ is a submodular function, and $f_{k,\ell}(V) = 0$ since $\ell \leq \sum_{i \in N_{j^*}^+} \pi_i^*(M_{j^*}) \leq (\beta_{j^*} - 1)|N_{j^*}^+| + k \leq \beta_{j^*}|N_{j^*}^+|$.

▶ **Lemma 32.** *There exists an allocation $\pi \in \{0,1\}^{N_{j^*} \times M_{j^*}}$ satisfying (a)–(d) if and only if there exists an integral flow $\xi \colon A \to \mathbb{Z}$ satisfying $\underline{c}(a) \leq \xi(a) \leq \bar{c}(a)$ (capacity constraints) and a constraint (called supply specification) that the boundary $\partial\xi \in \mathbb{Z}^V$ of the flow ξ, which is defined by $\partial\xi(v) = \sum_{a=(v,u) \in A} \xi(a) - \sum_{a=(u,v) \in A} \xi(a)$, is in the M-convex set $\ddot{\mathbf{B}}$ of $f_{k,\ell}$.*

Since the feasibility of the submodular flow problem can be determined in polynomial time [19], the existence of an allocation satisfying conditions (a)–(d) can be determined in polynomial time by Lemma 32. Moreover, if such an allocation exists, we can find one of such allocations in polynomial time.

Finally, because we do not know ℓ in advance, we enumerate all possibilities. That is, find a best allocation $\pi^{k,\ell}$ for each $\ell = 0, 1, \ldots, |M_{j^*}|$ by the above procedure, and choose the best one. Then the resulting allocation is as good as an optimal allocation π^*.

We give the formal description of our algorithm in Algorithm 1. By summarizing the discussions thus far, we can prove Theorem 4.

6 Hardness for Identical Indivisible Goods

In this section, we show a hardness result on the fair allocation setting when divisible goods are non-identical but indivisible goods are identical. By using Theorem 2, we prove the NP-hardness of finding a Φ-fair allocation by using the 3-dimensional matching (3DM) problem, which is known to be NP-hard [21].

▶ **Theorem 33** (restatement of Theorem 3). *For any fixed symmetric strictly convex function Φ, the problem (1) is NP-hard even in the fair allocation setting with identical indivisible goods. Hence, finding a Φ-fair allocation is NP-hard.*

Algorithm 1 Allocation algorithm when the divisible goods are identical.

input : A fair allocation instance (N, M, C, v) and a symmetric strictly convex function Φ
output : A Φ-fair allocation

Compute the canonical partition $N_1, \dots, N_q$, the essential values $\beta_1, \dots, \beta_q$, the canonical partition of the indivisible goods $M_1, \dots, M_q$, and the canonical partition of the divisible goods $C_1, \dots, C_q$;
Let j^* be the index such that $C_{j^*} = C$;
for $j \leftarrow 1, \dots, j^* - 1, j^* + 1, \dots, q$ **do**
    Allocate M_j to N_j so that each agent receives β_j or $\beta_j - 1$;
Let $N_{j^*}^+ \leftarrow \{j \in N_{j^*} : v_i(c) = 1 \ (\forall c \in C)\}$ and $N_{j^*}^- \leftarrow \{j \in N_{j^*} : v_i(c) = 0 \ (\forall c \in C)\}$;
Let $\Pi \leftarrow \emptyset$ be a set of candidate allocations;
for $k \leftarrow 0, 1, \dots, |N_{j^*}^+|$ *and* $\ell \leftarrow 0, 1, \dots, |M_{j^*}|$ **do**
    if $|N_{j^*}^+| \cdot (\beta_{j^*} - 1) + k \leq \ell + |C| \leq |N_{j^*}^+| \cdot \beta_{j^*}$ **then**
        Determine the existence an allocation $\pi^{k,\ell} \in \{0,1\}^{N_{j^*} \times M_{j^*}}$ satisfying the following conditions via the submodular flow problem:
        $|\{i \in N_{j^*}^+ : \pi_i(M_{j^*}) = \beta_{j^*}\}| \leq k$, $\pi_i(M_{j^*}) \leq \beta_{j^*}$ for each $i \in N_{j^*}^+$,
        $\sum_{i \in N_{j^*}^+} \pi_i(M_{j^*}) = \ell$, $\pi_i(M_{j^*}) \in \{\beta_{j^*}, \beta_{j^*} - 1\}$ for each $i \in N_{j^*}^-$;
        if *Such an allocation* $\pi^{k,\ell}$ *exists* **then**
            Let π be an allocation such that indivisible goods are allocated according to Algorithm 1 and $\pi^{k,\ell}$, and the divisible goods are allocated to agents in $N_{j^*}^+$ by a water-filling policy;
            $\Pi \leftarrow \Pi \cup \{\pi\}$;
return $\pi^* \in \arg\min_{\pi \in \Pi} \Phi(\pi(E))$;

We can also prove the following from the same proof of this theorem.

▶ **Corollary 34.** *The problems of finding an MNW allocation and an optimal egalitarian allocation are both NP-hard, even when indivisible goods are identical.*

Cut Sparsification and Succinct Representation of Submodular Hypergraphs

Abstract

In cut sparsification, all cuts of a hypergraph $H = (V, E, w)$ are approximated within $1 \pm \epsilon$ factor by a small hypergraph H'. This widely applied method was generalized recently to a setting where the cost of cutting each hyperedge e is provided by a splitting function $g_e : 2^e \to \mathbb{R}_+$. This generalization is called a submodular hypergraph when the functions $\{g_e\}_{e \in E}$ are submodular, and it arises in machine learning, combinatorial optimization, and algorithmic game theory.

Previous work studied the setting where H' is a reweighted sub-hypergraph of H, and measured the size of H' by the number of hyperedges in it. In this setting, we present two results: (i) all submodular hypergraphs admit sparsifiers of size polynomial in $n = |V|$ and ϵ^{-1}; (ii) we propose a new parameter, called spread, and use it to obtain smaller sparsifiers in some cases.

We also show that for a natural family of splitting functions, relaxing the requirement that H' be a reweighted sub-hypergraph of H yields a substantially smaller encoding of the cuts of H (almost a factor n in the number of bits). This is in contrast to graphs, where the most succinct representation is attained by reweighted subgraphs. A new tool in our construction of succinct representation is the notion of deformation, where a splitting function g_e is decomposed into a sum of functions of small description, and we provide upper and lower bounds for deformation of common splitting functions.

1 Introduction

A powerful tool for many graph problems is sparsification, where an input graph is replaced by a small graph that preserves (perhaps approximately) certain properties, for example all the input graph's cuts [7] or its spectrum [42, 6, 26]. Downstream applications can then be executed on the small graph, which improves the overall running time, and the small graph can also be stored (or sent to another site) instead of the input graph, which improves the memory (or communication) requirements. The extensive research on cut sparsification has started with the seminal work of Benczúr and Karger on cuts in graphs [7], and was later extended to hypergraphs [29, 5, 10] and to directed hypergraphs [40, 9, 27, 36]. In recent

months the study of sparsification has been extended to even more general objects such as semi-norms [25], matroid quotients [38], and linear codes [28]. We focus on sparsifying a generalized form of hypergraphs, as explained next.

In recent years, the notion of cuts in a weighted hypergraph $H = (V, E, w)$ has been generalized to a setting where each hyperedge $e \in E$ has a *splitting function* $g_e : 2^e \to \mathbb{R}_+$, such that $g_e(\emptyset) = 0$, and the *value* of a cut $S \subseteq V$ is defined as

$$\mathrm{cut}_H(S) \coloneqq \sum_{e \in E} g_e(S \cap e). \tag{1}$$

Associating every $e \in E$ with the *all-or-nothing* splitting function, given by $g_e^{\mathrm{aon}} : S \mapsto w_e \cdot \mathbb{1}_{\{S \neq \emptyset, e\}}$, clearly models an ordinary hypergraph $H = (V, E, w)$, where the value of a cut is the total weight of hyperedges that intersect both sides; in fact, a simple extension can model a directed hypergraph. Such a generalized hypergraph $H = (V, E, g)$, where $g = \{g_e\}_{e \in E}$, is called a *submodular hypergraph* if all its splitting functions g_e are submodular. Recall that a set function $g : 2^e \to \mathbb{R}_+$ is *submodular* if

$$\forall S, T \subseteq e, \qquad g(S \cup T) + g(S \cap T) \leq g(S) + g(T).$$

Submodular hypergraphs are useful in clustering data with higher-order relations that are not captured by ordinary hyperedges [31, 32, 44, 34, 45, 48]. For example, the *small-side splitting* function, given by $g_e^{\mathrm{sml}} : S \mapsto \min(|S|, |e \setminus S|)$, is employed when unbalanced cuts are preferable. Cut functions of submodular hypergraphs were studied also under a different name of *decomposable submodular functions*. A submodular function $f : 2^V \to \mathbb{R}_+$ is called *decomposable* if it can be written as $f = \sum_i f_i$, where each $f_i : 2^V \to \mathbb{R}_+$ is submodular. This notion is widely applied in data summarization [23, 33, 43], where each f_i is a submodular similarity function, and the task of summarizing the data under a given budget k is modeled by maximizing $f(S)$ over all $S \subset V$ of size $|S| \leq k$. Decomposable submodular functions arise also in welfare maximization, where each agent has a submodular utility function, for instance in approximation algorithms [16, 17] and in truthful mechanisms [15, 4].

We study how to succinctly represent all the cuts of a submodular hypergraph H up to $1 \pm \epsilon$ factor. We examine two complementary approaches: (1) *sparsification*, which reduces the number of hyperedges, i.e., H is represented using a sparse H'; and (2) *deformation*, which replaces large hyperedges or complicated splitting functions by new ones of low space complexity, i.e., H is represented using H' whose hyperedges can be stored succinctly. These approaches can yield (separately and/or together) a sparsifier H' that can be encoded using a small number of bits. More generally, we may consider a general encoding that *need not* rely on a sparsifier H', e.g., an explicit list of all the $2^{|V|}$ cut values.

Let us introduce some basic notation to make the discussion more precise. Throughout, let $n \coloneqq |V|$; we write $\tilde{O}(t)$ or $\tilde{\Omega}(t)$ to suppress a polylogarithmic factor in t, and $O_\alpha(t)$ or $\Omega_\alpha(t)$ to hide a factor that depends only on α.

▶ **Definition 1.1** (Sparsifier). *A* cut sparsifier *of* quality $1 + \epsilon$ *for* $H = (V, E, g)$*, or in short a* $(1 + \epsilon)$-sparsifier*, is a submodular hypergraph* $H' = (V, E', g')$ *such that*

$$\forall S \subseteq V, \qquad \mathrm{cut}_{H'}(S) \in (1 \pm \epsilon) \cdot \mathrm{cut}_H(S). \tag{2}$$

The size *of the sparsifier is* $|E'|$*. We call* H' *a* reweighted subgraph *of* H *if* $E' \subseteq E$ *and each function* g'_e *for* $e \in E'$ *is a scaling of* g_e *(i.e.,* $g'_e \equiv s_e g_e$ *for some* $s_e > 0$*).*

▶ **Question 1.2** (Sparsification). *Do all submodular hypergraphs admit a reweighted-subgraph sparsifier with few hyperedges, say* $\mathrm{poly}(\epsilon^{-1} n)$*? And which families of splitting functions admit even smaller sparsifiers, like* $\tilde{O}_\epsilon(n^2)$ *or even* $\tilde{O}_\epsilon(n)$*?*

The first question (about a polynomial bound) was previously answered for several families of splitting functions (see Section 1.1 for a detailed account), but despite this significant progress, the case of general submodular splitting was left open in [39], where the bound on the sparsifier size depends on g and is exponential in n in the worst case. We answer this first question in the affirmative, and also address the second question by showing families of splitting functions that admit even smaller sparsifiers.

We further ask about a more general notion, of encoding an approximation of all the cuts of H, which can potentially be more succinct than a sparsifier.

▶ **Question 1.3** (Succinct Representation). *What is the smallest encoding (in bits of space) that stores a submodular hypergraph H so as to report $(1+\epsilon)$-approximation to every cut value? In particular, what is the smallest number of bits $s = s(\epsilon, n)$ that suffices to store a sparsifier for H?*

For simplicity, we ask above only about the existence of a sparsifier or an encoding, but we are of course interested also in fast algorithms to build them. Fortunately, an algorithmic solution follows from the existential ones because our proofs are constructive. Furthermore, the running times are polynomial under the assumption that every g_e takes integral values and $\max_{S \subseteq e} g_e(S) \leq \text{poly}(n)$.[1]

1.1 Sparsification: All Submodular Hypergraphs

We start with addressing Question 1.2. Our first result (proved in Section 2) provides the first polynomial (in n) bound for all submodular splitting functions; the previous bound, due to [39], was $O_\epsilon(n^2 B_H)$, where $B_H := \max_{e \in E} |\mathcal{B}(g_e)|$ and $\mathcal{B}(g_e)$ is the set of extreme points in the polytope of g_e.[2] In general, B_H can be exponential in n, for example small-side splitting g_e^{sml} has $|\mathcal{B}(g_e^{\text{sml}})| = 2^{\Theta(|e|)}$.

▶ **Theorem 1.4.** *Every submodular hypergraph admits a $(1+\epsilon)$-sparsifier of size $O(\epsilon^{-2} n^3)$, which is in fact a reweighted sub-hypergraph.*

This bound is within factor $O_\epsilon(n)$ of the $\Omega(n^2/\epsilon)$ lower bound known for cut sparsification of directed hypergraphs [36]. We also show that if all the splitting functions are monotone (i.e., $g_e(S) \leq g_e(T)$ for all $S \subseteq T$), then the sparsifier size can be improved to $O_\epsilon(n^2)$. Monotone submodular functions arise in many applications, however no sparsification bound was previously known for this family.[3] The formal statement and its proof appear in Section 2.

Related Work. Previous work on sparsification focused mostly on specific splitting functions. The study of this problem began with sparsifiers for undirected graph cut; the current size bound is $O(\epsilon^{-2} n)$ edges [6], which improves over [7] and is known to be tight [2, 8]. Furthermore, sparsifiers of size $\tilde{O}_\epsilon(n)$ are known for all-or-nothing splitting g_e^{aon} [10] (see also [38]) and for *product splitting*, given by $g_e^{\text{prd}} : S \mapsto |S| \cdot |e \setminus S|$ [13]. In contrast, for the splitting that models cuts in a directed hypergraph, the best construction known has size $\tilde{O}_\epsilon(n^2)$ [36], which is near-tight with an $\Omega(n^2/\epsilon)$ lower bound [36]; this function, called

[1] The running times of Theorem 1.4 and Theorem 1.9 are polynomial in general. Theorem 1.6 is polynomial under the stated assumption.

[2] A recent manuscript [30] claims that the proof in [39] has a flaw and holds only for monotone submodular hypergraphs.

[3] The running time of [39] was improved in [30], where a sparsifier of size $O(\epsilon^{-2} n^2 B)$ for monotone functions with low curvature is constructed in polynomial time.

directed all-or-nothing splitting, is given by $g_e^{\text{d-aon}} : S \mapsto \mathbb{1}_{\{e_T \cap S \neq \emptyset \ \wedge \ e_H \not\subseteq S\}}$, where $e_H, e_T \subseteq e$ are the hyperedge's head and tail, respectively. A recent result is more general and shows that the entire family of symmetric splitting functions admits sparsifiers of size $\tilde{O}_\epsilon(n)$ [25].

Figure 1 depicts several families of splitting functions and the sparsification bounds known for them, including our results from above and from Section 1.2.

Techniques. Our sparsification method follows the importance-sampling approach, which has been used extensively in the literature. Every hyperedge $e \in E$ is assigned an importance σ_e, and sampled with probability p_e that is (at least) proportional to σ_e, and the splitting function of every sampled e is scaled by $1/p_e$. The expected sparsifier size is clearly proportional to $\sum_{e \in E} \sigma_e$.

A standard method to set the importance of a hyperedge $e \in E$, is to consider all its possible cuts, namely, $\sigma_e \coloneqq \max_{S \subseteq V} g_e(S \cap e)/\text{cut}_H(S)$, and this method was indeed used in [39]. Bounding $\sum_{e \in E} \sigma_e$ naively by replacing the maximization over $S \subseteq V$ by summation yields an exponential size bound. An improved bound was given in [39] based on a quantity B_H related to the polytopes of the splitting functions. Unfortunately, this improved bound is still exponential for many families of splitting functions.

Our main contribution is to identify a set of "basic" quantities for each hyperedge e that can serve as coarse approximations of its splitting function g_e. These approximations allow us to define new sampling probabilities and achieve an improved size bound: Given $e \in E$, define the minimum directed cut between $u, v \in V$ to be $g_e^{u \to v} \coloneqq \min_{S \subseteq V : u \in S, v \notin S} g_e(S \cap e)$;[4] then our main technical lemma bounds $g_e(\cdot)$ from below and from above by

$$\forall S \subseteq V, \qquad \max_{u \in S, v \in V \setminus S} g_e^{u \to v} \leq g_e(S \cap e) \leq \sum_{u \in S, v \in V \setminus S} g_e^{u \to v}. \tag{3}$$

The lower bound holds by definition, and the upper bound is analogous to bounding the value of a graph cut by the sum of the maximum flows between all pairs of vertices across the cut. It is well-known that importance sampling will produce a sparsifier even if σ_e is replaced with an over-estimate for it. We replace σ_e with $\rho_e \coloneqq \sum_{(u,v) \in V \times V} g_e^{u \to v} / \sum_{f \in E} g_f^{u \to v}$, which we can easily see is an over-estimate, i.e., $\rho_e \geq \sigma_e$, by using the two bounds from (3) to verify that

$$\forall S \subseteq V, \qquad \frac{g_e(S \cap e)}{\text{cut}_H(S)} = \frac{g_e(S \cap e)}{\sum_{f \in E} g_f(S \cap f)} \leq \sum_{u \in S, v \in V \setminus S} \frac{g_e^{u \to v}}{\sum_{f \in E} g_f^{u \to v}} \leq \rho_e.$$

The expected number of hyperedges in the sparsifier H' equals to $\sum_{e \in E} \rho_e$ times an amplification factor M, where $M = O(\epsilon^{-2} n)$ is sufficient by standard arguments (combining a concentration bound and a union bound). The crux here is that it is easy to bound $\sum_{e \in E} \rho_e \leq O(n^2)$, basically swapping the order of a double summation. Another advantage of ρ_e is that it can be computed in polynomial time, while computing σ_e requires maximizing the ratio of two submodular functions, which is NP-hard in general.

In the monotone case, we follow the same approach but employ a simpler over-estimate $\rho'_e \coloneqq \sum_{v \in e} g_e(\{v\})/\text{cut}_H(\{v\})$. The proof is similar to the general case, except that instead of (3) we use the straightforward bound

$$\forall S \subseteq V, \quad \max_{v \in S} g_e(\{v\} \cap e) \leq g_e(S \cap e) \leq \sum_{v \in S} g_e(\{v\} \cap e).$$

[4] The most natural case is $u, v \in e$, but considering all $u, v \in V$ streamlines the presentation.

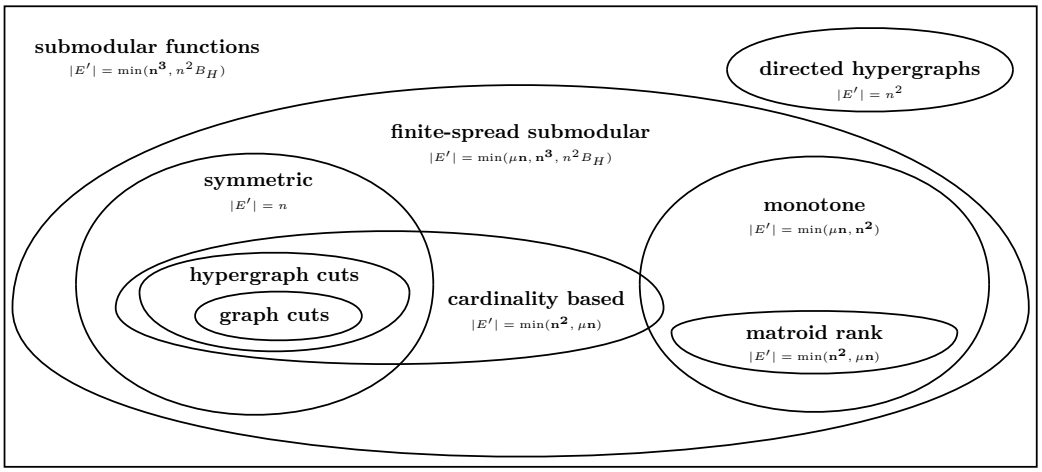

Figure 1 Sparsification bounds for various families of submodular functions, omitting for simplicity $\text{poly}(\epsilon^{-1} \log n)$ factors.

1.2 Sparsification: Parameterized by Spread

We already know that submodular splitting functions can have very different optimal sparsification bounds, see e.g. the bounds $\tilde{\Theta}_\epsilon(n)$ and $\tilde{\Theta}_\epsilon(n^2)$ mentioned above. However, there are too many submodular functions to analyze each one separately, and we thus seek a parameter that can control the sparsifier size. Our approach is inspired by the notion of imbalance in a directed graph $G = (V, E, w)$, defined as the worst ratio between antiparallel edge weights, i.e., $\beta_G := \max\{w(i,j)/w(j,i) : \ i, j \in V\}$. This parameter can be used to show that every directed graph admits a sparsifier of size $\tilde{O}_\epsilon(\beta_G n)$.[5] For submodular hypergraphs, we propose an analogous parameter, which is basically the ratio between the maximum and minimum values of the splitting function, excluding certain trivial cuts.

▶ **Definition 1.5** (Spread). *For hyperedge $e \in E$ with splitting function g_e, let $W_e := \{\emptyset\}$, unless $g_e(e) = 0$ in which case $W_e := \{\emptyset, e\}$. The* spread *of e is*

$$\mu_e := \frac{\max_{T \subseteq e} g_e(T)}{\min_{S \subseteq e : S \notin W_e} g_e(S)}. \tag{4}$$

Our third result (proved in the full version) constructs a sparsifier whose size depends on the spread of the input H, defined as $\mu_H := \max_{e \in E} \mu_e$. By convention, the spread μ_e is called *finite* if it is well-defined (the denominator in (4) is non-zero), and similarly μ_H is called finite if it is well-defined (all the terms μ_e are finite).

▶ **Theorem 1.6** (Sparsifier Parameterized by Spread). *Every submodular hypergraph $H = (V, E, g)$ with finite spread admits a $(1+\epsilon)$-sparsifier of size $\tilde{O}(\epsilon^{-2} \mu_H n)$, which is a sub reweighted-subgraph.*

Many natural submodular functions have finite spread, and in many common cases even $\mu_H \leq n$. This can be seen, for example, in an easy application of Theorem 1.6 to approximation of coverage functions, see the full version for details. Another example is the

[5] This condition can actually be relaxed significantly to $\beta_G := \max\{\text{cut}_G(S)/\text{cut}_G(\bar{S}) : \ S \subset V\}$, and the same sparsification bound still holds [9].

sparsification of the capped version of small-side splitting, given by $g_e : S \mapsto \min(|S|, |e \setminus S|, K)$ for $K > 0$, which clearly has spread $\mu_e \leq K$. This function is part of a much larger family, cardinality-based splitting functions, a notion formalized in [46] as follows: A submodular function $g_e : 2^e \to \mathbb{R}_+$ is called *cardinality-based* if there exists a function $f_e : [|e|] \to \mathbb{R}_+$ such that $g_e : S \mapsto f_e(|S|)$. Cardinality-based functions, which are commonly used in submodular hypergraph clustering, all have spread $\mu_e \leq n$, which is an easy consequence of the symmetry and subadditivity of g_e. By Theorem 1.6, these splitting function admit a $(1+\epsilon)$-sparsifier of size $\tilde{O}(\epsilon^{-2}n^2)$, which is the first bound for this family.

It is easily verified that for monotone splitting functions, the spread is approximately equal to the imbalance, when we generalize the imbalance from above to hyperedges by $\beta_e \coloneqq \max\{g_e(S)/g_e(e \setminus S) : S \subset V\}$.[6] Hence, we immediately obtain the following.

▶ **Corollary 1.7.** *Every finite-spread monotone splitting function admits a $(1+\epsilon)$-sparsisfier of size $\tilde{O}(\epsilon^{-2}\beta_H n)$.*

Two other examples of commonly used monotone functions with finite spread are set-coverage functions (defined in the full version) and the *matroid-rank functions*,[7] which have $\mu_e = r$ where r is the rank of the matroid.

We remark that spread does not fully characterize the sparsifier size. Indeed, symmetric functions can have a large spread μ_e but still admit $\tilde{O}_\epsilon(n)$ sparsifier due to [25], consider e.g. product splitting g_e^{prd} which has $\mu_e = O(n)$. Furthermore, directed all-or-nothing splitting $g_e^{\text{d-aon}}$ does not have finite spread, and nevertheless admits a sparsifier of size $\tilde{O}_\epsilon(n^2)$ [36]. Figure 1 depicts different families of splitting functions including that of finite spread, and the sparsification bounds known for them.

Techniques. Our technique is based on approximate H as an undirected hypergraph and use the sampling probabilities of [10] but amplified by μ_e for each hyperedge. This is a known technique in generalizing sampling mechanisms. Our main contribution is to identify the spread as a relevant and useful parameter. We remark that the generalization of balance, which is known to control the size of sparsifier in directed graphs, to submodular hypergraphs does not suffice for sparsification. Furthermore, we prove that the spread also characterizes other traits of splitting function, such as the deformation lower bound.

1.3 Succinct Representation

We provide the first example of submodular splitting functions for which sparsifiers that are not subgraphs are provably (much) more succinct than sparsifiers that are reweighted subgraphs.[8] To be more precise, we exhibit a natural family of splitting functions, where the former $(1+\epsilon)$-sparsifiers take only $\tilde{O}_\epsilon(n)$ bits (Corollary 1.10), while the latter $(1+\epsilon)$-sparsifiers require $\tilde{\Omega}_\epsilon(n^2)$ bits (Theorem 1.11). It follows that a reweighted subgraph *need not be* the smallest encoding that stores a $(1+\epsilon)$-approximation of the cuts values, and by a wide margin!

---

[6] For a monotone g_e, the spread is $\mu_e = g_e(V)/\min_{v\in V} g_e(\{v\})$ and the imbalance is $\beta_e = \max_{v\in V} g_e(V \setminus \{v\})/g_e(\{v\})$, and they differ by at most a constant factor by the subadditivity of g_e.

[7] For a matroid with ground set e and independent sets $\mathcal{I}$, the rank function is given by $g_e : S \mapsto \max_{T\subseteq S : T\in\mathcal{I}} |T|$. This rank function is submodular and monotone.

[8] Previously, a non-subgraph sparsifier was shown in [1] for small-side splitting, however it optimizes the number of hyperedges and not the encoding size.

Our plan for constructing a succinct representation has two stages. The first stage creates a $(1+\epsilon)$-sparsifier H', by deforming each $e \in E$ into multiple small hyperedges. The second stage computes for this H' a $(1+\epsilon)$-sparsifier H'' that is a reweighted subgraph. It then follows that H'' is a $(1+\epsilon)^2$-sparsifier, and has a few hyperedges that are all small.

▶ **Definition 1.8.** *A splitting function $g_e : 2^e \to \mathbb{R}_+$ on hyperedge e is called $(1+\epsilon)$-approximable with support size p if there are submodular functions $g_{e_i} : 2^{e_i} \to \mathbb{R}_+$ for $i = 1, \ldots, r$, each on a hyperedge $e_i \subseteq e$ of size $|e_i| \leq p$, such that*

$$\forall S \subseteq e, \qquad \sum_{i=1}^{r} g_{e_i}(S \cap e_i) \in (1 \pm \epsilon) g_e(S).$$

Our example is the family of *additive* splitting functions, defined as functions g_e that can be written as either $g_e : S \mapsto \min(|S|, K)$ or $g_e : S \mapsto \min(|S|, |e \setminus S|, K)$ for some $K > 0$. The next theorem (proved in the full version) achieves the first stage in our plan above; it shows that additive functions can be $(1+\epsilon)$-approximated by creating several copies of e and sampling the vertices.

▶ **Theorem 1.9** (Deformation of Additive Functions)**.** *Let g_e be an additive splitting function on hyperedge e. Then g_e can be $(1+\epsilon)$-approximated with support size $O(\epsilon^{-2}(|e|/K)\log|e|)$.*

Following our plan, suppose that given an input H, we first apply Theorem 1.9 to obtain a sparsifier H' with small support size. The construction of H' also implies that it has small spread, $\mu_{H'} \leq O(\epsilon^{-2}\log n)$. Applying Theorem 1.6 on H' we obtain a succinct representation H''. A straightforward encoding of H'' then proves the following corollary (see the full version for details).

▶ **Corollary 1.10** (Additive Functions admit Small Representation)**.** *Let $H = (V, E, \{g_e\})$ be a submodular hypergraph such that every g_e is additive with parameter $K_e > 0$, and let $\hat{K} := \min_{e \in E} K_e/|e|$ be a normalized bound on K_e over all hyperedges. Then H admits a $(1+\epsilon)$-sparsifier with encoding size $O(\epsilon^{-6}\hat{K}^{-1} n \log^4 n)$ bits.*

The next theorem (proved in the full version) shows that reweighted-subgraph sparsifiers of additive functions require $\Omega(n^2)$ bits in the worst-case. Putting this together with our succinct representation from Corollary 1.10, we conclude that relaxing the (natural) restriction to reweighted subgraphs improves the space complexity by a factor of $\tilde{\Omega}_\epsilon(n\hat{K})$, observe that this can be $\tilde{\Omega}_\epsilon(n)$ when $\hat{K} \in \Omega(1)$.

▶ **Theorem 1.11** (Reweighted Sparsifiers Require $\Omega(n^2)$ Bits)**.** *There exists a family $\mathcal{H}$ of hypergraphs with additive splitting functions with parameter $1 \leq K \leq n/3$, such that encoding a reweighted-subgraph $(1+\epsilon)$-sparsifier for an input $H \in \mathcal{H}$ requires $\Omega(n^2)$ bits.*

This lower bound is surprising because in the case of undirected graphs, the best encoding size is achieved by a reweighted-subgraph sparsifier [6, 2, 8]. Our proof is based on a technical lemma that can be applied to many cardinality-based splitting functions. Furthermore, Theorem 1.11 can be extended to the directed all-or-nothing splitting function $g_e^{\text{d-aon}}$, to show a lower bound of $\Omega(n^3/\epsilon)$ bits. For details see the full version.

Finally, we can also prove a space lower bound for an arbitrary encoding of cuts in a directed hypergraph (arbitrary means that it need not represent a reweighted-subgraph sparsifier, see the full version for details). This proof provides an ϵ^{-1} factor improvement over the trivial lower bound of $\Omega\left(n^2\right)$ bits. The proof combines the techniques from Theorem 1.11 with a lower bound from [36] on the number of edges in a reweighted-subgraph sparsifier.

▶ **Theorem 1.12.** *There exists a family of directed hypergraphs $\mathcal{H}$ such that encoding a $(1+\epsilon)$-approximation of their cuts requires $\Omega(n^2/\epsilon)$ bits.*

Techniques. Our lower bound for the encoding size of reweighted-subgraph sparsifiers (Theorem 1.11) boils down to a counting argument on a large family of hypergraphs $\mathcal{H}$, that have sufficiently different cut values and thus require distinct encodings. We construct hypergraphs in this family $\mathcal{H}$ by partitioning the vertices into three parts V, U, W, and adding hyperedges that contain vertices from all three parts. We first create hyperedges consisting of a large random subset of vertices from V; this adds entropy that will differentiate between hypergraphs in $\mathcal{H}$. We then augment each hyperedge with vertices from U, where each hyperedge is defined by a word in the Hadamard code. We use the structure of this code to show that by making cut queries to a hypergraph $H \in \mathcal{H}$, one can recover the random bits encoded in the adjacency matrix of H induced on V. We use W to create an unsparsifiable hypergraph, i.e., one where removing any hyperedge will violate the approximation guarantee. Finally, every hyperedge on $V \cup U$ is combined with a hyperedge on W.

1.4 Deformation Lower Bounds

Our success in finding a small succinct representation for additive functions motivates searching for deformations of other splitting functions.

A similar problem, of approximating a submodular function by functions of small support but over the uniform distribution (i.e., in average-case rather than worst-case), has received significant attention [19, 11, 24, 18, 20], and it is known that every submodular function $f : 2^V \to [0, 1]$ can be approximated within additive error ϵ using support size $O(\epsilon^{-2} \log \epsilon^{-1})$ [20]. We show (see the full version) that a similar result is unfortunately not possible in our setting (multiplicative error for worst-case approximation).

▶ **Theorem 1.13** (Approximation Requires Large Support Size). *Let g_e be an additive splitting function on a hyperedge e. Then every 1.1-approximation of g_e must have support size $p \geq \Omega(|e|/K)$.*

Techniques. The proof of Theorem 1.13 is based on a technical lemma that can be applied to many splitting functions. The main idea is to examine a certain quantity δ_t, which is related the notion of curvature (of a submodular function). The curvature is often used to parameterize approximation guarantees in maximization of submodular optimization [12, 47]. Intuitively, both the curvature and δ_t characterize the locality of the function, i.e., how much error is introduced by decomposing the function into smaller parts and summing them. The main difference between the two quantities is that the curvature looks at the marginal contributions and δ_t characterizes the curvature of the union of two sets of size t. Furthermore, in the approximation setting, a low worst-case curvature is desirable while for our proof it suffices that δ_t is high for many sets of size t. Specifically, we show that if a constant fraction of pairs of subsets of size t have constant positive δ_t, then g_e cannot be approximated with support size smaller than $O(\delta_t^2 n/t)$.

By applying the technical lemma, we obtain lower bounds on the support size required to approximate several natural splitting functions, as presented in Table 1.

1.5 Related Work

Submodular functions appear in many applications, and have been studied extensively in the literature. In particular, the problem of finding a simple representation for submodular functions has been studied in several works. An $O(\sqrt{n} \log n)$-approximation for monotone submodular functions by functions of the form $f(S) = \sqrt{\sum_{v \in S} c_v}$, where $c_v > 0$ are weights for all $v \in V$, was obtained in [22]. A later result [14] showed the same approximation using

Table 1 Our lower bounds on the support size for several families of splitting functions. They are all obtained by applying the technical lemma, stated for simplicity for sufficiently small fixed $\epsilon > 0$ and $|e| = n$.

coverage and budget-additive functions. The same paper also provided a lower bound of $\Omega(n^{1/3}\log^{-2} n)$ for approximating monotone submodular functions by coverage and budget additive. Approximating the all-or-nothing splitting function on n vertices using hyperedges with the all-or-nothing function and with support size r must incur approximation factor $\Omega(n/r)$ [37, Section 2.3].

It was previously shown that every symmetric cardinality-based splitting functions can be deformed into a sum of $|e|/2$ hyperedges with capped small-side splitting function, while preserving the value of g_e exactly [46]. Subsequent work by the same authors [45], achieves a similar deformation but with $(1+\epsilon)$-approximation and using only $O(\epsilon^{-1}\log|e|)$ hyperedges. Notice the difference from our work, which focuses on an approximation with small support size.

1.6 Concluding Remarks

Our work provides several promising directions for future work. We prove that all submodular hypergraph admit sparsifiers of polynomial size (Theorem 1.4), leaving a gap of $\tilde{\Omega}_\epsilon(n)$ between the upper and lower bounds. We conjecture that submodular hypergraphs admit the same sparsification bounds as (the special case of) directed hypergraphs.

▶ **Conjecture 1.14.** *Every submodular hypergraph admits a $(1+\epsilon)$-sparsifier of size $O(\epsilon^{-2}n^2)$, which is in fact a reweighted sub-hypergraph.*

Notice that the known lower bound of $\Omega(n^2/\epsilon)$ is not tight with this conjecture, and improving it is an interesting open problem. The main challenge in bridging the gap between our upper bound in Theorem 1.4 and the conjecture is the use of a union bound over all 2^n cuts. This challenge was overcome in graph and hypergraph sparsification by different methods, such as cut counting [7, 21, 10, 28], a matrix Chernoff bound [41], and chaining which uses progressively finer discretizations [5, 27, 36, 25]. Unfortunately, the matrix Chernoff bound is based on linear-algebra tools that are clearly inapplicable to hypergraphs. The cut-counting methods partition the cuts so that a union bound can be applied separately on each part; however these partitions rely on the binary nature of the all-or-nothing splitting function, which seems challenging in the submodular hypergraph setting, because the same g_e can contribute very different values to different cuts $S \subseteq V$. The chaining methods seem more promising, especially the recent one [25] for all symmetric submodular functions, in which the contribution of a single g_e is not binary, although it seems to rely on the splitting functions being symmetric.

In the sparsification setting, we obtain smaller sparsifiers for several families (monotone and finite-spread), however characterizing the optimal sparsifier size for each family remains open. In the succinct-representation setting, we found a useful deformation only for additive splitting functions (Theorem 1.9), and it would be desirable to find deformations for more families.

Another interesting avenue is to find applications or connections to other problems. For example, we show that Theorem 1.6 can be used to approximate a set-coverage function using a small ground set. Another potential application is constructing succinct representations for terminal cuts in a graph, see the full version for details on both applications.

2 Polynomial-Size Sparsifiers for Submodular Hypergraphs

This section proves Theorem 1.4 and its improvement in the monotone case. Our sparsification method is based on importance sampling, where hyperedges are sampled with probability that is (at least) proportional to their maximum relative contribution to any cut. A standard choice, that was indeed used in [39], is to sample every $e \in E$ with probability exactly proportional to its importance, defined as

$$\sigma_e \coloneqq \max_{S \subseteq V} \frac{g_e(S \cap e)}{\sum_{f \in E} g_f(S \cap f)}.$$

The expected size of this sparsifier is proportional to the total importance $\sum_{e \in E} \sigma_e$, which is non-trivial to bound (e.g., naively replacing the maximization over $S \subseteq V$ by summation yields an exponential size bound). An improved bound on the size of a sparsifier constructed in this manner is given in [39], based on a quantity B_H related to the polytopes of the splitting functions. Unfortunately, this improved bound is still exponential for many families of splitting functions.

Our approach achieves a polynomial bound by using a different set of sampling probabilities and a different analysis. Our main insight is that it suffices to consider only a few cuts. Formally, define the minimum directed cut of g_e between $(u, v) \in V \times V$ as

$$g_e^{u \to v} \coloneqq \min_{S \subseteq V : u \in S, v \notin S} g_e(S \cap e). \tag{5}$$

Notice that we do not require $u, v \in e$; clearly, $g_e^{u \to v} = 0$ if $u \notin e$, but $g_e^{u \to v}$ can be positive if $v \notin e$. Our sampling probabilities are proportional to

$$\rho_e \coloneqq \sum_{(u,v) \in V \times V} \frac{g_e^{u \to v}}{\sum_{f \in E} g_f^{u \to v}},$$

where by convention the fraction is equal to zero if the denominator (and thus also the numerator) is zero. The proof follows by showing that $\rho_e \geq \sigma_e$, hence sampling every $e \in E$ with probability proportional to ρ_e suffices to approximate the cuts, and that the expected number of hyperedges in the sparsifier $O(\epsilon^{-2} n^3)$. Since $\rho_e \geq \sigma_e$, our analysis implies that the same size bound holds also for sampling with probabilities proportional to σ_e, i.e., for the sparsifier of [39] but with our amplification factor $M = O(\epsilon^{-2} n)$.

Finally, observe that the directed minimum cuts $g_e^{u \to v}$ can be computed in polynomial time using standard submodular minimization techniques [35].[9] In contrast, calculating σ_e requires maximizing the ratio of two submodular functions, which is NP-hard. In the monotone case, previous work had achieved a polynomial running time [39, 30].

Proof of Theorem 1.4. Our construction of a quality $(1 + \epsilon)$-sparsifier for H utilizes the importance sampling method, where each hyperedge is sampled independently with probability p_e that is defined below, and the splitting functions of every sampled hyperedge d is scaled by factor $1/p_e$.

[9] In fact, computing an $O(1)$-approximation to ρ_e would suffice, and this may be used to speed up the computation, at the cost of increasing the sparsifier size only by a constant factor.

We will use the following claim to bound cuts of H by minimum directed cuts. Throughout, we denote $\bar{S} = V \setminus S$.

▷ Claim 2.1. For every $e \in E$ and $S \subset V$,

$$\max_{u \in S, v \in \bar{S}} g_e^{u \to v} \leq g_e(S \cap e) \leq \sum_{u \in S} \sum_{v \in \bar{S}} g_e^{u \to v}.$$

The proof of Claim 2.1 appears later. Intuitively, it is similar to bounding the capacity of a cut in a graph by the sum of maximum flows between each vertex from S and each vertex from $\bar{S}$. We proceed assuming this claim, to show that $\rho_e \geq \sigma_e$.

▶ **Corollary 2.2.** *For every $e \in E$ and $S \subseteq V$, we have $\rho_e \geq g_e(S \cap e)/\mathrm{cut}_H(S)$.*

Proof. By Claim 2.1, using both the upper bound and the lower bound on $g_e(\cdot)$,

$$\frac{g_e(S \cap e)}{\mathrm{cut}_H(S)} = \frac{g_e(S \cap e)}{\sum_{f \in E} g_f(S \cap f)} \leq \sum_{u \in S, v \in \bar{S}} \frac{g_e^{u \to v}}{\sum_{f \in E} g_f^{u \to v}} \leq \rho_e.$$

Note that the first inequality holds even if $\mathrm{cut}_H(S) = 0$, by our convention that if the denominator (and thus also numerator) is zero then the fraction is zero. ◀

For every hyperedge $e \in E$, set $\rho'_e := g_e(e)/\sum_{f \in E} g_f(f)$ as the importance of the cuts that contain the entire hyperedge (the case $S = V$), and let $p_e := \min(1, M(\rho_e + \rho'_e))$ for a suitable parameter $M = O(\epsilon^{-2} n)$. Now sample every hyperedge $e \in E$ independently with probability p_e and rescale the splitting functions of every sampled hyperedge by factor $1/p_e$. Let H' be the resulting hypergraph.

We first prove that the number of hyperedges in the sparsifier H' is $O(Mn^2)$, which satisfies the claimed size bound by our choice of $M = O(\epsilon^{-2} n)$. Let I_e be an indicator for the event that the hyperedge e is sampled into H'. The expected number of sampled hyperedges is

$$\begin{aligned}\mathbb{E}\left[\sum_{e \in E} I_e\right] = \sum_{e \in E} p_e &\leq M \sum_{e \in E} \left(\frac{g_e(e)}{\sum_{f \in E} g_f(f)} + \sum_{(u,v) \in V \times V} \frac{g_e^{u \to v}}{\sum_{f \in E} g_f^{u \to v}} \right) \\ &\leq M \left(1 + \sum_{(u,v) \in V \times V} \frac{\sum_{e \in E} g_e^{u \to v}}{\sum_{f \in E} g_f^{u \to v}} \right) \leq Mn^2,\end{aligned}$$

where the second inequality follows by changing the order of summation and the last one is because $|V \times V| = n^2$, but we can exclude from the summation the case $u = v$ (as it contributes 0 by our convention). By Markov's inequality, with high constant probability the sparsifier has at most $O(Mn^2)$ hyperedges.

Let us prove that the sparsifier H' indeed approximates the cuts of H. Fix some $S \subseteq V$ and notice that

$$\begin{aligned}\mathbb{E}\left[\mathrm{cut}_{H'}(S)\right] &= \mathbb{E}\left[\sum_{e \in E} I_e \cdot \frac{1}{p_e} g_e(S \cap e)\right] = \sum_{e \in E} \frac{g_e(S \cap e)}{p_e} \cdot \mathbb{E}\left[I_e\right] \\ &= \sum_{e \in E} g_e(S \cap e) = \mathrm{cut}_H(S).\end{aligned}$$

Hence, the cut is preserved in expectation. We shall now prove that the value of the cut is concentrated around its expectation. Let $Q_S = \{e \in E : p_e \in (0,1) \wedge g_e(S \cap e) > 0\}$ be the set of all hyperedges whose contribution to $\mathrm{cut}_{H'}(S)$ is random. Furthermore, denote the maximum contribution of any such hyperedge to $\mathrm{cut}_{H'}(S)$ by $b \coloneqq \max_{e \in Q_S} p_e^{-1} g_e(S \cap e)$. By the Chernoff bound for bounded variables (Theorem A.1),

$$\Pr\left[\mathrm{cut}_{H'}(S) \notin (1 \pm \epsilon) \cdot \mathrm{cut}_H(S)\right] \leq 2 \cdot \exp\left(-\frac{\epsilon^2 \cdot \mathrm{cut}_H(S)}{b}\right). \tag{6}$$

We first analyze the special case $S = V$. Observe that if $\mathrm{cut}_H(V) = 0$ then the cut is preserved trivially. Otherwise, note that $p_e \geq M\rho'_e = \frac{M g_e(e)}{\sum_{f \in E} g_f(f)}$ and hence

$$b = \max_{e \in Q_V} \frac{g_e(e)}{p_e} \leq \max_{e \in Q_V} g_e(e) \frac{\sum_{f \in E} g_f(f)}{M g_e(e)} = \frac{\mathrm{cut}_H(V)}{M}.$$

Plugging this into Equation (6), we find $\Pr\left[\mathrm{cut}_{H'}(V) \notin (1 \pm \epsilon) \cdot \mathrm{cut}_H(V)\right] \leq 2 \cdot \exp\left(-\epsilon^2 M\right)$. Now turning to the general case $S \subset V$, observe that by Corollary 2.2, $p_e \geq M g_e(S \cap e)/\mathrm{cut}_H(S)$. Hence, we again obtain that

$$b \leq \max_{e \in E} g_e(S \cap e) \cdot \frac{\mathrm{cut}_H(S)}{M g_e(S \cap e)} = \frac{\mathrm{cut}_H(S)}{M}. \tag{7}$$

Plugging this back into our concentration bound, Equation (6), we get

$$\Pr\left[\mathrm{cut}_{H'}(S) \notin (1 \pm \epsilon) \cdot \mathrm{cut}_H(S)\right] \leq 2 \cdot \exp\left(-\epsilon^2 M\right).$$

Notice that this is the same probability as the case $S = V$. Setting $M \coloneqq c \cdot \epsilon^{-2} n$ for large enough but fixed $c > 0$, we get that $\mathrm{cut}_{H'}(S)$ approximates $\mathrm{cut}_H(S)$ up to a $1 \pm \epsilon$ factor with probability at least $1 - 2\exp(-cn)$. Applying a union bound over all $S \subseteq V$ we get that the sparsifier approximates all cuts simultaneously with probability at least $1 - 2\exp(-cn) \cdot 2^n \geq 1 - 2\exp(-n)$. This completes the construction of a quality $1 + \epsilon$ sparsifier for H with $O(\epsilon^{-2} n^3)$ hyperedges.

We now turn back to proving Claim 2.1.

Proof of Claim 2.1. Fix some $e \in E$ and $S \subset V$. For each directed minimum cut, let $P_e^{u \to v} \coloneqq \arg\min_{S \subseteq V : S \cap \{u,v\} = \{u\}} g_e(S)$ be some set $S \subseteq V$ attaining the minimum cut value (breaking ties arbitrarily). We need to show that

$$\max_{u \in S, v \in \overline{S}} g_e(P_e^{u \to v}) \leq g_e(S \cap e) \leq \sum_{u \in S} \sum_{v \in \overline{S}} g_e(P_e^{u \to v}). \tag{8}$$

The lower bound is immediate because $g_e(P_e^{u \to v})$ is a minimizer over the cuts separating u from v. For the upper bound, since g_e is submodular and non-negative,

$$\forall A, B \subseteq e, \quad g_e(A) + g_e(B) \geq g_e(A \cap B) + g_e(A \cup B) \geq g_e(A \cap B),$$

and similarly, $g_e(A) + g_e(B) \geq g_e(A \cup B)$. Using these two inequalities and summing over all $v \in \overline{S}$ and $u \in S$, we get

$$\sum_{u \in S} \sum_{v \in \overline{S}} g_e(P_e^{u \to v}) \geq \sum_{u \in S} g_e\left(\bigcap_{v \in \overline{S}} P_e^{u \to v}\right) \geq g_e\left(\bigcup_{u \in S} \bigcap_{v \in \overline{S}} P_e^{u \to v}\right).$$

To conclude the proof we show that $S \cap e = \bigcup_{u \in S} \bigcap_{v \in \overline{S}} P_e^{u \to v}$. For all $u \in S \cap e$ we have $\{u\} \subseteq \bigcap_{v \in \overline{S}} P_e^{u \to v}$, therefore $S \cap e \subseteq \bigcup_{u \in S} \bigcap_{v \in \overline{S}} P_e^{u \to v}$. In addition, for all $u \in S$ we have $\bigcap_{v \in \overline{S}} P_e^{u \to v} \subseteq S \cap e$ if $u \in e$ and $P_e^{u \to v} = \emptyset$ otherwise, therefore $S \cap e = \bigcup_{u \in S} \bigcap_{v \in \overline{S}} P_e^{u \to v}$. We conclude that Equation (8) holds. ◁

This completes the proof of Theorem 1.4. ◀

2.1 Monotone Submodular Hypergraphs

This section proves that every monotone submodular hypergraph admits a quality $(1+\epsilon)$-sparsifier of size $O(\epsilon^{-2}n^2)$.

▶ **Theorem 2.3.** *Every hypergraph with monotone splitting functions admits a quality* $(1+\epsilon)$*-sparsifier of size* $O(\epsilon^{-2}n^2)$*, which is a reweighted sub-hypergraph.*

The proof for the monotone case is similar to the general case. However, since monotone splitting functions are more structured it suffices to examine the importance of all the singleton cuts for each hyperedge. This results in smaller sampling probabilities and a better bound on the number of hyperedges in the sparsifier. The proof utilizes the following well known property of monotone submodular functions.

▷ Claim 2.4. Let $g_e : 2^e \to \mathbb{R}_+$ be a monotone submodular splitting function. Then

$$\forall S \subseteq V, \qquad \max_{v\in S} g_e(\{v\}\cap e) \le g_e(S\cap e) \le \sum_{v\in S} g_e(\{v\}\cap e).$$

Proof. The lower bound holds as g_e is monotone. For the upper bound, since g_e is submodular and non-negative,

$$\sum_{v\in S} g_e(\{v\}\cap e) \ge g_e\left(\bigcup_{v\in S}\{v\}\cap e\right) = g_e(S\cap e). \qquad \blacktriangleleft$$

Similarly to the general case, our over sampling probabilities are proportional to

$$\rho_e = \sum_{v\in V} \frac{g_e(\{v\}\cap e)}{\sum_{f\in E} g_f(\{v\}\cap f)}.$$

The following corollary shows that $\rho_e \ge \sigma_e$. This implies that sampling every $e \in E$ with probability proportional to ρ_e suffices to approximate the cuts of H, in the same manner as in the general case.

▶ **Corollary 2.5.** *For every* $e \in E$ *and* $S \subseteq V$*, we have* $\rho_e \ge g_e(S\cap e)/\mathrm{cut}_H(S)$.

Proof. Observe that by Claim 2.4,

$$\frac{g_e(S\cap e)}{\mathrm{cut}_H(S)} = \frac{g_e(S\cap e)}{\sum_{f\in E} g_f(S\cap f)} \le \sum_{v\in S} \frac{g_e(\{v\}\cap e)}{\sum_{f\in E} g_f(\{v\}\cap f)} \le \rho_e.$$

Notice that the first inequality is well-defined by the convention that if the denominator (and thus also the numerator) is zero then the fraction is zero. ◀

We now turn to proving Theorem 2.3

Proof of Theorem 2.3. To construct H', sample each hyperedge with probability $p_e = \min(1, M\cdot\rho_e)$ for a suitable parameter $M = O(\epsilon^{-2}n)$. Then, reweigh every sampled hyperedge by factor p_e^{-1}. The proof that H' is with high probability a $(1+\epsilon)$-sparsifier is similar to the general case because $\rho_e \ge \sigma_e$, and we omit it.

To bound the number of hyperedges in the sparsifier, let I_e be an indicator for the event that the hyperedge e is sampled into H'. Then the expected number of sampled hyperedges is,

$$\begin{aligned}\mathbb{E}\left[\sum_{e\in E} I_e\right] &= \sum_{e\in E} p_e \le M \sum_{e\in E}\sum_{v\in V} \frac{g_e(\{v\}\cap e)}{\sum_{f\in E} g_f(\{v\}\cap f)} \\ &\le M \sum_{v\in V}\sum_{e\in E} \frac{g_e(\{v\}\cap e)}{\sum_{f\in E} g_f(\{v\}\cap f)} \le Mn,\end{aligned}$$

where the second inequality is from changing the order of summation. Hence, by Markov's inequality we find that with high constant probability the size of the sparsifier is at most $O(Mn) = O(\epsilon^{-2}n^2)$. This concludes the proof. ◀

Abstract

Recently, a number of variants of the notion of cut-preserving hypergraph sparsification have been studied in the literature. These variants include directed hypergraph sparsification, submodular hypergraph sparsification, general notions of approximation including spectral approximations, and more general notions like sketching that can answer cut queries using more general data structures than just sparsifiers. In this work, we provide reductions between these different variants of hypergraph sparsification and establish new upper and lower bounds on the space complexity of preserving their cuts. Specifically, we show that:

1. $(1 \pm \epsilon)$ directed hypergraph spectral (respectively cut) sparsification on n vertices efficiently reduces to $(1 \pm \epsilon)$ undirected hypergraph spectral (respectively cut) sparsification on n^2+1 vertices. Using the work of Lee and Jambulapati, Liu, and Sidford (STOC 2023) this gives us directed hypergraph spectral sparsifiers with $O(n^2 \log^2(n)/\epsilon^2)$ hyperedges and directed hypergraph cut sparsifiers with $O(n^2 \log(n)/\epsilon^2)$ hyperedges by using the work of Chen, Khanna, and Nagda (FOCS 2020), both of which improve upon the work of Oko, Sakaue, and Tanigawa (ICALP 2023).
2. Any cut sketching scheme which preserves all cuts in any directed hypergraph on n vertices to a $(1 \pm \epsilon)$ factor (for $\epsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$) must have worst-case bit complexity $n^{3-o(1)}$. Because directed hypergraphs are a subclass of submodular hypergraphs, this also shows a worst-case sketching lower bound of $n^{3-o(1)}$ bits for sketching cuts in general submodular hypergraphs.
3. $(1 \pm \epsilon)$ monotone submodular hypergraph cut sparsification on n vertices efficiently reduces to $(1 \pm \epsilon)$ symmetric submodular hypergraph sparsification on $n+1$ vertices. Using the work of Jambulapati et. al. (FOCS 2023) this gives us monotone submodular hypergraph sparsifiers with $\widetilde{O}(n/\epsilon^2)$ hyperedges, improving on the $O(n^3/\epsilon^2)$ hyperedge bound of Kenneth and Krauthgamer (arxiv 2023).

At a high level, our results use the same general principle, namely, by showing that cuts in one class of hypergraphs can be simulated by cuts in a simpler class of hypergraphs, we can leverage sparsification results for the simpler class of hypergraphs.

1 Introduction

Sparsification deals with the following natural question: given a large object, how much can we compress it while still retaining some of its key properties? In the realm of graphs, this has been a well-studied notion spanning decades of research. Starting with the work of Karger [9], the question of how sparse we can make a graph while still preserving the approximate sizes of every cut has been a central topic of research. Since then, numerous works by many authors have resolved this question (starting with the work of Benczúr and Karger [2]) and pushed the boundaries of this research beyond just graph cuts [1, 21, 12, 3].

More rigorously, for a weighted graph $G = (V, E)$ on n vertices, we can define a cut in the graph corresponding to each set $S \subseteq V$. For such a set S, we define the vector $\mathbf{1}_S \in \{0,1\}^{|V|}$ as the indicator vector of whether the ith vertex is in S. Using this vector, we say that $\text{cut}_G(S) = \sum_{(u,v)\in E} w_{(u,v)}(\mathbf{1}_{Su} - \mathbf{1}_{Sv})^2$, i.e., the weight of the edges crossing between S and $V - S$. A cut-sparsifier asks for a reweighted subset of edges $\hat{E} \subseteq E$ such that in the graph $G = (V, \hat{E})$, with the corresponding new weights $\hat{w}$, for every $S \subseteq V$

$$(1-\varepsilon)\text{cut}_G(S) \leq \text{cut}_{\hat{G}}(S) \leq (1+\varepsilon)\text{cut}_G(S).$$

The seminal work of [2] was the first to show the existence of such sparsifiers $\hat{G}$ for any graph G such that $|\hat{E}| = \widetilde{O}(n/\varepsilon^2)$. Subsequent work in the *spectral* regime asked whether such sparsifiers still exist when we consider real-valued vectors as opposed to cut-vectors. In this setting, we define a Laplacian L_G for our graph G. We say that for $x \in \mathbb{R}^{|V|}$

$$x^T L_G x = \sum_{(u,v)\in E} w_{(u,v)}(x_u - x_v)^2.$$

The goal in this regime instead becomes finding a reweighted subgraph $\hat{G}$ such that for every $x \in \mathbb{R}^{|V|}$,

$$(1-\varepsilon)x^T L_{\hat{G}} x \leq x^T L_G x \leq (1+\varepsilon)x^T L_{\hat{G}} x.$$

Work by Batson, Spielman, and Srivastava, and Spielman and Teng [1, 21] settled the size complexity of spectral sparsifiers for ordinary graphs by showing the existence of such sparsifiers of size $O(n/\varepsilon^2)$.

Recently, starting with the work of Kogan and Krauthgamer [12], a natural extension to the study of graph sparsification has been the study of sparsifying *hypergraphs*. In this setting, one is given a hypergraph $H = (V, E)$, and asked to preserve to a $(1 \pm \varepsilon)$ factor the weight of all hyperedges crossing a particular cut. A cut is given by a bichromatic coloring of the vertices and a hyperedge is considered cut if it is not monochromatic. Work by Chen, Khanna, and Nagda [3] was the first to completely characterize the cut-sparsifiability of hypergraphs, which showed that there exist $(1 \pm \varepsilon)$-cut-sparsifiers for any hypergraph on n vertices of size $O(n \log(n)/\varepsilon^2)$. As in the graph setting, where the natural next step from cut-sparsifiers was spectral-sparsifiers, Soma and Yoshida [20] later introduced this notion of spectral *hypergraph* sparsification. More explicitly, the "energy function" (also called the Laplacian) of an undirected hypergraph $H = (V, E)$ is as follows:

$$L_H(x) = \text{cut}_H(x) = \sum_{e\in E} w_e \max_{u,v\in e}(x_u - x_v)^2.$$

A $(1 \pm \varepsilon)$-spectral sparsifier for an undirected hypergraph then corresponds to a reweighted subhypergraph of H, denoted by $\hat{H}$ such that for any $x \in \mathbb{R}^{|V|}$,

$$(1-\varepsilon)L_H(x) \leq L_{\hat{H}}(x) \leq (1+\varepsilon)L_H(x).$$

This question of whether one could preserve the Laplacian of undirected hypergraphs with only a near-linear number of hyperedges was then resolved by Kapralov et. al. [7], Jambulapati, Liu, and Sidford [6], and Lee [14] in the affirmative.

More recently however, work has sought to generalize hypergraph sparsification even further. Indeed, given a hypergraph $H = (V, E)$, instead of viewing edge-cuts in the traditional way (i.e., for a bichromatic coloring of the vertices counting how many hyperedges are not one color), a more general *splitting* function is assigned to each hyperedge $e \subseteq V$. This splitting function is a set function $g_e : 2^e \to \mathbb{R}^{\geq 0}$. One natural extension to the case of ordinary hypergraphs that has received particular attention is the case in which these splitting functions g_e are also required to be submodular [10, 13] (though there has also been work on the regime where these functions are not submodular, for instance with parity functions in [11]). Such submodular hypergraphs appear in numerous contexts, for instance in clustering data points with complex relationships [15, 16, 22, 23] and summarizing data [17]. For such a submodular hypergraph $H = (V, E)$, the value on any cut $S \subset V$ is

$$\text{cut}_H(S) = \sum_{e \in E} g_e(S \cap e).$$

Recall that a function $g : 2^V \to \mathbb{R}^{\geq 0}$ is said to be *submodular* if it has the property of diminishing returns. That is, for any $S \subset T \subset V$, and any element $x \in V, x \notin T$,

$$g(S \cup \{x\}) - g(S) \geq g(T \cup \{x\}) - g(T).$$

Under this definition, one type of submodular hypergraph is a *directed hypergraph*. In a directed hypergraph, one can view each directed hyperedge instead as a tuple $(e_{\text{tail}}, e_{\text{head}})$ of subsets of V. The cut function of a directed hyperedge e on cut S is 1 if and only if an element from S is in e_{tail} and an element from $V - S$ is in e_{head}. More explicitly, for a directed hypergraph $G = (V, E, w)$ on n vertices, and a vector $x \in \mathbb{R}^n$, we can define the Laplacian for G as

$$L_G(x) = \sum_{e \in E} \max_{u \in L(e), v \in R(e)} (x_u - x_v)_+^2.$$

In this context, $(x_u - x_v)_+ = \max((x_u - x_v), 0)$, and directed hypergraph cuts are simply the restriction of the vector x to be in $\{0, 1\}^{|V|}$ (seen as the indicator vector for a set $S \subseteq V$). A non-zero contribution from a hyperedge occurs only if a tail vertex of the hyperedge has a larger value than a head vertex of the hyperedge.

One can check that in the cut regime (i.e. $x \in \{0, 1\}^n$), each directed hyperedge cut yields a submodular function $g_e : 2^{e_{\text{head}} \cup e_{\text{tail}}} \to \mathbb{R}^{\geq 0}$. In what follows, we describe our contributions to various problems in this area.

1.1 Improved Bounds for Directed Hypergraph Sparsification

In the graph case, it is known that directed graph cut-sparsifiers for graphs with n vertices can require as many as $\Omega(n^2)$ edges to preserve cuts to a $(1 \pm \varepsilon)$ factor. In this sense, directed graph cut-sparsification is a trivial task, as any graph has at most $O(n^2)$ edges to begin with. Contrary to this however, directed *hypergraph* sparsification is non-trivial. While the same $\Omega(n^2)$ lower bound exists, a directed hypergraph can have as many as 4^n directed hyperedges to start with, so a sparsifier with $O(n^2)$ directed hyperedges is a vast improvement. This observation has led to a rich line of research studying the feasibility of sparsifying directed hypergraphs. The first work on this front was the work of [20] which

showed the existence of directed hypergraph sparsifiers with $O(n^3/\varepsilon^2)$ directed hyperedges and gave a polynomial time algorithm for computing them. Later work by [7] presented a proof of sparsifiers with $\widetilde{O}(nr/\varepsilon^2)$ (where r is the maximum size of any hyperedge) hyperedges for undirected hypergraph spectral sparsification, and with $\widetilde{O}(n^2r^3/\varepsilon^2)$ directed hyperedges for directed hypergraph spectral sparsification by tuning their algorithm and performing a different analysis. In particular, this improved upon the result of [20] in the regime where r is constant. Note that as with graphs, spectral sparsification is a *stronger* notion than cut sparsification, so in particular, these proofs imply the existence of cut-sparsifiers of the same complexity.

Ultimately however, the complexity of directed spectral hypergraph sparsification was nearly settled by the work of Oko, Sakaue, and Tanigawa [18], who showed $(1 \pm \varepsilon)$ spectral-sparsifiers with $O(n^2 \log^3(n/\varepsilon)/\varepsilon^2)$ directed hyperedges exist for directed hypergraphs on n vertices.

Continuing this line of research, we show that fundamentally, the task of directed hypergraph sparsification can be reduced in a black-box manner to undirected hypergraph spectral sparsification.

More specifically, we show there is a lifting from a directed hypergraph on n vertices to an undirected hypergraph on $n^2 + 1$ vertices such that the Laplacian of every individual hyperedge is simultaneously preserved. That is, we show the following theorem:

▶ **Theorem 1.** *For $H = (V, E)$ an a directed hypergraph on n vertices, one can compute an undirected hypergraph $\psi(H)$ on $n^2 + 1$ vertices in time $O(mr^2)$ (where m is the number of hyperedges in H, and r is the maximum size of any hyperedge in H), such that for any $x \in \mathbb{R}^n$, one can also compute $\vartheta(x) \in \mathbb{R}^{n^2+1}$ in time $O(n^2)$ such that*

$$L_H(x) = L_{\psi(H)}(\vartheta(x)).$$

Moreover, for any hyperedge $e \in H$, there is a single corresponding hyperedge $\psi(e)$ in $\psi(H)$ such that

$$L_e(x) = L_{\psi(e)}(\vartheta(x)).$$

The size of $\psi(e)$ is at most $|e|^2$. Further, for $x \in \{0,1\}^n$, i.e. corresponding to a cut, $\vartheta(x)$ will be in $\{0,1\}^{n^2+1}$, i.e. also corresponding to a cut.

We can then use the existing state of the art literature of undirected spectral hypergraph sparsification [6, 14] to conclude the existence of directed spectral hypergraph sparsifiers with only $O(n^2 \log(n) \log(r)/\varepsilon^2)$ hyperedges which can be found in time $\widetilde{O}(mr^2)$, where m is the original number of hyperedges and r is the maximum size of any hyperedge. Note that this bound on the size of sparsifiers improves on the result of [18], and in particular, makes the dependence on ε exactly $O(1/\varepsilon^2)$, which now matches the literature for undirected sparsification. That is, we show the following:

▶ **Theorem 2.** *For any directed hypergraph $H = (V, E)$ on n vertices, and any $0 < \varepsilon < 1$ there exists a weighted sub-hypergraph $\hat{H}$ such that for all $x \in \mathbb{R}^n$:*

$$(1 - \varepsilon)L_H(x) \leq L_{\hat{H}}(x) \leq (1 + \varepsilon)L_H(x),$$

and $\hat{H}$ only has $O(n^2 \log(n) \log(r)/\varepsilon^2)$ hyperedges, where r is the maximum size of any hyperedge of H.

As an additional benefit, because the reduction of Theorem 1 preserves cut vectors, we can also invoke the result of [3] to conclude the existence of directed hypergraph *cut*-sparsifiers with $O(n^2 \log(n)/\varepsilon^2)$ hyperedges.

1.2 Lower Bounds for Sketching Cuts in Directed Hypergraphs

We next focus on the bit complexity of creating cut-sparsifiers for directed hypergraphs. This is done in hopes of answering an open question from [10] regarding the bit-complexity of arbitrary sketching schemes for submodular hypergraphs. In prior work [18, 10], a lower bound of size $\Omega(n^3)$ (ignoring ε) was established for the bit complexity of any directed hypergraph cut-*sparsifier*. However, lower bounds for sparsifiers explicitly take advantage of the sparsifier structure by starting with known examples of sparsifiers that require $\Omega(n^2)$ hyperedges, and then padding these hyperedges with random vertices in their tail such that the bit complexity of each hyperedge becomes $\Omega(n)$. One can trivially show that this padding does not change the requirement of preserving $\Omega(n^2)$ hyperedges. Because sparsifiers are limited to storing only hyperedges that were originally present, this then forces a bit complexity lower bound of $\Omega(n^3)$. However, this same technique is not amenable to a sketching lower bound as the padding procedure only adds complexity to each hyperedge, and not necessarily to the cut function as a whole. Thus, the difficulty is in showing that the cut function itself requires a large description size, regardless of how we choose to represent it. This marks a fundamental difference.

Addressing this, we show the following theorem:

▶ **Theorem 3.** *Any $(1 \pm \varepsilon)$ cut-sketching scheme for directed hypergraphs on n vertices must have worst-case space $\frac{n^3}{2^{O(\sqrt{\log(n)})}}$ bits (for $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$).*

At a high level, our proof takes advantage of a result of Kapralov et. al. [8]. In this work, the authors show that there exists a family of undirected hypergraphs on n vertices, each with at most n hyperedges, such that any sketching scheme which can sketch cuts in any of the hypergraphs in this family to an additive error of εn (for $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$) must have worst-case size at least $\frac{n^2}{2^{O(\sqrt{\log(n)})}}$. We show that by using a specific construction of a directed hypergraph, along with a specific reconstruction procedure, we can actually store an additive cut-approximation to n distinct undirected hypergraphs in a single cut-sketch of a directed hypergraph. That is, we show the following theorem:

▶ **Theorem 4.** *For any undirected hypergraphs $H_1, \dots H_n$, each on vertex set V, with $|V| = n$, there exists a directed hypergraph G on $2n$ vertices, such that given a $(1 \pm \varepsilon)$ cut-sketch for G, for any of the undirected hypergraphs $H_i = (V, E_i)$, one can recover $cut_{H_i}(S)$ to within additive error $3\varepsilon|E_i|$.*

Now, by sampling these undirected hypergraphs $H_1, \dots H_n$ from a specific family of hypergraphs, we can argue that simultaneously preserving the cut-values in all of these hypergraphs (even to an additive error) requires a data structure of size $\frac{n^2}{2^{O(\sqrt{\log(n)})}} \cdot n = \frac{n^3}{2^{O(\sqrt{\log(n)})}}$. In particular, by the previous reduction, any general scheme for sketching directed hypergraphs or submodular hypergraphs would be such a scheme, and therefore must have worst-case size at least $\Omega(n^{3-o(1)})$ (for $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$).

Prior to our work, there was no known super-quadratic (in n) lower bound on the sketching complexity of cuts in directed hypergraphs. In conjunction with our positive results on the sparsifiability of directed hypergraphs, this shows that directed hypergraph sparsification is almost-optimal even among all possible sketches for preserving cut values. That is, from the previous section, we know that directed hypergraph sparsifiers approximately preserve the sizes of all cuts in a directed hypergraph to a factor $(1 \pm \varepsilon)$ using $\widetilde{O}(n^3/\varepsilon^2)$ bits. In conjunction with our lower bound, we can conclude that this is almost the best possible (among *any* sketching scheme) in the regime where $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$. Thus, we show that for approximately storing cuts in directed hypergraphs using as few bits as possible, using a sparsifier is almost optimal. We view this as an important contribution of our work.

1.3 Cut Sparsifiers for Monotone Submodular Hypergraphs

Finally, we show that one can simulate cuts in monotone submodular hypergraphs with cuts in symmetric submodular hypergraphs. Recall that a set function is monotone if $f(S \cup \{t\}) \geq f(S)$, and we say that a submodular hypergraph is monotone if *every* splitting function is also monotone. This model of hypergraphs was specifically studied in the work of [10], where their sparsifiers ultimately achieved a complexity of $O(n^3/\varepsilon^2)$ hyperedges. In particular, monotone submodular functions capture a wide variety of natural and common functions such as matroid rank and entropy of random variables.

With respect to this, we show the following theorem:

▶ **Theorem 5.** *Suppose $f : 2^V \to \mathbb{R}^{\geq 0}$ is a monotone, submodular function. Then, $f' : 2^{V \cup \{*\}} \to \mathbb{R}^{\geq 0}$ defined as $\forall S \subseteq V$*

$$f'(S) = f(S) = f'(V - S \cup \{*\})$$

is submodular and symmetric.

Next, we show that given an arbitrary monotone, submodular hypergraph on n vertices, we can lift this to a symmetric submodular hypergraph on $n + 1$ vertices, where the single extra vertex is the $\{*\}$ vertex from the preceding theorem. Next, for each individual splitting function $g_e : 2^e \to \mathbb{R}^+$ in the monotone, submodular hypergraph, we replace g_e with g'_e, again using the preceding theorem.

Note that for each monotone submodular function, we *re-use* the same $\{*\}$ vertex. Thus, the increase in the size of the vertex set is only 1. Finally, we can then invoke a result from [5], which states that for any submodular hypergraph H where each splitting function is symmetric, one can calculate a sparsifier for H with only $\widetilde{O}(n/\varepsilon^2)$ hyperedges.

We then get the following:

▶ **Theorem 6.** *Let $H = (V, E)$ be a hypergraph, such that $\forall e \in E$, the corresponding splitting function $g_e : 2^e \to \mathbb{R}^{\geq 0}$ is submodular and monotone. Then there exists a $(1 \pm \varepsilon)$ cut-sparsifier for H retaining only $\widetilde{O}(n/\varepsilon^2)$ hyperedges.*

Prior to this work, the best known upper bound for the size complexity (in hyperedges) for $(1 \pm \varepsilon)$-sparsifying any monotone submodular hypergraph was $O(n^3/\varepsilon^2)$ hyperedges, proved in the work of [10]. Our result essentially improves this to the best possible, where we now only have a near-linear dependence on the size of the vertex set. We view it as an interesting open question if one can extend our proof method used here to general submodular functions (although this case will necessarily require a blow-up of at least quadratic size).

1.4 Overview

At a high level, all of our results use the same general principle, namely, by showing that cuts in one class of hypergraphs can be simulated by cuts in a simpler class of hypergraphs, we can leverage sparsification results for the simpler class of hypergraphs. This leads to our proofs being quite simple despite the fact that the results improve upon the state-of-the-art knowledge in hypergraph sparsification.

In Section 2 we introduce formal definitions and other preliminaries. In Section 3 we present the algorithms for sparsifying directed hypergraphs by reducing to undirected hypergraph sparsification. Next, in Section 4, we show how to simultaneously simulate cuts in many different undirected graphs thereby leading to new lower bounds for the worst case size of sketching cuts in directed hypergraphs. Finally, in Section 5, we show how to sparsify arbitrary monotone, submodular hypergraphs to near-optimal size.

2 Preliminaries

First, we introduce the definitions of undirected and directed hypergraphs.

▶ **Definition 7.** *An **undirected hypergraph** $G = (V, E)$ is a collection of vertices V, with associated hyperedges $e \in E$, where $e \subseteq V$ can be of arbitrary size.*

▶ **Definition 8.** *A **directed hypergraph** $H = (V, E)$ is a collection of vertices V along with directed hyperedges $e \in E$. Each directed hyperedge is of the form $e = (e_{tail}, e_{head})$, where $e_{head}, e_{tail} \subseteq V$. We will use $L(e) = e_{tail}, R(e) = e_{head}$. Note that e_{head}, e_{tail} are not necessarily disjoint.*

Next, we introduce the definition of spectral sparsifiers for both undirected and directed hypergraphs.

▶ **Definition 9.** *For an undirected hypergraph $G = (V, E, w)$ on n vertices, and a vector $x \in \mathbb{R}^n$, the **quadratic form of the Laplacian of G** is*

$$L_G(x) = \sum_{e \in E} \max_{u,v \in e} (x_u - x_v)^2.$$

▶ **Definition 10.** *For a directed hypergraph $G = (V, E, w)$ on n vertices, and a vector $x \in \mathbb{R}^n$, the **directed quadratic form of the Laplacian of G** is*

$$L_G(x) = \sum_{e \in E} \max_{u \in L(e), v \in R(e)} (x_u - x_v)_+^2.$$

In this context, $(x_u - x_v)_+ = \max((x_u - x_v), 0)$. A non-zero contribution from a hyperedge occurs only if a tail vertex of the hyperedge has a larger value than a head vertex of the hyperedge. Note that the head set and tail set of a directed hyperedge are not necessarily disjoint.

▶ **Definition 11.** *For a (directed or undirected) hypergraph $G = (V, E)$ on n vertices, a **$(1 \pm \varepsilon)$-spectral sparsifier** for G is a weighted (directed or undirected) sub-hypergraph H such that for every $x \in \mathbb{R}^n$,*

$$(1 - \varepsilon) L_G(x) \leq L_H(x) \leq (1 + \varepsilon) L_G(x).$$

Further, we require that the hyperedges of H are a subset of the hyperedges of G.

▶ Remark 12. For all the above definitions, if a reweighted sub-hypergraph H of G preserves the quadratic form for vectors $x \in \{0, 1\}^n$ to $(1 \pm \varepsilon)$ multiplicative error, we say that H is a **cut-sparsifiers**. Note that all spectral sparsifiers are cut-sparsifiers, while the converse is not necessarily true.

We also refer to cut-sizes in hypergraphs. A cut is specified by a set $S \subseteq V$, and we say the size of the cut S in G (denoted $|\text{cut}_G(S)|$) is $L_G(\mathbf{1}_S)^T$, where $\mathbf{1}_S$ is the indicator vector in $\{0, 1\}^n$ for the set S. Combinatorially, this refers to the weight of the hyperedges that are "leaving" the set S.

Next we define submodular functions and submodular hypergraphs.

▶ **Definition 13.** *A function $g : 2^V \to \mathbb{R}^{\geq 0}$ is said to be submodular if for any $S \subset T \subset V$, and any $x \in V - T$,*

$$g(S \cup \{x\}) - g(S) \geq g(T \cup \{x\}) - g(T).$$

Using this, we can define a submodular hypergraph.

▶ **Definition 14.** *A submodular hypergraph $H = (V, E)$ is a set of n vertices along with a set of hyperedges E. For each hyperedge $e \in E$, there is a corresponding submodular splitting function $g_e : 2^e \to \mathbb{R}^{\geq 0}$. For any subset $S \subseteq V$, the corresponding cut of the submodular hypergraph is*

$$cut_H(S) = \sum_{e \in E} g_e(S \cap e).$$

▶ **Definition 15.** *We say that a data structure G is a $(1 \pm \varepsilon)$-cut* sketch *of a submodular hypergraph $H = (V, E)$, if for any $S \subseteq V$ one can deterministically recover $cut_H(S)$ to within a $(1 \pm \varepsilon)$ factor using only the data structure G, and the set S.*

We will use the following result from [5] regarding the sparsifiability of symmetric, submodular hypergraphs. Note that a submodular function $f : 2^V \to \mathbb{R}^+$ is said to be symmetric if $\forall S \subseteq V, f(S) = f(V - S)$.

▶ **Theorem 16** (Corollary 1.2 of [5])**.** *For any symmetric submodular hypergraph H on n vertices, there is a $(1 \pm \varepsilon)$-sparsifier for H with $\widetilde{O}(n/\varepsilon^2)$ hyperedges.*

3 Directed to Undirected Hypergraph Sparsification

In this section, we will show that any algorithm that produces an undirected spectral hypergraph sparsifier with $f(n, r)$ hyperedges (for a vertex set of size n, and maximum hyperedge size r), can be used in a *black-box manner* to create a spectral sparsifier with $f(n^2 + 1, r^2)$ hyperedges for any n-vertex directed hypergraph.

To this end, we first have to define the "lifting" operation from a directed hypergraph on n vertices to an undirected hypergraph on $n^2 + 1$ vertices.

▶ **Definition 17.** *For a directed hypergraph $H = (V, E)$ on n vertices, let $\psi(H)$ be an undirected hypergraph on $n^2 + 1$ vertices defined as follows. For the first n^2 vertices of $\psi(H)$, associate these vertices with tuples of vertices from H, that is, each of these vertices is associated with an element from the set $V \times V$. The final vertex in $\psi(H)$ will be a special vertex we denote by $*$. Now, for each hyperedge $e \in E$ of H, define a corresponding hyperedge $\varphi(e)$ in $\psi(H)$ as follows: let the vertices in $L(e)$ be $u_1, \ldots u_\ell$, and let the vertices in $R(e)$ be $v_1, \ldots v_r$. Let $\varphi(e)$ contain*

$$L(e) \times R(e) \cup \{*\} = \{(u_1, v_1), (u_1, v_2), \ldots (u_1, v_r), (u_2, v_1), \ldots (u_2, v_r), \ldots (u_3, v_1), \ldots (u_\ell, v_r), *\}.$$

Note that this transformation is invertible. If we are given an undirected hyperedge of the form $\varphi(e) = L(e) \times R(e) \cup \{*\}$, we can invert this transformation to recover the directed hyperedge $e = (L(e), R(e))$. Additionally, note that this transformation and its inverse are efficiently computable (running in time $O(r^2)$, where r is the size of the undirected hyperedge).

Next, we define the lifting of a test vector.

▶ **Definition 18.** *For a vector $x \in \mathbb{R}^n$, we define the lifting of x denoted as $\vartheta(x)$. $\vartheta(x)$ is in $\mathbb{R}^{n^2+1}$, and in particular, for the first n^2 entries, we associate these with the set $[n] \times [n]$. We say that $(\vartheta(x))_{u,v} = \max(x_u - x_v, 0)$. For the final entry, which we associate with the special vertex $*$ in the lifted H, we let $\vartheta(x)_* = 0$.*

Note again that $\vartheta(x)$ is efficiently computable in time $O(n^2)$ where n is the dimension of x.

▶ **Theorem 19.** *Let $H = (V, E)$ be a directed hypergraph on n vertices. Then, for any $x \in \mathbb{R}^n$,*

$$L_H(x) = L_{\psi(H)}(\vartheta(x)).$$

Proof. It suffices to show that for a single hyperedge $e \in E$,

$$\max_{u \in L(e), v \in R(e)} (x_u - x_v)_+^2 = \max_{(y,z) \in \varphi(e)} (\vartheta(x)_y - \vartheta(x)_z)^2.$$

The reason this suffices is that there is one $\varphi(e)$ for each corresponding hyperedge $e \in E$. So, we are in effect showing that every term in the sum of the quadratic form of the Laplacians is the same.

To see why this equality is true, let some $\widehat{u} \in L(e), \widehat{v} \in R(e)$ be the maximizers for the expression on the left. Then, note that the corresponding entry $\vartheta(x)_{\widehat{u},\widehat{v}}$ is exactly $(x_{\widehat{u}} - x_{\widehat{v}})_+$. Now, because $\widehat{u} \in L(e)$ and $\widehat{v} \in R(e)$, it follows that $(\widehat{u}, \widehat{v}) \in \varphi(e)$. Because the special vertex $* \in \varphi(e)$, it follows that in the above expression

$$\max_{(y,z) \in \varphi(e)} (\vartheta(x)_y - \vartheta(x)_z)^2 \geq (\vartheta(x)_{(\widehat{u},\widehat{v})} - \vartheta(x)_*)^2 = (x_{\widehat{u}} - x_{\widehat{v}})_+^2 = \max_{u \in L(e), v \in R(e)} (x_u - x_v)_+^2.$$

Now, we will show the opposite direction. Indeed, suppose that some elements $\widehat{y}, \widehat{z}$ are maximizers for $\max_{(y,z) \in \varphi(e)} (\vartheta(x)_y - \vartheta(x)_z)^2$. Note that by construction, every entry in $\vartheta(x)$ is ≥ 0. This means that without loss of generality, we can assume that $\widehat{z} = *$ (the special vertex), as this vertex attains the smallest possible value 0. This means that the maximizing value of the expression is exactly $\vartheta(x)_{\widehat{y}}^2$, where $\widehat{y}$ is one of the first n^2 vertices in $\psi(H)$. So, let us write $\widehat{y} = (\widehat{a}, \widehat{b})$, where $\widehat{a}, \widehat{b}$ are both vertices in G. By construction, because $\widehat{y} \in \widehat{e}$, it follows that $\widehat{a} \in L(e)$, and $\widehat{b} \in R(e)$. As such it follows that

$$\max_{u \in L(e), v \in R(e)} (x_u - x_v)_+^2 \geq (x_{\widehat{a}} - x_{\widehat{b}})_+^2 = \vartheta(x)_{\widehat{y}}^2 = \max_{(y,z) \in \widehat{e}} (\vartheta(x)_y - \vartheta(x)_z)^2.$$

Thus, it follows that

$$\max_{u \in L(e), v \in R(e)} (x_u - x_v)_+^2 = \max_{(y,z) \in \varphi(e)} (\vartheta(x)_y - \vartheta(x)_z)^2,$$

as claimed. ◀

▶ **Corollary 20.** *Let H be a directed hypergraph on n vertices. Suppose that $\widehat{\psi(H)}$ is a $(1 \pm \varepsilon)$ undirected hypergraph spectral sparsifier to $\psi(H)$. Then, it follows that the unlifted graph $\widehat{H}$ which is calculated by applying φ^{-1} to each hyperedge in $\widehat{\psi(H)}$, is a $(1 \pm \varepsilon)$ directed hypergraph spectral sparsifier to H.*

Proof. Indeed, suppose $H, \psi(H), \widehat{H}, \widehat{\psi(H)}$ are as specified above, and let $x \in \mathbb{R}^n$. It follows that

$$(1 - \varepsilon) L_H(x) = (1 - \varepsilon) L_{\psi(H)}(\vartheta(x)) \leq L_{\widehat{\psi(H)}}(\vartheta(x)) = L_{\widehat{H}}(x)$$

$$= L_{\widehat{\psi(H)}}(\vartheta(x)) \leq (1 + \varepsilon) L_{\psi(H)}(\vartheta(x)) = (1 + \varepsilon) L_H(x).$$

To conclude, this implies that for $\widehat{H}, H$ as above,

$$(1 - \varepsilon) L_H(x) \leq L_{\widehat{H}}(x) \leq (1 + \varepsilon) L_H(x).$$ ◀

▶ **Theorem 21.** *For a directed hypergraph H on n vertices, one can find a directed hypergraph spectral sparsifier $\widehat{H}$ of H, with $O(n^2 \log(n) \log(r)/\varepsilon^2)$ hyperedges in time $\widetilde{O}(mr^2)$, where m is the number of directed hyperedges in H and r is the maximum size of a hyperedge in H.*

Proof. If the number of hyperedges in H is less than n^2, simply return H. Otherwise, lift H to $\psi(H)$, and spectrally sparsify $\psi(H)$ using [6]. This will result in a $(1 \pm \varepsilon)$ spectral sparsifier $\widehat{\psi(H)}$ to $\psi(H)$, with at most $O(n^2 \log(n^2) \log(r^2)/\varepsilon^2)$ hyperedges, as we desire. Here, we have used that the maximum rank of a hyperedge in $\widehat{G}$ is at most the squared rank of a hyperedge in G. Further, the running time of this algorithm is $\widetilde{O}(mr^2)$, as the number of hyperedges in $\widehat{G}$ is the same as the number of hyperedges in G, and the rank, again, is at most r^2. Now, we can unlift $\widehat{\psi(H)}$ to $\widehat{H}$ by applying φ^{-1} to each hyperedge, and use the previous corollary to conclude our theorem. ◀

▶ Remark 22. Note that if we restrict our original vector x to be in $\{0,1\}^n$, it follows that $\vartheta(x) \in \{0,1\}^{n^2+1}$. By repeating the exact same steps above, this means that we can use the same reduction from above to get directed hypergraph cut sparsifiers, by only using algorithms from undirected hypergraph cut sparsifiers.

▶ **Corollary 23.** *For a directed hypergraph H on n vertices, one can find a directed hypergraph cut sparsifier $\widehat{H}$ of H, with $O(n^2 \log(n)/\varepsilon^2)$ hyperedges in time $\widetilde{O}(mr^2/\varepsilon^2)$, where m is the number of directed hyperedges in H, and r the maximum size of any hyperedge.*

Proof. Simply perform the reduction from above, and invoke the algorithm for undirected hypergraph cut-sparsification from Theorem 1.3 of [19]. Specifically, for an undirected hypergraph G, Quanrud presents an algorithm running in time $\widetilde{O}(p(G))$ which constructs $(1 \pm \varepsilon)$ k-cut sparsifiers (a stronger requirement than the cut-sparsifiers required here), where $p(G) = \sum_{e \in G} |e|$. In our setting, for a directed hypergraph H, when we construct the undirected lifting $\psi(H)$, it will be the case that $p(\psi(H)) = \sum_{e \in \psi(H)} |e| \leq \sum_{e \in H} |e|^2 \leq mr^2$, yielding the desired runtime. ◀

4 Space Lower-bounds for Sketching Cuts in Directed Hypergraphs

In this section, we will establish an $\Omega(n^{3-o(1)})$ lower-bound for worst-case sketching of the cuts in a directed hypergraph on n vertices to a $(1 \pm \varepsilon)$ factor for ε being $\frac{1}{2^{O(\sqrt{\log(n)})}}$. As mentioned in the introduction, this improves upon a result of [10] who showed a lower bound of size $\Omega(n^3)$ for the bit complexity of any *sparsifier*. However, their lower bound explicitly takes advantage of the sparsifier structure by starting with known examples of sparsifiers that require $\Omega(n^2)$ hyperedges, and then padding these hyperedges with random vertices in their tail such that the bit complexity is $\Omega(n)$. One can trivially show that this padding does not change the requirement of preserving $\Omega(n^2)$ hyperedges. Because sparsifiers are limited to storing only hyperedges that were originally present, this then forces a bit complexity lower bound of $\Omega(n^3)$. However, this same technique is not amenable to a sketching lower bound as the padding procedure only adds complexity to each hyperedge, and not necessarily to the cut function as a whole.

To overcome this, we take advantage of a result of [8] who showed that, in general, any $(1 \pm \varepsilon)$ cut-sketching scheme for undirected hypergraphs on n vertices, with $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$ must have worst case bit complexity $\frac{n^2}{2^{O(\sqrt{\log(n)})}}$. This result uses encodings of Rusza-Szemerédi graphs into undirected hypergraphs, along with a reconstruction argument to show that general $(1 \pm \varepsilon)$ cut-sketching schemes in undirected hypergraphs give very non-trivial string

compression schemes. Then, by invoking known results on size lower bounds for string compression schemes, they are able to conclude worst-case lower bounds of $\frac{n^2}{2^{O(\sqrt{\log(n)})}}$ for the bit complexity of sketching cuts in undirected hypergraphs. To this end, we first reintroduce their notion of a string compression scheme:

▶ **Definition 24** ([4]). *Let ℓ, k be positive integers, and let $\varepsilon, g > 0$. We say that a pair of functions* $\text{Encode} : \{0,1\}^\ell \to \{0,1\}^k$ *and* $\text{Decode} : \{0,1\}^k \times 2^{[\ell]} \to \mathbb{N}$ *is an $(\ell, k, \varepsilon, g)$ string compression scheme (SCS) if there exists a set of strings $\mathcal{G} \subseteq \{0,1\}^\ell$ such that:*

1. $|\mathcal{G}| \geq g \cdot 2^\ell$.
2. *For every string $s \in \mathcal{G}$, and every query $q \in 2^{[\ell]}$,*

$$|\text{Decode}(\text{Encode}(s), q) - |s \cap q|| \leq \varepsilon\ell/2.$$

The work of [8] takes advantage of the following theorem, which is proved in [4]:

▶ **Theorem 25** ([4]). *Suppose* $(\text{Encode}, \text{Decode})$ *is an $(\ell, k, \varepsilon, g)$-SCS, where $\varepsilon \leq 1/10$. Then,*

$$k \geq \frac{\log(g) + 3\ell/50}{\log 2} - 1.$$

Qualitatively, [8] shows that for a specific family of *undirected* hypergraphs with n vertices, for some $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$ any $(1 \pm \varepsilon)$ cut-sketching scheme for these hypergraphs using $\leq k$ bits implicitly gives an $\left(\frac{n^2}{2^{O(\sqrt{\log(n)})}}, k, 1/10, 1/2\right)$-SCS. Thus, by invoking the previous theorem, these sparsifiers must have bit complexity $\frac{n^2}{2^{O(\sqrt{\log(n)})}}$. However, their proof actually provides a stronger result than stated. Although the sparsifiers they use give $(1 \pm \varepsilon)$ multiplicative approximations to cut-sizes, their argument makes uses of an *additive* error bound of $\varepsilon \cdot (\#$ of hyperedges). We take advantage of this in our method by showing that a $(1 \pm \varepsilon)$ cut-sketch for a directed hypergraph can be used to retrieve cut sizes in n distinct undirected hypergraphs with only additive error ε (with respect to each of these undirected hypergraphs). We first state the result of [8] more succinctly, and then describe our construction in more detail.

▶ **Theorem 26** ([8]). *For any n, and some $\ell = \frac{n^2}{2^{O(\sqrt{\log(n)})}}$, for at least $2^\ell/2$ strings $s \in \{0,1\}^\ell$, there exists an undirected hypergraph $H_s = (V, E_s)$ on n vertices, with $\leq n$ hyperedges, such that any data structure which can approximate cuts in H_s to within additive error $|E_s|/2^{O(\sqrt{\log(n)})}$ can for any query $q \subseteq [\ell]$, answer the subset sum $|q \cap s|$ to within additive error $\ell/20$.*

Now, we will prove our theorem regarding capability of directed hypergraphs to simulate cuts in undirected hypergraphs with only additive error.

▶ **Theorem 27.** *Given any undirected hypergraphs $H_1, \ldots H_n$, each on vertex set V, with $|V| = n$, there exists a directed hypergraph G on $2n$ vertices, such that given a $(1 \pm \varepsilon)$ cut-sketch for G, for any of the undirected hypergraphs $H_i = (V, E_i)$ and any set $S \subseteq V$, one can recover $|cut_{H_i}(S)|$ to within additive error $3\varepsilon|E_i|$.*

Proof. As stated, each of the undirected hypergraphs $H_1, \ldots H_n$ are on a vertex set of size n, which we denote by V. We also create a vertex set W of size n, which we associate with $w_1, \ldots w_n$. Now, we create the directed hypergraph G, which lives on the vertex set $V \cup W$ as follows: for each undirected hypergraph H_i for $i = 1, \ldots n$, and for each undirected hyperedge e in H_i, we add the corresponding directed hyperedge (e, w_i). That is, the head of the directed hyperedge has the vertices from V corresponding to e, and the tail of the directed hyperedge has only vertex w_i.

Clearly, G has $2n$ vertices, so now it suffices to argue that for any $H_i = (V, E_i)$, and for any cut $S \subseteq V$, we can recover $\text{cut}_{H_i}(S)$ within additive error $\varepsilon|E_i|$. Indeed, let any such H_i be given, and let $S \subseteq V$ be given as well. Then, suppose we have a $(1 \pm \varepsilon)$ cut-sketch for G, which we denote by $\widetilde{G}$. Let us consider the query to $\widetilde{G}$ with the set $S \cup W - \{w_i\}$. A directed hyperedge $e \in G$ is crossing this cut if and only if $e_{\text{head}} \cap (S \cup W - \{w_i\}) \neq \emptyset$ and $e_{\text{tail}} \cap ((V \cup W) - (S \cup W - \{w_i\})) \neq \emptyset$. In particular, note that by construction, e_{head} is a subset of V and e_{tail} is a subset of W. This means that a directed hyperedge e is crossing the cut if and only if $e_{\text{head}} \cap S \neq \emptyset$ and $e_{\text{tail}} \cap \{w_i\} \neq \emptyset$. The only directed hyperedges in G which satisfy this second condition are exactly those directed hyperedges in G which correspond to H_i. By construction, this means that the number of directed hyperedges crossing this cut $S \cup W - \{w_i\}$ in G is exactly the number of undirected hyperedges $e \in E_i$ such that $e \cap S \neq \emptyset$. Thus this query to $\widetilde{G}$ returns a $(1 \pm \varepsilon)$ approximation to $|\{e \in E_i | S \cap e \neq \emptyset\}|$. Note that the actual size of the cut S in H_i is $|\{e \in E_i | S \cap e \neq \emptyset \wedge S \cap e \neq e\}|$.

However, note that by symmetry, we can also query $\widetilde{G}$ with $(V - S) \cup (W - \{w_i\})$. By symmetry, this query to $\widetilde{G}$ returns a $(1 \pm \varepsilon)$ approximation to $|\{e \in E_i | (V - S) \cap e \neq \emptyset\}|$, which is the same as $|\{e \in E_i | S \cap e \neq e\}|$. Lastly, we can query $\widetilde{G}$ with $V \cup (W - \{w_i\})$. This query to $\widetilde{G}$ returns a $(1 \pm \varepsilon)$ approximation to $|\{e \in E_i | V \cap e \neq \emptyset\}|$, which is exactly $|\{e \in E_i\}|$.

Now, we operate by the principle of inclusion-exclusion (PIE). Let A be the event that a hyperedge $e \in E_i$ satisfies $e \cap S \neq \emptyset$, and let B be the event that e satisfies $e \cap S \neq e$. By PIE,

$$\begin{aligned}|\{e \in E_i | e \text{ satisfies } A \wedge \text{ satisfies } B\}| =& |\{e \in E_i | e \text{ satisfies } A\}| + |\{e \in E_i | e \text{ satisfies } B\}| \\ & - |\{e \in E_i | e \text{ satisfies } A \vee \text{ satisfies } B\}|.\end{aligned}$$

Note that this final expression is trivially satisfied, i.e. $|\{e \in E_i | e \text{ satisfies } A \vee \text{ satisfies } B\}| = |\{e \in E_i\}|$ as a hyperedge cannot simultaneously have an empty and a non-trivial intersection. Thus, we get that

$$\begin{aligned}\text{cut}_{H_i}(S) =& |\{e \in E_i | e \text{ satisfies } A \wedge \text{ satisfies } B\}| \\ =& |\{e \in E_i | e \text{ satisfies } A\}| + |\{e \in E_i | e \text{ satisfies } B\}| - |\{e \in E_i\}|.\end{aligned}$$

Now, note that our query to $\widetilde{G}$ with the set $S \cup W - \{w_i\}$ gave us a $(1 \pm \varepsilon)$ approximation to $|\{e \in E_i | e \text{ satisfies } A\}|$, our query with $(V - S) \cup W - \{w_i\}$ gave us a $(1 \pm \varepsilon)$ approximation to $|\{e \in E_i | e \text{ satisfies } B\}|$, and our query with $V \cup W - \{w_i\}$ gave us a $(1 \pm \varepsilon)$ approximation to $|\{e \in E_i\}|$. Because each of these has additive error at most $\varepsilon|E_i|$ (as the error from $\widetilde{G}$ is a multiplicative guarantee), in total, the expression

$$\text{cut}_{\widetilde{G}}(S \cup W - \{w_i\}) + \text{cut}_{\widetilde{G}}((V - S) \cup W - \{w_i\}) - \text{cut}_{\widetilde{G}}(V \cup W - \{w_i\})$$

gives us a $(3\varepsilon|E_i|)$-additive approximation to $\text{cut}_{H_i}(S)$, as we desire. ◀

Now, we will show how we can use the above construction to argue a lower bound of size $\frac{n^3}{2^{O(\sqrt{\log(n)})}}$ on the bit complexity of directed hypergraph cut-sketching. We will do this by showing that we can use a directed hypergraph cut-sketch of size k to create a $(\ell, k, 1/10, 2^{-n})$-SCS, for $\ell = \Omega\left(\frac{n^3}{2^{O(\sqrt{\log(n)})}}\right)$.

▶ **Theorem 28.** *A general unweighted directed hypergraph $(1 \pm \frac{1}{2^{O(\sqrt{\log(n)})}})$ cut-sketching scheme on n vertices with maximum sketch size of k bits yields an $(n \cdot \ell, k, 1/10, 2^{-n})$-SCS for $\ell = \frac{n^2}{2^{O(\sqrt{\log(n)})}}$.*

Proof. First, we will define the set $\mathcal{G}$ of size $\frac{2^{n\cdot\ell}}{2^n}$. Indeed, from Theorem 26, let L be the strings of length ℓ which are able to be compressed and still allow for estimating subset sum queries. Now, let $\mathcal{G} = L \circ L \circ L \circ \cdots \circ L$ (n times), where the $S_1 \circ S_2$ operation takes every string in S_1 and prepends it to every string in S_2 (resulting in a new set of size $|S_1| \cdot |S_2|$). Note that this means that strings in $\mathcal{G}$ will be of length $n \cdot \frac{n^2}{2^{O(\sqrt{\log(n)})}} = \frac{n^3}{2^{O(\sqrt{\log(n)})}}$ and $\mathcal{G}$ obtains the stated size bound.

Now we describe our string compression scheme. Indeed, for any string $s \in \mathcal{G}$, decompose s into $s_1, \ldots s_n$ such that each $s_i \in L$. Now, because each $s_i \in L$, we know there exists a corresponding undirected hypergraph $H_{s_i} = (V, E_{s_i})$ on n vertices such that preserving cuts in H_{s_i} to within additive error $|E_{s_i}|/2^{O(\sqrt{\log(n)})}$ allows us to answer subset sum queries in H_{s_i} to within additive error $\ell/20$. Now let G be the directed hypergraph on $2n$ vertices, built with hypergraphs $H_{s_1}, H_{s_2}, \ldots H_{s_n}$ as guaranteed by Theorem 27. It follows that G is an unweighted directed hypergraph on $2n$ vertices.

Now, suppose there exists a general, unweighted, directed hypergraph cut-sketching scheme on n vertices with maximum sketch size of k bits which preserves cuts to a $(1 \pm \frac{1}{2^{O(\sqrt{\log(n)})}})$ multiplicative factor. Then, we can invoke such a scheme on the directed hypergraph G as specified by Theorem 27 to conclude that such a scheme allows us to recover $\text{cut}_{H_{s_i}}(S)$ for any $S \subseteq V$ to within additive error $|E_{s_i}/2^{O(\sqrt{\log(n)})}|$. As a result, this means that for any s_i, and any query to s_i, denoted by $q_i \in [\ell]$, we can recover $|q_i \cap s_i|$ to within additive error $\ell/20$.

Finally, suppose we are given any subset query $q \subseteq [n \cdot \ell]$. We want to show that we can compute the size of $|s \cap q|$ (i.e. the sum of the bits of s on the positions indicated by q) to within additive error $\frac{n\ell}{20}$. For convenience, we view q as a bit string of length $n \cdot \ell$, where a bit is 1 if and only if the corresponding element of $[n \cdot \ell]$ was in the subset. Then, we break q into $q_1, \ldots q_n$ such that each q_i is of length ℓ. Now, we use the aforementioned sketch to compute $|s_i \cap q_i|$ to within additive error $\ell/20$ for every i. Adding these together, we get an estimate to $|s \cap q|$ with additive error at most $n\ell/20$. Thus, a general directed hypergraph cut-sketching scheme of size k bits to multiplicative error $(1 \pm \frac{1}{2^{O(\sqrt{\log(n)})}})$ yields a $(n \cdot \ell, k, 1/10, 2^{-n})$-SCS. ◀

▶ **Theorem 29.** *Any cut-sketching scheme for directed hypergraphs on $2n$ vertices which preserves cuts to a $(1 \pm \varepsilon)$ factor, for $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$ must have worst case bit complexity $\frac{n^3}{2^{O(\sqrt{\log(n)})}}$.*

Proof. Indeed, by the preceding theorem (Theorem 28), any such scheme for $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$, with bit complexity k implies a $(n \cdot \ell, k, 1/10, 2^{-n})$-SCS, for $\ell = \frac{n^2}{2^{O(\sqrt{\log(n)})}}$. By Theorem 25 [4], this means that

$$k \geq \frac{\log(2^{-n}) + 3n \cdot \ell}{\log 2} - 1 \geq \frac{n^3}{2^{O(\sqrt{\log(n)})}}.$$ ◀

▶ **Corollary 30.** *Any cut-sketching scheme for submodular hypergraphs on $2n$ vertices which preserves cuts to a $(1 \pm \varepsilon)$ factor, for $\varepsilon = \frac{1}{2^{O(\sqrt{\log(n)})}}$ must have bit complexity $\frac{n^3}{2^{O(\sqrt{\log(n)})}}$.*

Proof. This follows simply by noting that directed hypergraphs are a subclass of submodular hypergraphs, so in particular the lower bound from Theorem 29 must extend to this case. ◀

5 Monotone Hypergraph Sparsifiers

In this section, we show how to reduce sparsifying monotone submodular hypergraphs to sparsifying symmetric submodular hypergraphs. At this point, we then invoke the result of [5] to conclude. First, we detail the reduction:

▶ **Theorem 31.** *Suppose* $f : 2^V \to \mathbb{R}^{\geq 0}$ *is a monotone, submodular function. Then,* $f' : 2^{V \cup \{*\}} \to \mathbb{R}^{\geq 0}$ *defined as* $\forall S \subseteq V$

$$f'(S) = f(S) = f'(V - S \cup \{*\})$$

is submodular and symmetric.

Proof. First, the symmetry of f' is easy to see. Indeed, for any set $S \subseteq V \cup \{*\}$, it follows that $f'(S) = f'(V \cup \{*\} - S)$. So, all that remains to be shown is that f' is submodular. To do this, we will show that f' has decreasing marginals. So consider any $T \subset U \subset V \cup \{*\}$. We will show that for any $x \notin U$ that

$$f'(T \cup \{x\}) - f'(T) \geq f'(U \cup \{x\}) - f'(U).$$

We will do this by cases.

1. Suppose that $x = *$. Then, it must be the case that $x \notin U, T$. So, $f'(U) = f(U), f'(T) = f(T)$. Because $T \subset U$, it must also therefore be the case that $f'(T) \leq f'(U)$ (by the monotonicity of f). Next, we note that because $x = *$, $f'(T \cup \{x\}) = f(V - T), f'(U \cup \{x\}) = f(V - U)$. Because $T \subset U$ and f is monotone, it must be the case that $f'(T \cup \{x\}) = f(V - T) \geq f'(U \cup \{x\}) = f(V - U)$. Putting this together, we get that it must be the case that

   $$f'(T \cup \{x\}) - f'(T) \geq f'(U \cup \{x\}) - f'(U),$$

   as we desire.
2. Suppose that $x \neq *$, and that neither U, T contain $*$. Then the submodularity of f' follows by the submodularity of f.
3. Suppose that $x \neq *$, and that both U, T contain $*$. Then, let $\hat{U}, \hat{T}$ be $U - \{*\}, T - \{*\}$ respectively. It follows that $\hat{T} \subset \hat{U}$. Further, $f'(T \cup \{x\}) = f(V - (\hat{T} \cup \{x\})), f'(U \cup \{x\}) = f(V - (\hat{U} \cup \{x\}))$, and likewise $f'(T) = f(V - \hat{T}), f'(U) = f(V - \hat{U})$. It follows that

   $$\begin{aligned} f'(T \cup \{x\}) - f'(T) &= f(V - (\hat{T} \cup \{x\})) - f(V - \hat{T}) \\ &= f(V - (\hat{T} \cup \{x\})) - f(V - (\hat{T} \cup \{x\}) \cup \{x\}) \\ &\geq f(V - (\hat{U} \cup \{x\})) - f(V - (\hat{U} \cup \{x\}) \cup \{x\}) \\ &= f'(U \cup \{x\}) - f'(U). \end{aligned}$$

   The inequality in the middle holds because $V - (\hat{U} \cup \{x\}) \subset V - (\hat{T} \cup \{x\})$. Thus, the marginal gain from adding x to $V - (\hat{U} \cup \{x\})$ is larger than the marginal gain from adding x to $V - (\hat{T} \cup \{x\})$ by the submodularity of f.
4. Suppose that $x \neq *$, but that $* \notin T, * \in U$. Then, by the monotonicity of f, $f'(T \cup \{x\}) - f'(T) = f(T \cup \{x\}) - f(T) \geq 0$. Likewise,

   $$f'(U \cup \{x\}) - f'(U) = f(V - (\hat{U} \cup \{x\})) - f(V - \hat{U}) \leq 0,$$

   again using the monotonicity of f. Therefore, it must be the case that

   $$f'(T \cup \{x\}) - f'(T) \geq f'(U \cup \{x\}) - f'(U),$$

   as we desire. ◀

Next, we show how to use this reduction to create sparsifiers.

▶ **Corollary 32.** *Let $H = (V, E)$ be a hypergraph, such that $\forall e \in E$, the corresponding splitting function $g_e : 2^e \to \mathbb{R}^{\geq 0}$ is submodular and monotone. Then there exists a $(1 \pm \varepsilon)$ cut-sparsifier for H with $\widetilde{O}(|V|/\varepsilon^2)$ hyperedges.*

Proof. We first define the lifting of a monotone, submodular hypergraph into a symmetric submodular hypergraph.

▶ **Definition 33.** *Let $H = (V, E)$ be a monotone submodular hypergraph. Then, define H' to be the corresponding hypergraph defined on vertex set $V \cup \{*\}$, where for each edge $e \in E$, we replace it with a hyperedge $e' = e \cup \{*\}$, and replace the function g_e with the symmetric, submodular splitting function $g'_e : 2^{e'} \to \mathbb{R}^{\geq 0}$ defined in accordance with Theorem 31.*

Now, we construct this hypergraph H'. Because each g'_e is symmetric and submodular, we can invoke Theorem 16 to conclude the existence of a hypergraph $\hat{H}'$ such that $\forall S \subseteq V \cup \{*\}$

$$(1-\varepsilon)\text{cut}_{H'}(S) \leq \text{cut}_{\hat{H}'}(S) \leq (1+\varepsilon)\text{cut}_{H'}(S),$$

and $\hat{H}'$ only has $\widetilde{O}(|V|/\varepsilon^2)$ hyperedges remaining.

It follows that because $\forall S \subseteq V$, $g'_e(S) = g_e(S)$, the corresponding hyperedges chosen to create a $(1 \pm \varepsilon)$ cut-sparsifier for H' also create a $(1 \pm \varepsilon)$ cut-sparsifier for H. That is, if we create the hypergraph $\hat{H}$ by replacing $e' \in \hat{H}'$ with $e \in H$ (but keeping the same corresponding weights that $\hat{H}'$ assigns), it will be the case that $\forall S \subseteq V$

$$(1-\varepsilon)\text{cut}_{H'}(S) = (1-\varepsilon)\text{cut}_{H}(S) \leq \text{cut}_{\hat{H}'}(S) = \text{cut}_{\hat{H}}(S) \leq (1+\varepsilon)\text{cut}_{H'}(S) = (1+\varepsilon)\text{cut}_{H}(S).$$

Thus, $\hat{H}$ will be a $(1\pm\varepsilon)$-sparsifier for H, and $\hat{H}$ will only keep $\widetilde{O}(|V|/\varepsilon^2)$ hyperedges. ◀

Constrained Level Planarity Is FPT with Respect to the Vertex Cover Number

Boris Klemz
Universität Würzburg, Germany

Marie Diana Sieper
Universität Würzburg, Germany

Abstract

The problem Level Planarity asks for a crossing-free drawing of a graph in the plane such that vertices are placed at prescribed y-coordinates (called *levels*) and such that every edge is realized as a y-monotone curve. In the variant Constrained Level Planarity, each level y is equipped with a partial order $\prec_y$ on its vertices and in the desired drawing the left-to-right order of vertices on level y has to be a linear extension of $\prec_y$. Constrained Level Planarity is known to be a remarkably difficult problem: previous results by Klemz and Rote [ACM Trans. Alg.'19] and by Brückner and Rutter [SODA'17] imply that it remains NP-hard even when restricted to graphs whose tree-depth and feedback vertex set number are bounded by a constant and even when the instances are additionally required to be either *proper*, meaning that each edge spans two consecutive levels, or *ordered*, meaning that all given partial orders are total orders. In particular, these results rule out the existence of FPT-time (even XP-time) algorithms with respect to these and related graph parameters (unless P=NP). However, the parameterized complexity of Constrained Level Planarity with respect to the vertex cover number of the input graph remained open.

In this paper, we show that Constrained Level Planarity can be solved in FPT-time when parameterized by the vertex cover number. In view of the previous intractability statements, our result is best-possible in several regards: a speed-up to polynomial time or a generalization to the aforementioned smaller graph parameters is not possible, even if restricting to proper or ordered instances.

1 Introduction

A large body of literature related to graph drawing is dedicated to so-called upward planar drawings, which provide a natural way of visualizing a partial order on a set of items. An *upward planar drawing* of a directed graph is a crossing-free drawing in the plane where every edge $e = (u, v)$ is realized as a y-monotone curve that goes upwards from u to v, i.e., the y-coordinate strictly increases when traversing e from u towards v. The most classical computational problem in this context is Upward Planarity: given a directed graph, decide whether it admits an upward planar drawing. The standard version of this problem is NP-hard [18], but, if the y-coordinate of each vertex is prescribed, it can be solved in polynomial time [13, 21, 25], which suggests that a large part of the challenge of Upward

Planarity comes from choosing an appropriate y-coordinate for each vertex. However, when both the y-coordinate and the x-coordinate of each vertex are prescribed, the problem is yet again NP-hard [27], indicating that another part of the challenge comes from drawing the edges in a y-monotone non-crossing fashion while respecting the given or chosen coordinates of their endpoints. The paper at hand is concerned with the parameterized complexity of a generalization of the latter of these two variants of Upward Planarity, which is known as Constrained Level Planarity. It is expressed in terms of so-called level graphs, which are defined next; we adopt the notation and terminology used in [27].

Level Planarity. A *level graph* $\mathcal{G} = (G, \gamma)$ is a directed graph $G = (V, E)$ together with a *level assignment*, which is a function[1] $\gamma\colon V \to \mathbb{R}$ where $\gamma(u) < \gamma(v)$ for every edge $(u, v) \in E$. For every $i \in \mathbb{R}$ where $V_i = \{v \in V \mid \gamma(v) = i\}$ is non-empty, the set V_i is called a (the i-th) *level* of $\mathcal{G}$. The *width* of level V_i is $|V_i|$. The *level-width* of $\mathcal{G}$ is the maximum width of any level in $\mathcal{G}$ and the *height* of $\mathcal{G}$ is the number of (non-empty) levels. A *level planar drawing* of $\mathcal{G}$ is an upward planar drawing of G where the y-coordinate of each vertex v is $\gamma(v)$. We use L_i to denote the horizontal line with y-coordinate i. The level graph $\mathcal{G}$ is called *proper* if every edge spans two consecutive levels, that is, for every edge $(u, v) \in E$ there is no level V_j with $\gamma(u) < j < \gamma(v)$. The problem Level Planarity asks whether a given level graph admits a level planar drawing. In a series of papers [13, 21, 24, 25], it was shown that Level Planarity can be solved in linear[1] time; we refer to [16] for a more detailed discussion of the history of the corresponding algorithm and of alternative approaches to solve Level Planarity.

Constrained Level Planarity. In 2017, Brückner and Rutter [8] and Klemz and Rote [27] independently introduced and studied two closely related variants of Level Planarity, which are defined in the following. A *constrained level graph* $\mathcal{G} = (G, \gamma, (\prec_i)_i)$ is a triple corresponding to a level graph (G, γ) equipped with a family $(\prec_i)_i$ containing, for each level V_i, a partial order $\prec_i$ on the vertices V_i. A *constrained* level planar drawing of $\mathcal{G}$ is a level planar drawing of (G, γ) where, for each level V_i, the left-to-right order of the vertices V_i corresponds to a linear extension of $\prec_i$. For a pair of vertices $u, v \in V_i$ with $u \prec_i v$, we refer to $u \prec_i v$ as a *constraint* on u and v. The problem Constrained Level Planarity (CLP) asks whether a given constrained level graph admits a constrained level planar drawing. Ordered Level Planarity (OLP) corresponds to the special case of CLP where the given partial orders are total orders, which is polynomial time equivalent to prescribing the x-coordinate (in addition to the y-coordinate) of each vertex.

Klemz and Rote [27] established a complexity dichotomy for OLP with respect to both the maximum degree and the level-width. In particular, they showed that OLP is NP-hard even when restricted to the case where $\mathcal{G}$ has a level-width of 2 and the underlying undirected graph of G is a disjoint union of paths, i.e., a graph of maximum degree 2, path-width (and tree-width) 1, and feedback vertex/edge set number 0. In fact, with a simple modification[2]

[1] Traditionally, in the literature, the level assignment γ is defined as a surjective function that maps to an integer interval $\{1, 2, \ldots, h\}$; it merely acts as a convenient way to encode a total preorder on V. It is well known that the traditional and our (more general) definition are polynomial-time equivalent: algorithms designed assuming the classical definition can also be applied in the more general context: one simple has to first sort the vertices by y-coordinates and then apply the traditional algorithm using the sorting-ranks as y-coordinates. We are using the given general definition as it eases the description of our algorithms; though, specific polynomial runtimes obtained in previous work that are stated in our introduction assume the classical definition.

[2] In the variable gadget of every variable u_j, one can remove the subdivision vertices of the tunnels with index larger than j. This modification does not influence the realizability of the instance since the left-to-right order of all tunnels is already fixed due to the subdivision vertices on level ℓ_0.

to their construction, the underlying undirected graph produced by the reduction becomes a disjoint union of paths with constant length, implying that even the tree-depth is bounded. (The definitions of all these classical graph parameters can be found, e.g., in [10].) It follows that CLP is NP-hard in the same scenario and when, additionally, each of the prescribed partial orders $\prec_i$ is a total order. OLP is (trivially) solvable in linear[1] time when restricted to proper instances [27]. In contrast, an instance of CLP can always be turned into an equivalent proper instance by subdividing each edge on each level it passes through without introducing any constraints on the resulting subdivision vertices [8]. Hence, CLP is NP-hard even in the proper case. Independently, Brückner and Rutter [8] also presented a proof for the NP-hardness of CLP, which relies on a very different strategy. It is not obvious whether the graphs produced by their construction have bounded tree-width, however, it is not difficult to see[3] that the socket/plug gadget used in their reduction can be utilized in the context of a reduction from 3-Partition to show that CLP remains NP-hard for proper instances whose underlying undirected graph is a single (rooted) tree of constant depth. In fact, the unpublished full version of [8] features such a construction [29].

On the positive side, Brückner and Rutter [8] presented a polynomial time algorithm for the special case of CLP where the input graph G has a single source. They further improved the runtime of this algorithm in [9]. Very recently, Blažej, Klemz, Klesen, Sieper, Wolff, and Zink studied the parameterized complexity of CLP and OLP with respect to the height of the input graph [7]. They showed that OLP parameterized by height is XNLP-complete (implying that it is in XP, but $W[t]$-hard for every $t \geq 1$). In contrast, CLP is NP-hard even if restricted to instances of height 4, but it can be solved in polynomial time if restricted to instances of height at most 3.

Other related work. Several other restricted variants of Level Planarity have been studied, e.g., Clustered Level Planarity [15, 2, 27], T-Level Planarity [30, 2, 27], and Partial Level Planarity [8]. In particular, in Partial Level Planarity, a given level planar drawing of a subgraph of the input graph $\mathcal{G}$ has to be extended to a full drawing of $\mathcal{G}$, which can be seen as a generalization of OLP and, in the proper case, a specialization of CLP. Level Planarity has been extended to surfaces different from the plane [4, 1, 5]. There are also related problems with a more geometric flavor, e.g., finding a level planar straight-line drawing where each face is bounded by a convex polygon [23, 26], and problems where the input is an undirected graph without a level assignment and the task is to find a crossing-free drawing with y-monotone edges that, if interpreted as a level planar drawing, satisfies or optimizes certain criteria, e.g., being proper or having minimum height [6, 14, 22].

Contribution. As discussed above, the previous results of Brückner and Rutter [8] and Klemz and Rote [27] rule out the existence of FPT-time (even XP-time) algorithms for CLP when considering the tree-width, path-width, tree-depth, or feedback vertex set number as a parameter, even when restricted to OLP or proper CLP instances (unless P=NP). As all of these parameters are bounded[4] by the vertex cover number, it is natural to study the parameterized complexity of CLP with respect to this parameter. We prove the following main result:

[3] In the strongly NP-hard 3-Partition problem [17], one has to partition $3n$ positive integers $B/4 < a_1, a_2, \ldots, a_{3n} < B/2$ of total sum nB into n triples (or *buckets*) of sum (or *size*) B. To reduce to CLP, one can simulate a bucket of size B as a sequence of B consecutive sockets and a number a_i as a_i plugs that are connected in a star-like fashion to a common ancestor v_i located above all these plugs. Finally, all ancestors v_i and all sockets are connected in a star-like fashion to a common root vertex.

[4] More precisely, $\mathrm{tw}(G) \leq \mathrm{pw}(G) \leq \mathrm{td}(G) - 1 \leq \mathrm{vc}(G)$ and $\mathrm{fvs}(G) \leq \mathrm{vc}(G)$.

▶ **Theorem 1.** *CLP parameterized by the vertex cover number is FPT.*

In view of the previous intractability statements, Theorem 1 is best-possible in several regards: a speed-up to polynomial time or a generalization to the aforementioned smaller graph parameters is not possible, even if restricting to OLP or proper CLP instances.

Organization. The proof of Theorem 1 and the remainder of this paper are organized as follows. We begin by introducing some basic notation, terminology, and other preliminaries in Section 2. In particular, we describe a partition of the vertex set of a given constrained level graph $\mathcal{G}$ into different categories with respect to a given vertex cover C and we show that the vertices of two of these categories are, in some sense, easy to handle. In Section 3, we introduce cores and (refined) visibility extensions of level planar drawings with respect to a fixed vertex cover C. Intuitively, the core-induced subdrawing of a (refined) visibility extension of a constrained level planar drawing Γ^* of $\mathcal{G}$ with respect to C is a drawing Λ_{core} that captures crucial structural properties of Γ^* and whose total complexity is bounded in $|C|$. The latter allows us to efficiently obtain such a core-induced subdrawing via the process of exhaustive enumeration. This is the first main step of the algorithm corresponding to the proof of Theorem 1, which is described in Section 4. Due to the properties of the core-induced subdrawing, it is then possible to place the remaining vertices in the subsequent main steps of the algorithm, each of which is concerned with the placement of the vertices of a particular vertex category. We conclude with a discussion of an open problem in Section 5. Proofs of statements marked with a $\star$ can be found in the appendix of the full preprint version [28].

2 Preliminaries

Conventions. Recall that in a level graph $\mathcal{G} = (G = (V, E), \gamma)$, the graph G is directed by definition. However, when it comes to vertex-adjacencies, we always refer to the underlying undirected graph of G, that is, the neighborhood of $v \in V$ is $\mathrm{N}_G(v) = \{u \in V \mid (u, v) \in E \vee (v, u) \in E\}$, the degree of v is $|\mathrm{N}_G(v)|$, and "a vertex cover of G" refers to a vertex cover[5] of the underlying undirected graph of G. The *level planar embedding* of a level planar drawing of $\mathcal{G}$ lists, for each level V_i, the left-to-right sequence of vertices and edges intersected by the line L_i in the drawing. Note that this corresponds to an equivalence class of drawings from which an actual drawing is easily derived, which is why algorithms for constructing level planar drawings (including our algorithms) usually just determine a level planar embedding. For brevity, we often use the term "drawing" as a synonym for "embedding of a drawing".

Vertex categories & notation. For $m \in \mathbb{N}$, we use $[m]$ to denote the set $\{1, 2, \ldots, m\}$. Let $\mathcal{G} = (G = (V, E), \gamma)$ be a (constrained) level graph and let C be a vertex cover of G. An *ear* of $\mathcal{G}$ with respect to C is a degree-2 vertex of $V \setminus C$ that is a source or sink. For a subset $X \subseteq C$, we define $V_X(C) = \{v \in V \setminus C \mid \mathrm{N}_G(v) = X\}$. We partition the vertices $V \setminus C$ of the graph G into four sets $V_{=0}(C), V_{=1}(C), V_{=2}(C), V_{\geq 3}(C)$ where $V_{=0}(C) = \{v \in V \setminus C \mid \deg(v) = 0\}$, $V_{=1}(C) = \{v \in V \setminus C \mid \deg(v) = 1\}$ (the *leaves*), $V_{=2}(C) = \{v \in V \setminus C \mid \deg(v) = 2\}$, and $V_{\geq 3}(C) = \{v \in V \setminus C \mid \deg(v) \geq 3\}$. The set $V_{=2}(C)$ is further partitioned into two sets $V^{\mathrm{e}}_{=2}(C), V^{\mathrm{t}}_{=2}(C)$ where $V^{\mathrm{e}}_{=2}(C)$ contains the ears and $V^{\mathrm{t}}_{=2}(C)$ the non-ears, called *transition*

[5] A *vertex cover* of an undirected graph $G = (V, E)$ is a vertex set $C \subseteq V$ such that every edge in E is incident to at least one vertex in C. The *vertex cover number* of G is the size of a smallest vertex cover of G.

vertices. Let $v \in V_{=1}(C)$ and let $c \in C$ denote its (unique) neighbor. We say that v is a *leaf* of c. Similarly, let $u \in V_{=2}(C)$ and let $c_a, c_b \in C$ denote its (unique) two neighbors. We say that u is a *transition vertex* (*ear*) of c_a and c_b if $u \in V^{\mathrm{t}}_{=2}(C)$ (if $u \in V^{\mathrm{e}}_{=2}(C)$). We often omit C if it is clear from the context.

Let $\mathcal{G} = (G = (V, E), \gamma, (\prec_i)_i)$ be a constrained level graph and let C be a vertex cover of G. The main challenge when constructing a constrained level planar drawing of $\mathcal{G}$ is the placement of the leaves, ears, and transition vertices (along with their incident edges). Indeed, it is not difficult to insert the isolated vertices (which include $V_{=0}$) in a post-processing step (performing a topological sort on each level), see Lemma 4. Moreover, since we may assume G to be planar, the size of $V_{\geq 3}(C)$ is linear in $|C|$. This well known bound can be derived, e.g., by combining the fact that the complement of a vertex cover is an independent set with the following statement (setting $A = C$).

▶ **Lemma 2** ([10, Corollary 9.25]). *Let $G = (V, E)$ be a planar graph and $A \subseteq V$. Then there are at most $2|A|$ connected components in the subgraph of G induced by $V \setminus A$ that are adjacent to more than two vertices of A.*

▶ **Corollary 3** (Folklore). *Let G be a planar graph and let C be a vertex cover of G. Then $|V_{\geq 3}(C)| \leq 2k$, where $k = |C|$.*

▶ **Lemma 4** ($\star$). *Let $\mathcal{G} = (G, \gamma, (\prec_i)_i)$ be a constrained level graph, let G' be the subgraph of G induced by the non-isolated vertices V', and let γ' and $(\prec'_i)_i$ be the restrictions of γ and $(\prec_i)_i$ to V', respectively. There is an algorithm that, given $\mathcal{G}$ and a constrained level planar drawing Γ' of $\mathcal{G}' = (G', \gamma', (\prec'_i)_i)$, constructs a constrained level-planar drawing of $\mathcal{G}$ in polynomial time.*

Our main algorithm will exploit the fact that only few ears may share a common level:

▶ **Lemma 5** ($\star$). *Let $\mathcal{G} = (G, \gamma)$ be a level graph, let Γ be a level planar drawing of $\mathcal{G}$, let C be a vertex cover of G. Then there are at most $2|C|$ ears with respect to C per level.*

Compatible edge orderings. Let Γ be a level planar drawing of a (possibly constrained) level graph $\mathcal{G} = (G = (V, E), \gamma)$ without isolated vertices. We will now define a useful (not necessarily unique) linear order $\prec^{\mathrm{e}}$ on the edges E with respect to Γ. We refer to $\prec^{\mathrm{e}}$ as an edge ordering of E that is *compatible* with Γ. Compatible edge orderings can be seen as a generalization of a linear order described in [27, Proof of Lemma 4.4] for a set of pairwise disjoint y-monotone paths, which in turn follows considerations about horizontal separability of y-monotone sets by translations [12, 3, 19, 20]. Intuitively, $\prec^{\mathrm{e}}$ is a linear extension of a partial order in which $e \in E$ precedes $f \in E$ if it is possible to shoot a horizontal rightwards ray from e to f in Γ without crossing other edges before reaching f. Formally, we say that a vertex v is *visible from the left* in Γ if the horizontal ray r_v emanating from v to the left intersects Γ only in v. We say that an edge $e = (u, v)$ is *visible from the left* in Γ if the closed (unbounded) region that is to the left of e and whose boundary is described by e, r_u, r_v intersects Γ only in e. The order $\prec^{\mathrm{e}}$ is now constructed as follows: the minimum of $\prec^{\mathrm{e}}$ is an edge e_1 of E that is visible from the left in Γ. Such an edge always exists [27, 19, 20]: among the edges whose lower endpoint is visible from the left, the edge with the topmost lower endpoint is visible from the left. Let Γ' denote the drawing derived from Γ by removing e_1 and any isolated vertices created by the removal of e_1. The restriction of $\prec^{\mathrm{e}}$ to the remaining edges $E \setminus e_1$ corresponds to an edge ordering compatible with Γ', which is constructed recursively. Note that $\mathcal{G}$ and $\prec^{\mathrm{e}}$ uniquely describe the drawing Γ and, given $\mathcal{G}$ and $\prec^{\mathrm{e}}$, it is possible to construct Γ in polynomial time (by traversing $\prec^{\mathrm{e}}$ in reverse).

3 Visibility extensions and cores

In this section, we introduce and study (refined) visibility extensions and cores of level planar drawings. We will see that the core-induced subdrawing of a (refined) visibility extension of a level planar drawing Γ with respect to some vertex cover C captures crucial structural properties of Γ while having a size that is bounded in $|C|$.

Visibility extensions. Let Γ be a level planar drawing of a level graph $\mathcal{G} = (G = (V, E), \gamma)$. A *visibility edge* e for Γ is (1) a y-monotone curve that joins two vertices of Γ and can be inserted into Γ without creating any crossings (but possibly a pair of parallel edges); or (2) a horizontal segment that joins two consecutive vertices on a common level of Γ and can be inserted into Γ without creating any crossings. A *visibility extension* of Γ with respect to a vertex set $V' \subseteq V$ is a drawing Λ derived from Γ by inserting a maximal set of pairwise non-crossing visibility edges incident only to vertices of V' such that for each pair e, e' of parallel edges in Λ there is at least one vertex of V' in the interior of the simple closed curve formed by e and e'; for an illustration see Figure 1(a). We remark that if $V' = V$, then Λ is essentially an interior triangulation containing Γ. However, we will always choose V' to be a (small) vertex cover, resulting in a much sparser yet still connected augmentation:

▶ **Lemma 6 (⋆).** *Let $\mathcal{G} = (G = (V, E), \gamma)$ be a level graph without isolated vertices, let C be a vertex cover of G, let Γ be a level planar drawing of $\mathcal{G}$, let Λ be a visibility extension of Γ with respect to C, and let Λ_C be the subdrawing of Λ that is induced by C. Then Λ_C is connected and has $\mathcal{O}(k)$ edges, where $k = |C|$.*

Cores and refined visibility extensions. Intuitively, the core of a level planar drawing is a subset of the vertex set with certain crucial properties. To define it formally, we will first classify the ears of the drawing according to several categories. The concepts introduced in this paragraph are illustrated in Figure 1(b). Let $\mathcal{G} = (G = (V, E), \gamma)$ be a level graph, let C be a vertex cover of G, and let Γ be a level planar drawing of $\mathcal{G}$. Consider an ear $v \in V^{\mathrm{e}}_{=2}(C)$ with neighbors c_a, c_b where $\gamma(c_a) \geq \gamma(c_b)$. If $\gamma(v) > \gamma(c_a)$, we say that v is a *top* ear. Otherwise (if $\gamma(v) < \gamma(c_b)$), we say that v is a *bottom* ear. Assume that $\gamma(c_a) > \gamma(c_b)$ and that v is a top ear. If in Γ the edge $c_b v$ is drawn to the left (right) of c_a, we say that v is a *left* (*right*) ear in Γ. The terms "left" and "right" are defined analogously for bottom ears. If $\gamma(c_a) = \gamma(c_b)$, we consider v to be a left ear if it is a top ear; otherwise it is a right ear. Consider a pair $c_a, c_b \in C$ with at least one left ear in Γ and let Γ' denote the subdrawing of Γ induced by the set of edges that are incident to at least one left ear of c_a, c_b in Γ. Note that either all these ears are top ears or all these ears are bottom ears in Γ, and they are arranged in a nested fashion. In case of top (bottom) ears, we refer to the unique one with the largest (smallest) y-coordinate as the *outermost* left ear of c_a, c_b. The *innermost* left ear of c_a, c_b is defined symmetrically. If Γ' has an interior (i.e., bounded) face f such that the open region enclosed by the boundary of f contains a vertex of C in Γ, then we say that the two ears v_1, v_2 on the boundary of f are *bounding ears* of c_a, c_b in Γ with respect to C. Moreover, we say that v_1, v_2 are a pair of *matching* bounding ears whose *region* corresponds to f. The terms "outermost", "innermost" and "(region of matching pair of) bounding ears" are analogously defined for the right ears of c_a, c_b. Every vertex of Γ that is an outermost, innermost, or bounding ear (with respect to some pair $c_a, c_b \in C$) is called *crucial* with respect to C.

The *core* of Γ with respect to C is the (unique) subset of V that contains C, $V_{\geq 3}(C)$, as well as all crucial ears of Γ with respect to C. The subdrawing Λ_{core} of a visibility extension Λ of Γ with respect C that is induced by the core of Λ with respect to C captures crucial

structural properties of Γ, which we will exploit in our main algorithm for constructing constrained level planar drawings in FPT-time. Due to the fact that Λ_{core} has only $\mathcal{O}(|C|)$ vertices and edges, it is not difficult to "guess" Λ_{core} in XP-time (via the process of exhaustive enumeration) when given $\mathcal{G}$ and C. The main bottleneck is the enumeration of all possible sets of crucial ears. To improve the runtime of this step to FPT-time, we will now describe a variant of visibility extensions that contains some additional ears, which take over the role of the original crucial vertices. Loosely speaking, one can create such a drawing by placing one or two new ears near each crucial ear in a visibility extension. The resulting augmentation retains the helpful structural properties of its underlying visibility extension and we will see that the (positions of the) crucial vertices of some such augmentation can be guessed more efficiently since we can restrict the possible levels of these new vertices to a small set. Formally, a *refined visibilty extension* Λ' of Γ is a crossing-free drawing of a level graph $\mathcal{G}' = (G' = (V', E'), \gamma')$ such that G is a subgraph of G', C is a vertex cover of G', every vertex in $V' \setminus V$ is an ear with respect to C and its incident edges are drawn as y-monotone curves, the subdrawing of Λ' induced by V is a visibility extension Λ of Γ, the crucial ears of Λ' are precisely the vertices in $V' \setminus V$, and $|V' \setminus V| \in \mathcal{O}(|C|)$.

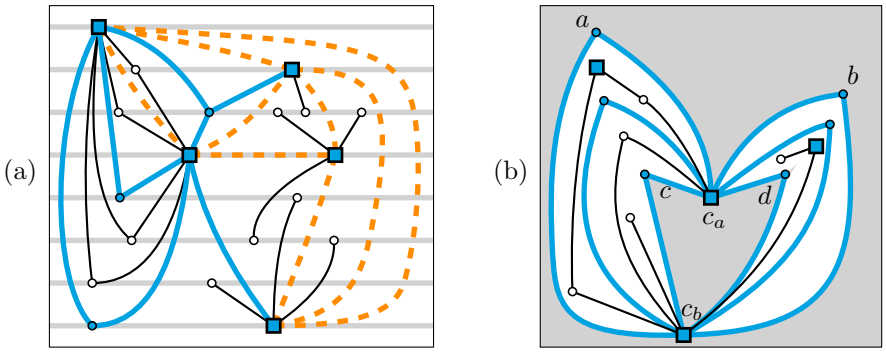

Figure 1 In this (and all other) figure(s), filled square vertices belong to a vertex cover C of the depicted graph and filled (round or square) vertices belong to the core of the shown drawing with respect to C. (a) A drawing Γ (non-dashed edges) is augmented with visibility edges (dashed) to obtain a visbility extension Λ with respect to C (note that this augmentation is not unique). The thick (non-dashed or dashed) edges and filled vertices represent Λ_{core}. (b) All filled round vertices are top crucial ears of c_a and c_b. All of them are bounding ears except for b and c. The vertex a / b / c / d is an outermost left / outermost right / innermost left / innermost right ear.

▶ **Lemma 7** (⋆). *Let $\mathcal{G} = (G = (V, E), \gamma)$ be a level graph without isolated vertices, let C be a vertex cover of G, let Γ be a level planar drawing of $\mathcal{G}$, let Λ be a refined or non-refined visibility extension of Γ with respect to C, and let Λ_{core} the subdrawing of Λ induced by the core of Λ with respect to C. Then Λ_{core} is connected and has $\mathcal{O}(k)$ vertices and $\mathcal{O}(k)$ edges, where $k = |C|$.*

4 Algorithm

In this section, we describe the algorithm corresponding to the proof of Theorem 1. Let $\mathcal{G} = (G = (V, E), \gamma, (\prec_i)_i)$ be a constrained level graph and let C be a vertex cover of G. Our goal is to construct a constrained level planar drawing of $\mathcal{G}$ or correctly report that such a drawing does not exist. In view of Lemma 4, we may assume that $\mathcal{G}$ has no isolated vertices. To construct the desired drawing, we proceed in three main steps. In Step 1, we "guess" a

core-induced subdrawing of a refined visibility extension of a constrained level planar drawing of $\mathcal{G}$ with respect to C (via the process of exhaustive enumeration). In Step 2, we augment our drawing by inserting the transition vertices of $\mathcal{G}$ with respect to C. In Step 3, we finalize our drawing by inserting the leaves and ears of $\mathcal{G}$ with respect to C.

Step 1: Guessing a core-induced subdrawing. Assume that there is a constrained level planar drawing Γ^* of $\mathcal{G}$, let Λ^* be a refined visibility extension of Γ^* with respect to C, and let Λ_{core} be the subdrawing of Λ^* induced by the core of Λ^* with respect to C. The procedures corresponding to Steps 2 and 3 of our algorithm are guaranteed to produce a constrained level planar drawing (not necessarily Γ^*) of $\mathcal{G}$ when given Λ_{core}. Hence, the goal of Step 1 is to determine (or, rather, guess) Λ_{core}, given $\mathcal{G}$ and C. More precisely, we will construct a set $\mathcal{F}$ of drawings such that $\Lambda_{\text{core}} \in \mathcal{F}$ and the number $|\mathcal{F}|$ of drawings in $\mathcal{F}$ is sufficiently small. For each drawing in $\mathcal{F}$, we then apply Steps 2 and 3 of the algorithm (incurring a factor of $|\mathcal{F}|$ in the total running time). Given that $\Lambda_{\text{core}} \in \mathcal{F}$, one of the iterations is guaranteed to terminate with a constrained level planar drawing of $\mathcal{G}$.

▶ **Lemma 8 ($\star$).** *Let $\mathcal{G} = (G = (V, E), \gamma, (\prec_i)_i)$ be a constrained level graph without isolated vertices, let C be a vertex cover of G, and let Γ^* be a constrained level planar drawing of $\mathcal{G}$. There is an algorithm that, given $\mathcal{G}$ and C, constructs a set $\mathcal{F}$ of $2^{\mathcal{O}(k \log k)}$ drawings in $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ time, where $n = |V|$ and $k = |C|$, such that all drawings in $\mathcal{F}$ have size $\mathcal{O}(k)$ and are level planar drawings of subgraphs of G induced by C and $V_{\geq 3}(C)$ that respect γ and the orderings $\prec_i$ and are augmented by some visibility edges and additional ears (with respect to C). Further, there exists a refined visibility extension Λ^* of Γ^* such that the subdrawing Λ_{core} of Λ^* induced by the core of Λ^* with respect to C is contained in $\mathcal{F}$.*

Proof sketch. We introduce the following terminology: let x be a vertex in a level planar drawing (possibly augmented by some horizontal edges). Let ℓ be the y-coordinate of x and let ℓ' be the largest y-coordinate of a vertex below x (if there no such vertex, we set $\ell' = \ell - 1$). We say that the line $L_{(\ell+\ell')/2}$ is *directly below* x. The line *directly above* x is defined symmetrically.

We proceed in two main steps. In the first main step, we show that there *exists* a refined visibility extension Λ^* of Γ^*. To this end, we start with a visibility extension Λ of Γ^* and describe an incremental strategy that performs a total of $\mathcal{O}(k)$ augmentation steps, in each of which a new ear is added that takes over the role of a crucial ear in Γ^*. (The description of this first main step is deferred to the appendix of the full preprint version [28].) In the second main step, we discuss the construction of the desired family $\mathcal{F}$. To this end, let Λ_{core} be the subdrawing of Λ^* induced by the core of Λ^* with respect to C. The drawing Λ_{core} is uniquely described by $\mathcal{G}$, C, the set of visibility edges of Λ_{core} (and Λ^*), the set of crucial ears of Λ_{core} (and Λ^*) together with their level assignments and their incident edges, and a compatible edge ordering of the nonhorizontal edges of Λ_{core}. The graph $\mathcal{G}$, as well as the vertex cover C are given, so it suffices to enumerate all possible options for the remaining elements.

There are $m_{\text{vis}} \in \mathcal{O}(k)$ visibility edges by Lemma 7 and each of these visibility edges joins a pair of vertices in C. Hence, there are at most $\binom{k}{2}^{m_{\text{vis}}} \subseteq k^{\mathcal{O}(k)} \subseteq 2^{\mathcal{O}(k \log k)}$ possible options for choosing the set of visibility edges. To enumerate the set of crucial ears along with their level assignments, we mimic the aforementioned incremental strategy for constructing Λ^*: we first enumerate all options to pick the pair of neighbors of the first new vertex along with its level, then, for each of these options, we enumerate all options to pick the pair of neighbors of the the second vertex along with its level, etc., until we have obtained all options to pick

the desired $\mathcal{O}(k)$ vertices together with their levels. More precisely, suppose we have already enumerated all options to pick the first i vertices together with their neighbors and levels. For each of these options, to enumerate all options to pick the next vertex v', we go through all ways to pick its two neighbors $u, w \in C$ and through all ways to pick the level of v'. There are $\mathcal{O}(k)$ pairs of vertices in C with ears (by Lemma 7). To bound the number of ways to pick the level of v', we make use of the fact that whenever the incremental strategy for constructing Λ^* places a new vertex v', it is assigned to a new level directly above or below a level of one of the following categories:

- a level with a vertex in C ($\mathcal{O}(k)$ possibilities),
- a level with a vertex in $V_{\geq 3}(C)$ ($\mathcal{O}(k)$ possibilities by Corollary 3),
- a level of a vertex that does not belong to $\mathcal{G}$, i.e., a level used for one of the already placed vertices ($\mathcal{O}(i) \subseteq \mathcal{O}(k)$ possibilities),
- a level with a top-most or bottom-most vertex of $\mathcal{G}$ ($\mathcal{O}(1)$ possibilities),
- a level with a top-most top ear, a top-most bottom ear, a bottom-most top ear, or a bottom-most bottom ear of some pair of vertices in C ($\mathcal{O}(k)$ possibilities by Lemma 7),
- a level with a top-most or bottom-most vertex of a connected component that contains a vertex of C in the graph obtained by removing u and w from the current graph ($\mathcal{G}$ together with the visbility edges and the already added vertices) ($\mathcal{O}(k)$ possibilities).

In total, for a fixed pair of neighbors u, w, there are thus $\mathcal{O}(k)$ options to pick a level for v'. We immediately discard level assignments for which v' is no ear. By multiplying with the number of ways to choose the neighbors, we obtain $\mathcal{O}(k^2)$ options to choose v' and its level. Multiplying the number of options for all $\mathcal{O}(k)$ steps together, we obtain a total number of $k^{\mathcal{O}(k)} \subseteq 2^{\mathcal{O}(k \log k)}$ ways to create the set of crucial ears along with their levels. By multiplying with the number of ways to choose the visibility edges, we obtain a total of $2^{\mathcal{O}(k \log k)}$ options to choose the graph that corresponds to Λ_{core}. For each of these options we enumerate all $k^{\mathcal{O}(k)} \subseteq 2^{\mathcal{O}(k \log k)}$ permutations of the set of non-horizontal edges and, interpreting the permutation as a compatible edge order, try to construct a level planar drawing for which this order is compatible (cf. Section 2). If we succeed, we check whether the drawing is conform with $(\prec_i)_i$ and can be augmented with the horizontal visibility edges. If so, we include the drawing in the set $\mathcal{F}$ of reported drawings. The size of the thereby constructed set $\mathcal{F}$ is bounded by $2^{\mathcal{O}(k \log k)}$ and it is guaranteed to contain Λ_{core} by construction. ◀

Step 2: Inserting transition vertices. We now describe how to insert the transition vertices into the core-induced subdrawing Λ_{core} of the (refined) visibility extension Λ^*. Our plan is to first show that in Λ^*, every transition vertex is placed "very close to" some visibility edge. Intuitively, this means that the visibility edges of Λ_{core} act as placeholders near which the transition vertices have to be placed. We will describe a procedure that does so while carefully taking into account the given partial orderings $\prec_i$ and prove its correctness by means of an (somewhat technical) exchange argument. To formalize the notion of "very close to", let e be an edge of a level planar drawing joining two vertices a, b such that there is a degree-2 vertex t with neighbors a, b and $\gamma'(b) < \gamma'(t) < \gamma'(a)$ where γ' is the level assignment. We say that t is drawn in the *vicinity* of e with respect to a vertex set V' if the simple closed curve formed by e and the two edges incident to t does not contain a vertex of V' in its interior.

▶ **Lemma 9** ($\star$). *Let $\mathcal{G} = (G = (V, E), \gamma, (\prec_i)_i)$ be a constrained level graph without isolated vertices, let C be a vertex cover of G, let Γ^* be a constrained level planar drawing of $\mathcal{G}$, let Λ^* be a refined or non-refined visibility extension of Γ^* with respect to C, and let Λ_{core} the subdrawing of Λ^* induced by the core of Λ^* with respect to C. There is an algorithm*

that, given $\mathcal{G}$, C and Λ_{core}, inserts all transition vertices $V^{\mathrm{t}}_{=2}(C)$ (and their incident edges) into vicinities (with respect to C) of visibility edges in Λ_{core} in polynomial time such that the resulting drawing $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ can be extended to a drawing whose restriction to G is a constrained level planar drawing of $\mathcal{G}$.

Step 3: Inserting leaves and ears. In this step, we start with the output of Step 2 and finalize our drawing by placing all the vertices that are still missing.

▶ **Lemma 10.** *Let $\mathcal{G} = (G = (V, E), \gamma, (\prec_i)_i)$ be a constrained level graph without isolated vertices, let C be a vertex cover of G, let Γ^* be a constrained level planar drawing of $\mathcal{G}$, let Λ^* be a refined or non-refined visibility extension of Γ^* with respect to C in which each transition vertex is placed in the vicinity of some visibility edge with respect to C, and let Λ_{core} ($\Lambda^{\mathrm{t}}_{\mathrm{core}}$) be the subdrawing of Λ^* induced by the core (and the transition vertices) of Λ^* with respect to C. There is an algorithm that, given $\mathcal{G}$, C, Λ_{core} and $\Lambda^{\mathrm{t}}_{\mathrm{core}}$, extends Λ_{core} to a drawing Γ whose restriction to G is a constrained level planar drawing of $\mathcal{G}$ in $2^{\mathcal{O}(k^2 \log k)} n^{\mathcal{O}(1)}$ time, where $n = |V|, k = |C|$.*

Proof. The only vertices of G that are missing in $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ are the leaves and the non-crucial ears with respect to C (in case Λ^* is a *refined* visibility extension, the non-crucial ears are exactly the ears of $\mathcal{G}$). Our plan to insert them into our drawing is as follows. We begin by introducing more structure in $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ and Λ^* by adding some additional visibility edges and making some normalizing assumptions, which will simplify the description of the upcoming steps. In particular, this step will ensure that for each missing ear, there are essentially only (up to) two possible placements, which will allow us to enumerate all possible ear placements (so-called ear orientations) on a given level in FPT-time. We then describe a partition of the plane into so-called cells in a way that is very reminiscent of the well-known trapezoidal decomposition from the field of computational geometry, cf. [11]. We merge some cells into so-called channels, which correspond to connected y-monotone regions in which the missing leaves along with their incident edges will be drawn (a region is *y-monotone* if its intersection with every horizontal line is connected). We then introduce (and describe an enumerative process that constructs in FPT-time) a so-called traversal sequence that is compatible with Λ^*, which is a sequence of sets of channels with several useful structural properties related to Λ^*. In particular, this sequence, in some sense, sweeps the plane from left to right in a way where for each edge incident to a leaf in Λ^*, at some point there is a channel that contains it. Exploiting the properties of the traversal sequence, we then describe how to construct a so-called insertion sequence for the leaves on a given level with respect to a given placement of the ears of that level in polynomial time. Such an insertion sequence does not necessarily exist for every placement of ears, but we are guaranteed to find one by enumerating all possible ear placements of the level. This computation is performed independently for each level. Finally, we show how to construct in polynomial time the desired drawing Γ when given an insertion sequence along with its ear placement for each level. Notably, the final step can be executed even if some of the ear placements are different from the ones used in Λ^*. Let us proceed to formalize these ideas.

Augmenting and normalizing Λ_{core}, $\Lambda^{\mathrm{t}}_{\mathrm{core}}$, and Λ^*. Let $e = (u, v)$ be a visibility edge of Λ^* (and $\Lambda^{\mathrm{t}}_{\mathrm{core}}$) that has at least one transition vertex in its vicinity. In both $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ and Λ^*, we add two copies of e; one directly to the left of the leftmost transition vertex and the other directly to the right of the rightmost transition vertex in the vicinity of e, which is possible to do in a y-monotone fashion and without introducing any crossings; see Figure 2(a). Note that the region enclosed by these two edges only contains transitions vertices of u and v, as well as leaves of u or v. We repeat this operation for all visibility edges e.

The following steps are illustrated in Figure 2(b). Let f be a face of Λ^t_{core} that is bounded by four vertices v_1, v_2, u_1, u_2 where $v_1, v_2 \in C$ and $u_1, u_2 \in V_{\{v_1,v_2\}}$ are either both left ears or both right ears. Without loss of generality, assume they are both left ears with $\gamma(v_1) \leq \gamma(v_2) < \gamma(u_1) < \gamma(u_2)$. We add copies of the edges (v_1, u_2) and (v_2, u_2) in f in both Λ^t_{core} and Λ^*, which can be done without introducing crossings. These edges partition f into three regions. Note that in Λ^* these regions only contain leaves and non-crucial ears. Without loss of generality, we will assume that each leaf in f is either placed in the region bounded by (v_1, u_2) and its copy or the region bounded by (v_2, u_2) and its copy (note that a leaf v that is adjacent to v_1 cannot have a constraint of the form $w \prec_i v$, where w is a non-crucial ear in f; the situation for leaves adjacent to v_2 is symmetric). Thus, the remaining (central) third region only contains non-crucial ears and is henceforth called an *ear-face* of Λ^t_{core}. We repeat this modification for all faces such as f.

For the remainder of the proof, Λ^t_{core} and Λ^* are used to refer to the thusly augmented and normalized drawings. We also add all the new edges to Λ_{core} and use Λ_{core} to refer to this augmentation. Note that this implies that it now suffices to search for a drawing of $\mathcal{G}$ in which every non-crucial ear is placed in an ear-face, whereas no leaf is placed in an ear-face.

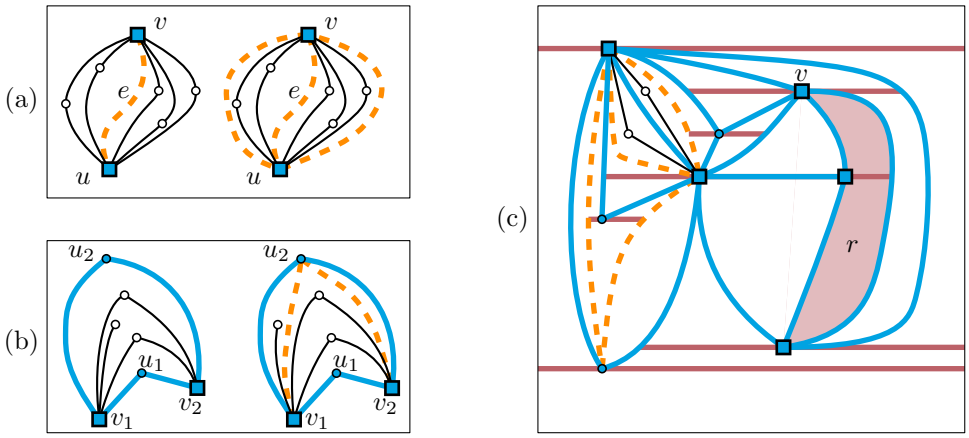

Figure 2 Like in all figures, filled square vertices belong to a vertex cover C of the depicted graph and filled (round or square) vertices belong to the core of the shown drawing with respect to C. Figures (a) and (b) visualize how Λ_{core}, Λ^t_{core}, and Λ^* are augmented by (a) enclosing transition vertices and (b) creating ear-faces with visibility edges (dashed). Moreover, (b) illustrates our normalizing assumption, i.e., the leaf can be moved to the exterior of the ear-face without violating any constraints. (c) The drawing Λ^t_{core} with its additional visibility edges (dashed) from the augmentation step and the horizontal rays and segments (thick, red) from the cell decomposition. The shaded region corresponds to a channel (v, r, R) from $v \in C$ to the cell r with $|R| = 2$.

Decomposition into cells. We will now describe a partition of the plane that essentially corresponds to a trapezoidal decomposition (cf. [11]) of Λ_{core}; for illustrations refer to Figure 2(c): for each vertex v in Λ_{core}, shoot a horizontal ray from v to the left until hitting an edge or vertex of Λ_{core}, then add the corresponding segment to Λ_{core}. In case the ray does not intersect any part of Λ_{core}, add the ray itself to Λ_{core}. Perform a symmetric augmentation by shooting a horizontal ray from v to the right. The maximal connected regions of the resulting partition of the plane are henceforth called *cells*. We consider the cells to be closed. Note that each cell is y-monotone and bounded by up to two horizontal segments or rays and up to two y-monotone curves. By Lemma 7, Λ_{core} has $\mathcal{O}(k)$ vertices and edges (note that the augmentation step copies each edge at most twice) and, hence, it has $\mathcal{O}(k)$ faces. Consequently, the number of cells is also $\mathcal{O}(k)$ since the insertion of a single segment or ray can only increase the number of faces (or, rather, maximal connected regions) by one.

Channels. Let $v \in C$, let R be a set of cells that do not belong to ear-faces, and let $r \in R$. Further, assume that R contains a cell that is incident to v. The triple $c = (v, r, R)$ is a *channel from v to r* if it is possible to draw a y-monotone curve in $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ in the interior of the union of R that intersects each cell in R and does not cross any edge of $\Lambda^{\mathrm{t}}_{\mathrm{core}}$; as illustrated in Figure 2(c). We say that c *can be used* by a leaf $w \in V_{\{v\}}$ and that the edge e_w incident to w *can be drawn in* c if e_w can be drawn in $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ in the union of R without any crossings and there is no channel (v, r', R') with this property for which $R' \subset R$. Further, we say that c *is used* by w if it can be used by w and the edge incident to w is drawn in the union of R in Λ^*. We use U to denote the set of all channels and $U_{\mathrm{used}} \subseteq U$ to denote the set of all channels that are used. The connectivity of $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ (cf. Lemma 7) can be used to show:

▷ Claim 11 (⋆). $|U_{\mathrm{used}}| \leq |U| \in \mathcal{O}(k^2)$.

Traversal sequences. Let $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \ldots, \mathcal{U}_m)$ be a sequence of sets of channels. We say $\mathcal{U}$ is a *traversal sequence* if the following properties are fulfilled (see Figure 3 for illustrations):

(T1) Let $i \in [m]$ and let $(v, r, R) \in \mathcal{U}_i$ and $(v', r', R') \in \mathcal{U}_i$ with $v \neq v'$. Then the intersection of the line $L_{\gamma(v)}$ with the interior of the union of R' is empty.

(T2) Let c be a channel and let $a \leq b$ be two indices such that $c \in \mathcal{U}_a$ and $c \in \mathcal{U}_b$. Then for every $a \leq i \leq b$, $c \in \mathcal{U}_i$.

We say a channel u is *active* in $\mathcal{U}_i$ if it is contained in it, and otherwise it is *inactive* in it. We say a traversal sequence $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \ldots, \mathcal{U}_m)$ is *compatible* with Λ^* if the following conditions are satisfied (refer again to Figure 3 for illustrations):

(C1) For every channel c, there exists an $i \in [m]$ such that $c \in \mathcal{U}_i$ if and only if c is used.

(C2) There exists a compatible edge ordering $\prec^{\mathrm{e}}$ for the restriction of Λ^* to its nonhorizontal edges (recall that some visibility edges are horizontal) such that:

- **a.** Let e, e' be two edges that are incident to leaves and where $e \prec^{\mathrm{e}} e'$, let c be the channel used by e, and let c' be the channel used by e'. Then there exist indices i, i' such that $i \leq i'$ and $c \in \mathcal{U}_i$, $c' \in \mathcal{U}_{i'}$.
- **b.** Let $c_1, c_2 \in U_{\mathrm{used}}$ such that for every edge e_1 using c_1 and for every edge e_2 using c_2 we have $e_1 \prec^{\mathrm{e}} e_2$. Then there is no index $i \in [m]$ such that $\mathcal{U}_i$ contains both c_1 and c_2 (and every index for which c_1 is active is smaller than every index where c_2 is active).
- **c.** For every pair of used channels c_1, c_2 such that c_2 is being used by an edge e that succeeds all edges that use c_1 in $\prec^{\mathrm{e}}$ there exists an index i such that $c_2 \in \mathcal{U}_i$ and $c_1 \notin \mathcal{U}_i$ (and c_1 is active for some index smaller than i).

▷ Claim 12 (⋆). There exists a traversal sequence $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \ldots, \mathcal{U}_m)$ that is compatible with Λ^* and whose length is $m \in \mathcal{O}(k^2)$. Moreover, there is an algorithm that, given $\mathcal{G}$, C and $\Lambda^{\mathrm{t}}_{\mathrm{core}}$, computes a set of $2^{\mathcal{O}(k^2 \log k)}$ traversal sequences that contains $\mathcal{U}$ in $2^{\mathcal{O}(k^2 \log k)} n^{\mathcal{O}(1)}$ time.

▷ Claim 13 (⋆). Let $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \ldots, \mathcal{U}_m)$ be a traversal sequence that is compatible with Λ^*, let $i \in [m]$, and let v be a leaf. Then $\mathcal{U}_i$ contains at most channel that can be used by v.

Ear orientations. Let $i \in [h]$ and let $V^{\mathrm{e}}_i \subseteq V_i$ be all non-crucial ears on the ith level. Further, consider a mapping $s \colon V^{\mathrm{e}}_i \to \{\mathrm{left}, \mathrm{right}\}$. We say that s is an *ear orientation* of level i. We say that s is *valid* if it is possible to insert the ears V^{e}_i (on the line L_i) along with their incident edges into $\Lambda^{\mathrm{t}}_{\mathrm{core}}$ such that the resulting drawing Λ is crossing-free, no constraint is violated (i.e., if $u \prec_i v$, then u is placed to the left of v), and for every $v \in V^{\mathrm{e}}_i$, we have that v is a left ear if and only if $s(v) = \mathrm{left}$. We say that Λ is *induced* by s. Note that for any ear $v \in V^{\mathrm{e}}_i$ there is at most one left ear-face and at most one right ear-face into which it can be

Figure 3 Like in all figures, filled square vertices belong to a vertex cover C of the depicted graph. (a) The drawing Λ^* together with its cell decomposition. (b) The dashed (green) "edges" represent the used channels $c_1 \dots, c_6$ of Λ^* leading from vertices of C to cells in R, which are represented by unfilled (red) squares. (c) A traversal sequence compatible with Λ^* for which Property (C2) is satisfied for any compatible edge ordering that contains the edges of $v_1, v_2, \dots, v_9$ in this order.

inserted without introducing crossings. Hence, a valid ear orientation uniquely describes the ear-face in which each ear is placed. Further, note that no two ears of V_i^{e} can be placed in the same ear-face without introducing crossings. In contrast, whenever an ear orientation assigns only one ear to a given ear-face, it is possible to place the ear without introducing crossings. These properties make it easy to test whether a given ear orientation is valid and, if so, construct the (unique) induced drawing in polynomial time. In view of Lemma 5, this means we can enumerate all valid ear orientations of a given level in $2^{2k}n^{\mathcal{O}(1)}$ time.

Insertion sequences. Let $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \dots, \mathcal{U}_m)$ be a traversal sequence that is compatible with Λ^*. Further, let $i \in [h]$, let s be a valid ear orientation of level i, and let Λ be its induced drawing. Finally, let $\mathcal{Q} = (Q_1, Q_2, \dots, Q_q)$ be a sequence with $Q_t = (v, j)$, $v \in V_i \cap V_{=1}$, and $1 \leq j \leq m$ for all $1 \leq t \leq q$. We say $\mathcal{Q}$ is an *insertion sequence* for i, s, and $\mathcal{U}$ if the following conditions are fulfilled (for an example, see Figure 4):

- **(I1)** Let $v \in V_i \cap V_{=1}$. Then there exists at most one index t such that $v \in Q_t$.
- **(I2)** Let $Q_x = (v_x, j_x) \in \mathcal{Q}$ and $Q_y = (v_y, j_y) \in \mathcal{Q}$ with $x < y$. Then $j_x \leq j_y$.
- **(I3)** Let $Q_x = (v, j) \in \mathcal{Q}$. Then there exists a channel $c \in \mathcal{U}_j$ that can be used by v.
- **(I4)** Let $Q_x = (v, j) \in \mathcal{Q}$. Then for every $w \in V_i \cap V_{=1}$ with $w \prec_i v$, there exists an index $x' < x$ such that $w \in Q_{x'}$.
- **(I5)** Let $Q_x = (v, j) \in \mathcal{Q}$ and let $(v, r, R) \in \mathcal{U}_j$ be the (unique, by Claim 13) channel usable by v in $\mathcal{U}_j$. Then for every $w \in V_i \setminus V_{=1}$ that is not a transition vertex in r and where $v \prec_i w$, w is to the right of r or on the right boundary of r. Symmetrically, for every $w \in V_i \setminus V_{=1}$ that is not a transition vertex in r and where $w \prec_i v$, w is to the left of r or on the left boundary of r.

Let $\mathcal{Q} = (Q_1, Q_2, \ldots, Q_q)$ be an insertion sequence for i, s, and $\mathcal{U}$. We say a leaf $v \in V_i \cap V_{=1}$ is *choosable* with regard to $\mathcal{Q}$ if (i) there exists an index j, such that $(Q_1, Q_2, \ldots, Q_q, (v, j))$ is an insertion sequence for i, s, and $\mathcal{U}$ as well and (ii) there exists no pair v', j', with $v' \in V_i \cap V_{=1}$ and $j' < j$ such that $\mathcal{Q} = (Q_1, Q_2, \ldots, Q_q, (v', j'))$ is an insertion sequence.

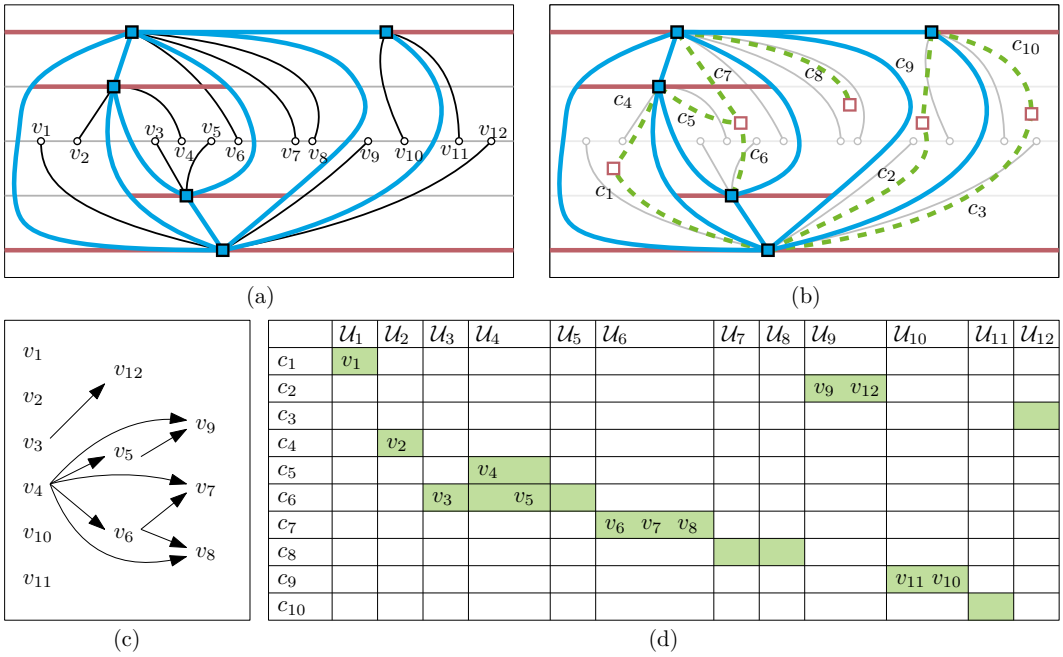

Figure 4 Like in all figures, filled square vertices belong to a vertex cover C of the depicted graph. (a) The drawing Λ^* together with its cell decomposition. (b) The dashed (green) "edges" represent the used channels $c_1, \ldots, c_{10}$ of Λ^* leading from vertices of C to cells in R represented by unfilled (red) squares. Figure (c) shows the constraints between the vertices of the third level depicted in (a) and Figure (d) illustrates the insertion sequences $\mathcal{Q} = ((v_1, 1), (v_2, 2), (v_3, 3), (v_4, 4), (v_5, 4), (v_6, 6), (v_7, 6), (v_8, 6), (v_9, 9), (v_{12}, 9), (v_{11}, 10), (v_{10}, 10))$ for this level and the depicted traversal sequence $\mathcal{U} = (\mathcal{U}_1, \ldots, \mathcal{U}_{12})$. Note that the order of the vertices in $\mathcal{Q}$ is different from the one in Λ^*.

▷ Claim 14 (⋆). Let $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \ldots, \mathcal{U}_m)$ be a traversal sequence that is compatible with Λ^* and let $\prec^{\mathrm{e}}$ be a compatible edge ordering for the restriction of Λ^* to its nonhorizontal edges, for which Property (C2) is fulfilled for $\mathcal{U}$. Further, let $i \in [h]$ and let s be the valid ear orientation of level i that is used in Λ^*. For every $q \in \{0, 1, \ldots, |V_i \cap V_{=1}|\}$, there exists an insertion sequence $\mathcal{Q}_q = (Q_1, Q_2, \ldots, Q_q)$ for i, s, and $\mathcal{U}$ such that the following two properties are satisfied (for an example, see Figure 4):

Interval property: For every vertex $v \in V_i \cap V_{=1}$ there exists at most one nonempty maximal interval $[a, b]$ where $0 \leq a \leq b \leq q$ such that v is choosable with regard to $\mathcal{Q}_j$ if and only if $a \leq j \leq b$. If such an interval $[a, b]$ exists, then $b = q$ or $v \in Q_{b+1}$. Conversely, if v occurs in some entry of $\mathcal{Q}_q$, then the interval exists.

Dominance property: Let $\prec_i^l$ be the restriction of $\prec^{\mathrm{e}}$ to edges incident to leaves on level i. Further, let $Q_\ell = (v_\ell, j_\ell) \in \mathcal{Q}_q$, let $v_{\ell'} \in V_i \cup V_{=1}$, and let e_ℓ ($e_{\ell'}$) be the edge incident to v_ℓ ($v_{\ell'}$). Then, if $e_\ell \prec_i^l e_{\ell'}$ or $v_\ell = v_{\ell'}$, we have $j_\ell \leq j'$, where j' is the maximum index such that the channel c' used by $v_{\ell'}$ (in Λ^*) is in $\mathcal{U}_{j'}$.

Moreover, $\mathcal{Q}_k$ is a prefix of $\mathcal{Q}_{k+1}$ for all $0 \leq k \leq |V_i \cap V_{=1}| - 1$. Finally, there is an algorithm that, given $\mathcal{G}$, C, $\Lambda^{\mathrm{t}}_{\mathrm{core}}$, $\mathcal{U}$, i and s, computes $\mathcal{Q}_{|V_i \cap V_{=1}|}$ in polynomial time.

Computing the drawing. When given a traversal sequence that is compatible with Λ^*, we can utilize Claim 14 to obtain a valid ear orientation together with an insertion sequence for a given level by simply trying to apply the algorithm corresponding to Claim 14 for all valid ear orientations of that level. We do so for each level and then use the gathered information to construct the desired drawing by means of the following claim. We remark that when the algorithm corresponding to Claim 14 successfully terminates, it is guaranteed to return an insertion sequence for the given valid ear orientation. It might output an insertion sequence even if the given valid ear orientation is not the one used in Λ^*. However, this does not invalidate our strategy as the following claim does *not* require that the given ear orientations are the ones used in Λ^*.

▷ Claim 15 ($\star$). There is an algorithm that, given $\mathcal{G}$, C, Λ_{core}, $\Lambda^{\text{t}}_{\text{core}}$, a traversal sequence $\mathcal{U} = (\mathcal{U}_1, \mathcal{U}_2, \ldots, \mathcal{U}_m)$ that is compatible with Λ^*, and, for each level $i \in [h]$, a valid ear orientation s^i, as well as an insertion sequence $\mathcal{Q}^i = (Q^i_1, Q^i_2, \ldots, Q^i_{q^i})$ for i, s^i, and $\mathcal{U}$ such that $q^i = |V_i \cap V_{=1}|$ (that is, $\mathcal{Q}^i$ contains all leaves of level i), computes an extension of Λ_{core} whose restriction to G is a constrained level planar drawing of $\mathcal{G}$ in polynomial time.

Wrap-up. In the beginning of (and throughout the) proof of Lemma 10, we have already sketched how the individual pieces of the proof fit together. We formally summarize our strategy in the proof of the following claim.

▷ Claim 16 ($\star$). There is an algorithm that, given $\mathcal{G}$, C, Λ_{core} and $\Lambda^{\text{t}}_{\text{core}}$, extends Λ_{core} to a drawing Γ whose restriction to G is a constrained level planar drawing of $\mathcal{G}$ in $2^{\mathcal{O}(k^2 \log k)} n^{\mathcal{O}(1)}$ time.

This concludes the proof of Lemma 10. ◀

Summary. In the beginning of Section 4, we have already sketched how Lemmas 4 and 8–10 can be combined to obtain Theorem 1. We formally summarize:

▶ **Theorem 17** ($\star$). *There is an algorithm that, given a constrained level graph $\mathcal{G} = (G = (V, E), \gamma, (\prec_i)_i)$ and a vertex cover C of G, either constructs a constrained level planar drawing of $\mathcal{G}$ or correctly reports that such a drawing does not exist in time $2^{\mathcal{O}(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$, where $n = |V|$ and $k = |C|$.*

Given that a smallest vertex cover can be obtained in FPT-time with respect to its size [10], our main result (Theorem 1) follows from Theorem 17.

5 Discussion

We have shown that CLP is FPT when parameterized by the vertex cover number. A speed-up to polynomial time or a generalization to the smaller graph parameters (in particular, tree-depth, path-width, tree-width, and feedback vertex set number) is not possible, even if restricting to OLP or proper CLP instances.

Recall from Section 1 that in the Level Planarity variant Partial Level Planarity (PLP), a given level planar drawing of a subgraph of the input graph $\mathcal{G}$ has to be extended to a full drawing of $\mathcal{G}$, which can be seen as a generalization of OLP and, in the proper case, a specialization of CLP. An instance of PLP can always be turned into an equivalent proper instance (and, thus, a CLP instance) by subdividing each edge on each level it passes through. However, in general this operation will (dramatically) increase the vertex cover number of the instance. Hence, our techniques cannot (directly) be applied. It thus is an interesting problem to study the parameterized complexity of PLP with respect to the vertex cover number.

Subquadratic Submodular Maximization with a General Matroid Constraint

Yusuke Kobayashi

Tatsuya Terao
Research Institute for Mathematical Sciences, Kyoto University, Japan

Abstract

We consider fast algorithms for monotone submodular maximization with a general matroid constraint. We present a randomized $(1-1/e-\epsilon)$-approximation algorithm that requires $\tilde{O}_\epsilon(\sqrt{r}n)$ independence oracle and value oracle queries, where n is the number of elements in the matroid and $r \leq n$ is the rank of the matroid. This improves upon the previously best algorithm by Buchbinder-Feldman-Schwartz [Mathematics of Operations Research 2017] that requires $\tilde{O}_\epsilon(r^2 + \sqrt{r}n)$ queries.

Our algorithm is based on continuous relaxation, as with other submodular maximization algorithms in the literature. To achieve subquadratic query complexity, we develop a new rounding algorithm, which is our main technical contribution. The rounding algorithm takes as input a point represented as a convex combination of t bases of a matroid and rounds it to an integral solution. Our rounding algorithm requires $\tilde{O}(r^{3/2}t)$ independence oracle queries, while the previously best rounding algorithm by Chekuri-Vondrák-Zenklusen [FOCS 2010] requires $O(r^2t)$ independence oracle queries. A key idea in our rounding algorithm is to use a directed cycle of arbitrary length in an auxiliary graph, while the algorithm of Chekuri-Vondrák-Zenklusen focused on directed cycles of length two.

1 Introduction

1.1 Submodular Maximization

Submodular maximization is a fundamental and well-studied problem in theoretical computer science and combinatorial optimization. This is because a number of important problems can be regarded as special cases of submodular maximization, including maximum coverage, generalized assignment, and facility location. Furthermore, submodular maximization has many practical applications in machine learning, economics, and many other areas. In the submodular maximization problem, the input consists of a (monotone) submodular set function $f\colon 2^V \to \mathbb{R}_+$ and a feasible region $\mathcal{F} \subseteq 2^V$ specified by some constraints, and the aim is to find a set $S \in \mathcal{F}$ maximizing $f(S)$.

The study of submodular maximization was initiated by a seminal work of Fisher, Nemhauser, and Wolsey in the 1970's [26,34,35]. They showed that, for monotone submodular maximization, the greedy algorithm achieves $(1 - 1/e)$-approximation for a cardinality constraint and $\frac{1}{2}$-approximation for a matroid constraint. The advantage of their algorithm is that it is very simple and fast, indeed, it runs in quadratic time. It is known that unless P = NP, for any $\varepsilon > 0$, there is no $(1 - 1/e + \varepsilon)$-approximation algorithm for the maximum coverage problem [24], which is a special case of monotone submodular maximization with a cardinality constraint or a matroid constraint. Thus, the factor $1 - 1/e$ is optimal for a cardinality constraint.

To obtain an optimal $(1 - 1/e)$-approximation algorithm for a matroid constraint, Calinescu-Chekuri-Pál-Vondrák [13] developed a framework based on continuous optimization and rounding technique. In their algorithm, they first solve the continuous optimization problem of maximizing the multilinear extension F of f, a natural continuous extension of f. By using a continuous greedy algorithm, they obtain a $(1 - 1/e)$-approximation solution for the continuous optimization problem. In order to round the obtained fractional solution to an integral one, they use a variant of the pipage rounding technique of Ageev-Sviridenko [1]. Consequently, their algorithm achieves the optimal $(1 - 1/e)$-approximation. Note that, although their algorithm runs in polynomial time, its running time is very high.

Since submodular maximization has a number of applications, providing efficient approximation algorithms is a fundamental task both in theory and in practice. Thus, it has received considerable attention to develop fast submodular maximization algorithms that achieve an approximation close to the optimal factor, typically with an approximation factor of $1 - 1/e - \varepsilon$ for any $\varepsilon > 0$.

In the submodular maximization problem with a general matroid constraint, it is standard to suppose that the objective function f is given as a value oracle, and the feasible region $\mathcal{F} \subseteq 2^V$ is given as an independence oracle of a matroid. In such a case, the efficiency of an algorithm is usually measured by the number of value and independence oracle queries used in it.

Badanidiyuru-Vondrák [3] presented a fast algorithm that achieves an almost optimal approximation factor $1-1/e-\varepsilon$, for any $\varepsilon > 0$, for a matroid constraint. Their algorithm uses $O\left(\frac{rn}{\varepsilon^4} \log^2\left(\frac{n}{\varepsilon}\right)\right)$ value oracle queries and $O\left(\frac{n}{\varepsilon^2} \log\left(\frac{n}{\varepsilon}\right) + \frac{r^2}{\varepsilon}\right)$ independence oracle queries, where n is the number of elements in the matroid and r is the rank of the matroid. To achieve this query complexity, they developed a fast implementation of the continuous greedy algorithm that uses $\tilde{O}_\varepsilon(rn)$ value oracle queries and $\tilde{O}_\varepsilon(n)$ independence oracle queries.[1] The output of their continuous greedy algorithm is a fractional solution represented as a convex combination of $1/\varepsilon$ bases. Then, they apply the swap rounding algorithm of Chekuri-Vondrák-Zenklusen [18] to round the obtained fractional solution to an integral solution, which requires $O(r^2/\varepsilon)$ independence oracle queries.

Buchbinder-Feldman-Schwartz [12] presented a $(1-1/e-\varepsilon)$-approximation algorithm that has a trade-off between the number of value oracle queries and the number of independence oracle queries used in the algorithm. In their algorithm, they combine a variant of the residual random greedy algorithm of Buchbinder-Feldman-Naor-Schwartz [11] and the fast continuous greedy algorithm of Badanidiyuru-Vondrák described above. Then, for a parameter $\lambda \in [1, r]$, their algorithm uses $\tilde{O}_\varepsilon(r\lambda + \frac{rn}{\lambda})$ value oracle queries and $\tilde{O}_\varepsilon(\lambda n + r^2)$ independence oracle queries. We note that the $\tilde{O}_\varepsilon(r^2)$ term in the independence query complexity is due to

[1] The $\tilde{O}_\varepsilon$ notation hides polylogarithmic factors in n and polynomial factors in ε^{-1}.

the rounding algorithm in the same way as the algorithm of Badanidiyuru-Vondrák. If we evaluate the algorithm by the total number of queries regardless of their types, then the query complexity is minimized when $\lambda = \Theta(\sqrt{r})$. In this case, their algorithm uses $\tilde{O}_\varepsilon(r^2 + \sqrt{r}n)$ value and independence oracle queries. This query complexity is better than that of Badanidiyuru-Vondrák [3] when $r = o(n)$, but a quadratic number of queries is still required when r is large.

Recently, for several important classes of matroids, faster algorithms for monotone submodular maximization with a matroid constraint have been investigated. Ene-Nguyễn [22] presented a $(1-1/e-\varepsilon)$-approximation algorithm for graphic matroid and partition matroid constraints in time nearly-linear in the size of their representation. Henzinger-Liu-Vondrák-Zheng [27] presented a $(1-1/e-\varepsilon)$-approximation algorithm for laminar matroid and transversal matroid constraints in nearly-linear time. A key ingredient in these algorithms is a fast dynamic data structure for maintaining an (approximate) maximum weight basis of the matroid.

1.2 Our Results

This paper focuses on the monotone submodular maximization problem with a general matroid constraint. In the problem, this input consists of a monotone submodular set function $f\colon 2^V \to \mathbb{R}_+$ given as a value oracle, and a matroid $\mathcal{M} = (V, \mathcal{I})$ given as an independence oracle. The objective is to find an independent set $S \in \mathcal{I}$ that maximizes $f(S)$. For $\alpha \in [0,1]$, a randomized algorithm is said to be an *α-approximation algorithm* if it returns a solution $S \in \mathcal{I}$ with $\mathbb{E}[f(S)] \geq \alpha \cdot \max\{f(T) \mid T \in \mathcal{I}\}$. A randomized algorithm is often called simply an algorithm throughout the paper. Our main result is to give a first $(1-1/e-\varepsilon)$-approximation algorithm for this problem that requires a subquadratic number of queries. Recall that $n = |V|$ and r is the rank of $\mathcal{M}$.

▶ **Theorem 1.** *For any $\varepsilon > 0$, there is a randomized algorithm that achieves $(1-1/e-\varepsilon)$-approximation for maximizing a monotone submodular function subject to a matroid constraint and uses $O(\sqrt{r}n \operatorname{poly}(1/\varepsilon, \log n))$ value and independence oracle queries.*

It is worth mentioning that, for the case of $r = \Theta(n)$, our algorithm uses $\tilde{O}_\varepsilon(n^{3/2})$ oracle queries, whereas the algorithm of Buchbinder-Feldman-Schwartz [12] uses $\tilde{O}_\varepsilon(n^2)$ oracle queries.

Our algorithm is based on continuous relaxation and rounding technique in the same way as previous algorithms [3, 12, 13]. In this framework, currently, the bottleneck of the query complexity comes from the rounding algorithm. Indeed, the swap rounding algorithm by Chekuri-Vondrák-Zenklusen [18] requires $O(r^2 t)$ independence oracle queries if the input point is represented as a convex combination of t bases of the matroid. Then, this rounding algorithm requires a quadratic number of independence oracle queries even when t is small. Therefore, in order to break the quadratic-independence-query barrier in this framework, it is necessary to devise a faster rounding algorithm.

The key technical contribution of this paper is to develop a new rounding algorithm that uses $o(r^2 t)$ independence oracle queries.

▶ **Theorem 2.** *For any $\varepsilon > 0$, there is a randomized algorithm satisfying the following conditions:*

- *the input consists of a matroid $\mathcal{M} = (V, \mathcal{I})$ given as an independence oracle and a point x in the base polytope of $\mathcal{M}$ that is represented as a convex combination of t bases,*
- *the output is a basis S of $\mathcal{M}$ such that $\mathbb{E}[f(S)] \geq (1-\varepsilon)F(x)$ for any submodular function $f\colon 2^V \to \mathbb{R}$ and its multilinear extension F, and*
- *it uses $O(r^{3/2} t \log^{3/2}(\frac{rt}{\varepsilon}))$ independence oracle queries.*

By combining this theorem with the submodular maximization algorithm by Buchbinder-Feldman-Schwartz [12], we obtain Theorem 1; see Section 3 for details.

We also show that if the matroid is given as a rank oracle instead of an independence oracle, then we obtain a $(1 - 1/e - \varepsilon)$-approximation algorithm using $\tilde{O}_\varepsilon(n + r^{3/2})$ value and rank oracle queries.

▶ **Theorem 3.** *For any $\varepsilon > 0$, there is a randomized algorithm that achieves $(1 - 1/e - \varepsilon)$-approximation for maximizing a monotone submodular function subject to a matroid constraint and uses $O((n + r^{3/2})\ \mathrm{poly}(1/\varepsilon, \log n))$ value and rank oracle queries.*

1.3 Overview of Our Rounding Algorithm

In this subsection, we give a technical overview of our new rounding algorithm. Since our rounding algorithm is based on that of Chekuri-Vondrák-Zenklusen [18], we first review their algorithm and then explain the key ideas behind ours.

Swap Rounding Algorithm of Chekuri-Vondrák-Zenklusen. The rounding algorithm by Chekuri-Vondrák-Zenklusen is called the swap rounding algorithm. Their algorithm takes as input a point x represented as a convex combination of t bases of $\mathcal{M}$ and returns an integral solution S such that $\mathbb{E}[f(S)] \geq F(x)$ for any submodular function f and its multilinear extension F. In each phase of the algorithm, we pick up two bases in the representation of x and merge them into a single basis. By applying this procedure $t - 1$ times, we obtain a single basis of $\mathcal{M}$.

In order to merge two bases, say B_1 and B_2, their swap rounding algorithm uses a *strongly exchangeable pair* of elements, that is, a pair of elements $u \in B_1 \setminus B_2$ and $v \in B_2 \setminus B_1$ such that $B_1 + v - u \in \mathcal{I}$ and $B_2 + u - v \in \mathcal{I}$. Since we can find a strongly exchangeable pair using $O(r)$ independence oracle queries and we need to find such a pair $O(rt)$ times in the algorithm, the total number of queries is $O(r^2 t)$. It is still not clear whether we can develop an algorithm for finding a strongly exchangeable pair using $o(r)$ independence oracle queries, and hence their algorithm is now stuck at $\Omega(r^2 t)$ independence oracle queries.

See Section 4 for details of the swap rounding algorithm of Chekuri-Vondrák-Zenklusen.

Our Faster Rounding Algorithm. We develop a new rounding algorithm that requires $\tilde{O}(r^{3/2} t)$ independence oracle queries with high probability. Our rounding algorithm is based on that of Chekuri-Vondrák-Zenklusen in a sense that we update bases by swapping a pair of elements $O(rt)$ times. Therefore, in each step of our algorithm, we need to update some basis by using only $\tilde{O}(\sqrt{r})$ independence oracle queries. To achieve this, we need substantially new ideas.

First, we introduce a digraph that represents exchangeability of the elements in the matroid (see Definition 8), and provide a new interpretation of the swap rounding algorithm of Chekuri-Vondrák-Zenklusen using this auxiliary graph. Indeed, each step of their algorithm can be seen as an update using a directed cycle of length two in the auxiliary graph. This interpretation motivates us to focus on a directed cycle of arbitrary length in the auxiliary graph instead of a directed cycle of length two. By extending the argument of Chekuri-Vondrák-Zenklusen, we show that we can appropriately update bases using a directed cycle of arbitrary length in the auxiliary graph.

Second, we show that we can find a directed cycle in the auxiliary graph using $o(r)$ independence oracle queries with high probability, which is the most technical part in our argument. To achieve this, we combine sampling technique and binary search technique.

In our algorithm for finding a directed cycle in the auxiliary graph, we first sample $\tilde{O}(\sqrt{r})$ vertices, and define D' as the subgraph induced by the sampled vertex set. If every vertex in D' has an incoming edge, then we can easily find a directed cycle in D' by traversing such directed edges in the opposite direction. Otherwise, by using a vertex with no incoming edge, we find a directed cycle of length two using $\tilde{O}(\sqrt{r})$ independence oracle queries with high probability. We can check whether each vertex in D' has an incoming edge or not using $\tilde{O}(1)$ independence oracle queries with the aid of the binary search technique proposed by Nguyễn [36] and Chakrabarty-Lee-Sidford-Singla-Wong [14]; see Lemma 4 for details. Note that this technique was used in recent studies on fast matroid intersection [8,10,14,36,39] and matroid partition [38] algorithms. Therefore, we obtain an algorithm that finds a directed cycle using $\tilde{O}(\sqrt{r})$ independence oracle queries with high probability.

In our rounding algorithm, we update bases using a directed cycle in the auxiliary graph repeatedly. Since we update bases $O(rt)$ times and each update requires $\tilde{O}(\sqrt{r})$ independence oracle queries, the total number of independence oracle queries is $\tilde{O}(r^{3/2}t)$ with high probability.

1.4 Related Work

We have mentioned several recent studies on fast submodular maximization with matroid constraints in Section 1.1. Other than these, there are a lot of studies on fast submodular maximization algorithms in the literature [2, 3, 15, 20, 25, 30, 32].

Badanidiyuru-Vondrák [3] developed a $(1 - 1/e - \varepsilon)$-approximation algorithm using $O(\frac{n}{\varepsilon}\log(\frac{n}{\varepsilon}))$ value oracle queries for the cardinality constraint. Mirzasoleiman-Badanidiyuru-Ashwinkumar-Karbasi-Vondrák-Krause [32] developed a $(1-1/e-\varepsilon)$-approximation algorithm using $O(n\log(1/\varepsilon))$ value oracle queries for the cardinality constraint. Ene-Nguyễn [20] developed a $(1 - 1/e - \varepsilon)$-approximation algorithm using $(1/\varepsilon)^{O(1/\varepsilon^4)}n\log^2 n$ value oracle queries for the knapsack constraint. Filmus-Ward [25] presented a combinatorial $(1 - 1/e)$-approximation algorithm for monotone submodular maximization with a matroid constraint, which uses $O(n^7r^2)$ oracle queries. They also obtain a $(1 - 1/e - O(\varepsilon))$-approximation algorithm that uses $O(\varepsilon^{-3}n^4r)$ value oracle queries and $O(\varepsilon^{-1}n^2r\log n)$ independence oracle queries.

Studies on fast submodular maximization algorithms have developed also in the direction of parallelized settings [4, 5, 16, 21, 23], distributed settings [7, 31], and dynamic settings [6, 19, 29, 33].

Chekuri-Quanrud-Torres [17] developed a fast swap rounding algorithm for graphic matroid constraints to obtain fast approximation algorithms for the Bounded Degree MST problem and the Crossing Spanning Tree problem.

1.5 Paper Organization

The remaining of this paper is organized as follows. In Section 2, we give some preliminaries. In Section 3, we show how to derive Theorem 1 from our fast rounding algorithm in Theorem 2. In Section 4, we describe the swap rounding algorithm by Chekuri-Vondrák-Zenklusen [18] in detail, because it is the basis of our rounding algorithm. In Section 5, we describe our fast rounding algorithm and prove Theorem 2, which is the main technical part of this paper. In Section 6, we discuss the rank oracle setting and prove Theorem 3.

2 Preliminaries

Basic Notation. Let $\mathbb{R}_+$ denote the set of non-negative real numbers. Throughout this paper, let V be a finite set and let n denote its cardinality. For a set $A \subseteq V$ and an element $v \in V$, we will often write $A+v := A \cup \{v\}$ and $A-v := A \setminus \{v\}$. For two sets $A, B \subseteq V$, their symmetric difference is denoted by $A \triangle B := (A \setminus B) \cup (B \setminus A)$. For $A \subseteq V$, the *characteristic vector* of A is defined as the vector $x \in \{0,1\}^V$ with $x_v = 1$ for $v \in A$ and $x_v = 0$ for $v \in V \setminus A$. We will denote by $\mathbf{1}_A$ the characteristic vector of A. For $v \in V$, we will write $\mathbf{1}_v := \mathbf{1}_{\{v\}}$.

Submodular Functions and Multilinear Extension. Let $f\colon 2^V \to \mathbb{R}_+$ be a set function on a finite ground set V of size n. The function is *submodular* if $f(A)+f(B) \geq f(A \cup B)+f(A \cap B)$ for any two subsets $A, B \subseteq V$. The function is *monotone* if $f(A) \leq f(B)$ for any subsets $A \subseteq B \subseteq V$. In this paper, we only consider monotone submodular functions.

For a function $f\colon 2^V \to \mathbb{R}_+$, we define its *multilinear extension* $F\colon [0,1]^V \to \mathbb{R}_+$ by

$$F(x) = \sum_{S \subseteq V} f(S) \prod_{v \in S} x_v \prod_{v \in V \setminus S} (1 - x_v)$$

for $x \in [0,1]^V$. Note that this value is equal to $\mathbb{E}[f(R(x))]$, where $R(x)$ is a random set that contains each element $v \in V$ independently with probability x_v. In particular, $F(\mathbf{1}_S) = f(S)$ for any $S \subseteq V$.

Matroids. A pair $\mathcal{M} = (V, \mathcal{I})$ of a finite set V and a non-empty set family $\mathcal{I} \subseteq 2^V$ is called a *matroid* if the following properties are satisfied.

(Downward closure property) if $S \in \mathcal{I}$ and $S' \subseteq S$, then $S' \in \mathcal{I}$.
(Augmentation property) if $S, S' \in \mathcal{I}$ and $|S'| < |S|$, then there exists $v \in S \setminus S'$ such that $S' + v \in \mathcal{I}$.

A set $S \subseteq V$ is called *independent* if $S \in \mathcal{I}$ and *dependent* otherwise. The *rank* of $\mathcal{M}$ is defined as the size of a largest independent set. In addition, for a subset $S \subseteq V$, the rank of S is defined as the size of a largest independent set contained in S. Inclusionwise maximal independent sets are called *bases*. Note that every basis has the same size. For an independent set $S \in \mathcal{I}$, let $\mathcal{M}/S = (V \setminus S, \mathcal{I}')$ be the matroid obtained by contracting S in $\mathcal{M}$, that is, $S' \in \mathcal{I}'$ if and only if $S' \cup S \in \mathcal{I}$.

Let $\mathcal{B}$ be the set of all bases of a matroid $\mathcal{M} = (V, \mathcal{I})$ and let $B, B' \in \mathcal{B}$ be two bases. It is well-known that, for any $u \in B \setminus B'$, there exists $v \in B' \setminus B$ such that $B - u + v \in \mathcal{B}$ and $B' - v + u \in \mathcal{B}$ (see e.g., [37, Theorem 39.12]). This property is called *strong basis exchange property* of matroids.

Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid whose rank function and basis family are denoted by $r_{\mathcal{M}}$ and $\mathcal{B}$, respectively. The *matroid polytope* $P(\mathcal{M})$ is defined as the convex hull of the characteristic vectors of all the independent sets of $\mathcal{M}$. The *matroid base polytope* $B(\mathcal{M})$ is defined as the convex hull of the characteristic vectors of all the bases of $\mathcal{M}$. It is well-known that $P(\mathcal{M})$ and $B(\mathcal{M})$ are described as follows (see e.g., [37, Section 40.2]):

$$P(\mathcal{M}) := \mathrm{conv}\{\mathbf{1}_I \mid I \in \mathcal{I}\} = \left\{ x \in \mathbb{R}_+^V \;\middle|\; \sum_{v \in S} x_v \leq r_{\mathcal{M}}(S) \text{ for any } S \subseteq V \right\},$$

$$B(\mathcal{M}) := \mathrm{conv}\{\mathbf{1}_B \mid B \in \mathcal{B}\} = \left\{ x \in P(\mathcal{M}) \;\middle|\; \sum_{v \in V} x_v = r_{\mathcal{M}}(V) \right\}.$$

Oracles. When we consider the submodular maximization problem, we assume that the submodular function f is given as a value oracle, which takes as input any subset $S \subseteq V$ and outputs $f(S)$. We also assume that we access a matroid $\mathcal{M}$ through an oracle. Given a subset $S \subseteq V$, an *independence oracle* outputs whether $S \in \mathcal{I}$ or not. Given a subset $S \subseteq V$, a *rank oracle* outputs the rank of S, i.e., the size of a largest independent set contained in S. Note that the rank oracle is more powerful than the independence oracle, since one query of the rank oracle can determine whether a given subset is independent or not.

Binary Search Technique. For a matroid $\mathcal{M} = (V, \mathcal{I})$, an independent set $S \in \mathcal{I}$, an element $u \in V \setminus S$, and $T \subseteq S$, we consider a procedure that finds an element $v \in T$ with $S + u - v \in \mathcal{I}$ if one exists. Chakrabarty et al. [14] and Nguyễn [36] independently proved that this procedure can be implemented efficiently by using the binary search technique in the independence oracle model. Their result is formally described as follows.

▶ **Lemma 4** ([14, 36]). *There is an algorithm* `FindExchangeElement` *which, given a matroid* $\mathcal{M} = (V, \mathcal{I})$*, an independent set* $S \in \mathcal{I}$*, an element* $u \in V \setminus S$*, and* $T \subseteq S$*, finds an element* $v \in T$ *such that* $S + u - v \in \mathcal{I}$ *or otherwise determines that no such element exists, and uses* $O(\log |T|)$ *independence oracle queries.*

3 Submodular Maxmization Algorithm (Proof of Theorem 1)

In this section, we give a proof of Theorem 1 by combining the algorithm of Buchbinder-Feldman-Schwartz [12] and our rounding algorithm in Theorem 2. Note that a proof of Theorem 2 is given in Section 5 later.

For monotone submodular maximization with a matroid constraint, Buchbinder-Feldman-Schwartz presented a $(1 - 1/e - \varepsilon)$-approximation algorithm that has a trade-off between the number of value oracle queries and the number of independence oracle queries used in the algorithm. The main part of their algorithm is to solve the continuous relaxation of the submodular maximization problem efficiently.

Let $\lambda \in [1, r]$ be a parameter that controls the trade-off. In their algorithm for solving the continuous relaxation problem, they first apply a variant of the residual random greedy algorithm of Buchbinder-Feldman-Naor-Schwartz [11]. This residual random greedy algorithm outputs $S \subseteq V$ and uses $\tilde{O}_\varepsilon(r\lambda + n)$ value oracle queries and $\tilde{O}_\varepsilon(\lambda n)$ independence oracle queries; see [12, Lemma 3.3]. Then they apply a variant of the fast continuous greedy algorithm of Badanidiyuru-Vondrák [3]. This continuous greedy algorithm outputs a point x' represented as a convex combination of $1/\varepsilon$ bases of $\mathcal{M}/S$ and uses $\tilde{O}_\varepsilon(\frac{rn}{\lambda})$ value oracle queries and $\tilde{O}_\varepsilon(n)$ independence oracle queries; see [12, Corollary 3.1]. Then $x = \mathbf{1}_S \vee x'$ is an approximate solution for the continuous relaxation problem, which can be represented as a convex combination of $1/\varepsilon$ bases of $\mathcal{M}$. Here, for vectors y and z, let $y \vee z$ denote the vector such that $(y \vee z)_i = \max\{y_i, z_i\}$ for all i.

Overall, Buchbinder-Feldman-Schwartz [12] presented an efficient algorithm for solving the continuous relaxation problem, which is formally stated as follows.

▶ **Theorem 5** (follows from [12, Corollary 3.1] and [12, Lemma 3.3]). *Given a non-negative monotone submodular function* $f\colon 2^V \to \mathbb{R}_+$*, a matroid* $\mathcal{M} = (V, \mathcal{I})$ *of rank* r*, and parameters* $\varepsilon > 0$ *and* $\lambda \in [1, r]$*, there is an algorithm satisfying the following conditions:*

- *the algorithm outputs a point* $x \in B(\mathcal{M})$ *represented as a convex combination of* $1/\varepsilon$ *bases such that* $\mathbb{E}[F(x)] \geq (1 - 1/e - \varepsilon) \cdot \max\{f(T) \mid T \in \mathcal{I}\}$ *holds, where* $F\colon [0,1]^V \to \mathbb{R}_+$ *is the multilinear extension of* f*,*

- *it uses* $O\left(r\lambda + \frac{rn}{\lambda\varepsilon^5}\log^2\left(\frac{n}{\varepsilon}\right)\right)$ *value oracle queries, and*
- *it uses* $O\left(\frac{\lambda n}{\varepsilon^2}\log\left(\frac{n}{\varepsilon}\right)\right)$ *independence oracle queries.*

Suppose that $x \in B(\mathcal{M})$ is a point as in Theorem 5. In the submodular maximization algorithm of Buchbinder-Feldman-Schwartz, they round x to an integral solution with the aid of the swap rounding algorithm of Chekuri-Vondrák-Zenklusen [18] using $O(r^2/\varepsilon)$ independence oracle queries. Therefore, their entire algorithm requires $\tilde{O}_\varepsilon(r\lambda + \frac{rn}{\lambda})$ value oracle queries and $\tilde{O}_\varepsilon(\lambda n + r^2)$ independence oracle queries.

▶ Remark 6. Theorem 5 is not explicitly stated in the paper by Buchbinder-Feldman-Schwartz [12], because they do not separately evaluate the query complexity for solving the continuous relaxation problem and for the rounding algorithm. Indeed, they just state that the entire algorithm requires $O(\frac{r^2}{\varepsilon} + \frac{\lambda n}{\varepsilon^2}\log\left(\frac{n}{\varepsilon}\right))$ independence oracle queries; see [12, Theorem 1.1]. The $O(\frac{r^2}{\varepsilon})$ term in this query complexity comes from [12, Corollary 3.1], which states that the continuous greedy algorithm together with the rounding algorithm requires $O(\frac{n}{\varepsilon^2}\log(\frac{n}{\varepsilon}) + \frac{r^2}{\varepsilon})$ independence oracle queries. This corollary is a direct consequence of [3, Claim 4.4], whose proof shows that the $O(\frac{r^2}{\varepsilon})$ term comes from the rounding algorithm, while the $O(\frac{n}{\varepsilon^2}\log(\frac{n}{\varepsilon}))$ term comes from the continuous greedy algorithm. Therefore, the $O(\frac{r^2}{\varepsilon})$ term is not needed to solve the continuous relaxation problem.

We now show that our submodular maximization algorithm with subquadratic query complexity is derived from Theorems 2 and 5.

Proof of Theorem 1. Let $\lambda = \Theta(\sqrt{r})$ and let $\varepsilon' = \varepsilon/2$. Note that we can compute r using $O(n)$ independence oracle queries by a greedy algorithm. We first run the algorithm in Theorem 5 with parameters λ and ε' to obtain a point $x \in B(\mathcal{M})$, in which we use $O(\sqrt{r}n\ \mathrm{poly}(1/\varepsilon, \log n))$ value and independence oracle queries. For the obtained point x, we apply our fast rounding algorithm in Theorem 2 with an error parameter ε'. Then, we obtain a basis S of $\mathcal{M}$ such that

$$\begin{aligned}\mathbb{E}[f(S)] &\geq (1-\varepsilon')\cdot\mathbb{E}[F(x)]\\ &\geq (1-\varepsilon')\cdot(1-1/e-\varepsilon')\cdot\max\{f(T)\mid T\in\mathcal{I}\}\\ &\geq (1-1/e-\varepsilon)\cdot\max\{f(T)\mid T\in\mathcal{I}\}.\end{aligned}$$

Since x is represented as a convex combination of $1/\varepsilon'$ bases of $\mathcal{M}$ by Theorem 5, our rounding algorithm requires $O(r^{3/2}\ \mathrm{poly}(1/\varepsilon, \log n))$ independence oracle queries by Theorem 2. Therefore, we obtain a $(1-1/e-\varepsilon)$-approximation algorithm that uses $O(\sqrt{r}n\ \mathrm{poly}(1/\varepsilon, \log n))$ value and independence oracle queries, which completes the proof. ◀

4 Swap Rounding Algorithm in Previous Work

In this section, we describe the swap rounding algorithm of Chekuri-Vondrák-Zenklusen [18] for a matroid base polytope, which we denote `SwapRound`. As described in Section 1.3, our new rounding algorithm is based on `SwapRound`. In `SwapRound`, we are given a point $x \in B(\mathcal{M})$ that is represented as a convex combination of the characteristic vectors of t bases of $\mathcal{M}$. The output is a single basis S of $\mathcal{M}$ such that $\mathbb{E}[f(S)] \geq F(x)$ for any submodular function $f\colon 2^V \to \mathbb{R}$ and its multilinear extension F. In each phase of `SwapRound`, we pick up two bases in the representation of x and merge them into a basis. By applying this procedure $t-1$ times, `SwapRound` finally returns a single basis of $\mathcal{M}$; see Algorithm 1.

The procedure for merging two bases is denoted by `MergeBases` (Algorithm 2). The input of `MergeBases` consists of two bases B_1 and B_2 together with their coefficients β_1 and β_2. In the procedure, until B_1 and B_2 coincide, we repeatedly update B_1 and B_2 so that $|B_1 \setminus B_2|$ decreases monotonically. In each update of B_1 and B_2, we need a *strongly exchangeable pair* of elements, that is, a pair of elements $u \in B_1 \setminus B_2$ and $v \in B_2 \setminus B_1$ such that $B_1 + v - u \in \mathcal{I}$ and $B_2 + u - v \in \mathcal{I}$. As described in `UpdateViaStrongBasisExchange` (Algorithm 3), for a strongly exchangeable pair u and v, we apply $B_1 \leftarrow B_1 + v - u$ with probability $\frac{\beta_2}{\beta_1+\beta_2}$ and apply $B_2 \leftarrow B_2 + u - v$ with the remaining probability. Note that, in `UpdateViaStrongBasisExchange`, B_1 and B_2 are updated to B_1' and B_2' so that $\mathbb{E}[\beta_1 \mathbf{1}_{B_1'} + \beta_2 \mathbf{1}_{B_2'}] = \beta_1 \mathbf{1}_{B_1} + \beta_2 \mathbf{1}_{B_2}$, which is a key property to show the validity of the algorithm.

The most time consuming part in `MergeBases` is to find a strongly exchangeable pair. By the strong basis exchange property of matroids, we can find such a pair of elements using $O(r)$ independence oracle queries in the following way: fix an element $u \in B_1 \setminus B_2$ arbitrarily and check the conditions for each element $v \in B_2 \setminus B_1$ one by one. Since we update the bases $|B_1 \setminus B_2| = O(r)$ times, `MergeBases` requires $O(r^2)$ independence oracle queries in total. Hence, `SwapRound` requires $O(r^2 t)$ independence oracle queries.

It is not clear whether we can develop an algorithm that finds a strongly exchangeable pair using $o(r)$ independence oracle queries. Therefore, their implementation of `SwapRound` is now stuck at $\Omega(r^2 t)$ independence oracle queries.

Algorithm 1 `SwapRound`$(x = \sum_{i=1}^{t} \beta_i \mathbf{1}_{B_i})$.

```
C_1 ← B_1
γ_1 ← β_1
for i = 1 to t − 1 do
    C_{i+1} ← MergeBases(γ_i, C_i, β_{i+1}, B_{i+1})
    γ_{i+1} ← γ_i + β_{i+1}
return C_t
```

Algorithm 2 `MergeBases`$(\beta_1, B_1, \beta_2, B_2)$.

```
while B_1 ≠ B_2 do
    Pick arbitrary u ∈ B_1 \ B_2
    Find v ∈ B_2 \ B_1 such that B_1 + v − u ∈ I and B_2 + u − v ∈ I
    UpdateViaStrongBasisExchange(β_1, B_1, β_2, B_2, v, u)
return B_1
```

5 Faster Rounding Algorithm

In this section, we present our fast rounding algorithm. We first show the following theorem, and then prove Theorem 2 using this theorem.

▶ **Theorem 7.** *There is a randomized algorithm satisfying the following conditions:*

- *the input consists of a matroid $\mathcal{M} = (V, \mathcal{I})$ given as an independence oracle and a point $x \in B(\mathcal{M})$ represented as a convex combination of t bases,*
- *the output is a basis S of $\mathcal{M}$ such that $\mathbb{E}[f(S)] \geq F(x)$ for any submodular function $f\colon 2^V \to \mathbb{R}$ and its multilinear extension F, and*
- *it uses $O(r^{3/2} t \log^{3/2}(rt))$ independence oracle queries with probability at least $1 - (rt)^{-1}$.*

Algorithm 3 `UpdateViaStrongBasisExchange`$(\beta_1, B_1, \beta_2, B_2, v, u)$.

Input: $\beta_1, \beta_2 \in \mathbb{R}_+$, two bases B_1, B_2, and elements $v \in B_2 \setminus B_1$ and $u \in B_1 \setminus B_2$ such that $B_1 + v - u \in \mathcal{I}$ and $B_2 + u - v \in \mathcal{I}$

Flip a coin with `Heads` probability $\dfrac{\beta_2}{\beta_1 + \beta_2}$

if *coin flipped* `Heads` **then**

  $B_1 \leftarrow B_1 + v - u$

else

  $B_2 \leftarrow B_2 + u - v$

To show this theorem, we propose an algorithm that merges the bases one by one in the same way as `SwapRound`. Our contribution is to improve `MergeBases`, that is, we give a faster algorithm for merging two bases into a single basis. The following auxiliary graph plays an important role in our algorithm.

▶ **Definition 8.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid, and let B_1, B_2 be two bases of $\mathcal{M}$. Then we define the bipartite directed graph $D_{\mathcal{M}}(B_1, B_2)$ whose vertex set and edge set are $B_1 \triangle B_2$ and $E_1(B_1, B_2) \cup E_2(B_1, B_2)$, respectively, where*

$$E_1(B_1, B_2) = \{(u, v) \mid u \in B_1 \setminus B_2, v \in B_2 \setminus B_1, B_1 + v - u \in \mathcal{I}\},$$
$$E_2(B_1, B_2) = \{(v, u) \mid u \in B_1 \setminus B_2, v \in B_2 \setminus B_1, B_2 + u - v \in \mathcal{I}\}.$$

In terms of this auxiliary graph, each step of `MergeBases` can be interpreted as follows: it finds a directed cycle of length two (or a bidirected edge) in $D_{\mathcal{M}}(B_1, B_2)$ and updates the bases B_1 and B_2 using this directed cycle as in `UpdateViaStrongBasisExchange`. Note that we use $O(r)$ independence oracle queries to find a directed cycle of length two.

A key idea in our algorithm is to focus on a directed cycle of arbitrary length in $D_{\mathcal{M}}(B_1, B_2)$ instead of a directed cycle of length two. More precisely, our contribution consists of the following two technical results.

1. We can find a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$ using $o(r)$ independence oracle queries with high probability.
2. We can appropriately update the bases using a directed cycle of arbitrary length in $D_{\mathcal{M}}(B_1, B_2)$.

We discuss the first and second technical results in Sections 5.1 and 5.2, respectively. Then, we describe the entire algorithm and give proofs for Theorems 2 and 7 in Section 5.3.

5.1 Finding a Directed Cycle

The objective of this subsection is to show the following proposition, which states that we can find a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$ using $o(r)$ independence oracle queries with high probability.

▶ **Proposition 9.** *Suppose we are given two bases B_1 and B_2 of a matroid $\mathcal{M}$ and an integer $t \geq 2$. Then, we can find a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$ using $O(\sqrt{r}\log^{3/2}(rt))$ independence oracle queries with probability at least $1 - (rt)^{-2}$.*

To show this proposition, we first show that a directed cycle of length two can be found efficiently if we have an element whose indegree is small in $D_{\mathcal{M}}(B_1, B_2)$.

▶ **Lemma 10.** *Suppose we are given two bases B_1 and B_2 of a matroid $\mathcal{M}$, and an element $a \in B_1 \triangle B_2$ whose indegree is d in $D_{\mathcal{M}}(B_1, B_2)$. Then, we can find a directed cycle of length two in $D_{\mathcal{M}}(B_1, B_2)$ using $O(d \log r)$ independence oracle queries.*

Proof. By symmetry, it suffices to consider the case when $a \in B_1 \setminus B_2$.

We give an algorithm that finds an element $v \in B_2 \setminus B_1$ such that $B_1 + v - a \in \mathcal{I}$ and $B_2 + a - v \in \mathcal{I}$. In our algorithm, let $A \subseteq B_2 \setminus B_1$ denote the set of elements v such that we have already checked that $B_1 + v - a \notin \mathcal{I}$. We initialize $A = \emptyset$.

In each step of our algorithm, by applying Lemma 4 in which $u = a$, $S = B_2$, and $T = B_2 \setminus (B_1 \cup A)$, we can find an element $v \in T$ such that $B_2 + a - v \in \mathcal{I}$ if it exists. For such v, we check whether $B_1 + v - a \in \mathcal{I}$ holds or not. If $B_1 + v - a \in \mathcal{I}$ holds, then a and v induce a desired directed cycle. Otherwise, we add v to A, and repeat the procedure.

This algorithm finds a directed cycle correctly by the strong basis exchange property. Since we apply Lemma 4 at most d times and $|T| \leq r$, this algorithm uses $O(d \log r)$ independence oracle queries. ◀

We now describe our algorithm for finding a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$. In our algorithm, we first sample $2\sqrt{r \log(rt)}$ elements from $B_1 \setminus B_2$ (resp. $B_2 \setminus B_1$) uniformly at random with replacement, where the base of the logarithm is e, and let L (resp. R) be the sampled vertex set, ignoring the multiplicity. Note that $1 \leq |L| \leq 2\sqrt{r \log(rt)}$ and $1 \leq |R| \leq 2\sqrt{r \log(rt)}$ as we ignore the multiplicity. Let D' be the subgraph of $D_{\mathcal{M}}(B_1, B_2)$ induced by $L \cup R$.

For each vertex u in D', we find a directed edge in D' that enters u or conclude that such a directed edge does not exist. This can be done by calling `FindExchangeElement` exactly once for each u. If every vertex in D' has an incoming edge, then we can easily find a directed cycle in D' by traversing such directed edges in the opposite direction. Otherwise, we pick up a vertex a in $L \cup R$ that has no incoming edge in D', and then apply Lemma 10 with this vertex a to find a directed cycle of length two.

Since the correctness of this algorithm is clear, it suffices to analyze the independence query complexity. We use the following lemma in our analysis.

▶ **Lemma 11.** *Let $u \in B_1 \triangle B_2$ be an element whose indegree in $D_{\mathcal{M}}(B_1, B_2)$ is at least $2\sqrt{r \log(rt)}$. Then, the probability that $D_{\mathcal{M}}(B_1, B_2)$ has no directed edge from $L \cup R$ to u is at most $(rt)^{-4}$.*

Proof. By symmetry, it suffices to consider the case when $u \in B_1 \setminus B_2$. Let $N = \{v \in B_2 \setminus B_1 \mid (v, u) \in E(B_1, B_2)\}$. Since R is obtained by sampling $2\sqrt{r \log(rt)}$ vertices from $B_2 \setminus B_1$ and $r \geq |B_2 \setminus B_1| \geq |N| \geq 2\sqrt{r \log(rt)}$, we have the following:

$$\begin{aligned}
\Pr\left[\{v \in R \mid (v, u) \in E(B_1, B_2)\} = \emptyset\right] &= \Pr\left[N \cap R = \emptyset\right] \\
&= \left(1 - \frac{|N|}{|B_2 \setminus B_1|}\right)^{2\sqrt{r \log(rt)}} \\
&\leq \left(1 - \frac{2\sqrt{r \log(rt)}}{r}\right)^{2\sqrt{r \log(rt)}} \\
&\leq \left(e^{-1}\right)^{4 \log(rt)} \\
&= (rt)^{-4},
\end{aligned}$$

which completes the proof. ◀

We are now ready to prove Proposition 9.

Proof of Proposition 9. We analyze the independence query complexity of the algorithm described above. First, since we call `FindExchangeElement` for each vertex $u \in L \cup R$ exactly once to find an incoming edge in D', the number of calls of `FindExchangeElement` is $|L \cup R| = O(\sqrt{r \log(rt)})$. Hence, by Lemma 4, the number of independence oracle queries used in this part is $O(\sqrt{r \log(rt)} \log r)$.

We next analyze the number of independence oracle queries when there exists a vertex $a \in L \cup R$ that has no incoming edge in D'.

We call a vertex $u \in L \cup R$ *bad* if D' has no directed edge entering u and $D_{\mathcal{M}}(B_1, B_2)$ has at least $2\sqrt{r \log(rt)}$ directed edges entering u. By Lemma 11, for each $u \in L \cup R$, the vertex u is bad with probability at most $(rt)^{-4}$. Thus, by taking the union bound over all vertices in $L \cup R$, we see that there exists a bad vertex in $L \cup R$ with probability at most $(rt)^{-2}$.

We now consider the case where there is no bad vertex in $L \cup R$. Suppose that there exists a vertex $a \in L \cup R$ that has no incoming edge in D'. Then, since a is not bad, the indegree of a is at most $2\sqrt{r \log(rt)}$ in $D_{\mathcal{M}}(B_1, B_2)$. Therefore, we can apply Lemma 10 with a using $O(\sqrt{r \log(rt)} \log r)$ independence oracle queries.

Therefore, the total number of independence oracle queries used in the algorithm is $O(\sqrt{r \log(rt)} \log r)$ with probability at least $1 - (rt)^{-2}$, which completes the proof. ◀

5.2 Update with a Directed Cycle

In this subsection, we describe how to update the bases using a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$. Let C be a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$ that traverses $u_0, v_0, u_1, v_1, \ldots, v_{l-1}$ in this order, where $u_i \in B_1 \setminus B_2$ and $v_i \in B_2 \setminus B_1$ for each i. In our algorithm, we first choose B_1 with probability $\frac{\beta_2}{\beta_1+\beta_2}$ and choose B_2 with the remaining probability. If we choose B_1, then we pick up an index i uniformly at random from $\{0, \ldots, l-1\}$ and update B_1 by $B_1 \leftarrow B_1 + v_i - u_i$. If we choose B_2, then we pick up an index i uniformly at random from $\{0, \ldots, l-1\}$ and update B_2 by $B_2 \leftarrow B_2 + u_{i+1} - v_i$, where we denote $u_l = u_0$. The pseudocode of this algorithm is shown in `UpdateWithCycle` (Algorithm 4). We note that, if the length of the directed cycle is two, then `UpdateWithCycle` coincides with `UpdateViaStrongBasisExchange`.

Algorithm 4 `UpdateWithCycle`$(\beta_1, B_1, \beta_2, B_2, C)$.

Input: $\beta_1, \beta_2 \in \mathbb{R}_+$, two bases B_1, B_2, and a directed cycle C in the bipartite directed graph $D_{\mathcal{M}}(B_1, B_2)$

Denote by $V(C) = \{u_0, v_0, u_1, v_1, \ldots, v_{l-1}\}$ the vertices in C in this order (with $u_i \in B_1 \setminus B_2$ and $v_i \in B_2 \setminus B_1$ for each i)

Flip a coin with `Heads` probability $\dfrac{\beta_2}{\beta_1 + \beta_2}$

if *coin flipped* `Heads` **then**

  Pick an index i uniformly at random from $\{0, \ldots, l-1\}$

  $B_1 \leftarrow B_1 + v_i - u_i$

else

  Pick an index i uniformly at random from $\{0, \ldots, l-1\}$

  $B_2 \leftarrow B_2 + u_{i+1} - v_i$ `// We define` $u_l = u_0$.

In order to show the validity of the algorithm, we use the following two lemmas.

▶ **Lemma 12.** *Given two bases B_1 and B_2 and a directed cycle C in the bipartite directed graph $D_{\mathcal{M}}(B_1, B_2)$, the procedure* `UpdateWithCycle` *updates B_1 and B_2 to B_1' and B_2', respectively, so that $\mathbb{E}[\beta_1 \mathbf{1}_{B_1'} + \beta_2 \mathbf{1}_{B_2'}] = \beta_1 \mathbf{1}_{B_1} + \beta_2 \mathbf{1}_{B_2}$.*

Proof. Recall that C traverses $u_0, v_0, u_1, v_1, \ldots, v_{l-1}$ in this order, where $u_i \in B_1 \setminus B_2$ and $v_i \in B_2 \setminus B_1$ for each i. In the procedure `UpdateWithCycle`, we obtain $B_1' = B_1 + v_i - u_i$ for some $i \in \{0, \ldots, l-1\}$ and $B_2' = B_2$ with probability $\beta_2/(\beta_1 + \beta_2)$, and we obtain $B_1' = B_1$ and $B_2' = B_2 + u_{i+1} - v_i$ for some $i \in \{0, \ldots, l-1\}$ with probability $\beta_1/(\beta_1 + \beta_2)$. Thus, we have the following equation:

$$\begin{aligned}\mathbb{E}[\beta_1 \mathbf{1}_{B_1'} + \beta_2 \mathbf{1}_{B_2'}] =& \frac{\beta_2}{\beta_1 + \beta_2} \left(\beta_1 \left(\mathbf{1}_{B_1} + \frac{1}{l} \sum_{i=0}^{l-1} (\mathbf{1}_{v_i} - \mathbf{1}_{u_i}) \right) + \beta_2 \mathbf{1}_{B_2} \right) \\ &+ \frac{\beta_1}{\beta_1 + \beta_2} \left(\beta_1 \mathbf{1}_{B_1} + \beta_2 \left(\mathbf{1}_{B_2} + \frac{1}{l} \sum_{i=0}^{l-1} (\mathbf{1}_{u_{i+1}} - \mathbf{1}_{v_i}) \right) \right) \\ =& \beta_1 \mathbf{1}_{B_1} + \beta_2 \mathbf{1}_{B_2}.\end{aligned}$$

This completes the proof. ◀

▶ **Lemma 13** ([18, Lemma VI.2]). *Let $x \in \mathbb{R}_+^n$ be a non-negative vector and $\mathbf{X} = (X_1, \ldots, X_n)$ be a non-negative vector-valued random variable satisfying the following properties:*

- *$\mathbb{E}[\mathbf{X}] = x$, and*
- *$\mathbf{X} - x$ has at most one positive coordinate and at most one negative coordinate.*

Then, we have $\mathbb{E}[F(\mathbf{X})] \geq F(x)$ for any function F that is a multilinear extension of some submodular function.

By combining these lemmas, we obtain the following proposition, which shows the validity of `UpdateWithCycle`.

▶ **Proposition 14.** *Let $x = \sum_{i=1}^t \beta_i \mathbf{1}_{B_i}$ be a point represented by a convex combination of the characteristic vectors of t bases of a matroid $\mathcal{M}$. Suppose that the procedure* `UpdateWithCycle` *updates B_1 and B_2 to B_1' and B_2' using a directed cycle in $D_{\mathcal{M}}(B_1, B_2)$. Let $B_i' = B_i$ for $i \in \{3, \ldots, t\}$ and let $x' = \sum_{i=1}^t \beta_i \mathbf{1}_{B_i'}$. Then, we obtain $\mathbb{E}[F(x')] \geq F(x)$ for any function F that is a multilinear extension of some submodular function.*

Proof. It is obvious that $x' - x$ has at most one positive coordinate and at most one negative coordinate, since only two coordinate are involved in `UpdateWithCycle`, and exactly one of them increases and the other decreases. We also see that $\mathbb{E}[x'] = x$ holds by Lemma 12. Therefore, Lemma 13 shows that $\mathbb{E}[F(x')] \geq F(x)$ for any function F that is a multilinear extension of some submodular function. ◀

5.3 Whole Algorithm

We now prove Theorem 7 by giving our fast swap rounding algorithm. See `FastMergeBases` (Algorithm 5) for the pseudocode of our algorithm.

Proof of Theorem 7. Suppose that $x = \sum_{i=1}^t \beta_i \mathbf{1}_{B_i}$ is a point represented by a convex combination of the characteristic vectors of t bases of a matroid $\mathcal{M}$. We pick up two bases, say B_1 and B_2, in the representation and merge them into a single basis in the following way: until B_1 and B_2 coincide, we find a directed cycle C in $D_{\mathcal{M}}(B_1, B_2)$ using Proposition 9, and update B_1 and B_2 by `UpdateWithCycle` using C. Our algorithm repeats this process $t - 1$ times so that all the bases are merged into a single basis.

Since the correctness of this algorithm is shown by Proposition 14, it remains to analyze the independence query complexity of this rounding algorithm.

For merging two bases into a single basis, since we apply Proposition 9 at most r times, we require $O(r^{3/2}\log^{3/2}(rt))$ independence oracle queries with probability at least $1-r^{-1}t^{-2}$. Furthermore, since we apply this procedure $t-1$ times in our swap rounding algorithm, the entire algorithm requires $O(tr^{3/2}\log^{3/2}(rt))$ independence oracle queries with probability at least $1-(rt)^{-1}$. This completes the proof of Theorem 7. ◀

We can remove the condition "with probability at least $1-(rt)^{-1}$" by losing a sufficiently small approximation factor $\varepsilon > 0$. That is, we obtain Theorem 2, which we restate here.

▶ **Theorem 2.** *For any $\varepsilon > 0$, there is a randomized algorithm satisfying the following conditions:*

- *the input consists of a matroid $\mathcal{M} = (V, \mathcal{I})$ given as an independence oracle and a point x in the base polytope of $\mathcal{M}$ that is represented as a convex combination of t bases,*
- *the output is a basis S of $\mathcal{M}$ such that $\mathbb{E}[f(S)] \geq (1-\varepsilon)F(x)$ for any submodular function $f\colon 2^V \to \mathbb{R}$ and its multilinear extension F, and*
- *it uses $O(r^{3/2}t\log^{3/2}(\frac{rt}{\varepsilon}))$ independence oracle queries.*

Proof. Recall that the algorithm in Theorem 7 (Algorithm 5) uses $O(r^{3/2}t\log^{3/2}(rt))$ independence oracle queries with probability at least $1-(rt)^{-1}$. If Algorithm 5 returns a basis using $O(r^{3/2}t\log^{3/2}(rt))$ independence oracle queries, then we say that it *succeeds*. Otherwise, we say that it *fails*. By a slight modification, when the algorithm fails, we suppose that it uses $O(r^{3/2}t\log^{3/2}(rt))$ independence oracle queries and terminates without returning a basis. This modified algorithm is denoted by Algorithm 5'. Note that Algorithm 5' fails with probability at most $(rt)^{-1}$.

Let $q := \lceil \log_{(rt)^{-1}} \varepsilon \rceil = \lceil \frac{\log(1/\varepsilon)}{\log rt} \rceil = O\left(\frac{\log(rt/\varepsilon)}{\log rt}\right)$. In our algorithm, we run Algorithm 5' q times. If at least one execution of Algorithm 5' succeeds, then our algorithm returns a basis that is obtained in the first successful execution of Algorithm 5'. If all the executions of Algorithm 5' fail, then our algorithm returns an arbitrary basis. Then, we use $O(r^{3/2}t\log^{3/2}(\frac{rt}{\varepsilon}))$ independence oracle queries in total. Furthermore, the probability that all the executions of Algorithm 5' fail is at most $(rt)^{-q} \leq \varepsilon$. Therefore, the output S satisfies $\mathbb{E}[f(S)] \geq (1-\varepsilon)F(x)$ for any submodular function f and its multilinear extension F. This completes the proof. ◀

6 Submodular Maximization with Rank Oracle

In this section, we present a fast submodular maximization algorithm in the rank oracle model and prove Theorem 3. In the rank oracle setting, the input consists of a monotone submodular set function $f\colon 2^V \to \mathbb{R}_+$ given as a value oracle, and a matroid $\mathcal{M} = (V, \mathcal{I})$ given as a rank oracle. The objective is to maximize $f(S)$ subject to $S \in \mathcal{I}$. We restate Theorem 3 here.

▶ **Theorem 3.** *For any $\varepsilon > 0$, there is a randomized algorithm that achieves $(1-1/e-\varepsilon)$-approximation for maximizing a monotone submodular function subject to a matroid constraint and uses $O((n+r^{3/2})\ \mathrm{poly}(1/\varepsilon, \log n))$ value and rank oracle queries.*

In the same way as the independence oracle setting, our algorithm is based on continuous relaxation and rounding technique.

Algorithm 5 `FastMergeBases`$(\beta_1, B_1, \beta_2, B_2)$.

while $B_1 \neq B_2$ **do**
  Sample a set L of $2\sqrt{r \log(rt)}$ elements drawn uniformly and independently from $B_1 \setminus B_2$ with replacement.
  Sample a set R of $2\sqrt{r \log(rt)}$ elements drawn uniformly and independently from $B_2 \setminus B_1$ with replacement.
  $a \leftarrow \emptyset$
  $E \leftarrow \emptyset$
  for $u \in L$ **do**
    $v \leftarrow$ `FindExchangeElement`$(\mathcal{M}, B_2, u, R)$
    if $v = \emptyset$ **then**
      $a \leftarrow u$
    else
      $E \leftarrow E \cup \{(u, v)\}$
  for $v \in R$ **do**
    $u \leftarrow$ `FindExchangeElement`$(\mathcal{M}, B_1, v, L)$
    if $u = \emptyset$ **then**
      $a \leftarrow v$
    else
      $E \leftarrow E \cup \{(v, u)\}$
  if $a = \emptyset$ **then**
    Find a directed cycle C in the bipartite directed graph $(L \cup R, E)$
    `UpdateWithCycle`$(\beta_1, B_1, \beta_2, B_2, C)$
  else
    if $a \in B_1 \setminus B_2$ **then**
      $A \leftarrow \emptyset$
      while $v =$ `FindExchangeElement`$(\mathcal{M}, B_2, a, B_2 \setminus (B_1 \cup A))$ *satisfies* $v \neq \emptyset$ **do**
        if $B_1 + v - a \in \mathcal{I}$ **then**
          `UpdateViaStrongBasisExchange`$(\beta_1, B_1, \beta_2, B_2, v, a)$
          break
        $A \leftarrow A + v$
    else
      $A \leftarrow \emptyset$
      while $u =$ `FindExchangeElement`$(\mathcal{M}, B_1, a, B_1 \setminus (B_2 \cup A))$ *satisfies* $u \neq \emptyset$ **do**
        if $B_2 + u - a \in \mathcal{I}$ **then**
          `UpdateViaStrongBasisExchange`$(\beta_1, B_1, \beta_2, B_2, a, u)$
          break
        $A \leftarrow A + u$
return B_1

Algorithm for the Continuous Relaxation Problem. Let F be the multilinear extension of f and let $P(\mathcal{M})$ be the matroid polytope of $\mathcal{M}$. Ene-Nguyễn [22] presented a framework to solve the continuous optimization problem $\max_{x \in P(\mathcal{M})} F(x)$ in near-linear time for several important classes of matroids. In their algorithm, they use a data structure for maintaining a maximum weight basis of the matroid, where each element has a weight and the weights are updated. In each update, the weight of exactly one element decreases, while all the other weights do not change. The data structure supports an operation that decreases the weight of an element and updates the current basis to a maximum weight basis with respect to the updated weights. This operation is called the *maximum weight basis data structure operation*. With this terminology, their result is stated as follows.

▶ **Lemma 15** (follows from Lemmas 8 and 9 in the arXiv version of [22]). *Given a non-negative monotone submodular function $f\colon 2^V \to \mathbb{R}_+$, a matroid $\mathcal{M} = (V, \mathcal{I})$ of rank r, and a parameter $\varepsilon > 0$, there is a randomized algorithm satisfying the following conditions:*

- *the algorithm finds a point $x \in P(\mathcal{M})$ represented as a convex combination of $1/\varepsilon$ bases such that $\mathbb{E}[F(x)] \geq (1 - 1/e - \varepsilon) \cdot \max\{f(T) \mid T \in \mathcal{I}\}$, where $F\colon [0,1]^V \to \mathbb{R}_+$ is the multilinear extension of f,*
- *it uses $O\left(\frac{n}{\varepsilon^5} \log^2\left(\frac{n}{\varepsilon}\right)\right)$ value oracle queries,*
- *it uses $O\left(\frac{n}{\varepsilon} \log\left(\frac{n}{\varepsilon}\right)\right)$ independence oracle queries, and*
- *it uses $O\left(\frac{r}{\varepsilon} \log^2\left(\frac{n}{\varepsilon}\right)\right)$ maximum weight basis data structure operations.*

Maximum Weight Basis Data Structure Operation. To implement a maximum weight basis data structure operation by using rank oracle queries efficiently, we use the following lemma obtained by the binary search technique of Nguyễn [36] and Chakrabarty et al. [14]; see also [39, Lemma 2].

▶ **Lemma 16** ([14, Lemma 10]; see also [39, Lemma 2] and [10]). *There is an algorithm* `FindFreeElement` *which, given a matroid $\mathcal{M} = (V, \mathcal{I})$, a weight function $w\colon V \to \mathbb{R}$, an independent set $S \in \mathcal{I}$, and $T \subseteq V \setminus S$, finds an element $u \in T$ maximizing $w(u)$ such that $S + u \in \mathcal{I}$ or otherwise determines that no such element exists, and uses $O(\log |T|)$ rank oracle queries.*

This lemma shows that the maximum weight basis data structure operation can be easily implemented in the rank oracle model as follows.

▶ **Lemma 17.** *Let $\mathcal{M} = (V, \mathcal{I})$ be a matroid given as a rank oracle and let $w\colon V \to \mathbb{R}$ be a weight function. Let $w'\colon V \to \mathbb{R}$ be a weight function such that $w'(v) < w(v)$ for some $v \in V$ and $w'(u) = w(u)$ for any $u \in V - v$. Given a maximum weight basis B of $\mathcal{M}$ with respect to w, we can compute a maximum weight basis B' of $\mathcal{M}$ with respect to w' using $\tilde{O}(1)$ rank oracle queries.*

Proof. If $v \notin B$, then $B' := B$ is a desired basis, because $w'(v) < w(v)$. Otherwise, we apply `FindFreeElement` with the weight function w' in which $S = B - v$ and $T = (V \setminus B) \cup \{v\}$. Let u be the element found by the procedure (possibly, $u = v$). Then our algorithm returns a basis $B' := B - v + u$, which is a maximum weight basis with respect to w' (see e.g., [28, Lemma 3.1] and Section 6 of the arXiv version of [9]). By Lemma 16, this algorithm requires $\tilde{O}(1)$ rank oracle queries. ◀

Putting Them Together (Proof of Theorem 3). We now prove Theorem 3. Lemma 17 shows that we can execute the maximum weight basis data structure operation using $\tilde{O}(1)$ rank oracle queries without a sophisticated data structure. Hence, by Lemma 15, we can solve the continuous optimization problem $\max_{x \in P(\mathcal{M})} F(x)$ using $\tilde{O}_\varepsilon(n)$ value and rank oracle queries, where we note that the rank oracle is more powerful than the independence oracle.

For the obtained point x, we apply our fast rounding algorithm given in Theorem 2 to obtain an integral solution. Note again that the rank oracle is more powerful than the independence oracle, and hence this rounding algorithm requires $\tilde{O}_\varepsilon(r^{3/2})$ value and rank oracle queries.

By replacing ε with $\varepsilon/2$ in the same way as in the proof of Theorem 1, we obtain a $(1 - 1/e - \varepsilon)$-approximation algorithm that uses $\tilde{O}_\varepsilon(n + r^{3/2})$ value and rank oracle queries, which completes the proof. ◀

Abstract

For an undirected unweighted graph $G = (V, E)$ with n vertices and m edges, let $d(u, v)$ denote the distance from $u \in V$ to $v \in V$ in G. An (α, β)-stretch approximate distance oracle (ADO) for G is a data structure that given $u, v \in V$ returns in constant (or near constant) time a value $\hat{d}(u, v)$ such that $d(u, v) \leq \hat{d}(u, v) \leq \alpha \cdot d(u, v) + \beta$, for some reals $\alpha > 1, \beta$.

Thorup and Zwick [34] showed that one cannot beat stretch 3 with subquadratic space (in terms of n) for general graphs. Pătraşcu and Roditty [27] showed that one can obtain stretch 2 using $O(m^{1/3}n^{4/3})$ space, and so if m is subquadratic in n then the space usage is also subquadratic. Moreover, Pătraşcu and Roditty [27] showed that one cannot beat stretch 2 with subquadratic space even for graphs where $m = \tilde{O}(n)$, based on the set-intersection hypothesis.

In this paper we explore the conditions for which an ADO can beat stretch 2 while using subquadratic space. In particular, we show that if the maximum degree in G is $\Delta_G \leq O(n^{1/k-\varepsilon})$ for some $0 < \varepsilon \leq 1/k$, then there exists an ADO for G that uses $\tilde{O}(n^{2-\frac{k\varepsilon}{3}})$ space and has a $(2, 1-k)$-stretch. For $k = 2$ this result implies a subquadratic sub-2 stretch ADO for graphs with $\Delta_G \leq O(n^{1/2-\varepsilon})$.

Moreover, we prove a conditional lower bound, based on the set intersection hypothesis, which states that for any positive integer $k \leq \log n$, obtaining a sub-$\frac{k+2}{k}$ stretch for graphs with $\Delta_G = \Theta(n^{1/k})$ requires $\tilde{\Omega}(n^2)$ space. Thus, for graphs with maximum degree $\Theta(n^{1/2})$, obtaining a sub-2 stretch requires $\tilde{\Omega}(n^2)$ space.

1 Introduction

One of the most fundamental and classic problems in algorithmic research is the task of computing distances in graphs. Formally, given an undirected unweighted graph $G = (V, E)$, $|V| = n$ and $|E| = m$, the distance between two vertices $u, v \in V$, denoted $d(u, v)$, is the length of a shortest path between u and v. A central problem in distance computations is the *all-pairs shortest paths* (APSP) problem [18, 10, 20, 16, 37, 12, 22] where the objective is to compute the distances between every pair of vertices in the graph. A main disadvantage in handling the output of the APSP problem is that storing the distances between every

pair of vertices in the graph requires $\Omega(n^2)$ space. As in many other problems in computer science, the lack of space efficiency in solving the APSP problem has motivated researchers to search for a tradeoff between space and accuracy. As a result, one central form of the APSP problem emerging from this line of research is constructing an *approximate distance oracle* where we sacrifice accuracy for space efficiency.

Approximate Distance Oracles. An approximate distance oracle (ADO) is a space efficient data structure that produces distance estimations between any two vertices in the graph in constant or near-constant time. Formally, given two vertices, $u, v \in V$, an ADO returns an estimation $\hat{d}(u,v)$ for the distance between u and v that satisfies: $d(u,v) \leq \hat{d}(u,v) \leq \alpha \cdot d(u,v)$, for some real $\alpha > 1$ which is called the *stretch* of the ADO. If the estimation of the ADO satisfies $d(u,v) \leq \hat{d}(u,v) \leq \max\{d(u,v), \alpha \cdot d(u,v) + \beta\}$ for some reals $\alpha > 1$ and β (which can be negative), we say that the stretch of the ADO is an (α, β)-stretch.

ADO for general graphs. ADOs were originally presented by Thorup and Zwick [34] who designed a randomized algorithm that for any positive integer k constructs an ADO for *weighted* undirected graphs in $O(kmn^{1/k})$ time that uses $O(kn^{1+1/k})$ space and returns a $2k-1$-stretch in $O(k)$ query time.

Thorup and Zwick [34] showed that the space usage of their ADO construction for their given stretch is optimal for *general graphs* based on the girth conjecture of Erdős. Moreover, for stretch 3 (when $k = 2$), the appropriate case of the girth conjecture is known to be true (due to complete bipartite graphs), and so the quadratic (in n) space lower bound for this case is unconditional. Notice that constructing an exact distance oracle in quadratic space is trivial.

In the case where one allows for an additive error, Pătraşcu and Roditty [27] designed an algorithm which constructs a $(2,1)$-stretch ADO for unweighted graphs using $O(n^{5/3})$ space and $O(1)$ query time. Their result demonstrates that in such a case the multiplicative error can be reduced while still using subquadratic space.

ADO for sparse graphs. The (conditional) lower bound of Thorup and Zwick [34] does not apply to sparser graphs with $m = o(n^{1+1/k})$, and indeed additional results show that it is possible to use subquadratic space and return a sub-3 stretch in such cases. Specifically, Pătraşcu and Roditty [27], designed an algorithm that constructs a 2-stretch ADO using $O(m^{1/3}n^{4/3})$ space, and so for subquadratic m the space usage is subquadratic. Pătraşcu, Roditty and Thorup [28] presented additional tradeoffs for sub-3 stretch using subquadratic space for graphs where $m = \tilde{O}(n)$[1]. Roditty and Tov [30] improved the stretch of the ADO presented by Thorup and Zwick [34] while using the same space for graphs with $m = \tilde{O}(n)$.

Conditional lower bounds and set-intersection. Pătraşcu and Roditty [27] proved a lower bound for the space usage of sub-2 stretch ADOs (i.e., ADOs which satisfy $d(u,v) \leq \hat{d}(u,v) < 2d(u,v)$) that holds (even) for sparse graphs, conditioned on the space usage for data structures that solve the following set intersection problem.

▶ **Problem 1.** *Let $X = \log^c N$ for a large enough constant c. Construct a data structure that preprocesses sets $S_1, \ldots, S_N \subseteq [X]$, and answers queries of the form "does S_i intersect S_j?" in constant time.*

[1] Throughout this paper we use $\sim$ when suppressing poly-logarithmic factors in asymptotic complexities.

The lower bound proof by Pătraşcu and Roditty [27] is based on the following hypothesis.

▶ **Hypothesis 2** ([27, 31, 17]). *A data structure that solves Problem 1 requires $\tilde{\Omega}(N^2)$ space.*

Since understanding the reduction by Pătraşcu and Roditty [27] is useful for our results, we provide an overview of their reduction tailored to our needs. Given an instance of Problem 1, we construct a 3 *layered* graph, where edges are only between adjacent layers, as follows. The first layer is $V_L = \{v_1, \ldots, v_N\}$, the second layer is $V_M = X$, and the third layer is $V_R = \{u_1, \ldots, u_N\}$. Vertices v_i and u_i represent S_i, and so for each set S_i and each $x \in S_i$, we add edges (v_i, x) and (x, u_i). Notice that the graph contains $\Theta(N)$ vertices. It is straightforward to observe that $S_i \cap S_j \neq \emptyset$ if and only if there is a path of length 2 between v_i and u_j. Moreover, since the graph is a 3 layered graph and the representatives of the sets are at the outer layers, there are no paths of length 3 between representatives of sets. Thus, one can solve Problem 1 using a solution to the following problem (for $a = 2$ and $b = 4$).

▶ **Problem 3.** *For positive integers a and b, an (a, b)-*distinguisher oracle *for a graph $G = (V, E)$, is a data structure that, given $u, v \in V$ establishes in constant time whether $d(u, v) \leq a$ or $d(u, v) \geq b$. If $a < d(u, v) < b$ then the data structure can return any arbitrary answer.*

We conclude that a $(2, 4)$-distinguisher oracle that uses $f(n)$ space can be used to solve Problem 1 using $f(N)$ space by applying the oracle onto the 3 layered graph. Finally, since a sub-2 stretch ADO is a $(2, 4)$-distinguisher oracle, any sub-2 stretch ADO must use at least $\Omega(n^2)$ space.

1.1 Main results: When can we beat stretch 2 with subquadratic space?

The line of work by [27, 28, 30] is a natural research path given the observation that the (conditional) lower bounds of [34] apply only to graphs with $m = \Omega(n^{1+1/k})$. Similarly, a natural goal, which we address in this paper, is to understand for which families of graphs can an ADO beat stretch 2 using subquadratic space. In particular, the conditional lower bound proof of Pătraşcu and Roditty [27] does not apply to graphs with maximum degree of $n^{\frac{1}{2}-\Omega(1)}$, since in such graphs the number of paths of length 2 is $n^{2-\Omega(1)}$, and so constructing a subquadratic space $(2, 4)$-distinguisher oracle is straightforward (by explicitly storing all length 2 paths).

Thus, a natural goal, which we investigate in this paper, is to understand the relationship between the maximum degree of G, denoted by Δ_G, and the best possible stretch obtainable for an ADO using subquadratic space. To address this question, we present two main results. The first result is an upper bound for $\Delta_G = n^{\frac{1}{k}-\Omega(1)}$ which is summarized in the following Theorem.

▶ **Theorem 4.** *For any graph G, positive real constant c, and positive integer k for which $\Delta_G \leq cn^{\frac{1}{k}-\varepsilon}$ for some real $0 < \varepsilon \leq 1/k$, there exists an ADO for G that uses $\tilde{O}(c^k n^{2-\frac{k\varepsilon}{3}})$ space and has a $(2, 1-k)$-stretch.*

For $k = 2$, Theorem 4 implies a subquadratic sub-2 stretch ADO for graphs for which $\Delta_G \leq n^{\frac{1}{2}-\Omega(1)}$.

The second result is a conditional lower bound, conditioned on Hypothesis 2, that applies when $\Delta_G = \Theta(n^{1/k})$, for all integers $k \geq 1$ [2]. The conditional lower bound is summarized in the following Theorem.

[2] The case $k = 1$ was proven by Thorup and Zwick [34] to hold unconditionally. Thus, Theorem 5 focuses on $k \geq 2$.

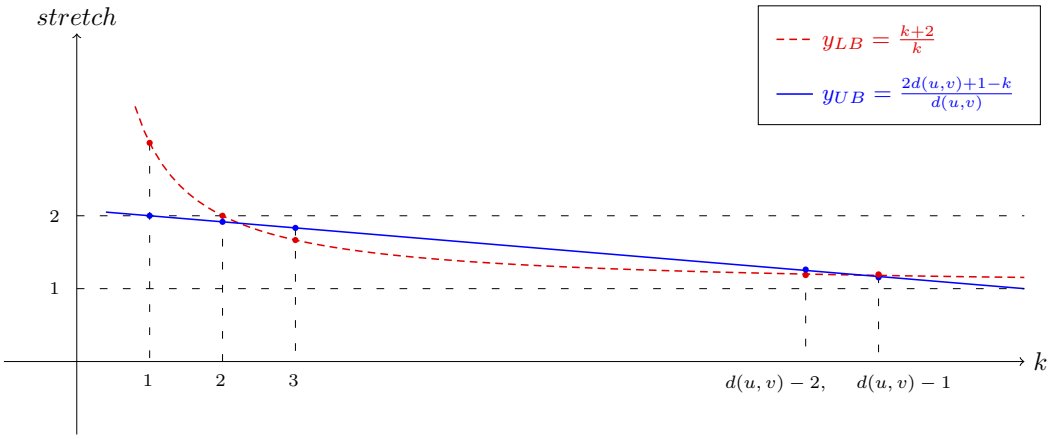

Figure 1 A comparison between the upper bound for graphs with $\Delta_G \leq O(n^{\frac{1}{k}-\varepsilon})$ (Theorem 4) and the lower bound for graphs with $\Delta_G = \Theta(n^{\frac{1}{k}})$ (Theorem 5). The figure demonstrates the stretch as a function of k for a fixed (sufficiently large) value of $d(u,v)$. The curves intersect at $2 < k_1 < 3$ and at $d(u,v) - 2 < k_2 < d(u,v) - 1$ which implies that for $k = 1, 2$ the ADO from Theorem 4 for graphs with $\Delta_G \leq O(n^{\frac{1}{k}-\varepsilon})$ produces a better stretch than the best possible stretch for graphs with $\Delta_G = \Theta(n^{\frac{1}{k}})$. On the other hand, the intersection point k_2 does not provide strong enough results; see the discussion following the statement of Theorem 5.

▶ **Theorem 5.** *Let $2 \leq k \leq \log n$. Assuming Hypothesis 2, a sub-$\frac{k+2}{k}$ stretch ADO for graphs with n vertices and maximum degree $\Theta(n^{1/k})$ must use $\tilde{\Omega}(n^2)$ space.*

When $k = 2$, the lower bound of Theorem 5 implies that Theorem 4 is essentially optimal, in the sense that there is no ADO for graphs with a maximum degree of $\Theta(n^{1/2})$ that still uses subquadratic space and has a sub-2 stretch.

For larger values of k, although the upper and lower bounds are defined only for integer values of k, the values lie on two curves: $y_{UB} = \frac{2d(u,v)+1-k}{d(u,v)}$ for the upper bound and $y_{LB} = \frac{k+2}{k}$ for the lower bound. See Figure 1 for a depiction and comparison of the two curves for a fixed value of $d(u,v)$. When $d(u,v) \leq 6$ (which is not the case shown in Figure 1), the upper bound will always produce a stretch which is equal or smaller to the lower bound. Otherwise, the curves intersect at $2 < k_1 < 3$ and $d(u,v) - 2 < k_2 < d(u,v) - 1$. We emphasize that the bounds on k_1 are independent of $d(u,v)$, and so for $k = 1, 2$, the fact that the upper bound curve is beneath the lower bound curve is relevant for all for all possible distances. On the other hand, the bounds on k_2 depend on $d(u,v)$, and so while it is true that for a fixed value of large enough $d(u,v)$ there are many values of k for which the ADO of Theorem 4 provides an approximation which beats the lower bound, it is also true that for any integer value of $k \geq 3$ there will always exist some distances for which the upper bound is above the lower bound. Thus, the intersection at k_2 is unfortunately not meaningful enough.

1.2 Organization

The rest of this paper is organized as follows. In Section 1.3 we provide an overview of the main ideas used in this paper. In Section 1.4 we survey some additional related work. In Section 2 we provide some definitions that are used in the more technical parts of the paper. In Section 3 we prove some useful lemmas that are used in the proof of Theorem 4, which is described in Section 4 together with the construction of our new ADO. In Section 5 we prove Theorem 5. Finally, in Section 6 we provide some conclusions and describe a natural open problem.

1.3 Overview of Results and Techniques

In this section we describe an overview of the intuition and techniques used to obtain our main results.

1.3.1 Upper Bound: A New ADO

Since our new ADO is based on the ADO of Agarwal and Godfrey [4], that has a $(2,1)$-stretch and uses $\tilde{O}(n^{5/3})$ space (which simplifies the ADO of [27]), we provide an overview of the construction of their ADO.

The ADO constructed by Agarwal and Godfrey [4] uses the concept of *bunches* and *clusters* introduced by Thorup and Zwick [33]. Following the conventions of Thorup and Zwick [33, 34], for a vertex $v \in V$ and set $A \subseteq V$, let $p_A(v)$ be the vertex in A which is closest to v (breaking ties arbitrarily). The *bunch* $B_A(v)$ of v with respect to A is defined as $B_A(v) = \{w \in V \mid d(v,w) < d(v,p_A(v))\}$. The *cluster* $C_A(w)$ of w with respect to A is defined as $C_A(w) = \{v \in V \mid d(w,v) < d(v,p_A(v))\}$. We omit A from the notation when it is clear from context. Thorup and Zwick [33] presented an algorithm that computes a set A of size $\tilde{O}(s)$ such that $|B(v)|, |C(v)| \leq 4n/s$, for every $v \in V$. The ADO of Agarwal and Godfrey [4] uses a hitting set A of size $\tilde{O}(n^{2/3})$ such that for every $v \in V$, $|B(v)|, |C(v)| \leq O(n^{1/3})$.

Given two vertices $u, v \in V$, the ADO first tests whether $B(u) \cap B(v) \neq \emptyset$, and, if so, then the ADO returns the exact distance $d(u,v)$. The method for testing whether the two bunches intersect is based on the observation (which follows from the definitions of bunch and cluster) that $B(u) \cap B(v) \neq \emptyset$ if and only if $u \in C(B(v))$[3]. Thus, each vertex $v \in V$ stores the exact distances to all vertices in $C(B(v))$, and now, the case of $B(u) \cap B(v) \neq \emptyset$ costs constant time and returns an exact distance. To deal with the case of $B(u) \cap B(v) = \emptyset$, the oracle stores the distances of pairs in $V \times A$, and the ADO returns the minimum of either the length of the shortest path between u and v passing through $p(u)$ or the length of the shortest path between u and v passing through $p(v)$. The space usage is $O(n^{5/3})$ for storing $C(B(v))$ for every $v \in V$, and $\tilde{O}(n|A|) = \tilde{O}(n^{5/3})$ for storing the distances for all pairs in $V \times A$.

Intuition for the new ADO. Our new ADO construction is based on the following intuition regarding the ADO construction of Agarwal and Godfrey [4]. If we enlarge $B(u)$ by moving $p(u)$ to a further vertex (from u), then we would increase the likelihood of $B(u) \cap B(v) \neq \emptyset$, and so the ADO would return exact distances for more pairs of vertices. However, in such a case, the quality guarantee on the stretch obtained by approximating $d(u,v)$ with the shortest path from u to v that passes through $p(u)$ becomes worse. Part of the challenge is to balance the size of $B(u)$ which affects the usefulness of the intersections and the role of $p(u)$ when approximating the distances.

Our approach, intuitively, is to separate the definition of $p(u)$ used for the approximations and the set chosen for the intersections. Specifically, the definition of $p(u)$ remains unchanged relative to A (we do however change the size of A), but instead of testing whether $B(u) \cap B(v) \neq \emptyset$, we use a larger set $N(u)$ (which contains $B(u)$), and test whether $N(u) \cap B(v) \neq \emptyset$ (or $B(u) \cap N(v) \neq \emptyset$). Testing whether $N(u) \cap B(v) \neq \emptyset$ is implemented by storing all of the distances between u and vertices in $C(N(u))$. We remark that one may consider the possibility of testing whether $N(u) \cap N(v) \neq \emptyset$ instead of testing whether $N(u) \cap B(v) \neq \emptyset$, however, such an approach seems to require too much space.

[3] For $S \subseteq V$, let $C(S) = \bigcup_{u \in S} C(u)$.

Recall that Agarwal and Godfrey [4] obtained a $(2,1)$-stretch. In our algorithm, we choose $N(u)$ in such a way that when $N(u) \cap B(v) = \emptyset$ then $\min_{x \in B(u), y \in B(v)}\{d(x,y)\} > k$ if $\Delta_G \leq n^{\frac{1}{k}-\Omega(1)}$, which ends up reducing the additive component of the stretch by at least k (see Claim 13). Thus, the approximation of the ADO is always at most $(2, 1-k)$, which is less than stretch 2 for $k \geq 2$.

1.3.2 Conditional Lower bound

In Section 5 we prove the following lemma, which directly implies Theorem 5 since a sub-$\frac{k+2}{k}$ stretch ADO is also a $(k, k+2)$-distinguisher oracle.

▶ **Lemma 6.** *Let $2 \leq k \leq \log n$. Assuming Hypothesis 2, any $(k, k+2)$-distinguisher oracle for graphs with n vertices and maximum degree $\Theta(n^{1/k})$ must use $\tilde{\Omega}(n^2)$ space.*

Notice that it is straightforward to construct a $(k, k+2)$-distinguisher oracle for graphs with n vertices and maximum degree $\Theta(n^{\frac{1}{k}-\varepsilon})$ in $O(n^{2-k\varepsilon})$ space by storing all pairs of vertices at distance exactly k. Thus, Lemma 6 shows that such a construction is essentially optimal.

The challenges. There are two issues that need to be addressed in order to extend the reduction by Pătraşcu and Roditty [27] in a way that proves Lemma 6. The first is to adjust the distances so that $S_i \cap S_j \neq \emptyset$ if and only if $d(v_i, u_j) = k$, and otherwise, $d(v_i, u_j) \geq k+2$. The second issue is that the degrees of vertices in V_M need to be adjusted to be at most $\tilde{O}(N^{1/k})$. In order to simplify our intuitive explanation, we focus our attention to the special case where $X = \{x\}$ has only one element.

One straightforward way of dealing with the first issue is to replace vertex $x \in V_M$ with a path $P_x = (w_1, \ldots, w_{k-1})$ of length $k-2$, and for each S_i that contains x we add edges (v_i, w_1) and (w_{k-1}, u_i). Thus, the constructed graph would be a $k+1$ layered graph. The number of vertices in such a graph is $O(k+N) = O(N)$, and the distance between vertices in the first and last layers are $k+2q$ for some integer $q \geq 0$. However, we still need to address the second issue of bounding the maximum degree, since w_1 and w_{k-1} may have a very high degree corresponding to the number of sets containing x.

On the other hand, one initial idea (that does not work) for dealing with the second issue is to replace $x \in V_M$ (in the original 3 layered graph) with N vertices $y_1, y_2, \ldots, y_N$, and for each S_i that contains x we add edges (v_i, y_i) and (y_i, u_i). Now the maximum degree of each node is constant, however, for $i \neq j$ such that $x \in S_i \cap S_j$, there is no path from v_i to u_j. This idea is missing the functionality of the path P_x which allows us to connect more than one pair of vertices from $V_L \times V_R$.

Combining approaches. Our reduction makes use of an underlying $k+1$ layered *infrastructure graph* $\mathcal{L}$, commonly known as the *butterfly graph* (see [26, 28]), which has the following three properties: (*i*) each layer contains N vertices, (*ii*) there is a path of length k from every vertex in the first layer to every vertex in the last layer, and (*iii*) the degree of every vertex is at most $2N^{1/k}$. The layers of $\mathcal{L}$ are numbered 0 to k. The vertices in each layer are (separately) indexed with integers from 1 to N, and the construction of $\mathcal{L}$ is based on the base $N^{1/k}$ representation of the these indices: for $1 \leq t \leq k$, vertices from layer $t-1$ are connected with vertices from layer t if and only if the base $N^{1/k}$ representation of their corresponding indices are the same, except for possibly the t'th digit. Similar to before, we denote the first layer of $\mathcal{L}$ by $V_L = \{v_1, \ldots, v_N\}$ and the last layer by $V_R = \{u_1, \ldots, u_N\}$.

Finally, we construct a $k+1$ layered graph G_x which is intuitively obtained by removing from $\mathcal{L}$ edges touching either v_i or u_i for every S_i that does not contain x. Thus, in G_x, if $x \in S_i \cap S_j$ then there is a path of length k from v_i to u_j in G_x, and otherwise, there is no path from v_i to u_j in G_x.

We remark that in the general case, where $|X|$ may be larger than 1, we combine G_x for different $x \in X$ in a special way, and so we may introduce paths from v_i to u_j even if $S_i \cap S_j = \emptyset$. However, since the resulting graph is still a $k+1$ layered graph, and we are interested in paths between vertices in the first layer and vertices in the last layer, the lengths of such paths must be at least $k+2$. Thus, a $(k, k+2)$-distinguisher oracle on the combined graph suffices for solving Problem 1. See Section 5 for more details.

1.4 Additional related work

Different aspects of Thorup and Zwick [34] ADOs were studied since they were introduced for the first time. Chechik [14, 13] reduced the query time from $O(k)$ to $O(1)$, while keeping the stretch and the space unchanged. (See also [36, 23].) Roditty, Thorup, and Zwick [29] presented a deterministic algorithm that constructs an ADO in $\tilde{O}(mn^{1/k})$ time while keeping the stretch and the space unchanged. Baswana and Kavitha [9] presented an algorithm with $O(n^2 \log n)$ running time[4]. Baswana, Goyaland and Sen [8] presented an $\tilde{O}(n^2)$ time algorithm that computes a $(2,3)$-distance oracle with $\tilde{O}(n^{5/3})$ space. Sommer [32] presented an $\tilde{O}(n^2)$ time algorithm that computes a $(2,1)$-distance oracle with $\tilde{O}(n^{5/3})$ space. Akav and Roditty [7] presented the first sub-quadratic time algorithm that constructs an ADO with stretch better than 3. They presented an $O(n^{2-\epsilon})$-time algorithm that constructs a ADO with $O(n^{11/6})$ space and $(2+\epsilon, 5)$-stretch. Chechik and Zhang [15] improved the result of Akav and Roditty [7]. Among their results is an $O(m + n^{1.987})$ time algorithm that constructs an ADO with $(2,3)$-stretch and $\tilde{O}(n^{5/3})$ space. Following the work by Pătraşcu and Roditty [27] who constructed an ADO for unweighted graphs that uses $O(n^{5/3})$ space and returns a $(2,1)$-stretch in $O(1)$ time, Abraham and Gavoille [2] extended the ADO by Pătraşcu and Roditty [27] for all even stretch values, by constructing for any integer $k \geq 2$, an ADO of size $\tilde{O}(n^{1+2/(2k-1)})$ with a $(2k-2,1)$-stretch returned in $O(k)$ time. Pătraşcu, Roditty and Thorup [28] focused on analyzing sparse graphs where $m = \tilde{O}(n)$ and noted that both the ADOs by Thorup and Zwick [34], and the ADOs by Abraham and Gavoille [2] use a space complexity that can be described by the curve $S(\alpha, m) = \tilde{O}(m^{1+2/(\alpha+1)})$ where α is the stretch of the ADO and m is the number of edges in the graph. Pătraşcu, Roditty and Thorup [28] extended the curve $S(\alpha, m)$ to work for non integer stretch values $\alpha > 2$. Although our research focuses on constant query time ADOs, another branch of research includes ADOs that have non constant query time [6, 24, 5, 3, 11].

In the lower bound regime, the problem of constructing a $(2,4)$-distinguisher oracle was analyzed from the perspective of time complexity as well. For graphs with degree of at most $n^{1/2}$, the problem of determining for each edge in the graph whether it is in a triangle in $O(n^{2-\varepsilon})$ time for some $\varepsilon > 0$ was shown to be hard under either the 3SUM [25, 21] or APSP [35] hypotheses. Since there exists a standard reduction from the problem of determining for each edge in the graph whether it is in a triangle to the problem of constructing a $(2,4)$-distinguisher oracle (see [1]), a $(2,4)$-distinguisher oracle is also hard to construct in subquadratic time for graphs with degree of at most $n^{1/2}$ under either the 3SUM or APSP hypotheses.

[4] For $k = 2$ the query time is $O(\log n)$. For $k > 2$ the query time is $O(k)$.

The problem of constructing a $(k, k+2)$-distinguisher oracle for a general integer $k \geq 2$ was also studied in the past in terms of time complexity. Dor, Halperin and Zwick [19] showed that if all distances in an undirected n vertex graph can be approximated with an additive error of at most 1 in $O(A(n))$ time, then *Boolean matrix multiplication* on matrices of size $n \times n$ can also be performed in $O(A(n))$ time. Dor, Halperin and Zwick [19] conclude that constructing a $(k, k+2)$-distinguisher oracle for an integer $k \geq 2$ is at least as hard as multiplying two Boolean matrices.

2 Preliminaries

Let $d_G(u, v)$ be the distance between vertices u and v in the graph G. The eccentricity of a vertex $v \in V$ in a graph G, denoted by $ecc_G(v)$, is defined as $ecc_G(v) = \max_{u \in V}\{d_G(v, u)\}$. The diameter of G is defined as $diam_G = \max_{v \in V}\{ecc_G(v)\}$ and the radius of G is defined as $rad_G = \min_{v \in V}\{ecc_G(v)\}$.

The eccentricity of a vertex v can be thought of as the distance between v and the last vertex met during a *Breadth First Search* (BFS) of the graph starting at v. Since our goal is to construct an ADO that uses subquadratic space, we cannot afford to store a separate BFS tree for each vertex. Instead, the construction algorithm of the ADO from Theorem 4 will store only a partial BFS tree for each vertex by truncating the BFS scan after some number of vertices. Motivated by this notion of a truncated scan, we introduce the following generalization of eccentricity which turns out to be useful for our purposes.

Let $N_G(v, s)$ be the first s vertices met during a BFS[5] starting from v in the graph G, i.e., the s closest vertices to v (excluding v). If s is not an integer, then let $N(v, s) = N(v, \lfloor s \rfloor)$. For an integer $r \geq 0$, define $L_G(v, r) = \{u \in V \setminus \{v\} \mid d_G(u, v) = r\}$ and $T_G(v, r) = \{u \in V \mid 0 < d_G(u, v) \leq r\}$. Notice that $T_G(v, r) = \bigcup_{i=1}^{r} L_G(v, i)$. For any real $1 \leq s \leq n-1$, define $ecc_G(v, s)$ to be the maximum integer $k \in [0, ecc_G(v)]$ for which $T_G(v, k) \subseteq N_G(v, s)$. Notice that $ecc_G(v, n-1) = ecc_G(v)$. Define $rad_G(s) = \min_{v \in V}\{ecc_G(v, s)\}$. Notice that $rad_G(n-1) = rad_G$. We omit the subscript G when using the definitions above whenever G is clear from context.

3 Useful Lemmas

In this section we prove several useful properties of the graph attributes defined in Section 2 which will be used throughout the paper.

The following observation and corollary address the relationship between $T(v, r)$ and $N(v, s)$, and follow from the definition of BFS.

▶ **Observation 7.** *Let $G = (V, E)$ be an unweighted undirected graph, with $|V| = n$. For any $v \in V$ and integers s and r such that $1 \leq s < n$ and $1 \leq r \leq diam_G$, either (i) $T(v, r) \subset N(v, s)$, (ii) $N(v, s) \subset T(v, r)$, or (iii) $N(v, s) = T(v, r)$*

▶ **Corollary 8.** *Let $G = (V, E)$ be an unweighted undirected graph, with $|V| = n$. For any $v \in V$ and integers s and r such that $1 \leq s < n$ and $1 \leq r \leq diam_G$, (i) if $|T(v, r)| < |N(v, s)|$ then $T(v, r) \subset N(v, s)$, (ii) if $|N(v, s)| < |T(v, r)|$ then $N(v, s) \subset T(v, r)$, and (iii) if $|N(v, s)| = |T(v, r)|$ then $N(v, s) = T(v, r)$.*

The following useful property addresses the relationship between $T(v, r)$ and $N(v, s)$ for the special cases where either $r = ecc(v, s)$ or $r = ecc(v, s) + 1$.

[5] The traversal order of vertices in the same layer during the BFS execution does not matter as long as the order is consistent.

▶ **Property 9.** *Let $G = (V, E)$ be an unweighted undirected graph, with $|V| = n$. For any $v \in V$ and integer s such that $1 \leq s < n$, we have: (i) $T(v, ecc(v, s)) \subseteq N(v, s)$, and (ii) if $s < n - 1$, then $T(v, ecc(v, s) + 1) \not\subseteq N(v, s)$.*

Proof. By definition, $ecc(v, s)$ is the largest integer $k \in [0, ecc(v)]$ for which $T(v, k) \subseteq N(v, s)$. Thus, (i) $T(v, ecc(v, s)) \subseteq N(v, s)$, and (ii) if $ecc(v, s) < ecc(v)$ then $T(v, ecc(v, s) + 1) \not\subseteq N(v, s)$. If $s < n - 1$, it must be that $ecc(v, s) < ecc(v)$, since if we assume towards a contradiction that $ecc(v, s) = ecc(v)$ for some $s < n - 1$ then $T(v, ecc(v, s)) = T(v, ecc(v)) = V \setminus \{v\} = N(v, n-1)$ but on the other hand, by definition of $ecc(v, s)$, we have $T(v, ecc(v, s)) \subseteq N(v, s) \subset N(v, n - 1)$, which is a contradiction. ◀

The following lemma states that $ecc_G(v, s)$ exhibits a behavior that is similar to the behavior of the distance function which cannot decrease when removing edges and vertices from G.

▶ **Lemma 10.** *Let $G = (V, E)$ be an unweighted undirected graph, $V' \subseteq V$, and let G' be the subgraph of G induced by the vertices in V'. For any vertex $v \in V'$ and for any integer s such that $1 \leq s < |V'|$, it holds that $ecc_G(v, s) \leq ecc_{G'}(v, s)$.*

Proof. Given an integer $1 \leq s < |V'|$, let $r = ecc_G(v, s)$ and $r' = ecc_{G'}(v, s)$. We want to show that $r \leq r'$. By definition of $ecc_{G'}(v, s)$, $r' = ecc_{G'}(v, s)$ is the largest value for which $T_{G'}(v, r') \subseteq N_{G'}(v, s)$. Thus, in order to show that $r \leq r'$, it suffices to show that $T_{G'}(v, r) \subseteq N_{G'}(v, s)$.

For any vertex pair $u, w \in V'$, we have $d_G(u, w) \leq d_{G'}(u, w)$ since G' is a subgraph of G. Thus,

$$\begin{aligned} T_{G'}(v, r) &= \{u \in V' \mid 0 < d_{G'}(v, u) \leq r\} \\ &\subseteq \{u \in V \mid 0 < d_G(v, u) \leq r\} \\ &= T_G(v, r) \\ &\underset{\text{Property 9}}{\subseteq} N_G(v, s). \end{aligned}$$

This implies that $|T_{G'}(v, r)| \leq |N_G(v, s)| = s = |N_{G'}(v, s)|$. By Corollary 8, since $|T_{G'}(v, r)| \leq |N_{G'}(v, s)|$ then $T_{G'}(v, r) \subseteq N_{G'}(v, s)$, as required. ◀

3.1 The Logarithmic-Like Behavior of Eccentricity

In the following lemma, which is an important ingredient in the analysis of our new ADO, we show that $ecc(v, s)$ satisfies a logarithmic-like behavior. Specifically, $\log(xy) = \log x + \log y$. The reason for this behavior is that the number of vertices in each layer of a BFS tree expands in a similar way to an exponential function. For a tree-graph G with minimum degree δ rooted at a vertex v, for integers $0 \leq i < t < ecc(v)$ it holds that $|L(v, t)| \geq \delta^i \cdot |L(v, t - i)|$. Since the number of vertices in every layer of the rooted tree grows exponentially, the eccentricity $ecc(v, s)$ grows logarithmically (in relation to s). Unlike in trees where the expansion of the number of vertices in every layer of a BFS can be analyzed using δ, for general graphs, in order to achieve a lower bound for the expansion rate of the eccentricity of the vertices, we use $rad_G(s)$ instead.

▶ **Lemma 11.** *Let $G = (V, E)$ be an unweighted undirected graph, with $|V| = n$. For any vertex $v \in V$ and integers $s_1, s_2 \geq 1$ such that $s_1(s_2 + 1) < n - 1$, it holds that $ecc_G(v, s_1(s_2 + 1)) \geq ecc_G(v, s_1) + rad_G(s_2)$.*

Proof. Assume towards a contradiction that $ecc_G(v, s_1(s_2+1)) < ecc_G(v,s_1) + rad_G(s_2)$. Thus, $ecc_G(v, s_1(s_2+1)) + 1 \leq ecc_G(v,s_1) + rad_G(s_2)$.

Let T_{BFS} be a BFS tree rooted at v in graph G. Let $\ell = |L(v, ecc_G(v,s_1))|$ and let $u_1, u_2, \ldots, u_\ell$ be the vertices in $L(v, ecc_G(v,s_1))$. For any i, where $1 \leq i \leq \ell$, let V_i be the set of descendant of u_i in T_{BFS} and let G_i be the graph induced by V_i in G[6].

Let $\mu = \min_{i\in[1,\ell]}\{ecc_{G_i}(u_i, s_2)\}$. We will show that:

$$\{u \in V \mid ecc_G(v,s_1) < d_G(v,u) \leq ecc_G(v,s_1) + \mu\} \subseteq \bigcup_{i=1}^{\ell} N_{G_i}(u_i, s_2). \tag{1}$$

Let $w \in \{u \in V \mid ecc_G(v,s_1) < d_G(v,u) \leq ecc_G(v,s_1) + \mu\}$. By the definition of BFS, since $d_G(v,w) > ecc_G(v,s_1)$, w must be a descendant of some vertex u_j, and so $w \in V_j$. Since T_{BFS} is a shortest path tree rooted at v and since $w \in V_j$, it must be that $d_G(v,w) = d_G(v,u_j) + d_G(u_j,w) = ecc_G(v,s_1) + d_G(u_j,w)$. By definition of w, $d_G(v,w) \leq ecc_G(v,s_1) + \mu$. Thus, $ecc_G(v,s_1) + d_G(u_j,w) \leq ecc_G(v,s_1) + \mu$ and so $d_G(u_j,w) \leq \mu$.

By definition, $T_{G_j}(u_j, ecc_{G_j}(u_j,s_2)) = \{x \mid x \in V_j \wedge 0 < d_{G_j}(u_j,x) \leq ecc_{G_j}(u_j,s_2)\}$. Since T_{BFS} is a shortest path tree, for any $y \in V_j$ it must be that $d_{G_j}(u_j,y) = d_G(u_j,y)$. Thus, $T_{G_j}(u_j, ecc_{G_j}(u_j,s_2)) = \{x \mid x \in V_j \wedge 0 < d_G(u_j,x) \leq ecc_{G_j}(u_j,s_2)\}$.

Since $w \in V_j$, and since $d_G(u_j,w) \leq \mu \leq ecc_{G_j}(u_j,s_2)$, then $w \in T_{G_j}(u_j, ecc_{G_j}(u_j,s_2))$. By Property 9, $T_{G_j}(u_j, ecc_{G_j}(u_j,s_2)) \subseteq N_{G_j}(u_j,s_2)$. It follows that every vertex in $\{u \in V \mid ecc_G(v,s_1) < d_G(v,u) \leq ecc_G(v,s_1) + \mu\}$ must be included in $N_{G_i}(u_i,s_2)$ for some i, thus confirming Equation (1).

By Property 9, $\{u \in V \mid 0 < d_G(v,u) \leq ecc_G(v,s_1)\} = T(v, ecc_G(v,s_1)) \subseteq N(v,s_1)$. Combining with Equation (1) we have that $\{u \in V \mid 0 < d_G(v,u) \leq ecc_G(v,s_1)\} \cup \{u \in V \mid ecc_G(v,s_1) < d_G(v,u) \leq ecc_G(v,s_1) + \mu\} \subseteq N(v,s_1) \cup \left(\bigcup_{i=1}^{\ell} N_{G_i}(u_i,s_2)\right)$, and so:

$$\begin{aligned}\{u \in V \mid 0 < d_G(v,u) \leq ecc_G(v,s_1) + \mu\} &= T(v, ecc_G(v,s_1) + \mu) \\ &\subseteq N(v,s_1) \cup \left(\bigcup_{i=1}^{\ell} N_{G_i}(u_i,s_2)\right).\end{aligned}$$

Now,

$$\begin{aligned} ecc_G(v,s_1) + \mu &\underset{\substack{\uparrow \\ \text{definition of } \mu}}{=} ecc_G(v,s_1) + \min_{i\in[1,\ell]}\{ecc_{G_i}(u_i,s_2)\} \\ &\underset{\substack{\uparrow \\ \text{by Lemma 10}}}{\geq} ecc_G(v,s_1) + \min_{i\in[1,\ell]}\{ecc_G(u_i,s_2)\} \\ &\geq ecc_G(v,s_1) + \min_{u\in V}\{ecc_G(u,s_2)\} \\ &\underset{\substack{\uparrow \\ \text{definition of } rad_G(s_2)}}{=} ecc_G(v,s_1) + rad_G(s_2) \\ &\underset{\substack{\uparrow \\ \text{assumption}}}{\geq} ecc_G(v, s_1(s_2+1)) + 1. \end{aligned}$$

[6] It is important to note that for all scans referenced in this proof, which include a BFS procedure of G starting at v and BFS procedures of G_i starting at u_i for $1 \leq i \leq \ell$, we require a consistent order of scanning, i.e., that for a given $1 \leq i \leq \ell$, and vertices $x, x' \in V_i \subseteq V$, if x is scanned before x' in G then x should also be scanned before x' in G_i (and vice versa). This is a valid requirement since for any vertices $y, y' \in V_i \subseteq V$, $d_G(v,y) \leq d_G(v,y')$ if and only if $d_{G_i}(u_i,y) \leq d_{G_i}(u_i,y')$.

Thus, $T(v, ecc_G(v, s_1(s_2+1))+1) \subseteq T(v, ecc_G(v, s_1)+\mu) \subseteq N(v, s_1) \cup \left(\bigcup_{i=1}^{\ell} N_{G_i}(u_i, s_2)\right)$.

Notice that $\ell \leq s_1$, since, by Property 9, $\ell = |L(v, ecc_G(v, s_1))| \leq |T(v, ecc_G(v, s_1))| \leq N(v, s_1) = s_1$. Therefore,

$$\begin{aligned}
|T(v, ecc_G(v, s_1(s_2+1))+1)| &\leq |N(v, s_1) \cup \left(\bigcup_{i=1}^{\ell} N_{G_i}(u_i, s_2)\right)| \\
&\leq |N(v, s_1)| + \sum_{i=1}^{\ell} |N_{G_i}(u_i, s_2)| \\
&\leq s_1 + \ell \cdot s_2 \\
&\leq s_1 + s_1 \cdot s_2 \\
&= s_1(1+s_2) \\
&= |N(v, s_1(s_2+1))|.
\end{aligned}$$

By Corollary 8, it follows that $T(v, ecc_G(v, s_1(s_2+1))+1) \subseteq N(v, s_1(s_2+1))$, which contradicts Property 9. ◀

4 The new ADO

In this section we prove Theorem 4 by introducing a new ADO which uses subquadratic space and produces a $(2, 1-k)$-stretch for graphs for which $\Delta_G \leq O(n^{1/k-\varepsilon})$ for a positive integer k and real constant $0 < \varepsilon \leq 1/k$. The ADO is parameterized by a parameter $0 \leq \alpha < 1/3$ which quantifies the tradeoff between the space and the stretch of the ADO. When $\alpha = 0$ the ADO is very similar to the ADO of Agarwal and Godfrey [4] which uses $\tilde{O}(n^{5/3})$ space and has a $(2,1)$-stretch. For $0 < \alpha < 1/3$, the ADO uses additional space and is able to improve the stretch of the ADO for the family of graphs for which $\Delta_G \leq O(n^{3\alpha/k})$.

4.1 The Construction Algorithm

The description of our construction algorithm follows the notations and definitions described in Section 1.3.1. The construction begins with an algorithm of Thorup and Zwick [33] that computes a set A of size $\tilde{O}(s)$ such that $|B(v)|, |C(v)| \leq 4n/s$, for every $v \in V$. In our case we set $s = n^{2/3+\alpha}$, thus $|A| = \tilde{O}(n^{2/3+\alpha})$ and $|B(v)|, |C(v)| \leq 4n^{1/3-\alpha}$, for every $v \in V$.

For every vertex $v \in V$, the ADO explicitly stores the distances between v and every vertex in $C(N(v, 16\hat{c}\, n^{1/3+2\alpha}))$ for some constant $\hat{c}$ to be decided later. In addition, for every vertex $v \in V$ the ADO stores $p(v)$, $d(v, p(v))$ and the distances between v and every vertex in A.

A distance query between vertices u and v is answered as follows. If one of the following conditions holds (i) $u \in A$ or $v \in A$, (ii) $u \in C(N(v, 16\hat{c}\, n^{1/3+2\alpha}))$ or $v \in C(N(u, 16\hat{c}\, n^{1/3+2\alpha}))$, then the exact distance is returned. Otherwise, the ADO returns $\hat{d}(u, v) = \min\{d(u, p(u)) + d(p(u), v),\ d(u, p(v)) + d(p(v), v)\}$. Notice that the query time is constant.

In Claim 12, we show that the space complexity of the ADO is $\tilde{O}(\hat{c}n^{5/3+\alpha})$ and in Claim 13, we show that the ADO satisfies a $(2, 1 - rad(\hat{c}n^{3\alpha}))$-stretch.

▷ Claim 12. The space complexity of the ADO is $\tilde{O}(\hat{c}n^{5/3+\alpha})$.

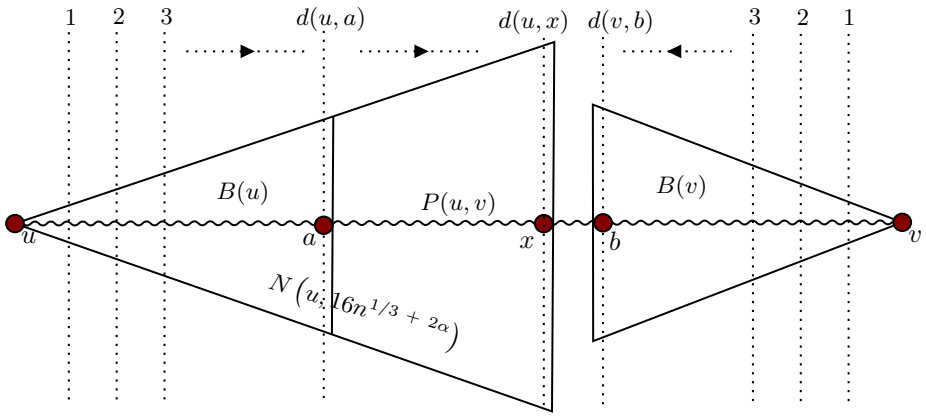

Figure 2 A query for $u, v \in V$ in the case that $N(u, 16\hat{c}\, n^{1/3+2\alpha}) \cap B(v) = \emptyset$. Since $x \in N(u, 16\hat{c}\, n^{1/3+2\alpha})$, $b \in B(v)$ and x and b are both on a shortest path between u and v, it must be that $d(u,x) \leq d(u,b) - 1$.

Proof. Storing $p(v)$, $d(v, p(v))$ and the distances between v and every vertex in A, for all vertices $v \in V$, uses $\tilde{O}(n \cdot n^{2/3+\alpha}) = \tilde{O}(n^{5/3+\alpha})$ space. As mentioned in the construction phase, $|B(v)|, |C(v)| \leq O(n^{1/3-\alpha})$ for every $v \in V$. Thus, storing the distances between every vertex v and $C(N(v, 16\hat{c}\, n^{1/3+2\alpha}))$ requires $O(n \cdot n^{1/3-\alpha} \cdot 16\hat{c}\, n^{1/3+2\alpha}) = \tilde{O}(\hat{c}n^{5/3+\alpha})$ space as well, leading to an overall space complexity of $\tilde{O}(\hat{c}n^{5/3+\alpha})$. ◁

▷ Claim 13. The distance estimation $\hat{d}(u,v)$ returned by the ADO satisfies $d(u,v) \leq \hat{d}(u,v) \leq 2d(u,v) + 1 - rad(\hat{c}n^{3\alpha})$.

Proof. Notice that $d(u,v) \leq \hat{d}(u,v)$ since the ADO always returns a length of some path in the graph between u and v. It is left to show that $\hat{d}(u,v) \leq 2d(u,v) + 1 - rad(\hat{c}n^{3\alpha})$.

If the exact distance is stored in the ADO then $\hat{d}(u,v) = d(u,v)$ and the claim follows. Consider the case that the exact distance is not stored. This implies that $u, v \notin A$ and $v \notin C(N(u, 16\hat{c}\, n^{1/3+2\alpha}))$. Assume towards a contradiction that $N(u, 16\hat{c}\, n^{1/3+2\alpha}) \cap B(v) \neq \emptyset$ and let w be a vertex such that $w \in N(u, 16\hat{c}\, n^{1/3+2\alpha}) \cap B(v)$. From the definitions of bunch and cluster, we have that $w \in B(v)$ if and only if $v \in C(w)$. Thus, $v \in C(w)$, and since $w \in N(u, 16\hat{c}\, n^{1/3+2\alpha})$, it must be that $v \in C(N(u, 16\hat{c}\, n^{1/3+2\alpha}))$ which is a contradiction. Thus, we have that $N(u, 16\hat{c}\, n^{1/3+2\alpha}) \cap B(v) = \emptyset$.

Let $P(u,v)$ be a shortest path between u and v. Let a be the furthest vertex from u in $B(u) \cap P(u,v)$, let x be the furthest vertex from u in $N(u, 16\hat{c}\, n^{1/3+2\alpha}) \cap P(u,v)$ and let b be the furthest vertex from v in $B(v) \cap P(u,v)$ (see Figure 2). Notice that, by definition of x and $ecc(v,s)$, if $T(u, d(u,x)) \subseteq N(u, 16\hat{c}\, n^{1/3+2\alpha})$ then $d(u,x) = ecc(u, 16\hat{c}\, n^{1/3+2\alpha})$ and if $T(u, d(u,x)) \not\subseteq N(u, 16\hat{c}\, n^{1/3+2\alpha})$ then $d(u,x) = ecc(u, 16\hat{c}\, n^{1/3+2\alpha}) + 1$. Thus, we get that $d(u,x) \geq ecc(u, 16\hat{c}\, n^{1/3+2\alpha})$.

Since $N(u, 16\hat{c}\, n^{1/3+2\alpha}) \cap B(v) = \emptyset$, $x \in N(u, 16\hat{c}\, n^{1/3+2\alpha})$, $b \in B(v)$ and x and b are both on a shortest path between u and v, it must be that $d(u,x) \leq d(u,b) - 1$. Since b is on a shortest path between u and v, it holds that $d(u,b) = d(u,v) - d(v,b)$, and so $d(u,x) \leq d(u,v) - d(v,b) - 1$. Since $d(u,x) \geq ecc(u, 16\hat{c}\, n^{1/3+2\alpha})$, it follows that:

$$ecc(u, 16\hat{c}\, n^{1/3+2\alpha}) \leq d(u,v) - d(v,b) - 1. \tag{2}$$

By Lemma 11, $ecc(u, \lceil 4n^{1/3-\alpha} \rceil) + rad(\lceil \hat{c}n^{3\alpha} \rceil) \leq ecc(u, (4n^{1/3-\alpha} + 1)(\hat{c}n^{3\alpha} + 2))$. Since $a \in B(u)$ and $|B(u)| \leq 4n^{1/3-\alpha}$, it follows from the definitions of $ecc(v,s)$ and bunch that $d(u,a) \leq ecc(u, 4n^{1/3-\alpha})$. We have that:

$$\begin{aligned} d(u,a) + rad(\hat{c}n^{3\alpha}) &\leq ecc(u, 4n^{1/3-\alpha}) + rad(\hat{c}n^{3\alpha}) \\ &\leq ecc(u, \left\lceil 4n^{1/3-\alpha} \right\rceil) + rad(\lceil \hat{c}n^{3\alpha} \rceil) \\ &\leq ecc(u, (4n^{1/3-\alpha}+1)(\hat{c}n^{3\alpha}+2)) \\ &\leq ecc(u, 16\hat{c}\, n^{1/3+2\alpha}) \\ &\underset{\text{Equation (2)}}{\leq} d(u,v) - d(v,b) - 1. \end{aligned}$$

Thus, $d(u,a) + d(b,v) \leq d(u,v) - rad(\hat{c}n^{3\alpha}) - 1$. It follows that:

$$2\min\{d(u,a), d(b,v)\} \leq d(u,v) - rad(\hat{c}n^{3\alpha}) - 1. \tag{3}$$

Notice that by the definitions of bunch, a and $p(u)$, it holds that $d(u,p(u)) = d(u,a) + 1$. Similarly, $d(v,p(v)) = d(v,b) + 1$. Thus:

$$\begin{aligned} \hat{d}(u,v) &\leq \min\{d(u,p(u)) + d(p(u),v), d(u,p(v)) + d(p(v),v)\} \\ &\underset{\text{triangle inequallity}}{\leq} \min\{2d(u,p(u)) + d(u,v), 2d(v,p(v)) + d(u,v)\} \\ &\underset{d(u,p(u)) = d(u,a)+1 \text{ and } d(v,p(v)) = d(v,b)+1}{=} \min\{2(d(u,a)+1) + d(u,v), 2(d(v,b)+1) + d(u,v)\} \\ &\leq 2\min\{d(u,a), d(v,b)\} + 2 + d(u,v) \qquad (4) \\ &\underset{\text{Equation (3)}}{\leq} d(u,v) - rad(\hat{c}n^{3\alpha}) + 1 + d(u,v) \\ &= 2d(u,v) + 1 - rad(\hat{c}n^{3\alpha}). \qquad (5) \end{aligned}$$

◁

By combining our ADO construction with Claims 12 and 13 we have proven the following lemma.

▶ **Lemma 14.** *For any graph G with n vertices, real $0 \leq \alpha < \frac{1}{3}$ and constant $\hat{c} \geq 1$, it is possible to construct an ADO that uses $\tilde{O}(\hat{c}n^{\frac{5}{3}+\alpha})$ space and has a $(2, 1 - rad(\hat{c}n^{3\alpha}))$-stretch.*

4.2 Proof of Main Upper Bound Theorem

The following lemma connects Δ_G and $rad(s)$, which is the last ingredient needed for proving Theorem 4.

▶ **Lemma 15.** *Let $G = (V, E)$ be an unweighted undirected graph, with $|V| = n$. For any real s such that $1 \leq s < n$, it holds that $rad_G(s) \geq \lfloor \log_{\Delta_G}(s/2) \rfloor$.*

Proof. For any vertex v and integer $t \geq 1$, $T(v,t)$ cannot include more than $\Delta_G \cdot \sum_{i=0}^{t-1}(\Delta_G - 1)^i$ vertices. Since $\Delta_G, t \geq 1$ we have that $\Delta_G \cdot \sum_{i=0}^{t-1}(\Delta_G - 1)^i \leq 2 \cdot \Delta_G^t$ and so for any integer $t \geq 1$ such that $2 \cdot \Delta_G^t < n$ it must be that $T(v,t) \subseteq N(v, 2 \cdot \Delta_G^t)$. By definition, $ecc(v,s)$ is equal to the largest integer $x \in [0, ecc(v)]$ for which $T(v,x) \subseteq N(v,s)$. Thus, $t \leq ecc(v, 2 \cdot \Delta_G^t)$. Since $t \leq ecc(v, 2 \cdot \Delta_G^t)$ for any vertex v, it follows from the definition of $rad(s) = \min_{v \in V}\{ecc(v,s)\}$ that $t \leq rad(2 \cdot \Delta_G^t)$. Setting $s \geq 2 \cdot \Delta_G^t$, or $t \leq \log_{\Delta_G}(s/2)$, it follows that for any integer t such that $t \leq \log_{\Delta_G}(s/2)$ it must be that $t \leq rad(2 \cdot \Delta_G^t) \leq rad(s)$. Thus, $\lfloor \log_{\Delta_G}(s/2) \rfloor \leq rad(s)$. ◀

Finally, we are ready to prove Theorem 4.

Proof of Theorem 4. It holds that $k = \lfloor \log_{\Delta_G}(\Delta_G^k) \rfloor \leq \lfloor \log_{\Delta_G}(c^k n^{1-k\varepsilon}) \rfloor$, and by Lemma 15, $\lfloor \log_{\Delta_G}(c^k n^{1-k\varepsilon}) \rfloor \leq rad_G(2c^k n^{1-k\varepsilon})$. Thus, the ADO from Lemma 14 constructed for G using $\alpha = \frac{1-k\varepsilon}{3}$ and $\hat{c} = 2c^k$ uses $\tilde{O}(c^k n^{2-\frac{k\varepsilon}{3}})$ space and produces a distance estimation that satisfies $d(u,v) \leq \hat{d}(u,v) \leq \max\{d(u,v), 2d(u,v) + 1 - rad_G(2c^k n^{1-k\varepsilon})\} \leq \max\{d(u,v), 2d(u,v) + 1 - k\}$. ◀

5 Reduction from the Set Intersection Problem

Proof of Lemma 6. Given an instance of Problem 1, we construct a graph G with $n = \tilde{O}(N)$ vertices and $\Delta_G = O(n^{1/k})$, such that a $(k, k+2)$-distinguisher oracle for G solves the instance of Problem 1.

We begin by focusing on a $k+1$ layered graph $\mathcal{L} = (V_{\mathcal{L}}, E_{\mathcal{L}})$, which we call the *infrastructure graph*. The infrastructure graph has three important properties: (*i*) each layer contains N vertices, (*ii*) there is a path of length k from every vertex in the first layer to every vertex in the last layer, and (*iii*) the degree of every vertex is at most $2N^{1/k}$.

We then construct for each $x \in X$ a graph $G_x = (V_x, E_x)$, which is a subgraph of (a copy of) $\mathcal{L}$, by removing some of the edges between the first (last) and second (second to last) layers of $\mathcal{L}$ in a way that expresses which sets contain x and which do not. Finally, we construct the graph G which is *specialized* union of all of the graphs G_x for all $x \in X$, and enables solving the instance of Problem 1 by using a $(k, k+2)$-distinguisher oracle on G.

The infrastructure graph. The infrastructure graph $\mathcal{L}$ is a $k+1$ layered graph where each layer contains N vertices, and each layer of N vertices is locally indexed from 1 to N. The layers are numbered 0 to k.

The edges of $\mathcal{L}$ are defined using the following labels. Assign a *label* $\ell(v)$ to every vertex v in $\mathcal{L}$ which is the k digit representation in base[7] $N^{1/k}$ of the local index (an integer between 1 and N) of v. Then, for every $1 \leq t \leq k$, connect u from layer $t-1$ with v from layer t if and only if the digits of $\ell(u)$ and the digits of $\ell(v)$ all match, except for possibly the t'th digit. It is straightforward to observe (since each digit has $N^{1/k}$ options) that the degree of every vertex in $\mathcal{L}$ is $2N^{1/k}$, except for the vertices in the first and last layers which have degree $N^{1/k}$. The following claim shows that there is a path of length k from every vertex in the first layer and every vertex in the last layer.

▷ Claim 16. Let v be a vertex in the first layer of $\mathcal{L}$ and let u be a vertex in the last layer of $\mathcal{L}$. Then there exists a path of length k from u to v in $\mathcal{L}$.

Proof. We describe the path of length k between u and v. For any $0 \leq t \leq k$, consider the vertex w_t in layer t of $\mathcal{L}$ with the label of the following form: the first t digits are the first t digits of $\ell(u)$, and the last $k-t$ digits are the last $k-t$ digits of $\ell(v)$. Thus, for $0 \leq t \leq k-1$, the edge (w_t, w_{t+1}) is in $\mathcal{L}$ since $\ell(w_t)$ and $\ell(w_{t+1})$ are the same, except for possibly the $(t+1)$-th digit. The set of edges which we described form a path of length k between v and u. ◁

[7] We assume for convenience that $N^{1/k}$ is an integer, since otherwise, one can increase N slightly without affecting the asymptotic complexities.

Constructing G_x. We construct V_x by making copies of each vertex in $V_{\mathcal{L}}$. Denote the first layer of $\mathcal{L}$ by $V_L = \{v_1, \ldots, v_N\}$ and the last layer by $V_R = \{u_1, \ldots, u_N\}$. Let $\hat{E}_x = \{(v_i, w) | x \notin S_i \wedge (v_i, w) \in E_{\mathcal{L}}\} \cup \{(u_i, w) | x \notin S_i \wedge (u_i, w) \in E_{\mathcal{L}}\}$. Thus, $\hat{E}_x$ is the set of edges in $\mathcal{L}$ that touch vertices in the first or last layers whose index corresponds to the index of sets that do not contain x. We construct E_x by making copies of all edges in $E_{\mathcal{L}} \setminus \hat{E}_x$. The reason for removing the edges in $\hat{E}_x$ is so that vertices in the first and last layers of G_x whose edges are in $\hat{E}_x$ are not connected to any other vertex in G_x. Thus, for each v_i (u_j) in the first (last) layer of G_x, $x \in S_i$ if and only if there are edges between v_i (u_j) and the second (second to last) layer in G_x. By Claim 16, if $S_i \cap S_j \neq \emptyset$ then there exists a path of length k between v_i and u_j, and otherwise, there is no path in G_x between v_i and u_j. Finally, since G_x is a partial copy of $\mathcal{L}$, the maximum degree in G_x is $2N^{1/k}$.

Constructing G. We construct the $k+1$ layered graph G by performing the following special union of G_x for all x: for $1 \leq t \leq k-1$ the t'th layer of G is the union of the t'th layer of all of the G_x graphs taken over all $x \in X$. Thus, each of the $k-1$ inner layers (excluding the first and last layer of G) has $|X|N$ vertices. For the first (last) layer G, instead of taking the union of all of the first (last) layers from all of the G_x graphs, we merge them all into one layer of N vertices. So the i'th vertex in the first (last) layer of G is a vertex obtained by merging the i'th vertex in the first (last) layer of every G_x, for all $x \in X$. Thus, the first and last layers of G_x contain N vertices each. Since the vertices in the first and last layer of G correspond directly to the vertices V_L and V_R in $\mathcal{L}$, respectively, we treat the first layer of G as $V_L = \{v_1, \ldots v_n\}$ and the last layer of G by $V_R = \{u_1, \ldots, u_N\}$. Thus, each node in $V_L \cup V_R$ has maximum degree at most $|X|N^{1/k} = \tilde{O}(N^{1/k})$.

Answering a set intersection query. Notice that for a set intersection query between S_i and S_j, if $S_i \cap S_j \neq \emptyset$, then there exists some $x \in S_i \cap S_j$, and since G contains G_x as a subgraph, the distance between v_i and u_j is at most (and actually exactly) k. On the other hand, if there exists a path P of length k between v_i and u_j, then by the construction of G, P must be completely contained within some G_x for some $x \in X$. By the construction of G_x, and specifically E_x, the existence of P in G_x implies that $x \in S_i$ and $x \in S_j$. So, in such a case $S_i \cap S_j \neq \emptyset$.

Notice that, since G is a $k+1$ layered graph, any path between a vertex in the first layer and a vertex in the last layer must be of length $k + 2q$ for some integer $q \geq 0$. Thus, to answer a set intersection query, it suffices to establish whether the distance in G between v_i and u_j is either k or at least $k+2$, which the $(k, k+2)$-distinguisher oracle returns in constant time.

Analysis. We conclude that a $(k, k+2)$-distinguisher oracle for graphs with $n = \tilde{O}(N)$ vertices and maximum degree $\tilde{O}(n^{1/k})$ also solves the instance of Problem 1 (of size N). Thus, according to Hypothesis 2, an ADO for graphs with $n = \tilde{O}(N)$ vertices, for which the maximum degree is $\tilde{O}(n^{1/k})$, must use $\tilde{O}(N^2) = \tilde{O}(n^2)$ space. We note that the maximum degree can be reduced to $O(n^{1/k})$ by artificially adding $\tilde{O}(n) = \tilde{O}(N)$ isolated vertices to G. ◀

6 Conclusions and Open Problems

In this paper we provide an algorithm (Theorem 4) and a conditional lower bound (Theorem 5) for subquadratic space ADOs as a function of the maximum degree. As mentioned in Section 1, the case of $k = 2$ in Theorem 5 essentially matches the upper bound of Theorem 4. Although

the upper bound from Theorem 4 improves the additive approximation of the ADO for larger values of k, a natural remaining open problem is whether it is also possible to reduce the multiplicative approximation of the ADO and design a sub-$\frac{k+2}{k}$ stretch ADO for graphs with maximum degree $\Theta(n^{\frac{1}{k}-\Omega(1)})$ while using subquadratic space for integers $k \geq 3$.

Lipschitz Continuous Allocations for Optimization Games

Soh Kumabe
CyberAgent, Tokyo, Japan

Yuichi Yoshida
National Institute of Informatics, Tokyo, Japan

Abstract

In cooperative game theory, the primary focus is the equitable allocation of payoffs or costs among agents. However, in the practical applications of cooperative games, accurately representing games is challenging. In such cases, using an allocation method sensitive to small perturbations in the game can lead to various problems, including dissatisfaction among agents and the potential for manipulation by agents seeking to maximize their own benefits. Therefore, the allocation method must be robust against game perturbations.

In this study, we explore optimization games, in which the value of the characteristic function is provided as the optimal value of an optimization problem. To assess the robustness of the allocation methods, we use the Lipschitz constant, which quantifies the extent of change in the allocation vector in response to a unit perturbation in the weight vector of the underlying problem. Thereafter, we provide an algorithm for the matching game that returns an allocation belonging to the $\left(\frac{1}{2}-\epsilon\right)$-approximate core with Lipschitz constant $O(\epsilon^{-1})$. Additionally, we provide an algorithm for a minimum spanning tree game that returns an allocation belonging to the 4-approximate core with a constant Lipschitz constant.

The Shapley value is a popular allocation that satisfies several desirable properties. Therefore, we investigate the robustness of the Shapley value. We demonstrate that the Lipschitz constant of the Shapley value for the minimum spanning tree is constant, whereas that for the matching game is $\Omega(\log n)$, where n denotes the number of vertices.

1 Introduction

1.1 Background and Motivation

Cooperative games model decision-making scenarios in which multiple agents can achieve greater benefits through cooperation. A primary concern in cooperative game theory is the allocation of payoffs or costs provided by the grand coalition in an acceptable manner to each agent. Among the cooperative games, those defined by optimization problems corresponding to the set of agents involved are known as *optimization games* [8].

Consider the following well-known examples formulated by the matching game (MG) [9, 3] and the minimum spanning tree game (MSTG) [6]:

MG: Members of a tennis club form pairs for a doubles tournament. Each pair of players has a predicted value for the prize money they would win if they teamed up. How should the total prize money won by all pairs be distributed among members?

MSTG: Multiple facilities cooperate to construct a power grid to receive electricity from a power plant. Each potential power line has a predetermined installation cost. When constructing a power grid that ensures electricity distribution to all facilities, what cost should each facility bear?

In these examples, the characteristic function of the game often contains errors, or can be manipulated through deliberate misreporting. For instance,

MG: It is challenging to accurately predict the compatibility of pairs who have never teamed up before. Moreover, pairs known to work well may hide this fact.

MSTG: Costs for power line installation might be misestimated owing to unforeseen terrain or geological conditions caused by natural disasters or inadequate surveys, land rights, or landscape regulations. Facilities may conceal these issues.

In such uncertain situations, allocations that drastically change with slight perturbations in the game can lead to problems, such as

MG: If minor estimation errors in predicted prize money significantly change the benefits for each player, players might not be satisfied with the allocation. In addition, when someone falsely reports a substantial increase in their gain, it becomes difficult to prove the intent of the manipulation if the degree of falsehood is small.

MSTG: Facilities might not accept the allocation if trivial issues in power line construction significantly increase their cost burden. Moreover, if such issues are used to significantly reduce their own costs or increase those of competing facilities, several minor construction issues may be concealed, leading to risk management problems.

To avoid these issues, it is desirable to use allocations that are robust against perturbations in real-world cooperative games.

Before proceeding, we define some terms in cooperative game theory. The *cooperative game* (V, ν) is defined as a pair consisting of a set of *agents* V and a *characteristic function* $\nu\colon 2^V \to \mathbb{R}_{\geq 0}$ representing the payoff or cost obtained when subsets of agents cooperate. An *optimization game* is defined by the optimization problem $\mathcal{P}$ in a discrete structure. The *$\mathcal{P}$-game* (G, w) is defined from a pair of structures G consisting of *agent set* V, *edge set* E, and a weight vector $w \in \mathbb{R}^E_{\geq 0}$. In several games, G is a graph (V, E). For each subset $S \subseteq V$, the characteristic function value $\nu(S)$ is defined as the optimum value of $\mathcal{P}$ on the substructure corresponding to S (e.g., the subgraph induced by S) with respect to weight vector w. An optimization game is a *welfare allocation game* (resp., *cost allocation game*) if each agent intends to maximize (resp., minimize) the value allocated to it.

Now, we formally introduce matching games and minimum spanning tree games, as discussed in previous examples.

▶ **Definition 1** (Matching game [3, 8]). *Let $G = (V, E)$ be an undirected graph. For a vertex set $S \subseteq V$ and an edge weight vector $w \in \mathbb{R}^E_{\geq 0}$, let $\mathrm{OPT}(S, w)$ denote the maximum matching weight in $G[S]$ with respect to weight w, where $G[S]$ represents the subgraph of G induced by S. The* matching game *of G with respect to weight w is defined as (V, ν), where $\nu(S) = \mathrm{OPT}(S, w)$. The matching game is a welfare-allocation game.*

▶ **Definition 2** (Minimum spanning tree game [4, 6]). *Let $G = (V \cup \{r\}, E)$ be an undirected graph. For a vertex set $S \subseteq V$ and edge weight vector $w \in \mathbb{R}^E_{\geq 0}$, let $\mathrm{OPT}(S, w)$ denote the minimum weight of a spanning tree in $G[S \cup \{r\}]$ with respect to weight w. Notably, vertex r does not correspond to the agent. To ensure that the characteristic function has finite values, we assume that edge (r, v) exists for all $v \in V$. The* minimum spanning tree game *of G with respect to weight w is defined as (V, ν), where $\nu(S) = \mathrm{OPT}(S, w)$. The minimum spanning tree game is a cost-allocation game.*

Let us return to the discussion of the robustness of the allocation. To measure the robustness of the allocation, we introduce the concept of *Lipschitz continuity* in the allocation of these games, analogous to the introduction of Kumabe and Yoshida [23] for discrete optimization problems under the same name. Algorithm $\mathcal{A}$ that takes a weight vector $w \in \mathbb{R}^E$ and returns an allocation $x \in \mathbb{R}^V_{\geq 0}$ is *L-Lipschitz* or has *Lipschitz constant* L if:

$$\sup_{\substack{w,w' \in \mathbb{R}^E_{\geq 0} \\ w \neq w'}} \frac{\|\mathcal{A}(w) - \mathcal{A}(w')\|_1}{\|w - w'\|_1} \leq L. \tag{1}$$

If the Lipschitz constant of the allocation method is small, the change in the allocation in response to a unit change in the weight vector is guaranteed to be small. Employing such an allocation method can resolve these problems as follows:

MG: Minor mistakes in estimating the compatibility of pairs will not significantly affect the overall distribution of prize money, making it easier for agents to accept the allocation. Additionally, substantial misreporting is necessary to increase benefits significantly through declaration adjustments, making schemes more likely to be exposed.

MSTG: Minor issues related to the installation of power lines will not cause significant fluctuations in the cost burden for each facility, making it easier for them to accept their share of the costs. Additionally, because the loss incurred by reporting such issues is small, the likelihood of these issues being concealed is reduced.

1.1.1 The core

The *core* is the most fundamental solution concept in cooperative game theory. An allocation vector $x \in \mathbb{R}^V$ is in the core of (welfare allocation) cooperative game (V, ν) if:

$$\sum_{v \in S} x_v \geq \nu(S) \quad (S \subsetneq V), \quad \sum_{v \in V} x_v = \nu(V). \tag{2}$$

Similarly, an allocation vector $x \in \mathbb{R}^V$ is in the core of (cost allocation) cooperative game (V, ν) if:

$$\sum_{v \in S} x_v \leq \nu(S) \quad (S \subsetneq V), \quad \sum_{v \in V} x_v = \nu(V). \tag{3}$$

Because the core is one of the most fundamental solution concepts, it is natural to desire a Lipschitz continuous algorithm $\mathcal{A}$ that takes a weight vector as the input and returns an allocation belonging to the core. However, this can only be achieved in a limited number of situations for two reasons. First, a non-empty core does not necessarily exist in all games. Second, even for games in which the core exists in all instances, there is no guarantee that a vector from the core can be selected such that the Lipschitz constant of $\mathcal{A}$ remains small.

To examine the second reason, we consider the *assignment game* introduced by Shapley and Shubik [29], which is a special case of the matching game in which the underlying graph is bipartite and known to have a non-empty core [8, 29].

▶ **Example 3.** Let n be an odd number greater than or equal to 5. Let us consider a path $G = (V, E)$ consisting of n vertices labeled sequentially as $v_1, \ldots, v_n$. The weight vectors $w, w' \in \mathbb{R}^E_{\geq 0}$ are defined as follows:

$$w_{(v_i, v_{i+1})} = 1 \quad (i = 1, \ldots, n-1), \qquad w'_{(v_i, v_{i+1})} = \begin{cases} 1 & \text{if } 2 \leq i \leq n-2 \\ 0 & \text{otherwise} \end{cases}$$

In this case, the allocations x, x' belonging to the core of the assignment game for w and w' are both unique and obtained as follows:

$$x_i = \begin{cases} 1 & \text{if } i \text{ is even} \\ 0 & \text{otherwise} \end{cases} \qquad x'_i = \begin{cases} 1 & \text{if } i \text{ is odd and } i \notin \{1, n\} \\ 0 & \text{otherwise} \end{cases}$$

If $\mathcal{A}$ is an algorithm that takes a weight vector and returns a vector in the core of the game, then it must satisfy:

$$\frac{\|\mathcal{A}(w) - \mathcal{A}(w')\|_1}{\|w - w'\|_1} = \frac{n-2}{2} = \Omega(n)$$

Thus, algorithm $\mathcal{A}$ must have a large Lipschitz constant, $\Omega(n)$.

Therefore, we consider providing a Lipschitz continuous algorithm that outputs allocations that satisfy some looser solution concepts. The least core [28] is one such solution concept that can be defined even for games in which a core does not exist. However, this does not resolve the problem of a large Lipschitz constant (for instance, in the game in Example 3, the core and the least core coincide, resulting in a Lipschitz constant of $\Omega(n)$). Instead, we consider the approximate core, which is a solution concept that multiplicatively relaxes the constraints of partial coalitions.

1.1.2 Approximate Core

The approximate core was introduced by Faigle and Kern [11] as a useful solution concept for games where the core is empty. Intuitively, the approximate core represents the core when the constraints for partial coalitions are relaxed by a factor α. For $\alpha \leq 1$, the allocation vector $x \in \mathbb{R}^V$ is in the *α-(approximate) core* of the (welfare allocation) cooperative game (V, ν) if:

$$\sum_{v \in S} x_v \geq \alpha \nu(S) \quad (S \subsetneq V), \quad \sum_{v \in V} x_v = \nu(V).$$

Similarly, for $\alpha \geq 1$, the allocation vector $x \in \mathbb{R}^V$ is in the *α-(approximate) core* of the (cost allocation) cooperative game (V, ν) if:

$$\sum_{v \in S} x_v \leq \alpha \nu(S) \quad (S \subsetneq V), \quad \sum_{v \in V} x_v = \nu(V).$$

In this study, we provide algorithms with small Lipschitz constants that return an α-approximate core for some constant α in several optimization games. For the matching game, we obtain the following:

▶ **Theorem 4.** *Let $\epsilon \in \left(0, \frac{1}{2}\right]$. For the matching game, there is a polynomial-time algorithm with a Lipschitz constant $O(\epsilon^{-1})$ that returns $\left(\frac{1}{2} - \epsilon\right)$-approximate core allocation.*

Note that Faigle and Kern [11] and Vazirani [32] showed that the $\frac{2}{3}$-approximate core of the matching game is non-empty, and that this is also a tight bound. However, their allocation, which is constructed using the optimal solution of the matching LP, is not Lipschitz continuous. Our allocation compromises the core approximability by $\frac{1}{6} + \epsilon$ to ensure Lipschitz continuity.

Our allocation was inspired by the Lipschitz continuous algorithm for the maximum weight-matching problem proposed by Kumabe and Yoshida [23]. Similarly, the proposed algorithm is based on the greedy method. We emphasize our results because their algorithm

reduces the approximation ratio to $\frac{1}{8} - \epsilon$ to obtain a Lipschitz constant of $O(\epsilon^{-1})$. Although the definitions of Lipschitz continuity and the approximation ratio for discrete algorithms differ from those for allocations, making a simple comparison infeasible, our analysis is simpler and offers better approximation guarantees.

For the minimum spanning tree game, we have the following.

▶ **Theorem 5.** *For the minimum spanning tree game, there is a polynomial-time algorithm with Lipschitz constant $O(1)$ that returns 4-approximate core allocation.*

The core of the minimum spanning tree game is non-empty; an allocation by Bird [4] is known to belong to the core and can be computed in polynomial time. However, it is not Lipschitz continuous. As in the matching game, our allocation compromises the core approximability to ensure Lipschitz continuity.

The original motivation for the approximate core was to provide useful solution concepts for games with non-empty cores. Therefore, no studies have been conducted on the approximate core of the minimum spanning tree game. In this regard, our setting demonstrates the usefulness of considering an approximate core, even for games with a non-empty core.

1.1.3 Shapley Value

Let $\mathfrak{S}_V$ be the set of all permutations over V. For $\sigma \in \mathfrak{S}_V$ and $v \in V$, let $x_{\sigma,v} = \nu(\{\sigma(1), \dots, \sigma(k)\}) - \nu(\{\sigma(1), \dots, \sigma(k-1)\})$, where k is the integer with $\sigma(k) = v$. The *Shapley value* [27] of game (V, ν) is the vector s defined by:

$$s_v = \frac{1}{|V|!} \sum_{\sigma \in \mathfrak{S}_V} x_{\sigma,v}.$$

The Shapley value does not necessarily belong to the core, even if it exists, and the computation is #P-hard in most optimization games. However, they exhibit various desirable properties and have a wide range of applications [16]. Therefore, investigating the Lipschitz continuity of Shapley values is a natural task.

Considering its various properties, it is natural to expect the Shapley value to always have a small Lipschitz constant for general optimization games. Conversely, given the difficulty in computing it, it is natural to anticipate that it may not have a bounded Lipschitz constant. However, neither was accurate. Specifically, we demonstrate that whether the Shapley value in optimization games has a small Lipschitz constant depends on the game.

▶ **Theorem 6.** *There is a graph G such that the Shapley value of the matching game on G has a Lipschitz constant $\Omega(\log n)$.*

▶ **Theorem 7.** *The Shapley value of the minimum spanning tree game has a Lipschitz constant of 2.*

Notably, the computation of the Shapley value for the minimum spanning tree game is #P-hard [1]. The result of Theorem 7 is particularly interesting because it shows a value that is computationally difficult to calculate may still have a small Lipschitz constant.

1.2 Related Work

1.2.1 Optimization Games

The history of optimization games begins with the *assignment game* proposed by Shapley and Shubik [29]. They showed that the core of the assignment game is represented by the optimal solution of dual linear programming and is always non-empty. Deng, Ibaraki, and

Nagamochi [8] defined a class of games in which the characteristic function is represented by integer programming, and discussed the core structures of such games. In particular, for the matching game, they proved that the core is not always non-empty, but that the core non-emptiness problem, core membership problem, and that of generating a vector in the core if it is non-empty are solvable in polynomial time. Aziz and de Keijzer [2] proved that computing the Shapley value of the matching game is #P-hard. Additionally, studies on the generalization of matching games such as the *hypergraph matching game* [7, 8, 20] and *b-matching game* [5, 19, 30, 34], are being conducted. For a more detailed survey of the algorithmic aspects of matching games, see [3].

The minimum spanning tree game was proposed by Claus and Kleitman [6]. Bird [4] later proposed an allocation defined as follows: Regarding the minimum spanning tree of a given graph as a rooted tree rooted at r, each agent corresponding to a vertex v is allocated a cost equal to the weight of the edge from v to its parent. Granot and Huberman [14] proved this allocation is in the core. Unfortunately, it is not (Lipschitz) continuous. Faigle et al. [13] proved that the core membership problem for the minimum spanning tree game is coNP-hard. Ando [1] proved that the Shapley value of the minimum spanning tree game is #P-hard.

The concept of an approximate core was introduced by Faigle and Kern [11] as a useful solution for games where the core is empty. Their work discussed the approximate core allocations for several optimization games, including the matching game. In particular, for the matching game, they constructed a $\frac{2}{3}$-core allocation based on LP relaxation. Subsequently, extensive studies have been conducted to determine the best α for which the α-core is always non-empty in various optimization games in which the core can be empty, such as the traveling salesman game [10, 11] and bin-packing games [11, 12, 17, 18, 26, 33]. Recently, following the rediscovery of Faigle and Kern's results by Vazirani [32], approximate cores have been derived for several optimization games such as the b-matching game [34] and the edge cover game [24].

Notably, in the definition by Faigle and Kern [11] and in subsequent papers, the right-hand side of Equations (2) or (3) being $(1 \pm \epsilon)\nu(S)$ is referred to as the ϵ-core. However, following the conventions in the field of discrete optimization and the study by Vazirani [32] and subsequent studies [24, 34], we adopt the definitions of Equations (2) and (3). An ϵ-core in our definition corresponds to a $|1 - \epsilon|$-core in Faigle and Kern's definition.

1.2.2 Lipschitz Continuity of Discrete Algorithms

Inspired by recent studies on the average sensitivity [15, 21, 25, 31, 35] for *unweighted* discrete optimization problems, Kumabe and Yoshida [23] introduced the Lipschitz continuity of a randomized algorithm $\mathcal{A}$ for *weighted* discrete optimization problems as follows:

$$\sup_{\substack{w,w' \in \mathbb{R}^V_{\geq 0}, \\ w \neq w'}} \frac{\min_{\mathcal{D} \in \Pi(\mathcal{A}(G,w), \mathcal{A}(G,w'))} \mathbf{E}_{(S,S') \sim \mathcal{D}} \left[d_{\mathrm{w}} \left((S, w), (S', w') \right) \right]}{\|w - w'\|_1}, \tag{4}$$

where $\mathcal{A}(G, w)$ represents the output distribution of algorithm $\mathcal{A}$ for input G with weight vector $w \in \mathbb{R}^V_{\geq 0}$, $\Pi(X, X')$ denotes the set of all joint distributions for random variables X and X', and

$$d_{\mathrm{w}}((S, w), (S', w')) = \left\| \sum_{v \in S} w_v \mathbf{1}_v - \sum_{v \in S'} w'_v \mathbf{1}_v \right\|_1 = \sum_{v \in S \cap S'} |w_v - w'_v| + \sum_{v \in S \setminus S'} w_v + \sum_{v \in S' \setminus S} w'_v.$$

They also proposed algorithms with small Lipschitz constants for the minimum spanning tree, shortest path, and maximum weight matching problems. In a subsequent study [22], the authors obtained algorithms with small Lipschitz constants for the minimum weight vertex cover, minimum weight set cover, and feedback vertex set problems.

In discrete optimization, the outputs of the algorithms are discrete sets. Thus, deterministic algorithms cannot be Lipschitz continuous; they consider randomized algorithms and adopt the earth mover's distance in the numerator of (4). In contrast, the outputs of our algorithms are allocations of continuous values, allowing deterministic algorithms to be Lipschitz continuous and randomized algorithms to be derandomized by taking the expectation. Therefore, in our setting, we can use a simple definition of the deterministic algorithms expressed in Equation (1).

1.3 Organization

The remainder of this paper is organized as follows: In Section 2, we provide several useful lemmas to analyze Lipschitz continuity of allocations. In Section 3, we prove Theorem 4 by providing a Lipschitz continuous polynomial-time algorithm that returns an approximate core allocation to the matching game. In Section 4, we prove Theorem 5 by providing a Lipschitz continuous polynomial-time algorithm that returns an approximate core allocation for the minimum spanning tree game. The proofs of Theorem 6 and Theorem 7 are given in the full version.

2 Basic Facts

In this section, we provide useful lemmas to analyze the core approximability and Lipschitz continuity of our allocations. The following lemma is useful for obtaining the Lipschitz constant: We omit this proof because it is similar to Lemma 1.7 of [23].

▶ **Lemma 8.** *Let $(G = (V, E), w)$ be an optimization game and $\mathcal{A}$ be an algorithm that takes a pair (G, w) and outputs an allocation. Suppose that there exist some $c > 0$ and $L > 0$ such that*

$$\|(\mathcal{A}(G, w), \mathcal{A}(G, w + \delta \mathbf{1}_e)\|_1 \leq \delta L$$

holds for any $e \in E$, $w \in \mathbb{R}^E_{\geq 0}$, and $\delta > 0$ with either $\delta \leq c \cdot w_e$ or $w_e = 0$, where $\mathbf{1}_e$ represents the characteristic vector of e. Then, $\mathcal{A}$ has a Lipschitz constant L.

In the analysis of the core approximability and Lipschitz continuity of allocations, we can simplify the discussion by ignoring the constraint $\sum_{v \in V} x_v = \nu(V)$ for a grand coalition. Therefore, we require a method to obtain an allocation with a bounded Lipschitz constant from vectors that satisfy only the constraints for partial coalitions with a bounded Lipschitz constant. To achieve this, we require a mild assumption in the game. An optimization game $(G = (V, E), w)$ is said to be *reasonable* if the inequality $|\nu(V, w) - \nu(V, w')| \leq \|w - w'\|_1$ holds for all $w, w' \in \mathbb{R}_{\geq} 0^E$. Notably, this is a fair assumption. For instance, games defined for optimization problems in the form of

$$\max \text{ or } \min \sum_{e \in X} w_e, \text{ subject to } X \in \mathcal{F}$$

for $\mathcal{F} \subseteq 2^E$ are all reasonable. The next lemma applies to welfare allocation games, such as the matching game. Due to the space limit, the proofs of the next two lemmas are given in the full version.

Algorithm 1 Lipschitz continuous allocation for the matching game.

Procedure MatchingGame(G, w, b, α)
  Input: A graph $G = (V, E)$, where the edge set is indexed with integers in $\{1, 2, \ldots, |E|\}$, a weight vector $w \in \mathbb{R}^E_{\geq 0}$, $b \in [0, 1]$, and $\alpha \in (1, 2]$.
  For each $e \in E$ with $w_e > 0$, let $\widehat{w}_e \leftarrow \alpha^{i_e+1+b}$, where i_e is the unique integer such that $\alpha^{i_e+b} \leq w_e < \alpha^{i_e+1+b}$;
  $z \leftarrow 0^V$, $M \leftarrow \emptyset$;
  for $e \in E$ *in descending order of* w_e*, where ties are broken according to their indices* **do**
    if *none of the two endpoints of* e *are covered by* M **then**
      Add e to M;
      $z_v \leftarrow \widehat{w}_e$ for each endpoint v of e;
  return z;

▶ **Lemma 9.** *Let $D \geq 1$. Let $\mathcal{A}$ be an algorithm that takes a weight vector $w \in \mathbb{R}^E_{\geq 0}$ and returns an allocation $\mathcal{A}(w) \in \mathbb{R}^V_{\geq 0}$ for a reasonable welfare allocation game. Assume $\mathcal{A}$ satisfies $\|\mathcal{A}(w)\|_1 \leq D\nu(V, w)$, $\sum_{v \in S} \mathcal{A}(w)_v \geq \nu(S, w)$ for all weight vector w and $S \subseteq V$, and $\|\mathcal{A}(w) - \mathcal{A}(w')\|_1 \leq L\|w - w'\|_1$ for all two weight vectors w and w'. Then, there is an algorithm that returns $\frac{1}{D}$-approximate core allocation with Lipschitz constant $2L + 1$.*

The next lemma applies to cost allocation games, such as the minimum spanning tree game.

▶ **Lemma 10.** *Let $D \geq 1$. Let $\mathcal{A}$ be an algorithm that takes a weight vector $w \in \mathbb{R}^E_{\geq 0}$ and returns an allocation $\mathcal{A}(w) \in \mathbb{R}^V_{\geq 0}$ for a reasonable cost allocation game. Assume $\mathcal{A}$ satisfies $\|\mathcal{A}(w)\|_1 \geq \nu(V, w)$, $\sum_{v \in S} \mathcal{A}(w)_v \leq D\nu(S, w)$ for all weight vector w, and $\|\mathcal{A}(w) - \mathcal{A}(w')\|_1 \leq L\|w - w'\|_1$ for all two weight vectors w and w'. Then, there is an algorithm that returns D-approximate core allocation with Lipschitz constant $2L + 1$.*

3 Matching Game

In this section, we prove Theorem 4 by giving a Lipschitz continuous algorithm that returns an approximate core allocation of the matching game. We obtain the proof by constructing an algorithm that satisfies the assumptions in Lemma 9. Specifically, we prove that an algorithm that returns a vector represented by

$$\int_0^1 \textsc{MatchingGame}(G, w, b, \alpha) \mathrm{d}b \tag{5}$$

satisfies the assumptions of Lemma 9, where the procedure MatchingGame is provided in Algorithm 1. We give a deterministic algorithm to compute this integral in Section 3.3.

MatchingGame(G, w, b, α) first rounds each edge weight w_e to a value $\widehat{w}_e$ that is proportional to a power of α, where the proportionality constant is determined by b. Thereafter, it sorts the edges in descending order of $\widehat{w}_e$ and greedily selects them to form maximal matching M. Finally, for each edge $e \in M$, the algorithm allocates $\widehat{w}_e$ to both endpoints of the edges in M.

3.1 Core Approximability

The proofs of the following two lemmas for the core approximability analysis of Algorithm 1 are relatively straightforward.

▶ **Lemma 11.** *We have* $\|z\|_1 \leq 2\alpha \mathrm{OPT}(V, w)$.

Proof. Because M is a matching of G, we have $\sum_{e\in M} w_e \leq \mathrm{OPT}(V, w)$. Because the modified weight $\widehat{w}_e$ of each edge e in M contributes twice to $\|z\|_1$, we obtain

$$\|z\|_1 = 2\sum_{e\in M} \widehat{w}_e \leq 2\alpha \sum_{e\in M} w_e \leq 2\alpha \mathrm{OPT}(V, w). \qquad \blacktriangleleft$$

▶ **Lemma 12.** *Let* $S \subseteq V$. *Then, we have* $\sum_{v\in S} z_v \geq \mathrm{OPT}(S, w)$.

Proof. Let $e = (u, v) \in E$. When edge e begins to be examined in the loop starting from Line 4, if at least one of u or v (say, u) is already covered by M, then we have $\widehat{w}_e \leq z_u$. If neither u nor v are covered, then edge e is added to M, resulting in $\widehat{w}_e = z_u = z_v$. Therefore, $\widehat{w}_e \leq \max\{z_u, z_v\} \leq z_u + z_v$. Let M' be the maximum matching of $G[S]$. Then, we have

$$\sum_{v\in S} z_v \geq \sum_{(u,v)\in M'} (z_u + z_v) \geq \sum_{e\in M'} \widehat{w}_e \geq \sum_{e\in M'} w_e = \mathrm{OPT}(S, w). \qquad \blacktriangleleft$$

3.2 Lipschitz Continuity

Let $G = (V, E)$ be a graph, $f \in E$, $\delta > 0$, $b \in [0, 1]$, and $\alpha > 1$. We will bound

$$\frac{1}{\delta}\int_0^1 \left\|\textsc{MatchingGame}(G, w, b, \alpha) - \textsc{MatchingGame}(G, w + \delta\mathbf{1}_f, b, \alpha)\right\|_1 \mathrm{d}b, \tag{6}$$

which is an upper bound on

$$\frac{1}{\delta}\left\|\int_0^1 \textsc{MatchingGame}(G, w, b, \alpha)\mathrm{d}b - \int_0^1 \textsc{MatchingGame}(G, w + \delta\mathbf{1}_f, b, \alpha)\mathrm{d}b\right\|_1.$$

From Lemma 8, bounding (6) for $\delta \leq w_f$ or $w_f = 0$ is sufficient to prove Lipschitz continuity. We denote the value of $\widehat{w}$, M, and z in $\textsc{MatchingGame}(G, w, b, \alpha)$ (resp., $\textsc{MatchingGame}(G, w + \delta\mathbf{1}_f, b, \alpha)$) as $\widehat{w}$, M, and z (resp., $\widehat{w}'$, M', and z').

When $\widehat{w}_f = \widehat{w}'_f$, $\textsc{MatchingGame}(G, w, b, \alpha)$ and $\textsc{MatchingGame}(G, w + \delta\mathbf{1}_f, b, \alpha)$ output the same vector. Assume otherwise. In $\textsc{MatchingGame}(G, w, b)$, edge e_1 coming *before* edge e_2 refers to e_1 being considered before e_2 in the loop starting from Line 4, and is denoted as $e_1 \prec_{\widehat{w}} e_2$. In other words, either $\widehat{w}_{e_1} > \widehat{w}_{e_2}$ or $\widehat{w}_{e_1} = \widehat{w}_{e_2}$ and the index of e_1 comes earlier than that of e_2. For $e_1 \neq f \neq e_2$, the relations $e_1 \prec_{\widehat{w}} e_2$ and $e_1 \prec_{\widehat{w}'} e_2$ are equivalent. Thus, we simply denote this as $e_1 \prec e_2$. The following lemma forms the core of our Lipschitzness analysis:

▶ **Lemma 13.** *Assume* $\widehat{w}_f \neq \widehat{w}'_f$. *Then, we have* $\|z - z'\|_1 \leq 2\widehat{w}'_f$.

Proof. For each edge $e \neq f$ such that $e \in M' \setminus M$ (resp., $e \in M \setminus M'$), edge g is a *witness* of e if it is adjacent to e in M (resp., M') and $g \prec_{\widehat{w}} e$ (resp., $g \prec_{\widehat{w}'} e$). Intuitively, a witness of e is the edge that directly causes e to be excluded from M or M'.

From this definition, the witness of $e \in M' \setminus M$ belongs to $M \setminus M'$ and vice versa. Because $\prec$ is an ordering on $E \setminus \{f\}$, by tracing the witnesses from any edge in $M \triangle M'$, we will consequently arrive at f. This implies that as long as $M \neq M'$, the edges in $M \triangle M'$

form a single path or cycle including f. Moreover, in this case, we have $f \in M' \setminus M$, because if we can add f to M in MatchingGame(G, w, b, α), we could also add f to M' in MatchingGame$(G, w + \delta \mathbf{1}_f, b, \alpha)$.

Let us now complete the proof. When $M = M'$, we have $\|z - z'\|_1 \leq 2(\widehat{w}'_f - \widehat{w}_f) \leq 2\widehat{w}'_f$. Otherwise, we let $f = (u_0, v_0)$. Then, there exists a unique maximal sequence of vertices $(u_0, \dots, u_k)$ such that $(u_i, u_{i+1}) \in M \triangle M'$ for all i and $f \prec_{\widehat{w}'} (u_0, u_1) \prec (u_1, u_2) \prec \cdots \prec (u_{k-1}, u_k)$, and a unique maximal sequence of vertices $(v_0, \dots, v_l)$ such that $(v_i, v_{i+1}) \in M \triangle M'$ for all i and $f \prec_{\widehat{w}'} (v_0, v_1) \prec (v_1, v_2) \prec \cdots \prec (v_{l-1}, v_l)$ (if $M \triangle M'$ forms a cycle, then $(u_{k-1}, u_k) = (v_l, v_{l-1})$). Now, we have

$$\begin{aligned}
\|z - z'\|_1 &\leq \sum_{i=0}^{k} |z_{u_i} - z'_{u_i}| + \sum_{i=0}^{l} |z_{v_i} - z'_{v_i}| \\
&= \left(|\widehat{w}'_f - \widehat{w}_{(u_0,u_1)}| + \sum_{i=1}^{k} |\widehat{w}_{(u_{i-1},u_i)} - \widehat{w}_{(u_i,u_{i+1})}| \right) + \\
&\qquad \left(|\widehat{w}'_f - \widehat{w}_{(v_0,v_1)}| + \sum_{i=1}^{l} |\widehat{w}_{(v_{i-1},v_i)} - \widehat{w}_{(v_i,v_{i+1})}| \right) \\
&\leq 2\widehat{w}'_f,
\end{aligned}$$

where the last inequality is from the fact that the sequences defined by $\left(\widehat{w}'_f, \widehat{w}_{(u_0,u_1)}, \dots, \widehat{w}_{(u_{k-1},u_k)}\right)$ and $\left(\widehat{w}'_f, \widehat{w}_{(v_0,v_1)}, \dots, \widehat{w}_{(v_{l-1},v_l)}\right)$ are both decreasing. ◀

The following lemma analyzes the probability that $\widehat{w}_f \neq \widehat{w}'_f$ happens.

▶ **Lemma 14.** *If b is sampled uniformly from $[0, 1]$, $\widehat{w}_f \neq \widehat{w}'_f$ happens with a probability of at most $\frac{\delta}{w_f \ln \alpha}$.*

Proof. $\widehat{w}_f \neq \widehat{w}'_f$ happens when there exists an integer i with $w_f < \alpha^{i+b} \leq w_f + \delta$, indicating that $\lfloor \log_\alpha w_f - b \rfloor \neq \lfloor \log_\alpha w_f + \delta - b \rfloor$. This happens with probability

$$\log_\alpha(w_f + \delta) - \log_\alpha w_f = \log_\alpha \left(1 + \frac{\delta}{w_f}\right) \leq \frac{1}{\ln \alpha} \cdot \frac{\delta}{w_f} = \frac{\delta}{w_f \ln \alpha}.$$ ◀

Now, we complete our Lipschitzness analysis.

▶ **Lemma 15.** *We have*

$$\int_0^1 \|\mathit{MatchingGame}(G, w, b, \alpha) - \mathit{MatchingGame}(G, w + \delta \mathbf{1}_f, b, \alpha)\|_1 \, \mathrm{d}b \leq \frac{12}{\alpha - 1}\delta.$$

Proof. If $w_f = 0$, we have

$$\begin{aligned}
&\int_0^1 \|\textsc{MatchingGame}(G, w, b, \alpha) - \textsc{MatchingGame}(G, w + \delta \mathbf{1}_f, b, \alpha)\|_1 \, \mathrm{d}b \\
&\leq 2\widehat{w}'_f \leq 2\alpha(w_f + \delta) = 2\alpha\delta \leq \frac{12}{\alpha - 1}\delta,
\end{aligned}$$

where the last inequality is from $\alpha \leq 2$. Otherwise, we have

$$\begin{aligned}
&\int_0^1 \|\textsc{MatchingGame}(G, w, b, \alpha) - \textsc{MatchingGame}(G, w + \delta \mathbf{1}_f, b, \alpha)\|_1 \, \mathrm{d}b \\
&\leq \frac{\delta}{w_f \ln \alpha} \cdot 2\widehat{w}'_f \leq \frac{\delta}{w_f \ln \alpha} \cdot 2\alpha(w_f + \delta) \leq \frac{\delta}{w_f \ln \alpha} \cdot 4\alpha w_f = \frac{4\alpha\delta}{\ln \alpha} \leq \frac{12}{\alpha - 1}\delta,
\end{aligned}$$

where the third inequality is from $\delta \leq w_f$ and the last inequality is from the fact that $\frac{\alpha}{\ln \alpha} \leq \frac{3}{\alpha - 1}$ holds for $\alpha \in (1, 2]$. ◀

3.3 Proof of Theorem 4

Combining Lemmas 11, 12, and 15 and applying Lemma 9 yields the following:

▶ **Lemma 16.** *Let $\epsilon \in \left(0, \frac{1}{2}\right]$. For the matching game, an algorithm that returns $\left(\frac{1}{2} - \epsilon\right)$-approximate core allocation with Lipschitz constant $O(\epsilon^{-1})$ exists.*

Proof. Let $\alpha = 1 + 2\epsilon$. By combining Lemmas 11, 12, 15, and 9, we obtain an algorithm that returns $\frac{1}{2\alpha}$-approximate core allocation for the matching game with Lipschitz constant $\frac{24}{\alpha - 1} + 1$. As $\frac{1}{2(1+2\epsilon)} \geq \frac{1}{2} - \epsilon$ and $\frac{24}{2\epsilon} + 1 \leq O(\epsilon^{-1})$, this algorithm satisfies the claims of the lemma. ◀

Proof of Theorem 4. It is sufficient to prove that the allocation defined by Lemma 16 can be computed in polynomial time. For each edge $e \in E$, let $b_e = \log_\alpha w_e - \lfloor \log_\alpha w_e \rfloor$, and sort the b_e values in ascending order to obtain a sequence $t_1, \ldots, t_{|E|}$. For convenience, we set $t_0 = 0$ and $t_{|E|+1} = 1$. For each $i = 0, \ldots, |E|$, the behavior of Algorithm 1 for any $b \in [t_i, t_{i+1})$ is identical, except for the constant multiplier on $\widehat{w}$. Therefore, by running Algorithm 1 for $b = t_i$ and appropriately scaling the result, and thereafter summing these results for each i, we can compute the integral in Equation (5) in polynomial time. ◀

4 Minimum Spanning Tree Game

In this section, we prove Theorem 5 by giving a Lipschitz continuous algorithm that returns an approximate core allocation for the minimum spanning tree game. The proof is obtained by constructing an algorithm that satisfies the assumption of Lemma 10. Specifically, we prove that an algorithm that returns a vector represented by

$$\int_0^1 \textsc{MSTGame}(G, w, b) \mathrm{d}b$$

satisfies the assumptions of Lemma 10, where the procedure MSTGame is provided in Algorithm 3. We give a deterministic algorithm to compute this integral in Section 4.3.

To derive our allocation, we use an *auxiliary tree* that simulates Kruskal's algorithm, constructed as in Algorithm 2. The auxiliary tree is a rooted tree such that each leaf corresponds to a vertex in $V \cup \{r\}$. We provide an overview of Algorithm 2. Initially, for each vertex $v \in V \cup \{r\}$, the algorithm prepares a vertex $u_{\{v\}}$ and sets its *height* $h_{u_{\{v\}}}$ to 0. The auxiliary tree is constructed by adding the edges of E in ascending order of weight to graph $(V \cup \{r\}, \emptyset)$. Edges of the same weight are added simultaneously. When adding the edges of a certain weight results in merging multiple connected components $C_1, \ldots, C_k$ into a single connected component C, the algorithm creates a vertex u_C corresponding to C in the auxiliary tree. The height of u_C is set as the weight of the edges at that time, and the edges are added to the auxiliary tree from u_C to $u_{C_1}, \ldots, u_{C_k}$.

For $x \in \mathbb{R}_{\geq 0}$ and a weight vector $\widehat{w}$, let $\mathcal{C}_{\widehat{w},<x}$ and $\mathcal{C}_{\widehat{w},\leq x}$ be the families of connected components of graphs whose vertex sets are $V \cup \{r\}$ and edge sets consist of edges $e \in E$ with $\widehat{w}_e < x$ and $\widehat{w}_e \leq x$, respectively. For the auxiliary tree T, we denote the subtree rooted at vertex u by T_u. When the edges of an auxiliary tree are referred to as (u, u'), u is the parent of u'. For an edge $e = (u, u')$, we denote $T_e = T_{u'}$. For simplicity, for $e = (u, u') \in E(T)$, we define $h_e := h_u$.

$\textsc{MSTGame}(G, w, b)$ first rounds each edge weight w_e to a value $\widehat{w}_e$ that is proportional to a power of 2, where the proportionality constant is determined by b. Let T be the auxiliary tree derived from $(G, \widehat{w})$. Then, for each edge e in T such that T_e does not have r as a

Algorithm 2 Construction of the auxiliary tree.

Procedure AuxiliaryTree$(G, \widehat{w})$
  Input: A graph $G = (V \cup \{r\}, E)$ and a weight vector $\widehat{w} \in \mathbb{R}^E_{\geq 0}$.
  $U \leftarrow \{u_{\{v\}} \mid v \in V \cup \{r\}\}$, $F \leftarrow \emptyset$;
  $h_u \leftarrow 0$ for each $u \in U$;
  for $x \in \mathbb{R}_{\geq 0}$ *such that* $\mathcal{C}_{\widehat{w},<x} \neq \mathcal{C}_{\widehat{w},\leq x}$, *in ascending order* **do**
    for $C \in \mathcal{C}_{\widehat{w},\leq x} \setminus \mathcal{C}_{\widehat{w},<x}$ **do**
      Add a new vertex u_C to U;
      $h_{u_C} \leftarrow x$;
      for $C' \in \mathcal{C}_{\widehat{w},<x}$ *such that* $C' \subseteq C$ **do**
        Add a new edge $(u_C, u_{C'})$ to F;
  return (U, F, h);

Algorithm 3 Lipschitz continuous allocation for the minimum spanning tree game.

Procedure MSTGame(G, w, b)
  Input: A graph $G = (V \cup \{r\}, E)$, a weight vector $w \in \mathbb{R}^E_{\geq 0}$, and $b \in [0, 1]$.
  For each $e \in E$ with $w_e > 0$, let $\widehat{w}_e \leftarrow 2^{i_e+1+b}$, where i_e be the unique integer such that $2^{i_e+b} \leq w_e < 2^{i_e+1+b}$;
  $T \leftarrow$ AuxiliaryTree$(G, \widehat{w})$ and identify the vertices of G with the corresponding leaves of T;
  for $e \in E(T)$ *such that* $r \notin T_e$ **do**
    Let X_e be the set of leaves in T_e;
    Let $z_e \leftarrow \frac{h_e}{|X_e|}\mathbf{1}_{X_e}$;
  return $\sum_{e \in E} z_e$;

leaf, the value h_e is evenly distributed among the agents corresponding to the leaves of T_e. At first glance, the total value distributed may seem unrelated to the value of the grand coalition. However, it can be proved in Lemmas 18 and 19 that the total value distributed by this method is at least $\mathrm{OPT}(G, \widehat{w})$ and at most $2\mathrm{OPT}(G, \widehat{w})$.

4.1 Core Approximability

We begin by analyzing the core approximability. Let T be the auxiliary tree for $(G, \widehat{w})$. For $X \subseteq V \cup \{r\}$, the *connector* $\mathrm{conn}(X)$ of X is the minimal connected subgraph of T that contains all leaves of T corresponding to X. The following lemma bounds the value of the characteristic function for a subset S of V using values that can be computed from connector $\mathrm{conn}(S \cup \{r\})$. Due to the space limit, proofs in this section are given in the full version.

▶ **Lemma 17.** *Let $S \subseteq V$. Then, we have*

$$\sum_{\substack{(u,u') \in E(\mathrm{conn}(S \cup \{r\})) \\ r \notin T_{u'}}} (h_u - h_{u'}) \leq \mathrm{OPT}(G[S \cup \{r\}], \widehat{w}).$$

When $V = S$, the equality holds.

Now, we have the following.

▶ **Lemma 18.** *Let $S \subseteq V$. Then, we have*

$$\sum_{v \in S} \sum_{e \in E(T)} z_{e,v} \leq 4\mathrm{OPT}(G[S \cup \{r\}], w).$$

We have the following bound for the grand coalition.

▶ **Lemma 19.** *We have*

$$\sum_{v \in V} \sum_{e \in E(T)} z_{e,v} \geq \mathrm{OPT}(G, w).$$

4.2 Lipschitz Continuity

Let $f \in E(G)$. We bound

$$\frac{1}{\delta} \int_0^1 \left\| \mathrm{MSTGame}(G, w, b) - \mathrm{MSTGame}(G, w + \delta \mathbf{1}_f, b) \right\|_1 \mathrm{d}b,$$

which is an upper bound on

$$\frac{1}{\delta} \left\| \int_0^1 \mathrm{MSTGame}(G, w, b) \mathrm{d}b - \int_0^1 \mathrm{MSTGame}(G, w + \delta \mathbf{1}_f, b) \mathrm{d}b \right\|_1.$$

Without loss of generality, we can assume $\delta \leq w_f$ or $w_f = 0$. Now we fix $b \in [0, 1]$. We denote the value of T, $\widehat{w}$, X, and z in $\mathrm{MSTGame}(G, w, b)$ (resp., $\mathrm{MSTGame}(G, w + \delta \mathbf{1}_f, b)$) as T, $\widehat{w}$, X, and z (resp. T', $\widehat{w}'$, X', and z').

When $\widehat{w}_f = \widehat{w}'_f$, T and T' are the same and $\mathrm{MSTGame}(G, w, b)$ and $\mathrm{MSTGame}(G, w + \delta \mathbf{1}_f, b)$ output the same vector. Otherwise, let C be the connected component of $\mathcal{C}_{\widehat{w}, \leq \widehat{w}_f}$ that contains both the endpoints of f. If C is still connected even after the removal of f, then we have $\mathcal{C}_{\widehat{w}, \leq x} = \mathcal{C}_{\widehat{w}', \leq x}$ for all $x \geq 0$ and thus $T = T'$. Otherwise, let C_1 and C_2 be two connected components of C after the removal of f. Subsequently, T' is obtained from T by the following operation:

(1.1) If no vertex u_{C_1} exists in T, create a vertex u_{C_1}, set $h_{u_{C_1}} = \widehat{w}_f$, and for each child u_X of u_C with $X \subseteq C_1$, replace the edge (u_C, u_X) with (u_{C_1}, u_X). Otherwise, delete the edge (u_C, u_{C_1}).

(1.2) Do exactly the same for C_2.

(2) If u_C has a parent u_Y with $h_{u_Y} = \widehat{w}'_f$, delete the vertex u_C and the edge (u_Y, u_C), and add two new edges (u_Y, u_{C_1}) and (u_Y, u_{C_2}). Otherwise, add two new edges (u_C, u_{C_1}) and (u_C, u_{C_2}) and then change the value of h_{u_C} from $\widehat{w}_f$ to $\widehat{w}'_f$.

We can observe that all edges e of T except for the edges (u_C, u_{C_1}) deleted in (1.1), (u_C, u_{C_2}) deleted in (1.2), and (u_Y, u_C) deleted in (2) naturally correspond to edges in T' that are not added in (2), and if we identify the edges of T with those of T' using that correspondence, it holds that $h_e = h'_e$ and $X_e = X'_e$, which implies $z_e = z'_e$. Therefore, we have the following.

▶ **Lemma 20.** *Assume $\widehat{w}_f \neq \widehat{w}'_f$. Then, we have*

$$\left\| \mathit{MSTGame}(G, w, b) - \mathit{MSTGame}(G, w + \delta \mathbf{1}_f, b) \right\|_1 \leq \widehat{w}_f + 2\widehat{w}'_f.$$

Proof. Let

$$z_1 = \begin{cases} \frac{1}{|C_1|} \mathbf{1}_{C_1} & \text{if } (u_C, u_{C_1}) \text{ is deleted in (1.1) and } r \notin C_1 \\ \mathbf{0} & \text{otherwise} \end{cases},$$

$$z_2 = \begin{cases} \frac{1}{|C_2|}\mathbf{1}_{C_2} & \text{if } (u_C, u_{C_2}) \text{ is deleted in (1.2) and } r \notin C_2 \\ \mathbf{0} & \text{otherwise} \end{cases},$$

$$z_3 = \begin{cases} \frac{1}{|C|}\mathbf{1}_{C} & \text{if } (u_Y, u_C) \text{ is deleted in (1.2) and } r \notin C \\ \mathbf{0} & \text{otherwise} \end{cases},$$

$$z_4 = \begin{cases} \frac{1}{|C_1|}\mathbf{1}_{C_1} & \text{if } r \notin C_1 \\ \mathbf{0} & \text{otherwise} \end{cases},$$

$$z_5 = \begin{cases} \frac{1}{|C_2|}\mathbf{1}_{C_2} & \text{if } r \notin C_2 \\ \mathbf{0} & \text{otherwise} \end{cases}.$$

Then, we have

$$\begin{aligned} &\|\text{MSTGame}(G, w, b) - \text{MSTGame}(G, w + \delta\mathbf{1}_f, b)\|_1 \\ &= \left\|(z_1 + z_2)\,\widehat{w}_f + (z_3 - z_4 - z_5)\,\widehat{w}'_f\right\|_1 \\ &= \left\|\left(z_1\widehat{w}_f + (z_3 \circ \mathbf{1}_{C_1} - z_4)\,\widehat{w}'_f\right)\right\|_1 + \left\|\left(z_2\widehat{w}_f + (z_3 \circ \mathbf{1}_{C_2} - z_5)\,\widehat{w}'_f\right)\right\|_1 \\ &\le \max\left(\widehat{w}_f + \frac{|C_1|}{|C|}\widehat{w}'_f, \widehat{w}'_f\right) + \max\left(\widehat{w}_f + \frac{|C_2|}{|C|}\widehat{w}'_f, \widehat{w}'_f\right) \le \widehat{w}_f + 2\widehat{w}'_f. \end{aligned}$$ ◀

The following lemma analyzes the probability that $\widehat{w}_f \neq \widehat{w}'_f$ happens.

▶ **Lemma 21.** *Assume $w'_f \le 2w_f$. If b is sampled uniformly from $[0, 1]$, $\widehat{w}_f \neq \widehat{w}'_f$ happens with a probability of at most $\frac{\delta}{w_f \log 2}$.*

Proof. $\widehat{w}_f \neq \widehat{w}'_f$ happens when there is an integer i with $w_f < 2^{i+b} \le w_f + \delta$, implying that $\lfloor \log_2 w_f - b \rfloor \neq \lfloor \log_2 w_f + \delta - b \rfloor$. This happens with probability

$$\log_2(w_f + \delta) - \log_2 w_f = \log_2\left(1 + \frac{\delta}{w_f}\right) \le \frac{\delta}{w_f \log 2}.$$ ◀

Now, we have the following:

▶ **Lemma 22.** *We have*

$$\frac{1}{\delta}\int_0^1 \|MSTGame(G, w, b) - MSTGame(G, w + \delta\mathbf{1}_f, b)\|_1 \,\mathrm{d}b \le \frac{10\delta}{\log 2}.$$

Proof. If $w_f = 0$, we have

$$\frac{1}{\delta}\int_0^1 \|\text{MSTGame}(G, w, b) - \text{MSTGame}(G, w + \delta\mathbf{1}_f, b)\|_1 \,\mathrm{d}b \le 2\widehat{w}'_f \le 4w'_f = 4\delta.$$

Otherwise, we have

$$\begin{aligned} &\frac{1}{\delta}\int_0^1 \|\text{MSTGame}(G, w, b) - \text{MSTGame}(G, w + \delta\mathbf{1}_f, b)\|_1 \,\mathrm{d}b \\ &\le \frac{\delta}{w_f \log 2}\left(\widehat{w}_f + 2\widehat{w}'_f\right) = \frac{\delta}{w_f \log 2} \cdot 5\widehat{w}_f \le \frac{\delta}{w_f \log 2} \cdot 10w_f = \frac{10\delta}{\log 2}. \end{aligned}$$ ◀

4.3 Proof of Theorem 5

Combining Lemmas 18, 19, and 22 and applying Lemma 10 yields Theorem 5.

Proof of Theorem 5. Combining Lemmas 18, 19, 22, and 10, we obtain an algorithm that returns 4-approximate core allocation for the matching game with Lipschitz constant $\frac{20}{\log 2} + 1 = O(1)$. The fact that the allocation defined by Lemma 16 can be computed in polynomial time is obtained using the same argument as in the proof of Theorem 4. ◀

Towards an Analysis of Quadratic Probing

William Kuszmaul

Abstract

Since 1968, one of the simplest open questions in the theory of hash tables has been to prove *anything* nontrivial about the correctness of quadratic probing. We make the first tangible progress towards this goal, showing that there exists a positive-constant load factor at which quadratic probing is a constant-expected-time hash table. Our analysis applies more generally to any fixed-offset open-addressing hash table, and extends to higher load factors in the case where the hash table examines blocks of some size $B = \omega(1)$.

1 Introduction

The field of open-addressed hash tables began with the introduction of linear probing in the 1950s [35, 24, 25]. Although early work [35] conjectured that linear probing should scale well to high load factors, with an insertion time of $O(x)$ at load factor $1-1/x$, subsequent analyses by Knuth [24] (unpublished) and by Konheim and Weiss [26] (published in 1966) showed that this is not the case. Due to *clustering effects*, in which elements group together to form long continuous runs of occupied slots, the true expected insertion time is asymptotically larger than researchers had hoped for, evaluating to $\Theta(x^2)$.

In the late 1960s, this prompted researchers to propose alternative hashing algorithms that preserved the simplicity (and in some cases data locality) of linear probing, while mitigating the clustering effects. Two solutions, in particular, emerged as natural alternatives, **double hashing**, which was introduced by de Balbine in his 1968 thesis [4] (and proposed independently by Bell and Kaman in 1970 [7]); and **quadratic probing**, which was introduced by Maurer in 1968 [32] and then refined by other sets of authors through the 1970s [5, 22, 16, 36].

Despite their data-structural simplicity, double hashing and quadratic probing proved far harder to analyze than linear probing. It wasn't until 1976, in a breakthrough paper by Guibas and Szemeredi [19], that double hashing was finally partially analyzed: they proved that, so long as the load factor of the hash table is at most ≈ 0.28, the hash table is

guaranteed to support constant-expected-time operations. This constant was subsequently improved to ≈ 0.31 in 1978 [20], which remained the state of the art until 1988, when Lueker [30, 31] finally extended the analysis to apply to all load factors. In particular, Lueker showed a coupling between double hashing and uniform probing, proving that the expected insertion times are within a $1 + o(1)$ factor of each other.

The coupling techniques [19, 20, 21, 30, 31] that allowed for an analysis of double hashing do not extend to quadratic probing. It has remained an open question for more than five decades to prove *anything* nontrivial about the behavior of quadratic-probing hash tables. It is not even known, for example, whether quadratic-probing is a constant-time data structure when used at a load factor of 0.001.

Linear Probing vs Double Hashing vs Quadratic Probing

Let us take a moment to briefly define the three hash-table designs described above. In each case, elements are stored in an array of some size n, and the **load factor** of the hash table is defined to be the fraction of slots that are occupied. To insert an element x, a sequence $p_1(x), p_2(x), \ldots$ of array positions are examined until an unoccupied spot is found for x. Where the three hash-table designs differ is in the choice of probe sequence: linear probing uses $p_i(x) = h(x) + i \mod n$, where $h(x) \in [n]$ is a random hash; double hashing uses $p_i(x) = h_1(x) + ih_2(x) \mod n$, where $h_1(x), h_2(x) \in [n]$ are both random hashes; and quadratic probing uses $p_i(x) = h(x) + (i-1)^2 \mod n$, where again $h(x) \in [n]$ is a random hash.

The analysis of linear probing [24, 26] hinges on the observation that, if an insertion x takes time k, there must be an array interval of the form $I = [h(x) - j, h(x) + k - 1]$, for some $j \geq 0$, such that the number of elements y with hashes $h(y) \in I$ is at least $|I| = j + k$. Thus, the analysis of linear probing reduces directly to the analysis of how many elements hash into each interval in the hash table. The analysis of double hashing [19, 20, 21, 30, 31] relies on the fact that the probe sequence $p_i(x) = h_1(x) + ih_2(x) \mod n$ is in some formal sense nearly as random as the fully random probe sequence $p_i(x) = h_i(x)$, where $h_1, h_2, \ldots$ are all independent hash functions.

Quadratic probing, on the other hand, sits in an unfortunate middle ground. It lacks the clean interval-based structure of linear probing – if an insertion x collides with another element y in position $p_i(x) = h(x) + (i-1)^2 \mod n$, then there is nothing substantive that we can say about the array interval $[h(x), h(y)]$. But it is not comparable to a fully random probe sequence – indeed, elements x and y with hashes $h(x)$ and $h(y)$ that are close together, are far more likely to interact than are a random pair of elements. The interactions between pairs of elements follow an apparently chaotic combinatorial structure: if an insertion x collides with another element y in position $p_i(x) = h(x) + (i-1)^2 \mod n$, then the same element x would not have interacted with y at all if y's hash had been 1 smaller; and, similarly, y might have been in a different position entirely had any of the elements *it* interacted with had even slightly different hashes, etc.

Yet, empirically, quadratic probing is an excellent hash table design [38, 32, 11, 15, 12, 6, 18, 23, 39, 40]. It preserves much of the data locality that makes linear probing special [38] while also empirically eliminating the asymptotic clustering effects that make linear probing bad [32]. It is recommended in textbooks and courses [11, 15, 12, 6, 18, 23, 39, 40], and is even used as the underlying design (with some modifications we will discuss later) for Google's in-house and open-source hash tables [1]. Thus, the problem would truly seem to be one of algorithm *analysis* rather than one of algorithm *design*.

This Paper: A Partial Analysis of Quadratic Probing

We give the first analysis for quadratic-probing hash tables at low load factors. We show that, at any load factor less than roughly 0.089, the expected time per operation is $O(1)$. In fact, our analysis applies not just to quadratic probing, but to any **fixed-offset** probing scheme, i.e., to any hash table that, like linear and quadratic probing, inserts elements via a probe sequence of the form $p_i(x) = h(x) + f(i)$ for some $f(i)$.

▶ **Theorem 1.** *There exists a positive constant $\alpha \geq 0.089$ such that all fixed-offset open addressing hash tables support constant-time insertions at load factor α and below. Moreover, the insertion time is bounded above by a geometric random variable with mean $O(1)$.*

The proof of Theorem 1 in Section 3 is achieved by a witness argument in which we construct two objects (a witness set S and a witness transcript T) that must exist in order for the insertion time to be large. The witness set S has the property that each individual option for S has only a very small probability of occurring. The witness transcript T, on the other hand, has the property there are only a relatively small number of options for what T can be. Finally, the relationship between the two (and, in particular, the fact T can be used to recover S), allows us to bound the probability of such a pair (S, T) existing at all.

The specific constant, 0.089, that we get from Theorem 1 stems from the careful enumeration of a family of strings that we call **witness strings** (i.e., candidates for the transcript T). Through a mixture of algebraic and combinatorial arguments, we obtain tight bounds on the growth rate for the family – this rate, in turn, dictates the best constant that we can get in our proof of Theorem 1.

Finally, in Section 4, we turn our attention to **chunked** fixed-offset open addressing, in which the probe sequence used is actually of the form

$$p_i(x) = h(x) + B \cdot f(\lfloor i/B \rfloor) + (i - 1)$$

for some **chunk size** B. The use of chunking is quite common in practice, as it reduces cache misses and allows for the use of hardware vectorization. A notable example is the hash table used at Google [1], which uses chunked quadratic probing with chunk size $B = 16$.

Our final result is an analysis of any chunk fixed-offset open-addressing scheme. We show that, when $B = \omega(1)$, such schemes can successfully handle load factors of the form $1 - o(1)$.

▶ **Theorem 2.** *There exists a constant $\alpha \in (0, 1)$ such that the following is true. Consider a chunked fixed-offset open-addressed hash table with chunk size B. Any insertion of an element x at a load factor $\alpha = 1 - 1/q$ satisfying $q \leq \alpha\sqrt{B/\log B}$ takes expected time at most $O(q^2)$. Moreover, the insertion time is bounded above by a geometric random variable with mean $O(q^2)$.*

We remark that, in general, the time/space tradeoff in Theorem 2 is nearly tight in the sense that linear probing (which is a trivial example of chunked open addressing) does, indeed, require $\Theta(q^2)$ time per insertion.

Other related work

In the half century since quadratic probing and double hashing were introduced, there has been a great deal of additional work on hash-table design. Notable examples include Cuckoo hashing [34], which allows for worst-case bounds on query time (and which has the interesting feature that, depending on the parameters with which it is implemented, there are genuine load-factor thresholds above which it cannot be used [34, 17, 14]); Robin-Hood

hashing [2, 10], which reorders elements in ways that reduce query time; graveyard hashing [9], which strategically leaves gaps within a linear probing hash table to reduce clustering; and many others [25]. In addition to these relatively practical designs, there has also been a great deal of progress on the theoretical extremes of how space/time efficient a hash table can be [29, 3, 13, 37]. In fact, recent works by Bender et al. [8] and by Li et al. [27, 28] close off the basic theoretical question of how space-efficient a hash table can be subject to a given set of time bounds. For a detailed but somewhat out-of-date survey, see Knuth's [25] 1998 edition of the Art of Computer Programming, Vol. 3.

2 Preliminaries

Let $h : U \to [n]$ be a random hash function, and let $r_1, r_2, \ldots, r_{n-1} \in \mathbb{N}$ be a permutation of the numbers 1 through $n-1$. Consider an open-addressing hash table with capacity n in which, to insert an element $x \in U$, we place it in the first available position from the sequence $h(x), h(x)+r_1, h(x)+r_2, \ldots$ (the positions wrap around, so position $n+1$ is the same as position 1). Such a hash table is said to perform **fixed-offset open-addressing** with **offset sequence** $r_1, r_2, \ldots$. The hash table is said to support **constant time insertions** at load factor $0 < \alpha \leq 1$ and below if, when the hash table is filled to a α-fraction full, each of the insertions is guaranteed to take constant expected time.

Additionally, a fixed-offset open-addressing scheme is said to be **chunked** (with **chunk size** B) if the $\{r_i\}$'s are broken into consecutive blocks of size B. That is, for each $i \geq 0$, and $j \in \{0, \ldots, B-1\}$, we have $r_{iB+j} = r_{iB} + j$.

One subtlety in the definition of fixed-offset open-addressing is the requirement that $r_1, r_2, \ldots, r_{n-1}$ form a *permutation* of $[n-1]$. We will see that, if our analysis is taking place at load factor $1 - 1/q$, the time per insertion is at most a geometric random variable with mean $O(1+q^2)$ (see Theorems 1 and 2), meaning that with probability $1 - 1/\operatorname{poly}(n)$, the hash table only ever uses the first $O((1+q^2)\log n)$ terms of any probe sequence. Therefore it is not strictly necessary to require that $r_1, r_2, \ldots, r_{n-1}$ are all distinct. It suffices for the probe sequence to satisfy the weaker requirement that $r_1, r_2, \ldots, r_{O((1+q^2)\log n)}$ are distinct, and to assume that the hash table is rebuilt from scratch if any operation ever takes $\omega((1+q^2)\log n)$ time. This distinction is important since the probe sequence used by quadratic probing is not a permutation for all table-sizes n [25], but is trivially guaranteed to have distinct entries for all of its first $\Omega(\sqrt{n})$ terms.

Finally, the reader may wonder whether our analyses can be extended to support deletions in addition to insertions and queries. Here there is a larger issue: quadratic probing does not natively *support* deletions. If one tries to implement deletions by simply removing items, then the query algorithm gets broken (it can no longer terminate when it sees a free slot) [25]. The standard way to implement deletions while preserving the correctness of queries is to use tombstones [9], which formally reduce the problem to the insertion-only setting.

3 Analysis for Sufficiently Small Constant Load Factors

In this section, we will show that there exists a universal load factor $\alpha \geq 0.089$ below which all fixed-offset open-addressing schemes are guaranteed to achieve $O(1)$-time operations.

▶ **Theorem 1.** *There exists a positive constant $\alpha \geq 0.089$ such that all fixed-offset open addressing hash tables support constant-time insertions at load factor α and below. Moreover, the insertion time is bounded above by a geometric random variable with mean $O(1)$.*

▶ **Corollary 3.** *There exists a positive constant $\alpha \geq 0.089$ such that quadratic probing supports constant-time insertions at load factor α and below.*

Let $r_1, r_2, \ldots$ be the offset sequence used by the hash table, and as a convention set $r_0 = 0$. Consider a sequence of up to αn insertions, followed by one additional insertion of an element x. Let D denote the state of the hash table when x is inserted, and for each element x that was inserted in the past, let $\text{index}(x, D)$ be the index i such that x resides in position $h(x) + r_i$.

Given a set $S \subseteq [n]$ we say that an element $x \in D$ **conflicts** with S if $h(x) \notin S$ and if $h(x) + r_i$ is in S for some $i \leq \text{index}(x, D)$. Moreover, if $h(x) + r_k$ is the first element of $h(x), h(x) + r_1, h(x) + r_2, \ldots$ to appear in the set S, then we say that the **pair** (x, k) **conflicts with** S **at position** $j = h(x) + r_k$. Finally, we define $\texttt{Conflicts}(S, j)$, which is referred to as a conflict set, to be the set of pairs that conflict with S at position $j \in S$, i.e.,

$$\texttt{Conflicts}(S, j) = \{(x, k) \mid x \in D, \\ 1 \leq k = \min\{i \mid h(x) + r_i \in S\},\ h(x) + r_k = j,\ k \leq \text{index}(x, D)\}.$$

We want to bound the probability that, when insertion x occurs, all of positions $h(x), h(x) + r_1, \ldots, h(x) + r_{\ell-1}$ are already occupied for some large ℓ, i.e., the insertion takes time greater than ℓ. Using the idea of a conflict set, we design a protocol BuildWitnesses (Algorithm 1) that takes as inputs D, $h(x)$, and ℓ, and returns a **witness set** S along with a **witness transcript** T. The witness set S will be a subset of $[n]$, and the witness transcript T will be a trinary string.

As we shall see, the basic idea is that, if the insertion of $h(x)$ into D takes time at least ℓ, then the $\text{BuildWitnesses}(D, h(x), \ell)$ protocol will return a pair (S, T) such that:

- the set $S \subseteq [n]$ is quite large, satisfying $|S| \geq \ell$;
- there are at least $|S|$ elements $x \in D$ satisfying $h(x) \in S$;
- the set S is fully determined by the triple $(h(x), \ell, T)$;
- and the transcript T is a trinary string of length $O(|S|)$.

We will then be able to argue that the probability of such a pair of objects existing is very small, at most $2^{-\Omega(\ell)}$. Thus, by analyzing BuildWitnesses, we will be able to indirectly arrive at a proof of Theorem 1. We emphasize that, although this approach uses an algorithm (BuildWitnesses) as part of the analysis, it is not an algorithm that actually gets executed by the hash table – it is simply for the sake of analysis.

Before we can dive into the analysis, we must show that Algorithm 1 terminates.

▶ **Lemma 4.** *Algorithm 1 terminates within finite time.*

Proof. First observe that Line 14 only adds elements to S that are not already in S. Since elements are never removed from S, it follows that each $j \in [n]$ can also be added to S (and therefore to `Unprocessed`) at most once. Since each phase (i.e., each iteration of Line 4) removes an item from `Unprocessed`, there can be at most n phases. Furthermore, since each iteration of Lines 11–15 increases the size of S, there can be at most n total iterations of lines 11–15. Therefore, the algorithm completes its construction of the witness objects S and T within $O(n)$ time. ◀

Next, we turn our attention to establishing the properties of S and T, along with their relationship to one another. Specifically, we will need the following three lemmas.

▶ **Lemma 5.** *Suppose the insertion x takes time greater than ℓ (that is, the length of the probe sequence is greater than ℓ). Then the witness set S has size at least ℓ, and at least $|S|$ elements $x \in D$ have hashes $h(x) \in S$.*

Algorithm 1

```
1:  procedure BuildWitnesses(D, h(x), ℓ)
2:      Set Unprocessed = {h(x), h(x) + r_1, h(x) + r_2, ..., h(x) + r_{ℓ−1}}.
3:      Set S = Unprocessed and T = (0)^{ℓ−1} ∘ 1.
4:      while |Unprocessed| > 0 do                    ▷ Each iteration is called a phase.
5:          Let j = max{Unprocessed}.
6:          Remove j from Unprocessed.
7:          Append 2 to T.
8:          while true do
9:              Let Conflicts(S, j) = {(x, k) | x ∈ D, 1 ≤ k = min{i | h(x) + r_i ∈ S},
10:                                                  h(x) + r_k = j, k ≤ index(x, D)}.
11:             if |Conflicts(S, j)| > 0 then
12:                 Let k = max_k{(x, k) ∈ Conflicts(S, j) for some x}.
13:                 Let x be an arbitrary element in {x | (x, k) ∈ Conflicts(S, j)}.
14:                 Add h(x), h(x) + r_1, h(x) + r_2, ..., h(x) + r_{k−1} to Unprocessed and to S.
15:                 Append (0)^{k−1} ∘ 1 to T.
16:             else
17:                 End while loop.
18:     return (S, T)
```

Proof. The fact that S has size at least ℓ is immediate from the initialization of S in BuildWitnesses. To prove that at least $|S|$ elements $x \in D$ have hashes $h(x) \in S$, we will show a stronger claim: that every position in S is occupied by an element x whose hash $h(x)$ is in S.

First, observe that, by design, every position in S is occupied. Indeed, by the assumption that x's insertion takes time greater than ℓ, we know that $h(x), h(x) + r_1, h(x) + r_2, \ldots, h(x) + r_{\ell-1}$ (the positions initially placed in S) are all occupied. And by the definition of $\texttt{Conflicts}(S, j)$, we know that the positions added by Line 14 are also always occupied.

Now suppose for contradiction that some position $s \in S$ contains an element x whose hash $h(x)$ is not in S. Then x must conflict with S, and, in particular, x must be part of a pair (x, k) that conflicts with S at some position $j \in S$. Now consider the phase that processed j, and define S' to be the state of S at the end of the phase. Because the phase ended, we must have had $\texttt{Conflicts}(S', j) = \emptyset$. But, because (x, k) conflicts with S at position j, and since $j \in S' \subseteq S$, it must be that (x, k) also conflicts with S' at position j. This means that $(x, k) \in \texttt{Conflicts}(S', j)$, which is a contradiction. ◀

▶ **Lemma 6.** *Given the witness transcript T, along with $h(x)$ and ℓ, one can reconstruct the witness set S.*

Proof. This is accomplished by the WitnessStringToSet protocol (Algorithm 2). The basic idea is that we can use the witness transcript T to simulate the execution of BuildWitnesses. Namely, we can use 2s in T to determine boundaries between phases; and then we can use runs of 0s in T to determine the value of k that is used in each iteration of the inner while loop. This allows for us to fully reconstruct the witness set S using just $T, h(x), \ell$. ◀

▶ **Lemma 7.** *The witness transcript T is a trinary string of length $2|S|$.*

Proof. Each time that we append a 2 to T, we remove an element from `Unprocessed`. We do this $|S|$ times, so there are $|S|$ 2s in T. Each time we append a string $(0)^{k-1} \circ 1$ to T, we also add k elements to S (and vice-versa). Thus, the total number of 0s and 1s in T is $|S|$. It follows that T is a trinary string of length $2|S|$. ◀

Algorithm 2

```
1: procedure WitnessStringToSet(h(x), ℓ, T)
2:     Set Unprocessed = {h(x), h(x) + r_1, h(x) + r_2, ..., h(x) + r_{ℓ−1}}.
3:     Set S = Unprocessed.
4:     Remove prefix (0)^{ℓ−1} ∘ 1 from T.
5:     while |Unprocessed| > 0 do
6:         Let j = max_{j∈Unprocessed} j.
7:         Remove j from Unprocessed.
8:         while first character of T is not a 2 do
9:             Let k − 1 be the number of 0s at the start of T before the first 1.
10:            Define g = j − r_k.
11:            Add g, g + r_1, g + r_2, ..., g + r_{k−1} to Unprocessed and to S.
12:            Remove first k characters of T, which are (0)^{k−1} ∘ 1.
13:        Remove first character of T, which is a 2.
14:    return S
```

In addition to these structural lemmas, we will need a basic concentration bound on the probability that $|S|$ elements hash to a set S of some size.

▶ **Lemma 8.** *Let $\alpha = 1/e - \Omega(1)$. Consider a set A of αn elements, each with random hashes in $[n]$. Let $B \subseteq [n]$ be a set of some size k. The probability that at least k elements from A have hashes in B is at most $\left((1+o(1))\alpha e^{(1-\alpha)}\right)^k$, where the o-notation is in terms of k.*

Proof. By a standard Poisson approximation (see, e.g., Theorem 5.10 in [33]), and because the event of at least k elements hashing to B is monotone (adding more elements never undoes the event), we have that the probability of at least k elements hashing to B is at most $2\Pr[\text{Poisson}(\alpha k) \geq k]$. This, in turn is

$$
\begin{aligned}
&2\sum_{j\geq k} \Pr[\text{Poisson}(\alpha k) = j] \\
&= 2\sum_{j\geq k} \frac{(\alpha k)^j e^{-\alpha k}}{j!} \\
&\leq 2\sum_{j\geq k} 2^{o(j)} (\alpha k)^j e^{-\alpha k}/(j^j/e^j) && \text{(by Stirling's approximation)} \\
&\leq 2\sum_{j\geq k} 2^{o(j)} \alpha^j e^{-\alpha k + j} \\
&= 2e^{-\alpha k}\sum_{j\geq k} (\alpha e \cdot (1+o(1)))^j \\
&= O\left(e^{-\alpha k}(\alpha e \cdot (1+o(1)))^k\right) && \text{(since } \alpha = 1/e - \Omega(1)\text{)} \\
&= \left((1+o(1))\alpha e^{1-\alpha}\right)^k . && \blacktriangleleft
\end{aligned}
$$

Putting these lemmas together, we can now prove a weak version of Theorem 1 in which we do not seek to optimize the constant α.

▶ **Theorem 9.** *There exists a positive constant α such that all fixed-offset open addressing hash tables support constant-time insertions at load factor α and below. Moreover, the insertion time is bounded above by a geometric random variable with mean $O(1)$.*

Proof. Let us bound the probability that the insertion of x, which takes place at a load factor of at most α, takes time greater than $\ell > 0$. Let S and T be the witness set and witness transcript produced by BuildWitnesses$(D, h(x), \ell)$.

Suppose the insertion takes time greater than ℓ. Then, by Lemma 5, witness set S has some size $q \geq \ell$ and has the property that at least q elements $x \in D$ satisfy $h(x) \in S$.

Define $\mathcal{S}_q$ to be the set of options for what S could be if its size is q, conditioned on $h(x)$ and ℓ. For each $R \in \mathcal{S}_q$, let X_R be the event that $|\{x \in D \mid h(x) \in R\}| \geq q$. Then, in order for the insertion of x to take time greater than ℓ, event X_R must occur for some $R \in \bigcup_{q \geq \ell} \mathcal{S}_q$. By a union bound, the probability of this happening is at most

$$\sum_{q \geq \ell} \sum_{R \in \mathcal{S}_q} \Pr[X_R].$$

By Lemma 8, and assuming that $\alpha \leq e^{-1} - \Omega(1)$, this is at most

$$\sum_{q \geq \ell} \left(|\mathcal{S}_q| \cdot ((1 + o(1)) \cdot \alpha e^{1-\alpha})^q \right). \tag{1}$$

To bound $|\mathcal{S}_q|$, observe that by Lemma 6, each set $R \in \mathcal{S}_q$ corresponds to a unique witness transcript $T \in [3]^{2q}$. Thus $|\mathcal{S}_q| \leq 9^q$, which allows us to bound (1) by

$$\sum_{q \geq \ell} \left(9 \cdot (1 + o(1)) \cdot \alpha e^{1-\alpha} \right)^q. \tag{2}$$

Supposing that $\alpha e^{1-\alpha} < 1/9$, this sum evaluates to $e^{-\Omega(\ell)}$. In other words, the probability of the insertion x taking time greater than ℓ is exponentially small in ℓ. This means that the insertion takes $O(1)$ expected time. ◀

To improve upon the constant α and obtain the full version of Theorem 1, we will need a tighter bound on the number of witness transcripts corresponding to a witness set of size ℓ.

We begin by defining an infinite family of strings that contains all possible witness transcripts. Define a **witness phrase** to be a string of the form

$$P = (0)^{i_1} \circ 1 \circ (0)^{i_2} \circ 1 \circ \cdots \circ (0)^{i_k} \circ 1$$

where $0 \leq i_1 < i_2 < \cdots < i_k$. Define a **witness string** to be a string of the form

$$W = P_1 \circ 2 \circ P_2 \circ 2 \circ P_3 \circ \cdots \circ P_j \circ 2,$$

where each of $P_1, P_2, \ldots, P_j$ are witness phrases. The number j is referred to as W's **phrase count**, and the number of 0s and 1s in W is referred to as W's **zero/one count**.

Let $\mathcal{W}_{a,b}$ be the set of witness strings with zero/one-count a and phrase-count b. Notice, in particular, that $\mathcal{W}_{m,m}$ contains all witness transcripts that correspond to witness sets of size m. In Section 3.1, we will prove the following proposition, which characterizes the exact growth rate of $|\mathcal{W}_{m,m}|$.

Let $u \in (0, 1)$ minimize the quantity

$$f(u) = u^{-1} \prod_{i=1}^{\infty} (1 + u^i).$$

Then,

$$|\mathcal{W}_{m,m}| = f(u)^{(1-o(1))m}.$$

Note that, since $\log f(u) = \log u^{-1} + \sum_i \log(1+u^i)$ is within a constant factor of $\log u^{-1} + \sum_i u^i$, we know that $f(u)$ converges for any $u \in (0,1)$, and that $f(u)$ has a minimum value (since $f(u) \to \infty$ as either $u \to 0$ or $u \to 1$).

A manual calculation shows that $f(u)$ minimizes to slightly smaller than 4.51. It follows that the number of witness strings corresponding to witness sets of size m is at most $O(4.51^m)$. Plugging this into the proof of Theorem 9, (2) becomes

$$\sum_{q \geq \ell} \left(4.51 \cdot (1+o(1)) \cdot \alpha e^{1-\alpha}\right)^q.$$

In order so that, as before, this sum comes out to $e^{-\Omega(\ell)}$, we need that $\alpha e^{1-\alpha} < 1/4.51$. Another manual calculation tells us that it suffices to have $\alpha \leq 0.089$. With this modification to the proof of Theorem 9, we get Theorem 1.

3.1 Proof of Proposition 3

In this subsection, we complete the final component needed to prove Theorem 1, namely, the proof of Proposition 3, restated below.

Let $u \in (0,1)$ minimize the quantity

$$f(u) = u^{-1} \prod_{i=1}^{\infty} (1+u^i).$$

Then,

$$|\mathcal{W}_{m,m}| = f(u)^{(1-o(1))m}.$$

We begin by reinterpreting $|W_{k,m}|$ as the coefficient of x^k in a certain polynomial $G(x)$.

▶ **Lemma 10.** *Consider the formal power series*

$$G(x) = \left(\prod_{i=1}^{\infty}(1+x^i)\right)^m = \sum_i g_i x^i, \tag{3}$$

where the g_i's denote the coefficients of G, and where x is a formal variable. Then, the coefficient g_k is precisely equal to $|\mathcal{W}_{k,m}|$.

Proof. The coefficient of x^k in

$$\prod_{i=1}^{\infty}(1+x^i)$$

is equal to the number of witness phrases with zero/one-count k; and so the coefficient g_k of x^k in

$$\left(\prod_{i=1}^{\infty}(1+x^i)\right)^m$$

is equal to the number of ways to pick m witness phrases with total one-count k. This, in turn, is precisely $|\mathcal{W}_{k,m}|$. ◀

Using a simple argument about what happens when we evaluate the polynomial $G(x)$ at a given value $u \geq 0$, we can obtain the upper-bound side of Proposition 3.

▶ **Lemma 11.** *For any $u \geq 0$, we have*

$$|\mathcal{W}_{m,m}| \leq f(u)^m.$$

Proof. Let G be the formal power series from Lemma 10, and let $f(u)$ be the function defined in Proposition 3. For any $u \geq 0$, we have

$$f(u)^m = G(u)/u^m = \sum_i g_i u^i/u^m \geq g_m u^m/u^m = g_m = |\mathcal{W}_{m,m}|. \quad \blacktriangleleft$$

The lower bound is a bit more tricky. The main step is to re-interpret $G(px)/G(p)$ (where $p \in (0,1)$ and x is a formal variable) as the generating function for a random variable $X^{(p)}$ (this reinterpretation is a trick of the analysis, since $X^{(p)}$ does not appear anywhere in the original problem formulation), and then prove a concentration bound on that random variable.

We begin by establishing some basic conventions for discussing the generating function of a random variable. Supposing that A is a random variable that takes non-negative integer values, we define the **generating function** for A to be the formal power series

$$f(x) = \sum_{i \geq 0} \Pr[A = i] \cdot x^i.$$

We will make extensive use of two standard facts:

- **Fact 1:** Given any formal power series $f(x)$ such that $f(1)$ exists, the polynomial $f(x)/f(1)$ is the generating function for some random variable.
- **Fact 2:** Given two generating functions $f(x)$ and $g(x)$ for random variables A and B, the polynomial $f(x)g(x)$ is the generating function for the random variable C obtained by summing independent copies of A and B.

With these properties in mind, we now argue that, for the formal power series $G(x)$ from Lemma 11, there exists some $p \in \Theta(1) \cap (1 - \Theta(1))$ such that $G(px)/G(p)$ is the generating function for some well-behaved random variable. We will then be able to obtain our lower bound by analyzing the properties of this random variable.

▶ **Lemma 12.** *Consider the formal power series*

$$G(x) = \left(\prod_{i=1}^{\infty} (1 + x^i) \right)^m = \sum_i g_i x^i.$$

Then there exists $p \in \Theta(1) \cap (1 - \Theta(1))$ such that

$$G^{(p)}(x) = \frac{G(px)}{G(p)} = \sum_i g_i^{(p)} x^i$$

is the generating function for a random variable X with mean m and standard deviation $O(\sqrt{m})$.

Proof. By design, for any $p \in (0,1)$, we have that $\sum_i g_i^{(p)} = G^{(p)}(1) = 1$, so by Fact 1, $G^{(p)}(x)$ is the generating function for *some* random variable $X^{(p)}$. We will show that there exists some $p \in (0,1)$, satisfying $p = \Theta(1) \cap (1 - \Theta(1))$, such that $\mathbb{E}[X^{(p)}] = m$; and that for any $p = 1 - \Theta(1)$, the standard deviation of $X^{(p)}$ is $\Theta(\sqrt{m})$.

First observe that

$$G^{(p)}(x) = \frac{G(px)}{G(p)} = \left(\frac{\prod_{i=1}^{\infty}(1+(px)^i)}{\prod_{i=1}^{\infty}(1+p^i)}\right)^m.$$

It follows by Facts 1 and 2 that $X^{(p)}$ can be interpreted as the sum of m independent random variables $X_1^{(p)}, \ldots, X_m^{(p)}$ where each $X_j^{(i)}$ has generating function

$$\frac{\prod_{i=1}^{\infty}(1+(px)^i)}{\prod_{i=1}^{\infty}(1+p^i)}.$$

Observe that, when $p = 0$, we have $\mathbb{E}[X_i^{(p)}] = 0$, and as $p \to 1$, we have $\mathbb{E}[X_i^{(p)}] \to \infty$. Thus, there must exist some $p \in (0,1)$ such that $\mathbb{E}[X_i^{(p)}] = 1$. Since this choice of p is oblivious to m, it must be that $p = \Theta(1) \cap (1 - \Theta(1))$. This value of p gives us $\mathbb{E}[X^{(p)}] = m$, as desired.

Having chosen p, it remains to show that the standard deviation of $X^{(p)}$ is $O(\sqrt{m})$, or equivalently, that the variance of $X^{(p)}$ is $O(m)$. Since $X^{(p)} = \sum_{j=1}^{m} X_j^{(p)}$ is a sum of independent random variables, it suffices to show that each $X_j^{(p)}$ has variance $O(1)$. Notice, however, that the generating function for $X_j^{(p)}$ can be written as

$$\prod_{i=1}^{\infty} \frac{(1+(px)^i)}{(1+p^i)} = \prod_{i=1}^{\infty} \frac{H^{(p,i)}(x)}{H^{(p,i)}(1)},$$

where $H^{(p,i)}(x)$ is the formal power series $1 + (px)^i$. By Facts 1 and 2, it follows that we can interpret $X_j^{(p)}$ as a sum of independent random variables $Y_{j,1}^{(p)}, Y_{j,2}^{(p)}, \ldots$ where each $Y_{j,i}^{(p)}$ has generating function $\frac{(1+(px)^i)}{(1+p^i)}$. This means that

$$\mathrm{var}(X_j^{(p)}) = \sum_i \mathrm{var}(Y_{j,i}^{(p)}) \leq \sum_i \mathbb{E}[(Y_{j,i}^{(p)})^2] = \sum_i \frac{p^i i^2}{(1+p^i)} = O(1),$$

where the final equality uses $p = 1 - \Theta(1)$. As noted above, this implies that $X^{(p)}$ has variance $O(m)$, which completes the proof. ◀

We will also need a straightforward lemma bounding $|\mathcal{W}_{m\pm k,m}|$ in terms of $|\mathcal{W}_{m,m}|$ (multiplicatively) for small k.

▶ **Lemma 13.** *For any $0 \leq k < m$, we have that*

$$|\mathcal{W}_{m-k,m}| \leq |\mathcal{W}_{m,m}|$$

and that

$$|\mathcal{W}_{m+k,m}| \leq 2^{O(k \log m)} |\mathcal{W}_{m,m}|.$$

Proof. Given a string $s \in \mathcal{W}_{m-k,m}$, we can obtain a string $\phi(s) \in \mathcal{W}_{m,m}$ by taking the final run of 1s in s and extending the length of that run by k. This function is injective, implying that $|\mathcal{W}_{m-k,m}| \leq |\mathcal{W}_{m,m}|$.

Given a string $s \in \mathcal{W}_{m+k,m}$, it is possible to remove some set of $O(k)$ characters (zeros and ones) in order to obtain a valid string $s' \in \mathcal{W}_{m,m}$; let $\psi(s)$ be the lexicographically smallest such string s' that one can achieve in this way. For a given $s' \in \mathcal{W}_{m,m}$, we can bound $|\psi^{-1}(s')| \leq 2^{O(k \log m)}$, since there are at most $2^{O(k \log m)}$ ways to *add* $O(k)$ characters to get a string $s \in \mathcal{W}_{m+k,m}$. It follows that $|\mathcal{W}_{m+k,m}| \leq 2^{O(k \log m)} |\mathcal{W}_{m,m}|$. ◀

Finally, we can put the pieces together in order to get the lower-bound side of Proposition 3.

▶ **Lemma 14.** *Let*

$$f(u) = u^{-1} \prod_{i=1}^{\infty} (1 + u^i).$$

Then, there exists $p \in (0, 1)$ *such that*

$$f(p)^m \leq 2^{o(m)} |\mathcal{W}_{m,m}|.$$

Proof. Consider the formal power series

$$G(x) = \left(\prod_{i=1}^{\infty} (1 + x^i) \right)^m = \sum_i g_i x^i.$$

By Lemma 12, there exists $p \in \Theta(1) \cap (1 - \Theta(1))$ such that

$$G^{(p)}(x) = \frac{G(px)}{G(p)} = \sum_i g_i^{(p)} x^i$$

is the generating function for a random variable X with mean m and standard deviation $O(\sqrt{m})$. By Chebyshev's inequality, at least half of X's probability mass must be concentrated between $m - O(\sqrt{m})$ and $m + O(\sqrt{m})$. That is, for some positive constant d,

$$\sum_{k=-d\sqrt{m}}^{d\sqrt{m}} g_{m+k}^{(p)} \geq \frac{1}{2} \sum_{i=0}^{\infty} g_i^{(p)}.$$

Since $g_i^{(p)} = p^i g_i / G(p)$, we can multiply both sides by $G(p)$ to get

$$\sum_{k=-d\sqrt{m}}^{d\sqrt{m}} p^{m+k} g_{m+k} \geq \frac{1}{2} \sum_{i=0}^{\infty} p^i g_i.$$

Since $p = \Theta(1)$ and since $g_{m+k} = |\mathcal{W}_{m+k,m}| \leq 2^{O(|k| \log m)} |\mathcal{W}_{m,m}|$ (by Lemmas 10 and 13), we have that each term $p^{m+k} g_{m+k}$ in the left sum is at most

$$2^{O(\sqrt{m} \log m)} p^{m+k} |\mathcal{W}_{m,m}| = 2^{O(\sqrt{m} \log m)} p^m |\mathcal{W}_{m,m}|.$$

This means that the entire left sum is at most

$$O(\sqrt{m}) 2^{O(\sqrt{m} \log m)} |\mathcal{W}_{m,m}| \leq 2^{o(m)} p^m |\mathcal{W}_{m,m}|.$$

Therefore,

$$\sum_{i=0}^{\infty} p^i g_i \leq 2^{o(m)} p^m |\mathcal{W}_{m,m}|,$$

which implies that

$$G(p)/p^m \leq 2^{o(m)} |\mathcal{W}_{m,m}|.$$

Finally, since $G(p)/p^m = f(p)^m$, the proof is complete. ◀

4 Chunked Fixed-Offset Open Addressing

We now turn our attention to obtaining bounds for chunked fixed-offset open-addressed hash tables. Recall that a fixed-offset open-addressed hash table is said to be chunked with chunk-size B if, for each $i \geq 0$ and $j \in \{0, \ldots, B-1\}$, we have $r_{iB+j} = r_{iB} + j$. As terminology, for a given element x, we will refer to the sequence $h(x) + r_{iB}, \ldots, h(x) + r_{iB+B-1}$ as the ***i*-th block** in x's probe sequence. Our goal will be to prove the following theorem.

▶ **Theorem 2.** *There exists a constant $\alpha \in (0,1)$ such that the following is true. Consider a chunked fixed-offset open-addressed hash table with chunk size B. Any insertion of an element x at a load factor $\alpha = 1 - 1/q$ satisfying $q \leq \alpha\sqrt{B/\log B}$ takes expected time at most $O(q^2)$. Moreover, the insertion time is bounded above by a geometric random variable with mean $O(q^2)$.*

The theorem can be interpreted as saying that, whenever $B = \omega(1)$, it is possible to support load factors of the form $\alpha = 1 - q$ were $q = o(1)$. We remark that the time bound $O(q^2)$ is optimal in general, since linear probing is an example of a chunked open-addressed hash table that has insertion time $\Theta(q^2)$ at load factor $1 - q$.

We will prove Theorem 2 with a slightly more intricate analysis of the BuildWitnesses procedure from Section 3. To do this, we must first define the notion of an *analytical run*.

In lines 2 and 14 of BuildWitnesses, when we add some sequence $Q = h(x), h(x)+r_1, \ldots$ to `Unprocessed`, we can break the positions that we add into **analytical runs**, where the first (up to) B entries of Q form the first analytical run, the next (up to) B entries form the next analytical run, and so on. The execution of the line creates $\lceil |Q|/B \rceil$ analytical runs, and all but the final one have size B.

Say that two analytical runs r_1, r_2 (not necessarily created by the same iteration of Line 14) are **adjacent** if they represent sub-intervals of the form $[i, j]$ and $[j+1, k]$ for some i, j, k. Finally, define the **adjusted size** of an analytical run r to be B if the sequence Q that added r to S satisfied $|Q| \geq B$ or if the analytical run r was created by Line 2 of the algorithm, and define the adjusted size to be $|r|$ otherwise.

A critical step in the proof of Theorem 2 is to observe that, whenever two analytical runs are adjacent, their adjusted sizes must sum to at least B.

▶ **Lemma 15.** *Consider the execution of BuildWitnesses$(D, h(u), \ell)$ for some $\ell > 0$. Consider two adjacent analytical runs r_1, r_2 with adjusted sizes s_1, s_2. Then $s_1 + s_2 \geq B$.*

Proof. Let x_1 and x_2 be the elements that created runs r_1 and r_2. Let t_1 and t_2 be the iterations at which x_1 and x_2 are added to S by BuildWitnesses, let $\texttt{Conflicts}_1$ and $\texttt{Conflicts}_2$ be the conflict sets that are constructed in the while-loop iterations that add x_1 and x_2 to S, and let S_1 and S_2 be the states of S immediately before x_1 and x_2 are added to S, respectively.

If either of r_1 or r_2 have adjusted size B, then the claim is trivial. We can therefore assume without loss of generality that r_1, r_2 are the first runs in the probe sequences for x_1 and x_2 and that $|r_1|, |r_2| < B$. Note that, as immediate consequences, we have that r_1 and r_2 were created by Line 14 of BuildWitnesses (rather than Line 2); that $h(x_1) < h(x_2)$; and that x_2 was added to S before x_1 (i.e., $t_2 < t_1$).

Let ℓ be the right endpoint of r_2. We claim that

$$\ell \geq h(x_1) + B - 1. \tag{4}$$

This would imply that $|r_1| + |r_2| \geq \ell - h(x_1) + 1 \geq B$, completing the proof.

Suppose for contradiction that (4) does not hold. Let $(x_2, k_2) \in \texttt{Conflicts}_2$ be the pair containing x_2 in $\texttt{Conflicts}_2$. Then the final position ℓ of run r_2 satisfies $\ell + 1 = h(x_2) + k_2$, and $\texttt{Conflicts}_2 = \texttt{Conflicts}(S_2, \ell + 1)$ expands to

$$\{(x,k) \mid x \in D, \\ 1 \le k = \min\{i \mid h(x) + r_i \in S_2\},\ h(x) + r_k = \ell + 1,\ k \le \text{index}(x, D)\}.$$

We will show that this forces the pair $(x_1, \ell - h(x_1) + 1)$ to be in $\texttt{Conflicts}_2$. But the fact that $h(x_1) < h(x_2)$ means that BuildWitnesses will rather select $(x_1, \ell - h(x_1) + 1)$ than $(x_2, \ell - h(x_2) + 1)$ from $\texttt{Conflicts}_2$ (see Line 12 of BuildWitnesses). This contradicts the fact that x_2 is added to S at iteration t_2 in the execution of BuildWitnesses.

It remains to prove that $(x_1, \ell - h(x_1) + 1) \in \texttt{Conflicts}_2$. Since $\ell < h(x_1) + B - 1$ (by assumption) and since $h(x_1) < h(x_2)$, we know that $\ell + 1 = h(x_1) + k_1$ for some $k_2 < k_1 < B$. To prove that $(x_1, k_1) \in \texttt{Conflicts}_2$, we must show that

$$k_1 = \min\{i \mid h(x_1) + r_i \in S_2\} \tag{5}$$

and that

$$k_1 \le \text{index}(x_1, D). \tag{6}$$

We begin by showing (5). The fact that $(x_2, k_2) \in \texttt{Conflicts}_2$ tells us that $k_2 = \min\{i \mid h(x_2) + r_i \in S_2\}$, which implies that $h(x_2), h(x_2) + 1, \ldots, \ell \notin S_2$. The fact that $(x_1, h(x_2) - h(x_1)) \in \texttt{Conflicts}_1$ tells us that $h(x_2) - h(x_1) = \min\{i \mid h(x_1) + r_i \in S_1\}$, which implies that $h(x_1), h(x_1) + 1, \ldots, h(x_2) - 1 \notin S_1$. Since BuildWitnesses always processes $\max\{\texttt{Unprocessed}\}$, we know that, between iterations t_2 and t_1, BuildWitnesses processes only values of j satisfying $j \ge h(x_2)$. Thus $S_2 \cap [h(x_2) - 1] \subseteq S_1 \cap [h(x_2) - 1]$. So the fact that $h(x_1), h(x_1) + 1, \ldots, h(x_2) - 1 \notin S_1$ implies that $h(x_1), h(x_1) + 1, \ldots, h(x_2) - 1 \notin S_2$. Therefore, $h(x_1), h(x_1) + 1, \ldots, \ell \notin S_2$, which implies (5).

Finally, we complete the proof by establishing (6). If we had $k_1 = \ell + 1 - h(x_1) > \text{index}(x_1, D)$, then x_1 would have to reside in one of positions $h(x_1), h(x_1) + 1, \ldots, \ell$. If x_1 resides in any of positions $h(x_2), \ldots, \ell - 1$, then at time $t_2 < t_1$, that position must have been vacant, which implies that x_2 could have used it – but this contradicts the fact that x_2 created run r_2. On the other hand, if x_1 resides in any of positions $h(x_1), h(x_1) + 1, \ldots, h(x_2) - 1$, then x_1 does not conflict with position $h(x_2)$, which contradicts the fact that x_1 created run r_1. Thus, x_1 does not reside in any of positions $h(x_1), h(x_1) + 1, \ldots, \ell$, which means that $k_1 = \ell + 1 - h(x_1) \le \text{index}(x_1, D)$. ◀

We can build on Lemma 15 to make a claim about the average size of all of the analytical runs, namely that, if the analytical runs are not *all* adjacent, then their average (non-adjusted!) size must be $\Omega(B)$. It may see odd at first glance that we need to separate out the case where all of the analytical runs are adjacent, but we will see later on that this case actually behaves very differently from the other cases. (Indeed, it is the case that causes the insertion time to be $O(q^2)$ instead of $O(1)$!)

▶ **Lemma 16.** *Consider the execution of* BuildWitnesses$(D, h(u), \ell)$ *for some* $\ell > 0$. *Let* $r_1, r_2, \ldots, r_j$ *be the analytical runs that we add to* `Unprocessed` *during the execution of the algorithm. If* $r_1, r_2, \ldots, r_j$ *are not all adjacent, then* $\sum_{i=1}^{j} |r_i| \ge B$ *and*

$$\frac{1}{j} \sum_{i=1}^{j} |r_i| \ge \Omega(B).$$

Proof. Define $s_1, s_2, \ldots, s_j$ be the sizes of the analytical runs and let $s'_1, s'_2, \ldots, s'_j$ to be the adjusted sizes of the analytical runs. Since $r_1, r_2, \ldots, r_j$ are not all adjacent, we know that at least one r_i satisfies $|s_i| = B$ (namely, the first time we add an r_i that is not adjacent with the other r_js added so far). Therefore, the lemma is immediately true if $j = O(1)$. Suppose for the rest of the proof that $j = \omega(1)$.

With the possible exception of the first analytical run added by Line 2 (recall analytical runs created by Line 2 automatically have adjusted size B), we have that for every analytical run r whose true size s_i is smaller than its adjusted size s'_i, there is some run with true size B. Indeed, such a run r must be the final analytical run added by some iteration of Line 14, and that that iteration of Line 14 must have added at least one analytical run with true size B. It follows that

$$B + \sum_{i=1}^{j} s_i \geq \frac{1}{2} \sum_{i=1}^{j} s'_i.$$

Because $j = \omega(1)$, this implies

$$o(B) + \frac{1}{j} \sum_{i=1}^{j} s_i \geq \Omega\left(\frac{1}{j} \sum_{i=1}^{j} s'_i\right).$$

Thus, to complete the proof, it suffices to show that the right side is $\Omega(B)$.

Now consider a maximal sequence of adjacent analytical runs $r_{a_1}, r_{a_2}, r_{a_3}, \ldots, r_{a_k}$. If $k = 1$, then the adjusted size of the run r_{a_1} is guaranteed to be B (because either its true size is B and it was created by Line 14, or it was created by Line 2 which only creates analytical runs with adjusted sizes of B). If $k > 1$, then Lemma 15 tells us that the runs $r_{a_1}, r_{a_2}, r_{a_3}, \ldots, r_{a_k}$ have adjusted sizes summing to at least $\lfloor k/2 \rfloor \cdot B \geq kB/3$.

Therefore, the average adjusted size over all analytical runs is at least $B/3$. This means that

$$\frac{1}{2j} \sum_{i=1}^{j} s'_i \geq B/6,$$

which completes the proof. ◀

Finally, using the fact that the average analytical run size is $\Omega(B)$, we can obtain a bound on the number of runs of 0s, 1s, and 2s in the witness transcript T. (Here, we are using the term "run" in the string sense, e.g., a run of 0s is a maximal sequence of consecutive zeros in the string.)

▶ **Lemma 17.** *Consider the execution of* BuildWitnesses$(D, h(u), \ell)$ *for some* $\ell > 0$ *and suppose that the analytical runs that are created are not all adjacent. Then the resulting witness transcript* T *is a trinary string that has at most* $O(|T|/B)$ *runs of 0s, 1s, and 2s.*

Proof. Let $s_1, s_2, \ldots, s_j$ be the sizes of the analytical runs that we add to `Unprocessed` during the execution of the algorithm. The total number of 1s and 0s in T is exactly $\sum_i s_j$, and the total number of 2s in T is also exactly $\sum_i s_j$, so $|T| = 2\sum_i s_j$. On the other hand, both the number of 1s in T and the number of *runs* of 0s in T are bounded by j. It follows that the total number of runs of 0s and 1s in T is at most $2j$, which by Lemma 16 is at most $O(\sum_i s_i/B) = O(|T|/B)$. The number of runs of 2s is at most one greater than the number of runs of 0s and 1s (this is true for any trinary string), so the total number of runs overall in T is at most $O(|T|/B)$. ◀

The fact that the witness transcript T has so few runs will lead to a much smaller bound on the number of options for T than we had in the non-chunked setting. This is the key insight that makes it possible to prove Theorem 2. As noted earlier, the proof actually separates into two cases, the case where the analytical runs are all adjacent (this case contributes $O(q^2)$ to the running time) and the case where they are not (this case contributes only $O(1)$ to the running time, and is where we make use of the previous lemmas).

Proof of Theorem 2. Suppose the insertion takes time $t \geq 0$, and let us bound $\Pr[t > \ell]$ for some ℓ. Consider the execution of BuildWitnesses$(D, h(u), \ell)$, producing witness set S and witness transcript T. Let $r_1, r_2, \ldots$ be the analytical runs produced by the algorithm. Let $\mathcal{C}$ be the indicator random variable for the event that $r_1, r_2, \ldots$ are all adjacent, and let $\overline{\mathcal{C}}$ be the indicator random variable for the event that they are not all adjacent.

We begin by considering the event $\mathcal{C} = 1$. In this case, the witness set S is a contiguous interval $[i, j]$ containing $h(u)$. By Lemma 5, if $t > \ell$, then at least $|S| \geq \ell$ elements y in the hash table have hashes $h(y) \in V$. From the standard analysis of linear-probing hash tables (e.g., Lemma 15 of [9]), we know that the probability of any such interval S existing is at most $2^{-\Omega(\ell/q^2)}$. We have therefore shown that

$$\Pr[t\mathcal{C} > \ell] \leq 2^{-\Omega(\ell/q^2)}.$$

So, $\mathbb{E}[t\mathcal{C}] = O(q^2)$ and for any $j \geq 1$, $\Pr[t\mathcal{C} > jq^2] \leq 2^{-\Omega(j)}$.

Now, for the rest of the proof, consider the event $\overline{\mathcal{C}}$. Define $\overline{t} = t\overline{\mathcal{C}}$. We will complete the proof by showing that $\mathbb{E}[\overline{t}] = O(1)$ and that for any $j \geq 1$, $\Pr[\overline{t} > jq^2] \leq 2^{-\Omega(j)}$.

Supposing that $\overline{\mathcal{C}}$ occurs, we have by Lemma 16 that $|T| \geq B$. We also have trivially that $|T| \geq \ell$, so $|T| \geq \max(B, \ell)$. The fact that we only need to consider $|T| \geq \max(B, \ell)$ will be important through the rest of the proof.

By Lemma 17, T has at most $O(|T|/B)$ runs. By standard counting arguments, the number of trinary strings of length ℓ' with $O(\ell'/B)$ runs is at most $B^{O(\ell'/B)}$. It follows, that for a given length $\ell' > \max(B, \ell)$ for T, the number of options for what T could be is at most $B^{O(\ell'/B)}$. Since the witness set S is fully determined by T, and is exactly half of T's size (Lemma 7), the number of options for S of a given size $\ell'' \geq \max(B, \ell)/2$ is at most $B^{O(\ell''/B)}$.

On the other hand, if the insertion took time more than ℓ, then, in order for a given option for S to occur, there would need to be at least $|S|$ elements y in the hash table satisfying $h(y) \in S$ (Lemma 5). For a given set S, the expected number of elements y satisfying $h(y) \in S$ is

$$\alpha|S| \leq (1 - 1/(c\sqrt{B/\log B}))|S| = |S| - \frac{\sqrt{S \log B}}{\sqrt{B}\alpha}\sqrt{|S|}.$$

By a Chernoff bound, the probability of a given candidate witness set S of size $\ell'' \geq \max(B, \ell)/2$ having ℓ'' elements hash to it is at most

$$2^{-\Omega(|S| \log B/(B\alpha^2))} = B^{-\Omega(\ell''/B)/\alpha^2}.$$

Taking a union bound over all $B^{O(\ell''/B)}$ options for S, the probability that any S of size $\ell'' \geq \max(B, \ell)/2$ occurs is at most

$$B^{O(\ell''/B)} B^{-\Omega(\ell''/B)/\alpha^2}.$$

Setting α to be a sufficiently small positive constant, this is at most

$$1/B^{10\ell''/B}.$$

Summing over all $\ell'' \geq \max(B,\ell)/2$, the probability that BuildWitnesses$(D, h(u), \ell)$ produces a saturated witness set S of size at least $\max(B,\ell)/2$ is at most

$$\sum_{\ell'' \geq \max(B,\ell)/2} 1/B^{10\ell''/B} \leq 1/B^{\max(B,\ell)/B}.$$

But, the only way that $\bar{t} \geq \ell$ can occur is if such a witness set S is produced. Thus

$$\Pr[\bar{t} \geq \ell] \leq 1/B^{\max(B,\ell)/B} = B^{B/2+\ell/(2B)} \leq q^{-\Omega(q^2 \log q + \ell/(q^2 \log q))} \leq q^{-\Omega(q^2 \log q)} \cdot 2^{-\Omega(\ell/q^2)}.$$

It follows that $\mathbb{E}[\bar{t}] \leq O(1)$, and that, for $j \geq 1$, $\Pr[\bar{t} > jq^2] \leq 2^{-\Omega(j)}$, as desired. ◀

Abstract

We present a simple and provably optimal non-adaptive cell probe data structure for the static dictionary problem. Our data structure supports storing a set of n key-value pairs from $[u] \times [u]$ using s words of space and answering key lookup queries in $t = O(\lg(u/n)/\lg(s/n))$ non-adaptive probes. This generalizes a solution to the membership problem (i.e., where no values are associated with keys) due to Buhrman et al. We also present matching lower bounds for the non-adaptive static membership problem in the deterministic setting. Our lower bound implies that both our dictionary algorithm and the preceding membership algorithm are optimal, and in particular that there is an inherent complexity gap in these problems between no adaptivity and one round of adaptivity (with which hashing-based algorithms solve these problems in constant time).

Using the ideas underlying our data structure, we also obtain the first implementation of a n-wise independent family of hash functions with optimal evaluation time in the cell probe model.

1 Introduction

The static membership problem is arguably the simplest and most fundamental data structure problem. In this problem, the input is a set S of n integer keys $x_1, \ldots, x_n \in [u] = \{0, \ldots, u-1\}$ and the goal is to store them in a data structure, such that given a query key $x \in [u]$, the data structure supports reporting whether $x \in S$.

The classic solution to the membership problem is to use *hashing*, suggested as early as by Tarjan-Yao [23]. The textbook hashing-based solution is hashing with chaining, where one draws a random *hash function* $h : [u] \to [m]$ and creates an array A with $m = O(n)$ entries. Each entry $A[i]$ of the array stores a linked list of all keys $x \in S$ such that $h(x) = i$. To answer a membership query for x, we compute $h(x)$ and scan the linked list in entry $A[h(x)]$. If h is drawn from a *universal* family of hash functions, the time to answer queries is $O(1)$ in expectation. The expected query time can be made worst case $O(1)$ using e.g. perfect hashing [11] or (static) Cuckoo hashing [16, 17]. All of the above solutions may also be easily extended to solve the dictionary problem in which the data to be stored is a set of n key-value pairs $\{(x_i, y_i)\}_{i=1}^n$. Upon a query x, the data structure must return the value y_i such that $x_i = x$, or report that no such pair exists.

1.1 Adaptivity and Membership

A common feature of all hashing based solutions to the membership and dictionary problem, is that they are *adaptive*. That is, the memory locations they access depend heavily on the random choice of hash functions. In particular, to answer a query we first need to read the description of the chosen hash function, and only based on that we can compute the next memory cells we should access. A *non-adaptive* data structure has the property that the memory cells to access on a query x are completely determined from x itself. Non-adaptive data structures are studied for several reasons, a common type being computational settings in which interaction with memory is either expensive or limited. Non-adaptive data structures allow retrieving all necessary memory cells in *parallel* when answering a query, circumventing any memory-access related latency. This property also allows simpler implementation of the data structure under cryptographic settings, such as encrypted computation with Fully Homomorphic Encryption (see [25] for more details on the importance of non-adaptive querying in cryptography).

In this work, we present a non-adaptive dictionary algorithm in which a query needs to only access logarithmically many memory cells, and also prove a matching lower bound (which holds even for the static membership problem).

Unlike the textbook solution of hashing with chaining, which requires many rounds of adaptivity due to scanning a linked list, other solutions (e.g., cuckoo hashing) only need one round of adaptivity (i.e., first they read the description of the hash function, and then read memory cells that are determined only by the query and the hash function). Our results imply that a single round of adaptivity is necessary and sufficient to reduce the query time from super-constant to constant.

The Cell Probe Model. The cell probe model by Yao [24] is the de-facto model for proving data structure lower bounds. In this model, a data structure consists of a memory of s cells with integer addresses $0, \ldots, s-1$, each storing w bits. Computation is free of charge in this model and only the number of memory cells accessed/probed when answering a query counts towards the query time. A lower bound in the cell probe model thus applies to any data structure implementable in the classic word-RAM upper bound model.

Previous Work. Buhrman, Miltersen, Radhakrishnan and Venkatesh [6] showed that it is possible to store a data structure of size $O(n \lg u)$ bits such that membership queries can be answered in $O(\lg u)$ non-adaptive *bit* probes (i.e., the cell probe model with $w = 1$). This of course implies a membership data structure with $O(\lg u)$ probes in the cell probe model, but it is not clear how to extend it to solve the dictionary problem with the same time and space complexity. Furthermore, the data structure by Buhrman et al. is non-explicit in the sense that they give a randomized argument showing existence of an efficient data structure. Buhrman et al. also show a lower bound of $t = \Omega(\lg(u/n)/\lg(s/n))$ bit probes. In the setting where n is polynomially smaller than u and s is $O(n)$ this matches the upper bound up to constant factors (but it is possible that a tighter analysis can be made). Alon and Feige [1] as well as Garg and Radhakrishnan [12] studied space lower bounds for dictionary data structures with three non-adaptive probes in the bit probe model. The best lower bound shows that space of $s = \Omega(\sqrt{un})$ is necessary.

Berger et al. [3] study the non-adaptive dictionary problem, but in the I/O model, i.e., a single memory access can retrieve $B \geq 1$ keys or values. In the Word RAM model this corresponds to having word size $B \lg u$. This means that their strongest results for the dictionary problem would require word size $\Omega(\lg(n) \lg(u))$ – as we will see later, our results hold for word size $\lg u$.

Brody et al. [5] present a *dynamic* non-adaptive data structure for the *predecessor search* problem, allowing insertions and deletions of keys while supporting predecessor queries in $O(\lg u)$ probes. A predecessor query for a key x must return the largest $x' \in S$ such that $x' \leq x$. Such a data structure clearly also supports membership queries. However, their data structure critically uses $s = \Theta(2^w) = \Theta(u)$ memory. For the membership problem in this setting, a bit-vector with constant time operations suffices. Brody et al. [5] however prove that for dynamic data structures for predecessor search, this query time is optimal even with $\Theta(u)$ space. Boninger et al. [4] as well as Ramamoorthy and Rao [21] also study lower bounds for the non-adaptive dynamic predecessor problem. Relating their results to the non-adaptive static dictionary problem, the two works show query time must be $t = \Omega(\lg u/\lg w)$ and $t = \Omega(\lg u/(\lg\lg u + \lg w))$ respectively in the cell probe model. To our knowledge, these are the highest known lower bounds for the static, non-adaptive dictionary problem.

This still leaves open the problem of obtaining an optimal static and non-adaptive membership data structure, in both the word-RAM model, and in the cell probe model.

Our Contribution. In this work, we present a simple and optimal non-adaptive cell probe data structure for the dictionary and membership problem:

▶ **Theorem 1.** *For any $s = \Omega(n)$, there is a non-adaptive static cell probe data structure for the dictionary problem, storing n key-value pairs $(x_i, y_i) \in [u] \times [u]$ using s memory cells of $w = \Theta(\lg u)$ bits and answering queries in $t = O(\lg(u/n)/\lg(s/n))$ probes.*

As stated in the theorem, our data structure is implemented in the cell probe model, meaning that we treat computation as free of charge. Implementing the data structure in the more standard upper bound model, the word-RAM, would require the construction of a certain type of explicit bipartite expander graph.

Compared to prior works (such as [6, 3]), our construction shows that we may rely on a significantly weaker expansion argument. Past constructions required an orientability argument to assign memory to keys that required expanders with a strong unique-neighbors property. In contrast, our construction utilizes weaker non-contractive expanders to argue that there is sufficient capacity to accommodate storage of all keys (using Hall's theorem).

This directly translates to a logarithmic improvement in space usage. Namely, we only require the existence of t-left-regular bipartite graphs with expansion factor one; however our bipartite graph is highly imbalanced. Our expansion property corresponds to an imbalanced disperser, and therefore is well-studied and has other applications (e.g., [13]). Such dispersers exist by a counting argument, but it remains an open problem to obtain explicit constructions. A recent work [2] constructs explicit expanders that may be plugged into our construction to obtain an explicit RAM upper bound. However, this incurs a poly-logarithmic blowup and obtaining a tight explicit RAM upper bound would require better explicit expanders.

We also present a matching lower bound for the non-adaptive dictionary and membership problem in the cell probe model:

▶ **Theorem 2.** *For any non-adaptive static cell probe data structure for the dictionary problem storing n key-value pairs $(x_i, y_i) \in [u] \times [u]$ using s memory cells of w bits and answering queries in t probes must satisfy*

$$t = \Omega\left(\min\left\{\frac{n\lg(u/n)}{w}, \frac{\lg(u/n)}{\lg(sw/(n\lg(u/n)))}\right\}\right).$$

Our lower bound shows that adaptivity is crucial to obtain constant query time. In particular, non-adaptive data structures require super-constant query time while well-known constructions with adaptivity (such as cuckoo hashing) can obtain constant query time.

We note that our lower bound peaks higher compared to the prior best lower bounds. For standard parameters of $u = n^{1+O(1)}$ and $w = \Theta(\lg u)$, our lower bound shows that optimal space constructions with $s = O(n)$ require query time $t = \Omega(\lg u)$ in the cell probe model. In contrast, prior works [4, 21] obtain lower bounds of $t = \Omega(\lg u / \lg\lg u)$.

1.2 Hash Functions with High Independence

When using hash functions in the design of data structures and algorithms, it is often assumed for simplicity of analysis that truly random hash functions are available. Such a hash function $h : [u] \to [m]$ maps each key *independently* to a uniform random value in $[m]$. Or said differently, when drawing the random hash function h, we choose a uniform random function in the family of hash functions $\mathcal{H}$ consisting of all (deterministic) functions from $[u]$ to $[m]$. Implementing such a hash function in practice is often infeasible as it requires $u \lg m$ random bits and thus the storage requirement may completely dominate that of any data structure making use of the hash function.

Fortunately, much weaker hash functions suffice in many applications. The simplest property of a family of hash functions $\mathcal{H} \subseteq [u] \to [m]$, is that it is *universal* [7]. A universal family of hash functions has the property that for a uniform random $h \in \mathcal{H}$, it holds for every pair of keys $x \neq y \in [u]$ that $\Pr[h(x) = h(y)] \leq 1/m$. Universal hashing for instance suffices for implementing hashing with chaining with expected constant time membership queries, but is not sufficient for implementing Cuckoo hashing [9]. The next step up from universal hashing is the notion of n-wise independent hashing. A family of hash functions $\mathcal{H}$ is n-wise independent if, for h drawn uniformly from $\mathcal{H}$, it holds for any set of n distinct keys $x_1, \ldots, x_n$ that $h(x_1), \ldots, h(x_n)$ are independent and uniformly random (or nearly uniformly random). The prototypical example of an n-wise independent family of hash function (with nearly uniform hash values) is

$$\mathcal{H} := \left\{ h_{\alpha_0,\ldots,\alpha_{n-1}}(x) = \left(\sum_{i=0}^{n-1} \alpha_i x^i \bmod p\right) \bmod m \mid \alpha_0, \ldots, \alpha_{n-1} \in [p] \right\}$$

where p is any prime greater than or equal to u. That is, to draw a hash function h from $\mathcal{H}$, we sample $\alpha_0, \ldots, \alpha_{n-1}$ uniformly and independently in $[p]$ and let $h(x)$ be the evaluation of the polynomial $(\sum_i \alpha_i x^i \bmod p) \bmod m$.[1] Clearly, the evaluation time of this hash function is $\Theta(n)$. Whether it is possible to implement n-wise independent hash functions with faster evaluation time has been the focus of much research. On the lower bound side, Siegel [22] proved that any implementation of an n-wise independent hash function $h : [u] \to [m]$ using s memory cells of $w = \Theta(\lg u)$ bits, must probe at least $t = \Omega(\min\{\lg(u/n)/\lg(s/n), n\})$ memory cells to evaluate h. The hash function above matches the second term in the minimum. For the first term, the result that comes closest is a recursive form of tabulation hashing by Christiani et al. [8] that gives an n-wise independent family of hash functions that can be implemented using $s = O(nu^{1/c})$ space and evaluation time $t = O(c \lg c)$ for any $c = O(\lg u/\lg n)$. Rewriting the space bound gives $c = \lg u/\lg(s/n)$ and thus $t = O(\lg(u)\lg(\lg(u)/\lg(s/n))/\lg(s/n))$. This is about a $\lg\lg u$ factor away from the lower bound of Siegel in terms of the query time t. This algorithm is adaptive and requires $s \geq n^{1+\Omega(1)}$ as they need $\lg u/\lg(s/n) = O(\lg u/\lg n)$.

Our Contribution. Designing an optimal n-wise independent family of hash functions thus remains open, with or without adaptivity. In this work, we show how to implement such a function in the cell probe model (where computation is free):

▶ **Theorem 3.** *For any $s = \Omega(n)$ and $p = \Omega(u)$, there is a non-adaptive static cell probe data structure for storing an n-wise independent hash function $h : [u] \to \mathbb{F}_p$ using s memory cells of $w = \Theta(\lg p)$ bits and answering evaluation queries in $t = O(\lg(u/n)/\lg(s/n))$ probes.*

We remark that Siegel's lower bound holds in the cell probe model, and thus our data structure is optimal. Furthermore, Siegel's lower bound holds *also* for adaptive data structures, whereas ours is even non-adaptive. Compared to the work of Christiani et al., we have a faster evaluation time and only require $s = \Omega(n)$. The downside is of course that our solution is only implemented in the cell probe model. Implementing our hash function in the word-RAM model would require the same type of explicit expander graph as for implementing our non-adaptive dictionary (and a bit more), further motivating the study of such expanders (see Section 5).

To compare with previous techniques, we note that the majority of prior works (such as [15, 10, 8]) consider adaptive constructions. The original work of Siegel [22] did not directly study non-adaptivity. However, Lemma 2 in [22] can be used to construct a non-adaptive construction in the cell probe model using a suitable expander graph. Our construction leads to a better (and tight) upper bound in addition to being simpler by replacing polynomials with a simple sum of memory cells.

2 Non-Adaptive Dictionaries

We consider the dictionary problem where we are to preprocess a set X of n key-value pairs from $[u] \times [u]$ into a data structure, such that given an $x \in [u]$, we can quickly return the corresponding value y such that $(x, y) \in X$ or conclude that no such y exists. We assume that any for any key x, there is at most one value y such that $(x, y) \in X$.

[1] Technically, this hash function is only approximately n-wise independent, in the sense that the hash values of any n keys *are* independent, but only approximately uniform random.

We focus on non-adaptive data structures in the cell probe model. Non-adaptive means that the memory cells probed on a query depends only on x. We assume $u = \Omega(n)$ and that the cell size w is $\Theta(\lg u)$.

As mentioned in Section 1, we base our data structure on expander graphs. We recall the standard definitions of bipartite expanders in the following:

▶ **Definition 4.** *A (u, s, t)-bipartite graph with u left vertices, s right vertices and left degree t is specified by a function $\Gamma : [u] \times [t] \to [s]$, where $\Gamma(x, y)$ denotes the y^{th} neighbor of x. For a set $S \subseteq [u]$, we write $\Gamma(S)$ to denote its neighbors $\{\Gamma(x, y) : x \in S, y \in [t]\}$.*

▶ **Definition 5.** *A bipartite graph $\Gamma : [u] \times [t] \to [s]$ is a (K, A)-expander if for every set $S \subseteq [u]$ with $|S| = K$, we have $|\Gamma(S)| \geq A \cdot K$. It is a $(\leq K_{\max}, A)$-expander if it is a (K, A)-expander for every $K \leq K_{\max}$.*

The literature on bipartite expanders, see e.g. [13], is focused on graphs with near-optimal expansion $A = (1 - \varepsilon)t$, i.e. very close to the largest possible expansion with degree t. However, for our non-adaptive dictionaries, we need significantly less expansion. We call such expanders *non-contractive* and define them as follows:

▶ **Definition 6.** *A bipartite graph $\Gamma : [u] \times [t] \to [s]$ is a $(\leq K_{\max})$-non-contractive expander if it is a $(\leq K_{\max}, 1)$-expander.*

Said in words, a bipartite is a $(\leq K_{\max})$-non-contractive expander, if every set of at most $K \leq K_{\max}$ left-nodes has at least K neighbors.

Before presenting our dictionary, we present the second ingredient in our dictionary, namely Hall's marriage theorem. For a bipartite graph with left-vertices X, right-vertices Y and edges E, an X-perfect matching is a subset of disjoint edges from E such that every vertex in X has an edge. Hall's theorem then gives the following:

▶ **Theorem 7** (Hall's Marriage Theorem)**.** *A bipartite graph with left-vertices X and right-vertices Y has an X-perfect matching if and only if for every subset $S \subseteq X$, the set of neighbors $\Gamma(S)$ satisfies $|\Gamma(S)| \geq |S|$.*

With these ingredients, we are ready to present our dictionary.

Dictionary from Non-Contractive Expander. Given a set of n key-value pairs $X = \{(x_i, y_i)\}_{i=1}^n \subset [u] \times [u]$ and a space budget of s memory cells, we build a data structure as follows:

Construction. Initialize s memory cells and let $\Gamma : [u] \times [t] \to [s]$ be a $(\leq n)$-non-contractive expander for some t. Construct the bipartite graph G with a left-vertex for each x_i and a right vertex for each of the s memory cells. Add an edge from x_i to each of the nodes $\Gamma(x_i, j)$ for $i = 0, \ldots, t - 1$. Note that this is a subgraph of the bipartite $(\leq n)$-non-contractive expander corresponding to Γ. It follows that for every subset $S \subseteq \{x_i\}_{i=1}^n$, we have $|\Gamma(S)| \geq |S|$. We now invoke Hall's Marriage Theorem (Theorem 7) to conclude the existence of an $\{x_i\}_{i=1}^n$-perfect matching on G. Let $M = \{(x_i, v_i)\}_{i=1}^n$ denote the edges of the matching. For each such edge (x_i, v_i), we store the key-value pair (x_i, y_i) in the memory cell of address v_i. For all remaining $s - n$ memory cells, we store a special *Nil* value.

Querying. Given a query $x \in [u]$, we query the t memory cells of address $\Gamma(x, i)$ for $i = 0, \ldots, t - 1$. If any of them stores a pair (x, y), we return y. Otherwise, we return *Nil* to indicate that no pair (x, y) exists in X.

Analysis. Correctness follows immediately from Hall's Marriage Theorem. The space usage is s memory cells of $w = \Theta(\lg u)$ bits and the query time is t. The required perfect matching M can be computed in $\text{poly}(n, s)$ times after performing $O(nt)$ queries to obtain the edges of the subgraph induced by the left-vertices $\{x_i\}_{i=1}^n$. We thus have the following result:

▶ **Lemma 8.** *Given a bipartite $(\leq n)$-non-contractive expander $\Gamma : [u] \times [t] \to [s]$, there is a non-adaptive dictionary for storing a set of n key-value pairs using s cells of $w = \Theta(\lg u)$ bits and answering queries in t evaluations of Γ and t memory probes. The dictionary can be constructed in $\text{poly}(n, s)$ time plus $O(nt)$ evaluations of Γ.*

Lemma 8 thus gives us a way of obtaining a non-adaptive dictionary from an expander. What remains is to give expanders with good parameters. As mentioned, we do not have optimal explicit constructions of such expanders. However, for the cell probe model where computation is free of charge, we merely need the existence of Γ and not that it is efficiently computable. Concretely, a probabilistic argument gives the following:

▶ **Lemma 9.** *For any $s \geq 2n$ and any $u \geq n$, there exists a (non-explicit) $(\leq n)$-non-contractive expander $\Gamma : [u] \times [t] \to [s]$ with $t = \lg(u/n)/\lg(s/n) + 5$.*

Combining Lemma 8 and Lemma 9 implies our Theorem 1.

Non-Explicit Expander. In the following, we prove Lemma 9. For this, consider drawing $\Gamma : [u] \times [t] \to [s]$ uniformly among all such functions/expanders. That is, we let $\Gamma(x, y)$ be uniform random and independently chosen in $[s]$ for each $x \in [u]$ and $y \in [t]$. For each $S \subseteq [u]$ with $|S| \leq n$ and each $T \subseteq [s]$ with $|T| = |S| - 1$, define an event $E_{S,T}$ that occurs if $\Gamma(S) \subseteq T$. We have that Γ is a $(\leq n)$-non-contractive expander if none of the events $E_{S,T}$ occur. For a fixed $E_{S,T}$, we have $\Pr[E_{S,T}] = (|T|/s)^{t|S|}$ and thus a union bound implies

$$\begin{aligned}
\Pr[\Gamma \text{ is not a } (\leq n)\text{-non-contractive expander}] &\leq \\
\sum_{S,T} \Pr[E_{S,T}] &= \\
\sum_{i=1}^{n} \sum_{S \subseteq [u]:|S|=i} \sum_{T \subseteq [s]:|T|=i-1} \Pr[E_{S,T}] &\leq \\
\sum_{i=1}^{n} \binom{u}{i}\binom{s}{i}(i/s)^{ti} &\leq \\
\sum_{i=1}^{n} (eu/i)^i (es/i)^i (i/s)^{ti} &= \\
\sum_{i=1}^{n} \left(\frac{e^2 u i^{t-2}}{s^{t-1}}\right)^i &\leq \\
\sum_{i=1}^{n} \left(e^2 (u/n)(n/s)^{t-1}\right)^i.
\end{aligned}$$

For $s \geq 2n$ and $t \geq \lg(u/n)/\lg(s/n) + 5$, this is at most $\sum_{i=1}^{n} (e^2/16)^i < 1$ and thus proves Lemma 9.

3 Hashing

In this section, we show how to construct a n-wise independent hash function with fast evaluation in the cell probe model. As a data structure problem, such a data structure has a query $h(x)$ for each $x \in [u]$. Upon construction, the data structure draws a random seed and initializes s memory cells of w bits. The data structure satisfies that the values $h(x)$ are uniform random in $\mathbb{F}_p$ and n-wise independent. Here the randomness is over the choice of random seed.

Similarly to our dictionary, our hashing data structures makes use of a bipartite expander. However, we need a (very) slightly stronger expansion property. Concretely, we assume the availability of a $(\leq n, 2)$-expander $\Gamma : [u] \times [t] \to [s]$ (rather than a $(\leq n, 1)$-expander). The expander Γ thus satisfies that for any $S \subseteq [u]$ with $|S| \leq n$, we have $|\Gamma(S)| \geq 2|S|$.

In addition to the $(\leq n, 2)$-expander Γ, we also need another function assigning *weights* to the edges of Γ. We say that $\Pi : [u] \times [t] \to \mathbb{F}_p$ makes Γ *useful* if the following holds: Construct from (Γ, Π) the $u \times s$ matrix $A_{\Gamma,\Pi}$ such that entry (x, y) equals

$$\sum_{j:\Gamma(x,j)=y} \Pi(x, j) \bmod p$$

We have that (Γ, Π) is useful if every subset of n rows in $A_{\Gamma,\Pi}$ is a linearly independent set of vector over $\mathbb{F}_p^s$. We show later that for any $(\leq n, 2)$-expander Γ, there exists at least one Π making Γ useful:

▶ **Lemma 10.** *If $\Gamma : [u] \times [t] \to [s]$ is a $(\leq n, 2)$-expander, then for $p \geq 2eu$, there exists a $\Pi : [u] \times [t] \to \mathbb{F}_p$ such that (Γ, Π) is useful.*

In the cell probe model, we may assume that Γ and Π are free to evaluate and are known to a data structure since computation is free of charge. With such a pair (Γ, Π) we may now construct our data structure for n-wise independent hashing.

Construction. Initialize the data structure by filling each of the s memory cells by uniformly and independently chosen values in $\mathbb{F}_p$ (the seed). Let $z_0, \ldots, z_{s-1}$ denote the values in the memory cells.

Querying. To evaluate $h(x)$ for an $x \in [u]$, compute and return the value

$$\sum_{j=0}^{t-1} \Pi(x, j) z_{\Gamma(x,j)} \bmod p.$$

Analysis. Observe that the value returned on the query x equals

$$\sum_{j=0}^{t-1} \Pi(x, j) z_{\Gamma(x,j)} \bmod p \equiv \sum_{y=0}^{s-1} \sum_{j:\Gamma(x,j)=y} \Pi(x, j) z_{\Gamma(x,j)} \bmod p.$$

But this is the same as $(A_{\Gamma,\Pi} z)_x$, i.e. the inner product of the x'th row of $A_{\Gamma,\Pi}$ with the randomly drawn vector z. Since the rows of $A_{\Gamma,\Pi}$ are n-wise independent and z is drawn uniformly, we conclude that the query values $h(0), \ldots, h(u-1)$ are n-wise independent as well. The query time is t probes and the space usage is s cells of $\lg p$ bits. We thus conclude

▶ **Lemma 11.** *Given a bipartite $(\leq n, 2)$ expander $\Gamma : [u] \times [t] \to [s]$ and a $p \geq 2eu$, there is a cell probe data structure for evaluating an n-wise independent hash function $h : [u] \to \mathbb{F}_p$ using s cells of $w = \Theta(\lg p)$ bits and answering queries in t cell probes.*

An argument similar to the proof of Lemma 9, we show the existence of the desired expanders:

▶ **Lemma 12.** *For any $s \geq 2n$ and any $u \geq n$, there exists a (non-explicit) $(\leq n, 2)$ expander $\Gamma : [u] \times [t] \to [s]$ with $t = 2\lg(u/n)/\lg(s/n) + 4$.*

Combining Lemma 12, Lemma 10 and Lemma 11 proves Theorem 3.

What remains is to prove Lemma 10 and Lemma 12. We start with Lemma 10.

Proof of Lemma 10. We give a probabilistic argument. Let $\Gamma : [u] \times [t] \to [s]$ be a $(\leq n, 2)$-expander. Draw $\Pi : [u] \times [t] \to \mathbb{F}_p$ by letting $\Pi(x, j)$ be chosen uniformly and independently from $\mathbb{F}_p$. Define an event E_β for every $\beta \in \mathbb{F}_p^u$ with $1 \leq \|\beta\|_0 \leq n$ ($\|\beta\|_0$ gives the number of non-zeros) that occurs if $\beta A_{\Gamma,\Pi} = 0$. We have that (Γ, Π) is useful if none of the events E_β occur.

Consider one of these events E_β. Since Γ is a $(\leq n, 2)$-expander, we have that the set of rows in $A_{\Gamma,\Pi}$ corresponding to non-zero coefficients of β have at least $2\|\beta\|_0$ distinct columns containing an entry that is chosen uniformly at random and independently from $\mathbb{F}_p$. We thus have $\Pr[E_\beta] \leq p^{-2\|\beta\|_0}$. A union bound finally implies:

$$\begin{aligned}
\Pr[(\Gamma, \Pi) \text{ is not useful}] &\leq \\
\sum_{i=1}^{n} \sum_{\beta \in \mathbb{F}_p^u : \|\beta\|_0 = i} \Pr[E_\beta] &\leq \\
\sum_{i=1}^{n} \binom{u}{i} p^i p^{-2i} &\leq \\
\sum_{i=1}^{n} (eu/(ip))^i.
\end{aligned}$$

For $p \geq 2eu$, this is less than 1, which concludes the proof of Lemma 10. ◀

Lastly, we prove Lemma 12.

Proof of Lemma 12. The proof follows that of Lemma 9 uneventfully. Draw Γ randomly, with each $\Gamma(x, y)$ uniform and independently chosen in $[s]$. Again, we define an event $E_{S,T}$ for each $S \subseteq [u]$ with $|S| \leq n$ and each $T \subseteq [s]$ with $|T| = 2|S| - 1$. The event $E_{S,T}$ occurs if $\Gamma(S) \subseteq T$. We have

$$\begin{aligned}
\Pr[\Gamma \text{ is not an } (\leq n, 2)\text{-expander}] &\leq \\
\sum_{S,T} \Pr[E_{S,T}] &\leq \\
\sum_{i=1}^{n} \binom{u}{i} \binom{s}{2i} ((2i)/s)^{ti} &\leq \\
\sum_{i=1}^{n} (eu/i)^i (s/(2i))^{2i} ((2i)/s)^{ti} &= \\
\sum_{i=1}^{n} \left(\frac{eu(2i)^{t-3}}{s^{t-2}} \right)^i &\leq \\
\sum_{i=1}^{n} \left(e(u/n)(2n/s)^{t-2} \right)^i
\end{aligned}$$

For $s \geq 4n$ and $t \geq 2\lg(u/n)/\lg(s/n) + 4 \geq \lg(u/n)/\lg(s/(2n)) + 4$, this is less than 1, completing the proof of Lemma 12. ◀

4 Lower Bound for Non-Adaptive Dictionaries

In this section, we prove cell probe lower bounds for non-adaptive dictionaries supporting membership queries (is x in the input set X?).

We adapt the "cell-sampling" technique from [18]. Roughly speaking, this proof technique shows that there exists a not-too-large subset of cells $C \subseteq [s]$ such that a large number of queries will only probe cells in C (we say such queries are resolved by C) assuming that the query time of the cell probe data structure is impossibly small. For adaptive and static data structures, it can be observed that the subset of cells C will be different for varying choices of the n input key-value pairs as the probed cells during queries can depend on the memory representation.

For our non-adaptive lower bound, we make the critical observation that the subset of sampled cells C need not depend on the n input key-value pairs. In particular, non-adaptive queries must choose the probed cells without any knowledge of the memory representation. As a result, we are able to separate the adaptive and non-adaptive setting for the dictionary problem and successfully prove a matching lower bound to our constructions as follows:

Proof of Theorem 2. Assume the space usage of a data structure is s cells of w bits each. We assume for the proof that $sw \geq 6n \lg(u/n)$. For smaller space usage, we can always pad with dummy memory cells.

For a query $x \in [u]$, let $p(x) \subseteq [s]$ denote the indices of the memory cells probed on query x.

By averaging, for any q with $t \leq q \leq s$, there is a set of q memory cells $C \subseteq [s]$ such that $u\binom{s-t}{q-t}/\binom{s}{q}$ queries x have $p(x) \subseteq C$. Fix such a set C. Assume for the sake of contradiction that

$$t \leq (1/4) \min\left\{q, \frac{\lg(u/n)}{\lg(sw/(n\lg(u/n)))}\right\}.$$

Then we have

$$u \cdot \frac{\binom{s-t}{q-t}}{\binom{s}{q}} = u \cdot \frac{q(q-1)\cdots(q-t+1)}{s(s-1)\cdots(s-t+1)} \geq u \cdot \left(\frac{(3/4)q}{s}\right)^t.$$

Letting $q = (1/4)n\lg(u/n)/w$, this is at least $u \cdot \left(\frac{(3/16)n\lg(u/n)}{sw}\right)^t \geq u \cdot \left(\frac{n\lg(u/n)}{sw}\right)^{2t} \geq u\sqrt{n/u} = \sqrt{un}$.

Let $U \subseteq [u]$ denote the set of queries x with $p(x) \subseteq C$. Notice that the memory cells in C serve as a membership data structure for the universe U and inputs $X \subseteq U$ of size n. Hence the number of bits in C must be at least $\lg\binom{|U|}{n} \geq (1/2)n\lg(u/n)$. But the cells only have $qw = (1/4)n\lg(u/n)$ bits, a contradiction. We thus conclude:

$$t = \Omega\left(\min\left\{\frac{n\lg(u/n)}{w}, \frac{\lg(u/n)}{\lg(sw/(n\lg(u/n)))}\right\}\right). \qquad \blacktriangleleft$$

5 Conclusion and Open Problems

In this work, we presented optimal non-adaptive cell probe dictionaries and data structures for evaluating n-wise independent hash functions. Our upper bounds rely on the existence of bipartite expanders with quite weak expansion properties, namely $(\leq n, 1)$ and $(\leq n, 2)$-bipartite expanders. If efficient explicit constructions of such expanders were to be developed,

they would immediately allow us to implement our dictionary in the standard word-RAM model. They would also go a long way towards a word-RAM implementation of n-wise independent hashing. We thus view our results as strong motivation for further research into such expanders. In personal communication with Bruno Bauwens and Marius Zimand, they have given a preliminary proof that an exciting explicit construction with $s = O(n)$ and $t = (\lg u)^{O(1)}$ exists, thus taking a first step towards an optimal word-RAM implementation.

Next, we remark that our non-explicit constructions of $(\leq n, 1)$ and $(\leq n, 2)$ expanders are essentially optimal. Concretely, a result of Radhakrishnan and Ta-Shma [20] shows that any (u, s, t)-bipartite graph with expansion 1 requires $t = \Omega(\lg(u/n)/\lg(s/n))$. In more detail, Theorem 1.5 (a) of [20] proves that if G is a (u, s, t)-bipartite graph that is an (n, ϵ) disperser (every set of n left-nodes has at least $(1 - \varepsilon)s$ right-nodes), then for $\varepsilon > 1/2$, the left-degree, t, is $\Omega(\lg(u/n)/\lg(1/(1 - \varepsilon)))$. Since a $(\leq n, 1)$-non-contractive expander is also an (n, ϵ)-disperser with $(1 - \epsilon) = n/s$, the lower bound $t = \Omega(\lg(u/n)/\lg(s/n))$ follows.

Finally, we also observe a near-equivalence between non-adaptive data structures for evaluating n-wise independent hash functions and non-constructive bipartite expanders. Concretely, assume we have a word-RAM data structure for evaluating an n-wise independent hash function from $[u]$ to $[u]$ and assume $w = \lg u$ for simplicity. If the data structure uses s space and answers queries in t time (including memory lookups and computation), then we may obtain an explicit expander from the data structure. Concretely, we form a right node for every memory cell, a left node for every query and an edge corresponding to each cell probed on a query. Now observe that if there was a set of n left nodes S with $|\Gamma(S)| < n$, then from those $|\Gamma(S)|$ memory cells, the data structure has to return n independent and uniform random values in $[u]$. But the cells only have $|\Gamma(S)|w < n \lg u$ bits, i.e. a contradiction. Hence the resulting expander is non-contractive. If the query time of the data structure was t, we may obtain the edges incident to a left node simply by running the corresponding query algorithm. Since the query algorithm runs in t time, it clearly accesses at most t right nodes and computing the nodes to access can also be done in t time. A similar connection was observed by [8].

An Improved Quantum Max Cut Approximation via Maximum Matching

Eunou Lee

Ojas Parekh
Sandia National Laboratories, Albuquerque, NM, USA

Abstract

Finding a high (or low) energy state of a given quantum Hamiltonian is a potential area to gain a provable and practical quantum advantage. A line of recent studies focuses on Quantum Max Cut, where one is asked to find a high energy state of a given antiferromagnetic Heisenberg Hamiltonian. In this work, we present a classical approximation algorithm for Quantum Max Cut that achieves an approximation ratio of 0.595, outperforming the previous best algorithms of Lee [10] (0.562, generic input graph) and King [8] (0.582, triangle-free input graph). The algorithm is based on finding the maximum weighted matching of an input graph and outputs a product of at most 2-qubit states, which is simpler than the fully entangled output states of the previous best algorithms.

1 Introduction

A quantum optimization problem seeks to compute the maximum (or minimum) of a function that is defined over the n-qubit Hilbert space. In a restricted case where the function is a sum of k-qubit Hamiltonians, it is well known that the problems are in general QMA-hard, i.e. hard to solve to an inverse polynomial precision even with a quantum computer [4]. One way to cope with the computational hardness is to try to find good approximate solutions.

Quantum Max Cut (QMC) has served as a benchmark problem to develop ideas for quantum Hamiltonian approximation. It has a simple definition, has a good physical motivation, namely the antiferromagnetic Heisenberg model, and extends the well-studied classical Max Cut problem. The task of QMC, given a positive weighted graph $G = (V, E, w)$, is to find a (description of a) maximum energy state for the Hamiltonian

$$H = \sum_{(i,j)\in E} w_{ij}(I - X_iX_j - Y_iY_j - Z_iZ_j)/4,$$

where X_i is the Pauli matrix X on qubit i and identity on the rest. The matrices, Y_i, Z_i are similarly defined.

Most of the existing approximation algorithms for QMC follow the framework of the seminal Goemans-Williamson algorithm [6]. The problem is first relaxed to a semidefinite program (SDP), then the SDP is solved in polynomial time, and finally, the SDP solution is rounded to a feasible solution of the original problem. Since QMC is a maximization problem over the n-qubit Hilbert space, the rounded solution should be an n-qubit quantum state instead of an n-bit string as for Max Cut. Assuming that we follow the Goemans-Williamson framework to approximate QMC, there are still three design choices: 1) which SDP to relax the original problem to, 2) which subset of quantum states (ansatz) to round the SDP solution to, and 3) how to round the SDP solution to an ansatz state. For Max Cut, optimal choices (up to the Unique Games Conjecture) of classical analogues of the above are known; however, these remain unsettled for QMC.

The Quantum Lasserre SDP hierarchy [9, 11] is a sequence of SDPs that upper bounds the maximum energy of a given quantum Hamiltonian. The Quantum Lasserre hierarchy does so by optimizing over pseudo-density operators that are not guaranteed to be positive. The level-k Lasserre SDP includes all valid linear constraints on moments of subsets of at most k qubits. It also includes global constraints characterized by polynomials where each term is tensor product of at most k non-trivial single-qubit Paulis (see e.g., [13]). Hence the SDPs in the hierarchy become tighter as the level increases, eventually converging to the given quantum Hamiltonian problem when $k = n$. The following is a way to view the SDP construction. Fix a quantum state $|\phi\rangle$. For an n-qubit Pauli matrix P, define $v(P) := P|\phi\rangle$. Then the energy of $|\phi\rangle$ for an arbitrary Hamiltonian can be expressed as a sum of inner products of these vectors. For example, $\langle\phi|I - X_iX_j - Y_iY_j - Z_iZ_j|\phi\rangle = \langle v(I), v(I)\rangle - \langle v(X_iX_j), v(I)\rangle - \langle v(Y_iY_j), v(I)\rangle - \langle v(Z_iZ_j), v(I)\rangle$. Additionally, it holds that $\|v(P)\| = 1$, and $\langle v(P_1), v(Q_1)\rangle = \langle v(P_2), v(Q_2)\rangle$ for all n-qubit Pauli matrices P_1, P_2, Q_1, Q_2 such that $P_1Q_1 = P_2Q_2$. Now forget about $|\phi\rangle$ and maximize the energy expression in terms of $v(P)$'s, while satisfying the inner product relations.

In the following definition, $\mathcal{P}_k(n)$ is the set of n-qubit Pauli matrices with non-trivial terms on up to k qubits.

▶ **Definition 1** (Level-k Quantum Lasserre SDP)**.**

$$\textit{Maximize} \sum_{(i,j)\in E} w_{ij} v(I)\cdot(v(I) - v(X_iX_j) - v(Y_iY_j) - v(Z_iZ_j))/4 \tag{S}$$

$$\begin{aligned}
\textit{subject to } & v(P) \in \mathbb{R}^{|\mathcal{P}_k(n)|}, && \forall P \in \mathcal{P}_k(n),\\
& v(P)\cdot v(P) = 1, && \forall P \in \mathcal{P}_k(n),\\
& v(P_1)\cdot v(Q_1) = v(P_2)\cdot v(Q_2), && \forall P_1, P_2, Q_1, Q_2 \in \mathcal{P}_k(n) \text{ s.t. } P_1Q_1 = P_2Q_2,\\
& v(P)\cdot v(Q) = 0, && \forall P, Q \in \mathcal{P}_k(n) \text{ s.t. } PQ + QP = 0.
\end{aligned}$$

Every existing QMC approximation algorithm that follows an SDP rounding framework uses a Quantum Lasserre SDP. The QMC approximation algorithm of Gharibian-Parekh [5] employs the level-1 Lasserre, and Parekh-Thompson [12], Parekh-Thompson [13], Lee [10], and King [8] employ the level-2 Lasserre SDP. More sophisticated SDP hierarchies that are aware of the $SU(2)$ symmetry in the QMC Hamiltonian have also been developed recently [14, 15], and such hierarchies are implicitly used in existing QMC approximation algorithms [13].

Once an SDP relaxation is solved, its solution is rounded to a quantum state. Current algorithms round SDP solutions to a proper subset (ansatz) of the n-qubit Hilbert space. Gharibian-Parekh [5] and Parekh-Thompson [13] round to product states, and Parekh-Thompson [12] rounds to a product of 1- and 2-qubit states, inspired by the non-SDP approximation algorithm of Anshu, Gosset, and Morenz [1]. Lee [10] and King [8] round to n-qubit entangled states.

In this paper, we introduce a simple classical approximation algorithm that solves the level-2 Lasserre SDP and rounds to either a product of 1-qubit states or a product of 1- and 2-qubit states. The former is obtained using the Gharibian-Parekh product state rounding algorithm. The latter is obtained by solving the Maximum Weight Matching problem in the weighted input graph on which the QMC Hamiltonian is defined, and this does not depend on the SDP solution at all. This distinguishes and drastically simplifies our algorithm relative to previous SDP rounding approaches, which crucially use information from a level-2 SDP solution to produce entangled states.

We show that the approximation ratio of our algorithm is 0.595, which improves the previous best algorithms for general graphs (Lee [10] with a ratio of 0.562), and triangle-free graphs (King [8] with a ratio of 0.582).

Quantum optimization

Another issue that we are concerned with is the definition of quantum optimization problems. A common way to define a quantum optimization problem in the literature is to define an energy function on n qubits and then seek a maximum-energy state with respect to the function. What does it mean for a classical algorithm to solve this problem? If we restrict classical algorithms to outputting basis states, then the above quantum optimization reduces to a classical one. A more relaxed and common approach is to only ask for a "description" of a quantum state. This definition accommodates a broader family of algorithms that output a description of an entangled state, such as our and other previous algorithms for approximating QMC. Now the issue is that the meaning of the word "description" is vague: an output state of any quantum algorithm has a classical description, namely the quantum algorithm itself written on paper. Therefore any quantum algorithm is a classical algorithm if we accept this definition. We propose the following definition for a more satisfying notion of a classical algorithm solving a quantum optimization problem.

▶ **Definition 2.** *Given an objective function f that maps an n-qubit state to a real number, a pair of polynomial time quantum or classical algorithms (P, V) maximizes f to a value ν if the following conditions hold:*

1. **a.** *If max $f \geq \nu$: $\exists\ |w\rangle$ of size polynomial in n such that $V(|w\rangle) = 1$ w.p. $\geq 2/3$,*
   b. *If max $f \leq \nu - 1/p(n)$ for some polynomial p: $\forall$ polynomial-sized $|w\rangle$, $V(|w\rangle) = 1$ w.p. $\leq 1/3$*
2. *P outputs $|w'\rangle$ such that $V(|w'\rangle) = 1$ w.p. $\geq 2/3$.*

Each of P and V can be either classical or quantum; when P or V is classical, it is assumed that classical states are employed. Therefore according to our definition, we can have a cc-, qc-, cq-, or qq-optimization algorithm for a quantum optimization problem depending on whether each of P and V is classical or quantum. Only cc-optimization algorithms for QMC are known to us so far.

We argue that finding an optimal qq-optimization algorithm for QMC is a viable path to achieve a *provable and practical quantum advantage*. Suppose the verifier algorithm V is fixed to be classical. Then, from the prover P's side, the task is to find a bit string to convince V that there is a high energy state. Assuming there is a tight NP-hard upper bound for a classical approximation for QMC (for example by the PCP theorem), we cannot find a quantum prover that provably gives a greater ratio than all classical provers unless we prove that NP is a proper subset of QMA. However, to the best of our knowledge, there are no unexpected complexity theoretic consequences of a qq-approximation having a greater ratio than all cc-approximations. Moreover, we already know how to upper bound classical approximation ratios in some cases via the PCP theorem and the Unique Games Conjecture, so we can hope to upper bound the classical ratio for QMC. The current best upper bound for a cc-approximation of QMC is 0.956 up to plausible conjectures [7].

Approximation algorithm

In all previous algorithms outputting entangled states, the following monogamy of entanglement relation on stars is used crucially.

▶ **Definition 3** (SDP solution values). *Let $G = (V = [n], E, w)$ be a weighted graph and let $(v(P))_{P\in\mathcal{P}_2(n)}$ be a feasible solution to the level-2 Lasserre SDP. Define, for $i, j \in V$,*

$$g_{ij} := \frac{1}{4}v(I)\cdot(v(I) - v(X_iX_j) - v(Y_iY_j) - v(Z_iZ_j))$$
$$h_{ij} := \frac{1}{4}v(I)\cdot(v(I) - v(X_iX_j) - v(Y_iY_j) - v(Z_iZ_j)) - \frac{1}{2}.$$

For $x \in \mathbb{R}$, denote $x^+ := max(x, 0)$. In particular for $i, j \in V$,

$$h_{ij}^+ := \max(h_{ij}, 0).$$

The objective function value of the SDP solution is then $\nu := \sum_{(i,j)\in E} w_{ij}g_{ij}$.

▶ **Lemma 4** (Monogamy of entanglement on a star, [12]). *Given a feasible solution to the level-2 Lasserre SDP on a graph $G = (V, E)$, for any vertex $i \in V$ and any $S \subseteq V$,*

$$\sum_{j\in S} h_{ij} \leq \frac{1}{2}.$$

In particular,

$$\sum_{j\in N(i)} h_{ij}^+ \leq \frac{1}{2}, \tag{1}$$

where $N(i) = \{j|(i, j) \in E\}$.

The last statement is obtained by taking the set of edges incident to i with positive h_{ij} values as S.

A matching in G corresponds naturally to a state that earns maximal energy on the Hamiltonian terms corresponding to matched edges. Notice that by Equation (1), $(2h_e^+)_{e\in E}$ forms a fractional matching in the sense that if all these values were either 0 or 1, then we would have a matching that would in turn yield a state. We can round this fractional matching to a true matching, with a loss in objective value. Since a maximum weight matching has weight at least that of any matching we might round to, we may simply use it instead. We solve the Maximum Weight Matching problem and assign the best 2-qubit state, namely the singlet, $(|01\rangle - |10\rangle)/\sqrt{2}$, to matched edges. To each unmatched qubit, we assign the maximally mixed 1-qubit state. The resulting n-qubit state has maximal energy on matched edges but low energy on edges that are not matched. To address this issue, we also run the product state algorithm of Gharibian-Parekh [5]. Below is the complete algorithm.

▶ **Algorithm 5** (Approximation algorithm for Quantum Max Cut). *Given a weighted graph $G = (V, E, w)$ as an input,*

1. *Find a product state as follows:*
   a. *Solve SDP* (S) *for $k = 2$ to get solution vectors $(v(P))_{P\in\mathcal{P}_2(n)}$.*
   b. *Sample a random matrix R with dimension $3\times 3|\mathcal{P}_2(n)|$ with each element independently drawn from $\mathcal{N}(0, 1)$.*
   c. *Perform Gharibian-Parekh rounding on each $v_i := (v(X_i)\|v(Y_i)\|v(Z_i))/\sqrt{3}$ to get $u_i := Rv_i/\|Rv_i\|$.*
   d. *Let $\rho_1 := \prod_{i\in V} \frac{1}{2}(I + u_{i,1}X_i + u_{i,2}Y_i + u_{i,3}Z_i)$.*
2. *Find a matching state as follows:*
   a. *Find the maximum weight matching $M : E \to \{0, 1\}$ of G, for example via Edmonds Algorithm [3].*
   b. *Let $\rho_2 := \prod_{(i,j):M_{(i,j)}=1}(I - X_iX_j - Y_iY_j - Z_iZ_j)/4 \prod_{i\in U} I/2$, where U is the set of qubits unmatched by M.*
3. *Output whichever of ρ_1 and ρ_2 that has greater energy.*

Using matchings to find a good QMC state is not a new idea. Anshu, Gosset, and Morenz [1] introduced the idea of using matchings for QMC approximations, proving that there exists a product of 1- and 2-qubit states with energy at least 0.55 times the maximum QMC energy. Parekh and Thompson use a level-2 Lasserre solution to identify [12, 13] a subgraph on which they find a maximum weight matching; they then output a product state or a product of 1- and 2-qubit states akin to our algorithm, yielding an approximation ratio of 0.533. To obtain our improvement, we relate a level-2 SDP solution to the value of a matching on the whole input graph, whereas Parekh-Thompson do so for a proper subgraph of the input graph that is obtained from the level-2 SDP solution.

Our algorithm is much simpler than previous algorithms producing entangled states. It may be surprising that we can establish that this algorithm offers a better approximation guarantee than previous algorithms, including those outputting states with potential global entanglement. In particular, our algorithm does not even need to solve an SDP to obtain the entangled solution ρ_2. We only use the level-2 Lasserre SDP to argue that a maximum weight matching provides a solution that has reasonably high energy when ρ_1 has low energy. This manifests itself when obtaining the product state ρ_1, which must be done so with respect to the level-2 SDP. Even though ρ_1 requires solving the level-2 SDP, it is obtained by only using the vectors, $v(X_i), v(Y_i), v(Z_i)$, corresponding to single-qubit Paulis (i.e., the level-1 part of a level-2 solution). In fact, our algorithm is well defined if we solve the level-1 SDP relaxation instead of the level-2 SDP in Step (1a); however, we do not expect approximation factors beyond 0.498 using only the level-1 SDP [7].

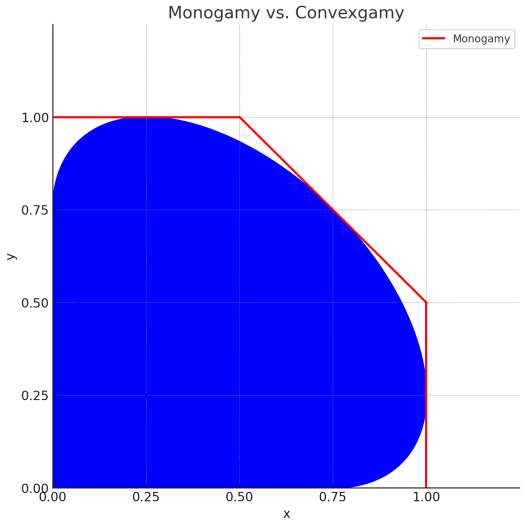

Figure 1 The solid region represents a feasible area characterized by entanglement convexgamy whereas the red line represents the boundary of the feasible region by monogamy of entanglement on a star.

Strengthening monogamy of entanglement on a star

All previous approximation algorithms for QMC outputting entangled states critically rely on monogamy of entanglement on a star (Lemma 4). The previously best-known algorithms by Lee [10] and King [8] both start with a good product state and evolve it to an entangled state while respecting these monogamy of entanglement constraints at each vertex. The key difference in our case is that we directly find a global solution satisfying the monogamy of entanglement constraints. If our algorithm is the optimal way to exploit these constraints, stronger inequalities obtained from the SDP are necessary to deliver a QMC approximation algorithm with a meaningful improvement in approximation ratio.

Even though Monogamy of Entanglement is tight when $h_{ij} = 1/|N(i)|$ for all $j \in N(i)$, it is easy to see that the inequality is far from tight at other points. Suppose $h_{ij} = 1/2$, with (i, j) being maximally entangled. Then on a neighbouring edge (i, k), the energy is $1/4$ and $h_{ik} = -1/4$. In this case, the deviation from the upper bound grows linearly as the number of connected edges grows. Parekh and Thompson derived nonlinear monogamy of entanglement inequalities on a triangle to address this issue in obtaining an optimal approximation for QMC using product states. Their result is captured in Lemma 6.

▶ **Lemma 6** (Monogamy of entanglement on a triangle, Lemma 1 of [13]). *Given a feasible solution to the level-2 Lasserre SDP on a graph $G = (V, E)$, for $i, j, k \in V$,*

$$0 \leq g_{ij} + g_{jk} + g_{ik} \leq \frac{3}{2} \tag{2}$$

$$g_{ij}^2 + g_{jk}^2 + g_{ik}^2 \leq 2g_{ij}g_{jk} + 2g_{ij}g_{ik} + 2g_{jk}g_{ik}. \tag{3}$$

The presentation of the above lemma is equivalent to that of [13] after a change of variables. From these relations, we obtain a tighter bound on star graphs with 2 edges as stated in the lemma below. We denote the relation "convexgamy" to distinguish it from the linear monogamy relation (Lemma 4), and the resulting relation gives a convex region.

▶ **Lemma 7** (Entanglement convexgamy on 2 edges). *Consider a graph $G = (V = \{1, 2, 3\}, E = \{(1, 2), (2, 3)\})$. Let x, y be defined by a feasible level-2 Lasserre SDP solution as $x := g_{12}$ and $y := g_{23}$. Then (x, y) is confined in the region defined by the x-axis, y-axis, and the ellipse touching the x- and y-axis and $x + y = 3/2$ as depicted in Figure 1. More specifically, the ellipse is defined as $3(x + y - 1)^2 + (x - y)^2 = 3/4$.*

Proof. Let $z = g_{13}$. Then $x, y, z \geq 0$. By Lemma 6, $x^2 + y^2 + z^2 \leq 2(xy + yz + zy)$, and $0 \leq x + y + z \leq 3/2$. The first inequality is equivalent to

$$\frac{\sqrt{x^2 + y^2 + z^2}}{x + y + z} \leq \frac{1}{\sqrt{2}}.$$

It means that if $x + y + z = c \geq 0$, then $\sqrt{x^2 + y^2 + z^2} \leq c/\sqrt{2}$. So (x, y, z) lies the intersection of the plane $x + y + z = c$ and the sphere of radius $c/\sqrt{2}$ centered at the origin, which is the incircle of the triangle defined by $x + y + z \geq c$ in the region $x, y, z \geq 0$. When the circle is projected to the xy-plane to give a feasible subset of (x, y), we get the ellipse inscribed in the triangle defined by $(0, 0), (c, 0), (0, c)$. Because $0 \leq c \leq 3/2$, we prove that a feasible point is in the region defined by the x-axis, y-axis, and the ellipse touching the x- and y-axis and $x + y = 3/2$.

The equation of the ellipse follows by solving the inscription condition. ◀

2 Analysis of the algorithm

In the rest of the paper, we introduce necessary concepts regarding matching theory and bound the approximation ratio of our algorithm.

▶ **Theorem 8** (Linear program for Maximum Weight Matching, [3]). *Given a weighted graph $G = (V, E, w)$, the following linear program gives the value of a maximum weight matching in G:*

$$\begin{aligned}
&\textit{maximize} && \sum_{e \in E} w_e x_e && && \text{(M)}\\
&\textit{subject to} && \sum_{j \in N(i)} x_{ij} \leq 1, && \textit{for all } i \in V, && (4)\\
& && \sum_{e \in E(S)} x_e \leq \frac{|S| - 1}{2}, && \textit{for all } S \subseteq V : |S| \textit{ odd}, && (5)\\
& && x_e \geq 0, && \textit{for all } e \in E. && (6)
\end{aligned}$$

where $E(S) := \{(i, j) \in E \mid i, j \in S\}$ for all $S \subseteq V$.

The above linear program (LP) cannot be efficiently solved directly since it has an exponential number of constraints; however, algorithms for Maximum Weight Matching, such as Edmonds Algorithm [3], obtain the optimal value in polynomial time using insights based on the LP and its dual. We will need to show that if we are given a solution $(x)_{e \in E}$ that only satisfies *some* of the constraints, then $(\alpha x)_{e \in E}$ satisfies *all* of the constraints for some $\alpha \in (0, 1)$. This will allow us to relate the objective value of the level-2 SDP to the weight of an optimal matching.

▶ **Lemma 9.** *If $(x)_{e \in E}$ satisfies constraints (4), (6), and (5) for $|S| = 3$, then $(\frac{4}{5}x)_{e \in E}$ is feasible for LP (M).*

Proof. Assume the hypothesis and consider the constraints of (5). We bound the value of the solution x on each such constraint. For $S \subseteq V$, define $\delta(S) := \{(i,j) \in E \mid |\{i,j\} \cap S| = 1\}$. Then,

$$2\sum_{e\in E(S)} x_e \leq 2\sum_{e\in E(S)} x_e + \sum_{e\in\delta(S)} x_e = \sum_{i\in S}\sum_{j\in N(i)} x_{ij} \leq |S|,$$

where the first inequality follows from (6) and the second from (4). So we have

$$\sum_{e\in E(S)} x_e \leq \frac{|S|}{2}, \text{for all } S \subseteq V;$$

however, to satisfy (5), we need a RHS of $\frac{|S|-1}{2}$ instead of $\frac{|S|}{2}$ for sets S of odd size. Since the $|S| = 3$ case is satisfied by assumption, $(\alpha x)_{e\in E}$ is feasible for LP (M), where

$$\alpha := \min_{\{s\in\mathbb{Z} | s \text{ odd}, s>3\}} \frac{s-1}{s} = \frac{4}{5}.$$ ◀

In order to appeal to the above lemma, we will need to show that the energy values arising from the level-2 SDP satisfy the constraints in the hypothesis of the lemma. For this we will rely on monogamy of entanglement on a star and triangle as established in Lemma 4 and the following corollary of Lemma 6, respectively.

▶ **Corollary 10.** *Given a feasible solution to the level-2 Lasserre SDP on a graph $G = (V, E)$, for $i, j, k \in V$,*

$$h^+_{ij} + h^+_{jk} + h^+_{ik} \leq \frac{1}{2}. \tag{7}$$

Proof. Let t be the number of $(u, v) \in \{(i, j), (j, k), (i, k)\}$ with $h^+_{uv} > 0$. If $t \leq 1$ then (7) holds since $h^+_{ij} \leq \frac{1}{2}$ for all $i, j \in V$. If $t \geq 2$ then (7) holds by (2). ◀

We are now in position to prove our main result.

▶ **Theorem 11** (main). *Algorithm 5 gives a 0.595-approximation for any weighted input graph $G = (V, E, w)$.*

Proof. Define

$$H_{ij} = (I - X_iX_j - Y_iY_j - Z_iZ_j)/4,$$
$$H = \sum_{(i,j)\in E} w_{ij}H_{ij}.$$

We bound the expected energy of each case of Steps 1 and 2 of the algorithm. The subroutine of Step 1 is directly from the main algorithm of [5], where in turn the analysis is borrowed from [2]. More precisely, the energy of ρ_1 with respect to H_{ij} is

$$\begin{aligned}\mathrm{Tr}\rho_1 H_{ij} &= \frac{1}{16}\mathrm{Tr}[(I - X\otimes X - Y\otimes Y - Z\otimes Z)\\ &\quad ((I + u_{i,1}X + u_{i,3}Y + u_{i,3}Z)\otimes(I + u_{j,1}X + u_{j,3}Y + u_{j,3}Z))]\\ &= \frac{1}{4}(1 - u_i\cdot u_j),\end{aligned}$$

and its expected value is

$$\mathrm{Tr}\rho_1 H_{ij} = \frac{1 - f_3(v_i\cdot v_j)}{4} \tag{8}$$

where

$$f_3(x) = \frac{2}{3}\left(\frac{\Gamma(2)}{\Gamma(1.5)}\right)^2 x_2F_1\left(\begin{matrix}1/2,1/2\\2\end{matrix}; x^2\right).$$

The estimation is from Lemma 2.1 of [2].

Now we turn to the analysis of the energy of ρ_2 from Step 2. Note that if an edge e is matched, then $\mathrm{Tr}\rho_2 H_e = 1$, and if e is not matched, then $\mathrm{Tr}\rho_2 H_e = 1/4$. More succinctly, $\mathrm{Tr}\rho_2 H_e = 1/4 + 3M_e/4$. Since the SDP values, $(h_e^+)_{e\in E}$ satisfy monogamy of entanglement on a star and triangle (Equations (1) and (7)), we have:

$$\sum_{j\in N(i)} 2h_{ij}^+ \le 1, \text{for all } i \in V,$$
$$2h_{ij}^+ + 2h_{jk}^+ + 2h_{ik}^+ \le 1, \text{for all } i,j,k \in V,$$

where the former correspond to the constraints (4) of the LP (M), and the latter correspond to the constraints (5) with $|S| = 3$. Then by Lemma 9, $(\frac{8}{5}h_e^+)_{e\in E}$ is feasible for the LP. This implies that the optimal solution of the LP, namely a maximum weight matching, has weight at least that of $(\frac{8}{5}h_e^+)_{e\in E}$:

$$\sum_{e\in E} w_e M_e \ge \frac{8}{5}\sum_{e\in E} w_e h_e^+.$$

Therefore,

$$\sum_{e\in E} w_e \mathrm{Tr}\rho_2 H_e = \sum_{e\in E} w_e\left(\frac{1}{4} + \frac{3}{4}M_e\right) \ge \sum_{e\in E} w_e\left(\frac{1}{4} + \frac{6}{5}h_e^+\right). \tag{9}$$

By definition, $v(I)\cdot(v(I) - v(X_iX_j) - v(Y_iY_j) - v(Z_iZ_j))/4 = (1 - 3v_i\cdot v_j)/4 = 1/2 + h_{ij}$. So we have

$$h_{ij} = -\frac{1 + 3v_i\cdot v_j}{4}. \tag{10}$$

Let σ be the density matrix of the output state of the algorithm. By combining the energy estimation of the two cases (8) and (9), we get,

$$\begin{aligned}\sum_{(i,j)\in E} w_{ij}\mathrm{Tr}\sigma H_{ij} &= \max\left\{\sum_{(i,j)\in E} w_{ij}\rho_1 H_{ij}, \sum_{(i,j)\in E} w_{ij}\rho_2 H_{ij}\right\}\\ &\ge \sum_{(i,j)\in E} w_{ij}\left[p\frac{1 - f_3(v_i\cdot v_j)}{4} + (1-p)\left(\frac{1}{4} + \frac{6}{5}\left(-\frac{1 + 3v_i\cdot v_j}{4}\right)^+\right)\right],\end{aligned}$$

for any $p \in [0,1]$. Since $-1 \le v_i\cdot v_j \le 1/3$, it suffices to find

$$\begin{aligned}\alpha &:= \max_{p\in[0,1]}\min_{x\in[-1,1/3]}\left[p\frac{1 - f_3(x)}{4} + (1-p)\left(\frac{1}{4} + \frac{6}{5}\left(-\frac{1+3x}{4}\right)^+\right)\right] \Big/ \frac{1-3x}{4}\\ &= 0.595,\end{aligned}$$

where the maximum occurs at $p = 0.674$. This proves the theorem since

$$\begin{aligned}
&\sum_{(i,j)\in E} w_{ij} \mathrm{Tr}\sigma H_{ij} \\
&\geq \sum_{(i,j)\in E} w_{ij} \left[p_0 \frac{1 - f_3(v_i \cdot v_j)}{4} + (1-p_0)\left(\frac{1}{4} + \frac{6}{5}\left(-\frac{1+3v_i\cdot v_j}{4}\right)^+\right)\right] \\
&\geq 0.595 \sum_{(i,j)\in E} w_{ij} \frac{1 - 3v_i \cdot v_j}{4} \geq 0.595 \lambda_{max}(H).
\end{aligned}$$

◀

▶ Remark 12. The present approach can be likely be improved by deriving analogues of Corollary 10 for larger odd-sized sets of qubits. This would enable a stronger version of Lemma 9 with $\alpha > \frac{4}{5}$. However, the best approximation ratio achievable by such approaches, corresponding to $\alpha = 1$, is 0.606. This is also the approximation ratio of our algorithm on bipartite graphs, since in this case LP (M) gives the value of a maximum weight matching even when constraints (5) are absent from the LP.

3 Open problems

Understanding the approximability of QMC is likely to bring a deeper understanding of the more general local Hamiltonian problem, just as resolving the approximability of Max Cut (up to the Unique Games Conjecture) has had surprising consequences for the theory of classical constraint satisfaction problems. We list relevant research directions below.

- Find a rigorous quantum approximation algorithm for QMC.
- Find a heuristic quantum algorithm (e.g. VQE-based) for QMC that outperforms rigorous classical algorithms.
- The approximability of QMC using product states (i.e. tensor products of 1-qubit states) is well understood [13, 7]. Find the best approximation ratio achievable using a tensor product of 1- and 2-qubit states. Can this be obtained using matchings? Which level of the lassere hierarchy is necessary to achieve this?
- Find an entanglement convexgamy relation (i.e. tighter non-linear inequalities on star graphs) from a valid level-k SDP solution on d edges. Does the optimal such relation (i.e. one precisely describing the feasible space) arise at a constant level k (with respect to d)?

Abstract

The paper revisits the Robust s-t Path problem, one of the most fundamental problems in robust optimization. In the problem, we are given a directed graph with n vertices and k distinct cost functions (scenarios) defined over edges, and aim to choose an s-t path such that the total cost of the path is always provable no matter which scenario is realized. Viewing each cost function as an agent, our goal is to find a fair s-t path, which minimizes the maximum cost among all agents. The problem is NP-hard to approximate within a factor of $o(\log k)$ unless NP $\subseteq$ DTIME($n^{\text{poly}\log n}$), and the best-known approximation ratio is $\widetilde{O}(\sqrt{n})$, which is based on the natural flow linear program. A longstanding open question is whether we can achieve a polylogarithmic approximation for the problem; it remains open even if a quasi-polynomial running time is allowed.

Our main result is a $O(\log n \log k)$ approximation for the Robust s-t Path problem in quasi-polynomial time, solving the open question in the quasi-polynomial time regime. The algorithm is built on a novel linear program formulation for a decision-tree-type structure, which enables us to overcome the $\Omega(\sqrt{n})$ integrality gap for the natural flow LP. Furthermore, we show that for graphs with bounded treewidth, the quasi-polynomial running time can be improved to a polynomial. We hope our techniques can offer new insights into this problem and other related problems in robust optimization.

1 Introduction

Robust optimization under uncertainty [5, 6, 17, 26] is one of the most important and challenging computational tasks in the real world. Uncertainty arises in many scenarios. For instance, the travel time for a road segment might be uncertain due to traffic jams. The paper revisits the Robust s-t Path problem [18], a cornerstone problem in the area of robust optimization. In the problem, there are several edge cost functions for a given graph and the

[1] All authors (ordered alphabetically) have equal contributions and are corresponding authors.

goal is to find an s-t path that minimizes the maximum cost across all the cost functions. Apart from serving a model for handling uncertainty, robustness also offers a method to integrate multiple objectives and fairness requirements.

In a routing network, each link (or edge) typically possesses multiple attributes, such as usage cost and delay. By representing each attribute as a cost function, we can formulate the multi-objective routing problem as our model [14, 15, 31]. In the context of fairness computation, diverse edge cost functions can be interpreted as various perspectives of agents on the edges. Our objective is to identify a public path that can accommodate these perspectives under the notion of min-max fairness [1, 27, 30].

The Robust s-t Path problem was initially studied by [18], and since then it has received widespread attention due to its broad applicability. In [18], the authors demonstrated that the problem is strongly NP-Hard even when there are only two scenarios. Later, [2] considers the problem with the constant number of scenarios, and shows that the problem admits a fully polynomial-time approximation scheme (FPTAS). When the number k of scenarios is part of the input, simply computing the shortest path w.r.t the summation of the k cost functions can obtain an approximation ratio of k. Kasperski and Zielinski [20] proved that the problem is hard to approximate within a factor of $o(\log k)$ unless NP $\subseteq$ DTIME($n^{\text{poly}\log n}$). Whether a polylogarithmic approximation can be achieved has been open ever since. A recent breakthrough in the approximation ratio is made by Kasperski and Zielinski [23] in which they gave a flow-LP-based algorithm that is $\widetilde{O}(\sqrt{n})$-approximate, where we use $\widetilde{O}$ to hide a polylogarithmic factor. They further showed that their analysis is nearly tight by proving an integrality gap of $\Omega(\sqrt{n})$ for the flow LP.

It should be noted that Bilò et al. [7] studied the ℓ_q-norm shortest path problem which is a generalized version of robust s-t path, i.e., the problem aims to find a s-t path $\mathcal{P}$ to minimize the value of $\left(\sum_{i\in[k]} c_i(\mathcal{P})^q\right)^{1/q}$, where $c_i(\mathcal{P})$ is agent i's cost for the selected path $\mathcal{P}$. Their algorithm [7, Algorithm 2]) extends the classical Dijkstra algorithm by replacing the distance with the ℓ_q-norm metric. Our directed graph is a DAG, so the Dijkstra-type algorithm becomes a dynamic programming-type algorithm, with nodes processed using a topological order. So, their algorithm just stores the best path in the ℓ_q-norm for every node. It is claimed in [7, Theorem 14] that such an algorithm achieves $O(\min\{q, \log k\})$-approximation for the ℓ_q-norm shortest path problem. However, unfortunately, there exists a crucial error in the analysis. In the full version [25], we give a hard instance on a series-parallel graph for the algorithm and show that the approximation ratio is at least $k^{1-1/q}$. In other words, when $q = O(\log k)$, the proposed algorithm [7, Algorithm 2] is $O(k)$-approximate for the robust s-t problem.

1.1 Our Contributions

This paper makes significant progress in closing the gap between the known upper and the lower bound for Robust s-t Path. We show that for two natural graph classes, a polylogarithmic approximation can be obtained in polynomial time; while for general graphs, there exists a polylogarithmic approximated algorithm running in a quasi-polynomial time. The following formalizes the model and summarizes our main results.

The Robust s-t Path Problem. Consider a directed graph $G(V, E)$ with n vertices and m edges. There are k scenarios (also referred to as "agents" hereafter), where each scenario $i \in [k]$ has an edge cost function $c_i : E \to \mathbb{R}_{\geq 0}$. Given two specified vertices s and t in the graph, the goal is to find an s-t path $\mathcal{P}$ that minimizes $\max_{i\in[k]} c_i(\mathcal{P})$, where $c_i(\mathcal{P}) := \sum_{e\in\mathcal{P}} c_i(e)$.

Main Result 1 (Theorem 1). There is a randomized polynomial-time $O(H \log k)$-approximation algorithm for Robust s-t Path for directed series-parallel graphs, where H is the height of the decomposition tree of the series-parallel graph and k is the number of agents.

Our first result is on the class of *series-parallel graphs* (Section 2), which are used by [20] to demonstrate a lower bound of $\Omega(\log^{1-\epsilon} k)$ (for any $\epsilon > 0$) for the Robust s-t Path problem. We begin by showing that the natural flow linear program (LP) for this class has integrality gaps of $\Omega(k)$ and $\Omega(\sqrt{n})$. The gaps hold even when we integrate the knowledge of the optimum cost to the LP to circumvent some obvious gap instances. This result aligns with the prior findings of [23], but our constructed instance is significantly simpler. It is worth noting that most prior algorithms in the existing literature rely on the flow LP mentioned above, and thus, their approximation ratios cannot be better than $O(\min\{k, \sqrt{n}\})$.

To overcome the gap, we develop a novel linear program based on the *decomposition tree* of series-parallel graphs and demonstrate that a dependent randomized rounding algorithm for the LP obtains an approximation ratio of $O(H \log k)$. Particularly, for the hard instance that leads to a lower bound $\Omega(\log^{1-\epsilon} k)$ (for any $\epsilon > 0$) stated in [20], our algorithm can return a $O(\log \log n \log k)$-approximate solution, which is nearly tight since there is only a $O(\log \log n)$-gap; the detailed discussion can be found in the full version [25].

Main Result 2 (Theorem 8). Given a directed graph with bounded treewidth, there is a randomized algorithm that obtains an approximation ratio of $O(\log n \log k)$ in polynomial time, where n is the number of vertices and k is the number of agents.

We then consider *graphs with bounded treewidth* (Section 3). When the treewidth is 2, it becomes the class of series-parallel graphs. Therefore, combining the above two results gives a $O(\min\{H, \log n\} \cdot \log k)$-approximation for series-parallel graphs. Besides series-parallel graphs, the graph class includes many other common graphs, such as trees, pseudoforests, Cactus graphs, outerplanar graphs, and Halin graphs. In this part, we employ the nice properties provided by the treewidth decomposition of these graphs and obtain a polylogarithmic approximation.

Main Result 3 (Theorem 12). Given any directed graph, there is a randomized algorithm that obtains a $O(\log n \log k)$-approximate solution in quasi-polynomial time, where n is the number of vertices and k is the number of agents. Moreover, any quasi-polynomial time algorithm for Robust s-t Path has an approximation lower bound of $\Omega(\log^{1-\epsilon} k)$ (even on series-parallel graphs) under the assumption that NP $\nsubseteq$ DTIME$(n^{\text{poly} \log n})$.

Finally, we consider general graphs (Section 4). The algorithm is also LP-based, following a similar framework as the algorithm for series-parallel graphs. The main challenge here is that we no longer have a simple tree structure for general graphs. To address this issue, we construct a decision-tree-type tree structure for the given graph and write a linear program based on it. Our algorithm then builds on this new LP to give the first polylogarithmic approximation for general graphs. Additionally, we show that the lower bound of $\Omega(\log^{1-\epsilon} k)$ can be extended to the algorithms running in quasi-polynomial time, i.e., the problem is still hard to approximate within $o(\log k)$ even if we allow quasi-polynomial time algorithms. This part is omitted in this version and can be found in the full version [25].

Main Result 4. For the problems of Robust s-t Path, weighted independent set, and spanning tree under the *maximin criteria*, it is NP-Hard to determine whether their instances have zero-cost optimal solutions or not. This implies that these problems do not admit any polynomial time α-approximate algorithm unless P = NP, where α is an arbitrary function of the input.

The paper also considers the *maximin criteria*, where the goal is to maximize the minimum cost among all agents. By observing that the classic algorithms (e.g., Dijkstra's algorithm) that work for the shortest path problem on DAGs (directed acyclic graphs) also work for the longest path problem on DAGs, one might expect that the maximin criteria is also a candidate objective to investigate the robustness of the s-t path problem, i.e., finding an s-t path $\mathcal{P}$ such that $\min_{i\in[k]} c_i(\mathcal{P})$ is maximized. We demonstrate this is not the case by providing a strong lower bound for the problem under the maximin criteria. Our reduction builds on a variant of the set cover problem. Employing a similar basic idea of the reduction, we also show that the maximin weighted independent set problem on trees or interval graphs is not approximable. This constitutes a strong lower bound for this problem, while the previous works [24, 28] only show the NP-Hardness. Our reduction idea can further be extended to the maximin spanning tree problem, which implies that the robust spanning tree problem is also not approximable under the maximin objective. This part is completely omitted in this version and can be found in the full version [25].

1.2 Other Related Works

Robust Minimax Combinatorial Optimization. Robust minimax optimization under different combinatorial structures has been extensively studied in the past three decades. See [3, 22] for a survey. Many problems that are polynomial-time solvable in the normal setting are shown to be NP-hard in the robust minimax setting: spanning trees, s-t cuts, and perfect matching on bipartite graphs [22]. Besides these fundamental problems, the minimax submodular ranking problem was studied in [10] very recently. For the minimax spanning tree, a $O(\log k/\log\log k)$-approximation algorithm is known [9], which is almost tight by the lower bound of $\Omega(\log^{1-\epsilon} k)$ (for any $\epsilon > 0$) stated in [21]. The problem of minimax perfect matching has a lower bound of $\Omega(\log^{1-\epsilon} k)$ (for any $\epsilon > 0$) [20], while the best upper bound so far is still $O(k)$ which is trivial. In the case where k is a constant, fully polynomial time approximation schemes are known for spanning trees, perfect matching, knapsacks, and s-t paths [3, 4, 22, 29].

Multiobjective s-t Path. Finding an s-t path is a fundamental problem in multi-objective optimization [15]. An Excellent survey of multiobjective combinatorial optimization, including multiobjective s-t path, can be found in [11]. Typically, we are given a directed graph $G := (V, E)$. Each edge $e \in E$ has a positive cost vector $\mathbf{c}(e) := (c_1(e), \ldots, c_k(e))$. For every s-t path $\mathcal{P} \subseteq E$, we have a cost vector $\mathbf{c}(\mathcal{P}) = (c_1(\mathcal{P}), \ldots, c_k(\mathcal{P}))$ with $c_i(\mathcal{P}) = \sum_{e\in\mathcal{P}} c_i(e)$. The goal is to compute an s-t path $\mathcal{P}$ such that $\mathcal{P}$ is *Pareto optimal*. An s-t path is called Pareto optimal if there is no other s-t path that makes one objective better off without making another worse off. Not surprisingly, this problem has been shown to be NP-hard even if the cost vector only has two coordinates [32] in which the problem is called the bi-objective s-t path minimization problem. Bi-objective s-t path minimization has also been studied extensively [14, 31], in which researchers mainly focus on the exact algorithms with exponential running time. In addition, a fully polynomial time approximation scheme is proposed by [29].

Fair Allocation with Public Goods. By observing the minimax objective as a fairness criterion, our problem shares some similarities with the problem of public goods, which was first used to distinguish the previous private goods by Conitzer et al. [12] in the field of fair division. Specifically, there is a multiagent system and different agents hold different opinions about the same goods. And, they aim to select a feasible set of goods to satisfy the various

fairness notions, such as propositional share or its generalization [12, 16]. In [16], they study some constraints of goods, i.e., the selected goods must form a matching or matroid. The minimax criterion is quite different from other fairness measures in the fair division field, which leads to different techniques.

1.3 Roadmap

Section 2 and Section 3 present results on series-parallel graphs and bounded-treewidth graphs, respectively. Subsequently, in Section 4, the general graph case is considered. Section 5 finally concludes the paper. Due to space constraints, all the results on the maximin criteria are deferred to the full version of the paper.Note that we focus on high-level descriptions of our methods in the main body. Some formal descriptions and proofs (including lemma statements) can be found in the corresponding appendices.

2 Series-Parallel Graphs

In this section, we show that there is a randomized algorithm that achieves $O(H \log k)$ approximation for series-parallel graphs, where H is the height of the series-parallel graph's decomposition tree; its meaning will be clear later. The algorithm can be viewed as a warm-up example for the general graph, as the algorithm for the general graph follows a similar algorithmic framework. Formally, we shall show the following theorem (Theorem 1) in this section. We only present the LP formulation and the complete algorithm due to space limits. All proofs can be found in the paper's full version.

▶ **Theorem 1.** *Given any series-parallel graph G, there is a polynomial time algorithm that returns a $O(H \log k)$-approximation solution with probability at least $1 - (\frac{1}{k} + \frac{1}{kH})$ for robust s-t path, where H is the height of G's decomposition tree and k is the number of agents.*

In Section 2.1, we give the basic concepts and properties of the series-parallel graphs, which we will use later to build our linear programming formulation. In Section 2.2, we formally present our LP formulation. We give the complete and rounding algorithm in Section 2.3. Finally, we show the analysis in Section 2.4.

2.1 Basic Concepts

▶ **Definition 2** (Series-Parallel Graph). *A directed graph $G := (V, E, s, t)$ with source s and sink t is called a* series-parallel graph, *if it contains a single edge from s to t, or it can be built inductively using the following* series *and* parallel composition *operations. The series composition of two-terminal graphs $G_1 := (V_1, E_1, s_1, t_1)$ and $G_2 := (V_2, E_2, s_2, t_2)$ is to identify t_1 and s_2, and let s_1 and t_2 be the new source and sink in the resulting graph. The parallel composition of two-terminal graphs $G_1 := (V_1, E_1, s_1, t_1)$ and $G_2 := (V_2, E_2, s_2, t_2)$ is to identify s_1 with s_2 and t_1 with t_2 respectively, and let $s_1 = s_2$ and $t_1 = t_2$ be the new source and sink.*

A series-parallel graph can be represented in a natural way by a tree structure that describes how to assemble some small graphs into a final series-parallel graph through series and parallel composition. Such a tree structure is commonly called the *decomposition tree* of the series-parallel graph in the literature [33]. Formally, a decomposition tree $\mathbf{T} := (\mathbf{V}, \mathbf{E})$ of a series-parallel graph $G := (V, E)$ is a tree such that (i) each leaf node $\mathbf{u} \in \mathbf{V}$ corresponds an edge in E; (ii) each internal node is either a series or parallel node; (iii) the child nodes of a parallel (resp. series) node must be leaf nodes or series (resp. parallel) nodes. The series

(resp. parallel) node corresponds to the series (resp. parallel) composition, and they are used to indicate how to merge the small subgraphs of its child nodes. The subgraph $G_{\mathbf{u}}$ of a node $\mathbf{u}$ is a subgraph of G such that $G_{\mathbf{u}}$ only contains those edges corresponding to the leaf nodes in the subtree rooted at $\mathbf{u}$. Let H be the height of $\mathbf{T}$. Given a series-parallel graph, it is known that its decomposition tree can be built in linear time by the standard series-parallel graph recognition algorithm [33]. An example can be found in Figure 1.

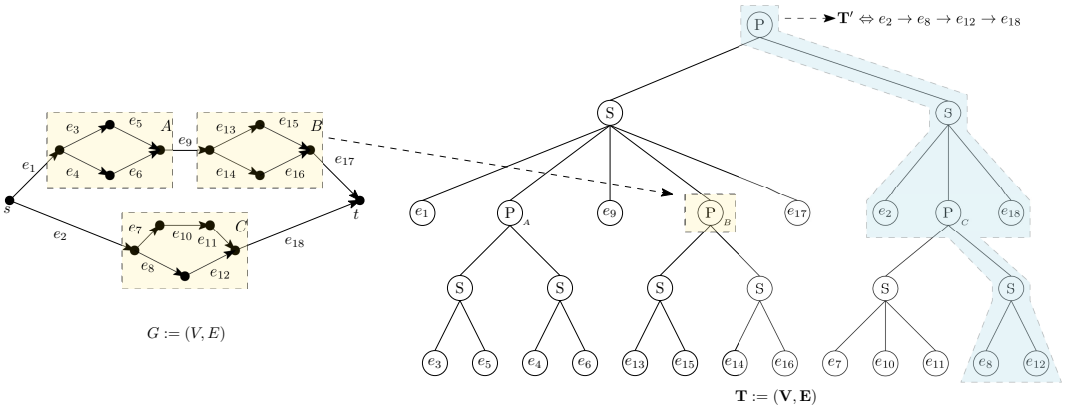

Figure 1 An example of the decomposition tree of a series-parallel graph. The series-parallel graph $G := (V, E)$ is shown on the left and its decomposition tree $\mathbf{T} := (\mathbf{V}, \mathbf{E})$ is shown on the right. Each leaf node in $\mathbf{T}$ corresponds to an edge in E. Each internal node is either a series node S or a parallel node P. And it indicates how to merge the child nodes' subgraph. For example, consider the S node and its two child nodes e_{13} and e_{15}. Then, the subgraph of this S node is $e_{13} \to e_{15}$ which merges its two child nodes' subgraph via the series composition. And also, the subgraph of this S node's parent corresponds to the subgraph B in G, which merges $e_{13} \to e_{15}$ and $e_{14} \to e_{16}$ via the parallel composition. An s-t path corresponds to a feasible subtree (Definition 3). For example, the feasible subtree $\mathbf{T}'$ can be converted to an s-t path $e_2 \to e_8 \to e_{12} \to e_{18}$.

We remark that the children of a parallel node are unordered, and for a series node, the children should be considered as ordered. However, for the s-t path problem, the order is not important, as permuting the children of a series node will lead to an equivalent instance.

We aim to give a linear program based on the decomposition tree $\mathbf{T}$. Clearly, not all subtrees of $\mathbf{T}$ correspond to an s-t path of G. In the following, we introduce the concept of a special subtree of $\mathbf{T}$ called *feasible subtree* (Definition 3), which is able to be converted into an s-t path.

▶ **Definition 3** (Feasible Subtree). *A subtree $\mathbf{T}'$ of $\mathbf{T}$ is called a feasible subtree if and only if (i) $\mathbf{T}'$ includes the root node of $\mathbf{T}$; (ii) for every series node $\mathbf{s}$ in $\mathbf{T}'$, $\mathbf{T}'$ includes all child nodes of $\mathbf{s}$; (iii) for every parallel node $\mathbf{p}$ in $\mathbf{T}'$, $\mathbf{T}'$ includes exactly one child node of $\mathbf{p}$.*

It now remains to define a cost function $f_i : 2^{\mathbf{V}} \to \mathbb{R}_{\geq 0}$ according to the cost function c_i. Since each edge corresponds to a unique leaf node in $\mathbf{T}$, it is easy to define f_i by c_i: for each $\mathbf{v} \in \mathbf{V}$, $f_i(\mathbf{v}) := c_i(e)$ if node $\mathbf{v}$ corresponds to some edge e; otherwise $f_i(\mathbf{v}) := 0$. Formally, we have the following simple observation (Observation 4).

▶ **Observation 4.** *Given any series-parallel graph $G := (V, E)$ and its decomposition tree $\mathbf{T} := (\mathbf{V}, \mathbf{E})$, fix an arbitrary agent $i \in [k]$, any s-t path $\mathcal{P}$ of G with the cost $c_i(\mathcal{P})$ corresponds to a feasible subtree $\mathbf{T}'$ of $\mathbf{T}$ with the cost $f_i(\mathbf{T}')$ such that $f_i(\mathbf{T}') = c_i(\mathcal{P})$ and vice versa.*

2.2 LP Formulation

Given any series-parallel graph $G := (V, E)$, we first employ the standard doubling technique to enhance the linear program. Given a guess of the optimal objective value GS, we discard those edges e such that there exists an agent $i \in [k]$ with $c_i(e) > \mathsf{GS}$. Clearly, these discarded edges cannot belong to the optimal solution. Then, we run the series-parallel graph recognition algorithm [33] to construct a decomposition tree $\mathbf{T} := (\mathbf{V}, \mathbf{E})$ of the series-parallel graph. See Algorithm 1 for the complete description.

The linear program is shown in (Tree-LP). For an internal node $\mathbf{v} \in \mathbf{V}$, use $\mathsf{child}(\mathbf{v})$ and $\Lambda(\mathbf{v})$ to denote its children and descendants in the tree, respectively. Let $P(\mathbf{T})$ and $S(\mathbf{T})$ be the set of parallel and series nodes in $\mathbf{T}$. For each node $\mathbf{v}$, $x_{\mathbf{v}}$ is a relaxed indicator variable denoting whether $\mathbf{v}$ is selected or not. The three constraints (2), (3) and (4) correspond to the three conditions stated in Definition 3 respectively, in order to ensure that the solution is a feasible subtree. The first constraint type (1) is a bit subtle, and it is the key that allows us to surpass the pessimistic $\Omega(k)$ and $\Omega(\sqrt{n})$ integrality gap. In these constraints, $\sum_{\mathbf{u}\in\Lambda(\mathbf{v})} x_{\mathbf{u}} \cdot f_i(\mathbf{u})$ denotes the cost of the selected subtree rooted at $\mathbf{v}$ with respect to agent i. Thus, when $\mathbf{v} = \mathbf{r}$, the constraint implies that for any agent, the total cost of all the selected nodes must be at most $x_{\mathbf{r}} \cdot \mathrm{OPT} = \mathrm{OPT}$. For the cases that $\mathbf{v} \neq \mathbf{r}$, these constraints do not affect the feasible region of integer solutions since $x_{\mathbf{v}}$ is either 1 or 0, but they can reduce the fractional solution's feasible region dramatically by restricting the contribution of each subtree $\Lambda(\mathbf{v})$. A more detailed discussion is given in the full version of the paper.

(Tree-LP)

$$\sum_{\mathbf{u}\in\Lambda(\mathbf{v})} x_{\mathbf{u}} \cdot f_i(\mathbf{u}) \le x_{\mathbf{v}} \cdot \mathsf{GS}, \qquad \forall i \in [k], \forall \mathbf{v} \in \mathbf{V} \tag{1}$$

$$x_{\mathbf{r}} = 1, \tag{2}$$

$$\sum_{\mathbf{u}\in\mathsf{child}(\mathbf{v})} x_{\mathbf{u}} = x_{\mathbf{v}}, \qquad \forall \mathbf{v} \in P(\mathbf{T}) \tag{3}$$

$$x_{\mathbf{u}} = x_{\mathbf{v}}, \qquad \forall \mathbf{v} \in S(\mathbf{T}), \mathbf{u} \in \mathsf{child}(\mathbf{v}) \tag{4}$$

$$x_{\mathbf{v}} \ge 0, \qquad \forall \mathbf{v} \in \mathbf{V} \tag{5}$$

2.3 Algorithms

This section formally describes the complete algorithm (Algorithm 1) for series-parallel graphs. The main algorithm mainly consists of two steps: the doubling step (lines 2-13 of Algorithm 1) and the rounding algorithm (Algorithm 2). After finishing the doubling step, we obtain a fractional solution x^* with the value of GS that is close to the optimal solution OPT (Observation 5). Then, we shall employ a dependent rounding algorithm to obtain a feasible subtree based on x^*. This dependent randomized rounding algorithm selects nodes level by level, starting from the top of $\mathbf{T}$ and proceeding downwards. For parallel nodes, the algorithm selects one of its child nodes with a probability determined by the optimal fractional solution x^*. For series nodes, the algorithm selects all of its child nodes with a probability of 1, ensuring that the resulting subtree is always feasible. A formal description of the algorithm can be found in Algorithm 2.

2.4 Analysis

This section analyzes the performance of our algorithm. We start by describing a simple observation (Observation 5). Let $\mathbf{T}'$ be the subtree returned by Algorithm 2. Recall that H is the height of $\mathbf{T}$.

Algorithm 1 The Complete Algorithm for Series-Parallel Graphs.

Input: A series-parallel graph $G := (V, E)$ with k cost functions $c_i : 2^E \to \mathbb{R}_{\geq 0}, i \in [k]$.
Output: An s-t path $\mathcal{P} \subseteq E$.

1: $\texttt{flag} \leftarrow \texttt{true}$; $\mathsf{GS} \leftarrow \max_{i\in[k]} \sum_{e\in E} c_i(e)$.
2: **while** $\texttt{flag} = \texttt{true}$ **do**
3: $\quad E' \leftarrow \{\, e \in E \mid \exists i \in [k] \text{ s.t. } c_i(e) > \mathsf{GS} \,\}$.
4: $\quad E \leftarrow E \setminus E'$; $G \leftarrow (V, E')$.
5: $\quad$ Compute the tree decomposition $\mathbf{T} := (\mathbf{V}, \mathbf{E})$ of G by [33].
6: $\quad$ Solve the linear program (Tree-LP).
7: $\quad$ **if** (Tree-LP) has a feasible solution **then**
8: $\quad\quad$ Let x^* be a feasible solution to (Tree-LP).
9: $\quad\quad \mathsf{GS} \leftarrow \frac{\mathsf{GS}}{2}$.
10: $\quad$ **else**
11: $\quad\quad \texttt{flag} \leftarrow \texttt{false}$.
12: $\quad$ **end if**
13: **end while**
14: Run Algorithm 2 with the optimal solution x^* to obtain a feasible subtree $\mathbf{T}'$ of $\mathbf{T}$.
15: Convert $\mathbf{T}'$ into an s-t path $\mathcal{P}$.
16: **return** $\mathcal{P}$.

▶ **Observation 5.** *Let GS^* be the guessing value at the beginning of the last round of the while-loop (lines 2-13 of Algorithm 1). Then, we have $\mathsf{GS}^* \leq 2 \cdot \mathrm{OPT}$*[2].

To show that the approximation ratio is $O(H \log k)$ with a constant probability, a natural step is to first bound the expectation of our solution. We first state some intuition. According to the description of the rounding scheme, it is easy to see that for each agent i,

$$\mathbb{E}[f_i(\mathbf{T}')] = \sum_{e\in E} c_i(e) \Pr[e \in \mathbf{T}'] = \mathsf{GS}^*.$$

Then by Markov inequality, we have for each agent i,

$$\Pr[f_i(\mathbf{T}') \geq H \log k \cdot \mathsf{GS}^*] \leq \frac{1}{H \log k}.$$

However, the above inequality is not sufficient because proving Theorem 1 needs to show that $\Pr[\forall i \in [k], f_i(\mathbf{T}') \geq H \log k \cdot \mathsf{GS}^*]$ is at most $\frac{1}{k} + \frac{1}{kH}$. To address this issue, we need to employ an analysis technique called *Moment Method*, which is widely used in the literature [13, 19]. More formally, we aim to show the following key lemma (Lemma 6); a similar proof can also be found in [13].

▶ **Lemma 6.** *For any agent $i \in [k]$, we have $\mathbb{E}[\exp\left(\ln(1 + \frac{1}{2H}) \cdot f_i(\mathbf{T}')\right)] \leq 1 + \frac{1}{H}$.*

Proof. We prove the theorem inductively. First, consider the case that $H = 1$, i.e., the decomposition tree $\mathbf{T}$ only contains a root $\mathbf{r}$. Since $x_{\mathbf{r}} = 1$, there is no randomness in selecting $\mathbf{T}'$. Thus, we have for any $z \geq 1$,

$$\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right] = z^{\frac{x_{\mathbf{r}} \cdot f_i(\mathbf{r})}{\mathsf{GS}^*}} \leq z,$$

where the last inequality uses constraint (1) in (Tree-LP).

[2] One can get a more accurate lower bound of the optimal solution (e.g., $\mathsf{GS}^* \leq (1+\epsilon) \cdot \mathrm{OPT}$ for any $\epsilon > 0$) by the standard binary search technique.

Algorithm 2 Dependent Randomized Rounding.

Input: A tree structure $\mathbf{T}(\mathbf{V}, \mathbf{E})$ rooted at $\mathbf{r}$; a fractional solution $x^* \in [0,1]^{|\mathbf{V}|}$.
Output: A feasible subtree $\mathbf{T}'$.

Initially, set $\mathbf{T}' \leftarrow \emptyset$ and a vertex queue $\mathcal{Q} \leftarrow \{\mathbf{r}\}$.
while $\mathcal{Q} \neq \emptyset$ **do**
  Use $\mathbf{v}$ to represent the front element of $\mathcal{Q}$.
  $\mathbf{T}' \leftarrow \mathbf{T}' \cup \{\mathbf{v}\}$, $\mathcal{Q} \leftarrow \mathcal{Q} \setminus \{\mathbf{v}\}$.
  if $\mathbf{v}$ is a parallel node **then**
    Pick one node $\mathbf{u} \in \mathsf{child}(\mathbf{v})$ randomly such that $\mathbf{u}$ is chosen with probability $\frac{x_{\mathbf{u}}}{x_{\mathbf{v}}}$.
    $\mathcal{Q} \leftarrow \mathcal{Q} \cup \{\mathbf{u}\}$.
  end if
  if $\mathbf{v}$ is a series node **then**
    for each $\mathbf{u} \in \mathsf{child}(\mathbf{v})$ **do**
      $\mathcal{Q} \leftarrow \mathcal{Q} \cup \{\mathbf{u}\}$.
    end for
  end if
end while
return $\mathbf{T}'$.

To streamline the analysis, we continue considering the case that $H = 2$. We further distinguish two subcases: (i) root $\mathbf{r}$ is a parallel node; (ii) root $\mathbf{r}$ is a series node. For the first subcase, Algorithm 2 selects exactly one child $\mathbf{v} \in \mathsf{child}(\mathbf{r})$ with probability $x_{\mathbf{v}}/x_{\mathbf{r}} = x_{\mathbf{v}}$. According to the law of total expectation and only leaves in $\mathbf{T}$ have non-zero costs, we have

$$\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right] = \sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} \Pr[\mathbf{v} \in \mathbf{T}'] \cdot \mathbb{E}\left[z^{\frac{f_i(\Lambda'(\mathbf{v}))}{\mathsf{GS}^*}} \middle| \mathbf{v} \in \mathbf{T}'\right],$$

where $\Lambda'(\mathbf{v}) := \Lambda(\mathbf{v}) \cap \mathbf{T}'$. Observing that once conditioned on $\mathbf{v} \in \mathbf{T}'$, the conclusion for the $H = 1$ case can be used to bound the expectation, we have

$$\begin{aligned}
\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right] &= \sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} \Pr[\mathbf{v} \in \mathbf{T}'] \cdot \mathbb{E}\left[z^{\frac{f_i(\Lambda'(\mathbf{v}))}{\mathsf{GS}^*}} \middle| \mathbf{v} \in \mathbf{T}'\right], \\
&= \sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} x_{\mathbf{v}} \cdot z^{\frac{f_i(\mathbf{v})}{\mathsf{GS}^*}} \\
&\leq \sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} x_{\mathbf{v}} \cdot \left(1 + (z-1) \cdot \frac{f_i(\mathbf{v})}{\mathsf{GS}^*}\right) \\
&\qquad \text{(Constraint (1) and } z^r \leq 1 + r(z-1) \forall z > 0, r \in [0,1]) \\
&= \left(\sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} x_{\mathbf{v}}\right) + (z-1) \cdot \frac{\sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} x_{\mathbf{v}} \cdot f_i(\mathbf{v})}{\mathsf{GS}^*} \\
&= 1 + (z-1) \cdot \frac{\sum_{\mathbf{v}\in\Lambda(\mathbf{r})} x_{\mathbf{v}} \cdot f_i(\mathbf{v})}{\mathsf{GS}^*} \qquad \text{(Constraint (3))} \\
&\leq e^{(z-1)\cdot\frac{\sum_{\mathbf{v}\in\Lambda(\mathbf{r})} x_{\mathbf{v}}\cdot f_i(\mathbf{v})}{\mathsf{GS}^*}}. \qquad (1 + x \leq e^x)
\end{aligned}$$

For the second subcase, according to Constraint (4), we have $x_{\mathbf{v}} = x_{\mathbf{r}} = 1$ for each $x_{\mathbf{v}} \in \mathsf{child}(\mathbf{r})$, and therefore,

$$\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right] = \mathbb{E}\left[z^{\frac{\sum_{\mathbf{v}\in\mathsf{child}(\mathbf{r})} f_i(\Lambda'(\mathbf{v}))}{\mathsf{GS}^*}}\right] \leq z^{\frac{\sum_{\mathbf{v}\in\Lambda(\mathbf{r})} x_{\mathbf{v}}\cdot f_i(\mathbf{v})}{\mathsf{GS}^*}}.$$

Since $z \leq e^{z-1}$, combing the two subcases, we have that when $H = 2$,

$$\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right] \leq (e^{(z-1)})^{\frac{\sum_{\mathbf{v}\in\Lambda(\mathbf{r})} x_{\mathbf{v}}\cdot f_i(\mathbf{v})}{\mathsf{GS}^*}}.$$

The above inequality shows that as the height increases by 1, the upper bound of the expectation grows exponentially. Furthermore, when the height increases from 1 to H, we can obtain a sequence $z_1 = z, z_2, \ldots, z_H$, where $z_h = e^{z_{h-1}-1}$ for each $h > 1$, and have

$$\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right] \leq z_h^{\frac{\sum_{\mathbf{v}\in\Lambda(\mathbf{r})} x_{\mathbf{v}}\cdot f_i(\mathbf{v})}{\mathsf{GS}^*}},$$

for any $\mathbf{T}$ with height h by almost the same analysis as above. Due to Constraint (1), we have $\sum_{\mathbf{v}\in\Lambda(\mathbf{r})} x_{\mathbf{v}} \cdot f_i(\mathbf{v}) \leq \mathsf{GS}^*$, and thus, $\mathbb{E}\left[z^{\frac{f_i(\mathbf{T}')}{\mathsf{GS}^*}}\right]$ is at most z_h.

Finally, to obtain the claimed upper bound, we set $z = 1 + \frac{1}{2H}$ such that $z_h \leq 1 + \frac{1}{H}$, and complete the proof. ◀

▶ **Lemma 7.** *Consider an arbitrary agent i, Algorithm 2 returns a feasible subtree $\mathbf{T}'$ such that $f_i(\mathbf{T}') \leq 4H \cdot \log k \cdot \mathsf{GS}$ with high probability, where H is the height of the decomposition tree of the series-parallel graph and GS is a guess of the optimal objective value such that the corresponding* (Tree-LP) *admits a feasible solution.*

Lemma 7 can be proved by Lemma 6 and Markov bound. Theorem 1 can be proved by Lemma 7 and union bound. All proofs are deferred to the full version of the paper.

3 Graphs with Bounded Treewidth

This section considers robust *s-t* path on graphs with bounded treewidth. We mainly show the following theorem. Noting that any series-parallel graph has a treewidth of 2, this result improves upon the above $O(H \log k)$ ratio for series-parallel graphs with large H.

▶ **Theorem 8.** *Given any directed graph G with treewidth $\mathsf{tw}(G) \leq \ell$, there is an algorithm that returns a $O(\log n \log k)$-approximate solution in poly$(n) \cdot n^{O(\ell^2)}$ time with probability at least $1 - (\frac{1}{k} + \frac{1}{k \log n})$ for robust s-t path, where n is the number of vertices and k is the number of agents.*

3.1 Algorithmic Framework

The basic idea of the algorithm is to reduce our problem to *the tree labeling problem* which was proposed by Dinitz et al. [13] very recently. In their paper, they provided a randomized algorithm for the tree label problem. Applying the algorithm to our reduced instance can obtain an *s-t* path whose expected cost with respect to each agent is bounded. Finally, we employ the concentration inequalities to show that with high probability, the returned path is a polylogarithmic approximation solution. To ensure the reduction's correctness, we also need to utilize some other tools. The complete description of our algorithm can be found in

the full version of the paper. Due to space limitations, in the main body, we only focus on the core of our algorithm – the reduction to tree labeling. Before introducing the reduction, it is necessary to restate the definition of tree labeling and the result proved in [13].

The Tree-labeling Problem. Consider a binary tree $\mathbf{T}(\mathbf{V}, \mathbf{E})$ rooted at $\mathbf{r} \in \mathbf{V}$. For each node $\mathbf{v} \in \mathbf{V}$, there is a finite set $L_{\mathbf{v}}$ of labels for $\mathbf{v}$. Let $L := \bigcup_{\mathbf{v}\in\mathbf{V}} L_{\mathbf{v}}$ be the set of all possible labels. The output is a label assignment $\mathcal{L} := (l_{\mathbf{v}} \in L_{\mathbf{v}})_{\mathbf{v}\in\mathbf{V}}$ of the node set $\mathbf{V}$, that satisfies the consistency and cost constraints.

- **(Consistency Constraints)** For every internal node $\mathbf{v}$ of $\mathbf{T}$ with two children $\mathbf{u}$ and $\mathbf{w}$ ($\mathbf{u}$ or $\mathbf{w}$ is possibly empty), we are given a set $\Gamma(\mathbf{v}) \subseteq L_{\mathbf{u}} \times L_{\mathbf{v}} \times L_{\mathbf{w}}$. A valid labeling $\mathcal{L} = (l_{\mathbf{v}} \in L_{\mathbf{v}})_{\mathbf{v}\in\mathbf{V}}$ must satisfy $(l_{\mathbf{u}}, l_{\mathbf{v}}, l_{\mathbf{w}}) \in \Gamma(\mathbf{v})$ for every internal node $\mathbf{v}$.
- **(Cost Constraints)** There are k additive cost functions $f_1, \ldots, f_k$ defined over the labels, i.e., for each $i \in [k]$, $f_i : L \to \mathbb{R}_{\geq 0}$. For each $i \in [k]$, a valid labeling $\mathcal{L}$ needs to satisfy $f_i(\mathcal{L}) := \sum_{\mathbf{v}\in\mathbf{V}} f_i(l_{\mathbf{v}}) \leq 1$.

A label assignment $\mathcal{L} := (l_{\mathbf{v}} \in L_{\mathbf{v}})_{\mathbf{v}\in\mathbf{V}}$ is called *consistent* if it satisfies the consistency constraints; it is *valid* if it satisfies both the consistency and cost constraints. Let H be the height of $\mathbf{T}$ and let $\Delta := \max_{\mathbf{v}\in\mathbf{V}} |L_{\mathbf{v}}|$ be the maximum size of any label set. Let n be the number of nodes in $\mathbf{T}$. In [13], they show the following result.

▶ **Lemma 9** ([13]). *Given a tree labeling instance such that the instance admits a valid label assignment. There is a randomized algorithm that in time poly$(n) \cdot \Delta^{O(H)}$ outputs a consistent label assignment $\mathcal{L}$ such that for every $i \in [k]$, we have* $\mathbb{E}\left[\exp\left(\ln(1 + \frac{1}{2H}) \cdot f_i(\mathcal{L})\right)\right] \leq 1 + \frac{1}{H}$.

3.2 Reduction Intuition

In this section, we give some intuition of our reduction. The formal description and an example can be found in the next section (Section 3.3). Given any directed graph with bounded treewidth, we aim to construct a tree-labeling instance such that the solution to the constructed tree-labeling instance can be converted into an s-t path of the original graph with some cost-preserved property. Note that the treewidth decomposition $\mathbf{T}(\mathbf{V}, \mathbf{E})$ of any input graph G can be computed efficiently [8]. We directly let the treewidth decomposition $\mathbf{T}$ be the binary tree in the reduced tree-labeling instance. The following shows how to construct the labels and the corresponding constraints such that a feasible label assignment can be successfully transformed into an s-t path.

Label Construction. For a graph's treewidth decomposition, each node $\mathbf{v} \in \mathbf{T}$ corresponds to a node subset $X(\mathbf{v})$ of the original graph. Each edge in the original graph is guaranteed to be covered by some $X(\mathbf{v})$, which is the completeness property of a tree decomposition. Use $C(\mathbf{v})$ to denote the edges covered by node $\mathbf{v} \in \mathbf{T}$. Without loss of generality, we can assume that s and t are included in any node $\mathbf{v} \in \mathbf{T}$ and each edge is assigned to a unique $C(\mathbf{v})$. The label of a node $\mathbf{v}$ is a vector of $|C(\mathbf{v})| + |X(\mathbf{v})| \cdot (|X(\mathbf{v})| - 1)$ dimensions, where the first $|C(\mathbf{v})|$ dimensions correspond to the edges covered by it and the last $|X(\mathbf{v})| \cdot (|X(\mathbf{v})| - 1)$ dimensions correspond to all the vertex pairs in $X(\mathbf{v})$. The intuition is the following. To ensure that a feasible label assignment can be translated to an s-t path, we first need to assign a "choosing indicator" to each edge to imply whether the edge is selected or not. However, having the choosing indicators is not enough because we only know some edges have been picked, but cannot determine whether s and t are connected. Thus, we introduce a "connectivity indicator" for each vertex pair (a, b) in $X(\mathbf{v})$ to indicate whether a is connected to b by the selected edges covered in the subtree rooted at node $\mathbf{v}$.

Constraint Construction. The cost constraints are used to bound the total cost of the selected edges. They can be obtained easily by letting the normalized cost of the edges selected by each label assignment be the corresponding cost. For the consistency constraints, the purpose of designing them is to ensure that s is connected to t, and the connectivity indicators can truthfully reflect the connectivity of the subgraph formed by the selected edges. To achieve the former requirement, we define that a label assignment is feasible only if the connectivity indicator of (s,t) in the root $\mathbf{r}$ is $\mathtt{1}$; while for the latter requirement, the constraint construction is still natural, but we note that proving such "local[3]" constraints are able to capture the global connectivity is non-trivial. Consider an arbitrary node $\mathbf{u}$ and its two children $\mathbf{v}, \mathbf{w}$. We can construct a subgraph where the vertex set is $X(\mathbf{u}) \cup X(\mathbf{v}) \cup X(\mathbf{w})$. Add an edge (a,b) in the subgraph if the connectivity indicator of (a,b) is $\mathtt{1}$ in one of the two children or the choosing indicator of edge (a,b) in node $\mathbf{u}$ is $\mathtt{1}$. A label is feasible if the connectivity indicator of node $\mathbf{u}$ is consistent with the connectivity in this subgraph. Note that this subgraph may not contain all nodes that occur in the subtree rooted at $\mathbf{u}$. Thus, to prove the efficiency of these constraints, we further need to show that there does not exist a vertex pair in $\mathbf{u}$ that is connected by $\mathbf{u}$'s subtree but not connected in the above subgraph. We formally show this claim in the paper's full version. The proof heavily relies on the connectivity property of a tree decomposition. Briefly speaking, a graph's tree decomposition can guarantee that all nodes in the tree containing the same node in the original graph form a connected subtree. This nice property allows us to show that the connectivity between vertices can be continuously propagated between nodes in $\mathbf{T}$.

3.3 Tree-labeling Instance Construction

Given an arbitrary node $\mathbf{v} \in \mathbf{V}$, we also use $\mathbf{v}$ to denote the vertices included in node $\mathbf{v}$, i.e., $\mathbf{v} \subseteq V$. Let $E_{\mathbf{v}} \subseteq E$ be the set of edges such that, for any edge (a,b) in $E_{\mathbf{v}}$, node $\mathbf{v}$ is the highest node that contains (a,b). Note that an edge (a,b) may be included in more than one node in $\mathbf{T}$ but the highest node that includes (a,b) is unique. For any node $\mathbf{v} \in \mathbf{V}$, we have two types of labels: choosing label and connectivity label. For each edge (a,b) (or e) in $E_{\mathbf{v}}$, the choosing label $\mathtt{chng}(a,b) = \mathtt{1}$ or (or $\mathtt{chng}(e) = \mathtt{1}$) indicates that the edge is chosen in current label assignment; otherwise, the edge is not chosen. For each pair of vertices (p,q) in $\mathbf{v}$, the connectivity label $\mathtt{conn}(p,q) = \mathtt{1}$ indicates that there is a $\mathcal{P} \subseteq E$ path from p to q such that every edge in $\mathcal{P}$ is chosen in some nodes of the subtree rooted at node $\mathbf{v}$; otherwise, p and q are not connected. Note that $\mathtt{conn}(p,q)$ and $\mathtt{conn}(q,p)$ are two different labels since G is a directed graph. Let $L_{\mathbf{v}}$ be the set of all possible labels and $l_{\mathbf{v}} \in L_{\mathbf{v}}$ be a specific label of node $\mathbf{v}$. We remark that the size of $L_{\mathbf{v}}$ is related to the treewidth of G. Since the treewidth of G is a constant, $|L_{\mathbf{v}}|$ is also constant. See the proof of Theorem 8 for details.

To ensure the feasibility of label assignments for obtaining an s-t path in $\mathbf{T}$, arbitrarily picking labels for each node is not a viable solution. Instead, we define a local constraint that applies to every adjacent set of three nodes $\mathbf{u}, \mathbf{v}, \mathbf{w}$ in $\mathbf{T}$, where $\mathbf{u}$ and $\mathbf{w}$ are the child nodes of $\mathbf{v}$. The purpose of this local constraint is to guarantee that all label assignments are capable of producing an s-t path. For every node $\mathbf{v}$ and its two children $\mathbf{u}$ and $\mathbf{w}$, let $\mathtt{CP}(\mathbf{v}) := L_{\mathbf{u}} \times L_{\mathbf{v}} \times L_{\mathbf{w}}$ be the set of all possible label combinations of these three nodes, i.e., $\mathtt{CP}(\mathbf{v})$ is the Cartesian product of $L_{\mathbf{u}}, L_{\mathbf{v}}, L_{\mathbf{w}}$. Note that $\mathbf{u}$ or $\mathbf{w}$ may not exist. In this case, we refer to $\mathbf{u}$ or $\mathbf{w}$ as empty nodes and $\mathtt{CP}(\mathbf{v})$ is defined as the $L_{\mathbf{v}} \times L_{\mathbf{w}}$ (or $L_{\mathbf{u}} \times L_{\mathbf{v}}$ or $L_{\mathbf{v}}$).

[3] Consistency constraints in the tree-labeling problem are "local" constraints because the feasibility of a node $\mathbf{u}$'s label is only influenced by its child nodes.

▶ **Definition 10** (Feasible Label Assignment). *A label assignment $\mathcal{L} := (l_{\mathbf{v}})_{\mathbf{v}\in\mathbf{V}}$ is a feasible label assignment if, for each $\mathbf{v} \in \mathbf{V}$ and its two children $\mathbf{u}$ and $\mathbf{w}$ ($\mathbf{u}$ and $\mathbf{w}$ maybe empty nodes), $l_{\mathbf{v}} \in \mathtt{CP}(\mathbf{v})$ satisfies the following three constraints:*

(C1) **(Choosing Constraints)** *For each edge $(a, b) \in E_{\mathbf{v}}$, if (a, b) is chosen, then a and b are connected and vice versa. Namely, $\mathtt{chng}(a, b) = \mathtt{1}$ if and only if $\mathtt{conn}(a, b) = \mathtt{1}$.*

(C2) **(Connectivity Constraints)** *For each vertex pair (p, q) in $\mathbf{v}$, vertex p and vertex q are connected (i.e. $\mathtt{conn}(p, q) = \mathtt{1}$) if and only if the following statement is true: there is a vertex sequence $(p, v_1, \ldots, v_d, q)$ such that every two adjacent vertices (a, b) in the sequence are connected in some nodes in $\mathbf{u}, \mathbf{v}, \mathbf{w}$, i.e., $\mathtt{conn}(a, b) = \mathtt{1}$ in some nodes in $\mathbf{u}, \mathbf{v}, \mathbf{w}$ for each pair of adjacent vertices.*

(C3) **(Feasibility Constraints)** *If $\mathbf{v}$ is the root of $\mathbf{T}$, then the source s and sink t are connected, i.e., $\mathtt{conn}(s, t) = \mathtt{1}$ must be true in the root.*

Given a feasible label assignment $\mathcal{L}$, an edge $(p, q) \in E$ is *chosen* by $\mathcal{L}$ if (p, q)'s choosing label is $\mathtt{1}$ in $\mathcal{L}$. (C1) defines the connectivity of each edge in E. If an edge (a, b) is chosen by a label assignment, then vertex a and b are connected. (C2) is the most important constraint which defines the connectivity of each pair of vertices in $\mathbf{v}$. In the case where $\mathbf{v}$ is a leaf node, $\mathbf{u}$ and $\mathbf{w}$ would be empty nodes and thus this constraint is equivalent to (C1). In the case where $\mathbf{v}$ is not a leaf node, an arbitrary vertices pair (a, b) in $\mathbf{v}$ are connected if the connected segments in $\mathbf{u}, \mathbf{v}, \mathbf{w}$ can be merged into a path from a to b. In Lemma 11, we show that such a local constraint is sufficient to describe the connectivity of vertex a and b in the subtree rooted at $\mathbf{v}$. (C3) ensures that a feasible label assignment must contain an s-t path, i.e., source s and sink t are connected.

Consider an arbitrary feasible label assignment $\mathcal{L}$, then $\mathcal{L}$ has the following crucial property (Lemma 11) by our definition. We shall use this property later to show that any feasible label assignment can be converted into an s-t path of the original graph. It is worth noting that an s-t path corresponds to a unique feasible label assignment, but a feasible label assignment may contain multiple s-t paths. An example is shown in Figure 2.

▶ **Lemma 11.** *Given an arbitrary feasible label assignment $\mathcal{L} := (l_{\mathbf{v}})_{\mathbf{v}\in\mathbf{V}}$, consider an arbitrary node $\mathbf{v} \in \mathbf{V}$. For any vertices pair (p, q) in $\mathbf{v}$, there is a path $\mathcal{P} \subseteq E$ from p to q such that every edge in $\mathcal{P}$ is chosen in some nodes in the subtree rooted at $\mathbf{v}$ if and only if (a, b) has a connectivity label of $\mathtt{1}$ in $\mathbf{v}$.*

To complete the instance construction, we also need to define an appropriate label cost function for each node in $\mathbf{T}$. It shall be used to connect the cost of our problem to the tree-labeling problem. This part, together with the proofs of Lemma 11 and Theorem 8, are deferred to the paper's full version.

4 General Graphs

We shall follow the same algorithmic framework stated in Section 2 and show the following result (Theorem 12). Namely, we first construct a tree structure and set up a linear program based on the tree. Then, we employ the same rounding algorithm (Algorithm 2) to obtain a feasible subtree and convert it back to an s-t path in the original graph. The following states some intuition to construct such a tree. We defer the formal descriptions of the construction, the LP formulation, the algorithm, and the analysis to the full version of the paper.

▶ **Theorem 12.** *Given any directed graph G, there is an algorithm that returns a $O(\log n \log k)$-approximate solution in $poly(n) \cdot n^{O(\log n)}$ time with probability at least $1 - (\frac{1}{k} + \frac{1}{k \log n})$ for robust s-t path, where n is the number of vertices and k is the number of agents.*

sadt	(a,d)	(a,d)

Figure 2 An example of the reduction. The subfigure (i) is the given directed graph. Then, we compute a tree decomposition with the logarithmic depth and add s and t to all nodes, which is shown in subfigure (ii). The edge set next to each node in subfigure (ii) is its corresponding $E_{\mathbf{v}}$. For example, the edge set $E_{\mathbf{r}}$ for root node $\mathbf{r}$ is $\{(d,f),(f,t)\}$ since $\mathbf{r}$ is the highest node that contains edge (d,f) and (f,t). Subfigure (iii) is an s-t path of the given directed graph and subfigure (iv) is the corresponding label assignment of the s-t path in (iii) in which we only list these labels with the value of `1`. The complete label of each node is obtained by merging these single labels, e.g., for the root $\mathbf{r}$, $l_{\mathbf{r}}$ consists of 14 bits (2 choosing labels and 12 connectivity labels). In these 14 bits, only $\texttt{conn}(s,d), \texttt{conn}(s,t), \texttt{conn}(d,t)$ has a value of `1` and all the remaining 11 labels have a value of `0`. Subfigure (v) shows another example and subfigure (vi) is its corresponding label assignment.

In Section 2, we use a tree-based linear program to break through the $\Omega(k)$ and $\Omega(\sqrt{n})$ integrality gap of the flow LP. However, on general graphs, we no longer have such a natural tree structure as in series-parallel graphs.To still obtain a polylogarithmic approximation, we construct a decision-tree-type metatree that maps every s-t path in the graph to a corresponding subtree in the metatree.

Metatree Construction Intuition. The basic idea of the meta tree construction is to iteratively guess the possible middle vertex of an s-t path. There are at most n possibilities for this middle vertex. Once we determine the middle vertex of the s-t path, say it is a, the whole path can be partitioned into two subpaths – path s-a and path a-t. We then recur on the obtained subpaths till level $O(\log n)$; the sufficiency of $O(\log n)$'s levels will be clear later. This process gives us a natural tree structure $\mathbf{T}$ with $O(\log n)$ depth. We define two types of nodes in $\mathbf{T}$. The first node type is referred to as *splitting node*. Each splitting node corresponds to a (sub-)path. It has n children, where each child represents a choice of the (sub-)path's middle vertex. The algorithm needs to ensure that only one of these children can be selected. The second node type is called *merging node*. A merging node has to be a child of a splitting node in $\mathbf{T}$ and represents a scheme for selecting a middle vertex. Further, a merging node has two splitting nodes as its children, corresponding to the two obtained subpaths by this scheme. We can view such a node as being used to merge its two children (subpaths). The algorithm needs to ensure that both children are selected simultaneously. See the paper's full version for more details of the construction.

As one may observe, a splitting (resp. merging) node in our metatree plays the same role as a parallel (resp. series) node in the decomposition tree of the series-parallel graph. Thus, the LP for the general graph is similar to (Tree-LP) and we can still use the same rounding algorithm. Consider an s-t path $\mathcal{P}$ of length n. If we write $\mathcal{P}$ in the form of a binary tree by

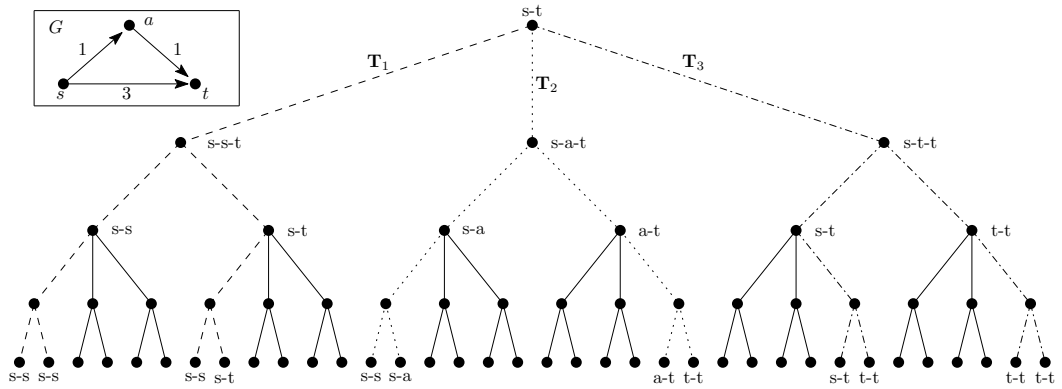

Figure 3 An example for the metatree $\mathbf{T}$ construction. The given directed graph G is shown in the up-left corner. Since there are three vertices in G, $\mathbf{T}$ will consist of five levels because the height of $\mathbf{T}$ is $2\lceil \log n \rceil + 1$. The dashed subtree $\mathbf{T}_1$ corresponds to the path $s \to t$ of G. The dotted subtree $\mathbf{T}_2$ represents the path $s \to a \to t$ of G. The dash-dotted subtree $\mathbf{T}_3$ also corresponds to the path $s \to t$.

guessing the middle vertex of each subpath, it will have at most $\lceil \log n \rceil$ levels. Thus, we can let the recursive tree $\mathbf{T}$ terminate at level $O(\log n)$, and therefore, its size is quasi-polynomial $O(n^{\log n})$ since each node has at most n children. From Section 2, we know that the rounding algorithm is able to find a $O(H \log k)$-approximate solution where H is the height of the tree. This also provides the intuition for the approximation ratio $O(\log n \log k)$ since the height of $\mathbf{T}$ is $O(\log n)$ (specifically, $H = 2\lceil \log n \rceil + 1$).

We now define a *feasible subtree* for $\mathbf{T}$. Recalling the feasible subtrees (Definition 3) on series-parallel graphs, unfortunately, we cannot use the same definition for general graphs. This is because not all leaf nodes in the constructed tree $\mathbf{T}$ correspond to edges in G. We refer to a subtree that satisfies three conditions in Definition 3 as a *consistent subtree*. To ensure that the subtree can be translated to an s-t path, one more condition is needed.

▶ **Definition 13** (Feasible Subtree for General Graphs). *A subtree $\mathbf{T}' \subseteq \mathbf{T}$ is called feasible if and only if (i) $\mathbf{T}'$ is consistent; (ii) each leaf node corresponds to either an edge or a single vertex in G.*

An example can be found in Figure 3. As one might be concerned, using a different definition of the feasible subtree may require a different LP formulation for general graphs, since a natural adaptation of (Tree-LP) can only find a consistent subtree. This issue can be fixed easily by directly disabling the infeasible leaf nodes in the linear program. See the paper's full version for more details of the LP formulation.

5 Conclusion

This paper considers the robust s-t path problem and proposes polylogarithmic approximation algorithms on different graph classes. For graphs with bounded treewidth, we obtain a $O(\log n \log k)$-approximate polynomial algorithm which partially answers the open question in [23]. For general graphs, we prove that there is a quasipolynomial algorithm that is $O(\log n \log k)$-approximate which leaves a logarithmic gap. Our approaches are based on a novel linear program that enables us to get rid of the $\Omega(k)$ and $\Omega(\sqrt{n})$ integrality gap from the natural linear program. We also investigate the robustness of the s-t path, weighted independent set, and spanning tree under the maximin criteria and show some hardness results.

There leave several future works. Closing the gap for robust s-t path still remains open. It is thus interesting to investigate whether there exists a better approximation upper bound or a tighter lower bound. We can also look at other robust optimization problems, e.g., the robust perfect matching problem. The best approximation known to date for robust matching is still $O(k)$ which can be achieved by a trivial algorithm. Since there exists a strong connection between s-t path and min-cost perfect matching, it would be intriguing to explore whether our methods can be applied to improving the upper bound of the robust matching problem.

Abstract

In this paper we present a new gap-creating randomized self-reduction for the parameterized Maximum Likelihood Decoding problem over $\mathbb{F}_p$ (k-MLD$_p$). The reduction takes a k-MLD$_p$ instance with $k \cdot n$ d-dimensional vectors as input, runs in $O(d2^{O(k)}n^{1.01})$ time for some computable function f, outputs a $(3/2-\varepsilon)$-Gap-k'-MLD$_p$ instance for any $\varepsilon > 0$, where $k' = O(k^2 \log k)$. Using this reduction, we show that assuming the randomized Exponential Time Hypothesis (ETH), no algorithms can approximate k-MLD$_p$ (and therefore its dual problem k-NCP$_p$) within factor $(3/2-\varepsilon)$ in $f(k) \cdot n^{o(\sqrt{k/\log k})}$ time for any $\varepsilon > 0$.

We then use reduction by Bhattacharyya, Ghoshal, Karthik and Manurangsi (ICALP 2018) to amplify the $(3/2-\varepsilon)$-gap to any constant. As a result, we show that assuming ETH, no algorithms can approximate k-NCP$_p$ and k-MDP$_p$ within γ-factor in $f(k) \cdot n^{o(k^{\varepsilon_\gamma})}$ time for some constant $\varepsilon_\gamma > 0$. Combining with the gap-preserving reduction by Bennett, Cheraghchi, Guruswami and Ribeiro (STOC 2023), we also obtain similar lower bounds for k-MDP$_p$, k-CVP$_p$ and k-SVP$_p$.

These results improve upon the previous $f(k) \cdot n^{\Omega(\text{poly} \log k)}$ lower bounds for these problems under ETH using reductions by Bhattacharyya et al. (J.ACM 2021) and Bennett et al. (STOC 2023).

1 Introduction

The study of linear error correcting codes has drawn attention to two dual fundamental computational problems called Nearest Codeword Problem (NCP) and Maximum Likelihood Decoding (MLD). Given a matrix $A \in \mathbb{F}_p^{m \times n}$ and a vector $\vec{t} \in \mathbb{F}_p^m$, the Nearest Codeword Problem (NCP) asks for a vector $\vec{x} \in \mathbb{F}_p^n$ such that $||A\vec{x} - \vec{t}||_0$ is minimized. Here $|| \cdot ||_0$ denotes the Hamming weight. While in the Maximum Likelihood Decoding (MLD), we are given a matrix $A \in \mathbb{F}_p^{m \times n}$ and a vector $\vec{t} \in \mathbb{F}_p^m$, the goal is to minimize $||\vec{x}||_0$ subject to $A\vec{x} = \vec{t}$. Another fundamental problem related to a linear code is the homogeneous version of NCP, known as Minimum Distance Problem (MDP), where the task is to find a non-zero vector $\vec{x}$ such that $||A\vec{x}||_0$ is minimized.

The computational complexity of MLD, NCP and MDP has been studied with great effort throughout the past several decades. It is known that MLD, NCP and MDP are not only NP-hard [12, 48], but also NP-hard to approximate within any constant ratio [6, 7, 18, 22, 42, 47]. Moreover, the variant of MLD that allows the code being preprocessed by unbounded computational resource is also NP-hard to approximate within a factor of $(3 - \varepsilon)$ [24, 44]. Also it is proven that assuming $\mathsf{NP} \not\subseteq \mathsf{DTIME}(n^{\mathsf{poly}(\log n)})$, no polynomial time algorithm can approximate NCP up to $2^{\log^{1-\epsilon} n}$ factor for any $\epsilon > 0$ [6, 43] and no polynomial time algorithm can approximate MDP up to $2^{\log^{1-\epsilon} n}$ for any $\epsilon > 0$ [7, 18, 22, 42]. For some specific codes, MLD is also shown to be NP-hard, e.g. product code [8], Reed-Solomon code [28], algebraic geometry code [17]. On the algorithmic side, it is known that NCP can be approximate to $O(n/\log n)$ in polynomial time [5].

The lattice version of NCP and MDP are known as Closest Vector Problem (CVP) and Shortest Vector Problem (SVP). In these problems, a lattice $\mathcal{L}$ is given instead of a linear code. For CVP a target $\vec{t}$ is additionally given and the goal is to find a vector $\vec{v} \in \mathcal{L}$ such that $||\vec{v} - \vec{t}||_p$ is minimized, where $||\cdot||_p$ denotes the ℓ_p-norm. And for SVP the goal is to find a non-zero vector $\vec{v} \in \mathcal{L}$ with minimum ℓ_p norm. The study for CVP and SVP also has long history [4, 6, 20, 25, 29, 33, 40–42, 47]. For CVP, it is NP-hard to approximate within factor $n^{c/\log\log n}$ for some constant $c > 0$ [20]. As for SVP, it was shown that no polynomial time algorithm can approximate SVP within any constant factor assuming $\mathsf{NP} \not\subseteq \mathsf{RP}$ [33], and no polynomial time algorithm can approximate SVP up to $2^{\log^{1-\epsilon} n}$ factor assuming $\mathsf{NP} \not\subseteq \mathsf{RTIME}(n^{\mathsf{poly}(\log n)})$ [29]. Lattice problems have many applications in cryptography [45, 46]. Due to their importance, lattice problems are also extensively studied in the fine-grained complexity area, see, e.g., [1–3, 11] and a very recent survey by Bennett [9] for more details on hardness of SVP.

Over the past three decades, parameterized complexity, a new framework to address NP-hard problems, has been rapidly developed and drawing growing attention. The study in the field of parameterized complexity focuses on whether a problem can be solved in $f(k) \cdot n^{O(1)}$ time (FPT time), where k is a parameter given along with the instance. In the parameterized version of k-MLD, k-NCP, k-MDP, k-CVP and k-SVP, an integer k is additionally given and the task is to decide whether the optimal value is no greater than k. Downey, Fellows, Vardy and Whittle [21] showed that k-MLD (and therefore k-NCP) is W[1]-hard and belongs to W[2]. They asked if k-CVP and k-SVP (in ℓ_2 norm) is W[1]-hard. 20 years later in recent breakthroughs [10, 13], the parameterized intractability of k-NCP, k-MDP, k-CVP and k-SVP are settled. Notably they ruled out not only exact FPT algorithms, but also FPT approximation algorithms as well. Specifically, [13] first presented a gap-creating reduction for k-NCP and then showed gap-preserving reductions from k-NCP towards k-MDP, k-CVP and k-SVP. Soon afterwards, Bennett, Cheraghchi, Guruswami and Ribeiro [10] improved the gap-preserving reductions for more general cases (general fields and general ℓ_p norm). These two works jointly showed that it is W[1]-hard to approximate k-NCP and k-MDP within any constant factor over any finite field $\mathbb{F}_p$, and it is W[1]-hard to approximate k-CVP in the ℓ_p norm within any constant factor for any $p \geq 1$. And they showed hardness for k-SVP to approximate within any constant factor in the ℓ_p norm for any $p > 1$, and some constant approaching 2 for $p = 1$.

After obtaining FPT-inapproximability results, it is natural to study fine-grained time lower bounds for parameterized approximability of these problems. Assuming Gap-ETH [19, 39], Manurangsi [38] showed that no $f(k) \cdot n^{o(k)}$ time algorithm can approximate k-NCP and k-CVP to any constant factor. With the gap-preserving reduction in [10], one can further show that no $f(k) \cdot n^{o(k)}$ time algorithm can approximate k-MDP and k-SVP to

any constant under the randomized Gap-ETH. All these results are based on an assumption with a gap. This raises the following open question:

(1) Can we establish similar lower bounds for these problems under the weaker and gap-free assumption of ETH?

We note that the gap-preserving reduction in [10] from Gap-k-NCP (Gap-k-CVP) to Gap-k'-MDP (Gap-k'-SVP) has $k' = O(k)$. So, it suffices to prove constant Gap-k-NCP (Gap-k-CVP) has no $f(k) \cdot n^{o(k)}$-time algorithm assuming ETH [30]. Unfortunately, the gap-creating reduction in [13] causes an exponential growth of the parameter and only gives an $\Omega(n^{(\log k)^{1/(2+\epsilon)}})$-time lower bound for constant Gap-k-NCP under ETH (See the analysis in Section 1.3). Therefore, finding better reductions for Gap-k-NCP and Gap-k-CVP is the crux of improving lower bounds for Gap-k-MDP and Gap-k-SVP.

1.1 Our Contributions

We take a step forward on closing the gap between results under gap-free assumption (ETH) and gap assumption (Gap-ETH). Our main result is a new direct gap-creating self reduction for k-MLD, which is the dual problem of k-NCP, with polynomial growth of the parameter.

▶ **Theorem 1** (informal; See Theorem 20 for a formal statement)**.** *For any constant $1 < \gamma < \frac{3}{2}$ and prime power $p > 1$, there is a reduction runs in $O_k(n^{O(1)})$ that on input a k-MLD$_p$ instance $(V, \vec{t})$, output a Gap-k'-MLD$_p$ instance $(V', \vec{t}')$ satisfies:*

- *(Completeness) If there exists k vectors in V with their sum [1] being $\vec{t}$, then there exists k' vectors in V' with their sum being $\vec{t}'$.*
- *(Soundness) If for any set $S \subseteq V$ with size at most k, $\vec{t} \notin Span(S)$, then for any set $S' \subseteq V'$ with size at most $\gamma k'$, $\vec{t}' \notin Span(S')$.*
- *Polynomial parameter growth $k' = O(k^2 \log k)$. (And $k' = O(k^3)$ if not allowing randomness).*

Combining this gap-creating reduction with the $f(k)n^{\Omega(k)}$-time ETH lower bound for k-MLD in [36, Theorem 11], we obtain improved lower bounds for Gap-k-NCP assuming ETH and randomized ETH.

▶ **Corollary 2.** *Assuming randomized ETH, for any prime power $p > 1$ and real number $\gamma \in (1, \frac{3}{2})$, no $f(k)n^{o(\sqrt{k/\log k})}$ time algorithm can solve γ-Gap-k-NCP$_p$.*

▶ **Corollary 3.** *Assuming ETH, for any prime power $p > 1$ and real number $\gamma \in (1, \frac{3}{2})$, no $f(k)n^{o(k^{1/3})}$ time algorithm can solve γ-Gap-k-NCP$_p$.*

By applying the gap amplification procedure in [14] ($\gamma \to \Omega(\gamma^2), k \to O(k^2)$, see Theorem 22 for a formal statement) sufficiently many (but still constant) times, we obtain a reduction for Gap-k-MLD with any constant gap with still polynomial growth of parameter. Therefore we obtain the following improved ETH lower bound for k-NCP.

▶ **Corollary 4.** *Assuming ETH, for any prime power $p > 1$ and real number $\gamma > 1$, no $f(k)n^{o(k^\epsilon)}$ time algorithm can solve γ-Gap-k-NCP$_p$ where $\epsilon = \frac{1}{\text{polylog}(\gamma)}$ is a constant.*

Combining our results of Gap-k-NCP$_p$ with the gap-preserving reductions in [13] and [10], we obtain improved ETH lower bounds for constant approximating k-NCP, k-CVP, k-MDP and k-SVP. The summarize of corollaries are present in Table 1.

[1] The definition of k-MLD used in our proof is a slightly different variant, where the vectors directly sum to the target in the YES case, but they are essentially equivalent, see Section 2.3 for more details.

Table 1 The $f(k)n^{\Omega(k^\epsilon)}$-time lower bound for k-NCP and k-CVP are based on ETH. The other lower bounds are based on randomized ETH.

Summarize of Corollaries

Problem	Inapprox Factor	Lower Bound	Dependency	Specification
k-NCP	any $\gamma \in (1, \frac{3}{2})$	$f(k)n^{\Omega(\sqrt{k/\log k})}$		any finite field $\mathbb{F}_p$
k-NCP	any $\gamma > 1$	$f(k)n^{\Omega(k^\epsilon)}$	$\epsilon = \frac{1}{\mathsf{polylog}(\gamma)}$	any finite field $\mathbb{F}_p$
k-MDP	any $\gamma > 1$	$f(k)n^{\Omega(k^\epsilon)}$	$\epsilon = \frac{1}{p\log\gamma\cdot\mathsf{polylog}(p)}$	any finite field $\mathbb{F}_p$
k-CVP	any $\gamma > 1$	$f(k)n^{\Omega(k^\epsilon)}$	$\epsilon = \Theta(\frac{1}{\mathsf{polylog}(\gamma)})$	in any ℓ_p norm, $p \geq 1$
k-SVP	any $\gamma > 1$	$f(k)n^{\Omega(k^\epsilon)}$	$\epsilon = \epsilon(p,\gamma)^2$	in any ℓ_p norm, $p > 1$
k-SVP	any $\gamma \in [1, 2)$	$f(k)n^{\Omega(k^\epsilon)}$	$\epsilon = \epsilon(p,\gamma)^3$	in any ℓ_p norm, $p \geq 1$

1.2 Technical Overview of Gap Creation Step

We implicitly use the threshold graph composition method [15, 34, 35, 37] to construct a $(3/2-\varepsilon)$-gap producing reduction for the k-MLD problem. This technique was first introduced in [34] to prove the W[1]-hardness of k-Biclique problem. A threshold graph is a bipartite graph that has a "threshold property", meaning that there is a significant gap in the number of common neighbors between any k vertices and any $k+1$ vertices on the left side. Threshold graph and its variants have been widely used to show hardness of approximation for various parameterized problems, such as k-DominatingSet [16], k-SetCover [32, 35], k-SetIntersection [15] or to create gap for subsequent reductions, e.g. [13].

Let $\dot\cup$ denotes for union set of multiple disjoint sets. In this paper, we implicitly use the strong threshold graphs in [37], which are bipartite graphs $T = (A \dot\cup B, E_T)$ with the following properties:

- **(i)** $A = A_1 \dot\cup A_2 \dot\cup \cdots \dot\cup A_k$.
- **(ii)** $B = B_1 \dot\cup B_2 \dot\cup \cdots \dot\cup B_m$.
- **(iii)** For any $a_1 \in A_1, \ldots, a_k \in A_k$ and $i \in [m]$, $a_1, \ldots, a_k$ have a common neighbor in B_i.
- **(iv)** For any $X \subseteq A$ and $I \subseteq [m]$ with $|I| \geq \varepsilon m$, if for every $i \in I$, there exists $b_i \in B_i$ has $k+1$ neighbors in X, then $|X| > h$.

These strong threshold graphs are constructed from error-correcting codes with large relative distance $(1-o(1))$, and such "threshold" properties essentially come from the following intuition of ECC: *If there is a collection of codewords* (X)*, and a constant fraction of entries of these codewords* $(I \subseteq [m], |I| \geq \varepsilon m)$ *such that, for each entry* $(i \in I)$*, there exists two distinct codewords in the collection having same content in it. Then, the collection must have huge size* (*at least* h). To characterize the aforementioned property, previous works [32, 37] introduced the definition of (ε-)*Collision Number* of an error-correcting code C, $\mathrm{Col}_\varepsilon(C)$, which is the minimum size of X mentioned above.

Diving into coding-based threshold graph. Our construction deeply relies on the collision number of an ECC, so we only use threshold graph as an intuitive illustration for readers, and we directly use the error-correcting codes in our formal analysis.

Below we illustrate the idea of our reduction. For simplicity, here we consider k-MLD problem on d-length vectors over binary field. Given k vectors sets $V_1, \ldots, V_k \subseteq \mathbb{F}_2^d$, a target vector $\vec{t}$ and a strong threshold graph $T = (A \dot\cup B, E_T)$, we first identify V_i with A_i for every

$i \in [k]$. Our goal is to construct a one-to-one mapping $f : A \cup B \to \mathbb{F}_2^D$ and a new target vector $\vec{t}' \in \mathbb{F}_2^D$ for some $D = \mathsf{poly}(d, k)$ such that in order to pick vectors from $f(A \cup B)$[4] with their sum being $\vec{t}'$, one has to pick a set $f(X)$ of vectors from $f(A)$ for some $X \subseteq A$ with $\sum_{\vec{a} \in X} \vec{a} = \vec{t}$ and a set $f(Y)$ of vectors from $f(B)$ for some $Y \subseteq B$ such that for every $i \in [m]$,

(a) either $|Y \cap B_i| \geq 2$,

(b) or $|Y \cap B_i| = 1$ and there exists $b_i \in B_i$ with one of following properties:

- **(b.1)** $|X| = k$ and b_i is the common neighbors of vertices in X.
- **(b.2)** b_i has at least $k + 1$ neighbors in X.

Then we argue that these properties imply a constant gap between the solution sizes in the (YES) and (NO) cases of the k-MLD problem.

(YES) Suppose there are $a_1 \in A_1, \ldots, a_k \in A_k$ such that $\sum_{i \in [k]} a_i = \vec{t}$. By the property (iii) of threshold graphs, $a_1, \ldots, a_k$ have a common neighbor $b_i \in B_i$ for every $i \in [m]$. Then according to (b), the sum of $f(a_1), \ldots, f(a_k)$ and $f(b_1), \ldots, f(b_m)$ is $\vec{t}'$.

(NO) On the other hand, if there are no $a_1 \in A_1, \ldots, a_k \in A_k$ such that $\sum_{i \in [k]} a_i = \vec{t}$, then one should pick either at least $(1 - \varepsilon)2m$ vectors from $f(B)$ and $k + 1$ vectors from $f(A)$, or pick a subset of vectors $f(X)$ from $f(A)$ and a subset of vectors $f(Y)$ from $f(B)$ for some $Y \subseteq B$ with $|\{i \in [m] : |Y \cap B_i| = 1\}| \geq \varepsilon m$. Let $I = \{i \in [m] : |Y \cap B_i| = 1\}$. According to the property (b.2), each vertex in $Y \cap B_i$ ($i \in I$) has $k + 1$ neighbors in X. Since $|I| \geq \varepsilon m$, by the property (iv) of threshold graphs, we have that $|X| > h$. Thus, either $(1 - \varepsilon)2m$ vectors in $f(B)$ and $k + 1$ vectors in $f(A)$ or m vectors in $f(B)$ and h vectors in $f(A)$ must be picked in this case.

To obtain a constant gap, we duplicate each vector in $f(A)$ m/k times and let $h = ck$ where c is some constant to be chosen. In the (yes) case, there are $2m$ vectors with their sum being $\vec{t}'$. In the (no) case, no $\min\{2(1 - \varepsilon)m + m, m + cm\}$ vectors from $f(A \cup B)$ can have sum $\vec{t}'$.

The proof framework above has two problems to be solved.

(P1) How to combine the threshold graph and the k-MLD instance to produce vectors $f(A \cup B)$ with the properties (a) and (b)?

(P2) The smaller parameter blow-up we create in reduction, the tighter running time lower bound we obtain. So how to construct a threshold graph with $h > ck$ and m as small as possible?

Our approach to solve Problem (P1). Problem (P1) is related to the composition step in the threshold graph composition method. For the k-SetCover problem, we can use the hypercube partition system [23] to solve this problem. Unfortunately, this does not apply to the k-MLD problem. To solve problem (P1), we exploit an additional property from the construction of strong threshold graph using error correcting codes. More precisely, we can assume that there is a encoding function $C : A \to \Sigma^m$ and each $b_i \in B_i$ can be written as a k-tuple in $(b_{i,1}, \ldots, b_{i,k}) \in \Sigma^k$ such that b_i is adjacent to $a_j \in A_j$ in the threshold graph if and only if $b_{i,j} = C(a_j)[i]$. Informally speaking, we choose the target vector $\vec{t}'$ and the one-to-one mapping $f : A \cup B \to \mathbb{F}_2^D$ such that any subset of vectors in $f(A \cup B)$ summing up to $\vec{t}'$ must contains, for each $i \in [m]$, at least one vector $f(b_i)$ for some $b_i \in B_i$. And if it contains exactly only one such vector $f(b_i)$, then one need to pick at least k vectors $f(a_1) \in f(A_1), \ldots, f(a_k) \in f(A_k)$ to cancel out the parts corresponding to $b_{i,1}, \ldots, b_{i,k}$ in the vector $f(b_i)$. A careful analysis shows that this construction has the properties (a) and (b).

[4] Here we let $f(X)$ denote the set $\{f(x) : x \in X\}$.

Our approach to solve Problem (P2). The construction of strong threshold graph in [37] was based on the idea of Karthik and Navon [32]. Karthik and Navon [32] observed that the "collision number" of an error-correcting code can be directly used to show the threshold property. Intuitively speaking, a set C of strings with high ε-collision number indicates that if there is some mechanism forces us to choose some strings in C that collides on at least ε fraction of entries, then we must choose at least $\mathrm{Col}_\varepsilon(C)$ strings.

Known analysis of collision number in [10,32] starts from the distance of an error-correcting code. For a code with relative distance δ, previous analysis shows that its ε-collision number is $\mathrm{Col}_\varepsilon(C) = \sqrt{\frac{2\varepsilon}{1-\delta}}$. Note that $\delta = 1 - \Theta(\frac{r}{m})$ for Reed-Solomon codes used in the previous works. To obtain a gap, we require $\mathrm{Col}_\varepsilon(C) \geq \Theta(k)$, which leads to $m = \Omega(k^2)r$. In our reduction, we additionally require $\Sigma^r \geq n$ to fit the input size, which requires $r \geq \frac{\log n}{\log |\Sigma|}$, then we have $m \geq k^2 \log n / \log |\Sigma|$. On the other hand, our reduction needs to enumerate every k-tuples in Σ^k, concerning the running time we require $|\Sigma|^k \leq n^{O(1)}$. Putting all together, we must have $m \geq \Omega(k^3)$. In fact, we showed that the Singleton bound of codes implies such construction must have parameter growth $\Omega(k^3)$.

To obtain a better parameter, we find the analysis by Karthik and Navon [32, Section 3.1] can be modified to show better lower bound for the ε-collision number of a random code. Following their idea, we show a random code $C_R : \Sigma^r \to \Sigma^m$ with superconstant-sized alphabet and $m = \Omega(|\Sigma|^{1/3} \log |\Sigma| r)$ would have ε-collision number $\mathrm{Col}_\varepsilon(C_R) \geq |\Sigma|^{1/3}$, with high probability. Setting $|\Sigma| = \Theta(k^3)$, we have $\mathrm{Col}_\varepsilon(C) \geq \Theta(k)$. But now the parameter $m = \Omega(|\Sigma|^{1/3} \log |\Sigma| r) \geq k \log n$ is too large. Our solution is to consider a new error correcting code with small dimension by increasing the alphabet size and show that this new code has the same collision number. More precisely, we partition the m bits into g blocks, each containing m/g bits and treat the code words as strings in Σ'^g where $\Sigma' = \Sigma^{m/g}$. Since $|\Sigma'^k| \leq n^{O(1)}$, we have $m/g \leq O(\frac{\log n}{k \log |\Sigma|}) = O(\frac{\log n}{3k \log k})$. Thus, $g \geq \Theta(\frac{mk \log k}{\log n}) \geq \Theta(k^2 \log k)$. This reduces the parameter growth from k^3 to $k^2 \log k$, and the (randomized) ETH-based running time lower bound can be improved to $n^{O(\sqrt{k/\log k})}$. We hope to see whether some better construction of threshold graph leads to better lower bound of problems we discuss.

1.3 Previous Work

The parameterized complexity of k-MDP had been open for many years. This problem was first resolved by [13]. Interestingly, the reduction in [13] also ruled out constant FPT-approximation algorithm for k-MDP over binary field. In addition, they also ruled out any constant FPT-approximation algorithm for k-CVP in all ℓ_p norms. Recent work by Bennett, Cheraghchi, Guruswami and Ribeiro [10] proved parameterized inapproximability for k-MDP over all finite fields and k-SVP in all ℓ_p norms and arbitrary constant gap. These results are all based on the W[1]-hardness of constant Gap-k-NCP or Gap-k-CVP in [13].

Unfortunately, the gap-creating reduction from k-Clique to constant Gap-k'-NCP or Gap-k'-CVP in [13] has a long reduction chain and causes a significant increase in the parameter. For example, the reduction from k-Clique to constant Gap-k'-NCP contains the following steps (the reduction for Gap-k'-CVP is similar):

- The first step is to reduce k-Clique to the One-Sided Gap Biclique problem. In this step, the reduction outputs a bipartite graph $H = (L \cup R, E)$ and three integers $s = k(k-1)/2$, $\ell = (k+1)!$ and $h > \ell$ on input a graph G and an integer k such that if G contains a k-clique, then there are s vertices in L with h common neighbors. On the other hand, if G contains no k-clique, then every s-vertex set of L has at most ℓ common neighbors in R.

- The second step is to reduce the One-Sided Gap Biclique problem to Gap-k'-Linear Dependent Set problem (Gap-k'-LDS)[5]. On input the bipartite graph $H = (L \cup R, E)$ and three positive integers $s, \ell, h \in \mathbb{N}$, the reduction outputs a set W of vectors and an integer $k' = hs$ such that, if H contains a $K_{s,h}$-subgraph, then there are k' vectors in W that are linearly dependent. If every s-vertex set in L has at most ℓ common neighbors, then any linearly dependent set of W must have size at least $(h/\ell)^{1/s}$. To create a constant gap, one must choose a large parameter h such that $(h/\ell)^{1/s} \geq \gamma hs$ for some $\gamma > 1$. Hence in [13], the authors have to set $h = (k+6)! \cdot (\gamma k^2)^{k^2}$ and $k' = hs \geq k^{\Omega(k^2)} = 2^{\Omega(k^2 \log k)}$.
- The next step is to reduce the Gap-k'-Linear Dependent Set problem (Gap-k'-LDS) to Gap-k''-Maximum Likelihood Decoding problem (Gap-k''-MLD)[6]. This reduction preserves the parameter i.e., $k'' = k$.
- The remaining step gives a reduction from constant Gap-k''-MLD to constant Gap-k''-NCP.

Combining this with the $f(k) \cdot n^{\Omega(k)}$-time lower bound for the k-Clique problem, we only get a $g(k) \cdot n^{\Omega((\log k)^{1/(2+\epsilon)})}$-time lower bound for Gap-k-NCP using the reduction from [13].

Under a stronger gap assumption (Gap-ETH), Manurangsi [38] showed a tight $n^{\Omega(k)}$ time lower bound for constant approximating problems discussed in this article. His approach is to show an $n^{\Omega(k)}$ time lower bound for constant approximating LaberCover, then reduce it to k-UniqueSetCover, then reduce k-UniqueSetCover to gap problems we discuss using reduction in [6]. The key step in his proof is to establish hardness result for approximating k-UniqueSetCover. To our best knowledge, there is no hardness of approximation result for the parameterized k-UniqueSetCover under gap-free assumptions, e.g. ETH and W[1] $\neq$ FPT.

Very recently, Guruswami, Ren and Sandeep [26] showed constant FPT-inapproximability of k-UniqueSetCover under the assumption that Average Baby PIH holds even for 2CSP instance having rectangular relations. It's interesting whether their result and method can shed some light on showing ETH-based $n^{\Omega(k)}$ time lower bound for k-UniqueSetCover. We remark that the ETH-based $n^{\Omega(k)}$ time lower bound for constant approximating k-UniqueSetCover is still an open problem, and so does its FPT-inapproximability assuming W[1] $\neq$ FPT.

1.4 Paper Organization

In Section 2, we give preliminary of this paper. In Section 3, we give a new analysis on collision number of random code, this section can be skipped if readers wants to see the reduction directly. In Section 4, we present our gap-creating reduction for k-MLD$_p$. In Section 5, we show how to apply our reduction to other results and show inapproximability of other problems. For self-containment, we give a proof of equivalence between k-MLD$_p$ and k-NCP$_p$ in Appendix A of our full version.

2 Preliminaries

For integer $m > 0$, let $[m] = \{1, 2, \cdots, m\}$. For prime power $p > 1$, we let $\mathbb{F}_p = \{0, 1 \cdots, p-1\}$ denote the p-sized finite field. We denote $\mathbb{F}_p^+$ as $\mathbb{F}_p \backslash \{0\}$. For a vector $\vec{v} \in \Sigma^m$ and $i \in [m]$, let $\vec{v}[i] \in \Sigma$ denote the i-th entry of $\vec{v}$. For two vectors $\vec{u}$, $\vec{v}$, let $\vec{u} \circ \vec{v}$ denote their concatenation.

[5] In fact, the reduction in [13] from One-Sided Gap Biclique to Gap-k-LDS goes though an intermediate problem called gap bipartite subgraph with minimum degree (GapBSMD).

[6] Again, they introduced a color-coding technique to Gap-k-LDS (Gap-k-Colored-LDS) and used it as an intermediate problem between Gap-k-LDS and Gap-k-MLD, for details see [13, Lemma 4.8, Theorem 5.4].

The symbol $\dot{\cup}$ denotes for the union set of multiple disjoint sets. As a supplement of big-O notation, we let $f(k,n) = O_k(g(n))$ denote there exists constant $c > 0$ and computable function $h : \mathbb{N} \to \mathbb{N}$ such that for any fixed $k > 0$, $f(k,n) < c \cdot h(k)g(n)$ holds for all sufficiently large n.

For alphabet Σ and vector $\vec{u}, \vec{v} \in \Sigma^m$, the relative distance of them is defined as $\mathsf{dist}(\vec{u}, \vec{v}) = \frac{|\{i \in [m] : \vec{u}[i] \neq \vec{v}[i]\}|}{m}$. In this article, we sometimes use "distance" as shorthand of relative distance. For vector $\vec{v} \in \mathbb{Z}^m$ and $p \geq 1$, let the ℓ_p norm of $\vec{v}$ be $\ell_p(\vec{v}) = (\Sigma_{1 \leq i \leq m} |\vec{v}[i]|^p)^{1/p}$.

2.1 Error-correcting Codes

Error-correcting code plays a fundamental role in computer science and information theory. The problem we mainly discuss in this article and the construction we use are closely related to them. We give a general definition of error-correcting code. A detailed and systematic introduction to coding theory can be found at [27].

▶ **Definition 5** (Error-correcting Codes). *Fix an alphabet Σ, an error-correcting code with length m and relative distance $\delta > 0$ is a subset $\mathcal{C} \subseteq \Sigma^m$ satisfying for all $\vec{x}, \vec{y} \in \mathcal{C}$, if $\vec{x} \neq \vec{y}$, $\mathsf{dist}(\vec{x}, \vec{y}) \geq \delta$.*

▶ **Definition 6** (Linear Codes). *Fix an alphabet Σ such that Σ^r and Σ^m being linear spaces, a linear code is an error-correcting code $\mathcal{C} \subseteq \Sigma^m$ associated with a linear function $f : \Sigma^r \to \Sigma^m$ that for all $x \in \Sigma^r$, $f(x) \in \mathcal{C}$.*

2.2 Hypothesis

We introduce the Exponential Time Hypothesis in this section.

▶ **Definition 7** (3-SAT). *Given a 3-CNF formula (conjunctive formal form, each clause contains exactly 3 literals) φ with n variables and m clauses, decide if there exists a boolean assignment $z \in \{0,1\}^n$ that satisfies φ, i.e., $\varphi(z) = 1$.*

▶ **Hypothesis 8** (Exponential Time Hypothesis [30, 31]). *There exists constant $\delta > 0$ such that 3-SAT with n variable and $O(n)$ clauses cannot be solved in time $O(2^{\delta n})$.*

▶ **Hypothesis 9** (Randomized Exponential Time Hypothesis). *There exists constant $\delta > 0$ such that 3-SAT with n variable and $O(n)$ clauses cannot be solved by randomized algorithm in time $O(2^{\delta n})$.*

2.3 Problems

We first give the definition of general parameterized Maximum Likelihood Decoding problem.

γ-Gap-k-MLD$_p$

Instance:	A vector multi-set $V \subseteq \mathbb{F}_p^d$ with size n and a target vector $\vec{t} \in \mathbb{F}_p^d$.
Parameter:	k.
Problem:	Distinguish between the following two cases:
(YES)	There exists k distinct vectors (with respect to multi-set), $\vec{v}_1, \cdots, \vec{v}_k \in V$ and $\alpha_1, \ldots, \alpha_l \in \mathbb{F}_p^+$ such that $\alpha_1\vec{v}_1 + \cdots + \alpha_k\vec{v}_k = \vec{t}$.
(NO)	Any $\ell \leq \gamma k$, l vectors $\vec{v}_1, \ldots, \vec{v}_l \in V$ and $\alpha_1, \ldots, \alpha_l \in \mathbb{F}_p^+$ satisfies $\alpha_1\vec{v}_1 + \cdots + \alpha_l\vec{v}_l \neq \vec{t}$.

To fit requirements in our reduction, we start from a special restricted type of parameterized Maximum Likelihood Decoding problem that vectors are partitioned into k different sets, and the YES case asks for selecting one vector from each set such that they directly add up to the target vector.

The other problems we study includes parameterized Nearest Codeword Problem, which asks if there is a codeword of the given linear code having distance no more than k to a given target vector; Minimum Distance Problem, which asks if the minimum distance of given linear code does not exceed k; Closest Vector Problem, asking if there is a vector in the given linear lattice having ℓ_p distance no more than k to a given target vector; Shortest Vector Problem, asking if the shortest non-zero vector of given linear lattice does not exceed k. Formal definitions of these problems are referred to the full version.

2.4 Probability Inequality

▶ **Theorem 10** (Chernoff Bound). *Consider independent random variables $X_1, \ldots, X_n \in \{0,1\}$ with $X = \sum_{i=1}^{m} X_i$ and $\mu = \mathbb{E}[X]$. For any $0 < \delta < 1$ we have*

$$\Pr[X \leq (1-\delta)\mu] \leq \exp\left(-\frac{\mu\delta^2}{2}\right).$$

3 Collision Number of Error Correcting Codes

In this section, we introduce the definition of collision number of a code, which is key to our gap-creating reductions. Given a collection of strings $S \subseteq \Sigma^m$, we say that S "collides" on the i-th coordinate if there are distinct $x, y \in S$ such that $x[i] = y[i]$. Following the work of [32, 37], we define the collision number of a set of strings as follows.

▶ **Definition 11** (ε-Collision Number). *For a set $C \subseteq \Sigma^m$ and $0 < \varepsilon < 1$, the ε-collision number of C, denote as $\mathrm{Col}_\varepsilon(C)$, is the smallest integer $s \in \mathbb{N}^+$ such that there exists $S \subseteq C$ with $|S| = s$ and S collides on more than εm coordinates, i.e.,*

$$|\{i \in [m] \mid \exists x, y \in S, x \neq y \text{ s.t. } x[i] = y[i]\}| > \varepsilon m.$$

To create a gap for the k-MLD$_p$ problem, we need to construct codes $C \subseteq \Sigma^m$ with collision number $\mathrm{Col}_\varepsilon(C) \geq \Omega(k)$ and m depends only on k. We sketch two constructions (Theorem 13 and Lemma 17).

▶ **Lemma 12** ([32], See also Theorem 10 in [37]). *For any constant $0 < \varepsilon \leq 1$, an error correcting code $C : \Sigma^r \to \Sigma^m$ with relative distance $0 < \delta < 1$ has $\mathrm{Col}_\varepsilon(C) \geq \sqrt{\frac{2\varepsilon}{1-\delta}}$.*

▶ **Theorem 13** ([32, 37]). *Fix any Reed-Solomon code $\mathcal{C}^{RS} : \Sigma^r \to \Sigma^m$ with $r < m \leq |\Sigma|$. For any $0 < \varepsilon < 1$, $\mathrm{Col}_\varepsilon(\mathcal{C}^{RS}) \geq \sqrt{\frac{2\varepsilon m}{r}}$.*

To fit the requirement in our reduction, i.e., $|\Sigma|^r \geq n$, we choose $|\Sigma| = n^{1/k}$ and $r = \Omega(k)$. To fit the requirement that $\mathrm{Col}_\varepsilon(C) = \Omega(k)$ in Lemma 19, the Reed-Solomon code here must satisfy $m = \Omega(k^2 r) = \Omega(k^3)$. Seeking for a shorter code with high ε-collision number, we turn to randomized construction of codes, and we show the following lemma. The proof is similar to [32, Claim 3.4] by showing each coordinate has collision with low probability in a small set, then apply Chernoff bound and union bound to show a small set can hardly have large collision number. Details see the full version.

▶ **Lemma 14.** *For any constant $0 < \varepsilon < 1$ and any random code $C_R : \Sigma^r \to \Sigma^m$ where each codeword is selected uniformly at random in Σ^m, if $m \geq 16\frac{1}{\varepsilon^2}|\Sigma|^{1/3} \ln |\Sigma| r$ and $|\Sigma| = \omega(1)$, then with high probability, $\mathrm{Col}_\varepsilon(C_R) > |\Sigma|^{1/3}$.*

By instantiating Lemma 14 with appropriate parameter, we have:

▶ **Lemma 15.** *For any constant $c > 0$ and $0 < \varepsilon < 1$, there is a randomized algorithm that given integers $n, k \in \mathbb{N}^+$, constructs a code $C \subseteq \Sigma^m$ with parameters $|C| = n, |\Sigma| = O(k^3)$ and $m = O(k \log n)$ such that with high probability, $\mathrm{Col}_\varepsilon(C) > ck$. Moreover, the running time of this algorithm is $O(nm|\Sigma|)$.*

▶ Remark 16. We remark that using an almost identical argument, Lemma 14 can be extended to the case that for each integer $t \geq 3$, if $m > \Omega(|\Sigma|^{1/t} \log |\Sigma| r)$ and $|\Sigma| = \omega(1)$, then w.h.p., $\mathrm{Col}_\varepsilon(C_R) > |\Sigma|^{1/t}$. For constant $t > 3$, setting $|\Sigma| = \Omega(k^t)$, Lemma 15 can be extended to the case with same parameter but larger code alphabet.

By merging the number of code blocks over small alphabet from Lemma 15, we obtain:

▶ **Lemma 17.** *For any constant $c > 1$ and $0 < \varepsilon < 1$, there is a randomized algorithm that given integers $n, k \in \mathbb{N}^+$, constructs a code $C \subseteq \Sigma^m$ with parameters $|C| = n, |\Sigma| = O(n^{1/k})$ and $m = O(k^2 \log k)$ such that with high probability $\mathrm{Col}_\varepsilon(C) > ck$. Moreover, the running time of this algorithm is $O(k^2 \log k n^{1+1/k})$.*

3.1 Limitation of Collision Analysis in [32, 37]

We have already shown the a direct collision analysis yields $m' = O(k^2 \log k)$. Below, we argue that collision analysis from distance must cause a cubic increase in the parameter.

To obtain a constant gap using Lemma 19 in Section 4, we require the collision number of code C to be $\mathrm{Col}_\varepsilon(C) = \Omega(k)$. Combining with Lemma 12, we immediately have the relative distance of code C must satisfy

$$\delta \geq 1 - 1/\Omega(k^2).$$

On the other hand, we have the following Singleton bound from coding theory, whose proof can be found in [27, Section 4.3].

▶ **Theorem 18** (Singleton Bound)**.** *For every code $C : \Sigma^r \to \Sigma^m$ with relative distance δ must have $r \leq m - \delta m + 1$.*

We apply the bound to parameter we choose and obtain $m - (1 - \frac{1}{\Omega(k^2)}))m + 1 \geq r$, i.e.,

$$m \geq \Omega(k^2) r.$$

Our reduction for MLD associates each input vector with a unique codeword, which requires $|C| = |\Sigma|^r \geq n$, leading to

$$r \geq (\log n)/(\log |\Sigma|).$$

Since our reduction runs in time $\Omega(|\Sigma|^k)$, we need $|\Sigma| \leq n^{O(1/k)}$. Thus $r \geq (\log n)/(\log |\Sigma|) \geq \Omega(k)$ and $m \geq \Omega(k^2) r \geq \Omega(k^3)$. Note that we've shown the Reed-Solomon code already achieves $m = O(k^3)$.

4 Gap-creating Reduction for k-MLD$_p$

In this section we present our gap-creation reduction for k-MLD$_p$. First we present a construction that illustrates our main idea and is the crux of our reduction. This construction produces an "unbalanced gap" k'-MLD$_p$ instance in the sense that the output instance is divided into two parts (with different sizes), any solution must contain an amount of vectors in each part. Further, for the NO case, any solution must contain constant fraction more vectors in at least one part. This construction still needs to be modified later to convert into an actual reduction.

▶ **Lemma 19.** *There is an algorithm which on input k sets of length-d vectors $V_1, \cdots, V_k \subseteq \mathbb{F}_p^d$ each of size n, a target vector $\vec{t} \in \mathbb{F}_p^d$ and a code $C \subseteq |\Sigma|^m$ with $|C| = n$ and $\mathrm{Col}_\varepsilon(C) \geq ck$ outputs $A = A_1 \dot\cup \cdots \dot\cup A_k \subseteq \mathbb{F}_p^D$ and $B = B_1 \dot\cup \ldots \dot\cup B_m \subseteq \mathbb{F}_p^D$ with $D = O(d + km|\Sigma|)$ and a target vector $\vec{t}' \in \mathbb{F}_p^D$ in $O(dm^2k^2|\Sigma|(n + |\Sigma|^k))$-time such that*

- **(i)** *If there exist $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ such that $\sum_{i\in[k]} \vec{v}_i = \vec{t}$, then there exists $\vec{a}'_1 \in A_1, \cdots, \vec{a}'_k \in A_k$ and $\vec{b}'_1 \in B_1, \cdots, \vec{b}'_m \in B_m$ with their sum being $\vec{t}'$.*
- **(ii)** *If for any $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ and $\alpha_1, \ldots \alpha_k \in \mathbb{F}_p^+$ it holds that $\alpha_1\vec{v}_1 + \cdots + \alpha_k\vec{v}_k \neq \vec{t}$, then any $X \subseteq A \dot\cup B$ and $\lambda : X \to \mathbb{F}_p^+$ such that $\sum_{\vec{x}\in X} \lambda(\vec{x})\vec{x} = \vec{t}'$ must satisfy at least one of the following:*
  - *$|X \cap A| \geq ck$ and $|X \cap B| \geq m$,*
  - *$|X \cap A| \geq k$ and $|X \cap B| \geq 2(1-\varepsilon)m$.*

Proof. The resulting dimension is $D = d + mk|\Sigma| + k + m$. We break the resulting dimension into 4 blocks respectively of size $d, mk|\Sigma|, k$ and m. To be precise, for any vector $\vec{x} \in \mathbb{F}_p^D$, let

- $\vec{x}^{(1)} \in \mathbb{F}_p^d$ be the first block,
- $\vec{x}^{(2)} \in \mathbb{F}_p^{mk|\Sigma|}$ be second block,
- $\vec{x}^{(3)} \in \mathbb{F}_p^k$ be the third block,
- $\vec{x}^{(4)} \in \mathbb{F}_p^m$ be the fourth block.

We further break the second block into m sub-blocks each of size $k|\Sigma|$, i.e., $\vec{x}^{(2)} = \vec{x}^{(2,1)} \circ \cdots \circ \vec{x}^{(2,m)}$.

We let $\vec{e}_i$ be the indicator vector of which the i-th entry is 1 and the other entries are 0. To be convenient, the dimension of $\vec{e}_i$ depends on the context. Specially we let $\iota : \Sigma \to [|\Sigma|]$ be an arbitrary bijection, and for every $\sigma \in \Sigma$ we let

$$\vec{e}_\sigma = (\overbrace{0, \ldots, 0}^{\iota(\sigma)-1}, \underbrace{1, 0 \ldots, 0}_{|\Sigma|}).$$

Construction of A. For every V_i, associate each $\vec{v} \in V_i$ a distinct codeword of C, denoted by $C(\vec{v})$. For every $i \in [k]$ and $\vec{v} \in V_i$, introduce a vector $\vec{a}_{i,\vec{v}}$ as

- $\vec{a}^{(1)}_{i,\vec{v}} = \vec{v}$,
- $\vec{a}^{(2,j)}_{i,\vec{v}} = (\underbrace{\overbrace{\vec{0}, \ldots, \vec{0}}^{(i-1)}, \vec{e}_{C(\vec{v})[j]}, \vec{0}, \ldots, \vec{0}}_{k})$, for every $j \in [m]$,
- $\vec{a}^{(3)}_{i,\vec{v}} = \vec{e}_i$,
- $\vec{a}^{(4)}_{i,\vec{v}} = \vec{0}_m$.

And we let $A_i = \{\vec{a}_{i,\vec{v}} \mid \vec{v} \in V_i\}$ and $A = A_1 \cup \cdots \cup A_k$.

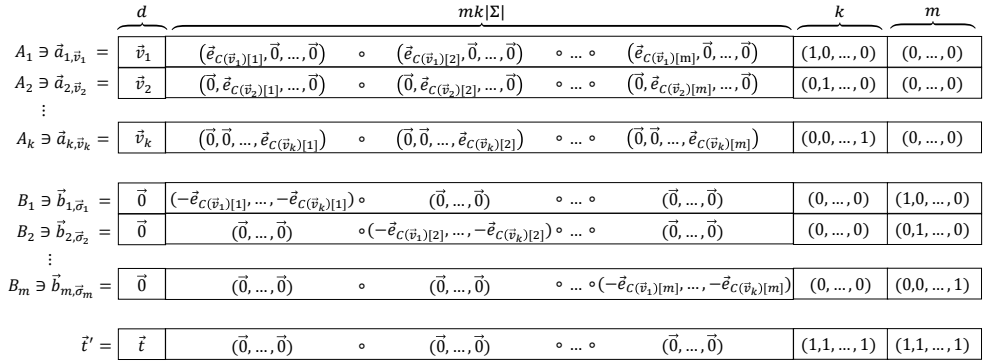

Figure 1 Illustration for the vectors of Lemma 19 in the completeness setting. We can choose each $\vec{b}_{j,\vec{\sigma}_j}$ as $\vec{\sigma}_j = (C(\vec{v}_1)[j], \cdots, C(\vec{v}_k)[j])$.

Construction of B. For every $j \in [m]$ and $\vec{\sigma} = (\sigma_1, \dots, \sigma_k) \in \Sigma^k$, introduce a vector $\vec{b}_{j,\vec{\sigma}}$ as

- $\vec{b}^{(1)}_{j,\vec{\sigma}} = \vec{0}_d$,
- $\vec{b}^{(2,j)}_{j,\vec{\sigma}} = (-\vec{e}_{\sigma_1}, \cdots - \vec{e}_{\sigma_k})$, $\vec{b}^{(2,j')}_{j,\vec{\sigma}} = \vec{0}_k$ for every $j' \in [m] \backslash \{j\}$,
- $\vec{b}^{(3)}_{j,\vec{\sigma}} = \vec{0}_k$,
- $\vec{b}^{(4)}_{j,\vec{\sigma}} = \vec{e}_j$.

We let $B_j = \{\vec{b}_{j,\vec{\sigma}} \mid \vec{\sigma} \in \Sigma^k\}$ and $B = B_1 \cup \cdots \cup B_m$.

Finally we set the target vector $\vec{t}'$ as

- $\vec{t}'^{(1)} = \vec{t}$,
- $\vec{t}'^{(2)} = \vec{0}_{mk|\Sigma|}$,
- $\vec{t}'^{(3)} = \vec{1}_k$,
- $\vec{t}'^{(4)} = \vec{1}_m$.

Time complexity. Producing each vector in A requires $O(d + mk|\Sigma| + km) = O(d + mk|\Sigma|)$ time, so the total time cost producing A is $O(dkn + mk^2 n|\Sigma|)$. Producing each vector in B also requires $O(d + mk|\Sigma|)$ time, and the total time cost producing B is $O(dm|\Sigma|^k + m^2 k|\Sigma|^{k+1})$. So the total time cost of this reduction is $O(dm^2k^2|\Sigma|(n + |\Sigma|^k))$.

Proof of (i). Suppose there exist $\vec{v}_1 \in V_1, \cdots, \vec{v}_k \in V_k$ satisfying $\sum_{i\in[k]} \vec{v}_i = \vec{t}$. For every $i \in [k]$ we choose a vector $\vec{a}_{i,\vec{v}_i} \in A_i$. And for every $j \in [m]$ we choose a vector $\vec{b}_{j,\vec{\sigma}_j} \in B_j$, where $\vec{\sigma}_j = (C(\vec{v}_1)[j], \dots, C(\vec{v}_m)[j]) \in \Sigma^k$. We now examine that $\sum_{i\in[k]} \vec{a}_{i,\vec{v}_i} + \sum_{j\in[m]} \vec{b}_{j,\vec{\sigma}_j} = \vec{t}'$ as:

- For the first block,

$$\sum_{i\in[k]} \vec{a}^{(1)}_{i,\vec{v}_i} + \sum_{j\in[m]} \vec{b}^{(1)}_{j,\vec{\sigma}_j} = \sum_{i\in[k]} \vec{v}_i + \sum_{j\in[m]} \vec{0}_d = \vec{t} = \vec{t}'^{(1)}.$$

- For every $j \in [m]$ the $(2, j)$-th block,

$$\begin{aligned}
\sum_{i\in[k]} \vec{a}^{(2,j)}_{i,\vec{v}_i} + \sum_{j'\in[m]} \vec{b}^{(2,j)}_{j',\vec{\sigma}_{j'}} &= \sum_{i\in[k]} \vec{a}^{(2,j)}_{i,\vec{v}_i} + \vec{b}^{(2,j)}_{j,\vec{\sigma}_j} \\
&= \sum_{i\in[k]} (\overbrace{\vec{0}, \dots, \vec{0}}^{i-1}, \vec{e}_{C(\vec{v}_i)[j]}, \vec{0}, \dots, \vec{0}) + (-\vec{e}_{C(\vec{v}_1)[j]}, \dots, -\vec{e}_{C(\vec{v}_k)[j]}) \\
&= (\vec{e}_{C(\vec{v}_1)[j]}, \dots, \vec{e}_{C(\vec{v}_k)[j]}) + (-\vec{e}_{C(\vec{v}_1)[j]}, \dots, -\vec{e}_{C(\vec{v}_k)[j]}) \\
&= \vec{0}_{k|\Sigma|} = \vec{t}'^{(2,j)}.
\end{aligned}$$

- For the third block,

$$\sum_{i\in[k]} \vec{a}^{(3)}_{i,\vec{v}_i} + \sum_{j\in[m]} \vec{b}^{(3)}_{j,\vec{\sigma}_j} = \sum_{i\in[k]} \vec{e}_i + \sum_{j\in[m]} \vec{0}_k = \vec{1}_k = \vec{t}'^{(3)}.$$

- For the fourth block,

$$\sum_{i\in[k]} \vec{a}^{(4)}_{i,\vec{v}_i} + \sum_{j\in[m]} \vec{b}^{(4)}_{j,\vec{\sigma}_j} = \sum_{i\in[k]} \vec{0}_m + \sum_{j\in[m]} \vec{e}_j = \vec{1}_m = \vec{t}'^{(4)}.$$

Proof of (ii). Suppose $X \subseteq A \dot\cup B$ and $\lambda : X \to \mathbb{F}_p^+$ such that $\sum_{\vec{x}\in X} \lambda(\vec{x})\vec{x} = \vec{t}'$. Observe the third block of the equation:

$$\sum_{\vec{x}\in X} \lambda(\vec{x})\vec{x}^{(3)} = \sum_{i\in[k]} \sum_{\vec{x}\in X\cap A_i} \lambda(\vec{x})\vec{e}_i = \vec{1}_m = \vec{t}'^{(3)}.$$

For every $i \in [k]$, $X \cap A_i$ must not be empty since $\sum_{\vec{x}\in X\cap A_i} \lambda(\vec{x}) = 1$. Also similarly by observing the fourth block it holds that $X \cap B_j$ must not be empty for every $j \in [m]$. Therefore $|X \cap A| \geq k$ and $|X \cap B| \geq m$.

Further suppose that any $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ and $\alpha_1, \ldots \alpha_k \in \mathbb{F}_p^+$ must satisfy $\alpha_1\vec{v}_1 + \cdots + \alpha_k\vec{v}_k \neq \vec{t}$, we show that either $|X \cap A| \geq ck$ or $|X \cap B| \geq 2(1-\varepsilon)m$.

We let $I \subseteq [m]$ be the set of indices j that $X \cap B_j$ contains only one vector, i.e.,

$$I = \{j \in [m] : |X \cap B_j| = 1\}.$$

Since $|X \cap B_j| \geq 1$ for every $j \in [m]$, if $|I| \leq \varepsilon m$ then

$$|X \cap B| \geq \sum_{j\in[m]\setminus I} |X \cap B_j| \geq 2(1-\varepsilon)m$$

as desired. It remains to show that if $|I| > \varepsilon m$ then $|X \cap A| \geq ck$.

First we claim that there must be an $i \in [k]$ such that $X \cap A_i$ contains more than one vector. Otherwise suppose that $|X \cap A_i| = 1$ for every $i \in [k]$, let $\vec{a}_{i,\vec{v}_i} \in X \cap A_i$ be the unique vector in $X \cap A_i$. Recall that in the first block, vectors in $X \cap B$ are all zero, so the sum of vectors in X in the first block is

$$\sum_{\vec{x}\in X} \lambda(\vec{x})\vec{x}^{(1)} = \sum \lambda(\vec{a}_{i,\vec{v}_i})\vec{a}'^{(1)}_{i,\vec{v}_i} = \sum_{i\in[k]} \lambda(\vec{a}_{i,\vec{v}_i})\vec{v}_i = \vec{t} = \vec{t}'^{(1)}$$

This contradicts to our assumption that for all $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ and $\alpha_1, \ldots, \alpha_k \in \mathbb{F}_p^+$, $\sum_{i\in[k]} \alpha_i\vec{v}_i \neq \vec{t}$. Therefore, there must be such an index $i^* \in [k]$ that $|A'_{i^*}| > 1$.

Let $l > 1$ be the size of $X \cap A_{i^*}$, we next show that $l \geq ck$. Suppose that $X \cap A_{i^*} = \{\vec{a}_{i^*,\vec{v}_1}, \ldots, \vec{a}_{i^*,\vec{v}_l}\}$ where $\vec{v}_1, \ldots \vec{v}_l \in V_{i^*}$. We show in the following that the codeword set $\{C(\vec{v}_1), \ldots, C(\vec{v}_l)\}$ must collide on every $j \in I$. Fix any $j \in I$, let $\vec{b}_{j,\vec{\sigma}}$ be the unique vector in $X \cap B_j$, where $\vec{\sigma} = (\sigma_1, \ldots, \sigma_k)$. Recall that the $(2, j)$-th block of the resulting dimension consists of $k|\Sigma|$ coordinates, here we further break it down into k sub-blocks each of size $|\Sigma|$, and we focus on the $(2, j, i^*)$-th sub-block:

$$\begin{aligned}
\sum_{\vec{x}\in X} \lambda(\vec{x})\vec{x}^{(2,j,i^*)} &= \lambda(\vec{a}_{i^*,\vec{v}_1})\vec{a}^{(2,j,i^*)}_{i^*,\vec{v}_1} + \cdots + \lambda(\vec{a}_{i^*,\vec{v}_l})\vec{a}^{(2,j,i^*)}_{i^*,\vec{v}_l} + \lambda(\vec{b}_{j,\vec{\sigma}})\vec{b}^{(2,j,i^*)}_{j,\vec{\sigma}} \\
&= \lambda(\vec{a}_{i^*,\vec{v}_1})\vec{e}_{C(\vec{v}_1)[j]} + \cdots + \lambda(\vec{a}_{i^*,\vec{v}_l})\vec{e}_{C(\vec{v}_l)[j]} - \lambda(\vec{b}_{j,\vec{\sigma}})\vec{e}_{\sigma_{i^*}} \\
&= \vec{0}_{|\Sigma|} = \vec{t}'^{(2,j,i^*)}.
\end{aligned}$$

If $C(\vec{v}_1)[j], \ldots, C(\vec{v}_l)[j]$ are all distinct, the equation $\lambda(\vec{a}_{i^*,\vec{v}_1})\vec{e}_{C(\vec{v}_1)[j]} + \cdots + \lambda(\vec{a}_{i^*,\vec{v}_l})\vec{e}_{C(\vec{v}_l)[j]} - \lambda(\vec{b}_{j,\vec{\sigma}})\vec{e}_{\sigma_{i^*}} = \vec{0}_{|\Sigma|}$ must not be satisfied since $l > 1$ and the λ's are nonzero. Therefore $\{C(\vec{v}_1), \ldots, C(\vec{v}_l)\}$ must collide on the j-th coordinate.

If $|I| > \varepsilon m$ then $\{C(\vec{v}_1), \ldots, C(\vec{v}_l)\}$ collide on more than εm coordinates, by the definition of collision number, it holds that $|\{C(\vec{v}_1), \ldots, C(\vec{v}_l)\}| \geq \mathrm{Col}_\varepsilon(C) \geq ck$. And thus $|X \cap A| \geq |X \cap A_{i^*}| \geq ck$. ◀

Since the codes (with good collision number) we construct has codeword length $m = O(k^2 \log k)$ (Lemma 17) much greater than k, the above construction cannot directly lead to a gap-creating reduction for k-MLD. To settle this, intuitively we further duplicate the vector sets $A_1, \ldots, A_k$ several times into m vector sets. This leads to our gap creating reduction as follows.

▶ **Theorem 20.** *For any $0 < \varepsilon < 1$, there is a randomized reduction which on input k sets of length-d vectors $V_1, \cdots, V_k \subseteq \mathbb{F}_p^d$ each of size n and a target vector $\vec{t} \in \mathbb{F}_p^d$ outputs k' vector sets $U_1, \ldots, U_{k'} \subseteq \mathbb{F}_p^D$ and a target vector $\vec{t}' \in \mathbb{F}_p^D$ with $k' = O(k^2 \log k)$ and $D = O(k'd + k'^2 n^{1/k})$ in $O(d2^{O(k)} n^{1.01})$ time such that*

- **(i)** *If there exist $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ such that $\sum_{i\in[k]} \vec{v}_i = \vec{t}$, then there exists $\vec{u}_1 \in U_1, \ldots, \vec{u}_{k'} \in U_{k'}$ with their sum being $\vec{t}'$.*
- **(ii)** *If any $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ and $\alpha_1, \ldots \alpha_k \in \mathbb{F}_p^+$ must satisfy $\alpha_1\vec{v}_1 + \cdots + \alpha_k\vec{v}_k \neq \vec{t}$, then any $X \subseteq \bigcup_{i\in[k']} U_i$ and $\lambda : X \to \mathbb{F}_p^+$ such that $\sum_{\vec{x}\in X} \lambda(\vec{x})\vec{x} = \vec{t}'$ must satisfy $|X| \geq (\frac{3}{2} - \varepsilon)k'$.*

▶ Remark 21. Consider the k-VectorSum$_q$ problem in [36], whose definition is identical to k-MLD$_q$ except that it requires all the coefficients being 1. A closer look at our reduction shows that it can directly create a gap of almost $(q+1)/2$ for k-VectorSum$_q$ rather than almost $\frac{3}{2}$ in the k-MLD$_q$ case.

5 Lower Bounds for Gap-k-NCP and Other Problems

In this section, we show the reduction described in the previous sections implies improved running time lower bounds for various problems under ETH.

5.1 Maximum Likelihood Decoding and Nearest Codeword Problem

In [14], Bhattacharyya, Ghoshal, Karthik and Manurangsi presented a gap amplification procedure for Gap-k-MLD$_p$. Although they only discussed the procedure on the binary field, it's straightforward to see the procedure also works for Gap-k-MLD$_p$ instances over all $\mathbb{F}_p$. Formally,

▶ **Theorem 22** (Generalization of Lemma 4.5 in [14]). *For integers $k_1, k_2 > 0$, $k' = k_2 + k_1k_2$ and reals $\gamma_1, \gamma_2 > 1$, $\gamma' \geq \gamma_1\gamma_2(1 - \frac{1}{k_1})$, there is a polynomial time algorithm that on input 2 vector sets $U \subseteq \mathbb{F}_p^{m_1}, V \subseteq \mathbb{F}_p^{m_2}$, $|U| = n_1, |V| = n_2$, two target vectors $\vec{t} \in \mathbb{F}_p^{m_1}, \vec{s} \in \mathbb{F}_p^{m_2}$, outputs a vector set $W \subseteq \mathbb{F}_p^{m_2+n_1m_1}$ and a target vector $\vec{t}' \in \mathbb{F}_p^{m_2+n_1m_1}$ satisfies:*

- *If $(U, \vec{t})$ is a YES instance of γ_1-Gap-k_1-MLD$_p$ instance and $(V, \vec{s})$ is a YES instance of γ_2-Gap-k_2-MLD$_p$ instance, then $(W, \vec{t}')$ is a YES instance of γ'-Gap-k'-MLD$_p$.*
- *If $(U, \vec{t})$ is a NO instance of γ_1-Gap-k_1-MLD$_p$ instance and $(V, \vec{s})$ is a NO instance of γ_2-Gap-k_2-MLD$_p$ instance, then $(W, \vec{t}')$ is a NO instance of γ'-Gap-k'-MLD$_p$.*

Readers seeking for a formal proof is referred to [14, Section 4.2].

5.1.1 ETH-based Running Time Lower Bound

Taking a closer look at the reduction from 3-SAT to k-VectorSum in [36, Theorem 11], we observe that by applying a minor modification, their reduction can actually have soundness condition as:

- If ϕ is not satisfiable, then for any $\vec{v}_1 \in V_1, \ldots, \vec{v}_k \in V_k$ and $\alpha_1, \ldots, \alpha_k \in \mathbb{F}_p^+$, $\Sigma_{i=1}^k \alpha_i \vec{v}_i \neq \vec{t}$.

The modification is simply appending a vector $(0^{i-1} \circ 1 \circ 0^{k-i})$ to each vector in V_i, for all $1 \leq i \leq k$. Then, the target vector is changed from a zero vector to $\vec{t} = 0^d \circ 1^k$. Completeness of their reduction is trivially preserved. For soundness we claim, we note that for any $\vec{v}_1 \in V_1, \cdots, \vec{v}_k \in V_k$ and $\alpha_1, \cdots, \alpha_k \in \mathbb{F}_p$, if $\Sigma_{i=1}^k \alpha_i \vec{v}_i = \vec{t}$, then $\alpha_1 = \cdots = \alpha_k = 1$.

By strengthening the soundness condition in [36], we obtain exactly the restricted version of k-MLD$_p$ in the previous sections. Combining with their soundness for k-VectorSum, we obtain the following hardness result for k-MLD$_p$ as:

▶ **Theorem 23** (Theorem 11 in [36]). *Assuming ETH, for any constant integer p, k-MLD$_p$ has no $n^{o(k)}$-time algorithm.*

The parameterized MLD and NCP are equivalent in the sense that there exist reductions preserving the solution size in both direction. Recall that Theorem 20 showed a reduction from k-MLD$_p$ to $(3/2-\varepsilon)$-Gap-k'-MLD$_p$ with $k' = k^2 \log k$ and $\varepsilon > 0$. Combining running time lower bound in Theorem 23, we have:

▶ **Theorem 24.** *Assuming randomized ETH, for any constant integer p, constant $1 < \gamma < \frac{3}{2}$, γ-Gap-k-MLD$_p$ and γ-Gap-k-NCP$_p$ has no $O_k(n^{o(\sqrt{k/\log k})})$-time algorithm.*

By applying Theorem 22 to the gap instance itself $O(\log\log\gamma)$ times, we can obtain the ETH-based time lower bound for approximating parameterized MLD and NCP to any constant factor.

▶ **Corollary 25.** *Assuming ETH, for any constant integer p and constant $\gamma > 1$, γ-Gap-k-MLD$_p$ and γ-Gap-k-NCP$_p$ have no $O_k(n^{o(k^\epsilon)})$ time algorithm, where $\epsilon = \frac{1}{\mathit{polylog}(\gamma)}$ is a constant.*

5.2 Minimum Distance Problem

The reduction from Gap-k-NCP to Gap-k-MDP in [10] is as follows.

▶ **Theorem 26** ([10], Theorem 3.1 and 3.3). *For any prime power $p \geq 2$ there is a randomized reduction from $(4p)$-Gap-k-NCP$_p$ to $\frac{4p}{4p-1}$-Gap-k'-MDP$_p$ runs in polynomial time with $k' = O(k)$.*

Use our gap-creating reduction for Gap-k-MLD, and apply the gap amplification for a constant number of times, then use Theorem 26 to reduce to Gap-k'-MDP and self-tensoring the instance for a constant number of times, we have:

▶ **Corollary 27.** *Assuming randomized ETH, for any prime power $p \geq 2$ and real number $\gamma > 1$, γ-Gap-k-MDP$_p$ has no $O_k(n^{o(k^\epsilon)})$ time algorithm, where $\epsilon = \Theta(\frac{1}{p \log \gamma \cdot \mathsf{polylog}(p)})$.*

5.3 Closest Vector Problem

We need a reduction from (2γ)-Gap-k-MLD$_q$ to γ-Gap-$2k$-CVP$_p$ from [13].

▶ **Theorem 28** ([13], Theorem 7.2). *For any real numbers $\gamma, p \geq 1$ and a prime number $q > 2\gamma$, there is a reduction from (2γ)-Gap-k-MLD$_q$ to γ-Gap-k'-CVP$_p$ runs in polynomial time, where $k' = 2k$.*

Use our gap-creating reduction for Gap-k-MLD, and apply gap amplification for a constant number of times to obtain 2γ-gap, then use Theorem 28 to reduce to Gap-k'-CVP, we have:

▶ **Corollary 29.** *Assuming ETH, there exists constant $c > 0$, for any real numbers $p, \gamma \geq 1$, γ-Gap-k-CVP$_p$ has no $O_k(n^{o(k^\epsilon)})$ time algorithm, where $\epsilon = \Theta(\frac{1}{\gamma^c})$.*

5.4 Shortest Vector Problem

Combining our work with [10], we show two ways of obtaining running time lower bound for γ-Gap-k-SVP$_p$. The first way reduces from Gap-k-CVP$_p$, obtaining lower bound for only a fixed constant ratio and all l_p norms where $p \geq 1$. The second way reduces from Gap-k-NCP$_q$, obtaining lower bound for all constant ratio and all l_p norms except for l_1.

5.4.1 Reduction From Gap-k-CVP$_p$

▶ **Theorem 30** ([10], Theorem 4.1 and 4.3, modified). *For any real numbers $p \geq 1$ and $\gamma' \in [1, 2)$ there exist a real number $\gamma \geq 1$ [7] and a reduction from γ-Gap-k-CVP$_p$ to γ'-Gap-k'-SVP$_p$ runs in polynomial time, where $k' \leq \gamma k$.*

Use Corollary 29 to obtain a γ_0-gap CVP instance, where γ_0 fits requirement in Theorem 30, then use Theorem 30 we have:

▶ **Corollary 31.** *Assuming randomized ETH, for any real numbers $p \geq 1$ and $\gamma \in [1, 2)$, γ-Gap-k-SVP$_p$ has no $O_k(n^{o(k^\epsilon)})$ time algorithm,where $0 < \epsilon < 1$ is some constant that depends on p and γ.*

5.4.2 Reduction From Gap-k-NCP$_2$

▶ **Theorem 32** ([10], Lemma 5.1 and Theorem 5.2, modified). *There exists a constant real $\mu \geq 1$ such that, for any real numbers $p > 1$ and $\gamma' \geq 1$, there exists a reduction from μ-Gap-k-NCP$_2$ to γ'-Gap-k'-SVP$_p$ runs in polynomial time, where $k' = O(k^c)$, $c > 1$ is a constant only depends on p and γ'*[8].

The reduction in Theorem 32 in fact proceeds in two steps: first reduces μ-Gap-k-NCP$_2$ to γ'-Gap-k'-SVP$_p$ for some fixed $\gamma' > 1$ with $k' < \mu k$ (while having some additional properties for the second step), then use a tensor technique to amplify the gap to any constant.

▶ **Corollary 33.** *Assuming randomized ETH, for any real numbers $p > 1$ and $\gamma \geq 1$, γ-Gap-k-SVP$_p$ has no $O_k(n^{o(k^\epsilon)})$ time algorithm, where $0 < \epsilon < 1$ is some constant that depends on p and γ.*

---

[7] $\gamma = (\max\left(12/\varepsilon, \frac{1}{(1+\varepsilon/2)^{1/p}-1}\right))^p$ where $\varepsilon = (\gamma')^{-1} - 1/2 > 0$.

[8] There are two problems here about the parameter blow-up, one is that $k' \leq (\mu k)^{O(1)}$ due to the Haviv-Regev "tensoring" step of SVP, the other is that to achieve final gap γ', the gap μ of NCP needs to satisfy $\frac{\mu}{2^p+1+\alpha\mu} > \gamma'$ for some $1/2 + 2^{-p} < \alpha < 1$, causing a polynomial blow-up of parameter to achieve such μ.

6 Conclusion

We have presented new ETH-based lower bounds for approximating parameterized nearest codeword problem and its related problems, improving upon the previous results from [10,13]. Our reduction technique is also simpler and more straight forward than the one used in [13]. However, our results still do not match the lower bound for constant Gap-k-NCP based on Gap-ETH [38]. A natural open problem is to close this gap by proving a stronger lower bound under an assumption that is weaker than Gap-ETH, such as constant Gap-k-Clique has no $n^{o(k)}$-time algorithm. This would be a key step towards understanding the fine-grained complexity of parameterized nearest codeword problem and its variants.

▶ **Open Problem 34.** *Prove $n^{o(k)}$ time lower bound of approximating k-NCP$_p$ or its related problems to any constant factor under assumptions weaker than Gap-ETH.*

To show such a result, as pointed out in [38], one might need to come up with a better "one-shot proof" that gives arbitrary constant factors without tensoring, and with linear parameter growth.

In this paper, we give a new method of composing *threshold graph* with vector problems to yield hardness of approximation results. We showed the limitation of analyzing collision number of a code from its relative distance in [32,37], and improved the analysis to bypass the limitation above. It might be interesting to consider whether this result can be further improved to yield threshold graph with better parameters, or some limitations of our method can be discovered, formally:

▶ **Open Problem 35.** *Give a better construction of strong threshold graph in Section 1.2 with $h = \Omega(k)$ and $m = O(k)$, or show that such graphs do not exist.*

Two-Source and Affine Non-Malleable Extractors for Small Entropy

Xin Li

Abstract

Non-malleable extractors are generalizations and strengthening of standard randomness extractors, that are resilient to adversarial tampering. Such extractors have wide applications in cryptography and have become important cornerstones in recent breakthroughs of explicit constructions of two-source extractors and affine extractors for small entropy. However, explicit constructions of non-malleable extractors appear to be much harder than standard extractors. Indeed, in the well-studied models of two-source and affine non-malleable extractors, the previous best constructions only work for entropy rate $> 2/3$ and $1 - \gamma$ for some small constant $\gamma > 0$ respectively by Li (FOCS' 23).

In this paper, we present explicit constructions of two-source and affine non-malleable extractors that match the state-of-the-art constructions of standard ones for small entropy. Our main results include:

- Two-source and affine non-malleable extractors (over F_2) for sources on n bits with min-entropy $k \geq \log^C n$ and polynomially small error, matching the parameters of standard extractors by Chattopadhyay and Zuckerman (STOC' 16, Annals of Mathematics' 19) and Li (FOCS' 16).
- Two-source and affine non-malleable extractors (over F_2) for sources on n bits with min-entropy $k = O(\log n)$ and constant error, matching the parameters of standard extractors by Li (FOCS' 23).

Our constructions significantly improve previous results, and the parameters (entropy requirement and error) are the best possible without first improving the constructions of standard extractors. In addition, our improved affine non-malleable extractors give strong lower bounds for a certain kind of read-once linear branching programs, recently introduced by Gryaznov, Pudlák, and Talebanfard (CCC' 22) as a generalization of several well studied computational models. These bounds match the previously best-known average-case hardness results given by Chattopadhyay and Liao (CCC' 23) and Li (FOCS' 23), where the branching program size lower bounds are close to optimal, but the explicit functions we use here are different. Our results also suggest a possible deeper connection between non-malleable extractors and standard ones.

1 Introduction

Randomness extractors are fundamental objects in the broad area of pseudorandomness. These objects have been studied extensively and found applications in diverse areas such as cryptography, complexity theory, combinatorics and graph theory, and many more.

Informally, randomness extractors are functions that transform imperfect randomness called weak random sources into almost uniform random bits. Originally, the motivation for studying these objects comes from the gap between the requirement of high-quality random bits in various computational and cryptographic applications, and the severe biases in natural random sources. In practice, weak random sources can arise in several different situations. For example, the random bits can become biased and correlated due to the natural process that generates them, or because of the fact that an adversary learns some partial information about a random string in cryptographic applications.

To measure the amount of randomness in a weak random source (a random variable) X, we use the standard definition of *min-entropy*: $H_\infty(X) = \min_{x \in \mathsf{supp}(X)} \log_2(1/\mathbf{Pr}[X = x])$. If $X \in \{0,1\}^n$, we say X is an $(n, H_\infty(X))$-source, or simply an $H_\infty(X)$-source if n is clear from context. We also say X has *entropy rate* $H_\infty(X)/n$. Ideally, one would like to construct deterministic extractors for all (n, k) sources when k is not too small. However, this is well known to be impossible, even if one only desires to extract one bit and k is as large as $n - 1$. Thus, to allow randomness extraction one has to put additional restrictions on the source.

Historically, many different models of randomness extractors have been studied. For example, if one gives the extractor an additional independent short uniform random seed, then there exist extractors that work for any (n, k) source. Such extractors, first introduced by Nisan and Zuckerman [64], are known as *seeded extractors*. These extractors have found wide applications, and by now we have almost optimal constructions (e.g., [62, 42, 35, 34]) after a long line of research.

However, seeded extractors may not be applicable in situations where the short uniform random seed is either not available (e.g., in cryptography) or cannot be simulated by cycling over all possible choices. For these applications, one needs *deterministic extractors* or *seedless extractors*, and many different models have also been studied in this setting. These include for example extractors for independent sources [20, 2, 3, 67, 7, 65, 4, 49, 52, 54, 53, 55, 22, 26, 18, 56, 30, 12, 23, 5, 27, 28, 57, 59, 47, 60], bit fixing sources [21, 46, 39, 66], affine sources [38, 8, 66, 72, 6, 69, 50, 56, 10, 60], samplable sources [70, 71], interleaved sources [68, 18], and small-space sources [45]. We define deterministic extractors below.

▶ **Definition 1.** *Let $\mathcal{X}$ be a family of distribution over $\{0,1\}^n$. A function $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}^m$ is a deterministic extractor for $\mathcal{X}$ with error ε if for every distribution $X \in \mathcal{X}$, we have*

$$\mathsf{Ext}(X) \approx_\varepsilon U_m,$$

where U_m stands for the uniform distribution over $\{0,1\}^m$, and $\approx_\varepsilon$ means ε-close in statistical distance. We say Ext is explicit if it is computable by a polynomial-time algorithm.

Among these models, two of the most well-studied are extractors for independent sources and affine sources. This is in part due to their connections to several other areas of interest. For example, extractors for independent sources are useful in distributed computing and cryptography with imperfect randomness [44, 43], and give explicit constructions of Ramsey graphs; while affine sources generalize bit-fixing sources, and extractors for affine sources have applications in exposure-resilient cryptography [21, 46] as well as Boolean circuit lower bounds [31, 37, 48].

Using simple probabilistic arguments, one can show that there exist extractors for two independent (n, k) sources with $k = \log n + O(1)$, which is optimal up to the constant $O(1)$. The first explicit construction of two-source extractors was given by Chor and Goldreich [20], which achieves $k > n/2$. Following a long line of research and several recent breakthroughs,

we now have explicit constructions of two-source extractors for entropy $k \approx 4n/9$ with error $\varepsilon = 2^{-\Omega(n)}$ [47], for entropy $k = \text{polylog}(n)$ with error $\varepsilon = 1/\mathsf{poly}(n)$ [18], and for entropy $k = O(\log n)$ with constant error [60]. Similarly, for affine sources which are uniform distributions over some unknown affine subspace over the vector space F_2^n, [1] one can show the existence of extractors for entropy $k = O(\log n)$, which is also optimal up to the constant $O(1)$. Regarding explicit constructions, we have affine extractors for entropy $k = \delta n$ with error $\varepsilon = 2^{-\Omega(n)}$ for any constant $\delta > 0$ [8, 72, 50], for entropy $k = \text{polylog}(n)$ with error $\varepsilon = 1/\mathsf{poly}(n)$ [56], and for entropy $k = O(\log n)$ with constant error [60].

In the past decade or so, a new kind of extractors, known as *non-malleable extractors*, has gained a lot of attention. These extractors are motivated from cryptographic applications. Informally, the setting is that an adversary can tamper with the inputs to an extractor in some way, and the non-malleable extractor guarantees that the output of the extractor is close to uniform even conditioned on the output of the extractor on the tampered inputs. The most well-studied non-malleable extractors include seeded non-malleable extractors [33], two-source non-malleable extractors [19], and affine non-malleable extractors [15]. These non-malleable extractors have wide applications in cryptography, such as privacy amplification with an active adversary [33] and non-malleable codes [36]. Furthermore, they turn out to have surprising connections to the constructions of standard extractors. Indeed, starting from the work of Li [52] which showed a connection between seeded non-malleable extractors and two-source extractors, these non-malleable extractors have played key roles, and now become important cornerstones in the recent series of breakthroughs that eventually lead to explicit constructions of two-source and affine extractors for asymptotically optimal entropy. In a more recent line of work [41, 17, 61], a special case of affine non-malleable extractors known as *directional affine extractors* is also shown to give strong lower bounds for certain read-once branching programs with linear queries, which generalize both standard read-once branching programs and parity decision trees. Given these applications, non-malleable extractors have become important objects that deserve to be studied on their own. We now define tampering functions and two kinds of non-malleable extractors below.

▶ **Definition 2** (Tampering Function). *For any function $f : S \to S$, We say f has no fixed points if $f(s) \neq s$ for all $s \in S$. For any $n > 0$, let $\mathcal{F}_n$ denote the set of all functions $f : \{0,1\}^n \to \{0,1\}^n$. Any subset of $\mathcal{F}_n$ is a family of tampering functions.*

▶ **Definition 3** ([19]). *A function $\mathsf{2nmExt} : (\{0,1\}^n)^2 \to \{0,1\}^m$ is a (k_1, k_2, ε) two source non-malleable extractor, if it satisfies the following property: Let X, Y be two independent, (n, k_1) and (n, k_2) sources, and $f, g : \{0,1\}^n \to \{0,1\}^n$ be two arbitrary tampering functions such that at least one of them has no fixed point,[2] then*

$$|\mathsf{2nmExt}(X, Y) \circ \mathsf{2nmExt}(f(X), g(Y)) - U_m \circ \mathsf{2nmExt}(f(X), g(Y))| < \varepsilon.$$

▶ **Definition 4** ([15]). *A function $\mathsf{anmExt} : \{0,1\}^n \to \{0,1\}^m$ is a (k, ε) affine non-malleable extractor if for any affine source X with entropy at least k and any affine function $f : \{0,1\}^n \to \{0,1\}^n$ with no fixed point, we have*

$$|\mathsf{anmExt}(X) \circ \mathsf{anmExt}(f(X)) - U_m \circ \mathsf{anmExt}(f(X))| \leq \varepsilon.$$

[1] In this paper we focus on the case where the field is F_2, for larger fields there are affine extractors with better parameters.

[2] We say that x is a fixed point of a function f if $f(x) = x$.

Using the probabilistic method, one can also prove the existence of these non-malleable extractors with excellent parameters. For example, [19] showed that two-source non-malleable extractors exist for (n, k) sources when $k \geq m + \frac{3}{2}\log(1/\varepsilon) + O(1)$ and $k \geq \log n + O(1)$. Similarly, it can be also shown that affine non-malleable extractors exist for entropy $k \geq 2m + 2\log(1/\varepsilon) + \log n + O(1)$.

However, constructing explicit non-malleable extractors appears to be significantly harder than constructing standard extractors, despite considerable effort. Indeed, even for seeded non-malleable extractors, the initial explicit constructions [32, 29, 51] only work for sources with entropy rate $> 1/2$, and it was not until [11] that explicit seeded non-malleable extractors for sources with poly-logarithmic entropy are constructed. After a long line of research [32, 29, 51, 52, 11, 24, 25, 12, 15, 23, 27, 28, 57, 59, 60], an asymptotically optimal seeded non-malleable extractor is finally constructed in [60]. On the other hand, the situation for two-source non-malleable extractors and affine non-malleable extractors is much worse, where the best-known constructions in [60] only achieve entropy $k > 2n/3$ and $k \geq (1-\gamma)n$ for a small constant $\gamma > 0$. This is in sharp contrast to the constructions of standard two-source and affine extractors, where explicit constructions can work for entropy $k = \text{polylog}(n)$ with polynomially small error [18, 56], and for entropy $k = O(\log n)$ with constant error [60].

1.1 Our Results

In this paper, we study two-source and affine non-malleable extractors for small entropy. Our main results give explicit constructions of such non-malleable extractors that essentially match their standard counterparts in the small entropy regime. Specifically, we give explicit two-source and affine non-malleable extractors for $\text{polylog}(n)$ entropy with polynomially small error and for $O(\log n)$ entropy with constant error. We have the following theorems.

▶ **Theorem 5.** *There exists a constant $C > 1$ such that for any $k \geq \log^C n$, there exists an explicit construction of a $(k, k, n^{-\Omega(1)})$ two-source non-malleable extractor with output length $\Omega(k)$.*

▶ **Theorem 6.** *There exists a constant $C > 1$ such that for any $k \geq \log^C n$, there exists an explicit construction of a $(k, n^{-\Omega(1)})$ affine non-malleable extractor with output length $k^{\Omega(1)}$.*

▶ **Theorem 7.** *There exists a constant $c > 1$ such that for any $k \geq c\log n$, there exists an explicit construction of a $(k, k, O(1))$ two-source non-malleable extractor with output length 1.*

▶ **Theorem 8.** *There exists a constant $c > 1$ such that for any $k \geq c\log n$, there exists an explicit construction of a $(k, O(1))$ affine non-malleable extractor with output length 1.*

▶ Remark 9. The output length in the two theorems for entropy $k \geq c\log n$ can be extended to a constant number by using the standard XOR lemma and previous techniques (e.g., those in [56]). Furthermore, our constructions can also be extended to handle multiple tampering functions as in [11]. For simplicity, we omit the details here.

The following tables summarize our results compared to some of the best previous constructions.

Table 1 Prior and current results on two-source non-malleable extractors.

Two-source Non-malleable Extractor	Entropy k_1	Entropy k_2	Output m	Error ε
[11]	$n - n^{\gamma}$	$n - n^{\gamma}$	$n^{\Omega(1)}$	$2^{-n^{\Omega(1)}}$
[59]	$(1-\gamma)n$	$(1-\gamma)n$	$\Omega(n)$	$2^{-\Omega(\frac{n \log\log n}{\log n})}$
[1]	$(\frac{4}{5}+\delta)n$	$\log^C n$	$\Omega(\min\{k_1,k_2\})$	$2^{-\min\{k_1,k_2\}^{\Omega(1)}}$
[60]	$(\frac{2}{3}+\gamma)n$	$k = O(\log n)$	$\Omega(k)$	$2^{-\Omega(k)}$
This work (Theorem 5)	$k \geq \text{polylog}(n)$	$k \geq \text{polylog}(n)$	$\Omega(k)$	$n^{-\Omega(1)}$
This work (Theorem 7)	$O(\log n)$	$O(\log n)$	1	$O(1)$

Table 2 Prior and current results on affine non-malleable extractors.

Affine Non-malleable Extractor	Entropy k	Output m	Error ε
[15]	$n - n^{\delta}$ for some constant $\delta \in (0,1)$	$n^{\Omega(1)}$	$2^{-n^{\Omega(1)}}$
[60]	$(1-\gamma)n$, $\gamma < 1/1000$	$\Omega(n)$	$2^{-\Omega(n)}$
This work (Theorem 6)	$\text{polylog}(n)$	$k^{\Omega(1)}$	$n^{-\Omega(1)}$
This work (Theorem 8)	$O(\log n)$	1	$O(1)$

Our results thus significantly improve the entropy requirement of previous non-malleable extractors. As a comparison, we list below the best-known explicit two-source extractors and affine extractors for small entropy.

Table 3 Best-known results on two-source extractors.

Two-source Extractor	Entropy k	Output m	Error ε
[18]	$\text{polylog}(n)$	1	$n^{-\Omega(1)}$
[63, 56, 13]	$\text{polylog}(n)$	$k^{\Omega(1)}$	$n^{-\Omega(1)}$
[5]	$O(\log n 2^{O(\sqrt{\log\log n})})$	1	$O(1)$
[27]	$O(\log n (\log\log n)^{O(1)})$	1	$O(1)$
[58]	$O(\log n \log\log n)$	1	$O(1)$
[59]	$O(\log n \frac{\log\log n}{\log\log\log n})$	1	$O(1)$
[60]	$O(\log n)$	1	$O(1)$

Table 4 Best-known results on affine extractors.

Affine Extractor	Entropy k	Output m	Error ε
[56]	$\text{polylog}(n)$	$k^{\Omega(1)}$	$n^{-\Omega(1)}$
[10]	$O(\log n \log\log n \log\log\log^6 n)$	1	$O(1)$
[16]	$O(\log n \log\log n \log\log\log^3 n)$	1	$O(1)$
[60]	$O(\log n)$	1	$O(1)$

It can be seen that the parameters of our two-source and affine non-malleable extractors essentially match those of standard two-source and affine extractors for small entropy. We also point out that the error of our non-malleable extractors is the best one can hope for without first improving the error of standard two-source and affine extractors for small entropy, since the non-malleable extractors are stronger versions of extractors, and in particular, they are themselves two-source and affine extractors. Finally, given that our constructions use many of the key components in the constructions of standard extractors, we believe that any future

techniques that improve the error of standard two-source and affine extractors for small entropy (e.g., to negligible error) are also likely applicable to our constructions to get the same improvement on the error of two-source and affine non-malleable extractors.

1.2 Applications to Lower bounds for Read-Once Linear Branching Programs

Our affine non-malleable extractors have applications in proving average-case hardness against read-once linear branching programs (ROLBPs). This computational model was recently introduced by Gryaznov, Pudlák, and Talebanfard [41] as a generalization of several important and well-studied computational models such as decision trees, parity decision trees, and standard read-once branching programs. Roughly, a read-once linear branching program is a branching program that can make linear queries to the input string, while these queries are linearly independent along any path. Formally, we have the following definition.

▶ **Definition 10** (Linear branching program [41]). *A linear branching program on F_2^n is a directed acyclic graph P with the following properties:*

- *There is only one source s in P.*
- *There are two sinks in P, labeled with 0 and 1 respectively.*
- *Every non-sink node v is labeled with a linear function $\ell_v : \mathsf{F}_2^n \to \mathsf{F}_2$. Moreover, there are exactly two outgoing edges from v, one is labeled with 1 and the other is labeled with 0.*

The size of P is the number of non-sink nodes in P. P computes a Boolean function $f : \{0,1\}^n \to \{0,1\}$ in the following way. For every input $x \in \mathsf{F}_2^n$, P follows the computation path by starting from s, and when on a non-sink node v, moves to the next node following the edge with label $\ell_v(x) \in \{0,1\}$. The computation ends when the path ends at a sink, and $f(x)$ is defined to be the label on this sink.

[41] defines two kinds of read-once linear branching programs (ROLBP for short).

▶ **Definition 11** ([41]). *Given any linear branching program P and any node v in P, let Pre_v denote the span of all linear queries that appear on any path from the source to v, excluding the query ℓ_v. Let Post_v denote the span of all linear queries in the subprogram starting at v.*

- *A linear branching program P is weakly read-once if for every inner node v of P, it holds that $\ell_v \notin \mathsf{Pre}_v$.*
- *A linear branching program P is strongly read-once if for every inner node v of P, it holds that $\mathsf{Pre}_v \cap \mathsf{Post}_v = \{0\}$.*

Both kinds of ROLBPs generalize the aforementioned computational models, but weakly read-once linear branching programs (WROLBPs) are more flexible than strongly read-once linear branching programs (SROLBPs). As a result, proving lower bounds for WROLBPs turns out to be much harder than for SROLBPs. Indeed, so far we only have non-trivial lower bounds for SROLBPs. To state our results, we use the following definition.

▶ **Definition 12** ([17]). *For a Boolean function $f : \{0,1\}^n \to \{0,1\}$, let $\mathsf{SROLBP}(f)$ denote the smallest possible size of a strongly read-once linear branching program that computes f, and $\mathsf{SROLBP}_\varepsilon(f)$ denote the smallest possible size of a strongly read-once linear branching program P such that*

$$\mathbf{Pr}_{x \leftarrow_U \mathsf{F}_2^n}[P(x) = f(X)] \geq \frac{1}{2} + \varepsilon.$$

The definition can be adapted to ROBPs naturally.

[41] shows that a stronger version of affine extractors known as *directional affine extractors* give strong average case lower bounds for SROLBPs. They give an explicit construction of directional affine extractors for entropy $k \geq \frac{2n}{3} + c$ with error $\varepsilon \leq 2^{-c}$ for any constant $c > 1$, which also implies exponential average-case hardness for SROLBPs of size up to $2^{\frac{n}{3} - o(n)}$. In a follow-up work, Chattopadhyay and Liao [17] used another kind of extractors known as *sumset extractors* [14] to give an alternative average-case hardness for SROLBPs. In particular, they gave an explicit function Ext such that $\mathsf{SROLBP}_{n^{-\Omega(1)}}(\mathsf{Ext}) \geq 2^{n - \log^{O(1)} n}$. More recently, Li [60] gave an improved sumset extractor which in turn yields an explicit function Ext such that $\mathsf{SROLBP}_{2^{-\Omega(1)}}(\mathsf{Ext}) \geq 2^{n - O(\log n)}$. In these two constructions, the branching program size lower bounds become quite close to optimal (the result of [60] is optimal up to the constant in $O(\cdot)$), while the correlation becomes polynomially large or a constant. Another recent work by Li and Zhong [61] gave explicit directional affine extractor for entropy $k \geq cn(\log\log\log n)^2/\log\log n$ with error $\varepsilon = 2^{-n^{\Omega(1)}}$ for some constant $c > 1$, which implies exponential average-case hardness for SROLBPs of size up to $2^{n - o(n)}$.

For simplicity, we do not define directional affine extractors here, but just mention that directional affine extractors are a special case of affine non-malleable extractors. Hence, our new constructions of affine non-malleable extractors directly imply improved directional affine extractors, which in turn also give average-case hardness for SROLBPs. Specifically, we have the following theorem.

▶ **Theorem 13.** *There exist explicit functions* anmExt_1, anmExt_2 *such that* $\mathsf{SROLBP}_{n^{-\Omega(1)}}(\mathsf{anmExt}_1) \geq 2^{n - \log^{O(1)} n}$ *and* $\mathsf{SROLBP}_{2^{-\Omega(1)}}(\mathsf{anmExt}_2) \geq 2^{n - O(\log n)}$.

These bounds match the previously best-known average-case hardness results for SROLBPs given in [17] and [60], where the branching program size lower bounds are close to optimal, but the explicit functions we use here are different. Specifically, here we use affine non-malleable extractors while [17] and [60] use sumset extractors.

2 Technical Overview

Here we outline the main techniques used in this paper, opting for an informal approach at times for clarity while omitting certain technical details.

We use the standard notation in the literature where a letter with $'$ represents a tampered version. Let f and g denote the tampering functions on X and Y in two-source non-malleable extractors, respectively, and $\mathcal{A}$ be the affine tampering function in affine non-malleable extractors.

Since two-source and affine non-malleable extractors are themselves two-source and affine extractors, our high-level idea is to adapt the constructions of standard extractors for polylogarithmic or logarithmic entropy into the stronger, non-malleable version. Clearly, a direct naive application of standard extractors may not work, since the output on the tampered inputs may be correlated to the output on the original inputs. Below we start with two-source extractors to illustrate our main ideas. Let us first briefly review the constructions of two-source extractors for small entropy. Generally, these extractors are double-layered: the outer layer is a suitable resilient function, which is designed to be an extractor for non-oblivious bit-fixing (NOBF) sources with t-wise independent property for some parameter t. That is, most of the bits are t-wise independently uniform, while the rest of the bits can depend arbitrarily on these bits. Here, the extractor uses a crucial property that bounded independence suffices to work for several resilient functions (or equivalently these functions are *fooled* by bounded independence), such as the derandomized Ajtai-Linial function in [18]

or the Majority function. The inner layer is a transformation that transforms two independent sources into a single NOBF source with the t-wise independent property. This step itself utilizes techniques from seeded non-malleable extractors or correlation breakers, which are functions designed to break correlations between random variables.

To adapt the construction to two-source non-malleable extractors, our first observation is that there is an easy case. Intuitively, this is the case where one input source has large entropy conditioned on the tampered version. For instance, say the source X has high entropy conditioned on every fixing of $X' = f(X) = x'$. Then in the analysis, we can first fix X', and then further fix the tampered output of the extractor, which is now a deterministic function of Y and can be chosen to have a relatively small size. Conditioned on these fixings, we have X and Y are still independent and have good entropy, hence any two-source extractor will give an output that is close to uniform conditioned on the tampered output.

However, it is certainly possible that the above does not hold. For example, the tampering function f can be an injective function, so that conditioned on any fixing of $X' = f(X) = x'$, we have that X is also fixed. In this case, our observation is that X' itself must also have large entropy (since f injective), therefore we can possibly create structures in the distribution of the tampered version as well. Specifically, our strategy is to modify the inner layer of the two-source extractor while essentially using the same outer layer. For simplicity, let us consider extractors with just one bit of output. A standard approach to show the output bit is close to uniform conditioned on the tampered output, is to show that the parity of these two bits is close to uniform. Since the outer extractor is a resilient function, this suggests to look at the parity of two copies of resilient functions on two correlated distributions.

Now another crucial observation behind our construction is that just like in the construction of standard two-source extractors, for certain resilient functions, the parity of two copies of such functions is still fooled by bounded independence. Thus, if in the inner layer, we can create structures such that the *joint distribution* of the NOBF source and the tampered version has the t-wise independent property, then we will be able to show that the extractor is non-malleable. Note that we are now in the case where the tampered sources also have high entropy, which works in our favor since achieving t-wise independence requires a certain amount of entropy. However, we cannot simply use previous techniques since the tampered sources are correlated with the original sources. Therefore, we appropriately modify previous constructions of correlation breakers to ensure the t-wise independent property in the joint distribution.

Finally, in the actual analysis, we are not guaranteed to be in either case; and it may happen that for some x', conditioned on $X' = x'$ we have that X has large entropy, while for others conditioned on $X' = x'$ we have that X has small entropy. The analysis thus needs a careful interpolation between different cases in terms of a convex combination of subsources. We now elaborate with more details on each of these aspects below.

First we give some notation that will help with our presentation.

▶ **Definition 14** (t-non-malleable (k, ε) seeded extractor)**.** *A function* $\mathsf{nmExt} : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ *is a t-non-malleable (k, ε) extractor if it satisfies the following property: if X is a (n, k)-source and Y is uniform on $\{0,1\}^d$, and $f_1, \cdots, f_t$ are arbitrary functions from d bits to d bits with no fixed point, then*

$$(\mathsf{nmExt}(X, Y), \mathsf{nmExt}(X, f_1(Y)), \cdots, \mathsf{nmExt}(X, f_t(Y)), Y) \approx_\varepsilon (U_m, \mathsf{nmExt}(X, f_1(Y)), \cdots, Y).$$

We say a distribution or a source X on n bits is (q, t, γ) independent if there exists a subset $S \subseteq [n]$ with $|S| \leq q$ such that if we consider the bits of X in $[n] \setminus S$, then every t bits are γ-close to uniform.

A t-non-malleable (k, ε) seeded extractor nmExt with seed length d can be used to generate a (q, t, γ) source from a source X with entropy at least k in the following way: cycle over all possible seeds i, and for each one output a bit $\mathsf{nmExt}(X, i)$. The output is now $(\sqrt{\varepsilon}D, t+1, t\sqrt{\varepsilon})$ independent with $D = 2^d$.

2.1 Taking the parity of two resilient functions

A Boolean function on n variables is a resilient function if it is nearly balanced, and no small coalition can have a significant influence on the output of the function. Such functions are equivalent to extractors for NOBF sources. The resilient functions that have played a key role in the recent advancement of extractors are the derandomized Ajtai-Linial function in [18] and the Majority function. The former is a monotone AC^0 function, that is fooled by polylog(n)-wise independence, while the latter is a threshold function that can be fooled by constant-wise independence.

It is not hard to show that the parity of two independent copies of resilient functions is still a resilient function. What is left to show is that such a parity can also be fooled by bounded independence. When the resilient function is in AC^0, we observe that the parity of two such functions is also in AC^0, because the parity of two bits can be written as a constant size AC^0 circuit. Therefore, the parity of two derandomized Ajtai-Linial functions is still in AC^0, and can be fooled by polylog(n)-wise independence by Braverman's celebrated result [9] on bounded independence fooling AC^0 circuits, together with some standard techniques.

To show that constant-wise independence fools the parity of two Majority functions, we use the work of Gopalan, O'Donnell, Wu, and Zuckerman [40], which shows that constant-wise independence fools any function of halfspaces under product distributions, as long as the function can be implemented as a constant size circuit. In our case, this clearly holds since we are just taking the parity of two Majority functions. Using the XOR lemma and previous techniques (e.g., those in [56], our construction can also be extended to output a constant number of bits.

2.2 Generating NOBF sources from the inputs and its tampered counterparts

We want to construct a function such that when the tampered sources have sufficient entropy, the joint distribution of the generated bits from the input sources and the tampered sources is (q, t, γ) independent for some suitable parameters q, t, and γ.

The standard approach for two-source extractors, as introduced in [18], is to first apply a seeded non-malleable extractor to one source, say Y, and then use another source X to sample a small number of bits from the output. However, in our case, this black-box approach does not work since the tampered sources are correlated with the original inputs. Therefore, we have to create some kind of difference between the tampered sources and the original sources, which will enable us to get the desired (q, t, γ) independent property.

To achieve this, we dig into the constructions of seeded non-malleable extractors and existing two-source non-malleable extractors, which roughly go as follows. First, one uses an *advice generator* to create a short string that is different from the tampered version with high probability. Then, conditioned on the fixing of the advice strings, one can argue that the two sources are still independent and have sufficient entropy. At this point one uses a *correlation breaker with advice*, together with the advice strings to compute the output, which is guaranteed to have the non-malleable property. However, the steps of generating advice and subsequent application of correlation breakers require the sources to have very large entropy (e.g., at least 2/3), which is the main reason that previous two-source non-malleable extractors can only work for large entropy.

To get around this barrier, our approach is to first apply a standard seeded extractor to one source Y, and output say $\Omega(k)$ bits where k is the entropy. By cycling over all possible seeds, we potentially get a matrix with $D = 2^d$ rows where d is the seed length of the seeded extractor. We then use the other source X to sample a small number ($\mathsf{poly}(n)$) of rows from the output. Now, again a standard argument implies that most of the rows are close to uniform. Since we are in the case where the tampered sources X', Y' have sufficient entropy, this is also true for the tampered version. Note that we haven't achieved the (q, t, γ) independent property yet. Our next step is to generate advice from the original sources and the tampered sources. However, in the low-entropy regime, it is hard to generate a single advice for the input sources and the tampered version – the advice generator requires generating uniform seeds to sample from an encoding of the inputs and it is hard to do so from a slice of the sources which could have zero entropy. Therefore, we generate advice from each row. We can then append the index of this row to the advice. This ensures that the advice strings are both different from the tampered version, and also different between different rows. Now, we can apply existing constructions of correlation breakers with advice, which will ensure that for any t rows in the combined matrix from the original sources and the tampered sources, as long as all these rows have high entropy initially, the joint distribution of the final outputs from the correlation breaker is γ-close to uniform.

However, there are additional tricky issues with this approach. First, the correlation breaker requires two independent sources to work, while in our case the outputs in the matrices are already functions of both X and Y. Second, the analysis of the correlation breaker usually requires fixing the advice strings first and arguing that the sources still have sufficient entropy, but now since the matrices have $\mathsf{poly}(n)$ rows and the entropy of the sources is just $k = \mathrm{polylog}(n)$, or even $k = O(\log n)$, if we fix all the advice strings then conditioned on the fixing the sources may not have any entropy left. Finally, the set of "good" rows (the rows that are close to uniform after the sampling using X) in the matrices depends on the source X and Y, and after we fix the advice strings in the analysis, X and Y may have become different, and this could potentially change the set of "good" rows in the first place.

To solve these issues, we use an argument similar to that in [55]. The idea is that since eventually we only need (q, t, γ) independence, in the analysis we can just focus on every subset of t rows from the good rows. In particular, we can set t and the entropy k appropriately, i.e., t is relatively small compared to k. This is because we only need $t = \mathrm{polylog}(n)$ to apply the derandomized Ajtai-Linial in [18] and $t = O(1)$ to apply the Majority function. Now in the analysis, notice that the process of sampling using the source X basically corresponds to $\mathsf{Ext}(Y, \mathsf{Ext}'(X, i))$ where $\mathsf{Ext}, \mathsf{Ext}'$ are two seeded extractors. Thus when t is small, for any subset T with $|T| = t$, we can first fix all $\mathsf{Ext}'(X, i)$ with $i \in T$. By restricting the size of $\mathsf{Ext}'(X, i)$, X still has sufficient entropy conditioned on these fixings, and now the t rows of the outputs $\mathsf{Ext}(Y, \mathsf{Ext}'(X, i))$ are deterministic functions of Y, while X and Y are still independent. By restricting the size of the advice strings, we can preserve the above properties when the analysis fixes the advice strings and goes into the correlation breaker. Finally, as in the analysis in [55], the final error pays a price of a $\mathsf{poly}(n)^t$ factor from a union bound on all possible subsets of size t, which is still fine as long as we set $k \gg t \log n$ and use seeded extractors with error $2^{-\Omega(k)}$ in the correlation breaker.

2.3 Convex combination of subsources

In the above two subsections, we dealt with the case where the tampered sources have sufficient entropy. We now sketch the analysis for the general case.

Let 2nmExt be the two-source non-malleable extractor which works if both X and X' have entropy at least k_x, and both Y and Y' have entropy at least k_y, with error $\varepsilon/2$ and output length m. Now assume X has min-entropy $2k_x + \log(2/\varepsilon)$, and Y has min-entropy $2k_y + \log(2/\varepsilon)$. Further assume without loss of generality that both X and Y are flat sources, i.e., uniform distributions over some unknown subset. The analysis goes by considering the "heavy" elements in the tampered sources X' and Y'. Specifically, for any $x' \in \{0,1\}^n$ and $y' \in \{0,1\}^n$, we consider the pre-image size of $X' = x'$ and $Y' = y'$. If one of them is large, say without loss of generality that the pre-image size of $X' = x'$ is at least 2^{k_x}, then $H_\infty(X|X' = x) \geq k_x$. We can first fix $X' = x'$ and then $\mathsf{2nmExt}(x', Y')$, which is a deterministic function of Y now conditioned on the fixing of $X' = x'$. Since $\mathsf{2nmExt}(x', Y')$ is short compared to $H_\infty(Y)$, conditioned on these fixings we have that X and Y are still independent and have sufficient entropy, so $\mathsf{2nmExt}(X, Y)$ is close to uniform because 2nmExt is itself a two-source extractor. Note that we have already fixed $\mathsf{2nmExt}(x', Y')$, and thus 2nmExt is indeed non-malleable in this case.

Next, consider the set of all the x' whose pre-image size under f is at most 2^{k_x}, and call it BAD_X. If the total probability mass of these x' is at most $\varepsilon/2$, then we can just ignore them (and the corresponding x in the support of X) since this only adds an extra error of $\varepsilon/2$. Similarly, we can also ignore the set of all the y' whose pre-image size under g is at most 2^{k_y} (call it BAD_Y), if the total probability mass of these y' is at most $\varepsilon/2$. In either case, we are done. Otherwise, the subsource of X' formed by all the $x' \in \mathrm{BAD}_X$ has min-entropy at least $-\log(2^{k_x}/(\varepsilon 2^{2k_x}/\varepsilon)) = k_x$, and the corresponding subsource of X has min-entropy at least $2k_x$. Similarly, the subsource of Y' formed by all the $y' \in \mathrm{BAD}_Y$ has min-entropy at least k_y, and the corresponding subsource of Y has min-entropy at least $2k_y$. In this case, both sources and their tampered versions have sufficient entropy, thus by the analysis before, 2nmExt is also a non-malleable extractor.

Since X is just a convex combination of subsources $(X \mid X' = x' \in \mathrm{BAD}_x)$ and $\{(X \mid X' = x' \notin \mathrm{BAD}_x)\}$, and the same is true for Y, the correctness of 2nmExt follows.

Finally, we note that we can modify the two-source non-malleable extractor to output $k^{\Omega(1)}$ bits, by using a similar approach based on the XOR lemma as in [56]. Then, since the two-source non-malleable extractor is strong, we can further apply a standard seeded extractor to increase the output length to $\Omega(k)$.

2.4 Affine non-malleable extractors

Our construction of affine non-malleable extractors roughly follows the same ideas. The difference is that now we do not have access to two independent sources, but the affine source itself has nice structures and the tampering function is affine. Thus, by using appropriate linear seeded extractors as in previous works, certain parts of the affine source behave like independent sources. Therefore, we can suitably adapt our construction of two-source non-malleable extractors to affine non-malleable extractors. One particularly nice property of affine sources is that when applying a strong linear seeded extractor on an affine source, the output on most seeds *is uniform*. This implies that we can generate from an affine source a somewhere random source with no error. In the two-source case, we cannot analyze the generation of NOBF source directly from the definition of the correlation breaker (and have to resort to additional techniques as mentioned in previous paragraph 2.2) due to the error of the somewhere random source. In the affine case, there is no such concern. Therefore, we can argue that we obtain a NOBF source directly from the definition of affine correlation breaker, as in prior works on affine extractors for small entropy (e.g., [10]).

3 Conclusion and Open Problems

In this paper, we significantly improved constructions of two-source and affine non-malleable extractors, and our constructions essentially match standard extractors in the regime of small entropy. We note that any future improvement of extractors for NOBF sources (e.g., improvement in the error) can also translate into improvements of our two-source and affine non-malleable extractors. Furthermore, our results suggest that there may be a deeper connection between standard extractors and their non-malleable counterparts, since their constructions and parameters appear quite similar. In particular, previous works have extensively used non-malleable extractors to construct standard extractors, but is it possible that the reverse direction may also be true? That is, can one also use standard extractors to construct non-malleable extractors?

Better Decremental and Fully Dynamic Sensitivity Oracles for Subgraph Connectivity

Yaowei Long

Yunfan Wang
Tsinghua University, Beijing, China

Abstract

We study the *sensitivity oracles problem for subgraph connectivity* in the *decremental* and *fully dynamic* settings. In the fully dynamic setting, we preprocess an n-vertices m-edges undirected graph G with n_{off} deactivated vertices initially and the others are activated. Then we receive a single update $D \subseteq V(G)$ of size $|D| = d \leq d_\star$, representing vertices whose states will be switched. Finally, we get a sequence of queries, each of which asks the connectivity of two given vertices u and v in the activated subgraph. The decremental setting is a special case when there is no deactivated vertex initially, and it is also known as the *vertex-failure connectivity oracles* problem.

We present a better deterministic vertex-failure connectivity oracle with $\widehat{O}(d_\star m)$ preprocessing time, $\widetilde{O}(m)$ space, $\widetilde{O}(d^2)$ update time and $O(d)$ query time, which improves the update time of the previous almost-optimal oracle [14] from $\widehat{O}(d^2)$ to $\widetilde{O}(d^2)$.

We also present a better deterministic fully dynamic sensitivity oracle for subgraph connectivity with $\widehat{O}(\min\{m(n_{\text{off}} + d_\star), n^\omega\})$ preprocessing time, $\widetilde{O}(\min\{m(n_{\text{off}} + d_\star), n^2\})$ space, $\widetilde{O}(d^2)$ update time and $O(d)$ query time, which significantly improves the update time of the state of the art [9] from $\widetilde{O}(d^4)$ to $\widetilde{O}(d^2)$. Furthermore, our solution is even almost-optimal assuming popular fine-grained complexity conjectures.

1 Introduction

We study the *sensitivity oracles problem for subgraph connectivity* in the *decremental* and *fully dynamic* settings, which is one of the fundamental dynamic graph problems in undirected graphs. In the fully dynamic setting, this problem has three phases. In the preprocessing phase, given an integer $d_\star$, we preprocess an n-vertices m-edges undirected graph $G = (V, E)$ in which some vertices are *activated*, called *on-vertices* and denoted by V_{on}, while the others are *deactivated*, called *off-vertices* and denoted by V_{off}. We let $n_{\text{on}} = |V_{\text{on}}|$ and $n_{\text{off}} = |V_{\text{off}}|$ denote the number of initial on-vertices and off-vertices respectively. In the update phase, we will receive a set $D \subseteq V$ with $|D| = d \leq d_\star$, representing vertices whose states will be switched, and we update the oracle. In the subsequent query phase, let $V_{\text{new}} = (V_{\text{on}} \setminus D) \cup (V_{\text{off}} \cap D)$ denote the activated vertices after the update. Each query will give a pair of vertices $u, v \in V_{\text{new}}$ and ask the connectivity of u and v in the new activated subgraph $G[V_{\text{new}}]$. The decremental setting is a special case where there is no off-vertices initially, i.e. V_{off} is empty.

The decremental version of this problem is also called the *vertex-failure connectivity oracles* problem, which has been studied extensively, e.g. [4, 5, 18, 17, 14, 13], and its complexity was well-understood up to subpolynomial factors. Specifically, a line of works by

Duan and Pettie [4, 5] started the study on vertex-failure connectivity oracles for general $d_\star$, and they finally gave a deterministic oracle with $\widetilde{O}(mn)$ preprocessing time, $\widetilde{O}(md_\star)$ space, $\widetilde{O}(d^3)$ update time and $O(d)$ query time. Following [4, 5], Long and Saranurak [14] presented an improved solution with $\widehat{O}(m) + \widetilde{O}(md_\star)$ preprocessing time, $\widetilde{O}(m)$ space, $\widehat{O}(d^2)$ update time and $O(d)$ query time[1], which is optimal up to subpolynomial factors because matching (conditional) lower bounds for all the four complexity measurements were shown in [7, 5, 14]. We refer to Table 1 for more solutions to this problem (for example, Kosinas [13] proposed a simple and practical algorithm using a conceptually different approach). However, there are still relatively large subpolynomial overheads on the current almost-optimal upper bounds (i.e., on the preprocessing time and update time of the LS-oracle), so a natural question is whether we can improve them:

Can we design an almost-optimal deterministic vertex-failure connectivity oracle with only polylogarithmic overheads on the update time, or even on all complexity bounds?

The fully dynamic sensitivity oracles problem for subgraph connectivity was studied by [8, 9]. Henzinger and Neumann [8] showed a black-box reduction from the decremental setting. Plugging in the almost-optimal decremental algorithm of [14], this reduction leads to a fully dynamic sensitivity oracle with $\widehat{O}(n_{\text{off}}^2 m) + \widetilde{O}(d_\star n_{\text{off}}^2 m)$ preprocessing time, $\widetilde{O}(n_{\text{off}}^2 m)$ space, $\widehat{O}(d^4)$ update time and $O(d^2)$. Hu, Kosinas and Polak [9] studied this problem from an equivalent but different perspective called *connectivity oracles for predictable vertex failures*, which gave a solution with $\widetilde{O}((n_{\text{off}} + d_\star)m)$ preprocessing time, $\widetilde{O}((n_{\text{off}} + d_\star)m)$ space, $\widetilde{O}(d^4)$ update time and $O(d)$ query time[2]. Despite the efforts, there are still gaps between the upper bounds of the fully dynamic setting and the decremental setting (except the query time). Naturally, one may have the following question:

Can we match the upper bounds in the fully dynamic and decremental settings or show separations between them for all the four measurements?

Notably, [9] showed a conditional lower bound $\widehat{\Omega}((n_{\text{off}} + d_\star)m)$ on the preprocessing time[3], which separated two settings at the preprocessing time aspect. However, the right complexity bounds are still not clear for the space and the update time. In particular, given that two different approaches [8, 9] both showed upper bounds around d^4 for update time, it is interesting to identify if this is indeed a barrier or it just happened accidentally. Furthermore, we note that it seems hard to improve the update time following either of these two approaches, because the black-box reduction by [8] has been plugged in the almost-optimal decremental oracle, and the fully dynamic oracle by [9] generalizes the decremental oracle by [13], where the latter already has $\widetilde{O}(d^4)$ update time.

1.1 Our Results

We give a partially affirmative answer to the first question and answer the second question affirmatively by the following results.

---

[1] Throughout the paper, we use $\widetilde{O}(\cdot)$ to hide a polylog(n) factor and use $\widehat{O}(\cdot)$ to hide a $n^{o(1)}$ factor.

[2] In [9], they modeled the problem using slightly different parameters, and here we describe their bounds using our parameters. Basically, they defined a parameter d' (named d in their paper) in the preprocessing phase and η in the update phase. Their η is equivalent to our d. Besides, fixing $d_\star$ and n_{off}, our input instances can be reduced to theirs with d' at most $n_{\text{off}} + d_\star$. In the other direction, fixing d', their input instances can be reduced to ours with $d_\star + n_{\text{off}}$ at most $3d'$. Furthermore, their space complexity was not specified, but to our best knowledge, it should be roughly proportional to their preprocessing time.

[3] This lower bound is obtained from input instances with $n_{\text{off}} = \Theta(n)$ and m is roughly linear to n.

The Decremental Setting

We show a better vertex-failure connectivity oracle by improving the $\widehat{O}(d^2)$ update time of the current almost-optimal solution [14] to $\widetilde{O}(d^2)$. See Corollary 8 for a detailed version of Theorem 1.

▶ **Theorem 1.** *There exists a deterministic vertex-failure connectivity oracle with $\widehat{O}(m) + \widetilde{O}(d_\star m)$ preprocessing time, $\widetilde{O}(m)$ space, $\widetilde{O}(d^2)$ update time and $O(d)$ query time.*

Same as all the previous vertex-failure connectivity oracles, we can substitute all the m factors in Theorem 1 with $\bar{m} = \min\{m, n(d_\star + 1)\}$ using a standard sparsification by Nagamochi and Ibaraki [15] at a cost of an additional $O(m)$ preprocessing time.

Table 1 Complexity of known vertex-failure connectivity oracles. All the m factors can be replaced by $\bar{m} = \min\{m, n(d_\star + 1)\}$ at a cost of an additional $O(m)$ preprocessing time. The randomized algorithms are all Monte Carlo. The notation $\bar{O}(\cdot)$ hides a polyloglog(n) factor.

	Det.	$O(m \log^* n)$	$\hat{O}(m) + \tilde{O}(d_\star m)$	$\hat{O}(d^2)$	$O(d)$
Kosinas [13]	Det.	$O(d_\star m \log n)$	$O(d_\star m \log n)$	$O(d^4 \log n)$	$O(d)$
This paper	Det.	$O(m \log^3 n)$	$\widehat{O}(m) + O(d_\star m \log^3 n)$	$O(d^2(\log^7 n + \log^5 n \log^4 d))$	$O(d)$

We emphasize that our result is a strict improvement on [14]. In addition to the improvement on update time, our algorithm also improves the hidden subpolynomial overheads on the preprocessing time. We achieve this by giving a new construction algorithm of the *low degree hierarchy*, a graph decomposition technique widely used in this area [5, 14, 16]. Roughly speaking, the previous almost-linear-time construction [14] relies on modern graph techniques including vertex expander decomposition and approximate vertex capacitated maxflow algorithm, which are highly complicated and will bring relatively large subpolynomial overheads. Our new construction bypasses the vertex expander decomposition to obtain improvement on both efficiency and quality, which is also considerably simpler. Finally, we point out that the subpolynomial factors in our preprocessing time still comes from the construction of the low degree hierarchy, which can be traced back to the subpolynomial overheads of the current approximate vertex capacitated maxflow algorithm [2].

The Fully Dynamic Setting

We also show a better fully dynamic sensitivity oracle for subgraph connectivity, with update time and query time matching the decremental bounds up to polylogarithmic factors. See Theorem 17 for a detailed version of Theorem 2. The first upper bound $\widehat{O}(m)+\widetilde{O}(m(n_{\text{off}}+d_\star))$ is obtained from a combinatorial algorithm[4].

[4] *Combinatorial* algorithms [1] are algorithms that do not use fast matrix multiplication.

▶ **Theorem 2.** *There exists a deterministic fully dynamic sensitivity oracle for subgraph connectivity with $\widehat{O}(m) + \widetilde{O}(\min\{m(n_{\text{off}} + d_\star), n^\omega\})$ preprocessing time, $\widetilde{O}(\min\{m(n_{\text{off}} + d_\star), n^2\})$ space, $\widetilde{O}(d^2)$ update time and $O(d)$ query time, where ω is the exponent of matrix multiplication.*

Table 2 Complexity of known fully dynamic sensitivity oracles for subgraph connectivity.

	Det./ Rand.	Space	Preprocessing	Update	Query
Henzinger & Neumann [8]	Det.	$\widetilde{O}(n_{\text{off}}^2 m)$	$\widehat{O}(n_{\text{off}}^2 m) + \widetilde{O}(d_\star n_{\text{off}}^2 m)$	$\widehat{O}(d^4)$	$O(d^2)$
Hu, Kosinas & Polak [9]	Det.	$\widetilde{O}((n_{\text{off}} + d_\star)m)$	$\widetilde{O}((n_{\text{off}} + d_\star)m)$	$\widetilde{O}(d^4)$	$O(d)$
This paper	Det.	$O(\min\{(n_{\text{off}} + d_\star)m \log^2 n, n^2\})$	$\widehat{O}(m)+$ $O(\min\{(n_{\text{off}} + d_\star)m, n^\omega\} \log^2 n)$	$O(d^2 \log^7 n)$	$O(d)$

We also show conditional lower bounds on the preprocessing time and the space, which separate the fully dynamic and decremental settings. Furthermore, combining our new lower bounds and the existing ones, our solution in Theorem 2 is optimal up to subpolynomial factors.

▶ **Theorem 3.** *Let $\mathcal{A}$ be a fully dynamic sensitivity oracle for subgraph connectivity with S space, t_p preprocessing time, t_u update time and t_q query time upper bounds. Assuming popular conjectures, we have the following:*

1. *If $t_u + t_p = f(d) \cdot n^{o(1)}$, then $S = \widehat{\Omega}(n^2)$. (See Lemma 7.10 in the full version)*
2. *If $t_u + t_p = f(d) \cdot n^{o(1)}$, then $t_u = \widehat{\Omega}((n_{\text{off}} + d)m)$ (See [9])*
3. *If $t_u + t_p = f(d) \cdot n^{o(1)}$, then $t_u = \widehat{\Omega}(n^{\omega_{\text{bool}}})$ (See Lemma 7.3 in the full version)*
4. *If $t_p = \text{poly}(n)$, then $t_u + t_q = \widehat{\Omega}(d^2)$. (See [14])*
5. *If $t_p = \text{poly}(n)$ and $t_u = \text{poly}(dn^{o(1)})$, then $t_q = \widehat{\Omega}(d)$. (See [7])*

The $f(d)$ above can be an arbitrary growing function, and ω_{bool} is the exponent of Boolean matrix multiplication.

We make some additional remarks here. When discussing lower bounds, we assume $d = d_\star$ for each update. The lower bound on the space (item 1) holds even when the input graphs are sparse, so it naturally holds for input graphs with general density. The lower bounds on the preprocessing time (items 2 and 3) are not contradictory, because item 2 is obtained from sparse graphs while item 3 is obtained from dense graphs. The lower bounds on the update time and query time (items 4 and 5) are from those in the decremental setting. See Section 7 in the full version for the omitted proofs and more discussions.

1.2 Organization

In Section 2, we give an overview of our techniques. In Section 3, we give the preliminaries. In Section 4, we introduce our new construction of the low degree hierarchy and obtain a better vertex-failure connectivity oracle as a corollary. In Sections 5 and 6, we describe the preprocessing, update and query algorithms of our fully dynamic sensitivity oracle for subgraph connectivity. Due to space constraints, some proofs are omitted and can be found in the full version. In particular

2 Technical Overview

Better Vertex-Failure Connectivity Oracles

Our main contribution is a new construction of the *low degree hierarchy*. Then we obtain a better vertex-failure connectivity oracle as a corollary by combining the new construction of the low degree hierarchy and the remaining part in [14].

It is known that the construction of the low degree hierarchy can be reduced to $O(\log n)$ calls to the *low-degree Steiner forest decomposition* [5, 14]. Basically, for an input graph G with terminal set $U \subseteq V(G)$, we say a forest $F \subseteq E(G)$ is a *Steiner forest* of U in G if F spans the whole U (may also span some additional non-U vertices) and for each $u, v \in U$, u, v are connected in F if and only if they are connected in G. We propose a new almost-linear time low-degree Steiner forest decomposition algorithm as shown in Lemma 4, which improves the degree parameter Δ from $n^{o(1)}$ to $O(\log^2 n)$ compared to the previous one by [14]. This will leads to an improvement to the quality of the low degree hierarchy, and finally reflects on the update time.

▶ **Lemma 4** (Lemma 12, Informal). *Let G be an undirected graph with terminals $U \subseteq V(G)$. There is an almost-linear-time algorithm that computes a* separator *$|X| \subseteq V(G)$ of size $|X| \leq |U|/2$, and a low-degree Steiner forest of $U \setminus X$ in $G \setminus X$ with maximum degree $\Delta = O(\log^2 n)$.*

In the following discussion, we assume $U = V(G)$ for simplicity (hence spanning trees/-forests and Steiner trees/forests are now interchangable). To obtain Lemma 4, our starting point is that it is *not* necessary to perform a vertex expander decomposition (which will bring large $n^{o(1)}$ overheads to Δ) to get a low-degree Steiner forest decomposition. Basically, in [14], they obtain a fast low-degree Steiner forest decomposition by first proving that any vertex expander admits a low-degree spanning tree, so then it suffices to perform the stronger vertex expander decomposition. The way they prove the former is to argue that for any vertex expander H, one can embed another expander W into H with low vertex-congestion, which implies that H has a low-degree subgraph including all vertices in $V(H)$.

The key observation is that, to make the above argument work, W does not need to be an expander and W can be an arbitrary *connected graph*. This inspires us to design the following subroutine Lemma 5. Then Lemma 4 can be shown by invoking Lemma 10 using a standard divide-and-conquer framework.

▶ **Lemma 5** (Lemma 10, Informal). *Let G be an undirected graph. There is an almost-linear-time algorithm that computes either*

- *a balanced sparse vertex cut (L, S, R) with $|R| \geq |L| \geq |V(G)|/12$ and $|S| \leq 1/(100 \log n) \cdot |L|$.*
- *a large subset $V' \subseteq V(G)$ with $|V'| \geq 3|U|/4$ s.t. we can embed a connected graph W' with $V(W') = V'$ into $G[V']$ with vertex congestion $O(\log^2 n)$, which implies a spanning tree in $G[V']$ with maximum degree $O(\log^2 n)$.*

We design the algorithm in Lemma 5 using a simplified *cut-matching game*. The original cut-matching game [12, 11] can be used to embed an expander into a graph with low congestion (or produce a balanced sparse cut). To embed a connected graph, consider the following procedure. Assume a standard matching player (i.e. Lemma 9) which, given a graph G and a balanced partition (A, B) of $V(G)$, either embeds a large matching between A and B into G with low vertex-congestion or outputs a balanced sparse vertex cut in almost-linear time. Start with a graph W with $V(W) = V(G)$ but no edge and perform several rounds. At each round, we (as the cut player) partition the connected components of W into two parts with balanced sizes, and feed the partition to the matching player. If

the matching player gives a matching, we add it to W and go to the next round. The game stops once a giant connected component (of size at least $3|V(G)|/4$) appears in W, which will roughly serve as W'. Roughly speaking, the game will stop in $O(\log n)$ rounds because at each round, there exists a large fraction of vertices, s.t. for each of them (say vertex v), the component containing v has its size doubled.

Fully Dynamic Sensitivity Oracles for Subgraph Connectivity

Our fully dynamic oracle is actually a generalization of a simplified version of the decremental oracle in [14].

Initially, we construct a low degree hierarchy on the activated subgraph $G_{\text{on}} := G[V_{\text{on}}]$. As mentioned in [14], the hierarchy will roughly reduce G_{on} to the following *semi-bipartite* form. First, V_{on} can be partitioned into L_{on} and R_{on}, called *left on-vertices* and *right on-vertices* respectively, s.t. there is no edge connecting two vertices in R_{on}. Second, L_{on} is spanned by a known path τ. Therefore, we assume the original graph G has a semi-bipartite G_{on} from now.

When there is no off-vertices initially (i.e. the decremental setting), the properties of a semi-bipartite G_{on} naturally support the following update and query strategy. In the update phase, removing vertices in D will break the path τ into at most $d+1$ *intervals*, and we will somehow (we will not explain this in the overview) recompute the connectivity of these intervals in the graph $G_{\text{on}} \setminus D$. Then, for each query of $u, v \in V_{\text{on}} \setminus D$, it suffices to find two intervals I_u, I_v connecting with u, v in $G_{\text{on}} \setminus D$ respectively. When u, v are left on-vertices, I_u, I_v can be found trivially. When u, v are right on-vertices, we just need to scan at most $d+1$ neighbors of each of u, v, which takes $O(d)$ time. Note that removing D will generate at most $d+1$ intervals is a crucial point to achieve fast update time.

Back to the fully dynamic setting, for an update D, in addition to removing vertices $D_{\text{on}} := D \cap V_{\text{on}}$ from G_{on}, we will also add vertices $D_{\text{off}} := D \cap V_{\text{off}}$ and their incident edges. The key observation is that $G[V_{\text{on}} \cup D_{\text{off}}]$ is still roughly a semi-bipartite graph. The first property will still hold if we put the newly activated vertices D_{off} into the left side. The second property may not hold because we do not have a path spanning the new left vertices $L_{\text{on}} \cup D_{\text{off}}$. However, this will not hurt because we can still partition $L_{\text{on}} \cup D_{\text{off}}$ into $O(d)$ connected parts after removing D_{on} from $G[V_{\text{on}} \cup D_{\text{off}}]$, i.e. at most $d+1$ intervals covering $L_{\text{on}} \setminus D_{\text{on}}$, and at most d vertices in D_{off}.

Giving this key observation, it is quite natural to adapt the decremental algorithm to the fully dynamic setting. Using the ideas of *adding artificial edges* (intuitively, substituting each right vertex and its incident edges with an artificial clique on its left neighbors) and applying *2D range counting structure*, we can design an update algorithm with $\widetilde{O}(d^3)$ update time [5]. To improve the update time to $\widetilde{O}(d^2)$, we can use a *Borůvka's styled* update algorithm and implement it by considering *batched adjacency queries* on intervals [14].

3 Preliminaries

Throughout the paper, we use the standard graph theoretic notation. For any graph, we use $V(\cdot)$ and $E(\cdot)$ to denote its vertex set and edge set respectively. If there is no other specification, we use G to denote the original graph on which we will build the oracle, and we let $n = |V(G)|$ and $m = |E(G)|$. Initially, the vertices $V(G)$ in the original graph are partitioned into *on-vertices* V_{on} and *off-vertices* V_{off}, and we let $n_{\text{off}} = |V_{\text{off}}|$. For a graph H and any $S \subseteq V(H)$, we let $H[S]$ denote the subgraph induced by vertices S. Also, for any $S \subseteq V(H)$, we use $H \setminus S$ to denote the graph after removing vertices in S and edges incident to them. Similarly, for any $F \subseteq E(H)$, $H \setminus F$ denote the graph after removing edges in F.

We also use the notion of *multigraphs*. For a multigraph H, its edge set $E(H)$ is a *multiset*. We use $+$ and $\sum$ to denote the union operation and use $-$ to denote the subtraction operation on multiset. We let ω denote the exponent of matrix multiplication and ω_{bool} denote the exponent of Boolean matrix multiplication. To our best knowledge, currently ω and ω_{bool} have the same upper bound.

4 The Low Degree Hierarchy

The *low degree hierarchy* was first introduced in [5] to design efficient vertex-failure connectivity oracles. The construction of this hierarchy in [5] is based on the approximate minimum degree Steiner forest algorithm of [6], which gives $\tilde{O}(mn)$ construction time. Later, an alternative construction algorithm was shown in [14] by exploiting vertex expander decomposition, which improves the construction time to $m^{1+o(1)}$, at a cost of a small quality loss.

In this section, we will show a new construction algorithm, which still runs in almost-linear time and gives a hierarchy with quality better than the one in [14] (but still worse than the one in [5]). To obtain the quality improvement, we basically simplify the construction in [14] and bypass the vertex expander decomposition.

We define the low degree hierarchy in Definition 6, and the main result of this section is Theorem 7. It was known that constructing a low degree hierarchy reduces to several rounds of *low-degree Steiner forest decomposition*. In Section 4.1, we introduce our key subroutine Lemma 10, which given an input graph, either computes a balanced sparse vertex cut or a low-degree Steiner tree covering a large fraction of terminals. In Section 4.2, we show the low-degree Steiner forest decomposition algorithm Lemma 12 using Lemma 10 in a standard divide and conquer framework, and then complete the proof of Theorem 7.

▶ **Definition 6** (Low Degree Hierarchy [5], Definition 5.1 in [14]). *Let G be a connected undirected graph. A (p, Δ)-low degree hierarchy with height p and degree parameter Δ on G is a pair $(\mathcal{C}, \mathcal{T})$ of sets, where $\mathcal{C}$ is a set of vertex-induced connected subgraphs called components, and $\mathcal{T}$ is a set of Steiner trees with maximum vertex degree at most Δ.*

The set $\mathcal{C}$ of components is a laminar set. Concretely, it satisfies the following properties.

(1) *Components in $\mathcal{C}$ belong to p levels and we denote by $\mathcal{C}_i$ the set of components at level i. In particular, at the top level p, $\mathcal{C}_p = \{G\}$ is a singleton set with the whole G as the unique component. Furthermore, for each level $i \in [1, p]$, components in $\mathcal{C}_i$ are vertex-disjoint and there is no edge in $E(G)$ connecting two components in $\mathcal{C}_i$.*

(2) *For each level $i \in [1, p-1]$ and each component $\gamma \in \mathcal{C}_i$, there is a unique component $\gamma' \in \mathcal{C}_{i+1}$ such that $V(\gamma) \subseteq V(\gamma')$, where we say that γ' is the parent-component of γ and that γ is a child-component of γ'.*

(3) *For each component $\gamma \in \mathcal{C}$, the terminals of γ, denoted by $U(\gamma)$, are vertices in γ but not in any of γ's child-components. Note that $U(\gamma)$ can be empty. In particular, for each $\gamma \in \mathcal{C}_1$, $U(\gamma) = V(\gamma)$.*

Generally, for each level $i \in [1, p]$, we define the terminals at level i be terminals in all components in $\mathcal{C}_i$, denoted by $U_i = \bigcup_{\gamma \in \mathcal{C}_i} U(\gamma)$.

The set $\mathcal{T}$ of low-degree Steiner trees has the following properties.

(4) *$\mathcal{T}$ can also be partitioned into subsets $\mathcal{T}_1, ..., \mathcal{T}_p$, where $\mathcal{T}_i$ denote trees at level i and trees in $\mathcal{T}_i$ are vertex-disjoint.*

(5) *For each level $i \in [1, p]$ and tree $\tau \in \mathcal{T}_i$, the terminals of τ is defined by $U(\tau) = U_i \cap V(\tau)$.*

(6) *For each level $i \in [1, p]$ and each component $\gamma \in \mathcal{C}_i$ with $U(\gamma) \neq \emptyset$, there is a tree $\tau \in \mathcal{T}_i$ such that $U(\gamma) \subseteq U(\tau)$, denoted by $\tau(\gamma)$. We emphasize that two different components γ and $\gamma' \in \mathcal{C}_i$ may correspond to the same tree $\tau \in \mathcal{T}_i$.*

For better understanding, we note that the terminal sets of component $\{U(\gamma) \mid \gamma \in \mathcal{C}\}$, levels $\{U_i \mid 1 \leq i \leq p\}$, and Steiner trees $\{U(\tau) \mid \tau \in \mathcal{T}\}$ are all partitions of $V(G)$. One may also get the picture of the hierarchy from the perspective of construction. See the construction described in Algorithm 2, which invokes Lemma 12 in a black-box way.

▶ **Theorem 7.** *Let G be an undirected graph. There is a deterministic algorithm that computes a (p, Δ)-low degree hierarchy with $p = O(\log n)$ and $\Delta = O(\log^2 n)$. The running time is $m^{1+o(1)}$.*

Corollary 8 is obtained by substituting the construction of low degree hierarchy in [14] with ours. Formally speaking, it is a corollary of Theorem 7, and Lemma 6.14, Theorem 7.2 and Section 7.3 in [14].

▶ **Corollary 8.** *There is a deterministic vertex-failure connectivity oracle with $\widehat{O}(m) + O(d_\star m \log^3 n)$ preprocessing time, $O(m \log^3 n)$ space, $O(d^2(\log^7 n + \log^5 n \cdot \log^4 d))$ update time and $O(d)$ query time.*

4.1 A Balanced Sparse Vertex Cut or a Low-Degree Steiner Tree

The goal of this subsection is to show Lemma 10, a subroutine which given a graph with terminals, outputs either a balanced sparse vertex cut or a low-degree Steiner tree covering a large fraction of terminals. In fact, some expander decomposition algorithms (e.g. [3]) exploit a similar subroutine which either computes a balanced sparse cut or certifies that a large part of the graph is an expander. Our subroutine can be viewed as a weaker and simplified version, because similar to the notion of expanders, a low-degree Steiner tree is also an object that certifies some kind of (weaker) well-linkedness.

At a high level, our algorithm uses a simplified *cut-matching-game* framework. A cut-matching game is an interactive process between a cut player and a matching player with several rounds. Start from a graph with no edge. In each round, the cut player will select a cut and then the matching player is required to add a perfect matching on this cut. It is known that there exists cut-player strategies against an arbitrary matching player that guarantees the final graph is an expander after $\widetilde{O}(1)$ rounds [12, 11]. In the proof of Lemma 10, we show a cut-player strategy that only guarantees the final graph is a *connected graph*. Combining a classic matching player as shown in Lemma 9, we can either find a balanced sparse vertex cut or embed a connected graph covering most of the terminals into the original graph with low vertex congestion. In the latter case, the embedding leads to a low-degree subgraph covering most of the terminals. Finally, picking an arbitrary spanning tree in this subgraph suffices.

Given a cut w.r.t. terminals, Lemma 9 will either output a balanced sparse vertex cut or a large matching between terminals that is embeddable into the original graph with low vertex congestion. In fact, it is a simplified version of the matching player in [14], and the proof can be found in Appendix A.1 of the full version.

▶ **Lemma 9.** *Let G be an undirected graph with a terminal set U. Given a parameter ϕ and a partition (A, B) of U, there is a deterministic algorithm that computes either*

- *a vertex cut (L, S, R) with $|R \cap U| \geq |L \cap U| \geq \min\{|A|, |B|\}/3$ and $|S| \leq \phi \cdot |L \cap U|$, or*
- *a matching M between A and B with size $|M| \geq \min\{|A|, |B|\}/3$ s.t. there is an embedding $\Pi_{M \to G}$ of M into G with vertex congestion at most $\lceil 1/\phi \rceil$.*

The running time is $m^{1+o(1)}$. If the output is a matching M, the algorithm can further output the edge set $E(\Pi_{M \to G})$ of the embedding $\Pi_{M \to G}$.

▶ **Lemma 10.** *Let G be an undirected graph with a terminal set U. Given parameters $0 < \epsilon, \phi \leq 1/4$, there is a deterministic algorithm that computes either*

- *a vertex cut (L, S, R) with $|R \cap U| \geq |L \cap U| \geq \epsilon|U|/3$ and $|S| \leq \phi \cdot |L \cap U|$, or*
- *a subset $U_{\text{drop}} \subseteq U$ of terminals with $|U_{\text{drop}}| \leq \epsilon|U|$ and a Steiner tree τ on $G \setminus U_{\text{drop}}$ of terminal set $U \setminus U_{\text{drop}}$ with maximum degree $O(\log |U|/\phi)$.*

Proof. The algorithm is made up of an iteration phase and a postprocessing phase. The iteration phase will maintain an incremental graph W with $V(W) = U$, called the *witness graph*, and its embedding $\Pi_{W \to G}$ into G. Precisely, instead of storing the embedding $\Pi_{W \to G}$ explicitly, the algorithm will only store its edge set $E(\Pi_{W \to G})$. Initially, the witness graph $W^{(0)}$ has no edge and $E(\Pi_{W^{(0)} \to G})$ is empty. We use $W^{(i)}$ and $E(\Pi_{W^{(i)} \to G})$ to denote the witness graph and the edge set of the embedding right after the i-th round.

In the iteration phase, we do the following steps in the i-th round.

1. We compute all the connected components of $W^{(i-1)}$, which forms a partition $\mathcal{Q}^{(i-1)}$ of U s.t. each $Q \in \mathcal{Q}^{(i-1)}$ is a subset of $|U|$, called a *cluster*. If there is a cluster $Q^\star \in \mathcal{Q}^{(i-1)}$ has $|Q^\star| \geq (1-\epsilon)|U|$, then we terminate the iteration phase and go to the postprocessing phase, otherwise we proceed to the next step.
2. Because step 1 guarantees that all clusters in $\mathcal{Q}^{(i-1)}$ have size at most $(1-\epsilon)|U|$, we will partition $\mathcal{Q}^{(i-1)}$ into two groups $\mathcal{Q}_A$ and $\mathcal{Q}_B$ depending on the following two cases.
   - **(a)** If all clusters in $\mathcal{Q}^{(i-1)}$ have size at most $|U|/2$, then we partition $\mathcal{Q}^{(i-1)}$ into $\mathcal{Q}_A$ and $\mathcal{Q}_B$ s.t. $\sum_{Q \in \mathcal{Q}_A} |Q| \geq |U|/4$ and $\sum_{Q \in \mathcal{Q}_B} |Q| \geq |U|/4$.
   - **(b)** Otherwise, there is a unique cluster $Q^\star$ s.t. $|U|/2 < |Q^\star| \leq (1-\epsilon)|U|$, and we let $\mathcal{Q}_A = \mathcal{Q} \setminus \{Q^\star\}$ and $\mathcal{Q}_B = \{Q^\star\}$.

   Let $A_i = \bigcup_{Q \in \mathcal{Q}_A} Q$ and $B_i = \bigcup_{Q \in \mathcal{Q}_B} Q$. Note that by definition, (A_i, B_i) forms a partition of U. We have $|A_i|, |B_i| \geq |U|/4$ in case (a) and $|A_i|, |B_i| \geq \epsilon|U|$ in case (b).
3. We apply Lemma 9 on graph G and terminal U with parameter ϕ and the partition (A_i, B_i) of U. If we get a vertex cut (L, S, R), it will satisfy $|R \cap U| \geq |L \cap U| \geq \min\{|A_i|, |B_i|\}/3 \geq \epsilon|U|/3$ and $|S| \leq \phi \cdot |L \cap U|$ as desired, so we can terminate the whole algorithm with (L, S, R) as the output. Otherwise, we get a matching M_i between A_i and B_i with size $|M_i| \geq |A_i|/3$, and the edge set $E(\Pi_{M_i \to G})$ of some embedding $\Pi_{M_i \to G}$ that has vertex congestion $O(1/\phi)$. Then we let $W^{(i)} = W^{(i-1)} \cup M_i$ and $E(\Pi_{W^{(i)} \to G}) = E(\Pi_{W^{(i-1)} \to G}) \cup E(\Pi_{M_i \to G})$, and proceed to the next round.

If the algorithm does not end at step 3, it exits the iteration phase at step 1, and then we perform the following postprocessing phase. Let W denote the final witness graph with connected components $\mathcal{Q}$ and a cluster $Q^\star \in \mathcal{Q}$ s.t. $|Q^\star| \geq (1-\epsilon)|U|$. Note that $Q^\star \subseteq U$. Let G' be the subgraph of G induced by $E(\Pi_{W \to G})$. By the definition of embedding, vertices in $Q^\star$ are also connected in G'. In other words, $Q^\star$ is contained by a connected component of G'. We can take an arbitrary spanning tree τ of this component as a Steiner tree of $V(\tau) \cap U$, and define $U_{\text{drop}} = U \setminus V(\tau)$ be the uncovered terminals.

We now show that U_{drop} and τ have the desire property. The number of uncovered terminals is bounded by $|U_{\text{drop}}| \leq |U| - |V(\tau) \cap U| \leq |U| - |Q^\star| \leq \epsilon|U|$, and τ is a Steiner tree of $U \setminus U_{\text{drop}}$ with maximum degree $O(\log |U|/\phi)$ because G' has maximum degree at most the vertex congestion of $\Pi_{W \to G}$, which is at most $O(\log |U|/\phi)$ by Claim 11.

▷ Claim 11. The number of rounds in the iteration phase is at most $O(\log |U|)$, and the vertex congestion of the final embedding $\Pi_{W \to G}$ is at most $O(\log |U|/\phi)$.

Proof. Note that the early rounds will go into case (a) in step 2, while the late rounds will go into case (b). We bound the number of case-(a) rounds and case-(b) rounds separately.

The number of case-(a) rounds is at most $O(\log |U|)$ by the following reason. We define a potential function $\Phi(W)$ of the witness graph by

$$\Phi(W) = \sum_{Q \in \mathcal{Q}} \sum_{v \in Q} \log |Q| = \sum_{Q \in \mathcal{Q}} |Q| \cdot \log |Q|.$$

In particular, for each cluster $Q \in \mathcal{Q}$ and each vertex $v \in Q$, we say the potential at v is $\log |Q|$.

Because initially $\Phi(W^{(0)}) = 0$ and we always have $\Phi(W) \leq |U| \log |U|$, it is sufficient to show that each case-(a) round increases the potential by at least $\Omega(|U|)$. To see this, consider the i-th case-(a) round. For each matching edge $\{u, v\} \in M_i$, let $Q_v^{(i-1)}$ (resp. $Q_u^{(i-1)}$) be the connected component of $W^{(i-1)}$ that contains v (resp. u), and assume without loss of generality that $|Q_v^{(i-1)}| \leq |Q_u^{(i-1)}|$. Then the connected component $Q_v^{(i)}$ of $W^{(i)}$ that contains v will have $|Q_v^{(i)}| \geq 2|Q_v^{(i-1)}|$, because $Q_v^{(i)} \supseteq Q_u^{(i-1)} \cup Q_v^{(i-1)}$. In other words, this round will increase the potential at v (from $\log |Q_v^{(i-1)}|$ to $\log |Q_v^{(i)}|$) by at least 1. Summing over $|M_i|$ matching edges, the total potential $\Phi(W)$ will be increased by at least $|M_i| \geq |U|/12$ as desired, because the potential at any $v \in V(W)$ will never drop.

It remains to show that the number of case-(b) rounds is at most $O(\log |U|)$. This is simple because in each round, the matching M_i will merge at least $|A_i|/3$ terminals in $|A_i|$ into the giant cluster $Q^\star$, which means $|Q^\star|$ will reach the threshold $(1 - \epsilon)|U|$ in $O(\log |U|)$ many case-(b) rounds and then the iteration phase ends.

The final embedding $\Pi_{W \to G}$ has vertex congestion $O(\log |U|/\phi)$ because there are $O(\log |U|)$ rounds and the embedding $\Pi_{M_i \to G}$ has vertex congestion $O(1/\phi)$ each round. ◁

4.2 The Low-Degree Steiner Forest Decomposition

Lemma 12 describes the low-degree Steiner forest decomposition algorithm, which invokes Lemma 10 in a divide-and-conquer fashion. For simplicity, the readers can always assume $\epsilon = 1/2$, which is the value we will choose when constructing the low degree hierarchy. We introduce this tradeoff parameter ϵ just to show that our algorithm has the same flexibility as those in [5, 14].

▶ **Lemma 12.** *Let G be an undirected graph with a terminal set U. Given a parameter $0 < \epsilon \leq 1/2$, there is a deterministic algorithm that computes*

- *a vertex set $X \subseteq V(G)$, called the separator, s.t. $|X| \leq \epsilon |U|$, and*
- *for each connected component Y of $G \setminus X$ s.t. U intersects $V(Y)$, a Steiner tree τ_Y spanning $U \cap V(Y)$ on Y with maximum degree $O(\log^2 |U|/\epsilon)$.*

The running time is $m^{1+o(1)}/\epsilon$.

We include the algorithm of Lemma 12 in Algorithm 1, and the complete proof can be founded in the full version.

Algorithm 1 The low-degree Steiner forest decomposition $\text{SFDecomp}(G, U)$.

Input: An undirected graph G with terminals U.
Output: A separator X and a collection $\mathcal{T}$ of Steiner trees $\{\tau_Y\}$.

Let $\epsilon' = \epsilon/2$ and $\phi = \epsilon'/\log|U|$
Apply Lemma 10 on G and U with parameters ϵ' and ϕ.
if Lemma 10 outputs a vertex cut (L, S, R) **then**
    $(X_L, \mathcal{T}_L) \leftarrow \text{SFDecomp}(G[L], L \cap U)$
    $(X_R, \mathcal{T}_R) \leftarrow \text{SFDecomp}(G[R], R \cap U)$
    Return $X = X_L \cup X_R \cup S$ and $\mathcal{T} = \mathcal{T}_L \cup \mathcal{T}_R$.
else
    Otherwise Lemma 10 outputs $U_{\text{drop}} \subseteq U$ and a Steiner tree τ of $U \setminus U_{\text{drop}}$ on $G \setminus U_{\text{drop}}$.
    Return $X = U_{\text{drop}}$ and $\mathcal{T} = \{\tau\}$.
end if

As shown in [5], to construct a low-degree hierarchy $(\mathcal{C}, \mathcal{T})$, it suffices to invoke the low-degree Steiner forest decomposition (with $\epsilon = 1/2$) $O(\log n)$ times. The algorithm is shown in Algorithm 2, and the proof of correctness is included in Appendix A.2 in the full version.

Algorithm 2 The construction of the low-degree hierarchy.

Input: An undirected graph G.
Output: A low-degree hierarchy $(\mathcal{C}, \mathcal{T})$.

Initialize $i = 1$, $X_1 = V(G)$.
while X_i is not empty **do**
    $(X_{i+1}, \mathcal{T}_i) \leftarrow \text{SFDecomp}(G, X_i)$ with $\epsilon = 1/2$.
    $i \leftarrow i + 1$.
end while
$p \leftarrow i - 1$, which denotes the number of levels.
for each level i **do**
    $U'_i \leftarrow X_i \cup ... \cup X_p$.
    $\mathcal{C}_i \leftarrow$ the connected component of $G \setminus U'_{i+1}$ (particularly, $U'_{p+1} = \emptyset$).
    $U_i \leftarrow U'_i \setminus U'_{i+1}$, which denotes the terminals of level i.
end for

5 The Preprocessing Algorithm

In this section, we will describe the preprocessing algorithm, which basically first computes the low degree hierarchy on $G_{\text{on}} := G[V_{\text{on}}]$, and then constructs some affiliated data structures on top of the hierarchy.

The low degree hierarchy $(\mathcal{C}, \mathcal{T})$ is computed by applying Theorem 7 on G_{on}, if G_{on} is a connected graph. In the case that G_{on} is not connected, we simply apply Theorem 7 on each of the connected components of G_{on}. To simplify the notations, we use $(\mathcal{C}, \mathcal{T})$ to denote the union of hierarchies of connected components of G_{on}, and still say $(\mathcal{C}, \mathcal{T})$ is the low degree hierarchy of G_{on}. Note that $(\mathcal{C}, \mathcal{T})$ has all properties in Definition 6, except that the top level $\mathcal{C}_1$ are now made up of connected components of G_{on}.

In Section 5.1, we introduce the notions of artificial edges and the artificial graph $\hat{G}$. In Section 5.2, we define a global order π based on Euler tour orders of Steiner trees in $\mathcal{T}$, and then construct a 2D range counting structure which can answer the number of edges in $E(\hat{G})$ between two intervals on π. Finally, in Section 5.3, we summarize what we will store, and analyse the preprocessing time and the space complexity.

5.1 Artificial Edges and the Artificial Graph $\hat{G}$

The artificial graph $\hat{G}$ is a multi-graph constructed by adding some *artificial edges* into the original graph G in the following way. For each component $\gamma \in \mathcal{C}$, let A_γ collect the neighbors of $V(\gamma)$ in G, formally defined by $A_\gamma = \{v \mid v \in V(G) \setminus V(\gamma) \text{ s.t. } \exists\{u, v\} \in E(G) \text{ with } u \in V(\gamma)\}$. We call A_γ the *adjacency list* of γ. Let $A_{\gamma,\text{on}} = A_\gamma \cap V_{\text{on}}$ and $A_{\gamma,\text{off}} = A_\gamma \cap V_{\text{off}}$. Next, we let $B_{\gamma,\text{off}} = A_{\gamma,\text{off}}$ and let $B_{\gamma,\text{on}}$ be an arbitrary subset of $A_{\gamma,\text{on}}$ with size $\min\{d_\star + 1, |A_{\gamma,\text{on}}|\}$. Then define $B_\gamma = B_{\gamma,\text{on}} \cup B_{\gamma,\text{off}}$.

The artificial edges added by the component γ is then $\hat{E}_\gamma = \{\{u, v\} \mid u \in A_\gamma, v \in B_\gamma, u \neq v\}$. Namely, $\hat{E}_\gamma$ consists of a clique on B_γ and a biclique between B_γ and $A_\gamma \setminus B_\gamma$. Finally, the artificial graph $\hat{G}$ is defined by $\hat{G} = G + \sum_{\gamma \in \mathcal{C}} \hat{E}_\gamma$. We emphasize that $\hat{G}$ is a multi-graph, and those edges connecting the same endpoints will have different identifiers.

We show some useful properties in Proposition 13. Item 3 of Proposition 13 basically says that, if A_γ has an on-vertex after update, then B_γ also has one.

▶ **Proposition 13.** *We have the following.*

1. $\sum_{\gamma \in \mathcal{C}} |A_\gamma| \leq O(pm)$.
2. $|E(\hat{G})| \leq O(pm(n_{\text{off}} + d_\star))$.
3. *Given any update $D \subseteq V$ with $|D| \leq d_\star$, if $(A_{\gamma,\text{on}} \setminus D) \cup (A_{\gamma,\text{off}} \cap D) \neq \emptyset$, then we have $(B_{\gamma,\text{on}} \setminus D) \cup (B_{\gamma,\text{off}} \cap D) \neq \emptyset$.*

Proof.

Part 1. For each $\gamma \in \mathcal{C}$, observe that $|A_\gamma| \leq \sum_{v \in V(\gamma)} \deg_G(v)$. Hence $\sum_{\gamma \in \mathcal{C}} |A_\gamma| \leq O(pm)$ because each vertex can appear in at most p components (at most one at each level).

Part 2. By definition, $|E(\hat{G})| \leq m + \sum_{\gamma \in C} |\hat{E}_\gamma| \leq m + \sum_{\gamma \in \mathcal{C}} |A_\gamma| \cdot |B_\gamma|$. Note that $|B_\gamma| \leq n_{\text{off}} + d_\star + 1$ for all $\gamma \in \mathcal{C}$ by construction. Combining part 1, we have $|E(\hat{G})| \leq O(pm(n_{\text{off}} + d_\star))$.

Part 3. If $|A_{\gamma,\text{on}}| \leq d_\star + 1$, we have $A_\gamma = B_\gamma$ by construction and the proposition trivially holds. Otherwise, B_γ will include $d_\star + 1$ vertices in $A_{\gamma,\text{on}}$. Because $|D| \leq d_\star$, at least one of them will survive in $B_{\gamma,\text{on}} \setminus D$, which implies $(B_{\gamma,\text{on}} \setminus D) \cup (B_{\gamma,\text{off}} \cap D) \neq \emptyset$. ◀

5.2 The Global Order and Range Counting Structures

Next, we define an order, called the *global order* and denoted by π, over the whole vertex set $V(G)$, based on the Euler Tour orders of Steiner trees in $\mathcal{T}$.

For each $\tau \in \mathcal{T}$, we define its Euler tour order $\text{ET}(\tau)$ as an ordered list of vertices in $V(\tau)$ ordered by the time stamps of their first appearances in an Euler tour of τ (starting from an arbitrary root). Intuitively, the Euler tour order $\text{ET}(\tau)$ can be interpreted as a linearization of τ, i.e. after the removal of failed vertices in τ, the remaining subtrees will corresponding to intervals on $\text{ET}(\tau)$, as shown in Lemma 14.

▶ **Lemma 14** (Lemma 6.3 in [14], Rephrased). *Let τ be an undirected tree with maximum vertex degree Δ. A removal of d failed vertices from τ will split τ into at most $O(\Delta d)$ subtrees $\hat{\tau}_1, \hat{\tau}_2, ..., \hat{\tau}_{O(\Delta d)}$, and there exists a set $\mathcal{I}_\tau$ of at most $O(\Delta d)$ disjoint intervals on $ET(\tau)$, such that each interval is owned by a unique subtree and for each subtree τ_i, $V(\tau_i)$ is equal to the union of intervals it owns.*

Furthermore, by preprocessing τ in $O(|V(\tau)|)$ time, we can store $\mathrm{ET}(\tau)$ and some additional information in $O(|V(\tau)|)$ space, which supports the following operations.

- *Given a set D_τ of d failed vertices, the intervals $\mathcal{I}_t$ can be computed in $O(\Delta d \log(\Delta d))$ update time.*
- *Given a vertex $v \in V(\tau) \setminus D_\tau$, it takes $O(\log d)$ query time to find an interval $I \in \mathcal{I}_t$ s.t. vertices in I are connected to v in $\tau \setminus D_\tau$.*

Given the Euler tour orders of all $\tau \in \mathcal{T}$, we define the global order π as follows. We first concatenate $\mathrm{ET}(\tau) \cap U(\tau)$ (i.e. the restriction of $\mathrm{ET}(\tau)$ on the terminals of τ) of all $\tau \in \mathcal{T}$ in an arbitrary order, and then append all vertices in V_{off} to the end. Recall that $\{U(\tau) \mid \tau \in \mathcal{T}\}$ partitions V_{on}, so π is well-defined.

With the global order π, we will construct a 2D-range counting structure Table, which can answer the number of edges in $E(\hat{G})$ that connect two disjoint intervals on π. We first initialize $\mathsf{Table}_{\text{init}}$ to be an ordinary 2D array on range $\pi \times \pi$. For each $u, v \in \pi$, we store a non-negative integer in the entry $\mathsf{Table}_{\text{init}}(u, v)$ representing the number of edges in $E(\hat{G})$ connecting vertices u and v.

▶ **Lemma 15.** *Suppose that we can access the lists A_γ and B_γ for all $\gamma \in \mathcal{C}$. There is a combinatorial algorithm that computes $\mathsf{Table}_{\text{init}}$ in $O(|E(\hat{G})|)$ time, or $\mathsf{Table}_{\text{init}}$ can be computed in $O(p \cdot n^\omega)$ time using fast matrix multiplication.*

Proof. A trivial construction of $\mathsf{Table}_{\text{init}}$ is to construct the edge sets $E(\hat{G})$ explicitly, and then scan the edges one by one. Obviously, this takes $O(|E(\hat{G})|)$ time.

When $|E(\hat{G})|$ is large, we can use fast matrix multiplication (FMM) to speed up the construction of $\mathsf{Table}_{\text{init}}$. Recall that $E(\hat{G}) = E(G) + \sum_{\gamma \in \mathcal{C}} \hat{E}_\gamma$. We first add the contribution of $E(G)$ into $\mathsf{Table}_{\text{init}}$ using the trivial algorithm, which takes $O(m)$ time. Next, we compute the contribution of artificial edges, i.e. $\sum_{\gamma \in \mathcal{C}} \hat{E}_\gamma$, using FMM. We construct a matrix X with n rows and $|\mathcal{C}|$ columns, where rows are indexed by the global order π and columns are indexed by components (in an arbitrary order). For each vertex $u \in \pi$ and component $\gamma \in \mathcal{C}$, the entry $X(u, \gamma) = 1$ if and only if $u \in A_\gamma$. Similarly, we define an n-row $|\mathcal{C}|$-column matrix Y, in which each entry $Y(u, \gamma) = 1$ if and only if $u \in A_\gamma \setminus B_\gamma$. Let $Z = X \cdot X^\intercal - Y \cdot Y^\intercal$. Observe that, for each pair of distinct vertices $u, v \in \pi$,

$$\begin{aligned} Z(u, v) &= \sum_{\gamma \in \mathcal{C}} (X(u, \gamma) \cdot X(v, \gamma) - Y(u, \gamma) \cdot Y(v, \gamma)) \\ &= \sum_{\gamma \in \mathcal{C}} \mathbb{1}[u, v \in A_\gamma] - \mathbb{1}[u, v \in A_\gamma \setminus B_\gamma] \\ &= \sum_{\gamma \in \mathcal{C}} \mathbb{1}[\{u, v\} \in \hat{E}_\gamma]. \end{aligned}$$

Therefore, the matrix Z count the contribution of $\sum_\gamma \hat{E}_\gamma$ correctly and the last step is to add Z to $\mathsf{Table}_{\text{init}}$. The construction time is dominated by the computation of Z, which takes $O(p \cdot n^\omega)$ time because it involves multiplying an $n \times |\mathcal{C}|$ matrix and a $|\mathcal{C}| \times n$ matrix, and $|\mathcal{C}| = O(pn)$. ◀

▶ **Lemma 16.** *With access to the positive entries of* $\mathsf{Table}_{\text{init}}$*, we can construct a data structure* Table *that given any disjoint intervals* I_1 *and* I_2 *on* π*, answers in* $O(\log n)$ *time the number of edges in* $E(\hat{G})$ *with one endpoint in* I_1 *and the other one in* I_2*. The structure* Table *can be constructed in* $O(N \log n)$ *time and takes space* $O(N \log n)$*, where* N *denotes the number of positive entries in* $\mathsf{Table}_{\text{init}}$*.*

Proof. We simply construct Table as a standard weighted 2D range counting structure of $\mathsf{Table}_{\text{init}}$, By using textbook algorithms such as range trees and persistent segment trees, we can construct Table in $O(N \log n)$ time and it takes space $O(N \log n)$. The correctness of Table follows the definition of $\mathsf{Table}_{\text{init}}$. ◀

5.3 Preprocessing Time and Space Analysis

In conclusion, we will compute and store the following in the preprocessing phase.

- First, we store the low degree hierarchy $(\mathcal{C}, \mathcal{T})$. Constructing the low degree hierarchy takes $\hat{O}(m)$ time by Theorem 7. Storing the low degree hierarchy explicitly takes $O(pn)$ space, because for each level i, the components in $\mathcal{C}_i$ are vertex disjoint, also Steiner trees in $\mathcal{T}_i$.
- Next, for each $\gamma \in \mathcal{C}$, we store the lists A_γ and B_γ after ordering them by π. Computing the lists A_γ and B_γ takes $O(pm)$ time by checking the incident edges of each vertex in each component. Storing the lists A_γ and B_γ takes $O(pm)$ space by Item 1 in Proposition 13. Additionally, for each $\gamma \in \mathcal{C}$, store the list $A_{\gamma,\text{on}}$.
  For each $v \in V_{\text{off}}$ and $\gamma \in \mathcal{C}$, store a binary indicator to indicate whether $v \in A_{\gamma,\text{off}}$ or not. Computing the indicators takes $O(pm)$ time by scanning all the lists A_γ. Storing the indicators explicitly takes $O(|V_{\text{off}}| \cdot |\mathcal{C}|) = O(pn \cdot |V_{\text{off}}|)$ space.
- We also store the global order π, which takes $O(n)$ space. For each $\tau \in \mathcal{T}$, we store $\mathrm{ET}(\tau)$ and the additional information stated in Lemma 14 in $O(|V(\tau)|)$ space. Computing the things above takes totally $\sum_{\tau \in \mathcal{T}} |V(\tau)| = O(pn)$ time by Lemma 14.
- Finally, we store the data structure Table. Combining Item 2 in Proposition 13 and Lemmas 15 and 16, we can compute Table in $O(pm(n_{\text{off}} + d) \log n)$ time using an combinatorial algorithm, or in $O(p \cdot n^\omega \log n)$ time using fast matrix multiplication. The space to store Table is $\min\{pm(n_{\text{off}} + d) \log n, n^2\}$.

In conclusion, the total preprocessing time can be upper bounded by $\widehat{O}(m) + O(pm(n_{\text{off}} + d) \log n)$ using an combinatorial algorithm, then $t_p = \hat{\Omega}(md)$, or $\hat{O}(m) + O(p \cdot n^\omega \log n)$ using fast matrix multiplication. The space complexity is $O(\min\{pm(n_{\text{off}} + d) \log n, n^2\})$. Because the low degree hierarchy has $p = O(\log n)$ levels, the preprocessing time is $\widehat{O}(m) + O(\min\{m(n_{\text{off}} + d) \log^2 n, n^\omega \log^2 n\})$, and the space is $O(\min\{m(n_{\text{off}} + d) \log^2 n, n^2\})$.

6 The Update and Query Algorithms

Let $D \subseteq V(G)$ be a given update. We use $D_{\text{on}} = D \cap V_{\text{on}}$ to denote the vertices that will be turned off in this update and $D_{\text{off}} = D \cap V_{\text{off}}$ to denote the vertices that will be turned on. Let $V_{\text{new}} = (V_{\text{on}} \setminus D_{\text{on}}) \cup D_{\text{off}}$ be the on-vertices after updates.

Our update strategy is to recompute the connectivity of a subset of *affected vertices* $Q^\star \subseteq V_{\text{new}}$ on some affected graph $G^\star$. In Section 6.1, we will define $Q^\star$ and $G^\star$, and prove that $Q^\star$ has the same connectivity on the affected graph $G^\star$ and the updated original graph $G[V_{\text{new}}]$. In Section 6.2, we will partition $G^\star$ into a small number of sets s.t. each set forms an *interval* on the global order π and it is certified to be connected by some Steiner tree in $\mathcal{T}$. Thus, it suffices to solve the connectivity of intervals on $Q^\star$, which is formalized in Lemma 19.

▶ **Theorem 17.** *There exists a deterministic fully dynamic sensitivity oracle for subgraph connectivity with $O(\min\{m(n_{\text{off}}+d_\star)\log^2 n, n^2\})$ space, $O(d^2\log^7 n)$ update time and $O(d)$ query time. The preprocessing time is $\widehat{O}(m)+O(m(n_{\text{off}}+d_\star)\log^2 n)$ by a combinatorial algorithm, and $\widehat{O}(m)+O(n^\omega\log^2 n)$ using fast matrix multiplication.*

We first conclude our fully dynamic sensitivity oracle for subgraph connectivity in Theorem 17. The bounds on preprocessing time and space are shown in Section 5.3. The update time is given by Lemma 19. The query algorithm and the query time analysis are omitted here and they can be founded in the full version.

6.1 Affected Vertices $Q^\star$ and the Affected Graph $G^\star$

For each component $\gamma\in\mathcal{C}$, we call γ an *affected component* if $V(\gamma)$ intersects D_{on}, otherwise it is *unaffected*. Let $\mathcal{C}_{\text{aff}}$ denote the set of affected components. Let $\mathcal{T}_{\text{aff}}=\{\tau(\gamma)\mid\gamma\in\mathcal{C}_{\text{aff}}\}$ denote the Steiner trees corresponding to affected components.

We then define the *affected vertices* to be $Q^\star=D_{\text{off}}\cup\bigcup_{\tau\in\mathcal{T}_{\text{aff}}}U(\tau)\setminus D_{\text{on}}$. Namely, $Q^\star$ collect the newly opened vertices and the open terminals of affected components. Note that $Q^\star\subseteq V_{\text{new}}$. The *affected graph* $G^\star$ is $G^\star=\hat{G}[Q^\star]-\sum_{\gamma\in\mathcal{C}_{\text{aff}}}\hat{E}_\gamma$. In other words, $G^\star$ is the subgraph of the artificial graph $\hat{G}$ induced by the affected vertices $Q^\star$, with the artificial edges from affected components removed.

▶ **Lemma 18.** *For any two vertices $u,v\in Q^\star$, u and v are connected in $G[V_{\text{new}}]$ if and only if u and v are connected in $G^\star$.*

The proof of Lemma 18 can be founded in the full version. Intuitively, this lemma holds because those maximal unaffected components in $\mathcal{C}$ partition $V_{\text{new}}\setminus Q^\star$, and the artificial edges will capture the connectivity contributed by these maximal unaffected components.

6.2 Solving Connectivity of Intervals

Although the primary goal of our update algorithm is to compute the connectivity of $Q^\star$ on $G[V_{\text{new}}]$, Lemma 18 tells that it is equivalent to compute the connectivity of $Q^\star$ on $G^\star$.

▶ **Lemma 19.** *There is a deterministic algorithm that computes a partition $\mathcal{I}$ of $Q^\star$ s.t. each set $I\in\mathcal{I}$ forms an interval on π and all vertices in $\mathcal{I}$ are connected in $G^\star$, and then computes a partition $\mathcal{R}$ of $\mathcal{I}$ s.t. for each group $R\in\mathcal{R}$, the union of intervals in R forms a (maximal) connected component of $G^\star$. The running time is $O(p^2d^2\Delta^2\log n)$.*

Intervals

We first describe how to compute the partition $\mathcal{I}$ of $Q^\star$. Because we require each set $I\in\mathcal{I}$ forms an *interval* on the global order π, we can represent I by the positions of its endpoints on π. Recall that $Q^\star=(\bigcup_{\gamma\in\mathcal{T}_{\text{aff}}}U(\gamma)\setminus D_{\text{on}})\cup D_{\text{off}}$.

- We first construct the intervals of $\bigcup_{\tau\in\mathcal{T}_{\text{aff}}}U(\tau)\setminus D_{\text{on}}$ by exploiting the Steiner trees. For each $\tau\in\mathcal{T}_{\text{aff}}$, by invoking Lemma 14 on τ with failed vertices D_{on}, we will obtain a partition $\mathcal{I}'_\tau$ of $V(\tau)\setminus D_{\text{on}}$ s.t. each $I'\in\mathcal{I}'_\tau$ is an interval on $\text{ET}(\tau)$ and it is contained by a subtree of $\tau\setminus D_{\text{on}}$. We construct a set $\mathcal{I}_t$ of intervals on $\text{ET}(\tau)\cap U(\tau)$ by taking the restriction of intervals $\mathcal{I}'_t$ on $U(\tau)$. Therefore, intervals in $\mathcal{I}_t$ are indeed intervals on π because $\text{ET}(\tau)\cap U(\tau)$ is a consecutive sublist of π. Also, for each interval $I\in\mathcal{I}_\tau$, vertices in I are connected in $G[V_{\text{new}}]$ (because $\tau\setminus D_{\text{on}}$ is a subgraph of $G[V_{\text{new}}]$), which implies vertices in I are connected in $G^\star$ by Lemma 18.
- For each vertex $v\in D_{\text{off}}\subseteq Q^\star$, we construct a singleton interval $I_v=\{v\}$.

Finally, the whole set of intervals is $\mathcal{I} = \bigcup_{\tau \in \mathcal{T}_{\text{aff}}} \mathcal{I}_\tau \cup \{I_v \mid v \in D_{\text{off}}\}$.

▶ **Proposition 20.** *The total number of intervals is $|\mathcal{I}| = O(pd\Delta)$, and computing all intervals takes $O(pd\Delta \log(d\Delta))$ time.*

Proof. By Lemma 14, the number of intervals generated by a tree $\tau \in \mathcal{T}_{\text{aff}}$ is at most $O(|V(\tau) \cap D_{\text{on}}| \cdot \Delta)$, and it takes $O(|V(\tau) \cap D_{\text{on}}| \cdot \Delta \cdot \log(|V(\tau) \cap D_{\text{on}}| \cdot \Delta))$ time to generate them. Observe that $\sum_{\tau \in \mathcal{T}_{\text{aff}}} |V(\tau) \cap D_{\text{on}}| = O(p \cdot |D_{\text{on}}|)$ because each vertex in D_{on} can appear in at most p trees in $\mathcal{T}$ (at most one at each level). Furthermore, the trivial intervals generated by vertices in D_{off} is obviously $|D_{\text{off}}|$. Therefore, the total number of intervals in $O(p|D_{\text{on}}|\Delta) + |D_{\text{off}}| = O(pd\Delta)$, and computing all intervals takes $O(pd\Delta(d\Delta))$ time. ◀

Borůvka's Algorithm

We now discuss how to compute the partition $\mathcal{R}$ of $\mathcal{I}$. We will merge the intervals by a Borůvka's styled algorithm. The algorithm has several *phases*, and each phase j receives a partition $\mathcal{R}^{(j)}$ of $\mathcal{I}$ as input. each group $R \in \mathcal{R}^{(j)}$ is either *active* or *inactive*. Initially, $\mathcal{R}^{(1)} = \{\{I\} \mid I \in \mathcal{I}\}$ is the trivial partition of $\mathcal{I}$ and all groups in $\mathcal{R}^{(1)}$ are active. For each phase j, we do the following to update $\mathcal{R}^{(j)}$ to $\mathcal{R}^{(j+1)}$.

1. For each active group R in $\mathcal{R}^{(j)}$, we will ask the following *adjacency query*.
   - **(Q1)** Given an active group $R \in \mathcal{R}^{(j)}$, find another active group $R' \in \mathcal{R}^{(j)}$ s.t. there exists an edge $e = \{u, v\} \in E(G^\star)$ with $u \in I_u \in R$ and $v \in I_v \in R'$, or claim that there is no such R'.

   After asking (Q1) for all active groups, for each active group R, if (Q1) tells that no such R' exists, we mark R as an inactive group, otherwise we find an *adjacent group-pair* $\{R, R'\}$.
2. Given the adjacent group-pairs in step 1, we construct a graph K with vertices corresponding to active groups and edges corresponding to adjacent group-pairs. Note that for each adjacent group-pair $\{R, R'\}$, R and R' must still be active. Then, for each connected component of K, we merge the groups inside it into a new active group.

The algorithm terminates once it reaches a phase $\bar{j}$ s.t. all groups in $\mathcal{R}^{(\bar{j})}$ are inactive, and we let $\mathcal{R} = \mathcal{R}^{(\bar{j})}$ be the final output. Obviously, $\mathcal{R}$ satisfies the output requirement of Lemma 19. Furthermore, the number of phases is bounded in Proposition 21. Let $\mathcal{R}^{(j)}_{\text{act}} \subseteq \mathcal{R}^{(j)}$ denote the active groups in $\mathcal{R}^{(j)}$ at the moment when phase j starts and let $\bar{k}^{(j)} = |\mathcal{R}^{(j)}_{\text{act}}|$.

▶ **Proposition 21.** *For each $j \geq 2$, $\bar{k}^{(j)} \leq \bar{k}^{(j-1)}/2$. The number of phases is $O(\log |\mathcal{I}|)$.*

Proof. At each phase, the number of active groups is halved because we mark all old active groups without adjacent group inactive in step 1, and each connected component of the graph K in step 2 contains at least two old active groups. Because initially $\bar{k}^{(0)} = |\mathcal{R}^{(0)}| = |\mathcal{I}|$, the number of phases is $O(\log |\mathcal{I}|)$. ◀

Next, we will discuss the implementation of step 1. Basically, for each phase j, we need an algorithm that answers the *adjacency query* (Q1) efficiently. Instead of answering (Q1) directly, we will reduce (Q1) to the following *batched adjacency query* (Q2). We give an arbitrary order to the groups in $\mathcal{R}^{(j)}_{\text{act}}$, denoted by $\mathcal{R}^{(j)}_{\text{act}} = \{R^{(j)}_1, R^{(j)}_2, ..., R^{(j)}_{\bar{k}^{(j)}}\}$.

- **(Q2)** Given a group $R^{(j)}_k \in \mathcal{R}^{(j)}_{\text{act}}$ and a batch of consecutive groups $R^{(j)}_\ell, R^{(j)}_{\ell+1}, ..., R^{(j)}_r \in \mathcal{R}^{(j)}_{\text{act}}$ s.t. $k \notin [\ell, r]$, decide if there exists $R^{(j)}_{k'}$ s.t. $k' \in [\ell, r]$ and $R^{(j)}_{k'}$ is adjacent to $R^{(j)}_k$.

▶ **Lemma 22.** *At phase j, one adjacency query can be reduced to $O(\log \bar{k}^{(j)})$ batched adjacency queries.*

Proof. Consider an adjacency query for some $R_k^{(j)} \in \mathcal{R}_{\text{act}}^{(j)}$. We can either find some $R_{k'}^{(j)} \in \mathcal{R}_{\text{act}}^{(j)}$ s.t. $k+1 \le k' \le \bar{k}^{(j)}$ and $R_{k'}^{(j)}$ is adjacent to $R_k^{(j)}$ or claim there is no such $R_{k'}^{(j)}$ in the following way: first fix $\ell = k+1$, and then perform a binary search on r in range $[k+1, \bar{k}^{(j)}]$, in which each binary search step is guided by a batched adjacency query with parameters k, ℓ, r. Similarly, we can try to find an adjacent group $R_{k'}^{(j)}$ to the left of $R_k^{(j)}$ by fixing $r = k-1$ and performing a binary search on ℓ in range $[1, k-1]$. The total number of calls to (Q2) is obviously $O(\log \bar{k}^{(j)})$ in these two binary searches. ◀

To answer batched adjacency queries in each phase, we will first introduce some *additional structures*, and then use them to design the algorithm answering (Q2), which is formalized in Lemma 23.

▶ **Lemma 23.** *There is a deterministic algorithm that computes some additional structures in $O(p^2d^2\Delta^2 \log n)$ time to support any batched adjacency query in $O(pd)$ time.*

We are now ready to analyse the running time of the Borůvka's algorithm, which completes the proof of Lemma 19. At each phase j, the number of adjacency queries is at most $\bar{k}^{(j)}$ (one for each active group in $\mathcal{R}^{(j)}$), so the number of batched adjacency queries is $O(\bar{k}^{(j)} \log \bar{k}^{(j)})$ by Lemma 22. Thus the total number of batched adjacency queries is $\sum_{j \ge 1} O(\bar{k}^{(j)} \log \bar{k}^{(j)}) = O(|\mathcal{I}| \log |\mathcal{I}|)$ by Proposition 21. By Lemma 23, the total running time of step 1 is $O(p^2d^2\Delta^2 \log n) + O(pd|\mathcal{I}| \log |\mathcal{I}|) = O(p^2d^2\Delta^2 \log n)$. The total running time of the Borůvka's algorithm is asymptotically the same because step 2 takes little time.

In what follows, we prove Lemma 23.

The Additional Structures

We start with introducing some notations. For a group $R \subseteq \mathcal{I}$, we use $V(R) = \bigcup_{I \in R} I$ to denote its vertex set. For two disjoint groups $R_1, R_2 \subseteq \mathcal{I}$ and a (multi) set E of undirected edges, let $\delta_E(R_1, R_2)$ denote the number of edges in E with one endpoint in $V(R_1)$ and the other one in $V(R_2)$. Also, recall that we gave an order to groups in $\mathcal{R}_{\text{act}}^{(j)}$, denoted by $\mathcal{R}_{\text{act}}^{(j)} = \{R_1^{(j)}, ..., R_{\bar{k}^{(j)}}^{(j)}\}$.

For each phase j, we will construct the following data structures.

- First, we construct a two-dimensional $(\bar{k}^{(j)} \times \bar{k}^{(j)})$-array $\mathsf{CountAll}^{(j)}$, where for each $1 \le x, y \le \bar{k}^{(j)}$, the entry $\mathsf{CountAll}^{(j)}(x, y) = \delta_{E(\hat{G})}(R_x^{(j)}, R_y^{(j)})$. Furthermore, we store the 2D-prefix sum of $\mathsf{CountAll}^{(j)}$.
- For each affected component γ, we prepare a one-dimensional array $\mathsf{CountA}_\gamma^{(j)}$ with length $\bar{k}^{(j)}$, where for each $1 \le x \le \bar{k}^{(j)}$, the entry $\mathsf{CountA}_\gamma^{(j)}(x) = |A_\gamma \cap V(R_x^{(j)})|$. Similarly, we construct an one-dimensional array $\mathsf{CountB}_\gamma^{(j)}$ with length $\bar{k}^{(j)}$ in which the entry $\mathsf{CountB}_\gamma^{(j)}(x) = |B_\gamma \cap V(R_x^{(j)})|$. Furthermore, we store the prefix sum of $\mathsf{CountA}_\gamma^{(j)}$ and $\mathsf{CountB}_\gamma^{(j)}$.

▶ **Lemma 24.** *The total construction time of arrays $\mathsf{CountAll}^{(j)}$, $\mathsf{CountA}_\gamma^{(j)}$ and $\mathsf{CountB}_\gamma^{(j)}$ summing over all phases j and all affected components γ is $O(p^2d^2\Delta^2 \log d)$.*

Proof. We first initialize $\mathsf{CountAll}^{(1)}, \mathsf{CountA}_\gamma^{(1)}, \mathsf{CountB}_\gamma^{(1)}$ for phase 1. For each entry $\mathsf{CountAll}^{(1)}(x, y)$ of $\mathsf{CountAll}^{(1)}$, note that $R_x^{(1)}$ and $R_y^{(1)}$ are both singleton groups. Let I_x and I_y be the intervals in $R_x^{(1)}$ and $R_y^{(1)}$. Then $\mathsf{CountAll}^{(1)}(x, y)$ is exactly the number of $E(\hat{G})$-edges that connect I_x and I_y, which can be answered by querying Table in $O(\log n)$ time by Lemma 16 because I_x and I_y are intervals on the global order π. For an entry $\mathsf{CountA}_\gamma^{(1)}(x)$ of $\mathsf{CountA}_\gamma^{(1)}$, let I_x be the single interval in $R_x^{(1)}$, and we can easily compute

$|A_\gamma \cap I_x|$ by binary search in $O(\log n)$ time because I_x is an interval on π and A_γ is ordered consistently with π. Similarly, we can compute the array $\mathsf{CountB}_\gamma^{(1)}$. The construction time of additional structures at phase 1 is $O(((\bar{k}^{(1)})^2 + |\mathcal{C}_{\text{aff}}| \cdot \bar{k}^{(1)}) \log n)$.

For each phase $j \geq 2$, we will compute $\mathsf{CountAll}^{(j)}, \mathsf{CountA}_\gamma^{(j)}, \mathsf{CountB}_\gamma^{(j)}$ based on the arrays of phase $j-1$. For an entry $\mathsf{CountAll}^{(j)}(x,y)$ of $\mathsf{CountAll}^{(j)}$, recall that $R_x^{(j)}$ is the union of several groups $R_{x_1}^{(j-1)}, R_{x_2}^{(j-1)}, ...$ inside $\mathcal{R}_{\text{act}}^{(j-1)}$, and $R_y^{(j)} = R_{y_1}^{(j-1)} \cup R_{y_2}^{(j-1)} \cup ....$ Furthermore, $x_1, x_2, ..., y_1, y_2, ...$ are distinct indexes in $[1, \bar{k}^{(j-1)}]$. Therefore,

$$\mathsf{CountAll}^{(j)}(x,y) = \sum_{x'=x_1,x_2,...} \sum_{y'=y_1,y_2,..} \mathsf{CountAll}^{(j-1)}(x',y').$$

We can compute $\mathsf{CountA}_\gamma^{(j)}$ and $\mathsf{CountB}_\gamma^{(j)}$ in a similar way. The construction time of additional structures at phase j is proportional to the total size of additional structures at phase $j-1$, i.e. $O((\bar{k}^{(j-1)})^2 + |\mathcal{C}_{\text{aff}}| \cdot \bar{k}^{(j-1)})$.

The overall construction time is

$$O(((\bar{k}^{(1)})^2 + |\mathcal{C}_{\text{aff}}| \cdot \bar{k}^{(1)}) \log n) + \sum_{j \geq 2} O((\bar{k}^{(j-1)})^2 + |\mathcal{C}_{\text{aff}}| \cdot \bar{k}^{(j-1)}) = O(p^2 d^2 \Delta^2 \log n),$$

because $\bar{k}^{(1)} = |\mathcal{I}| = O(pd\Delta)$, $|\mathcal{C}_{\text{aff}}| = O(pd)$ and $\bar{k}^{(j)} \leq \bar{k}^{(j-1)}/2$ for each phase j. ◀

Answering Batched Adjacency Queries

Consider a batched adjacency query at phase j with parameters k, ℓ, r. It is equivalent to decide whether the number of $G^\star$-edges connecting $R_k^{(j)}$ and some $R_{k'}^{(j)}$ where $k' \in [\ell, r]$ is greater than zero or not. Namely, it suffices to decide whether

$$\sum_{\ell \leq k' \leq r} \delta_{E(G^\star)}(R_k^{(j)}, R_{k'}^{(j)}) > 0. \tag{1}$$

▶ **Lemma 25.** *For any two disjoint groups $R_1, R_2 \subseteq \mathcal{I}$,*

$$\delta_{E(G^\star)}(R_1, R_2) = \delta_{E(\hat{G})}(R_1, R_2) - \sum_{\gamma \in \mathcal{C}_{\text{aff}}} \delta_{\hat{E}_\gamma}(R_1, R_2).$$

Proof. First the RHS is equal to $\delta_{E(\hat{G}) - \sum_{\gamma \in \mathcal{C}_{\text{aff}}} \hat{E}_\gamma}(R_1, R_2)$ because $\hat{E}_\gamma$ of all $\gamma \in \mathcal{C}_{\text{aff}}$ are disjoint subsets of $E(\hat{G})$ (note that $E(\hat{G})$ is defined to be a multiset).

Recall that $G^\star = \hat{G}[Q^\star] - \sum_{\gamma \in \mathcal{C}_{\text{aff}}} \hat{E}_\gamma$. The LHS is at most the RHS because $E(G^\star) \subseteq E(\hat{G}) - \sum_{\gamma \in \mathcal{C}_{\text{aff}}} \hat{E}_\gamma$. On the other direction, each edge in $E(\hat{G})$ connecting $V(R_1)$ and $V(R_2)$ is inside $\hat{G}[Q^\star]$ since $V(R_1), V(R_2) \subseteq Q^\star$, so the RHS is at most the LHS. ◀

▶ **Lemma 26.** *For each $\gamma \in \mathcal{C}_{\text{aff}}$ and two disjoint groups $R_1, R_2 \subseteq \mathcal{I}$,*

$$\delta_{\hat{E}_\gamma}(R_1, R_2) = |A_\gamma \cap V(R_1)| \cdot |A_\gamma \cap V(R_2)| - |(A_\gamma \setminus B_\gamma) \cap V(R_1)| \cdot |(A_\gamma \setminus B_\gamma) \cap V(R_2)|.$$

Proof. Recall that $\hat{E}_\gamma$ is the union of a clique on B_γ and a biclique between $A_\gamma \setminus B_\gamma$ and B_γ. In other words, $\hat{E}_\gamma$ is a clique on A_γ with the clique on $A_\gamma \setminus B_\gamma$ removed. Because $V(R_1)$ and $V(R_2)$ are disjoint, the equation follows. ◀

Using Lemma 25 and Lemma 26, we can rewrite the LHS of inequality 1 as follows.

$$\begin{aligned}\sum_{\ell\le k'\le r}\delta_{E(G^\star)}(R_k^{(j)},R_{k'}^{(j)}) &= \sum_{\ell\le k'\le r}\delta_{E(\hat{G})}(R_k^{(j)},R_{k'}^{(j)}) - \sum_{\ell\le k'\le r}\sum_{\gamma\in\mathcal{C}_{\text{aff}}}\delta_{\hat{E}_\gamma}(R_k^{(j)},R_{k'}^{(j)})\\ &= \sum_{\ell\le k'\le r}\delta_{E(\hat{G})}(R_k^{(j)},R_{k'}^{(j)})\\ &- \sum_{\gamma\in\mathcal{C}_{\text{aff}}}\sum_{\ell\le k'\le r}|A_\gamma\cap V(R_k^{(j)})|\cdot|A_\gamma\cap V(R_{k'}^{(j)})|\\ &+ \sum_{\gamma\in\mathcal{C}_{\text{aff}}}\sum_{\ell\le k'\le r}|(A_\gamma\setminus B_\gamma)\cap V(R_k^{(j)})|\cdot|(A_\gamma\setminus B_\gamma)\cap V(R_{k'}^{(j)})|.\end{aligned}$$

For convenience, we denote $\alpha_\gamma^{(j)}(k)=\mathsf{CountA}_\gamma^{(j)}(k)$, $\beta_\gamma^{(j)}(k)=\mathsf{CountB}_\gamma^{(j)}(k)$
Combining the definition of the additional structures, we further have

$$\begin{aligned}\sum_{\ell\le k'\le r}\delta_{E(G^\star)}(R_k^{(j)},R_{k'}^{(j)}) &= \sum_{\ell\le k'\le r}\mathsf{CountAll}^{(j)}(k,k') - \sum_{\gamma\in\mathcal{C}_{\text{aff}}}\left(\alpha_\gamma^{(j)}(k)\cdot\sum_{\ell\le k'\le r}\alpha_\gamma^{(j)}(k')\right)\\ &+ \sum_{\gamma\in\mathcal{C}_{\text{aff}}}\left((\alpha_\gamma^{(j)}(k)-\beta_\gamma^{(j)}(k))\cdot\sum_{\ell\le k'\le r}(\alpha_\gamma^{(j)}(k')-\beta_\gamma^{(j)}(k'))\right)\end{aligned}$$

Because we have stored the prefix sum of the arrays $\mathsf{CountAll}^{(j)}$, $\mathsf{CountA}_\gamma^{(j)}$, $\mathsf{CountB}_\gamma^{(j)}$, computing the value of the above expression takes $O(|\mathcal{C}_{\text{aff}}|)=O(pd)$ time.

Impagliazzo's Worlds Through the Lens of Conditional Kolmogorov Complexity

Zhenjian Lu
University of Warwick, UK

Rahul Santhanam
University of Oxford, UK

Abstract

We develop new characterizations of Impagliazzo's worlds Algorithmica, Heuristica and Pessiland by the intractability of conditional Kolmogorov complexity K and conditional probabilistic time-bounded Kolmogorov complexity pK^t.

In our first set of results, we show that $\mathsf{NP} \subseteq \mathsf{BPP}$ iff $\mathsf{pK}^t(x \mid y)$ can be computed efficiently in the worst case when t is sublinear in $|x| + |y|$; $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ iff $\mathsf{pK}^t(x \mid y)$ can be computed efficiently over all polynomial-time samplable distributions when t is sublinear in $|x| + |y|$; and infinitely-often one-way functions fail to exist iff $\mathsf{pK}^t(x \mid y)$ can be computed efficiently over all polynomial-time samplable distributions for t a sufficiently large polynomial in $|x| + |y|$. These results characterize Impagliazzo's worlds Algorithmica, Heuristica and Pessiland purely in terms of the tractability of conditional pK^t. Notably, the results imply that Pessiland fails to exist iff the average-case intractability of conditional pK^t is insensitive to the difference between sublinear and polynomially bounded t. As a corollary, while we prove conditional pK^t to be NP-hard for sublinear t, showing NP-hardness for large enough polynomially bounded t would eliminate Pessiland as a possible world of average-case complexity.

In our second set of results, we characterize Impagliazzo's worlds Algorithmica, Heuristica and Pessiland by the distributional tractability of a natural problem, i.e., approximating the conditional Kolmogorov complexity, that is provably intractable in the worst case. We show that $\mathsf{NP} \subseteq \mathsf{BPP}$ iff conditional Kolmogorov complexity can be approximated in the *semi-worst case*; and $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ iff conditional Kolmogorov complexity can be approximated on average over all *independent polynomial-time samplable distributions*. It follows from a result by Ilango, Ren, and Santhanam (STOC 2022) that infinitely-often one-way functions fail to exist iff conditional Kolmogorov complexity can be approximated on average over all *polynomial-time samplable distributions*. Together, these results yield the claimed characterizations. Our techniques, combined with previous work, also yield a characterization of auxiliary-input one-way functions and equivalences between different average-case tractability assumptions for conditional Kolmogorov complexity and its variants. Our results suggest that novel average-case tractability assumptions such as tractability in the semi-worst case and over independent polynomial-time samplable distributions might be worthy of further study.

1 Introduction

In his influential survey on average-case complexity [12], Impagliazzo described five possible computational worlds: Algorithmica, Heuristica, Pessiland, Minicrypt and Cryptomania. Algorithmica is a world where NP is easy in the worst case; Heuristica a world where NP is hard in the worst case but easy on average; Pessiland a world where NP is hard on average but one-way functions do not exist; Minicrypt a world where one-way functions exist but public-key cryptography does not; and Cryptomania a world where public-key cryptography exists. The general belief among complexity theorists and cryptographers is that we live in Cryptomania, but we are very far from a proof, as even ruling out Algorithmica would involve showing $\mathsf{NP} \neq \mathsf{P}$.

There is the possibility, however, that we might be able to unconditionally rule out some of the intermediate worlds, such as Heuristica, Pessiland and Minicrypt. Until recently, there was little progress on ruling out these intermediate worlds. All that was known was that there are various black-box and relativization barriers to ruling out these worlds.

The study of *meta-complexity*, i.e., the complexity of computational problems that are themselves about complexity, has enabled new attacks on these questions. Examples of meta-complexity problems are the Minimum Circuit Size Problem (MCSP), which asks whether a Boolean function represented by its truth table has circuits of a given size, and the problem of computing Kolmogorov complexity and its resource-bounded variants such as Levin's time-bounded Kolmogorov complexity. The average-case complexity of meta-complexity problems is of particular interest [9]. Hirahara [5] gave an approach via meta-complexity to ruling out the analogue of Heuristica for the Polynomial Hierarchy. More recently, the Polynomial Hierarchy analogue of Pessiland has been ruled out [10], again using meta-complexity techniques.

There have been several successful efforts to characterize the existence of one-way functions via meta-complexity. In [23], a conditional characterization was given, based on a believable but seemingly hard-to-establish conjecture. Liu and Pass [14] unconditionally characterized one-way functions by the average-case hardness of polynomial-time-bounded Kolmogorov complexity over the uniform distribution. This characterization was extended to other meta-complexity problems and notions of one-way function in [15, 21, 1]. A different characterization of one-way functions via the hardness of approximating Kolmogorov complexity over samplable distributions was given in [11]. More recently, Hirahara [7] introduced a meta-complexity problem whose NP-hardness and the worst-case hardness of NP characterize the existence of one-way functions.

These connections between meta-complexity, average-case complexity and one-way functions raise the following question: Can we characterize Impagliazzo's worlds Algorithmica, Heuristica and Pessiland by different notions of hardness for a single computational problem? A positive answer to this question is implicit in [16], who study the problem of conditional polynomial-time-bounded Kolmogorov complexity. They show that the worst-case hardness of conditional polynomial-time-bounded Kolmogorov complexity captures worst-case hardness of NP, and the average-case hardness of conditional polynomial-time-bounded Kolmogorov complexity over the uniform distribution captures the existence of one-way functions. Their result on worst-case hardness immediately implies that the average-case hardness of NP is equivalent to the hardness of conditional polynomial-time-bounded Kolmogorov complexity over some samplable distribution.

In this work, we give two new characterizations of Impagliazzo's worlds by different notions of hardness for a single problem - first for conditional probabilistic time-bounded Kolmogorov complexity pK^t [3], and second for the standard notion of conditional Kolmogorov complexity.

These new characterizations have some interesting features. The first characterization implies that ruling out Pessiland corresponds to *robustness* of the average-case tractability of conditional pK^t over time regimes t that vary from sublinear to polynomial. As a consequence, while we are able to prove (by building on [6]) that pK^t is NP-hard to compute exactly when t is sublinear, Pessiland would fail to exist if pK^t were NP-hard to compute for *arbitrary* polynomial t. This could be a promising route to ruling out Pessiland, since pK^t is a fairly powerful complexity measure with nice properties such as the coding theorem which could potentially be exploited when showing hardness, and the computational version is in (promise) AM but is not known to be in NP.

The second characterization is for a fundamental problem that is *provably intractable in the worst case*, i.e., the problem of approximating conditional Kolmogorov complexity. A somewhat surprising aspect of our results (which is also present in the main result of [11] on which we build) is that conditional Kolmogorov complexity is uncomputable, yet natural average-case hardness assumptions on conditional Kolmogorov complexity capture complexity worlds related to average-case hardness of NP. What this indicates is that the distinctions between Impagliazzo's worlds can be encoded in a natural way into the *distributional assumptions* that are made, while considering a single well-understood problem.

As a corollary of our second set of results together with those in [16], we get new equivalences between hardness assumptions for conditional Kolmogorov complexity and hardness assumptions for conditional time-bounded Kolmogorov complexity. The proofs of these equivalences crucially use the various characterizations of Impagliazzo's worlds, and it seems tricky to show such equivalences directly.

1.1 Results

We state our results formally in this subsection.

1.1.1 Characterizing Both $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ and Non-Existence of One-Way Functions by Average-Case Easiness of Conditional pK^t

We present a meta-complexity problem whose average-case tractability over polynomial-time samplable distributions can be used to characterize both the non-existence of one-way functions and $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$, while considering different time regimes in the measure of time-bounded Kolmogorov complexity. Specifically, we consider the problem of computing conditional probabilistic t-time-bounded Kolmogorov complexity.

As defined in [3], we let $\mathsf{pK}^t_\lambda(x \mid y)$ be the smallest integer k such that, with probability at least λ over the choice of a random string $w \sim \{0,1\}^t$, there is a (deterministic) program of size k that, when running on w and given oracle access to y, prints x within t steps (see [20, Definition 16] for the formal definition).

For $\tau\colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, let $\mathsf{Cond\text{-}pK}[\tau]$ be the following promise problem $(\mathsf{YES}, \mathsf{NO})$:

$$\mathsf{YES} := \left\{ (x, y, 1^s) \mid \mathsf{pK}^{\tau(|x|,|y|)}_{2/3}(x \mid y) \leq s \right\},$$
$$\mathsf{NO} := \left\{ (x, y, 1^s) \mid \mathsf{pK}^{\tau(|x|,|y|)}_{1/3}(x \mid y) > s \right\}.$$

We will refer to this problem as "computing conditional pK^t".

We will consider two specific settings for the time bound function τ. For the purpose of illustration, let us consider the following simplified problem. For $\tau\colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, we are given x, y and s, and the task is to decide whether $\mathsf{K}^{\tau(|x|,|y|)}(x \mid y) \leq s$, i.e., whether there is a program of size at most s such that given *oracle access* to y, the program outputs x within time $\tau(|x|, |y|)$.

A typical setting of τ is $\tau(n,m) := n^c \cdot m^c$, where $c > 1$ is some constant. For this τ, we want to decide if there is a program of size at most s that, given *oracle access* to y, outputs x within time $\tau(|x|,|y|)$, and such a program has enough time to read the entire string y.

Now consider another setting of τ where $\tau(n,m) := n^c \cdot m^{1-1/c}$ for a constant $c > 1$. In this case, for a string $y \in \{0,1\}^m$, where $m := n^{2c^2}$, we have

$$\tau(n,m) = n^c \cdot m^{1-1/c} = n^{2c^2-c} \ll m.$$

Again, we want to decide if there is a program of size at most s that, given *oracle access* to y, outputs x within time $\tau(|x|,|y|)$. However, in this case any such program does not have time to read the entire string y

We will show that the non-existence of one-way functions corresponds to the average-case tractability of $\mathsf{Cond\text{-}pK}[\tau]$ over polynomial-time samplable distributions for the "polynomial-time regime" of τ, and that $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ corresponds to that of the "sublinear-time regime".[1] We state our results formally next.

For an algorithm A, $x, y \in \{0,1\}^*$, and $s \in \mathbb{N}$, we say that A *decides* $\mathsf{Cond\text{-}pK}[\tau]$ *on* $(x, y, 1^s)$ if the following holds:

$$A(x,y,1^s) = \begin{cases} 1 & \text{if } \mathsf{pK}^{\tau(|x|,|y|)}_{2/3}(x \mid y) \le s, \\ 0 & \text{if } \mathsf{pK}^{\tau(|x|,|y|)}_{1/3}(x \mid y) > s, \\ \textbf{either } 0 \textbf{ or } 1 & \text{otherwise.} \end{cases}$$

▶ **Theorem 1.** *The following are equivalent.*

1. *Infinitely-often one-way functions do not exist.*
2. **(Computing conditional pK^t in the polynomial-time regime is easy-on-average over samplable distributions.)**
   For every polynomial-time samplable distribution family $\{\mathcal{D}_{\langle n,m\rangle}\}_{n,m}$ supported over $\{0,1\}^n \times \{0,1\}^m$, every polynomial q, and for all large enough constant c, there exists a probabilistic polynomial-time algorithm A such that for all $n, m, s \in \mathbb{N}$,

$$\Pr_{(x,y)\sim\mathcal{D}_{\langle n,m\rangle}}[A \text{ decides } \mathsf{Cond\text{-}pK}[\tau] \text{ on } (x,y,1^s)] \ge 1 - \frac{1}{q(n,m)},$$

   where $\tau(n,m) := n^c \cdot m^c$.

▶ **Theorem 2.** *The following are equivalent.*

1. $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$.
2. **(Computing conditional pK^t in the sublinear-time regime is easy-on-average over samplable distributions.)**
   For every polynomial-time samplable distribution family $\{\mathcal{D}_{\langle n,m\rangle}\}_{n,m}$ supported over $\{0,1\}^n \times \{0,1\}^m$, every polynomial q, and for all large enough constant c, there exists a probabilistic polynomial-time algorithm A such that for all $n, m, s \in \mathbb{N}$,

$$\Pr_{(x,y)\sim\mathcal{D}_{\langle n,m\rangle}}[A \text{ decides } \mathsf{Cond\text{-}pK}[\tau] \text{ on } (x,y,1^s)] \ge 1 - \frac{1}{q(n,m)},$$

   where $\tau(n,m) := n^c \cdot m^{1-1/c}$.

[1] Note that even in the "sublinear-time regime" of τ, the program can still run in polynomial time with respect to the the length of x; the word "sublinear-time" refers to the fact that the program runs in sublinear time with respect to the length of y.

In proving Theorem 2, we also show that it is NP-hard to compute conditional pK^t in the sublinear-time regime in the worst case.

▶ **Theorem 3** (Informal). *For any constant $c > 1$, Cond-$\mathsf{pK}[\tau]$ is NP-hard under randomized polynomial-time reductions, where $\tau(n, m) := n^c \cdot m^{1-1/c}$.*

In fact, Theorem 3 holds even if we consider the problem of approximating $\mathsf{pK}^t(x \mid y)$ in the sublinear-time regime within a multiplicative factor of $|x|^{1/\log\log|x|^{O(1)}}$. This also extends a result by Liu and Pass [16] and Hirahara [6], which showed that the problem of computing/approximating conditional K^t in the sublinear-time regime is NP-hard.

Theorem 3, Theorem 1 and Theorem 2 together give characterizations of Impagliazzo's worlds Algorithmica, Heuristica and Pessiland based on different hardness assumptions for the computation of conditional pK^t.

In particular, Theorem 1 and Theorem 2 imply that the task of ruling out Pessiland[2] is equivalent to showing that the problem of computing conditional pK^t on average over polynomial-time samplable distributions is robust with respect to the two different time regimes.

Also, we get that to rule out Pessiland, it suffices to show that it is NP-hard to compute conditional pK^t in the *polynomial-time regime* in the worst case.

▶ **Corollary 4** (Informal. See [20, Corollary 55] for the formal version). *If computing conditional pK^t in the polynomial-time regime is NP-hard, then Pessiland does not exist.*

A proof sketch of Corollary 4 can be found in [20, Section 4.4].

For comparison, it was observed in [7] that if one can show the NP-hardness of *approximating* a certain variant of time-bounded Kolmogorov complexity called q^t, then Pessiland does not exist. It is known that $\mathsf{q}^{\mathsf{poly}}$ and $\mathsf{pK}^{\mathsf{poly}}$ are equivalent to each other up to an additive logarithmic factor. This implies that showing the NP-hardness of *approximating* pK^t will allow us to rule out Pessiland.[3] It can also be shown that the problem of *approximating* pK^t is reducible to that of computing conditional pK^t.[4] On the other hand, Corollary 4 only requires showing the NP-hardness of computing conditional pK^t, which might be easier. Moreover, we note that the barrier of [22] to showing NP-hardness of approximating Kolmogorov complexity and its variants does not seem to apply directly to exact computation.

Equivalences between Average-Case Easiness of Approximating and Computing (Conditional) pK^t

By combining Theorem 1 with existing characterizations of one-way functions, we get that the average-case easiness of approximating and computing different variants of probabilistic (conditional) time-bounded Kolmogorov complexity are in fact equivalent. We state this result more formally below.

We say that "approximating pK^t is easy-on-average over samplable distributions" if the following holds.

---

[2] In this case, we mean basing infinitely-often one-way functions on DistNP $\not\subseteq$ HeurBPP.

[3] Here, we refer to the problem called Gap-MINpKT. For a polynomial τ, Gap-MINpK$\mathsf{T}[\tau]$ is the (promise) problem of deciding, given as input $(x, 1^s, 1^t)$, whether $\mathsf{pK}^t(x) \le s$ or $\mathsf{pK}^{\tau(|x|,t)}(x) > s + \log\tau(|x|, t)$.

[4] More precisely, if we can solve Cond-$\mathsf{pK}[\tau]$ for some polynomial τ, then we can also solve Gap-MINpK$\mathsf{T}[\tau']$ for some polynomial τ'.

> For every polynomial-time samplable distribution family $\{\mathcal{D}_n\}_n$ supported over $\{0,1\}^n$, every polynomial q, and for all large enough polynomial τ, there is a probabilistic polynomial-time algorithm A that can decide, given as input $(x, 1^s, 1^t)$, whether $\mathsf{pK}^t(x) \leq s$ or $\mathsf{pK}^{\tau(|x|,t)}(x) > s + \log \tau(|x|, t)$,[5] with probability at least $1 - 1/q(n)$ over $x \sim \mathcal{D}_n$ and the internal randomness of A.

The above can be naturally generalized to the conditional setting, where we consider any samplable distribution family $\{\mathcal{D}_{\langle n,m\rangle}\}_{n,m}$ supported over $\{0,1\}^n \times \{0,1\}^m$, and for all large enough polynomial τ, we can decide whether $\mathsf{pK}^t(x \mid y) \leq s$ or $\mathsf{pK}^{\tau(|x|,|y|,t)}(x \mid y) > s + \log \tau(|x|, |y|, t)$ with high probability over (x, y) sampled from $\mathcal{D}_{\langle n,m\rangle}$. In this case, we say that "approximating conditional pK^t is easy-on-average over samplable distributions"

Also, we say that "computing pK^t is easy-on-average over samplable distributions" if the following holds.

> For every polynomial-time samplable distribution family $\{\mathcal{D}_n\}_n$ supported over $\{0,1\}^n$, every polynomial q, and for all large enough polynomial τ, there is a probabilistic polynomial-time algorithm A that can decide, given as input $(x, 1^s)$, whether $\mathsf{pK}^{\tau(|x|)}_{2/3}(x) \leq s$ or $\mathsf{pK}^{\tau(|x|)}_{1/3}(x) > s$,[6] with probability at least $1 - 1/q(n)$ over $x \sim \mathcal{D}_n$ and the internal randomness of A.

▶ **Theorem 5** (Informal). *The following are equivalent.*

1. *Infinitely-often one-way functions do not exist.*
2. *Approximating* pK^t *is easy-on-average over samplable distributions.*
3. *Approximating conditional* pK^t *is easy-on-average over samplable distributions.*
4. *Computing* pK^t *is easy-on-average over samplable distributions.*
5. *Computing conditional* pK^t *is easy-on-average over samplable distributions.*

A sketch of the proof of Theorem 5 can be found in [20, Section 3.3].

1.1.2 Characterizing Impagliazzo's Worlds by Tractability of Conditional Time-Unbounded Kolmogorov Complexity

We present a meta-complexity problem, namely approximating conditional Kolmogorov complexity up to an $O(\log n)$ additive term, that is unconditionally hard (even uncomputable) in the worst case, but such that its average-case intractability for different classes of distributions characterize Algorithmica, Heuristica and Pessiland.

Characterizing DistNP $\subseteq$ BPP and DistNP $\subseteq$ HeurBPP by Tractability of Time-Unbounded Kolmogorov Complexity

To begin, we recall a recent result by Ilango, Ren, and Santhanam [11] characterizing the non-existence of one-way functions by the tractability of approximating Kolmogorov complexity over polynomial-time samplable distributions. We consider the following conditional variant from [8].

---

[5] Note that this is the problem Gap-MINpKT mentioned in Footnote 3.
[6] This problem is referred to as $\mathsf{MpK}^\tau\mathsf{P}$ in [17].

▶ **Theorem 6** ([8, Lemma 27], cf. [11]). *The following are equivalent.*

1. *Infinitely-often one-way functions do not exist.*
2. **(Approximating conditional Kolmogorov complexity is easy-on-average over polynomial-time samplable distributions.)**
   For every polynomial-time samplable distribution family $\{\mathcal{D}_n\}_n$, where each $\mathcal{D}_n$ is over $\{0,1\}^n \times \{0,1\}^n$, and every polynomial q, there exist a probabilistic polynomial-time algorithm A and a polynomial p such that for all $n \in \mathbb{N}$,

$$\Pr_{(x,y)\sim\mathcal{D}_n}[\mathsf{K}(x \mid y) \leq A(x,y) \leq \mathsf{K}(x \mid y) + \log p(n)] \geq 1 - \frac{1}{q(n)}.$$

Note that a one-way function is a function that is efficiently computable but hard to invert on average; thus, this notion is based on *average-case* hardness. Theorem 6 characterizes the existence of one-way functions by the average-case hardness of approximating (conditional) Kolmogorov complexity. Then, for $\mathsf{NP} \not\subseteq \mathsf{BPP}$, which is a worst-case hardness notion, one might think that it can be characterized by the worst-case hardness of approximating (conditional) Kolmogorov complexity. However, it is well known that the task of approximating the conditional Kolmogorov complexity is provably intractable in the worst case, so such a characterization would imply $\mathsf{NP} \not\subseteq \mathsf{BPP}$ unconditionally.

Consider a polynomial-time samplable distribution $\mathcal{D}$ over $\{0,1\}^n \times \{0,1\}^n$. Also, let $\mathcal{D}^{(2)}$ be the marginal distribution of $\mathcal{D}$ on the second half, and let $\mathcal{D}(\cdot \mid y)$ denote the conditional distribution of $\mathcal{D}$ on the first half given that the second half is y. Now, observe the following equivalent way of sampling a pair of strings (x,y) from $\mathcal{D}$: We first sample y from $\mathcal{D}^{(2)}$ and then x from $\mathcal{D}(\cdot \mid y)$.

Note that Theorem 6 essentially says that one-way functions do not exist if and only if, for every polynomial-time samplable distribution $\mathcal{D}$, one can approximate $\mathsf{K}(x \mid y)$ on average over (x,y), where we sample y from $\mathcal{D}^{(2)}$ and then x from $\mathcal{D}(\cdot \mid y)$. In order to characterize $\mathsf{NP} \subseteq \mathsf{BPP}$, we consider the tractability of approximating conditional Kolmogorov complexity in the *semi-worst case*, meaning that we can approximate $\mathsf{K}(x \mid y)$ on average over x sampled from $\mathcal{D}(\cdot \mid y)$ for *all* $y \in \{0,1\}^n$ (instead of an average y from $\mathcal{D}^{(2)}$). Our first result is a characterization of $\mathsf{NP} \subseteq \mathsf{BPP}$ by the tractability of approximating conditional Kolmogorov complexity in this semi-worst case. Formally, we show the following.

▶ **Theorem 7.** *The following are equivalent.*

1. $\mathsf{NP} \subseteq \mathsf{BPP}$.
2. **(Approximating conditional Kolmogorov complexity is easy in the semi-worst case.)**
   For every polynomial-time samplable distribution family $\{\mathcal{D}_n\}_n$, where each $\mathcal{D}_n$ is over $\{0,1\}^n \times \{0,1\}^n$, and every polynomial q, there exist a probabilistic polynomial-time algorithm A and a polynomial p such that for all $n \in \mathbb{N}$ and $y \in \{0,1\}^n$,

$$\Pr_{x\sim\mathcal{D}_n(\cdot|y)}[\mathsf{K}(x \mid y) \leq A(x,y) \leq \mathsf{K}(x \mid y) + \log p(n)] \geq 1 - \frac{1}{q(n)}.$$

Theorem 7 shows that $\mathsf{NP} \subseteq \mathsf{BPP}$ if and only if for every polynomial-time samplable distribution $\mathcal{D}$, approximating $\mathsf{K}(x \mid y)$ is easy on average over x sampled from $\mathcal{D}(\cdot \mid y)$ for *every* $y \in \{0,1\}^n$. Now, instead of considering every $y \in \{0,1\}^n$ (a worst-case notion), it is also natural to consider an average y sampled from some polynomial-time samplable distribution $\mathcal{C}$ (an average-case notion). However, the distribution $\mathcal{C}$ here can be independent of $\mathcal{D}$. In particular, it does not necessarily have to be $\mathcal{D}^{(2)}$.

Next, we show that the average-case tractability of approximating conditional Kolmogorov complexity over such *independent polynomial-time samplable distributions*, in fact characterizes the *average-case* easiness of NP (i.e., DistNP $\subseteq$ HeurBPP). We first state formally the definition of independent polynomial-time samplable distributions.

▶ **Definition 8** (Independent Polynomial-Time Samplable [8]). *We say that a distribution family $\{\mathcal{D}_n\}_n$, where each $\mathcal{D}_n$ is over $\{0,1\}^n \times \{0,1\}^n$, is* independent polynomial-time samplable *if there exist two polynomial-time samplable distribution families $\{\mathcal{A}_n\}_n$ and $\{\mathcal{B}_n\}_n$, where each $\mathcal{A}_n$ is over $\{0,1\}^n$ and each $\mathcal{B}_n$ is over $\{0,1\}^n \times \{0,1\}^n$, such that $\mathcal{D}_n$ can be equivalently sampled as follows: sample $y \sim \mathcal{A}_n$, sample $x \sim \mathcal{B}_n(\cdot \mid y)$, and then output (x,y).*

It is easy to see that every polynomial-time samplable distribution is also independent polynomial-time samplable, by letting $\mathcal{A}$ be the marginal distribution of $\mathcal{D}$ on the second half and letting $\mathcal{B}$ be $\mathcal{D}$. However, the converse is not necessarily true. Nevertheless, Theorem 6 and Theorem 9 (which we state below) imply that the task of ruling out Pessiland is equivalent to showing that the hardness of approximating conditional Kolmogorov complexity remains unchanged over these two classes of distributions.

▶ **Theorem 9.** *The following are equivalent.*

1. DistNP $\subseteq$ HeurBPP.
2. **(Approximating conditional Kolmogorov complexity is easy-on-average over independent polynomial-time samplable distributions.)**
   For every independent polynomial-time samplable distribution family $\{\mathcal{D}_n\}_n$ and every polynomial q, there exist a probabilistic polynomial-time algorithm A and a polynomial p such that for all $n \in \mathbb{N}$,

$$\Pr_{(x,y)\sim\mathcal{D}_n}[\mathsf{K}(x \mid y) \le A(x,y) \le \mathsf{K}(x \mid y) + \log p(n)] \ge 1 - \frac{1}{q(n)}.$$

Finally, we extend Theorem 6 to characterize the non-existence of *auxiliary-input one-way functions* by the tractability of approximating conditional Kolmogorov complexity over P/poly-*samplable distributions*.

▶ **Theorem 10.** *The following are equivalent.*

1. *Auxiliary-input one-way functions do not exist.*
2. *For every sequence of strings $\{y_n\}_n$ where each $y_n \in \{0,1\}^n$, every distribution family $\{\mathcal{D}_n\}_n$ samplable in polynomial time using $\{y_n\}_n$ as advice, where each $\mathcal{D}_n$ is over $\{0,1\}^n$, and every polynomial q, there exist a probabilistic polynomial-time algorithm A and a polynomial p such that for all $n \in \mathbb{N}$,*

$$\Pr_{x\sim\mathcal{D}_n}[\mathsf{K}(x \mid y_n) \le A(x,y_n) \le \mathsf{K}(x \mid y_n) + \log p(n)] \ge 1 - \frac{1}{q(n)}.$$

The results above characterize the non-existence of one-way functions, DistNP $\subseteq$ HeurBPP, and NP $\subseteq$ BPP by the *distributional* tractability of approximating the conditional Kolmogorov complexity. They imply that the tasks of ruling out Impagliazzo's certain worlds are equivalent to showing that the hardness of this problem is the same with respect to different classes of distributions. For example, Theorem 6 and Theorem 9 imply that basing one-way functions on DistNP $\not\subseteq$ HeurBPP (a.k.a., ruling out Pessiland) is equivalent to showing that the hardness of approximating conditional Kolmogorov complexity over polynomial-time samplable distributions is the same as the hardness over independent polynomial-time samplable distributions.

Equivalences between Tractability of Time-Unbounded and Time-Bounded Kolmogorov Complexity

We first recall the definition of time-bounded Kolmogorov complexity. For $x, y \in \{0,1\}^*$ and $t \in \mathbb{N}$, we define $\mathsf{K}^t(x \mid y)$ to be the minimum length of a program $p \in \{0,1\}^*$ such that $U^y(p)$ outputs x within t steps. Here, U is a fixed time-optimal universal Turing machine and has oracle access to the string y.

For $\tau\colon \mathbb{N} \to \mathbb{N}$ and $\kappa\colon \mathbb{N} \to \mathbb{N}$, let $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ be the problem where we are given input $x \in \{0,1\}^n$ and $y \in \{0,1\}^{\kappa(n)}$, and we are asked to compute $\mathsf{K}^{\tau(|x|)}(x \mid y)$. Given a polynomial τ and a polynomial κ, we say that:

- $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is *easy in the worst case* if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ can be solved in polynomial time.
- $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is *easy-on-average over polynomial-time samplable distributions* if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ admits a heuristic scheme. That is for any polynomial-time samplable distribution $\mathcal{D} = \{D_n\}_n$, where each $\mathcal{D}_n$ samples (x, z) with $x \in \{0,1\}^n$ and $y \in \{0,1\}^{\kappa(n)}$, there exists a probabilistic polynomial-time algorithm A such that for all $n, k \in \mathbb{N}$,

$$\Pr_{x,y\sim\mathcal{D}_n}\left[A(x, y; 1^n, 1^k) = \mathsf{K}^{\tau(|x|)}(x \mid y)\right] \geq 1 - \frac{1}{k}.$$

- $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is *easy-on-average over the uniform distribution* if for every polynomial p, there exists a probabilistic polynomial-time algorithm A such that for all $n \in \mathbb{N}$,

$$\Pr_{x\sim\{0,1\}^n, y\sim\{0,1\}^{\kappa(n)}}\left[A(x, y) = \mathsf{K}^{\tau(|x|)}(x \mid y)\right] \geq 1 - \frac{1}{p(n)}.$$

▶ **Theorem 11** (Implicit in [16]). *The following hold.*

- *For all polynomial $\tau(n) \geq n^2$, there exists a polynomial κ such that $\mathsf{NP} \subseteq \mathsf{BPP}$ if and only if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is easy in the worst-case.*
- *For all polynomial $\tau(n) \geq n^2$, there exists a polynomial κ such that $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ if and only if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is easy-on-average over polynomial-time samplable distributions.*
- *For every polynomial $\tau(n) \geq 1.1n$ and polynomial κ, infinitely-often one-way functions do not exist if and only if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is easy-on-average over the uniform distribution.*

As a corollary, we get the following equivalences between the tractability of conditional Kolmogorov complexity and that of conditional time-bounded Kolmogorov complexity.

▶ **Corollary 12** (Informal). *The following hold.*

- *For all polynomial $\tau(n) \geq n^2$, there exists a polynomial κ such that approximating conditional Kolmogorov complexity is easy in the semi-worst case if and only if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is easy in the worst-case case.*
- *For all polynomial $\tau(n) \geq n^2$, there exists a polynomial κ such that approximating conditional Kolmogorov complexity is easy-on-average over independent polynomial-time samplable distributions if and only if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is easy-on-average over polynomial-time samplable distributions.*
- *For every polynomial $\tau(n) \geq 1.1n$ and polynomial κ, approximating conditional Kolmogorov complexity is easy-on-average over polynomial-time samplable distributions if and only if $\mathsf{McK}^\tau\mathsf{P}[\kappa]$ is easy-on-average over the uniform distribution.*

Proof. This follows directly from Theorem 6, Theorem 7, Theorem 9, and Theorem 11. ◀

1.2 Techniques

In this section, we explain the main ideas behind our proofs.

Characterizing Non-Existence of One-Way Functions by Average-Case Easiness of Conditional pK^t

A recent result by Liu and Pass [17] characterized the non-existence of (infinitely-often) one-way functions by the average-case easiness of computing pK^t over polynomial-time samplable distributions. Here, we describe a proof of this result that is slightly different than the original one and show how to generalize it to *conditional* pK^t.

It will be convenient to think of the pK^t complexity of a string as its K^t complexity *conditioning on a random string* r (see [20, Proposition 17]).

First of all, by employing ideas from [14, 17], one can construct a function, which outputs the string x produced by a randomly selected (time-bounded) program (resp. conditioning on a random string r), and show that if this function can be inverted, then we can obtain a shortest program for x (resp. conditioning on r) "on average". In particular, it can be shown that if infinitely-often one-way functions do not exist, then for every time bound function $\tau(n) = n^{O(1)}$, there exists an efficient algorithm A (for simplicity, think of it as being deterministic) such that with high probability over a uniformly random string r, $A(x;r)$ computes $\mathsf{K}^\tau(x \mid r)$ for an average x sampled from some distribution $\mathcal{E}^\tau_r$, defined as $\mathcal{E}^\tau_r(x) := 2^{-\mathsf{K}^\tau(x|r)}$.

Next, we want to say that, for almost all r, the algorithm $A(-;r)$, which works for the distribution $\mathcal{E}^\tau_r$, also works for a given polynomial-time samplable distribution $\mathcal{D}$ (provided that τ is a sufficiently large polynomial). To get this, it suffices to show that $\mathcal{E}^\tau_r$ *dominates*[7] $\mathcal{D}$, i.e., $2^{-\mathsf{K}^\tau(x|r)} \gtrsim \mathcal{D}(x)$ for *every* x. The observation here is that this follows from the recently discovered coding theorem for $\mathsf{pK}^{\mathsf{poly}}$ [19], which asserts that for *every* string x, $\mathsf{pK}^\tau(x) \lesssim \log(1/\mathcal{D}(x))$ (again, provided that τ is a sufficiently large polynomial). To see this, note that by the definition of pK^t, we have for a uniform random r, $\mathsf{K}^\tau(x \mid r) \leq \mathsf{pK}^\tau(x)$.

Given the above, we have that with high probability over a uniformly random r, $A(x;r) = \mathsf{K}^\tau(x \mid r)$ for an average x sampled from $\mathcal{D}$. By an averaging argument, we get that with high probability over $x \sim \mathcal{D}$, $A(x;r) = \mathsf{K}^\tau(x \mid r)$ with high probability over a uniformly random r. For any such *good* x, if $\mathsf{pK}^\tau_{2/3}(x) \leq s$ (resp. $\mathsf{pK}^\tau_{1/3}(x) > s$), which means $\mathbf{Pr}_r[\mathsf{K}^\tau(x \mid r) \leq s] \geq 2/3$ (resp. $\mathbf{Pr}_r[\mathsf{K}^\tau(x \mid r) > s] \geq 2/3$), then $A(x,r) \leq s$ (resp. $A(x,r) > s$) with high probability over r. This allows us to solve the problem of computing pK^τ on average over the distribution $\mathcal{D}$.

Now we describe how to generalize the above to *conditional* pK^t.

Suppose we want to compute $\mathsf{pK}^\tau(x \mid y)$ over (x,y) sampled from some polynomial-time distribution $\mathcal{D}$. It will be convenient to consider the following equivalent way of sampling $\mathcal{D}$: We first sample $y \sim \mathcal{D}^{(2)}$, where $\mathcal{D}^{(2)}$ is the marginal distribution of $\mathcal{D}$ on the second half, and then sample $x \sim \mathcal{D}(\cdot \mid y)$, where $\mathcal{D}(\cdot \mid y)$ is the conditional distribution of $\mathcal{D}_n$ on the first half given that the second half is y. Finally, we output (x,y).

First of all, by modifying the construction of the candidate one-way function described above (e.g., by incorporating the distribution $\mathcal{D}^{(2)}$ into the construction), we can show that if infinitely-often one-way functions do not exist, then there exists an efficient algorithm A such that with high probability over a uniformly random string r and over y sampled from $\mathcal{D}^{(2)}$, $A(x;y,r)$ computes $\mathsf{K}^\tau(x \mid y,r)$ for an average x sampled from some distribution $\mathcal{E}^\tau_{y,r}$, where $\mathcal{E}^\tau_{y,r}(x) := 2^{-\mathsf{K}^\tau(x|y,r)}$.

[7] Recall that a distribution $\mathcal{D}$ dominates another distribution $\mathcal{D}'$ if $\mathcal{D}(x) \geq \mathcal{D}'(x)/\mathsf{poly}(n)$ for every x.

Now similar to the previous case, we want to say that, with high probability over r and $y \sim \mathcal{D}^{(2)}$, the algorithm $A(-; y, r)$, which works for the distribution $\mathcal{E}^{\tau}_{y,r}$, also works for the distribution $\mathcal{D}(\cdot \mid y)$. Again, it suffices to show that $\mathcal{E}^{\tau}_{y,r}(x) = 2^{-\mathsf{K}^{\tau}(x|y,r)} \gtrsim \mathcal{D}(x \mid y)$ for every x. However, this would require a conditional version of the coding theorem for $\mathsf{pK}^{\mathsf{poly}}$ applying to the distribution $\mathcal{D}(\cdot \mid y)$ (which is not necessarily efficiently samplable given y). Such a coding theorem is not known (in fact, is unlikely to hold).

The key observation is that in order to show that the algorithm $A(-; y, r)$, which works on average over the distribution $\mathcal{E}^{\tau}_{y,r}$, also works for $\mathcal{D}(\cdot \mid y)$, it suffices to have that $\mathcal{E}^{\tau}_{y,r}(x)$ dominates $\mathcal{D}(x \mid y)$ *on almost all* x, instead of every x. Then this weaker condition can be obtained from an *average-case* coding theorem for $\mathsf{pK}^{\mathsf{poly}}$, which has been shown under the assumption that infinitely-often one-way functions do not exist [8] (see [20, Theorem 29]).

More specifically, [8] showed that if infinitely-often one-way functions do not exist, then with high probability over $y \sim \mathcal{D}^{(2)}$ and $x \sim \mathcal{D}(\cdot \mid y)$, it holds that

$$\mathsf{pK}^{\tau}(x \mid y) \lesssim \log \frac{1}{\mathcal{D}(x \mid y)}.$$

Again, by the definition of pK^t and an averaging argument, this yields that with high probability over a uniformly random r and $y \sim \mathcal{D}^{(2)}$,

$$\mathsf{K}^{\tau}(x \mid y, r) \leq \log \frac{1}{\mathcal{D}(x \mid y)}$$

holds for almost all $x \sim \mathcal{D}(\cdot \mid y)$. This allows us to say that with high probability over r and $y \sim \mathcal{D}^{(2)}$, the distribution $\mathcal{E}^{\tau}_{y,r}$ dominates $\mathcal{D}(\cdot \mid y)$ *on average*, so the algorithm $A(-; y, r)$, which works for $\mathcal{E}^{\tau}_{y,r}$, also works for $\mathcal{D}(\cdot \mid y)$.

At this point, we get that with high probability over $(x, y) \sim \mathcal{D}$ and over a uniformly random r, $A(x; y, r) = \mathsf{K}^{\tau}(x \mid y, r)$. By the same argument as described above, this allows us to compute $\mathsf{pK}^{\tau}(x \mid y)$ on average over (x, y) sampled from $\mathcal{D}$.

The converse direction, i.e., that computing conditional pK^t on average allows us to break one-way functions, follows from the standard observation that computing pK^t on average over samplable distributions allows us to distinguish pseudo-random distributions (which are supported on strings of low pK^t complexity) from random strings (which have high pK^t complexity).

Characterizing DistNP $\subseteq$ HeurBPP by Average-Case Easiness of Conditional pK^t in Sublinear-Time Regime

To show that the average-case easiness of computing conditional pK^t (in the sublinear-time regime) implies the average-case easiness of NP (both with respect to polynomial-time samplable distributions), we first show that it is NP-hard to compute conditional pK^t (again, in the sublinear-time regime). Recently, Liu and Pass [16] and Hirahara [6] showed that the problem of computing the conditional K^t in the sublinear-time regime is NP-hard. We generalize this result to pK^t.

At a high level, our proof follows a similar approach but also requires some crucial observations to address the more complex notion of pK^t and to make it applicable to show Theorem 2. In particular, we adapt the proof in [6] which relies on the use of a *secret sharing scheme* (see [6, Section 2.3] for an exposition). More specifically, it reduces the problem of approximating the hamming weight of a *minimum satisfying assignment* of a given monotone formula, which is known to be NP-hard, to that of computing conditional K^t in the sublinear-time regime. That is, for every constant $c > 1$ and time bound function

$\tau(n,m) := n^c \cdot m^{1-1/c}$, there is a randomized reduction R such that if a given monotone formula ψ has a satisfying assignment of hamming weight at most ζ (resp. much larger than ζ), then with high probability, R produces a pair of strings (x,y) and ρ such that $\mathsf{K}^{\tau(|x|,|y|)}(x \mid y) \leq \rho$ (resp. $\mathsf{K}^{\tau(|x|,|y|)}(x \mid y) > \rho$).

Our key observation is that this reduction still works in the presence of any fixed string r. Roughly put, the reason for this is that a secret sharing scheme remains secure even if an adversary has access to some fixed string. More specifically, we can show that with respect to any string r, if a given monotone formula ψ has a satisfying assignment of hamming weight much larger than ζ, then with high probability the algorithm R produces a pair of strings (x,y) and ρ such that $\mathsf{K}^{\tau(|x|,|y|)}(x \mid y,r) > \rho$. This allows us to say that if the minimum weight of ψ is much larger than ζ, then with high probability over a random string r and over the internal randomness of R, $\mathsf{K}^{\tau(|x|,|y|)}(x \mid y,r) > \rho$. By an averaging argument, this gives that with high probability over the internal randomness of R, $\mathsf{K}^{\tau(|x|,|y|)}(x \mid y,r) > \rho$ for more than $2/3$ of the r's, which essentially means $\mathsf{pK}^{\tau(|x|,|y|)}_{1/3}(x \mid y) > \rho$.

Now we have showed that computing conditional pK^t (in the sublinear-time regime) is NP-hard. To solve an NP problem L over a given polynomial-time samplable distribution $\mathcal{D}$, we can compose $\mathcal{D}$ with the reduction R to obtain a new distribution $\mathcal{D}'$. Then we can show that computing conditional pK^t on average over $\mathcal{D}'$ will allow us to solve L on average over $\mathcal{D}$. However, there is an additional subtle issue here, the original reduction R depends on the time bound function (i.e., for every sublinear time bound τ, there is a reduction R that will work). On the other hand, to show Theorem 2 (Item 2 $\implies$ Item 1), it is required that the reduction works for all time bound functions τ of the form $\tau(n,m) = n^c \cdot m^{1-1/c}$. We will then need to further modify the reduction to achieve this. (See [20, Lemma 45] for the details.)

Now we need to show the other direction saying that the average-case easiness of NP implies the average-case easiness of computing conditional pK^t. Unlike the problem of computing (conditional) K^t, computing (conditional) pK^t is not known to be in NP, so we can not get the desired implication directly. However, it is not hard to see that the problem of computing conditional pK^t is in fact in (promise) AM.[8] If we can solve NP, then we can also solve AM (in the randomized setting), by a standard trick that combines the instance of an AM problem with a random string to produce an instance for an NP problem. (See [20, Lemma 53] for the details.)

Characterizing DistNP $\subseteq$ BPP and DistNP $\subseteq$ HeurBPP by Tractability of Time-Unbounded Kolmogorov Complexity.

First, we recap the proof of Theorem 6 as presented in [11]. We will ignore the issue of "infinitely often" in this subsection.

To show that the non-existence of one-way functions implies efficient algorithms for approximating conditional Kolmogorov complexity on average over polynomial-time samplable distributions, we use a powerful result from [13], which asserts that if one-way functions do not exist, then for any polynomial-time samplable distribution $\mathcal{D}$ over $\{0,1\}^n \times \{0,1\}^n$, one can efficiently estimate $\mathcal{D}(x \mid y)$ on average over $(x,y) \sim \mathcal{D}$. In addition, we combine two fundamental properties related to time-unbounded Kolmogorov complexity: The first is called the coding theorem, which roughly says that for every $(x,y) \in \mathsf{Support}(\mathcal{D})$,

[8] Here, we refer to the problem $\mathsf{Cond\text{-}pK}$ instead of the one that asks to decide whether $\mathsf{pK}^{\tau(|x|,|y|)}(x \mid y) \leq s$ for a given input $(x,y,1^s)$ and time bound τ.

$$\mathsf{K}(x \mid y) \lesssim \log \frac{1}{\mathcal{D}(x \mid y)},$$

and the second is the incompressibility property, which states that all $y \in \{0,1\}^n$ and for almost all $x \sim \mathcal{D}(\cdot \mid y)$,

$$\mathsf{K}(x \mid y) \gtrsim \log \frac{1}{\mathcal{D}(x \mid y)}.$$

It follows that for almost all $(x, y) \sim \mathcal{D}$,

$$\mathsf{K}(x \mid y) \approx \log \frac{1}{\mathcal{D}(x \mid y)}.$$

This allows us to approximate $\mathsf{K}(x \mid y)$ by estimating $\mathcal{D}(x \mid y)$, and the latter can be done efficiently if one-way functions do not exist.

For the other direction, the idea is that an efficient algorithm for approximating Kolmogorov complexity on average can be used to construct a function that distinguishes the output distribution of a cryptographic pseudorandom generator from the uniform distribution. Intuitively, this is because the outputs of such a generator have low $\mathsf{K}^{\mathsf{poly}}$ complexity while a random string has high Kolmogorov complexity. Then such an algorithm implies the non-existence of pseudorandom generators and hence of one-way functions [4].

Now, let us try to see if we can adapt the above proof paradigm to show Theorem 9, which characterizes $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ by the tractability of approximating conditional Kolmogorov complexity on average over *independent polynomial-time samplable distributions*.

One direction is in fact easy by using tools developed in [8]. In particular, it is observed in [8] that if $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$, then every independent polynomial-time samplable distribution can be simulated by some polynomial-time samplable distribution (see [20, Lemma 26]). Consequently, if $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ (which also implies that one-way functions do not exist), then we can reduce the task of approximating conditional Kolmogorov complexity over independent polynomial-time samplable distributions to that of approximating conditional Kolmogorov complexity over polynomial-time samplable distributions, which is tractable if one-way functions do not exist.

However, for the other direction, it is unclear how we can get $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ from the tractability of approximating conditional Kolmogorov complexity over independent polynomial-time samplable distributions, by using ideas from the proof of the characterization for one-way functions. In that scenario, we use the algorithm for approximating conditional Kolmogorov complexity as a distinguisher to break the security of a cryptographic pseudorandom generator.

Here, we will use a different approach. Specifically, we rely on a recently discovered characterization of $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ by the validity of a certain property called *conditional coding* for pK^t. More precisely, the authors of [8] showed that $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ if and only if conditional coding property for $\mathsf{pK}^{\mathsf{poly}}$ holds on average over pairs of strings drawn from independent polynomial-time samplable distributions, i.e., for any independent polynomial-time samplable distribution $\mathcal{D}$ over $\{0,1\}^n \times \{0,1\}^n$ and for almost all $(x, y) \sim \mathcal{D}$,

$$\mathsf{pK}^{\mathsf{poly}(n)}(x \mid y) \lesssim \log \frac{1}{\mathcal{D}(x \mid y)}$$

(see [20, Theorem 30]).

Now given this characterization of $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$ using conditional coding, it suffices to show that conditional coding property for $\mathsf{pK}^{\mathsf{poly}}$ over independent polynomial-time samplable distributions follows from the tractability of approximating conditional Kolmogorov complexity over the same class of distributions.

How can we show this? First of all, note that by the coding theorem for *time-unbounded* Kolmogorov complexity, we have that for every $(x, y) \in \mathsf{Support}(\mathcal{D})$,

$$\mathsf{K}(x \mid y) \lesssim \log \frac{1}{\mathcal{D}(x \mid y)}.$$

Then to get the desired conditional coding property for $\mathsf{pK}^{\mathsf{poly}}$, it suffices to show that for almost all $(x, y) \sim \mathcal{D}$,

$$\mathsf{pK}^{\mathsf{poly}(n)}(x \mid y) \leq \mathsf{K}(x \mid y) + O(\log n). \tag{1}$$

Now, let us describe how to show the above, assuming efficient algorithms for approximating conditional Kolmogorov complexity over independent polynomial-time samplable distributions.

The key ingredient here is a pseudorandom generator construction with reconstruction property. Such a generator is instantiated with a target string, it then takes as input a random seed and outputs a string that is longer than the seed. The reconstruction property allows us to say that if there exists a function that can distinguish the output distribution of the generator from the uniform distribution, then it can be used to recover the target string, using an additional advice string. This enables us to say that given a distinguisher, the target string has poly-time-bounded Kolmogorov complexity bounded by the length of the advice string. An algorithm for approximating Kolmogorov complexity can naturally be used as such a distinguisher, since the outputs of the generator have low Kolmogorov complexity while a random string has high Kolmogorov complexity. By appropriately configuring the parameters of the generator, we can ensure that the length of the advice string is comparable to the Kolmogorov complexity of the target string. This allows us to upper bound the poly-time-bounded Kolmogorov complexity of the target string by its Kolmogorov complexity.

Using this approach, the authors of [8] showed that if efficient algorithms exist for approximating conditional Kolmogorov complexity over polynomial-time samplable distributions, then for every polynomial-time samplable distribution $\mathcal{D}$ over $\{0,1\}^n \times \{0,1\}^n$ and almost all $(x, y) \sim \mathcal{D}$,

$$\mathsf{rK}^{\mathsf{poly}(n)}(x \mid y) \leq \mathsf{K}(x \mid y) + O(\log^3 n). \tag{2}$$

Here, rK^t is a certain randomized variant of time-bounded Kolmogorov complexity measure [2, 18].

The $O(\log^3 n)$ additive term in Equation (2) results from the use of a specific pseudorandom generator construction with an rK^t-style reconstruction property (as they need to upper bound $\mathsf{rK}^{\mathsf{poly}}$ by K), and such a generator has sub-optimal "advice complexity" in its reconstruction. In our case, we need to upper bound $\mathsf{pK}^{\mathsf{poly}}$ by K, and we can use a different pseudorandom generator construction with a pK^t-style reconstruction property that is known to have optimal "advice complexity" (see [20, Section 2.7]). This results in only an $O(\log n)$ additive term instead of $O(\log^3 n)$ as in the previous case.

The description provided above does not address an important technical distinction between showing Equation (1) and showing Equation (2) in [8]. In our case, we need to show Equation (1) over *independent polynomial-time samplable distributions*, whereas the

other case involves the simpler class of *polynomial-time samplable samplable distributions*. In fact, in the proof of Equation (2), a crucial fact used is that the uniform mixture of two polynomial-time samplable distributions is also polynomial-time samplable. Intuitively, the reason why this is needed is that we need to obtain a function that can distinguish the output distribution of a pseudorandom generator (induced by a polynomial-time samplable distribution) and the uniform distribution (also combined with a polynomial-time samplable distribution), so we need to apply an algorithm to approximate Kolmogorov complexity over the mixture uniform of those two distributions.

However, in our case, we are dealing with independent polynomial-time samplable distributions, and the uniform mixture of two independent polynomial-time samplable distributions is not necessarily independent polynomial-time samplable. The key insight here is that we don't really need to be concerned with the uniform mixture of two *generic* independently polynomial-time samplable distributions. Instead, the two distributions have the property that they are identical when restricted to the second half. We then show that the uniform mixture of such two distributions remains independently polynomial-time samplable. (See the proofs of [20, Lemma 59] and [20, Lemma 63] for details.)

We now describe the proof of Theorem 7. Again, the direction of showing the tractability of approximating conditional Kolmogorov complexity in the semi-worst case from $\mathsf{NP} \subseteq \mathsf{BPP}$ can be done in a way similar to that of Theorem 6 (as described earlier in this subsection). This is because if $\mathsf{NP} \subseteq \mathsf{BPP}$, then one can estimate $\mathcal{D}(x \mid y)$ for every polynomial-time samplable distribution $\mathcal{D}$ and $(x, y) \in \mathsf{Support}(\mathcal{D})$, a result due to [24] (see also [20, Lemma 27]).

For the other direction, we will employ the same approach as used to to show Theorem 9. In this case, we will use a similar characterization of $\mathsf{NP} \subseteq \mathsf{BPP}$ through conditional coding. Specifically, it has been shown in [8] that $\mathsf{NP} \subseteq \mathsf{BPP}$ if and only if *worst-case* conditional coding for $\mathsf{pK}^{\mathsf{poly}}$ holds, i.e., for every polynomial-time samplable distribution $\mathcal{D}$ over $\{0,1\}^n \times \{0,1\}^n$ and *every* $(x, y) \in \mathsf{Support}(D)$,

$$\mathsf{pK}^{\mathsf{poly}(n)}(x \mid y) \lesssim \log \frac{1}{\mathcal{D}(x \mid y)}. \tag{3}$$

Unfortunately, it is unclear how we can obtain the above worst-case conditional coding property from the tractability of approximating conditional Kolmogorov complexity in the *semi-worst case* by following the same approach. To overcome this, we observe that we can modify the original proof in [8] to obtain a characterization of $\mathsf{NP} \subseteq \mathsf{BPP}$ by *semi-worst-case* conditional coding, which only requires Equation (3) to hold for almost all $x \sim \mathcal{D}(\cdot \mid y)$ and for all $y \in \{0,1\}^n$ (see [20, Lemma 64]).

By using this alternative characterization and addressing a similar issue that arises when transitioning from polynomial-time samplable distributions to semi-worst-case input distributions, as described above in the case of showing Theorem 9, we can now use efficient algorithms for approximating conditional Kolmogorov complexity in the semi-worst case to obtain the desired semi-worst-case conditional coding property, which then yields $\mathsf{NP} \subseteq \mathsf{BPP}$.

1.3 Open Problems

Can we show NP-hardness of computing conditional pK^t in the polynomial-time regime? By Corollary 4, this would imply that Pessiland does not exist. Are there any barriers to showing such an NP-hardness result?

Theorem 9 characterizes the *error-prone* average-case easiness of NP (i.e., $\mathsf{DistNP} \subseteq \mathsf{HeurBPP}$) by the tractability of approximating conditional Kolmogorov complexity over independent polynomial-time samplable distributions. Can we obtain a similar characterization for the *errorless* average-case easiness of NP (i.e., $\mathsf{DistNP} \subseteq \mathsf{AvgBPP}$)?

Abstract

We present polylogarithmic approximation algorithms for variants of the Shortest Path, Group Steiner Tree, and Group ATSP problems with vector costs. In these problems, each edge e has a vector cost $c_e \in \mathbb{R}^\ell_{\geq 0}$. For a feasible solution – a path, subtree, or tour (respectively) – we find the total vector cost of all the edges in the solution and then compute the ℓ_p-norm of the obtained cost vector (we assume that $p \geq 1$ is an integer). Our algorithms for series-parallel graphs run in polynomial time and those for arbitrary graphs run in quasi-polynomial time.

To obtain our results, we introduce and use new flow-based Sum-of-Squares relaxations. We also obtain a number of hardness results.

1 Introduction

In this work, we study robust versions of network design problems. In the ℓ_p-Shortest Path problem, we are given $p \geq 1$, a graph $G = (V, E)$ with vector-valued edge costs $c_e \in \mathbb{R}^\ell_{\geq 0}$, and two vertices s and t; the goal is to find a path P from s to t in G that minimizes the following cost:

$$\mathrm{cost}_{\ell_p}(P) = \left\| \sum_{e \in P} c_e \right\|_p .$$

This problem is a natural generalization of the classical shortest path problem, but surprisingly has not received much attention till recently. The problem has been studied for $p = \infty$ under the name Robust Shortest Path. Aissi, Bazgan and Vanderpooten [1] used dynamic programming to obtain a fully polynomial-time approximation scheme for the case when the number of coordinates ℓ is a constant and $p = \infty$ (this result generalizes to other p). Kasperski and Zieliński [18] proved that ℓ_∞-Shortest Path is hard to approximate within $\log^{1-\varepsilon} \ell$ for all $\varepsilon > 0$ unless NP $\subseteq$ DTIME($n^{\text{polylog}\, n}$). More recently, the same authors [21] gave an $O(\sqrt{n \log \ell / \log\log \ell})$-approximation to the problem by rounding a flow-based linear programming relaxation and proved that their LP has the integrality gap of $\Omega(\sqrt{n})$. In a recent breakthrough, Li, Xu, and Zhang [23] gave an $O(\log n \log \ell)$-approximation algorithm for ℓ_∞-Shortest Path with running time quasi-polynomial in the size of the input instance. In particular, their algorithm is the first polylogarithmic approximation known to date. They also show that the same approximation guarantees can be obtained in polynomial time for graphs of bounded treewidth, and they give a polynomial time $O(d \log \ell)$ approximation algorithm for series-parallel graphs, where d is the depth (order) of the series-parallel decomposition of the input graph. No results were known for any other exponents $p \in (1, \infty)$. However, it is trivial to get an $\ell^{1-1/p}$-approximation by solving standard shortest path with edge costs $\|c_e\|_1$.

Introducing vector-valued costs to the graph's edges allows this model to capture a number of different applications. First, it allows us to describe a situation in which different parties, each corresponding to a different coordinate of the cost vectors, incur different cost when an edge is added to the solution. In this interpretation, as $p \to \infty$, the problem will increasingly favor paths in which every party simultaneously incurs small cost. Alternatively, each coordinate of the cost vectors may represent the cost incurred in terms of a different resource. This model would then allow one to balance minimizing the total amount of resources spent and ensuring that no single resource is depleted. Furthermore, one can think of this problem as providing an avenue for modeling robustness of a solution in the presence of uncertainty. Each coordinate would then represent the cost incurred by adding an edge in a distinct possible scenario, and the value of the ℓ_p-Shortest Path problem would amount to a trade-off between average and worst-case cost among all scenarios. Finally, this problem generalizes congestion minimization in directed graphs (a fact that we prove in Section 8 of the full version of the paper [24]).

Our results for the ℓ_p-Shortest Path problem. In this paper, we introduce a natural flow-based sum-of-squares (SoS) relaxation for ℓ_p-Shortest Path (Section 3) and present approximation algorithms for all integer $p \geq 1$.

First, we give an $O(pd^{1-1/p})$-approximation algorithm for the problem running in $n^{O(p)}$ time for series-parallel graphs of depth/order d (Section 5). We do this by considering a natural rounding algorithm for the SoS relaxation. We prove the following theorem:

▶ **Theorem 1.** *There exists an approximation algorithm for the ℓ_p-Shortest Path problem in series-parallel graphs that, given a series-parallel graph G of order/depth d and parameters $p \in \mathbb{Z}_{\geq 1}$ and $\varepsilon \in (0, 1)$, finds a $(1 + \varepsilon)\mathcal{B}_d(p)^{1/p} = O(pd^{1-1/p})$ approximation in time $m^{O(p)}/\varepsilon^{O(1)}$ (which is polynomial time when p and ε are fixed). Here, $\mathcal{B}_d(p)$ is the p^{th} d-dimensional Bell number.*[1]

[1] We provide a review of Bell numbers in the preliminaries.

For graphs of small series-parallel order/depth $d \le \log^* p$, the approximation factor is $\mathscr{B}_d^{1/p} \le O(p/\log^{(d)} p)$. Remarkably, in a complementary analysis given in Section 8 of the full version of the paper, we show that the approximation factor $\mathscr{B}_d(p)^{1/p}$ is tight for our rounding scheme. In all algorithms, we assume that ℓ is at most polynomial in n (if not, the running times will also depend on ℓ).

Then, we give a $O(p\log^{1-1/d} n)$-approximation for arbitrary graphs (Section 6 of the full version of the paper), obtaining the following theorem:

▶ **Theorem 2.** *There exists an approximation algorithm for the ℓ_p-Shortest Path problem in arbitrary graphs that, given a graph G and parameters $p \in \mathbb{Z}_{\ge 1}$ and $c \in (0, 1/2)$, finds a $cp\log^{1-1/p} n$ approximation in time $m^{ce^{O(1/c)}\log n} = m^{O_c(\log n)}$.*

Note that when $p = \log \ell$, this result yields an $O(c \log n \log \ell)$ approximation. This is very similar to the approximation guarantee of $O(\log n \log k)$ by Li, Xu, and Zhang, except that in our algorithm c can be an arbitrarily small constant.

▶ Remark 3. As previously discussed, an $\ell^{1-1/p}$-approximation is trivial to achieve in polynomial time by solving standard shortest path with edge costs $\|c_e\|_1$. On the other hand, for each fixed ℓ' there is a polynomial-time approximation scheme (PTAS) for ℓ_p-Shortest Path in ℓ' dimensions that runs in time $n^{O(\ell')}$. We now explain how to combine these two results. Fix $\delta \in (1/\ell, 1/2)$. Divide the coordinates of the cost vectors $c_e \in \mathbb{R}^\ell$ into $\ell' = \lceil 1/\delta \rceil$ groups, each of size at most $k = \lceil \delta \ell \rceil$ and then add up the coordinates in each group. For each cost vector $c_e \in \mathbb{R}^\ell$, we obtain a new vector $c'_e \in \mathbb{R}^{\ell'}$. Costs c'_e approximate costs c_e within a factor of $k^{1-1/p}$ in the following sense: for every path P,

$$\Big\|\sum_{e\in P} c_e\Big\|_p \le \Big\|\sum_{e\in P} c'_e\Big\|_p \le k^{1-1/p}\Big\|\sum_{e\in P} c_e\Big\|_p. \tag{1}$$

Using the PTAS, we solve the problem with costs c'_e and by (1) get a $(1+\varepsilon)k^{1-1/p}$ approximation to the original problem. We conclude that there exists an approximation algorithm that finds an $O((\delta\ell)^{1-1/p})$ approximation in time $n^{O(1/\delta)}$ (for every $\delta \in (1/\ell, 1/2)$).

In the course of analyzing our algorithms, we prove a new majorization inequality for pseudo-expectations (see Section 4) generalizing pseudo-expectation Lyapunov's and Hölder inequality (for the latter see [2, arXiv version]). We believe this result to be of independent interest.

Hardness results. We also complement the analysis above with several hardness results for ℓ_p-Shortest Path. First, in Section 8.1 of the full version of the paper, we give a reduction showing that the problem of congestion minimization can be reduced to the ℓ_∞-Shortest Path problem. This simultaneously speaks to the broad applicability of ℓ_p-Shortest Path and implies hardness for the ℓ_∞-version of the problem, following a result of Chuzhoy and Khanna [9].

▶ **Theorem 4.** *The ℓ_∞-Shortest Path problem is hard to approximate within an $\Omega(\log n/\log\log n)$-factor unless* NP $\subseteq$ ZPTIME$(n^{\log\log n})$.

This theorem slightly strengthens the $\Omega(\log^{1-\varepsilon}\ell)$-hardness of approximation result by Kasperski and Zieliński [18]. Finally, in Section 8.2 of the full version of the paper, we show that allowing the entries of the cost vectors to be negative makes the problem substantially harder. We do this by giving a reduction from the Closest Vector problem in lattices to this (potentially negative costs) version of the ℓ_p-Shortest Path problem. Below, Ω_p hides a constant depending on p.

▶ **Theorem 5.** *For every $p \in [1, \infty]$, it is* NP*-Hard to approximate the ℓ_p-Shortest Path problem allowing negative edge costs within a factor of $n^{\Omega_p(1/\log\log n)}$.*

▶ Remark 6. The requirement that all the coordinates of cost vectors c_e are non-negative can be slightly relaxed when $p = 2$. For our algorithms to work, it is sufficient that all pairwise inner products of cost vectors are non-negative. That is, instead of requiring that the Gram matrix of cost vectors is completely positive, we can only require that it is doubly non-negative.

From shortest path to network design. In network design problems, one is given a graph $G = (V, E)$ with non-negative edge costs $c_e \geq 0$, and wishes to find a subgraph $F = (V_F, E_F)$ that minimizes the total cost $\sum_{e \in E_F} c_e$ subject to some connectivity constraints. By varying the set of allowed subgraphs F, this paradigm encapsulates many central and well-studied network design problems, including the Survivable Network Design, Steiner Forest, Steiner Tree, and Minimum Spanning Tree. In this paper we explore two network design problems, Group Steiner Tree and Asymetric Traveling Salesperson (ATSP). We first recall the Group Steiner Tree problem.

▶ **Problem 7** (Group Steiner Tree)**.** *Given a weighted undirected graph $G = (V, E, c)$, as well as k subsets $R_1, \ldots, R_k$ of V, find a minimum-cost subtree T of G containing at least one vertex from each R_i.*

We then introduce an analogous group variant of ATSP:

▶ **Problem 8** (Group ATSP)**.** *Given a weighted directed graph $G = (V, E, c)$ and a collection of subsets $R_1, \ldots, R_k$ of V, find a minimum-cost tour that visits at least one vertex in each R_i.*

As in the case of Shortest Path, it is natural to ask whether we can approximately solve ℓ_p versions of other network design problems efficiently. Prior work has been done in this area. Hamacher and Ruhe [15] studied ℓ_∞-Minimum Spanning Tree, and proved that it is NP-complete. Following that, the complexity of the problem has been nearly completely settled: Chekuri, Vondrák, and Zenklusen [8] presented an $O(\log \ell / \log\log \ell)$-approximation algorithm, while Kasperski and Zielinski [19] (also see [20], Table 1) proved an $\Omega(\log^{1-\varepsilon} \ell)$-hardness of approximation for every $\varepsilon > 0$, unless all problems in NP can be solved in quasi-polynomial time. Laddha, Singh and Vempala [22] studied the ℓ_∞-version of a subclass of network design problems which encompasses the Generalized Steiner Network problem, and gave a polynomial-time ℓ-approximation algorithm for it.

Our results for ℓ_p-Group Steiner Tree and ℓ_p-Group ATSP. We consider the ℓ_p-version of the Group Steiner Tree and the Group ATSP problems.

In Section 7 of the full version of the paper, we refine the SoS relaxation for ℓ_p-Shortest Path to obtain approximation algorithms for ℓ_p-Group ATSP and ℓ_p-Group Steiner Tree, and thus obtain approximation algorithms for these problems as well. In particular, we prove the following two results:

▶ **Theorem 9.** *There exists an approximation algorithm for ℓ_p-Group ATSP that given graph G, groups R_i, and parameters $p \in \mathbb{Z}_{\geq 0}$ and $c \in (0, 1/2)$ finds a $c^2 p \log^{2-1/p} n \log k$ approximation in time $m^{O(p)+ce^{O(1/c)}\log n} = m^{O_c(\log n)}$. We assume that k is at most polynomial in n.*

▶ **Theorem 10.** *There exists an approximation algorithm for the ℓ_p-Group Steiner Tree problem in undirected graphs that given a graph G, groups R_i, and parameters $p \in \mathbb{Z}_{\geq 1}$ and $c \in (0, 1/2)$ finds a $c^2 p \log^{2-1/p} n \log k$ approximation in time $m^{ce^{O(1/c)}\log n} = m^{O_c(\log n)}$. We assume that k is at most polynomial in n.*

Note that for $p = \lceil \log \ell \rceil$, we get an approximation algorithm for the ℓ_∞ norm.

1.1 Related Works

Previous results on the scalar-cost group Steiner tree problem. Group Steiner Tree with scalar costs was introduced by Reich and Widmayer [29]. Garg, Konjevod, and Ravi [14] gave an $O(\log^2 n \log k)$-approximation to the problem, the first polylogarithmic approximation. Charikar, Chekuri, Goel, and Guha [6] gave the same $O(\log^2 n \log k)$-approximation with a deterministic algorithm. Then Charikar, Chekuri, Cheung, Dai, Goel, Guha, and Li [5] gave an $O(\log^3 k)$ approximation that works even with directed graphs; however, it required quasipolynomial time. Finally, Chekuri and Pál [7] gave an $O(\log^2 k)$ approximation for undirected graphs also in quasipolynomial time. The approximation guarantees of [14] and [6] are presented above with the improvement resulting from using metric embedding by Fakcharoenphol, Rao and Talwar [12]. In terms of the approximation guarantee and running time, out algorithm is most similar to that by Chekuri and Pál [7]: when $k = \Theta(n)$, the approximation guarantees match. In terms of techniques used, our algorithm uses some ideas from that by Garg, Konjevod, and Ravi [14].

Dijkstra-style Algorithm for ℓ_p-Shortest Path. The authors of [3] describe a Dijkstra-style algorithm for the ℓ_p-Shortest Path problem and claim that it achieves an $O(\min\{p, \log \ell\})$-approximation. However, we show that this claim is incorrect and, in fact, the approximation factor of their algorithm is at least $\Omega(n^{1-1/p})$. We discuss this algorithm in Appendix B of the full version of the paper.

Multi-objective combinatorial optimization for shortest path and network design. The work in this paper is closely related to multi-objective combinatorial optimization (MOCO). This area studies combinatorial optimization problems in the presence of multiple competing objective functions. Much of the literature on MOCO is concerned with finding all or some Pareto efficient solutions, that is, solutions that are not dominated in every objective by any other solution, a problem which is often intractable due to the exponential number of these points. In particular, there is prior MOCO work on both shortest path [16, 25, 4] and network design problems [28]. We refer the reader to the paper of Ruzika and Hamacher [30] for a survey on multi-objective spanning tree problems, and the book of Ehrgott [11] for an overview of multi-criteria optimization area as a whole.

1.2 Technical Overview

Let us first discuss the ℓ_p-Shortest Path problem. The most basic variant of this problem is when G is a series-parallel graph (see Section 2 for definitions) and $p = 2$. The first idea is to write an LP flow relaxation with a convex objective: minimize $\| \sum_{e \in E} c_e x_e \|^2$ subject to the constraint that $(x_e)_{e \in E}$ define a unit flow from s to t. However, this LP has an integrality gap of $\sqrt{\ell}$. To deal with this problem, Li, Xu, and Zhang [23] introduced a new constraint for ℓ_∞-Shortest Path: the constraint loosely speaking says that the LP cost of every subgraph/block B in the series-parallel decomposition of G is at most OPT times the probability (according to the LP) that the path visits B. Unfortunately, this new constraint does not help when $p = 2$.

Instead, we consider a sum-of-squares (SoS) strengthening of this LP.[2] The SoS relaxation gives valuations not only to individual edges but also to tuples of edges. Using the standard notation of pseudo-expectations (see Section 2), the SoS relaxation for $p = 2$ gives $\widetilde{\mathbb{E}}[x_e]$ for every edge e and $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}]$ for every pair of edges e_1 and e_2. The former could be interpreted as the probability that $e \in P$ and the latter as the probability as both $e_1, e_2 \in P$ according to the relaxation. To the best of our knowledge, this is the first flow-based SoS or SDP relaxation studied in the literature.

Our algorithm is very straightforward. We start at $u_0 = s$, then choose one of the edges outgoing from u_1 with probability of choosing e being equal to $\widetilde{\mathbb{E}}[x_e]$. We get to a vertex u_1 and then again sample one of the edges leaving u_1 with probability of choosing e proportional to $\widetilde{\mathbb{E}}[x_e]$. We repeat this step over and over until we reach t. It is clear that the algorithm finds an s-t path P.

Now we need to upper bound the cost of P. We do that recursively using the series-parallel decomposition of G.[3] Assume that G is composed of subgraphs/blocks $B_1, \dots, B_t$ and our algorithm achieves an α approximation for the squared ℓ_2-cost in each of them. For simplicity, assume that $t = 2$ for now. There are two cases: G is a (i) parallel and (ii) series composition of B_1 and B_2. Consider the first case. The SoS relaxation ensures that $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}] = 0$ for all $e_1 \in B_1$ and $e_2 \in B_2$; this means that the SoS solution is simply a convex combination of solutions for B_1 and B_2 with some weights p_1 and p_2. Also, with probability p_1, the first edge of P will be in B_1 and then the entire path will be in B_1; similarly, with probability p_2, the entire path will be in B_2. Thus running the algorithm reduces to randomly choosing a block B_i with probability p_i and then running the algorithm in B_i. Since the algorithm gets an α approximation in each B_i, it also gets an α approximation in the entire graph. Interestingly, this step would already fail if we used the basic LP relaxation; however, a Sherali–Adams or configuration LP would work in *this* case.

The second case – when G is a series composition of B_1 and B_2 is more challenging and requires the power of an SDP relaxation. Let $P_i = P \cap B_i$. Write the squared objective as follows:

$$\Big\|\sum_{e\in P} c_e\Big\|_2^2 = \underbrace{\Big\|\sum_{e\in P_1} c_e\Big\|_2^2 + \Big\|\sum_{e\in P_2} c_e\Big\|_2^2}_{\leq \alpha \mathsf{OPT}^2 \text{ (in expectation)}} + 2\sum_{\substack{e_1\in P_1\\ e_2\in P_2}} \langle c_{e_1}, c_{e_2}\rangle. \tag{2}$$

The first two terms are squared ℓ_2-costs of paths P_1 and P_2. As we assumed, they are at most α times their SoS costs, and thus their sum is at most $\alpha\mathsf{OPT}^2$ (in expectation). We now analyze the third term. It is not hard to see that our algorithm samples edges in P_1 and P_2 independently (because the last vertex of P_1 and the first vertex of P_2 are fixed). Therefore,

$$\mathbb{E}\Big[\sum_{\substack{e_1\in P_1\\ e_2\in P_2}} \langle c_{e_1}, c_{e_2}\rangle\Big] = \sum_{\substack{e_1\in B_1\\ e_2\in B_2}} \langle c_{e_1}, c_{e_2}\rangle \cdot \Pr\left(e_1, e_2 \in P\right) = \sum_{\substack{e_1\in B_1\\ e_2\in B_2}} \langle c_{e_1}, c_{e_2}\rangle \cdot \Pr\left(e_1 \in P\right) \cdot \Pr\left(e_2 \in P\right). \tag{3}$$

[2] It is sufficient to use a vector-flow SDP with one vector variable per edge in order to approximate the ℓ_2-cost in series-parallel graphs. However, we need higher degree SoS relaxations when $p > 2$ and in general graphs.

[3] Interestingly, neither the relaxation nor the algorithm uses the series-parallel decomposition of G.

It would be natural to upper bound this expression by the corresponding expression in the SoS objective (appropriately scaled):

$$\sum_{\substack{e_1\in B_1\\ e_2\in B_2}} \langle c_{e_1}, c_{e_2}\rangle \cdot \widetilde{\mathbb{E}}[x_{e_1}x_{e_2}].$$

However, this is not possible, since it may happen that $\Pr(e_1 \in P)\cdot\Pr(e_2\in P) > 0$ but $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}] = 0$. Instead, observing that for every edge e, $\Pr(e\in P) = \widetilde{\mathbb{E}}[x_e]$, we rewrite and upper bound (3):

$$\sum_{\substack{e_1\in B_1\\ e_2\in B_2}} \langle c_{e_1}, c_{e_2}\rangle \widetilde{\mathbb{E}}[x_{e_1}]\widetilde{\mathbb{E}}[x_{e_2}] \le \sum_{e_1,e_2\in E} \langle c_{e_1}, c_{e_2}\rangle \cdot \widetilde{\mathbb{E}}[x_{e_1}]\cdot\widetilde{\mathbb{E}}[x_{e_2}]$$
$$= \Big\|\widetilde{\mathbb{E}}\Big[\sum_{e\in E} c_e x_e\Big]\Big\|_2^2 \le \widetilde{\mathbb{E}}\Big[\Big\|\sum_{e\in E} c_e x_e\Big\|^2\Big] \le \mathsf{OPT}^2.$$

Here, we first expanded the summation, then used the pseudo-expectation Lyapunov's inequality $\|\widetilde{\mathbb{E}}[f]\|_2^2 \le \widetilde{\mathbb{E}}[\|f\|_2^2]$ (see Fact 18), and finally observed that the last pseudo-expectation is the SoS objective for G. We conclude that the expected squared cost of P is at most $(\alpha+2)\mathsf{OPT}$. Applying this argument recursively, we get an $O(d)$-approximation for the squared cost and an $O(\sqrt{d})$-approximation for the cost itself in series-parallel graphs of order/depth d.

When $p > 2$ and blocks in the series-parallel composition of G are formed by $t > 2$ lower-order blocks, the proof becomes more technical. In particular, we need to use a new majorization inequality for pseudo-expectation, which we present in Section 4.

The SoS relaxation for arbitrary graphs is the same as that for series-parallel graphs (except that its degree is higher). However, the rounding algorithm is quite different. Very informally, the algorithm in its simplest form resembles Savitch's algorithm for s-t connectivity in $O(\log^2 n)$ space [31] (see also [7]): (i) we sample the middle edge $e = (u, v)$ of the path using probabilities provided by $\widetilde{\mathbb{E}}[\cdot]$, (ii) condition $\widetilde{\mathbb{E}}[\cdot]$ on e being the middle edge, (iii) then recursively find paths P_1 from s to u and (independently) P_2 from v to t, using the *conditional* pseudo-expectation. To upper bound the cost, as in the analysis of the algorithm for series-parallel graphs, we first use (2) , then bound the third term using a variant of (3), and finally use the majorization inequality for pseudo-expectations.

To solve Group ATSP, we loosely speaking add SoS constraints that require that the tour P visits every group (for technical reasons, we need to require that P visits each group exactly once). Then we run the rounding algorithm for ℓ_p-Shortest Path in arbitrary graphs. It is not guaranteed that P indeed visits every group; however, using the machinery we developed for bounding the cost of P, we show that P visits every group with probability at least $\Omega(1/\log n)$. By sampling sufficiently many tours and concatenating them, we obtain the desired solution with high probability. The Group Steiner Tree problem easily reduces to Group ATSP.

1.3 Paper Organization

The rest of the paper is organized as follows. In Section 2 we define series-parallel graphs, relevant combinatorial quantities and notation used in the rest of the paper, and give some basic facts on Sum-of-Squares relaxations. In Section 3, we describe our Sum-of-Squares relaxation for ℓ_p-Shortest Path in directed acyclic graphs. In Section 4 we show a majorization inequality for pseudo-expectations used in the analysis of our algorithms. In Section 5 we describe and analyze our rounding algorithm for ℓ_p-Shortest Path in series-parallel graphs. In Section 6 we describe our approximation algorithm for ℓ_p-Shortest Path in arbitrary graphs.

The remaining sections appear in the full version of the paper [24]. Section 6 of the full version of the paper contains the proofs of the theorems that have been ommitted in this version. In Section 7 of the full version, we present our algorithms for ℓ_p-Group ATSP and ℓ_p-Group Steiner Tree. In Section 8 of the full version, we give our hardness results: hardness of approximation results for ℓ_p-Shortest Path with potentially negative edge costs and for ℓ_∞-Shortest Path. We also show that our analysis of the ℓ_p-Shortest Path algorithm in series-parallel graphs is tight. In Appendix A of the full version, we prove a recurrence formula and upper bound on multidimensional Bell numbers, which are used in the analyses of our algorithms for ℓ_p-Shortest Path.

2 Preliminaries and Notation

In this paper, all logs are base 2. In this paper, we consider Shortest Path and Group ATSP in directed graphs and Group Steiner Tree in undirected graphs. We assume that graphs may have parallel edges. Let $G = (V, E)$ be a directed graph. We denote $n = |V|$ and $m = |E|$. For $v \in V$, denote the sets of its outgoing and incoming edges by $\delta^+(v)$ and $\delta^-(v)$, respectively. Similarly, define $\delta^+(A)$ and $\delta^-(A)$ for subsets of vertices A. Finally, denote the set of edges from A to B by $\delta(A, B)$. We denote the i-th coordinate of vector edge cost c_e by $c_e(i)$.

2.1 Series-Parallel Graphs

We start with providing a recursive definition of directed series-parallel graphs with source s and sink t. A graph on two vertices s, t and one or more edges from s to t is a series-parallel graph of order (depth) 0. We denote the order of G as $\mathrm{ord}(G)$.

- **Parallel Composition.** Let $B_1, \ldots, B_t$ be series-parallel graphs that share only vertices s and t. Then their union G is a series-parallel graph. Define $\mathrm{ord}(G) = \max_j \mathrm{ord}(B_j)$.
- **Series Composition.** Let $B_1, \ldots, B_t$ be series-parallel graphs. Denote the source and sink of B_i by s_i and t_i (respectively). Assume that $t_i = s_{i+1}$ for all $i \in \{1, \ldots, t-1\}$ and that graphs B_i do not share any other vertices. Then the union G of graphs B_i is a series-parallel graph. Define $\mathrm{ord}(G) = \max_j \mathrm{ord}(B_j) + 1$.

In this definition, we only count *series* compositions when we compute the order of a series-parallel graph. We call vertices s and t *terminals*. We call intermediate graphs that we obtain while constructing G *blocks*. We denote the source and sink of a block B by s_B and t_B, respectively.

2.2 Combinatorics

Unlabeled Partitions. We say that a tuple of integers $\lambda = (\lambda_1, \ldots, \lambda_k)$ is an unlabeled partition of an integer $n \geq 1$ if $n = \sum_{i=1}^k \lambda_i$ and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k \geq 1$. We will denote this by $\lambda \vdash n$. We will denote the length of $\lambda = (\lambda_1, \ldots, \lambda_k)$ by $|\lambda| = k$.

Given an n and some tuple of non-negative integers α with $\alpha_1 + \ldots + \alpha_k = n$, we use standard notation for the multinomial coefficient

$$\binom{n}{\alpha} \stackrel{\text{def}}{=} \frac{n!}{\prod_{i=1}^k \alpha_i!}$$

Multidimensional Bell Numbers. Recall that the nth Bell number $\mathcal{B}_n$ equals the number of labeled partitions of a set of size n. In this paper, we will need a generalization of Bell numbers, known as multidimensional Bell numbers (see [32, Example 5.2.4] and [10]).

▶ **Definition 11.** *We say that a collection of subsets P is a partition of a set S if all subsets in P are disjoint and their union is S. Consider two partitions P and P' of S. We say that P' is a refinement of P if every $A \in P'$ is a subset of some $B \in P$.*

A d-dimensional partition of p is a tuple $(P_1, \dots, P_d)$ where all P_i are partitions of $[p] \stackrel{\text{def}}{=} \{1, \dots, p\}$ and each P_{i+1} is a refinement of P_i. The d-dimensional Bell number $\mathscr{B}_d(p)$ is the number of d-dimensional partitions of p. If $d = 0$ or $p = 0$, we let $\mathscr{B}_d(p) \stackrel{\text{def}}{=} 1$.

Note that 1-dimensional Bell numbers are simply the standard Bell numbers: $\mathscr{B}_1(i) = \mathscr{B}(i)$. We can also restate the definition of $\mathscr{B}_d(n)$ as follows. $\mathscr{B}_d(n)$ is the number of $(d+2)$-level rooted trees with n labeled leaves: the root must be in level 0, all leaves must be in level $d+1$, and all leaves are labeled with numbers from 1 to n with each number being used exactly once.

We will need the following recurrence formula for d-dimensional Bell numbers, which is proved in Appendix A of the full version of the paper.

▶ **Lemma 12.** *For every $d \geq 1$ and $p \geq 1$, we have*

$$\mathscr{B}_d(p) = \sum_{\lambda \vdash p} \binom{p}{\lambda} \prod_{i=1}^{|\lambda|} \mathscr{B}_{d-1}(\lambda_i) \Big/ \prod_{j=1}^{p} \mathrm{count}(j, \lambda)!$$

where $\mathrm{count}(j, \lambda)$ is the number of times j appears in λ.

Now, we describe the exponential generating function for sequence $(\mathscr{B}_d(i))_i$ when d is fixed.

▶ **Fact 13** ([32, Example 5.2.4])**.** *Let $f_0(x) = \exp(x)$ and $f_{i+1}(x) = \exp(f_i(x) - 1)$. Then the exponential generating function for sequence $(\mathscr{B}_d(i))_{i=0}^{\infty}$ is given by:*

$$\sum_{i=0}^{\infty} \frac{\mathscr{B}_d(i) x^i}{i!} = f_d(x). \tag{4}$$

In this paper, we will present an approximation algorithm for ℓ_p-Shortest Path in depth-d series-parallel graphs with approximation factor $\mathscr{A}_d(p) \stackrel{\text{def}}{=} \mathscr{B}_d(p)^{1/p}$. From Fact 13, we obtain the following upper bound on $\mathscr{A}_d(p)$, proved in Appendix A of the full version of the paper.

▷ Claim 14. For all $p \geq 1$ and $d \geq 1$, we have

$$\mathscr{A}_d(p) = \mathscr{B}_d(p)^{1/p} = O(p d^{1-1/p}).$$

Let $\log^{(j)} p = \underbrace{\log \cdots \log}_{j \text{ times}} p$ and $\log^* p$ be the largest value of j such that $\log^{(j)} p \geq 1$. Then, the following upper bound on $\mathscr{A}_d(p)$ holds for $d \leq \log^* p$:

$$\mathscr{A}_d(p) = \mathscr{B}_d(p)^{1/p} \leq O\Big(\frac{p}{\log^{(d)} p}\Big).$$

2.3 Sum-of-Squares Relaxations

We recall some basics about the sum-of-squares relaxations. Sum-of-squares relaxations can be thought of in terms of moment matrices, pseudo-distributions, and pseudo-expectations. As is common, we will use the pseudo-expectation framework in this paper. We refer the reader to [13] for a detailed description of the sum-of-squares framework.

Consider a set of variables x_i where i belongs to some set of indices $\mathcal{I}$. We denote the entire collection of all variables $(x_i)_{i\in\mathcal{I}}$ by $\mathbf{x}$. Consider the set of multivariate polynomials $\mathbb{R}_{\le d}[\mathbf{x}] \stackrel{\text{def}}{=} \mathbb{R}_{\le d}[\{x_i : i \in \mathcal{I}\}]$ in variables x_i of degree at most d. We say that $f \in \mathbb{R}_{\le d}[\mathbf{x}]$ is a sum of squares (SoS) if $f = \sum_{i=1}^m f_i^2$ for some polynomials $f_1, \dots, f_m$. Note that the product of SoS polynomials is a SoS, and so is any linear combination of SoS polynomials with positive coefficients.

In this paper, we consider SoS relaxations for the Boolean hypercube; that is, all variables x_i take values 0 and 1 in the intended solution. Therefore, we work with the quotient ring $\mathbb{R}_{\le d}/\langle x_i^2 - x_i\rangle_i$, where $\langle x_i^2 - x_i\rangle_i$ is the ideal generated by polynomials $x_i^2 - x_i$. In other words, we identify monomials $x_{i_1}^{a_1}, \dots, x_{i_t}^{a_t}$ and $x_{i_1}, \dots, x_{i_t}$ for all $i_1, \dots, i_t$ and $a_1, \dots, a_t \ge 1$ such that $\sum_{i=1}^t a_i \le d$. In particular, we will write $f = g$ if $f - g \in \langle x_i^2 - x_i\rangle_i$.

▶ **Definition 15.** *A linear map $\widetilde{\mathbb{E}} : \mathbb{R}_{\le d}[\mathbf{x}]/\langle x_i^2 - x_i\rangle_i \to \mathbb{R}$ is a pseudo-expectation of degree d if it satisfies the following properties.*

- $\widetilde{\mathbb{E}}[1] = 1$,
- $\widetilde{\mathbb{E}}[f^2] \ge 0$ *for every polynomial f of degree at most $d/2$,*

We say that a pseudo-expectation $\widetilde{\mathbb{E}}$ satisfies an equality constraint $f = 0$ if $\widetilde{\mathbb{E}}[fg] = 0$ whenever $\deg fg \le d$.

Given an objective function f and sets of equality and inequality constraints, we can find a pseudo-expectation $\widetilde{\mathbb{E}}$ that maximizes $\widetilde{\mathbb{E}}[f]$ and satisfies all the constraints in time polynomial in $N^{O(d)}$, where N is the number variables, as long as it satisfies certain regularity conditions [27]. When we prove any statements about pseudo-expectations $\widetilde{\mathbb{E}}[f]$ below, we will *always* implicitly assume that $d \ge \Omega(\deg f)$ so that all the inequalities appearing in the proofs have degree at most d.

▶ **Definition 16.** *Let $\widetilde{\mathbb{E}}$ be a pseudo-expectation of degree d. Assume that g is a sum of squares and $\widetilde{\mathbb{E}}[g] > 0$. Then the conditional pseudo-expectation $\widetilde{\mathbb{E}}[\cdot \mid g]$ operator is defined as follows: $\widetilde{\mathbb{E}}[f \mid g] \stackrel{\text{def}}{=} \widetilde{\mathbb{E}}[fg]/\widetilde{\mathbb{E}}[g]$.*

▶ **Fact 17.** *A conditional pseudo-expectation $\widetilde{\mathbb{E}}[\cdot \mid g]$ is a pseudo-expectation of degree $d' = d - \deg g$. If $\widetilde{\mathbb{E}}$ satisfies an equality or inequality constraint of degree at most d', then so does $\widetilde{\mathbb{E}}$.*

We will use Lyapunov's inequality for pseudo-expectations (which is also referred to as Jensen's inequality in the literature).

▷ Claim 18. Let g be a sum of squares and f be any polynomial. Assume that $\deg f^2 g \le d$. Then,

$$\widetilde{\mathbb{E}}[fg]^2 \le \widetilde{\mathbb{E}}[f^2 g]\,\widetilde{\mathbb{E}}[g]. \tag{5}$$

If $\widetilde{\mathbb{E}}[g] > 0$, the inequality can be restated as

$$\widetilde{\mathbb{E}}[f \mid g]^2 \le \widetilde{\mathbb{E}}[f^2 \mid g]. \tag{6}$$

▷ Claim 19. Let $f_1, \dots, f_t$ be SoS polynomials. Then, $\widetilde{\mathbb{E}}[\left(\sum_{i=1}^t f_i\right)^p] \ge \sum_{i=1}^t \widetilde{\mathbb{E}}[f_i^p]$.

Proof. We expand $\left(\sum_{i=1}^t f_i\right)^p$ as $\sum_{\substack{\alpha_1,\dots,\alpha_t \ge 0 \\ \alpha_1+\cdots+\alpha_t = p}} \binom{p}{\alpha} f_1^{\alpha_1} \cdots f_t^{\alpha_t}$. All terms in the expansion are SoS polynomials and thus have non-negative pseudo-expectations. The claim follows from the observation that all terms f_i^p are present in the expansion. ◁

3 Sum of Squares Relaxation for ℓ_p-Shortest Path

In this section, we first present our SoS relaxation for ℓ_p-Shortest Path in directed acyclic graphs (DAGs). In Section 5, we will present a rounding algorithm for series-parallel graphs and then, in Section 6 of the full version of the paper, for layered graphs. The latter result will also yield an algorithm for arbitrary graphs. We will also describe a few basic properties that feasible solutions for this relaxation satisfy.

Relaxation. We use a degree $2p$ SoS relaxation with variables $\mathbf{x} = (x_e)_{e\in E}$ for ℓ_p-Shortest Path in series-parallel graphs.

$$\begin{aligned} \min \quad & \widetilde{\mathbb{E}}\Big[\sum_{i=1}^{\ell}\Big(\sum_e c_e(i)x_e\Big)^p\Big] \\ \text{subject to} \quad & (x_e)_{e\in E} \text{ is a unit flow from } s \text{ to } t \end{aligned}$$

The flow constraint says that $\sum_{e\in\delta^+(u)} x_e - \sum_{e\in\delta^-(u)} x_e = 0$ for all u other than s and t (flow conservation) and $\sum_{e\in\delta^+(s)} x_e - 1 = 0$ (x_e sends 1 unit of flow from s to t). It is clear that this is a relaxation for the ℓ_p-Shortest Path problem: $\widetilde{\mathbb{E}}[\sum_{i=1}^{\ell}(\sum_e c_e(i)x_e)^p\Big] \le \mathsf{OPT}^p$, where OPT is the ℓ_p-cost of the optimal s-t path.

Basic properties of the SoS relaxation. We say that two edges e_1 and e_2 are *compatible* if both of them belong to some s-t path; otherwise, we say that e_1 and e_2 are *incompatible*. In a series-parallel graph edges e_1 and e_2 are incompatible if and only if there exist two parallel blocks B_1 and B_2 such that e_1 lies in B_1 and e_2 lies in B_2. For any set of vertices A, let $\mathbf{x}_A^+ = \sum_{e\in\delta^+(A)} x_e$ and $\mathbf{x}_A^- = \sum_{e\in\delta^-(A)} x_e$.

▷ Claim 20. Assume that G is a DAG and $\widetilde{\mathbb{E}}$ is a feasible pseudo-expectation for the relaxation. Let h be a multivariate polynomial. Then

1. If $A \subseteq V$ contains neither of the terminals, then $\widetilde{\mathbb{E}}[(\mathbf{x}_A^+ - \mathbf{x}_A^-)h] = 0$. If A contains s but not t, $\widetilde{\mathbb{E}}[(\mathbf{x}_A^+ - \mathbf{x}_A^-)h] = \widetilde{\mathbb{E}}[h]$.
2. If e_1 and e_2 are not compatible, then $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}h] = 0$.
3. Assume further that G is a series-parallel graph. Let (L, R) be an s_B-t_B cut in a block B. Let $f_{LR} = \sum_{e\in\delta(L,R)} x_e$. Then

$$\widetilde{\mathbb{E}}\Big[f_{LR}h\Big] = \widetilde{\mathbb{E}}\Big[\Big(\sum_{e\in\delta^+(s_B)\cap B} x_e\Big)h\Big].$$

In particular, $\widetilde{\mathbb{E}}[f_{LR}h]$ does not depend on the cut (L, R) in B.

Proof.

1. The SoS relaxation satisfies the flow conservation constraints and the constraint that the amount of flow being routed equals 1. Therefore, it satisfies any linear combination of them. In particular, it satisfies degree-1 polynomial equations $\mathbf{x}_A^+ - \mathbf{x}_A^- = 0$ when $s, t \notin A$ and $\mathbf{x}_A^+ - \mathbf{x}_A^- = 1$ when $s \in A$ but $t \notin A$. The first item follows.
2. It is sufficient to prove the statement for all monomials (the claim then follows by the linearity of $\widetilde{\mathbb{E}}$). Thus, we will assume that h is a monomial. Recall that an s-t cut is monotone if it cuts exactly one edge on every s-t path. Since e_1 and e_2 are incompatible, there is a monotone s-t cut $(A, \bar{A})$ that cuts both of them. We apply item 1 to polynomial

$x_{e_1}h$ and get $\widetilde{\mathbb{E}}[x_{e_1}h] = \widetilde{\mathbb{E}}[x_{e_1}\mathbf{x}_A^+h] = \widetilde{\mathbb{E}}[x_{e_1}(x_{e_1}+x_{e_2}+\dots)h]$. Here, $\dots$ is a sum of some x_e (the coefficient of each of them is 1). Note that x_eh is a monomial, thus $x_eh = (x_eh)^2$ and therefore $\widetilde{\mathbb{E}}[x_eh] \geq 0$. We conclude that

$$\widetilde{\mathbb{E}}[x_{e_1}h] \geq \widetilde{\mathbb{E}}[x_{e_1}(x_{e_1}+x_{e_2})h] = \widetilde{\mathbb{E}}[(x_{e_1}+x_{e_1}x_{e_2})h]$$

and simplifying, we get $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}h] \leq 0$. Since $x_{e_1}x_{e_2}h$ is a monomial, $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}h] \geq 0$, and thus $\widetilde{\mathbb{E}}[x_{e_1}x_{e_2}h] = 0$.

3. Item 3 follows immediately from item 1. ◁

4 Majorization Inequalities for Pseudo-expectations

In this section, we will prove a majorization inequality for pseudo-expectations. This inequality generalizes already known pseudo-expectation Lyapunov's (see Claim 18) and Hölder's (see [2]) inequalities.

▶ **Definition 21.** *Consider two integer sequences $a_1 \geq a_2 \geq \dots \geq a_k \geq 0$ and $b_1 \geq \dots \geq b_k \geq 0$. We say a majorizes b and write $a \succeq b$, if $\sum_{i=1}^k a_i = \sum_{i=1}^k b_i$ and for all $1 \leq i \leq k$ we have*

$$a_1 + \dots + a_i \geq b_1 + \dots + b_i.$$

Sequence majorization is a powerful tool for proving inequalities; it appears in widely used Muirhead's [26] and Karamata's [17] majorization inequalities. We now present a majorization inequality for pseudo-expectations. An analogous inequality for true expectations easily follows both from Karamata's and from Muirhead's majorization inequality.

▶ **Lemma 22.** *Consider a degree d pseudo-expectation $\widetilde{\mathbb{E}}$. Let $a \succeq b$ and f be an SoS polynomial of degree $\deg(f^{a_1}) \leq d$. Then*

$$\prod_{i=1}^k \widetilde{\mathbb{E}}[f^{a_i}] \geq \prod_{i=1}^k \widetilde{\mathbb{E}}[f^{b_i}]. \tag{7}$$

Proof. First, observe that this inequality for sequences $(r+1, r-1) \succeq (r, r)$ follows from Lyapunov's inequality for pseudo-expectations (Claim 18). Indeed, let $g = f^{r-1}$. Then, Lyapunov's inequality states that

$$\widetilde{\mathbb{E}}[f^r]^2 = \widetilde{\mathbb{E}}[fg]^2 \leq \widetilde{\mathbb{E}}[f^2g]\,\widetilde{\mathbb{E}}[g] = \widetilde{\mathbb{E}}[f^{r+1}]\,\widetilde{\mathbb{E}}[f^{r-1}], \tag{8}$$

as required. Now we use this inequality to show the desired inequality (7) for a more general case $(p+1, q-1) \succeq (p, q)$.

▷ Claim 23. Let $p \geq q \geq 1$ be integers. Then

$$\widetilde{\mathbb{E}}[f^{p+1}]\,\widetilde{\mathbb{E}}[f^{q-1}] \geq \widetilde{\mathbb{E}}[f^p]\,\widetilde{\mathbb{E}}[f^q].$$

Proof. We just proved the inequality when $p = q$. So we will assume below that $p > q$. Since f is an SoS polynomial, $\widetilde{\mathbb{E}}[f^r] \geq 0$ for all integers $0 \leq r \leq p$. Let us assume first that the inequality is strict for all r: $\widetilde{\mathbb{E}}[f^r] > 0$. Then, by dividing and multiplying $\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^p]$ by $\prod_{r=q}^{p-1} \widetilde{\mathbb{E}}[f^r]$, we obtain the following identity.

$$\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^p] = \frac{\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^{q+1}]\dots\widetilde{\mathbb{E}}[f^{p-1}]\,\widetilde{\mathbb{E}}[f^p]}{\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^{q+1}]\dots\widetilde{\mathbb{E}}[f^{p-1}]}$$

Now we upper bound the numerator of this fraction by iteratively applying (8).

$$\left(\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^q]\right)\widetilde{\mathbb{E}}[f^{q+1}]\cdots\widetilde{\mathbb{E}}[f^{p-1}]\,\widetilde{\mathbb{E}}[f^p] \le \left(\widetilde{\mathbb{E}}[f^{q-1}]\,\widetilde{\mathbb{E}}[f^{q+1}]\right)\widetilde{\mathbb{E}}[f^{q+1}]\cdots\widetilde{\mathbb{E}}[f^{p-1}]\,\widetilde{\mathbb{E}}[f^p]$$

$$\widetilde{\mathbb{E}}[f^{q-1}]\left(\widetilde{\mathbb{E}}[f^{q+1}]\,\widetilde{\mathbb{E}}[f^{q+1}]\right)\cdots\widetilde{\mathbb{E}}[f^{p-1}]\,\widetilde{\mathbb{E}}[f^p] \le \widetilde{\mathbb{E}}[f^{q-1}]\left(\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^{q+2}]\right)\cdots\widetilde{\mathbb{E}}[f^{p-1}]\,\widetilde{\mathbb{E}}[f^p]$$

$$\vdots$$

$$\widetilde{\mathbb{E}}[f^{q-1}]\,\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^{q+1}]\cdots\left(\widetilde{\mathbb{E}}[f^p]\,\widetilde{\mathbb{E}}[f^p]\right) \le \widetilde{\mathbb{E}}[f^{q-1}]\,\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^{q+1}]\cdots\left(\widetilde{\mathbb{E}}[f^{p-1}]\,\widetilde{\mathbb{E}}[f^{p+1}]\right)$$

We conclude that

$$\widetilde{\mathbb{E}}[f^q]\,\widetilde{\mathbb{E}}[f^p] \le \widetilde{\mathbb{E}}[f^{q-1}]\,\widetilde{\mathbb{E}}[f^{p+1}],$$

as desired. If $\widetilde{\mathbb{E}}[f^r] = 0$ for some r, we apply the inequality to $\hat{f} = f + \varepsilon$ (where $\varepsilon > 0$). Now $\widetilde{\mathbb{E}}[\hat{f}^r] \ge \varepsilon^r > 0$, since f is a SoS polynomial. Therefore, $\widetilde{\mathbb{E}}[\hat{f}^q]\,\widetilde{\mathbb{E}}[\hat{f}^p] \le \widetilde{\mathbb{E}}[\hat{f}^{q-1}]\,\widetilde{\mathbb{E}}[\hat{f}^{p+1}]$. Letting $\varepsilon \to 0$, we obtain the desired inequality in the limit. ◁

Consider an integer sequence $a_1 \ge \ldots a_k \ge 0$ and two indices $1 \le i^* < j^* \le k$ such that $a_{i^*} - a_{j^*} \ge 2$. Define a *transfer* or *T-transform* as follows: we decrease a_{i^*} by 1, increase a_{j^*} by 1, and then sort the obtained sequence in descending order. Claim 23 implies that Lemma 22 holds for sequence a and sequence b obtained from a by a T-transform.

Finally, we use that if $a \succeq b$ then b can be obtained by a sequence of T-transforms [26]: $a = a^{(0)} \mapsto a^{(1)} \mapsto a^{(2)} \mapsto \cdots \mapsto a^{(T)} = b$. As we proved, the value of the product $\prod_{i=1}^k \widetilde{\mathbb{E}}[f^{a_i^{(t)}}]$ may only decrease each time we apply a T-transform. This concludes the proof of the lemma. ◀

Importantly, conditional pseudo-expectations are pseudo-expectations (see Fact 17) and thus Lemma 22 holds for conditional pseudo-expectations as well.

5 Sum-of-Squares Relaxation Rounding

In this section, we describe and analyze a rounding algorithm for series-parallel graphs. It gives an $(1+\varepsilon)A_d(p) = O(pd)$ approximation for ℓ_p-Shortest Path in series-parallel graphs of order d. Later we use a different algorithm with a similar analysis to solve the problem in layered and arbitrary graphs.

5.1 Algorithm

Let us denote $p_e = \widetilde{\mathbb{E}}[x_e]$ and $p_u = \sum_{e\in\delta^+(u)} \widetilde{\mathbb{E}}[x_e]$. Note that the SoS relaxation constraints ensure that p_e is an s-t flow; p_u equals the amount of flow that leaves vertex u. The total amount of flow is 1.

Algorithm 1 Rounding algorithm for SoS.

Input: series-parallel graph G with source s and sink t, a pseudo-expectation $\widetilde{\mathbb{E}}$
Output: an s-t path in G
Let $u = s$ and P be an empty path.
while $u \neq t$ **do**
    Sample $e \in \delta^+(u)$ with probability $\frac{p_e}{p_u} = \frac{\widetilde{\mathbb{E}}[x_e]}{\sum_{e\in\delta^+(u)}\widetilde{\mathbb{E}}[x_e]}$
    Append e to path P
end while
return P

▶ **Lemma 24.** *Let P be the path returned by Algorithm 1. Then $\Pr(e \in P) = p_e$ for every edge e and $\Pr(u \in P) = p_u$ for every vertex u.*

Proof. We consider all vertices in topological order and prove the desired formulas for $\Pr(u \in P)$ and $\Pr((u,v) \in P)$ by induction. For $u = s$, we have $\Pr(s \in P) = 1 = p_s$. Then, $\Pr((s,v) \in P) = p_{(s,v)}/p_s = p_{(s,v)}$, as required. Now assume that we proved the formulas for vertices u' proceeding u in the topological order. We have,

$$\Pr(u \in P) = \sum_{e=(u',u)\in\delta^-(u)} \Pr(e \in P) = \sum_{e=(u,u')\in\delta^-(u)} p_e = p_u.$$

Here, we used the induction hypothesis and the flow conservation condition at vertex u. Now let $e = (u,v)$.

$$\Pr(e \in P) = \Pr(e \in P \mid u \in P)\Pr(u \in P) = (p_e/p_u)\cdot p_u. \qquad \blacktriangleleft$$

Now we will prove an upper bound on the ℓ_p-cost of path P. The proof will be by induction on the series-parallel decomposition of G, going from lower to higher order blocks B. To analyze different blocks B, we first introduce some relevant notation.

Let us say that a path P visits block B if it contains at least one edge from B. Let $P_B = P \cap B$ be the restriction of P to B. If P does not visit B, let $P_B = \varnothing$. Note that if P visits B then it must go through the source s_B and sink t_B of B. However, if B has a parallel block B', a path may go through s_B and t_B but visit B' rather than B itself. It follows from Lemma 24 that the probability that P visits B equals $p_B \stackrel{\text{def}}{=} \sum_{e\in\delta^+(s_B)\cap B} p_e$.

Now, we define conditional expectations and pseudo-expectations restricted to B (that is, conditioned on the event that P visits B). Let $h_B = \sum_{e\in\delta^+(s_B)\cap B} x_e = \sum_{e\in\delta^+(s_B)\cap B} x_e^2$ be a SoS indicator of the event that P visits B. We let

$$\mathbb{E}_B[\cdot] \stackrel{\text{def}}{=} \mathbb{E}[\cdot \mid P \text{ visits } B] \qquad \text{and} \qquad \widetilde{\mathop{\mathbb{E}}_{B}}[\cdot] \stackrel{\text{def}}{=} \widetilde{\mathbb{E}}[\cdot \mid h_B].$$

In the sequel, we shall bound the costs of P coordinate-by-coordinate. Thus, we consider a set of scalar non-negative edge weights $a_e \geq 0$. Define $f_B \stackrel{\text{def}}{=} \sum_{e\in B} a_e \cdot x_e$. For a path P', let $\mathrm{cost}(P') = \sum_{e\in P'} a_e$. Note that $f_B = \sum_{e\in B} a_e \cdot x_e^2$ and thus is a sum of squares.

▷ Claim 25. Let B' be a block inside B (possibly $B' = B$). Assume $p_B > 0$. Then, we have $\mathbb{E}_B[\mathrm{cost}(P_{B'})^r] = \frac{\mathbb{E}[\mathrm{cost}(P_{B'})^r]}{p_B}$ and $\widetilde{\mathbb{E}}_B[f_{B'}^r] = \frac{\widetilde{\mathbb{E}}[f_{B'}^r]}{p_B}$ when $r \in \{1,\dots,p\}$.

Proof. We have

$$\begin{aligned}\mathbb{E}[\mathrm{cost}(P_{B'})^r] &= \mathbb{E}[\mathrm{cost}(P_{B'})^r \mid P_B \neq \varnothing]\cdot\Pr(P_B \neq \varnothing) + \mathbb{E}[\mathrm{cost}(P_{B'})^r \mid P_B = \varnothing]\cdot\Pr(P_B = \varnothing)\\ &= \mathbb{E}_B[\mathrm{cost}(P_{B'})^r]\cdot p_B + 0\cdot(1-p_B) = p_B\cdot\mathbb{E}_B[\mathrm{cost}(P_{B'})^r],\end{aligned}$$

as required. To prove the second identity, consider a monomial g in the expansion of $f_{B'}^r$. We now prove that $\widetilde{\mathbb{E}}[gh_B] = \widetilde{\mathbb{E}}[g]$ and thus $\widetilde{\mathbb{E}}_B[g] \stackrel{\text{def}}{=} \widetilde{\mathbb{E}}[gh_B]/p_B = \widetilde{\mathbb{E}}[g]/p_B$. Note that only x_e with $e \in B'$ appear in g, and $\deg g = r \geq 1$. Choose an arbitrary x_e in g, say $e = (u,v)$ and let g' be such that $g = g'x_e$. Let (L,R) be a monotone s_B-t_B cut in B that cuts e. By Claim 20, item 3,

$$\widetilde{\mathbb{E}}[gh_B] = \widetilde{\mathbb{E}}\Big[g\sum_{e'\in\delta(L,R)} x_{e'}\Big] = \widetilde{\mathbb{E}}\Big[g'\sum_{e'\in\delta(L,R)} x_e x_{e'}\Big].$$

Now all edges $e' \in \delta(L,R)$ other than e are incompatible with e; for them, $\widetilde{\mathbb{E}}[g'x_ex_{e'}] = 0$ by Claim 20, item 2. Also, $\widetilde{\mathbb{E}}[g'x_ex_{e'}] = \widetilde{\mathbb{E}}[g'x_e]$ for $e' = e$. Therefore, $\widetilde{\mathbb{E}}[gh_B] = \widetilde{\mathbb{E}}[g'x_e] = \widetilde{\mathbb{E}}[g]$, as required. ◁

▶ **Lemma 26.** *Let $\widetilde{\mathbb{E}}$ be a feasible solution for the SoS relaxation of ℓ_p-Shortest Path. Let B be a block of order $\hbar = \mathrm{ord}(B)$ with $p_B > 0$. Then for every $r \le p$, we have*

$$\mathbb{E}_B\left[cost(P_B)^r\right] \le \mathscr{B}_\hbar(r)\,\widetilde{\mathop{\mathbb{E}}_B}[f_B^r].$$

Here, $\mathscr{B}_\hbar(r)$ is an $\hbar$-dimensional Bell number (see Section 2.2 for details).

Proof. We will prove the upper bound on $\mathbb{E}\left[\mathrm{cost}(P_B)^r\right]$ by induction on r and on the series-parallel decomposition of B. If $r = 0$ or $\hbar = 0$, the claim trivially holds. We consider two cases: when a block B is a parallel composition and when it is a series composition of lower-level blocks. We start with the former, much simpler case when B is a parallel composition of blocks $B_1, \dots, B_t$ sharing the same source s_B and sink t_B. If P visits B, then it visits exactly one of the blocks $B_1, \dots, B_t$. Therefore,

$$\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] = \sum_{i=1}^t \mathbb{E}_{B_i}\left[\mathrm{cost}(P_{B_i})^r\right] \Pr\left(P \text{ visits } B_i | P \text{ visits } B\right) = \sum_{i=1}^t \frac{p_{B_i}}{p_B}\mathbb{E}_{B_i}\left[\mathrm{cost}(P_{B_i})^r\right]. \quad (9)$$

Note that $f_B = \sum_{i=1}^t f_{B_i}$. Applying Claim 19 and then Claim 25 twice, we get

$$\widetilde{\mathop{\mathbb{E}}_B}[f_B^r] \ge \sum_{i=1}^t \widetilde{\mathop{\mathbb{E}}_B}[f_{B_i}^r] = \sum_{i=1}^t \frac{1}{p_B}\,\widetilde{\mathbb{E}}[f_{B_i}^r] = \sum_{i=1}^t \frac{p_{B_i}}{p_B}\,\widetilde{\mathop{\mathbb{E}}_{B_i}}[f_{B_i}^r]. \quad (10)$$

In fact the inequality above is an equality by Claim 20, part 2, but we do not need that here. Comparing (9) and (10) term-by-term, and using the induction hypothesis, we get

$$\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] \le \mathscr{B}_\hbar(r)\,\widetilde{\mathop{\mathbb{E}}_B}[f_B^r].$$

This concludes the analysis of this case. Now we assume that B is a series composition of blocks $B_1, \dots, B_t$. In this case, if P visits B then it visits all B_i; if it visits B_i, it visits B and all other B_j. Thus, $p_B = p_{B_1} = \dots = p_{B_t}$. Also, P_B is the concatenation of $P_{B_1}, \dots, P_{B_t}$. Using the multinomial theorem, we get

$$\begin{aligned}\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] &= \mathbb{E}_B\left[\left(\sum_{i=1}^t \mathrm{cost}(P_{B_i})\right)^r\right] = \mathbb{E}_B\left[\sum_{\substack{\alpha_1,\dots,\alpha_t \ge 0\\ \alpha_1+\dots+\alpha_t = r}} \binom{r}{\alpha} \prod_{i=1}^t \mathrm{cost}(P_{B_i})^{\alpha_i}\right] \quad (11)\\ &= \sum_{\substack{\alpha_1,\dots,\alpha_t \ge 0\\ \alpha_1+\dots+\alpha_t = r}} \binom{r}{\alpha} \mathbb{E}_B\left[\prod_{i=1}^t \mathrm{cost}(P \cap B_i)^{\alpha_i}\right].\end{aligned}$$

Observe that if P enters B, it necessarily visits $s_{B_1}, \dots, s_{B_t}$ and thus paths $P_{B_1}, \dots, P_{B_t}$ are mutually independent. We then have

$$\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] = \sum_{\substack{\alpha_1,\dots,\alpha_t \ge 0\\ \alpha_1+\dots+\alpha_t = r}} \binom{r}{\alpha} \prod_{i=1}^t \mathbb{E}_B\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right].$$

By Claim 25, $\mathbb{E}_B\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right] = \mathbb{E}\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right]/p_B = \mathbb{E}\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right]/p_{B_i} = \mathbb{E}_{B_i}\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right]$ and $\widetilde{\mathbb{E}}_B[f_{B_i}^{\alpha_i}] = \widetilde{\mathbb{E}}[f_{B_i}^{\alpha_i}]/p_B = \widetilde{\mathbb{E}}[f_{B_i}^{\alpha_i}]/p_{B_i} = \widetilde{\mathbb{E}}_{B_i}[f_{B_i}^{\alpha_i}]$. Using that $\mathrm{ord}(B_i) \le h - 1$ and applying the induction hypothesis, we get

$$\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] = \sum_{\substack{\alpha_1,\dots,\alpha_t\geq 0\\ \alpha_1+\dots+\alpha_t=r}} \binom{r}{\alpha} \prod_{i=1}^{t} \mathbb{E}_B\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right] = \sum_{\substack{\alpha_1,\dots,\alpha_t\geq 0\\ \alpha_1+\dots+\alpha_t=r}} \binom{r}{\alpha} \prod_{i=1}^{t} \mathbb{E}_{B_i}\left[\mathrm{cost}(P_{B_i})^{\alpha_i}\right]$$

$$\leq \sum_{\substack{\alpha_1,\dots,\alpha_t\geq 0\\ \alpha_1+\dots+\alpha_t=r}} \binom{r}{\alpha} \prod_{i=1}^{t} \mathscr{B}_{\hbar-1}(\alpha_i)\cdot \widetilde{\mathbb{E}}_{B_i} f_{B_i}^{\alpha_i} = \sum_{\substack{\alpha_1,\dots,\alpha_t\geq 0\\ \alpha_1+\dots+\alpha_t=r}} \binom{r}{\alpha} \prod_{i=1}^{t} \mathscr{B}_{\hbar-1}(\alpha_i)\cdot \widetilde{\mathbb{E}}_{B} f_{B_i}^{\alpha_i}.$$

Now, every α in the summation defines an unlabeled partition λ of n: λ is obtained by sorting all non-zero entries α_i of α. Let us denote this $\alpha \to \sigma$. For example, $\alpha = (4,1,0,2,4,0,2,2) \to \lambda = (4,4,2,2,2,1)$. Thus, to go over all α, it is sufficient to go over all $\lambda \vdash r$ and then all α such that $\alpha \to \lambda$. To do the latter, we go over all choices of distinct indices $j_1,\dots,j_{|\lambda|}$ and define α as follows: $\alpha_{j_i} = \lambda_i$ for $i \in [|\lambda|]$ and $\alpha_j = 0$ for all other j. However, if $\lambda_i = \lambda_{i'}$, then indices $j_1,\dots,j_{|\lambda|}$ and those with j_i and $j_{i'}$ swapped define the same α. It is easy to see that the above procedure defines every α exactly $\prod_{j=1}^{r}\mathrm{count}(j,\lambda)$ times. In the example above with $\lambda = (4,4,2,2,2,1)$, this procedure defines every α exactly $2!\cdot 3!$ times. Finally note that $\binom{r}{\alpha} = \binom{r}{\lambda}$. Keeping this discussion in mind, we rewrite the upper bound on $\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right]$ as follows.

$$\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] \leq \sum_{\lambda\vdash r,\ |\lambda|\leq t} \binom{r}{\lambda} \frac{\sum_{j_1,\dots,j_{|\lambda|}\in[t]\ \text{distinct}} \prod_{i=1}^{|\lambda|} \mathscr{B}_{\hbar-1}(\lambda_i)\cdot \widetilde{\mathbb{E}}_B[f_{B_{j_i}}^{\lambda_i}]}{\prod_{j=1}^{r}\mathrm{count}(j,\lambda)}$$

$$\leq \sum_{\lambda\vdash r,\ |\lambda|\leq t} \binom{r}{\lambda} \cdot \frac{\prod_{i=1}^{|\lambda|}\mathscr{B}_{\hbar-1}(\lambda_i)}{\prod_{j=1}^{r}\mathrm{count}(j,\lambda)} \sum_{j_1,\dots,j_{|\lambda|}\in[t]} \prod_{i=1}^{|\lambda|} \widetilde{\mathbb{E}}_B[f_{B_{j_i}}^{\lambda_i}].$$

Note that we removed the requirement that all j_i are distinct in the last inequality (this is valid, since all terms are non-negative). Now we use Claim 19 and then the majorization inequality (see Lemma 22) to upper bound each term in the inner sum.

$$\sum_{j_1,\dots,j_{|\lambda|}\in[t]} \prod_{i=1}^{|\lambda|} \widetilde{\mathbb{E}}_B[f_{B_{j_i}}^{\lambda_i}] = \prod_{i=1}^{|\lambda|} \sum_{j\in[t]} \widetilde{\mathbb{E}}_B\Big[f_{B_j}^{\lambda_i}\Big] = \prod_{i=1}^{|\lambda|} \widetilde{\mathbb{E}}_B\Big[\sum_{j\in[t]} f_{B_j}^{\lambda_i}\Big] \leq \prod_{i=1}^{|\lambda|} \widetilde{\mathbb{E}}_B[f_B^{\lambda_i}] \leq \widetilde{\mathbb{E}}[f_B^r].$$

Using the recurrence relation for multidimensional Bell numbers from Lemma 12, we conclude that

$$\mathbb{E}_B\left[\mathrm{cost}(P_B)^r\right] \leq \sum_{\lambda\vdash r} \frac{\binom{r}{\lambda}\prod_{i=1}^{|\lambda|}\mathscr{B}_{\hbar-1}(\lambda_i)}{\prod_{j=1}^{r}\mathrm{count}(j,\lambda)}\,\widetilde{\mathbb{E}}[f_B^r] = \mathscr{B}_\hbar(r)\,\widetilde{\mathbb{E}}[f_B^r]. \qquad \blacktriangleleft$$

▶ **Theorem 27.** *Algorithm 1 gives an $(1+\varepsilon)\mathscr{A}_d(p) \stackrel{\text{def}}{=} (1+\varepsilon)\mathscr{B}_d(p)^{1/p}$ approximation for the problem in series-parallel graphs of order d in time polynomial in $n^{O(p)}$ and $1/\varepsilon$.*

Proof. We apply Lemma 26 with $a_e = c_e(i)$ to every coordinate $i \in [\ell]$ and add up the obtained upper bounds on $\mathbb{E}\left[\left(\sum_{e\in P} c_e(i)\right)^p\right]$. We get that

$$\mathbb{E}\left[\Big\|\sum_{e\in P} c_e\Big\|_p^p\right] \leq \mathscr{B}_\hbar(p)\,\widetilde{\mathbb{E}}\Big[\sum_{i=1}^{\ell}\Big(\sum_e c_e(i)x_e\Big)^p\Big] \leq \mathscr{B}_\hbar(p)\cdot \mathsf{OPT}^p.$$

By Markov's inequality, $\left\|\sum_{e\in P} c_e\right\|_p^p \leq (1+\varepsilon)\mathscr{B}_\hbar(p)\cdot\mathsf{OPT}^p$ with probability at least $\varepsilon/(1+\varepsilon)$. By running the algorithm $1/\varepsilon$ times, we find a solution of cost at most $\left\|\sum_{e\in P} c_e\right\|_p \leq (1+\varepsilon)^{1/p}\mathscr{B}_\hbar(p)^{1/p}\cdot\mathsf{OPT} \leq (1+\varepsilon)\mathscr{A}_\hbar(p)\cdot\mathsf{OPT}$ with constant probability. (As is standard, we can run this procedure many times and make the failure probability exponentially small.) $\blacktriangleleft$

6 Algorithms for ℓ_p-Shortest Path in Arbitrary Graphs

In this section, we describe an approximation algorithm for ℓ_p-Shortest Path in arbitrary graphs. We note that there is a black-box reduction from the problem in arbitrary graphs to that in series-parallel graphs, which is implicitly used by Li, Xu, and Zhang [23] in their algorithm for ℓ_∞-Shortest Path (which they call Robust s-t Path). This reduction outputs a series-parallel graph with $O(n^{\log n})$ vertices, where n is the number of vertices in the original graph. By using this reduction, we immediately get an $O(p\log^{1-1/p} n)$-approximation algorithm for general graphs with running time $n^{O(p\log n)}$. We describe here how to get an approximation algorithm for general graphs with an improved running time and slightly improved approximation factor; namely we describe how to get a $O(cp\log^{1-1/p} n)$-approximation in time $m^{O(ce^{1/c}\log n)}$ for every $c\in(0,1/2)$. We assume below that ℓ is at most polynomial in n; thus, we may assume $p\le\lceil\log_2\ell\rceil=O(\log n)$ (since all norms $\|\cdot\|_r$ with $r\ge\log_2\ell$ are equivalent within a factor of 2).

Layered graphs and reduction from general graphs to layered graphs. We say that a directed acyclic graph (DAG) $G=(V,E)$ is an s-t layered graph with Δ edge layers if V is the disjoint union of vertex layers $V_0,V_1,\dots,V_\Delta$, E is the disjoint union of layers $E_1,\dots,E_\Delta$, and each edge in E_i goes from V_{i-1} to V_i. Further, we require that $V_0=\{s\}$ and $V_\Delta=\{t\}$.

We transform an arbitrary graph $G=(V_G,E_G)$ with terminals s and t into a layered graph $\hat G=(V_{\hat G},E_{\hat G})$ with $\Delta=n-1$ edge layers. We create vertex layers $V_0,V_1,\dots,V_\Delta$: $V_0=\{s\}$, $V_\Delta=\{t\}$, and each of the other V_is is a disjoint copy of V_G. We connect $\hat u\in V_i$ with $\hat v\in V_{i+1}$ if there is an edge $(u,v)\in E_G$ between the corresponding vertices in G. The vector cost of $(\hat u,\hat v)$ equals that of (u,v). Additionally, we add *padding* edges between copies of t in adjacent layers and assign these edges cost 0.

For every s-t path P with at most Δ edges in G there is a corresponding path $\hat P$ in $\hat G$ and vice versa (P might not be a simple path); if path P has $k<\Delta=n-1$ edges, then $\hat P$ contains k non-padding edges and ends with $\Delta-k$ padding edges. Paths P and $\hat P$ have the same vector costs. Note that the ℓ_p-Shortest Path P^* between s and t is a simple path and thus contains at most $\Delta=n-1$ edges. Therefore, there is a path $\hat P^*$ in $\hat G$ corresponding to P^*. An α-approximation for $\hat P^*$ in $\hat G$ gives an α-approximation for P^* in G. This reduction shows that it is sufficient to consider layered graphs.

An algorithm for layered graphs. Assume that G is a layered graph with Δ edge layers, source s, and sink t. We use the SoS relaxation from Section 3 for G. Let $a=\lceil e^{1/c}\rceil$. We require that $\widetilde{\mathbb{E}}$ be a pseudo-expectation of degree $2d=2(p+(a+1)\lceil\log_{a+1}\Delta\rceil)=\Theta(p+ce^{1/c}\log\Delta)$. For a set of edges A of size at most d, we define polynomial $h_A=\sum_{e\in A}x_a$ and conditional pseudo-expectation $\widetilde{\mathbb{E}}_A[\cdot]\stackrel{\text{def}}{=}\widetilde{\mathbb{E}}[\cdot\,|\,h_A]$. Given A and a set of layer indices $I\subseteq[\Delta]$ so that $|A|+|I|\le d$, we define a sampling procedure that samples an edge from each layer E_i with $i\in I$ using pseudo-expectation $\widetilde{\mathbb{E}}_A$. We assume that the two algorithms below have access to graph G and pseudo-expectation $\widetilde{\mathbb{E}}$.

Algorithm 2 Edge sampling procedure.

Input: a subset of layer indices $I\subseteq[\Delta]$ and a subset A of edges.
Output: one edge from every layer E_i with $i\in I$.
$R=\varnothing$
for all $i\in I$ **do**
    Sample $e\in E_i$ with probability of choosing e equal to $\widetilde{\mathbb{E}}_{A\cup R}[x_e]$
    $R=R\cup\{e\}$
end for
return R

We say that we sample edges $e_1, \ldots, e_k$ in layers $i_1, \ldots, i_k$ conditioning on set A to mean that we run Algorithm 2 with parameters $I = \{i_1, \ldots, i_k\}$ and A.

Algorithm 3 Rounding algorithm for layered graphs.

Input: indices y and z of two edge layers ($1 \le y \le z \le \Delta$) and a subset of edges A.
Output: a path in $\hat{G}$ traversing layers E_y to E_z.
function FindPath(y, z, A)
  if $z - y + 1 \le a$ **then**
    Sample edges $e_0, \ldots, e_{z-y}$ in layers $E_y, E_{y+1}, \ldots, E_z$ conditioning on A.
    return the path formed by $e_0, \ldots, e_{z-y}$.
  end if
  Let $m_i = y + \lceil \frac{z-y}{a+1} \cdot i \rceil$ for $i \in [a]$.
  Sample edges $e_1, \ldots, e_a$ in layers $m_1, \ldots, m_a$ conditioning on A.
  Let $A' = A \cup \{e_i : i \in [a]\}$.
  Let $m_0 = z - 1$ and $m_{a+1} = y + 1$.
  for $i = 0$ **to** a **do**
    $P_i = \text{FindPath}(m_i + 1, m_{i+1} - 1, A')$ unless $m_i + 1 > m_{i+1} - 1$ then $P_i = \varnothing$
  end for
  Let P be the path formed by $P_0, e_1, P_1, e_2, \ldots, e_a, P_a$.
  return P
end function

To solve the problem, we run Algorithm 3 with $y = 1$, $z = \Delta$, and $A = \varnothing$. The analysis of this algorithm is quite similar to that of Algorithm 1 for series-parallel graphs, with the main difference that instead of the series-parallel decomposition of G, we consider the recursion tree whose nodes correspond to invocations of FindPath. The full analysis of this algorithm can be found in the full version of this paper [24], where the following theorems are shown.

▶ **Theorem 28.** *Algorithm 1 gives an $O(cp \log^{1-1/p} \Delta)$ approximation for the ℓ_p-Shortest Path problem in layered graphs with Δ layers in time $m^{O(p+ce^{1/c} \log \Delta)}$ for $c \in (0, 1/2)$.*

As a corollary, we get the following result for arbitrary graphs.

▶ **Theorem 29.** *There is an $O(cp \log^{1-1/p} n)$ approximation algorithm for the ℓ_p-Shortest Path problem in arbitrary graphs that runs in time $m^{O(p+ce^{1/c} \log n)}$ for $c \in (0, 1/2)$.*

Testing Spreading Behavior in Networks with Arbitrary Topologies

Augusto Modanese

Abstract

Given the full topology of a network, how hard is it to test if it is evolving according to a local rule or is far from doing so? Inspired by the works of Goldreich and Ron (J. ACM, 2017) and Nakar and Ron (ICALP, 2021), we initiate the study of property testing in dynamic environments with arbitrary topologies. Our focus is on the simplest non-trivial rule that can be tested, which corresponds to the 1-BP rule of bootstrap percolation and models a simple spreading behavior: Every "infected" node stays infected forever, and each "healthy" node becomes infected if and only if it has at least one infected neighbor. Our results are subdivided into two main groups:

- If we are testing a single time step of evolution, then the query complexity is $O(\Delta/\varepsilon)$ or $\tilde{O}(\sqrt{n}/\varepsilon)$ (whichever is smaller), where Δ and n are the maximum degree of a node and the number of vertices in the underlying graph, respectively. We also give lower bounds for both one- and two-sided error testers that match our upper bounds up to $\Delta = o(\sqrt{n})$ and $\Delta = O(n^{1/3})$, respectively. If ε is constant, then the first of these also holds against adaptive testers.
- When testing the environment over T time steps, we have two algorithms that need $O(\Delta^{T-1}/\varepsilon T)$ and $\tilde{O}(|E|/\varepsilon T)$ queries, respectively, where E is the set of edges of the underlying graph.

All of our algorithms are one-sided error, and all of them are also non-adaptive, with the single exception of the more complex $\tilde{O}(\sqrt{n}/\varepsilon)$-query tester for the case $T = 2$.

1 Introduction

Imagine we are observing the state of a network as it evolves over time. The network is static and we have complete knowledge about the connections; it is too large for us to keep track of the state of every single node, though nevertheless we are able to query nodes directly and learn their states. We might hypothesize that the global behavior can be explained by a certain local rule that is applied at every node, and we would like to verify if our hypothesis is correct or not. In this paper, we focus on this question: *How hard is it to test, given a local rule R, if the network is following R or is far from doing so?*

Following previous works [10, 18], we refer to the series of configurations assumed by the network over time as the *environment* ENV that we are observing. The network itself is static and its connections defined by a graph $G = (V, E)$. The local rule R is a map (admitting a finite description) from the states that a node observes in its neighborhood (including the node itself) to the new state it will assume in the next time step. Plausible scenarios that could be modeled in this context include not only rumor dissemination in social networks but also spreading of infectious diseases (where the connections between nodes represent proximity or contact between the organisms that we are observing). As is common in property testing [5], we assume that the bottleneck of this problem is keeping track of the states across the entire network, and hence we consider only the number of queries made by a testing algorithm as its measure of efficiency (and otherwise assume that the algorithm has access to unbounded computational resources).

1.1 Problem Setting

There exist two previous works [10, 18] that study the problem of determining whether ENV evolves according to R in the context of property testing (and, in the case of [10], also in the context of learning theory). In these works, the structure underlying ENV is always a cellular automaton (in the case of [18] one-dimensional, whereas [10] also considers automata of multiple dimensions), and thus ENV corresponds to the time-space diagram of such an automaton. This perspective is certainly meaningful when we are interested in phenomena that take place on a lattice or can be represented in such grid-like structures, for instance the movement of particles on a surface or across three-dimensional space. Nevertheless there are limits as to what can be modeled in this way. A prominent example are social networks, in which the connections hardly fit well into a regular lattice (even with several dimensions).

In this work we cast off these restraints and instead take the radically different approach of making no assumptions about the underlying structure or the space it is embedded in. Our only requirement is that it corresponds to a static graph G that is known to us in advance. This leaves a much broader avenue open when it comes to applications. In addition, the rule that we consider is effectively the simplest rule possible in such a setting that is not trivial. As we will see, despite the rule being very simple, it is rather challenging to fully determine the complexity of the problem. Indeed, compared to the previous works mentioned above, it might seem as if our progress is more modest; however, one should keep in mind that, in our case, the underlying network G has a much more rich structure (whereas in cellular automata we are dealing with a highly regular one).

The rule that we study is the 1-BP rule of *bootstrap percolation* [11, 20, 13, 2]. For $\tau \in \mathbb{N}_0$, the rule τ-BP is defined based on two states, *black* and *white*, as follows: If a node is black, then it always remains black; if a node is white, then it turns black if and only if it has at least τ black neighbors. These rules were originally inspired in the behavior observed in certain materials, and they are very naturally suited for modeling spreading phenomena.

Seen from the lenses of property testing, testing for the 1-BP rule in a sense resembles monotonicity testing [7]. Although we cannot directly apply one strategy to the other, if we view black as 1 and white as 0, then in both cases we have a violation whenever we see a 1 preceding a 0. The difference is that in 1-BP *every* 1 must arise from a preceding 1, whereas in the case of monotonicity we are happy if an isolated 0 spontaneously turns into a 1.

Another way of modeling the 1-BP rule is as a *constraint satisfaction problem* (CSP). CSPs have been studied in the context of property testing to some extent [4, 6]. We can characterize 1-BP by two constraints: A black node in step t implies every one of its neighbors is also black in step $t + 1$; meanwhile, a node is white in step $t + 1$ if and only if every one of

its neighbors in step t was white. Then we can recast testing if ENV follows 1-BP as testing if ENV is a satisfying assignment for these constraints. Nevertheless, although this seems to be a useful rephrasing of the problem, the current methods in CSPs in the context of property testing are not sufficient to tackle it. And, even if we could indeed test either constraint with a sublinear number of queries, ENV being close to satisfying both constraints would not necessarily imply that ENV is close to satisfying their intersection.

1.2 Results and Techniques

We now present our results and the methods used to obtain them. As this is a high-level discussion, formal definitions are postponed to Section 2, which the reader is invited to consult as needed.

The relevant parameters for the results are the number of nodes n in the graph $G = (V, E)$, the number of steps T during which the environment ENV evolves, the maximum degree Δ of G, and the accuracy parameter $\varepsilon > 0$. The size of the environment is nT, which is the baseline for linear complexity in this context (instead of n). We write ENV $\in$ 1-BP to indicate that ENV follows the 1-BP rule and $\mathrm{dist}(\texttt{ENV}, \text{1-BP}) \geq \varepsilon$ when it is ε-far from doing so, that is, one must flip at least εnT colors in ENV in order for 1-BP to be obeyed everywhere. (As already mentioned, see Section 2 for the precise definitions.)

In most cases we will be interested in optimizing the dependency of the query complexity on Δ. This is due to the fact that, intuitively, graphs with small Δ should be easier to verify locally, that is, by looking only at each node's neighborhood. (Indeed, this is the strategy followed by the first algorithm we present below in Theorem 1.)

Another desirable property that we wish our algorithms to have is *non-adaptiveness*; that is, the algorithm first produces a list of queries (without looking at the input), gathers their results, and then decides whether to accept or not. This is in contrast to an *adaptive* algorithm, which may perform later queries based on the answers it has seen so far. A third property "in-between" these is *time-conformability*, meaning that the algorithm does not make queries in step t if it has already queried nodes at some later step $t' > t$. It is easy to see that the existence of a non-adaptive algorithm with query complexity q implies a time-conforming algorithm with the same complexity: Just gather the q queries in a list, sort them according to the time step queried, and then execute the queries in order. The converse is not true in general, however, since a time-conforming algorithm might choose its queries in a later time step based on what it has seen beforehand (or in the same time step, even).

Recalling our motivation of testing the evolution of huge networks, we see that non-adaptive algorithms are the most desirable because the queries may all be performed in parallel (at each time step). In case this cannot be achieved, an adaptive, time-conforming algorithm is still satisfactory, even though it might require "freezing" the network at a specific time step (so that the algorithm has time to gather the results received and decide on the next queries to make on the same time step). Adaptive algorithms that violate time-conformability are not particularly desirable since they require "rewinding" the state of the network back in time. Nevertheless, depending on the nodes' capabilities, there might still be strategies to cope with this; for example, if T is small, it is plausible to have nodes can cache their state in previous steps (and thus answer any of the algorithm's queries, even about previous states).

In this paper, we study two different settings: testing a single time step of evolution ($T = 2$) and testing multiple steps ($T > 2$). In the first case we prove both upper and lower bounds, which also match up to certain values of Δ. In the second we show only upper bounds, but which suffice to demonstrate that the problem admits non-trivial testers, at least for moderate (non-constant) values of Δ.

1.2.1 The Case $T = 2$

Let us first discuss our results for the case where $T = 2$. In this case there is a natural graph-theoretical rephrasing of the problem: For $t \in \{1, 2\}$, let S_t be the set corresponding to $\texttt{ENV}(\cdot, t)$ where we see $\texttt{ENV}(\cdot, t)$ as an indicator function (i.e,. S_t is exactly the set of nodes $v \in V$ for which $\texttt{ENV}(v, t) = 1$). Then $\texttt{ENV} \in$ 1-BP if and only if S_2 is dominated by S_1 (in graph-theoretic terms).[1] From this perspective, the distance from ENV to 1-BP is the (relative) total number of nodes we need to add or remove from either of S_1 or S_2 in order for the domination property to be satisfied.

The hardness of the problem in this case is highly dependent on the maximum degree Δ. Our first result is that there is a very natural and simple algorithm that achieves query complexity $O(\Delta/\varepsilon)$.

▶ **Theorem 1.** *Let $T = 2$ and $\varepsilon > 0$. There is a* non-adaptive, one-sided error *algorithm with query complexity $O(\Delta/\varepsilon)$ that decides whether* $\texttt{ENV} \in$ 1-BP *or* $\mathrm{dist}(\texttt{ENV}, \text{1-BP}) \geq \varepsilon$.

The algorithm simply selects nodes at random and then queries their entire neighborhoods in both time steps. Since we are dealing with a local rule, this is sufficient to detect if ENV contains too many violations of the rule or not. One detail that needs care here is that, in general, our notion of distance does *not* match the number of violations of the rule. Nevertheless, as we show, the cases where it does not are only playing in our favor, and so this strategy always succeeds.

It turns out that this algorithm is optimal when we are in regimes where there is a constant $b \geq 2$ such that $\varepsilon = \Omega(\Delta^b/n)$. We also prove lower bounds for the case where $b \geq 1$, which are especially useful in regimes where Δ is larger than $\sqrt{n}$.

▶ **Theorem 2.** *There is a constant $\varepsilon_0 > 0$ such that the following holds: Let $\varepsilon = \Omega(\Delta^b/n)$ be given where $b \geq 1$ is constant, and let $\varepsilon \leq \varepsilon_0$. Then deciding if* $\texttt{ENV} \in$ 1-BP *or is ε-far from* 1-BP *with a* one-sided error *tester requires at least q queries in general, where:*

1. *If $b > 2$, then $q = \Omega(\Delta/\varepsilon)$ if the tester is non-adaptive or $q = \Omega(1/\varepsilon + \Delta)$ if it is adaptive.*
2. *If $b = 2$, then $q = \Omega(\Delta/\varepsilon \log \Delta)$ if the tester is non-adaptive or $q = \Omega(1/\varepsilon + \Delta/\log \Delta)$ if it is adaptive.*
3. *If $1 \leq b < 2$, then $q = \Omega(\Delta^{b-1}/\varepsilon)$ if the tester is non-adaptive or $q = \Omega(1/\varepsilon + \Delta^{b-1})$ if it is adaptive.*

Note the lower bounds hold even for adaptive testers in general, even for those that do not respect time-conformability.

If we are only interested in the regime where ε is constant, then setting $b = \log_\Delta n$ above we obtain a lower bound of $\Omega(\Delta)$ whenever $\Delta = O(n^{1/2-c})$ for a constant $c > 0$. This is matched by the upper bound of Theorem 1. For $\Delta = \Theta(\sqrt{n})$, the lower bound is $\Omega(\Delta/\log n)$; for larger Δ the lower bound becomes $\Omega(n/\Delta)$ and thus deteriorates as Δ increases.

The lower bound is based on an adequate construction of expander graphs. More specifically, the expanders we construct are bipartite, Δ-regular, and have *distinct* expansion guarantees for sets of nodes on either side. This is needed because the expansion in one direction guarantees ε-farness whereas the one in the other direction yields the actual lower bound on the number of queries that a correct algorithm must make.

[1] Technically the definition of domination is so that A dominates B if and only if $B \subseteq A \cup N(A)$. Using this definition the equivalence is only true if the graph G contains self-loops everywhere. (Nevertheless, adding self-loops everywhere does not impact the maximum degree, which is the relevant parameter here.) The equivalence is certainly true if we change the definition so that A dominates B if $B \subseteq N(A)$.

The hard instances themselves are simple: We color a moderately large set B of randomly chosen nodes black in the second time step and leave the rest colored white. The intuition is that, since B is chosen at random, it will not match nicely with a cover $C = \bigcup_{u \in S} N(u)$ induced by some set of nodes S in the first time step; that is, the symmetric difference between B and C will likely be large, giving us ε-farness. At the same time, since a one-sided error algorithm A cannot reject good instances, it is hard for it to detect that there is something wrong with B without having to "cover" a considerable number of nodes in either step. Indeed, in order to ascertain that a node $v \in B$ is incorrect, A must verify that there is no black node in $N(v)$ in the first step; if the existence of some black $u \in N(v)$ is compatible with its view, then there is no contradiction to v being black, and hence A cannot reject. Querying all of $N(v)$ requires $\Omega(\Delta)$ queries, but it is also possible for A to determine the colors *indirectly* by querying neighbors of nodes in $N(v)$. To obtain the lower bound we show that this other strategy also requires too many queries – although it might not be as inefficient when Δ is large (thus explaining why we get a weaker result in that case).

For two-sided error algorithms, we are able to prove similar, though slightly more modest lower bounds. These are also based on expander graphs but require a more complex set of instances for the argument to go through.

▶ **Theorem 3.** *There are constants $\varepsilon_0, \zeta > 0$ such that, for any $0 < \varepsilon \leq \varepsilon_0$ with $\varepsilon \geq \zeta \Delta^b / n$ where $b \geq 1$ is constant, deciding if* ENV $\in$ 1-BP *or is ε-far from* 1-BP *with a* non-adaptive, two-sided error *tester requires q queries in general, where:*

- *If $b > 3$, then $q = \Omega(\Delta/\varepsilon)$.*
- *If $b = 3$, then $q = \Omega(\Delta/\varepsilon \log \Delta)$.*
- *If $1 \leq b < 3$, then $q = \Omega(\Delta^{(b-1)/2}/\varepsilon)$.*

Again focusing on the regime where ε is constant, we now obtain $\Omega(\Delta)$ as the lower bound for regimes where $\Delta = O(n^{1/3-c})$ for a constant $c > 0$ or also $\tilde{\Omega}(\Delta)$ when $\Delta = \Theta(n^{1/3})$. Hence, given the algorithm of Theorem 1, up to $\Delta = \Theta(n^{1/3})$ there is essentially *no advantage* for two-sided error algorithms compared to one-sided error ones. For larger values of Δ, the lower bound is $\Omega(\sqrt{n/\Delta})$ and again deteriorates as Δ increases.

Since we are dealing with two-sided error algorithms, we apply Yao's minimax principle, and we now generate instances according to two different distributions D_Y and D_N where D_Y follows 1-BP whereas D_N generates instances that are (with high probability) far from doing so. The point is that we can show that it is hard to distinguish between D_Y and D_N without making a considerable number of queries. The distributions are such that, in both cases, we pick a set S of $\Theta(\varepsilon n/\Delta)$ vertices in the first time step uniformly at random. Then we color S and $N(S)$ black in D_Y (and leave the remaining nodes white) while in D_N we color only *a (constant) fraction* of $N(v)$ for $v \in S$ black. (We must also offset the fact that nodes in the second step in D_N are colored black with less probability by using a larger S when generating D_N instances.) By the expansion guarantees, this then gives us ε-farness of the instances in D_N. Observe that in this setting it is meaningless to query nodes in the first step since only a small fraction of them can ever be black; hence we need only deal with a set Q of nodes that are queried in the second step. The indistinguishability of D_Y and D_N follows from using the expansion guarantee from nodes in the second step to those in the first one. The argument is that, unless the set Q of queried nodes is large, almost all neighbors of Q are in fact *unique neighbors* and, moreover, it is impossible to distinguish D_Y from D_N if the set S only intersects the unique neighbors of Q. (That is, one can only distinguish D_Y and D_N if one queries *two* distinct neighbors $u, u' \in N(v)$ of some $v \in S$; due to the expansion guarantees, this requires a large number of queries.)

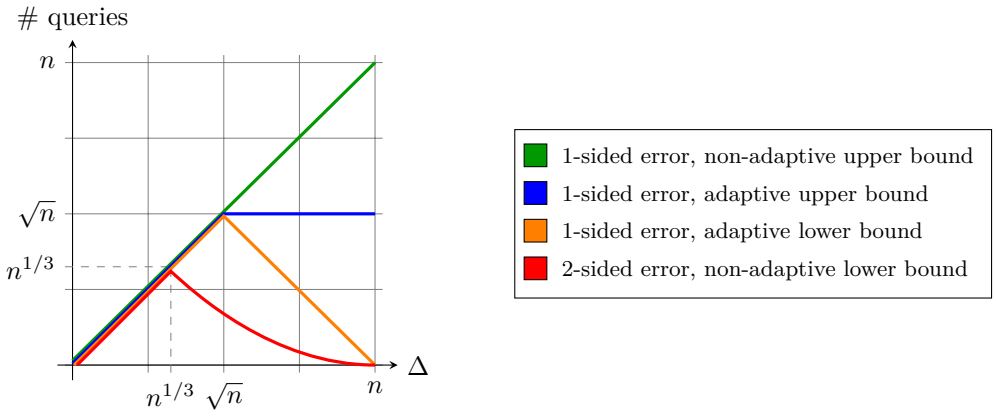

Figure 1 Summary of results for the case $T = 2$ and constant ε, ignoring logarithmic factors.

In light of these lower bounds, looking back at the algorithm of Theorem 1 we realize that its single weakness is that it does not perform well when Δ is large. Unfortunately our lower bounds do not say as much in that case, and thus a wide gap is left between lower and upper bounds in that regime. Nevertheless, we can narrow this gap by using a more complex strategy – if we are prepared to let go of non-adaptiveness and time-conformability (though we can still obtain a one-sided error algorithm). As previously discussed, this is not such a large limitation when taking possible applications into account (as when $T = 2$ it is plausible to, e.g., require nodes to cache their previous state) and indeed it is offset by the significant reduction in the query complexity.

▶ **Theorem 4.** *Let $T = 2$ and let $\varepsilon > 0$ be given. There is an* adaptive, one-sided error *algorithm for testing whether* ENV $\in$ 1-BP *or is ε-far from* 1-BP *with query complexity* $O(\sqrt{n}\log^{3/2}(n)/\varepsilon)$.

The algorithm achieving this is much more complex than that of Theorem 1. Indeed, it must decide whether ENV $\in$ 1-BP or not *without being able to query the entire neighborhood of any node*. To achieve this, we use a "filtering" process in which we first try to infer the color (assuming ENV $\in$ 1-BP) of as many nodes as we can (in either step) by querying some of their neighbors indirectly. Since we are certain of which color these nodes must have, we can verify these separately using a small number of random queries. Making careful observations, we then realize that we can simply ignore these nodes afterwards and thus reduce the degree of most of the remaining nodes to $\tilde{O}(\sqrt{n})$. This allows us to essentially fall back to a strategy as in the algorithm of Theorem 1, though a particular corner case requires special attention.

The results for $T = 2$ and the regime where ε is constant are summarized in Figure 1.

1.2.2 Case of General T

Let us now discuss the case $T > 2$. Here we obtain a couple of upper bounds that show that the problem admits testing algorithms with sublinear query complexity, at least in a few regimes of interest. We present two algorithms that complement each other.

A quick observation shows the problem becomes essentially trivial when $T \geq 2\,\mathrm{diam}(G)/\varepsilon$. (In a nutshell, this is because otherwise ENV $\in$ 1-BP reaches a fixed point well before T, and thus most configurations of ENV must all be this one fixed point.) Hence for this discussion it should be kept in mind that the problem is only interesting when $\mathrm{diam}(G)$ is non-trivial and $T = o(\mathrm{diam}(G)/\varepsilon)$. Furthermore, recall that, since ENV has nT entries, the benchmark for a non-trivial testing algorithm is not $o(n)$ but $o(nT)$.

The first algorithm we present is a direct generalization of the one from Theorem 1.

▶ **Theorem 5.** *Let $\varepsilon > 0$ and $T > 2$. There is a* non-adaptive, one-sided error *algorithm that performs $O(\Delta^{T-1}/\varepsilon T)$ queries and decides if* $\texttt{ENV} \in \textsf{1-BP}$ *or* $\mathrm{dist}(\texttt{ENV}, \textsf{1-BP}) \geq \varepsilon$.

The algorithm is only useful in settings where, say, $T = O(\log_\Delta n)$. Nevertheless, it is relatively simple to obtain and outperforms our more complex algorithm in certain regimes.

▶ **Theorem 6.** *Let $\varepsilon > 0$ and $T \geq 4/\varepsilon$. Then there is a* non-adaptive, one-sided error *algorithm with query complexity $O(|E| \log(n)/\varepsilon T)$ that decides whether* $\texttt{ENV} \in \textsf{1-BP}$ *or* $\mathrm{dist}(\texttt{ENV}, \textsf{1-BP}) \geq \varepsilon$. *In addition, if G excludes a fixed minor H (which includes the case where G is planar or, more generally, G has bounded genus), then $O(|E|/\varepsilon T)$ queries suffice.*

To better judge what this algorithm achieves, let us suppose that the underlying graph is Δ-regular, in which case $|E| = n\Delta$. Then this gives a non-trivial testing algorithm whenever $T = \omega(\sqrt{(\Delta/\varepsilon)\log n})$ (or $T = \omega(\sqrt{\Delta/\varepsilon})$ if we also assume G is planar). Hence, together with Theorem 5, we obtain non-trivial testing algorithms in the regime where $\Delta = o(\log n)$ (or even $\Delta = o(\log^2 n)$ in planar graphs) and *for all values of T*.

The algorithm of Theorem 6 combines some ideas from the work of Nakar and Ron [18] with *graph decompositions*. A graph decomposition is a set C of edges which cuts the graph into components pairwise disjoint components $V_1, \ldots, V_r$ of small diameter. In our case the appropriate choice of diameter will be $d = O(\varepsilon T)$. The basic approach is to query the endpoints of C after d steps have elapsed and then use this view to predict the colors of every node in the graph in the subsequent steps. As we show, the view actually suffices to predict all but at most an $O(\varepsilon)$ fraction of $\texttt{ENV}$ (and hence we need only query the predicted values using $O(1/\varepsilon)$ independent queries to check if $\texttt{ENV}$ is following $\textsf{1-BP}$ or not). We refer to Appendix A.2 for a more in-depth description of the strategy and the ideas involved.

1.3 Open Problems

Since this work is but a first step in an unexplored direction, several questions remain open:

- *The case $T = 2$ and large Δ.* The algorithm of Theorem 1 is essentially optimal up to $\Delta = O(\sqrt{n})$ (if we consider only one-sided error algorithms), but for larger values of Δ the best we have is the $\tilde{O}(\sqrt{n})$-query algorithm of Theorem 4. Can we reduce this, say, to $\tilde{O}(\Delta^{b-1}/\varepsilon)$ for $\varepsilon = \Omega(\Delta^b/n)$ so as to match the lower bound of Theorem 2? Is it really necessary to give up time-conformity in order to do better than $O(\Delta/\varepsilon)$ in this setting? In addition, improving our lower bounds in the case of (both one- and two-sided error) adaptive algorithms seems well within reach.
- *The case $T > 2$.* Our results show that, in this case, we can get non-trivial algorithms for graphs of small degree (e.g., $\Delta = o(\log n)$). Due to the difficulties in the case $T = 2$, larger values of Δ pose additional challenges. In this sense a first step in this direction would be to port the lower bounds from the $T = 2$ case. Nevertheless, it is not immediately clear how to do so since ε-farness there is even harder to achieve given the cascading effects that might occur over multiple time steps (see in particular Lemma 17).
- *Testing other rules.* Finally, from a broader perspective it would also be meaningful to consider other rules than $\textsf{1-BP}$. Of course, by inverting the roles of 0 and 1, all of our results also hold for AND rule (i.e., a node becomes a 1 if and only if all its neighbors are 1; otherwise it becomes a 0). Some very natural rules to consider next are, for instance, τ-$\textsf{BP}$ or the majority rule. There has been extensive study of these rules in other contexts [11, 20, 13, 16, 21, 2, 12, 8, 14], and so there is solid ground to build on there.

1.4 Paper Overview

The rest of the paper is structured as follows: In Section 2 we introduce basic notation, review some standard graph-theoretic results, and formally specify the model and problem we study. For the case $T = 2$, in Section 3 we address the two algorithms (Theorems 1 and 4); the two lower bounds (Theorems 2 and 3) are covered in the full version of the paper [17]. Finally in Appendix A we discuss the two algorithms for the case $T > 2$ (Theorems 5 and 6).

2 Preliminaries

The set of non-negative integers is denoted by $\mathbb{N}_0$ and that of strictly positive integers by $\mathbb{N}_+$. For $n \in \mathbb{N}_+$, we write $[n] = \{i \in \mathbb{N}_+ \mid i \leq n\}$ for the set of the first n positive integers. Without ambiguity, for a statement S, we write $[S]$ for the indicator variable of S (i.e., $[S] = 1$ if S holds; otherwise, $[S] = 0$).

An event is said to occur with high probability if it occurs with probability $1 - o(1)$. For a set X, we write U_X to denote a random variable that takes on values from X following the uniform distribution on X. We assume the reader is familiar with basic notions of discrete probability theory (e.g., Markov's inequality and the union bound). We will use the following version of the Chernoff bound (see, e.g., [9, 19]):

▶ **Theorem 7** (Chernoff bound). *Let $n \in \mathbb{N}_+$ and $\varepsilon > 0$, and let $X_1, \ldots, X_n$ be independent and identically distributed random variables taking values in the interval $[0, 1]$. Then, for $X = (\sum_{i=1}^{n} X_i)/n$ and $\mu = \mathsf{E}[X]$, $\Pr[|X - \mu| > \varepsilon] < 2e^{-n\varepsilon^2/3\mu}$.*

2.1 Graph Theory

We consider only undirected graphs. Except when explicitly written otherwise, we always write just "graph" for a simple graph, though self-loops are allowed.

Let $G = (V, E)$ be a graph. For $S \subseteq V$, $G[S]$ denotes the subgraph of G induced by S. For two nodes $u, v \in V$, $\mathrm{dist}_G(u, v)$ is the length of the shortest path between u and v; we drop the subscript if G is clear from the context. The *diameter* $\mathrm{diam}(G)$ of G is the maximum length among all shortest paths between any pair of vertices $u, v \in V$, that is, $\mathrm{diam}(G) = \max_{u,v \in V} \mathrm{dist}(u, v)$. This notion extends to any $V' \subseteq V$ by considering only pairs of vertices in V', that is, $\mathrm{diam}(V') = \max_{u,v \in V'} \mathrm{dist}(u, v)$.We write $\delta(G)$ for the minimum degree of G and $\Delta(G)$ for the maximum one. If G is clear from the context, we simply write δ and Δ, respectively. If $\delta = \Delta$, then G is Δ-*regular*.

For a node $v \in V$, $N(v) = \{u \in V \mid uv \in E\}$ denotes the set of *neighbors* of v. Generalizing this notation, for a set $S \subseteq V$ we write $N(S)$ for the union $\bigcup_{v \in S} N(v)$. A vertex $u \in V$ is said to be a *unique neighbor* of S if there is a *unique* $s \in S$ such that $us \in E$. When S is clear from the context, we also refer to a unique neighbor of $v \in S$ as a node $u \in V$ for which $u \in N(v')$ if and only if $v' \notin S$ or $v' = v$.

A graph $G = (V, E)$ is *bipartite* if $V = L \cup R$ for disjoint sets L and R and any edge has exactly one endpoint in L and one in R. In this context, we refer to the nodes of L as *left-* and to those of R as *right-vertices*. Additionally, the graph is *balanced* if $|L| = |R|$.

The following is a spin-off of a well-known result on the size of the dominating set of a graph (see, e.g., [1]):

▶ **Lemma 8** (Cover from minimum degree). *Let $G = (V, E)$ be a bipartite graph where each right-vertex has degree at least δ. Then there is a set D of $n \log(n)/\delta$ left-vertices such that every right-vertex has a neighbor in D.*

Proof. We use the probabilistic method. Fix a right-vertex $v \in V$. If we pick a set D of $m = n\log(n)/\delta$ left-vertices uniformly at random, then the probability that $N(v) \cap D$ is empty is at most $(1-\delta/n)^m < e^{-\log n} < 1/n$. Hence, by the union bound, there is a non-zero probability that D is such that $N(v) \cap D$ is non-empty for every right-vertex v. ◀

2.2 Model and Problem Definition

We use the standard query model of property testing [5]. The testing algorithm has unlimited computational power and access to a source of infinitely many random bits that are fully independent from one another. In addition, the model has full knowledge of the underlying topology of the network, which is presented as a graph $G = (V, E)$ with $|V| = n$ nodes. We assume there are no singleton nodes (i.e., every node is such that there is an edge incident to it). The topology remains fixed during the evolution of the network, whose nodes take on different states over a set of discrete time steps. As in the previous works [18, 10], the formal object we are testing is an *environment* $\texttt{ENV}\colon V \times [T] \to Z$ where $T \geq 2$ and Z is the set of states that each node may assume.

The goal is to detect whether $\texttt{ENV}$ is following a certain *local rule* ρ, which is defined as a function that maps every multiset μ over Z to $\rho(\mu) \in Z$. The environment $\texttt{ENV}$ is said to *follow* ρ if, for every time step $t \leq T$ and every node $v \in V$, we have that $\texttt{ENV}(v, t+1) = \rho(\texttt{ENV}(N(v), t))$ (where $\texttt{ENV}(N(v), t)$ here is seen as a multiset, that is, counting multiplicities of the occurrence of each element of Z). Blurring the distinction between ρ and the set of environments that follow it, we write $\texttt{ENV} \in \rho$ if $\texttt{ENV}$ follows ρ.

The *distance* between two environments $\texttt{ENV}, \texttt{ENV}'\colon V \times [T] \to Z$ is the (normalized) number of pairs on which $\texttt{ENV}$ and $\texttt{ENV}'$ differ:

$$\operatorname{dist}(\texttt{ENV}, \texttt{ENV}') = \frac{1}{nT} \sum_{(v,t) \in V \times [T]} [\texttt{ENV}(v,t) \neq \texttt{ENV}'(v,t)].$$

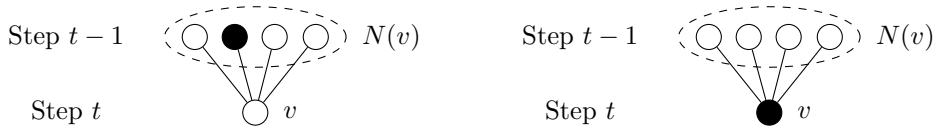
For a set of environments X (all over the same domain $V \times [t]$), we write $\operatorname{dist}(\texttt{ENV}, X) = \min_{\texttt{ENV}' \in X} \operatorname{dist}(\texttt{ENV}, \texttt{ENV}')$ for the minimum distance between $\texttt{ENV}$ and X. Being a bit sloppy, we write $\operatorname{dist}(\texttt{ENV}, \rho)$ for the minimum distance from $\texttt{ENV}$ to the set of environments $\texttt{ENV}'$ for which $\texttt{ENV}' \in \rho$. For $\varepsilon \geq 0$, $\texttt{ENV}$ is *ε-far* from ρ if $\operatorname{dist}(\texttt{ENV}, \rho) \geq \varepsilon$; otherwise it is *$\varepsilon$-near* ρ.

In this work, we focus on $Z = \{0, 1\}$ and on testing the 1-BP rule of bootstrap percolation. The rule is defined by $\rho(\mu) = [1 \in \mu]$ (i.e., $\rho(\mu) = 1$ if $1 \in \mu$ and $\rho(\mu) = 0$ otherwise). Seeing states as colors, we identify state 1 with the color *black* and state 0 with *white*.[2]

For $t \geq 2$, a pair (v, t) is a *successor* of $(u, t-1)$ if there is an edge between v and u; at the same time, $(u, t-1)$ is a *predecessor* of (v, t). If the respective time steps t and $t-1$ are clear from the context, we might also drop any mention of them and simply say that v (as a node) is a successor of u. This is particularly convenient when analyzing the case $T = 2$.

Testing algorithms. Fix $\varepsilon > 0$. A *testing algorithm* A for 1-BP accesses $\texttt{ENV}\colon V \times [T] \to Z$ by means of *queries*, which are pairs $(v, t) \in V \times [T]$. Upon querying the pair (v, t), A receives $\texttt{ENV}(v, t)$ as answer. If the queries are performed in an order where, for every t and t' with $t' > t$, A never makes a $(\cdot, t)$ query after it has queried $(\cdot, t')$, then A is said to be *time-conforming*. As usual in property testing, our interest lies in the *query complexity* of A, that is, the maximum number of queries that A makes, regardless of its randomness.

[2] Being pedantic, the 1-BP rule in the context of bootstrap percolation is such that a black node always remains black. This behavior can be enforced in the model we describe by adding self-loops to all nodes.



(a) Type I **(b)** Type II

Figure 2 Violations can be of two different types. Here we see a node v and its state in time step t (as a color) as well as its neighbors $N(v)$ and their respective states in step $t-1$.

The algorithm A is a *one-sided error tester* for $\texttt{ENV} \in$ 1-BP if the following holds, where the probabilities are taken over the randomness of A:

- If $\texttt{ENV} \in$ 1-BP, then always $A(\texttt{ENV}) = 1$.
- If $\texttt{ENV}$ is ε-far from 1-BP, then $\Pr[A(\texttt{ENV}) = 1] < 1/2$.

In contrast, A is a *two-sided error tester* if it may also err on $\texttt{ENV} \in$ 1-BP:

- If $\texttt{ENV} \in$ 1-BP, then $\Pr[A(\texttt{ENV}) = 1] \geq 2/3$.
- If $\texttt{ENV}$ is ε-far from 1-BP, then $\Pr[A(\texttt{ENV}) = 1] < 1/3$.

Violations. Observe that our notion of distance is *not* the same as counting the number of failures of $\texttt{ENV}$ in following 1-BP. There are two kinds of failures that may occur:

▶ **Definition 9** (Violations). *A pair* $(v,t) \in V \times [T]$ *is* violating *if* $t \geq 2$ *and one of the following conditions hold:*

(I) $\texttt{ENV}(v,t) = 0$ *and* $\exists u \in N(v) : \texttt{ENV}(u, t-1) = 1$

(II) $\texttt{ENV}(v,t) = 1$ *and* $\forall u \in N(v) : \texttt{ENV}(u, t-1) = 0$

We refer to these violations as violations of type I and II*, respectively. We write* viol($\texttt{ENV}$) *for the set of violating pairs in* $\texttt{ENV}$.

Although a larger distance to 1-BP implies a greater number of violations, there is not an exact correspondence between the two. For example, it might be the case that $\texttt{ENV}$ exhibits a great number of violations, but correcting them requires recoloring only a few nodes. We will prove upper and lower bounds between the distance and the number of violations further below (Lemmas 10 and 17).

3 Upper Bounds for the Case $T = 2$

In this section we present our two algorithms for the case where $T = 2$. The first of these (Section 3.1) is quite simple and has query complexity $O(\Delta/\varepsilon)$, which turns out to be optimal for the regimes where $\Delta = o(\sqrt{n})$. The second one (Section 3.2) is much more intricate and gives query complexity $\tilde{O}(\sqrt{n}/\varepsilon)$, which makes it more suitable for the regimes where $\Delta = \omega(\sqrt{n})$. Although both are one-sided error algorithms, the first algorithm is non-adaptive and thus time-conforming whereas the second has neither of these properties (i.e., it is adaptive and also does not respect time-conformity).

3.1 An Upper Bound that Scales with the Maximum Degree

In this section, we prove:

▶ **Theorem 1.** *Let* $T = 2$ *and* $\varepsilon > 0$*. There is a* non-adaptive, one-sided error *algorithm with query complexity* $O(\Delta/\varepsilon)$ *that decides whether* $\texttt{ENV} \in$ 1-BP *or* $\operatorname{dist}(\texttt{ENV}, \text{1-BP}) \geq \varepsilon$.

The claim is that Algorithm 1 satisfies the requirements of Theorem 1. As mentioned above, the strategy followed by Algorithm 1 is quite simple: It chooses a certain subset of nodes U uniformly at random and then queries the states of $u \in U$ and all of $N(u)$ in both time steps. The algorithm then rejects if and only if a violation of either type is detected.

Algorithm 1 Algorithm for the case $T = 2$ with query complexity $O(\Delta/\varepsilon)$.

```
Pick U ⊆ V uniformly at random where |U| = ⌈2/ε⌉;
Query ENV(v, 1) and ENV(u, 2) for every u ∈ U and v ∈ N(u) in a time-conforming
  manner;
for u ∈ U do
    if ENV(u, 2) = 0 and ∃v ∈ N(u) : ENV(v, 1) = 1 then reject;
    if ENV(u, 2) = 1 and ∀v ∈ N(u) : ENV(v, 1) = 0 then reject;
end
accept;
```

At the core of the correctness of Algorithm 1 is the relation between the number of violations and the distance of ENV to 1-BP. With a bit of care, we can relate the two quantities as shown next. (Actually for the correctness of Algorithm 1 we only need one of the two bounds below; the other one comes as a "bonus".)

▶ **Lemma 10.** *Let $T = 2$. Then*

$$\frac{|\mathrm{viol}(\mathtt{ENV})|}{2\Delta n} \leq \mathrm{dist}(\mathtt{ENV}, \text{1-BP}) \leq \frac{|\mathrm{viol}(\mathtt{ENV})|}{2n}.$$

Proof. Every violating pair (u, t) can be corrected by flipping the value of $\mathtt{ENV}(u, t)$, which does not create a new violating pair since $t = T = 2$. In addition, if ENV does not have any violating pair, then $\mathtt{ENV} \in$ 1-BP. This implies $\mathrm{dist}(\mathtt{ENV}, \text{1-BP}) \leq |\mathrm{viol}(\mathtt{ENV})|/2n$. On the other hand, flipping the color of a node can only correct at most Δ violating pairs. Hence we also have $\mathrm{dist}(\mathtt{ENV}, \text{1-BP}) \geq |\mathrm{viol}(\mathtt{ENV})|/2\Delta n$. ◀

The lemma directly implies that, if $\mathrm{dist}(\mathtt{ENV}, \text{1-BP}) \geq \varepsilon$, then $|\mathrm{viol}(\mathtt{ENV})| \geq 2\varepsilon n$. Hence the probability that Algorithm 1 errs in this case is

$$\Pr[(U, 2) \cap \mathrm{viol}(\mathtt{ENV}) = \varnothing] \leq (1 - 2\varepsilon)^{|U|} < \frac{1}{e} < \frac{1}{2}.$$

Since Algorithm 1 only rejects when a violation of either type is detected, Algorithm 1 always accepts if $\mathtt{ENV} \in$ 1-BP. The query complexity and other properties of Algorithm 1 are clear, and hence Theorem 1 follows.

3.2 An Upper Bound Independent of the Maximum Degree

Next we show our second algorithm, which is much more complex than Algorithm 1. Since Algorithm 1 is already optimal for $\Delta = O(\sqrt{n})$, we focus on the regime where $\Delta = \Omega(\sqrt{n})$ and present an algorithm with query complexity that is independent of Δ. The algorithm requires adaptiveness and unfortunately is no longer time-conforming; obtaining a time-conforming or even non-adaptive algorithm with the same query complexity for these large values of Δ (or proving none exists) remains an interesting open question.

▶ **Theorem 4.** *Let $T = 2$ and let $\varepsilon > 0$ be given. There is an* adaptive, one-sided error *algorithm for testing whether $\mathtt{ENV} \in$ 1-BP or is ε-far from 1-BP with query complexity $O(\sqrt{n}\log^{3/2}(n)/\varepsilon)$.*

We claim Algorithm 2 satisfies the requirements of the theorem. Next we give a brief description of the strategy followed by Algorithm 2.

Algorithm 2 Algorithm for the case $T = 2$ with query complexity $\tilde{O}(\sqrt{n}/\varepsilon)$.

1 Select $Q_1, Q_1', Q_2, Q_2' \subseteq V$ with $|Q_i| = |Q_i'| = (24/\varepsilon)\sqrt{n}\log^{3/2} n$ uniformly at random;
2 Query $\texttt{ENV}(Q_1, 1)$ and $\texttt{ENV}(Q_2', 1)$;
3 $B_2 \leftarrow \{v \in V \mid \exists u \in N(v) \cap Q_1 \colon \texttt{ENV}(u, 1) = 1\}$;
4 Query $\texttt{ENV}(Q_1', 2)$ and $\texttt{ENV}(Q_2, 2)$;
5 $W_1 \leftarrow \{v \in V \mid \exists u \in N(v) \cap Q_2 \colon \texttt{ENV}(u, 2) = 0\}$;
6 **if** $\exists u \in Q_1' \cap B_2 : \texttt{ENV}(u, 2) = 0$ *or* $\exists u \in Q_2' \cap W_1 : \texttt{ENV}(u, 1) = 1$ **then reject**;
7 $F \leftarrow \{v \in V \mid |N(v) \setminus W_1| \leq 4\sqrt{n \log n}\}$;
8 Select $Q_3 \subseteq F$ with $|Q_3| = (4/\varepsilon)\log n$ uniformly at random;
9 Query $\texttt{ENV}(v, 2)$ and $\texttt{ENV}(N(v) \setminus W_1, 1)$ for every $v \in Q_3$;
10 **if** $\exists v \in Q_3 : \texttt{ENV}(v, 2) = 0 \wedge \exists u \in N(v) \setminus W_1 : \texttt{ENV}(u, 1) = 1$ *or*
$\exists v \in Q_3 : \texttt{ENV}(v, 2) = 1 \wedge \nexists u \in N(v) \setminus W_1 : \texttt{ENV}(u, 1) = 1$ **then reject**;
11 **accept**;

Approach. The operation of Algorithm 2 can be divided into two parts. The first one is up to line 2. Here we query nodes from the first and second time steps at random (Q_1 and Q_2) and try to ascertain the color of as many nodes as possible using these queries. More specifically, if a node v has a neighbor $u \in N(v)$ which is black in the first step, then we know v must be black in the second step. We gather these nodes in the set B_2. A similar observation holds for the nodes in the set W_1, which must be white since they have a neighbor in the second step that is white. At the same time we query another set of nodes from the first and second step uniformly at random (Q_1' and Q_2') to verify that all but a very small fraction of nodes in W_1 (resp., B_2) are indeed white (resp., black).

The second part of the algorithm starts after line 2. Here we will ignore nodes in W_1 (since we already know they are white) and "filter" nodes that have not too large degree to nodes not in W_1. These nodes are added to the set F. Intuitively we can then test these nodes in the same fashion as Algorithm 1: We select a few nodes $v \in F$ uniformly at random (Q_3) and then query the entire neighborhood of these nodes in the first step, so $\texttt{ENV}(u, 1)$ for $u \in N(v) \setminus W_1$, as well as $\texttt{ENV}(v, 2)$. If any violations are detected here, then we can safely reject. What then remains are only nodes with high degree; as we argue in the analysis below, any set of nodes not in F that are black (which might occur when $\texttt{ENV} \notin$ 1-BP) and which have no white predecessor can actually be covered by recoloring only a small set of nodes (and hence ENV must be close to 1-BP).

Analysis. The query complexity of Algorithm 2 is clear, so we focus on the analysis on its correctness. First we show that Algorithm 2 is indeed a one-sided error algorithm; that is:

▷ Claim 11. If $\texttt{ENV} \in$ 1-BP, then Algorithm 2 always accepts.

Intuitively this is the case because we are only trying to detect violations (and accept unconditionally if we do not manage to find any).

Proof. Since $\texttt{ENV} \in$ 1-BP, we have $\texttt{ENV}(W_1, 1) = 0$ and $\texttt{ENV}(B_2, 2) = 1$. As a result, Algorithm 2 never rejects in line 2. Consider the two possibilities for Algorithm 2 to reject in line 2. The first is that there is a node $v \in Q_3$ with $\texttt{ENV}(v, 2) = 0$ and some $u \in N(v)$

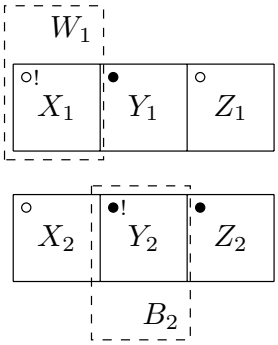


Figure 3 Relation between the sets used in the analysis of Algorithm 2. The sets form a partition of the nodes in the first and second time steps. The small circles indicate the color of the nodes in each set or, in the case of X_1 of Y_2, that the algorithm rejects unless (almost all) nodes in the set have the respective color (denoted with an exclamation mark).

so that $\texttt{ENV}(u,1) = 1$, which contradicts $\texttt{ENV} \in \text{1-BP}$. The second is that $\texttt{ENV}(v,2) = 1$ and $\texttt{ENV}(u,1) = 0$ for every $u \in N(v) \setminus W_1$; however, since $\texttt{ENV}(W_1,1) = 0$, this means $\texttt{ENV}(u,1) = 0$ for every $u \in N(v) \cap W_1$ as well and then $\texttt{ENV}(u,1) = 0$ for every $u \in N(v)$, thus also contradicting $\texttt{ENV} \in \text{1-BP}$. ◁

Now we turn to proving that Algorithm 2 does not have false positives. More specifically we show that Algorithm 2 can only accept with constant probability if $\text{dist}(\texttt{ENV}, \text{1-BP}) < \varepsilon$ is the case (and so, conversely, Algorithm 2 rejects with high probability if $\text{dist}(\texttt{ENV}, \text{1-BP}) \geq \varepsilon$).

For $v \in V$ and $t \in \{1,2\}$, we write $\text{bn}_t(v)$ and $\text{wn}_t(v)$ for the number of black and white neighbors, respectively, of v in step t; formally,

$$\text{bn}_t(v) = |\{u \in N(v) \mid \texttt{ENV}(u,t) = 1\}|, \qquad \text{wn}_t(v) = |\{u \in N(v) \mid \texttt{ENV}(u,t) = 0\}|.$$

Let $\theta = (\varepsilon/4)\sqrt{n/\log n}$ and consider the following sets:

$$\begin{aligned} X_1 &= \{v \in V \mid \text{wn}_2(v) \geq \theta\}, & X_2 &= \{v \in V \mid \text{bn}_1(v) < \theta \wedge \texttt{ENV}(v,2) = 0\}, \\ Y_1 &= \{v \in V \mid \text{wn}_2(v) < \theta \wedge \texttt{ENV}(v,1) = 1\}, & Y_2 &= \{v \in V \mid \text{bn}_1(v) \geq \theta\}, \\ Z_1 &= \{v \in V \mid \text{wn}_2(v) < \theta \wedge \texttt{ENV}(v,1) = 0\}, & Z_2 &= \{v \in V \mid \text{bn}_1(v) < \theta \wedge \texttt{ENV}(v,2) = 1\}. \end{aligned}$$

The sets X_1 and Y_2 contain the nodes for which we can detect that they must be white and black, respectively, by using the query sets Q_1 and Q_2.

▷ Claim 12. With high probability over the choices made by Algorithm 2, $X_1 \subseteq W_1$ and $Y_2 \subseteq B_2$.

Proof. Fix $v \in X_1$. By the Chernoff bound, the probability that no $u \in N(v)$ with $\texttt{ENV}(u,2) = 0$ lands in Q_2 is at most $2e^{-2\log n} < 2/n^2$. Hence, by the union bound, the probability that $X_1 \setminus W_1$ is non-empty is $O(1/n)$. The same applies to Y_2 and B_2. ◁

Next we observe that the queries from Q_1' and Q_2' significantly "reduce" the number of black or white nodes in X_1 or Y_2, respectively; that is, if there is a significant number of such nodes in these sets, then Algorithm 2 will detect them anyway and reject (and thus we can focus the analysis on instances where this is not the case).

▷ Claim 13. If $\texttt{ENV}$ is such that there are $\varepsilon\sqrt{n}$ nodes $v \in X_1$ with $\texttt{ENV}(v,1) = 1$ or $\varepsilon\sqrt{n}$ nodes $v \in Y_2$ with $\texttt{ENV}(v,2) = 0$, then Algorithm 2 rejects $\texttt{ENV}$ with high probability.

Proof. Let $S \subseteq V$ be a subset of $|S| \geq \varepsilon\sqrt{n}$ vertices. Then the probability that $S \cap Q'_i$ is empty is at most

$$\left(1 - \frac{\varepsilon}{\sqrt{n}}\right)^{(24/\varepsilon)\sqrt{n}\log^{3/2} n} < e^{-24\log^{3/2} n} = o\left(\frac{1}{n}\right).$$

Using Claim 12, we have $X_1 \subseteq W_1$ and $Y_2 \subseteq B_2$ with high probability. In this case Algorithm 2 rejects if any node $v \in X_1 \subseteq W_1$ with $\texttt{ENV}(v, 1) = 1$ lands in Q'_2 or any $v \in Y_2 \subseteq B_2$ with $\texttt{ENV}(v, 2) = 0$ lands in Q'_1. Therefore Algorithm 2 rejects with high probability if there are at least $\varepsilon\sqrt{n}$ nodes of either type. ◁

Hence we may now safely assume that all but at most $O(\varepsilon\sqrt{n})$ nodes in X_1 are white in the first time step and that all but at most $O(\varepsilon\sqrt{n})$ nodes in Y_2 are black in the second one. The next observation is that nodes in X_2 are highly connected to X_1. This justifies filtering nodes based on their connections to $W_1 \supseteq X_1$.

▷ Claim 14. On average, a node from X_2 has at most $\theta n/|X_2|$ neighbors not in X_1.

Proof. Every node in Y_1 or Z_1 has at most θ white neighbors by definition, so at most this many neighbors in X_2. Hence there are at most θn edges in total between X_2 and nodes not in X_1. ◁

Finally we show that, if Algorithm 2 accepts ENV with at least constant probability, then we can correct all violations of either type with at most $\varepsilon n/2$ modifications in total for each type. In both cases we must be careful so that these modifications do not create new violations of their own.

▷ Claim 15. If Algorithm 2 accepts ENV with at least constant probability, then there are at most $\varepsilon n/2$ many type I violations in ENV. These violations can be corrected (without creating any new ones) by recoloring $\texttt{ENV}(v, 2)$ black for every violation $(v, 2)$.

Proof. Let R be the set of nodes corresponding to type I violations, that is, $R = \{v \in V \mid \texttt{ENV}(v, 2) = 0 \wedge \exists u \in N(v) : \texttt{ENV}(u, 1) = 1\}$. We prove the claim by proving the contrapositive; that is, if $|R| \geq \varepsilon n/2$, then Algorithm 2 rejects ENV with high probability.

The first observation is that we have $|R \setminus X_2| = o(\varepsilon n)$ (with high probability) due to Claim 13 and then, by the assumption on R, $|X_2| \geq (1 - o(1))\varepsilon n/2$. Hence we focus our analysis on $R \cap X_2$. By Claim 14, on average a node from X_2 has at most $2\theta/\varepsilon = (1/2)\sqrt{n/\log n}$ many neighbors that are outside X_1. By Markov's inequality, this gives us that there are at most $O(n/\log n)$ many nodes $v \in X_2$ for which $|N(v) \setminus X_1| > 4\sqrt{n \log n}$. Using Claim 12, we have $X_1 \subseteq W_1$ and so altogether we have $|R \cap F| \geq \varepsilon n/4$ (with high probability). In this case the probability that $R \cap Q_3$ is empty is at most $(1 - \varepsilon/4)^{4\log(n)/\varepsilon} < e^{-\log(n)} = O(1/n)$, and so Algorithm 2 rejects with high probability. ◁

▷ Claim 16. If Algorithm 2 accepts ENV with at least constant probability, then all type II violations in ENV can be corrected by recoloring at most $\varepsilon n/2$ nodes. In particular, this recoloring is such that we color $\texttt{ENV}(v, 1)$ and $\texttt{ENV}(N(v), 2)$ black for a certain subset of nodes v (and hence does create any new violations).

Proof. Similar to the proof of Claim 15, let $R = \{v \in V \mid \texttt{ENV}(v, 2) = 1 \wedge \forall u \in N(v) : \texttt{ENV}(u, 1) = 0\}$. be the set of type II violations. We show that, if Algorithm 2 accepts with at least constant probability, then we can correct R by recoloring at most $\varepsilon n/2$ nodes black. (Note this does not necessarily mean that $|R| < \varepsilon n/2$ as in the proof of Claim 15. Instead what we prove is an upper bound on the number of recolorings needed to correct R.)

By Claim 13, $|R \setminus Z_2| = o(\varepsilon n)$ and thus $|Z_2| \geq (1 - o(1))\varepsilon n/2$. Arguing as in the proof of Claim 15, if $|R \cap F| \geq \varepsilon n/4$, then Algorithm 2 must reject with high probability. Hence let us focus on the nodes in $R' = R \setminus F$. Consider the bipartite graph where the set of left-vertices is $V \setminus W_1$, that of right-vertices is R', and the edges are as in G. Then the minimum degree of R' in this graph is $4\sqrt{n \log n}$, which means we can apply Lemma 8 and obtain a cover $D \subseteq V \setminus W_1$ of R' with $|D| = (1/4)\sqrt{n \log n}$ nodes. By Claim 12, $D \cap X_1 = \varnothing$ and hence $\mathrm{wn}_2(v) < \theta$ for every $v \in D$ (with high probability). Therefore we can correct R' by coloring $\texttt{ENV}(D, 1)$ and $\texttt{ENV}(N(D), 2)$ all black, which means coloring at most $(\theta/4)\sqrt{n \log n} \leq \varepsilon n/16$ nodes black. Together with $|R \cap F| < \varepsilon n/4$, this means we must color at most $(1/4 + 1/16)\varepsilon n < \varepsilon n/2$ many nodes black in total in order to correct R. ◁

A Upper Bounds for the Case $T > 2$

In this appendix we consider two different strategies for the case where $T > 2$. An immediate observation to make is that the diameter $\operatorname{diam}(G)$ plays a much more significant role in this setting. For instance, the case where $T \geq (1 + 2/\varepsilon) \operatorname{diam}(G)$ is more or less trivial since then after $\operatorname{diam}(G)$ steps every connected component must be either all-black or all-white and the first $\operatorname{diam}(G)$ steps constitute at most an $\varepsilon/2$ fraction of $\texttt{ENV}$.

A.1 Structure-independent Upper Bound

First we give a generalization of Theorem 1, which is simple to obtain and adequate for settings where Δ and T are not too large. For constant Δ, for instance, it still gives a sublinear query algorithm when $T = O(\log n)$. As the algorithm of Theorem 1, it does not use the graph structure in any way except for determining the neighborhood of each node.

▶ **Theorem 5.** *Let $\varepsilon > 0$ and $T > 2$. There is a* non-adaptive, one-sided error *algorithm that performs $O(\Delta^{T-1}/\varepsilon T)$ queries and decides if $\texttt{ENV} \in \mathsf{1\text{-}BP}$ or $\operatorname{dist}(\texttt{ENV}, \mathsf{1\text{-}BP}) \geq \varepsilon$.*

We adapt Algorithm 1 to obtain Algorithm 3. The analysis does not carry over automatically since we need to consider what happens if we are correcting violations in a time step $t < T$. Unlike in Lemma 10, this kind of correction may now propagate to time steps after t. In addition, we have to assume $\Delta \geq 2$; however, the case $\Delta = 1$ is trivial since then $\operatorname{diam}(G) = 1$ and we need only follow the strategy described at the beginning of this section.

▶ **Lemma 17.** *Let $\Delta \geq 2$. Then*

$$\frac{|\operatorname{viol}(\texttt{ENV})|}{(\Delta+1)nT} \leq \operatorname{dist}(\texttt{ENV}, \mathsf{1\text{-}BP}) \leq \frac{\Delta^{T-1}-1}{(\Delta-1)nT} |\operatorname{viol}(\texttt{ENV})|.$$

Algorithm 3 Structure-independent algorithm for the case of general T with query complexity $O(\Delta^{T-1}/\varepsilon)$.

Pick $Q \subseteq V \times \{t \mid 2 \leq t \leq T\}$ uniformly at random where $|Q| = \lceil 2\Delta^{T-2}/\varepsilon T \rceil$;
Query $\texttt{ENV}(v, t-1)$ and $\texttt{ENV}(u, t)$ for every $(u, t) \in Q$ and $v \in N(u)$ in a time-conforming manner;
for $(u, t) \in Q$ **do**
  if $\texttt{ENV}(u, t) = 0$ *and* $\exists v \in N(u) : \texttt{ENV}(v, t-1) = 1$ **then reject**;
  if $\texttt{ENV}(u, t) = 1$ *and* $\forall v \in N(u) : \texttt{ENV}(v, t-1) = 0$ **then reject**;
end
accept;

See the full version of the paper [17] for the proof.

Now as before with Theorem 1 we have that $\text{dist}(\texttt{ENV}, \text{1-BP}) \geq \varepsilon$ implies

$$\text{viol}(\texttt{ENV}) \geq \frac{\varepsilon(\Delta - 1)nT}{\Delta^{T-1} - 1} > \frac{\varepsilon nT}{2\Delta^{T-2}}.$$

Hence the probability that Algorithm 3 errs is

$$\Pr[Q \cap \text{viol}(\texttt{ENV}) = \varnothing] \leq \left(1 - \frac{\varepsilon T}{2\Delta^{T-2}}\right)^{|Q|} < \frac{1}{e} < \frac{1}{2}.$$

As was the case with Algorithm 1, the query complexity and other properties required in Theorem 5 are clear, and hence Theorem 5 follows.

A.2 Upper Bound Based on Graph Decompositions

The second algorithm is suited for larger values of T and not too dense graphs.

▶ **Theorem 6.** *Let $\varepsilon > 0$ and $T \geq 4/\varepsilon$. Then there is a* non-adaptive, one-sided error *algorithm with query complexity $O(|E| \log(n)/\varepsilon T)$ that decides whether $\texttt{ENV} \in$ 1-BP or $\text{dist}(\texttt{ENV}, \text{1-BP}) \geq \varepsilon$. In addition, if G excludes a fixed minor H (which includes the case where G is planar or, more generally, G has bounded genus), then $O(|E|/\varepsilon T)$ queries suffice.*

The strategy followed by the algorithm relies on graph decompositions. These are partitions induced by sets of edges that cut the graph into components of bounded diameter.

▶ **Definition 18.** *Let $d \in \mathbb{N}_+$ and $\alpha > 0$. A (d, α)-*decomposition *of a graph $G = (V, E)$ is a set of edges $C \subseteq E$ with $|C| \leq \alpha|E|$ and such that there is a partition $V = V_1 + \cdots + V_r$ satisfying the following:*

1. *For $u, v \in V$, $uv \in C$ if and only if there are i and j such that $i \neq j$, $u \in V_i$, and $v \in V_j$.*
2. *For every i, $\text{diam}(V_i) \leq d$.*

The following is a renowned result in graph decompositions:

▶ **Theorem 19** ([3])**.** *For any $d \in \mathbb{N}_+$, every graph G admits a $(d, O(\log(n)/d))$-decomposition.*

This trade-off is optimal for graphs in general. For the special case of graphs excluding a fixed minor (which includes most notably planar graphs or also graphs of bounded genus), we have the following small improvement:

▶ **Theorem 20** ([15])**.** *Let H be a fixed graph. For any $d \in \mathbb{N}_+$, every graph G excluding H as a minor admits a $(d, O(1/d))$-decomposition.*

Algorithm 4 Algorithm for the case of general T based on network decompositions.

$t_1 \leftarrow \lfloor \varepsilon T/4 \rfloor$;
Compute a (t_1, α)-decomposition of G according to Theorem 19 or Theorem 20 and obtain a set of edges C that cuts G into components $V_1, \ldots, V_r$ as in Definition 18;
$B \leftarrow \{v \mid v \text{ is incident to an edge in } C\}$;
Pick $Q \subseteq \{(v,t) \mid v \in V_i \text{ and } t \geq t_1\}$ uniformly at random where $|Q| = \lceil 3/\varepsilon \rceil$;
$Q' \leftarrow \{v \in V \mid \exists t : (v,t) \in Q\}$;
Query $\texttt{ENV}(B, t_1)$, $\texttt{ENV}(Q)$, and $\texttt{ENV}(Q', t_1)$ in a time-conforming fashion;
if $\texttt{ENV}(B, t_1)$ *is not feasible* **then reject**;
for $i \in [r]$ **do**
    $B_i \leftarrow B \cap V_i$;
    $B_i' \leftarrow \{u \in B_i \mid \texttt{ENV}(u, t_1) = 1\}$;
end
for $v \in V$ **do**
    for $i \in [r]$ **do**
        if $B_i' \neq \varnothing$ **then**
            $\alpha_i(v) \leftarrow \min_{u \in B_i' \cup (V_i \setminus B_i)} \operatorname{dist}(u, v)$;
            $\beta_i(v) \leftarrow \min_{u \in B_i'} \operatorname{dist}(u, v)$;
        else
            $\alpha_i(v) \leftarrow \infty$;
            $\beta_i(v) \leftarrow \infty$;
        end
    end
    $\alpha(v) \leftarrow \min_i \alpha_i(v)$;
    $\beta(v) \leftarrow \min_i \beta_i(v)$;
end
for $(v,t) \in Q$ **do**
    Let i be such that $v \in V_i$;
    if $\texttt{ENV}(v, t_1) = 1$ **then**
        if $\texttt{ENV}(v, t) \neq 1$ **then reject**;
    else
        if $t_1 \leq t < t_1 + \alpha(v)$ *and* $\texttt{ENV}(v, t) \neq 0$ **then reject**;
        if $t \geq t_1 + \beta(v)$ *and* $\texttt{ENV}(v, t) \neq 1$ **then reject**;
    end
end
accept;

The claim is that Algorithm 4 satisfies the requirements of Theorem 6. As mentioned in the introduction, the strategy followed by the algorithm is loosely based on a similar testing routine from the paper by Nakar and Ron [18]. In a nutshell, the idea is to split the environment into more manageable components and then use the properties of the local rule to predict how each component must behave.

Approach. Let us recall the relevant details of the strategy of Nakar and Ron [18]. In their paper, the authors studied local rules resembling the majority rule in the restricted setting where G is a path. Their idea involved splitting the path into intervals that intersect at

periodic control points. The first queries yield the state of these control points at a certain time step t_1. If there is no initial configuration leading to what we observe at t_1 (i.e., the configuration is not *feasible*), then we can immediately reject. Otherwise we can use the states of the nodes at the control points (plus some additional queries) to fully predict almost the entirety of $\texttt{ENV}$ after t_1. Hence we only need to test a certain number of times if $\texttt{ENV}(v,t)$ matches our prediction where $(v,t) \in V \times \{t \in \mathbb{N}_+ \mid t \geq t_1\}$ is chosen uniformly at random.

Our approach is more or less the same, though we need to cater for a couple differences between our setting and theirs. We are not in a path, and so in general we cannot split our graph into intervals of the same size; rather we must work with a graph decomposition, which does give us the adequate control points (the vertices incident to the edges of the cut C, which form the set B in Algorithm 4) but only an upper bound on the diameter of each component (which correspond to the intervals in the setting of Nakar and Ron [18]). Fortunately the 1-BP rule is much simpler than majority or the like, and hence the prediction in each component is easier to make. The relevant observation is that the 1-BP rule converges fast to an (all-black) fixed point in graphs of small diameter. (Indeed, the 1-BP rule converges in at most $\operatorname{diam}(G)$ steps.) More specifically, components that started in an all-zero configuration must stay zero until they enter in contact with a black node; meanwhile a component V_i that had at least one black node in it will converge to an all-black configuration in at most $\operatorname{diam}(V_i) \leq t_1$ steps.

Let us now give a more detailed overview of the steps performed by Algorithm 4. For a set $S \subseteq V$ and $t \in [T]$, we say that $\texttt{ENV}(S,t)$ is *feasible* if there is $\texttt{ENV}' \in$ 1-BP such that $\texttt{ENV}'(v,t) = \texttt{ENV}(v,t)$ for every $v \in S$. Theorem 6 first sets t_1 appropriately and determines a graph decomposition of G where the components $V_1, \ldots, V_r$ have diameter at most t_1. We wait for t_1 steps to elapse and then query the states of B, which are the nodes incident to the edge cut C of the graph decomposition, and can immediately reject if what we see is not feasible. At the same time we query a uniformly sampled set Q of pairs corresponding to the states of nodes in time steps after t_1, whose values we shall use later. We then set $B_i = B \cap V_i$ and B_i' to the nodes that are black in B_i in time step t_1. With these we can then compute estimates $\alpha_i(v)$ and $\beta_i(v)$ for each node v and each component V_i. These are only intended to be useful if v is white in time step t_1 and are determined as follows:

- $\alpha_i(v)$ is a *lower bound* on the number of time steps that elapse after t_1 until v turns from white to black. To compute $\alpha_i(v)$, we consider both nodes in B_i' (whose state in t_1 is known to us) and nodes in the inside of V_i (whose state is unknown and which means we must assume that they are black). If there are no nodes in B_i', then we know that V_i was all white at the beginning and we just set $\alpha_i(v) = \infty$.
- $\beta_i(v)$ is an *upper bound* on the number of time steps after t_1 until v turns black at the latest. To compute $\beta_i(v)$ we take into account only nodes which we are sure that are black in t_1, that is, nodes in B_i'. Again, if B_i' is empty, then V_i must have been all white in the first time step; in that case we set $\beta_i(v) = \infty$.

See Figure 4 for an example. Based on these estimates, we can then use the values of Q to make random tests on the state of nodes after t_1 based on what we know from B_i' and $\alpha(v) = \min_i \alpha_i(v)$ and $\beta(v) = \min_i \beta_i(v)$. More precisely, for a pair $(v,t) \in Q$:

- If v was already black in time step t_1, then it must still be black in time step $t \geq t_1$.
- Otherwise v was white in time step t_1 and we can use our estimates $\alpha(v)$ and $\beta(v)$ to verify the predicted state of v in step t, if possible.

The algorithm accepts by default if $\texttt{ENV}$ passes the tests.

The query complexity of Theorem 6 is evident. We refer for the full version of the paper [17] for the proof of its correctness.

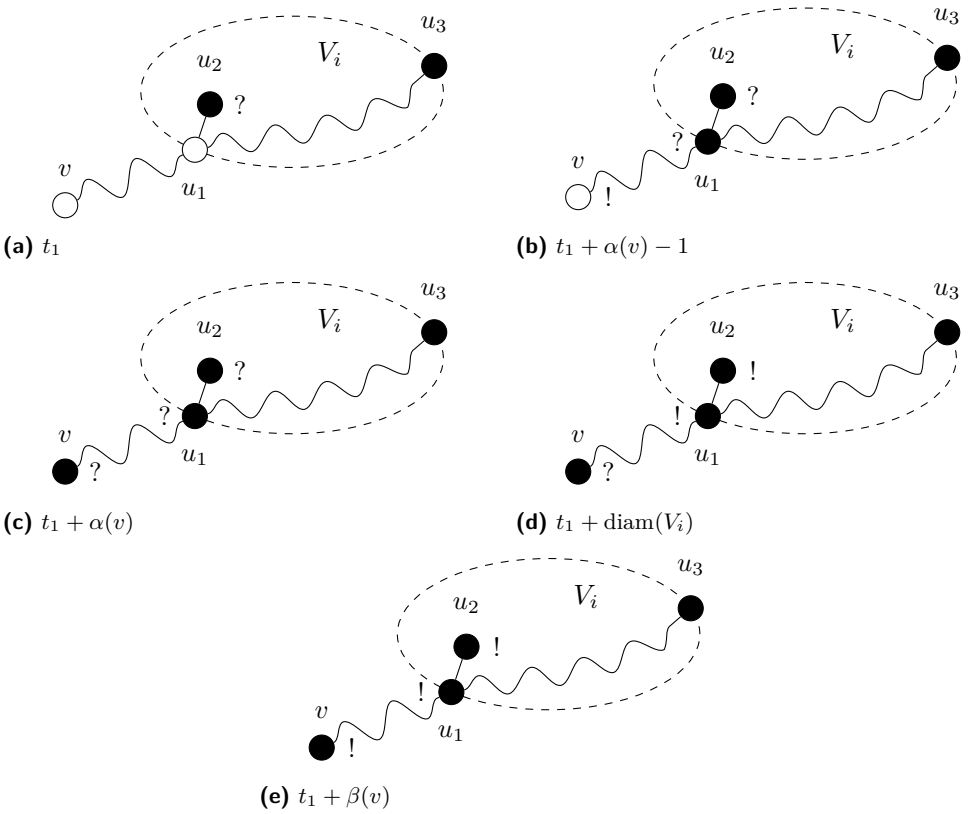

Figure 4 How to predict the color of a node v based on knowledge about the states of nodes in other components. For the sake of illustration, here we are assuming that v belongs to some component which is all white in step t_1 and that the component nearest to v on which a black node appears is V_i. We also suppose that $B_i = \{u_1, u_3\}$ and $\mathrm{dist}(v, u_1) \ll \mathrm{dist}(u_1, u_3) = \mathrm{diam}(V_i)$. In time step t_1 the situation is as in (a). Since $B_i' = \{u_3\}$ is not empty, we must treat V_i as potentially having black nodes since the first time step. We see the states of u_1 and u_3 in t_1 and determine that $\alpha(v) = \mathrm{dist}(v, u_1) + 1 = \mathrm{dist}(v, u_2)$ and $\beta(v) = \mathrm{dist}(v, u_3)$; however, we do not know the color of u_2 since it is inside V_i and we do not query it, so we have to treat it as a potentially black node (denoted by a question mark). After $\alpha(v) - 1$ steps (b) we know that v must still be white (denoted by an exclamation mark) since the closest node to it that is possibly black in step t_1 is the node u_2. After $\alpha(v)$ steps (c) we are no longer certain about the color of v. After $\mathrm{diam}(V_1)$ steps (d) we know that u_1 must be black, but we still cannot say anything about v. Finally after $\beta(v)$ steps (e) we are sure that v has turned black at the latest since u_3 was black in t_1.

Alphabet Reduction for Reconfiguration Problems

Naoto Ohsaka
CyberAgent, Inc., Tokyo, Japan

Abstract

We present a reconfiguration analogue of *alphabet reduction* à la Dinur (J. ACM, 2007) [7] and its applications. Given a binary constraint graph G and its two satisfying assignments ψ^{ini} and ψ^{tar}, the Maxmin 2-CSP Reconfiguration problem requests to transform ψ^{ini} into ψ^{tar} by repeatedly changing the value of a single vertex so that the minimum fraction of satisfied edges is maximized. We demonstrate a polynomial-time reduction from Maxmin 2-CSP Reconfiguration with arbitrarily large alphabet size $W \in \mathbb{N}$ to itself with universal alphabet size $W_0 \in \mathbb{N}$ such that

1. the perfect completeness is preserved, and
2. if any reconfiguration for the former violates ε-fraction of edges, then $\Omega(\varepsilon)$-fraction of edges must be unsatisfied during any reconfiguration for the latter.

The crux of its construction is the *reconfigurability of Hadamard codes*, which enables to reconfigure between a pair of codewords, while avoiding getting too close to the other codewords. Combining this alphabet reduction with gap amplification due to Ohsaka (SODA 2024) [26], we are able to amplify the 1 vs. $1-\varepsilon$ gap for arbitrarily small $\varepsilon \in (0,1)$ up to the 1 vs. $1-\varepsilon_0$ for some universal $\varepsilon_0 \in (0,1)$ *without* blowing up the alphabet size. In particular, a 1 vs. $1-\varepsilon_0$ gap version of Maxmin 2-CSP Reconfiguration with alphabet size W_0 is **PSPACE**-hard given a probabilistically checkable reconfiguration proof system having any soundness error $1-\varepsilon$ due to Hirahara and Ohsaka (STOC 2024) [14] and Karthik C. S. and Manurangsi (2023) [17]. As an immediate corollary, we show that there exists a universal constant $\varepsilon_0 \in (0,1)$ such that many popular reconfiguration problems are **PSPACE**-hard to approximate within a factor of $1-\varepsilon_0$, including those of 3-SAT, Independent Set, Vertex Cover, Clique, Dominating Set, and Set Cover. This may not be achieved only by gap amplification of Ohsaka [26], which makes the alphabet size gigantic depending on ε^{-1}.

1 Introduction

1.1 Background

Combinatorial reconfiguration is a brand-new field in theoretical computer science that concerns the reachability and connectivity over the solution space of a combinatorial problem. One canonical **PSPACE**-complete reconfiguration problem is 2-CSP Reconfiguration: given a binary constraint graph G over alphabet Σ and its two satisfying assignments ψ^{ini} and ψ^{tar}, we are requested to transform ψ^{ini} into ψ^{tar} by repeatedly changing the value of a single vertex while the feasibility of intermediate assignments is maintained. Such a sequence of

feasible solutions is referred to as a *reconfiguration sequence*. Since the establishment of the unified framework due to Ito, Demaine, Harvey, Papadimitriou, Sideri, Uehara, and Uno [16], the complexity of many reconfiguration problems has been investigated, including those of Satisfiability, Coloring, Independent Set, Vertex Cover, and Clique. We refer the readers to the survey by Bousquet, Mouawad, Nishimura, and Siebertz [6], Mynhardt and Nasserasr [20], Nishimura [21], and van den Heuvel [31]. One latest trend is to study *approximate reconfigurability* [23, 24, 26], which affords to relax the feasibility of intermediate solutions during reconfiguration. For example, in Maxmin 2-CSP Reconfiguration [23], which is an *optimization version* of 2-CSP Reconfiguration, we can adopt any *non-satisfying assignments*, but are required to maximize the minimum fraction of edges satisfied during reconfiguration. Such optimization versions would be come up with naturally to deal with **PSPACE**-hardness of many reconfiguration problems. See Section 1.5 for other optimization versions of reconfiguration problems.

One of the most important questions concerning approximate reconfigurability was **PSPACE**-*hardness of approximation* for reconfiguration problems, posed by Ito, Demaine, Harvey, Papadimitriou, Sideri, Uehara, and Uno [16, Section 5] as an open problem. Though **NP**-hardness of approximation for reconfiguration problems (e.g., Maxmin SAT Reconfiguration) was shown by [16], their proofs do not imply **PSPACE**-hardness because of relying on the **NP**-hardness of approximating the corresponding optimization problems (e.g., Max SAT). The significance of showing **PSPACE**-hardness compared to **NP**-hardness is that it disproves the existence of a witness (especially a reconfiguration sequence) of polynomial length under **NP** $\neq$ **PSPACE**. Ohsaka [23] showed that a host of (optimization versions of) reconfiguration problems are **PSPACE**-hard to approximate under the *Reconfiguration Inapproximability Hypothesis* (RIH), which postulates that a gap version of Maxmin CSP Reconfiguration is **PSPACE**-hard. Very recently, Hirahara and Ohsaka [14] and Karthik C. S. and Manurangsi [17] independently announced the proof of RIH, thereby affirmatively resolving the open problem of Ito, Demaine, Harvey, Papadimitriou, Sideri, Uehara, and Uno [16]. The proof is based on a construction of *probabilistically checkable reconfiguration proof* (PCRP) systems for **PSPACE**. The present study delves deeper into **PSPACE**-hardness of approximation for reconfiguration problems *given* the resolution of RIH.

The limitation of [23] along with the PCRP theorem [14, 17] is that the degree of inapproximability is not explicitly shown: although the PCRP theorem implies that Maxmin 2-CSP Reconfiguration is **PSPACE**-hard to approximate within a factor of $1-\varepsilon$, its *gap parameter* $\varepsilon \in (0,1)$ is implicit and thus might be very tiny. To circumvent this limitation, Ohsaka [26] successfully developed Dinur's style *gap amplification* [7] for Maxmin 2-CSP Reconfiguration, which amplifies the 1 vs. $1-\varepsilon$ gap for arbitrarily small $\varepsilon \in (0,1)$ up to the 1 vs. 0.9942 gap. This result can be used to show 1.0029-inapproximability for Minmax Set Cover Reconfiguration [26]. Unfortunately, there still remains another issue: *the alphabet size becomes gigantic depending on* ε^{-1}.[1] Consider for example reducing Maxmin 2-CSP Reconfiguration with alphabet size W to Maxmin 3-SAT Reconfiguration in a gap-preserving manner. According to [23], if the former problem has a δ-gap, the latter problem's gap turns out to be $\frac{\delta}{2^{\Omega(W)}}$. This is undesirable if W depends on ε. Our target in this paper is thus a reconfiguration analogue of *alphabet reduction*, i.e., a polynomial-time reduction from Maxmin 2-CSP Reconfiguration to itself that makes a large alphabet into a tiny one without much deteriorating the gap value.

[1] Precisely, the alphabet size becomes $W^{d^{\mathcal{O}(\varepsilon^{-1})}}$ for some $W, d \in \mathbb{N}$ by [26], which is doubly exponential in ε^{-1}.

Table 1 Gap-preserving reductions used in Corollary 1.2. We can reduce $\mathsf{Gap}_{1,1-\varepsilon}$ q-CSP_W Reconfiguration (i.e., the PCRP theorem) to $\mathsf{Gap}_{1,1-\varepsilon_0}$ 2-CSP_{W_0} Reconfiguration regardless of the values of $\varepsilon \in (0,1)$ and $q, W \in \mathbb{N}$.

gap problem	ref.	technique	gap value	alphabet size
q-CSP Reconf	—	—	arbitrarily small ε	arbitrarily large W
2-CSP Reconf	[23]	degree reduction	depends on ε, q, W	universal const.
2-CSP Reconf	[26]	gap amplification	universal const.	depends on ε, q, W
2-CSP Reconf	(this paper)	alphabet reduction	universal const. ε_0	universal const. W_0

1.2 Our Results

We present alphabet reduction for Maxmin 2-CSP Reconfiguration à la Dinur [7] and its applications. Given an instance of Maxmin 2-CSP Reconfiguration with arbitrarily large alphabet, we are able to reduce the alphabet size to a universal constant $W_0 \in \mathbb{N}$ preserving the gap value by up to a constant factor:

▶ **Theorem 1.1** (Alphabet reduction; informal; see Theorem 3.1)**.** *There exist universal constants $W_0 \in \mathbb{N}$ and $\kappa \in (0,1)$ and a polynomial-time reduction from* Maxmin 2-CSP Reconfiguration *with arbitrarily large alphabet size $W \in \mathbb{N}$ to itself with alphabet size W_0 such that*

1. *the perfect completeness is preserved, and*
2. *if any reconfiguration for the former violates ε-fraction of edges, then $\kappa \cdot \varepsilon$-fraction of edges must be unsatisfied during any reconfiguration for the latter.*

Our reduction is independent of ε; namely, ε does not have to be constant, e.g., $\varepsilon = (\#\text{ of edges})^{-1}$. The main ingredient of its construction is the *reconfigurability of Hadamard codes*, which appears later in Section 1.3.

As a corollary of Theorem 3.1 and [23, 26], we are able to amplify the 1 vs. $1-\varepsilon$ gap for arbitrarily small $\varepsilon \in (0,1)$ up to the 1 vs. $1-\varepsilon_0$ gap for some universal $\varepsilon_0 \in (0,1)$ *without* blowing up the alphabet size. Slightly more formally, for any $\varepsilon \in (0,1)$ and $W \in \mathbb{N}$, $\mathsf{Gap}_{1,1-\varepsilon}$ 2-CSP_W Reconfiguration requests to distinguish whether, for a binary constraint graph with alphabet size W and its two satisfying assignments ψ^{ini} and ψ^{tar}, (1) there exists a reconfiguration sequence from ψ^{ini} to ψ^{tar} consisting only of satisfying assignments, or (2) every reconfiguration sequence violates more than ε-fraction of edges.

▶ **Corollary 1.2** (from Theorem 3.1 and [23, 26])**.** *There exist universal constants $\varepsilon_0 \in (0,1)$ and $W_0 \in \mathbb{N}$ such that for arbitrarily small $\varepsilon \in (0,1)$ and large $q, W \in \mathbb{N}$, there exists a gap-preserving reduction from* $\mathsf{Gap}_{1,1-\varepsilon}$ q-CSP_W Reconfiguration *to* $\mathsf{Gap}_{1,1-\varepsilon_0}$ 2-CSP_{W_0} Reconfiguration*. In particular, the latter problem is* **PSPACE***-hard.*

Since *both* ε_0 and W_0 do not depend on either ε, q, or W, Corollary 1.2 makes the degree of inapproximability and alphabet size of Maxmin 2-CSP Reconfiguration *oblivious to* the soundness error, query complexity, and alphabet size of any PCRP system [14, 17]. Concretely, we would have $\varepsilon_0 = \kappa \cdot (1 - 0.9942) > 10^{-18}$ and $W_0 < 2{,}000{,}000$, where number 0.9942 comes from [26]. See also the proof of Theorem 3.1. This may not be achieved only by gap amplification due to Ohsaka [26]. See also Table 1 for a sequence of gap-preserving reductions used in Corollary 1.2.

By Corollary 1.2, we immediately obtain the following gap-preserving reducibility from any PCRP system to many popular reconfiguration problems:

▶ **Theorem 1.3** (from Corollary 1.2 and [23, 26]). *There exists a universal constant $\varepsilon_0 \in (0,1)$ such that for every $\varepsilon \in (0,1)$ and $q, W \in \mathbb{N}$, $\mathsf{Gap}_{1,1-\varepsilon}$ q-CSP_W Reconfiguration is polynomial-time reducible to a 1 vs. $1-\varepsilon_0$ gap version of the following reconfiguration problems*:

2-CSP Reconfiguration, 3-SAT Reconfiguration, Independent Set Reconfiguration, Vertex Cover Reconfiguration, Clique Reconfiguration, Dominating Set Reconfiguration, Set Cover Reconfiguration, *and* Nondeterministic Constraint Logic.

In particular, optimization versions of the above problems are **PSPACE***-hard to approximate within a factor of* $1-\varepsilon_0$.

Once again, Theorem 1.3 is different from a consequence of gap-preserving reductions due to Ohsaka [23] in a sense that it renders ε_0 *independent of* the value of ε.[2] Such **PSPACE**-hardness results seem to be known only for (optimization versions of) 2-CSP Reconfiguration (0.9942-factor) [26], Set Cover Reconfiguration (1.0029-factor) [26], and Clique Reconfiguration ($n^{-\Omega(1)}$-factor) [14] (to the best of our knowledge).

Proofs marked with $*$ are omitted and can be found in the full version of this paper [25].

1.3 Proof Overview

The construction of alphabet reduction for Maxmin 2-CSP Reconfiguration (Theorem 3.1) is based on that for Max 2-CSP due to Dinur [7], which comprises two partial steps: The first step is **robustization**, which replaces each constraint π_e of edge e by a Boolean circuit C_e that accepts $f \circ g$ if and only if $f \circ g = \mathsf{Had}(\alpha) \circ \mathsf{Had}(\beta)$ such that (α, β) satisfies π_e, where Had is the Hadamard code (see Section 2 for the definition).[3] The soundness case ensures that for "many" edges e, the restricted assignment is $\Theta(1)$-far from any satisfying truth assignment to C_e. The second step is **composition**, which composes each circuit C_e with an *assignment tester* [7, 8] (a.k.a. *PCP of proximity* [4]) of constant size to break down C_e into a system of binary constraints over small alphabet while sharing the common variables for different circuits.

The main challenge to achieving alphabet reduction for Maxmin 2-CSP Reconfiguration is its robustization. Simply applying the above robustization procedure to Maxmin 2-CSP Reconfiguration, we are required to reconfigure between a pair of codewords, say, $\mathsf{Had}(\alpha_1)$ and $\mathsf{Had}(\alpha_2)$ for $\alpha_1 \neq \alpha_2$. Such reconfiguration must pass through a function $\gtrapprox \frac{1}{4}$-far from the codeword and thus from any satisfying truth assignment to the above circuit C_e, sacrificing the perfect completeness. There is a dilemma that distinct codewords should be far from each other, yet they need to be reconfigurable with each other. One might thus think of enforcing C_e to accept functions that are $\frac{1}{4}$-close to the codeword. Unfortunately, this modification reduces the robustness to $o(1)$ in the soundness case, as shown in an example below (see also Example 3.7). This explains why robustization for Maxmin 2-CSP Reconfiguration is nontrivial.

▶ **Example 1.4** (Failed attempt). Define a binary constraint $\pi_e \coloneqq \{(\alpha_1, \beta_1), (\alpha_2, \beta_2)\} \subset \Sigma \times \Sigma$ and a Hadamard code $\mathsf{Had}\colon \Sigma \to \mathbb{F}_2^\ell$. Construct a (seemingly promising) circuit $\widetilde{C}_e$ such that $\widetilde{C}_e(f \circ g) = 1$ if and only if

[2] We stress that Theorem 1.3 is essentially different from the following statement (where ε_0 can depend on ε, q, and W), which is immediate from [23]: "For arbitrarily small $\varepsilon \in (0,1)$ and large $q, W \in \mathbb{N}$, there exists $\varepsilon_0 \in (0,1)$ such that $\mathsf{Gap}_{1,1-\varepsilon}$ q-CSP_W Reconfiguration is polynomial-time reducible to a 1 vs. $1-\varepsilon_0$ gap version of the reconfiguration problems listed in Theorem 1.3."

[3] Though Dinur [7] used an error-correcting code $\mathsf{enc}\colon \Sigma \to \mathbb{F}_2^\ell$ having *linear dimension* (i.e., $\ell = \mathcal{O}(\log|\Sigma|)$), we can afford to use the Hadamard code for our purpose because $|\Sigma| = \mathcal{O}(1)$.

1. both f and g are $\frac{1}{4}$-close to some Hadamard codewords;
2. if f and g are $\frac{1}{4}$-close to $\mathsf{Had}(\alpha)$ and $\mathsf{Had}(\beta)$, respectively, then (α, β) must satisfy π_e.

Then, the following issue arises: even if f is closest to $\mathsf{Had}(\alpha)$ and g is closest to $\mathsf{Had}(\beta)$ such that $(\alpha, \beta) \notin \pi$, we cannot exclude the possibility that $f \circ g$ is $o(1)$-close to some satisfying truth assignment to $\widetilde{C}_e$. Suppose f is $\frac{1}{4}$-close to both $\mathsf{Had}(\alpha_1)$ and $\mathsf{Had}(\alpha_2)$ and g is $\frac{1}{4}$-close to both $\mathsf{Had}(\beta_1)$ and $\mathsf{Had}(\beta_2)$. Changing particular two bits of $f \circ g$, we obtain $f^\star \circ g^\star$ that is $\left(\frac{1}{4} - \frac{1}{\ell}\right)$-close to $\mathsf{Had}(\alpha_1) \circ \mathsf{Had}(\beta_1)$. Since $\widetilde{C}(f^\star \circ g^\star) = 1$, $f \circ g$ is $\frac{1}{\ell}$-close to a satisfying truth assignment to $\widetilde{C}_e$. ⌟

The crux of a reconfiguration analogue of robustization is what we call the *reconfigurability of Hadamard codes*:

▶ **Lemma 1.5** (Reconfigurability of Hadamard codes; informal; see Lemma 3.2)**.** *There exists a universal constant $\delta_0 \in (0, 1)$ such that for any $n \geqslant 9$ and $\boldsymbol{\alpha} \neq \boldsymbol{\beta} \in \mathbb{F}_2^n$, there exists a reconfiguration sequence from $\mathsf{Had}(\boldsymbol{\alpha})$ to $\mathsf{Had}(\boldsymbol{\beta})$ such that every function in it is*

- *$\frac{1}{4}$-close to either $\mathsf{Had}(\boldsymbol{\alpha})$ or $\mathsf{Had}(\boldsymbol{\beta})$, and*
- *$\left(\frac{1}{4} + \delta_0\right)$-far from $\mathsf{Had}(\boldsymbol{\gamma})$ for every $\boldsymbol{\gamma} \neq \boldsymbol{\alpha}, \boldsymbol{\beta}$.*

Lemma 3.2 enables us to reconfigure between a pair of codewords, avoiding getting too (say, $\frac{1}{4} + \delta_0$) close to the other codewords. The existence of such a reconfiguration sequence is shown by a simple application of the structural property of a triple of distinct Hadamard codewords and the probabilistic method. Lemma 3.2 is still nontrivial in that it does not hold if $n = 3$ (see Observation 3.3). Using the reconfigurability of Hadamard codes, we implement alphabet reduction of Maxmin 2-CSP Reconfiguration as follows:

- **Robustization** (Lemma 3.6): Convert a binary constraint π_e for edge e into a circuit C_e such that $C_e(f \circ g) = 1$ if and only if
  1. both f and g are $\frac{1}{4}$-close to some Hadamard codewords;
  2. if f and g are $\left(\frac{1}{4} + \frac{\delta_0}{2}\right)$-close to $\mathsf{Had}(\alpha)$ and $\mathsf{Had}(\beta)$, respectively, then (α, β) must satisfy π_e.

  (The difference from $\widetilde{C}_e$ of Example 1.4 is highlighted.) Consider π_e, f, and g appearing in Example 1.4 again for the soundness case. Suppose C_e is constructed from π_e. To make $f \circ g$ to satisfy C_e, we must modify them so that f and g are $\left(\frac{1}{4} + \frac{\delta_0}{2}\right)$-far from $\mathsf{Had}(\alpha_2)$ and $\mathsf{Had}(\beta_2)$ (or $\mathsf{Had}(\alpha_1)$ and $\mathsf{Had}(\beta_1)$), respectively; namely, $f \circ g$ is $\frac{\delta_0}{2}$-far from any satisfying truth assignment to C_e. Even though C_e demands stricter conditions than $\widetilde{C}_e$ of Example 1.4, the perfect completeness can be derived using Lemma 3.2.
- **Composition** (Proposition 3.10): Just feeding each circuit C_e to an assignment tester $\mathcal{P}$ of [7] breaks the perfect completeness; instead, we apply $\mathcal{P}$ to C_e *twice* to create twins of binary constraint systems sharing the input variables to C_e. Our 4-query verifier then picks a pair of edges from each of the twins uniformly at random, and accepts if either of them is satisfied, which may be thought of as *rectangular PCPs* [5]. This kind of redundancy is crucial for ensuring the perfect completeness of reconfiguration problems. On the other hand, if δ-fraction of the edges are unsatisfied in both of the twins, the verifier rejects with probability δ^2 owing to its rectangularity.

In the language of probabilistic proofs, the above alphabet reduction may be thought of as a composition of (PCRPs) due to Hirahara and Ohsaka [14], where the outer PCRP is a 2-query PCRP verifier and the inner PC(R)P is an assignment tester. To make the outer PCRP enjoy a reconfiguration analogue of the robustness as in Lemma 3.6, we replace each variable by a block of bits and modify the original circuit associated with each edge e (i.e., binary constraint π_e) appropriately so as to reflect the reconfigurability of Hadamard codes.

1.4 Towards Dinur's Style Proof of RIH?

Given degree reduction [23], gap amplification [26], and alphabet reduction (this paper) for Maxmin 2-CSP Reconfiguration, one might think of proving RIH imitating Dinur's proof of the PCP theorem [7]. Though the resolution of RIH is not the main motivation for developing alphabet reduction and RIH has already been proven by Hirahara and Ohsaka [14] and Karthik C. S. and Manurangsi [17], such a different proof is still useful in a sense that it would rely only on (slightly) simpler tools. Unfortunately, merely putting them together does not work as expected because some of the reductions are only *gap-preserving*, which requires that there is already a constant gap $\varepsilon \in (0,1)$ between completeness and soundness, and thus weaker than those of Dinur [7]. Consider for example degree reduction of Maxmin 2-CSP Reconfiguration. Unlike Papadimitriou–Yannakakis's degree reduction for Max 2-CSP [28], Ohsaka's degree reduction [23] uses near-Ramanujan graphs [2, 19] of degree $\Theta(\varepsilon^{-2})$. Since we need to begin gap amplification with $\varepsilon = (\#\text{ of edges})^{-1} = o(1)$, applying the degree reduction step of [23] results in a superconstant degree, failing to reduce the degree of Maxmin 2-CSP Reconfiguration. Gap amplification of Ohsaka [26] also relies on the assumption that the gap value is a constant, see [26, Claim 3.7]. Note that alphabet reduction in the present study works for any subconstant gap.

1.5 Additional Related Work

In [16], **NP**-hardness of approximation is shown for optimization versions of Clique Reconfiguration and SAT Reconfiguration using **NP**-hardness of approximating Max Clique [12] and Max SAT [13], respectively. Other reconfiguration problems whose approximability was investigated include Subset Sum Reconfiguration, which admits a PTAS [15] and Submodular Reconfiguration, which admits a constant-factor approximation [27]. It is known that a naive parallel repetition for Maxmin 2-CSP Reconfiguration fails to decrease the soundness error [24] unlike the parallel repetition theorem due to Raz [30]; in fact, Maxmin 2-CSP Reconfiguration is approximable within a factor of nearly $\frac{1}{4}$ [24] while **NP**-hard to approximate within a factor better than $\frac{3}{4}$ [26]. Karthik C. S. and Manurangsi [17] demonstrate matching lower and upper bounds, i.e., **NP**-hardness of $\left(\frac{1}{2}+\varepsilon\right)$-factor approximation and a $\left(\frac{1}{2}-\varepsilon\right)$-factor approximation algorithm for every $\varepsilon \in \left(0, \frac{1}{2}\right)$.

The *overlap gap property* [10, 1, 18, 11, 32] refers to the separation phenomena of the overlaps between near-optimal solutions on random instance, which implies approximate reconfigurability; see also [26].

2 Preliminaries

2.1 Notations

For a nonnegative integer $n \in \mathbb{N}$, let $[n] \coloneqq \{1, 2, \ldots, n\}$. Denote by $\mathfrak{S}_n$ the set of all permutations over $[n]$. A *sequence* $\mathscr{S}$ of a finite number of objects $S^{(1)}, \ldots, S^{(T)}$ is denoted by $(S^{(1)}, \ldots, S^{(T)})$, and we write $S^{(t)} \in \mathscr{S}$ to indicate that $S^{(t)}$ appears in $\mathscr{S}$. The symbol $\circ$ stands for a concatenation of two strings, $\langle \cdot, \cdot \rangle$ for the inner product, $\mathbb{F}_2 = \{0,1\}$ for the finite field with two elements. We use $\uplus$ to emphasize that the union is taken over disjoint sets. Let Σ be a finite set called *alphabet*. For a length-n string $f \in \Sigma^n$ and index set $I \subseteq [n]$, we use $f|_I$ to denote the restriction of f to I. The *relative distance* between two strings $f, g \in \Sigma^n$, denoted $\Delta(f,g)$, is defined as the fraction of positions on which f and g differ; namely,

$$\Delta(f,g) \coloneqq \mathop{\mathbb{P}}_{i\sim[n]}\Big[f_i \neq g_i\Big] = \frac{|\{i\in[n] \mid f_i \neq g_i\}|}{n}. \tag{2.1}$$

We say that f is *ε-close* to g if $\Delta(f,g) \leqslant \varepsilon$ and *ε-far* from g if $\Delta(f,g) > \varepsilon$. For a set of strings $S \subseteq \Sigma^n$, analogous notions are used; e.g., $\Delta(f,S) \coloneqq \min_{g\in S}\Delta(f,g)$ and f is ε-close to S if $\Delta(f,S) \leqslant \varepsilon$. For a string $\boldsymbol{\alpha} \in \mathbb{F}_2^n$, its *Hadamard code* is defined as a function $\mathsf{Had}(\boldsymbol{\alpha})\colon \mathbb{F}_2^n \to \mathbb{F}_2$ such that $\mathsf{Had}(\boldsymbol{\alpha})(\mathbf{x}) = \langle \boldsymbol{\alpha}, \mathbf{x}\rangle$ for all $\mathbf{x} \in \mathbb{F}_2^n$. We call $\mathsf{Had}(\boldsymbol{\alpha})$ for each $\boldsymbol{\alpha}$ a *codeword* of the Hadamard code, and write $\mathsf{Had}(\cdot)$ for the set of all codewords. Note that the relative distance between any pair of distinct codewords of $\mathsf{Had}(\cdot)$ is $\frac{1}{2}$; i.e., $\Delta(\mathsf{Had}(\boldsymbol{\alpha}), \mathsf{Had}(\boldsymbol{\beta})) = \frac{1}{2}$ for all $\boldsymbol{\alpha} \neq \boldsymbol{\beta} \in \mathbb{F}_2^n$.

2.2 Constraint Satisfaction Problem and Reconfigurability

We introduce reconfiguration problems on constraint satisfaction. The notion of constraint graphs is first introduced.

▶ **Definition 2.1.** A *q-ary constraint graph* is defined as a tuple $G = (V, E, \Sigma, \Pi)$ such that (V, E) is a q-uniform hypergraph called the *underlying graph*, Σ is a finite set called the *alphabet*, and $\Pi = (\pi_e)_{e\in E}$ is a collection of q-ary *constraints*, where each constraint $\pi_e \subseteq \Sigma^e$ is a set of q-tuples of acceptable values that q vertices in e can take. ⌟

For an *assignment* $\psi\colon V \to \Sigma$, we say that ψ *satisfies* hyperedge $e = \{v_1, \dots, v_q\} \in E$ (or constraint π_e) if $\psi(e) \coloneqq (\psi(v_1), \dots, \psi(v_q)) \in \pi_e$, and ψ *satisfies* G if it satisfies all hyperedges of G. For two satisfying assignments ψ^{ini} and ψ^{tar} for G, a *reconfiguration sequence from ψ^{ini} to ψ^{tar}* over Σ^V is any sequence $(\psi^{(1)}, \dots \psi^{(T)})$ such that $\psi^{(1)} = \psi^{\mathsf{ini}}$, $\psi^{(T)} = \psi^{\mathsf{tar}}$, and every two neighboring assignments $\psi^{(t)}$ and $\psi^{(t+1)}$ differ in at most one vertex. In the q-CSP Reconfiguration problem, for a q-ary constraint graph G and its two satisfying assignments ψ^{ini} and ψ^{tar}, we are asked to decide if there is a reconfiguration sequence of satisfying assignments for G from ψ^{ini} to ψ^{tar}. Hereafter, the suffix "$_W$" designates the restricted case that the alphabet size $|\Sigma|$ is integer $W \in \mathbb{N}$.

Subsequently, we formulate an optimization version of q-CSP Reconfiguration [16, 23], which allows going through non-satisfying assignments. For a constraint graph $G = (V, E, \Sigma, \Pi)$ and an assignment $\psi\colon V \to \Sigma$, its *value* is defined as the fraction of edges of G satisfied by ψ; namely,

$$\mathsf{val}_G(\psi) \coloneqq \frac{1}{|E|} \cdot \left|\left\{e \in E \;\middle|\; \psi \text{ satisfies } e\right\}\right|. \tag{2.2}$$

For a reconfiguration sequence $\boldsymbol{\psi} = (\psi^{(1)}, \dots, \psi^{(T)})$ of assignments, let $\mathsf{val}_G(\boldsymbol{\psi})$ denote the *minimum fraction* of satisfied edges over all $\psi^{(t)}$'s in $\boldsymbol{\psi}$; namely,

$$\mathsf{val}_G(\boldsymbol{\psi}) \coloneqq \min_{\psi^{(t)}\in\boldsymbol{\psi}} \mathsf{val}_G(\psi^{(t)}). \tag{2.3}$$

In Maxmin q-CSP Reconfiguration, we wish to maximize $\mathsf{val}_G(\boldsymbol{\psi})$ subject to $\boldsymbol{\psi} = (\psi^{\mathsf{ini}}, \dots, \psi^{\mathsf{tar}})$. For two assignments $\psi^{\mathsf{ini}}, \psi^{\mathsf{tar}}\colon V \to \Sigma$ for G, let $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}})$ denote the maximum value of $\mathsf{val}_G(\boldsymbol{\psi})$ over all possible reconfiguration sequences $\boldsymbol{\psi}$ from ψ^{ini} to ψ^{tar}; namely,

$$\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) \coloneqq \max_{\boldsymbol{\psi}=(\psi^{\mathsf{ini}},\dots,\psi^{\mathsf{tar}})} \mathsf{val}_G(\boldsymbol{\psi}). \tag{2.4}$$

The gap version of Maxmin q-CSP Reconfiguration is defined as follows.

▶ **Problem 2.2.** For every numbers $0 \leqslant s \leqslant c \leqslant 1$ and integer $q \in \mathbb{N}$, $\mathsf{Gap}_{c,s}$ q-CSP Reconfiguration requests to determine for a q-ary constraint graph G and its two assignments ψ^{ini} and ψ^{tar}, whether $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) \geqslant c$ (the input is a YES instance) or $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) < s$ (the input is a NO instance). Here, c and s are respectively called *completeness* and *soundness*. ⌟

We can assume ψ^{ini} and ψ^{tar} satisfy G whenever $c = 1$. The *Reconfiguration Inapproximability Hypothesis* (RIH) [23] postulates that $\mathsf{Gap}_{1,1-\varepsilon}$ q-CSP_W Reconfiguration is **PSPACE**-hard for some $\varepsilon \in (0,1)$ and $q, W \in \mathbb{N}$, which has been recently proven by Hirahara and Ohsaka [14] and Karthik C. S. and Manurangsi [17].

3 Alphabet Reduction for Maxmin 2-CSP Reconfiguration

In this section, we prove the main result of this paper, i.e., an explicit construction of *alphabet reduction* for Maxmin 2-CSP Reconfiguration, as formally stated below.

▶ **Theorem 3.1** (Alphabet reduction). *There exist universal constants $W_0 \in \mathbb{N}$ and $\kappa \in (0,1)$, and a polynomial-time algorithm $\mathcal{A}$ that takes an instance $(G, \psi^{\mathsf{ini}}, \psi^{\mathsf{tar}})$ of* Maxmin 2-CSP_W Reconfiguration *with alphabet size $W \in \mathbb{N}$ and produces an instance $(G', \psi'^{\mathsf{ini}}, \psi'^{\mathsf{tar}})$ of* Maxmin 2-CSP_{W_0} Reconfiguration *with alphabet size W_0 such that the following hold:*

- *(Perfect completeness) If $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) = 1$, then $\mathsf{val}_{G'}(\psi'^{\mathsf{ini}} \leftrightsquigarrow \psi'^{\mathsf{tar}}) = 1$.*
- *(Soundness) If $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) < 1 - \varepsilon$, then $\mathsf{val}_{G'}(\psi'^{\mathsf{ini}} \leftrightsquigarrow \psi'^{\mathsf{tar}}) < 1 - \kappa \cdot \varepsilon$.*

In particular, for every $\varepsilon \in (0,1)$ and $W \in \mathbb{N}$, $\mathcal{A}$ is a gap-preserving reduction from $\mathsf{Gap}_{1,1-\varepsilon}$ 2-CSP_W Reconfiguration *to* $\mathsf{Gap}_{1,1-\kappa\cdot\varepsilon}$ 2-CSP_{W_0} Reconfiguration.

The remainder of this section is organized as follows: Section 3.1 introduces and proves the reconfigurability of Hadamard codes, which will be applied to robustization of Maxmin 2-CSP Reconfiguration in Section 3.2. Subsequently, Section 3.3 composes the assignment tester of [7, 22] into Circuit SAT Reconfiguration, concluding the proof of Theorem 3.1.

3.1 Reconfigurability of Hadamard Codes

Here, we prove the reconfigurability of Hadamard codewords. A *reconfiguration sequence from f^{ini} to f^{tar}* over $\mathbb{F}_2^N$ is a sequence $(f^{(1)}, \dots, f^{(T)})$ such that $f^{(1)} = f^{\mathsf{ini}}$, $f^{(T)} = f^{\mathsf{tar}}$, and every two neighboring functions $f^{(t)}$ and $f^{(t+1)}$ differ in at most one bit.

▶ **Lemma 3.2** (Reconfigurability of Hadamard codes). *Let n be a positive integer at least 9, $\delta_0 \coloneqq \frac{1}{400}$ be a universal constant, and $\boldsymbol{\alpha}, \boldsymbol{\beta} \in \mathbb{F}_2^n$ be two distinct strings. Then, there exists a reconfiguration sequence $\Pi = (\mathsf{Had}(\boldsymbol{\alpha}), \dots, \mathsf{Had}(\boldsymbol{\beta}))$ from $\mathsf{Had}(\boldsymbol{\alpha})$ to $\mathsf{Had}(\boldsymbol{\beta})$ such that for every string $\boldsymbol{\gamma} \in \mathbb{F}_2^n \setminus \{\boldsymbol{\alpha}, \boldsymbol{\beta}\}$ and every function $f \colon \mathbb{F}_2^n \to \mathbb{F}$ in Π,*

$$\min\Big\{\Delta(f, \mathsf{Had}(\boldsymbol{\alpha})), \Delta(f, \mathsf{Had}(\boldsymbol{\beta}))\Big\} \leqslant \frac{1}{4}, \tag{3.1}$$

$$\Delta(f, \mathsf{Had}(\boldsymbol{\gamma})) > \frac{1}{4} + \delta_0. \tag{3.2}$$

Before going to its proof, we remark that Lemma 3.2 *does not* hold if $n = 3$.

▶ **Observation 3.3** (∗). *For $n = 3$ and $\boldsymbol{\alpha} \neq \boldsymbol{\beta} \in \mathbb{F}_2^n$, let Π be a reconfiguration sequence from $\mathsf{Had}(\boldsymbol{\alpha})$ to $\mathsf{Had}(\boldsymbol{\beta})$ such that $\min\{\Delta(f, \mathsf{Had}(\boldsymbol{\alpha})), \Delta(f, \mathsf{Had}(\boldsymbol{\beta}))\} \leqslant \frac{1}{4}$ for every function f in Π. Then, Π contains a function f° such that $\Delta(f^\circ, \mathsf{Had}(\boldsymbol{\gamma})) \leqslant \frac{1}{4}$ for some $\boldsymbol{\gamma} \in \mathbb{F}_2^n \setminus \{\boldsymbol{\alpha}, \boldsymbol{\beta}\}$.*

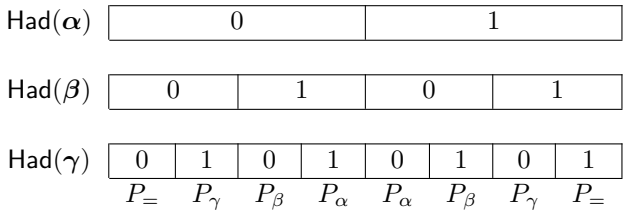

Figure 1 Illustration of $(P_\alpha, P_\beta, P_\gamma, P_=)$ for three distinct nonzero vectors $\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma} \in \mathbb{F}_2^n$.

To prove Lemma 3.2, we first analyze the partial sum of a random sequence consisting of an equal number of plus ones and minus ones.

▶ **Lemma 3.4** (∗). *Let $N > N_0 := 100$ be any positive integer, $\eta_0 := \frac{1}{100}$, and $\mathbf{a} = (a_1, \dots, a_{2N})$ be a random sequence made up of N plus ones and N minus ones obtained by applying a random permutation of $\mathfrak{S}_{2N}$ to $(\underbrace{+1, \dots, +1}_{N \text{ times}}, \underbrace{-1, \dots, -1}_{N \text{ times}})$. Then, the minimum k-partial sum over all $k \in [2N]$; i.e.,*

$$\operatorname*{argmin}_{1 \leqslant k \leqslant 2N} \sum_{1 \leqslant i \leqslant k} a_i = \operatorname*{argmin}_{1 \leqslant k \leqslant 2N} \sum_{k+1 \leqslant i \leqslant 2N} a_i, \tag{3.3}$$

is at most $-(1-\eta_0)N = -0.99N$ with probability at most 0.9^N.

Besides, given the Hadamard codewords of any three distinct strings, we partition their bits into four equal-sized groups.

▷ Claim 3.5 (∗). For three distinct vectors $\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma} \in \mathbb{F}_2^n$, the following hold:

$$\begin{aligned}
&\mathop{\mathbb{P}}_{\mathbf{x} \in \mathbb{F}_2^n}\Big[\langle \boldsymbol{\alpha}, \mathbf{x}\rangle \neq \langle \boldsymbol{\beta}, \mathbf{x}\rangle = \langle \boldsymbol{\gamma}, \mathbf{x}\rangle\Big] = \frac{1}{4}, \quad \mathop{\mathbb{P}}_{\mathbf{x} \in \mathbb{F}_2^n}\Big[\langle \boldsymbol{\beta}, \mathbf{x}\rangle \neq \langle \boldsymbol{\gamma}, \mathbf{x}\rangle = \langle \boldsymbol{\alpha}, \mathbf{x}\rangle\Big] = \frac{1}{4}, \\
&\mathop{\mathbb{P}}_{\mathbf{x} \in \mathbb{F}_2^n}\Big[\langle \boldsymbol{\gamma}, \mathbf{x}\rangle \neq \langle \boldsymbol{\alpha}, \mathbf{x}\rangle = \langle \boldsymbol{\beta}, \mathbf{x}\rangle\Big] = \frac{1}{4}, \quad \mathop{\mathbb{P}}_{\mathbf{x} \in \mathbb{F}_2^n}\Big[\langle \boldsymbol{\alpha}, \mathbf{x}\rangle = \langle \boldsymbol{\beta}, \mathbf{x}\rangle = \langle \boldsymbol{\gamma}, \mathbf{x}\rangle\Big] = \frac{1}{4}.
\end{aligned} \tag{3.4}$$

Using Lemma 3.4 and Claim 3.5, we now prove Lemma 3.2.

Proof of Lemma 3.2. Fix two strings $\boldsymbol{\alpha} \neq \boldsymbol{\beta} \in \mathbb{F}_2^n$ for $n \geqslant 9$. Let $D \subset \mathbb{F}_2^n$ be a set of strings on which $\mathsf{Had}(\boldsymbol{\alpha})$ and $\mathsf{Had}(\boldsymbol{\beta})$ disagree with each other; namely,

$$D := \Big\{ \mathbf{x} \in \mathbb{F}_2^n \;\Big|\; \langle \boldsymbol{\alpha}, \mathbf{x}\rangle \neq \langle \boldsymbol{\beta}, \mathbf{x}\rangle \Big\}. \tag{3.5}$$

The random subsum principle ensures $|D| = 2^{n-1}$ (cf. [3, Claim A.31]). Consider a random reconfiguration sequence $\Pi = (\mathsf{Had}(\boldsymbol{\alpha}), \dots, \mathsf{Had}(\boldsymbol{\beta}))$ obtained by the following procedure:

Random reconfiguration Π from Had(α) to Had(β).

1: $(\mathbf{x}_1, \dots, \mathbf{x}_{2^{n-1}}) \leftarrow$ a sequence obtained by applying a random permutation of $\mathfrak{S}_{2^{n-1}}$ to D.
2: **for** $i = 1$ **to** 2^{n-1} **do**
3: flip $\mathbf{x}_i{}^{\text{th}}$ entry of the current function.

Observe easily that any intermediate function of Π is always $\frac{1}{4}$-close to either $\mathsf{Had}(\boldsymbol{\alpha})$ or $\mathsf{Had}(\boldsymbol{\beta})$. Fix any string $\boldsymbol{\gamma} \in \mathbb{F}_2^n \setminus \{\boldsymbol{\alpha}, \boldsymbol{\beta}\}$. We would like to show that with probability at least $1 - 0.9^{2^{n-2}}$, every function of Π is $\left(\frac{1}{4} + \delta_0\right)$-far from $\mathsf{Had}(\boldsymbol{\gamma})$; i.e.,

$$\Delta(\mathsf{Had}(\boldsymbol{\gamma}), \Pi) := \min_{f \in \Pi} \Delta(\mathsf{Had}(\boldsymbol{\gamma}), f) > \frac{1}{4} + \delta_0. \tag{3.6}$$

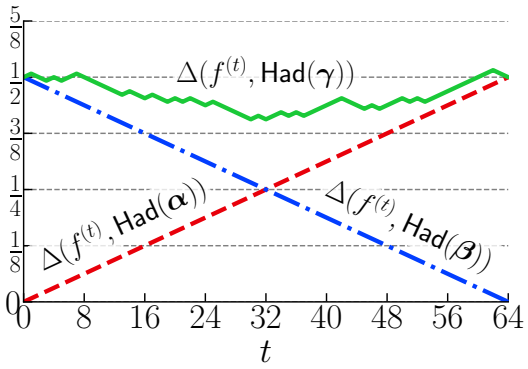

Figure 2 Plot of the distance from $f^{(t)}$ to $\mathsf{Had}(\boldsymbol{\alpha})$, $\mathsf{Had}(\boldsymbol{\beta})$, and $\mathsf{Had}(\boldsymbol{\gamma})$ for a random reconfiguration Π from $\mathsf{Had}(\boldsymbol{\alpha})$ to $\mathsf{Had}(\boldsymbol{\beta})$ described in the proof of Lemma 3.2.

By Claim 3.5, there exists a partition $(P_\alpha, P_\beta, P_\gamma, P_=)$ of $\mathbb{F}_2^n$ such that $|P_\alpha| = |P_\beta| = |P_\gamma| = |P_=| = 2^{n-2}$ and

$$\begin{aligned} &\langle \boldsymbol{\alpha}, \mathbf{x}\rangle \neq \langle \boldsymbol{\beta}, \mathbf{x}\rangle = \langle \boldsymbol{\gamma}, \mathbf{x}\rangle \text{ for all } \mathbf{x} \in P_\alpha, \quad \langle \boldsymbol{\beta}, \mathbf{x}\rangle \neq \langle \boldsymbol{\gamma}, \mathbf{x}\rangle = \langle \boldsymbol{\alpha}, \mathbf{x}\rangle \text{ for all } \mathbf{x} \in P_\beta, \\ &\langle \boldsymbol{\gamma}, \mathbf{x}\rangle \neq \langle \boldsymbol{\alpha}, \mathbf{x}\rangle = \langle \boldsymbol{\beta}, \mathbf{x}\rangle \text{ for all } \mathbf{x} \in P_\gamma, \quad \langle \boldsymbol{\alpha}, \mathbf{x}\rangle = \langle \boldsymbol{\beta}, \mathbf{x}\rangle = \langle \boldsymbol{\gamma}, \mathbf{x}\rangle \text{ for all } \mathbf{x} \in P_=. \end{aligned} \tag{3.7}$$

See also Figure 1. Here, we always have $P_\alpha \uplus P_\beta = D$ (though P_α and P_β themselves depend on $\boldsymbol{\gamma}$).

For any intermediate function $f\colon \mathbb{F}_2^n \to \mathbb{F}_2$ of Π, if its entry on P_α is flipped, its Hamming distance to $\mathsf{Had}(\boldsymbol{\gamma})$ must decrease by 1, whereas if its entry on P_β is flipped, its Hamming distance to $\mathsf{Had}(\boldsymbol{\gamma})$ must increase by 1; see also Figure 2. Since $|P_\alpha| = |P_\beta| = 2^{n-2} > 100$ and $\|\mathsf{Had}(\boldsymbol{\alpha}) - \mathsf{Had}(\boldsymbol{\gamma})\| = \|\mathsf{Had}(\boldsymbol{\beta}) - \mathsf{Had}(\boldsymbol{\gamma})\| = 2^{n-1}$, we can apply Lemma 3.4 with $N = 2^{n-2}$ to conclude that

$$\begin{aligned} &\mathop{\mathbb{P}}_{\Pi}\left[\min_{f\in\Pi}\|\mathsf{Had}(\boldsymbol{\gamma}) - \Pi\| \leqslant 2^{n-1} - 0.99N\right] \leqslant 0.9^N \\ \Longrightarrow\ &\mathop{\mathbb{P}}_{\Pi}\left[\Delta(\mathsf{Had}(\boldsymbol{\gamma}), \Pi) \leqslant \frac{1}{4} + \frac{1}{400}\right] \leqslant 0.9^{2^{n-2}}. \end{aligned}$$

Taking a union bound over all possible strings $\boldsymbol{\gamma} \in \mathbb{F}_2^n \setminus \{\boldsymbol{\alpha}, \boldsymbol{\beta}\}$, we derive

$$\begin{aligned} &\mathop{\mathbb{P}}_{\Pi}\left[\exists \boldsymbol{\gamma} \notin \{\boldsymbol{\alpha}, \boldsymbol{\beta}\} \text{ s.t. } \Delta(\mathsf{Had}(\boldsymbol{\gamma}), \Pi) \leqslant \frac{1}{4} + \frac{1}{400}\right] \\ &\leqslant \sum_{\boldsymbol{\gamma}\notin\{\boldsymbol{\alpha},\boldsymbol{\beta}\}} \mathop{\mathbb{P}}_{\Pi}\left[\Delta(\mathsf{Had}(\boldsymbol{\gamma}), \Pi) \leqslant \frac{1}{4} + \frac{1}{400}\right] < 2^n \cdot 0.9^{2^{n-2}} < 1 \quad (\text{for all } n \geqslant 9). \end{aligned} \tag{3.8}$$

Consequently, the probabilistic method guarantees the existence of a reconfiguration sequence $\Pi = (\mathsf{Had}(\boldsymbol{\alpha}), \ldots, \mathsf{Had}(\boldsymbol{\beta}))$ that is entirely $\left(\frac{1}{4} + \delta_0\right)$-far from $\mathsf{Had}(\boldsymbol{\gamma})$ for every $\boldsymbol{\gamma} \notin \{\boldsymbol{\alpha}, \boldsymbol{\beta}\}$. ◀

3.2 Robustization

Subsequently, we advance to *robustization* of Maxmin 2-CSP Reconfiguration, relying on the reconfigurability of Hadamard codes. For a system of Boolean circuits $\mathscr{C}$ and its two satisfying truth assignments $\sigma^{\mathsf{ini}}, \sigma^{\mathsf{tar}}\colon \mathbb{F}_2^N \to \mathbb{F}_2$, Circuit SAT Reconfiguration requires to decide the existence of a reconfiguration sequence from σ^{ini} to σ^{tar} over $\mathbb{F}_2^{\mathbb{F}_2^N}$ consisting only of satisfying truth assignments to $\mathscr{C}$.

▶ **Lemma 3.6** (Robustization). *There exists a polynomial-time algorithm that takes an instance* $(G, \psi^{\mathsf{ini}}, \psi^{\mathsf{tar}})$ *of* Maxmin 2-CSP$_W$ Reconfiguration *with alphabet size* $W \in \mathbb{N}$*, where* ψ^{ini} *and* ψ^{tar} *satisfy* G*, and then produces an instance* $(\mathscr{C}, \sigma^{\mathsf{ini}}, \sigma^{\mathsf{tar}})$ *of* Circuit SAT Reconfiguration*, where* $\mathscr{C} = (C_e)_{e \in E}$ *is a system of circuits and* σ^{ini} *and* σ^{tar} *satisfy* $\mathscr{C}$*, such that the following hold*:

- (*Perfect completeness*) *If* $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) = 1$*, there exists a reconfiguration sequence from* σ^{ini} *to* σ^{tar} *made up of satisfying truth assignments to* $\mathscr{C}$*.*
- (*Soundness*) *If* $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) < 1 - \varepsilon$*, any reconfiguration sequence from* σ^{ini} *to* σ^{tar} *includes assignment* σ° *such that for more than* ε*-fraction of edges* e *of* G*,* $\sigma^\circ|_{[\![e]\!]}$ *is* $\frac{\delta_0}{8}$*-far from any satisfying truth assignment to* C_e*, where* $\delta_0 = \frac{1}{400}$ *as in Lemma 3.2.*

Reduction. Our polynomial-time robustization of Maxmin 2-CSP$_W$ Reconfiguration into Circuit SAT Reconfiguration is described as follows. Let $(G, \psi^{\mathsf{ini}}, \psi^{\mathsf{tar}})$ be an instance of Maxmin 2-CSP$_W$ Reconfiguration, where $G = (V, E, \Sigma, \Pi)$ is a binary constraint graph, and ψ^{ini} and ψ^{tar} satisfy G. Without loss of generality, we can assume that $W = |\Sigma| = 2^n$ for some integer $n \geqslant 9$,[4] and we can identify $\mathbb{F}_2^n$ with Σ.

Consider replacing binary constraints of G by a system of circuits. We first specify a *truth assignment* to the entire circuit system by a function $\sigma \colon \mathbb{F}_2^n \times V \to \mathbb{F}_2$, which can be thought of as a concatenation of functions $\sigma_v \colon \mathbb{F}_2^n \to \mathbb{F}_2$ associated with each vertex $v \in V$. For vertex $v \in V$, let $[\![v]\!]$ denote the set of 2^n Boolean variables associated with v, and for edge $e = (v, w) \in E$, let $[\![e]\!] \coloneqq [\![v]\!] \uplus [\![w]\!]$.[5] By this representation, we can identify $\mathbb{F}_2^n \times V$ with $\biguplus_{v \in V} [\![v]\!]$. In particular, for edge $e = (v, w) \in E$, $\sigma|_{[\![e]\!]}$ is equal to $\sigma|_{[\![v]\!]} \circ \sigma|_{[\![w]\!]}$. For each edge $e = (v, w)$ of G and its constraint π_e, we define a circuit $C_e \colon ([\![v]\!] \to \mathbb{F}_2) \times ([\![w]\!] \to \mathbb{F}_2) \to \mathbb{F}_2$ (or equivalently, $C_e \colon \mathbb{F}_2^{[\![v]\!]} \times \mathbb{F}_2^{[\![w]\!]} \to \mathbb{F}_2$) that depends *only* on $\sigma|_{[\![e]\!]} = \sigma|_{[\![v]\!]} \circ \sigma|_{[\![w]\!]}$ such that $C_e(\sigma|_{[\![v]\!]} \circ \sigma|_{[\![w]\!]}) = 1$ if and only if

$$\begin{aligned} &\Delta(\sigma|_{[\![v]\!]}, \mathsf{Had}(\cdot)) \leqslant \frac{1}{4} \text{ and } \Delta(\sigma|_{[\![w]\!]}, \mathsf{Had}(\cdot)) \leqslant \frac{1}{4}, \\ &\forall \alpha, \beta \in \Sigma, \Delta(\sigma|_{[\![v]\!]}, \mathsf{Had}(\alpha)) \leqslant \frac{1}{4} + \frac{\delta_0}{2} \text{ and } \Delta(\sigma|_{[\![w]\!]}, \mathsf{Had}(\beta)) \leqslant \frac{1}{4} + \frac{\delta_0}{2} \implies (\alpha, \beta) \in \pi_e, \end{aligned} \tag{3.9}$$

where $\delta_0 = \frac{1}{400}$ as in Lemma 3.2. Note that each C_e has constant size and can be constructed in constant time since $n = \mathcal{O}(1)$. Consequently, we obtain a system of circuits, denoted $\mathscr{C} = (C_e)_{e \in E}$. Given a satisfying assignment $\psi \colon V \to \Sigma$ for G, we can construct a satisfying truth assignment $\sigma \colon \mathbb{F}_2^n \times V \to \mathbb{F}_2$ such that $\sigma|_{[\![v]\!]} \coloneqq \mathsf{Had}(\psi(v))$ for all $v \in V$. Constructing σ^{ini} from ψ^{ini} and σ^{tar} from ψ^{tar} according to this procedure, we obtain an instance $(\mathscr{C}, \sigma^{\mathsf{ini}}, \sigma^{\mathsf{tar}})$ of Circuit SAT Reconfiguration. Observe that the above reduction completes in polynomial time.

Proof of Lemma 3.6. We first prove the perfect completeness. It suffices to consider the case that ψ^{ini} and ψ^{tar} differ in exactly one vertex, say, $v^\star \in V$. Using Lemma 3.2, we obtain a reconfiguration sequence $(f^{(1)}, \dots, f^{(T)})$ from $\mathsf{Had}(\psi^{\mathsf{ini}}(v))$ to $\mathsf{Had}(\psi^{\mathsf{tar}}(v))$. Construct then a reconfiguration sequence $\boldsymbol{\sigma} = (\sigma^{(1)}, \dots, \sigma^{(T)})$ from σ^{ini} to σ^{tar} such that for all t, $\sigma^{(t)}|_{[\![w]\!]} \coloneqq \sigma^{\mathsf{ini}}|_{[\![w]\!]} = \sigma^{\mathsf{tar}}|_{[\![w]\!]}$ for all $w \neq v^\star$, and $\sigma^{(t)}|_{[\![v^\star]\!]} \coloneqq f^{(t)}$. For each edge $e = (v^\star, w)$ of G, any intermediate function $\sigma^{(t)}$ of $\boldsymbol{\sigma}$ satisfies the following:

[4] Otherwise, we can augment Σ by padding so that $|\Sigma| \geqslant 2^9$.
[5] Similar notations are used in [7].

- By Lemma 3.2, $\sigma^{(t)}|_{[\![v^\star]\!]}$ is $\frac{1}{4}$-close to $\mathsf{Had}(\psi^{\mathsf{ini}}(v))$ or $\mathsf{Had}(\psi^{\mathsf{tar}}(v))$, but $\left(\frac{1}{4}+\delta_0\right)$-far from $\mathsf{Had}(\gamma)$ for every $\gamma \notin \{\psi^{\mathsf{ini}}(v), \psi^{\mathsf{tar}}(v)\}$.
- $\sigma^{(t)}|_{[\![w]\!]}$ is equal to $\mathsf{Had}(\psi^{\mathsf{ini}}(w)) = \mathsf{Had}(\psi^{\mathsf{tar}}(w))$; i.e., it is $\left(\frac{1}{2}-o(1)\right)$-far from $\mathsf{Had}(\gamma)$ for every $\gamma \notin \{\psi^{\mathsf{ini}}(w), \psi^{\mathsf{tar}}(w)\}$.

Since $\{\psi^{\mathsf{ini}}(v^\star), \psi^{\mathsf{tar}}(v^\star)\} \times \{\psi^{\mathsf{ini}}(w), \psi^{\mathsf{tar}}(w)\} = \{(\psi^{\mathsf{ini}}(v^\star), \psi^{\mathsf{ini}}(w)), (\psi^{\mathsf{tar}}(v^\star), \psi^{\mathsf{tar}}(w))\} \subseteq \pi_e$, it turns out that $\sigma^{(t)}|_{[\![e]\!]}$ satisfies C_e, and thus every $\sigma^{(t)}$ in $\boldsymbol{\sigma}$ satisfies $\mathscr{C}$ entirely.

We then prove the soundness. Suppose $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) < 1-\varepsilon$ and we are given a reconfiguration sequence $\boldsymbol{\sigma} = (\sigma^{(1)}, \dots, \sigma^{(T)})$ from σ^{ini} to σ^{tar}. Construct then a reconfiguration sequence $\boldsymbol{\psi} = (\psi^{(1)}, \dots, \psi^{(T)})$ from ψ^{ini} to ψ^{tar} such that $\psi^{(t)}(v)$ is defined as a value of Σ whose Hadamard codeword is closest to $\sigma^{(t)}|_{[\![v]\!]}$; namely,[6]

$$\psi^{(t)}(v) \coloneqq \operatorname*{argmin}_{\alpha\in\Sigma} \Delta(\sigma^{(t)}|_{[\![v]\!]}, \mathsf{Had}(\alpha)). \tag{3.10}$$

Since $\boldsymbol{\psi}$ is a valid reconfiguration sequence, there exists some $\psi^{(t)}$ that violates more than $\varepsilon\cdot|E|$ edges.

Hereafter, we denote $\psi \coloneqq \psi^{(t)}$ and $\sigma \coloneqq \sigma^{(t)}$ for notational simplicity. Suppose ψ violates edge $e=(v,w)$; i.e., $(\psi(v),\psi(w)) \notin \pi_e$. We would like to show that $\sigma|_{[\![e]\!]}$ is $\frac{\delta_0}{8}$-far from any satisfying truth assignment to C_e. Let $f\circ g\colon [\![e]\!] \to \mathbb{F}_2$ be a satisfying truth assignment to C_e. In particular, there exists a pair $(\alpha^\star,\beta^\star) \in \pi_e$ such that $\Delta(f, \mathsf{Had}(\alpha^\star)) \leqslant \frac{1}{4}$ and $\Delta(g, \mathsf{Had}(\beta^\star)) \leqslant \frac{1}{4}$. Observe now that "$f$ is $\left(\frac{1}{4}+\frac{\delta_0}{2}\right)$-far from $\mathsf{Had}(\psi(v))$" or "g is $\left(\frac{1}{4}+\frac{\delta_0}{2}\right)$-far from $\mathsf{Had}(\psi(w))$" because otherwise, $C_e(f\circ g)=0$.

Suppose first $\Delta(f, \mathsf{Had}(\psi(v))) > \frac{1}{4}+\frac{\delta_0}{2}$, implying that $\alpha^\star \neq \psi(v)$. Putting together, we have the following three inequalities in hand:

$$\Delta(f, \mathsf{Had}(\alpha^\star)) \leqslant \frac{1}{4} \qquad \text{by assumption,} \tag{3.11}$$

$$\Delta(f, \mathsf{Had}(\psi(v))) > \frac{1}{4}+\frac{\delta_0}{2} \qquad \text{by assumption,} \tag{3.12}$$

$$\Delta(\sigma|_{[\![v]\!]}, \mathsf{Had}(\psi(v))) \leqslant \Delta(\sigma|_{[\![v]\!]}, \mathsf{Had}(\alpha^\star)) \qquad \text{by construction of } \sigma|_{[\![v]\!]}. \tag{3.13}$$

Simple calculation using the triangle inequality derives

$$\begin{aligned} \Delta(f, \mathsf{Had}(\psi(v))) &\leqslant \Delta(f, \sigma|_{[\![v]\!]}) + \Delta(\sigma|_{[\![v]\!]}, \mathsf{Had}(\psi(v))) \\ &\leqslant \Delta(f, \sigma|_{[\![v]\!]}) + \Delta(\sigma|_{[\![v]\!]}, \mathsf{Had}(\alpha^\star)) \\ &\leqslant \Delta(f, \sigma|_{[\![v]\!]}) + \Delta(\sigma|_{[\![v]\!]}, f) + \Delta(f, \mathsf{Had}(\alpha^\star)) \\ &= 2\cdot\Delta(\sigma|_{[\![v]\!]}, f) + \Delta(f, \mathsf{Had}(\alpha^\star)) \end{aligned} \tag{3.14}$$

$$\implies 2\cdot\Delta(\sigma|_{[\![v]\!]}, f) \geqslant \underbrace{\Delta(f, \mathsf{Had}(\psi(v)))}_{>\frac{1}{4}+\frac{\delta_0}{2}} - \underbrace{\Delta(f, \mathsf{Had}(\alpha^\star))}_{\leqslant\frac{1}{4}} \tag{3.15}$$

$$\implies \Delta(\sigma|_{[\![v]\!]}, f) > \frac{\delta_0}{4}. \tag{3.16}$$

Consequently, $\sigma|_{[\![e]\!]}$ should be $\frac{\delta_0}{8}$-far from $f\circ g$.

Suppose next $\Delta(g, \mathsf{Had}(\psi(w))) > \frac{1}{4}+\frac{\delta_0}{2}$, implying that $\beta^\star \neq \psi(w)$. Similarly to the first case, we can show that $\Delta(\sigma|_{[\![w]\!]}, g) > \frac{\delta_0}{4}$, deriving that $\sigma|_{[\![e]\!]}$ is $\frac{\delta_0}{8}$-far from $f\circ g$. This completes the proof of the soundness. ◀

[6] Ties are broken according to any prefixed order of Σ.

Example 3.7 explains why the reconfigurability of Hadamard codes is needed, by using a slightly different definition of circuits that fails robustization.

▶ **Example 3.7.** For edge $e = (v, w)$, define a binary constraint $\pi_e := \{(\alpha_1, \beta_1), (\alpha_2, \beta_2)\} \subset \mathbb{F}_2^n \times \mathbb{F}_2^n$. Construct a circuit $\widetilde{C}_e \colon (\llbracket v \rrbracket \to \mathbb{F}_2) \times (\llbracket w \rrbracket \to \mathbb{F}_2) \to \mathbb{F}_2$ such that $\widetilde{C}_e(\sigma|_{\llbracket v \rrbracket} \circ \sigma|_{\llbracket w \rrbracket}) = 1$ if and only if

$$\begin{aligned} &\Delta(\sigma|_{\llbracket v \rrbracket}, \mathsf{Had}(\cdot)) \leqslant \frac{1}{4} \text{ and } \Delta(\sigma|_{\llbracket w \rrbracket}, \mathsf{Had}(\cdot)) \leqslant \frac{1}{4}, \\ &\forall \alpha, \beta \in \Sigma, \Delta(\sigma|_{\llbracket v \rrbracket}, \mathsf{Had}(\alpha)) \leqslant \frac{1}{4} \text{ and } \Delta(\sigma|_{\llbracket w \rrbracket}, \mathsf{Had}(\beta)) \leqslant \frac{1}{4} \implies (\alpha, \beta) \in \pi_e. \end{aligned} \tag{3.17}$$

Note that reconfiguring from (α_1, β_1) to (α_2, β_2) over $\Sigma \times \Sigma$ (not $\mathbb{F}_2^n \times \mathbb{F}_2^n$) must break π_e (at some point). Analogously, we might expect that any reconfiguration sequence from $\mathsf{Had}(\alpha_1) \circ \mathsf{Had}(\beta_1)$ to $\mathsf{Had}(\alpha_2) \circ \mathsf{Had}(\beta_2)$ over $\mathbb{F}_2^{\llbracket v \rrbracket} \times \mathbb{F}_2^{\llbracket w \rrbracket}$ includes a function that is $\Theta(1)$-far from any satisfying truth assignment to $\widetilde{C}_e$. Consider now the following reconfiguration:

Reconfiguration Π from $\mathsf{Had}(\alpha_1) \circ \mathsf{Had}(\beta_1)$ to $\mathsf{Had}(\alpha_2) \circ \mathsf{Had}(\beta_2)$.

1: $f :=$ a function $\frac{1}{4}$-close to both $\mathsf{Had}(\alpha_1)$ and $\mathsf{Had}(\alpha_2)$.
2: $g :=$ a function $\frac{1}{4}$-close to both $\mathsf{Had}(\beta_1)$ and $\mathsf{Had}(\beta_2)$.
3: change $\mathsf{Had}(\alpha_1)$ to f one by one.
4: change $\mathsf{Had}(\beta_1)$ to g one by one.
5: ▷ *obtain $f \circ g$.* ◁
6: change f to $\mathsf{Had}(\alpha_2)$ one by one.
7: change g to $\mathsf{Had}(\beta_2)$ one by one.

Changing particular two bits of $f \circ g$, we obtain $f^\star \circ g^\star$, which is $\left(\frac{1}{4} - \frac{1}{2^n}\right)$-close to $\mathsf{Had}(\alpha_1) \circ \mathsf{Had}(\beta_1)$, implying $\widetilde{C}_e(f^\star \circ g^\star) = 1$. Thus, $f \circ g$ is $\frac{1}{2^n}$-close to some satisfying truth assignment to $\widetilde{C}_e$. Similarly, every intermediate function of Π is $\frac{1}{2^n}$-close to some satisfying truth assignment to $\widetilde{C}_e$. ⌟

3.3 Composition of Assignment Testers

We are now ready to compose an assignment tester into Circuit SAT Reconfiguration to accomplish alphabet reduction of Maxmin 2-CSP Reconfiguration. Here, we recapitulate *assignment testers* [7, 8], a.k.a. *PCPs of proximity* [4], and refer to an explicit construction due to Dinur [7] and O'Donnell [22].[7]

▶ **Definition 3.8** ([8, 4])**.** An *assignment tester* over alphabet $\Sigma_0 \supset \mathbb{F}_2$ with *rejection rate* $\rho \in (0, 1)$ is an algorithm $\mathcal{P}$ that takes a circuit $\Phi \colon \mathbb{F}_2^X \to \mathbb{F}_2$ over Boolean variables X as input, and produces a binary constraint graph $G = (V = X \uplus Y, E, \Sigma_0, \Pi)$ over X and auxiliary variables Y such that the following hold for any truth assignment $\sigma \colon X \to \mathbb{F}_2$ for Φ:

- (Perfect completeness) If σ satisfies Φ, there exists an assignment $\tau \colon Y \to \Sigma_0$ such that $\mathsf{val}_G(\sigma \circ \tau) = 1$.
- (Soundness) If σ is δ-far from any satisfying truth assignment to Φ, for every assignment $\tau \colon Y \to \Sigma_0$, $\mathsf{val}_G(\sigma \circ \tau) < 1 - \rho \cdot \delta$. ⌟

[7] Note that an assignment tester of O'Donnell [22, Theorem 7.16] takes the form of verifiers, which can be represented as a binary constraint graph by a standard reduction from probabilistically checkable proofs to two-prover games, e.g., [9, 29].

▶ **Theorem 3.9** ([7, Theorem 5.1] and [22, Theorem 7.16]). *There exists an explicit construction of an assignment tester $\mathcal{P}$ with alphabet $\Sigma_0 = \mathbb{F}_2^3$ and rejection rate $\rho := \frac{1}{10{,}000}$.*

▶ **Proposition 3.10** (Composition). *There exist universal constants $\widetilde{W}_0 := 8$ and $\widetilde{\kappa} := \frac{\delta_0^2 \rho^2}{64} \in (0,1)$, and a polynomial-time algorithm that takes an instance $(G, \psi^{\mathsf{ini}}, \psi^{\mathsf{tar}})$ of* Maxmin 2-CSP$_W$ Reconfiguration *with alphabet size $W \in \mathbb{N}$, where ψ^{ini} and ψ^{tar} satisfy G, and then produces an instance $(G', \psi'^{\mathsf{ini}}, \psi'^{\mathsf{tar}})$ of* Maxmin 4-CSP$_{\widetilde{W}_0}$ Reconfiguration *with alphabet size $\widetilde{W}_0$, where ψ'^{ini} and ψ'^{tar} satisfy G', such that the following hold:*

- *(Perfect completeness) If $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) = 1$, then $\mathsf{val}_{G'}(\psi'^{\mathsf{ini}} \leftrightsquigarrow \psi'^{\mathsf{tar}}) = 1$.*
- *(Soundness) If $\mathsf{val}_G(\psi^{\mathsf{ini}} \leftrightsquigarrow \psi^{\mathsf{tar}}) < 1 - \varepsilon$, then $\mathsf{val}_{G'}(\psi'^{\mathsf{ini}} \leftrightsquigarrow \psi'^{\mathsf{tar}}) < 1 - \widetilde{\kappa} \cdot \varepsilon$.*

Reduction. We now describe a polynomial-time reduction from Circuit SAT Reconfiguration introduced in the previous subsection to Maxmin 4-CSP$_8$ Reconfiguration. Let $(\mathscr{C}, \sigma^{\mathsf{ini}}, \sigma^{\mathsf{tar}})$ be an instance of Circuit SAT Reconfiguration obtained by applying Lemma 3.6 to an instance $(G, \psi^{\mathsf{ini}}, \psi^{\mathsf{ini}})$ of Maxmin 2-CSP$_W$ Reconfiguration. Here, $\mathscr{C} = (C_e)_{e \in E}$ is a system of circuits over Boolean variables $\mathbb{F}_2^n \times V$, associated with underlying graph (V, E), and σ^{ini} and σ^{tar} entirely satisfy $\mathscr{C}$.

Running the assignment tester $\mathcal{P}$ of Theorem 3.9 on each circuit $C_e \colon \mathbb{F}_2^{[\![e]\!]} \to \mathbb{F}_2$ for edge $e \in E$ produces a binary constraint graph $G_e = (V_e = [\![e]\!] \uplus Y_e, E_e, \Sigma_0, \widetilde{\Pi}_e = (\widetilde{\pi}_{\widetilde{e}})_{\widetilde{e} \in E_e})$, where Y_e is the set of auxiliary variables and $|\Sigma_0| = 8$. Create a pair of copies of G_e "sharing" $[\![e]\!]$, denoted G_e^1 and G_e^2; namely,

$$G_e^1 := (V_e^1 = [\![e]\!] \uplus Y_e^1, E_e^1, \Sigma_0, \widetilde{\Pi}_e^1), \tag{3.18}$$

$$G_e^2 := (V_e^2 = [\![e]\!] \uplus Y_e^2, E_e^2, \Sigma_0, \widetilde{\Pi}_e^2). \tag{3.19}$$

We then "superimpose" G_e^1 and G_e^2 to obtain a 4-ary constraint graph $G'_e = (V'_e, E'_e, \Sigma_0, \Pi'_e = (\pi'_{(\widetilde{e}_1, \widetilde{e}_2)})_{(\widetilde{e}_1, \widetilde{e}_2) \in E_e})$, where

$$\begin{aligned} V'_e &:= [\![e]\!] \uplus Y_e^1 \uplus Y_e^2, \text{ and } E'_e := E_e^1 \times E_e^2, \\ \pi'_{(\widetilde{e}_1, \widetilde{e}_2)} &:= \widetilde{\pi}_{\widetilde{e}_1} \times \widetilde{\pi}_{\widetilde{e}_2} = \left\{ (\alpha_1, \beta_1, \alpha_2, \beta_2) \in \Sigma^4 \;\middle|\; (\alpha_1, \beta_1) \in \widetilde{\pi}_{\widetilde{e}_1} \vee (\alpha_2, \beta_2) \in \widetilde{\pi}_{\widetilde{e}_2} \right\} \\ &\qquad \text{for all } (\widetilde{e}_1, \widetilde{e}_2) \in E_e^1 \times E_e^2. \end{aligned} \tag{3.20}$$

Note that each pair of edges from E_e^1 and E_e^2 forms a hyperedge of G'_e, which would be satisfied if so is either of the two edges. We can safely assume that E'_e has the same size for all $e \in E$.

Finally, the new 4-ary constraint graph $G' = (V', E', \Sigma_0, \Pi')$ is defined as follows:

$$\begin{aligned} V' &:= \bigcup_{e \in E} V'_e = \left(\biguplus_{v \in V} [\![v]\!] \right) \uplus \left(\biguplus_{e \in E} Y_e^1 \uplus Y_e^2 \right), \\ E' &:= \biguplus_{e \in E} E'_e \text{ and } \Pi' := \biguplus_{e \in E} \Pi'_e. \end{aligned} \tag{3.21}$$

For any satisfying truth assignment $\sigma \colon \biguplus_{v \in V} [\![v]\!] \to \mathbb{F}_2$ of $\mathscr{C}$, consider an assignment $\psi' \colon V' \to \Sigma_0$ such that $\psi'|_{[\![v]\!]} := \sigma|_{[\![v]\!]}$ for all $v \in V$ and $\psi'|_{Y_e^1} = \psi'|_{Y_e^2} = \tau_e$ for all $e \in E$, where $\tau_e \colon Y_e \to \Sigma_0$ is an assignment to auxiliary variables Y_e such that $\sigma|_{[\![e]\!]} \circ \tau_e$ satisfies G'_e, whose existence is guaranteed by Definition 3.8. Observe easily that ψ' satisfies G'. Constructing ψ'^{ini} from σ^{ini} and ψ'^{tar} from σ^{tar} according to this procedure, we obtain an instance $(G', \psi'^{\mathsf{ini}}, \psi'^{\mathsf{tar}})$ of Maxmin 4-CSP$_8$ Reconfiguration, completing the reduction.

Proof of Proposition 3.10. Recall that $(G, \psi^{\mathsf{ini}}, \psi^{\mathsf{tar}})$ is an instance of Maxmin 2-CSP$_W$ Reconfiguration, $(\mathscr{C}, \sigma^{\mathsf{ini}}, \sigma^{\mathsf{tar}})$ is an instance of Circuit SAT Reconfiguration obtained by applying Lemma 3.6, and $(G', \psi'^{\mathsf{ini}}, \psi'^{\mathsf{tar}})$ is an instance of Maxmin 4-CSP$_8$ Reconfiguration obtained by composing the assignment tester [7] as described above.

We first prove the perfect completeness. By Lemma 3.6, it suffices to consider the case that σ^{ini} and σ^{tar} differ in exactly one variable, say, $(\mathbf{x}, v^\star) \in \mathbb{F}_2^n \times V$. Consider a reconfiguration sequence $\boldsymbol{\psi}'$ from ψ'^{ini} to ψ'^{tar} obtained by the following procedure:

Reconfiguration $\boldsymbol{\psi}'$ from ψ'^{ini} to ψ'^{tar}.

1: **for all** edge $e = (v^\star, w) \in E$ **do**
2: let $\tau_e^{\mathsf{tar}} \colon Y_e \to \Sigma_0$ be assignment such that $\sigma^{\mathsf{tar}}|_{[\![e]\!]} \circ \tau_e^{\mathsf{tar}}$ satisfies G_e.
3: change the entries on Y_e^1 to τ_e^{tar} one by one.
4: flip $\mathbf{x}^{\text{th}}$ entry of $[\![v^\star]\!]$.
5: **for all** edge $e = (v^\star, w) \in E$ **do**
6: change the entries on Y_e^2 to τ_e^{tar} one by one.

Observe easily that for any edge $e = (v^\star, w) \in E$, either of G_e^1 or G_e^2 is entirely satisfied by any intermediate assignment, implying that $\mathsf{val}_{G'}(\boldsymbol{\psi}') = 1$, as desired.

We then prove the soundness. Suppose we are given a reconfiguration sequence $\boldsymbol{\psi}' = (\psi'^{(1)}, \dots, \psi'^{(T)})$ from ψ'^{ini} to ψ'^{tar} such that $\mathsf{val}_{G'}(\boldsymbol{\psi}') = \mathsf{val}_{G'}(\psi'^{\mathsf{ini}} \leftrightsquigarrow \psi'^{\mathsf{tar}})$. Consider a reconfiguration sequence $\boldsymbol{\sigma} = (\sigma^{(1)}, \dots, \sigma^{(T)})$ such that $\sigma^{(t)} \coloneqq \psi'^{(t)}|_{\biguplus_{v \in V} [\![v]\!]}$ for all t. Since $\boldsymbol{\sigma}$ is a valid reconfiguration sequence from σ^{ini} to σ^{tar}, by Lemma 3.6, there exists some $\sigma^{(t)}$ such that for more than ε-fraction of edges e of G, $\sigma^{(t)}|_{[\![e]\!]} = \psi'^{(t)}|_{[\![e]\!]}$ is $\frac{\delta_0}{8}$-far from any satisfying truth assignment to C_e. Let $F \subset E$ be the set of such edges of G; note that $|F| \geqslant \varepsilon |E|$. By Theorem 3.9, $\psi'^{(t)}$ violates more than $\frac{\delta_0 \rho}{8}$-fraction of edges of each G_e^1 and G_e^2 for any $e \in F$. Since $\psi'^{(t)}$ violates hyperedge $(\widetilde{e}_1, \widetilde{e}_2) \in E_e^1 \times E_e^2$ if and only if it violates $\widetilde{e}_1 \in E_e^1$ with respect to $\widetilde{\Pi}_e^1$ and $\widetilde{e}_2 \in E_e^2$ with respect to $\widetilde{\Pi}_e^2$ *simultaneously*, there are more than $\left(\frac{\delta_0 \rho}{8}\right)^2$-fraction of hyperedges of G'_e that are violated by $\psi'^{(t)}$; i.e., $1 - \mathsf{val}_{G_e}(\psi'^{(t)}) > \frac{\delta_0^2 \rho^2}{64}$. Consequently, we derive

$$\begin{aligned}
1 - \mathsf{val}_{G'}(\boldsymbol{\psi}') &\geqslant 1 - \mathsf{val}_{G'}(\psi'^{(t)}) \\
&= \frac{1}{|E|} \sum_{e \in E} \left(1 - \mathsf{val}_{G'_e}(\psi'^{(t)})\right) \quad \text{(since every } E_e \text{ has the same size)} \\
&\geqslant \frac{1}{|E|} \sum_{e \in F} \left(1 - \mathsf{val}_{G'_e}(\psi'^{(t)})\right) \qquad (3.22) \\
&> \frac{|F|}{|E|} \frac{\delta_0^2 \rho^2}{64} > \varepsilon \cdot \underbrace{\frac{\delta_0^2 \rho^2}{64}}_{=\widetilde{\kappa}},
\end{aligned}$$

implying that $\mathsf{val}_{G'}(\psi'^{\mathsf{ini}} \leftrightsquigarrow \psi'^{\mathsf{tar}}) = \mathsf{val}_{G'}(\boldsymbol{\psi}') < 1 - \widetilde{\kappa} \cdot \varepsilon$, as desired. ◀

Proof of Theorem 3.1. Our construction of alphabet reduction for Maxmin 2-CSP Reconfiguration follows from Lemma 3.6 and Proposition 3.10 and a gap-preserving reduction [26, Lemma 5.4] (which is in fact approximation-preserving) from Gap$_{1,1-\varepsilon}$ 4-CSP$_{\widetilde{W}_0}$ Reconfiguration to Gap$_{1,1-\frac{\varepsilon}{4}}$ 2-CSP$_{W_0}$ Reconfiguration, where $W_0 = \left(\frac{\widetilde{W}_0(\widetilde{W}_0+1)}{2}\right)^4 = 36^4$. The value of κ in Theorem 3.1 should be $\frac{\widetilde{\kappa}}{4} = \frac{\delta_0^2 \rho^2}{256} = \frac{1}{256 \cdot 400^2 \cdot 10{,}000^2} = \frac{1}{8{,}000^4}$. ◀

4 Conclusions

We presented Dinur's style alphabet reduction [7] for Maxmin 2-CSP Reconfiguration, which now makes both the degree of inapproximability and alphabet size oblivious to the soundness error of the PCRP system [14, 17]. The main ingredient of its construction is the *reconfigurability of Hadamard codes*, which may be of independent interest and have further applications. We leave some open questions:

- **(Question 1).** Can we prove RIH [23] by Dinur's style gap amplification [7]? As discussed in Section 1.4, an approximation-preserving version for degree reduction and gap amplification of Maxmin 2-CSP Reconfiguration [23, 26] seems mandatory.
- **(Question 2).** Can we derive more meaningful inapproximability factors? Alas, we acknowledge that the current inapproximability factor is so small as to be almost meaningless in practice.
- **(Question 3).** Given the reconfigurability of Hadamard codes (Lemma 3.2), it is natural to ask that of other error-correcting codes: One may say that an error-correcting code enc is (δ, μ)-*reconfigurable* if for any $\boldsymbol{\alpha} \neq \boldsymbol{\beta}$, there exists a reconfiguration sequence from $\mathsf{enc}(\boldsymbol{\alpha})$ to $\mathsf{enc}(\boldsymbol{\beta})$ such that every function in it is
  - δ-close to either $\mathsf{enc}(\boldsymbol{\alpha})$ or $\mathsf{enc}(\boldsymbol{\beta})$, and
  - $(\delta + \mu)$-far from $\mathsf{enc}(\boldsymbol{\gamma})$ for every $\boldsymbol{\gamma} \neq \boldsymbol{\alpha}, \boldsymbol{\beta}$.

  Is there any such reconfigurable error-correcting code? Also, is there any general composition scheme for PCRPs [14]?

Abstract

In 1986 Robertson and Seymour proved a generalization of the seminal result of Erdős and Pósa on the duality of packing and covering cycles: A graph has the *Erdős-Pósa property* for minors if and only if it is planar. In particular, for every non-planar graph H they gave examples showing that the Erdős-Pósa property does not hold for H. Recently, Liu confirmed a conjecture of Thomas and showed that every graph has the *half-integral* Erdős-Pósa property for minors. Liu's proof is non-constructive and to this date, with the exception of a small number of examples, no constructive proof is known.

In this paper, we initiate the delineation of the half-integrality of the Erdős-Pósa property for minors. We conjecture that for every graph H, there exists a *unique* (up to a suitable equivalence relation on graph parameters) graph parameter EP_H such that H has the Erdős-Pósa property in a minor-closed graph class $\mathcal{G}$ if and only if $\sup\{\mathsf{EP}_H(G) \mid G \in \mathcal{G}\}$ is finite. We prove this conjecture for the class $\mathcal{H}$ of Kuratowski-connected shallow-vortex minors by showing that, for every non-planar $H \in \mathcal{H}$, the parameter $\mathsf{EP}_H(G)$ is *precisely* the maximum order of a Robertson-Seymour counterexample to the Erdős-Pósa property of H which can be found as a minor in G. Our results are constructive and imply, for the first time, parameterized algorithms that find either a packing, or a cover, or one of the Robertson-Seymour counterexamples, certifying the existence of a half-integral packing for the graphs in $\mathcal{H}$.

1 Introduction

In 1965 Erdős and Pósa published a paper [9] proving the following min-max duality theorem.

For every positive integer k and every graph G, either G contains k pairwise vertex-disjoint cycles, or there exists a set $S \subseteq V(G)$ with $|S| = \mathcal{O}(k \cdot \log(k))$ such that $G - S$ has no cycles.

This result has since become central in both graph theory and algorithm design [36, 4, 21, 45, 26]. A collection of pairwise vertex-disjoint cycles is called a (cycle) *packing*, while a set S as above is commonly referred to as a (cycle) *cover* or *transversal*. In a more general context, one may consider any family $\mathcal{M}$ of graphs and define $\mathsf{pack}_{\mathcal{M}}(G)$ to be the largest size of a *packing* of members of $\mathcal{M}$ in G, while $\mathsf{cover}_{\mathcal{M}}(G)$ is the minimum size of a set $S \subseteq V(G)$ such that $G - S$ contains[1] no member of $\mathcal{M}$. Clearly $\mathsf{pack}_{\mathcal{M}}(G) \leq \mathsf{cover}_{\mathcal{M}}(G)$. We say that $\mathcal{M}$ has the *Erdős-Pósa property* (EP-property) in a graph class $\mathcal{G}$ if there exists a function f such that, for every $G \in \mathcal{G}$, it holds that $\mathsf{cover}_{\mathcal{M}}(G) \leq f(\mathsf{pack}_{\mathcal{M}}(G))$.

If we now fix some graph H and select $\mathcal{M}_H$ to be the class of all graphs containing H as a minor, we enter the realm of the *Graph Minors Series* of Robertson and Seymour. In Graph Minors V. [36], as an implication of their min-max duality between the treewidth of a graph and its largest grid-minor, they prove that

For every graph H, $\mathcal{M}_H$ has the EP-property in the class of all graphs if and only if H is planar. (1)

The tools and ideas of Erdős-Pósa-type dualities have since found many applications and interpretations [34, 27, 18, 3, 12, 33]. Moreover, the study of Erdős-Pósa dualities has led to important advances in structural graph theory. As an example, the proof for the directed version of Erdős and Pósa's result [35], known as *Younger's Conjecture* has paved the way for proving the *Directed Grid Theorem* [24].

Half-integral Erdős-Pósa. We call a collection $\mathcal{C}$ of subgraphs of G a *half-integral packing* of $\mathcal{M}$ in G if every graph in $\mathcal{C}$ belongs to $\mathcal{M}$ and no vertex of G belongs to more than two of them. We define $\frac{1}{2}\text{-}\mathsf{pack}_{\mathcal{M}}(G)$ to be the maximum size of such a half-integral packing. Accordingly, $\mathcal{M}$ has the $\frac{1}{2}$EP-property in a graph class $\mathcal{G}$ if there exists a function f such that, for every $G \in \mathcal{G}$, it holds that $\mathsf{cover}_{\mathcal{M}}(G) \leq f(\frac{1}{2}\text{-}\mathsf{pack}_{\mathcal{M}}(G))$.

Attempting to generalize Robertson and Seymour's seminal result on planar graphs, Robin Thomas conjectured the following relaxation of the EP-property (see [22, 26]).

For every graph H, $\mathcal{M}_H$ has the $\frac{1}{2}$EP-property in the class of all graphs. (2)

The above conjecture was recently proven by Liu [26]. As before, it is apparent from the definition that $\frac{1}{2}\text{-}\mathsf{pack}_{\mathcal{M}}(G) \leq 2 \cdot \mathsf{cover}_{\mathcal{M}}(G)$. Hence, Liu's theorem reveals a min-max duality between half-integral packing and covering in all graphs. Moreover, it is a consequence of the Graph Minors Theorem [37] that for every graph H and every graph parameter $\mathsf{p} \in \{\mathsf{pack}_{\mathcal{M}_H}, \frac{1}{2}\text{-}\mathsf{pack}_{\mathcal{M}_H}, \mathsf{cover}_{\mathcal{M}_H}\}$ one can decide in time $f_{H,\mathsf{p}}(k)|V(G)|^3$ if $\mathsf{p}(G) \geq k$ (or $\mathsf{p}(G) \leq k$ in the case where $\mathsf{p} = \mathsf{cover}_{\mathcal{M}_H}$) [10] for some function $f_{H,\mathsf{p}}$.

In light of the above results, it appears that the story of the Erdős-Pósa property in the regime of graph minors, from both a structural and an algorithmic perspective, is quite complete. However, we should stress the following two points.

First: The algorithm from [10] is inherently *non-constructive*. Indeed, while for $\mathsf{pack}_{\mathcal{M}_H}$ and $\mathsf{cover}_{\mathcal{M}_H}$ constructive algorithms are known [40, 39, 23], with the exception of some small special cases [22], *no* such results exist for $\frac{1}{2}\text{-}\mathsf{pack}_{\mathcal{M}_H}$, not even approximation algorithms.

[1] At this point we consider containment to be defined through the subgraph relation.

Second: Let $\mathcal{C}$ be a graph class and let p be a graph parameter. We say that p is *bounded* in $\mathcal{G}$ if there exists $c \in \mathbb{N}$ such that, for every $G \in \mathcal{G}$, it holds that $\mathsf{p}(G) \leq c$. The proof of the "if" direction of (1) was based on the fact that, for every H, $\mathcal{M}_H$ has the EP-property in every graph class of bounded treewidth. This leads to the following *intermediate* question: *For which graph parameters* p *it holds that* $\mathcal{M}_H$ *has the EP-property in every class where* p *is bounded?* To be specific, if we fix some graph H, is it possible to find a graph parameter EP_H such that $\mathcal{M}_H$ has the EP-property in some minor-closed[2] graph class $\mathcal{G}$ *if and only if* EP_H is bounded in $\mathcal{G}$? Indeed, we conjecture that for every graph H, such a graph parameter exists and *precisely* delineates the half-integrality of the Erdős-Pósa property of $\mathcal{M}_H$.

▶ **Conjecture 1.** *For every graph H, there exists a minor-monotone graph parameter EP_H such that $\mathcal{M}_H$ has the Erdős-Pósa property in a minor-closed graph class $\mathcal{G}$ if and only if EP_H is bounded in $\mathcal{G}$.*

Notice that for any planar graph P, we can simply set EP_P to be the constant zero-function and thus, Conjecture 1 trivially holds for all planar graphs, because of (1). However, for non-planar graphs, the existence of such a parameter does not follow from any known results. Even if EP_H would exist for some particular non-planar graph H, it would be desirable to have some constructive, and ideally canonical, characterization of EP_H. That is, we aim at a description of EP_H that allows for algorithmic applications.

There are reasons to believe that EP_H exists and moreover has some canonical representation. It has recently been shown in [31], that this assertion is tied to the conjecture that graphs are ω^2-well quasi ordered by minors, which is a wide open question in order theory (see the classic result of Thomas in [44] for the most advanced result on this conjecture).

The contribution of this paper is *resolving* Conjecture 1 for an infinite family of non-planar graphs. Moreover, our results are constructive and provide a canonical representation of EP_H yielding parameterized approximation algorithms[3] for $\frac{1}{2}$-pack_H for any H in our family.

1.1 The threshold of half-integrality

In Graph Minors V [36], towards proving the "only if" direction of (1), Robertson and Seymour gave counterexamples of graphs where non-planar graphs cannot have the EP-property. Let us investigate such an example for the graph K_5. One may embed K_5 in both the projective plane and the torus, but it is impossible to have two disjoint drawings of K_5 in either of them.

Consider the two graphs in the middle of Figure 1 and notice that the number of cycles and paths can be scaled. We call the infinite sequences defined by such "scalable graphs" *parametric graphs*[4]. These parametric graphs are the *handle grid* $\mathcal{H}$ and the *cross-cap grid* $\mathcal{C}$ and represent the torus and the projective plane respectively. None of them contains two disjoint copies of graphs from $\mathcal{M}_{K_5}$, both have a half-integral packing of $\Omega(k)$ members of $\mathcal{M}_{K_5}$, and any minimum-size cover of all $\mathcal{M}_{K_5}$ has $\Omega(k)$ vertices.

The seminal theorem of Reed [34] on the $\frac{1}{2}$EP-property of odd cycles exhibits exactly this kind of behaviour. Reed showed that odd cycles have the EP-property in every *odd-minor*[5]-closed graph class excluding an *Escher-wall*, while the Escher-wall itself is a counterexample

[2] A graph class is *minor-closed* if it contains all minors of its graphs.
[3] This means that our algorithms run in time $f(k) \cdot |V(G)|^{\mathcal{O}(1)}$ for some computable function f where k is the size of the half-integral packing we are looking for.
[4] We postpone the formal definition of parametric graphs to a later point. See Section 2.
[5] *Odd-minors* are a variant of the minor relation that preserves the parity of cycles. For example, bipartite graphs are exactly the K_3-odd-minor-free graphs. We refer the interested reader to [14] for a formal definition.

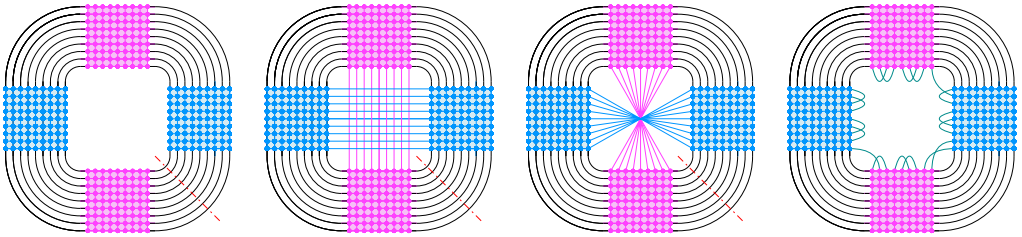

Figure 1 The parametric graphs representing the annulus grid $\mathcal{A}_k$, the handle grid $\mathcal{H}_k$, the cross-cap grid $\mathcal{C}_k$, and the shallow-vortex grid $\mathcal{V}_k$.

to the EP-property of odd cycles. Here, the k-Escher-wall is obtained by taking exactly the bipartite graphs from the parametric graph $\mathcal{C}$, representing the projective plane, and subdividing each of the "crossing" edges once. The result is a non-bipartite graph where every odd cycle must use an odd number of these subdivided edges. In the realm of odd-minors, this establishes a positive instance of Conjecture 1: pick EP_{K_3} as the maximum k for which G contains the k-Escher-wall as an odd minor.

It is tempting to suspect that Reed's strategy can apply for the Erdős-Pósa property for minors. That is, for K_5, the two parametric graphs $\mathcal{H}$ and $\mathcal{C}$ are essentially the only counterexamples for the EP-property of $\mathcal{M}_{K_5}$ and excluding both of them as minors always yields a class in which $\mathcal{M}_{K_5}$ exhibits the EP-property. Notice that this would imply that the $\subseteq$-minimal minor-closed classes where the EP-property fails for $\mathcal{M}_{K_5}$ are precisely two: the class of graphs embeddable in the projective plane and the class of graphs embeddable in the torus. Clearly, both these two classes have bounded Euler genus. Our next step is to observe that this is not true in general.

Kuratowski-connectivity. We say that a graph G is *Kuratowski-connected* if for every separation (A, B) of G of order at most 3, if there is a component C of $G[A \setminus B]$ and a component D of $G[B \setminus A]$, such that every vertex in $A \cap B$ has a neighbour in $V(C)$ and a neighbour in $V(D)$, then one of $G[A]$, $G[B]$ can be drawn in a disc Δ with $A \cap B$ drawn in the boundary of Δ. We denote by $\mathcal{K}$ the set of all Kuratowski-connected graphs. This definition was introduced by Robertson, Seymour, and Thomas as a tool for their characterization of *linklessly embeddable graphs* via a finite set of minimal obstructions [38] (see also [46, 30]).

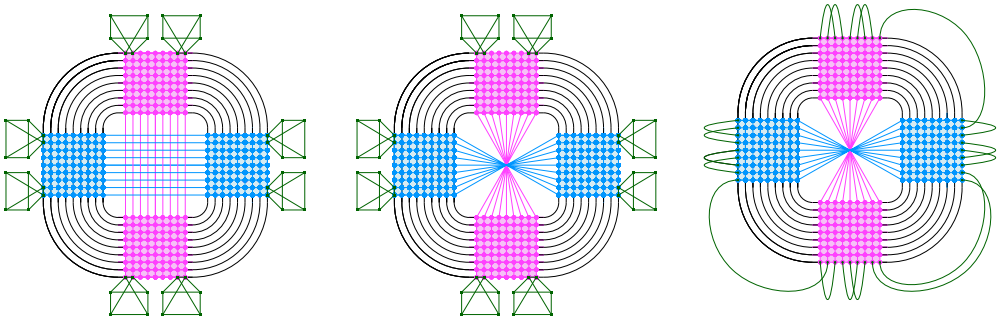

Figure 2 The two first parametric graphs serve as counterexamples for the Erdős-Pósa property of the graph J. The third parametric graph is a counterexample for the Erdős-Pósa property of K_8. All three parametric graphs have unbounded Euler-genus. For the first two this is witnessed by a large packing of $K_{3,3}$ while the last one can be observed to contain $K_{3,r}$ as a minor.

Consider the graph J obtained by identifying two adjacent vertices of $K_{3,3}$ with two vertices of K_5 and observe that J is not Kuratowski-connected. Similar to K_5, there cannot be two disjoint drawings of $K_{3,3}$ on the torus. So, if we take the parametric graph representing the torus ($\mathcal{H}_k$) or the projective plane ($\mathcal{C}_k$) from Figure 1 and paste "many" copies of $K_{3,3}$ around the "outer cycle", we obtain a parametric graph without two disjoint J-minors but where no small vertex-set can hit all J-minors (see the two first graphs in Figure 2).

Shallow-vortex minors. There is a second property, that poses a similar issue. In [41] Thilikos and Wiederrecht introduced the parametric graph $\mathcal{V}$ of *shallow-vortex grids* where $\mathcal{V}_k$ is obtained from the annulus grid $\mathcal{A}_k$ by adding k consecutive crossings in its internal cycle (see the fourth graph in Figure 1 for an illustration of $\mathcal{V}_9$). The class $\mathcal{V}$ of *shallow-vortex minors* was defined in [41] as the class containing all minors of $\mathcal{V}_k$, for all $k \in \mathbb{N}$. Notice that K_8 is a Kuratowski-connected graph. It was shown by Curticapean and Xia [6] that K_8 is not a shallow-vortex minor. However, this is the case for $K_{3,r}$, for every $r \in \mathbb{N}$, which implies that the parametric graph $\mathcal{V}_k$ has unbounded Euler-genus. If we now paste the k extra crossings of $\mathcal{V}_k$ to the "outer cycle" of $\mathcal{C}_k$, we obtain a parametric graph that is a counterexample for the EP-property of K_8 but which is of unbounded Euler-genus (see the last graph in Figure 2). These observations indicate that, if we want to understand the graphs for which the counterexamples of Robertson and Seymour precisely define the boundary to the $1/2$EP-property, we have to consider the graphs in $\mathcal{K} \cap \mathcal{V}$.

Our contribution. The main combinatorial result (stated in Theorem 2 in its full generality) is that Conjecture 1 holds, for every graph H that is Kuratowski-connected and a shallow vortex minor. Moreover, for every such non-planar H, $\mathsf{EP}_H(G)$ is equivalent to the exclusion of the parametric graphs representing some particular set of surfaces where H embeds. Therefore, for the non-planar graphs $H \in \mathcal{K} \cap \mathcal{V}$, the boundary between the Erdős-Pósa property and its half-integral relaxation is drawn *precisely* by a set of surfaces, depending on H. Notice, that the class $\mathcal{K} \cap \mathcal{V}$ encompasses, apart from planar graphs, several important graphs such as $K_5, K_{3,3}, K_{4,4}, K_6, K_7$, and the entire *Petersen family*. These last observations imply that our results extend, both algorithmically and combinatorially, to the half-integral packing of *links* and *knots*.

2 Notation and definitions

Let us introduce some notation in order to present our results in full generality. A *minor antichain* is a family $\mathcal{A}$ of graphs such that no graph $G_1 \in \mathcal{A}$ is a minor of another graph $G_2 \in \mathcal{A} \setminus \{G_1\}$. Since we focus on the minor relation, we refer to minor antichains simply as *antichains*. Let us denote by $\mathbb{K}$ the collection of all antichains $\mathcal{A}$ where *every* member of $\mathcal{A}$ is Kuratowski-connected. Moreover, let us denote by $\mathbb{V}$ the collection of all antichains containing *at least* one shallow-vortex minor. Finally, let $\mathbb{P}$ be the collection of all antichains containing at least one planar graph and set $\mathbb{H} := \mathbb{K} \cap \mathbb{V}$ and $\mathbb{H}^- := \mathbb{H} \setminus \mathbb{P}$.

The Erdős-Pósa property for antichains. Let H and G be graphs. A subgraph $H' \subseteq G$ is an *H-host* in G if H is a minor of H'. An *H-packing* in G is a collection of pairwise vertex-disjoint H-hosts in G. An *H-cover* is a set $S \subseteq V(G)$ such that $G - S$ is H-minor-free. A *half-integral H-packing* is a collection of H-hosts in G such that no vertex of G belongs to more than two of them.

Given an antichain $\mathcal{Z}$, we say that a subgraph $H' \subseteq G$ is a $\mathcal{Z}$-host in G if it is an H-host for some $H \in \mathcal{Z}$. A *$\mathcal{Z}$-packing* is an H-packing of *some* $H \in \mathcal{Z}$ and a *$\mathcal{Z}$-cover* is an H-cover for *all* $H \in \mathcal{Z}$, finally a *half-integral $\mathcal{Z}$-packing* is a half-integral H-packing for some $H \in \mathcal{Z}$. We define the two graph parameters $\mathsf{cover}_{\mathcal{Z}}$ and $\mathsf{pack}_{\mathcal{Z}}$ as follows.

$\mathsf{cover}_{\mathcal{Z}}(G) \coloneqq \min\{k \mid G \text{ has an } \mathcal{Z}\text{-cover of size } k\}$ and

$\mathsf{pack}_{\mathcal{Z}}(G) \coloneqq \max\{k \mid G \text{ has an } \mathcal{Z}\text{-packing of size } k.$

We say that $\mathcal{Z}$ has the *Erdős-Pósa property* in a graph class $\mathcal{G}$ if there exists some function $f\colon \mathbb{N} \to \mathbb{N}$ such that $\mathsf{cover}_{\mathcal{Z}}(G) \leq f(\mathsf{pack}_{\mathcal{Z}}(G))$, for all $G \in \mathcal{G}$.

Equivalence of graph parameters. We use $\mathcal{G}_{\mathsf{all}}$ for the class of all graphs. Given two graph parameters $\mathsf{p}, \mathsf{q}\colon \mathcal{G}_{\mathsf{all}} \to \mathbb{N}$, we say that p and q are *equivalent*, and write $\mathsf{p} \sim \mathsf{q}$, if there exists a function $f\colon \mathbb{N} \to \mathbb{N}$ such that, for every graph G, $\mathsf{p}(G) \leq f(\mathsf{q}(G))$ and $\mathsf{q}(G) \leq f(\mathsf{p}(G))$. We refer to the function f as the *gap* of this equivalence.

Our result is the identification of a graph parameter EP such that $\mathcal{Z}$ has the Erdős-Pósa property in a minor-closed graph class $\mathcal{G}$ with single-exponential gap if and only if EP is bounded in $\mathcal{G}$, for every $\mathcal{Z} \in \mathbb{H}$.

Surfaces and embeddability. We consider a containment relation $\preceq$ between surfaces where we write $\Sigma \preceq \Sigma'$ if the surface Σ' can be obtained by adding handles or cross-caps to the surface Σ. The *empty surface* will be denoted by $\Sigma^{\varnothing}$ and the surface obtained by adding h handles and c cross-caps to the sphere $\Sigma^{(0,0)}$ is denoted by $\Sigma^{(h,c)}$. Its *Euler-genus* is defined to be $2h + c$. Notice that, by Dyck's Theorem [8], we may assume that $c \leq 2$ for all surfaces. Let $\mathbb{S}$ be a set of surfaces. We say that $\mathbb{S}$ is *closed*, if $\Sigma \in \mathbb{S}$ and $\Sigma' \preceq \Sigma$ imply that $\Sigma' \in \mathbb{S}$ and that it is *proper*, if it does not contain all surfaces. If $\mathbb{S}$ is closed and proper we define the "surface obstruction set" $\mathsf{sobs}(\mathbb{S})$ as the set of all $\preceq$-minimal surfaces which do not belong to $\mathbb{S}$. It is easy to observe that $\mathsf{sobs}(\mathbb{S})$ always consists of one or two surfaces [43]. Notice that $\mathsf{sobs}(\emptyset) = \{\Sigma^{\varnothing}\}$, $\mathsf{sobs}(\{\Sigma^{\varnothing}\}) = \{\Sigma^{(0,0)}\}$, $\mathsf{sobs}(\{\Sigma^{\varnothing}, \Sigma^{(0,0)}\}) = \{\Sigma^{(1,0)}, \Sigma^{(0,1)}\}$, and, for a more complicated example, $\mathsf{sobs}(\{\Sigma^{\varnothing}, \Sigma^{(0,0)}, \Sigma^{(0,1)}, \Sigma^{(0,2)}\}) = \{\Sigma^{(1,0)}\}$.

We say that a graph G is *embeddable* in a surface Σ (or Σ-embeddable) if it has a drawing in Σ without crossings. The *Euler genus* of a graph G, denoted by $\mathsf{eg}(G)$, is the smallest Euler genus of a surface where G is embeddable.

Parametric graphs and Dyck-grids. A *parametric graph* is a sequence $\mathcal{G} = \langle \mathcal{G}_i \rangle_{i \in \mathbb{N}}$ of graphs indexed by non-negative integers. We say that $\mathcal{G}$ is *minor-monotone* if for every $i \in \mathbb{N}$ we have that $\mathcal{G}_i$ is a minor of $\mathcal{G}_{i+1}$. All parametric graphs considered in this paper are minor-monotone. We write $\mathcal{G}^{(1)} \lesssim \mathcal{G}^{(2)}$ for two minor-monotone parametric graphs $\mathcal{G}^{(1)}$ and $\mathcal{G}^{(2)}$ if there exists a function $f\colon \mathbb{N} \to \mathbb{N}$ such that for every $i \in \mathbb{N}$ it holds that $\mathcal{G}^{(1)}_i$ is a minor of $\mathcal{G}^{(2)}_{f(i)}$. A *minor-monotone parametric family* is a finite collection of $\mathfrak{G} = \{\mathcal{G}^{(j)} \mid j \in [r]\}$ of minor-monotone parametric graphs such that for distinct $i, j \in [r]$ it holds that $\mathcal{G}^{(i)} \not\lesssim \mathcal{G}^{(j)}$ and $\mathcal{G}^{(j)} \not\lesssim \mathcal{G}^{(i)}$. We define the minor-monotone parameter

$$\mathsf{p}_{\mathfrak{G}}(G) \coloneqq \max\{k \mid \text{there exists } i \in [r] \text{ such that } G \text{ contains } \mathcal{G}^{(i)}_k \text{ as a minor}\}. \tag{3}$$

The three parametric graphs $\mathcal{A} = \langle \mathcal{A}_k \rangle_{k\in\mathbb{N}}$, $\mathcal{H} = \langle \mathcal{H}_k \rangle_{k\in\mathbb{N}}$, and $\mathcal{C} = \langle \mathcal{C}_k \rangle_{k\in\mathbb{N}}$ are defined as follows: The *annulus grid* $\mathcal{A}_k$ is the $(4k, k)$-cylindrical grid[6] depicted in the far left of Figure 1. The *handle grid* $\mathcal{H}_k$ (resp. *cross-cap grid* $\mathcal{C}_k$) is obtained by adding in $\mathcal{A}_k$ edges as indicated in the middle left (resp. middle right) part of Figure 1. We refer to the added edges as *transactions* of the handle grid $\mathcal{H}_k$ or of the cross-cap grid $\mathcal{C}_k$.

Let now $h \in \mathbb{N}$ and $c \in [0, 2]$. We define the parametric graph $\mathcal{D}^{(h,c)} = \langle \mathcal{D}_k^{(h,c)} \rangle_{k\in\mathbb{N}}$ by taking one copy of $\mathcal{A}_k$, h copies of $\mathcal{H}_k$, and $c \in [0, 2]$ copies of $\mathcal{C}_k$, then "cut" them along the dotted red line, as in Figure 1, and join them together in the cyclic order $\mathcal{A}_k, \mathcal{H}_k, \ldots, \mathcal{H}_k, \mathcal{C}_k, \ldots, \mathcal{C}_k$, as indicated in Figure 3.

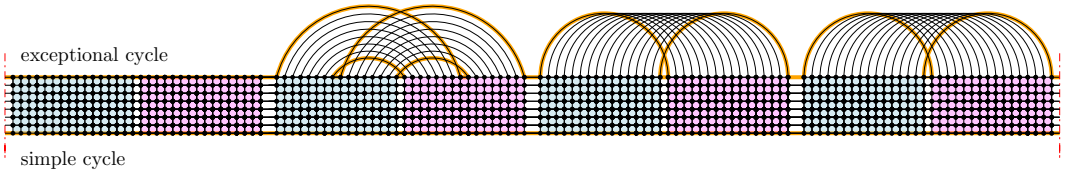

Figure 3 The Dyck-grid $\mathcal{D}_8^{1,2}$. The simple and the exceptional cycles are drawn in orange.

We call the graph $\mathcal{D}_k^{(h,c)}$ the *Dyck-grid* of *order* k *with* h *handles and* c *cross-caps*. Given some surface $\Sigma = \Sigma^{(h,c)}$, we say that the graph D is the $(\Sigma; d)$-*Dyck-grid* if $D = \mathcal{D}_d^{(h,c)}$ and we use $\mathcal{D}^\Sigma$ to denote the parametric graph $\langle \mathcal{D}_i^\Sigma \rangle_{i\in\mathbb{N}}$, where $\mathcal{D}_i^\Sigma$ is the $(\Sigma; i)$-Dyck-grid.

Let us return to our antichain $\mathcal{Z} \in \mathbb{H}^-$. We denote by $\mathbb{S}_\mathcal{Z}$ the set of surfaces where none of the graphs in $\mathcal{Z}$ can be embedded. Notice that $\mathbb{S}_\mathcal{Z}$ is closed and proper and, for every $\Sigma \in \mathsf{sobs}(\mathbb{S}_\mathcal{Z})$, there exists some $H \in \mathcal{Z}$ such that H embeds in Σ.

3 Our results

We associate with $\mathcal{Z}$ the parametric family $\mathfrak{D}_\mathcal{Z} := \{\mathcal{D}^\Sigma \mid \Sigma \in \mathsf{sobs}(\mathbb{S}_\mathcal{Z})\}$. Let $\mathsf{EP}_\mathcal{Z} := \mathsf{p}_{\mathfrak{D}_\mathcal{Z}}$. Our combinatorial result determines precisely when a member in $\mathbb{H}^-$ has the Erdős-Pósa in some minor-closed graph class.

▶ **Theorem 2.** *For every $\mathcal{Z} \in \mathbb{H}^-$, for every minor-closed graph class $\mathcal{G}$, $\mathcal{Z}$ has the Erdős-Pósa property in $\mathcal{G}$ if and only if $\mathsf{EP}_\mathcal{Z}$ is bounded in $\mathcal{G}$.*

Let $h_\mathcal{Z} := \max\{|V(H)| \mid H \in \mathcal{Z}\}$ and $\gamma_\mathcal{Z} := \max\{\mathsf{eg}(H) \mid H \in \mathcal{Z}\}$. The engine that drives the proof of Theorem 2 and which represents our first main algorithmic result is the following.

▶ **Theorem 3.** *There exists a function $f_3 : \mathbb{N}^4 \to \mathbb{N}$ such that, for every antichain $\mathcal{Z} \in \mathbb{H}^-$, there exists an algorithm such that, given $k, t \in \mathbb{N}$ and a graph G, outputs one of the following:*

- *a $\mathcal{D}_t^\Sigma$-host in G, for some $\Sigma \in \mathsf{sobs}(\mathbb{S}_\mathcal{Z})$, or*
- *an $\mathcal{Z}$-packing of size at least k in G, or*
- *an $\mathcal{Z}$-cover of size at most $f_3(\gamma_\mathcal{Z}, h_\mathcal{Z}, t, k)$ in G.*

Moreover, the algorithm runs in time $2^{2^{\mathcal{O}_{\gamma_\mathcal{Z}}(\mathsf{poly}(t))+\mathcal{O}_{h_\mathcal{Z}}(\mathsf{poly}(k))}} \cdot |V(G)|^3 \cdot \big(\log(|V(G)|)\big)^2$ and $f_3(\gamma_\mathcal{Z}, h_\mathcal{Z}, t, k) = 2^{\mathcal{O}_{\gamma_\mathcal{Z}}(\mathsf{poly}(t))+\mathcal{O}_{h_\mathcal{Z}}(\mathsf{poly}(k))}$.

By a recent result of Gavoille and Hilaire [13], it holds that there exists some constant c such that for every $\mathcal{Z} \in \mathbb{H}^-$ and $\Sigma \in \mathsf{sobs}(\mathbb{S}_\mathcal{Z})$, there exists some $H \in \mathcal{Z}$ such that H is a minor of $\mathcal{D}^\Sigma_{c\gamma_\mathcal{Z}^4 h_\mathcal{Z}^2}$. Moreover, as observed in [43], every Dyck-grid of big enough order

[6] An $(n \times m)$-cylindrical grid is a Cartesian product of a cycle on n vertices and a path on m vertices.

contains a large half-integral packing of itself of smaller order. Combining these two results with Theorem 3, yields the following (constructive) parameterized approximation algorithm for $1/2\text{-}\mathsf{pack}_{\mathcal{Z}}$.

▶ **Theorem 4.** *There exists a function $f_4 : \mathbb{N}^2 \to \mathbb{N}$ such that, for every antichain $\mathcal{Z} \in \mathbb{H}^-$, there exists an algorithm such that, given $k \in \mathbb{N}$ and a graph G, outputs one of the following:*
1. *a half-integral $\mathcal{Z}$-packing of size at least k in G, or*
2. *an $\mathcal{Z}$-cover of size at most $f_4(h_{\mathcal{Z}}, k)$ in G.*

Moreover, the algorithm runs in time[7] $2^{2^{\mathsf{poly}_{h_{\mathcal{Z}}}(k)}} \cdot |V(G)|^3 \cdot \big(\log(|V(G)|)\big)^2$ *and* $f_4(h_{\mathcal{Z}}, k) = 2^{\mathsf{poly}_{h_{\mathcal{Z}}}(k)}$.

We wish to stress that, given the combinatorial bounds of Theorem 3, we may directly apply the minor-checking algorithm of [23] for the two first outcomes of Theorem 3 and the algorithm of [29] for its third outcome. Both these algorithms are quadratic on $|V(G)|$ and this implies alternative quadratic algorithms to those in Theorem 3 and Theorem 4. However, this would come with the cost of enormous parametric dependencies on k.

3.1 Some implications of our results

Half-integral Erdős-Pósa for linked pairs and knots. As mentioned above, $\mathbb{H} = \mathbb{K} \cap \mathbb{V}$ contains several antichains of particular interest. A first example is the *Petersen family*, which is exactly the (minor) obstruction set[8] for the so-called *linklessly embeddable* graphs (in short, *link-less* graphs). Indeed, the origin of the definition of Kuratowski-connectivity comes from the paper of Robertson, Seymour, and Thomas [38], where this obstruction set was found. All obstructions for link-less graphs as well as those for knot-less graphs are Kuratowski-connected. Moreover, as the shallow-vortex minor K_6 (resp. K_7) is a member of the obstruction set of link-less (resp. knot-less) graphs, we also have that both these obstruction sets belong to $\mathbb{H}^-$. This insight allows us to apply Theorem 4 to topological objects such as *links* and *knots*.

Let G be a graph and let $\mathcal{C} = \{C_1, \ldots, C_k\}$ be a collection of subgraphs of G. The *intersection graph* of $\mathcal{C}$ is the graph $I(\mathcal{C}) = (\mathcal{C}, E_{\mathcal{C}})$ where $CC' \in E_{\mathcal{C}}$ if and only if $C \cap C'$ is not the empty graph. We say that $\mathcal{C}$ is a *collection of double cycles* (resp. *cycles*) if each C_i is union of two disjoint cycles (resp. a cycle).

Given a collection $\mathcal{C}$ of double cycles (resp. cycles) of G, and some $\mathbb{R}^3$-embedding of G, we say that $\mathcal{C}$ is a $1/2$-*packing* of links (resp. knots) if for every $i \in [k]$, the two components of C_i are linked (resp. the cycle C_i is knotted) in this particular embedding (see [1] for more on links and knots). The *half-integral linked pair (resp. knot) packing number of a graph G*, denoted by $1/2\text{-}\mathsf{lppack}(G)$ (resp. $1/2\text{-}\mathsf{knpack}(G)$), is the maximum k such that, for every $\mathbb{R}^3$-embedding of G, there exists a $1/2$-packing of links (resp. knots) in G of size k. Both $1/2\text{-}\mathsf{lppack}(G)$ and $1/2\text{-}\mathsf{knpack}(G)$ are minor-monotone parameters, therefore we know (non-constructively) that there exists an algorithm for checking whether $1/2\text{-}\mathsf{lppack}(G) \geq k$ ($1/2\text{-}\mathsf{knpack}(G) \geq k$) in time $f(k) \cdot |V(G)|^2$. Up to now, no constructive (on k) algorithm is known for these problems. Our results imply the following.

[7] Given two functions $\chi, \psi \colon \mathbb{N} \to \mathbb{N}$, we write $\chi(n) = \mathcal{O}_x(\psi(n))$ in order to denote that there exists a computable function $f \colon \mathbb{N} \to \mathbb{N}$ such that $\chi(n) = \mathcal{O}(f(x) \cdot \psi(n))$. We also use $\chi(n) = \mathsf{poly}_x(\psi(n))$ instead of $\chi(n) = \mathcal{O}_x((\psi(n))^c)$, for some $c \in \mathbb{N}$.

[8] The obstruction set of some minor-closed class $\mathcal{G}$ is the set $\mathsf{obs}(\mathcal{G})$ of the minor-minimal graphs that are not in $\mathcal{G}$.

▶ **Theorem 5.** *There exists a function $f : \mathbb{N} \to \mathbb{N}$ and algorithms that, given a graph G and a $k \in \mathbb{N}$, outputs either that $1/2$-$\mathsf{lppack}(G) \geq k$ (resp. $1/2$-$\mathsf{knpack}(G) \geq k$) or a vertex set A of at most $f(k)$ vertices such that $G - A$ has a link-less (knot-less) $\mathbb{R}^3$-embedding. Moreover, both algorithms run in time $2^{2^{\mathsf{poly}(k)}} \cdot |V(G)|^3 \cdot \big(\log(|V(G)|)\big)^2$ and $f(k) = 2^{\mathsf{poly}(k)}$.*

Theorem 5 implies that both the parameter $1/2$-lppack as well as the parameter $1/2$-knpack admit FPT-approximation algorithms with exponential approximation gap. Moreover, in case the output is that $1/2$-$\mathsf{lppack}(G) \geq k$ (resp. $1/2$-$\mathsf{knpack}(G) \geq k$), the algorithms output a $1/2$-packing of k graphs certifying that, every $\mathbb{R}^3$-embedding of G contains a $1/2$-packing $\mathcal{C}$ of k links (resp. knots) such that $I(\mathcal{C})$ is either edgeless or a clique. We stress that the above algorithms become constructive (on k) as we know the obstructions of link-less/knot-less graphs or at least an upper bound to their size. For the later class not such bound is known.

Other implications of our results, related to canonical approximate characterizations of the parameters we study, are discussed in the conclusion section (Section 4).

3.2 Outline of the proof

We begin the description of the main ideas of our proof with the definition of a tree decomposition.

Tree decompositions. Let G be a graph. A *tree decomposition* of a graph G is a pair (T, β) where T is a tree and $\beta : V(T) \to 2^{V(G)}$ is a function, whose images are called the *bags* of $\mathcal{T}$, such that $\bigcup_{t \in V(T)} \beta(t) = V(G)$, for every $e = xy \in E(G)$, there exists $t \in V(T)$ with $\{x, y\} \subseteq \beta(t)$, and for every $v \in V(G)$, the set $\{t \in V(T) \mid v \in \beta(t)\}$ induces a subtree of T. We refer to the vertices of T as the *nodes* of the tree decomposition $\mathcal{T}$. The *width* of $\mathcal{T}$ is the value $\max_{t \in V(T)} |\beta(t)| - 1$. The *treewidth* of G, denoted by $\mathsf{tw}(G)$, is the minimum width over all tree decompositions of G.

The classic approach. In order to facilitate the presentation of our proof, let us briefly explain the two main ideas of the proof that planar graphs enjoy the Erdős-Pósa property in the set of all graphs. The key ingredient is that every planar graph is a minor of a graph of sufficiently large treewidth. The proof follows in two steps.

Step 1. Assuming that $\mathsf{pack}_H(G) \leq k$, based on the grid theorem by Robertson and Seymour, we may assume that the treewidth of G is bounded by some function of k.

Step 2. With the tree decomposition (T, β) of G at hand, we build an H-cover A of G by adding to it (if any exists) an adhesion $D_{xy} = \beta(x) \cap \beta(y)$ such that both $G_x := G[\beta(V(T_x)) \setminus D_{xy}]$ and $G_y := G[\beta(V(T_y)) \setminus D_{xy}]$ contain H as a minor (here T_x and T_y are the two components of $T - xy$) and then recursing on the corresponding tree decompositions of G_x and G_y. If $\mathsf{pack}_H(G) \leq k$, eventually this procedure returns an H-cover of size at most $k \cdot (\mathsf{tw}(G) + 1)$.

Throughout the present outline we describe arguments that can be paralleled to the two steps above. Moreover, in each step we explain the challenges that are met and the way we deal with them in our proof.

For simplicity, instead of an antichain $\mathcal{Z}$, we consider a non-planar graph H that is Kuratowski-connected and a shallow-vortex minor. We denote by $\mathbb{S}_H$ the set of all surfaces where H cannot be embedded and by $\mathbb{S}'_H := \mathsf{sobs}(\mathbb{S}_H)$ the corresponding surface obstruction set. We stress that the graphs in $\mathfrak{D}_H = \{\mathcal{D}^\Sigma \mid \Sigma \in \mathbb{S}'_H\}$ can be seen as "generators of

half-integrality". Indeed, it is possible to prove that, for every $t \in \mathbb{N}$, $\mathsf{pack}_H(\mathcal{D}_t^\Sigma) \leq 1$, and $\mathsf{cover}_H(\mathcal{D}_t^\Sigma) = \Theta(1/2\text{-}\mathsf{pack}_H(\mathcal{D}_t^\Sigma)) = \Omega(t)$. This already proves the easy direction of Theorem 2.

Let $\mathcal{T} = (T, \beta)$ be a tree decomposition of a graph G. For each $t \in V(T)$, we define the *adhesions* of t as the sets in $\{\beta(t) \cap \beta(d) \mid d \text{ adjacent with } t\}$ and the maximum size of them is called the *adhesion* of t. The *adhesion* of $\mathcal{T}$ is the maximum adhesion of a node of $\mathcal{T}$. The *torso* of $\mathcal{T}$ on a node t is the graph, denoted by G_t, obtained by adding edges between every pair of vertices of $\beta(t)$ which belongs to a common adhesion of t.

We now consider a graph G where $\mathsf{pack}_H(G) \leq k$ and we assume that G excludes as a minor the Dyck grid $\mathcal{D}_t^\Sigma$, for every $\Sigma \in \mathbb{S}'_H$. Under these circumstances, our aim is to find an H-cover whose size is bounded by some function of t and k.

Graphs excluding Dyck grids. As a first step, we need a deeper understanding of how the graphs excluding $\mathcal{D}_t^\Sigma$ look like. In general, the structure of graphs excluding a given graph as a minor is given by the Graph Minors Structure theorem (in short GMST). However, the formal definition of GMST involves complicated concepts which we prefer not to introduce in this brief outline. Instead we give a more compact statement, proved in [43].

Given a graph H and a set $A \subseteq V(G)$, we say that H is an *A-minor of G* if there is a collection $\mathcal{S} = \{S_v \mid v \in V(H))\}$ of pairwise vertex-disjoint connected[9] subsets of $V(G)$, each containing at least one vertex of A and such that, for every edge $xy \in E(H)$, the set $S_x \cup S_y$ is connected in G. Given an annotated graph (G, A) where G is a graph and $A \subseteq V(G)$, we define $\mathsf{tw}(G, A)$ as the maximum treewidth of an A-minor of G. A streamlined way to restate the GMST is the following.

▶ **Proposition 6** ([43]). *There exists a function $f : \mathbb{N} \to \mathbb{N}$ such that every graph G excluding a graph on k vertices as a minor, has a tree decomposition (T, β) where, for every $t \in V(T)$, the torso G_t contains some set A_t where $\mathsf{tw}(G_t, A_t) \leq f(k)$ and such that $G_t - A_t$ can be embedded in a surface of Euler genus at most $f(k)$.*

To deal with the exclusion of Dyck grids (corresponding to surfaces), we need a more refined version of Proposition 6 that works for every (closed and proper) set of surfaces $\mathbb{S}$. In this direction, Thilikos and Wiederrecht defined in [43] an extension of treewidth, namely $\mathbb{S}$-tw, where for a graph G,

$$\begin{aligned}&\mathbb{S}\text{-}\mathsf{tw}(G) \text{ is the minimum } k \text{ for which } G \text{ has a tree decomposition } (T, \beta) \text{ where, for every}\\ &t \in V(T), \text{ the torso } G_t \text{ contains some set } A_t \text{ where } \mathsf{tw}(G_t, A_t) \leq k \text{ and } G_t - A_t \text{ is}\\ &\text{embeddable in a surface in } \mathbb{S}.\end{aligned} \tag{4}$$

The main result of [43] is that in order to exclude the graphs in $\mathfrak{D}_H = \{\mathcal{D}_t^\Sigma \mid \Sigma \in \mathsf{cobs}(\mathbb{S})\}$, we have to fix the surface of Proposition 6 to be one of the surfaces in $\mathbb{S}$.

▶ **Proposition 7.** *For every closed and proper set of surfaces $\mathbb{S}$, there exists some function $f : \mathbb{N} \to \mathbb{N}$ such that, for every graph G, if G excludes all graphs in $\{\mathcal{D}_t^\Sigma \mid \Sigma \in \mathsf{sobs}(\mathbb{S})\}$ as minors, then $\mathbb{S}$-$\mathsf{tw}(G) \leq f(t)$.*

Notice that the above proposition already gives us the grid theorem when applied for the set $\mathbb{S}_\emptyset$ containing the empty surface $\Sigma^\varnothing$. It is easy to verify that $\mathsf{tw} + 1 = \mathbb{S}_\emptyset$-$\mathsf{tw}$. As $\mathsf{sobs}(\mathbb{S}_\emptyset) = \{\Sigma^{(0,0)}\}$, Proposition 7 implies that graphs excluding $\mathcal{D}_t^{\Sigma^{(0,0)}} = \mathcal{A}_t$ have bounded treewidth (see Figure 1 for an example of an annulus grid).

[9] A set $X \subseteq V(G)$ is *connected* in G if the induced subgraph $G[X]$ is a connected graph.

From small treewidth modulators to small size modulators. Proposition 7 gives valuable information on the structure of the graphs that exclude the "half-integrality generators" in $\mathfrak{D}_H = \{\mathcal{D}_t^\Sigma \mid \Sigma \in \mathsf{sobs}(\mathbb{S}_H)\}$. Therefore, we can assume that $\mathbb{S}\text{-}\mathsf{tw}(G) \leq f(k)$, which provides a tree decomposition as the one in (4). In order to make progress, we need to further refine this decomposition as small treewidth modulators are not particularly helpful in finding an H-cover of small size. For this we exploit the assumption that H is a shallow-vortex minor.

To elaborate, we need some additional information, analogous to the exclusion of a planar graph in **Step 1**. This corresponds to the assumption that H is a minor of the shallow-vortex grid $\mathcal{V}_{h'}$ for some h' depending on H. One can observe that $\mathcal{V}_{3(k+1)h'}$ contains a $\mathcal{V}_{h'}$-packing of size $(k+1)$. Therefore, the assumption that $H\text{-}\mathsf{pack}(G) \leq k$ gives us the right to additionally assume that G also excludes the shallow-vortex minor $\mathcal{V}_{3(k+1)h'}$. Using this and the fact that $\mathbb{S}\text{-}\mathsf{tw}(G) \leq f(k)$, we are able to further restrict the decomposition of (4). To quantify this, we introduce a new graph parameter $\mathbb{S}\text{-}\mathsf{tw}_{\mathsf{apex}}$ defined as follows.

$$\begin{aligned}&\mathbb{S}\text{-}\mathsf{tw}_{\mathsf{apex}}(G) \text{ is the minimum } k \text{ for which } G \text{ has a tree decomposition } (T,\beta) \text{ where, for}\\ &\text{every } t \in V(T), \text{ the torso } G_t \text{ contains some set } A_t \text{ where } |A_t| \leq k \text{ and } G_t - A_t \text{ is}\\ &\text{embeddable in a surface in } \mathbb{S}.\end{aligned} \tag{5}$$

Notice that the only difference between (4) and (5) is the measure defined on the "modulator" A_t. While in (4) it is the treewidth of the annotated graph (G_t, A_t), in (5) it is the *size* of A_t. The first ingredient of our proof is that, under the absence of some shallow-vortex minor, the two parameters $\mathbb{S}\text{-}\mathsf{tw}_{\mathsf{apex}}$ and $\mathbb{S}\text{-}\mathsf{tw}$ are equivalent. This is proved by combining the results of [43] with the results of [41] on the structure of the graphs excluding a shallow-vortex grid.

As a consequence, we may now assume that we have a tree decomposition (T,β) as the one in (5). This decomposition is not yet in position to play the role of the tree decomposition in **Step 2**, as its torsos may have unbounded size. To circumvent this issue, we instead prove a local structure theorem for the exclusion of $\mathfrak{D}_H \cup \{\mathcal{V}\}$, that can be extended to a global one (the desired tree decomposition), using the results of [42]. The general approach is to consider some big enough wall W_t and locally focus on a torso G_t that contains most of the essential part of W_t.

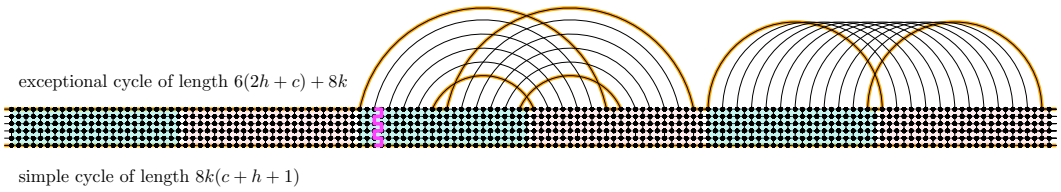

Figure 4 The elementary $(h, c; k)$-Dyck wall, where $h = 1$, $c = 1$, and $k = 6$.

Torsos with Dyck walls. According to Proposition 7, (5), and the equivalence of $\mathbb{S}\text{-}\mathsf{tw}_{\mathsf{apex}}$ and $\mathbb{S}\text{-}\mathsf{tw}$, G_t comes together with a set A_t such that the graph $G_t' := G_t - A_t$ is accompanied by some Σ-embedding for a surface $\Sigma \in \mathbb{S}_H$, where H cannot be embedded. However, we require some additional infrastructure in G_t that will come in the form of a large wall-like object that is controlled by our Σ-embedding.

Notice that every adhesion $\beta(t) \cap \beta(t')$ of t defines a separation $(X_{t'}, Y_{t'})$ of $G - A_t$ of order at most 3 where $G[X_{t'} \cap Y_{t'}]$ is drawn in Σ as a clique. We fix the orientation $(X_{t'}, Y_{t'})$ such that $V(G_t) \subseteq Y_{t'}$, thereby indicating that $Y_{t'}$ is the "important" part of the separation.

Due to the results in [43], G_t contains a $(\Sigma; d)$-*Dyck wall*[10] D_t, which is highly linked to the wall W_t above. Here d is chosen "large enough" so as to ensure the applicability of the next steps of our proof. Also, we may assume that the "essential" part of D_t is drawn "inside" G_t in the sense that, for each $(X_{t'}, Y_{t'})$, at most one branch vertex of D_t is in $Y_{t'} \setminus X_{t'}$. The wall W_t is chosen large enough to represent some *tangle*, that is an orientation of the separations of G of some suitably bounded order. The way to algorithmically detect such a big wall W_t is given in [43].

The role of Kuratowki-connectivity. We next make some observations on how "models" of H can behave with respect to the Σ-embedding of G_t. These observations will play a key role in understanding how to "attack" and later "kill" copies of H in our graph.

The first comes from the non-Σ-embeddability property of H: "minimal" H-hosts in G, called *H-inflated copies*, *cannot be entirely inside* G_t, otherwise we would be able to embed H in a surface where it cannot be embedded. Another important feature comes from the fact that H is Kuratowski-connected: every H-inflated copy M in G is "well oriented" with respect to the adhesions of t in the sense that, when M traverses some adhesion $X_{t'} \cap Y_{t'} = \beta(t) \cap \beta(t')$ of G, *exactly one* of the two parts of M induced by $X_{t'}$ and $Y_{t'}$ should *not* be embeddable in the disk bounding $\beta(t) \cap \beta(t')$ with the vertices of $\beta(t) \cap \beta(t')$ on its boundary. This implies that the "non-disk-embeddable" part will always lie inside the set $X_{t'}$ of the separation $(X_{t'}, Y_{t'})$ above. Given now some adhesion $\beta(t) \cap \beta(t')$, we say that it is *H-red* if it is intersected by the (unique, due to Kuratowski-connectivity) non-disk-embeddable part of some H-inflated copy M in G. That way, it is convenient to visualize H-red adhesions as the "entrances" from which the H-inflated copies of G "invade" G_t.

Updating the Σ-embedding. From our previous observations it follows that to eliminate all copies of H locally in G_t it suffices to deal with all H-inflated copies that invade G_t through H-red adhesions. Therefore, our next objective is to update A_t, $G'_t = G_t - A_t$, and the Σ-embedding of G'_t in a way that the remaining part of G'_t will not contain any H-red adhesions, i.e., in a way that no invading H-inflated copy survives.

During our proof, this updating procedure will focus on some closed disk Δ containing some collection of H-red adhesions (these disks will be gathered together in what we call *H-red railed flat vortices*) and detect some separation (X, Y) of G where $X \setminus Y$ contains the vertices of the Dyck wall D_t and Y contains all H-red adhesions in Δ. We call such a separation a *carving separation*. Each time we find such a separation, we move $X \cap Y$ to A and also move $Y \setminus X$ "outside" G_t. As the set $X \cap Y$ adds up to the size of A we also need that $X \cap Y$ has "small" order. We refer to this operation as *taking a carving* of our Σ-embedding at the carving separation (X, Y). When the whole procedure terminates, none of the adhesions of the updated G'_t is H-red. This implies that $(V(G_t), A_t)$ is what we call an *H-dominion* of G, that is: *if the non-disk-embeddable part of some H-inflated copy in G intersects $V(G_t)$ then it also intersects A_t.*

To achieve the previously described objective we adopt the following strategy. Recall that in the Σ-embedding of G_t, H-red adhesions are cliques of size at most three that may be drawn all around Σ. Our first step is to show that H-red adhesions can be cornered in the "interior" of less than k pairwise-disjoint territories of Σ, each maintaining a large enough "buffer" around a disk where the H-red adhesions reside. Afterwards we refine these territories in order to bound their complexity in the sense that there is no large flow in G_t

[10] Here a $(\Sigma; d)$-Dyck wall is certifying the existence of the Dyck grid $\mathcal{D}_d^{\Sigma}$ as a minor. See Figure 4.

that crosses through these territories. Through this refinement step we obtain some some additional structural information so that in the last part of the proof, these territories along with their infrastructure will allow us to finally eliminate all H-inflated copies by removing a bounded number of vertices from their interiors.

Redrawing H-inflated copies inside a railed flat vortex. To formalize the aforementioned territories that will encapsulate the H-red adhesion of our embedding, we utilize the concept of a *railed nest* $(\mathcal{C}, \mathcal{P})$ of G *around* some closed disk Δ^{int} of Σ. Here $\mathcal{C} = \langle C_1, \dots, C_\ell \rangle$ is a sequence of ℓ disjoint cycles of G_t, where each C_i bounds some closed disk Δ_i in Σ, where $\Delta^{\text{int}} \subseteq \Delta_1 \subsetneq \cdots \subsetneq \Delta_\ell$, along with a set of paths $\mathcal{P} = \langle P_1, \dots, P_\ell \rangle$, drawn in $\Delta^{\text{ext}} := \Delta_\ell$, not traversing the interior of Δ^{int}, joining vertices of C_1 with vertices of C_ℓ, and traversing the cycles in $\mathcal{C}$ *orthogonally*, that is $P_i \cap C_j$ is connected for every $(i, j) \in [\ell]^2$. We refer to such a railed nest, as a *railed flat vortex* and we refer to the disk Δ^{int} (resp. Δ^{ext}) as its *internal* (resp. *external disk*). Moreover, if all H-red adhesions drawn in Δ^{ext} are also drawn inside Δ^{int}, then we call it an *H-red railed flat vortex*. An important ingredient of our proof is to show that we may use the infrastructure of the cycles and the paths in $(\mathcal{C}, \mathcal{P})$ in order to *redraw* inside Δ^{ext} every H-inflated copy M that invades G_t via an H-red adhesion of Δ^{ext}. Even if the part of M that is embedded inside Δ^{ext} is not necessarily a disk embedding, we can make this redrawing possible by using disk embedability properties emerging from the Kuratowski-connectivity of H and the "linkage combing" lemma from [17, 16, 15]. We refer to this as *the redrawing lemma*.

Gathering H-adhesions in railed flat vortices. The next step of our strategy, is to corner all H-red adhesions in the interior of less than k H-red railed flat vortices. Towards this, we take advantage of the infrastructure provided by the $(\Sigma; d)$-*Dyck wall* D_t. A brick of D_t is called H-red if it "contains" an H-red adhesion. More precisely, this is formalized by the notion of the *influence* of a brick which roughly corresponds to a set of H-red adhesions that are intersected or contained by a closed disk in Σ that bounds the "area" that is enclosed by the corresponding brick. This assigns each H-red adhesion to the influence of at most three neighbouring H-red bricks and defines a notion of distance between H-red adhesions expressed by the distance of the corresponding H-red bricks in D_t. Next, we prove that under this distance notion, no scattered enough set of H-red bricks of size k can exist. For this, we use the fact that each H-red brick B implies the existence of an H-inflated copy in G that, due to the aforementioned "redrawing lemma", can be redrawn in a small radius around B. This radius is bounded but also big enough so as to permit the redrawing. Likewise, we prove that there are few H-red bricks away from the exceptional and the simple cycle of D_t (see Figure 4 for a visualization of these two cycles). Next we use a greedy procedure in order to group together this bounded number of bricks and maintain enough railed nest infrastructure around them to cluster them into less than k railed flat vortices. The construction is completed by creating two more railed flat vortices, one for the simple cycle of D_t and one for the exceptional one.

Refining H-red railed flat vortices. We are now in the position where we have defined a set of less than k many H-red railed flat vortices whose internal disks contain all H-red adhesions and whose external disks are pairwise disjoint. The next step is to further refine these flat vortices.

In our proof, we treat what is drawn in the external disk Δ^{ext} as a vortex in the classic sense and our goal is to bound their *depth*, that is to ensure that no large *transaction* goes through the society defined by each railed flat vortex. Each of them consists of a

subgraph $G_{\Delta^{\text{ext}}}$ of G (the one that is drawn in Δ^{ext}) where the vertices in the boundary of the external disk Δ^{ext} are arranged in some cyclic ordering $\Omega_{\Delta^{\text{ext}}}$. A *segment* of $\Omega_{\Delta^{\text{ext}}}$ is a set $S \subseteq V(\Omega_{\Delta^{\text{ext}}})$ such that there do not exist $s_1, s_2 \in S$ and $t_1, t_2 \in V(\Omega_{\Delta^{\text{ext}}}) \setminus S$ such that s_1, t_1, s_2, t_2 occur in Ω_Δ in the order listed. A *transaction* in $(G_{\Delta^{\text{ext}}}, \Omega_{\Delta^{\text{ext}}})$ is a set of pairwise disjoint paths, drawn in Δ, between two disjoint segments A, B of $\Omega_{\Delta^{\text{ext}}}$. The *depth* of $(G_{\Delta^{\text{ext}}}, \Omega_{\Delta^{\text{ext}}})$ is the maximum size of a transaction in $(G_{\Delta^{\text{ext}}}, \Omega_{\Delta^{\text{ext}}})$. Our next objective is to refine each of our H-red railed flat vortices so that, in the end, some disk $\Delta' \subseteq \Delta^{\text{ext}}$ defines a vortex $(G_{\Delta'}, \Omega_{\Delta'})$ of *bounded* depth and, moreover, the vertices in the boundary of Δ' are all connected with disjoint paths to the boundary of the external disk Δ^{ext}. We do this as follows: If there is no transaction in $(G_{\Delta^{\text{ext}}}, \Omega_{\Delta^{\text{ext}}})$ where a big part of its paths also traverse Δ^{int}, we make use of the "nest tightening"-lemma from [41] in order to either update the nest to a "tighter" one (which allows us to recurse), or find the disk Δ' claimed above, or find a small-order carving separation (X, Y) (again defined by some closed disk) at which we may take a carving of our Σ-embedding. If there is a transaction in $(G_{\Delta^{\text{ext}}}, \Omega_{\Delta^{\text{ext}}})$ where a big enough part of its paths also traverse Δ^{int}, then we use this transaction in order to split the vortex into two vortices and recurse. This split is performed using the path infrastructure offered by the transaction, along with the cycles of the railed nest and may result in either a "tighter" H-red railed flat vortex around Δ^{int} or in two H-red railed flat vortices. In both cases, this allows us to recurse. As we know by the redrawing lemma, that k such H-red railed flat vortices may give an H-packing, this procedure will end and will produce less than k H-red railed flat vortices, each with some closed disk Δ' defining a bounded depth vortex, as above.

Killing H-red flat vortices. In the next and final step we exploit all the additional structure we obtained via the refinement step and "attack" each of the obtained H-red railed flat vortices separately. For each of them we "kill" all H-red adhesions residing in its internal disk $\Delta^{\text{int}} \subseteq \Delta'$ by identifying a bounded set of vertices drawn within Δ^{int}.

Towards this, recall that the refinement step ensures that the vortex $(G_{\Delta'}, \Omega_{\Delta'})$ has bounded depth. Using a known result of [19], we construct a *bounded width linear decomposition* of $G_{\Delta'}$, that is a path decomposition $\langle X_1, X_2, \ldots, X_n \rangle$ where every bag X_i contains some vertex x_i of the boundary of Δ' in a way that these $x_1, \ldots, x_n$ are the vertices of $V(\Omega_{\Delta'})$, appearing in the same order as they appear in $\Omega_{\Delta'}$. We next partition $\langle X_1, X_2, \ldots, X_n \rangle$ into r segments $\{\langle X_{p_{i-1}}, \ldots, X_{p_i - 1}, X_{p_i} \rangle, i \in [r]\}$ each "minimally capable" to host some H-red adhesion from which an H-inflated copy invades G_t. Likewise, we find equally many H-inflated copies in G where the parts drawn inside Δ' are disjoint. Then we bound the number of these segments by proving that they may be extended to an H-packing of size r, inside Δ^{ext}. For this, we use the full power of the redrawing lemma along with the infrastructure offered by the railed nest. As long as there are less than k segments in $\{\langle X_{p_{i-1}}, \ldots, X_{p_i} \rangle, i \in [r]\}$ we define a carving separation (X, Y) of G where Y contains the union of all $X_{p_{i-1}} \cup X_{p_i}$, $i \in [r]$ and $X \cap Y$ contains the union of all $(X_{p_{i-1}} \cap X_{p_i}) \cup (X_{p_i} \cap X_{p_{i+1}})$, $i \in [r]$. As the size of $X \cap Y$ depends on k and the width of the decomposition (that is bounded), we have that (X, Y) has bounded order. Therefore, we may take a carving of our Σ-embedding at the carving separation (X, Y). When this is done for all H-red flat vortices, we know that what remains from G'_t has a Σ-embedding that has no H-red adhesions.

From local to global. Recall that all above steps were applied to an initial torso G_t and, in particular, to the corresponding Σ-embedding of $G'_t = G_t - A_t$. In the end, what we obtained is a new G'_t and A_t and a Σ-embedding of G'_t with no H-red adhesions. The elimination

of H-red adhesions was done by taking successive carvings of the Σ-embedding of G'_t at a bounded number of carving separations (X, Y), each of bounded order. This came at some cost: By taking these carvings, we added all $X \cap Y$'s to A_t and, moreover, removed all $Y \setminus X$'s from G'. As we already mentioned above, the resulting pair $(V(G_t), A_t)$ is an *H-dominion* of G, which means that if the non-disk-embeddable part of some H-inflated copy in G intersects $V(G_t)$, then it also intersects A_t. At this point we should forget the initial tree decomposition and just keep in mind that we started with a wall W_t of some torso G_t and we finally computed an H-dominion (X_t, A_t) of G where X_t still maintains a big part of the Dyck grid D_t that is the "essential" part of W_t. This constitutes the proof of a "local structure theorem" that, apart from excluding the Dyck graphs in $\{\mathcal{D}_t^\Sigma \mid \Sigma \in \mathsf{sobs}(\mathbb{S}_H)\}$, assumes that G has no H-packing of size k, and, given a big enough wall W, returns an H-dominion (X, A) of G where the "essential part" of W is intact in X. What we need now is to bring this result to the form of a global structure theorem, that is a new tree decomposition (T, β) where each node t is accompanied by a set $\alpha(t) \subseteq \beta(t)$ where $(\beta(t), \alpha(t))$ is an H-dominion of G. This decomposition may serve as the analogue of the tree decomposition in **Step 2**. For this we use an appropriate application of a recent result in [5].

From connected to disconnected. Given the decomposition (T, β) from above, we may now delete adhesions, as it was performed in **Step 2**. After this, we obtain an $\mathcal{Z}$-dominion (X, A) of G such that $G - X$ is H-minor-free and $|A|$ is bounded. With some more preprocessing, this decomposition may be used to obtain a separation (X, Y) of G of bounded order where $(X, X \cap Y)$ is an $\mathcal{Z}$-dominion and $G[Y \setminus X]$ is H-minor-free. Notice that at this point, if H is connected, then we are done. To deal with the case where H is not connected, we set up a recursive algorithm which uses the connected case as the base case and each time it is called, it is called for the union of a smaller number of connected components of H. The final outcome is an H-cover of G whose size depends single-exponentially on the size of the excluded Dyck grids from $\mathfrak{D}_H$ and the size of the maximum H-packing in G.

4 Conclusion and open problems

Obstructions of graph classes. The (minor)-*obstruction set* of a graph class $\mathcal{G}$, denoted by $\mathsf{obs}(\mathcal{G})$, consists of the minor-minimal elements of $\mathcal{G}_{\mathsf{all}} \setminus \mathcal{G}$. Clearly $\mathsf{obs}(\mathcal{G})$ is an antichain. Moreover, it is finite by Robertson's & Seymour's theorem. Obstruction sets permit the following equivalent statement of Theorem 2.

▶ **Theorem 8.** *Let $\mathcal{Z}$ be an antichain in $\mathbb{H}^-$ and let $\mathcal{G}$ be a minor-closed graph class. $\mathcal{Z}$ has the Erdős-Pósa property in $\mathcal{G}$ if and only if, for every surface $\Sigma \in \mathsf{sobs}(\mathbb{S}_{\mathcal{Z}})$, there exists an obstruction in $\mathsf{obs}(\mathcal{G})$ which is Σ-embeddable.*

Universal obstructions. Let $\mathsf{p} : \mathcal{G}_{\mathsf{all}} \to \mathbb{N}$ be a minor-monotone graph parameter. We say that a set $\mathfrak{H}$ of minor-monotone parametric graphs is a (minor-)*universal obstruction* for p if $\mathsf{p} \sim \mathsf{p}_{\mathfrak{H}}$ (recall (3) for the definition of $\mathsf{p}_{\mathfrak{H}}$). Universal obstruction may serve as canonical representations of graph parameters. (For more on the foundation of universal obstructions of parameters, see [31, 32].) From this point of view, Theorem 2 can be restated follows:

▶ **Theorem 9.** *For every $\mathcal{Z} \in \mathbb{H}^-$, the set of parametric graphs $\mathfrak{D}_{\mathcal{Z}} = \{\mathcal{D}^\Sigma \mid \Sigma \in \mathsf{sobs}(\mathbb{S}_{\mathcal{Z}})\} \cup \{\langle k \cdot H \rangle_{k \in \mathbb{N}} \mid H \in \mathcal{Z}\}$ is a universal obstruction for both $\mathsf{cover}_{\mathcal{Z}}$ and $1/2\text{-}\mathsf{pack}_{\mathcal{Z}}$.*

Given some $\mathcal{Z} \in \mathbb{H}$, for every $k \in \mathbb{N}$, we define $\mathcal{C}_k^{\mathcal{Z}} = \{G \mid \mathsf{cover}_{\mathcal{Z}}(G) \leq k\}$. Theorem 9 (or the equivalent Theorem 8) gives us some valuable information about the obstructions in $\mathsf{obs}(\mathcal{C}_k^{\mathcal{Z}})$, for every k.

Certainly, the simplest antichain in $\mathbb{H}^-$ is the one consisting of the two Kuratowski graphs $\mathcal{K} = \{K_5, K_{3,3}\}$. The parameter $\mathsf{cover}_{\mathcal{K}}$ is the *planarizer number* that is the minimum number of vertices whose removal can make a graph planar. The obstruction $\mathsf{obs}(\mathcal{C}_k^{\mathcal{K}})$ is unknown for every positive value of k and its size is expected to grow rapidly as a function of k (see [7] for an exponential lower bound and [40] for a triply exponential upper bound). The identification of $\mathsf{obs}(\mathcal{C}_k^{\mathcal{K}})$ is a non-trivial problem even for small values of k. In particular, it has been studied extensively for the case where $k = 1$ in [25, 28, 47]. In this direction, Mattman and Pierce conjectured that $\mathsf{obs}(\mathcal{C}_k^{\mathcal{K}})$ contains the $Y\Delta Y$-families of K_{n+5} and $K_{3^2,2^n}$ and provided evidence towards this in [11]. Recently, Jobson and Kézdy identified *all* graphs in $\mathsf{obs}(\mathcal{C}_1^{\mathcal{K}})$ of connectivity two in [20], where they also reported that $|\mathsf{obs}(\mathcal{C}_1^{\mathcal{K}})| \geq 401$.

It is easy to see that $\{(k+1)\cdot K_5, (k+1)\cdot K_{3,3}\} \subseteq \mathsf{obs}(\mathcal{C}_k^{\mathcal{K}})$, for every $k \in \mathbb{N}$. Our results, together with the fact that $\mathsf{sobs}(\mathbb{S}_{\mathcal{K}}) = \{\Sigma^{(1,0)}, \Sigma^{(0,1)}\}$, provide the following extra information about $\mathsf{obs}(\mathcal{C}_k^{\mathcal{K}})$: for every $k \in \mathbb{N}$, it contains some graph, say G_k^{t}, embeddable in the torus and some graph, say G_k^{p}, embeddable in the projective plane. Most importantly, our results indicate, that the four-member subset $\{(k+1)\cdot K_5, (k+1)\cdot K_{3,3}, G_k^{\mathsf{t}}, G_k^{\mathsf{p}}\}$ of $\mathsf{obs}(\mathcal{C}_k^{\mathcal{K}})$ is sufficient to determine the approximate behaviour of the planarizer number.

Similar implications can be derived for every $\mathcal{Z} \in \mathbb{H}^-$. For instance, if $\mathcal{P}$ is the Petersen family, we again have that $\mathsf{sobs}(\mathbb{S}_{\mathcal{P}}) = \{\Sigma^{(1,0)}, \Sigma^{(0,1)}\}$. Therefore the parameter defined as the minimum number of vertices to remove so as to make a graph linkless, is approximately characterized by picking only nine graphs of $\mathsf{obs}(\mathcal{C}_k^{\mathcal{P}})$, for every $k \in \mathbb{N}$.

Other examples of surface obstructions corresponding to graphs that are known to be both Kuratowski-connected and shallow-vortex minors are $\mathsf{sobs}(\mathbb{S}_{\{K_5\}}) = \mathsf{sobs}(\mathbb{S}_{\{K_6\}}) = \mathsf{sobs}(\mathbb{S}_{\{M_{2n}\}}) = \{\Sigma^{(1,0)}, \Sigma^{(0,1)}\}$, where M_{2n} is the $2n$-Möbius ladder,[11] for $n \in \mathbb{N}_{\geq 3}$. Two other examples are $\mathsf{sobs}(\mathbb{S}_{\{K_{4,4}\}}) = \{\Sigma^{(1,0)}, \Sigma^{(0,2)}\}$ and $\mathsf{sobs}(\mathbb{S}_{\{K_7\}}) = \{\Sigma^{(1,0)}\}$.

Another implication of our results is the following.

▶ **Theorem 10.** *For every closed and proper set of surfaces $\mathbb{S}$, the set of parametric graphs $\mathfrak{V}_{\mathcal{Z}} = \{\mathcal{D}^{\Sigma} \mid \Sigma \in \mathsf{sobs}(\mathbb{S})\} \cup \{\langle \mathcal{V}_k \rangle_{k\in\mathbb{N}}\}$ is a universal obstruction for $\mathbb{S}$-$\mathsf{tw}_{\mathsf{apex}}$.*

The theorem above is a direct consequence of the second step in our proof outline, that is the step "From small treewidth modulators to small size modulators", where we obtain a local structure theorem for graphs excluding the parametric graphs in $\mathfrak{V}_{\mathcal{Z}}$, i.e., graphs where $\mathsf{p}_{\mathfrak{V}_{\mathcal{Z}}}$ is bounded. The parameter $\mathbb{S}$-$\mathsf{tw}_{\mathsf{apex}}$ (defined in (5)) corresponds to the global version of this theorem. In particular, the equivalence between $\mathbb{S}$-$\mathsf{tw}_{\mathsf{apex}}$ and $\mathsf{p}_{\mathfrak{V}_{\mathcal{Z}}}$ follows directly by [42, Theorem 5.18] or, alternatively, by applying [5, Theorem 6.17]. Notice that $\mathbb{S}$-$\mathsf{tw}_{\mathsf{apex}}$ can be seen as a parametric extension of graph embeddability and that the exclusion of shallow-vortex minors is pivotal for its definition. The potential algorithmic applications of $\mathbb{S}$-$\mathsf{tw}_{\mathsf{apex}}$ are open to investigate.

Notice that for both the equivalences in Theorem 9 and in Theorem 10 we have a single exponential gap which, in turn, determines the gap of our FPT-approximations. Is it possible to reduce this to a polynomial one? Certainly, this requires a polynomial dependency on k and t in Theorem 3. There are two sources of exponentiality in the proof of Theorem 3. The first is in the exclusion of the Dyck grid $\mathcal{D}_t^{\Sigma'}$, for $\Sigma' \in \mathsf{sobs}(\mathbb{S})$ that comes from [43], where we have an exponential dependency on t. This dependency already emerges from the bounds in [19]. On the other hand the exponential dependency on k emerges from the redrawing lemma, where the exponential bound comes from the dependencies of the planar linkage

[11] The *Möbius ladder* M_{2n} is formed if we consider a cycle on $2n$ vertices and then connect by edges the n anti-diametrical pairs of vertices. Notice that $M_6 = K_{3,3}$. M_8 is called the *Wagner Graph*.

theorem in [2]. Avoiding these two sources of exponentiality appears to be a hard task. An alternative approach is to try instead to "enlarge" the size of the universal obstructions to obtain a polynomial parametric graph. This would also be desirable for the purposes of better FPT-approximation algorithms.

Going further than $\mathbb{K} \cap \mathbb{V}$. The central question proposed by this work is to chart the threshold of half-integrality when covering and packing graphs as minors. In this paper we resolved this question for every antichain in $\mathbb{K} \cap \mathbb{V}$. The wide open question is whether and how this can be done for more general families of antichains. For this, one needs to prove structure theorems on the exclusion of parameterized graphs of unbounded genus, as those in Figure 2. The challenges that have to be met for this, when going beyond $\mathbb{K}$, are different from those encountered when going beyond $\mathbb{V}$. We believe that the proof strategy of our paper can serve as a starting point for both directions towards the general case. The resolution of the general case is highly non-trivial and requires new tools and ideas.

We conclude with a conjecture. Our guess is that when we insist on universal obstructions of bounded genus, then we cannot go much further than the horizon of $\mathbb{K} \cap \mathbb{V}$. Let $\mathbb{B}$ be the set of all antichains consisting of graphs where each of them can be embedded in both the torus and the projective plane. As an example, observe that $\{K_{3,4}\} \in \mathbb{B} \setminus \mathbb{K}$, while $\{K_{3,5}\} \notin \mathbb{B}$. We conjecture the following.

▶ **Conjecture 11.** *Let $\mathcal{Z}$ be an antichain and let $\mathsf{EP}_{\mathcal{Z}} : \mathcal{G}_{\mathsf{all}} \to \mathbb{N}$ be a graph parameter such that $\mathcal{Z}$ has the Erdős-Pósa property in a minor-closed graph class $\mathcal{G}$ if and only if $\mathsf{EP}_{\mathcal{Z}}$ is bounded in $\mathcal{G}$. Then $\mathcal{Z} \in (\mathbb{K} \cap \mathbb{V}) \cup \mathbb{B}$ if and only there exists some $g_{\mathcal{Z}}$ such that all universal obstructions of $\mathsf{EP}_{\mathcal{Z}}$ consist of parametric graphs of Euler genus $\leq g_{\mathcal{Z}}$.*

Abstract

We consider the problem of query-efficient global max-cut on a weighted undirected graph in the value oracle model examined by [31]. Graph algorithms in this cut query model and other query models have recently been studied for various other problems such as min-cut, connectivity, bipartiteness, and triangle detection. Max-cut in the cut query model can also be viewed as a natural special case of submodular function maximization: on query $S \subseteq V$, the oracle returns the total weight of the cut between S and $V \backslash S$.

Our first main technical result is a lower bound stating that a deterministic algorithm achieving a c-approximation for any $c > 1/2$ requires $\Omega(n)$ queries. This uses an extension of the cut dimension to rule out approximation (prior work of [20] introducing the cut dimension only rules out exact solutions). Secondly, we provide a randomized algorithm with $\tilde{O}(n)$ queries that finds a c-approximation for any $c < 1$. We achieve this using a query-efficient sparsifier for undirected weighted graphs (prior work of [31] holds only for unweighted graphs).

To complement these results, for most constants $c \in (0, 1]$, we nail down the query complexity of achieving a c-approximation, for both deterministic and randomized algorithms (up to logarithmic factors). Analogously to general submodular function maximization in the same model, we observe a phase transition at $c = 1/2$: we design a deterministic algorithm for global c-approximate max-cut in $O(\log n)$ queries for any $c < 1/2$, and show that any randomized algorithm requires $\Omega(n/\log n)$ queries to find a c-approximate max-cut for any $c > 1/2$. Additionally, we show that any deterministic algorithm requires $\Omega(n^2)$ queries to find an exact max-cut (enough to learn the entire graph).

1 Introduction

For the most part, the field of graph algorithms has focused on extensive study in the "standard" model where the entire graph is given to the algorithm as input e.g. in the form of an adjacency list or an adjacency matrix. However, another growing body of work focuses on the case where the algorithm does not know the graph; rather, it has query access to an

oracle that knows the graph, and aims to make as few queries as possible. Different models restrict the algorithm to make different types of queries e.g. individual edge queries, linear measurements [1, 5], matrix-vector products [32], etc.

One model that has attracted particular attention is the *cut query model* [21, 15, 31, 20, 30, 28, 4, 14]. In this model, the algorithm has query access to the cut function of a graph G with vertex set $[n]$: it provides subsets $S \subseteq [n]$ as queries and the oracle returns the total weight of all edges of G with exactly one endpoint in S. An additional reason for the wide interest in this model is that the graph's cut function is in particular a submodular function; [20] and [28] obtained new lower bounds for the query complexity of submodular function minimization by considering the special case of graph min-cut in the cut query model.

A range of graph problems has been studied in the cut query model and related models. Perhaps the most fundamental is that of learning the entire graph [21, 16, 9, 15, 10]; once the entire graph is known to the algorithm, it has all the standard graph algorithm literature at its disposal to solve the problem of interest. A more subtle question is whether the given problem can be solved with fewer queries than one would need to learn the graph. This was first answered affirmatively for the case of min-cut [31, 30, 4]: an undirected, unweighted graph requires $\Omega(n^2/\log n)$ queries to learn [21] but $O(n)$ queries suffice to find its min-cut. Since then, novel algorithms have been developed in the cut query model and related models for problems such as connectivity [1, 32, 5, 4, 14], testing bipartiteness [1], and triangle detection [32].

In this work, we initiate the study of max-cut in the cut-query model. We aim to understand how many queries are necessary and sufficient for an algorithm to find a c-approximate global max-cut in an undirected, weighted graph.

1.1 Our Results

Our two main results are stated below. Both are concerned with the setting where $c \in (1/2, 1)$ i.e. one wants to do better than a straightforward greedy algorithm or guessing a random cut, but does not want an exact max-cut. The first result is a lower bound against deterministic algorithms, and the second result is a randomized algorithm.

▶ **Theorem 1** (See Corollary 7 for a precise statement). *For $c > 1/2$, any deterministic algorithm achieving a c-approximation requires $\Omega(n)$ queries.*

▶ **Theorem 2** (See Corollary 29 for a precise statement). *For $c < 1$, there exists a randomized algorithm with query complexity $\tilde{O}(n)$ that achieves a c-approximation.*

These results naturally beg the question of how the query complexity behaves for other ranges of c, for both deterministic and randomized algorithms. We also answer this question in most cases. The content of all of our results is summarized in the following three theorems, and also tabulated in Figure 1. Soon after, we provide context for these results.

▶ **Theorem 3** (See Theorems A.1 and B.1 in the full version for precise statements). *For $c = 1$, the query complexity for a deterministic algorithm to achieve a c-approximation is $\Theta(n^2)$ and the query complexity for a randomized algorithm to do the same is between $\tilde{\Omega}(n)$ and $O(n^2)$.*

▶ **Theorem 4** (See Corollary 29, Corollary 7, and Theorem B.1 in the full version for precise statements). *For $c \in (1/2, 1)$, the query complexity for a deterministic algorithm to achieve a c-approximation is between $\Omega(n)$ and $O(n^2)$ and the query complexity for a randomized algorithm to do the same is $\tilde{\Theta}(n)$.*

c	Deterministic	Randomized
1	$\Theta(n^2)$	$(\tilde{\Omega}(n), O(n^2))$
$(1/2, 1)$	$(\Omega(n), O(n^2))$	$\tilde{\Theta}(n)$
$(0, 1/2)$	$\Theta(\log n)$	$\Theta(1)$

Figure 1 Summary of our results. For each range of c, we state the query complexity (up to constant and logarithmic factors) that we show for achieving a c-approximation in both the deterministic and randomized settings. (n, n^2) indicates settings where we have a lower bound of $\tilde{\Omega}(n)$ and an upper bound of $O(n^2)$.

▶ **Theorem 5** (See Corollary E.2, Theorem E.4, and Corollary C.3 in the full version for precise statements). *For $c \in (0, 1/2)$, the query complexity for a deterministic algorithm to achieve a c-approximation is $\Theta(\log n)$ and the query complexity for a randomized algorithm to do the same is $\Theta(1)$.*

We now provide context for each of our results, beginning with Theorem 1. Observe that there is a straightforward non-adaptive $O(n^2)$-query deterministic algorithm to find the max-cut exactly (observed in [31], as it applies to the min-cut as well). The algorithm can query all singletons and sets of size 2 and from this learn $w_{i,j} = \frac{1}{2}(F(\{i\}) + F(\{j\}) - F(\{i,j\}))$ for all i, j and thus the entire graph. The algorithm can then find the max cut exactly using brute force, since no more queries need to be made. This addresses all of the $O(n^2)$ upper bounds stated in the theorems. Theorem 3 shows that this trivial algorithm is optimal among deterministic algorithms: up to constant factors, any deterministic algorithm must learn the entire graph in order to find the global max-cut with cut queries.

Next, observe that there is a phase transition at $c = 1/2$. Theorem 5 establishes that a $(1/2 - \varepsilon)$-approximation can be achieved deterministically with $O(\log n)$ queries (which happen to also be necessary). On the other hand, even a randomized algorithm needs $\tilde{\Omega}(n)$ queries to guarantee a $(1/2 + \varepsilon)$-approximation.

Finally, observe that we resolve the asymptotic query complexity for most cases. For randomized algorithms, the only unresolved cases are $c = 1/2$ and $c = 1$.[1] For deterministic algorithms, the range $[1/2, 1)$ remains unresolved.

Before continuing, we note several facts about our results. In the positive direction, we note that all of our algorithms find a set S that is a c-approximation to the global max-cut (for undirected, weighted graphs with arbitrarily large weights), rather than simply estimating the value of the max-cut within a factor of c. We refer to these two settings as the *cut finding* and *value estimation* settings respectively. On the other hand, most of our lower bounds hold even against algorithms in the value estimation setting. The only exception is our $\tilde{\Omega}(n)$ lower bound on randomized algorithms for $c > 1/2$, which we only prove in the cut finding setting. Similarly, all algorithms we discuss, except for our $\tilde{O}(n)$-query randomized algorithm for $c \in (1/2, 1)$ and the well-known $O(n)$-query deterministic greedy algorithm for $c = 1/2$, are non-adaptive. On the other hand, all of our lower bounds hold even against adaptive algorithms.

It may appear at first glance that Theorem 1 is subsumed by the randomized lower bound in Theorem 4. Both results are lower bounds for $c > 1/2$: the former states that a deterministic algorithm in this setting requires $\Omega(n)$ queries, while the latter says that

[1] For the $c = 1/2$ case, simply outputting a random cut will achieve a $(1/2)$-approximation in expectation in $O(1)$ queries. But we are concerned with the algorithm's ability to achieve a c-approximation with some probability $p > 0$. In this setting, there exists a deterministic $O(n)$-query algorithm (see Section E.3 of the full version) but we do not have a matching lower bound.

a randomized algorithm requires $\tilde{\Omega}(n)$ queries. However, the deterministic lower bound is interesting on its own for two reasons. The first reason is that the randomized lower bound is only $\Omega(n/\log n)$, which is weaker than the $\Omega(n)$ we are able to prove in the deterministic case. Secondly, and more critically, the deterministic lower bound holds even for the value estimation setting while the randomized lower bound is only for the cut finding setting. Our argument for the randomized lower bound does not appear adaptable to the value estimation setting; indeed, the hard distribution used in our proof is actually very easy in the value estimation setting.[2]

In the negative direction, we note here that most of our algorithms have exponential time complexity even though they are query-efficient. For example, the $O(n^2)$-query algorithm we just described learns the graph in polynomial time, but then uses exponential brute force search to actually find its max-cut. This illustrates that, by focusing on query complexity, we are primarily concerned with the information theoretic question of how much the algorithm must learn about the graph to be able to estimate its max-cut, even with unlimited computation. Note that the most query-efficient algorithms for submodular function minimization are exponential time as well [24], so this is not uncommon when prioritizing query complexity.

1.2 Technical Highlights

Our results follow from a wide array of techniques. Some results (e.g. our $\tilde{\Omega}(n)$ lower bound on randomized algorithms for c-approximate max-cut and $c > 1/2$) follow from direct constructions of hard distributions – we defer further discussion of these constructions to the corresponding technical sections and appendices. Some of our results follow from novel techniques that are likely of independent interest for subsequent work – we quickly highlight these below.[3]

The key ingredient in our $\Omega(n^2)$-lower bound for exact max-cut is the *cut dimension* introduced by [20] for min-cuts (which has also been studied in follow-up work [28]). The lower bound follows immediately after establishing that the complete graph on n vertices has max-cut dimension $\Omega(n^2)$. More interestingly, we extend the concept of the cut-dimension to what is roughly a notion of "c-approximate cut-dimension" using strong LP duality. We show that this technique provides a lower bound on the number of queries needed by a deterministic algorithm to find a c-approximate max-cut for $c > 1/2$, and that for the complete graph on n vertices this gives a bound of $\Omega(n)$. This approach should also be of independent interest, given recent interest in the exact cut dimension. Completing this analysis also requires a technical lemma (Lemma 13) stating a simple geometric property of the Boolean hypercube, which may additionally be of independent interest.

Our $\tilde{O}(n)$-query randomized c-approximation for $c \in (1/2, 1)$ follows from a query-efficient sparsifier for global cuts in undirected, weighted graphs (once we have learned a sparsifier for the graph, we can just exhaust to find its max-cut, which is a $(1-\varepsilon)$-approximation). A query-efficient sparsifier for unweighted graphs appears in [31], based on ideas by [7]. We first give a natural extension of their sparsifier that accommodates graphs with weights in $[1, \text{poly}(n)]$. We then go a step further and provide a novel query-efficient sparsifier for *all*

[2] In more detail, the hard distribution is a random complete bipartite graph with edge weights 1. For this distribution in the value estimation setting, an algorithm could just immediately output $n^2/4$ without making any queries at all.

[3] Additionally, some of our results are reasonably straightforward (e.g. our $O(\log n)$ deterministic algorithm for c-approximate max-cut when $c < 1/2$) – we include discussion of these results in Appendices B, C, and E of the full version for completeness.

weighted graphs, using other ideas from [7] relating edge strengths to maximum spanning trees. For completeness, we show in Appendix D of the full version that in fact a slight modification of the [31] sparsifier also suffices for approximate max-cut for all weighted graphs (however, this modification may not produce a sparsifier). Our stronger sparsifier is hence not "necessary" to resolve approximate max-cut, but is of independent interest as not all weighted graph problems can be reduced to one with weights in $[1, \text{poly}(n)]$ (e.g. exact min-cut). In fact, our stronger sparsifier is already used in recent work [30].[4]

1.3 Related Work

Learning graphs in the cut-query model. The first natural question when an algorithm has restricted query access to a graph is how many queries it needs to learn the entire graph. For the case of cut queries, this was first studied by [21], who show that the query complexity of deterministically learning an unweighted graph is $\Theta(n^2/\log n)$, and that this can be attained non-adaptively. A later line of work [16, 9, 15, 10] answered this question for weighted graphs while also being sensitive to the number m of edges in the graph with nonzero weight, finding that the query complexity in this case is $\Theta(m \log n/\log m)$.

Min-cut in the cut-query model. A very active line of work is that of understanding what properties an algorithm can learn about a graph that it only has query access to, without using up enough queries to learn the entire graph. The particular case of most relevance to this work is that of min-cut in the cut-query model. The first progress on this problem was the algorithm by [31] for *unweighted* graphs using $\tilde{O}(n)$ queries. This was later improved to $O(n)$ queries by [4]. For *weighted* graphs, an algorithm using $\tilde{O}(n)$ cut queries was presented by [30] (as previously noted, their result leverages a query-efficient sparsifier for weighted graphs, which our paper is the first to provide).

On the lower bound side, [20] show using a linear algebraic argument that $\Omega(n)$ queries are necessary for weighted graphs (the constant-factors have since been improved by [28]), thus resolving the query complexity of exact min-cut in weighted graphs up to logarithmic factors. As mentioned earlier, our deterministic lower bounds arise from adapting and extending the concept of the cut dimension to approximation.

The cut dimension was introduced by [20], and further studied in [28]. [28] further nail down that undirected graphs have a min-cut dimension of no more than $2n - 3$ (and there exist graphs realizing this bound). They also introduce the ℓ_1-approximate cut dimension. The ℓ_1-approximate cut dimension is motivated by a similar thought experiment as our "c-approximate cut dimension" technique – both consider an adversary changing the original graph in a way that respects all queries made, and both consider the magnitude of the changes made to the max/min-cut (rather than just whether or not the cut is changed). However, their ℓ_1-approximate cut dimension does not imply lower bounds on the query complexity of finding approximately-optimal cuts. Finally, they further consider "the dimension of approximate min-cuts", and prove a linear upper bound on this. This concept does not have any relation to our approximate cut dimension technique (and in particular, only our technique implies lower bounds on the deterministic query complexity). In summary, the cut dimension is an active concept of study in related work, but our work is the first to use this concept to lower bound the query complexity of approximately-optimal cuts.

[4] [30, Theorem 5.2] seems to credit [31] for handling weighted graphs (whereas their query-efficient sparsifier only accommodates unweighted graphs). They use this result as part of their $\tilde{O}(n)$ query algorithm for *weighted* min-cut.

Other graph algorithms in other query models. Many works have considered other graph problems in other query models as well. These query models include cut queries [14], linear measurements [1, 5], matrix-vector products [32], OR queries [5, 8], XOR queries [8], and AND queries [8]. Some of these models e.g. linear measurements and matrix-vector products generalize the cut query model, while the others do not appear directly related. These works also consider a variety of graph problems, including connectivity [1, 32, 5, 4, 14], bipartiteness [1], triangle detection [32], minimum spanning tree [1], and maximum matching [1, 8].

Graph sparsification. [31] also provide an algorithm for graph sparsification in $\tilde{O}(n)$ queries for unweighted graphs, based on the idea of *edge strength-based sampling* used by [7] to construct sparsifiers in the classical computational model. There are also other lines of work that adapt the ideas from [7] to construct sparsifiers in other limited-access computational models, particularly (semi-)streaming [1, 2, 3, 25, 32]. Some of these algorithms are adaptable to the cut-query model. However, these algorithms either only support unweighted graphs or incur a performance cost for weighted graphs. For example, the natural extension of the algorithm in [31] to weighted graphs requires $\tilde{O}(n \log W)$ queries, where W is the ratio between the largest and smallest nonzero edge weight in the graph. Our novel sparsifier avoids this pitfall by using results from [7] connecting edge strengths to maximum spanning trees to remove the $\log W$ factor.

While these results and ours all use randomization to construct a sparsifier, there are also classical algorithms for constructing sparsifiers deterministically [6, 17]. Implementing such an algorithm directly would require being able to learn the spectrum of the graph's Laplacian. It may indeed be possible to do this (exactly or approximately) in a query-efficient way, but doing so would require significantly new ideas. A deterministic query-efficient implementation of these algorithms would also yield a deterministic query-efficient algorithm for a $(1-\epsilon)$-approximation to max cut.

Max-cut in the classical computational model. Max-cut is extremely well-studied in the computational model, but algorithms in the cut-query model differ significantly. For example, [19] present a randomized polynomial-time algorithm using semidefinite programming that achieves a ≈ 0.878 approximation in expectation. However, this algorithm does not imply anything in our model; even formulating the necessary SDP requires access to the entire graph.

It has since been shown by [23] that it is NP-hard to beat a $16/17 \approx 0.941$ approximation. Moreover, [27] show that it is NP-hard to beat the constant achieved by Goemans and Williamson assuming the unique games conjecture [26]. These lower bounds do not imply anything in our model either. In fact, many of our algorithms (and those in prior work) involve exponential computation even if they use an efficient number of queries. Once we have either learned the entire graph ($c = 1$) or constructed a sparsifier of the graph ($c \in (1/2, 1)$), we use brute force search to find the exact max cut on the graph we have learned.

Submodular function maximization. Our problem can be viewed as a special case of symmetric submodular function maximization, by taking $f(\cdot)$ to be the cut function of a graph. However, the additional structure imposed by the cut function of a graph opens up possibilities for new algorithms and requires new lower bound arguments. For example, when $c > 1/2$, [18] show that achieving a c-approximation to symmetric submodular function maximization requires $\exp(\Omega(n))$ queries to the oracle. For global max-cut, the situation

is significantly different: $O(n^2)$ queries suffice to trivially learn the entire function (and therefore, there seems to be little hope of embedding hard SFM instances as graphs). Still, we show that this trivial algorithm is optimal among deterministic algorithms when $c = 1$, and show that $\tilde{\Omega}(n)$ queries are necessary for even a randomized algorithm to achieve a c-approximation for $c > 1/2$.

For $c \leq 1/2$, randomized [12] and deterministic [11] algorithms are known that achieve a $1/2$-approximation with $O(n)$ and $O(n^2)$ queries respectively, even when the submodular function is not symmetric. [18] show in the symmetric case that picking a random set ($O(1)$ queries) achieves a $1/2$-approximation in expectation. They also provide a deterministic algorithm based on local search that achieves a c-approximation for any $c < 1/2$ in $\tilde{O}(n^3)$ queries. When restricting to max-cut, [18] immediately implies a randomized algorithm for all $c \leq 1/2$ with $O(1)$ queries (which is optimal). For deterministic algorithms, however, our bound of $\Theta(\log n)$ is again an exponential improvement over the general case of submodular function maximization.

In summary, global max-cut demonstrates a similar phase transition at $c = 1/2$ as general submodular function maximization: the query complexity for $c < 1/2$ is exponentially smaller than the query complexity for $c > 1/2$. However, the distinction for max-cut is between logarithmic and polynomial queries, whereas the distinction for general submodular functions is between polynomial and exponential.

Submodular function minimization. Just as submodular function maximization generalizes max-cut in the cut query model, submodular function minimization generalizes min-cut. Unlike the maximization case which requires exponentially many queries, general submodular function minimization can be solved exactly with polynomially many queries; state-of-the-art algorithms use $\tilde{O}(n^2)$ queries [24, 29].

However, until relatively recently, most query lower bounds for submodular function minimization were only $\Omega(n)$ [22, 20, 28]. The last two results proceed using the aforementioned cut dimension technique. This was recently improved to $\Omega(n \log n)$ by [13], using different ideas unrelated to graph cuts.

2 Preliminaries

G is an undirected, weighted graph with weights $w_{i,j}$ on the edge (i, j). G induces a cut function F. We denote the cut function by $F(\cdot)$, so $F(S) := \sum_{i \in S, j \notin S} w_{i,j}$. Additionally, for any cut $S \subseteq [n]$, we define the indicator vector $v_S \in \mathbb{R}^{\binom{n}{2}}$ by $(v_S)_{i,j} = 1$ if (i, j) crosses the cut defined by S and 0 otherwise.

We consider algorithms that have black-box access to $F(\cdot)$, and aim to find $\arg\max_{S \subseteq [n]}\{F(S)\}$ (exact maximization) or a set T such that $F(T) \geq c \cdot \max_{S \subseteq [n]}\{F(S)\}$ (c-approximation). We refer to the query complexity as the number of queries to $F(\cdot)$ that the algorithm makes (the algorithm has no other access to G or F, and may perform unlimited computation).

3 Lower Bound for Deterministic $(1/2 + \epsilon)$-approximation

In this section, we extend the cut dimension technique by [20] using linear programming and the strong duality theorem to show the deterministic hardness part of Theorem 4. (We refer the reader to Appendix A of the full version for a discussion of this technique and its direct application to show the deterministic lower bound in Theorem 3.) Our exact result is as follows:

▶ **Theorem 6.** *Suppose we have* $c \in (1/2, 1), \epsilon \in (0, 1), \alpha > 0$ *such that* $c > \frac{1}{1+\epsilon^2}$ *and* $\alpha < \frac{(1-\epsilon)^3}{108(1+\epsilon)}$. *Then for* n *sufficiently large,* αn *queries do not suffice for a deterministic algorithm to estimate the max cut value within a factor of* c.

Before proving this theorem, we state a cleaner lower bound as a corollary:

▶ **Corollary 7.** *For* $c \in (1/2, 1)$, *a deterministic algorithm that estimates the max cut value within a factor of* c *requires at least* $n(\frac{(\sqrt{c}-\sqrt{1-c})^4}{108c(2c-1)} - o(1))$ *queries.*

This implies that the query complexity for a deterministic algorithm to achieve a c*-approximation for global max-cut on a weighted undirected graph in the value estimation setting is* $\Omega(n)$.

Proof. See Appendix F.1 of the full version. ◀

The first step is conceptually similar to the cut dimension argument from Theorem A.1 in the full version. We consider an adversary that answers all queries as if the graph were K_n (there is an edge of weight 1 between all pairs of vertices). Then we would like to find a perturbation z to the weight vector of K_n such that $w, w + z$ agree on all queries but have differing max cut values. The difference here is that we would like to show that the algorithm cannot even achieve a c-approximation, so we require the perturbation to be so large that the max cut value of $w + z$ is a multiplicative factor greater than the max cut of w. To do this, we will have to go beyond linear algebraic tools and consider linear programming instead. Our argument comprises the following steps:

1. Write the conditions we require of the perturbation z as linear constraints and thus formulate a linear program LP1, which we would like to show has high value.
2. LP1 works with vectors in $\mathbb{R}^{\binom{n}{2}}$ that represent cuts, which are unwieldy and unnatural. Rewrite this in terms of indicator vectors in $\mathbb{R}^n$.
3. Define another linear program LP2 and show that a high value for LP2 implies that LP1 must also have high value.
4. Show that LP2 has high value by taking its dual, and showing that the dual has high value. This comes down to showing a key technical lemma, which essentially states that the n-dimensional hypercube cannot be covered by an ℓ_1 neighborhood of an αn-dimensional subspace of $\mathbb{R}^n$. We show this using an ℓ_1 ϵ-net argument.

We now work through each step in detail. We retain all notation used in Appendix A of the full version for the cut dimension argument, and introduce additional notation as necessary.

3.1 Step 1: Formulating LP1

Throughout these proofs, we use $\mathbf{1}$ to denote a vector with all entries equal to 1 in either $\mathbb{R}^n$ or $\mathbb{R}^{\binom{n}{2}}$. It will be clear from context which of these we are referring to at any given time, but for now we are taking $\mathbf{1} \in \mathbb{R}^{\binom{n}{2}}$ to denote the weight vector of K_n. Let $q = \alpha n$ and $Q_1, Q_2, \ldots, Q_q \subseteq [n]$ be the q queried cuts. As in Appendix A of the full version, they have the corresponding 0/1 indicator vectors $v_{Q_1}, v_{Q_2}, \ldots, v_{Q_q} \in \mathbb{R}^{\binom{n}{2}}$. We are interested in finding a perturbation z such that $\mathbf{1}, \mathbf{1} + z$ are both weighted, undirected graphs (with non-negative edge weights) and agree on all queries but have max cut values differing by a multiplicative factor.

First, we require $\mathbf{1} + z$ to define a valid graph i.e. its entries should all be non-negative since these correspond to edge weights:

$$\mathbf{1} + z \geq 0 \Leftrightarrow z \geq -\mathbf{1}. \tag{1}$$

Next, we need $\mathbf{1}, \mathbf{1} + z$ to agree on all queries. This guarantees that the algorithm cannot tell the difference between $\mathbf{1}$ and $\mathbf{1} + z$ based only on the queries made so far.

$$\mathbf{1}^T v_{Q_i} = (\mathbf{1} + z)^T v_{Q_i},\ \forall i \Leftrightarrow z^T v_{Q_i} = 0,\ \forall i. \tag{2}$$

Finally, we would like the graph corresponding to $\mathbf{1} + z$ to have a much larger max cut value than the graph corresponding to $\mathbf{1}$. We capture this in the following definition and lemma:

▶ **Definition 8.** *Define a* near-max cut *to be any cut* $C \subseteq [n]$ *such that* $n/2 - \sqrt{n \log n} \leq |C| \leq n/2 + \sqrt{n \log n}$.

Note that a near-max cut is nearly a max-cut in K_n. As hinted at earlier, we will show that we can find a near-max cut C and a perturbation z to the graph that will preserve the value of all queries while blowing up the value of C by a factor of c. In this case, the algorithm cannot distinguish between K_n and the perturbed graph and thus cannot achieve a c-approximation.

▶ **Lemma 9.** *To prove Theorem 6, it suffices to show that there exists a near-max cut* C *such that the following linear program has value at least* $\epsilon^2 n^2/4$. *We call this linear program LP1.*

$$\begin{aligned} &\textit{Maximize } z^T v_C \\ &\textit{subject to } z^T v_{Q_j} = 0 \quad \textit{for all } j \in [q], \textit{ and} \\ &\qquad\qquad z \geq -\mathbf{1}. \end{aligned}$$

Proof. We have already explained how the constraints arise. To justify that the objective corresponds to a bound on the approximation ratio, see Appendix F.2 of the full version. ◀

3.2 Step 2: Rewriting LP1

As already mentioned, the vectors $v_S \in \mathbb{R}^{\binom{n}{2}}$ are unnatural and difficult to work with. Intuitively, the reason for this is that a cut only has n degrees of freedom (each vertex can be included or not included in S), but we are representing it with a vector with $\binom{n}{2}$ entries, thereby creating unwanted dependencies between entries of these vectors.

We would thus like to find a more natural parametrization of these cuts that can still be connected naturally to the vectors v_S. To construct such a parametrization, we assign to each cut S a ± 1 indicator vector $u_S \in \mathbb{R}^n$. Entries are indexed by vertices in $[n]$, and for each $i \in [n]$ we have $(u_S)_i = 1$ if $i \in S$ and -1 otherwise.

Now we connect these new indicator vectors to v_S as follows. Define the matrix $M_S \in \mathbb{R}^{n \times n}$ by $M_S = \frac{\mathbf{1}\mathbf{1}^T - u_S u_S^T}{2}$. (Note that from here onwards, $\mathbf{1}$ now refers to the vector in $\mathbb{R}^n$ with all entries equal to 1.) M_S's entries are indexed by ordered pairs of vertices. Now observe that:

$$
\begin{aligned}
(M_S)_{i,j} &= \frac{\mathbf{1}_i\mathbf{1}_j - (u_S)_i(u_S)_j}{2} \\
&= \frac{1 - (u_S)_i(u_S)_j}{2} \\
&= \begin{cases} 0, & i,j \in S \text{ or } i,j \notin S, \\ 1, & \text{otherwise} \end{cases} \\
&= \begin{cases} (v_S)_{i,j}, & i \neq j, \\ 0, & i = j. \end{cases}
\end{aligned}
$$

Thus if we flatten M_S into a vector, it consists of two copies of v_S (each unordered vertex pair (i,j) in v_S appears twice in M_S since the vertex pairs indexing M_S are ordered) and n 0's (corresponding to vertex pairs (i,i) for $i \in [n]$). This allows us to rewrite LP1 in terms of the u_S's as stated in the following lemma. For matrices A, B of the same shape, we use $\langle A, B\rangle$ to denote the matrix inner product $\mathrm{tr}(A^TB) = \sum_{i,j} A_{i,j}B_{i,j}$.

▶ **Lemma 10.** *For any C, LP1 has value $\geq \epsilon^2n^2/4$ if and only if the following LP has value at least $\epsilon^2n^2/2$. We call this the "matrix LP". Here, $Z \in \mathbb{R}^{n\times n}$.*

$$
\begin{aligned}
&\textit{Maximize } \langle Z, M_C\rangle \\
&\textit{subject to } \langle Z, M_{Q_j}\rangle = 0 \quad \textit{for all } j \in [q], \textit{ and} \\
&\qquad\qquad Z \geq -\mathbf{1}.
\end{aligned}
$$

Proof. See Appendix F.3 of the full version. ◀

3.3 Step 3: Defining LP2 and Connecting LP2 to LP1

For a near-max cut C, define a new linear program which we call LP2 as follows. Here $y \in \mathbb{R}^n$.

$$
\begin{aligned}
&\text{Maximize } y^Tu_C \\
&\text{subject to } y^Tu_{Q_j} = 0 \quad \text{for all } j \in [q], \\
&\qquad\qquad y^T\mathbf{1} = 0, \text{ and} \\
&\qquad\qquad -\mathbf{1} \leq y \leq \mathbf{1}.
\end{aligned}
$$

We claim that it suffices to show that LP2 has value at least ϵn:

▶ **Lemma 11.** *If there exists a near-max cut C such that LP2 has value at least ϵn then the matrix LP for C has value at least $\epsilon^2n^2/2$, which would imply Theorem 6.*

Proof Sketch. Take such a near-max cut C and $y \in \mathbb{R}^n$ such that y is in the feasible region of LP2 and $y^Tu_C \geq \epsilon n$. Then we claim that $Z = -yy^T$ is feasible for the matrix LP and attains a value $\geq \epsilon^2n^2/2$. Intuitively, y can be thought of as a vector representing a "pseudo-cut" in the same way that u_S represents S. LP2 having high value means that y aligns non-trivially with C, and what we are claiming is that perturbing towards the "pseudo-cut" corresponding to y will align the graph's weights with the cut corresponding to C. We provide details in Appendix F.4 of the full version. ◀

3.4 Step 4: Showing that LP2 has High Value

Finally, we show that we can find a near-max cut C such that LP2 has value at least ϵn, which by Lemma 11 will complete the proof of Theorem 6. We do this by taking the dual of LP2, which has a simple characterization captured by the following lemma:

▶ **Lemma 12.** *Consider vectors $w, w_1, w_2, \ldots, w_k \in \mathbb{R}^d$, and the following LP:*

$$\begin{aligned} &\textit{Maximize } z^T w \\ &\textit{subject to } z^T w_i = 0 \quad \textit{for all } i \in [k], \textit{ and} \\ &\qquad -\mathbf{1} \leq z \leq \mathbf{1}. \end{aligned}$$

Let $W = \text{span}(w_1, w_2, \ldots, w_k)$. Then the value of this LP is $\min_{v \in W} ||v - w||_1$. (If there is no such v then by this minimum we mean ∞.)

Proof. See Appendix F.5 of the full version. ◀

To use this lemma, let $V = \text{span}(u_{Q_1}, \ldots, u_{Q_q}, \mathbf{1})$. Then Lemma 12 tells us that LP2 has value equal to $\min_{u \in V} ||u - u_C||_1$.

Now note that V depends only on the set of queries and not at all on C. Thus we would like to show that there exists a near-max cut C such that $\min_{u \in V} ||u - u_C||_1 \geq \epsilon n$. We will show the strict version of this inequality i.e. that $\min_{u \in V} ||u - u_C||_1 > \epsilon n$. Denote by B_r the ℓ_1 ball of radius r in $\mathbb{R}^n$. Then what we want to show is that there exists a near-max cut C such that $u_C \notin V + B_{\epsilon n}$. This brings us to our key technical lemma, which has little to do with graphs and may be of independent interest:

▶ **Lemma 13.** *Let $\epsilon \in (0,1)$ and $d \leq \alpha' n$ for $\alpha' < \frac{(1-\epsilon)^3}{108(1+\epsilon)}$. Suppose D is a d-dimensional subspace of $\mathbb{R}^n$. Denote by B_r the ℓ_1 ball of radius r in $\mathbb{R}^n$. Then there exists $p \in \{-1,1\}^n$ such that $p \notin D + B_{\epsilon n}$ and $|\mathbf{1}^T p| \leq 2\sqrt{n \log n}$.*

Proof. We show this by a volume argument. Specifically, we estimate the size of $(D + B_{\epsilon n}) \cap \{-1,1\}^n$ using an ℓ_1 ϵ-net argument and show that this must be much less than 2^n. We provide details in Appendix F.6 of the full version. ◀

With this lemma, we can complete this step and thus the proof of Theorem 6:

▶ **Corollary 14.** *For n sufficiently large, there exists a near-max cut C such that $u_C \notin V + B_{\epsilon n}$.*

Proof. See Appendix F.7 of the full version. ◀

4 Sparsifier-based Randomized Algorithms for $(1-\epsilon)$-approximation

Here we address the randomized upper bound part of Theorem 4, namely that a $(1-\epsilon)$-approximation can be achieved in the cut finding setting with $\tilde{O}(n)$ queries. Our algorithms are adaptive. The key notion is that of a *sparsifier*:

▶ **Definition 15.** *Given weighted graphs G, H on the same set of n vertices with non-negative weights, we say H is an ϵ-sparsifier of G if all of the following conditions hold:*
1. *H has $\tilde{O}_\epsilon(n)$ edges with nonzero weight.*
2. *For any cut $S \subseteq [n]$, we have $(1-\epsilon)F(S;G) \leq F(S;H) \leq (1+\epsilon)F(S;G)$.*

Here $F(S;G)$ denotes the value of the cut defined by S on the graph G, and similarly for $F(S;H)$.

▶ **Lemma 16.** *If an algorithm can compute an ϵ-sparsifier of G in $\tilde{O}(n/\epsilon^2)$ queries with high probability, then it can also find a $(1-2\epsilon)$-approximate max cut with no additional queries.*

Proof. Once the algorithm has a sparsifier H, it can just try all possible cuts and output the cut U maximizing $F(U;H)$. Indeed, for any other cut S, we would have $F(U;G) \geq \frac{F(U;H)}{1+\epsilon} \geq \frac{F(S;H)}{1+\epsilon} \geq \frac{(1-\epsilon)F(S;G)}{1+\epsilon} \geq (1-2\epsilon)F(S;G)$, so U is indeed a $(1-\epsilon)$-approximate max cut. ◀

Throughout this section, let $d > 5$ be constant, and let $\delta \in (1/2, 1)$ be a constant sufficiently close to 1. Then let c_0 and c_1 be sufficiently large positive constants. Also, let W_{tot} be the total weight of all edges in the graph, and W the ratio between the largest and smallest nonzero edge weights. Finally, for a vertex set $S \subseteq V(G)$, let $G[S]$ denote the vertex-induced subgraph of G on S. Note that we do not require that G be connected. We organize the remainder of this section as follows:

1. In Section 4.1, we set up and analyze the algorithmic tools necessary to adapt [31]'s algorithm to weighted graphs.
2. In Section 4.2, we present the direct adaptation of [31]'s algorithm to weighted graphs and show that it constructs a sparsifier in $\widetilde{O}(n \log W)$ queries.
3. In Section 4.3, we use ideas introduced by [7] relating edge strengths to maximum spanning trees in order to construct a sparsifier for weighted graphs in $\widetilde{O}(n)$ queries, thus eliminating the dependence of the query complexity on W.
4. Additionally, in Appendix D of the full version, we show that we can achieve a $(1-\epsilon)$-approximation for max-cut in $\widetilde{O}(n)$ queries without needing the optimizations in Section 4.3. This is achieved by essentially stopping our adaptation of [31]'s algorithm early. This will not construct a sparsifier, but it will construct something "close enough" to suffice for max-cut. Intuitively, we do this by discarding edges of weight $< W_{\text{tot}}/\text{poly}(n)$ since these will not have much effect on the max cut, thereby reducing the problem to one where $W = \text{poly}(n)$.
   Given this result, our sparsifier for weighted graphs in Section 4.3 is not necessary for max-cut specifically, but it makes for a conceptually cleaner algorithm for max-cut and may be applicable to other problems.

4.1 Setup and Algorithmic Tools

The key idea is the notion of edge strength introduced by [7].

▶ **Definition 17** (([7], as stated in [31])**.** *The* strong connectivity *of G, denoted $K(G)$, is the value of G's min cut.*

▶ **Definition 18** ([7], as stated in [31])**.** *Given an edge e in G, the strong connectivity or* edge strength *k_e of e is the maximum min cut over all vertex-induced subgraphs of G containing e:*

$$k_e = \max_{S \subseteq V : u,v \in S} K(G[S]).$$

The idea introduced by [7] and used by [31] is that subsampling edges of G with probabilities inversely proportional to their strength will give a sparsifier. We cannot do exactly this in the cut query model, but we can subsample in a way that is "close enough" to independent. We need some basic primitives to support our algorithm, and we capture all of them in the following lemma:

▶ **Lemma 19.** *There exists a data structure supporting the following operations.*

1. *InitializeDS(H): Initialize the structure's state and carry out any preprocessing needed with the starting graph H.*
2. *Contract(S): Contract a given supernode set S.*
3. *GetEdge(): Find and return an edge from H (that has not been contracted) with weight at least $\frac{2W(H)}{n^2}$. Here $W(H)$ is the total weight of not-yet-contracted edges.*
4. *GetTotalWeight(S): Return the total weight of all edges with both endpoints in S (that have not yet been contracted). S must once again be a set of supernodes.*
5. *Sample(S): Sample a random edge with both endpoints in S (that has not yet been contracted), with probability proportional to its weight. S must be a set of supernodes here as well.*

It takes $O(n)$ queries for each call to InitializeDS, $O(1)$ queries for each call to Contract, $O(\log n)$ queries for each call to GetEdge, $O(1)$ queries for each call to GetTotalWeight, and $O(\log n)$ queries for each call to Sample.

Proof. The pre-processing and queries when contracting are due to having to keep track of (super)node degrees. GetEdge and Sample can be handled using recursive bisection procedures similar to that used to prove Corollary 2.2 in [31]. We provide details in Appendix G.1 of the full version. ◀

Before we go any further, we make an important comment about how we regard contraction in our algorithms (including Lemma 19). When we contract a set of vertices, we regard that set of vertices as one supernode as usual, but we do not merge any edges that have now become parallel. So the set of edges will always be a subset of the edges from the original graph.

It will be convenient to regard our algorithms as having two separate stages, although the two stages share some ingredients. In the first stage, the algorithm iteratively subsamples and contracts the graph to estimate the strengths of all edges within a constant factor. In the second stage, the algorithm uses these edge strength estimates to construct the sparsifier, following the ideas of [7]. We address these two stages in the next two subsections respectively.

We note that these algorithms are very similar to those presented by [31]; the key difference is that whenever the sparsification algorithm in [31] subsamples the graph, it does so independently for each edge. This works because [31] focuses on unweighted graphs. With weighted graphs, we would like to sample edges proportionately to their weight, and this cannot be done independently without knowledge of the graph. We modify their subsampling procedures to obtain algorithms that do not sample completely independently, but still have the concentration properties that we need.

4.1.1 Constant-Factor Edge Strength Estimates

We next describe the main tool of our edge strength estimation, which we call EstimateAndContract. It takes in the input graph G where some vertex sets S_i have already been contracted and a strength parameter κ, and further contracts G while also estimating the strength of any edges that get contracted. For any graph H, let $W(H)$ denote the total edge weight of H.

We state some key properties of Algorithm 4.1 and defer their proofs to Appendix G.4 of the full version:

▶ **Lemma 20** (Analogous to claim 3.6 from [31]). *With probability $1 - O(n^{1-d})$, for all e such that $k_e \geq \kappa$ and e is not contracted by any of the sets in $\mathcal{C}$, it will be assigned $k'_e = \kappa/2$ and contracted.*

Algorithm 4.1 EstimateAndContract$(G, \mathcal{C}, \kappa, X)$.

Data: Initial graph G with vertex set $V(G) \subseteq [n]$, disjoint collection $\mathcal{C}$ of contracted sets, strength parameter κ, partial list X of strength estimates
Result: Updated collection of contracted sets $\mathcal{C}$, updated list X of strength estimates
Let G' be G with all sets from $\mathcal{C}$ contracted and $\lambda = \frac{c_0 \log^2 n}{\kappa} W(G')$. (We can find $W(G')$ using GetTotalWeight from Lemma 19.)

1. Sample λ edges from G', proportionally to their weights, with replacement. If an edge e is sampled at least once, assign weight $\frac{w(e)}{p(e)}$ to it, where $p(e) = 1 - (1 - \frac{w_e}{W(G')})^\lambda$. These newly weighted edges form a new graph G''.
2. While there exists a connected component of G'' with a cut of size $\leq (1-\delta)\kappa$, delete all edges of that cut from G''. Let the resulting connected components of G'' be $C_1, C_2, \ldots, C_r$.
3. For each $i \in [r]$, append the tuple $(C_i, \kappa/2)$ to X. (Here, what we are saying is "assign a strength estimate of $\kappa/2$ to any edge with both endpoints in C_i that has not already been contracted", but we phrase it differently to account for the fact that the algorithm may not actually know these edges.)
4. Add C_i to $\mathcal{C}$ (and remove any subsets of C_i to maintain disjointness) for all $i \in [r]$.

▶ **Lemma 21** (Analogous to claim 3.7 from [31]). *Assume that any edge contracted by $\mathcal{C}$ has strength $\geq \kappa/2$. Then with probability $1 - O(n^{1-d})$, no edge e such that $k_e < \kappa/2$ is assigned a strength estimate or contracted.*

4.1.2 Sparsifier Construction

Next, we describe our algorithm that will construct a sparsifier if provided constant-factor strength estimates for all edges in the graph, which we call ConstructSparsifier.

We capture the desired sparsification properties in the following lemma:

▶ **Lemma 22.** *Fix $X = [(C_1, \beta_1), (C_2, \beta_2), \ldots, (C_r, \beta_r)]$ as in ConstructSparsifier (X might be random, but we condition on a particular list of values for now). Then for each i, define:*

$$E(C_i) = \{e \in G : \text{ both endpoints of } e \text{ are in } C_i\}$$
$$\widetilde{E}(C_i) = E(C_i) \setminus \bigcup_{j : C_j \subset C_i} E(C_j)$$

(Thus $\widetilde{E}(C_i)$ is the set of edges that will be contracted at the time that C_i is contracted.)

Assume each of the following conditions:

1. *Each connected component of G is contained in at least one C_i (every edge in G gets contracted), and*
2. *For all i and edges $e \in \widetilde{E}(C_i)$, we have $\beta_i \in [k_e/4, k_e]$ (edge strength estimates are correct within a constant factor).*

Then with probability $1 - O(n^{-d})$, ConstructSparsifier will output a sparsifier H that approximates the cuts of G within a factor of $1 \pm 2\epsilon$. (Thus this probability is only considering the randomness of ConstructSparsifier.)

Proof. This follows using similar ideas to [7], but we need to take some extra care because the subsampling we use to construct the sparsifier is not independent. We provide details in Appendix G.2.2 of the full version. ◀

Algorithm 4.2 ConstructSparsifier(G, X).

Data: Graph G with vertex set $[n]$, list $X = [(C_1, \beta_1), (C_2, \beta_2), \ldots, (C_r, \beta_r)]$ of strength estimates. We assume that $\{C_1, \ldots, C_r\}$ is a laminar family of vertex sets and that if $C_i \subset C_j$ then $i < j$. (This is because we will be contracting $C_1, \ldots, C_r$ in that order.) Note that we do **not** assume here that X includes a strength estimate for every edge.
Result: Potential sparsifier H
Initialize $G' = G$ and H to be empty.
InitializeDS(G'). (This is just to reset and ignore any previous contractions we may have done in EstimateAndContract.)
for $i \leftarrow 1$ **to** r **do**
1. Let $\mu_i = \frac{c_1 \log^2 n}{\epsilon^2 \beta_i} W(C_i)$. (Here $W()$ is with respect to G', and once again can be found using GetTotalWeight from Lemma 19.)
2. Sample μ_i edges from C_i proportionally to their weights, with replacement. If an edge e is sampled at least once, add it to H with weight $\frac{w_e}{p_e}$, where $p_e = 1 - (1 - \frac{w_e}{W(C_i)})^{\mu_i}$ is the probability that e is sampled at least once. (Note that this sampling would be done by calling Sample(C_i) from Lemma 19.)
3. Contract C_i in G'.

end

4.2 Sparsification with $\widetilde{O}(n \log W)$ Queries

Here we analyze the naive generalization of [31]'s sparsifier to weighted graphs. The procedure is described in Algorithm 4.3.

Algorithm 4.3 NaiveWeightedSubsample(G, T).

Data: Graph G on n vertices, positive real parameter T
Result: A potential (2ϵ)-sparsifier H of G.
Initialize $\mathcal{C} = \emptyset$ and X as an empty list.
InitializeDS(G).
Find W_{tot} by running GetTotalWeight(G).
Initialize κ to be the smallest power of 2 that is at least W_{tot}.
while *GetTotalWeight*$(G) > 0$ *and* $\kappa > W_{tot}/T$ **do**
  EstimateAndContract$(G, \mathcal{C}, \kappa, X)$
  $\kappa \leftarrow \kappa/2$
end
$H \leftarrow$ ConstructSparsifier(G, X).

▶ **Theorem 23.** *NaiveWeightedSubsample*(G, ∞) *runs in* $O(n \log^3 n(\log n + \log W + \frac{1}{\epsilon^2}))$ *queries and outputs a* (2ϵ)*-sparsifier* H *with probability* $1 - O(n^{1-d}(\log n + \log W))$.

Proof. We outline the proof here and provide details in Appendices G.5 (correctness) and G.8 (efficiency) of the full version. The proof proceeds in two parts.

First, we address the calls to EstimateAndContract. Given Lemmas 4.6 and 4.7, EstimateAndContract can be thought of as estimating the strengths of and then contracting edges whose strengths are within a window that is a factor of 4 wide. The lemmas tell us that these strength estimates are accurate within a factor of 4. Then NaiveWeightedSubsample

essentially "slides" this window across all possible edge strengths so that all edges of G are assigned a strength estimate. This part has query complexity $O(n \log^3 n(\log n + \log W))$; the $\log W$ term is because the outer loop could run for $O(\log n + \log W)$ iterations. This is also why the success probability depends on W, as this is obtained by taking a union bound over all iterations.

Secondly, because all edges are assigned an accurate strength estimate (within a constant factor), Lemma 22 tells us that ConstructSparsifier will output a (2ϵ)-sparsifier with high probability. This part has query complexity $O(n \log^3 n/\epsilon^2)$. ◀

4.3 Sparsification with $\widetilde{O}(n)$ Queries

We now show how to eliminate the dependence of the query complexity and success probability on W, thus constructing sparsifiers in $\widetilde{O}(n)$ queries. We begin by setting up the necessary ideas.

4.3.1 Crude Edge Strength Estimates

Recall that the key problem with Algorithm 4.3 was that our "sliding window" for edge strength estimation could potentially repeat $O(\log n + \log W)$ times. The key idea is to mitigate this by finding very crude (within a factor of n^4) estimates for the edge strengths for all edges in G, before refining these estimates using EstimateAndContract. We do this using the idea of [7] to estimate edge strengths from the maximum spanning forest (MSF) of G. Fix an MSF $\mathcal{T}$ of G. Then for any edge e with endpoints i, j, define $d_e = d_{i,j}$ to be the minimum weight of an edge on the MSF path between the endpoints of e. We first state a lemma shown in [7]:

▶ **Lemma 24** ([7]). *For all edges e, we have $d_e \leq k_e \leq n^2 d_e$.*

This would immediately give us sufficient edge strength estimates but we do not know of a way to find the MSF efficiently in the cut query model. In fact, we can adapt the max cut dimension argument from Lemma A.3 in the full version to a "max tree dimension" argument to show that deterministically finding the MSF requires $\Omega(n^2)$ queries; see Appendix A.1 of the full version for details. So instead, we run what we call "approximate Kruskal" using the primitives we have available from Lemma 19.

Algorithm 4.4 ApproximateKruskal(G).

Data: Graph G on n vertices
Result: A forest $\widetilde{\mathcal{T}}$ using the edges of G.
Initialize $\widetilde{\mathcal{T}}$ to be the empty graph on n vertices.
InitializeDS(G).
while *GetTotalWeight*(G) > 0 **do**
  e = GetEdge()
  Contract(e)
  Add e to $\widetilde{\mathcal{T}}$.
end

It follows from Lemma 19 that ApproximateKruskal can be run in $O(n \log n)$ queries. Once we run ApproximateKruskal, we will have a spanning forest of G so we will also know its connected components. Moreover, the following lemma tells us that even this crude approximation to the MSF suffices to give us edge strength estimates. We defer the proofs of this lemma and its straightforward corollary to Appendix G.6.1 of the full version.

▶ **Lemma 25.** *For any distinct i, j, define $\tilde{d}_{i,j}$ as follows:*

- *If i, j are connected in G, then let $\tilde{d}_{i,j}$ be the minimum weight of an edge on the path in $\widetilde{\mathcal{T}}$ connecting i and j.*
- *Otherwise, let $\tilde{d}_{i,j} = 0$.*

Then for any i, j that are connected in G, we have $\frac{2}{n^2} d_{i,j} \leq \tilde{d}_{i,j} \leq d_{i,j}$ for all i, j.

Note that we only assume here that $\mathcal{T}$ is maximal; any assumptions we make about $\widetilde{\mathcal{T}}$ are baked into GetEdge.

▶ **Corollary 26.** *For all distinct i, j, we have $k_{i,j} \in [\tilde{d}_{i,j}, \frac{n^4}{2}\tilde{d}_{i,j}]$.*

4.3.2 Fast Weighted Subsampling

We now describe how to use our crude edge strength estimates to construct a sparsifier in $\tilde{O}(n)$ queries. The idea is that by Lemma 21, any edges with strength $< \kappa/2$ will be deleted in Step 2 of Algorithm 4.1. But we can use our crude edge strength estimates to preemptively identify some edges that will definitely be deleted, and then delete these edges to disconnect the graph a bit *before* running EstimateAndContract. We describe this procedure in Algorithm 4.5.

Algorithm 4.5 FastWeightedSubsample(G).

Data: Graph G on n vertices
Result: A potential (2ϵ)-sparsifier H of G.
Run ApproximateKruskal on a copy of G and calculate $\tilde{d}_{i,j}$ for all i, j.
Initialize L to a list of all nonzero values of $\tilde{d}_{i,j}$.
Initialize $\mathcal{C} = \emptyset$, $\kappa = \infty$, and X as an empty list.
InitializeDS(G).
while $L \neq \emptyset$ **do**
  Let $\tilde{D} = \max L$ and $C = \{(i, j) : \tilde{d}_{i,j} < \tilde{D}/(2n^5)\}$.
  Let $S_1, \ldots, S_r$ be the connected components of K_n after we remove all edges from C.
  Let κ' be the smallest power of 2 that is at least $n^4\tilde{D}/2$.
  $\kappa \leftarrow \min(\kappa, \kappa')$
  while $\kappa \geq \tilde{D}/(2n)$ **do**
    for $i \leftarrow 1$ **to** r **do**
      EstimateAndContract($G[S_i], \mathcal{C}, \kappa, X$)
      Remove all contracted edges from L.
    end
    $\kappa \leftarrow \kappa/2$
  end
end
$H \leftarrow$ ConstructSparsifier(G, X).

We make one comment here about FastWeightedSubsample: for the algorithm as presented to even be well-defined, we need to check that each S_i at any stage of the algorithm is the union of some collection of supernodes. If not, it does not make sense to run EstimateAndContract on each $G[S_i]$. This condition is also necessary to ensure the applicability of Lemma 19 to each call to EstimateAndContract; Contract, GetTotalWeight, and Sample all require that their input S be a union of supernodes. We defer the verification of this and the proof of our final theorem to Appendices G.7 (correctness) and G.8 (efficiency) of the full version:

▶ **Theorem 27.** *FastWeightedSubsample runs in* $O(n \log^3 n(\log n + \frac{1}{\epsilon^2}))$ *queries and outputs a* (2ϵ)*-sparsifier* H *with probability* $1 - O(n^{5-d})$.

▶ **Corollary 28.** *For any* $\epsilon > 0$*, the query complexity for a randomized algorithm to construct an* ϵ*-sparsifier with* $1 - o(1)$ *probability for a weighted undirected graph is* $\widetilde{O}(n)$*. This algorithm is adaptive.*

By Lemma 16, this yields our desired algorithmic result for max-cut:

▶ **Corollary 29.** *For any* $c < 1$*, the query complexity for a randomized algorithm to achieve a c-approximation with* $1 - o(1)$ *probability for global max-cut on a weighted undirected graph in the cut finding setting is* $\tilde{O}(n)$*. This algorithm is adaptive.*

We remind the reader that Theorem 27 extends the query-efficient sparsifier of [31] to weighted graphs (as we saw in Section 4.2, a naive generalization of [31] requires $\widetilde{O}(n \log W)$ queries).

One-Way Communication Complexity of Partial XOR Functions

Vladimir V. Podolskii

Dmitrii Sluch
Nebius, Tel Aviv, Israel

Abstract

Boolean function $F(x, y)$ for $x, y \in \{0,1\}^n$ is an XOR function if $F(x, y) = f(x \oplus y)$ for some function f on n input bits, where $\oplus$ is a bit-wise XOR. XOR functions are relevant in communication complexity, partially for allowing the Fourier analytic technique. For total XOR functions, it is known that deterministic communication complexity of F is closely related to parity decision tree complexity of f. Montanaro and Osbourne (2009) observed that one-way communication complexity $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ of F is exactly equal to non-adaptive parity decision tree complexity $\mathrm{NADT}^{\oplus}(f)$ of f. Hatami et al. (2018) showed that unrestricted communication complexity of F is polynomially related to parity decision tree complexity of f.

We initiate the study of a similar connection for partial functions. We show that in the case of one-way communication complexity whether these measures are equal, depends on the number of undefined inputs of f. More precisely, if $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = t$ and f is undefined on at most $O\left(\frac{2^{n-t}}{\sqrt{n-t}}\right)$ inputs, then $\mathrm{NADT}^{\oplus}(f) = t$. We also provide stronger bounds in extreme cases of small and large complexity.

We show that the restriction on the number of undefined inputs in these results is unavoidable. That is, for a wide range of values of $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ and $\mathrm{NADT}^{\oplus}(f)$ (from constant to $n-2$) we provide partial functions (with more than $\Omega\left(\frac{2^{n-t}}{\sqrt{n-t}}\right)$ undefined inputs, where $t = \mathrm{D}^{\rightarrow}_{\mathrm{cc}}$) for which $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) < \mathrm{NADT}^{\oplus}(f)$. In particular, we provide a function with an exponential gap between the two measures. Our separation results translate to the case of two-way communication complexity as well, in particular showing that the result of Hatami et al. (2018) cannot be generalized to partial functions.

Previous results for total functions heavily rely on the Boolean Fourier analysis and thus, the technique does not translate to partial functions. For the proofs of our results we build a linear algebraic framework instead. Separation results are proved through the reduction to covering codes.

1 Introduction

In communication complexity model two players, Alice and Bob, are computing some fixed function $F\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ on a given input (x, y). However, Alice knows only x and Bob knows only y. The main object of studies in communication complexity is the amount of communication $\mathrm{D}_{\mathrm{cc}}(F)$ needed between Alice and Bob to compute the function.

Function F is a XOR-function if for all $x, y \in \{0,1\}^n$ we have $F(x,y) = f(x \oplus y)$ for some $f\colon \{0,1\}^n \to \{0,1\}$, where $x \oplus y$ is a bit-wise XOR of Boolean vectors x and y. XOR-functions are important in communication complexity [27, 19, 25, 26, 3, 13, 15, 1, 23, 21, 5, 2, 8, 11, 9], on one hand, since there are important XOR-functions defined based on Hamming distance between x and y, and on the other hand, since the structure of XOR-functions allows for the Fourier analytic techniques. In particular, this connection suggests an approach for resolving Log-rank Conjecture for XOR-functions [27, 13].

In recent years there was considerable progress in the characterization of communication complexity of a XOR-function F in terms of the complexity of f in parity decision tree model. In this model the goal is to compute a fixed function f on an unknown input $x \in \{0,1\}^n$ and in one step we are allowed to query XOR of any subset of input bits. We want to minimize the number of queries that is enough to compute f on any input x. The complexity of f in this model is denoted by $\mathrm{DT}^{\oplus}(f)$. It was shown by Hatami et al. [13] that for any total f we have $\mathrm{D}_{\mathrm{cc}}(F) = \mathrm{poly}(\mathrm{DT}^{\oplus}(f))$.

Even stronger connection holds for one-way communication complexity case. In this setting only very restricted form of communication is allowed: Alice sends Bob a message based on x and Bob has to compute the output based on this message and y. We denote the complexity of F in this model by $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$. The relevant model of decision trees is the model of non-adaptive parity decision trees. In this model we still want to compute some function f on an unknown input and we still can query XORs of any subsets of input bits, but now all queries should be provided at once (in other words, each query cannot depend on the answers to the previous queries). The complexity of f in this model is denoted by $\mathrm{NADT}^{\oplus}(f)$. It follows from the results of Montanaro, Osbourne [19] and Gopalan et al. [10] that for any total XOR-function $F(x,y) = f(x \oplus y)$ we have $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = \mathrm{NADT}^{\oplus}(f)$.

These results on the connection between communication complexity and parity decision trees can be viewed as lifting results. This type of results have seen substantial progress in recent years (see [20]). The usual structure of a lifting result is that we start with a function f that is hard in some weak computational model (for example, a decision tree type model), compose it with some gadget function g to obtain $f \circ g$ (each variable of f is substituted by a copy of g defined on fresh variables) and show that $f \circ g$ is hard in a stronger computational model (for example, a communication complexity type model). The results on XOR-functions can be viewed as lifting results for $g = \mathrm{XOR}$.

The results on the connection between communication complexity of XOR-functions and parity decision trees discussed above are proved only for total functions f for the reason that the proofs heavily rely on the Fourier techniques. However, in communication complexity and decision tree complexity it is often relevant to consider a more general case of partial functions, and many lifting theorems apply to this type of functions as well, see e.g. [7, 17, 4, 22]. In particular, there are some lifting results for partial functions for gadgets that are stronger than XOR: Mande et al. [18] proved such a result for one-way case for inner product gadget (inner product is XOR applied to ANDs of pairs of variables) and Loff, Mukhopadhyay [17] proved a result on lifting with equality gadget for general case (note that equality for inputs of length 1 is practically XOR function). In [17] a conjecture is mentioned that for partial XOR-functions $\mathrm{D}_{\mathrm{cc}}(F)$ is approximately equal to $\mathrm{DT}^{\oplus}(f)$ as well.

Our results

In this paper we initiate the studies of the connection between communication complexity for the case of partial XOR functions and parity decision trees. It turns out that for one-way case whether they are equal depends on the number of inputs on which the function is undefined: if the number of undefined inputs is small, then the complexity measures are equal and if it is too large, they are not equal.

More specifically, we show that for $t = \mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ the equality $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = \mathrm{NADT}^{\oplus}(f)$ holds if f is undefined on at most $O\left(\frac{2^{n-t}}{\sqrt{n-t}}\right)$ inputs.

On the other hand, we provide a family of partial functions for which $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) < \mathrm{NADT}^{\oplus}(f)$[1]. More specifically, we show that for any constant $0 < c < 1$ there is a function f with $\mathrm{NADT}^{\oplus}(f) = cn$ and $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) \leq c'n$ for some $c' < c$.

The number of undefined inputs for the function is $O\left(\frac{2^{dn}}{\sqrt{n}}\right)$ if $c > 1/2$, is equal to 2^{n-1} if $c = 1/2$, and is $2^n - O\left(\frac{2^{dn}}{\sqrt{n}}\right)$ if $c < 1/2$, where $0 < d < 1$ is some constant (depending of c).

We provide a function f for which $\mathrm{NADT}^{\oplus}(f) = \sqrt{n \log n}$ and $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) \leq O(\log n)$, the number of undefined inputs for f is $2^n - 2^{\Theta(\sqrt{n}\log^{3/2} n)}$. Thus, we provide an exponential gap between the two measures.

We provide stronger bounds for small and large values of complexity. For $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = 1$ we show that the equality $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = \mathrm{NADT}^{\oplus}(f)$ is true for all partial f. For $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = 2$ the equality is true for at most $2^{n-3} - 1$ undefined inputs. The smallest values of measures for which we provide a separation are $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = 7$ and $\mathrm{NADT}^{\oplus}(f) = 8$. On the other end of the spectrum we show that for any partial function if $\mathrm{NADT}^{\oplus}(f) \geq n - 1$, then $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = \mathrm{NADT}^{\oplus}(f)$. The largest value of $\mathrm{NADT}^{\oplus}$ for which we provide a separation is $n - 2$, this complements the result that starting with $\mathrm{NADT}^{\oplus}(f) = n - 1$ the measures are equal.

All our separation results translate to the setting of two-way communication complexity vs. parity decision trees. In particular, we provide a partial function f with exponential gap between $\mathrm{D}_{\mathrm{cc}}(F)$ and $\mathrm{DT}^{\oplus}(f)$, which refutes the conjecture mentioned in [17]. It is an interesting open problem whether the polynomial relation between these measures discovered by Hatanami et al. for total functions holds for partial functions with some restriction on the number of undefined points.

The techniques behind the results on the connections between communication complexity of XOR-functions and parity decision tree complexity for total functions heavily rely on the Fourier analysis. However, it is not clear how to translate this technique to partial functions. To prove our results, we instead translate the Fourier-based approach of [19, 10] into the language of linear algebra. We design a framework to capture the notion of one-way communication complexity of partial XOR-functions and use this framework to establish equality of $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ and $\mathrm{NADT}^{\oplus}(f)$ for the small number of undefined points. The separation results can be proved using our framework, but in these version of the paper we provide self-contained proof. The separation results are proved by a reduction to the covering codes.

The rest of the paper is organized as follows. In Section 2 we provide necessary preliminary information and introduce the notations. In Section 3 we introduce our linear-algebraic framework. In Section 4 we prove main results on the equality of complexity measures. In Section 5 we prove separation results. In Section 6 we provide results for extreme cases. Some of the technical proofs are edited out of this version and can be found in the full paper `https://eccc.weizmann.ac.il/report/2023/157/`.

[1] Note that the gap in the other direction is impossible: it is easy to see that $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) \leq \mathrm{NADT}^{\oplus}(f)$ for all f (see Lemma 4 below). Similar inequality (with an extra factor of 2) holds for general communication complexity and parity decision tree complexity.

2 Preliminaries

2.1 Boolean cube

A Boolean cube is a graph on the set $\{0,1\}^n$ of Boolean strings of length n. We connect two vertices with an edge if they differ in a single bit only. The set $\{0,1\}^n$ can also be thought of as the vector space $\mathbb{F}_2^n$, with the bitwise XOR as the group operation. An inner product over this space can be defined as

$$\langle x, y\rangle = \bigoplus_i x_i \wedge y_i.$$

Hamming weight of x denoted $|x|$ is defined as the number of coordinates of x equal to 1. Hamming distance $\mathrm{dist}(x,y)$ between $x \in \{0,1\}^n$ and $y \in \{0,1\}^n$ is the number of coordinates at which x and y differ. The Hamming ball of radius r is a set of vertices of Boolean cube $\{0,1\}^n$ with Hamming weight not exceeding r. We denote by $V(n,r)$ the volume of a Hamming ball in $\{0,1\}^n$ of radius r.

2.2 Isoperimetric inequalities

▶ **Definition 1.** *For a set A we denote the set of neighbors of elements of A as ΓA. We denote $\Gamma' A := \Gamma A \setminus A$.*

We will need the vertex isoperimetric inequality for a Boolean cube known as Harper's theorem. To state it we first define Hales order.

▶ **Definition 2** (Hales order [12, Page 56])**.** *Consider two subsets $x, y \subseteq [m]$ for some natural m. We define $x \prec y$ if $|x| < |y|$ or $|x| = |y|$ and the smallest element of the symmetric difference of x and y belongs to x. In other words, there exists an i such that $i \in x, i \notin y$, and i is the smallest element in which x and y differ. Here is an example of Hales order for $m = 4$:*

$$\varnothing, \{1\}, \{2\}, \{3\}, \{4\}, \{1,2\}, \{1,3\}, \{1,4\}, \{2,3\}, \{2,4\}, \{3,4\},$$
$$\{1,2,3\}, \{1,2,4\}, \{1,3,4\}, \{2,3,4\}, \{1,2,3,4\}.$$

We can induce Hales order on the set $\{0,1\}^m$ by identifying subsets of $[m]$ with their characteristic vectors. We define I_a^m to be the set of the first a elements of $\{0,1\}^m$ in Hales order.

▶ **Theorem 3** (Harper's theorem [12, Theorem 4.2])**.** *Let $A \subseteq \{0,1\}^m$ be a subset of vertices of m-dimensional Boolean cube and denote $a = |A|$. Then $|\Gamma A| \geq |\Gamma I_a^m|$.*

2.3 Communication Complexity and Decision Trees

Throughout this paper, f denotes a partial function $\{0,1\}^n \to \{0,1,\perp\}$, we let $\mathrm{Dom}(f) = f^{-1}(\{0,1\})$. We define an XOR-function $F : \{0,1\}^n \times \{0,1\}^n \to \{0,1,\perp\}$ as

$$F(x,y) = f(x \oplus y).$$

In communication complexity model two players, Alice and Bob, are computing some fixed function $F\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ on a given input (x,y). However, Alice knows only x and Bob knows only y. The main subject of studies in communication complexity is the amount of communication $\mathrm{D}_{\mathrm{cc}}(F)$ needed between Alice and Bob to compute the function. Formal definition of the model can be found in [16].

We will be mostly interested the in one-way communication model. This is a substantially restricted setting, in which only Alice is permitted to send bits to Bob. Formally, the one-way communication complexity $D^{\rightarrow}_{cc}(F)$ is defined to be the smallest integer t, allowing for a protocol where Alice knowing her input x sends t bits to Bob, which together with Bob's input y enable Bob to calculate the value of F.

The bits communicated by Alice depend only on x, that is Alice's message to Bob is $h(x)$ for some fixed total function $h\colon \{0,1\}^n \to \{0,1\}^t$. Bob computes the output $F(x,y)$ based on $h(x)$ and his input y. That is, Bob outputs $\varphi(h(x),y)$ for some fixed total function $\varphi\colon \{0,1\}^t \times \{0,1\}^n \to \{0,1\}$. If (x,y) is within the domain of F, then the equality $\varphi(h(x),y) = F(x,y)$ must be true.

The notion of parity decision tree complexity is a generalization of the well-known decision tree complexity model. In this model, to evaluate a function f for a given input x the protocol queries the parities of some subsets of the bits in x. The cost of the protocol on specified input x is the number of queries the protocol makes on that input. The cost of the protocol (sometimes referred to as the worst-case cost) is maximum over all inputs x, costs of protocol on the input x. The complexity of problem f in the model of parity decision trees $\mathrm{DT}^{\oplus}(f)$ is the minimal over all valid protocols, cost of a protocol for f.

We consider the non-adaptive parity decision tree complexity $\mathrm{NADT}^{\oplus}(f)$. This version differs from its adaptive counterpart in that all the queries should be fixed at once. In other words, each next query should not depend on the answers to previous queries. Next, we give a more formal definition of $\mathrm{NADT}^{\oplus}(f)$.

The protocol of complexity p is defined by n-bit strings $s_1,\dots,s_p$ and a total function $l\colon \{0,1\}^p \to \{0,1\}$. On input x the protocol queries the values of

$$\langle s_1, x\rangle, \dots, \langle s_p, x\rangle$$

and outputs

$$l(\langle s_1, x\rangle, \dots, \langle s_p, x\rangle).$$

The protocol computes partial function f, if for any $x \in \mathrm{Dom}(f)$ we have

$$l(\langle s_1, x\rangle, \dots, \langle s_p, x\rangle) = f(x).$$

Throughout the paper $t, h, \varphi, p, s_1, \dots, s_p, l$ have the same meaning as defined above.

It is easy to see that there is a simple relation between $\mathrm{NADT}^{\oplus}(f)$ and $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$.

▶ **Lemma 4.** *For any f we have $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) \le \mathrm{NADT}^{\oplus}(f)$.*

Proof. Alice and Bob can compute $F(x,y)$ by a simple simulation of $\mathrm{NADT}^{\oplus}$ protocol for f. The idea is that they privately calculate the parities of their respective inputs according to $\mathrm{NADT}^{\oplus}$ protocol, then Alice sends the computed values to Bob, who XORs them with his own parities, and then computes the value of F.

More formally, assume that $\mathrm{NADT}^{\oplus}(f) = p$ and the corresponding protocol is given by $s_1,\dots,s_p \in \{0,1\}^n$ and a function l, that is

$$\forall x \in \mathrm{Dom}(f), f(x) = l(\langle s_1, x\rangle, \dots, \langle s_p, x\rangle).$$

For $i \in [p]$, we let

$$h_i(x) := \langle s_i, x\rangle.$$

For the communication protocol of complexity p we let

$$h(x) = (h_1(x), \dots, h_p(x)),$$
$$\varphi(a, y) := l(a_1 \oplus \langle s_1, y\rangle, \dots, a_p \oplus \langle s_p, y\rangle).$$

Then for any (x, y) such that $x \oplus y \in \mathrm{Dom}(f)$ we have

$$\begin{aligned}\varphi(h(x), y) = l(h_1(x) \oplus \langle s_1, y\rangle, \dots, h_p(x) \oplus \langle s_p, y\rangle) = \\ l(\langle s_1, x\rangle \oplus \langle s_1, y\rangle, \dots, \langle s_p, x\rangle \oplus \langle s_p, y\rangle) = \\ l(\langle s_1, x \oplus y\rangle, \dots, \langle s_p, x \oplus y\rangle) = f(x \oplus y) = F(x, y).\end{aligned}$$

We constructed a p-bit communication protocol for F, and thus

$$\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) \le p = \mathrm{NADT}^{\oplus}(f). \qquad \blacktriangleleft$$

In this paper, we are mainly interested in whether the inequality in the opposite direction is true.

2.4 Covering Codes

▶ **Definition 5.** *A subset $\mathcal{C} \subseteq \{0,1\}^n$ is a (n, K, R) covering code if $|\mathcal{C}| \le K$ and for any $x \in \{0,1\}^n$ there is $c \in \mathcal{C}$ such that $\mathrm{dist}(x, c) \le R$. In other words, all points in $\{0,1\}^n$ are covered by balls of radius R with centers in $\mathcal{C}$.*

The following general bounds on K are known for covering codes.

▶ **Theorem 6** ([6, Theorem 12.1.2])**.** *For any (n, K, R) covering code we have*

$$\log K \ge n - \log V(n, R).$$

For any n and any $R \le n$ there is a (n, K, R) covering code with

$$\log K \le n - \log V(n, R) + \log n.$$

We will use the following well known fact.

▶ **Theorem 7** ([6, Section 2.6])**.** *If $n = 2^m - 1$ for some m, then Boolean cube $\{0,1\}^n$ can be splitted into disjoint balls of radius 1.*

This construction is known as a Hamming error correcting code. Note that it is a $(n = 2^m - 1, \frac{2^n}{n+1}, 1)$ covering code.

▶ **Definition 8.** *For two covering codes $\mathcal{C}_1$ and $\mathcal{C}_2$ their direct sum is*

$$\mathcal{C}_1 \oplus \mathcal{C}_2 = \{(c_1, c_2) \mid c_1 \in \mathcal{C}_1, c_2 \in \mathcal{C}_2\}.$$

▶ **Lemma 9** ([6, Theorem 12.1.2])**.** *If $\mathcal{C}_1$ is a (n_1, K_1, R_1) covering code and $\mathcal{C}_2$ is a (n_2, K_2, R_2) covering code, then $\mathcal{C}_1 \oplus \mathcal{C}_2$ has parameters $(n_1 + n_2, K_1K_2, R_1 + R_2)$.*

We need the following bounds on the sizes of Hamming balls (see, e.g. [14, Appendix A]).

▶ **Lemma 10.** *For any n and $k \le n$ we have*

$$\left(\frac{n}{k}\right)^k \le V(n, k) \le \left(\frac{en}{k}\right)^k.$$

▶ **Lemma 11.** *For any constant $0 < c < 1$ we have*

$$\binom{n}{cn} = O\left(\frac{1}{\sqrt{n}} 2^{H(c)n}\right).$$

For any constant $0 < c < 1/2$ we have

$$V(n, cn) = O\left(\frac{1}{\sqrt{n}} 2^{H(c)n}\right),$$

where H is the binary entropy function.

▶ **Lemma 12** ([24, Section 5.4])**.**

$$V\left(n, \frac{n}{2} - \Theta(\sqrt{n \log n})\right) = \frac{2^n}{poly(n)}.$$

For the binary entropy function $H(x)$ we will use the following simple fact.

▶ **Lemma 13.** *For any constant $c \in (0, 1)$ and for any $\alpha_n \xrightarrow[n\to\infty]{} 0$ we have*

$$H(c + \alpha_n) = H(c) + O(\alpha_n),$$

where the constant in O-notation might depend on c, but not on n.

This is true since the derivative of H is upper bounded by a constant in any small enough neighborhood of c.

3 Linear-algebraic framework

3.1 Graph-based analysis of one-way communication protocols

Recall that in a one-way communication protocol of complexity t for $F(x, y) = f(x \oplus y)$ Alice on input $x \in \{0,1\}^n$ first sends to Bob $h(x)$ for some fixed $h\colon \{0,1\}^n \to \{0,1\}^t$. After that Bob computes the output $\varphi(h(x), y)$, where $y \in \{0,1\}^n$ is Bob's input and $\varphi\colon \{0,1\}^t \times \{0,1\}^n \to \{0,1\}$.

Let's consider the partition $\mathcal{H} = \{H_a \mid a \in \{0,1\}^t\}$, where for any $a \in \{0,1\}^t$

$$H_a = h^{-1}(a).$$

We refer to $\mathcal{H}$ as *h-induced partition*. A class H_a of this partition is the set of inputs for which Alice sends Bob the same message.

Consider two arbitrary inputs $x, y \in \{0,1\}^n$. We call the vector $\Delta = x \oplus y$ the *shift* between x and y. The intuition is that y is equal to the shift $x \oplus \Delta$ of x by y (and vise versa).

We say that $\Delta \in \{0,1\}^n$ is a *good shift* if there is a pair $x, y \in \{0,1\}^n$ such that $x \oplus y = \Delta$ and $h(x) = h(y)$, or equivalently, if x and y belong to the same class of $\mathcal{H}$. Note that f does not necessarily need to be defined on inputs x and y. However, it turns out that on the domain of f the value of f is invariant under good shifts.

▶ **Lemma 14.** *Assume that Δ is a good shift. Consider any $v, u \in \mathrm{Dom}(f)$ such that $v \oplus u = \Delta$. Then, $f(v) = f(u)$.*

Proof. Since Δ is good, there are x and y such that $h(x) = h(y)$ and $x \oplus y = \Delta$. Then

$$f(v) = \varphi(h(x), x \oplus v) = \varphi(h(y), x \oplus v) = f(v \oplus x \oplus y) = f(v \oplus \Delta) = f(u). \quad \blacktriangleleft$$

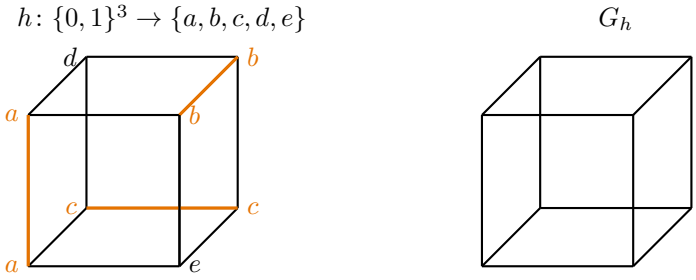

Figure 1 Example of total h-induced graph.

This leads us to the following notion.

▶ **Definition 15.** *For the functions $f : \{0,1\}^n \to \{0,1\}$, $f(x \oplus y) = \varphi(h(x), y)$ let the* total h-induced graph *be the graph with vertices $\{0,1\}^n$ and with an edge between $x \in \{0,1\}^n$ and $y \in \{0,1\}^n$ if $x \oplus y$ is a good shift for h. Now remove vertices where the function f is undefined. The resulting graph is called the* partial h-induced graph.

There is an alternative way of thinking about total h-induced graph. Consider a graph with vertices labeled $\{0,1\}^n$ in which we connect two vertices if the value of h on these vertices is the same. Clearly it is a subgraph of the total h-induced graph. Now consider a shift of this graph, that is, a graph in which we XORed labels of all vertices with some fixed vector. This graph is also a subset of the total h-induced graph. By considering all possible shifts and taking the union of all graphs we will get the total h-induced graph. See Figure 1 for an example of total h-induced graph.

By transitivity, if (h, φ) form a valid communication protocol then f assigns identical values to each connected component in partial h-induced graph. The converse is also true.

▶ **Theorem 16.** *Consider a function $f : \{0,1\}^n \to \{0,1\}$. For a function $h : \{0,1\}^n \to \{0,1\}^t$ there is a function $\varphi : \{0,1\}^t \times \{0,1\}^n \to \{0,1\}$ such that (h, φ) form a valid communication protocol for f if and only if f assigns the same value to each connected component in the partial h-induced graph.*

Proof. As discussed above, if (h, φ) forms a valid communication protocol, then f assigns the same value to each connected component of the partial h-induced graph.

It remains to prove the converse statement. We assume that f assigns the same value to each connected component and we need to show that there is φ such that

$$\forall (x, y) \in \mathrm{Dom}(F), \quad F(x, y) = \varphi(h(x), y).$$

The proof idea is the following. Each input $(x, y) \in \{0,1\}^n \times \{0,1\}^n$ to F yields an input $(a, y) \in \{0,1\}^t \times \{0,1\}^n$ to φ where $\alpha = h(x)$. We define φ on (α, y) to be equal to F on a single corresponding F-input (x', y) with $x' \in h^{-1}(\alpha)$. Then we prove that φ defined that way gives a communication protocol computing F correctly on all inputs $(x, y) \in \mathrm{Dom}(f)$

Formally, we define φ as follows. For each $\alpha \in \{0,1\}^t$ and $y \in \{0,1\}^n$, consider $x' \in \{0,1\}^n$ such that $h(x') = \alpha$ and $(x', y) \in \mathrm{Dom}(F)$. If there is no such x' we define $\varphi(\alpha, y)$ arbitrarily. If there is such an x', let

$$\varphi(\alpha, y) := F(x', y).$$

Now we show that the resulting protocol computes $F(x, y)$ correctly for any (x, y).

Consider arbitrary $(x, y) \in \mathrm{Dom}(F)$. Consider x' chosen for $\alpha = h(x)$ and y (it exists, since clearly x itself satisfies all the necessary conditions).

Thus, we have

$$\varphi(h(x), y) = F(x', y).$$

It remains to prove that

$$F(x', y) = F(x, y)$$

or equivalently,

$$f(x' \oplus y) = f(x \oplus y).$$

For XOR of these two inputs of f we have

$$(x' \oplus y) \oplus (x \oplus y) = x' \oplus x.$$

Since $h(x) = h(x')$, we have that $x' \oplus x$ is a good shift. And since

$$(x, y), (x', y) \in \mathrm{Dom}(F),$$

we have

$$x \oplus y, x' \oplus y \in \mathrm{Dom}(f).$$

We have that vertices $x \oplus y$ and $x' \oplus y$ are connected in the partial h-induced graph and by Lemma 14 f assigns the same value to them. Hence, the function φ, together with h, forms a communication protocol for F. ◀

3.2 Using coset structures on a Boolean cube to analyze non-adaptive parity decision trees

We consider the vertices of the Boolean cube as a vector space $\mathbb{F}_2^n$. We show that a NADT$^{\oplus}$ protocol corresponds to a linear subspace of $\mathbb{F}_2^n$ such that f is constant on each of its cosets (the coset for a linear subspace L and a vector l is defined as the set $\{x + l | l \in L\}$ and denoted $L + l$).

▶ **Theorem 17.** *Let $f\colon \{0,1\}^n \to \{0,1\}$. There is a p-bit* NADT$^{\oplus}$ *protocol for f if and only if there exists an $n - p$ dimensional subspace of $\{0,1\}^n$ such that for each coset of that subspace, f assigns the same value to all inputs of the coset where f is defined.*

Proof. Suppose $s_1, \ldots, s_p, l$ form a valid NADT$^{\oplus}$ protocol for f. We construct a matrix S with rows $s_1, \ldots, s_p$. If some of the rows are linearly dependent, we add rows arbitrarily to make the rank of S equal to p. When S is multiplied on the right by some vector x, we obtain all inner products of x with vectors $s_1, \ldots, s_p$ (and possibly other bits if we added rows).

Consider the vector subspace $\{x | Sx = 0\}$. This is an $n - p$ dimensional space. For all points in the same coset of this subspace, the tuple consisting of values of the inner products $(\langle s_1, x\rangle, \ldots, \langle s_p, x\rangle)$ is the same, so is the value of $l(\langle s_1, x\rangle, \ldots, \langle s_p, x\rangle)$. For all points where f is defined and lying in the same coset, the value of f must be equal to the value of l and thus the same for all points in the coset.

In the reverse direction, let $\langle e_1, \ldots, e_{n-p} \rangle$ be an $n-p$ dimensional subspace of $\{0,1\}^n$ such that for each of its cosets f is constant on all points of that coset on which it is defined. We can represent this subspace in the form $\{x | Sx = 0\}$ for some matrix S of size $p \times n$.

Vectors x and y are in the same coset of $\langle e_1, \ldots, e_{n-p} \rangle$ iff $Sx = Sy$. Thus, to compute $f(x)$ it is enough to compute the inner product of x with the rows of S. ◀

▶ **Corollary 18.** *Consider a function $f : \{0,1\}^n \to \{0,1\}$ having valid communication protocol $f(x \oplus y) = \varphi(h(x), y)$ where $h : \{0,1\}^n \to \{0,1\}^t, \varphi : \{0,1\}^t \times \{0,1\}^n \to \{0,1\}$. Suppose there is an $n-t$ dimensional subspace L of $\{0,1\}^n$ and consider subgraphs of partial h-induced graph each over vertices belonging to different cosets of L. If all of these subgraphs are connected then $\mathrm{NADT}^{\oplus}(f) \leq t$.*

Proof. By Theorem 16 f is constant on each coset. By Theorem 17 it follows that $\mathrm{NADT}^{\oplus}(f) \leq t$. ◀

4 Equality between $\mathrm{D}^{\to}_{\mathrm{cc}}(F)$ and $\mathrm{NADT}^{\oplus}(f)$

In this section we will show that if $\mathrm{D}^{\to}_{\mathrm{cc}}(F) = t$ and the number of undefined inputs is small, then $\mathrm{NADT}^{\oplus}(f) = t$ as well. More specifically, we prove the following theorem.

▶ **Theorem 19.** *If for the function $f\colon \{0,1\}^n \to \{0,1\}$ we have $\mathrm{D}^{\to}_{\mathrm{cc}}(F) = t$, where $F(x,y) = f(x \oplus y)$, and f is undefined on less than $\binom{n-t+1}{\lfloor \frac{n-t}{2} \rfloor - 1}$ inputs, then $\mathrm{NADT}^{\oplus}(f) = t$.*

By Lemma 11 we have that $\binom{n-t+1}{\lfloor \frac{n-t+1}{2} \rfloor} = O(\frac{2^{n-t}}{\sqrt{n-t}})$ and since $\lfloor \frac{n-t}{2} \rfloor - 1$ differs from $\lfloor \frac{n-t+1}{2} \rfloor$ by only a constant, it is easy to see that the same estimate applies to $\binom{n-t+1}{\lfloor \frac{n-t}{2} \rfloor - 1}$ as well. Thus, the number of undefined inputs is $O(\frac{2^{n-t}}{\sqrt{n-t}})$.

The rest of the section is devoted to the proof of Theorem 19. The idea of the proof is as follows. Consider the h-induced partition $\mathcal{H}$ corresponding to the communication protocol of complexity t. We show that either the partition $\mathcal{H}$ corresponds to the cosets of an $n-t$ dimensional subspace of $\{0,1\}^n$, which allows us to construct an $\mathrm{NADT}^{\oplus}$ protocol, or there exist *many* good shifts. The structure of these good shifts imposes restrictions on f that again allow us to construct an $\mathrm{NADT}^{\oplus}$ protocol.

We start with a simple case.

▶ **Lemma 20.** *If there exists t-bit communication protocol, (h, φ) for a function $f\colon \{0,1\}^n \to \{0,1\}$, and the h-induced partition $\mathcal{H}$ corresponds to cosets of an $n-t$ dimensional subspace L of $\{0,1\}^n$, then $\mathrm{NADT}^{\oplus}(f) \leq t$.*

Proof. Since the partition $\mathcal{H}$ corresponds to the cosets of L, we have that for any inputs x and y, if $h(x) = h(y)$, then $x \oplus y \in L$ and vice versa. In other words, all good shifts are in L and any shift in L is good. Thus, connected components of the total h-induced graph are cosets of L and are fully connected. By Corollary 18 we have that $\mathrm{NADT}^{\oplus}(f) \leq t$. ◀

The structure of the proof for the other case is the following. We show that the total h-induced graph is structured into connected components, each of which is a coset of a k-dimensional subspace of $\{0,1\}^n$ for $k \geq n-t$. We show that there is a bijective graph homomorphism of the k-dimensional Boolean cube onto each component. Furthermore, each vertex in the total h-induced graph has a degree of at least $\frac{2^n}{2^t} - 1$. We show that if we remove fewer than $\binom{n-t+1}{\lfloor \frac{n-t}{2} \rfloor - 1}$ vertices, each coset still contains one connected component. By the way of contradiction, suppose this is not the case and some coset contains more than one

connected component. We consider the smallest of these components, denote the set of its nodes by S. We show that the number of neighboring vertices of S in the total h-induced graph (excluding S itself) is not less than $\binom{n-t+1}{\lfloor\frac{n-t}{2}\rfloor-1}$. This implies that after removing the undefined inputs of f S cannot not be separated from other nodes in the coset. To show this we treat separately cases of large and small $|S|$. For small $|S|$ we use the fact that vertices have high degree. For large $|S|$ we use the vertex-isoperimetric inequality for the Boolean cube.

▶ **Lemma 21.** *Suppose there exists a t-bit communication protocol (h, φ) for $f\colon \{0,1\}^n \to \{0,1\}$ and the h-induced partition $\mathcal{H}$ classes do not correspond to cosets of an $n-t$-dimensional subspace of $\{0,1\}^n$. Let D be the set of good shifts for h. Then D contains a minimum of $n-t+1$ linearly independent vectors.*

Proof. Suppose there are at most $n-t$ linearly independent good shifts $e_1, \dots, e_{n-t}$. Consider a linear subspace of $\{0,1\}^n$ spanned over by these shifts and add some vectors to it to make it exactly $n-t$ dimensional if needed. Denote the resulting subspace L. As classes of $\mathcal{H}$ do not correspond to the cosets of L and there are 2^t of both classes and cosets there exist two elements belonging to the same class and different cosets. Their XOR is a good shift linearly independent with $e_1, \dots, e_{n-t}$. We got a contradiction implying the lemma. ◀

▶ **Lemma 22.** *Suppose there exists t-bit communication protocol (h, φ) for f. Let D be the set of all good shifts for h and $\{e_1, \dots, e_k\}$ be the largest linearly independent subset of D. Then the total h-induced graph $\mathcal{H}$ has the following properties.*

- *Cosets of the subspace $\langle e_1, \dots, e_k\rangle$ are connected components of $\mathcal{H}$.*
- *There is a bijective graph homomorphism of k-dimensional Boolean cube into each coset.*

Proof. It is easy to see that all vertices in any coset are connected to each other. Let's show that no edges exist between vertices of different cosets. Assume by contradiction that there is an edge between vertices v and u from different cosets. Note that $u \oplus v \notin \langle e_1, \dots, e_k\rangle$. Thus, vectors $e_1, \dots, e_k, u \oplus v$ form a linearly independent system of size $k+1$, which is a contradiction.

Now, let's construct a homomorphism q from the Boolean cube $\{0,1\}^k$ into the coset $v + \langle e_1, \dots, e_k\rangle$ for an arbitrary vertex v. Consider a matrix B that has vectors $e_1, \dots, e_k$ as its columns and let $q(x) = v \oplus Bx$. The image of q is within the coset $v + \langle e_1, \dots, e_k\rangle$, as columns of B belong to the subspace $\langle e_1, \dots, e_k\rangle$. The mapping is bijective on $v + \langle e_1, \dots, e_k\rangle$, as B's columns are linearly independent. Finally, consider a pair of vertices x, y adjacent in a Boolean cube. Since the vertices are adjacent, they only differ in a single bit i. Thus,

$$q(x) \oplus q(y) = (v \oplus Bx) \oplus (v \oplus By) = B(x \oplus y) = e_i.$$

Since $e_i \in D$, an edge exists between $q(x)$ and $q(y)$, implying that q is a graph homomorphism. ◀

▶ **Lemma 23.** *Suppose there exists t-bit communication protocol (h, φ) for $f\colon \{0,1\}^n \to \{0,1\}$. Then in the total h-induced graph, the degree of any vertex is not less than $\frac{2^n}{2^t} - 1$.*

Proof. Let's consider the largest class in the h-induced partition $\mathcal{H}$. Since the number of classes is at most 2^t, the largest class contains at least $\frac{2^n}{2^t}$ elements. Fix an element of the class and compute its XOR with all elements in the same class $\mathcal{H}$. We have $\frac{2^n}{2^t}$ XORs in total, $\frac{2^n}{2^t} - 1$ of which are non-zero. Since each XOR is computed between elements in the same class, these XORs are good shifts. For all vertices in the h-induced graph for each good shift we draw an edge from the vertex corresponding to this shift. Therefore, the degree of any vertex is at least $\frac{2^n}{2^t} - 1$. ◀

▶ **Lemma 24.** *If A is a subset of k-dimensional Boolean cube satisfying $V\left(m, \left\lfloor \frac{m-1}{2} \right\rfloor - 2\right) \leq |A| \leq 2^{k-1}$ for some m, then $|\Gamma' A| \geq \binom{m}{\left\lfloor \frac{m-1}{2} \right\rfloor - 1}$.*

The proof of the lemma can be found in the full version of the paper. The proof heavily relies on Theorem 3. Finally, we are ready to prove Theorem 19.

Proof of Theorem 19. We are given t-bit communication protocol (h, φ) for F. By Lemma 21, the h-induced partition $\mathcal{H}$ either corresponds to cosets of an $n-t$ dimensional subspace of $\{0,1\}^n$ (and then by Lemma 20 we have $\mathrm{NADT}^{\oplus}(f) \leq t$), or the set of good shifts D contains at least $n-t+1$ linearly independent vectors. Let $\langle e_1, \ldots, e_k \rangle$, where $k \geq n-t+1$, be the largest subset of linearly independent vectors in D. Consider the cosets of the subspace $\langle e_1, \ldots, e_k \rangle$. We will show that if we remove fewer than $\binom{n-t+1}{\left\lfloor \frac{n-t}{2} \right\rfloor - 1}$ vertices from the total h-induced graph, each coset will contain no more than one connected component. Assume by contradiction that after removing the vertices, some coset splits into several connected components. Let A be the smallest of these components. If there are at most $V(n-t+1, \lfloor \frac{n-t}{2} \rfloor - 2) - 1$ vertices in A, consider a vertex a in A. Given the degree of a is at least $2^{n-t} - 1$, a has at least

$$2^{n-t} - V\left(n-t+1, \left\lfloor \frac{n-t}{2} \right\rfloor - 2\right) \geq V\left(n-t+1, \left\lfloor \frac{n-t}{2} \right\rfloor\right) - V\left(n-t+1, \left\lfloor \frac{n-t}{2} \right\rfloor - 2\right) \geq \binom{n-t+1}{\left\lfloor \frac{n-t}{2} \right\rfloor - 1}$$

neighbors outside A.

On the other hand, suppose A has at least $V(n-t+1, \lfloor \frac{n-t}{2} \rfloor - 2)$ vertices. Since A is the smallest connected component in its coset it also follows that A has no more than 2^{k-1} vertices. By Lemma 24 we have $|\Gamma' A| \geq \binom{n-t+1}{\left\lfloor \frac{n-t}{2} \right\rfloor - 1}$, which is more than the number of removed vertices, a contradiction. Thus, cosets cannot be split into several components and by Corollary 18 we have $\mathrm{NADT}^{\oplus}(f) \leq n-k \leq t-1$, which is a contradiction. ◀

5 Separations between $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ and $\mathrm{NADT}^{\oplus}(f)$

In this section we show that if the number of undefined inputs is large, there is a gap between $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ and $\mathrm{NADT}^{\oplus}(f)$. That is, we aim to come up with a function f such that $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F)$ is small and $\mathrm{NADT}^{\oplus}(f)$ is large.

The key idea in our construction is that in h-induced graph for the intended communication protocol the edges connect only vertices with small Hamming distance between them. Then, if the function f has 0-inputs and 1-inputs far away from each other, they are not connected and h corresponds to a valid protocol. We will ensure that at the same time f has large $\mathrm{NADT}^{\oplus}$ complexity.

We start with the construction of the functions, then investigate their $\mathrm{NADT}^{\oplus}$ complexity and then prove upper bounds on $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}$ complexity of the corresponding XOR functions. The latter part is through the reduction to covering codes.

▶ **Definition 25.** *For a parameter k define $f_k \colon \{0,1\}^n \to \{0,1,\perp\}$ in the following way.*

$$f_k(x) = \begin{cases} 0 & \text{for } |x| \leq k, \\ \perp & \text{for } k+1 \leq |x| \leq n-1, \\ 1 & \text{for } |x| = n. \end{cases}$$

We denote the corresponding XOR function by F_k.

Note, that the number of undefined inputs in f_k is $V(n, n-k-1)-1$.

It turns out that f_k has reasonably large $\mathrm{NADT}^{\oplus}$ and $\mathrm{DT}^{\oplus}$ complexities.

▶ **Theorem 26.** $\mathrm{NADT}^{\oplus}(f_k) = \mathrm{DT}^{\oplus}(f_k) = k+1$.

Proof. Since $\mathrm{DT}^{\oplus}(f) \le \mathrm{NADT}^{\oplus}(f)$ for any f, it is enough to prove that $\mathrm{NADT}^{\oplus}(f_k) \le k+1$ and $\mathrm{DT}^{\oplus}(f_k) \ge k+1$.

For the upper bound, observe that it is enough to query variables $x_1, \dots, x_{k+1}$. If all of them are equal to 1, we output 1, otherwise we output 0. It is easy to see that this protocol computes f_k correctly.

For the lower bound suppose, for the sake of contradiction, that an adaptive parity decision tree exists that can compute the function f with k or fewer queries. Consider the path corresponding to the input $e = (1, \dots, 1)$. Let's assume that the decision tree queried the parities $\langle s_i, e\rangle$ for $s_1, \dots, s_k$. The answers to the queries are equal to $\langle s_1, e\rangle, \dots, \langle s_k, e\rangle$. Consider a matrix $B \subseteq \mathbb{F}^{k\times n}$ consisting of rows $s_1, \dots, s_k$.

Denote $a = Be$. In particular, we have that a lies in the subspace generated by columns of B. Since the rank of B is at most k (the matrix has k rows), there is a subset of at most k columns generating this subspace. In particular, there is $x \in \{0,1\}^n$ with $|x| \le k$, such that $a = Bx$. That is, $Be = Bx$ and the protocol behaves the same way on e and x, which is a contradiction, since $f_k(e) = 1$ and $f_k(x) = 0$. ◀

▶ Remark 27. Since f_k has large (adaptive) parity decision tree complexity and for any $F : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ we have $\mathrm{D}^{\to}_{\mathrm{cc}}(F) \ge \mathrm{D}_{\mathrm{cc}}(F)$, all separations provided by functions f_k translate into the same separations between $\mathrm{DT}^{\oplus}$ and D_{cc}.

Next, we proceed to the upper bound on the $\mathrm{D}^{\to}_{\mathrm{cc}}(F_k)$.

▶ **Theorem 28.** *Suppose for some n, k and t there is a $(n, 2^t, R)$ covering code $\mathcal{C}$ for $R = \left\lfloor \frac{n-k-1}{2} \right\rfloor$. Then, $\mathrm{D}^{\to}_{\mathrm{cc}}(F_k) \le t$.*

Proof. Split the points of $\{0,1\}^n$ into balls with radius R with centers in the points of $\mathcal{C}$ (if some point belongs to several balls, attribute it to one of them arbitrarily). This results in a partition of the cube into 2^t subsets with the diameter of each subset at most $n-k-1$.

The proof can be finished through Theorem 16, but to make it more self-contained we directly describe communication protocol.

On input x Alice sends as $h(x)$ the index of the ball containing x. Bob computes $\neg y$, componentwise negation of y, and outputs 1 if it is in the same ball. If this is not the case, Bob outputs 0.

Clearly, the complexity of this protocol is at most t. For the correctness of the protocol, if $f(x \oplus y) = 1$, then $x = \neg y$ and the protocol clearly outputs 1. However, if $f(x \oplus y) = 0$, then $|x \oplus y| \le k$ and thus $\mathrm{dist}(x, \neg y) \ge n-k$. In this case x and $\neg y$ are not in the same ball and the protocol outputs 0. ◀

▶ **Theorem 29.** *For any n and k we have*

$$\mathrm{D}^{\to}_{\mathrm{cc}}(F_k) \le n - \log V(n, R) + \log n$$

for $R = \left\lfloor \frac{n-k-1}{2} \right\rfloor$.

Proof. By Theorem 6 there exists a $(n, 2^t, R)$ covering code for

$$\log 2^t = t \le n - \log V(n, R) + \log n.$$

The theorem follows from Theorem 28. ◀

From this we can get a separation for a wide range of parameters.

▶ **Corollary 30.** *Suppose $k = cn$ for some constant $0 < c < 1$. Then* $\mathrm{NADT}^{\oplus}(f_k) = cn + 1$ *and*

$$\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_k) \leq \left(1 - H\left(\frac{1-c}{2}\right)\right) n + O(\log n).$$

In particular, $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_k) < \mathrm{NADT}^{\oplus}(f_k)$. *The number of undefined inputs for f_k is $2^n - O(\frac{2^{H(c)n}}{\sqrt{n}})$ if $c < 1/2$, is equal to $(1 + o(1))2^{n-1}$ if $c = 1/2$, and is $O(\frac{2^{H(1-c)n}}{\sqrt{n}})$ if $c > 1/2$.*

Proof. The equality for $\mathrm{NADT}^{\oplus}$ is proved in Theorem 26.

For communication complexity bound we apply Theorem 29. We have $R = \left\lfloor \frac{(1-c)n-1}{2} \right\rfloor = \frac{(1-c)n}{2} + O(1)$ and by Lemmas 11 and 13 we have

$$\log V(n, R) = H\left(\frac{1-c}{2}\right) n - O(\log n).$$

By Theorem 29 we have

$$\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_k) \leq n - \log V(n, R) + \log n = \left(1 - H\left(\frac{1-c}{2}\right)\right) n + O(\log n).$$

To show that $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_k) < \mathrm{NADT}^{\oplus}(f_k)$ we need to compare $k = cn$ with the bound on communication complexity. It is easy to see that

$$1 - H\left(\frac{1-c}{2}\right) < c$$

for all $0 < c < 1$ (the left hand-side and the right hand-side are equal for $c = 0$ and $c = 1$ and the left hand-side is concave in c).

The bounds on the number of undefined inputs follow easily from Lemma 11. ◀

The largest gap we can get is the following.

▶ **Corollary 31.** *For $k = \Theta(\sqrt{n \log n})$ we have that* $\mathrm{NADT}^{\oplus}(f_k) = \Theta(\sqrt{n \log n})$ *and* $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_k) = O(\log n)$. *The number of undefined inputs for f_k is $2^n - 2^{\Theta(\sqrt{n}\log^{3/2} n)}$.*

Proof. For $k = \Theta(\sqrt{n \log n})$ we have $R = \frac{n}{2} - \Theta(\sqrt{n \log n})$ in Theorem 29. By Lemma 12 we have $V(n, R) = \frac{2^n}{\mathrm{poly}(n)}$ and as a result $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_k) = O(\log n)$.

For the number of undefined inputs, we apply Lemma 10:

$$\left(\frac{n}{k}\right)^k \leq V(n, k) \leq \left(\frac{en}{k}\right)^k.$$

For $k = \Theta(\sqrt{n \log n})$ it is easy to see that both sides are $2^{\Theta(\sqrt{n}\log^{3/2} n)}$. From this the estimate on the number of undefined inputs follows. ◀

6 Extreme Cases

In this section we discuss extreme cases. All proves can be found in the full version of the paper.

For small values of complexity measures we have the following equality results.

▶ **Theorem 32.** *Suppose F satisfies* $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = 1$. *It then follows that* $\mathrm{NADT}^{\oplus}(f) = 1$.

▶ **Theorem 33.** *If function f is undefined on fewer than 2^{n-3} inputs and $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = 2$, then $\mathrm{NADT}^{\oplus}(f) = 2$.*

On the other end of the spectrum, we show that if $\mathrm{NADT}^{\oplus}(f)$ is really large, then it is equal for all partial functions.

▶ **Theorem 34.** *For any partial function $f\colon \{0,1\}^n \to \{0,1,\perp\}$, if $\mathrm{NADT}^{\oplus}(f) \geq n-1$, then $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F) = \mathrm{NADT}^{\oplus}(f)$.*

The largest value of $\mathrm{NADT}^{\oplus}$ for which we get separation is $n-2$.

▶ **Theorem 35.** *$\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_{n-3}) \leq n - \Theta(\log n)$, whereas $\mathrm{NADT}^{\oplus}(f_{n-3}) = n-2$. The number of undefined inputs for f_{n-3} is $\frac{n(n+1)}{2}$.*

The smallest value of $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}$ for which we get a separation is 7.

▶ **Theorem 36.** *For any $n \geq 32$ we have $\mathrm{D}^{\rightarrow}_{\mathrm{cc}}(F_7) \leq 7$, whereas $\mathrm{NADT}^{\oplus}(f_7) = 8$.*

Aaron Zhang
The Voleon Group, Berkeley, CA, USA

Abstract

We show that the minimum total coefficient size of a Nullstellensatz proof of the pigeonhole principle on $n+1$ pigeons and n holes is $2^{\Theta(n)}$. We also investigate the ordering principle and construct an explicit Nullstellensatz proof for the ordering principle on n elements with total coefficient size $2^n - n$.

1 Introduction

Given a system $\{p_i = 0 : i \in [m]\}$ of m polynomial equations, a Nullstellensatz proof of infeasibility is an equality of the form $1 = \sum_{i=1}^{m} p_i q_i$ for some polynomials $\{q_i = 0 : i \in [m]\}$. Hilbert's Nullstellensatz[1] says that the Nullstellensatz proof system is complete over algebraically closed fields, i.e., a system of polynomial equations has no solutions over an algebraically closed field if and only if there is a Nullstellensatz proof of infeasibility. However, Hilbert's Nullstellensatz does not give any bounds on the degree or size needed for Nullstellensatz proofs.

The degree of Nullstellensatz proofs has been extensively studied. Grete Hermann showed a doubly exponential degree upper bound for the ideal membership problem [24] which implies the same upper bound for Nullstellensatz proofs. Several decades later, W. Dale Brownawell gave an exponential upper bound on the degree required for Nullstellensatz proofs over algebraically closed fields of characterisic zero [11]. A year later, János Kollár showed that this result holds for all algebraically closed fields [27].

For specific problems, the degree of Nullstellensatz proofs can be analyzed using designs [14]. Using designs, Nullstellensatz degree lower bounds have been shown for many problems including the pigeonhole principle, the induction principle, the housesitting principle, and the mod m matching principles [6, 5, 15, 16, 12]. More recent work showed that there is a close connection between Nullstellensatz degree and reversible pebbling games [19] and that lower bounds on Nullstellensatz degree can be lifted to lower bounds on monotone span programs, monotone comparator circuits, and monotone switching networks [28].

[1] Technically, this is the weak form of Hilbert's Nullstellensatz. Hilbert's Nullstellensatz actually says that given polynomials $p_1, \ldots, p_m$ and another polynomial p, if $p(x) = 0$ for all x such that $p_i(x) = 0$ for each $i \in [m]$ then there exists a natural number r such that p^r is in the ideal generated by $p_1, \ldots, p_m$.

For analyzing the size of Nullstellensatz proofs (i.e., the number of monomials in the proof), a powerful technique is the size-degree relation shown by Russell Impagliazzo, Pavel Pudlák, and Jiří Sgall for polynomial calculus [25], which also holds for resolution proofs [7] and for sum of squares proofs with $\{0,1\}$ variables [3]. The size-degree relation says that if there is a size S polynomial calculus proof then there is a polynomial calculus proof of degree $O(\sqrt{n \log S})$. Thus, if we have an $\Omega(n)$ degree lower bound for polynomial calculus, this implies a $2^{\Omega(n)}$ size lower bound for polynomial calculus (which also holds for Nullstellensatz as Nullstellensatz is a weaker proof system). However, the size-degree relation does not give any size lower bound when the degree is $O(\sqrt{n})$, and we know of few other techniques for analyzing the size of Nullstellensatz proofs.

In this paper, instead of investigating the degree or size of Nullstellensatz proofs, we investigate the total coefficient size of Nullstellensatz proofs, i.e., the sum of the magnitudes of the coefficients of the monomials in the proof. Total coefficient size is a reasonably natural measure which is relatively unexplored (though as we discuss below, there has been considerable research on closely related measures such as unary Nullstellensatz size, unary Sherali-Adams size, and the total bit complexity of proofs [2, 1, 9, 20, 31]). There are several reasons why total coefficient size bounds in particular are interesting.

First, analyzing the total coefficient size of proofs may give insight into proof size in settings where we currently cannot prove size lower bounds. If we can prove a large total coefficient size lower bound, this shows that any proof must either have large size or involve large coefficients. Unless there is a reason to suspect that large coefficients are helpful for making the proof shorter, this gives considerable evidence for a lower bound on proof size.

Second, lower bounds on total coefficient size have some direct implications. As observed by [20], a total coefficient size lower bound for the stronger Sherali-Adams proof system implies a lower bound for the reversible resolution proof system which captures the Max-SAT resolution proof system (see [10]) for Max SAT. Similarly, [20] observes that a total coefficient size lower bound for Nullstellensatz implies a lower bound for the reversible resolution with terminals proof system, which is a weaker variant of reversible resolution.

Finally, investigating the total coefficient size of proofs gives insight into the following question. Are there natural examples where having fractional coefficients greatly reduces the total coefficient size needed for Nullstellensatz and/or Sherali-Adams proofs? We note that this question is not addressed by [20]. For example, [20] shows that there are n-variate CNF formulas F such that F can be refuted by constant width resolution proofs but any Sherali-Adams proof of F requires either exponentially many monomials or requires coefficients of exponential size (see Theorem 1 and the last paragraph of Section 1.1 in [20]). However, this does not rule out the existence of a proof where there are exponentially many monomials but the coefficient for each monomial is exponentially small so the total coefficient size is still small.

Proving total coefficient size lower bounds for a problem rules out this possibility. Conversely, if there is a natural example where the minimum proof size is large but the total coefficient size is small, that would be quite interesting.

1.1 Our results

In this paper, we show that the minimum total coefficient size of a Nullstellensatz proof of the pigeonhole principle is $2^{\Theta(n)}$. More precisely, we show the following bounds.

▶ **Theorem 1.** *For all $n \geq 1$, any Nullstellensatz proof of the pigeonhole principle with $n+1$ pigeons and n holes has total coefficient size $\Omega\left(n^{\frac{3}{4}}\left(\frac{2}{\sqrt{e}}\right)^n\right)$.*

We note that this lower bound also holds for the functional pigeonhole principle, where each pigeon must go to exactly one hole (instead of at least one hole).

▶ **Theorem 2.** *For all $n \geq 1$, there is a Nullstellensatz proof of the pigeonhole principle with $n+1$ pigeons and n holes with total coefficient size at most $2^{5(n+1)}$.*

▶ Remark 3. Note that Nullstellensatz size lower bounds do not imply total coefficient size lower bounds, because we could have a proof with many monomials but a small coefficient (absolute value less than 1) on each monomial. Indeed, in Appendix A, we show an example where the minimum total coefficient size of a Nullstellensatz proof is smaller than the minimum size of a Nullstellensatz proof. Thus, the exponential size polynomial calculus lower bounds for the pigeonhole principle from Razborov's $\Omega(n)$ degree lower bound for polynomial calculus [30] and the size-degree relation [25] do not imply total coefficient size lower bounds for the pigeonhole principle.

In addition, we investigate the total coefficient size of Nullstellensatz proofs of the ordering principle in Appendix C. We show the following upper bound by constructing an explicit Nullstellensatz proof.

▶ **Theorem 4.** *For all $n \geq 3$, there is a Nullstellensatz proof of the ordering principle on n elements with size and total coefficient size $2^n - n$. This upper bound is tight for $n \leq 5$.*

In the full version of this paper [29], we also discuss total coefficient size for the Sherali-Adams and sum of squares proof systems. We observe that even though resolution is a dynamic proof system, the $O(n^3)$ size resolution proof of the ordering principle found by Gunnar Stålmark [32] can be captured by a one line sum of squares proof with small size and coefficients.

1.2 Comparison with related work

Like previous resolution, polynomial calculus, and Sherali-Adams lower bounds for the pigeonhole principle (e.g. [22, 30, 18]), our analysis is inspired by the idea that if we only look at a small number of pigeons, we cannot detect a problem. That said, our analysis differs considerably from previous analyses of the pigeonhole principle as we need to bound the value of a linear program by constructing a dual certificate (see Proposition 12). To construct this dual certificate, we need to assign a value to every possible assignment of the variables, so we need to consider all n pigeons at once which requires a different analysis.

In terms of the overall framework, the work which is most similar to ours is that of De Rezende, Potechin, and Risse [31] which shows a total coefficient size Sherali-Adams lower bound for showing that a random graph does not contain a large clique. Like our paper, [31] constructs a dual certificate which assigns a value to every possible assignment of the variables. That said, [31] uses different techniques to construct and analyze their dual certificate. In particular, while the construction in [31] is inspired by the pseudo-calibration technique used to prove SoS lower bounds for planted clique [4] and the analysis heavily uses the fact that the graph is random, our construction and analysis is combinatorial and takes advantage of symmetry.

Another work which is closely related to ours is that of Göös et al. [20]. [20] analyzes the size of unary Nullstellensatz and Sherali-Adams proofs, which is equivalent to analyzing the total coefficient size of Nullstellensatz and Sherali-Adams proofs with the added restriction that all coefficients are integers. The authors show that there are deep connections between unary Nullstellensatz, unary Sherali-Adams, resolution, and total NP search problems (TFNP). In particular, they prove the following results (among others) which show that there are considerable advantages to having the restriction that all coefficients are integers.

1. Resolution is not polynomially simulated by unary Sherali-Adams, and reversible resolution is not polynomially simulated by Nullstellensatz. Since unary Sherali-Adams can simulate reversible resolution, this implies that resolution is not simulated by reversible resolution.
2. Roughly speaking, unary Nullstellensatz corresponds to the TFNP class PPAD which corresponds to the principle that every directed graph with an unbalanced node (i.e., a node whose indegree is not equal to its outdegree) must have another unbalanced node. Similarly, unary Sherali-Adams corresponds to the TFNP class PPADS which corresponds to the principle that every directed graph with a postitively unbalanced node (outdegree exceeds indegree) must have a negatively unbalanced node (indegree exceeds outdegree).
3. There is a reversible resolution refutation of a CNF F if and only if there is both a resolution refutation of F and a unary Sherali-Adams refutation of F. Similarly, there is a reversible resolution with terminals refutation of a CNF F if and only if there is both a resolution refutation of F and a unary Nullstellensatz refutation of F.

In this paper, we show that there are also advantages to allowing fractional coefficients. Proving a total coefficient size lower bound when fractional coefficients are allowed removes the possibility of having a proof with many monomials but a small total coefficient size. In addition, allowing fractional coefficients gives us a linear program for minimum total coefficient size which can be analyzed directly. As a result, while [20] needs several steps to show their separations, we show our bounds directly.

Finally, a natural alternative to analyzing the size or total coefficient size of proofs is to analyze the bit complexity of proofs. One way to prove a lower bound on the bit complexity of a proof is to show an exponentially larger lower bound on the total coefficient size of the proof. Hakoniemi [23] uses this approach to give an example where there is a polynomial size sum of squares proof of degree 2 but every sum of squares proof requires doubly exponential total coefficient size and thus exponential bit complexity.

While it is generally hard to lower bound the bit complexity of a proof without lower bounding the proof size or total coefficient size, this has been done for the binary value principle which says that a number written in binary with no minus sign must be non-negative. More precisely, if $x_1, \ldots, x_n \in \{0, 1\}$ then we cannot have that $1 + x_1 + 2x_2 + \ldots + 2^{n-1}x_n = 0$. By considering the primes $p \in [1, 2^n]$ and showing that the proof must involve a coefficient which is divisible by all such primes, [1] and [2] show bit complexity lower bounds for powerful proof systems, namely polynomial calculus with extensions and the ideal proof system (see [21]) where the latter bound is conditional on the Shub-Smale hypothesis. This technique is powerful but is specialized to this problem and is very different from our techniques.

2 Nullstellensatz total coefficient size

We start by defining total coefficient size for Nullstellensatz proofs and describing a linear program for finding the minimum total coefficient size of a Nullstellensatz proof. In this paper, we only consider problems on Boolean variables, so we give definitions which are specialized for this setting.

▶ **Definition 5.** *For each Boolean variable x_i, we define the twin variable $\bar{x}_i$ to be $\bar{x}_i = 1 - x_i$.*

▶ **Definition 6.** *Given Boolean variables $x_1, \ldots, x_N$, we define a monomial to be a product of the form $\left(\prod_{i \in S} x_i\right)\left(\prod_{j \in T} \bar{x}_j\right)$ for some disjoint subsets S, T of $[N]$.*

▶ **Definition 7.** *Given a polynomial f on Boolean variables $x_1, \dots, x_N$, we define the total coefficient size $T(f)$ of f to be the minimum sum of the magnitudes of coefficients when we decompose f into monomials. For example, if $f(x_1, x_2) = 1 - x_1 - x_2 + 2x_1x_2$, then $T(f) = 2$ as we can write $f = \bar{x}_1\bar{x}_2 + x_1x_2 = (1 - x_1)(1 - x_2) + x_1x_2$.*

We will use the following terminology:

▶ **Definition 8.** *Given a system $\{p_i = 0 : i \in [m]\}$ of polynomial equations, we call each of the p_i an axiom. We say that a polynomial W is a weakening of the axiom p_i if $W = rp_i$ for some monomial r.*

We now define Nullstellensatz proofs and their total coefficient size.

▶ **Definition 9.** *Given a system $\{p_i = 0 : i \in [m]\}$ of polynomial equations on Boolean variables $x_1, \dots, x_N$, a Nullstellensatz proof of infeasibility is an equality of the form*

$$1 = \sum_{i=1}^{m} p_i q_i + \sum_{j=1}^{N} (x_j^2 - x_j) g_j + \sum_{j=1}^{N} (x_j + \bar{x}_j - 1) h_j$$

for some polynomials $\{q_i : i \in [m]\}$, $\{g_j : j \in [N]\}$, and $\{h_j : j \in [N]\}$. We define the total coefficient size of such a Nullstellensatz proof to be $\sum_{i=1}^{m} T(q_i)$.

▶ Remark 10. We do not include the total coefficient size of p_i, g_j, or h_j in the total coefficient size of the proof as we want to focus on the complexity of the proof as opposed to the complexity of the axioms and manipulating the Boolean variables. That said, in this paper we only consider systems of polynomial equations where each p_i is a monomial, so this choice does not matter: in this setting $T(p_i) = 1$ for all i, and it is both possible and optimal to take $g_j = 0$ for all j.[2] In terms of weakenings, in this setting a Nullstellensatz proof is an equality

$$1 = \sum_{W} c_W W,$$

where W ranges over all possible weakenings of axioms and $c_W \in \mathbb{R}$. The total coefficient size of a Nullstellensatz proof is $\sum_W |c_W|$.

The minimum total coefficient size of a Nullstellensatz proof can be found using a linear program. To illustrate this, we now give an example.

▶ **Example 11.** Consider the following system of equations on two variables x_1, x_2:

$$1 - x_1 = 0$$
$$1 - x_2 = 0$$
$$x_1x_2 = 0$$

Given these axioms, the possible weakenings W (modulo the Boolean axioms) are $1 - x_1$, $(1 - x_1)x_2$, $(1 - x_1)(1 - x_2)$, $1 - x_2$, $x_1(1 - x_2)$, and x_1x_2.

[2] In other words, we can assume without loss of generality that all terms in a Nullstellensatz proof have degree at most 1 in each variable. If an axiom contains a variable x_i, there is no point in multiplying the axiom by x_i or $\bar{x}_i = (1 - x_i)$, because $x_i^2 = x_i$ and $x_i(1 - x_i) = 0$ modulo the Boolean axioms. The reasoning is similar in the case that an axiom contains a variable $\bar{x}_i = (1 - x_i)$.

To find a Nullstellensatz proof with minimum total coefficient size, we write a linear program with a variable c_W for each weakening W. We also have a variable b_W for each weakening W representing the absolute value of c_W with the constraints $b_W - c_W \geq 0$ and $b_W + c_W \geq 0$. The objective is to minimize $\sum_W b_W$.

To ensure that $\sum_W c_W W = 1$, we have a constraint for each of the 4 possible assignments of values to the variables. For example, one possible assignment is $x_1 = 0, x_2 = 0$. We ensure that $\sum_W c_W W$ evaluates to 1 on this assignment by having the constraint

$$c_{(1-x_1)} + c_{(1-x_2)} + c_{(1-x_1)(1-x_2)} = 1,$$

because the weakenings $1 - x_1$, $1 - x_2$, and $(1 - x_1)(1 - x_2)$ evaluate to 1 on this assignment while the other weakenings evaluate to 0. The analogous constraints for the other 3 possible assignments of values to the variables are as follows:

1. $c_{(1-x_1)} + c_{(1-x_1)x_2} = 1$ for the assignment $x_1 = 0$, $x_2 = 1$
2. $c_{(1-x_2)} + c_{x_1(1-x_2)} = 1$ for the assignment $x_1 = 1$, $x_2 = 0$
3. $c_{x_1x_2} = 1$ for the assignment $x_1 = 1$, $x_2 = 1$.

The set of optimal solutions to this linear program is

$$\{c_{x_1x_2} = 1, c_{(1-x_1)} = c_{x_1(1-x_2)} = a, c_{(1-x_1)x_2} = c_{(1-x_2)} = 1-a, c_{(1-x_1)(1-x_2)} = 0 : a \in [0,1]\}$$

which corresponds to the equality

$$1 = x_1x_2 + a\left((1 - x_1) + x_1(1 - x_2)\right) + (1 - a)\left((1 - x_1)x_2 + (1 - x_2)\right).$$

In the same way as the above example, we can find the minimum total coefficient size of any system of equations with a linear program. In order to show a lower bound on total coefficient size, we will analyze the dual of this linear program. Because the primal has a constraint for each assignment of values to the variables $x \in \{0,1\}^N$, the dual has a variable for each assignment $x \in \{0,1\}^N$. We will let $D : \{0,1\}^N \to \mathbb{R}$ denote the dual.

We observe that D induces a linear map $\widehat{D}$ from polynomials to $\mathbb{R}$ in a natural way, by taking $\widehat{D}(f) = \sum_{x\in\{0,1\}^N} D(x)f(x)$. It turns out that the dual is equivalent to:

Maximize $\widehat{D}(1)$ subject to the constraint that for each weakening W, $|\widehat{D}(W)| \leq 1$.

Weak duality, which is what we need to prove lower bounds on total coefficient size, can be seen directly as follows.

▶ **Proposition 12.** *If $\widehat{D}$ is a linear map from polynomials to $\mathbb{R}$ such that $|\widehat{D}(W)| \leq 1$ for all weakenings W, then any Nullstellensatz proof has total coefficient size at least $\widehat{D}(1)$.*

Proof. Given a Nullstellensatz proof $1 = \sum_{i=1}^m p_iq_i$, applying $\widehat{D}$ to both sides gives $\widehat{D}(1) = \sum_{i=1}^m \widehat{D}(p_iq_i) \leq \sum_{i=1}^m T(q_i)$. The inequality holds because for any q_i, for any way of writing q_i in terms of monomials r as $q_i = \sum_r c_{ir}r$, we have $\widehat{D}(p_iq_i) = \sum_r c_{ir}\widehat{D}(rp_i) \leq \sum_r |c_{ir}|$ because rp_i is a weakening. ◀

3 Total coefficient size lower bound for the pigeonhole principle

In this section, we prove Theorem 1, our total coefficient size lower bound for the pigeonhole principle. We start by formally defining the pigeonhole principle.

▶ **Definition 13** (pigeonhole principle (PHP_n)). *Intuitively, the pigeonhole principle says that if $n+1$ pigeons are assigned to n holes, then some hole must have more than one pigeon. Formally, for $n \geq 1$, we define PHP_n to be the statement that the following system of axioms is infeasible:*

- *For each $i \in [n+1]$ and $j \in [n]$, we have a variable $x_{i,j}$ and the Boolean axiom $x_{i,j}^2 - x_{i,j} = 0$. $x_{i,j} = 1$ represents pigeon i being in hole j, and $x_{i,j} = 0$ represents pigeon i not being in hole j.*
- *For each $i \in [n+1]$, we have the axiom $\prod_{j=1}^{n} \bar{x}_{i,j} = 0$ representing the constraint that each pigeon must be in at least one hole.*
- *For each pair of distinct pigeons $i_1, i_2 \in [n+1]$ and each hole $j \in [n]$, we have the axiom $x_{i_1,j}x_{i_2,j} = 0$ representing the constraint that pigeons i_1 and i_2 cannot both be in hole j.*

We prove our lower bound on total coefficient size for PHP_n by constructing and analyzing a dual solution $D : \{0,1\}^{(n+1)n} \to \mathbb{R}$. In our dual solution, the only assignments of values to the variables $x \in \{0,1\}^{(n+1)n}$ for which $D(x) \neq 0$ are those where each pigeon goes to exactly one hole, i.e., for each pigeon i, exactly one of the $x_{i,j}$ is 1. As a result, Theorem 1 also applies to the functional pigeonhole principle. Note that there are n^{n+1} such assignments. In the rest of this section, when we refer to assignments or write a summation or expectation over assignments x, we refer specifically to these n^{n+1} assignments.

Recall that the dual constraints are

$$\widehat{D}(W) = \sum_{x \in \{0,1\}^N} D(x)W(x) \in [-1,1]$$

for all weakenings W. Note that since $D(x)$ is only nonzero for assignments x where each pigeon goes to exactly one hole, for any weakening W of an axiom of the form $\prod_{j=1}^{n} \bar{x}_{i,j} = 0$, we have $\widehat{D}(W) = 0$. Thus, it is sufficient to consider weakenings W of the axioms $x_{i_1,j}x_{i_2,j} = 0$.

For simplicity, in order to construct a dual solution, we first ignore the constraints $|\widehat{D}(W)| \leq 1$. Then, we obtain a dual solution by normalizing D, i.e., dividing D by $\max_W |\widehat{D}(W)|$. Thus, we can rewrite the objective value of the dual program as $\frac{\widehat{D}(1)}{\max_W |\widehat{D}(W)|}$. Letting $\mathbb{E}$ denote the expectation over a uniform assignment where each pigeon goes to exactly one hole, $\frac{\widehat{D}(1)}{\max_W |\widehat{D}(W)|} = \frac{\mathbb{E}(D)}{\max_W |\mathbb{E}(DW)|}$. Thus, it is sufficient to construct D and analyze $\mathbb{E}(D)$ and $\max_W |\mathbb{E}(DW)|$.

Before constructing and analyzing D, we provide some intuition for our construction. The idea is that if we consider a subset of n pigeons then D should behave like the indicator function for whether those n pigeons all go to different holes. More concretely, for any polynomial p which does not depend on some pigeon i (i.e., p does not contain $x_{i,j}$ or $\bar{x}_{i,j}$ for any $j \in [n]$), we want

$$\mathbb{E}(Dp) = \frac{n!}{n^n}\mathbb{E}(p \mid \text{all pigeons in } [n+1] \setminus \{i\} \text{ go to different holes})$$

Given this intuition, we now present our construction. Our dual solution D will be a linear combination of the following functions:

▶ **Definition 14** (functions J_S). *For each subset of pigeons $S \subsetneq [n+1]$ of size at most n, we define the function J_S that maps assignments to $\{0,1\}$ so that for each assignment x, $J_S(x) = 1$ if all pigeons in S are in different holes according to x and $J_S(x) = 0$ otherwise.*

Note that if $|S| = 0$ or $|S| = 1$, then J_S is the constant function 1. In general, the expectation of J_S over a uniform assignment is $\mathbb{E}(J_S) = \left(\prod_{k=1}^{|S|}(n+1-k)\right)/n^{|S|}$.

▶ **Definition 15** (dual solution D)**.** *Our dual solution D is:*

$$D = \sum_{S \subsetneq [n+1]} c_S J_S,$$

where the coefficients c_S are $c_S = \frac{(-1)^{n-|S|}(n-|S|)!}{n^{n-|S|}}$.

We will lower-bound the dual value $\mathbb{E}(D)/\max_W |\mathbb{E}(DW)|$ by computing $\mathbb{E}(D)$ and then upper-bounding $\max_W |\mathbb{E}(DW)|$. In both calculations, we will use the following key property of D which we introduced in our intuition for the construction:

▶ **Lemma 16.** *If p is a polynomial which does not depend on pigeon i (i.e., p does not contain any variables of the form $x_{i,j}$ or $\bar{x}_{i,j}$), then $\mathbb{E}(Dp) = \mathbb{E}(J_{[n+1]\setminus\{i\}}p)$.*

Proof. Without loss of generality, suppose p does not contain any variables of the form $x_{1,j}$ or $\bar{x}_{1,j}$. Let T be any subset of pigeons that does not contain pigeon 1 and that has size at most $n-1$. Observe that

$$\mathbb{E}(J_{T\cup\{1\}}p) = \frac{n-|T|}{n}\mathbb{E}(J_T p)$$

because when the pigeons in T go to different holes, the probability that pigeon 1 goes to a different hole is $\frac{n-|T|}{n}$, and p does not depend on the location of pigeon 1. Since

$$\begin{aligned} c_{T\cup\{1\}} &= \frac{(-1)^{n-1-|T|}(n-1-|T|)!}{n^{n-1-|T|}} \\ &= -\frac{n}{n-|T|}\cdot\frac{(-1)^{n-|T|}(n-|T|)!}{n^{n-|T|}} = -\frac{n}{n-|T|}c_T \end{aligned}$$

we have that for all $T \subsetneq \{2,\ldots,n+1\}$, $\mathbb{E}(c_{T\cup\{1\}}J_{T\cup\{1\}}p) + \mathbb{E}(c_T J_T p) = 0$. Thus, all terms in the sum $\mathbb{E}(Dp) = \sum_{S\subsetneq[n+1]}\mathbb{E}(c_S J_S p)$ cancel, except $J_{\{2,3,\ldots,n+1\}}$. Since $c_{\{2,3,\ldots,n+1\}} = 1$, we have that $\mathbb{E}(Dp) = \mathbb{E}(J_{\{2,3,\ldots,n+1\}}p)$, as needed. ◀

The value of $\mathbb{E}(D)$ follows immediately:

▶ **Corollary 17.**

$$\mathbb{E}(D) = \frac{n!}{n^n}.$$

Proof. Let $p = 1$. By Lemma 16, $\mathbb{E}(D) = \mathbb{E}(J_{\{2,\ldots,n+1\}}) = \frac{n!}{n^n}$. ◀

3.1 Upper bound on $\max_W |\mathbb{E}(DW)|$

We now upper bound $\max_W |\mathbb{E}(DW)|$. To do this, we introduce the following notation:

▶ **Definition 18** ($H_{W,i}$)**.** *Given a weakening W, we define a set of holes $H_{W,i} \subseteq [n]$ for each pigeon $i \in [n+1]$ so that $W(x) = 1$ if and only if each pigeon $i \in [n+1]$ is mapped to one of the holes in $H_{W,i}$. More precisely,*

- *If W contains terms x_{i,j_1} and x_{i,j_2} for distinct holes j_1, j_2, then $H_{W,i} = \emptyset$ (i.e., it is impossible that $W(x) = 1$ because pigeon i cannot go to both holes j_1 and j_2).*
- *If W contains exactly one term of the form $x_{i,j}$, then $H_{W,i} = \{j\}$. (i.e., for all x such that $W(x) = 1$, pigeon i goes to hole j).*

- *If W contains no terms of the form $x_{i,j}$, then $H_{W,i}$ is the subset of holes j such that W does not contain the term $\bar{x}_{i,j}$. (i.e., if W contains the term $\bar{x}_{i,j}$, then for all x such that $W(x) = 1$, pigeon i does not go to hole j.)*

The key property we will use to bound $\max_W |\mathbb{E}(DW)|$ follows immediately from Lemma 16:

▶ **Lemma 19.** *Let W be a weakening. If there exists some pigeon $i \in [n+1]$ such that $H_{W,i} = [n]$ (i.e., W does not contain any terms of the form $x_{i,j}$ or $\bar{x}_{i,j}$), then $\mathbb{E}(DW) = 0$.*

Proof. Without loss of generality, suppose W is a weakening of the axiom $x_{2,1}x_{3,1} = 0$ and $H_{W,1} = [n]$. By Lemma 16, $\mathbb{E}(DW) = \mathbb{E}(J_{\{2,\dots,n+1\}}W)$. However, $\mathbb{E}(J_{\{2,\dots,n+1\}}W) = 0$ because if $W(x) = 1$, then pigeons 2 and 3 must both go to hole 1. ◀

We now make the following definition and then state a corollary of Lemma 19.

▶ **Definition 20** (W_S^{flip})**.** *Let W be a weakening of the axiom $x_{i_1,j}x_{i_2,j} = 0$ for pigeons i_1, i_2 and hole j. Let $S \subseteq [n+1] \setminus \{i_1, i_2\}$. We define W_S^{flip}, which is also a weakening of the axiom $x_{i_1,j}x_{i_2,j} = 0$, as follows.*

- *For each pigeon $i_3 \in S$, we define W_S^{flip} so that $H_{W_S^{\text{flip}},i_3} = [n] \setminus H_{W,i_3}$.*
- *For each pigeon $i_3 \notin S$, we define W_S^{flip} so that $H_{W_S^{\text{flip}},i_3} = H_{W,i_3}$.*

Note: Technically, there are multiple possible weakenings W_S^{flip} which satisfy these properties (e.g. if $n = 2$, $W = x_{1,1}x_{2,1}x_{3,1}$, and $S = \{3\}$, then W_S^{flip} can be $x_{1,1}x_{2,1}\bar{x}_{3,1}$ or $x_{1,1}x_{2,1}x_{3,2}$ or even $x_{1,1}x_{2,1}\bar{x}_{3,1}x_{3,2}$, among others). We arbitrarily choose any such weakening W_S^{flip}.

In other words, W_S^{flip} is obtained from W by flipping the sets of holes that the pigeons in S can go to in order to make the weakening evaluate to 1.

▶ **Corollary 21.** *Let W be a weakening of the axiom $x_{i_1,j}x_{i_2,j} = 0$ for pigeons i_1, i_2 and hole j. Let $S \subseteq [n+1] \setminus \{i_1, i_2\}$. Then*

$$\mathbb{E}\left(DW_S^{\text{flip}}\right) = (-1)^{|S|} \cdot \mathbb{E}(DW).$$

Proof. It suffices to show that for $i_3 \in [n+1] \setminus \{i_1, i_2\}$, we have $\mathbb{E}\left(DW_{\{i_3\}}^{\text{flip}}\right) = -\mathbb{E}(DW)$. Indeed, let W' be a weakening such that $W'(x) = W(x) + W_{\{i_3\}}^{\text{flip}}(x)$ for all assignments x where each pigeon goes to exactly one hole. (For example, if $n = 2$, $W = x_{1,1}x_{2,1}x_{3,1}$, and $i_3 = 3$, then we can take $W_{\{3\}}^{\text{flip}}$ to be $x_{1,1}x_{2,1}x_{3,2}$, in which case $W' = x_{1,1}x_{2,1}$.) Then $\mathbb{E}(DW') = 0$ by Lemma 19 because $H_{W',i_3} = [n]$, so $\mathbb{E}\left(DW_{\{i_3\}}^{\text{flip}}\right) = -\mathbb{E}(DW)$. ◀

Using Corollary 21, we can bound $\max_W |\mathbb{E}(DW)|$ using Cauchy-Schwarz. We first show an approach that does not give a strong enough bound. We then show how to modify the approach to achieve a better bound.

▶ **Definition 22.** *Given functions F, G on the assignments mapping each pigeon to exactly one hole, we define $\langle F, G\rangle = \mathbb{E}(FG)$. We define $\|F\| = \sqrt{\langle F, F\rangle} = \sqrt{\mathbb{E}(F^2)}$.*

3.1.1 Unsuccessful approach to upper bound $\max_W |\mathbb{E}(DW)|$

Consider $\max_W |\mathbb{E}(DW)|$. By Lemma 21, it suffices to take the max over weakenings W such that, if W is a weakening of the axiom $x_{i_1,j}x_{i_2,j} = 0$, then for all pigeons $i_3 \in [n+1] \setminus \{i_1, i_2\}$, we have $|H_{W,i_3}| \leq \lfloor n/2 \rfloor$ (because if $|H_{W,i_3}| > \lfloor n/2 \rfloor$, we can flip H_{W,i_3} without changing $|\mathbb{E}(DW)|$). For any such W, we have

$$\|W\| = \sqrt{\mathbb{E}(W^2)} \leq \sqrt{\left(\frac{1}{n}\right)^2 \left(\frac{1}{2}\right)^{n-1}} = n^{-1}2^{-(n-1)/2}.$$

By Cauchy-Schwarz,

$$\begin{aligned} |\mathbb{E}(DW)| &\leq \|D\|\|W\| \\ &\leq \|D\|n^{-1}2^{-(n-1)/2}. \end{aligned}$$

Using the value of $\mathbb{E}(D)$ from Corollary 17, the dual value $\mathbb{E}(D)/\max_W |\mathbb{E}(DW)|$ is at least

$$\frac{n!}{n^n} \cdot \frac{n2^{(n-1)/2}}{\|D\|} = \widetilde{\Theta}\left(\left(\frac{e}{\sqrt{2}}\right)^{-n} \cdot \frac{1}{\|D\|}\right)$$

by Stirling's formula. Thus, in order to achieve an exponential lower bound on the dual value, we would need $1/\|D\| \geq \Omega(c^n)$ for some $c > e/\sqrt{2}$. However, this requirement is too strong, as we will show in Lemma 26 that $1/\|D\| = \widetilde{\Theta}\left((\sqrt{e})^n\right)$. Directly applying Cauchy-Schwarz results in too loose of a bound on $\max_W |\mathbb{E}(DW)|$, so we now modify our approach.

3.1.2 Successful approach to upper bound $\max_W |\mathbb{E}(DW)|$

▶ **Definition 23** ($W_{i_1,i_2}^{\{-1,0,1\}}$). *Let W be a weakening of the axiom $x_{i_1,j}x_{i_2,j} = 0$ for pigeons i_1, i_2 and hole j. We define a function $W_{i_1,i_2}^{\{-1,0,1\}}$ that maps assignments to $\{-1, 0, 1\}$. For an assignment x,*

- *If pigeons i_1 and i_2 do not both go to hole j, then $W_{i_1,i_2}^{\{-1,0,1\}}(x) = 0$.*
- *Otherwise, let $V(x) = |\{i_3 \in [n+1] \setminus \{i_1, i_2\} : \text{pigeon } i_3 \text{ does not go to } H_{W,i_3}\}|$. Then $W_{i_1,i_2}^{\{-1,0,1\}}(x) = (-1)^{V(x)}$.*

Note that $W_{i_1,i_2}^{\{-1,0,1\}}$ is a linear combination of the W_S^{flip}:

▶ **Lemma 24.** *Let W be a weakening of the axiom $x_{i_1,j}x_{i_2,j} = 0$ for pigeons i_1, i_2 and hole j. We have:*

$$W_{i_1,i_2}^{\{-1,0,1\}} = \sum_{S \subseteq [n+1] \setminus \{i_1,i_2\}} (-1)^{|S|} \cdot W_S^{\text{flip}}.$$

It follows that:

$$\mathbb{E}\left(DW_{i_1,i_2}^{\{-1,0,1\}}\right) = 2^{n-1} \cdot \mathbb{E}(DW).$$

Proof. To prove the first equation, consider any assignment x. If pigeons i_1 and i_2 do not both go to hole j, then both $W_{i_1,i_2}^{\{-1,0,1\}}$ and all the W_S^{flip} evaluate to 0 on x. Otherwise, exactly one of the $W_S^{\text{flip}}(x)$ equals 1, and for this choice of S we have $W_{i_1,i_2}^{\{-1,0,1\}}(x) = (-1)^{|S|}$.

The second equation follows because:

$$\begin{aligned}\mathbb{E}\left(DW_{i_1,i_2}^{\{-1,0,1\}}\right) &= \sum_{S\subseteq[n+1]\setminus\{i_1,i_2\}} (-1)^{|S|}\cdot\mathbb{E}\left(DW_S^{\text{flip}}\right)\\ &= \sum_{S\subseteq[n+1]\setminus\{i_1,i_2\}} (-1)^{|S|}(-1)^{|S|}\cdot\mathbb{E}(DW) && \text{(Corollary 21)}\\ &= 2^{n-1}\cdot\mathbb{E}(DW).\end{aligned}$$

◀

Using Lemma 24, we now improve on the approach to upper-bound $\max_W |\mathbb{E}(DW)|$ from section 3.1.1:

▶ **Lemma 25.** *The dual value* $\mathbb{E}(D)/\max_W|\mathbb{E}(DW)|$ *is at least* $\frac{n!}{n^n}\cdot\frac{n2^{n-1}}{\|D\|}$.

Proof. If W is a weakening of the axiom $x_{i_1,j}x_{i_2,j}=0$ for pigeons i_1,i_2 and hole j,

$$\begin{aligned}|\mathbb{E}(DW)| &= 2^{-(n-1)}\cdot\left|\mathbb{E}\left(DW_{i_1,i_2}^{\{-1,0,1\}}\right)\right| && \text{(Lemma 24)}\\ &\le 2^{-(n-1)}\cdot\|D\|\|W_{i_1,i_2}^{\{-1,0,1\}}\| && \text{(Cauchy-Schwarz)}\\ &= 2^{-(n-1)}\cdot\|D\|\sqrt{\mathbb{E}\left(\left(W_{i_1,i_2}^{\{-1,0,1\}}\right)^2\right)}\\ &= n^{-1}2^{-(n-1)}\cdot\|D\|.\end{aligned}$$

Using the value of $\mathbb{E}(D)$ from Corollary 17, the dual value $\mathbb{E}(D)/\max_W|\mathbb{E}(DW)|$ is at least $\frac{n!}{n^n}\cdot\frac{n2^{n-1}}{\|D\|}$. ◀

It only remains to compute $\|D\|$:

▶ **Lemma 26.**

$$\|D\|^2 = \frac{n!}{n^n}\cdot(n+1)!\cdot\sum_{c=0}^{n}\frac{(-1)^{n-c}}{n+1-c}\cdot\frac{1}{n^{n-c}c!}$$

Proof. Recall the definition of D (Definition 15):

$$\begin{aligned}D &= \sum_{S\subsetneq[n+1]} c_S J_S,\\ c_S &= \frac{(-1)^{n-|S|}(n-|S|)!}{n^{n-|S|}}.\end{aligned}$$

We compute $\|D\|^2=\mathbb{E}(D^2)$ as follows.

$$\mathbb{E}(D^2) = \sum_{S\subsetneq[n+1]}\sum_{T\subsetneq[n+1]} c_S c_T\mathbb{E}(J_S J_T).$$

Given $S,T\subsetneq[n+1]$, we have:

$$\begin{aligned}\mathbb{E}(J_S J_T) &= \mathbb{E}(J_S)\mathbb{E}(J_T\mid J_S=1)\\ &= \left(\left(\prod_{i=1}^{|S|}(n+1-i)\right)/n^{|S|}\right)\left(\left(\prod_{j=|S\cap T|+1}^{|T|}(n+1-j)\right)/n^{|T\setminus S|}\right).\end{aligned}$$

Therefore,

$$c_S c_T \mathbb{E}(J_S J_T) = \left(c_S \left(\prod_{i=1}^{|S|} (n+1-i) \right) / n^{|S|} \right) \left(c_T \left(\prod_{j=|S\cap T|+1}^{|T|} (n+1-j) \right) / n^{|T\setminus S|} \right).$$

Note that the product of $(-1)^{n-|S|}$ (from the c_S) and $(-1)^{n-|T|}$ (from the c_T) is $(-1)^{-|S|-|T|} = (-1)^{|S|-|T|}$, so the above equation becomes:

$$c_S c_T \mathbb{E}(J_S J_T) = (-1)^{|S|-|T|} \left(\frac{n!}{n^n} \right) \left(\frac{(n-|S\cap T|)!}{n^{n-|S\cap T|}} \right).$$

Now, we rearrange the sum for $\mathbb{E}(D^2)$ in the following way:

$$\begin{aligned} \mathbb{E}(D^2) &= \sum_{S\subsetneq[n+1]} \sum_{T\subsetneq[n+1]} c_S c_T \mathbb{E}(J_S J_T) \\ &= \frac{n!}{n^n} \sum_{c=0}^{n} \frac{(n-c)!}{n^{n-c}} \sum_{\substack{S,T\subsetneq[n+1],\\ |S\cap T|=c}} (-1)^{|S|-|T|}. \end{aligned}$$

To evaluate this expression, fix $c \le n$ and consider the inner sum. Consider the collection of tuples $\{(S,T) \mid S,T \subsetneq [n+1], |S\cap T| = c\}$. We can pair up most of these tuples in the following way. For each S, let m_S denote the minimum element in $[n+1]$ that is not in S (note that m_S is well defined because S cannot be $[n+1]$). We pair up the tuple (S,T) with the tuple $(S, T\triangle\{m_S\})$, where $\triangle$ denotes symmetric difference. The only tuples (S,T) that cannot be paired up in this way are those where $|S| = c$ and $T = [n+1]\setminus\{m_S\}$, because T cannot be $[n+1]$. There are $\binom{n+1}{c}$ unpaired tuples (S,T), and for each of these tuples, we have $(-1)^{|S|-|T|} = (-1)^{n-c}$. On the other hand, each pair $(S,T), (S, T\triangle\{m_S\})$ contributes 0 to the inner sum. Therefore, the inner sum equals $(-1)^{n-c}\binom{n+1}{c}$, and we have:

$$\begin{aligned} \mathbb{E}(D^2) &= \frac{n!}{n^n} \sum_{c=0}^{n} \frac{(-1)^{n-c}(n-c)!}{n^{n-c}} \binom{n+1}{c} \\ &= \frac{n!}{n^n} \sum_{c=0}^{n} \frac{(-1)^{n-c}(n-c)!}{n^{n-c}} \cdot \frac{(n+1)!}{c!(n+1-c)!} \\ &= \frac{n!}{n^n} \cdot (n+1)! \cdot \sum_{c=0}^{n} \frac{(-1)^{n-c}}{n+1-c} \cdot \frac{1}{n^{n-c}c!}. \end{aligned}$$

◀

▶ **Corollary 27.** $\mathbb{E}(D^2) \le \frac{(n+1)!}{n^n}$

Proof. Observe that the sum $\sum_{c=0}^{n} \frac{(-1)^{n-c}}{n+1-c} \cdot \frac{1}{n^{n-c}c!}$ is an alternating series where the magnitudes of the terms decrease as c decreases. The two largest magnitude terms are $\frac{1}{n!}$ and $-\frac{1}{2}\cdot\frac{1}{n!}$. Therefore, the sum is at most $\frac{1}{n!}$, and we conclude that $\mathbb{E}(D^2) \le \frac{n!}{n^n} \cdot \frac{(n+1)!}{n!} = \frac{(n+1)!}{n^n}$, as needed. ◀

We can now complete the proof of Theorem 1.

Proof of Theorem 1. By Lemma 25, any Nullstellensatz proof for PHP_n has total coefficient size at least $\frac{n!}{n^n} \cdot \frac{n2^{n-1}}{\|D\|}$. By Corollary 27, $\|D\| \le \sqrt{\frac{(n+1)!}{n^n}}$. Combining these results, any Nullstellensatz proof for PHP_n has total coefficient size at least

$$\frac{n!}{n^n} \cdot \frac{n2^{n-1}}{\sqrt{\frac{(n+1)!}{n^n}}} = \frac{n2^{n-1}}{\sqrt{(n+1)}} \cdot \frac{\sqrt{n!}}{n^{\frac{n}{2}}}$$
$$= \frac{n2^{n-1}}{\sqrt{n+1}} \sqrt{\frac{n!}{n^n}}$$

Using Stirling's approximation that $n!$ is approximately $\sqrt{2\pi n}\left(\frac{n}{e}\right)^n$, $\sqrt{\frac{n!}{n^n}}$ is approximately $\sqrt[4]{2\pi n}\left(\frac{1}{\sqrt{e}}\right)^n$, and this expression is $\Omega\left(n^{\frac{3}{4}}\left(\frac{2}{\sqrt{e}}\right)^n\right)$, as needed. ◀

4 Open problems

Our work raises a number of open problems. First, while we showed that the minimum total coefficient size of a Nullstellensatz proof of the pigeonhole principle on $n+1$ pigeons and n holes is $2^{\Theta(n)}$, it is natural to ask what happens when we increase the number of pigeons.

1. If we increase the number of pigeons from $n+1$ to $n+2$ while still having n holes, our lower bound proof no longer applies. Can we prove a total coefficient size lower bound on Nullstellensatz when there are m pigeons where $m \geq n+2$? More ambitiously, how does the minimum total coefficient size of a proof depend on m and whether or not we add the axioms that pigeons can only go to one hole (i.e., considering the functional pigeonhole principle rather than the pigeonhole principle)?

Second, we are still far from understanding the total coefficient size of Nullstellensatz proofs of the ordering principle. In Appendix C we construct an explicit Nullstellensatz proof for the ordering principle on n elements with total coefficient size $2^n - n$, but we have no non-trivial lower bounds.

2. Can we prove superpolynomial lower bounds on the total coefficient size of Nullstellensatz proofs of the ordering principle and/or improve the $O(2^n)$ upper bound?

In the full version of this paper [29], we also discuss total coefficient size for the Sherali-Adams and sum of squares proof systems. Some questions regarding these related proof systems are:

3. Are there Sherali-Adams proofs for the ordering principle with polynomial total coefficient size? If so, this shows that the seemingly dynamic $O(n^3)$ size resolution proof of the ordering principle [32] can be captured by a one line Sherali-Adams proof. If not, this gives a natural example separating resolution proof size and the total coefficient size of Sherali-Adams proofs. We note that this separation has been shown by [20] for unary Sherali-Adams using pebbling principles.
4. Are there natural examples where the minimum total coefficient size is very different (either larger or smaller) than the minimum size for Nullstellensatz, Sherali-Adams, or sum of squares proofs?
5. Can the minimum total coefficient size of a strong proof system be used to lower bound the size of another proof system? For example, can resolution proof size be lower bounded by the minimum total coefficient size of a sum of squares proof, or can we find an example where there is a polynomial size resolution proof but any sum of squares proof has superpolynomial total coefficient size?

A Nullstellensatz total coefficient size can be smaller than size

The following example shows that Nullstellensatz total coefficient size can be smaller than Nullstellensatz proof size. (See Section 2 for the definition of total coefficient size.)

The idea behind our example is as follows. If we have three points p_1, p_2, p_3 and three polynomials f_1, f_2, f_3 such that

1. $f_1(p_1) = 1$, $f_1(p_2) = 1$, $f_1(p_3) = 0$
2. $f_2(p_1) = 1$, $f_2(p_2) = 0$, $f_2(p_3) = 1$
3. $f_3(p_1) = 0$, $f_3(p_2) = 1$, $f_3(p_3) = 1$

then given the axioms $f_1 = 0$, $f_2 = 0$, and $f_3 = 0$, the equality $\frac{1}{2}f_1 + \frac{1}{2}f_2 + \frac{1}{2}f_3 = 1$ is a Nullstellensatz proof of infeasibility which has total coefficient size $\frac{3}{2}$. However, if we want to use integer coefficients then we need coefficient size 2 as we need two of f_1, f_2, and f_3 in order to cover the three points p_1, p_2, p_3.

Our actual example is as follows. We have variables $x_1, x_2, x_3, x_4, x_5, x_6$ and we have the following axioms:

1. For all $I \subseteq \{4,5,6\}$, $x_1 \left(\prod_{i\in I} x_i\right)\left(\prod_{j\in\{4,5,6\}\setminus I} \bar{x}_j\right) = 0$
2. For all $I \subseteq \{4,5,6\}$, $x_2 \left(\prod_{i\in I} x_i\right)\left(\prod_{j\in\{4,5,6\}\setminus I} \bar{x}_j\right) = 0$
3. For all $I \subseteq \{4,5,6\}$, $x_3 \left(\prod_{i\in I} x_i\right)\left(\prod_{j\in\{4,5,6\}\setminus I} \bar{x}_j\right) = 0$
4. $x_1x_2x_3 = 0$
5. $\bar{x}_1\bar{x}_2 = 0$, $\bar{x}_1\bar{x}_3 = 0$, $\bar{x}_2\bar{x}_3 = 0$

We now observe that $1 = \frac{1}{2}\bar{x}_1\bar{x}_2 + \frac{1}{2}\bar{x}_1\bar{x}_3 + \frac{1}{2}x_1\bar{x}_2\bar{x}_3 + \frac{1}{2}(x_1 + x_2 + x_3) - \frac{1}{2}x_1x_2x_3$. We can show this by checking that the right hand side is 1 for all $(x_1, x_2, x_3) \in \{0,1\}^3$.

1. If $x_1 = x_2 = x_3 = 0$ then the first two terms are $\frac{1}{2}$ and the remaining terms are 0.
2. If $x_1 + x_2 + x_3 = 1$ then the fourth term and exactly one of the first three terms are $\frac{1}{2}$ and the remaining terms are 0.
3. If $x_1 + x_2 + x_3 = 2$ then the fourth term is 1 and the remaining terms are 0.
4. If $x_1 = x_2 = x_3 = 1$ then the fourth term is $\frac{3}{2}$, the fifth term is $-\frac{1}{2}$, and the remaining terms are 0.

Using this equation, we have that

$$1 = \frac{1}{2}\bar{x}_1\bar{x}_2 + \frac{1}{2}\bar{x}_1\bar{x}_3 + \frac{1}{2}x_1\bar{x}_2\bar{x}_3 - \frac{1}{2}x_1x_2x_3 + \frac{1}{2}(x_1 + x_2 + x_3)\sum_{I\subseteq\{4,5,6\}}\left(\prod_{i\in I} x_i\right)\left(\prod_{j\in\{4,5,6\}\setminus I} \bar{x}_j\right)$$

This Nullstellensatz proof has total coefficient size $4 * \frac{1}{2} + \frac{3*8}{2} = 14$. However, for each $I \subseteq \{4,5,6\}$, two of the axioms of the form $x_k \left(\prod_{i\in I} x_i\right)\left(\prod_{j\in\{4,5,6\}\setminus I} \bar{x}_j\right) = 0$ for $k \in \{1,2,3\}$ are needed to prove infeasibility. We also need one of the three axioms $\bar{x}_1\bar{x}_2 = 0$, $\bar{x}_1\bar{x}_3 = 0$, and $\bar{x}_2\bar{x}_3 = 0$. Thus, any Nullstellensatz proof of infeasibility must have size at least $2 * 8 + 1 = 17$.

B Total coefficient size upper bound for the pigeonhole principle

In this section, we use a divide and conquer approach to give a unary Nullstellensatz proof of the pigeonhole principle with size $2^{O(n)}$. Before giving our proof, we discuss other potential approaches for constructing a Nullstellensatz proof for the pigeonhole principle and why they were insufficient for our purposes.

One approach is to use the observation that if we have a tree-like resolution proof with S leaves, this gives us a Nullstellensatz proof of size S where every coefficient is 1.

There is a simple tree-like resolution proof of size $O((n+1)!)$ which works as follows. For each pigeon i, we query the variables $\{x_{ij} : j \in [n]\}$ one by one and stop when we find a j such that $x_{i,j} = 1$ or we have queried all of these variables. If we already had that $x_{i',j} = 1$ for some $i' < i$ then this contradicts the axiom $\neg x_{i',j} \vee \neg x_{i,j}$. If none of the $x_{i,j}$ are 1 then this contradicts the axiom $\bigvee_{j\in[n]} x_{i,j}$. If pigeon i was placed in a new hole j then we continue on to pigeon $i+1$.

This gives an upper bound of $O((n+1)!)$. However, it has been shown [8, 17, 26] that every tree-like resolution proof for the pigeonhole principle has size $n^{\Omega(\log(n))}$ so this is essentially the best that we can do with this approach.

Buss and Pitassi [13] showed that there is a resolution proof of size $O(n^3 2^n)$ for the pigeonhole principle. The idea behind this proof is as follows.

▶ **Definition 28.** *Given $S = \{s_1, \ldots, s_j\} \subseteq [n+1]$, define $C_{S,[j,n]}$ to be the clause*

$$C_{S,[j,n]} = \bigvee_{i\in[j],k\in[j,n]} x_{s_i,k}.$$

In other words, the clause $C_{S,[j,n]}$ says that at least one of the j pigeons in S must go into one of the holes in $[j,n]$.

At stage j, we start with the clauses $\{C_{S,[j,n]} : S \subseteq [n+1], |S| = j\}$ and derive the clauses $\{C_{S',[j+1,n]} : S' \subseteq [n+1], |S'| = j+1\}$. After stage n, this gives us the empty clause, which proves that the pigeonhole axioms are infeasible. However, it is not clear how to translate this proof into a Nullstellensatz proof without blowing up the size and total coefficient size.

We now give a unary Nullstellensatz proof of the pigeonhole principle which has size $2^{O(n)}$.

▶ **Theorem 29.** *For all $n \in \mathbb{N}$, there is a unary Nullstellensatz proof of size at most $2^{5(n+1)}$ for the pigeonhole principle with $n+1$ pigeons and n holes.*

Proof. We construct this proof recursively as follows. Given $k \in \mathbb{N}$, a set $S = \{p_1, \ldots, p_{k+1}\}$ of $k+1$ pigeons, and a set $H = \{h_1, \ldots, h_k\}$ of k holes, we want to show the equality

$$\prod_{a=1}^{k+1}\left(1 - \prod_{b=1}^{k}(1 - x_{p_a,h_b})\right) = \prod_{a=1}^{k+1}\left(1 - \prod_{b=1}^{k}\bar{x}_{p_a,h_b}\right) = 0$$

using the hole axioms. Note that this equality coresponds to the statement that there is at least one pigeon in S which does not go to any of the holes in H.

We do this as follows. If $k = 1$ then this equality is a hole axiom. If $k > 2$ then

1. For each $a \in [k]$, we decompose the term $\left(1 - \prod_{b=1}^{k}\bar{x}_{p_a,h_b}\right)$ as

$$\left(1 - \prod_{b=1}^{k}\bar{x}_{p_a,h_b}\right) = \left(1 - \prod_{b=1}^{\lfloor\frac{k+1}{2}\rfloor}\bar{x}_{p_a,h_b}\right) + \left(\prod_{b=1}^{\lfloor\frac{k+1}{2}\rfloor}\bar{x}_{p_a,h_b}\right)\left(1 - \prod_{b=\lfloor\frac{k+1}{2}\rfloor+1}^{k}\bar{x}_{p_a,h_b}\right)$$

This gives us the equality

$$\prod_{a=1}^{k+1}\left(1-\prod_{b=1}^{k}\bar{x}_{p_a,h_b}\right)=$$
$$\sum_{A\subseteq[k+1]}\left(\prod_{a\in A}\left(1-\prod_{b=1}^{\lfloor\frac{k}{2}\rfloor}\bar{x}_{p_a,h_b}\right)\right)\left(\prod_{a\in[k+1]\setminus A}\left(\prod_{b=1}^{\lfloor\frac{k+1}{2}\rfloor}\bar{x}_{p_a,h_b}\right)\right)\left(1-\prod_{b=\lfloor\frac{k+1}{2}\rfloor+1}^{k}\bar{x}_{p_a,h_b}\right)\right)$$

2. For each of the 2^{k+2} resulting terms, we check whether $|A|\geq\lfloor\frac{k+1}{2}\rfloor+1$ or $|A|\leq\lfloor\frac{k+1}{2}\rfloor$. If $|A|\geq\lfloor\frac{k+1}{2}\rfloor+1$ then letting A' be the first $\lfloor\frac{k+1}{2}\rfloor+1=\lceil\frac{k+2}{2}\rceil$ elements of A, we recursively construct a proof that $\prod_{a\in A'}\left(1-\prod_{b=1}^{\lfloor\frac{k+1}{2}\rfloor}\bar{x}_{p_a,h_b}\right)=0$. If $|A|\leq\lfloor\frac{k+1}{2}\rfloor$ then $|[k+1]\setminus A|\geq\lceil\frac{k+1}{2}\rceil$ so letting A'' be the first $\lceil\frac{k+1}{2}\rceil$ elements of $[k+1]\setminus A$, we recursively construct a proof that $\prod_{a\in A''}\left(1-\prod_{b=\lfloor\frac{k+1}{2}\rfloor+1}^{k}\bar{x}_{p_a,h_b}\right)=0$.

To obtain our Nullstellensatz proof, we construct this proof for $S=[n+1]$ and $H=[n]$. We then use the following equality (recall that the pigeon axioms are $\{\prod_{b=1}^{n}\bar{x}_{a,b}=0:a\in[n+1]\}$):

$$1=\prod_{a=1}^{n+1}\left(1-\prod_{b=1}^{n}\bar{x}_{a,b}\right)+\sum_{j=1}^{n+1}\left(\prod_{b=1}^{n}\bar{x}_{j,b}\right)\left(\prod_{a=1}^{j-1}\left(1-\prod_{b=1}^{n}\bar{x}_{a,b}\right)\right)$$

The size of the resulting unary Nullstellensatz proof can be upper bounded by $S(n)+2^{n+1}$ where $S(n)$ is the solution to the recurrence relation $S(n)=2^{2(n+1)}S(\lceil\frac{n+2}{2}\rceil)$ where $S(1)=1$. It is not hard to show by induction that $S(n)\leq 2^{5(n+1)}-2^{(n+1)}$ so this gives an upper bound of $2^{5(n+1)}$. ◀

C Total coefficient size upper bound for the ordering principle

In this section, we construct an explicit Nullstellensatz proof for the ordering principle on n elements with total coefficient size 2^n-n. In the full version of this paper [29], we also present experimental results obtained by implementing the linear program for minimum total coefficient size. One of our experimental results is that the 2^n-n upper bound is tight for $n\leq 5$.

We start by formally defining the ordering principle.

▶ **Definition 30** (ordering principle (ORD_n)). *Intuitively, the ordering principle says that any well-ordering on n elements must have a minimum element. Formally, for $n\geq 1$, we define ORD_n to be the statement that the following system of axioms is infeasible:*

- *We have a variable $x_{i,j}$ for each pair $i,j\in[n]$ with $i<j$, with the Boolean axiom $x_{i,j}^2-x_{i,j}=0$. $x_{i,j}=1$ represents element i being less than element j in the well-ordering, and $x_{i,j}=0$ represents element i being more than element j in the well-ordering. We write $x_{j,i}$ as shorthand for $\bar{x}_{i,j}=1-x_{i,j}$.*
- *For each $i\in[n]$, we have the axiom $\prod_{j\in[n]\setminus\{i\}}x_{i,j}=0$ which represents the constraint that element i is not a minimum element. We call these axioms non-minimality axioms.*
- *For each triple $i,j,k\in[n]$ where $i<j<k$, we have the two axioms $x_{i,j}x_{j,k}x_{k,i}=0$ and $x_{k,j}x_{j,i}x_{i,k}=0$ which represent the constraints that elements i,j,k satisfy transitivity. We call these axioms transitivity axioms.*

In our Nullstellensatz proof $1=\sum_W c_W W$, each c_W is either 0 or 1. Non-minimality axioms have coefficient 1, and all weakenings of transitivity axioms that have coefficient 1 must have a special form:

▶ **Definition 31** (nice transitivity weakening). *Let W be a weakening of the axiom $x_{i,j}x_{j,k}x_{k,i}$ or the axiom $x_{k,j}x_{j,i}x_{i,k}$ for some $i < j < k$. Let $G(W)$ be the following directed graph. The vertices of $G(W)$ are $[n]$. For distinct $i', j' \in [n]$, $G(W)$ has an edge from i' to j' if W contains the term $x_{i',j'}$. We say that W is a nice transitivity weakening if $G(W)$ has exactly n edges and all vertices are reachable from vertex i.*

In other words, if W is a weakening of the axiom $x_{i,j}x_{j,k}x_{k,i}$ or the axiom $x_{k,j}x_{j,i}x_{i,k}$, then $G(W)$ contains a 3-cycle on vertices $\{i, j, k\}$. W is a nice transitivity weakening if and only if contracting this 3-cycle results in a directed spanning tree rooted at the contracted vertex. Note that if W is a nice transitivity weakening and x is an assignment with a minimum element, then $W(x) = 0$.

▶ **Theorem 32.** *There is a Nullstellensatz proof for* ORD_n *satisfying:*

1. *The total coefficient size is $2^n - n$.*
2. *Each c_W is either 0 or 1.*
3. *If A is a non-minimality axiom, then $c_A = 1$, and $c_W = 0$ for all other weakenings W of A.*
4. *If W is a transitivity weakening but not a nice transitivity weakening, then $c_W = 0$.*

Proof. We prove Theorem 32 by induction on n. When $n = 3$, the desired Nullstellensatz proof sets $c_A = 1$ for each axiom A. It can be verified that $\sum_W c_W W$ evaluates to 1 on each assignment, and that this Nullstellensatz proof satisfies the properties of Theorem 32.

Now suppose we have a Nullstellensatz proof for ORD_n satisfying Theorem 32, and let S_n denote the set of transitivity weakenings W for which $c_W = 1$. The idea to obtain a Nullstellensatz proof for ORD_{n+1} is to use two copies of S_n, the first copy on elements $\{1, \ldots, n\}$ and the second copy on elements $\{2, \ldots, n+1\}$. Specifically, we construct the Nullstellensatz proof for ORD_{n+1} by setting the following c_W to 1 and all other c_W to 0.

1. For each non-minimality axiom A in ORD_{n+1}, we set $c_A = 1$.
2. For each $W \in S_n$, we define the transitivity weakening W' on $n+1$ elements by $W' = W \cdot x_{1,n+1}$ and set $c_{W'} = 1$.
3. For each $W \in S_n$, first we define the transitivity weakening W'' on $n+1$ elements by replacing each variable $x_{i,j}$ that appears in W by $x_{i+1,j+1}$ (e.g., if $W = x_{1,2}x_{2,3}x_{3,1}$, then $W'' = x_{2,3}x_{3,4}x_{4,2}$). Then, we define $W''' = W''x_{n+1,1}$ and set $c_{W'''} = 1$.
4. For each $i \in \{2, \ldots, n\}$, for each of the 2 transitivity axioms A for elements $\{1, i, n+1\}$, we set $c_W = 1$ for the following weakening W of A:

$$W = A\left(\prod_{j \in \{2,\ldots,n\} \setminus \{i\}} x_{i,j}\right).$$

In other words, $W(x) = 1$ if and only if $A(x) = 1$ and i is the minimum element among $\{2, \ldots, n\}$.

The desired properties 1 through 4 in Theorem 32 can be verified by induction. It remains to show that for each assignment x, there is exactly one nonzero c_W for which $W(x) = 1$. If x has a minimum element $i \in [n+1]$, then the only nonzero c_W for which $W(x) = 1$ is the non-minimality axiom for i. Now suppose that x does not have a minimum element. Consider two cases: either $x_{1,n+1} = 1$, or $x_{n+1,1} = 1$. Suppose $x_{1,n+1} = 1$. Consider the two subcases:

1. Suppose that, if we ignore element $n+1$, then there is still no minimum element among the elements $\{1, \ldots, n\}$. Then there is exactly one weakening W in point 2 of the construction for which $W(x) = 1$, by induction.
2. Otherwise, for some $i \in \{2, \ldots, n\}$, we have that i is a minimum element among $\{1, \ldots, n\}$ and $x_{n+1,i} = 1$. Then there is exactly one weakening W in point 4 of the construction for which $W(x) = 1$ (namely, the weakening W of the axiom $A = x_{i,1}x_{1,n+1}x_{n+1,i}$).

The case $x_{n+1,1} = 1$ is handled similarly by considering whether there is a minimum element among $\{2, \ldots, n+1\}$. Assignments that do have a minimum element among $\{2, \ldots, n+1\}$ are handled by point 3 of the construction, and assignments that do not are handled by point 4 of the construction. ◀

Adaptive Sparsification for Matroid Intersection

Kent Quanrud
Dept. of Computer Science, Purdue University, West Lafayette, IN, USA

Abstract

We consider the matroid intersection problem in the independence oracle model. Given two matroids over n common elements such that the intersection has rank k, our main technique reduces approximate matroid intersection to logarithmically many primal-dual instances over subsets of size $\tilde{O}(k)$. This technique is inspired by recent work by [2] and requires additional insight into structuring and efficiently approximating the dual LP. This combination of ideas leads to faster approximate maximum cardinality and maximum weight matroid intersection algorithms in the independence oracle model. We obtain the first nearly linear time/query approximation schemes for the regime where $k \leq n^{2/3}$.

1 Introduction

Matroid intersection is a classical problem in combinatorial optimization for which faster algorithms have been a recent topic of interest.

A *matroid*, $\mathcal{M} = (\mathcal{N}, \mathcal{I})$, consists of a set of n elements $\mathcal{N}$ and a collection of subsets $\mathcal{I}$ of $\mathcal{N}$, known as the independent sets, that satisfy the following properties: (i) the empty set is independent, (ii) every subset of an independent set is independent (hereditary property), and (iii) if A and B are two independent sets with $|A| > |B|$, then there exists an element in $A \setminus B$ that can be added to B to still have an independent set (exchange property). These properties imply that every *maximal* set also has maximum cardinality. The maximum cardinality of any independent set is called the *rank*. Examples of matroids include the family of forests of a graph (the graphic matroid) and the family of independent sets of vectors in a vector space (the linear matroid).

Matroid intersection. The problem of matroid intersection considers two matroids, $\mathcal{M}_1 = (\mathcal{N}, \mathcal{I}_1)$ and $\mathcal{M}_2 = (\mathcal{N}, \mathcal{I}_2)$, defined on a common ground set $\mathcal{N}$, and seeks the largest set that is independent in both matroids. Formally, the goal is to maximize the size of a set $S \subseteq \mathcal{N}$ such that $S \in \mathcal{I}_1 \cap \mathcal{I}_2$. Unlike matroids, a maximal cardinality independent set in the matroid intersection is not necessarily a maximum cardinality independent set. The maximum cardinality, denoted OPT, is also called the *rank* of the matroid intersection and denoted by k. Matroid intersection generalizes bipartite matching, and has other connections in combinatorial optimization. For example, by Edmonds' directionless tree packing theorem,

matroid intersection captures the maximum number of rooted arborescences that can be packed into a directed graph, and the directed rooted connectivity [11]. See [27, 15] for additional background and connections.

Algorithms addressing matroid intersection in general are commonly framed in the *independence oracle model*. Here the algorithm is allowed to query if a given set S is independent in a matroid. When stating running times in this model, we let Q denote the running time of a single independence oracle.

The first polynomial time algorithm for matroid intersection was given by [10] by reduction to matroid union [12]. This algorithm ran in $O\big(n^4Q\big)$ time. More direct augmenting path algorithms were developed by [1, 21]. The algorithm in [21] ran in $O\big(nk^2Q\big)$ time. Generalizing ideas from bipartite matching [17], [9] gave a faster matroid intersection algorithm running in $O\big(nk^{1.5}Q\big)$ time. Truncating the algorithm early implies a $(1-\epsilon)$-approximation in $O(nkQ/\epsilon)$ time for $\epsilon \in (0,1)$ [8].

Recently there has been a resurgence of interest in faster algorithms in the independence oracle model. [7, 23] gave $O(nk\log(k)Q)$ time algorithms, leveraging the observation that the auxiliary graph can be searched faster than it can be built out explicitly. [5] pushed this direction further and obtained $\tilde{O}\big(n^{9/5}Q\big)$ randomized and $\tilde{O}\big(n^{11/6}Q\big)$ deterministic time algorithms, the first $o(n^2)$ time algorithms for $k = \Omega(n)$.[1] Finally, [4] obtained a $\tilde{O}\Big(n\sqrt{k}Q/\epsilon\Big)$ time deterministic algorithm for $(1-\epsilon)$-matroid intersection. This faster approximation algorithm implied faster exact algorithms running in $\tilde{O}\big(nk^{3/4}Q\big)$ randomized time and $\tilde{O}\big(nk^{5/6}Q\big)$ deterministic time. [4]'s algorithms represent the state of the art.

Weighted matroid intersection. In the weighted matroid intersection problem, we are also given weights $c : \mathcal{N} \to \mathbb{R}_{>0}$. The goal is to compute $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ of maximum weight $c(I)$. Edmonds [10] gave the first polynomial time algorithm. Faster algorithms were developed in [21, 13, 6, 16, 22]. Frank's citeFrank1981a algorithm runs in $O(k(T + n\log n))$ time, where T is the running time of any exact matroid intersection algorithm. The algorithm in [22] runs in $O\big(n^2\log(n)Q + n^3\,\mathrm{polylog}(n)\big)$ time.

There is also recent interest in fast $(1-\epsilon)$-approximation algorithms [18, 8]. The $(1-\epsilon)$-approximation algorithm in [8] runs in $\tilde{O}\big(nkQ/\epsilon^2\big)$ time.

1.1 Results

Our primary focus is on faster approximation algorithms. As alluded to above, approximation algorithms can play a role in exact algorithms. (The fastest algorithms use augmenting paths to extend approximate solutions to exact ones.) They are also useful in their own right when one is willing to tolerate some error in exchange for scalability.

We introduce adaptive sparsification to matroid intersection in order to develop faster approximation algorithms. The new sparsification technique reduces approximate matroid intersection to $O(\log(n))$ instances of approximate matroid intersection and the dual problem over a subset of $O(k\log(n))$ elements. The technique holds for both weighted and unweighted matroid intersection. We leverages these ideas to obtain improved running times for approximating the unweighted and weighted settings.

Maximum cardinality matroid intersection. Henceforth, let $\mathcal{M}_1 = (\mathcal{N}, \mathcal{I}_1)$ and $\mathcal{M}_2 = (\mathcal{N}, \mathcal{I}_2)$ be two matroids over a common groundset of n elements, let k be the rank of their intersection, and let $\epsilon \in (0,1)$. In the following, the "dual" refers to the dual of the standard

[1] $\tilde{O}(\cdots)$ hides polylogarithmic factors.

packing LP for matroid intersection, and is introduced formally below in Section 1.2. We first show how to reduce approximate matroid intersection over n elements to approximating $O(\log n)$ primal-dual instances of matroid intersection over $\tilde{O}(k)$ elements.

▶ **Lemma 1.** *Suppose a $(1-\epsilon)$-maximum matroid intersection and a $(1+\epsilon)$-approximate dual solution in $\mathcal{I}_1 \cap \mathcal{I}_2$, over a subset of m elements, can be computed with high probability in $T_\epsilon(m)$ time in the independence oracle model. Then a $(1-\epsilon)$-approximate matroid intersection can be computed with high probability in $O(n\log(n)Q/\epsilon + \mathcal{T}_\epsilon(k\log(n)/\epsilon)/\epsilon)$ randomized time in the independence oracle model, where Q represents an independence query.*

To apply Lemma 1 to matroid intersection, we need a fast algorithm to compute both a $(1-\epsilon)$-maximum matroid intersection and an $(1+\epsilon)$-dual solution. Recall that [4] computes a $(1-\epsilon)$-maximum matroid intersection in $\tilde{O}\left(n\sqrt{k}Q/\epsilon\right)$ time. The solution returned by [4] has stronger properties (based on the length of augmenting paths), and we leverage these properties to compute a $(1+\epsilon)$-approximate dual solution without increasing the running time.

▶ **Lemma 2.** *A $(1-\epsilon)$-maximum matroid intersection I, and an $(1+\epsilon)$-dual solution (S,T), can be computed in $\tilde{O}\left(n\sqrt{k}Q/\epsilon\right)$ deterministic time.*

Using this as a $(1\pm\epsilon)$-primal dual approximation algorithm in Lemma 1, with $\mathcal{T}_\epsilon(n) = \tilde{O}\left(n\sqrt{k}Q/\epsilon\right)$, we have the following improved running time for approximate matroid intersection.

▶ **Theorem 3.** *A $(1-\epsilon)$-maximum matroid intersection and an $(1+\epsilon)$-dual solution can be computed with high probability in $O\left(n\log(n)Q/\epsilon + k^{3/2}\log^{O(1)}(k)Q/\epsilon^3\right)$ randomized time in the independence oracle model.*

Compared to previous results, the improved running time in Theorem 3 removes the $\text{poly}(k)$-factor from the dominant term of n. Theorem 3 gives the first nearly linear time approximation scheme for the regime where $k \le n^{2/3}$.

Theorem 3 does not imply a faster algorithm for exact matroid intersection, but brings us significantly closer. This is because there are two bottlenecks in [4]. Theorem 3 addresses one of them. The remaining bottleneck is a subroutine augmenting an independent set one element at a time. The current best bound for this subroutine is $\tilde{O}\left(n\sqrt{k}Q\right)$ time per augmenting path [5].

Maximum weight matroid intersection. We now consider maximum weight matroid intersection. In addition to the inputs $\mathcal{M}_1$, $\mathcal{M}_2$, and $\epsilon \in (0,1)$, let $c : \mathcal{N} \to \mathbb{R}_{\ge 0}$ be an input weight vector.

As in the unweighted case, we show how to reduce approximate maximum weight matroid intersection to approximating $O(\log(n))$ primal-dual instances over subsets of $\tilde{O}(k)$ elements. Here the "dual" refers to the dual LP, introduced later in Section 3. For the weighted setting, the sparsification technique requires particularly structured dual solutions which we call "compact" dual solutions. We elaborate more on compact dual solutions in Section 3 and for the time being state the lemma informally.

▶ **Lemma 4** (Informal). *Suppose that a $(1-\epsilon)$-maximum weight matroid intersection and a "compact" $(1+\epsilon)$-minimum dual solution over a subset of m elements can be computed in $\mathcal{T}_\epsilon(m)$ time with high probability. Then a $(1-\epsilon)$-maximum weight matroid intersection and a $(1+\epsilon)$-minimum dual solution can be computed with high probability in $O(n\log(n)Q/\epsilon + \mathcal{T}_\epsilon(k\log(n)/\epsilon)/\epsilon)$ randomized time in the independence oracle model.*

Using this technique requires a $(1 \pm \epsilon)$-primal-dual approximation algorithm where the dual solution has nice "compact" properties. A fast primal algorithm is given by [8] (accelerated by [4]) and we extend it to give an approximate dual solution that is also compact.

▶ **Lemma 5** (Informal). *A $(1-\epsilon)$-maximum weight matroid intersection and a "compact" $(1+\epsilon)$-minimum dual solution can be computed in $\tilde{O}\left(n\sqrt{k}Q/\epsilon^2\right)$ time.*

Putting these two results together gives the following improved running time for approximate maximum weight matroid intersection.

▶ **Theorem 6.** *A $(1-\epsilon)$-maximum weight matroid intersection and a $(1+\epsilon)$-minimum dual solution can be computed with high probability in $O\left(n\log(n)Q/\epsilon + k^{3/2}Q/\epsilon^4\right)$ randomized time in the independence oracle model.*

Compared to the previous state of the art, Theorem 6 removes the poly(k)-factor from the dominant term n. It also reduces the poly$(1/\epsilon)$-factor against n, from $1/\epsilon^2$ to $1/\epsilon$. Theorem 6 is the first approximation scheme for weighted matroid intersection running in nearly linear time for all $k \leq n^{2/3}$.

1.2 High-level overview of the algorithms and techniques

The first technique we introduce to matroid intersection is adaptive sparsification. In graph algorithms, sparsification is a powerful and (by now) standard technique where a dense input graph is reduced to a sparse one, while (approximately) preserving salient properties like the size of every cut [3] or the Laplacian [29, 28]. These algorithms are also fast. There is previous work sparsifying matroids individually [20, 25, 26], generalizing cut sparsification.

For matroid intersection, we are aware of two instances of sparsification. [7] sparsifies matroid intersection by first approximating a linear relaxation for matroid intersection. They then randomly round their solution x to a solution y with support of size $O\left(k\log(n)/\epsilon^2\right)$. Concentration bounds from [20] imply that the support of y contains a $(1-\epsilon)$-approximate matroid intersection with high probability. The only catch to this approach is that it takes $\tilde{O}\left(n^2Q/k\epsilon^2\right)$ time to compute the point x. The second instance is the very recent work of [19], which reduces the number of elements to $\tilde{O}\left(k/\epsilon^{O(1)}\right)$ while preserving the value of the matroid intersection up to a $(3/2+\epsilon)$-factor. However this is far from preserving the intersection up to a $(1+\epsilon)$-factor. (We note that the techniques of [19] have additional motivating factors including communication complexity and the streaming model.) It seems difficult to accurately preserve the matroid intersection via a "one-shot" static sparsifier without introducing another bottleneck in the running time.

This work pivots away from static sparsifiers to *adaptive* ones, where a large instance of matroid intersection is reduced to a limited number of sparse instances. The sparse instances are generated sequentially by random samples, where the distribution of each sample adapts to the outcomes of previous iterations. We are inspired by and build upon a recent and elegant work by Assadi [2], which used adaptive sampling to compute $(1-\epsilon)$-approximate maximum weight matchings in the semi-streaming model. We briefly sketch the ideas from [2]. While [2]'s techniques extend to general graphs, we restrict our discussion to bipartite matching as it is a special case of matroid intersection. The input is a bipartite graph $G = (V, E)$, and we are constrained to memory of size $\tilde{O}(|V|)$. In particular, for dense graphs, one cannot hold the entire graph in memory. The algorithm may read the edges E one by one in a streaming fashion; each iteration over E is called a "pass".

There are several known results in this model and the contribution of [2] was to give a simpler algorithm competitive with the state of the art. [2] reduces $(1-\epsilon)$-maximum weight matching to $O(\log(n)/\epsilon)$ successive instances of $(1-\epsilon)$-maximum weight matching and $(1+\epsilon)$-minimum vertex cover over subgraphs of $\tilde{O}(|V|/\epsilon)$ edges. Each $\tilde{O}(|V|/\epsilon)$-size instance is obtained by a nonuniform sample of the edges that can be implemented in a single pass over the edges.

The probabilities are based on multiplicative weights. Initially, all edges have the same weight and are sampled uniformly. Each iteration, the algorithm obtains a $(1+\epsilon)$-minimum vertex cover that covers all the sampled edges, but not necessarily all the input edges. The sampling probability of each uncovered edge is doubled. Intuitively the algorithm is trying to sample a small set of edges that forces the dual covering solutions of the sample to cover all the edges, at least on average. Edges that are frequently covered have exponentially smaller weight; edges that are not covered much have exponentially larger weight.

While [2] gives a direct analysis, one can interpret their algorithm a little more generally within a standard MWU framework applied to the dual vertex cover LP. We broaden the argument to covering problems in general. In the following, a $(1+\epsilon)$-approximation algorithm refers to a point $x \in \mathcal{P}$ such that $\langle b, x\rangle \le (1+\epsilon)\,\mathrm{OPT}$ and $(1+\epsilon)Ax \ge \mathbb{1}$.

▶ **Lemma 7.** *Consider a covering LP of the form*

$$\textit{mimimize } \langle b, x\rangle \textit{ over } x \in \mathcal{P} \textit{ s.t. } Ax \ge \mathbb{1},$$

where $\mathcal{P}$ is a convex set, and A has nonnegative coefficients and m constraints. Suppose one has access to an oracle that, given any nonnegative set of weights $w \in \mathbb{R}^m_{\ge 0}$, computes a point x such that:

(a) $\langle b, x\rangle \le (1+\epsilon)\,\mathrm{OPT}$

(b) $\sum_{i:(Ax)_i \ge 1} w_i \ge (1-\epsilon)\sum_i w_i$.

Suppose the oracle also returns a list of all constraints $i \in [m]$ covered by x (i.e., such that $(Ax)_i \ge 1$). Then one can compute a $(1+\epsilon)$-approximation solution as the average of $L = O(\log(m)/\epsilon)$ solutions returned by the oracle for an adaptively chosen sequence of L weight vectors.

The intuition for the oracle problem is as follows. We are given a covering LP, and the challenge is to satisfy *all* the covering constraints simultaneously. The oracle problem relaxes this uniform requirement by assigning nonnegative weights to each constraint, and asks for a solution that satisfies *most* of the constraints by weight. The small difference between satisfying all constraints, and satisfying *almost* all the constraints, is just large enough to permit random sampling and other techniques that trade a controlled amount of error for significantly faster running times. The surrounding framework adjusts the weights dynamically so that on average, the oracle solutions (approximately) cover all the constraints simultaneously.

Matroid intersection. To apply this framework to matroid intersection we must understand the dual covering problem, which requires the notions of a rank function and a span function. For a given matroid $\mathcal{M} = (\mathcal{N}, \mathcal{I})$, and set $S \subseteq \mathcal{N}$, the *rank of* S, denoted $\mathrm{rank}(S)$, is the maximum cardinality of any independent subset of S. For $S \subseteq \mathcal{N}$, the *span* of S, $\mathrm{span}(S)$, is the set of elements whose inclusion does not increase the rank, including the elements in S: $\mathrm{span}(S) = \{e \in \mathcal{N} : \mathrm{rank}(S+e) = \mathrm{rank}(S)\}$. A set S is *closed* if $S = \mathrm{span}(S)$. Let rank_1 and rank_2 denote the rank functions of $\mathcal{M}_1$ and $\mathcal{M}_2$, respectively. Similarly, let span_1 and span_2 denote the span functions of $\mathcal{M}_1$ and $\mathcal{M}_2$, respectively.

The standard LP relaxation for matroid intersection asks for the maximum nonnegative modular function dominated by rank_1 and rank_2:

$$\begin{aligned} &\text{maximize } x(\mathcal{N}) \text{ over } x : \mathcal{N} \to \mathbb{R}_{\geq 0} \\ &\quad \text{s.t. } x(S) \leq \text{rank}_1(S) \text{ and } x(S) \leq \text{rank}_2(S) \text{ for all } S \subseteq \mathcal{N}. \end{aligned} \tag{1}$$

Here we denote the sum $x(S) \stackrel{\text{def}}{=} \sum_{e \in S} x_e$ for $S \subseteq \mathcal{N}$.

From a dual perspective, for all partitions $(S, \bar{S})$ of the ground set (where $\bar{S} = \mathcal{N} \setminus S$), $\text{rank}_1(S) + \text{rank}_2(\bar{S})$ is an upper bound on the size of any matroid intersection $I \in \mathcal{I}_1 \cap \mathcal{I}_2$. (We have $|I \cap S| \leq \text{rank}_1(S)$ and $|I \cap \bar{S}| \leq \text{rank}_2(\bar{S})$). It is also an upper bound on the LP relaxation as can be seen from duality as follows.

Consider the problem of minimizing $\text{rank}_1(S) + \text{rank}_2(\bar{S})$ over all $S \subseteq V$. The standard LP relaxation is the dual LP of the matroid intersection LP (1):

$$\begin{aligned} &\text{minimize } \sum_{S \subseteq \mathcal{N}} y_S \, \text{rank}_1(S) + z_S \, \text{rank}_2(S) \text{ over } y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0} \\ &\quad \text{s.t. } \sum_{S : e \in S} y(S) + z(S) \geq 1 \text{ for all } e \in \mathcal{N}. \end{aligned} \tag{2}$$

A classical theorem by [10] states that $\max_{I \in \mathcal{I}_1 \cap \mathcal{I}_2} |I| = \min_{S \subseteq V} \text{rank}_1(S) + \text{rank}_2(\bar{S})$, hence both LPs (1) and (2) have integral optimum solutions.

Lemma 7 applies a variation of the MWU framework to the dual covering LP (2). The MWU framework incrementally builds a fractional solution (y, z) over $L = O(\log(n)/\epsilon)$ iterations. Initially $(y, z) = (\mathbb{0}, \mathbb{0})$. Each iteration ℓ queries the oracle for a particular set of weights $w^{(\ell)} \in \mathbb{R}^{\mathcal{N}}_{\geq 0}$, returning $(\tilde{y}^{(\ell)}, \tilde{z}^{(\ell)})$ as described in Lemma 7. We increase y by $\tilde{y}^{(\ell)}/L$ and z by $\tilde{z}^{(\ell)}/L$. The key point is how the weights are chosen. For each element e, in the ℓth iteration, we have

$$w^{(\ell)}(e) = \exp(-(\#\text{ iterations } k < \ell \text{ where } (\tilde{y}^{(k)}, \tilde{z}^{(k)}) \text{ covers } e)).$$

The weight of an element e decays exponentially with the number of oracle solutions that cover e.

To implement the oracle for matroid intersection, given a set of weights $w : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$, we sample $O(k \log(n)/\epsilon)$ elements $\mathcal{N}' \subseteq \mathcal{N}$ in proportion to w. We then compute a $(1-\epsilon)$-maximum matroid intersection I and a dual $(1+\epsilon)$-minimum dual integral solution (S', T'), where $S', T', \subseteq \mathcal{N}'$, for the subproblem over $\mathcal{N}'$. Of course S' and T' do not cover any elements outside of $\mathcal{N}'$, and would fail to satisfy Item b of Lemma 7. We enlarge these sets by taking their spans, $S = \text{span}_1(S')$ and $T = \text{span}_2(T')$, which hopefully includes most of the elements from $\mathcal{N} \setminus \mathcal{N}'$ (by weight w). (S, T) (encoded in the LP by their indicator vectors) is the solution returned by our oracle.

Assuming each iteration implements the oracle of Lemma 7, Lemma 7 asserts that the average of the dual solutions gives a $(1+\epsilon)$-approximate dual solution to the matroid intersection problem. We really want a $(1 - O(\epsilon))$-approximate matroid intersection. Recall that each iteration also gives a matroid intersection I within a $(1 - O(\epsilon))$-factor of a dual solution over the subproblem. Therefore the maximum cardinality of I over all iterations is within a $(1 - O(\epsilon))$-factor of the average dual solution. The average dual solution is feasible (up to scaling by $(1 + O(\epsilon))$), certifying that I is a $(1 - O(\epsilon))$-matroid intersection.

This describes the approximation algorithm for maximum cardinality matroid intersection. Pseudocode is given in Figure 1. The analysis requires both an MWU analysis of Lemma 7, and a more matroid-specific analysis to implement the oracle. The former is similar to

1. Let $w(d) = 1$ for all $d \in \mathcal{N}$.
2. For $\ell = 1, \dots, L$, where $L = O(\log(n)/\epsilon)$:
   A. Let $\mathcal{N}' \subseteq \mathcal{N}$ sample $O(k \log(n)/\epsilon)$ elements with repetition in proportion to $w(e)$. // $\tilde{O}(n + k/\epsilon)$
   B. Compute a $(1-\epsilon)$-approximate matroid intersection $I^{(\ell)}$ and a $(1+\epsilon)$-approximate dual solution $(\tilde{S}^{(\ell)}, \tilde{T}^{(\ell)})$. // $\tilde{O}(k^{3/2}Q/\epsilon^2)$
   C. Let $S^{(\ell)} = \mathrm{span}_1(\tilde{S}^{(\ell)})$ and $T^{(\ell)} = \mathrm{span}_2(\tilde{T}^{(\ell)})$. // $\tilde{O}(nQ)$
   D. For all elements $d \in S^{(\ell)} \cup T^{(\ell)}$, set $w(d) = w(d)/e$. // $\tilde{O}(n)$
3. Let $I^{(\ell)}$ maximize $|I^{(\ell)}|$ over all iterations $\ell \in [L]$. Define (y, z) to be the fractional average of the dual solutions,

$$y = \frac{1}{L}\sum_{\ell=1}^{L} 1_{S^{(\ell)}} \text{ and } z = \frac{1}{L}\sum_{\ell=1}^{L} 1_{T^{(\ell)}},$$

   where 1_X denotes the indicator vector of $X \subseteq \mathcal{N}$.
   Return $(I^{(\ell)}, (1+O(\epsilon))y, (1+O(\epsilon))z)$.

Figure 1 A randomized, $(1 \pm \epsilon)$-approximation algorithm for maximum cardinality matroid intersection and the dual LP.

the analysis given in [2]. Implementing the oracle has two components. First we need to show how to extend $(1-\epsilon)$-approximate matroid intersection algorithms to also produce a $(1+\epsilon)$-approximate dual solutions, without increasing the running time. We also need to prove that a $(1+\epsilon)$-approximate dual solution on the sampled subset $\mathcal{N}'$ extends to a solution satisfying the oracle model of Lemma 7.

Consider this latter point regarding sampling and the oracle problem. For the special case of bipartite matching, where dual solutions are vertex covers, the argument in [2] takes a union bound over all $2^{|V|}$ possible subsets of vertices; the logarithm of this bound is then approximately the size of the sample that is needed. For matroid intersection the dual is more abstract. There are naively 2^n dual integral solutions, which is too large. To transfer [2]'s argument to matroid intersection, we need a bound of the order of $n^{O(k)}$ on the number of dual solutions. We obtain this bound by restricting our attention to closed sets, and identifying closed sets with maximal independent subsets.

Weighted matroid intersection. One can approach weighted matroid intersection similarly. At a high level, to implement the oracle of Lemma 7, we reduce the input size in each iteration by random sampling, and build on previous $(1+\epsilon)$-maximum weight matroid intersection algorithms to extract good dual solutions. The weights inject additional technical details to each component. Greater effort is needed to bound the number of dual solutions, and this motivates the notion of "compact" dual solutions (defined in Section 3). Computing a compact dual solution efficiently requires a closer examination of the "approximate weight splitting" certificate of [8]. To this end, we give a new primal-dual proof of correctness that also efficiently constructs a compact dual solution. After addressing these combinatorial components, we recover the high-level theme of using adaptive sampling to reduce a problem over n elements to smaller primal-dual instances of the problem over roughly k elements.

Pseudocode for the approximate maximum weight matroid intersection algorithm is given in Figure 2. Several of the steps require technical elaboration and we defer a detailed discussion to Section 3.

1. Let $w(e) = 1$ for all $e \in \mathcal{N}$.
2. For $\ell = 1, \ldots, L$, where $L = O(\log(n)/\epsilon)$:
   A. Let $\mathcal{N}' \subseteq \mathcal{N}$ sample $O(k \log(n)/\epsilon)$ elements with repetition in proportion. // $\tilde{O}(k/\epsilon)$
   B. Compute a $(1-\epsilon)$-approximate matroid intersection $I^{(\ell)}$ and a ϵ-approximate cost-splitting certificate $(c_{1,\ell}, c_{2,\ell})$. // $\tilde{O}\big(k^{3/2}/\epsilon^2\big)$
   C. Extract from $(I^{(\ell)}, c_{1,\ell}, c_{2,\ell})$ a compact, $(1+\epsilon)$-approximate dual solution $\tilde{y}^{(\ell)}, \tilde{z}^{(\ell)} : 2^{\mathcal{N}'} \to \mathbb{R}_{\geq 0}$ over $\mathcal{N}'$. // $\tilde{O}(kQ)$
   D. Define $y^{(\ell)}, z^{(\ell)} : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ by

$$y^{(\ell)}(\mathrm{span}_1(S')) = \lceil \tilde{y}^{(\ell)}(S') \rceil_{1+\epsilon} \qquad \text{for all } S' \in \mathrm{support}(\tilde{y}^{(\ell)}),$$
$$z^{(\ell)}(\mathrm{span}_2(T')) = \lceil \tilde{z}^{(\ell)}(T') \rceil_{1+\epsilon} \qquad \text{for all } T' \in \mathrm{support}(\tilde{z}^{(\ell)}),$$

   where $\lceil x \rceil_{1+\epsilon} \stackrel{\text{def}}{=} (1+\epsilon)^{\lceil \log_{1+\epsilon} x \rceil}$ rounds x up to the nearest power of $1+\epsilon$. // $\tilde{O}(nQ)$
   E. For all elements $e \in \mathcal{N}$, if e is covered by $(y^{(\ell)}, z^{(\ell)})$, set $w(e) = e^{-1} w(e)$. // $O(n \log(k) Q)$
3. Let $I^{(\ell)}$ maximize $c(I^{(\ell)})$ over $\ell \in [L]$. Return $I^{(\ell)}$ and $\frac{1+O(\epsilon)}{L} \sum_{\ell=1}^{L} (y^{(\ell)}, z^{(\ell)})$.

Figure 2 A randomized, $(1 - O(\epsilon))$-approximation algorithm for weighted matroid intersection and the dual LP.

Conclusion. These algorithms are natural extensions of [2]'s algorithm for approximate bipartite matching. Conceptually, they highlight two new perspectives beyond improved running times for approximate matroid intersection. The first is exposing the versatility of the techniques in [2], beyond matchings in graphs. While we focus on matroid intersection abstractly in the independence oracle model, the techniques are simple and high-level enough to be applied to the diverse family of concrete instances of matroid intersection studied elsewhere. We also give an explicit interface to an oracle model for positive LPs that extends beyond matroid intersection. The second is to reiterate the importance of the dual of matroid intersection problems, at least from the perspective of fast approximation algorithms. Improvements for the dual approximation problems were critical to sparsifying and ultimately accelerating approximation algorithms for the primal problem.

The clear open problem is improving the running time for exact unweighted matroid intersection. We were surprised to realize that the improved approximation algorithm did not immediately imply a faster exact running time. We hope this work draws attention to the remaining bottleneck mentioned above.

Organization. We divide the rest of the article into three main parts:

Section 2: The full details of the matroid intersection algorithm and analysis, completing the description in Section 1.2, assuming and interfacing with the oracle framework of Lemma 7.

Section 3: The weighted matroid intersection algorithm and analysis, again interfacing with the oracle framework of Lemma 7.

Section 4: An MWU analysis of the general oracle framework described in Lemma 7.

2 Matroid intersection

The matroid intersection algorithm was described in Section 1.2, along with an overview of the techniques and the analysis. Pseudocode was presented in Figure 1. To briefly review, the overall algorithm follows the MWU framework described in Lemma 7, applied to the dual LP for matroid intersection, (2). The dual LP has a constraint for each element, so the MWU framework maintains a weight for each element reflecting how well the constraint is being met. The oracle problem in Lemma 7 is a relaxation of (2) where we are only required to satisfy most, rather than all, of the dual covering constraints by weight. To solve the oracle problem quickly, we first randomly sample $O(k\log(n)/\epsilon)$ elements in proportion to their weights. Then we compute a $(1-\epsilon)$-approximate matroid intersection, and a $(1+\epsilon)$-approximate dual solution over the sampled elements. We then extend the dual solution to an infeasible dual solution over all the elements, that satisfies the oracle.

The MWU framework has $O(\log(n)/\epsilon)$ iterations. Each iteration has two bottlenecks. The first bottleneck comes from sampling and updating the weights of each element, and takes $O(nQ)$ time. The second bottleneck is approximating the matroid intersection and its dual over the sampled set of elements. If we let $\mathcal{T}_\epsilon(m)$ denote the time of this step, then the algorithm takes $O(n\log(n)/\epsilon + \mathcal{T}_\epsilon(k\log(n)/\epsilon)\log(n)/\epsilon)$ randomized time overall.

To complete the proof of Theorem 3, there are two points to address:

Section 2.1: Given an $(1\pm\epsilon)$-primal dual oracle for matroid intersection running in $\mathcal{T}_\epsilon(m)$ time, we implement the oracle from Lemma 7 in $O(nQ + \mathcal{T}_\epsilon(k\log(n)/\epsilon))$ randomized time. This implies Lemma 1, which formalizes the reduction to approximate primal-dual matroid intersection.

Section 2.2: Recall that the framework requires solutions to both matroid intersection and its dual LP. We extend the $(1-\epsilon)$-maximum matroid intersection algorithm for [4] to give a $(1+\epsilon)$-dual solution without increasing the running time. This gives $\mathcal{T}_\epsilon(m) = \tilde{O}\big(m^{1.5}Q/\epsilon\big)$, hence Lemma 2, and completes the proof of Theorem 3 via Lemma 1.

2.1 Implementing the oracle

In this section, we assume access to a $(1\pm\epsilon)$-primal dual approximation algorithm for matroid intersection in $\mathcal{M}_1$ and $\mathcal{M}_2$, running in $\mathcal{T}_\epsilon(m)$ time for any subset of m elements. We show how to use this algorithm to implement an oracle satisfying Lemma 7 for the dual LP of matroid intersection.

Recall that the algorithm takes as input w, samples $\tilde{O}(k/\epsilon)$ elements $\mathcal{N}' \subseteq \mathcal{N}$ in proportion to w, computes $(1\pm\epsilon)$-primal and dual solutions over $\mathcal{N}'$, and expands out the dual solution by taking their spans in all of $\mathcal{N}$. The key point of the analysis is understanding the random sample $\mathcal{N}'$. We want to ensure that any approximate dual solution (S', T') over $\mathcal{N}'$, when expanded out to (S, T) where $S = \mathrm{span}_1(S')$ and $T = \mathrm{span}_2(T')$, covers most of $\mathcal{N}$ by weight. The approach is based on [2] and will use an upper bound the number of distinct pairs (S, T) with certain nice properties. The first step in this direction is to count the number of closed sets in a given matroid.

▶ **Lemma 8.** *Let $\mathcal{M} = (\mathcal{N}, \mathcal{I})$ be a matroid with n elements and rank k. Then there are at most n^k closed sets in $\mathcal{M}$.*

Proof. For every closed set S, let I_S be a maximum independent subset of S. We have, $I_S \in \mathcal{I}$, $I_S \subseteq S$, and $\mathrm{span}(I_S) = \mathrm{span}(S)$. We claim the mapping from S to I_S is injective. Indeed, if S and T are closed and $I_S = I_T$, then $S = \mathrm{span}(S) = \mathrm{span}(I_S) = \mathrm{span}(I_T) = \mathrm{span}(T) = T$, so $S = T$. Thus the sets I_S are distinct. Meanwhile, every $I \in \mathcal{I}$ has cardinality at most k. So there are at most n^k closed sets. ◀

The following lemma shows that with high probability, any closed pair of sets (S, T) (with S closed in $\mathcal{M}_1$ and T closed in $\mathcal{M}_2$) either covers almost all of $\mathcal{N}$ by weight, or with high probability, does not cover at least one element in the random sample $\mathcal{N}'$.

▶ **Lemma 9.** *Let $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$ be a set of nonnegative weights. Let $\mathcal{N}'$ sample $O(k \log(n)/\epsilon)$ elements from $\mathcal{N}$ with repetition. Then with high probability we have the following: for all $A, B \subseteq \mathcal{N}$ such that A is closed in $\mathcal{M}_1$, B is closed in $\mathcal{M}_2$, $\operatorname{rank}_1(A) = \operatorname{rank}_2(B) \leq O(k)$, and $w(A \cup B) < (1-\epsilon)w(\mathcal{N})$, $\mathcal{N}'$ samples at least one element outside $A \cup B$.*

Proof. Since $\operatorname{rank}_1(A), \operatorname{rank}_2(B) \leq O(k)$, we can assume that $\mathcal{M}_1$ and $\mathcal{M}_2$ each have rank $O(k)$. Then, by Lemma 8, there are at most $n^{O(k)}$ choices of sets $A, B \subseteq \mathcal{N}$ such that A is closed in $\mathcal{M}_1$ and B is closed in $\mathcal{M}_2$.

Now fix such a pair A, B, and suppose $w(A \cup B) \leq (1-\epsilon)w(\mathcal{N})$. The probability that $\mathcal{N}' \subseteq A \cup B$ is

$$\left(\frac{w(A \cup B)}{w(\mathcal{N})}\right)^{|\mathcal{N}'|} \leq e^{-\epsilon|\mathcal{N}'|} \leq n^{-Ck}$$

for an arbitrarily large constant C. The claim now follows by taking the union bound over A, B. ◀

Now we put everything together. The following lemma gives a subroutine satisfying the requirements of the oracle in Lemma 7.

▶ **Lemma 10.** *Let $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$ be a set of nonnegative weights.*
In $O(n \log(n) Q + \mathcal{T}_\epsilon(k \log(n)/\epsilon))$ randomized time, one can compute an independent set I and sets S closed in $\mathcal{M}_1$ and T closed in $\mathcal{M}_2$ such that, with high probability:

- **i** $\operatorname{rank}(S) + \operatorname{rank}(T) \leq (1+\epsilon)|I|$.
- **ii** $w(S \cup T) \geq (1-\epsilon)w(\mathcal{N})$.

Proof. For ease of convention, we prove the claim with ϵ replaced by $O(\epsilon)$; the constant can then be removed by decreasing ϵ by a constant factor. (We adopt the same convention in subsequent proofs.)

Let $\mathcal{N}'$ sample $O(k \log(n)/\epsilon)$ elements with repetition in proportion to w. In $\mathcal{T}_\epsilon(k \log(n)/\epsilon)$ time, we compute a $(1-\epsilon)$-maximum matroid intersection I and a $(1+\epsilon)$-dual solution (A', B') in the restriction to $\mathcal{N}'$. We compute $A = \operatorname{span}_1(A')$ and $B = \operatorname{span}_2(B')$ in $O(nQ)$ time. We claim that I, A, and B satisfy the lemma.

First, we have $\operatorname{rank}_1(A) + \operatorname{rank}_2(B) = \operatorname{rank}_1(A') + \operatorname{rank}_2(B') \leq (1 + O(\epsilon))|I|$. Second, by Lemma 9, with high probability; since $\mathcal{N}' \subseteq A' \cup B' \subseteq A \cup B$, A is closed in $\mathcal{M}_1$, and B is closed in $\mathcal{M}_2$; we have $w(A \cup B) \geq (1-\epsilon)w(\mathcal{N})$, as desired. ◀

2.2 Fast primal-dual approximations for matroid intersection

It remains to give a fast primal-dual approximation for matroid intersection. The algorithm in [4] gives a $(1-\epsilon)$-maximum matroid intersection but not a $(1+\epsilon)$-dual solution. That said, one might expect a $(1+\epsilon)$-dual solution to be implicit in any given $(1-\epsilon)$-maximum matroid intersection algorithm in order to certify that the solution I is $(1-\epsilon)$-maximum. Such is the case here and we show how to extract a $(1+\epsilon)$-dual solution efficiently.

The $(1-\epsilon)$-maximum matroid intersection algorithm in [4], like other $(1-\epsilon)$-approximation algorithms, outputs an independent set $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ for which the length of the minimum "augmenting path" (defined in a moment) is at least $2/\epsilon$. This length implies that I is a $(1-\epsilon)$-maximum matroid intersection (just as in bipartite matching). We use this bound on the minimum length of an augmenting bound to extract a $(1+\epsilon)$-dual solution.

To go into further detail we must first introduce augmenting paths in the context of matroid intersection. The notion generalizes augmenting paths in bipartite matching. In the context of matroid intersection, for a fixed independent set I, an augmenting path is a sequence $P = (e_0, e_1, \dots, e_h)$ of elements alternating between $\mathcal{N} \setminus I$ and I. Additionally, an augmenting path must start and end with elements in $\mathcal{N} \setminus I$, and its symmetric difference with I, $I \triangle P$, must be independent in both matroids.

Augmenting paths are paths in an auxiliary directed bipartite graph between $\mathcal{N} \setminus I$ and I called the *exchange graph*. We have a directed edge (e, d) from $\mathcal{N} \setminus I$ to I iff $I - d + e \in \mathcal{I}_2$. We have a directed edge (d, e) from I to $\mathcal{N} \setminus I$ iff $I - d + e \in \mathcal{I}_1$.

Let $F_1 = \mathcal{N} \setminus \text{span}_1(I)$ be the set of free/uncovered elements in $\mathcal{M}_1$, and $F_2 = \mathcal{N} \setminus \text{span}_2(I)$ be the free elements in $\mathcal{M}_2$. All augmenting paths are between F_1 and F_2, but unlike bipartite matching, not all paths from F_1 to F_2 in the exchange graph are augmenting paths. However, all shortest paths from F_1 to F_2 are always augmenting paths. Thus many matroid intersection algorithms augment along shortest (F_1, F_2)-paths in the exchange graph.

If the minimum length of any augmenting path for I is at least $2/\epsilon$, then the typical argument that I is $(1-\epsilon)$-maximum is as follows. Given an optimal solution I^*, by contracting $I \cap I^*$, we may assume I^* and I are disjoint. $I \triangle I^*$ decomposes into even-length cycles and augmenting paths in the exchange graph. I and I^* have the same number of elements in each even-length cycle. For an augmenting path P, if P has length at least $2/\epsilon$, then $|I^* \cap P| \leq (1+\epsilon)|I \cap P|$. It follows that $|I^*| \leq (1+\epsilon)|I|$.

This argument does not imply an algorithm for a $(1+\epsilon)$-dual solution. (We do not have access to I^*.) Still, we can use the length bound to obtain a $(1+\epsilon)$-dual solution, giving another proof that I is $(1-\epsilon)$-maximum. Formally we prove the following.

▶ **Lemma 11.** *Let $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ be an independent point in the intersection. Suppose the minimum length of any augmenting path is at least $2/\epsilon$. Then in $O(n \log(k) Q/\epsilon)$ time, one can compute sets $S, T \subseteq \mathcal{N}$ such that $S \cup T = \mathcal{N}$ and $\text{rank}_1(S) + \text{rank}_2(T) \leq (1+\epsilon)|I|$.*

Proof. The desired sets S and T will be induced by the distances layers from F_1 in the exchange graph. For each index $i \in \mathbb{Z}_{\geq 0}$, let L_i be the set of elements at distance i from F_1. For example, $L_0 = F_1$, $L_i \subseteq \mathcal{N} \setminus I$ for even i, and $L_i \subseteq I$ for odd i.

To extract a good dual solution from these layers, we first need to construct them quickly. [7, 23] provide the following.

▶ **Fact 12.** *For $h = O(1/\epsilon)$, the first h layers $L_0, L_1, \dots, L_{h-1}$ of the exchange graph can be computed in $O(n \log(k) Q/\epsilon)$ time.*

To refer to elements in I and $\mathcal{N}$ by distance layer, we introduce the following notation. For all i, let $\mathcal{N}_i = \mathcal{N} \cap L_i$, and for odd i, let $\mathcal{I}_i = \mathcal{I} \cap L_i$. These layers partition the ground set, with the even layers partitioning $\mathcal{N} \setminus I$ and the odd layers partitioning I.

Suppose we construct the layers $(L_0 = F_1), \dots, L_h$ up to distance h from F_1 for $h \geq 2/\epsilon$. Since $h \geq 2/\epsilon$, there is an odd index i with $1 \leq i \leq h$ such that $|I_i| \leq \epsilon |I|$. Let $S = \mathcal{N} \setminus \left(\bigcup_{j<i} \mathcal{N}_i \right)$ be all elements in layer i and beyond, and $T = \bigcup_{j \leq i} \mathcal{N}_j$ be all the elements up to layer i. (S, T) is a discrete and feasible solution to the dual because $S \cup T = \mathcal{N}$. To prove that it is a $(1+\epsilon)$-dual solution, it suffices to show that $\text{rank}_1(S) + \text{rank}_2(T) \leq (1+\epsilon)|I|$.

Let $I^+ = I \setminus \left(\bigcup_{j<i} I_j \right) = I \cap S$. We claim that $S \subseteq \text{span}_1(I^+)$. Clearly $S \cap I = I^+ \subseteq \text{span}_1(I^+)$. Now consider an element $e \in S \setminus I$. We have $e \in \text{span}_1(I)$ because $e \notin \mathcal{N}_0$. If $e \notin \text{span}_1(I^+)$, then $I - d + e \in \mathcal{I}_1$ for some $d \in I \setminus I^+$. Then (d, e) is an exchange in the exchange graph. We have $d \in I_j$ for some $j \leq i - 2$, hence $d \in \mathcal{N}_\ell$ for some $\ell < i$. But then $e \notin S$, a contradiction.

Now let $I^- = \bigcup_{j \le i} I_j = I \cap T$. We claim that $T \subseteq \text{span}_2(I^-)$. We have $T \cap I \subseteq \text{span}_2(I^-)$. Consider any element $e \in T \setminus I$. We have $e \in \text{span}_2(I)$ since $e \in L_j$ for some $j < i \le h$, and there are no (F_1, F_2)-paths of length $< h$. If $e \notin \text{span}_2(I^-)$, then $I - d + e \in \mathcal{I}_2$ for some $d \in I \setminus I^-$. That is, (e, d) is an edge in the exchange graph. $e \in T$ implies that the distance from F_1 to e is at most $i - 1$, and the distance from F_1 to d is at most i. But $d \notin I^-$ implies that the distance from F_1 to d is at least $i + 2$, a contradiction.

Thus $S \subseteq \text{span}_1(I^+)$ and $T \subseteq \text{span}_2(I^-)$ where I^+ and I^- are subsets of I overlapping on I^-. Since $I^+ \cap I^- = I_i$, we have

$$\begin{aligned}\text{rank}(S) + \text{rank}(T) &\le \text{rank}(\text{span}_1(I^+)) + \text{rank}(\text{span}_2(I^-)) \\ &= |I^+| + |I^-| = |I| + |I_i| \le (1+\epsilon)|I|,\end{aligned}$$

as desired.

To recap, given an independent set $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ for which the length of the minimum augmenting path is at least $2/\epsilon$, we build out the first $O(1/\epsilon)$ layers of the exchange graph in $O(n \log(k) Q/\epsilon)$ time. We identify an index i such that $|I_i| \le \epsilon |I|$. We assemble the set $S = \mathcal{N} \setminus (L_0 \cup L_1 \cup \cdots \cup L_{i-1})$ of all elements in the ith layer and beyond, and the set $T = L_0 \cup L_1 \cdots \cup L_i$ of all elements up to the ith layer. This takes $O(n)$ time given the first $O(1/\epsilon)$ layers. (S, T) is the desired $(1+\epsilon)$-dual solution, completing the proof of Lemma 11. ◀

This concludes our discussion on maximum cardinality matroid intersection.

3 Weighted matroid intersection

We now consider the weighted matroid intersection problem. Similar to the unweighted setting, the high-level approach combines adaptive sparsification with a fast $(1 \pm \epsilon)$-primal-dual approximation algorithm to improve the running time dependence on the input n. These components are more technically challenging in the weighted setting.

Recall that $\mathcal{M}_1 = (\mathcal{N}, \mathcal{I}_1)$ and $\mathcal{M}_2 = (\mathcal{N}, \mathcal{I}_2)$ are two matroids over the same ground set $\mathcal{N}$, $c : \mathcal{N} \to \mathbb{R}_{\ge 1}$ is a set of input costs over $\mathcal{N}$, and $\epsilon \in (0, 1)$ is an input parameter.[2] The goal is to compute $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ with cost $c(I)$ at least a $(1 - \epsilon)$-fraction of the maximum cost of any such I. We assume without loss of generality that $c(e) \in [1, \text{poly}(n)]$ for all e.[3]

We start by introducing the LP relaxation of weighted matroid intersection:

$$\begin{aligned}&\text{maximize } \langle c, x \rangle \text{ over } x \in \mathbb{R}^E_{\ge 0} \\ &\quad \text{s.t. } x(S) \le \text{rank}_1(S) \text{ and } x(S) \le \text{rank}_2(S) \text{ for all } S \subseteq \mathcal{N}.\end{aligned} \tag{3}$$

The dual LP is as follows.

$$\begin{aligned}&\text{minimize } \sum_S \text{rank}_1(S) y_S + \text{rank}_2(S) z_S \text{ over } y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\ge 0} \\ &\quad \text{s.t. } \sum_{S : e \in S} y_S + z_S \ge c_e \text{ for all } e \in \mathcal{N}.\end{aligned} \tag{4}$$

For $e \in \mathcal{N}$, we say that (y, z) covers e if it meets the covering constraint for e in the dual LP (4).

---

[2] c is normally called "weights" in the weighted matroid intersection problem, but we will refer to them as "costs" to help distinguish them from the auxiliary weights generated by the framework.

[3] We assume each singleton set $\{e\}$ is independent for all e by removing all violating e in a preprocessing step. Then $\text{OPT} \ge \max_e c(e)$, and we can drop any element e with $c(e) \le (\epsilon/k) \max_f c(f)$ without decreasing the optimum value by more than an ϵ-fraction. Rescaling, all weights lie in the range $[1, k/\epsilon]$.

Recall that the overall framework maintains auxiliary weights $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$. For a fixed set of weights $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$, we say that y, z covers a $(1-\epsilon)$-fraction of elements by w if the total weight of elements covered by e is at least $(1-\epsilon)$-fraction of the total weight of all elements.

To apply Lemma 7 to the LPs (3) and (4), we need to fulfill an oracle problem defined as follows. The oracle takes as input a set of auxiliary weights $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$. With high probability, the oracle must return a dual solution y, z that covers a $(1-\epsilon)$-fraction of elements by weight.

Our implementation of the oracle is broken down into two components: (a) a randomized sparsification step applying a $(1 \pm \epsilon)$-primal-dual approximation algorithm to a randomly sampled subset of $\tilde{O}(k \log(n)/\epsilon)$ elements; and (b) the $(1 \pm \epsilon)$-primal-dual approximation oracle. Formally stating the interface of these two parts requires the notion of "compact" dual solutions and compact primal-dual algorithms. We define these now and give further background in appropriate subsections later.

We say that (y, z) is *compact* if the supports of y and z are of the form

$$\text{support}(y) \subseteq \{\text{span}_1(e_1), \text{span}_1(e_1, e_2), \ldots, \text{span}_1(e_1, \ldots, e_k)\}$$
$$\text{support}(z) \subseteq \{\text{span}_2(f_1), \text{span}_2(f_1, f_2), \ldots, \text{span}_2(f_1, \ldots, f_k)\}$$

for two sequences of k elements $e_1, \ldots, e_k \in \mathcal{N}$ and $f_1, \ldots, f_k \in \mathcal{N}$. We define a *compact* $(1 \pm \epsilon)$*-primal-dual weighted matroid intersection* algorithm that takes as input $\mathcal{M}_1 = (\mathcal{N}, \mathcal{I}_1)$, $\mathcal{M}_2 = (\mathcal{N}, \mathcal{I}_2)$, and $c : \mathcal{N} \to \mathbb{R}_{\geq 0}$, and returns $(1-\epsilon)$-maximum weight independent set and a compact $(1+\epsilon)$-minimum solution to the dual LP (4).

Now we can state the guarantees of part (a).

▶ **Lemma 13.** *Let $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$, and suppose there is a compact $(1 \pm \epsilon)$-primal-dual weighted matroid intersection algorithm running in $\mathcal{T}_\epsilon(m)$ on subsets of $\mathcal{N}$ of size m. Then in $O(\mathcal{T}_\epsilon(k \log(n)/\epsilon))$ time, one can compute an independent set I and a compact dual solution (y, z) such that (y, z) covers a $(1-\epsilon)$-fraction of $\mathcal{N}$ by w.*

Now we formally state the guarantees for part (b); namely, a compact $(1 \pm \epsilon)$-primal-dual approximation algorithm for weighted matroid intersection. The following algorithm extends the $(1-\epsilon)$-approximation for weighted matroid intersection to also give a compact dual solution.

▶ **Lemma 14.** *There is a compact $(1 \pm \epsilon)$-primal dual algorithm running in $\mathcal{T}_\epsilon(m) = \tilde{O}\left(m\sqrt{k}Q/\epsilon^2\right)$ time.*

We prove Lemma 13 in Section 3.1 and Lemma 14 in Section 3.2. Combining Lemmas 13 and 14 gives a subroutine implementing the oracle of Lemma 7 running in $\tilde{O}\left(nQ/\epsilon + k^{1.5}/\epsilon^3\right)$ time. Because the dual solution (y, z) returned by the oracle is compact, we can identify all the elements covered by (y, z) in $O(n \log(k)Q)$ time.[4] Lemma 7 repeats these two steps for $O(\log(n)/\epsilon)$ iterations, giving a total running time of $O\left(n \log(n)Q/\epsilon + k^{1.5} \log^{O(1)}(n)Q/\epsilon^4\right)$.

[4] For example, suppose the support of y is generated by the elements $e_1, \ldots, e_k$. Given an element d, one can binary search for the first index i such that $d \in \text{span}_1(e_1, \ldots, e_i)$. Then d is covered by $\text{span}_1(e_1, \ldots, e_j)$ for all $j \geq i$. With simple preprocessing, one then extracts the total amount that y covers d in $O(1)$ time. Similarly the amount that z covers d can be computed in $O(\log(k)Q)$ time with simple preprocessing.

3.1 Sparse reduction to compact $(1 \pm \epsilon)$-primal-dual approximations: proof of Lemma 13

In this section we prove Lemma 13. Let $w : \mathcal{N} \to \mathbb{R}_{\geq 0}$. We need to compute an independent set $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ and a compact $y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ such that:

(i) $(1 + O(\epsilon))c(I) \geq \sum_S \operatorname{rank}_1(S) y_S + \operatorname{rank}_2(S) z_S$.

(ii) (y, z) covers a $(1 - \epsilon)$-fraction of $\mathcal{N}$ by w.

The algorithm is as follows.

1. Let $\mathcal{N}' \subseteq \mathcal{N}$ sample $O(k \log(n)/\epsilon)$ elements, with repetition, in proportion to w.
2. Run the $(1 \pm \epsilon)$-primal dual approximation algorithm on $\mathcal{N}'$, producing $I \subseteq \mathcal{N}'$ with $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ and a compact solution $y', z' : 2^{\mathcal{N}'} \to \mathbb{R}_{\geq 0}$. Without loss of generality, the nonzero coordinates of y' and z' are in the range $[1/\operatorname{poly}(n), \operatorname{poly}(n)]$.
3. Define $y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ by setting $y(\operatorname{span}_1(S)) = \lceil y'(S) \rceil_{1+\epsilon}$ for $S \in \operatorname{support}(y')$ and similarly set $z(\operatorname{span}_2(T)) = \lceil z'(T) \rceil_{1+\epsilon}$ for $T \in \operatorname{support}(z')$, where $\lceil x \rceil_{1+\epsilon} \stackrel{\text{def}}{=} (1+\epsilon)^{\lceil \log_{1+\epsilon} x \rceil}$ rounds x up to the nearest power of $1 + \epsilon$.
4. Return I and (y, z).

Consider the range of (y, z) output by the algorithm. We first observe that (y, z) is compact. Indeed, since (y', z') was compact, there is a sequence of elements $e_1, \ldots, e_k$ such that all sets in the support of y' have the form $S'_i = \operatorname{span}_1(e_1, \ldots, e_i) \cap \mathcal{N}'$ for some prefix $e_1, \ldots, e_i$. Then the sets in the support of y have the form $S_i = \operatorname{span}_1(S'_i) = \operatorname{span}_1(e_1, \ldots, e_i)$. Thus the support of y is generated by prefixes of $e_1, \ldots, e_k$. Symmetrically the same holds for z for a different sequence of k elements depending on z'. Thus (y, z) is compact.

We also observe that each nonzero value of y or z is one of the $O(\log(n)/\epsilon)$ powers of $(1 + \epsilon)$ in the range $[1/\operatorname{poly}(n), \operatorname{poly}(n)]$.

For y, there are at most n^k ways to choose the sequence $e_1, \ldots, e_k$ that determines its support, and $(C \log(n)/\epsilon)^k$ ways to assign their values for some constant $C > 0$. Likewise for z. Altogether, there are at most $n^{O(k)}$ choices of (y, z) in the range of the algorithm.

Call a solution (y, z) in the range *good* if it covers an $(1 - \epsilon)$-fraction of $\mathcal{N}$ by w, and *bad* otherwise. We want to argue that with high probability, the solution (y, z) returned by the algorithm is good. We know that the output (y, z) covers all the elements in $\mathcal{N}'$. Thus it suffices to show that for all bad (y, z) in the range, $\mathcal{N}'$ samples at least one element that is not covered by (y, z).

To this end, fix a bad (y, z) in the range. A random element sampled from $\mathcal{N}$ in proportion to w is covered by (y, z) with probability at most $1 - \epsilon$. The probability that all of $\mathcal{N}'$ is covered by (y, z) is bounded above by $(1 - \epsilon)^{|\mathcal{N}'|} = n^{-O(k)}$. Taking the union bound over all bad (y, z) in the range, we conclude with high probability, $\mathcal{N}'$ samples at least one uncovered element for every bad (y, z). In this event, since the output (y, z) covers $\mathcal{N}'$, (y, z) must be good.

This completes the proof of Lemma 13.

3.2 Compact $(1 \pm \epsilon)$-primal-dual weighted matroid intersection: proof of Lemma 14

In this section we prove Lemma 14. We are given two matroids $\mathcal{M}_1 = (\mathcal{N}, \mathcal{I}_1)$ and $\mathcal{M}_2 = (\mathcal{N}, \mathcal{I}_2)$ over a common set $\mathcal{N}$ of size n, $c : \mathcal{N} \to \mathbb{R}_{\geq 1}$, and $\epsilon \in (0, 1)$. We let k be the rank of the intersection $\mathcal{I}_1 \cap \mathcal{I}_2$. We will compute $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ and a *compact* dual solution $y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ such that $(1 + O(\epsilon))c(I) \geq \sum_S \operatorname{rank}_1(S) y(S) + \operatorname{rank}_2(S) z(S)$.

As mentioned previously, a fast approximation algorithm for weighted matroid intersection is given by [8]. The stated running time is $\tilde{O}\left(nkQ/\epsilon^2\right)$ and breaks down as follows. There are $\tilde{O}(1/\epsilon)$ outer iterations. Each iteration invokes an approximation algorithm for unweighted matroid intersection that returns an independent set I with minimum augmenting path length $O(1/\epsilon)$. [8] truncate Cunningham's algorithm to execute an inner iteration in $\tilde{O}(nkQ/\epsilon)$ time. The subroutine using Cunningham's algorithm can be replaced by the $\tilde{O}\left(n\sqrt{k}Q/\epsilon\right)$-time algorithm of [4].[5] This gives a $(1-\epsilon)$-approximation algorithm for weighted matroid intersection running in $\tilde{O}\left(n\sqrt{k}Q/\epsilon^2\right)$ time.

The real challenge is to also compute a compact $(1+\epsilon)$-approximate dual solution within the same running time. This requires additional background on the framework of [8].

Cost-splitting. The fast approximation algorithm in [8] is based on the cost-splitting approach to matroid intersection described in [14]. A *cost-splitting* of c is a decomposition $c_1 + c_2$ where $c_1, c_2 : \mathcal{N} \to \mathbb{R}_{\geq 0}$.[6] A cost-splitting can be used to certify a maximum cost independent set as follows.

▶ **Fact 15** ([14]). *Suppose $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ and $c = c_1 + c_2$ is a cost-splitting such that I is a c_1-maximum independent set in $\mathcal{M}_1$ and c_2-maximum independent set in $\mathcal{M}_2$. Then I is a maximum cost independent set in the intersection of $\mathcal{M}_1$ and $\mathcal{M}_2$.*

The proof is immediate: given (I, c_1, c_2) as in fact 15, and letting I^* denote an optimum solution, we have $c_1(I) \geq c_1(I^*)$ and $c_2(I) \geq c_2(I^*)$. Since $c = c_1 + c_2$, $c(I) \geq c(I^*)$. Note that this proof does not involve the dual LP.

An approximate version of fact 15 is given in [8] to certify $(1-\epsilon)$-approximate solutions. This proof also does not construct a dual solution, let alone compact one.

Before describing how to extract the desired dual solution from [8], we give additional background on the LPs Equations (3) and (4). This background is not necessary for our analysis, but it gives some intuition for the eventual claim.

[10] proved that LP (3) is totally dual integral. Moreover, any optimal solution (y, z) can be uncrossed and merged so that the supports of y and z each form a chain. Expanding on the latter point, suppose the support of y is a chain of the form $S_1 \subsetneq S_2 \subsetneq \cdots \subsetneq S_\ell$. We can replace each S_i with $\text{span}(S_i)$ without increasing the objective or decreasing the coverage on any element. Thus, replacing each S_i with $\text{span}(S_i)$, we can assume each S_i is closed. We have $0 < \text{rank}_1(S_1) < \text{rank}_1(S_2) < \cdots < \text{rank}_1(S_\ell) \leq \text{rank}_1(\mathcal{N})$. Let $I_0 = \emptyset$, and for $i = 1, 2, \ldots, \ell$ in sequence, let I_i extend I_{i-1} to a maximum cardinality independent set of S_i. Then $S_i = \text{span}(I_i)$ for each i. Let $e_1, \ldots, e_h$ enumerate the elements of I_1, then $I_2 \setminus I_1$, and so forth, so that each I_i is a prefix of the form $I_i = \{e_1, \ldots, e_{j_i}\}$ for some index $j_i \in [h]$. Since $I_\ell = \{e_1, \ldots, e_h\} \in \mathcal{I}_1$, $h \leq \text{rank}_1(\mathcal{N})$.

This exercise shows that if the support of y is a chain, then it is induced by prefixes of a sequence of $h \leq \text{rank}_1(\mathcal{N})$ elements $e_1, \ldots, e_h$. Symmetrically if the support of z is a chain, then it is also generated by a sequence of $\text{rank}_2(\mathcal{N})$ elements. Consequently there are at most $n^{\text{rank}_1(\mathcal{N}) + \text{rank}_2(\mathcal{N})}$ ways for y and z to have chain supports.

[5] A minor technical point to address is that the unweighted matroid intersection is not over $\mathcal{M}_1$ and $\mathcal{M}_2$, but auxiliary "weight-induced matroids" $\mathcal{M}_{1,c_1}$ and $\mathcal{M}_{2,c_2}$ induced by weights c_1 and c_2. Fortunately it is easy to identify edges of the exchange graph of $\mathcal{M}_{1,c_1}$ and $\mathcal{M}_{2,c_2}$ via independence oracles to the input matroids $\mathcal{M}_1$ and $\mathcal{M}_2$. The algorithm in [4] can be adapted to $\mathcal{M}_{1,c_1}$ and $\mathcal{M}_{2,c_2}$ just as Cunningham's algorithm was adapted in [8].

[6] [14] calls this a "weight-splitting". We refer to this as a "cost-splitting" because we are referring to c as costs.

Thus a compact solution (y, z) is similar to a solution (y, z) where the support is a chain. However, compact solutions restrict the generating sequences of elements to have length at most k, and $k \leq \min\{\text{rank}_1(\mathcal{N}), \text{rank}_2(\mathcal{N})\}$.

As alluded to earlier, [8] computes a $(1-\epsilon)$-approximation I along with vectors c_1, c_2 that approximate the (exact) cost-splitting describe in [14]. We formalize the approximation conditions as follows: For fixed I and $\epsilon \in (0, 1)$, an *ϵ-approximate cost-splitting certificate* is a pair of weight vectors $c_1, c_2 : \mathcal{N} \to \mathbb{R}_{\geq 0}$ with the following properties:

(a) $(1+\epsilon)(c_1 + c_2) \geq c$ elementwise.
(b) $c_1(I) + c_2(I) \leq (1+\epsilon)c(I)$.
(c) I is a c_1-maximum independent set in $\mathcal{M}_1$ restricted to $\text{span}_1(I)$.
(d) I is a c_2-maximum independent set in $\mathcal{M}_2$ restricted to $\text{span}_2(I)$.
(e) $c_1(e) \leq \epsilon$ for all $e \in \mathcal{N} \setminus \text{span}_1(I)$.
(f) $c_2(e) \leq \epsilon$ for all $e \in \mathcal{N} \setminus \text{span}_2(I)$.

[8] produces an independent set $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ and an ϵ-approximate cost-splitting certificate c_1, c_2. We show how to extract a compact $(1+\epsilon)$-approximate dual solution from I, c_1, and c_2.

▶ **Lemma 16.** *Let $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ and let $c_1, c_2 : \mathcal{N} \to \mathbb{R}_{\geq 0}$ be an ϵ-approximate cost-splitting certificate. Then in $\tilde{O}(nQ)$ time, one can compute $y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ such that*

(i) *(y, z) are feasible for the dual LP (4).*
(ii) *(y, z) are compact.*
(iii) $\sum_S \text{rank}_1(S) y_S + \text{rank}_2(S) y_S \leq (1 + O(\epsilon))c(I)$

The last point says that I and (y, z) mutually certify each other to be $(1 \pm O(\epsilon))$-approximations to their respective problem. Taking ϵ down to 0 gives an exact compact dual optimum solution certifying I to be exactly optimum.

Proof of Lemma 16. For $t \in \mathbb{R}_{\geq 0}$, let

$$Y_t = \text{span}_1(\{e \in I : c_1(e) \geq t\}) \text{ and } Z_t = \text{span}_2(\{e \in I : c_2(e) \geq t\}).$$

Let $y, z : 2^{\mathcal{N}} \to \mathbb{R}_{\geq 0}$ be defined by

$$y = (1 + O(\epsilon)) \int_0^\infty 1_{Y_t}\, dt \text{ and } z = (1 + O(\epsilon)) \int_0^\infty 1_{Z_t}\, dt,$$

where 1_S denotes the indicator vector for $S \subseteq \mathcal{N}$ in $\mathbb{R}^{2^{\mathcal{N}}}$. Observe that y is supported by a chain of elements listing I in decreasing order of c_1, and z is supported by a chain of elements listing I in decreasing order of c_2. It remains to show that y, z is feasible for the dual LP (4), and has objective value within a $(1 + O(\epsilon))$-factor of $c(I)$.

To show that (y, z) is feasible, fix $e \in \mathcal{N}$. If $c_1(e) \geq \epsilon$, then $e \in \text{span}_1(I)$. Since I is c_1-maximum in $\mathcal{M}_1$, $e \in \text{span}(Y_t)$ for all $t \leq c_1(e)$. Therefore,

$$\sum_{S : e \in S} y_S \geq (1 + O(\epsilon)) \int_0^{c_1(e)} 1\, dt = (1 + O(\epsilon))c_1(e).$$

Symmetrically, if $c_2(e) \geq \epsilon$, then $\sum_{S : e \in S} z_S \geq (1 + O(\epsilon))c_2(e)$.

Now we have three cases. If $c_1(e) \geq \epsilon$ and $c_2(e) \geq \epsilon$, then

$$\sum_{S : e \in S} y_S + z_S \geq (1 + O(\epsilon))c_1(e) + (1 + O(\epsilon))c_2(e) \geq c(e).$$

If $c_1(e) \le \epsilon$, then $c_1(e) \le \epsilon c(e)$, and

$$\sum_{S:e\in S} y_S + z_S \ge \sum_{S:e\in S} z_S \ge (1+O(\epsilon))c_2(e) \ge (1+O(\epsilon))((1-\epsilon)c(e) - c_1(e))$$
$$\ge (1+O(\epsilon))(1-2\epsilon)c(e) \ge c(e).$$

Symmetrically, if $c_2(e) \le \epsilon$, then $\sum_{S:e\in S} y_S + z_S \ge (1-2\epsilon)c(e)$. Thus (y,z) forms a feasible dual solution if $c_1(e) \le \epsilon$, $c_2(e) \le \epsilon$, or neither.

Now consider the objective value. The contribution from y is

$$\sum_S \operatorname{rank}_1(S) y_S = (1+O(\epsilon)) \int_0^\infty \operatorname{rank}(Y_t)\, dt$$
$$= (1+O(\epsilon)) \int_0^\infty |Y_t \cap I|\, dt = (1+O(\epsilon))c_1(I).$$

Symmetrically, z contributes $\sum_S \operatorname{rank}_2(S) z_S = (1+O(\epsilon))c_2(I)$. Together, we have

$$\sum_S \operatorname{rank}_1(S) y_S + \operatorname{rank}_2(S) z_S = (1+O(\epsilon))(c_1(I)+c_2(I)) \le (1+O(\epsilon))I,$$

as desired. ◀

Now we complete the proof of Lemma 13. Using the algorithm of [8] with the $(1-\epsilon)$-approximated unweighted matroid intersection algorithm of [4] as a subroutine, we compute an $(1-\epsilon)$-approximate maximum cost independent set I and a ϵ-approximate cost-splitting certificate c_1, c_2, in $\tilde{O}\left(n\sqrt{k}Q/\epsilon^2\right)$ time. By Lemma 16, we extract a feasible compact $(1+\epsilon)$-dual solution (y,z) in $\tilde{O}(nQ/\epsilon)$ time. We return I and (y,z). The overall running time is $\tilde{O}\left(nQ/\epsilon + k^{3/2}/\epsilon^3\right)$. This completes the proof of Lemma 13 and of the faster approximate matroid intersection algorithm.

4 MWU analysis

In this section we prove Lemma 7, which claims that given a covering LP, solving a certain relaxed coverage problem for $\tilde{O}(1/\epsilon)$ iterations leads to a $(1-\epsilon)$-approximation overall.

Like other proofs, we fix ϵ, and describe and analyze an algorithm that returns a point $x \in \mathcal{P}$ with objective value $\langle b, x\rangle \le (1+O(\epsilon))\,\mathrm{OPT}$ and coverage $Ax \ge (1-O(\epsilon))\mathbb{1}$. The claimed $(1\pm\epsilon)$ bounds then follow by decreasing ϵ by a constant factor.

There are multiple perspectives on the MWU framework presenting essentially the same proof in different styles. Our presentation follows the conventions of the analysis from [24].

The algorithm builds a solution x incrementally over $L = O(\log(m)/\epsilon)$ iterations. We let $x^{(\ell)}$ denote the value of x after ℓ iterations. It starts with $x^{(0)} = \mathbb{0}$. Each iteration ℓ invoke the oracle for a set of weights $w^{(\ell)}$ and produces a point $y^{(\ell)}$, and updates $x^{(\ell)} = x^{(\ell-1)} + y^{(\ell)}/L$. The output, $x^{(L)} = \sum_\ell y^{(\ell)}/L$, is the average of the points returned by the oracle. The exact steps in the ℓth iteration are as follows:

1. For each $i \in [m]$, compute $w_i^{(\ell)} = e^{-\operatorname{load}^{(\ell-1)}(i)}$, where
$$\operatorname{load}^{(\ell-1)}(i) = |\{k \in \{1,\dots,\ell-1\} : (Ay^{(k)})_i \ge 1\}|$$
is the number of previous iterations k where $y^{(k)}$ covers w_i.
2. Invoke the oracle with respect to $w^{(\ell)}$, returning $y^{(\ell)}$.
3. Set $x^{(\ell)} = x^{(\ell-1)} + y^{(\ell)}/L$.

Each call to the randomized oracle succeeds with high probability, and there are $L = O(\log(m)/\epsilon)$ iterations. By the union bound, all oracle calls succeed with high probability. For the remainder of the analysis we assume this is the case.

We want to show that $x^{(L)} = \sum_{\ell=1}^{L} y^{(\ell)}/L$ is a $(1 + O(\epsilon))$ approximation. It is easy to see that the objective value is good: we have

$$\langle b, x^{(L)} \rangle = \frac{1}{L} \sum_{\ell=1}^{L} \langle b, y^{(\ell)} \rangle \geq (1+\epsilon)\,\mathrm{OPT}$$

because the oracle guarantees $\langle b, y^{(\ell)} \rangle \geq (1+\epsilon)\,\mathrm{OPT}$ for all ℓ. It remains to show that $Ax^{(L)} \geq (1 - O(\epsilon))\mathbb{1}$. The key to the analysis is understanding why the weights are selected as they are.

For each iteration ℓ, let $M_\ell = \{i \in [m] : (Ay^{(\ell)})_i \geq 1\}$ be the set of coordinates covered in the ℓth iteration. The oracle guarantees that for each iteration $\ell \in [L]$,

$$\sum_{i \in M_\ell} w_i^{(\ell-1)} \geq (1-\epsilon)\langle w^{(\ell-1)}, \mathbb{1} \rangle.$$

We claim that

$$\sum_{i \in M_\ell} w_i^{(\ell)} \geq (1 - O(\epsilon))\langle w^{(\ell)}, \mathbb{1} \rangle \tag{5}$$

for all $\ell \in [L]$. To this end, we have

$$\begin{aligned}\sum_{i \notin M_\ell} w_i^{(\ell)} &\overset{(a)}{\leq} \sum_{i \notin M_\ell} w_i^{(\ell-1)} \leq \epsilon \langle w^{(\ell-1)}, \mathbb{1} \rangle \leq \frac{\epsilon}{(1-\epsilon)} \sum_{i \in M_\ell} w_i^{(\ell-1)} \\ &\overset{(b)}{=} \frac{\epsilon e}{(1-\epsilon)} \sum_{i \in M_\ell} w_i^{(\ell)} \leq \frac{\epsilon e}{(1-\epsilon)} \langle w^{(\ell)}, \mathbb{1} \rangle,\end{aligned}$$

as desired. Here, (a) is because $w^{(\ell)}$ is decreasing in ℓ. (b) is because for each $i \in M_\ell$, the weight decreases by e^{-1}.

To complete the analysis, define $f(\ell)$ by

$$f(\ell) = -\frac{1}{L} \log \left(\sum_{i=1}^{m} e^{-\mathrm{load}^{(\ell)}(i)} \right) = -\frac{1}{L} \log \left(\sum_{i=1}^{m} w_i^{(\ell)} \right).$$

$f(\ell)$ gives a smooth approximation of the minimum value of $\mathrm{load}^{(\ell)}$; we have

$$\min_i \frac{\mathrm{load}^{(\ell)}(i)}{L} - \epsilon \leq f(x) \leq \min_i \frac{\mathrm{load}^{(\ell)}(i)}{L}$$

because $L \geq \log(m)/\epsilon$. Since $(Ax^{(L)})_i \geq \mathrm{load}^{(L)}(i)$ for all i, it suffices to show that $f(L) \geq 1 - O(\epsilon)$. We have

$$f(L) = f(0) + \sum_{\ell=1}^{L} f(\ell) - f(\ell-1) = -\epsilon - \frac{1}{L} \sum_{\ell=1}^{L} \log \left(\frac{\sum_{i=1}^{m} w_i^{(\ell)}}{\sum_{i=1}^{m} w_i^{(\ell-1)}} \right)$$

For each iteration ℓ, we have

$$\begin{aligned}\sum_{i=1}^{m} w_i^{(\ell)} &\overset{(c)}{\leq} (1 + O(\epsilon)) \sum_{i \in M_\ell} w_i^{(\ell)} \overset{(d)}{=} (1 + O(\epsilon)) e^{-1} \sum_{i \in M_\ell} w_i^{(\ell-1)} \\ &\leq (1 + O(\epsilon)) e^{-1} \sum_{i} w_i^{(\ell-1)} \leq e^{-(1-O(\epsilon))} \sum_{i} w_i^{(\ell-1)}.\end{aligned}$$

Here (c) critically uses inequality (5). (d) is because all elements $i \in M_\ell$ are covered by $y^{(\ell)}$, increasing their loads by 1 and their weight by e^{-1}. Thus

$$\log\left(\frac{\sum_{i=1}^m w_i^{(\ell)}}{\sum_i w_i^{(\ell-1)}}\right) \leq -(1 - O(\epsilon)).$$

Plugging back in, we have $f(L) \geq -\epsilon - \frac{1}{L}\sum_{\ell=1}^{L}(-(1 - O(\epsilon))) = 1 - O(\epsilon)$, as desired.

Better Sparsifiers for Directed Eulerian Graphs

Abstract

Spectral sparsification for directed Eulerian graphs is a key component in the design of fast algorithms for solving directed Laplacian linear systems. Directed Laplacian linear system solvers are crucial algorithmic primitives to fast computation of fundamental problems on random walks, such as computing stationary distributions, hitting and commute times, and personalized PageRank vectors. While spectral sparsification is well understood for undirected graphs and it is known that for every graph G, $(1+\varepsilon)$-sparsifiers with $O(n\varepsilon^{-2})$ edges exist [Batson-Spielman-Srivastava, STOC '09] (which is optimal), the best known constructions of Eulerian sparsifiers require $\Omega(n\varepsilon^{-2}\log^4 n)$ edges and are based on short-cycle decompositions [Chu et al., FOCS '18].

In this paper, we give improved constructions of Eulerian sparsifiers, specifically:

1. We show that for every directed Eulerian graph $\vec{G}$, there exists an Eulerian sparsifier with $O(n\varepsilon^{-2}\log^2 n \log^2 \log n + n\varepsilon^{-4/3}\log^{8/3} n)$ edges. This result is based on combining short-cycle decompositions [Chu-Gao-Peng-Sachdeva-Sawlani-Wang, FOCS '18, SICOMP] and [Parter-Yogev, ICALP '19], with recent progress on the matrix Spencer conjecture [Bansal-Meka-Jiang, STOC '23].
2. We give an improved analysis of the constructions based on short-cycle decompositions, giving an $m^{1+\delta}$-time algorithm for any constant $\delta > 0$ for constructing Eulerian sparsifiers with $O(n\varepsilon^{-2}\log^3 n)$ edges.

1 Introduction

Given a graph $G(V, E)$, a sparsifier of G is a graph H on the same set of vertices V, but hopefully supported on a subset of the edges $E' \subset E$ such that H approximately preserves certain properties of G. Several notions of graph sparsification have been well studied for undirected graphs, e.g. spanners (approximately preserving distances), cut sparsifiers, spectral sparsifiers, etc.

Spectral sparsification is a particularly influential notion of undirected graph sparsification [44]. Spectral sparsifiers generalize cut-sparsifiers introduced by Benczur-Karger [10], which guarantees that the total weight of every vertex cut is preserved up to a multiplicative factor of $(1+\varepsilon)$ in the sparsifier. Efficient spectral sparsification was a core development that led to nearly-linear time solvers for Laplacian linear systems [44]. It further inspired the Laplacian paradigm, resulting in faster algorithms for many graph problems including sampling/counting random spanning trees [16, 17] and approximating edge centrality measures [31].

The first construction of spectral sparsifiers for undirected graphs by Spielman and Teng required $\Omega(n\varepsilon^{-2}\text{poly}(\log n))$ number of edges with a large, unspecified power of $\log n$. Subsequently, Spielman and Srivastava [42] constructed a spectral sparsifier with $O(n\varepsilon^{-2}\log n)$ edges probabilistically by independently sampling each edge with probability proportional to its leverage score. In a complete graph, sampling edges independently with probability p requires $p=\Omega(\varepsilon^{-2}\log n)$ to achieve $(1+\varepsilon)$-spectral sparsification; thus such construction requires $\Omega(n\varepsilon^{-2}\log n)$ edges. Batson-Spielman-Srivastava [7] further improved this to show that there exist spectral sparsifiers for undirected graphs with $O(n\varepsilon^{-2})$ edges and that this is tight even for the complete graph. Thus, they essentially settled the question of the optimal size of undirected spectral sparsifiers.

For directed graphs, sparsification has been trickier to define. It is immediate to see that in a complete bipartite graph with all edges directed from the left vertices to the right vertices, if one wishes to approximately preserve all directed cuts, one must preserve all the edges. This means that there is no non-trivial cut-sparsification (or its generalization) for arbitrary directed graphs. Such pathological cases can be avoided if one restricts to Eulerian directed graphs, i.e. a graph where each vertex has its total weighted in-degree equal to its total weighted out-degree, in which case cut sparsification becomes equivalent to cut sparsification of undirected graphs. Indeed, Cohen-Kelner-Peebles-Peng-Rao-Sidford-Vladu [13] defined a meaningful generalization of spectral sparsification (and hence cut sparsification) to Eulerian directed graphs. The standard notion of Eulerian approximation and (sparsification) requires exact preservation of the differences between in and out degrees while ensuring the difference in directed Eulerian Laplacians is small with respect to the Laplacian of the undirectification of the graph. That is, for $\epsilon\in(0,1)$,

$$\left\|\mathbf{L}_G^{\frac{+}{2}}(\mathbf{L}_{\vec{H}}-\mathbf{L}_{\vec{G}})\mathbf{L}_G^{\frac{+}{2}}\right\|\leq\epsilon.$$

We call these sparsifiers Eulerian sparsifiers for brevity. In a manner similar to the original Spielman-Teng construction, [13] gives a nearly-linear time $\widetilde{O}(m)$-time algorithm to build an Eulerian sparsifier with $O(n\varepsilon^{-2}\text{poly}(\log n))$ edges, with a large unspecified power of $\log n$.

Since Eulerian sparsification generalizes undirected spectral sparsification, $\Omega(n\varepsilon^{-2})$ edges are necessary for constructing Eulerian sparsifiers. There has been progress in proving the existence of Eulerian sparsifiers with fewer edges: Chu-Gao-Peng-Sachdeva-Sawlani-Wang [11] introduced the short-cycle decomposition, a decomposition of an unweighted graph as a union of short edge-disjoint cycles, and a few extra edges. As a simple lemma, they showed that every undirected graph can be represented as a union of edge-disjoint cycles of length $2\log n$, with at most $2n$ extra edges. Using this short-cycle decomposition, [11] were able to prove Eulerian sparsifiers with $O(n\varepsilon^{-2}\log^4 n)$ edges exist. However, the following natural question remains unanswered:

What is the best possible sparsity guarantee for constructing Eulerian sparsifiers?

In this paper, we make progress on this question. First, we present an improved analysis of the short-cycle based Eulerian sparsification from [11].

▶ **Theorem 1.** *For every constant $\delta > 0$, there is an algorithm that takes as input a directed Eulerian graph $\vec{G}$ and returns an ε-Eulerian sparsifier of $\vec{G}$ with $O(n\varepsilon^{-2}\log^3 n)$ edges in $m^{1+\delta}$ time.*

The above algorithm relies on independently toggling short cycles: with probability $\frac{1}{2}$ all clockwise edges are deleted and counter-clockwise edges are doubled, otherwise vice-versa. Given that the edges in each $O(\log n)$ length short-cycle are toggled in a completely correlated manner, and the cycles are toggled independently, this approach cannot lead to a sparsity better than $O(n\varepsilon^{-2}\log^3 n)$ (see Remark 9). To go past the above result, we leverage discrepancy theory, specifically recent progress on the matrix Spencer conjecture by Bansal, Jiang, and Meka [6]. (See Section 1.1 for a description of the matrix Spencer conjecture.) While the matrix Spencer conjecture is not directly useful for our application, we utilize the underlying machinery from [6] and the short-cycle decomposition to prove the following:

▶ **Theorem 2** (Informal)**.** *There is an algorithm that given an Eulerian graph $\vec{G}$, can compute in poly-time an ε-Eulerian sparsifier of $\vec{G}$ with $n\varepsilon^{-2}\log^2 n + n\varepsilon^{-3/4}\log^{8/3} n$ edges (up to $\log\log n$ factors).*

For small ε, e.g. $\varepsilon^{-1} = \Omega(\log n)$, the above theorem gives an $n\varepsilon^{-2}\log^2 n$ bound, only a $\log^2 n$ factor away from the lower bound. In Section 4.1 we show that assuming the matrix partial colouring conjecture, one can improve this result to prove the existence of ε-Eulerian sparsifiers with $n\varepsilon^{-2}\log^2 n$ edges for all ε (up to $\log\log n$ factors).

Sparsification

There are four major approaches for undirected spectral sparsification: expander decomposition [45, 4, 20], spanners [21, 23, 26], importance sampling [43, 22], and potential function based sparsification [8, 3, 28, 29]. More closely related to Eulerian sparsification is undirected degree preserving sparsification, introduced by Chu-Gao-Peng-Sachdeva-Sawlani-Wang [11]. Degree preserving sparsification is useful for constructing spectral sketches. More importantly for us, techniques for degree preserving sparsification can generally be extended to work for directed Eulerian sparsification.

Cohen-Kelner-Peebles-Peng-Rao-Sidford-Vladu [13] showed the first degree preserving (implicitly) and Eulerian sparsifier using expander decomposition. The algorithm performs random sampling of the directed edges with probability related to the degrees within each expander. Recent work by Ahmadinejad-Peebles-Pyne-Sidford-Vadhan [2] establishes an "equivalence", albeit with significantly stronger requirements than spectral approximations, between degree preserving and Eulerian sparsification under the notion of singular value approximation. They established the first Eulerian sparsifier with both nearly-linear sparsity and nearly-linear runtime, albeit with a large $\text{poly}(\log n)$ factor in both. However, the expander approach bottlenecks at $\Omega(n\varepsilon^2\log^3 n)$ due to a lowerbound on the optimal tradeoff between the expansion factor and the number of expanders [41].

The technique of using short cycles for sparsification [11] also applies to degree preserving and Eulerian sparsifications with sparsity $O(n\varepsilon^{-2}\log^2 n)$ and $O(n\varepsilon^{-2}\log^4 n)$ respectively. Improved short cycle decompositions were subsequently designed in [32, 35] to facilitate faster construction of sparsifiers. Our first result Theorem 1 follows closely to [11] and reduces the gap between degree-preserving and Eulerian sparsification under this technique.

Recently Jambulapati-Reis-Tian [19] constructed new degree preserving sparsifiers using discrepancy theory. They showed operator norm discrepancy bodies are well conditioned[1] for the symmetric and PSD matrices that arise from undirected sparsification and used an approximate version of the framework from Reis-Rothvoss [39] to give a colouring of the edges (corresponding to adding and deleting edges) under the linear constraint needed for degree preservation. However, the underlying discrepancy bodies studied by Jambulapati-Reis-Tian [19] do not align with Eulerian sparsification where matrices are no longer positive semidefinite and the primary statistic one has control over is matrix variance (see Section 4).

Directed Laplacian solvers

Cohen-Kelner-Peebles-Peng-Sidford-Vladu [14] initiated the line of work that studies solving directed Laplacian linear systems. They established a reduction from solving general directed Laplacian systems to Eulerian Laplacian systems.Cohen-Kelner-Peebles-Peng-Rao-Sidford-Vladu [13] gave an almost linear time algorithm for solving Eulerian Laplacians using the squaring identities from Peng-Spielman [37]. Subsequently, Cohen-Kelner-Kyng-Peebles-Peng-Rao-Sidford [12] gave the first nearly linear time solver using the standard approximate LU factorization techniques that enjoyed great success in undirected Laplacian solvers [27, 24, 40]. Ahmadinejad-Jambulapati-Saberi-Sidford [1] further established a reduction from solving systems of (asymmetric) M-matrices to Eulerian Laplacian systems, giving fast computation of several problems closely associated with the Perron-Frobenius theorem. Peng-Song [36] extended the approach from [12] and gave an approach for extending an algorithm for building Eulerian sparsifiers to a fast solver for Eulerian Laplacian linear systems. Combined with Theorem 1, they give an $O(n \log^4 n \log(\frac{n}{\varepsilon}))$ time solver with $m^{1+\delta}$ preprocessing time for any constant $\delta > 0$. Kyng-Meierhans-Probst-Gutenberg [25] established the first derandomized directed Laplacian solver in almost linear time.

Discrepancy theory

The Matrix Spencer Conjecture [47, 34] is a major open problem in discrepancy theory:

▶ **Conjecture 3** (Matrix Spencer Conjecture). *Given $n \times n$ symmetric matrices $\mathbf{A}_1, \ldots, \mathbf{A}_m \in \mathbb{R}^{n \times n}$ with $\|\mathbf{A}_i\| \leq 1$, there exist signs $x \in \{\pm 1\}^m$ such that $\|\sum_{i=1}^m x_i \mathbf{A}_i\| \leq O(\sqrt{m} \cdot \max\{1, \sqrt{\min\{1, \log(\frac{n}{m})\}}\})$.*

As a natural comparison, for a uniform random colouring $x \in \{\pm 1\}^m$, the matrix Chernoff bound [46] gives the following bound which has a gap of $\sqrt{\log n}$ to Conjecture 3 when $m \geq n$:

$$\mathbb{E}\left[\left\|\sum_i x_i \mathbf{A}_i\right\|\right] = O\left(\sqrt{\log n}\right) \cdot \left\|\sum_i \mathbf{A}_i^2\right\|^{\frac{1}{2}} \leq O(\sqrt{m \log n}).$$

We refer readers to [30, 18, 15] for recent progress toward solving this conjecture.

Many natural problems in studying the spectra of matrices can be viewed as discrepancy theory problems, e.g., graph sparsification [8, 38] and the Kadison-Singer problem [33]. Reis-Rothvoss [38] studies the geometry of operator norm balls for a collection of matrices where, $\|\sum_i |\mathbf{A}_i|\|$ is small. This was subsequently used in Jambulapati-Reis-Tian [19] to show optimal degree preserving sparsification. As previously mentioned, this line of work does not apply to Eulerian sparsification since matrices that emerge from our setting do not satisfy

[1] I.e., satisfy certain Gaussian measure lowerbound

that $\|\sum_i |\mathbf{A}_i|\|$ is small. Bansal-Jiang-Meka [6] resolved the Matrix Spencer Conjecture for matrices of rank $n/(\log^{O(1)} n)$ using a recent advancement in matrix concentration bounds due to Bandeira-Boedihardjo-van-Handel [5]. The partial colouring result for controlling operator norm used in [6] serves as the main machinery in our existential results (see Lemma 4). Specifically, the matrices we study naturally satisfy $\|\sum_i \mathbf{A}_i^2\|$ is small.

1.2 Technical overview

Our approach to constructing Eulerian sparsifiers builds on the framework of Chu-Gao-Peng-Sachdeva-Sawlani-Wang [11]. The sparsification algorithm in [11] combines importance sampling of edges with a short cycle decomposition. At each iteration, the algorithm restricts its attention to edges with small "importance" in the undirected graph (edges with leverage score $w_e \mathbf{b}_e^\top \mathbf{L}_G^+ \mathbf{b}_e$ at most constant times the average leverage score, $O(\frac{n}{m})$). The algorithm then performs a short cycle decomposition on these edges – expressing the graph as a union of uniformly weighted edge-disjoint short cycles and a few extra edges. For each short cycle, the algorithm independently keeps either the clockwise edges or the counter-clockwise edges with probability $\frac{1}{2}$ each. The number of edges reduces by a constant fraction in expectation at each iteration. After doubling the weights of the cycle edges retained, the algorithm guarantees that the Eulerianess of each cycle is preserved and, hence, the entire graph. Moreover, when combined with the undirected leverage score condition above, changes in directed short cycles also have a small variance overall. The matrix Bernstein inequality for asymmetric matrices guarantees a small approximation error for this randomized step. We repeat this process until the desired approximation error is met.

Our improved result of this algorithm is due to th improved variance bounds in Lemma 8 for random matrices corresponding to short cycles. Rather than bounding the variance through complete graphs as in [11], we bound it with respect to the undirected cycle. This improved variance also serves a critical role in our partial colouring approach in Section 4.

In the rest of our paper, we present our existential result which uses the partial colouring lemma, Lemma 4, from [6] to choose how to sparsify the short cycles. The algorithm follows the same high-level approach as the random sampling construction above. For each directed short cycle, instead of independently sampling cycle edges, we will use the partial colouring given by Lemma 4. In each iteration, Lemma 4 gives a partial colouring with sufficiently many fully coloured entries (i.e., ± 1 entries) on all cycles. It then allows us to remove a constant fraction of the cycle edges with less error than random sampling.

▶ **Lemma 4** ([6] Lemma 3.1). *There exists constants $c, c' > 0$ such that given symmetric matrices $\mathbf{A}_1, \ldots, \mathbf{A}_m \in \mathbb{R}^{n \times n}$ satisfying $\|\sum_{i=1}^m \mathbf{A}_i^2\| \leq \sigma^2$ and $\sum_{i=1}^m \|\mathbf{A}_i\|_F^2 \leq mf^2$ and a point $\mathbf{y} \in (-1,1)^m$, there is an algorithm* PartialColour *that returns in polynomial time a point $\mathbf{x} \in [-1,1]^m$ such that $|\{i : x_i \in \{\pm 1\}\}| > c'm$ and*

$$\left\| \sum_{i=1}^m (x_i - y_i)\mathbf{A}_i \right\| \leq c(\sigma + (\log^{\frac{3}{4}} n)\sqrt{\sigma f}). \tag{1}$$

There are two major challenges in applying Lemma 4. Firstly, within each iteration, we cannot afford to fully colour all the cycles by recursively applying Lemma 4, since we might have to perform the partial colouring $O(\log n)$ times, resulting in an additional log factor in the sparsity. Thus, we are always left with fractionally coloured cycles (i.e., entries with magnitude < 1). Such cycles must still be incorporated into the sparsified graph to guarantee the error given by Lemma 4. However, we cannot explicitly modify the graph to include edges corresponding to these cycles, as we would lose the integral and polynomially

bounded weight conditions and the short cycle decomposition could no longer be applied to this new graph. The second challenge also comes from incorporating fractionally coloured cycles in the next iteration. Unlike the undirected case, the two parts of a directed cycle do not necessarily have the same number of edges. For example, a directed cycle with all edges in the same direction has all the edges in one part and none in the other. If we start our colouring process from a non-zero initial partial colouring (i.e., a non-zero $\mathbf{y}$ to Lemma 4), we could end up at a colouring where almost no edges are removed.

To deal with these problems, our algorithm handles the integral weighted portion $\vec{G}$ of the graph $\vec{G}'$ and the fractionally coloured cycles $\overline{S}$ separately (see Algorithm 4). For the integral weighted portion, we perform the partial colouring to guarantee at least a constant fraction of edges are removed. We then add the fractionally coloured cycles into the set $\overline{S}$. For the set of fractionally coloured cycles $\overline{S}$, we adjust their colouring by considering the difference between the partial colours and ± 1 to ensure that a good portion of cycles in $\overline{S}$ are fully coloured after the procedure to guarantee the size of $\overline{S}$ does not blow up. In both cases, the error incurred by the partial colouring operation is controlled to guarantee our desired final error (Theorem 2).

2 Preliminaries

We use $\widetilde{O}(\cdot)$ to suppress polylog factors in n, m. We say "with high probability in n" for an event occuring with probability $1 - n^{-\Omega(1)}$. For graphs, n is assumed to be the number of vertices and is often omitted. All logarithms in the paper are base 2.

Linear Algebra

We use boldface to denote vectors, and use $\mathbf{0}$ and $\mathbf{1}$ for the all-zeros and all-ones vectors. We let $\mathbf{e}_u$ denote the vector that is 1 in the uth coordinate and 0 elsewhere. We denote $\mathbf{b}_{uv} = \mathbf{e}_u - \mathbf{e}_v$ for any $u \neq v$. For vectors $\mathbf{u}, \mathbf{v}$ of equal dimension, $\mathbf{u} \circ \mathbf{v}$ is the entrywise product. For a linear subspace $\mathcal{W}$ of a vector space $\mathcal{V}$, we denote $\mathcal{W}^{\perp}$ as the orthogonal complement of $\mathcal{W}$ in $\mathcal{V}$.

Matrices are denoted in boldface capticals. We use $\ker(\mathbf{A}), \mathrm{im}(\mathbf{A})$ to denote the kernel and image of $\mathbf{A}$. For any u, we let $(\mathbf{A})_u$ denote the uth column of $\mathbf{A}$. The Kronecker product of matrices $\mathbf{A}$ and $\mathbf{B}$ is denoted $\mathbf{A} \otimes \mathbf{B}$. A symmetric matrix $\mathbf{A}$ is positive semidefinite (PSD) (resp. positive definite (PD)) if, for any vector $\mathbf{x}$ of compatible dimension, $\mathbf{x}^\top \mathbf{A}\mathbf{x} \geq 0$ (resp. $\mathbf{x}^\top \mathbf{A}\mathbf{x} > 0$). Let $\mathbf{A}$ and $\mathbf{B}$ be two symmetric matrices of the same dimension, then we write $\mathbf{B} \preccurlyeq \mathbf{A}$ or $\mathbf{A} \succcurlyeq \mathbf{B}$ if $\mathbf{A} - \mathbf{B}$ is PSD. The ordering given by $\preccurlyeq$ is called Loewner partial order.

▶ **Lemma 5.** *If $\mathbf{A} \succcurlyeq \mathbf{B}$ and $\mathbf{C}$ is any matrix of compatible dimension, then $\mathbf{C}\mathbf{A}\mathbf{C}^\top \succcurlyeq \mathbf{C}\mathbf{B}\mathbf{C}^\top$.*

Let $\|\mathbf{A}\|$ and $\|\mathbf{A}\|_F = \sqrt{\mathrm{Tr}\,(\mathbf{A}^*\mathbf{A})}$ denote the operator norm and Frobenius norm of a matrix $\mathbf{A}$. The operator norm is equal to the largest singular value of $\mathbf{A}$. For a matrix $\mathbf{A} \in \mathbb{R}^{n \times m}$, we define the Hermitian (symmetric) lift of $\mathbf{A}$ by

$$\mathsf{hlift}(\mathbf{A}) = \begin{bmatrix} & \mathbf{A} \\ \mathbf{A}^\top & \end{bmatrix} \in \mathbb{R}^{(n+m)\times(n+m)}$$

The norms of Hermitian lifts satisfy $\|\mathsf{hlift}(\mathbf{A})\| = \|\mathbf{A}\|$ and $\|\mathsf{hlift}(\mathbf{A})\|_F = 2\|\mathbf{A}\|_F$. Given a symmetric matrix with eigenvalue decomposition $\mathbf{A} = \sum_i \lambda_i \mathbf{v}_i \mathbf{v}_i^\top$, where $\{\mathbf{v}_i\}_i$ form an orthonormal basis, the pseudoinverse is defined as $\mathbf{A}^+ = \sum_{i:\lambda_i \neq 0} \frac{1}{\lambda_i} \mathbf{v}_i \mathbf{v}_i^\top$. The absolute value of $\mathbf{A}$ on eigenvalues is defined as $|\mathbf{A}| = \sum_{i:\lambda_i \neq 0} |\lambda_i| \mathbf{v}_i \mathbf{v}_i^\top$. Note that $|\mathbf{A}|$ is PSD. Similarly for symmetric PSD matrix $\mathbf{A}$ we have $\mathbf{A}^{1/2} = \sum_{i:\lambda_i \neq 0} \sqrt{\lambda_i} \mathbf{v}_i \mathbf{v}_i^\top$ and $\mathbf{A}^{+/2} = \sum_{i:\lambda_i \neq 0} \frac{1}{\sqrt{\lambda_i}} \mathbf{v}_i \mathbf{v}_i^\top$.

Graphs and Laplacians

$\vec{G} = (V, E, \mathbf{w})$ denotes a weighted directed graph (allowing multi-edges) with edge weights $\mathbf{w} : E \to \mathbb{R}_{\geq 0}$. G denotes the undirected graph of $\vec{G}$ where directed edgex $e \in E(\vec{G})$ correspond to undirected edges between the same vertices with half the weight. $\vec{G}$ is Eulerian if the weighted in degree equals the weighted out degree for each vertex $v \in V$.

We define the adjacency matrix of $\vec{G}$ as a non-negative matrix $\mathbf{A}_{\vec{G}}$ with $\mathbf{A}_{uv} = w_{uv}$ if $(u, v) \in E$ and 0 otherwise. The weighted degree matrix of $\vec{G}$ is a non-negative diagonal matrix $\mathbf{D}_{\vec{G}}$ corresponding to the weighted out-degrees of $\vec{G}$. We define the directed Laplacian of $\vec{G}$ as $\mathbf{L}_{\vec{G}} = \mathbf{D}_{\vec{G}} - \mathbf{A}_{\vec{G}}^\top$ and it satisfies $\mathbf{1}^\top \mathbf{L}_{\vec{G}} = \mathbf{0}^\top$, i.e. $(\mathbf{L}_{\vec{G}})_{uu} = -\sum_{v \neq u} \mathbf{L}_{vu}$ for all $u \in V$. For a weighted Eulerian directed graph $\vec{G}$, its graph Laplacian additionally satisfies $\mathbf{L}_{\vec{G}}\mathbf{1} = \mathbf{0}$. Assuming Eulerian graph $\vec{G}$, the associated undirected graph Laplacian matrix of G is $\mathbf{L}_G = \frac{1}{2}(\mathbf{L}_{\vec{G}} + \mathbf{L}_{\vec{G}}^\top)$. $\mathbf{L}_G$ is symmetric and PSD. For an undirected Laplacian $\mathbf{L}_G$, the effective resistance and leverage score of an edge $e \in E(G)$ are defined by $\mathrm{Reff}_G(e) = \mathbf{b}_e^\top \mathbf{L}_G^+ \mathbf{b}_e$ and $\boldsymbol{\tau}_G(e) = w_e \mathrm{Reff}_G(e)$ where we fixed an arbitrary orientation for the undirected edge e. We use n and m for the number of vertices and edges in G. As is standard, we study strongly connected Eulerian graphs with positive integral and polynomially bounded edge weights (i.e., weights bounded by $n^{O(1)}$).

3 Eulerian sparsification via short cycle decomposition

We first present an improved analysis of constructing Eulerian sparsifiers using short cycle decompositions analogous to [11]. In particular, we provide a better variance analysis of the error terms in sparsification than what was used by [11]; by Matrix Bernstein [46] this will allow us to use fewer edges to retain a desired error bound.

We first recall the definition of a short cycle decomposition of a graph G.

▶ **Definition 6.** *An $(\hat{m}, L)$-short cycle decomposition of an unweighted undirected graph G, decomposes G into several edge-disjoint cycles, each of length at most L, and at most $\hat{m}$ edges are not in the union of the cycles.*

We let CycleDecomposition be an algorithm that takes as input an unweighted graph with n vertices and m edges and returns a $(\hat{m}, L)$-short cycle decomposition in time $\mathrm{T}_{\mathrm{CD}}(m, n)$. As in [11], we assume the *super-additivity* of T_{CD}, $\sum_i \mathrm{T}_{\mathrm{CD}}(m_i, n) \leq \mathrm{T}_{\mathrm{CD}}\left(\sum_i m_i, n\right)$, for all $m_i \geq n$. Relevant to us is a construction of short cycle decompositions which for every constant $\delta > 0$, gives an $(O(n \log n), O(\log n))$-short cycle decomposition in time $m^{1+\delta}$.

▶ **Lemma 7** ([35] Theorem 2). *For any $\delta > 0$, there is an algorithm that computes an $(O(n \log n), O(2^{\frac{1}{\delta}} \log n))$-short cycle decomposition of an undirected unweighted graph in $2^{O(\frac{1}{\delta})} mn^{\delta}$ time.*

Our random sampling based sparsification algorithm is the same as [11]. We repeatedly sparsify an Eulerian graph by keeping only the "clockwise" or "counter-clockwise" edges of each cycle in a short cycle decomposition of the graph, see CycleSparsify in Algorithm 2 and CycleSparsifyOnce in Algorithm 3.

Stated in other words, we will sparsify a cycle by partitioning it into two sets and removing one randomly. For a directed cycle $\vec{C}$, we take $\vec{F}, S$ to be the outputs of CorrectOrientation$(\vec{C})$. In particular, $\vec{F}$ is the cycle $\vec{C}$ corrected so that every vertex has an incoming edge and an outgoing edge, and S is the undirected graph coming from the set of edges in $\vec{C}$ whose direction we reversed (where the edge weight in S are the same as the original edge

Algorithm 1 CorrectOrientation($\vec{C}$).

1 Pick an arbitrary edge e_1 in $\vec{C}$ and let v_1 be its tail vertex. Define $V_{\vec{C}}$ as the vertex set of $\vec{C}$.
2 Initialize $E_{\vec{S}} \leftarrow \emptyset$, $E_{\vec{F}} \rightarrow \{e_1\}$, $V_{\vec{F}} = \{v_1\}$, $i = 1$
3 **while** $|V_{\vec{C}} \setminus V_{\vec{F}}| > 0$ **do**
4 $\quad i \leftarrow i + 1$
5 $\quad$ Take e_{i+1} be the other edge incident on v_i.
6 $\quad$ If e_{i+1} is outgoing from v_i, take v_{i+1} the head of e_{i+1} and update $E_{\vec{F}} \leftarrow E_{\vec{F}} \cup \{e_{i+1}\}$, $V_{\vec{F}} \leftarrow V_{\vec{F}} \cup \{v_{i+1}\}$.
7 $\quad$ Else let v_{i+1} be the tail of e_{i+1} and update $E_{\vec{S}} \leftarrow E_{\vec{S}} \cup \{e_{i+1}\}$, $E_{\vec{F}} \leftarrow E_{\vec{F}} \cup \{\text{rev}(e_{i+1})\}$, $V_{\vec{F}} \leftarrow V_{\vec{F}} \cup \{v_{i+1}\}$.
8 **return** $\vec{F}$ *defined by* $E_{\vec{F}}$ *and* $V_{\vec{F}}$*, and* S *the undirected graph defined by* $E_{\vec{S}}$ *and the incident vertices of* $E_{\vec{S}}$.

Algorithm 2 CycleSparsify($\vec{G}, \varepsilon,$ CycleDecomposition).

1 Decompose each edge by its binary representation.
2 Compute $\mathbf{r}$ a 1.5-approximate effective resistances in G.
3 **while** $|E(\vec{G})| \geq O(\hat{m} \log n + \varepsilon^{-2} n L^2 \log n)$ **do**
4 $\quad \vec{G} \leftarrow$ CycleSparsifyOnce($\vec{G}, \mathbf{r},$CycleDecomposition).
5 **return** $\vec{G}$.

weights). We consider the direction of edges defined by $\vec{F}$ as clockwise. Then, the edges in S are all the counter-clockwise edges in $\vec{C}$. For a cycle C and its corresponding directed cycle $\vec{C}$, the directed graph Laplacian added at line 7 in CycleSparsifyOnce is the following:

$$\begin{cases} \mathbf{L}_{\vec{C}} + \mathbf{L}_{\vec{F}} - \mathbf{L}_S & \text{w.p. } \frac{1}{2} \\ \mathbf{L}_{\vec{C}} - \mathbf{L}_{\vec{F}} + \mathbf{L}_S & \text{w.p. } \frac{1}{2} \end{cases}$$

which means the changes incurred on the directed graph Laplacian is

$$\begin{cases} \widetilde{\mathbf{L}} & \text{w.p. } \frac{1}{2} \\ -\widetilde{\mathbf{L}} & \text{w.p. } \frac{1}{2} \end{cases}, \text{where } \widetilde{\mathbf{L}} = \mathbf{L}_{\vec{F}} - \mathbf{L}_S. \tag{2}$$

Note that this change preserves the difference between the in and out degrees of $\vec{C}$. Either a vertex had an incoming and outgoing edge (and so difference 0), in which case both edges are either in $\vec{F} \setminus S$ or in S and hence always added together with the same weights (so still difference 0). Alternatively a vertex had two incoming or outgoing edges, in which case only one is ever added with twice the weight, which then still preserves the difference between in and out degree.

To obtain the improved approximation error guarantees, we show Lemma 8 that bounds the effect of $\mathbf{L}_{\vec{F}}$. Compared to Lemma 5.6 in [11], our result improves the bound by a factor of L.

▶ **Lemma 8.** *If* $\vec{C}$ *is a equal weighted directed cycle of length* L *contained in a graph* $\vec{G}$ *where each edge* $\vec{e} \in \vec{C}$ *satisfies* $\boldsymbol{\tau}_G(e) \leq \rho$*. Then,* $\mathbf{L}_{\vec{F}}^\top \mathbf{L}_G^+ \mathbf{L}_{\vec{F}} \preceq O(L^2 \rho) \mathbf{L}_C$.

Algorithm 3 CycleSparsifyOnce($\vec{G}, \mathbf{r}$, CycleDecomposition).

Input: A directed Eulerian graph $\vec{G}$ where edge weights are integral powers of 2,a 2-approximate effective resistances $\mathbf{r}$ in G, a short cycle decomposition algorithm CycleDecomposition.

Output: A directed Eulerian graph $\vec{H}$ where edge weights are integral powers of 2.

$\vec{H} \leftarrow \vec{G}$ with only the edges which satisfies $w_e r_e > \frac{4n}{m}$ and remove these edges from $\vec{G}$.

Partition $\vec{G}$ into uniformly weighted graph $\vec{G}_1, \ldots, \vec{G}_s$ where $\vec{G}_i$ has all edge weights 2^i and $s = O(\log n)$.

for *each* $\vec{G}_i$ **do**

  $\{C_{i,1}, \ldots, C_{i,t}\} \leftarrow$ CycleDecomposition(G_i) and let $\vec{C}_{i,j}$ be the corresponding directed graph of $C_{i,j}$ in $\vec{G}_i$.

  $\vec{H} \leftarrow \vec{H} + \vec{G}_i \setminus \left(\bigcup_{j=1}^{t} \vec{C}_{i,j}\right)$.

  for *each cycle* $\vec{C}_{i,j}$ **do**

    With probability $\frac{1}{2}$, add all its clockwise edges with twice their weight to $\vec{H}$. Otherwise, add the counter-clockwise edges instead.

return $\vec{H}$.

Proof. Let $\mathbf{\Pi}_C = \mathbf{I}_C - \frac{1}{L}\mathbf{1}_C\mathbf{1}_C^\top$ be the projection matrix on the support of C except the all one vector on C. Notice that $\ker^\perp(\mathbf{L}_C) = \mathrm{im}(\mathbf{L}_C) = \mathrm{im}(\mathbf{\Pi}_C)$. Furthermore, we have $\mathrm{im}(\mathbf{L}_{\vec{F}}) \subset \mathrm{im}(\mathbf{\Pi}_C)$ (as $\mathbf{1}_C \in \mathrm{im}^\perp(\mathbf{L}_{\vec{F}})$) so $\mathbf{\Pi}_C\mathbf{L}_{\vec{F}} = \mathbf{L}_{\vec{F}}$, and also $\mathrm{im}^\perp(\mathbf{\Pi}_C) \subset \ker(\mathbf{L}_{\vec{F}}^\top)$ hence $\mathbf{L}_{\vec{F}}^\top\mathbf{\Pi}_C = \mathbf{L}_{\vec{F}}^\top$. Thus, $\mathbf{L}_{\vec{F}}^\top\mathbf{L}_G^+\mathbf{L}_{\vec{F}} = \mathbf{L}_{\vec{F}}^\top\mathbf{\Pi}_C\mathbf{L}_G^+\mathbf{\Pi}_C\mathbf{L}_{\vec{F}}$.

Let w be the weight of each edge in $\vec{C}$. Then, $\mathbf{L}_{\vec{F}} = w(\mathbf{I} - \mathbf{P})$ where $\mathbf{P}$ is a permutation matrix on the vertices of C corresponding to the transition matrix $\vec{F}$ and $\mathbf{L}_C = \frac{w}{2}(2\mathbf{I} - \mathbf{P} - \mathbf{P}^\top)$. Now, $\mathbf{L}_{\vec{F}}^\top\mathbf{\Pi}_C\mathbf{L}_{\vec{F}} = \mathbf{L}_{\vec{F}}^\top\mathbf{L}_{\vec{F}} = w^2(\mathbf{I} - \mathbf{P}^\top)(\mathbf{I} - \mathbf{P}) = w^2(2\mathbf{I} - \mathbf{P} - \mathbf{P}^\top) = 2w\mathbf{L}_C$. As $\ker(\mathbf{L}_G^+) \subseteq \ker(\mathbf{\Pi}_C)$, it suffices to show $\|\mathbf{\Pi}_C\mathbf{L}_G^+\mathbf{\Pi}_C\| = O(\frac{L^2\rho}{w})$. We can write out each column of $\mathbf{\Pi}_C$ by $(\mathbf{\Pi}_C)_u = \frac{1}{L}\sum_{v \in C, v \neq u} \mathbf{b}_{uv}$ for $u \in C$ and $\mathbf{0}$ otherwise. As effective resistance is a metric, $w\mathbf{b}_{uv}^\top\mathbf{L}_G^+\mathbf{b}_{uv} \leq (L-1)\rho$ for any distinct vertices $u, v \in C$. Note that this factor of L is an upperbound on the combinatorial distance from u to v in C. Then,

$$\begin{aligned}
\left|(\mathbf{\Pi}_C)_x^\top\mathbf{L}_G^+(\mathbf{\Pi}_C)_u\right| &= \left|\left(\frac{1}{L}\sum_{y \in C, y \neq x} \mathbf{L}_G^{\frac{+}{2}}\mathbf{b}_{xy}\right)^\top\left(\frac{1}{L}\sum_{v \in C, v \neq u} \mathbf{L}_G^{\frac{+}{2}}\mathbf{b}_{uv}\right)\right| \\
&\leq \sum_{y \neq x, y \in C}\sum_{v \neq u, v \in C} \frac{1}{wL^2}\left\|w^{\frac{1}{2}}\mathbf{L}_G^{\frac{+}{2}}\mathbf{b}_{xy}\right\| \cdot \left\|w^{\frac{1}{2}}\mathbf{L}_G^{\frac{+}{2}}\mathbf{b}_{uv}\right\| \\
&\leq (L-1)^2 \times \frac{(L-1)\rho}{wL^2} \leq \frac{L\rho}{w}.
\end{aligned}$$

By Gershgorin circle theorem and the length of C, any eigenvalue of $\mathbf{\Pi}_C\mathbf{L}_G^+\mathbf{\Pi}_C$ cannot exceed $\frac{L^2\rho}{w}$ as required. ◀

▶ Remark 9. There is still a gap of factor L when comparing Lemma 8 to the undirected case. It turns out Lemma 8 is tight. Consider the multi-graph $\vec{G}$ that consists of a directed cycle with edges of weight 1 in the same orientation $\vec{F}$ and a undirected cycle C on the same vertices of edge weight ρ^{-1} for $\rho < \frac{1}{2}$. Then, each edge of the directed graph has undirected leverage score $\Theta(\rho)$ while $\mathbf{L}_{\vec{F}}^\top\mathbf{L}_G^+\mathbf{L}_{\vec{F}} = \Theta(\frac{\rho}{L})\mathbf{L}_K$ where $\mathbf{L}_K$ is the Laplacian of unit clique on the vertices of $\vec{G}$. Since $\mathbf{L}_K$ cannot be bounded by $o(L^3)\mathbf{L}_F$, this gives the lowerbound.

When combined with Lemma 5.5 of [11], we obtain the following spectral bounds on matrices which appear later in our variance analysis. We refer readers to [11] and the full version of our paper for the proofs of all subsequent claims in this section.

▶ **Lemma 10.** *Let $\vec{C}$ is an equal weighted directed cycle of length L contained in a graph $\vec{G}$ where each edge $\vec{e} \in \vec{C}$ satisfies $\boldsymbol{\tau}_G(e) \leq \rho$. Then $\mathbf{L}_G^{\frac{+}{2}}(\widetilde{\mathbf{L}}^\top \mathbf{L}_G^{+}\widetilde{\mathbf{L}})\mathbf{L}_G^{\frac{+}{2}} \preceq O(L^2\rho)\cdot \mathbf{L}_G^{\frac{+}{2}}\mathbf{L}_C\mathbf{L}_G^{\frac{+}{2}}$ and $\mathbf{L}_G^{\frac{+}{2}}(\widetilde{\mathbf{L}}\mathbf{L}_G^{+}\widetilde{\mathbf{L}}^\top)\mathbf{L}_G^{\frac{+}{2}} \preceq O(L^2\rho)\cdot \mathbf{L}_G^{\frac{+}{2}}\mathbf{L}_C\mathbf{L}_G^{\frac{+}{2}}$.*

The matrix Bernstein's inequality [46] then gives the sparsification and error guarantees of running CycleSparsifyOnce in Lemma 11.

▶ **Lemma 11.** *Given a directed Eulerian graph $\vec{G}$ whose edge weights are integral powers of 2, and additionally 2-approximate effective resistances $\mathbf{r}$ in G, the algorithm* CycleSparsify-Once *returns in $O(m) + \mathrm{T}_{\mathrm{CD}}(m,n)$ time a directed Eulerian graph $\vec{H}$ with edge weights still being powers of 2 such that if the number of edges in G satisfy $m = \Omega(\hat{m}\log n + nL^2\log n)$, then with high probability, the number of edges in $\vec{H}$ is at most $\frac{15}{16}m$ and*

$$\left\|\mathbf{L}_G^{\frac{+}{2}}(\mathbf{L}_{\vec{G}} - \mathbf{L}_{\vec{H}})\mathbf{L}_G^{\frac{+}{2}}\right\| \leq O\left(\sqrt{\frac{nL^2\log n}{m}}\right).$$

We now provide the guarantees of CycleSparsify, which repeatedly calls CycleSparsifyOnce until a criterion on the number of edges is met.

▶ **Theorem 12.** *Given as input an Eulerian graph $\vec{G}$ with polynomial bounded integral edge weights and $\varepsilon \in (0, \frac{1}{2})$, the algorithm* CycleSparsify *returns in $O(m\log^2 n) + \mathrm{T}_{\mathrm{CD}}(O(m\log n), n)$ time a Eulerian graph $\vec{H}$ with $O(\hat{m}\log n + \varepsilon^{-2}nL^2\log n)$ edges such that with high probability,*

$$\left\|\mathbf{L}_G^{\frac{+}{2}}(\mathbf{L}_{\vec{G}} - \mathbf{L}_{\vec{H}})\mathbf{L}_G^{\frac{+}{2}}\right\| \leq \varepsilon.$$

Plugging in Lemma 7, we obtain the improved results on constructing Eulerian Sparsifiers with short cycle decompositions, summarized in Theorem 1.

▶ **Theorem 1.** *For every constant $\delta > 0$, there is an algorithm that takes as input a directed Eulerian graph $\vec{G}$ and returns an ε-Eulerian sparsifier of $\vec{G}$ with $O(n\varepsilon^{-2}\log^3 n)$ edges in $m^{1+\delta}$ time.*

4 Sparsification via partial colouring

In the previous algorithm CycleSparsify, the approach to sparsifying was to randomly pick one part of each cycle (out of a partitioning of the cycle into two parts) to remove from the graph. The analysis then followed by observing on average this leads to a good approximation, and that furthermore the variance in this random construction is sufficiently small. In this section, we show, however, that by using recent partial colouring results on operator norm discrepancy bodies to pick what parts of a cycle to remove, we can obtain better sparsifiers. The main partial colouring result we use, relevant for picking a subset of matrices to keep with minimal error, is restated below.

Algorithm 4 ColourSparsify($\vec{G}, \varepsilon$).

Decompose each edge by its binary representation.
Compute $\mathbf{r}$ a 1.5-approximate effective resistances in G.
Let $\overline{S}$ be a set of cycles initialized to empty and let $\overline{x}$ be its corresponding partial colouring.
Set $\vec{G}' \leftarrow \vec{G}+$ ColourWeights($\overline{S}, \overline{x}$).
while $m' \geq O(n\varepsilon^{-2}\log^2 n(\log\log n)^2 + n\varepsilon^{-\frac{4}{3}}\log^{\frac{8}{3}} n)$ **do**
  if $4m \geq m'$ **then**
    $\vec{G}, \vec{G}', \overline{S}, \overline{x} \leftarrow$ ColourSparsifyGraph($\vec{G}, \vec{G}', \overline{S}, \overline{x}, \mathbf{r}$).
  else
    $\vec{G}, \vec{G}', \overline{S}, \overline{x} \leftarrow$ ColourSparsifyCycle($\vec{G}, \vec{G}', \overline{S}, \overline{x}, \mathbf{r}$).
return $\vec{G}'$.

Algorithm 5 ColourWeights(S, x).

Let $\vec{H}$ be an empty directed graph.
for *each cycle* $C \in S$ *and corresponding directed cycle* $\vec{C}$ **do**
  Add all the clockwise (resp. counter-clockwise) edges in $\vec{C}$ with $1 + x_C$ (resp. $1 - x_C$) times their weight to $\vec{H}$. Note if $1 + x_C = 0$ (resp. $1 - x_C = 0$) the corresponding edge is not added.
return $\vec{H}$.

▶ **Lemma 4** ([6] Lemma 3.1). *There exists constants $c, c' > 0$ such that given symmetric matrices $\mathbf{A}_1, \ldots, \mathbf{A}_m \in \mathbb{R}^{n\times n}$ satisfying $\|\sum_{i=1}^m \mathbf{A}_i^2\| \leq \sigma^2$ and $\sum_{i=1}^m \|\mathbf{A}_i\|_F^2 \leq mf^2$ and a point $\mathbf{y} \in (-1,1)^m$, there is an algorithm* PartialColour *that returns in polynomial time a point $\mathbf{x} \in [-1,1]^m$ such that $|\{i : x_i \in \{\pm 1\}\}| > c'm$ and*

$$\left\|\sum_{i=1}^m (x_i - y_i)\mathbf{A}_i\right\| \leq c(\sigma + (\log^{\frac{3}{4}} n)\sqrt{\sigma f}). \tag{1}$$

For this section, we assume the short cycle decomposition guarantees by Lemma 7 with $\hat{m} = O(n\log n)$ and $L = O(\log n)$. For each cycle C with its corresponding directed cycle $\vec{C}$, we set $\mathbf{A}(C) = \mathsf{hlift}(\mathbf{L}_{\vec{G}'}^{\frac{+}{2}}(\mathbf{L}_{\vec{F}_C} - \mathbf{L}_{S_C})\mathbf{L}_{\vec{G}'}^{\frac{+}{2}})$ where $\vec{F}_C$ is the cycle $\vec{C}$ with all edges set in clockwise direction and S_C is undirected graph with the set of edges corresponding to the counter-clockwise edges in $\vec{C}$, same as in Section 3. Note that this orientation is set initialy by CorrectOrientation after a short cycle decomposition step and fixed through out the execution. Given a set of cycles S, we let $\mathcal{A}[S]$ be the collection $\{\mathbf{A}(C)\}_{C\in S}$.

ColourWeights is our partial colouring alternative of the random selection of edges in a cycle in CycleSparsifyOnce. It similarly does not change the difference between the in-degree and out-degree and preserves integral weights, stated in Lemma 13.

▶ **Lemma 13.** *Given a set of cycles S where each cycle is uniformly weighted, and any partial colouring $x \in [-1,1]^S$, the algorithm* ColourWeights *returns a directed graph $\vec{H}$ such that the difference in the in and out degrees are the same as in $\sum_{C\in S}\vec{C}$. If $x \in \{\pm 1\}^S$, $\vec{H}$ also has integral edge weights with the largest edge weight at most twice the largest edge weight in cycles in S.*

Algorithm 6 ColourSparsifyGraph$(\vec{G}, \vec{G}', \overline{S}, \overline{\mathbf{x}}, \mathbf{r})$.

Input: A directed Eulerian graph $\vec{G}$ where edge weights are integral powers of 2, a set of cycles $\overline{S}$ where each cycle is edge disjoint from G, a partial colouring $\overline{\mathbf{x}} \in (-1,1)^{\overline{S}}$, a graph $\vec{G}' = \vec{G}+$ ColourWeights$(\overline{S}, \overline{\mathbf{x}})$, a 2-approximate effective resistances $\mathbf{r}$ in G'.

Output: A directed Eulerian graph $\vec{H}$ where edge weights are integral powers of 2, a set of cycles $\overline{T}$ where each cycle is edge disjoint from H, a partial colouring $\overline{\mathbf{z}} \in (-1,1)^{\overline{T}}$, a graph $\vec{H}' = \vec{H}+$ ColourWeights$(\overline{T}, \overline{z})$.

1 Let $\vec{H} \leftarrow \vec{G}$ with only the edges which satisfy $w_e r_e > \frac{16n}{m'}$ and remove them from $\vec{G}$.

2 Partition $\vec{G}$ into uniformly weighted graph $\vec{G}_1, \ldots, \vec{G}_q$ where $\vec{G}_i$ has all edge weights 2^i and $q = O(\log n)$.

3 Let S be the set of all cycles after applying CycleDecomposition on $\vec{G}_1, \ldots, \vec{G}_s$ and set $\vec{H} \leftarrow \vec{H} + \sum_{i=1}^{s} \vec{G}_i \setminus \left(\bigcup_{j=1}^{t} \vec{C}_{i,j}\right)$.

4 $T', \overline{T}', \mathbf{y}, \overline{\mathbf{y}} \leftarrow$ ColourTarget$(S, \mathbf{0}, \frac{1}{8}m)$.

5 If ColourWeights $(T', \mathbf{y})$ has more edges than ColourWeights $(T', -\mathbf{y})$, we take $\mathbf{y} \leftarrow -\mathbf{y}$ and $\overline{\mathbf{y}} \leftarrow -\overline{\mathbf{y}}$.

6 $\vec{H} \leftarrow \vec{H} +$ ColourWeights$(T', \mathbf{y})$.

7 $\overline{T} \leftarrow \overline{T}' \cup \overline{S}$ and set $\overline{\mathbf{z}} \leftarrow \overline{\mathbf{y}} + \overline{\mathbf{x}}$.

8 $\vec{H}' \leftarrow \vec{H}+$ ColourWeights$(\overline{T}, \overline{\mathbf{z}})$.

9 **return** $\vec{H}, \vec{H}', \overline{T}, \overline{\mathbf{z}}$.

Proof. For the degree condition, it suffices to consider a single cycle C and show that the reweighted directed cycle, say $\vec{C}'$ in line 3 preserves the differences of the in and out degrees of $\vec{C}$. Recall the definition of $\vec{F}$ and S of C, see CorrectOrientation,and the argument in Section 3 for showing degree differences preservation under the special case of $x \in \{\pm 1\}$. Note first that the edge weights are the same. Either a vertex has an incoming and outgoing edge (and so difference 0), in which case both edges are either in $\vec{F} \setminus S$ or in S and hence always added together with the same weights of (so still difference 0). Alternatively a vertex has two incoming or outgoing edges, in which case one edge gets a new weight of $1 + x$ and the other gets $1 - x$, which then still preserves the difference between in and out degree.

If $x \in \{\pm 1\}$ the edge weights of $\vec{C}'$ is exactly twice that of C unless $\vec{C}'$ is emtpy. Thus, $\vec{H}$ still has integral edge weights with largest weight at most doubled. ◀

For the rest of this section, we refer to a set of uniformly weighted cycles (two cycles can have different weights) as a set of cycles for simplicity. We write $m(S) = \sum_{C \in S} |E(C)|$ as the total number of edges in S. In ColourSparsify, ColourSparsifyGraph and ColourSparsifyCycle, by applying $'$ to a graph we mean $\vec{G}' = \vec{G}+$ ColourWeights$(\overline{S}, \overline{x})$. We denote m' as the number of edges in $\vec{G}'$. Note that this is the primary number of edges we consider rather than m.

Towards analyzing ColourSparsify, we first state the guarantees of the ColourTarget subroutine which guarantees a partial colouring of at least a specified size.

▶ **Lemma 14.** *The outputs of* ColourTarget(S, y, m_t) *satisfy that* $m(\overline{S}) \le m_t$ *and the number of calls to* PartialColour *is* $O\left(\log(\frac{|S|L}{m_t})\right)$. *If additionally the set of cycles* S *satisfies* $\sum_{C \in S} \|\mathbf{A}(C)\| \le \sigma^2$ *and* $\sum_{C \in S} \|\mathbf{A}(C)\|_F^2 \le v$, *then the outputs also satisfy*

$$\left\| \sum_{C \in S} (x + \overline{x} - y)\mathbf{A}(C) \right\| \le O\left(\sigma \cdot \log\left(\frac{|S|L}{m_t}\right) + (\log^{\frac{3}{4}} n)\sigma^{\frac{1}{2}} \left(\frac{vL}{m_t}\right)^{\frac{1}{4}} \right)$$

Algorithm 7 ColourSparsifyCycle$(\vec{G}, \vec{G}', \overline{S}, \overline{\mathbf{x}}, \mathbf{r})$.

Input: A directed Eulerian graph $\vec{G}$ where edge weights are integral powers of 2, a set of cycles $\overline{S}$ where each cycle is edge disjoint from G, a partial colouring $\overline{\mathbf{x}} \in (-1,1)^{\overline{S}}$, a graph $\vec{G}' = \vec{G} +$ ColourWeights$(\overline{S}, \overline{\mathbf{x}})$, a 2-approximate effective resistances $\mathbf{r}$ in G'.

Output: A directed Eulerian graph $\vec{H}$ where edge weights are integral powers of 2, a set of cycles $\overline{T}$ where each cycle is edge disjoint from H, a partial colouring $\overline{\mathbf{z}} \in (-1,1)^{\overline{T}}$, a graph $\vec{H}' = \vec{H} +$ ColourWeights$(\overline{T}, \overline{z})$.

Set $\overline{S}'$ be an empty set of cycles initialy. For each $C \in \overline{S}$, let C' be C with its weight by $(1 - |\overline{x}_C|)$ and add C' to $\overline{S}'$.

$T', \overline{T}', \mathbf{y}, \overline{\mathbf{y}} \leftarrow$ ColourTarget$(\overline{S}', \mathbf{0}, \frac{1}{4}m')$

if $m(\{C' \in T' : |\overline{x}_C - (1 - |\overline{x}_C|)y_{C'}| = 1\}) > m(\{C' \in T' : |\overline{x}_C + (1 - |\overline{x}_C|)y_{C'}| = 1\})$ **then**

  $\mathbf{y} \leftarrow -\mathbf{y}, \overline{\mathbf{y}} \leftarrow -\overline{\mathbf{y}}$.

Set $\mathbf{z}, \overline{\mathbf{z}}$ to be the parts of $\overline{\mathbf{x}} + (1 - |\overline{\mathbf{x}}|) \circ (\mathbf{y} + \overline{\mathbf{y}})$ with magnitude 1 and < 1 respectively. Here we abused $\circ$ to let C and C' refering to the same index, Set the partition $T, \overline{T}$ of $\overline{S}$ accordingly.

$\vec{H} \leftarrow \vec{H} +$ ColourWeights$(T, \mathbf{z})$.

$\vec{H}' \leftarrow \vec{H} +$ ColourWeights$(\overline{T}, \overline{\mathbf{z}})$.

return $\vec{H}, \vec{H}', \overline{T}, \overline{\mathbf{z}}$.

Proof. Notice that each cycle has its number of edges bounded by L. We have $m(\overline{S}) \leq L|\overline{S}| \leq m_t$ by the terminating condition of the while loop in ColourTarget. Since the size of $\overline{S}$ decreases by a factor of $1 - c'$ by Lemma 4, by the ith round we have $|\overline{S}| \leq (1 - c')^i |S|$ and at termination this is $\leq \frac{m_t}{L}$. This then gives the claimed number of iterations.

Consider the error bound. Combine the number of iterations with the first term in (1) of Lemma 4, we get our desired first term. For the second term, recall from above that $|\overline{S}|$ decreases geometrically. Then $f = \left(\frac{v}{|\overline{S}|}\right)^{\frac{1}{2}}$ increases exponentially over the iterations. Hence the sum of the second terms in (1) is bounded by the last one with $f = O\left((\frac{vL}{m_t})^{\frac{1}{2}}\right)$, giving

$$O\left((\log^{\frac{3}{4}} n)\sigma^{\frac{1}{2}} f^{\frac{1}{2}}\right) = O\left((\log^{\frac{3}{4}} n)\sigma^{\frac{1}{2}} \left(\frac{vL}{m_t}\right)^{\frac{1}{4}}\right)$$

as required. ◀

Now, parallel to Lemma 11, we state the approximation guarantees of ColourSparsifyGraph and ColourSparsifyCycle in Lemmas 15 and 16. The proof of Lemma 15 follows closely to that of Lemma 16 and we refer reader to the full version of our paper.

▶ **Lemma 15.** *If the input graphs $\vec{G}, \vec{G}'$ satisfy $4m \geq m'$ and the input set of cycles $\overline{S}$ and it corresponding partial colours $\overline{x}$ satisfies that each cycle $C \in \overline{S}$ has $w_e r_e \leq \frac{4n}{m'}$ for each edge $e \in C$, the algorithm* ColourSparsifyGraph *returns $\vec{H}$ with edge weights still being powers of 2 and at most twice the largest weight in $\vec{G}$, a set of cycles $\overline{T}$ with its corresponding partial colours $\overline{\mathbf{z}}$ satisfying $\vec{H}' = \vec{H} +$ ColourWeights$(\overline{T}, \overline{\mathbf{z}})$ is an Eulerian graph and each cycle $C \in \overline{T}$ also has $w_e r_e \leq \frac{4n}{m'_H}$ for each edge $e \in C$, where $m'_H = |E(\vec{H})|$. and,*

$$\left\| \mathbf{L}_{G'}^{\frac{+}{2}} (\mathbf{L}_{\vec{G}'} - \mathbf{L}_{\vec{H}'}) \mathbf{L}_{G'}^{\frac{+}{2}} \right\| \leq O\left(\sqrt{\frac{n \log^2 n}{m'}} \log\log n + \left(\frac{n \log^{\frac{8}{3}} n}{m'} \right)^{\frac{3}{4}} \right).$$

Algorithm 8 ColourTarget(S, y, m_t).

Input: A set of cycles S of size $s = |S|$, a partial colouring $y \in (-1,1)^S$, and a target mass of m_t edges.

Output: A set of fully coloured cycles $S\backslash\overline{S}$ with colouring x, A set of partially coloured cycles $\overline{S}$ with colouring $\overline{x}$ satisfying $\overline{x} \in (-1,1)^{\overline{S}}$.

1 Initialize $x = 0$ be a empty colouring over S.
2 Define $\overline{S}$ to always be the set of fractionally coloured cycles in S and let $\overline{s} = |\overline{S}|$ always. Set $\overline{x}$ be the partial colour on $\overline{S}$ always.
3 **while** $\overline{s} > \frac{m_t}{L}$ **do**
4 $\quad x[\overline{S}] \leftarrow$ PartialColour$(\mathcal{A}[\overline{S}], \overline{x})$.
5 Let $\overline{x} \leftarrow x$ with entries of magnitude < 1 and set $x \leftarrow x - \overline{x}$.
6 **return** $S\backslash\overline{S}, \overline{S}, x, \overline{x}$.

▶ **Lemma 16.** *If the input set of cycles $\overline{S}$ and it corresponding partial colours $\overline{x}$ satisfies that each cycle $C \in \overline{S}$ has $w_e r_e \le \frac{4n}{m'}$ for each edge $e \in C$, the algorithm* ColourSparsifyCycle *returns $\vec{H}$ with edge weights still being powers of 2 and at most twice the largest weight in $\vec{G}$, a set of cycles $\overline{T}$ with its corresponding partial colours $\overline{y}$ satisfying $\vec{H}' = \vec{H} +$* ColourWeights$(\overline{T}, \overline{y})$ *is an Eulerian graph and each cycle $C \in \overline{T}$ also has $w_e r_e \le \frac{4n}{m'_H}$ for each edge $e \in C$, where $m'_H = |E(\vec{H})|$. and,*

$$\left\| \mathbf{L}_{G'}^{\frac{+}{2}} (\mathbf{L}_{\vec{G}'} - \mathbf{L}_{\vec{H}'}) \mathbf{L}_{G'}^{\frac{+}{2}} \right\| \le O\left(\sqrt{\frac{n \log^2 n}{m'}} \log\log n + \left(\frac{n \log^{\frac{8}{3}} n}{m'} \right)^{\frac{3}{4}} \right).$$

Before we prove Lemma 16, we need Lemma 17 regarding scaling matrices in the set of extra cycles $\overline{S}$.

▶ **Lemma 17.** *For directed Eulerian graph $\vec{G}$, a set of cycles $\overline{S}$ where each cycle $C \in \overline{S}$ satisfies that $\vec{G}$ and $\vec{C}$, the corresponding directed cycle of C, are edge-disjoint. Let $\overline{x} \in (-1,1)^S$ be a fractional colouring on $\overline{S}$. Then the Eulerian graph $\vec{G}' = \vec{G} +$* ColourWeights$(\overline{S}, \overline{x})$ *satisfies*

$$\mathbf{L}_G + \sum_{C \in \overline{S}} (1 - |\overline{x}_C|) \mathbf{L}_C \preceq \mathbf{L}_{G'}.$$

Proof. For any $C \in \overline{S}$, let $\vec{C}' =$ ColourWeights$(C, \overline{x}_C)$ where we abused the definition to take in a single cycle instead of a set of cycles. Note that the undirectification $\mathbf{L}_{G'} = \mathbf{L}_G + \sum_{C \in \overline{S}} \mathbf{L}_{C'}$. Since $|\overline{x}_C| < 1$, all edges in C must be present in C' and the minimum edge weight is at least $1 - |\overline{x}_C|$ times the original uniform edge weights of C. Then, $(1 - |\overline{x}_C|)\mathbf{L}_C \preceq \mathbf{L}_{C'}$. Summing over all C, we get

$$\mathbf{L}_G + \sum_{C \in \overline{S}} (1 - |\overline{x}_C|) \mathbf{L}_C \preceq \mathbf{L}_G + \sum_{C \in \overline{S}} \mathbf{L}_{C'} = \mathbf{L}_{G'}. \qquad \blacktriangleleft$$

Proof of Lemma 16. The edge weights condition of $\vec{H}$ is guaranteed by Lemma 13. Also by Lemma 13, both $\vec{H}$ and $\vec{H}'$ are Eulerian. Observe that $m'_H \le m$ always, and $\overline{T} \subset \overline{S}$. Then, the output cycles still satisfy the approximate leverage score condition. Now, by line 5, the output Eulerian graph $\vec{H}'$ satisfies

$$\mathsf{hlift}\left(\mathbf{L}_{G'}^{\frac{+}{2}} (\mathbf{L}_{\vec{H}'} - \mathbf{L}_{\vec{G}'}) \mathbf{L}_{G'}^{\frac{+}{2}} \right) = \sum_{C \in \overline{S}} (z_C + \overline{z}_C - x_C) \mathbf{A}(C) = \sum_{C \in \overline{S}} (1 - |x_C|)(y_C + \overline{y}_C) \mathbf{A}(C)$$

where all vectors are taken as the final values. By definition $\mathbf{A}(C') = (1 - |x_C|)\mathbf{A}(C)$ and

$$\sum_{C \in \overline{S}} (1 - |x_C|)(y_C + \overline{y}_C)\mathbf{A}(C) = \sum_{C' \in \overline{S}'} (y_C + \overline{y}_C)\mathbf{A}(C')$$

By definition of hlift, each matrix $\mathbf{A}(C)^2$ is block diagonal with blocks $\mathbf{L}_{G'}^{\pm\frac{2}{2}} \widetilde{\mathbf{L}}_{\vec{C}}^{\top} \mathbf{L}_{G'}^{+} \widetilde{\mathbf{L}}_{\vec{C}} \mathbf{L}_{G'}^{\pm\frac{2}{2}}$ and $\mathbf{L}_{G'}^{\pm\frac{2}{2}} \widetilde{\mathbf{L}}_{\vec{C}} \mathbf{L}_{G'}^{+} \widetilde{\mathbf{L}}_{\vec{C}}^{\top} \mathbf{L}_{G'}^{\pm\frac{2}{2}}$. Here $\widetilde{\mathbf{L}}_{\vec{C}} = \mathbf{L}_{\vec{F}} - \mathbf{L}_S$ with fixed orientation (recall CorrectOrientation). Since every cycle $C \in \overline{S}$ satisfies $\boldsymbol{\tau}_{G'}(e) \leq \rho$ for each $e \in C$, by Lemma 10, both matrices are spectrally bounded by $O(L\rho) \cdot \mathbf{L}_{G'}^{\pm\frac{2}{2}} \mathbf{L}_C \mathbf{L}_{G'}^{\pm\frac{2}{2}}$. Thus, by the disjointness of G and $\overline{S}$,

$$\begin{aligned}\sum_{C' \in \overline{S}'} \mathbf{A}(C')^2 &\preceq \sum_{C \in \overline{S}} (1 - |x_C|)\mathbf{A}(C)^2 \preceq O(L\rho) \cdot \mathbf{I}_2 \otimes \mathbf{L}_{G'}^{\pm\frac{2}{2}} \left(\sum_{C \in \overline{S}} (1 - |x_C|)\mathbf{L}_C \right) \mathbf{L}_{G'}^{\pm\frac{2}{2}} \\ &\preceq O(L^2\rho) \cdot \mathbf{I}_{2n},\end{aligned}$$

where we used the PSD property of $\mathbf{A}(C)^2$ and the fact $1 - |x_C| \leq 1$ for the first inequality and Lemma 17 for the second inequality. The sum of Frobenius norm squared is then

$$\sum_{C' \in \overline{S}'} \|\mathbf{A}(C')\|_F^2 \leq \sum_{C \in \overline{S}} (1 - |x_C|) \operatorname{Tr}\left(\mathbf{A}(C)^2\right) = \operatorname{Tr}\left(\sum_{C \in \overline{S}} (1 - |x_C|)\mathbf{A}(C)^2 \right) = O(nL^2\rho).$$

We can now apply Lemma 14 with $m_t = \frac{1}{4}m', \sigma^2 = O(L^2\rho)$ and $v = O(nL^2\rho)$ to get

$$\begin{aligned}\left\| \sum_{C' \in \overline{S}'} (y_C + \overline{y}_C - 0)\mathbf{A}(C') \right\| &\leq O\left(\sqrt{L^2\rho} \cdot \log\left(\frac{4|\overline{S}|L}{m'} \right) + (\log^{\frac{3}{4}} n)(L^2\rho)^{\frac{1}{4}} \left(\frac{4nL^3\rho}{m'} \right)^{\frac{1}{4}} \right) \\ &= O\left(\sqrt{\frac{nL^2}{m'}} \log L + \left(\frac{nL^{\frac{5}{3}} \log n}{m'} \right)^{\frac{3}{4}} \right)\end{aligned}$$

where we used $|\overline{S}'| = |\overline{S}| \leq m'$. Finally, note that

$$\left\| \mathbf{L}_{G'}^{\pm\frac{2}{2}} (\mathbf{L}_{\vec{G}'} - \mathbf{L}_{\vec{H}'}) \mathbf{L}_{G'}^{\pm\frac{2}{2}} \right\| = \left\| \mathsf{hlift}\left(\mathbf{L}_{G'}^{\pm\frac{2}{2}} (\mathbf{L}_{\vec{G}'} - \mathbf{L}_{\vec{H}'}) \mathbf{L}_{G'}^{\pm\frac{2}{2}} \right) \right\| = \left\| \sum_{C' \in \overline{S}'} (y_C + \overline{y}_C - 0)\mathbf{A}(C) \right\|. \blacktriangleleft$$

The sparsification induced by ColourSparsifyGraph is conditional, and we state the condition and sparisification induced in Lemma 18. However, even when the condition is not met, we are guaranteed each ColourSparsifyCycle will geometrically make progress towards satisfying the condition needed for Lemma 18. This is stated in Lemma 19.

▶ **Lemma 18.** *For inputs $\vec{G}, \vec{G}', \overline{S}, \overline{x}, \mathbf{r}$ to* ColourSparsifyGraph *satisfying that $4m \geq m' \geq \Omega(n \log^2 n)$, the outputs satisfy that the number of edges in $\vec{H}'$ is upperbounded by $m'_H \leq \frac{63}{64}m'$.*

Proof. Since $\mathbf{r}$ is 2-approximate effective resistances, $\sum_e w_e r_e \leq 2(n-1)$, we have at most $\frac{1}{8}m' \leq \frac{1}{2}m$ edges are removed from $\vec{G}$ in line 1. Since $m \geq \frac{1}{4}m' = \Omega(n \log^2 n)$ and the number of edges not in any cycle is $\hat{m}q = O(n \log^2 n)$, by picking an appropriate constant in $\Omega(n \log^2 n)$, we can guarantee the total number of edges in all cycles satisfies $m(S) \geq \frac{1}{4}m$. Lemma 14 then guarantees $m(\overline{T}') \leq \frac{1}{8}m$ and that $m(T') \geq \frac{1}{8}m$.

Now, by ColourWeights, the total number of edges in ColourWeights$(T', \mathbf{y})$ and ColourWeights$(T', -\mathbf{y})$ is exactly $m(T')$. Thus, line 5 means at least $\frac{1}{2}m(T') \geq \frac{1}{16}m \geq \frac{1}{64}m'$ edges are removed in total as required. ◀

▶ **Lemma 19.** *If inputs $\vec{G}, \vec{G}', \overline{S}, \overline{x}, \mathbf{r}$ to* ColourSparsifyCycle *satisfies that $4m < m'$, then either the number of edges in $\vec{H}'$ decreases to $m'_H \leq \frac{63}{64}m'$, or the number of edges in $\vec{H}$ satisfies $4m_H \geq m'_H$.*

Proof. Suppose $m'_H > \frac{63}{64}m'$. By Lemma 14, $m(\overline{T'}) \leq \frac{1}{8}m'$. Since $\mathbf{y} \in \{\pm 1\}^{T'}$, we have $\{C' \in T' : |\overline{x}_C - (1 - |\overline{x}_C|)y_{C'}| = 1\} \cup \{C' \in T' : |\overline{x}_C + (1 - |\overline{x}_C|)y_{C'}| = 1\} = T'$. Let the two sets above be T'_1 and T'_2, Then, $m(T'_1) + m(T'_2) \geq m(T')$ [2]. This means, after re-adjusting the colouring in line 4,

$$m(\overline{T}) \leq \frac{1}{2}m(T') + m(\overline{T'}) \leq \frac{1}{2}m' + \frac{1}{8}m' = \frac{5}{8}m' \leq \frac{40}{63}m'_H.$$

Then, we get the desired inequality, $m_H = m'_H - m(\overline{T}) \geq \frac{23}{63}m'_H \geq \frac{1}{4}m'_H$. ◀

With these analyses above, we can now formally state and prove Theorem 2.

▶ **Theorem 20** (Theorem 2 Formal)**.** *Given input a Eulerian graph $\vec{G}$ with polynomial bounded integral edge weights and $\varepsilon \in (0, \frac{1}{2})$, the algorithm* ColourSparsify *returns in polynomial time a Eulerian graph $\vec{H}$ with $O(n\varepsilon^{-2}\log^2 n(\log\log n)^2 + n\varepsilon^{-\frac{3}{4}}\log^{\frac{8}{3}} n)$ edges satisfying*

$$\left\| \mathbf{L}_{\vec{G}}^{\frac{+}{2}}(\mathbf{L}_{\vec{G}} - \mathbf{L}_{\vec{H}})\mathbf{L}_{\vec{G}}^{\frac{+}{2}} \right\| \leq \varepsilon.$$

Proof. By Lemmas 18 and 19, in every two iterations the number of edges must decreases by at least a constant fraction, as the condition $4m \geq m'$ must be satisfied at least once. Note that initialy $m = m' \geq \frac{1}{4}m'$ is satisfied. Thus, the total number of iterations is at most $O\left(\log(\frac{m\log n}{n})\right) = O(\log n)$ where the extra $\log n$ comes from the decomposition by weights.

By Lemmas 15 and 16, the largest edge weight doubles each iteration. Thus, the edge weights in each $\vec{G}$ are still integral and polynomially bounded over $O(\log n)$ iterations.

As the number of edges decreases geometrically every $O(1)$ iterations, the total error is asymptotically bounded by the error in the last round for both terms in Lemmas 15 and 16:

$$O\left(\sqrt{\frac{n\log^2 n}{m'}}\log\log n + \left(\frac{n\log^{\frac{8}{3}} n}{m'}\right)^{\frac{3}{4}}\right).$$

where m' is the number of edges in $\vec{G}'$ in the last round. Since the algorithm stops at $m' \geq \Omega(n\varepsilon^{-2}\log^2 n(\log\log n)^2)$ and $m' \geq \Omega(n\varepsilon^{-\frac{3}{4}}\log^{\frac{8}{3}} n)$ edges, the largest of both terms must be bounded by $\frac{1}{2}\varepsilon$ by picking appropriate constant for the stopping condition.

This small error also implies that our 1.5-approximate effective resistances $\mathbf{r}$ stays as 2-approximate throughout the algorithm. Then, by Lemma 15 and Lemma 16, the set of cycles $\overline{S}$ always satisfy $w_e r_e \leq \frac{4n}{m'}$ where m' is the number of edges in $\vec{G}'$ throughout as required. Lemma 4 guarantees the polynomial running time of our algorithm. ◀

4.1 Conjectural improvements

In this section we consider an improvement on our existential results due to the partial colouring conjecture, Conjecture 21. Corollary 22 then follows by changing the termination condition of the while loop on line 5 to $m' \geq O(n\varepsilon^{-2}\log^2 n(\log\log n)^2)$.

[2] Contrary to the proof of Lemma 18, this is an inequality since magnitude of 1 can be achieved using both $y_{C'}$ and $-y_{C'}$ if $x_C = 0$.

▶ **Conjecture 21** (Matrix partial colouring conjecture). *There exists constants $c_1, c_2 > 0$ and $c_3 > 1$ such that the following holds. Given symmetric matrices $\mathbf{A}_1, \ldots, \mathbf{A}_m \in \mathbb{R}^{n \times n}$ that satisfy $m \geq c_3 n$, $\|\sum_{i=1}^m \mathbf{A}_i^2\| \leq \sigma^2$, and a point $\mathbf{y} \in (-1,1)^m$, there exists a point $\mathbf{x} \in [-1,1]^m$ such that $|\{i : x_i \in \{\pm 1\}\}| > c_2 m$ and*

$$\left\| \sum_{i=1}^m (x_i - y_i)\mathbf{A}_i \right\| \leq c_1 \sigma. \tag{3}$$

▶ **Corollary 22.** *Assume Conjecture 21. There is an algorithm that given a Eulerian graph $\vec{G}$, computes a ε-Eulerian sparsifier of $\vec{G}$ with $n\varepsilon^{-2}\log^2 n$ edges (up to $\log\log n$ factors).*

▶ Remark 23. While improvements on matrix concentration results for Gaussian random variables [5] naturally leads to improved matrix partial colouring through the Gaussian measure analysis of matrix discrepancy bodies, Conjecture 21 need not rely on this approach (e.g. [9, 15]). On the other hand, even if the matrix concentration guarantees of [5] hold for Rademacher random variables, it does not lead to an efficient algorithm for Theorem 2. This is due to the difficulties in controlling the matrix covariance factor in Theorem 1.2 of [5]. We refer reader to the proof of Lemma 3.1 in [6].

Caching Connections in Matchings

Yaniv Sadeh
Tel Aviv University, Israel

Haim Kaplan
Tel Aviv University, Israel

Abstract

Motivated by the desire to utilize a limited number of configurable optical switches by recent advances in Software Defined Networks (SDNs), we define an online problem which we call the *Caching in Matchings* problem. This problem has a natural combinatorial structure and therefore may find additional applications in theory and practice.

In the *Caching in Matchings* problem our cache consists of k matchings of connections between servers that form a bipartite graph. To cache a connection we insert it into one of the k matchings possibly evicting at most two other connections from this matching. This problem resembles the problem known as *Connection Caching* [20], where we also cache connections but our only restriction is that they form a graph with bounded degree k. Our results show a somewhat surprising qualitative separation between the problems: The competitive ratio of any online algorithm for caching in matchings must depend on the size of the graph.

Specifically, we give a deterministic $O(nk)$ competitive and randomized $O(n \log k)$ competitive algorithms for caching in matchings, where n is the number of servers and k is the number of matchings. We also show that the competitive ratio of any deterministic algorithm is $\Omega(\max(\frac{n}{k}, k))$ and of any randomized algorithm is $\Omega(\log \frac{n}{k^2 \log k} \cdot \log k)$. In particular, the lower bound for randomized algorithms is $\Omega(\log n)$ regardless of k, and can be as high as $\Omega(\log^2 n)$ if $k = n^{1/3}$, for example. We also show that if we allow the algorithm to use at least $2k - 1$ matchings compared to k used by the optimum then we match the competitive ratios of connection catching which are independent of n. Interestingly, we also show that even a single extra matching for the algorithm allows to get substantially better bounds.

1 Introduction

We define the *Caching in Matchings* online problem, on a fixed set of n nodes. Requests are edges between these node. The algorithm maintains a cache of k matchings, i.e. a k-edge-colorable graph. To serve a request for an edge (u, v) which is not in its cache (i.e. a miss), the algorithm has to insert it into one of its matchings. To do this it may need to evict the edges incident to u and v in this specific matching. Note that an evicted edge may later be re-inserted into a different matching. The algorithm has to choose which matching to use for each miss in order to minimize its total number of misses.

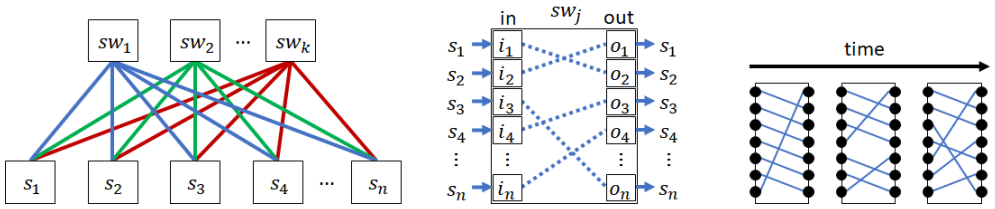

Figure 1 The physical topology that motivates our problem: n servers $s_1, \ldots, s_n$, each is connected to the in/out ports of k optical switches sw_1 through sw_k. Each switch sw_j uses mirrors to switch optical links, effectively inducing an in/out permutation, which may change over time at a reconfiguration cost of 1 per each new pairing. Abstractly, we get a bipartite graph with n nodes on each side (one per server), and each permutation is a matching that caches links.

One can look at this problem as a new variation of the online Connection Caching problem. In *Connection Caching* [20] the setup is the same, but the cache maintained by the algorithm must be a graph in which each node is of degree at most k. In case of a miss on an edge (u, v) we may choose any edge incident to u and any edge incident to v to evict. We do not have to maintain the edges partitioned into a particular set of k matchings. Thus in Caching in Matchings we are less flexible in our eviction decisions. Once we color the new edge then the two edges we have to evict are determined.

At a first glance, the two caching problems seem similar. In fact, the only difference is the added restriction of the coloring (matchings) that affects how the cache is maintained. Interestingly, it turns out that this seemingly small difference makes Caching in Matchings a much harder online problem compared to Connection Caching.

A common measure to evaluate online algorithms is their competitive ratio. We say that an online algorithm is c-competitive if its cost (in our case, miss count) on every input sequence is at most c times the minimal possible cost for serving this sequence. One would like to design algorithms with as small c as possible. The problem of Connection Caching is known to be $\Theta(k)$ (deterministic) and $\Theta(\log k)$ (randomized) competitive, and in contrast we show that the dependence on n (the number of nodes) in Caching in Matchings cannot be avoided.

The motivation to our Caching in Matchings problem comes from a data-center architecture described in [4]. In this setting we have n servers connected via a communication network which is equipped with a set O of k optical switches. Each server is connected to all the k optical switches and in each of them it is connected to both an input and an output port. Each switch is configured to implement a matching between the input and the output ports of the servers, see Figure 1. Since each server is connected to both input and output sides, the optical switches effectively induce a degree k bipartite graph with $2n$ nodes (two nodes per server). Each optical switch corresponds to a matching in our cache. It is dynamic as we can insert and evict connections from the switch, but we try to minimize these reconfigurations since they are costly (involve shifting mirrors, and down-time).

At this point we clarify that there are two "kinds" of optical switching architectures. The one which we model, as explained, is based on off-the-shelf commodity switches and is sometimes referred to as Optical Circuit Switching (OCS). Each switch is a separate box, and each box, at any time, implements a matching between its ports. We use k switches and connect every server to every switch, so this architecture induces k matching at any time. To add a connection between two servers we have to choose through which box we want to do it (choose a matching to insert it to) and then reconfigure the matching implemented by this particular box to include this edge. The other kind of switching is known as Free Space Optics (FSO) where every transmitter can point towards any receiver. When each server is

connected to k transmitters and k receivers we get the standard connection caching setting. This is *not* the architecture that we model here. See Table-1 of [26] for several references and their architecture types.

Several cost models considering both communication and adjustment cost were suggested for this setting [4]. We choose to work with arguably the simplest model of paying 1 for an insertion of a new edge (formally defined in Section 2). This simple model already captures the qualitative properties of the problem. We note that the competitive results shown here can be adapted (up to constant factors) to a more complicated cost model that has additional communication costs per request. We believe that our combinatorial abstraction of this setting is natural and will find additional applications.

Here is a detailed summary of our results.

Our contributions

1. We define a new caching problem, "Caching in Matchings" (Problem 1), on a bipartite graph with n nodes on each side.[1] In this problem, the cache is a union of k matchings. When we insert an edge we pick the matching to insert it to and evict edges from this matching if necessary.
2. We show that the competitive ratio of Caching in Matchings depends not only on the cache size k as is common for caching problems, but also on the number of nodes in the network n. One might argue that since we define the cache to be k matchings, its size is $\Theta(nk)$ rather than k, so the dependency on n is not surprising. But such an argument also applies to Connection Caching [20] and in that problem the competitive ratio does not depend on n. In other words, Caching in Matchings is provably harder than Connection Caching.[2] Specifically we prove the following.
   a. An $\Omega(\max(\frac{n}{k}, k))$ lower bound on the competitive ratio of deterministic algorithms, and we give a deterministic algorithm with nk competitive ratio. For $k = O(1)$ this gives a tight bound of $\Theta(n)$ on the competitive ratio.
   b. In contrast, in the randomized case we have a larger gap. We describe an $O(n \log k)$ competitive algorithm and prove a lower bound of $\Omega(\log \frac{n}{k^2 \log k} \cdot \log k)$ on the competitive ratio. This bound is $\Omega(\log n)$ for any k, and can get as worse as $\Omega(\log^2 n)$, for example if $k = n^{1/3}$. This is in contrast to other caching problems whose randomized competitive ratio is logarithmic.[3]
3. We show that resource augmentation of almost-twice as many matchings, specifically $2k - 1$ for the algorithm versus k for the optimum, allows to get rid of the dependence on n. Specifically, we show a deterministic $O(k)$ competitive algorithm and a randomized $O(\log k)$ competitive algorithm for this case. Furthermore, with $2(1+\alpha)k$ matchings we get a deterministic $O(1+\frac{1}{\alpha})$ competitive algorithm. We also show that a single extra matching already helps by allowing us to "trade" $\sqrt{n}$ for $\sqrt{k}$ in the competitive ratio. Concretely and more generally, with $h \geq 1$ extra matchings we get a deterministic $O(n^{1/2}(k/h)^{3/2})$ and a randomized $O(n^{1/2}(k/h)^{1/2} \log \frac{2k+h}{h})$ competitive algorithms. Moreover, it is even possible to reduce the dependence on n to polylogarithmic at the cost of higher polynomial dependency on k, which is beneficial for small k. Concretely, following [19], we get a deterministic $O\left(\frac{k^6 \log n}{h} \min(k, \log n)\right)$ and a randomized $O\left(\left(\frac{k \log k}{h}\right)^6 \log \frac{2k+h}{h} \log^9 n\right)$ competitive algorithms. The deterministic algorithm is not efficient.

[1] The problem makes sense on a general graph as well.
[2] In terms of the architecture, we show that the FSO architecture has a better competitive ratio than the the OCS architecture.
[3] Throughout the paper, where it matters, our logarithms are in base 2.

Our problem is a special case of a more general problem of convex body chasing in L_1. Bhattacharya et al. [11] gave a fractional algorithm for this body chasing problem with packing and covering constraints. Their fractional algorithm requires a slight resource augmentation. For a few special cases, they show how to round their fractional solution to an integral solution that does not use additional resources. Our problem is another interesting test-case of this general setting (for more details, see the appendix in [30]).

Our full list of results is summarized in Table 1. The rest of the paper is structured as follows. Section 2 formally defines the model, the notations that we use, and the caching problems. Section 3 studies in depth the Caching in Matchings problem (Problem 1). Section 4 surveys related work on caching and coloring problems, and in Section 5 we conclude and list a few open questions. Section 6 serves as an appendix that contains deferred proofs, and a few additional discussions. Due to a strict page limit, the complete appendix can be found in the extended version [30].

2 Model and Definitions

In the following we formally define two caching problems of interest, the premise of each of them is a graph with a set V of n nodes. Every turn, a new edge is requested. If it is already cached, we have a "hit" and no cost is paid. Otherwise, we have a "miss", and the edge must be brought into the cache at a cost of 1, possibly at the expense of evicting other edges. In fact, the problem that arises from [4] consists of a bipartite graph in which each server v is associated with two nodes $v^{in} \in V^{in}$ and $v^{out} \in V^{out}$, modeling its receiving and sending ports, respectively. Each among v^{in} and v^{out} can be incident to one edge in each matching.[4] Formally the problem is as follows.

▶ **Problem 1** (Caching in Matchings)**.** Requests arrive for edges $(u, v) \in V^{in} \times V^{out}$. The cache M is a union of k matchings. When a requested edge is missing from all the matchings, an algorithm must fetch it into one of the matchings (possibly evicting other edges from this matching). In addition, the algorithm may choose to add any edge to the cache at any time (while maintaining the cache's restrictions), the cost of adding an edge to the cache is 1. It is not allowed to move an edge between matchings, but an edge may be evicted and immediately re-fetched into a new matching.

▶ Remark 1. There are other caching models in which reorganizing the cache is free, such as [16, 25]. In our model reorganizing the matchings incurs a cost. This is because we model a setting where changing the cache (physical links) is slow. In other cases accessing the slow memory is the costly operation.

We use the terminology of coloring edges when discussing Caching in Matchings (Problem 1). Recoloring an edge implies that we evict it, and then immediately fetch it back into a different matching according to the new color of the edge. Recoloring is not free, but has the same cost of standard fetching. This models, for example, the physical setting in which such a rearrangement requires reconfiguring the link in a different optical switch.

▶ **Problem 2** (Connection Caching [20])**.** Requests arrive for edges $(u, v) \in V^{in} \times V^{out}$. The cache M is a set of edges such that every node is of degree at most k in the sub-graph induced by M. When a requested edge is missing from M, an algorithm must fetch it (possibly

[4] Technically, the physical switch can be configured with links of the form (v^{in}, v^{out}), but it makes no sense and practically such requests do not exist. However, our algorithms can deal with all possible requests, and our lower bounds are proven without relying on such requests, so we ignore this nuance.

evicting other edges). In addition, the algorithm may choose to add any edge to the cache at any time while maintaining the degrees at most k. Adding an edge to the cache costs 1.

▶ Remark 2. Note that in both problems that we defined, an algorithm is allowed to add (fetch) and remove (evict) additional edges. Technically, it is not strictly necessary because a non-lazy algorithm can always be simulated by a lazy version that fetches an edge only when it is actually needed. This is also true for the offline optimum. We will describe non-lazy algorithms for Caching in Matchings, that recolor edges, to simplify the presentation.

To emphasize the difference between the problems see Figure 2, which shows the difference on bipartite graphs, as well as on general graphs (for the generalized problem).

Figure 2 An example of the difference between connection caching versus caching in matchings. (left) With $k = 2$ max degree and $n = 3$ nodes, all the connections can be cached simultaneously, but not in 2 matchings, red and blue. (right) Bipartite example: Caching the edge (s_1^i, s_2^o) (i/o for in/out) is not possible without changing the matchings (red: $\{(s_1^i, s_3^o), (s_3^i, s_1^o)\}$; blue: $\{(s_3^i, s_2^o), (s_2^i, s_1^o)\}$), although both s_1^i and s_2^o only have a single connection.

The objective of an online algorithm is to minimize the number of fetched edges. We are interested in the competitive-ratio of our algorithms.

▶ **Definition 3** (Cost, Competitive Ratio)**.** Consider a specific caching problem. Let A be an online algorithm that serves requests, and let σ be a sequence of requests. We denote by $A(\sigma)$ the execution of A on σ, and $cost(A(\sigma))$ for the cost of A when processing σ.

We denote by $OPT(\sigma)$ the optimum (offline) algorithm to serve the sequence, or simply OPT when σ is clear from the context. If there exist functions of the problem's parameters (in our case: k and n) $c = c(n, k)$ and $d = d(n, k)$ such that $\forall\sigma : cost(A(\sigma)) \leq c \cdot cost(OPT(\sigma)) + d$ then we say that A is c-competitive. Note that σ may be arbitrarily long, so the "asymptotic ratio" is indeed c.

▶ Remark 4. Denote the optima for Caching in Matchings and Connection Caching by OPT_m and OPT_c, respectively. Since OPT_m implicitly maintains a connections cache as required by Connection Caching (ignore the colors), then for any sequence of edge requests σ, $cost(OPT_c(\sigma)) \leq cost(OPT_m(\sigma))$.

3 Caching in Matchings

In this section we study the problem of Caching in Matchings (Problem 1). We summarize the results of this section in Table 1. We start with upper bounds (Section 3.1), then lower bounds (Section 3.2). Then we study resource augmentation (Section 3.3). Some additional discussion on randomization is detailed in the appendix in [30].

3.1 Upper Bounds for Bipartite Graphs

In this section we prove upper bounds on the competitive ratio of algorithms for Caching in Matchings, focusing on the non-trivial case of $2 \leq k \leq n - 1$. Indeed, if $k = 1$ there are no eviction-decisions to take so the only (lazy) algorithm is the optimal one. The other

Table 1 Our bounds on the competitive ratio for Caching in Matchings (Problem 1), for $2 \leq k < n$. If $k = 1$ or $k \geq n$ optimality is trivial. Results marked with $*$ also apply to general graphs. "RA: x" shortens Resource-Augmentation, i.e., the algorithm has more matchings (x) than the optimum (k).

Result		Deterministic	Randomized	Notes
Thm. 7		$\leq nk$	$O(n \log k)$	The standard scenario
Thm. 9	$*$	.	$\Omega(\log \frac{n}{k^2 \log k} \cdot \log k)$	.
Cor. 10	$*$	$\Omega(max(\frac{n}{k}, k))$	$\Omega(\log n)$	Due to Theorems 8+9
Cor. 10	$*$	.	$\Omega(\epsilon \cdot \log n \cdot \log k)$	$k = O(n^{1/2-\epsilon})$; Due to Theorem 9
Cor. 25(1)		$O(n^{1/2}(k/h)^{3/2})$	$O(n^{1/2}(k/h)^{1/2} \log \frac{2k+h}{h})$	RA: $k+h$ for $1 \leq h \leq k$
Cor. 25(2)	$*$	$O\left(\frac{k^6 \log n}{h} \min(k, \log n)\right)$	$O\left(\left(\frac{k \log k}{h}\right)^6 \log \frac{2k+h}{h} \log^9 n\right)$	RA: $k+h$ for $1 \leq h \leq k$
Cor. 25(3)	$*$	$\leq k$	$O(\log k)$	RA: $2k-1$
Cor. 25(4)	$*$	.	$O(\alpha^4 \log k)$	RA: $(1+O(\frac{1}{\alpha}))k$ for $k \geq \Theta(\alpha^4 \log n)^{\Theta(\alpha \log \alpha)}$
Thm. 27	$*$	$O(1+\frac{1}{\alpha})$	.	RA: $(2+\alpha)k$ for $\alpha > 0$

extreme case of $k \geq n$ in bipartite graphs is also easy since we can just cache the entire graph: Number the nodes 0 to $n-1$ on each side, and use matching i to store edges from node j to $i+j$ modulo n.

Our general technique is to reduce the problem of Caching in Matchings to Connection Caching. Our algorithm, A_m, will run a Connection Caching algorithms A_c with cache parameter k to insert requested edges into the cache. Then, layered on top of A_c, we have the "coloring component" of A_m that chooses the color of the new edge, and also recolors existing edges in order to produce a proper Caching in Matchings algorithm. A_m can be thought of as an edge coloring algorithm in the dynamic graph settings, and in this context A_c is the adversary that tells A_m which edges are inserted and which are removed (with a guarantee of bounded degree k). As a consequence we would like to use algorithms that are efficient in terms of recoloring, to achieve the best competitive results. Unfortunately, since edge coloring of graphs of bounded degree k may require $k+1$ colors by Vizing's theorem, the dynamic graph coloring literature studies this coloring problem while typically allowing more than k colors. The number of extra colors ranges from $k+1$ colors [29, 10], to $(1+\epsilon)k$ colors [21, 19, 13], to $2k-1$ colors [9, 12], and sometimes even more [8, 31] (the last citations actually study vertex coloring). Extra colors correspond to resource augmentation, which we study later in Section 3.3.

▶ Remark 5. There are known algorithms that are k competitive deterministic and $O(\log k)$ competitive randomized for Connection Caching, as studied in [20].

▶ Remark 6. Due to Remark 4 and Remark 5, it suffices to analyze the cost ratio between A_m and A_c. A ratio of ρ implies a $\rho \cdot k$ deterministic and a $O(\rho \cdot \log k)$ randomized competitive algorithms for Caching in Matchings.

▶ **Theorem 7.** There exist nk deterministic and $O(n \log k)$ randomized competitive algorithms in bipartite graphs for Caching in Matchings.

Proof. By Remark 5 and Remark 6, it suffices to show that A_m pays no more than n times compared to A_c. Whenever an edge (u, v) is requested, A_m has it cached if and only if A_c has it cached. Therefore when A_m has a miss, so does A_c. To accommodate for the edge, A_c ensures that u and v are both of degree $k-1$ before (u, v) is inserted. Now consider how many edge recolorings are required from A_m. Nodes u and v each have at least one free color. If both have some common free color c, we are done. Otherwise, u has c_1 free and v has $c_2 \neq c_1$ free. Let P_u and P_v be the (c_1, c_2) bi-colored paths that originate in u and v

respectively. P_u and P_v must be disjoint because the graph is bipartite and does not contain odd cycles. Flipping the colors ($c_1 \leftrightarrow c_2$) for each edge on either P_u or P_v enables A_m to insert and color (u, v). since P_u, P_v and (u, v) form a simple path in a graph with $2n$ nodes, by flipping the shorter bi-colored path, A_m colors at most n edges when inserting (u, v). ◀

3.2 Lower Bounds

Caching in Matchings is a generalization of caching, if we restrict the requests to edges of a single fixed node. Observe, therefore, that any c-competitive online algorithm for Caching in Matchings with $2 \leq k < n$ satisfies $c = \Omega(\log k)$. Moreover, if the algorithm is deterministic then $c \geq k$. The following lower bounds depend on n as well as k. These bounds hold for the non-trivial case of $2 \leq k < n$, in bipartite graphs, and therefore also hold for general graphs. Theorem 8 is proven later in this section, the proof of Theorem 9 is deferred to Appendix 6.1.

▶ **Theorem 8.** Any *deterministic* Caching in Matchings algorithm is $\Omega(\frac{n}{k})$ competitive.

▶ **Theorem 9.** *Any* Caching in Matchings algorithm is $\Omega(\log \frac{n}{k^2 \log k} \cdot \log k)$ competitive.

▶ **Corollary 10.** *Any* online algorithm for Caching in Matchings with $2 \leq k < n$ is $\Omega(\log n)$ competitive. Moreover, if $k = O(n^{1/2-\epsilon})$ for some $\epsilon > 0$, we get that any online algorithm for Caching in Matchings is $\Omega(\epsilon \cdot \log n \cdot \log k)$ competitive. If the algorithm is deterministic then the competitive ratio is $\Omega(\max\{\frac{n}{k}, k\})$.

Proof. The deterministic claim follows from the initial observation and Theorem 8. In the general case (randomized), we get $\Omega(\log n)$ from the maximum between the observation (when $k \geq n^{1/3}$) and Theorem 9 (when $k < n^{1/3}$). The $\Omega(\epsilon \cdot \log n \cdot \log k)$ bound follows from Theorem 9: If $k \leq c \cdot n^{1/2-\epsilon}$ for some constant c then $\log \frac{n}{k^2 \log k} > \log \frac{n^{2\epsilon}}{c^2 \log(cn)} = 2\epsilon \log n - 2 \log c - \log \log(cn) = \Omega(\epsilon \cdot \log n)$. ◀

We prove the lower bounds in a setting that is closer to dynamic graph coloring. Specifically, we define Problem 3 below, where we control which edges must be cached both by the algorithm and the optimum. We prove (Lemma 11 below, proven in Appendix 6.1) that lower bounds for algorithms for Problem 3 imply lower bounds for Caching in Matchings, and then study lower bounds for Problem 3.

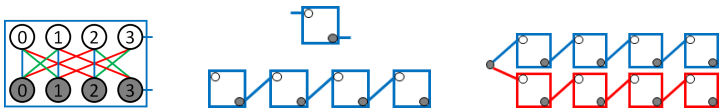
▶ **Problem 3.** Given a graph with n vertices, we get a sequence of actions that define a subset of edges at any time. Each action either adds a missing edge or deletes an existing edge. We are guaranteed that at any point in time the graph induced by existing edges, denote it (or the set of edges) by G, has a proper k-edge-coloring. An algorithm, online or OPT, must maintain k matchings, denote their union by M, such that G is a subgraph of M. For every edge that is added to a matching, the algorithm pays 1.

Note that Problem 3 is similar but not equivalent to dynamic edge coloring. On one hand a dynamic edge coloring algorithm that recolors $O(C)$ edges per update is not necessarily $O(C)$ competitive for Problem 3. The reason for this is that we allow M to contain G. By maintaining an edge in M we can avoid paying for it when it is inserted again. For example, in the proof of Theorem 8 an algorithm may do $O(1)$ worst-case recolorings per step, but its competitive ratio is $\Omega(\frac{n}{k})$ since OPT stores in M extra edges that this online algorithm keeps paying for. On the other hand, an algorithm that is $O(C)$ competitive for Problem 3 does not give a dynamic edge coloring algorithm that recolors $O(C)$ edges per update, even amortized, because it could be that both OPT and the algorithm pay a lot per edge update on some sequence, and while the ratio is $O(C)$, the absolute cost is large.

▶ **Lemma 11.** A lower bound of C on the competitive ratio of an online algorithm for Problem 3 implies a lower bound of C on the competitive ratio of an online algorithm for Caching in Matchings.

We now focus on deriving lower bounds for Problem 3. We define a *road* gadget (Definition 13) which is a connected component with a large diameter, that is also very restricted in the way it can be colored. A road is constructed from *brick* sub-gadgets (Definition 12), each of size $\Theta(k)$ nodes and $\Theta(k^2)$ edges. By connecting $r \geq 2$ roads together we get the *r-road* gadget, whose structure enforces those roads to be colored in a distinct and different way.

▶ **Definition 12** (Brick)**.** A *colorless-brick* is a union of k perfect matchings in a bipartite graph with the following structure. Each side has w nodes where w is the unique power of 2 that satisfies $\frac{w}{2} < k \leq w$. Number the nodes on each side $0, \ldots, w-1$, and number the colors $0, \ldots, k-1$. The matching of color c matches node i with node $i \oplus c$ where $\oplus$ is the bitwise exclusive-or. See Figure 3a for an example. Note that every color c indeed defines a matching that is in fact a permutation of order 2, and that $v \oplus c \neq v \oplus c'$ for any two colors $c \neq c'$ so the matchings are all disjoint. When we remove an edge from a colorless-brick, we get a *brick* whose color is associated with the color of the non-perfect matching. The two nodes of degree $k-1$ are the *endpoints* of the brick.



(a) Brick. **(b)** Road. **(c)** r-Road for $r = 2$.

Figure 3 Visualization of a *brick* (Definitions 12), a *road* and an *r-road* (Definition 13). (a) A brick for $k = 3$ ($w = 4$). The number of each node is written, and the colors are as follows: blue (0), green (1), red (2). Thus, for example, $1 \oplus red = 3$. We removed a single edge, blue $(3, 3)$, thus the brick is blue. (b) A schematic way to draw a brick (top) and a road of length 4 (bottom) which is a chain of bricks connected to each other by their endpoints. The color of a road is well-defined by the color of its bricks. (c) An r-road for $r = 2$, of length 4. The node that connects to both roads is its hub. Nodes are colored by gray and white according to their side in the bipartite graph.

▶ **Definition 13** (Road, r-road)**.** A *road* of length $d \geq 1$ is an edge colored graph obtained by connecting a sequence of d bricks. Each brick is connected by an edge to the next brick in the sequence. The edge connecting two consecutive bricks is adjacent to an endpoint of each brick. Note that the color of two connected bricks must be the same since they must agree on their free color which is the color of the edge which connects them. Therefore, we define the *color of a road* to be the color of its bricks. A road has two *ends*, which are the endpoints of its first and last bricks. We also refer to r $(2 \leq r \leq k)$ roads of the same length d that are all connected to a single shared node as an *r-road* of length d. The shared node is its *hub*. The edges of the hub all have different colors, therefore all the roads of an r-road have different colors. See Figure 3 for examples.

▶ **Lemma 14.** Given a brick B of color c_1, and a new color $c_2 \neq c_1$, it is always possible to recolor 3 edges to change the color of B to c_2.

Note that when we recolor B, it no longer satisfies the $\oplus$-property of Definition 12, but for convenience we still consider it as a brick. This would not affect our arguments below (by more than a constant factor) since we will make sure to always return to the original coloring (undo) before recoloring again.

Proof. Denote by u one endpoint of the brick. By definition of the matching scheme, the other endpoint is $u \oplus c_1$, and when we restrict the graph to edges of colors c_1 and c_2, we find that the path between u and $u \oplus c_1$ is of length 3: $u \oplus c_1 \to u \oplus c_1 \oplus c_2 \to u \oplus c_2 \to u$. Therefore, it suffices to flip the color of these three edges from c_2 to c_1 and vice versa. ◀

In the remainder of this section we prove the deterministic lower bound, and a simpler but weaker version of the randomized lower bound. The more involved randomized lower bound is proven in Appendix 6.1, using the same gadgets.

Proof of Theorem 8. We prove the lower bound for Problem 3. Then the theorem follows by Lemma 11. We present an adversarial construction against a given algorithm ALG.

We begin by setting aside one special node u to serve as a 2-road hub, and divide the rest of the vertices into bricks. We construct from these bricks the longest possible road, of length $N = \Theta(\frac{n}{k})$. We number the bricks in order, from 1 to N, and denote the edge between bricks i and $i+1$ by $(i, i+1)$. Let $L = \lfloor \frac{N}{3} \rfloor$. Initially we insert all the edges of all the bricks, without the edges connecting the bricks. These edges are never deleted. Our sequence has as many steps as we like as follows, based on the state of ALG, see also Figure 4:

1. Simple step: If there exist consecutive bricks i and $i+1$ of different colors, we insert the edge $(i, i+1)$. This forces ALG to recolor at least one of the bricks and pay $\Omega(1)$ (it could pay more if it recolors more bricks or does other actions). We then delete $(i, i+1)$.
2. Split step: Otherwise, all the bricks of ALG have the same color. We insert all the edges between bricks 1 through to L, and between $N+1-L$ through to N. We also insert edges from u to bricks 1 and $N+1-L$. These insertions construct a 2-road with u as its hub, that guarantees different colors for bricks 1 to L compared to bricks $N+1-L$ to N. ALG must recolor at least $L = \Omega(N)$ bricks. We then delete the edges that we inserted.

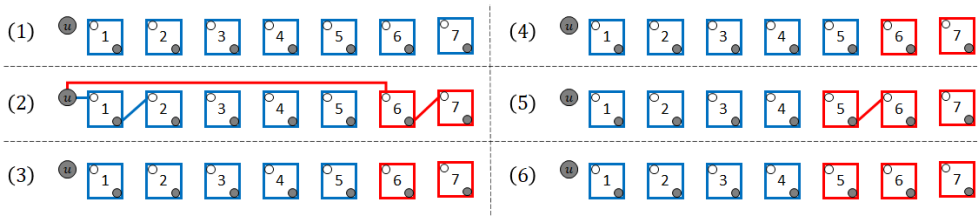


Figure 4 Visualization for the proof of Theorem 8, for $N = 7$, $L = \lfloor \frac{N}{3} \rfloor = 2$. (1)-(3) A *split step* temporarily creates a 2-road of length L out of the first and last bricks, with u as the hub, to guarantee consecutive bricks with different colors. (4)-(6) A *simple step* finds two consecutive bricks with different color (here: 5 and 6), and inserts temporarily the edge between them to enforce recoloring one of them.

In simple terms, we maintain a hole in the road which is where the color of the bricks changes (there could be multiple holes). In every step we request this hole, and once the hole disappears, the split action re-introduces a hole back near the middle of the road.[5]

Now let us analyze the costs. If the sequence contains m simple steps and s split steps, then $cost(ALG) = \Omega(m + s \cdot N)$. For OPT, we define a family of strategies B_i for $L < i < N+1-L$, to bound its cost. We define B_i to store all the edges of all the bricks, all the edges connecting them, and the edge that connects u to the first brick, except for

[5] This idea is similar to the way one can prove a deterministic lower bound for k-server [15], by always requesting a server-less location. The analogy stops here, since in our case sometimes there is no hole.

the edges that connect brick i to its neighbours, paying an initial $O(N \cdot k^2)$ cost. B_i colors all the bricks from 1 to i in one color, and all the bricks from $i+1$ to N in another color. Whenever a simple step happens in $(i-1, i)$ or in $(i, i+1)$, B_i simply recolors brick i to have the same color of the neighbour it connects to, and also inserts the connecting edge. Simple steps at other locations do not affect B_i. When a split step happens, B_i pays exactly 2: It inserts the edge that connects u to brick $N+1-L$ instead of the edge $(N-L, N+1-L)$. When the split step ends, it undoes the change, re-inserting $(N-L, N+1-L)$ instead of the edge of u. Since $L < i < N+1-L$, B_i does not have to recolor any other edge.

Thus, if we denote by m_i the number of simple steps that insert the edge $(i, i+1)$, then $cost(OPT) \leq cost(B_i) = O(m_i + m_{i-1} + s + N \cdot k^2)$. Now: $\frac{N}{3} \cdot cost(OPT) \leq (N - 2L) \cdot cost(OPT) \leq \sum_{i=L+1}^{N-L} cost(B_i) = O(m + N \cdot s + N^2 k^2)$. Note that $N^2 k^2 = O(n^2)$. Thus by extending the sequence such that $m + s = \Omega(n^2)$, we get: $\frac{N}{3} \cdot cost(OPT) = O(m + N \cdot s) = O(cost(ALG))$. Therefore, $\frac{cost(ALG)}{cost(OPT)} = \Omega(N)$. Recall that $N = \Theta(\frac{n}{k})$, and the claim follows. ◀

When proving the deterministic lower bound (Theorem 8) we heavily relied on determinism to know where to find neighbouring bricks of different colors. In the randomized case, we may not know where colors mismatch. Instead, we use a different and weaker construction for the randomized case. Relying on Yao's principle [32] (see also [15]), we define a distribution over sequences that is hard for any algorithm.

The following Lemma 15 is a weaker but also simpler version of Theorem 9 (proven in Appendix 6.1). Proving this lemma demonstrates our main technique.

▶ **Lemma 15.** *Any* Caching in Matchings algorithm with $2 \leq k < n$ matchings is $\Omega(\log \frac{n}{k})$ competitive.

Proof. We prove the lower bound for Problem 3. Then the theorem follows by Lemma 11. For convenience, since any action of fetching or recoloring can be lazily postponed to the next request for adding an edge to G, we assume that the algorithm does nothing else when an edge is removed.

Given a fixed k, we divide the nodes to r-roads of length d_0. We aim to have 2^h r-roads in total, for h as large as possible. We can bound h from below by noting that a brick requires at most $4k$ nodes, a road of length d_0 requires at most $4k \cdot d_0$ nodes (d_0 bricks), and an r-road requires at most $4k \cdot d_0 \cdot r + 1$ nodes (r roads and a hub). So we get that $h \geq \lfloor \log \frac{n}{4k \cdot d_0 \cdot r + 1} \rfloor$. Simplified, we get $h = \Omega(\log \frac{n}{k \cdot d_0 \cdot r})$. Eventually we will choose $r = 2$ and $d_0 = 1$ to get $h = \Omega(\log \frac{n}{k})$.

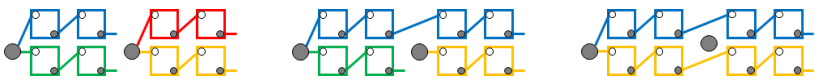
We construct the distribution over request sequences in phases. A phase begins with 2^h r-roads. Then, during each phase we have h rounds, numbered from $i = 1$ to $i = h$. In each round we pair the r-roads, and merge each pair into a single twice-longer r-road. Note that in round i there are 2^{h-i} pairs of r-roads whose length is $d_i = d_0 \cdot 2^{i-1}$. Once we get to a final single r-road of length d_h, we delete the edges that were used to connect the roads of length d_0, and insert back hub edges to re-form the initial r-roads of length d_0. Then a new phase begins.

We explain later exactly how a pair of r-roads of length d_i are merged, for now just assume that OPT pays $O(r)$ and that any algorithm pays $\Omega(r \cdot d_i)$ in expectation for such merge, and let us analyze the competitive ratio. When a phase begins, OPT can choose a consistent color for each road of the r-roads such that no further recoloring is necessary during this phase, at a cost of $O(2^h \cdot r \cdot d_0)$ by recoloring $O(1)$ edges in each brick (according to Lemma 14) and each edge that connects to a brick to the desired color. Then, throughout the rounds it pays additional $\sum_{i=1}^{h} 2^{h-i} \cdot O(r) = O(2^h \cdot r)$. Finally, when a phase ends it pays $O(2^h \cdot r)$

more to re-attach hubs when re-creating the initial r-roads of length d_0, and $O(2^h \cdot r \cdot d_0)$ more to undo any recoloring made when the phase begun.[6] Overall, OPT pays per phase $O(2^h \cdot r \cdot d_0)$. In contrast, ALG pays at least $\sum_{i=1}^{h} 2^{h-i} \cdot \Omega(r \cdot 2^{i-1} \cdot d_0) = \Omega(h \cdot 2^h \cdot r \cdot d_0)$.

Let t be the number of phases. The one-time initialization cost is $c_0 = \Theta(k^2 \cdot (2^h \cdot r \cdot d_0))$ for inserting $\Theta(k^2)$ edges per brick. Therefore, the competitive ratio that we get is $\frac{\mathbb{E}[cost(ALG)]}{cost(OPT)} \geq \frac{c_0 + t \cdot \Omega(h \cdot 2^h \cdot r \cdot d_0)}{c_0 + t \cdot O(2^h \cdot r \cdot d_0)}$. For $t = \Omega(k^2)$ we can neglect c_0 and get that $\frac{\mathbb{E}[cost(ALG)]}{cost(OPT)} = \Omega(h)$. Recall that $h = \Omega(\log \frac{n}{k \cdot r \cdot d_0})$, so we choose $r = 2$ and $d_0 = 1$ to maximize the competitive ratio and get $\Omega(\log \frac{n}{k})$, as claimed.

It remains to explain how we merge a pair of r-roads of length d, X and Y, see Figure 5 for a visual example for $r = 2$ and $k = 4$. We have r iterations, where iteration i cuts the ith road of Y away from the hub, and extends a uniformly random not yet extended road of X. OPT pays at most r for the newly introduced r edges because it can refrain from recoloring roads. As for ALG, observe that it must recolor a road if the colors of the extended road and its extension do not match. For the first two roads that we combine (one from each r-road), there is a probability of at most $\frac{1}{r}$ for the colors to agree (the probability is maximized if X and Y use the same colors for their roads, out of the k possible colors). More generally, in the ith iteration there is a probability of at most $\frac{1}{r+1-i}$ for the colors to agree, maximized if the remaining roads of Y share their colors with the not yet extended roads of X. Thus ALG recolors in expectation at least $\sum_{i=1}^{r} (1 - \frac{1}{r+1-i}) = r - H_r$ roads throughout the process, where H_r is the rth harmonic number. For $r \geq 2$, this amounts to a cost of $\Omega(r \cdot d)$ recolorings. ◀



(a) Initial state. **(b)** One road extended. **(c)** Merge complete.

Figure 5 Visualization of merging a pair of 2-roads of length $d = 2$ to a single twice longer 2-road. In this example $k \geq 4$. Initially the 2-roads are disjoint. Then, we cut a road from the right 2-road and extend another road in the left 2-road. If necessary, the algorithm recolors one or more of the roads. Then we do the same for the remaining road. In the end, the hub of the cut-down 2-road is a node of degree 0.

3.3 Upper Bounds with Resource Augmentation

In this section we study upper bounds with resource augmentation. That is, we assume that the optimum still has k matchings, but our algorithm has more. Interestingly, it dramatically improves the competitive ratios, in both deterministic and randomized settings.

Recall our general approach and notations: our caching in matchings algorithm A_m implements a component of an edge-coloring algorithm, over a component of a connection caching algorithm which we denote by A_c. By Remark 6, we can divide our attention between connection caching and dynamic edge-coloring. Concretely, given $h \geq 1$ extra matchings, we maintain connection caching with $k' \equiv k + h_1$ connections per node, and maintain edge-coloring of a graph of maximum degree k', with $k' + h_2$ colors, such that $h_1 + h_2 = h$. We choose $h_2 \geq 1$ because a single extra color yields a dramatic improvement. We use either $h_2 = \lceil \frac{h}{2} \rceil$ or $h_2 = h$, Corollary 25 summarizes our choices.

[6] It is necessary to revert to the exact initial coloring before the next phase because Lemma 14 for recoloring bricks requires a very specific coloring scheme.

We begin by listing three important facts about caching and connection caching algorithms, which we use as A_c. Concretely, Lemma 16 details a deterministic algorithm for Connection Caching, and Lemma 17 together with Theorem 18 yield a randomized algorithm for Connection Caching in Corollary 19.

▶ **Lemma 16** (Corollary 8 of [20]). There is a deterministic Connection Caching algorithm with cache of size r, that is $\frac{2r}{r-k+1}$-competitive against the optimum with cache of size $k \leq r$.

▶ **Lemma 17** (Section 2.2 of [33]). Let r be the cache size of the randomized caching algorithm *MARK* [24], and let k be the cache size of the optimum. Then *MARK* is: $O(\log r)$-competitive if $r = k$; $O(\log \frac{r}{r-k})$-competitive if $\frac{e-1}{e}r < k < r$; and, 2-competitive if $k \leq \frac{e-1}{e}r$.

▶ **Theorem 18** (Theorem 7 of [20]). Let A be a $c(r,k)$-competitive caching algorithm, with additive term δ, where r and k are the cache sizes of the algorithm and the optimum, respectively. Then there is a $2 \cdot c(r,k)$-competitive algorithm for Connection Caching, with additive term $|V| \cdot \delta$ where $|V|$ is the number of nodes in the graph.

The explicit reduction and proof of Theorem 18 can be found in [30].

▶ **Corollary 19.** There exists a randomized connection caching algorithm, with cache size r compared to k of the optimum, that is $O(\log r)$-competitive if $r = k$; $O(\log \frac{r}{r-k})$-competitive if $\frac{e-1}{e}r < k < r$; and, 4-competitive if $k \leq \frac{e-1}{e}r$.

Next, we list several results for dynamic edge coloring.

▶ **Lemma 20** (Greedy, Folklore). Let G be a dynamic graph with the guarantee that its maximum degree is at most k at any time. Then we can maintain for it a $2k-1$ edge-coloring without needing to recolor any edge.

Proof. When (u,v) is inserted, both u and v are of degree at most $k-1$, thus each has at least k free colors, and they must have at least one common free color that we can use. ◀

▶ **Lemma 21.** Let G be a dynamic *bipartite* graph with the guarantee that its maximum degree is at most k at any time, and let $h \geq 1$. We can maintain a deterministic $(k+h)$-edge-coloring of G in amortized $O(\sqrt{nk/h})$ recolorings per insertion.

The proof of Lemma 21 is deferred to Appendix 6.2. It is like the proof of Theorem 7 but we only have few edges from each extra color, such that we can recolor bi-chromatic paths quickly. Periodically, we recolor the graph using only k colors and amortize this work over several operations.

The following results are particularly useful when k is small. The high probability in Theorem 23 below is for bounding the running time, not for getting a proper coloring.

▶ **Theorem 22.** Let $G' \equiv G \cup \{e\}$ be a graph with maximum degree k, such that G is $(k+1)$-edge-colored, and e is uncolored. Then there is a $(k+1)$-edge-coloring of G' which recolors only N edges in G where $N = O(k^7 \log n)$ by [19] (Theorem 3), or $N = (k+1)^6 \log^2 n$ by [10] (Corollary 6.4).

▶ **Theorem 23** (Theorem 6 of [19]). Let G be a dynamic graph such that its maximum degree never exceeds k. Then there exists a fully-dynamic algorithm that maintains a $\lceil (1+\epsilon)k \rceil$-edge-coloring with $O(\epsilon^{-6} \log^6 k \log^9 n)$ worst-case update time with high probability.

The paper [13] gives an efficient randomized edge-coloring for sufficiently large k.

▶ **Theorem 24** ([13]). Let G be a dynamic graph such that its maximum degree never exceeds k. If $k \geq (100\alpha^4 \log n)^{30\alpha \log \alpha}$, there is a fully-dynamic algorithm maintaining a $(1 + O(\frac{1}{\alpha}))k$-edge-coloring with $O(\alpha^4)$ edge recolorings in expectation per update.

Finally, we combine the various results of connection caching and edge coloring to derive the following competitive algorithms.

▶ **Corollary 25.** Given resource augmentation of extra $1 \leq h = O(k)$ matchings, that is $k + h$ for the algorithm versus k for OPT, the following competitive algorithms for caching in matchings exist:

1. $O(n^{1/2}(k/h)^{3/2})$ deterministic and $O(n^{1/2}(k/h)^{1/2} \log \frac{2k+h}{h})$ randomized competitive algorithms in bipartite graphs.
2. $O\left(\frac{k^6 \log n}{h} \min(k, \log n)\right)$ deterministic and $O\left(\left(\frac{k \log k}{h}\right)^6 \log \frac{2k+h}{h} \log^9 n\right)$ randomized competitive algorithms in general graphs. The deterministic algorithm is inefficient.
3. If $h = k - 1$ we can remove the dependence on n, yielding k deterministic and $O(\log k)$ randomized competitive algorithms in general graphs.
4. $O(\alpha^4 \log k)$ randomized competitive algorithm, where $\alpha = O(\frac{k}{h})$ and provided that $k \geq (100\alpha^4 \log n)^{30\alpha \log \alpha}$.

Proof. We use the augmentation to have extra h_2 colors for the coloring component, where $h_2 = h$ for Part-(3), and $h_2 = \lceil \frac{h}{2} \rceil$ for the rest. Part-(1) is by Lemma 21 with Lemma 16 and Corollary 19. Part-(2) is by Theorem 22 with Lemma 16, and by Theorem 23 with Corollary 19. The deterministic algorithm is inefficient because Theorem 22 only proves the existence of the stated recoloring by probabilistic arguments. Regarding the randomized part, Theorem 23 guarantees recoloring that is cheap with high probability. We can choose the constants such that the failure probability is $\leq \frac{1}{n^2}$, and fully recolor the graph if the cheap method fails. The expected number of recolorings is negligibly affected, and proper edge coloring is guaranteed. Notice that we set $\epsilon = \frac{h}{k}$. Part-(3) is by Lemma 20. Part-(4) is by Theorem 24 and Corollary 19. ◀

▶ Remark 26. Choosing $h_2 = \lceil \frac{h}{2} \rceil$ in Corollary 25 divides the augmentation into equal halves and is good enough if we do not optimize the constants, since essentially both caching and coloring components "benefit" from $\Theta(h)$ augmentation.

In Part-(4) it is simplest to think of α as a constant, in which case the requirement $k \geq f(n, \alpha)$ for the function f given in the statement, requires $k = \Omega(poly(\log n))$. However, α can also depend on k, as long as there are values of k that satisfy $k \geq f(n, \alpha(k))$. Observe that because $(\log n)^{\log n / \log \log n} = n$, for $k \leq n$ it must be that $\alpha = O(\frac{\log n}{\log \log n})$ or else the inequality cannot be satisfied. Then in particular $\alpha = o(\log n)$, and $k^{1/\tilde{\Theta}(\alpha)} \geq \log n$ (for the appropriate constants) implies $k \geq f(n, \alpha(k))$. Crudely simplified for the sake of a clean example, if $k^{\frac{1}{\alpha}} \geq \log n$ we could choose $\alpha = \frac{\log k}{2 \log \log k}$, and still have a non-empty range of applicable k values.

Finally, we improve the competitive ratio further with a larger resource augmentation.

▶ **Theorem 27.** Given $k+h$ matchings to the algorithm compared to only k matchings to the optimum, for $h \geq k - 1$, there is a deterministic algorithm that is $2(1 + \frac{k-1}{\lfloor \frac{h+3-k}{2} \rfloor})$-competitive for Caching in Matchings. In particular, with $h = (1 + \alpha)k$ extra matchings we get a competitive ratio of $O(1 + \frac{1}{\alpha})$.

The proof is in Appendix 6.2. It follows from Lemma 20 and Lemma 16.

▶ **Corollary 28.** Consider the Caching in Matchings problem where the optimum is given k matchings. There is a 6-competitive algorithm that uses $3k - 3$ matchings ($h = 2k - 3$).

A note on the running times. This work focuses on competitive analysis and therefore we do not attempt to optimize polynomial running time. We note that the algorithms in Corollary 25(1),(3) take $O(n)$ time: maintaining connection caching takes $O(k)$ time, and the coloring algorithms in Lemma 20 and Lemma 21 naively take time of $O(\Delta)$ to find a color and $O(\rho)$ to recolor a path of length ρ. The randomized algorithms of Corollary 25(2),(4) also run in polynomial time per update.

4 Related Work

Caching Problems. Caching problems have been studied in many variants and cost models. *Connection caching* is the caching variant closest to our problem. We presented it in a centralized setting, Cohen et al. [20] introduced it in a distributed setting. Albers [3] studies generalized connection caching. Bienkowski et al. [14] study connection caching in a cost model that is similar to that of caching with rejections [23]. Another related variant is *restricted caching* [16, 25] where not every page can be put into every cache slot. Buchbinder et al. [16] study the case where each page p has a subset of cache slots in which it can be cached. In our problem we also have a restriction of similar flavour, implied by the separation into matchings. We note that the cost model in [16, 25] only counts cache-misses, while we also pay for rearranging the cache.

Coloring Problems. As mentioned in Section 3, an efficient dynamic edge coloring that uses a small number of colors can be useful for competitive analysis. Subsection 3.3 covers results which we use for our advantage. The coloring literature studies the tradeoff between the number of colors, amount of recoloring (sometimes called *recourse*), and the running time of the algorithms. Some algorithms require a bound Δ on the maximum degree of the dynamic graph, while others are adaptive with respect to the maximum degree in their running time or recoloring. Literature on vertex coloring also exists, but reducing edge coloring to vertex coloring by coloring the line-graph is too wasteful in the number of colors, whether this number is parameterized by Δ, or by the arboricity of the graph as in [27]. Works on maintaining dynamically an *implicit coloring* [18, 27] cannot apply to our case because the matchings form an explicit coloring. Azar et al. [5] study dynamic vertex coloring in the context of competitive analysis.

El-Hayek et al. [22] are motivated by the same architecture as us. They solve a problem of dynamically maximizing the size of a k-edge-colorable subgraph of a dynamic graph.

Linear Programming and Convex Body Chasing in L_1. The aforementioned caching problems, like many other combinatorial problems, can be formulated as a linear program [17]. This line of research led to the development of competitive algorithms for weighted and generalized caching [1, 2, 6, 7]. A recent result of Bhattacharya et al. [11] uses linear programming with packing and covering constraints to formulate and frame the problem as convex body-chasing in L_1. They give a fractional algorithm that requires a slight resource augmentation, along with some rounding schemes to get randomized algorithms for specific problems. Our problem can be thought of as another special case of the problem considered by [11], see the appendix in the extended version [30] for this formulation and further details.

5 Conclusions and Future Work

In this paper we studied the online Caching in Matchings problem, in which we receive requests for edges in a graph and need to maintain a cache of the edges which is a union of k matchings. The problem abstracts some hardware architecture in which a datacenter is enhanced with reconfigurable optical links. Interestingly, we proved that the Caching in Matchings problem is inherently harder than the similar-looking Connection Caching problem and other caching problems. Specifically, its competitive ratio depends not only on the number of matchings k ("cache size") but also on the number of nodes in the graph. Our randomized lower bound rules out an $O(\log n)$ competitive algorithm, and the best competitive ratio we can hope for is $O(poly(\log n))$. Our lower bound for deterministic algorithms is linear in n.

We derived our algorithms by running a coloring algorithm that maintains a coloring of the cache of a connection caching algorithm. This approach is simple to describe and analyze, but inherently multiplies the competitive ratios of the two algorithms. It is natural to ask whether a "direct" algorithm for Caching in Matchings exists, and if so does it improve the competitive ratio?

Regarding resource augmentation of $h \geq 1$ extra matchings, we see that there are two interesting "discontinuities". First, immediately for $h = 1$ the competitive ratio drops to $poly(k, \log n)$, in particular "breaking" the deterministic lower bound. Second, there seems to be a point in which the competitive ratio becomes independent of n. It clearly happens for $h = k - 1$, and even sooner if k is large enough (revisit Corollary 25). These "discontinuities" beg the following two questions. First, is there an $1 \leq h < k - 1$ and an algorithm that uses h extra matchings with a competitive ratio of $O(poly(\log n))$ for any $2 \leq k < n$? Differently phrased, can we achieve a competitive ratio that is $poly(\log k, \log n)$ instead of $poly(k, \log n)$? Second, is it possible to remove the dependence on n using less than $h = k-1$ extra matchings for any k, and if so how small can h be?

A natural generalization would be to study upper bounds for Caching in Matchings in general graphs. When $k = 1$ optimality is still trivial, and when $k = n$, by Vizing's theorem, we are also optimal since we can edge-color the full n-clique with n colors. In fact, for $n \geq 2$, $k = n - 1$ colors are sufficient if and only if n is even. In the non-trivial regime $2 \leq k < n$, there exists a naive deterministic $O(n^2k^2)$ competitive algorithm (the extended version [30] contains exlicit proofs). Resource augmentation of an extra matching ($k + 1$ colors) dramatically reduces the competitive ratio to $O(nk)$ (deterministic) and $O(n \log k)$ (randomized) by allowing us to update the coloring of the graph when a new edge is inserted according to a single step of the Misra-Gries algorithm [29],[7] or to $O(poly(k, \log n))$ as in Corollary 25(2). It is an interesting question whether the problem without augmentation is indeed that much harder in general graphs. General graphs also provide additional difficulties, such as the fact that finding minimal edge coloring for $k \geq 3$ is generally NP-complete [28].

[7] The Misra-Gries algorithm edge-colors an uncolored graph with m edges and n nodes in m iterations. In each iteration it colors an edge and fixes the colors of previously colored edges, by recoloring $O(n)$ of them in $O(n)$ time. In our case, the graph is always fully colored up to the newly requested edge, so we get the competitive ratio of a connection caching algorithm, multiplied by $O(n)$.

6 Appendix: Deferred Proofs and Discussions

6.1 Caching in Matchings Lower Bounds (Proofs)

▶ **Lemma 11.** A lower bound of C on the competitive ratio of an online algorithm for Problem 3 implies a lower bound of C on the competitive ratio of an online algorithm for Caching in Matchings.

Proof. Let A_1 be a c-competitive algorithm for Caching in Matchings (Problem 1), with some additive term d. We show how to derive from it an algorithm A_3 that is c-competitive for Problem 3, which proves the claim. We will also use corresponding subscripts OPT_1 and OPT_3 for the optimum of each problem (with respect to a given sequence).

Given a sequence τ, Algorithm A_3 takes its decisions while processing τ by simulating A_1 on a sequence σ which is constructed as follows. We traverse τ in order, and whenever an edge is inserted, we add to σ a batch of requests which is a concatenation of $r = nk$ identical subsequences, each subsequence contains all the edges currently in G (in some arbitrary order). When an edge is deleted, we do nothing.

We now specify A_3 such that $cost(A_3(\tau))) \leq cost(A_1(\sigma))$ by having A_3 maintain its state such that it "jumps" between "check-points" in the state of A_1.

A_3 works as follows. When an edge is inserted by τ, A_3 feeds σ to A_1 until one of two things happens: either (1) the state of A_1 provides a proper coloring of G, or (2) it reaches the end of the batch that corresponds to the current edge inserted by τ. In case (1), A_3 changes its state by replaying the changes that A_1 made. Then by definition of this case, it ends up with a proper coloring of G. In case (2), we know that during the whole batch A_1 did not have a proper coloring of G, which means that in each of the r rounds it paid at least 1 for a missing edge, for a total of at least r. Rather than replaying the changes and ending up with an illegal state for A_3, we have a budget of r to completely change its state. A_3 uses half of the budget to completely empty its state and fetch all of G with some proper coloring (such coloring exists by definition of the problem). Indeed it has the budget, $|G| \leq |M| \leq \frac{nk}{2}$. The other half of its budget is used to copy the state from which A_1 continues to process σ, by flushing everything, and fetching into the cache the state of A_1. This ensures that the state of A_3 is once again identical to A_1. We showed $cost(A_3(\tau))) \leq cost(A_1(\sigma))$. It holds in the deterministic case, and also for the randomized case for every fixing of the random coins.

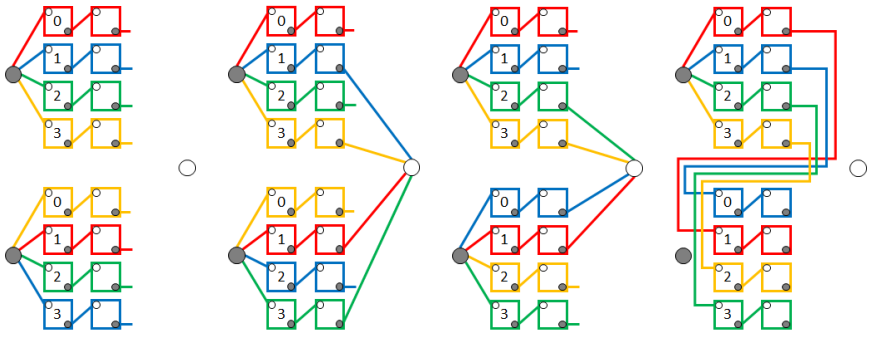
Now observe that $cost(OPT_1(\sigma)) \leq cost(OPT_3(\tau))$. Indeed, OPT_1 may simulate the behavior of OPT_3 by making changes to its own state at the beginning of each batch in σ. In conclusion, we get that $cost(A_3(\tau))) \leq cost(A_1(\sigma)) \leq c \cdot cost(OPT_1(\sigma)) + d \leq$

$c \cdot cost(OPT_3(\tau)) + d$ in the deterministic case, or similarly $\mathbb{E}[cost(A_3(\tau))] \leq \mathbb{E}[cost(A_1(\sigma))] \leq c \cdot cost(OPT_1(\sigma)) + d \leq c \cdot cost(OPT_3(\tau)) + d$ in the randomized case (recall that c and d were defined at the beginning of the proof). ◀

▶ **Theorem 9.** *Any* Caching in Matchings algorithm is $\Omega(\log \frac{n}{k^2 \log k} \cdot \log k)$ competitive.

Proof. This proof uses a similar high-level construction as the one used to prove Lemma 15, and the only difference is in the way we merge pairs of r-roads. Here we set $r = k$. Assume for now that when merging two k-roads of length d, OPT pays $O(k \log k)$ and any algorithm pays $\Omega(k \log k \cdot d)$ in expectation.

With this in mind, revisit the competitive analysis: when a phase begins OPT pays $O(2^h \cdot k \cdot d_0)$ to recolor bricks to their desired color, it then pays $\sum_{i=1}^{h} 2^{h-i} \cdot O(k \log k) = O(2^h \cdot k \log k)$ in the merging rounds, and finally it pays $O(2^h \cdot k \cdot d_0)$ to restore the original k-roads for the next phase. Overall, its cost is $O(2^h \cdot k \cdot (d_0 + \log k))$. In comparison, ALG pays for recoloring, in expectation, at least $\sum_{i=1}^{h} 2^{h-i} \cdot \Omega(k \log k \cdot 2^{i-1} \cdot d_0) = \Omega(h \cdot 2^h \cdot k \log k \cdot d_0)$. Assuming a sequence with $t = \Omega(k^2)$ phases, we get that the competitive ratio is $\frac{\mathbb{E}[cost(ALG)]}{cost(OPT)} = \Omega(\frac{h \cdot 2^h \cdot k \log k \cdot d_0}{2^h \cdot k \cdot (d_0 + \log k)}) = \Omega(\frac{h \cdot \log k \cdot d_0}{d_0 + \log k})$. To maximize the expression we balance and choose $d_0 = \lceil \log k \rceil$, getting $\Omega(h \log k)$. We determine h as before, except that the complicated merging technique requires a reusable extra node, so we have that $h \geq \lfloor \log \frac{n-1}{4k^2 \cdot d_0 + 1} \rfloor$. Simplified, and with $d_0 = \lceil \log k \rceil$, we get $h = \Omega(\log \frac{n}{k^2 \log k})$, therefore the competitive ratio is $\Omega(\log \frac{n}{k^2 \log k} \cdot \log k)$.



(a) Initial state. **(b)** Step 1. **(c)** Step 2. **(d)** Final merge.

Figure 6 Visualization of merging a pair of k-roads, for $k = 4$, of length $d = 2$ to a single twice longer k-road, by "negative information". (a) The roads are numbered from 0 to 3, with their number written inside their first brick. There are $\log k = 2$ steps. (b) In the first step we temporarily connect roads $\{1, 3\}$ (least significant bit 1) of the top k-road with either roads $\{0, 2\}$ or $\{1, 3\}$ of the bottom k-road, to a shared hub (the white node). In this example we connect $\{1, 3\}$, and as a results roads 2 and 3 of the bottom k-road were recolored. (c) In the second step we temporarily connect roads $\{2, 3\}$ (second bit is 1) of the top k-road with either roads $\{0, 1\}$ or $\{2, 3\}$ of the bottom k-road to a shared hub. In this example we connect $\{0, 1\}$, and as a result roads 0 and 2 of the bottom k-road were recolored. (d) Finally there is a round of "positive information" in which we simply extend each road on the top color-consistently with a road on the bottom. The consistency depends on the choices of the previous steps, and in this example it matches road x on the top with road $x \oplus 1$ on the bottom. The recoloring in this example is such that in the final extension no road is recolored.

Now we explain and analyze the merging of two k-roads, denote them by X and Y. See Figure 6 for a visual example with $k = 4$. For simplicity, let us start with k being an integer power of 2, say $k = 2^\ell$. We start with ℓ steps of "negative information" in which we reveal

roads that are of *different* colors, and do so by connecting the free end of these roads to a new shared hub, denote it by v. Concretely, number the roads of X from 0 to $k-1=2^\ell-1$ and denote by $X_{i,b}$ the roads of X whose ith bit is b. We define similarly the subsets of roads for Y. In round i, we connect to v the roads $X_{i,1}$ and Y_{i,b_i} where b_i is chosen uniformly at random between 0 and 1. Note that $|X_{i,1}|=|Y_{i,b_i}|=\frac{k}{2}$ so the degree of v is k (legal). When the round ends, we delete the edges of v. Finally, in the $\ell+1$ step we produce the longer k-road with "positive information" by cutting the roads of Y from their hub and extending the roads of X, according to the unique way which does not contradict the previous ℓ steps. This way exists: road $y\in Y$ extends the road x whose binary representation is $x=y\oplus B$ where the bits of B are b_i and $\oplus$ is the bitwise exclusive-or operation.

Let us analyze the costs of OPT and ALG. Since OPT knows the correct colors in advance, it can pay at most 1 per edge that is inserted. We insert k edges per step (even if most of them are later deleted), in a total of $\ell+1$ steps. This totals to $O(k\log k)$. We argue that ALG recolors in expectation $\Omega(k)$ roads per each of the first ℓ steps. To simplify the analysis, assume that ALG recolors after learning b_i rather than being introduced online each edge of v one by one (which can only hurt ALG). Then indeed every road in $X_{i,1}$ has probability $\frac{1}{2}$ to be in a conflict of color with a road of Y_{i,b_i}, so by the linearity of expectation, we get at least $\frac{k}{2}=\Omega(k)$ road recolorings (if ALG is "reasonable", it recolors $O(k)$ roads per step, so allowing it to be semi-offline did not lose more than a constant factor). Observe that our bound for round i is not affected by previous rounds. So we conclude that ALG pays $\Omega(\ell\cdot k\cdot d)=\Omega(k\log k\cdot d)$ for recoloring in expectation.

The case of k not being a power of 2 is similar. Each road is still assigned a number, and we regard its binary representation with $\lceil\log k\rceil$ bits, but only make $\ell=\lfloor\log k\rfloor$ rounds. Note that now $X_{i,1}$ is not necessarily of size $\frac{k}{2}$, but rather might be smaller. The bias is always in favor of 0 because of how counting works, and it is such that $|X_{i,1}|\geq\frac{k-2^i}{2}$ ($i=0$ is the least significant bit). So we can still choose Y_{i,b_i} with b_i uniformly random, there is no problem to connect all the roads of $X_{i,1}$ and Y_{i,b_i} to their shared hub. Also, each road in $X_{i,1}$ still has a color conflict with probability $\frac{1}{2}$. The only thing that changes is that the expectation of road recolorings is not $\frac{k}{2}$ per round, but rather $|X_{i,1}|$ in round i. This yields at least $\sum_{i=0}^{\ell-1}|X_{i,1}|\geq\ell\cdot\frac{k}{2}-\frac{1}{2}\sum_{i=0}^{\ell-1}2^i>\ell\cdot\frac{k}{2}-\frac{2^\ell}{2}>\frac{(\ell-1)k}{2}$ road recolorings in expectation for ALG, which is still $\Omega(k\log k)$ in total. The analysis of OPT is unchanged, and its total cost is $O(k\log k)$ in total per merging a pair of k-roads (of any length). ◀

▶ Remark 29. A few notes on the proofs of Lemma 15 and Theorem 9:

1. The random choices of the adversary can be boiled-down to the random order of extending roads (in Lemma 15) and the bits b_i (in Theorem 9). The 2-roads and k-roads themselves are chosen once, and even the pairings of each merging round may be fixed.
2. For clarity, we presented it as if we need 2^h different hubs, one per r-road. In fact, we only need $h+1$ hubs if we reuse them: h of them to maintain an r-road for each unique length, and another one for the length in which we currently merge a pair of r-roads. This saving is negligible compared to the number of nodes used to compose the roads.

6.2 Caching in Matchings With Resource Augmentation (Proofs)

In this section we restate and prove the claims from Section 3.1 that we did not prove there.

▶ **Lemma 21.** Let G be a dynamic *bipartite* graph with the guarantee that its maximum degree is at most k at any time, and let $h\geq 1$. We can maintain a deterministic $(k+h)$-edge-coloring of G in amortized $O(\sqrt{nk/h})$ recolorings per insertion.

Proof. Recall the proof of Theorem 7, we will use the same idea of a color-swap on a bi-colored path. The key difference is how we use the $h \geq 1$ extra colors.

First consider $h = 1$ and denote the extra color as yellow. We allow at most y yellow edges in the graph, and if we need more, we recolor the whole graph from scratch without using yellow. Such a recoloring is possible because the graph is bipartite and every node is of degree at most k. When coloring a newly inserted edge (u, v), both u and v have at least one free color. We have three cases:

1. If u and v share a free color, including yellow: Then use this color.
2. If u does not have a yellow edge and v does (the other case is symmetric): Let c be a free color of v, and apply a color-swap of c and yellow with respect to v. This makes yellow a free color of v. Note that u is unaffected by the color-swap, because the graph is bipartite (affecting u implies that the path of the swap closes an odd cycle with the edge (u, v)). Now color (u, v) in yellow.
3. If both u and v have a yellow edge: Let c be a free color of u. Apply a color-swap of c and yellow with respect to u to make yellow a free color of u. Now apply the previous case.

We apply up to two color-swaps, each of length $O(y)$ because there are at most y yellow edges in the whole graph. Recall that we might have a global recoloring once we reach y yellow edges. We charge these recolorings to the yellow edges. Formally, we define a potential for the cache which equals $\frac{nk}{y} \cdot i$ when there are i yellow edges. Thus when we accumulate y yellow edges, the potential can pay for the global recoloring. Each insertion of an edge causes $O(y)$ recoloring and increases the potential by at most $\frac{nk}{y}$, due to possibly inserting a yellow edge (our color-swaps never increase the number of yellow edges). We conclude that the amortized cost is $O(y + \frac{nk}{y})$ per insertion. Balancing with $y = \sqrt{nk}$ gives $O(\sqrt{nk})$.

We generalize the previous logic for $h \geq 1$ by allowing each extra color to have at most y edges, and when it fills up we proceed to use the next extra color. Only when all h colors have y edges we invoke a full recoloring. The potential in this case is $\frac{nk}{hy}$ per edge, and the amortized cost is therefore $O(y + \frac{nk}{hy})$. Balancing with $y = \sqrt{nk/h}$ gives $O(\sqrt{nk/h})$. ◀

▶ **Theorem 27.** Given $k+h$ matchings to the algorithm compared to only k matchings to the optimum, for $h \geq k - 1$, there is a deterministic algorithm that is $2(1 + \frac{k-1}{\lfloor \frac{h+3-k}{2} \rfloor})$-competitive for Caching in Matchings. In particular, with $h = (1 + \alpha)k$ extra matchings we get a competitive ratio of $O(1 + \frac{1}{\alpha})$.

Proof. Let σ be a sequence of requests. Denote an algorithm A with cache parameter x as A^x, and use subscripts m for Caching in Matchings and c for Connection Caching. We have $cost(A_m^{2r-1}(\sigma)) = cost(A_c^r(\sigma))$ for any integer $r \geq 1$ by considering $r-1$ matchings as resource augmentation, such that we require no recoloring (by Lemma 20). Since this reduction halves the cache parameter, and our algorithm initially has cache of size $k + h$, we use $r = \lfloor \frac{k+h+1}{2} \rfloor$. If $k + h = 2r$, we do not use one of the colors, on purpose, to ensure using exactly $2r - 1$ colors. Taking A_c to be the algorithm that satisfies Lemma 16, $cost(A_c^r(\sigma)) \leq \frac{2r}{r-k+1} \cdot cost(OPT_c^k(\sigma)) + d$ for some fixed term d. By Remark 4, $cost(OPT_c^k(\sigma)) \leq cost(OPT_m^k(\sigma))$. Plugging everything together we get that $cost(A_m^{2r-1}(\sigma)) \leq \frac{2r}{r-k+1} \cdot cost(OPT_m^k(\sigma)) + d$, hence A_m^{2r-1} is $\frac{2r}{r-k+1} = 2(1 + \frac{k-1}{r-k+1}) = 2(1 + \frac{k-1}{\lfloor \frac{h+3-k}{2} \rfloor})$ competitive for Caching in Matchings. ◀

Streaming Edge Coloring with Asymptotically Optimal Colors

Mohammad Saneian

Soheil Behnezhad
Northeastern University, Boston, MA, USA

Abstract

Given a graph G, an *edge-coloring* is an assignment of colors to *edges* of G such that any two edges sharing an endpoint receive different colors. By Vizing's celebrated theorem, any graph of maximum degree Δ needs at least Δ and at most $(\Delta + 1)$ colors to be properly edge colored. In this paper, we study edge colorings in the *streaming* setting. The edges arrive one by one in an *arbitrary* order. The algorithm takes a single pass over the input and must output a solution using a much smaller space than the input size. Since the output of edge coloring is as large as its input, the assigned colors should also be reported in a streaming fashion.

The streaming edge coloring problem has been studied in a series of works over the past few years. The main challenge is that the algorithm cannot "remember" all the color assignments that it returns. To ensure the validity of the solution, existing algorithms use many more colors than Vizing's bound. Namely, in n-vertex graphs, the state-of-the-art algorithm with $\widetilde{O}(ns)$ space[1] requires $O(\Delta^2/s + \Delta)$ colors. Note, in particular, that for an asymptotically optimal $O(\Delta)$ coloring, this algorithm requires $\Omega(n\Delta)$ space which is as large as the input. Whether such a coloring can be achieved with sublinear space has been left open.

In this paper, we answer this question in the affirmative. We present a randomized algorithm that returns an asymptotically optimal $O(\Delta)$ edge coloring using $\widetilde{O}(n\sqrt{\Delta})$ space. More generally, our algorithm returns a proper $O(\Delta^{1.5}/s + \Delta)$ edge coloring with $\widetilde{O}(ns)$ space, improving prior algorithms for the whole range of s.

1 Introduction

Motivated by its applications in processing massive graphs, the *graph streaming model* has gained significant attention over the past two decades. This model assumes that the input graph is too large to be stored in memory and is presented to the algorithm in a sequence of edges. Many graph problems have been studied in this model, including maximum matching [7, 36, 5, 28, 6], graph connectivity [2, 13], vertex coloring [10, 12, 9, 19, 21, 8], edge coloring [17, 22, 4], cut and spectral sparsifiers [3, 37, 11, 24, 38], and graph clustering [15, 16, 26, 1] among many others (this is by no means a comprehensive list). In this paper, we continue the line of work on the *edge coloring* problem in the streaming model. The goal of edge coloring is to assign colors to edges of a graph such that no two adjacent edges share the same color.

[1] Here and throughout the paper, $\widetilde{O}(f) = O(f \cdot \operatorname{poly}\log n)$.

Since the output of edge coloring is as large as its input, a streaming algorithm cannot return it in memory. Instead, the goal is to also return the solution in a streaming fashion. Doing so, the main challenge is that the algorithm cannot "remember" all the reported edge colors, yet has to ensure that any two incident edges receive different colors.

Edge coloring is a fundamental problem in graph theory and has many practical applications in areas such as scheduling, communication networks, and VLSI design. By a classic result of Vizing, any graph of maximum degree Δ needs at least Δ and at most $(\Delta+1)$ colors to be properly edge colored.[2] While existing algorithms for finding a $(\Delta+1)$ edge coloring are rather complicated, a $(2\Delta-1)$ coloring can be found by a simple greedy algorithm that iterates over the edges and chooses an arbitrary available color for each. Unfortunately, even this simple greedy algorithm is hard to implement in the streaming setting. Recall that the algorithm cannot remember all the assigned edge colors in memory, hence it is unclear how to verify which color is available for the next edge that arrives.

Prior works. The streaming edge coloring problem was first studied by Behnezhad, Derakhshan, Hajiaghayi, Knittel, and Saleh [17] who gave a randomized algorithm for $O(\Delta^2)$ edge-coloring with $\widetilde{O}(n)$ space, where n is the number of vertices. In a follow up work, Charikar and Liu [22] showed that, more generally, for any parameter $s \geq 1$ there is a randomized streaming algorithm that $O(\Delta^2/s+\Delta)$ edge-colors the graph using $\widetilde{O}(ns)$ space. Later, Ansari, Saneian, and Zarrabi-Zadeh [4] obtained the same bound but using a simple and clean *deterministic* algorithm. Note that for an asymptotically optimal $O(\Delta)$ edge coloring, the algorithms above require $O(n\Delta)$ space. This, unfortunately, is *not* sublinear in the input size as any graph of maximum degree Δ has at most $O(n\Delta)$ edges. Put differently, for the case of $O(\Delta)$ coloring, no improvement over the trivial algorithm that stores the whole graph in memory and then colors it is known. This state of affairs leaves an important question open:

Does there exist a streaming algorithm with sublinear space for $O(\Delta)$ edge coloring?

Our contribution. In this paper, we answer the question above in the affiramtive. Our main result is the following algorithm:

▶ **Theorem 1.1.** *For any $s \geq 1$, there is a randomized streaming algorithm that with high probability reports a $O(\Delta^{1.5}/s+\Delta)$ edge-coloring under arbitrary edge arrivals using $\widetilde{O}(ns)$ space.*

Setting $s=\sqrt{\Delta}$, we obtain the following corollary, answering the question above:

▶ **Corollary 1.2.** *There is a randomized streaming algorithm that with high probability reports a $O(\Delta)$ edge-coloring under arbitrary edge arrivals using $\widetilde{O}(n\sqrt{\Delta})$ space.*

We show that the space-complexity can be further improved to $\widetilde{O}(n)$ under arbitrary *vertex* arrivals. Here instead of edges arriving in an arbitrary order, the vertices of the graph arrive one by one and when a vertex v arrives, all of its edges to the previous vertices are revealed.

[2] To see the lower bound, note that Δ colors are needed just to color the edges of a vertex with degree Δ.

▶ **Theorem 1.3.** *There is a randomized streaming algorithm that $O(\Delta)$ edge colors the graph under arbitrary vertex arrivals using $\widetilde{O}(n)$ space.*

1.1 Further Related Work

Streaming algorithms for edge coloring have also been studied under the extra assumption that the edges arrive in a random order. Behnezhad, Derakhshan, Hajiaghayi, Knittel, and Saleh [17] showed that there is a single pass $\widetilde{O}(n)$ space algorithm that obtains a 5.44Δ coloring. Charikar and Liu [22] later showed the number of colors can in fact be improved to $(1 + o(1))\Delta$ under random arrivals while keeping the memory $\widetilde{O}(n)$. Both of these algorithms rely heavily on the random-arrival assumption and do not have any implications for adversarial edge arrivals, which is the focus of this paper.

Online edge-coloring is another related problem. In this problem, the algorithm has no space constraints, but edges arrive one by one and each edge has to be colored upon arrival irrevocably. Note that the greedy algorithm can easily be implemented in the online setting; therefore much of the research has been focused on whether the greedy bound can be improved. For low-degree graphs, Bar-Noy, Motwani, and Naor [14] showed that the greedy algorithm is optimal for online edge coloring. However, there has been several improvements over the past few years for graphs of degree at least $\omega(\log n)$ starting from the work of Cohen, Peng, and Wajc [25]; see [25, 41, 20, 40] and the references therein. The best current bound for general edge arrivals is a beautiful $\frac{e}{e-1}\Delta$ coloring algorithm of Kulkarni, Liu, Sah, Sawhney, and Tarnawski [40]. Whether the number of colors can be improved to $(1 + o(1))\Delta$ for $\Delta = \omega(\log n)$ under arbitrary edge arrivals remains an important open problem.

Independent work. Two other works by Ghosh and Stoeckl [32] and Chechik, Mukhtar, and Zhan [23], which appeared concurrently with our paper, also consider the streaming edge coloring problem. The algorithm of Ghosh and Stoeckl [32], for any $1 \leq s \leq \sqrt{\Delta}$, obtains a (Δ^2/s^2)-edge-coloring using $\widetilde{O}(ns)$ space.[3] The algorithm of Chechik, Mukhtar, and Zhan [23] obtains a $\widetilde{O}(\Delta^{1.5})$-edge-coloring using $\widetilde{O}(n)$ space.

Our Theorem 1.1 subsumes both of these results: for any $1 \leq s \leq \sqrt{\Delta}$, we achieve a $(\Delta^{1.5}/s)$-edge-coloring using $\widetilde{O}(ns)$ space. Letting $s = 1$, this gives an $O(\Delta^{1.5})$-edge-coloring with $\widetilde{O}(n)$ space matching the result of Chechik, Mukhtar, and Zhan [23]. Moreover, since $\Delta^{1.5}/s \leq \Delta^2/s^2$ for the whole range of $1 \leq s \leq \sqrt{\Delta}$, our color/space trade-off is never worse than that of Ghosh and Stoeckl [32], but is strictly better when s is small. For instance, letting $s = 1$, the algorithm of Ghosh and Stoeckl [32] requires $O(\Delta^2)$ colors whereas ours requires $O(\Delta^{1.5})$ colors.

Finally, we note that Ghosh and Stoeckl [32] also consider vertex arrival streaming algorithms achieving the same bound as our Theorem 1.3. They also consider online algorithms.

1.2 Preliminaries

Unless otherwise stated, we use $G = (V, E)$ to denote the input graph. We use $n := |V|$ and $m := |E|$ to respectively denote the number of vertices and edges in G. We use Δ to denote the maximum degree of the graph G. For any integer k, we use $[k]$ to denote the set $\{1, \ldots, k\}$.

[3] In their paper this is equivalently stated as an $O(\Delta t)$ coloring using $\widetilde{O}(n\sqrt{\Delta/t})$ space.

The graph streaming model. In the standard graph streaming model, edges of an arbitrary graph G arrive one by one in an arbitrary order. The algorithm has a space much smaller than the total number of edges, can take few – preferrably just one – pass over the input, and should return the output. In the case of edge coloring, the output size is as large as the input, making it impossible to store the entire output and return it all at once. Therefore, we allow the algorithm to output the solution in a streaming manner as well. This model is also referred to as the "W-streaming" model in the literature [33, 27]. All of the algorithms presented in this paper take only a single pass over the input. We measure the space in the number of words, each consisting of $\Theta(\log n)$ bits.

Our algorithms for the general edge arrival model build on algorithms that we develop for two more restrictive arrival models of *general vertex arrivals* and *one-sided vertex arrivals in bipartite graphs*. We present the definition of these standard models below.

▶ **Definition 1.4** (vertex arrival model)**.** *In this model, vertices of the input graph G arrive one by one according to some arbitrary permutation π. Upon arrival of a vertex, all of its edges to previous vertices in the permutation π arrive.*

▶ **Definition 1.5** (one-sided vertex arrivals in bipartite graphs)**.** *In this model, the input graph G is assumed to be bipartite with vertex sets U and V. The "offline" vertices in V are present from the beginning, but the "online" vertices in U arrive one by one in an arbitrary order. Every time an online vertex u arrives, all of its edges to the offline vertices V are revealed.*

In our proofs, we use the following standard variant of the Chernoff bound.

▶ **Proposition 1.6** (Chernoff bound)**.** *Let $X_1, ..., X_n$ be independent random variables in $[0, 1]$. Let $X = \sum_{i=1}^{n} X_i$ and $\mu = \mathbb{E}[X]$. Then for all $\delta \geq 0$ and $\mu' \geq \mu$, $\Pr[X \geq (1+\delta)\mu'] \leq \exp\left(-\frac{\delta^2}{2+\delta}\mu'\right)$.*

2 Overview of Techniques

In this section, we give an informal high-level overview of our algorithms.

As we discussed, the main challenge in solving the streaming edge-coloring problem is that the algorithm cannot "remember" all the colors that we assign to the edges as this takes too much space. This turns out to be a challenge particularly when the degrees evolve unevenly. To convey the key intuitions in this section, let us first focus on the one-sided vertex arrival model in bipartite graphs (Definition 1.5). We note that even in this restricted arrival model, the best known algorithm from the literature remains to be those of [17, 22, 4] which require $O(\Delta^2)$ colors with $O(n)$ space. Here, we describe how this can be improved to an asymptotically optimal $O(\Delta)$ coloring with only $\widetilde{O}(n)$ space. Our final algorithm of Theorem 1.1 in the more general edge-arrival model builds on this vertex-arrival algorithm.

Since all edges of an online vertex arrive at the same time, it is not hard to ensure they receive different colors. What is challenging is to do so while ensuring that all edges of an *offline* vertex receive different colors too. Towards this, we first describe an algorithm that uses $O(\Delta \log n)$ colors, $O(n\Delta)$ "pre-processing space," and $O(n)$ working space. We then show how this can be turned into an $O(\Delta)$ coloring algorithm that uses $\widetilde{O}(n)$ space overall.

With regards to the second reviewer's question, for the streaming model, we measure the space in terms of the number of words. We point this out in the preliminaries section. In the paragraph describing the algorithm that uses $O(\triangle \log n)$ colors the counters keep track of a number which is at most $K = \Theta(\Delta \log n)$. Thus it can be stored in $O(\log(K)) = O(\log n)$ bits of space. Since we set the size of words to be $\Theta(\log n)$, each counter can be stored in $O(1)$ space. Hence, to store counters for all the $O(n)$ vertices we need $O(n)$ space.

An algorithm with $O(\Delta \log n)$ colors but large space. Let $K = \Theta(\Delta \log n)$ be the number of colors we use. In the pre-processing step (i.e., before seeing any edges of the graph), for every offline vertex $v \in V$, we store a random permutation π_v of the colors $\{1, \ldots, K\}$ in memory which overall takes $\widetilde{O}(n\Delta)$ pre-processing space. Now suppose that the first online vertex u arrives. For each of its offline neighbors v_i, we consider the first random color $\pi_{v_i}(1)$ of v_i. Since the random permutations of offline vertices are independent, when $\Delta \geq 2$ we get the color chosen for v_i is different from $\pi_{v_j}(1)$ for all other neighbors v_j of u with probability $(1 - \frac{1}{K})^{\deg(u)} \geq (1 - \frac{1}{\Delta})^{\Delta} \geq 0.25$. Note that $(1 - \frac{1}{\Delta})^{\Delta}$ is a monotonically increasing and for $\Delta = 2$ the value is 0.25. If this happens, we assign color $\pi_{v_i}(1)$ to edge (u, v_i). If the first color of v_i is not unique, we discard it and reveal the next color $\pi_{v_i}(2)$ of v_i. Every round of this process successfully colors a constant fraction of the remaining uncolored edges of u. Thus it takes $O(\log n)$ rounds to color all edges of u w.h.p. On the other hand, since we have reserved $K = \Theta(\Delta \log n)$ colors for each offline vertex, we can afford to reveal up to $\Theta(\log n)$ colors for each of their edges, hence fully coloring the graph w.h.p. To implement this algorithm, we only need to maintain a counter d_v for every offline vertex v on how many colors of its random permutation we have revealed so far, which can be done with $O(n)$ total working memory.

Reducing space. To get rid of the huge pre-processing space of $\widetilde{O}(n\Delta)$ in the previous algorithm, we limit the amount of randomness needed. To do so, instead of choosing a fully random permutation of $\{1, \ldots, K\}$ for every offline vertex v, which requires $\Theta(nK) = \widetilde{\Theta}(n\Delta)$ space, we just pick a random number $r_v \in [K]$ and use the randomly *shifted* permutation $(r_v, r_v+1, \ldots, K, 1, \ldots, r_v-1)$. The advantage of doing so is that this shifted permutation can be stored using $O(1)$ space, by just storing the random number r_v in memory. Its downside is that lack of independence breaks the analysis above. For example, if $\pi_{v_i}(1) = \pi_{v_j}(1)$ then we also have $\pi_{v_i}(2) = \pi_{v_j}(2)$ and so cannot argue that every round colors a constant fraction of the edges of the online vertex u. To fix this, we take $t = \Theta(\log n)$ random numbers $r_v^1, \ldots, r_v^t$ for each offline vertex v and considering the t shifted permutations

$$[r_v^1, \ldots, \Delta, 1, \ldots, r_v^1 - 1], \ldots, [r_v^t, \ldots, \Delta, 1, \ldots, r_v^t - 1].$$

Now if the first color choice of v_i and v_j according to the first shifted permutation are the same, we consider the second shifted permutations, then the thirds, and so on and so forth. This gets rid of the dependence between the colors proposed for the edges of an online vertex, but not the edges of an offline vertex. Luckily, the latter is not needed for the analysis to go through and we can implement this algorithm with $\widetilde{O}(n)$ space overall.

Reducing colors via k-out sampling. The algorithm above is greedy in that we first reveal a random color for each edge of the online vertex u, greedily color those whose proposed colors are unique, then reveal the next batch of proposals. Instead of this greedy algorithm which takes up to $O(\log n)$ rounds, inevitably stretching the number of colors to $O(\Delta \log n)$, we first draw 3 random colors x_i^1, x_i^2, x_i^3 for each edge $e_i = (u, v_i)$ of the online vertex u and consider all these 3 colors *at the same time*. We show that with probability $1 - 1/\operatorname{poly}(\Delta)$, it is possible to pick one of the colors x_i^1, x_i^2, x_i^3 for each edge e_i of u such that all edges of u receive different colors. Our proof of this theorem builds on a new lemma (Lemma 3.6) that we prove on the existence of perfect matchings in a *one-sided random k-out model*. This lemma, which might be of independent interest, says that if we have a random bipartite graph with vertex sets V and U, and every vertex in V is made adjacent to exactly k vertices in U chosen uniformly, then G has a perfect matching provided that $k \geq 3$ and $|U| > e|V|$.

While k-out sampling has been used recently in obtaining more efficient algorithms for distributed graph connectivity [34] and minimum cuts [31, 11], this is to our knowledge its first application in graph coloring.

From vertex-arrivals to edge-arrivals. We now overview how we go from the vertex arrival model to the more general edge arrival model. To convey the key intuitions, we focus only on the simpler special case of Theorem 1.1 where $s = 1$. That is, an algorithm that uses $O(n)$ space and returns an $O(\Delta^{1.5})$ edge coloring. Our first step is to generalize the algorithm above to work in the non-bipartite vertex arrival model (Definition 1.4). This step, in fact, follows more or less from a known random bipartization technique of the literature that we present in Appendix A. Our next, more challenging, step is to generalize the algorithm to a *batch* arrival setting, where at each step instead of all of the edges of a vertex, we see some $\Theta(\sqrt{\Delta})$ edges of it (without having any guarantee about when the next batch of this vertex arrives). Once we achieve this more general algorithm, we run an instance $\mathcal{A}$ of it. To feed our edges to this batch arrival algorithm $\mathcal{A}$, we keep storing edges in a set H. Whenever the number of edges in H reaches n, we look at the vertex v with the largest degree in H. If $\deg_H(v) \geq \sqrt{\Delta}$, we feed $\Theta(\sqrt{\Delta})$ of these edges of vertex v as the next batch to algorithm $\mathcal{A}$ and remove them from H. Otherwise, the maximum degree in H is less than $\sqrt{\Delta}$; in this case, we edge color all edges in H greedily using $O(\sqrt{\Delta})$ colors and remove them all from H. Every time that we color H greedily, we color n edges of the graph. Therefore this happens at most $m/n = O(\Delta)$ times, requiring a total of $O(\Delta^{1.5})$ colors. The proof of Theorem 1.1 for larger values of s requires a more involved white-box application of the vertex-arrival algorithm; see the edge arrival section in the full version of our paper [18] for the details of the algorithm.

3 Streaming Edge Coloring Under Vertex Arrivals

In this section, we start by proving Theorem 1.3, restated below, for the streaming edge-coloring under vertex arrivals. Our algorithm in the more general edge-arrival model builds on the vertex-arrival algorithm that we describe in this section.

▶ **Theorem 1.3** (restated). *There is a randomized streaming algorithm that $O(\Delta)$ edge colors the graph under arbitrary vertex arrivals using $\widetilde{O}(n)$ space.*

3.1 Basic Reductions

We start with two basic reductions that essentially reduce the edge coloring problem in general graphs under vertex arrivals to the same problem in bipartite graphs under one-sided vertex arrivals.

The following lemma asserts that instead of general graphs, we can focus on bipartite graphs. The idea is to randomly partition the vertex set V into two sets A and B, edge color the bipartite subgraph of G between A and B, and recurse on the induced subgraphs $G[A]$ and $G[B]$. Since the idea is standard and follows from known reductions, we present its proof in Appendix B.

▶ **Lemma 3.1.** *Suppose there is a streaming algorithm that edge colors any n-vertex bipartite graph of maximum degree Δ with $f(\Delta) \geq \Delta$ colors using $s(n, \Delta)$ words of space. Then there is a streaming algorithm that edge colors any general (i.e., not necessarily bipartite) n-vertex graph of maximum degree Δ using*

$$f(\Delta) + f(\Delta/2) + f(\Delta/4) + ... + f(1)$$

colors and $\widetilde{O}(n + s(n, \Delta))$ space. If the algorithm for bipartite graphs works under vertex arrivals (resp. edge arrivals), then the algorithm for general graphs also works under vertex arrivals (resp. edge arrivals).

We emphasize that to solve general graphs under vertex arrivals, we have to ensure that the bipartite algorithm that we feed into Lemma 3.1 works under two-sided vertex arrivals. The next reduction shows that any one-sided vertex arrival algorithm also solves two-sided vertex arrivals by losing a factor of 2 in the number of colors.

▷ Claim 3.2. Suppose there is a streaming algorithm A, that edge colors any n-vertex bipartite graph of maximum degree Δ under one-sided vertex arrivals using $f(\Delta)$ colors. Then this can be turned into an algorithm that $2f(\Delta)$ colors the bipartite graph under two-sided vertex arrivals using asymptotically the same space.

Proof. Let $G = (V, U, E)$ be the bipartite graph under two-sided vertex arrivals. We partition its edges into two subgraphs G_U and G_V. If a vertex in V arrives, we add its edges to G_V, and if a vertex in U arrives, we add its edges to G_U. This way, G_V (resp. G_U) will be a bipartite graph under one-sided vertex arrivals with the online part being vertex set V (resp. U). Since both G_U and G_V will have maximum degree upper bounded by Δ (as they are subgraphs of G), we can run one instance of A on G_U and one on G_V in parallel using disjoint colors. This only multiplies the number of colors by two and the space by two, finishing the proof. ◁

3.2 The Algorithm

The reductions of the previous section show that instead of general graphs, we can focus on bipartite graphs under one-sided vertex arrivals. The following lemma is our main contribution in the rest of Section 3.

▶ **Lemma 3.3.** *There is a streaming algorithm that edge colors any bipartite graph of maximum degree Δ, using $O(\Delta)$ colors under one-sided vertex arrivals and uses $O(n)$ space w.h.p. (The coloring is always valid and the space-bound holds with probability $1 - 1/\operatorname{poly}(n)$.)*

Let us first see how Lemma 3.3 proves Theorem 1.3 using the reductions of the previous section.

Proof of Theorem 1.3. First, we feed the algorithm of Lemma 3.3 to Claim 3.2 to obtain a streaming algorithm that for some constant C, $C(\Delta)$ colors a bipartite graph under two-sided vertex arrivals with $O(n)$ space. We then plug in this algorithm into Lemma 3.1 to obtain an algorithm for general graphs. The algorithm uses $\widetilde{O}(n)$ space and the number of its colors by Lemma 3.1 is

$$C\Delta + C(\Delta/2) + C(\Delta/4) + \ldots + C \leq 2C\Delta = O(\Delta).$$ ◀

So it only remains to prove Lemma 3.3. In this section, we present the algorithm formalized below as Algorithm 1. We analyze the space complexity of the algorithm in Section 3.3 and analyze its correctness and the number of used by it in Section 3.4. Finally, we show in Section 3.5 that the algorithm can be generalized to a batch arrival model as well.

Algorithm 1. Streaming edge coloring for one-sided vertex arrivals in bipartite graphs.

Parameter: $c := 2.72$

1. For each offline vertex v draw 3 *distinct* random numbers r_v^1, r_v^2 and r_v^3 from $[c\Delta]$ uniformly and store them in memory.[a]
2. Additionally, for each offline vertex v, we store a counter $\deg_v$ in memory to keep track of its degree as the edges arrive.
3. Upon arrival of an online vertex u:
   a. For each edge $e_i = (u, v_i)$ consider the following three colors x_i^1, x_i^2, x_i^3:

$$x_i^1 := \big((r_{v_i}^1 + \deg_{v_i}) \bmod c\Delta\big),$$
$$x_i^2 := \big((r_{v_i}^2 + \deg_{v_i}) \bmod c\Delta\big) + c\Delta,$$
$$x_i^3 := \big((r_{v_i}^3 + \deg_{v_i}) \bmod c\Delta\big) + 2c\Delta.$$

   b. If there is an assignment of colors to edges of u such that each edge e_i receives a color from $\{x_i^1, x_i^2, x_i^3\}$ and all the edges of u receive different colors, then we assign these colors, stream them out, and remove edges of u from memory. Otherwise, we add all edges of u to set S which we store in memory.
   (In Claim 3.4 we show u's edges are successfully colored with probability $1 - O(1/\Delta^5)$.)
4. It only remains to color the edges in S. Note that since S is a subgraph of G, its maximum degree is no larger than Δ. Thus we can edge-color it using Δ fresh colors via existing offline edge-coloring algorithms for bipartite graphs; see e.g. [30].

[a] For brevity, here and in the rest of the analysis we assume that $c\Delta$ is an integer. If it is not, $c\Delta$ must be replaced by $\lceil c\Delta \rceil$.

3.3 Space Complexity

In Algorithm 1, for every vertex, we keep its degree and three random numbers which together can all be stored with $O(n)$ words. The only non-trivial part of the space that we need to bound is the size of the set S of the edges that we store in memory and color at the end. Our main result in this section is to show that the set S has size $O(n)$ w.h.p. We start by bounding the expected size of S in Claim 3.4 using a connection to k-out subgraphs (formalized in Lemma 3.6). We then prove a high probability bound on the size of S in Claim 3.7.

▷ Claim 3.4. Take any online vertex u. The probability that we store the edges of u in Step 3b of Algorithm 1 is at most $O(1/\Delta^5)$. This, by linearity of expectation, implies that

$$\mathbb{E}|S| \leq O(n/\Delta^4).$$

Proof. Our main idea to prove this claim is to use the maximum matching problem on an appropriately defined "color graph" defined below. When an online vertex u arrives in the input we construct the bipartite graph H_u in the following way.

▶ **Definition 3.5** (the color graph). *For any online vertex u, we define the color graph $H_u = (X, Y, E)$ as follows. The set X corresponds to the edges of u, i.e., for each edge (u, v_i), we have a vertex corresponding to v_i in X. For each color in the range $[c\Delta]$ we have a corresponding vertex in set Y. Each vertex in X has exactly three edges to Y which are to the three colors:*

$$y_i^1 := \big((r^1_{v_i} + \deg_{v_i}) \bmod c\Delta\big),$$
$$y_i^2 := \big((r^2_{v_i} + \deg_{v_i}) \bmod c\Delta\big),$$
$$y_i^3 := \big((r^3_{v_i} + \deg_{v_i}) \bmod c\Delta\big),$$

where v_i is any offline vertex adjacent to u. Note that since $r^1_{v_i}, r^2_{v_i}, r^3_{v_i}$ are distinct in Algorithm 1, the three colors y_i^1, y_i^2, y_i^3 will be distinct as well.

We first describe that a perfect matching in H_u corresponds to a valid edge-coloring of all edges of u. Let M be a perfect matching in H_u. Suppose that the node corresponding to edge e_i is matched in M to color y_i^j (which is distinct for all e_i's). In this case, we assign color x_i^j to e_i where x_j^i is as defined in Algorithm 1. To see why all edges of u receive different colors note that

$$y_i^j = x_i^j \bmod c\Delta.$$

In addition, all matched y_i^j are unique because M is a matching. Therefore, if we find a perfect matching in the color graph H_u we can easily color edges incident to u using this matching.

Thus, it remains to show that H_u does indeed have a perfect matching (with large enough probability). We do so using the following Lemma 3.6 on existence of perfect matchings in a so-called k-out model. Lemma 3.6 proves that if each vertex of one side of a bipartite graph is made adjacent to 3 random vertices on the other side, then the graph has a perfect matching provided that the other side is sufficiently large. We note that by a classic result of Frieze [29] from 1986, if vertices in *both* sides of the bipartite graph pick k random edges, then the graph has a perfect matching w.h.p. if and only if $k \geq 2$. However, this does not hold when only one side of the graph pick random edges, which is the focus of the following Lemma 3.6.

▶ **Lemma 3.6.** *Consider a random bipartite graph G with vertex sets V and U where each vertex $v \in V$ is adjacent to exactly 3 distinct vertices in U picked uniformly (from all subsets of size 3 of U) and independently from the choice of the rest of vertices in V. If $|V| \leq n$ and $|U| = cn$ for fixed $c > e$, the graph G has a perfect matching with probability at least $1 - O(1/n^5)$.*

Proof. First, we argue that we can w.l.o.g. assume that $|V| = n$. Since if we have $|V| < n$ we can add some dummy vertices to side V and draw random neighbors for them to U. Any perfect matching in this new graph gives us a perfect matching in the original graph by removing its dummy edges. Therefore the probability of finding a perfect matching in this graph is no smaller than the case with $|V| = n$.

We let $c = (1 + \varepsilon)e$ for some fixed $\varepsilon > 0$. We assume that n is larger than any needed constant (possibly a function of ε). Note that if n is fixed, then by adjusting the constants we can ensure $1 - O(1/n^5) = 0$, making the probablistic statement of the lemma trivial.

By Hall's theorem, G has a perfect matching iff for every subset $S \subseteq V$ it holds that $|N_G(S)| \geq |S|$. This condition deterministically holds if $|S| \leq 3$ as every vertex in V has degree exactly 3. Therefore it suffices to show that it holds with high probability for all sets of size at least 4. Let us fix $4 \leq k \leq n$. The probability that all the edges of a vertex $v \in V$ go to a fixed subset U of size at most $k - 1$ in U is exactly $\binom{k-1}{3}/\binom{|U|}{3}$. Therefore, we have

$$\Pr[\text{exists } S \subseteq V : |S| = k \text{ and } |N(S)| < k] \leq \binom{n}{k} \cdot \binom{|U|}{k-1} \cdot \left(\frac{\binom{k-1}{3}}{\binom{|U|}{3}}\right)^k$$

$$\leq \left(\frac{ne}{k}\right)^k \cdot \left(\frac{cne}{k-1}\right)^{k-1} \cdot \left(\frac{(k-1)(k-2)(k-3)}{cn(cn-1)(cn-2)}\right)^k$$

(since $\binom{n}{k} \leq \left(\frac{ne}{k}\right)^k$ for all n and k)

$$\leq \left(\frac{ne}{k}\right)^k \cdot \left(\frac{cne}{k-1}\right)^{k-1} \cdot \left(\frac{k-1}{cn/(1+0.1\varepsilon)}\right)^{3k}$$

(Here we use $cn/(1+0.1\varepsilon) \leq cn-2$ which holds for n larger than some constant.)

$$= \frac{(1+0.1\varepsilon)^{3k} e^{2k-1} (k-1)^{2k+1}}{c^{2k+1} \cdot k^k \cdot n^{k+1}}$$

$$\leq \left(\frac{(1+0.5\varepsilon)e}{c}\right)^{2k-1} \cdot \left(\frac{k}{n}\right)^{k+1}$$

(Here we use $(1+0.1\varepsilon)^2 \leq 1+0.5\varepsilon$ for small enough ε)

$$\leq \left(\frac{1+0.5\varepsilon}{1+\varepsilon}\right)^{2k-1} \left(\frac{k}{n}\right)^{k+1}. \qquad \text{(Since } c = (1+\varepsilon)e.\text{)}$$

To finish the proof, note that as discussed, for $k \leq 3$ the Hall's guarantee holds deterministically. For $k = 4$, the inequality above is upper bounded by $(k/n)^{k+1} = O(1/n^5)$ and thus all subsets of size $k = 4$ in V have at least 4 neighbors in U with probability at least $1 - O(1/n^5)$. For each choice of $5 \leq k \leq n^{0.1}$, the inequality above is upper bounded by $(k/n)^{k+1} \leq n^{-0.9\times 6} = n^{-5.4}$; a union bound over all $O(n^{0.1})$ such choices of k gives that with probability at least $1 - O(n^{-5.3})$, any set of size $5 \leq k \leq n^{0.1}$ in V has at least k neighbors in U as well. Finally, for the case where $n^{0.1} < k \leq n$, the inequality above is upper bounded by

$$\left(\frac{1+0.5\varepsilon}{1+\varepsilon}\right)^{2k-1} \left(\frac{k}{n}\right)^{k+1} \leq \left(\frac{1+0.5\varepsilon}{1+\varepsilon}\right)^{2k-1} = 2^{-O_\varepsilon(k)} = 2^{-O_\varepsilon(n^{0.1})} \ll O(1/n^6).$$

Thus, again by a union bound over all such choices of k, we get that with probability at least $1 - O(1/n^5)$, any set of size $n^{0.1} < k \leq n$ in V has at least k neighbors in U as well. Putting together all of these cases of k, we get that with probability at least $1 - O(1/n^5)$, Hall's condition holds and G has a perfect matching. ◀

Now observe that the color graph H_u meets the conditions of Lemma 3.6. There are at most Δ edges incident to u so $|X| \leq \Delta$. On the other hand $|Y| \geq c\Delta$. Moreover, for each edge $e_i = (u, v_i)$ its corresponding vertex in X is made adjacent to the vertices corresponding to colors y_i^1, y_i^2, y_i^3 as specified in Definition 3.5. Since the $r_{v_i}^j$'s are distinct and uniform, each vertex in X is made adjacent to 3 distinct uniform vertices in Y in graph H_u and so we can apply Lemma 3.6. This implies that H_u has a perfect matching with probability at least $1 - O(1/\Delta^5)$. This means that we store the edges of each online vertex in S with probability at most $O(1/\Delta^5)$, concluding the proof of Claim 3.4. ◁

It is worth noting that to find the maximum matching in H_u we use the algorithm of [35] that has space complexity of $O(|V| + |E|)$ which is $O(\Delta)$ here. We can delete this part of the memory before seeing the next online vertex.

While Claim 3.4 bounds the expected space of Algorithm 1, our next Claim 3.7 bounds the space by $O(n)$ w.h.p.

▷ Claim 3.7. Algorithm 1 uses $O(n)$ space with probability $1 - 1/\operatorname{poly}(n)$.

Proof. For an online vertex u, define X_u to be the indicator random variable where $X_u = 1$ iff we store edges of u in S. Additionally, define $X = \sum_{u \in U} X_u$. We know that

$$\Pr[|S| > O(n)] \leq \Pr[\Delta \cdot X > O(n)] = \Pr[X > O(n/\Delta)].$$

We know that $\mathbb{E}[X] \leq n \cdot O(1/\Delta^5)$ by Claim 3.4. However, since the X_u's are *not* independent we can not use Chernoff bound to provide a concentration bound on their sum. To see why, take two online vertices u_1, u_2 that share the same set of offline neighbors and come one after another in the input. If $X_{u_1} = 1$ then also $X_{u_2} = 1$ since the colors used for H_{u_2} are exactly the same as the colors used for H_{u_1} except they are shifted by one.

To bound X our plan is to divide all X_u's into groups such that in each group all the random variables are independent and then apply the Chernoff bound on each group separately. We know that if two online vertices u and w do not share any offline vertex as their neighbor then X_u and X_w are independent. This is because the colors specified in Step 3a of Algorithm 1 are all a function of the randomness on the set of neighbors an online vertex has. So if these sets are disjoint then X_u and X_w are independent.

Let us define the dependency graph between these variables as follows: The vertex set of this dependency graph is $\{X_u : u \in U\}$ and there is an edge between X_u, X_w with $u, w \in U$ iff u and w share an offline neighbor. The maximum degree in this graph is at most Δ^2 since each vertex $u \in U$ has at most Δ offline neighbors that each has at most Δ online neighbors.

Since any graph of maximum degree Δ' can be *vertex* colored using at most $\Delta' + 1$ colors via a simple sequential greedy algorithm, the dependency graph can be vertex colored via at most $\Delta^2 + 1$ colors. Doing so, note that vertices in each color class become independent random variables by definition of the dependency graph. Therefore, we can apply the Chernoff bound on the sum in each color class. With a slight abuse of notation, let $X_1, ..., X_t$ be a group of variables in a color class. Define $\mu = \mathbb{E}[X_1 + X_2 + ... + X_t]$. Since $\mathbb{E}[X_i] = O(1/\Delta^5)$ (by Claim 3.4) by linearity of expectation we get that for some constant C,

$$\mu = O(t/\Delta^5) \leq C \cdot t/\Delta^5. \tag{1}$$

Applying the Chernoff bound we get that for any $\delta > 0$ and $\mu' \geq \mu$,

$$\Pr[X_1 + X_2 + ... + X_t \geq (1+\delta)\mu'] \leq \exp\left(\frac{-\delta^2}{2+\delta}\mu'\right). \tag{2}$$

Let us call this color class *small* if $t \leq n/\Delta^3$ and *large* otherwise. For small groups, we do not need to prove any concentration bound, since a total of $(\Delta^2+1)(n/\Delta^3) = O(n/\Delta)$ vertices belong to small groups and each stores Δ edges in S, giving a deterministic upper bound of $O(n)$ on the number of such edges in S. It thus remains to analyze large groups only.

To deal with large groups we consider two cases for Δ.

Case 1: $\Delta = O((n/\log n)^{1/4})$. Letting $\delta = \Delta^4$ in Equation (2), we get:

$$\Pr\left[\sum_{i=1}^{t} X_i \geq (1+\Delta^4)\mu'\right] \leq \exp\left(\frac{-\Delta^8}{2+\Delta^4}\mu'\right).$$

Let $\mu' = C \cdot t/\Delta^5$. Note that $\mu \leq C \cdot t/\Delta^5 = \mu'$ and $t \geq \frac{n}{\Delta^3}$ since we are only considering large groups we get,

$$\exp\left(\frac{-\Delta^8}{2+\Delta^4}\mu'\right) \leq \exp\left(\frac{-\Delta^8}{2+\Delta^4} \cdot \frac{Cn}{\Delta^8}\right) = \exp\left(\frac{-Cn}{2+\Delta^4}\right).$$

Since we have $\Delta \leq O\left(\frac{n}{\log n}\right)^{1/4}$ the last term can be upper bounded by n^{-10}. Take $t_1, t_2, ..., t_k$ to be the size of the groups. We know that $k \leq n$; thus by a union bound over k, the probability that there is one group that deviates from its mean with a multiplicative factor of more than Δ^4 is at most n^{-9}. Therefore, with probability at least $1 - n^{-9}$, all groups deviate from their mean with a multiplicative factor of less than Δ^4. In this case, noting that $\sum_i t_i = n$, we get

$$X \leq \Delta^4 \cdot \sum_i \frac{C \cdot t_i}{\Delta^5} = O(n/\Delta).$$

Recalling that X is the total number of online vertices that store their edges in S, we get that the total number of edges in S is upper bounded by $\Delta \cdot O(n/\Delta) = O(n)$ w.h.p.

Case 2: $\Delta = \Omega((n/\log n)^{1/4})$. Notice that the probability of storing any u edges in S is $n^{-5/4+o(1)}$. By union bounding over all n online vertices, none will be stored in S with a probability of $O(n^{-0.25+o(1)})$. ◁

3.4 Correctness and the Number of Colors

In this section, we discuss why any two adjacent edges receive different colors in our algorithm. We can ignore the edges colored in Step 4 of Algorithm 1 as they use a totally new set of colors from the rest of the edges. So we focus on the rest of the edges in the remainder of this section.

For an online vertex u, its edges by Step 3b all receive different colors (and if this is not possible, we store u's edges in S which we discussed can be ignored earlier). So it remains to prove that there are no conflicts for the offline vertices.

For an offline vertex v, firstly, note that for any edge e_i:

$$x_i^1 \in [0, c\Delta), \qquad x_i^2 \in [c\Delta, 2c\Delta), \qquad x_i^3 \in [2c\Delta, 3c\Delta).$$

Since these ranges are disjoint, for two edges to receive the same color they must be in the same range.

Note that when the algorithm is running $\deg_v$ is increasing by one after we see an edge of v. Let $x_i^1 = x_j^1$ for two edges of v where e_i arrives before e_j. Define α to be the value of $\deg_v$ when the edge e_i arrives and β to be the value of $\deg_v$ when the edge e_j arrives. Then we get that,

$$\big((r_v^1 + \alpha) \bmod c\Delta\big) = \big((r_v^1 + \beta) \bmod c\Delta\big),$$

which is equivalent to $\alpha - \beta \bmod c\Delta = 0$. Since $|\alpha - \beta| \leq \Delta$ and $c > 1$, this is a contradiction and thus we cannot have $x_i^1 \neq x_j^1$. Same can be applied to the second and the third ranges of colors. Therefore, offline vertices also recieve distinct colors on all their edges and the coloring our algorithm finds is a valid edge coloring.

Finally, it can be verified from Algorithm 1 that the number of colors used is $3c\Delta + \Delta = O(\Delta)$. This section, put together with the previous section concludes the proof of Lemma 3.3 and, as discussed, this finishes the proof of Theorem 1.3.

3.5 Generalization to Batch Arrivals

Our Algorithm 1 considers the vertex arrival model, i.e., all edges of an online vertex arrive at the same time. Here, we consider a more general *batch arrival* model that interpolates between edge arrivals and vertex arrivals. We show that our Algorithm 1 can be generalized to this model.

▶ **Definition 3.8** (one-sided batch arrival model)**.** *In this model, we have a bipartite graph $G = (U, V, E)$ with* online *vertices U and* offline *vertices V. For a parameter k of the problem, edges arrive in batches of size k where all edges in the same batch are incident to the same online vertex u. The edges of a single online vertex v can arrive in up to Δ/k different batches. Importantly, there is no guarantee that different batches of the same online vertex arrive consecutively (otherwise the model would be equivalent to the vertex arrival model). We use $B_i(u)$ to denote the i'th batch of online vertex u.*

We prove that Algorithm 1 leads to the following bound in the one-sided batch arrival model. Note that setting $k = \Delta$ recovers Theorem 1.3, so this is only more general.

▶ **Lemma 3.9.** *There is a streaming algorithm that in the one-sided batch arrival model with batches of size k, uses $O(n)$ space and w.h.p. reports a proper $O(\Delta^2/k)$ edge coloring.*

Proof. Note that the only part of Algorithm 1 where we use the assumption that all edges of the online vertices arrive at the same is in Step 3b. There, the offline vertex of each edge e_i of u proposes three colors $\{x_i^1, x_i^2, x_i^3\}$ for e_i. Committing to choose a color from $\{x_i^1, x_i^2, x_i^3\}$ for each edge e_i already ensures there will be no conflicts among the edges of the offline vertices. On the other hand, our Lemma 3.6 guarantees that for each online vertex u, with probability $1 - O(1/\Delta^5)$, there is a proper coloring of all of its edges using their proposed colors. However, to find this proper coloring, it is important to have all edges of the online vertex at once. If, as in our case in this lemma, the edges of the online vertex arrive in batches, then we cannot ensure that edges in two different batches of the same online vertex u receive different colors. To fix this, first we only properly color the edges of each batch of the online vertex using their proposed colors. If this assigns color c to edge e, the final color that we report for e is (c, i) where i denotes which batch of u this edge e belongs to. Since there are at most Δ/k batches for each vertex, the total number of colors needed with this approach is $O(\Delta \cdot \Delta/k) = O(\Delta^2/k)$. Finally, note that the space remains $O(n)$ since the only additional information that we need is the number of batches that have arrived for each vertex which can be stored with $O(n)$ counters, one for each online vertex. ◀

4 Edge-Arrivals: $O(\Delta)$ Edge-Coloring with $\widetilde{O}(n\sqrt{\Delta})$ Space

In this section, we prove Theorem 1.1 for the special case where $s = \sqrt{\Delta}$. That is, we obtain an asymptotically optimal $O(\Delta)$ edge-coloring using $\widetilde{O}(n\sqrt{\Delta})$ space.

To solve the edge arrival model, we present a reduction to the one-sided batch arrival model of Definition 3.8. Throughout this section, we only consider the batch arrival model for batches of size $k := \lceil \sqrt{\Delta} \rceil$.

▷ Claim 4.1. Suppose that there is a streaming algorithm $\mathcal{A}$ that edge colors a bipartite graph of maximum degree Δ using $O(\Delta)$ colors under one-sided batch arrivals with batches of size $k = \Theta(\sqrt{\Delta})$ using space $\widetilde{O}(n\sqrt{\Delta})$. Then there is a streaming edge coloring $\mathcal{A}'$ algorithm that $O(\Delta)$ edge colors any general graph of maximum degree Δ under edge arrivals using $\widetilde{O}(n\sqrt{\Delta})$ space.

Proof. Let us first assume that graph G is bipartite with vertex sets U and V but its edges arrive in an arbitrary order. We start with a buffer $T = \emptyset$ and add any edge that arrives in the stream to T. Whenever there is some vertex u that has at least k edges in T, we remove those edges of u from T and feed them into the batch-arrival algorithm $\mathcal{A}$. This way, each batch has exactly k edges all adjacent to the same vertex. However, this vertex could belong to either of U and V. That is, this is not one-sided arrivals but rather two-sided

arrivals. The reduction to one-sided arrivals simply follows from Claim 3.2 at the expense of multiplying the final number of colors by two. Finally, if the stream ends and there are any remaining edges in T, we color them all using Δ colors via offline algorithms. Note that since each vertex in T has degree at most k at any point, the space of this reduction is only $O(nk) = O(n\sqrt{\Delta})$ as desired.

From the reduction above, we get that under edge arrivals, there is an algorithm $\mathcal{A}''$ that edge-colors the graph using $C(\Delta)$ colors for some constant C and $\widetilde{O}(n\sqrt{\Delta})$ space provided that the graph is bipartite. We now apply Lemma 3.1. This gives an algorithm for general graphs under edge-arrivals that uses $\widetilde{O}(n\sqrt{\Delta})$ space and the number of colors that it uses is at most

$$C\Delta + C\Delta/2 + C\Delta/4 + \ldots + C \leq 2C\Delta = O(\Delta). \quad \blacktriangleleft$$

Our goal for the rest of this section is to prove the following algorithm which plugged to Claim 4.1 proves Theorem 1.1 for $s = \sqrt{\Delta}$:

▶ **Lemma 4.2.** *There is a streaming algorithm that edge-colors any bipartite graph of maximum degree Δ under one-sided batch-arrivals (Definition 3.8) with batches of size $k = \Theta(\sqrt{\Delta})$ using $O(\Delta)$ colors and $\widetilde{O}(n\sqrt{\Delta})$ space.*

Proof. One may wonder whether we can now directly apply the naive algorithm of Lemma 3.9 in order to prove Lemma 4.2. This is not doable because Lemma 3.9 would require $O(\Delta^2/k) = O(\Delta^{1.5})$ colors which is much larger than our desired $O(\Delta)$ colors. So we need more ideas.

First, we assume that $\Delta \geq 300 \log^2 n$. If not, the whole graph has at most $O(n\Delta) = \widetilde{O}(n)$ edges, so we can store them all and run an offline Δ edge coloring algorithm.

Consider the subgraphs $H_1, H_2, \ldots, H_k$ where

$$H_i := \bigcup_{u \in U} B_i(u),$$

recalling that $B_i(u)$ is the i'th batch of online vertex u. In words, H_i is the collection of the i'th batches of all online vertices. Observe that the arrival order of the edges of each subgraph H_i follow the vertex arrival model. That is, for each online vertex v, all of its edges arrive at the same time. Note also that the maximum degree on the online side of each subgraph H_i is at most k. Now, if we also had the same upper bound of k on the degrees on the offline side of each subgraph H_i, then we could run $\Delta/k = O(\sqrt{\Delta})$ instances of Algorithm 1, which works under vertex arrivals, for each of the k subgraphs H_i all in parallel, using disjoint color palettes. This way, the total number of colors used would be $\frac{\Delta}{k} \cdot O(k) = O(\Delta)$ and the space would be $\frac{\Delta}{k} \cdot O(n) = O(n\sqrt{\Delta})$. Unfortunately, however, the offline vertices in each H_i may have degree as large as Δ. This is because all edges of an offline vertex might be in the first batch of their corresponding online vertices, making the maximum degree in H_1 equal to Δ rather than k. This is the main obstacle that we overcome in the remainder the proof.

Let us for each online vertex u choose a random number $b_u \in [k]$ at the beginning of the algorithm uniformly and independently at random. Now for the i'th batch of u define its *permuted batch number* $\rho_u(i)$ to be

$$\rho_u(i) := (i + b_u) \bmod k.$$

Doing so, we now redefine H_i for $i \in [k]$ as

$$H_i := \bigcup_{u \in U} B_{\rho_u^{-1}(i)}(u).$$

In words, H_i is now the graph including, for each online vertex u, its edges in its j'th batch such that $\rho_u(j) = i$. Since the total number of batches of each online vertex u is at most $\Delta/k \leq k$, all of u's batches receive different batch numbers. It remains to bound the degree of offline vertices in each H_i. The following lemma asserts that with high probability this is in fact $O(k)$.

▶ **Lemma 4.3.** *All H_i's have maximum degree at most $2k$ with probability $1 - 1/\operatorname{poly}(n)$.*

Due to space constraints, we defer the proof of this lemma to the appendix.

Now that both the offline and online vertices of each H_i have degree at most $2k$, we can follow the approach outline before to achieve a $O(\Delta)$ coloring with $O(n\sqrt{\Delta})$ space. The final algorithm is formalized below as Algorithm 2.

Algorithm 2. A streaming edge coloring for bipartite graphs under one-sided batch arrivals with batches of size $k = \Theta(\sqrt{\Delta})$. The algorithm uses $O(\Delta)$ colors and $O(n\sqrt{\Delta})$ space. This is the algorithm used for Lemma 4.2 which plugged into Claim 4.1 proves Theorem 1.1 for $s = \sqrt{\Delta}$.

Parameter: $k := \sqrt{\Delta}$, $c := 300$ (Lemma 4.3)

1. If $\Delta \leq c \cdot \log^2 n$ we read all the edges from the stream and color them with Δ colors, so assume for the rest of the algorithm that $\Delta > c \cdot \log^2 n$.
2. As the edges of G arrive, we decompose them into k subgraphs $H_1, \ldots, H_k$ and run k instances of the vertex-arrival Algorithm 1 in parallel on these subgraphs using disjoint colors in these instances, and an overall space of $O(nk)$. Each graph H_i will have maximum degree k, so overall we use $O(k \cdot k) = O(\Delta)$ colors.
3. For each online vertex u choose a random number $b_u \in [k]$ uniformly and independently.
4. For each online vertex u store a counter I_u. This will keep track of the number of *batches* of u seen at any point. Initially we have $I_u \leftarrow 0$.
5. Upon arrival of a batch of size k for an online vertex u:
   a. $I_u \leftarrow I_u + 1$.
   b. Add the edges of u to graph H_x where
   $$x := (I_u + b_u) \bmod k.$$
   c. These will be the only edges of u in graph H_x, thus this is indeed a bipartite graph under one-sided vertex arrivals and so we can run the instance of Algorithm 1 on graph H_x to color the edges of u in it.

Space-complexity. Since we are running $k = O(\sqrt{\Delta})$ instances of Algorithm 1 in Algorithm 2, the space needed for keeping all these instances is also $O(n\sqrt{\Delta})$ as each has a space of $O(n)$ words by Claim 3.7. Moreover, note that the size of T never exceeds nk or else there must be a vertex of degree at least k in it. We also use at most $O(n)$ space for the counters and random numbers (specified in Step 3 and 4). So in total, the space that Algorithm 2 uses is $O(nk) = O(n\sqrt{\Delta})$.

Number of colors. For the number of colors used by Algorithm 2, note that we run k instances of Algorithm 1, and in each instance the maximum degree is w.h.p. $2k$ by Lemma 4.3. Since Algorithm 1 uses linear colors in the maximum degree, the total number of colors is thus $O(k \cdot k) = O(\Delta)$ w.h.p.

This completes the proof of Lemma 4.2. ◀

As discussed, plugging Lemma 4.2 into Claim 4.1 completes the proof of Theorem 1.1 for $s = \sqrt{\Delta}$, concluding this section. For the final algorithm that does $O(\Delta^{1.5}/s + \Delta)$ Edge-coloring with $\widetilde{O}(ns)$ space see the full version of our paper at [18].

A Reduction To Bipartite Graphs

In this section, we present the proof of Lemma 3.1 using a random bipartization idea that has been used extensively in the literature of edge colorings. To our knowledge, this idea was first used by Karloff and Shmoys [39] in the context of parallel algorithms and by by Behnezhad et al [17] in the context of streaming edge coloring. We emphasize that we claim no novelty in the algorithm of this section and merely present it here for the sake of self-containment.

Proof of Lemma 3.1. If $\Delta \leq 10 \log n$, then we store the whole graph in memory using $\widetilde{O}(n)$ space and edge color the graph via $(\Delta + 1)$ colors using offline algorithms. So assume that $\Delta > 10 \log n$.

Let V be the vertex-set of the graph. We partition V into two subsets A and B by putting each vertex randomly in either A or B chosen uniformly and independently from the rest of the vertices. Now consider the bipartite subgraph G' of G including any edge (u, v) of G that has one endpoint in A and one endpoint in B. Note that conditioned on $v \in A$, each neighbor of v in the original graph belongs to B independently with probability $1/2$. This means that the expected degree of v in G' is $\deg_G(v)/2$. By a simple application of the Chernoff bound and recalling that $\Delta > 10 \log n$, we get that G' has maximum degree $\Delta/2 + O(\sqrt{\Delta \log n}) = (1/2 + o(1))\Delta$ with probability $1 - 1/n^{10}$. We can thus run the bipartite edge coloring algorithm on G'. Notice, however, that this leaves the edges that go from A to A or from B to B uncolored. We recursively apply the same algorithm. That is, we recursively partition A and B into two subsets each. This results in a subgraph of maximum degree $\Delta/4 + O(\sqrt{\Delta \log n})$ w.h.p. We continue this for $O(\log \Delta)$ steps until the resulting subgraph has maximum degree smaller than $O(\log n)$, at which point we store the whole subgraph in memory and color it using offline algorithms. Overall, the total number of colors used by the algorithm is

$$\sum_{i=1}^{\log \Delta} f\left(\left(\frac{1}{2^i} + o(1)\right)\Delta\right) \leq \sum_{i=1}^{\log \Delta} f\left(\frac{\Delta}{2^{i-1}}\right).$$

Note that this partitioning of the vertices can be done at the beginning of the stream before any edges arrive. It only suffices to store, for each vertex, which of the two random subsets it belongs to at each of the $O(\log \Delta)$ levels. So this only requires an overhead space of $O(n \log \Delta)$. Additionally, if the edges of the original graph arrive under vertex arrivals, then so do the edges of the random bipartite graphs. ◀

B Deferred Proofs

▶ **Lemma 4.3** (restated). *All H_i's have maximum degree at most $2k$ with probability $1 - 1/\operatorname{poly}(n)$.*

Proof. Due to symmetry, let us focus on bounding the degree of a given offline vertex v in H_1. Let neighbors of v be $u_1, u_2, ..., u_l$ where each u_i is an online vertex. Define X_i to be the indicator random variable where $X_i = 1$ iff the edge (v, u_i) receives a batch number of 1. The degree of v in H_1 can be written as

$$X = \sum_{i=1}^{l} X_i.$$

Since $l \leq \Delta$ and also $\mathbb{E}[X_i] = \frac{1}{k}$, by linearity of expectation, we get

$$\mathbb{E}[X] = \sum_{i=1}^{l} \mathbb{E}[X_i] \leq \frac{\Delta}{k} \leq k.$$

Observe that all b_{u_i}'s are chosen at the beginning of the algorithm and uniformly at random. Therefore the batch number of any given edge being 1 has a probability of $\frac{1}{k}$. Since all b_{u_i}'s are independent of each other, also all X_i's will be independent. Thus, we can apply the Chernoff bound for $\delta = 1$ and having $\Delta \geq 300 \log^2 n$ (as assumed at the start of the proof of Lemma 4.2) we get,

$$\Pr[\text{degree } v \text{ in } H_1 \geq 2k] = \Pr\left[\sum_{i=1}^{l} X_i \geq 2k\right] \leq \exp\left(\frac{-k}{3}\right) \leq n^{-10}$$

By a union bound over all n choices of v and over k choices of H_i, we get

$$\Pr[\text{exists } v \in V \text{ and } i \in [k] \text{ such that degree } v \text{ in } H_i \geq 2k] \leq n^{-8}.$$ ◀

An Improved Integrality Gap for Disjoint Cycles in Planar Graphs

Abstract

We present a new greedy rounding algorithm for the Cycle Packing Problem for uncrossable cycle families in planar graphs. This improves the best-known upper bound for the integrality gap of the natural packing LP to a constant slightly less than 3.5. Furthermore, the analysis works for both edge- and vertex-disjoint packing. The previously best-known constants were 4 for edge-disjoint and 5 for vertex-disjoint cycle packing.

This result also immediately yields an improved Erdős–Pósa ratio: for any uncrossable cycle family in a planar graph, the minimum number of vertices (edges) needed to hit all cycles in the family is less than 8.38 times the maximum number of vertex-disjoint (edge-disjoint, respectively) cycles in the family.

Some uncrossable cycle families of interest to which the result can be applied are the family of all cycles in a directed or undirected graph, in undirected graphs also the family of all odd cycles and the family of all cycles containing exactly one edge from a specified set of demand edges. The last example is an equivalent formulation of the fully planar Disjoint Paths Problem. Here the Erdős–Pósa ratio translates to a ratio between integral multi-commodity flows and minimum cuts.

1 Introduction

Given a family $\mathcal{C}$ of cycles in a (directed or undirected) graph G, the Cycle Packing Problem asks for a maximum-cardinality subset $\mathcal{C}^* \subseteq \mathcal{C}$ of pairwise vertex- or edge-disjoint cycles. It admits the natural packing LP

$$\max \left\{ \sum_{C \in \mathcal{C}} x_C : \sum_{C \in \mathcal{C}: v \in C} x_C \leq 1 \ (v \in V),\ x_C \geq 0 \ (C \in \mathcal{C}) \right\} \tag{1}$$

for vertex-disjoint cycle packing and

$$\max \left\{ \sum_{C \in \mathcal{C}} x_C : \sum_{C \in \mathcal{C}: e \in C} x_C \leq 1 \ (e \in E),\ x_C \geq 0 \ (C \in \mathcal{C}) \right\} \tag{2}$$

for edge-disjoint cycle packing. Despite its exponentially many variables, optimum LP solutions can be computed in polynomial time if $\mathcal{C}$ is given by a *weight oracle* [24]:

▶ **Definition 1** ([24]). *Let $\mathcal{C}$ be a family of cycles in a graph G. $\mathcal{C}$ has a* weight oracle *if for any edge weights $w\colon E(G) \to \mathbb{R}_{\geq 0}$ we can compute a weight-minimal cycle in $\mathcal{C}$ in polynomial time.*

For arbitrary graphs the integrality gap of the LPs (1) and (2) is unbounded even if $\mathcal{C}$ is the set of all odd cycles in G [20, 18]. For planar graphs however, Schlomberg, Thiele and Vygen [24] have recently shown constant upper bounds for the integrality gaps if the cycle family $\mathcal{C}$ is *uncrossable*.

▶ **Definition 2** (Goemans, Williamson [10]). *A family $\mathcal{C}$ of cycles in a graph is called* uncrossable *if the following property holds.*

Let $C_1, C_2 \in \mathcal{C}$ and let P_2 be a path in C_2 such that P_2 shares only its endpoints with C_1. Then there is a path P_1 in C_1 between these endpoints such that $P_1 + P_2 \in \mathcal{C}$ and $(C_1 - P_1) + (C_2 - P_2)$ contains a cycle in $\mathcal{C}$ (as an edge set).

In their work they give an upper bound of 5 for the vertex-disjoint cycle packing LP (1), using a greedy rounding algorithm. For the edge-disjoint LP (2) they show an upper bound of 4, generalizing a similar result for the edge-disjoint paths problem by Garg, Kumar and Sebő [9]. In this work we modify their greedy rounding algorithm and analyze it using a new structural lemma. This improves the integrality gaps of both LPs to below 3.5:

▶ **Theorem 3.** *Let G be a planar graph, embedded in the sphere, and $\mathcal{C}$ an uncrossable family of cycles in G. Then there exists an integral solution to the vertex- or edge-disjoint cycle packing LP (1) or (2) with at least $\frac{6}{13+3\sqrt{7}} > \frac{1}{3.5}$ the LP value. If $\mathcal{C}$ is given by a weight oracle we can compute such a solution in polynomial time.*

1.1 The Erdős–Pósa ratio

The duals of the LPs (1) and (2) are relaxations of the Cycle Transversal Problem: This asks for a minimum subset of vertices or edges, respectively, that hit each cycle in $\mathcal{C}$. Berman and Yaroslavtsev [2] have shown an upper bound of 2.4 for the integrality gaps of the edge and vertex cycle transversal LPs, improving on a previous bound of 3 by Goemans and Williamson [10]. Multiplying the integrality gaps of the primal and dual LPs directly yields a maximum ratio between integral solutions to the primal and the dual:

▶ **Corollary 4.** *Let G be a planar graph and $\mathcal{C}$ an uncrossable family of cycles in G. Let ν_v respectively ν_e be the maximum number of vertex- and edge-disjoint cycles in $\mathcal{C}$ and let τ_v respectively τ_e be the minimum size of vertex and edge transversals for $\mathcal{C}$.*
Then $\frac{\tau_v}{\nu_v} \leq 2.4 \cdot \frac{13+3\sqrt{7}}{6} \leq 8.38$ and $\frac{\tau_e}{\nu_e} \leq 2.4 \cdot \frac{13+3\sqrt{7}}{6} \leq 8.38$

The supremum of $\frac{\tau_v}{\nu_v}$ respectively $\frac{\tau_e}{\nu_e}$ is known as the Erdős–Pósa ratio for the Cycle Packing and Transversal Problem. The previously best-known upper bound for general uncrossable cycle families was 12 for vertex-disjoint Cycle Packing and 9.6 for edge-disjoint Cycle Packing [24]; both resulting from multiplying the upper bounds for the primal and dual integrality gaps.

1.2 New Techniques

Our main algorithm that we use to find integral solutions to the Cycle Packing LP with the claimed approximation guarantee is similar to the greedy rounding algorithm used in [24]: Similar to [24], we start by solving the LP and applying an uncrossing procedure to obtain an optimum LP solution where the cycles in the support form a *laminar* family $\mathcal{L}$. Afterwards, we iteratively pick a set $\mathcal{F}^* \subseteq \mathcal{L}$ of pairwise disjoint cycles, add them to our solution and remove all "neighbours", i.e. cycles that are not disjoint to $\mathcal{F}^*$, from the support.

Schlomberg, Thiele and Vygen [24] showed that they can always find a single cycle C^* with LP value at most 5 on its neighbourhood. In this work we prove a new Structure Lemma, showing that after a slight modification of our LP solution, for a *one-sided* cycle C (i.e. a cycle with a side that contains no other cycles in $\mathcal{L}$) the average LP value on the neighbours of C without C itself is at most 3.

In Section 3 we observe that this already improves the bound of 5 from [24] to 4. However, by exploiting that we can also add several cycles in a single iteration to our solution, we can improve the bound further to below 3.5 (see Section 5). To this end, we add further candidates for our set $\mathcal{F}^*$: For any $\frac{1}{4} \leq \alpha < \frac{1}{2}$ we can find a large set of pairwise disjoint cycles among the one-sided cycles with LP value at least α due to the Four Colour Theorem. Using either a single cycle or one of those candidates for $\mathcal{F}^*$ in each iteration of the greedy rounding algorithm allows us to bound the integrality gap of the Cycle Packing LP by $\frac{13+3\sqrt{7}}{6}$.

Key of the new results is the Structure Lemma 13, which we prove by constructing a set M^* of LP constraints (i.e. vertices or edges) that cover each cycle in $\mathcal{L}$ enough often. Section 4 is dedicated to the construction of M^*. We proceed by an induction on the number of cycles in $\mathcal{L}$. If all cycles are one-sided, an auxiliary graph, similar to the planar dual, directly yields a feasible set M^*. Otherwise, we pick a minimal two-sided cycle, find feasible sets M^* for both sides of it and carefully put them together to a solution for the whole family.

1.3 Examples for uncrossable cycle families

There are several examples for cycle families in G that are always uncrossable and many of them have been studied individually. A list of the most interesting examples together with proofs of their uncrossability can be found in [24].

The first example of interest is the set of all cycles in an undirected graph G. For this problem Erdős and Pósa [6] showed that even in general, not necessarily planar, graphs with bounded cycle packing number the transversal number is bounded, although in general the ratio is unbounded. This property is known as the Erdős–Pósa property. In planar graphs the Erdős–Pósa ratio is 4 for edge-disjoint packing (the upper bound comes from a result by Ma, Yu and Zang [16], tightness was shown by an example by Král' [16]). For vertex-disjoint packing [4] and [16] gave an upper bound of 3 on the Erdős–Pósa ratio.

Also the set of all directed cycles in a digraph G is uncrossable. Here again the Erdős–Pósa property holds on arbitrary graphs [21]. For planar G the famous Lucchesi-Younger Theorem [15] shows that the edge-disjoint version has Erdős–Pósa ratio 1. For the vertex-disjoint version (1) in planar graphs, Reed and Shepherd [22] gave the first constant upper bound on the Erdős–Pósa ratio. After three improvements by Fox and Pach as well as Cames van Batenburg, Esperet and Müller [3] and then Schlomberg, Thiele and Vygen [24], this work decreases it below 8.38.

The next example of an uncrossable family is the set of all odd cycles in an undirected graph G. In this variant (in planar graphs) the edge-disjoint problem has an Erdős–Pósa ratio of exactly 2 [14]. For the vertex-disjoint problem Fiorini et al. [7] showed that the Erdős–Pósa ratio is at most 10, which was improved to 6 by Král', Sereni and Stacho [13].

Finally, one of the most interesting and well-studied variants of the Cycle Packing Problem is given as follows: Given a graph G and a set D of demand edges, then a D-cycle is a cycle in G that contains exactly one demand edge. Since removing the demand edge from a D-cycle results in a path between the endpoints of the demand edge, the D-Cycle Packing Problem is equivalent to the Disjoint Paths Problem, and D-Cycle Packing in planar graphs corresponds to the Disjoint Paths Problem in fully planar instances.

For the Fully Planar Edge-Disjoint Paths Problem the first constant-factor approximations and bounds on the integrality gap were given by Huang et al. [12] and Garg, Kumar and Sebő [9]; the best upper bound on the integrality gap is 4 [9]. Garg and Kumar [8] showed that also the Erdős–Pósa ratio for this problem is at most 4. Due to a result by Middendorf and Pfeiffer [17] the Fully Planar Vertex-Disjoint Paths Problem contains the edge-disjoint version as a special case. The first constant upper bound on the integrality gap of 5 was found only recently by Schlomberg, Thiele and Vygen [24]. The best upper bound for the Erdős–Pósa ratio of 12 comes in this variant from multiplying the upper bounds for the integrality gaps of the primal and the dual.

This work now decreases both best-known upper bounds on the integrality gaps to the same value below 3.5. For the Fully Planar Vertex-Disjoint Paths Problem we also improve the Erdős–Pósa ratio to below 8.38:

▶ **Corollary 5.** *Given an instance (G, D) of the Fully Planar Vertex-Disjoint Paths Problem, we can compute in polynomial time a set $\mathcal{P}$ of vertex-disjoint D-cycles and $T \subseteq V(G)$ such that every D-cycle contains a vertex of T with $|T| \leq 2.4 \cdot \frac{13+3\sqrt{7}}{6}|\mathcal{P}| \leq 8.38|\mathcal{P}|$.*

For most of the uncrossable families discussed above a lower bound of 2 on the integrality gaps of (1) and (2) is known, which is also the best-known lower bound for general uncrossable families. Most of the corresponding examples can be constructed by modifying a K_4. Regarding the Erdős–Pósa ratio, the best-known lower bound for vertex-disjoint cycle packing (for uncrossable families) is still 2, but for edge-disjoint cycle packing and transversal Král' (see [16]) showed a lower bound of 4 on the Erdős–Pósa ratio for the family of all cycles in G. See [24] for a more detailed overview on lower bounds for the integrality gaps and Erdős–Pósa ratios.

There exist other examples of uncrossable cycle families that have been studied. For example, Rautenbach and Regen [19] considered the Cycle Packing Problem with the family of shortest cycles in G, which is also uncrossable. Furthermore, the (uncrossable) family of all cycles that contain at least one vertex from a specified set $S \subseteq V(G)$ has been considered, for example by Goemans and Williamson [10]. This work yields the best-known upper bounds for the integrality gaps of the corresponding Cycle Packing LPs.

For cycle families $\mathcal{C}$ that are not uncrossable surprisingly few is known. For example, the set of all even cycles is not uncrossable. Here Göke et al. [11] generalized Goemans and Williamson's [10] technique to get a constant upper bound on the vertex transversal LP; for the Cycle Packing Problem no constant-factor approximation algorithm is known.

2 Preliminaries

For the rest of the paper we fix a planar graph G, together with an embedding in the sphere $\mathbb{S}^2$, and an uncrossable family $\mathcal{C}$ of cycles in G. By a result by Schlomberg, Thiele and Vygen [24] we can compute optimum solutions to (1) and (2) with *laminar* support, i.e. any two cycles in the support can only "touch" but not "cross":

▶ **Definition 6.** *Let G be a planar graph, embedded in the sphere. Deleting the embedding of a cycle C in G from the sphere results in two connected components of the sphere, which we call the* sides *of C. Given a side S of C and another cycle C' in G, we say that C' is* inside *S or that S* contains *C' if S contains a side of C'.*

We call a family $\mathcal{L}$ of cycles in G laminar *if for any $C_1, C_2 \in \mathcal{L}$ there exist sides S_1 of C_1 and S_2 of C_2 that are disjoint.*

▶ **Definition 7.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere. By $V(\mathcal{L})$ and $E(\mathcal{L})$, respectively, we denote the set of all vertices, respectively edges, in cycles of $\mathcal{L}$.*

The cycles corresponding to $\subseteq$-minimal sides in $\mathcal{L}$ are called one-sided*, while the others are called* two-sided*. For a one-sided cycle, the $\subseteq$-minimal side is also called* one-sided*.*

We call two cycles $C_1, C_2 \in \mathcal{L}$ homotopic *if there exist sides S_1 of C_1 and S_2 of C_2 that contain the same set of one-sided sides.*

For any connected component D of $E(\mathcal{L})$ we call the set of all cycles in $\mathcal{L}$ that are in D a connected component *of $\mathcal{L}$.*

A chain *is a laminar family of cycles with only two one-sided sides.*

It is easy to see that the sides S_1 and S_2 in Definition 6 are unique if $C_1 \neq C_2$. Also, our notion of laminarity is equivalent to the definition in [24]. In particular we can use the following Lemma from [24]:

▶ **Lemma 8.** *Let G be a planar graph, embedded in the sphere, and $\mathcal{C}$ an uncrossable family of cycles in G. Then there exist optimum solutions to the LPs (1) and (2) with laminar support. If $\mathcal{C}$ has a weight oracle such solutions can be computed in polynomial time.*

3 Bounding the integrality gap

In this section we explain our main algorithm, which is a slight generalization of the greedy rounding algorithm used in [24]. We first only analyze the easiest variant of the algorithm. This already yields an upper bound of 4 on the integrality gap for the cycle packing LP, equalizing the best known upper bounds for edge-disjoint and vertex-disjoint Cycle Packing. In Section 5 we will analyze a more refined version of the algorithm, which yields an upper bound of below 3.5.

Here we only describe the algorithm for vertex-disjoint cycle packing. The edge-disjoint version can be deduced similarly or sometimes even easier; also there exists a reduction for laminar cycle families ([24]) that allows us to immediately transfer our results from vertex-disjoint to edge-disjoint packing. For more details we refer to Section 5.2.

▶ **Definition 9.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere. Let $\mathcal{L}_1$ be the set of one-sided cycles in $\mathcal{L}$. For any $C \in \mathcal{L}$ let $\mathcal{N}_{\mathcal{L}}(C)$ be the set of "neighbours" of C, i.e. cycles in $\mathcal{L}$ that contain a vertex of C. In particular, $C \in \mathcal{N}_{\mathcal{L}}(C)$. Define $\mathcal{N}^1_{\mathcal{L}}(C) := \mathcal{N}_{\mathcal{L}}(C) \cap \mathcal{L}_1$ to be the set of one-sided "neighbours" of C.*

Given this definition, we can outline our algorithm:

Algorithm 1 Greedy Rounding for Cycle Packing.

Input: A planar graph G and an uncrossable family $\mathcal{C}$ of cycles in G.
Output: A set $\mathcal{L}^* \subseteq \mathcal{C}$ of pairwise vertex-disjoint cycles.

Compute an embedding of G in the sphere.
Compute an optimum solution x to the LP (1) with laminar support.
while $x \neq 0$ **do**
  Modify x to make it structured (see Definition 11).
  Let $\mathcal{L}_x := \{C \in \mathcal{C} : x_C > 0\}$ be the support of x.
  Pick a non-empty subset $\mathcal{F}^* \subseteq \mathcal{L}_x$ of pairwise vertex-disjoint cycles.
  Add all cycles in $\mathcal{F}^*$ to the solution $\mathcal{L}^*$.
  Set $x_C := 0$ for all $C \in \bigcup_{C' \in \mathcal{F}^*} \mathcal{N}_{\mathcal{L}_x}(C')$.
end while
Output $\mathcal{L}^*$.

Throughout the algorithm we maintain a feasible solution x to the LP (1) with laminar support $\mathcal{L}_x$ and a set $\mathcal{L}^*$ of pairwise vertex-disjoint cycles with $V(\mathcal{L}_x) \cap V(\mathcal{L}^*) = \emptyset$. Step 1 can be done in polynomial time [5]. For step 2 we apply Lemma 8. Then, in each iteration we add a set $\mathcal{F}^*$ of cycles in the support of x to $\mathcal{L}^*$ and set x on all neighbours of $\mathcal{F}^*$ to 0.

We will make use of the following observation: If in each iteration we find a set $\mathcal{F}^*$ with $x\left(\bigcup_{C\in\mathcal{F}^*} \mathcal{N}_{\mathcal{L}_x}(C)\right) \leq \alpha|\mathcal{F}^*|$ then the algorithm will return a solution of size at least $\frac{1}{\alpha}$ times the LP value. Thus, in order to bound the integrality gap of the cycle packing LP we only need to analyze the minimum values of $\frac{x\left(\bigcup_{C\in\mathcal{F}^*} \mathcal{N}_{\mathcal{L}_x}(C)\right)}{|\mathcal{F}^*|}$ that we can achieve with different choices of $\mathcal{F}^*$.

Note that after step 2 the algorithm only operates on the (explicitly given) set of cycles in the support of the LP solution and does not depend on $\mathcal{C}$ any more. Both the uncrossing property and the weight oracle are used only in this step. In particular, our results apply to any cycle family $\mathcal{C}$ where step 2 can be done, for example if $\mathcal{C}$ is already laminar.

We first explain in more detail what step 4 does:

▶ **Definition 10.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embeddded in the sphere. We call a two-sided cycle $C \in \mathcal{L}$* redundant *if it is homotopic to a one-sided cycle in $\mathcal{L}$ (cf. Figure 1).*

▶ **Definition 11.** *Let $x \in \mathbb{R}^{\mathcal{C}}$ be a solution to the LP* (1)*. We call it* structured *if the support of x is laminar and each connected component $\mathcal{L}$ of the support of x contains no redundant cycles.*

▶ **Lemma 12.** *Let $x \in \mathbb{R}^{\mathcal{C}}$ be a feasible solution to the LP* (1) *with laminar support $\mathcal{L}$. Then we can compute a structured solution $x' \in \mathbb{R}^{\mathcal{L}}$ to* (1) *with $\sum_{C\in\mathcal{L}} x_C = \sum_{C\in\mathcal{L}} x'_C$ in polynomial time in the size of $\mathcal{L}$.*

Proof. We can consider connected components of $\mathcal{L}$ separately, so assume w.l.o.g. that $E(\mathcal{L})$ is connected. Assume that x is not structured. Let $C \in \mathcal{L}$ be redundant with a side S that contains no other redundant cycles. In particular, S contains only one cycle $C' \neq C$ in $\mathcal{L}$. Since $E(\mathcal{L})$ is connected, $x(C) + x(C') \leq 1$. Thus, we can shift the LP value from C to C', i.e. set $x'(C') := x(C) + x(C')$ and $x'(C) := 0$, removing C from the support. This does not affect feasibility of the LP solution since it increases the LP value only on vertices strictly inside S, which are contained in no other cycles than C' due to minimality of S. See Figure 1.

Applying this reduction at most $|\mathcal{L}|$ times results in a solution as desired. ◀

Next, we analyze the ratio $\frac{x\left(\bigcup_{C\in\mathcal{F}^*} \mathcal{N}_{\mathcal{L}_x}(C)\right)}{|\mathcal{F}^*|}$ that we can achieve. In this section we only consider the case that $\mathcal{F}^*$ consists of a single one-sided cycle. We use the following Structure Lemma. The proof can be found in Section 4.

▶ **Lemma 13.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere, such that $\mathcal{L}$ contains no redundant cycles. Let $\mathcal{L}_1$ be the set of one-sided cycles in $\mathcal{L}$. Then there is a multi-subset $M^* \subseteq V(G)$ with $|M^*| \leq 3|\mathcal{L}_1|$ such that for any $C \in \mathcal{L}$ we have $|M^* \cap V(C)| \geq |\mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}|$.*

▶ **Lemma 14.** *Let x be a structured solution to the vertex-disjoint cycle packing LP. Let $\mathcal{L}$ be a connected component of the support of x and $\mathcal{L}_1$ the set of one-sided cycles in $\mathcal{L}$. Then*

$$\sum_{C\in\mathcal{L}_1} x(\mathcal{N}_{\mathcal{L}}(C) \setminus \{C\}) \leq 3|\mathcal{L}_1|.$$

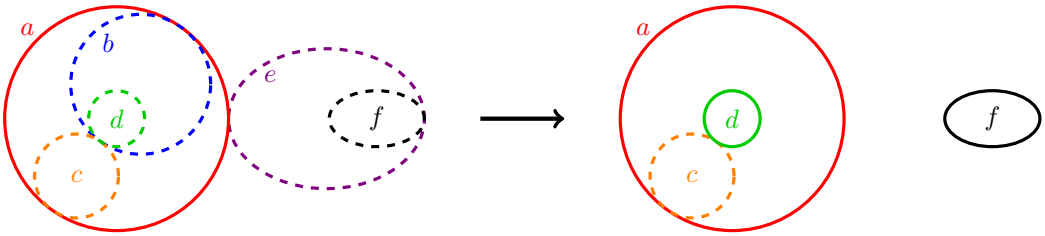

Figure 1 The left picture shows a possible laminar support of a feasible LP solution, consisting of six cycles. Dashed cycles have LP value $\frac{1}{3}$, while the others have LP value $\frac{2}{3}$. The cycles b and e are redundant because their interiors each contain only one other cycle; also a is redundant because its exterior only contains the one-sided side of f.
In the proof of Lemma 12 we would pick the interiors of b and e as S in the first and second step, increasing the LP value of d and f and removing b and e from the support. This yields a support as in the right image. The cycle a is still redundant, however in the laminar family given by its connected component it is one-sided and therefore not redundant. Thus, the solution is structured.

Proof. By the Structure Lemma 13, choose $M^* \subseteq V(G)$ with $|M^*| \leq 3|\mathcal{L}_1|$ such that for any $C \in \mathcal{L}$ we have $|M^* \cap V(C)| \geq |\mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}|$. We get

$$\begin{aligned}
&\sum_{C \in \mathcal{L}_1} x(\mathcal{N}_{\mathcal{L}}(C) \setminus \{C\}) \\
&= \sum_{C \in \mathcal{L}} x(C) \cdot |\mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}| \\
&\leq \sum_{C \in \mathcal{L}} x(C) \cdot |M^* \cap V(C)| \\
&\leq \sum_{v \in M^*} \sum_{C \in \mathcal{L}: v \in C} x(C) \;\leq\; |M^*| \;\leq\; 3|\mathcal{L}_1|.
\end{aligned}$$

◀

Since the LP value of each single cycle itself is bounded by 1 this immediately yields an upper bound of 4 for the integrality gap of (1):

▶ **Theorem 15.** *Let G be a planar graph, embedded in the sphere, and $\mathcal{C}$ an uncrossable family of cycles in G. Then there exists an integral solution to the vertex-disjoint cycle packing LP with at least $\frac{1}{4}$ the LP value. If $\mathcal{C}$ is given by a weight oracle we can compute such a solution in polynomial time.*

Proof. Let x be an optimum solution to the LP (1) with laminar support, as given by Lemma 8. By applying Lemma 12 we can assume x to be structured. Let $\mathcal{L}_x := \{C \in \mathcal{C} : x_C > 0\}$ be the (laminar) support of x. We proceed on each connected component of $\mathcal{L}_x$ individually, so we may assume $E(\mathcal{L}_x)$ to be connected.

Let $\mathcal{L}_1 \subseteq \mathcal{L}_x$ be the set of one-sided cycles. In each step of our greedy rounding algorithm we add a one-sided cycle C^* in $\mathcal{L}_x$ to our solution and set x on all cycles containing a vertex of C^* to 0, removing them from the support of x.

Lemma 14 implies

$$\sum_{C \in \mathcal{L}_1} x(\mathcal{N}_{\mathcal{L}_x}(C)) \leq 3|\mathcal{L}_1| + \sum_{C \in \mathcal{L}_1} x(C) \leq 4|\mathcal{L}_1|.$$

So there exists a one-sided cycle C^* where removing $\mathcal{N}_{\mathcal{L}_x}(C^*)$ decreases x by at most 4.

After the first iteration we again apply Lemma 12 and split the support of x into connected components. Iterating this procedure until $x = 0$ yields a solution as desired.

Note that Lemma 8 works in polynomial time if $\mathcal{C}$ has a weight oracle. Thus, also the size of $\mathcal{L}$ is polynomial in the size of G and Lemma 12 also works in polynomial time. In each step we can find C^* by picking the one-sided cycle in $\mathcal{L}_x$ minimizing $x(\mathcal{N}_{\mathcal{L}_x}(C^*))$. ◀

The greedy rounding algorithm described above also allows for adding several cycles at once to the solution. We will exploit this in Section 5 to decrease the upper bound for the integrality gap to below 3.5.

4 Proof of the Structure Lemma

The proof of the Structure Lemma 13 is fairly technical. In this version of the paper we only give a full proof for the case that no two-sided cycles exist and afterwards briefly discuss how to extend this proof to the general version of the Lemma. A detailed proof of Lemma 13 can be found in the full version of the paper.

First, let us consider the case that all cycles are one-sided. In this case we start by constructing another planar graph G' on vertex set $\mathcal{L}_1 = \mathcal{L}$ as follows:

For any vertex $v \in V(G)$ let $\mathcal{L}_v \subseteq \mathcal{L}$ be the set of cycles containing v. Since all cycles are one-sided, there is a natural cyclic order $\mathcal{L}_v = \{C_1 =: C_{k+1}, C_2, \dots, C_k\}$ on $\mathcal{L}_v$. Then we add for any $i = 1, \dots, k$ the edge $\{C_i, C_{i+1}\}$ with its obvious planar embedding to G'. Finally, we identify homotopic edges in G' (i.e. parallel edges bounding an area homeomorphic to the disk). See Figure 2.

Now from G' we can construct our multi-set M^*: For each $e = \{C_1, C_2\} \in E(G')$ we add an arbitrary vertex in $V(C_1) \cap V(C_2)$ to M^*; furthermore, for each vertex $v \in V(G)$ that is contained in $k > 3$ cycles we add $k - 3$ copies of v to M^*. Since in this case v lies inside a face of G' with exactly k edges on its boundary we can construct another planar graph G^* from G' by triangulating each such face F with $k - 3$ edges inside F (cf. Figure 2).

This yields a planar graph G^* on vertex set $\mathcal{L}_1$ with $|M^*|$ edges and no homotopic edges. Euler's formula implies $|M^*| = |E(G^*)| \leq 3|V(G^*| - 6 = 3|\mathcal{L}_1| - 6$.

Let now $C \in \mathcal{L}$ and $\mathcal{B} \subseteq \mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}$ be the set of all neighbours of C that are not connected to C in G'. By construction of G' this means that for any vertex $v \in V(C)$ that is contained in k cycles at most $k - 3$ of them can be in $\mathcal{B}$. But we added $k - 3$ copies of v to M^*. This proves $|M^* \cap V(C)| \geq |\mathcal{B}| + |\delta_{G'}(C)| \geq |\mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}|$.

Next, we have to consider also two-sided cycles. However, we do not know how to extend the relatively easy construction of G' and G^* to this more general case. Instead, we will use the notion of *incidences*:

▶ **Definition 16.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere. Let $\mathcal{L}_1 \subseteq \mathcal{L}$ be the set of one-sided cycles. A* neighbour pair *is a pair $(\{C, N\}, v)$ of a set of two cycles $C, N \in \mathcal{L}$ that are not homotopic and a vertex $v \in V(C) \cap V(N)$. We call two neighbour pairs $(\{C, N\}, v)$ and $(\{C, N\}, v')$* homotopic *if there exist v-v'-paths P in C and P' in N such that $P + P'$ bounds an area that contains all one-sided sides in $\mathcal{L}$.*

It is easy to see that homotopy defines an equivalence relation on neighbour pairs. An equivalence class of neighbour pairs for C and N is called an incidence *between C and N. The* vertex set *$V(I)$ of an incidence I between C and N is the set of all v with $(\{C, N\}, v) \in I$. We also denote I by $I = (\{C, N\}, V(I))$. For a cycle $C \in \mathcal{L}$ let $\mathcal{I}^1_{\mathcal{L}}(C)$ be the set of all incidences between C and one-sided cycles in $\mathcal{N}^1_{\mathcal{L}}(C)$.*

Let now I be an incidence between $C \in \mathcal{L}$ and $N \in \mathcal{N}_{\mathcal{L}}(C)$. Let S_C be a side of C and S_N a side of N such that S_C and S_N are disjoint. We call an incidence $I' = (\{C', N'\}, V(I'))$ a sub-incidence *of I if C' is inside S_C, N' is inside S_N and $V(I') \subseteq V(I)$. We call I*

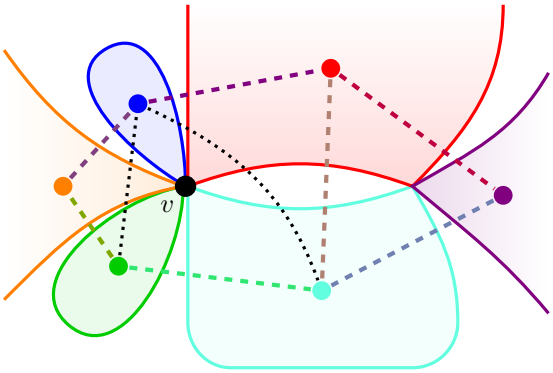

Figure 2 Example for the case that no two-sided cycles exist: The coloured cycles are the elements of $\mathcal{L}_1$. The vertices of G' are drawn as nodes inside the one-sided sides. The edges of G' are drawn as thick dashed lines. Since five cycles meet in the vertex v we would add v twice to M^*, in addition to the vertices in M^* corresponding to edges of G'. This is possible while keeping $|M^*| \leq 3|\mathcal{L}_1| - 6$ because we can triangulate the face of G' that v lies in with two additional edges; as indicated by the dotted lines.

minimal *if any sub-incidence of I is equal to I. We call I* crossing *if $V(I) = \{v\}$ for some $v \in V(G)$ and there exist cycles $C_1, C_2 \in \mathcal{L}$ that also contain v with sides S_1 and S_2 such that S_C, S_1, S_N, S_2 are all disjoint and are ordered in this way around v. Such incidences are also called* v-incidences. *If I is not crossing we call it* non-crossing.

Extending the idea of including the edges of G' in M^*, in order to prove Lemma 13 we will construct a set of incidences instead of a set of vertices.

▶ **Definition 17.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere. Let $\mathcal{L}_1 \subseteq \mathcal{L}$ be the set of one-sided cycles. Let M be a multi-set of incidences in $\mathcal{L}$. We say that an element $I \in M$* hits *a cycle $C \in \mathcal{L}$ if $V(I) \subseteq V(C)$. We call a cycle $C \in \mathcal{L}$* M-good *if at least $|\mathcal{I}^1_{\mathcal{L}}(C)|$ elements of M hit C. We call M* good *if all cycles in $\mathcal{L}$ are M-good and $|M| \leq 3|\mathcal{L}_1| - 6$. Furthermore, we call M* structured *if the following properties hold:*

1. *M contains every non-crossing incidence between one-sided cycles.*
2. *For each $C \in \mathcal{L}_1$ and $v \in V(C)$ there exist at least as many v-incidences in M as there are v-incidences between C and $\mathcal{N}^1_{\mathcal{L}}(C)$ in $\mathcal{L}$.*

This notion of structured incidence sets is inspired from the construction of M^* in the case $\mathcal{L} = \mathcal{L}_1$: The edges in G' correspond to non-crossing incidences between one-sided cycles, which are included in M by property 1. Property 2 makes sure that vertices in which many one-sided cycles meet are included in M. In particular, we get the following as a direct consequence of the above definition:

▶ **Lemma 18.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere. Let M be a structured set of incidences in $\mathcal{L}$. Then every one-sided cycle is M-good.*

Via an induction on the number of cycles in a laminar family $\mathcal{L}$ we can show existence of a good and structured set. The proof is a bit technical and can be found in the full version of the paper.

▶ **Lemma 19.** *Let $\mathcal{L}$ be a laminar family of at least two cycles in a planar graph G, embedded in the sphere. Let $\mathcal{L}_1$ be the set of one-sided cycles in $\mathcal{L}$. Then there exists a good and structured set M of incidences in $\mathcal{L}$.*

As a direct consequence of this lemma we get the Structure Lemma 13:

▶ **Lemma 13.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere, such that $\mathcal{L}$ contains no redundant cycles. Let $\mathcal{L}_1$ be the set of one-sided cycles in $\mathcal{L}$. Then there is a multi-subset $M^* \subseteq V(G)$ with $|M^*| \leq 3|\mathcal{L}_1|$ such that for any $C \in \mathcal{L}$ we have $|M^* \cap V(C)| \geq |\mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}|$.*

Proof. W.l.o.g. $|\mathcal{L}| \geq 2$. By Lemma 19 let M be a good set of incidences in $\mathcal{L}$. Let M^* arise from adding one element of $V(I)$ for every $I \in M$. In particular, $|M^*| = |M| \leq 3|\mathcal{L}_1| - 6$.

Let $C \in \mathcal{L}$. Since no side of C is redundant, it is not homotopic to any cycle in $\mathcal{L}_1$. Thus,

$$|\mathcal{N}^1_{\mathcal{L}}(C) \setminus \{C\}| \leq |\mathcal{I}^1_{\mathcal{L}}(C)| \leq |\{I \in M : V(I) \subseteq V(C)\}| \leq |M^* \cap V(C)|. \qquad \blacktriangleleft$$

5 Improving the bounds below 3.5

In this section we improve the bound on the integrality gaps of the LPs (1) and (2) to $\frac{13+3\sqrt{7}}{6} < 3.5$. We first only consider the vertex-disjoint cycle packing LP (1); an extension to the edge-disjoint case is given in Section 5.2.

5.1 The vertex-disjoint version

We still use Algorithm 1 from Section 3 for the improved approximation guarantee, but add further possibilities for the set $\mathcal{F}^*$ of cycles that are added to our solution during a single iteration. Note that the single cycle that we use in Theorem 15 already gives a good approximation guarantee if the average LP value on one-sided cycles is small. On the other hand, if the average LP value on one-sided cycles is large then we will find a large set of pairwise vertex-disjoint cycles with relatively small neighbourhood which we can take as $\mathcal{F}^*$. For analyzing the case of $\mathcal{F}^*$ containing more than one cycle we use the following Lemma:

▶ **Lemma 20.** *Let $\mathcal{L}$ be a laminar family of cycles in a planar graph G, embedded in the sphere. Let $\mathcal{L}_1$ be the set of one-sided cycles in $\mathcal{L}$. Let $\mathcal{F} \subseteq \mathcal{L}_1$. Then there is a set $M \subseteq V(\mathcal{F})$ with $|M| \leq |\mathcal{F}| + |\mathcal{L}_1|$ such that each cycle in $\mathcal{L}$ is either vertex-disjoint to all cycles in $\mathcal{F}$ or contains a vertex from M.*

Proof. W.l.o.g. $|\mathcal{L}| > 1$. We can also assume that there exists a point p_∞ on the sphere that lies neither on the embedding of vertices or edges in G nor in any one-sided side of a cycle in $\mathcal{L}_1$ (if this is not the case we can replace an arbitrary edge in G by two parallel edges, which does not affect the lemma's statement). For this proof, we call the side of a cycle $C \in \mathcal{L}$ that does not contain p_∞ the interior of C and say C contains a cycle $C' \in \mathcal{L}$, or $C' \subseteq C$, if the interior of C' is contained in the interior of C.

Let $\mathcal{B}_{\text{int}} \subseteq \mathcal{L}$ be the set of cycles C such that there is a cycle $C' \in \mathcal{F}$ with $C' \subseteq C$ and $V(C) \cap V(C') \neq \emptyset$. In particular, $\mathcal{F} \subseteq \mathcal{B}_{\text{int}}$. Let $f \colon \mathcal{B}_{\text{int}} \to \mathcal{F}$ such that each $C \in \mathcal{B}_{\text{int}}$ contains $f(C)$ and shares a vertex with $f(C)$. Then for any $C \in \mathcal{F}$ all cycles in $f^{-1}(C)$ must build a chain and therefore meet in some vertex $v_C \in V(C)$. Thus, $M_{\text{int}} := \{v_C : C \in \mathcal{F}\}$ hits all cycles in $\mathcal{B}_{\text{int}}$.

Let now $\mathcal{B}_{\text{ext}} \subseteq \mathcal{L} \setminus \mathcal{B}_{\text{int}}$ be the set of all cycles in $\mathcal{L} \setminus \mathcal{B}_{\text{int}}$ that share a vertex with any cycle in $\mathcal{F}$. We show by induction on $|\mathcal{L}_1|$ that we can hit all cycles in $\mathcal{B}_{\text{ext}}$ with some $M_{\text{ext}} \subseteq V(\mathcal{F})$ with $|M_{\text{ext}}| \leq |\mathcal{L}_1|$: For $|\mathcal{L}_1| = 1$ this is trivial. Otherwise, let $C_1 \in \mathcal{B}_{\text{ext}}$ be minimal w.r.t. $\subseteq$ and $C_2 \in \mathcal{F}$ with some vertex $v \in V(C_1) \cap V(C_2)$ (cf. Figure 3). Construct another laminar family $\mathcal{L}'$ by deleting all cycles inside C_1 and all cycles in $\mathcal{L} \setminus \mathcal{F}$ that contain v. Since C_1 contains some one-sided cycle, $\mathcal{L}'$ contains strictly less one-sided cycles and we

can use the induction hypothesis on $\mathcal{L}'$. Also the deletion of cycles inside C_1 does (except for C_1 itself) not change $\mathcal{B}_{\text{ext}}$ because $C_1 \notin \mathcal{B}_{\text{int}}$ and C_1 was minimal. Thus, the induction hypothesis gives us a set $M'_{\text{ext}} \subseteq V(\mathcal{F})$ that hits all cycles in $\mathcal{B}_{\text{ext}} \cap \mathcal{L}'$ with $|M'_{\text{ext}}| \leq |\mathcal{L}_1| - 1$, so $M_{\text{ext}} := M'_{\text{ext}} \cup \{v\}$ has the desired properties.

Setting $M := M_{\text{int}} \cup M_{\text{ext}}$ yields a set as desired in the Lemma. ◀

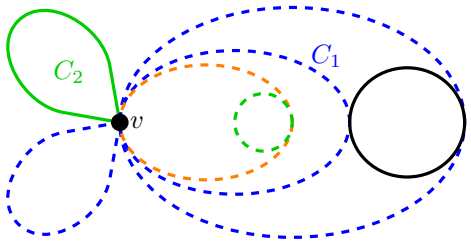

Figure 3 The cycles in $\mathcal{F}$ are drawn in green, the cycles in $\mathcal{B}_{\text{ext}}$ in blue. Note that the orange cycle is not in $\mathcal{B}_{\text{ext}}$ because it is in $\mathcal{B}_{\text{int}}$. The inside of C_1 contains no other cycles in $\mathcal{B}_{\text{ext}}$ and C_1 meets $C_2 \in \mathcal{F}$ in v. We then add v to our set M_{ext} and recurse on the laminar family $\mathcal{L}'$ that is constructed by removing all cycles inside C_1 and all cycles that contain v and are not in $\mathcal{F}$. These cycles are drawn dashed. This step decreases the number of one-sided cycles.

In the following, we assume $\mathcal{C}$ to be an uncrossable family of cycles in a graph G, embedded in the sphere. We further assume $x \in \mathbb{R}^{\mathcal{C}}$ to be a structured solution to the LP (1) with support $\mathcal{L}_x$. As in Theorem 15 we can assume $E(\mathcal{L}_x)$ to be connected. Let $\mathcal{L}_1 \subseteq \mathcal{L}_x$ be the set of one-sided cycles in $\mathcal{L}_x$. For each $0 \leq \alpha < 1$ we define $\mathcal{L}_1^{>\alpha} \subseteq \mathcal{L}_1$ to be the set of one-sided cycles with LP value $> \alpha$ and set $r_\alpha := \frac{|\mathcal{L}_1^{>\alpha}|}{|\mathcal{L}_1|}$.

We will now give two possible choices for $\mathcal{F}^*$ in Algorithm 1. The first possibility is to choose a set consisting of a single cycle in $\mathcal{L}_1$ as $\mathcal{F}^*$, as in Theorem 15. By Lemma 14 we directly get:

▶ **Lemma 21.** *There exists a cycle $C^* \in \mathcal{L}_1$ with $x(\mathcal{N}_{\mathcal{L}_x}(C^*)) \leq 3 + \frac{x(\mathcal{L}_1)}{|\mathcal{L}_1|}$.*

As a second possibility we will define a set $\mathcal{F}^*_\alpha$ for each $\frac{1}{4} \leq \alpha < \frac{1}{2}$. Given such an α, we consider the set $\mathcal{L}_1^{>\alpha}$. We know that at most three cycles in $\mathcal{L}_1^{>\alpha}$ can share a vertex. Let G' be the *conflict graph* for the cycles in $\mathcal{L}_1^{>\alpha}$; i.e. G' is the graph on vertex set $\mathcal{L}_1^{>\alpha}$ such that two cycles in $\mathcal{L}_1^{>\alpha}$ are connected by an edge in G' if and only if they share a vertex in G. Since each vertex is contained in at most three cycles of $\mathcal{L}_1^{>\alpha}$, G' can be constructed similarly to the graph G' in the proof of the Structure Lemma for $\mathcal{L} = \mathcal{L}_1$ (see Section 4). Thus, G' is planar. Furthermore, the cycles in $\mathcal{L}_1^{>1-\alpha} \subseteq \mathcal{L}_1^{>\alpha}$ correspond to isolated vertices in G'. By the Four Colour Theorem [1] we can partition $V(G') - \mathcal{L}_1^{>1-\alpha}$ into four stable sets. The largest of those, together with $\mathcal{L}_1^{>1-\alpha}$, yields a stable set in G' of size at least $|\mathcal{L}_1^{>1-\alpha}| + \frac{1}{4}(|\mathcal{L}_1^{>\alpha}| - |\mathcal{L}_1^{>1-\alpha}|)$. We let $\mathcal{F}^*_\alpha$ be the set of cycles in $\mathcal{L}_1^{>\alpha}$ corresponding to such a stable set in G'. By the definition of G' this means that the cycles in $\mathcal{F}^*_\alpha$ are pairwise vertex-disjoint.

▶ **Lemma 22.** *For any $\frac{1}{4} \leq \alpha < \frac{1}{2}$ we have*

$$\frac{x\left(\bigcup_{C' \in \mathcal{F}^*_\alpha} \mathcal{N}_{\mathcal{L}_x}(C')\right)}{|\mathcal{F}^*_\alpha|} \leq 1 + \frac{4(1-\alpha)}{r_\alpha + 3r_{1-\alpha}}.$$

Proof. Let $\frac{1}{4} \leq \alpha < \frac{1}{2}$. By Lemma 20 there is a set $M \subseteq V(\mathcal{F}^*_\alpha)$ with $|M| \leq |\mathcal{F}^*_\alpha| + |\mathcal{L}_1|$ such that each cycle in $\bigcup_{C' \in \mathcal{F}^*_\alpha} \mathcal{N}_{\mathcal{L}_x}(C')$ contains a vertex of M. Now

$$\begin{aligned} & x\left(\bigcup_{C' \in \mathcal{F}^*_\alpha} \mathcal{N}_{\mathcal{L}_x}(C')\right) \\ \leq & \sum_{v \in M} x(\{C \in \mathcal{L}_x \setminus \mathcal{F}^*_\alpha : v \in V(C)\}) + x(\mathcal{F}^*_\alpha) \\ \leq & |\mathcal{F}^*_\alpha| + (1-\alpha)|\mathcal{L}_1| \end{aligned}$$

holds, where the last inequality follows from the fact that there are $|\mathcal{F}^*_\alpha|$ vertices in M covering $\mathcal{F}^*_\alpha$, and for the other vertices we only have to count the LP value of cycles not in $\mathcal{F}^*_\alpha$. Inserting the bound $|M^*_\alpha| \geq |\mathcal{L}_1^{>1-\alpha}| + \frac{1}{4}(|\mathcal{L}_1^{>\alpha}| - |\mathcal{L}_1^{>1-\alpha}|)$ yields

$$\frac{x\left(\bigcup_{C' \in \mathcal{F}^*_\alpha} \mathcal{N}_{\mathcal{L}_x}(C')\right)}{|\mathcal{F}^*_\alpha|} \leq 1 + \frac{(1-\alpha)|\mathcal{L}_1|}{|\mathcal{F}^*_\alpha|} \leq 1 + \frac{4(1-\alpha)}{r_\alpha + 3r_{1-\alpha}}.$$ ◀

One of these possibilities for $\mathcal{F}^*$ will be sufficient to prove the desired upper bound of $\frac{13+3\sqrt{7}}{6}$ for the integrality gap:

▶ **Lemma 23.** *There exists a set $\mathcal{F}^* \subseteq \mathcal{L}_1$ with $\frac{x\left(\bigcup_{C' \in \mathcal{F}^*} \mathcal{N}_{\mathcal{L}_x}(C')\right)}{|\mathcal{F}^*|} \leq \frac{13+3\sqrt{7}}{6}$.*

Proof. Define $\beta := \frac{13+3\sqrt{7}}{6}$. We will either pick one of the sets $\mathcal{F}^*_\alpha$ for $\frac{1}{4} \leq \alpha < \frac{1}{2}$ from Lemma 22 or we will use $\mathcal{F}^* := \{C^*\}$ with the cycle C^* from Lemma 21. Assume none of these sets $\mathcal{F}^*$ fulfills the above inequality. Then Lemma 22 implies

$$\begin{aligned} & 1 + \frac{4(1-\alpha)}{r_\alpha + 3r_{1-\alpha}} > \beta \\ \Leftrightarrow \quad & r_\alpha + 3r_{1-\alpha} < \frac{4(1-\alpha)}{\beta - 1} \end{aligned}$$

for $\frac{1}{4} \leq \alpha < \frac{1}{2}$. Furthermore, we have

$$x(\mathcal{L}_1) = \sum_{C \in \mathcal{L}_1} \int_0^1 \mathbb{1}_{x(C) > \alpha} d\alpha = \int_0^1 \sum_{C \in \mathcal{L}_1} \mathbb{1}_{x(C) > \alpha} d\alpha = |\mathcal{L}_1| \int_0^1 r_\alpha d\alpha.$$

Thus, Lemma 21 implies

$$\beta < 3 + \int_0^1 r_\alpha d\alpha$$

By using the fact that the r_α are non-increasing, we get:

$$\begin{aligned} \beta < & \ 3 + \int_0^1 r_\alpha d\alpha \\ = & \ 3 + \int_0^{\frac{1}{3}} r_\alpha d\alpha + \int_{\frac{1}{3}}^{\frac{1}{2}} r_\alpha d\alpha + \int_{\frac{1}{2}}^1 r_\alpha d\alpha \\ \leq & \ 3 + \int_0^{\frac{1}{3}} r_\alpha d\alpha + \int_{\frac{1}{3}}^{\frac{1}{2}} r_\alpha d\alpha + 3\int_{\frac{1}{2}}^{\frac{2}{3}} r_\alpha d\alpha \\ = & \ 3 + \int_0^{\frac{1}{3}} r_\alpha d\alpha + \int_{\frac{1}{3}}^{\frac{1}{2}} r_\alpha + 3r_{1-\alpha} d\alpha \end{aligned}$$

$$\leq 3 + \int_0^{\frac{1}{3}} 1 d\alpha + \int_{\frac{1}{3}}^{\frac{1}{2}} \frac{4(1-\alpha)}{\beta - 1} d\alpha$$
$$= \frac{10}{3} + \frac{7}{18(\beta - 1)}.$$

This is a contradiction for $\beta = \frac{13+3\sqrt{7}}{6}$, which finishes the proof. ◀

As an immediate consequence we get our main theorem, similar to Theorem 15:

▶ **Theorem 24.** *Let G be a planar graph, embedded in the sphere, and $\mathcal{C}$ an uncrossable family of cycles in G. Then there exists an integral solution to the vertex-disjoint cycle packing LP with at least $\frac{6}{13+3\sqrt{7}}$ times the LP value. If $\mathcal{C}$ is given by a weight oracle we can compute such a solution in polynomial time.*

Proof. As in Theorem 15 we apply Algorithm 1. In contrast to the procedure in Theorem 15 however we use a set $\mathcal{F}^*$ as guaranteed by Lemma 23 in step 6 of the algorithm instead of a set consisting of just one one-sided cycle. Thus, in each step we increase the number of cycles with LP value 1 by $|\mathcal{F}^*|$ while decreasing the LP value on $\mathcal{L}_x$ by at most $\frac{13+3\sqrt{7}}{6}|\mathcal{F}^*|$. Therefore we arrive at an integral solution to the LP with at least $\frac{6}{13+3\sqrt{7}}$ times the LP value.

Note that a set $\mathcal{F}^*$ as in Lemma 23 can be found in time polynomial in $|\mathcal{L}_x|$: For the cycle guaranteed by Lemma 21 we can try all one-sided cycles. For the sets $\mathcal{F}^*_\alpha$ used in Lemma 22, note that there are only linearly many different sets $\mathcal{L}_1^{>\alpha}$ to consider. From those the sets $\mathcal{F}^*_\alpha$ are constructed by applying the Four Colour Theorem, which can also be done in polynomial time [23]. ◀

The upper bound on the integrality gap can still be slightly improved by also considering the sets $\mathcal{L}_1^{>\alpha}$ for $\alpha \geq \frac{1}{2}$ as candidates for $\mathcal{F}^*$. Using these candidates for large values of α in the inequality in Lemma 23 improves the bound in Lemma 23 and therefore also the bound in Theorem 24 slightly from $\frac{13+3\sqrt{7}}{6} \approx 3.4895$ to $\frac{20+\sqrt{130}}{9} \approx 3.4891$. We omit details here since the improvement is only marginal.

5.2 The edge-disjoint version

This section is dedicated to proving an edge-disjoint version of Theorem 24. One possibility to do this is to give edge-disjoint versions of Algorithm 1, the Structure Lemma 19 as well as Lemma 20 and then Lemma 23. All of this is possible analogous to the vertex-disjoint versions; however, we can also use a simple reduction by Schlomberg, Thiele and Vygen [24]. This does not generally reduce edge-disjoint cycle packing to vertex-disjoint cycle packing, but it does so for cycle packing in laminar cycle families.

▶ **Lemma 25** (similar to Schlomberg, Thiele, Vygen [24]). *Given a planar graph G, embedded in the sphere, and a laminar family $\mathcal{L}$ of cycles in G, we can compute in polynomial time a planar graph G' and a laminar family $\mathcal{L}'$ of cycles in G', together with a bijection $f\colon \mathcal{L} \to \mathcal{L}'$ such that for any $C_1, C_2 \in \mathcal{L}$ we have that $E(C_1) \cap E(C_2) = \emptyset$ if and only if $V(f(C_1)) \cap V(f(C_2)) = \emptyset$.*

Proof. Define $V(G') := E(G)$. For any path $P = e_1e_2$ of length two in a cycle $C \in \mathcal{L}$ we add the edge $e_C^P := \{e_1, e_2\}$ to $E(G')$. For any $C \in \mathcal{L}$ let $f(C)$ be the cycle consisting of all edges $e_C^P \in E(G')$ for any path P of length two inside C.

Since $\mathcal{L}$ is laminar, G' can be embedded planarly such that $\mathcal{L}' := \{f(C) : C \in \mathcal{L}\}$ defines a laminar family of cycles, as shown in Figure 4. By definition, all cycles in $\mathcal{L}'$ are edge-disjoint and two cycles $C_1, C_2 \in \mathcal{L}$ share an edge in G if and only if $f(C_1)$ and $f(C_2)$ share a vertex in G'. ◀

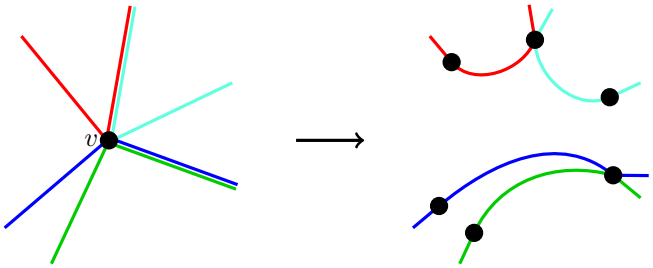

Figure 4 Example for the construction of G' and $\mathcal{L}'$: The left picture shows four cycles in $\mathcal{L}$ containing the vertex v. The six edges incident to v correspond to vertices of G', as shown in the right picture. Since $\mathcal{L}$ is laminar, the paths of length two in cycles of $\mathcal{L}$ can be embedded planarly as edges of G'. Cycles in $\mathcal{L}$ share an edge if and only if the corresponding cycles in $\mathcal{L}'$ share a vertex.

Using this reduction, we can easily extend Theorem 24 to the edge-disjoint case:

▶ **Theorem 26.** *Let G be a planar graph, embedded in the sphere, and $\mathcal{C}$ an uncrossable family of cycles in G. Then there exists an integral solution to the edge-disjoint cycle packing LP (2) a with at least $\frac{6}{13+3\sqrt{7}}$ times the LP value. If $\mathcal{C}$ is given by a weight oracle we can compute such a solution in polynomial time.*

Proof. We first apply Lemma 8 to get an optimum LP solution x to (2) with laminar support $\mathcal{L}$. We then apply Lemma 25 to get a laminar set $\mathcal{L}'$ of cycles in a planar graph G' with a bijection $f\colon \mathcal{L} \to \mathcal{L}'$ such that edge-disjointness in $\mathcal{L}$ translates to vertex-disjointness in $\mathcal{L}'$.

Note that $y \in \mathbb{R}^{\mathcal{L}'}$ with $y_{f(C)} = x_C$ for all $C \in \mathcal{L}$ defines a feasible solution to the LP (1) on $\mathcal{L}'$. Similar to Theorem 24 we can find an integral solution $\bar{y} \in \mathbb{R}^{\mathcal{L}'}$ to (1) on $\mathcal{L}'$ with $\bar{y}(\mathcal{L}') \geq \frac{6}{13+3\sqrt{7}} y(\mathcal{L}')$. Setting $\bar{x}_C := \bar{y}_{f(C)}$ for all $C \in \mathcal{L}$ then yields an integral solution to (2) on $\mathcal{L}$ with $\bar{x}(\mathcal{L}) = \bar{y}(\mathcal{L}') \geq \frac{6}{13+3\sqrt{7}} y(\mathcal{L}') = \frac{6}{13+3\sqrt{7}} x(\mathcal{L})$. ◀

Limits of Sequential Local Algorithms on the Random k-XORSAT Problem

Kingsley Yung
The Chinese University of Hong Kong, Hong Kong, China

Abstract

The random k-XORSAT problem is a random constraint satisfaction problem of n Boolean variables and $m = rn$ clauses, which a random instance can be expressed as a $G\mathbb{F}(2)$ linear system of the form $Ax = b$, where A is a random $m \times n$ matrix with k ones per row, and b is a random vector. It is known that there exist two distinct thresholds $r_{core}(k) < r_{sat}(k)$ such that as $n \to \infty$ for $r < r_{sat}(k)$ the random instance has solutions with high probability, while for $r_{core} < r < r_{sat}(k)$ the solution space shatters into an exponential number of clusters. Sequential local algorithms are a natural class of algorithms which assign values to variables one by one iteratively. In each iteration, the algorithm runs some heuristics, called local rules, to decide the value assigned, based on the local neighborhood of the selected variables under the factor graph representation of the instance.

We prove that for any $r > r_{core}(k)$ the sequential local algorithms with certain local rules fail to solve the random k-XORSAT with high probability. They include (1) the algorithm using the Unit Clause Propagation as local rule for $k \geq 9$, and (2) the algorithms using any local rule that can calculate the exact marginal probabilities of variables in instances with factor graphs that are trees, for $k \geq 13$. The well-known Belief Propagation and Survey Propagation are included in (2). Meanwhile, the best known linear-time algorithm succeeds with high probability for $r < r_{core}(k)$. Our results support the intuition that $r_{core}(k)$ is the sharp threshold for the existence of a linear-time algorithm for random k-XORSAT.

Our approach is to apply the Overlap Gap Property OGP framework to the sub-instance induced by the core of the instance, instead of the whole instance. By doing so, the sequential local algorithms can be ruled out at density as low as $r_{core}(k)$, since the sub-instance exhibits OGP at much lower clause density, compared with the whole instance.

1 Introduction

1.1 Background

The k-XORSAT problem is a Boolean constraint satisfaction problem and closely related to the well-known k-SAT problem. An instance Φ of the k-XORSAT problem consists of m clauses in n Boolean variables. Each clause is a Boolean linear equation of k variables of the form $x_{j_1} \oplus x_{j_2} \oplus \cdots \oplus x_{j_k} = b_j$, where $\oplus$ is the modulo-2 addition. By convention, when we say an XORSAT instance, without the prefix "k", we mean the same except we do not require the clauses to have exactly k variables. An **assignment** σ to the n variables is a mapping from the set $\{x_i : i \in [n]\}$ of all n variables to the set $\{0, 1\}$ of the two Boolean values. By abusing

the notation, we can write it as the Boolean vector $\sigma = (\sigma(x_1), \sigma(x_2), \cdots, \sigma(x_n)) \in \{0,1\}^n$ containing the assigned values. The **distance** $d(\sigma, \sigma')$ between any two assignments σ and σ' is defined to be the Hamming distance $d(\sigma, \sigma') = \sum_{i=1}^{n} \mathbb{1}(\sigma(x_i) \neq \sigma'(x_i))$. A clause is **satisfied by** an assignment if the equation of the clause holds when the variables are replaced by the corresponding assigned values, and an instance of the k-XORSAT problem is **satisfied by** an assignment if all its clauses are satisfied by the assignment. An instance is **satisfiable** if it has at least one satisfying assignment, or **unsatisfiable** if it does not have any satisfying assignment. The assignment σ that satisfies the instance Φ is called a **solution** for the instance. The set of all satisfying solutions for the instance Φ is called the **solution space** of the instance, denoted by $\mathcal{S}(\Phi)$. We are interested in the complexity of finding a solution.

Since each clause is just a Boolean linear equation, an instance Φ can be viewed as a Boolean linear system $Ax = b$, where $A \in \{0,1\}^{m \times n}$ is an $m \times n$ Boolean matrix and $b \in \{0,1\}^n$ is a vector of length n. Note that each row in A contains exactly k ones, since each clause has exactly k variables. We can see that finding solutions for a k-XORSAT instance is equivalent to solving a Boolean linear system, and the solution space $\mathcal{S}(\Phi)$ is an affine space inside $\{0,1\}^n$. By abusing the notation, we can simply write $\Phi = (A, b)$, and the terms "clause" and "equation" are interchangeable here.

We are particularly interested in random instances of the k-XORSAT problem. In a random instance $\mathbf{\Phi}$, each clause is drawn over all $2\binom{n}{k}$ possibilities, independently. In particular, the left-hand side of the equation is the modulo-2 sum of k variables chosen uniformly from $\binom{n}{k}$ possibilities, and the right-hand side is either 0 or 1 with even probabilities. Therefore, a random instance $\mathbf{\Phi}$ of the k-XORSAT problem is drawn uniformly from the ensemble $\mathbf{\Phi}_k(n, m)$ of all possible instances of the k-XORSAT problem with n variables and m clauses, each clause containing exactly k variables, and we denote this by $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, m)$. We focus on the regime in which the number of variables n goes to the infinity and the number of clauses m is proportional to the number of variables n, that is, $m = rn$, where r is a constant independent of n and called the *clause density*.

Since a k-XORSAT instance can be represented by a system of linear equations in $G\mathbb{F}(2)$, given an instance, some standard linear algebra methods such as the Gaussian elimination can determine whether the instance is satisfiable, find a solution, and even count the total number of solutions, in polynomial time. However, beyond this particular algebraic structure, some variants of the k-XORSAT problem is hard to solve. Achlioptas and Molloy mentioned in their paper [6] that random instances of the k-XORSAT problem seems to be extremely difficult for both generic CSP solvers and SAT solvers, which do not take the algebraic structure into account. Guidetti and Young [22] suggested that the random k-XORSAT is the most difficult for random walk type algorithms such as WalkSAT, among many random CSPs. The difficulty of solving random k-XORSAT instances becomes more apparent when we only consider linear-time algorithms as efficient algorithms, since we do not have linear-time algebraic method to solve a linear system in general.

Many studies suggest that the difficulties of solving random CSPs are related to the *phase transition* of the solution spaces when the clause density r grows. (We will have more detailed discussion in Section 1.3.) Pittel and Sorkin [34] obtained the sharp *satisfiability threshold* $r_{sat}(k)$ of random k-XORSAT, for general $k \geq 3$: The random k-XORSAT instance is satisfiable w.h.p. when $r < r_{sat}(k)$, and it is unsatisfiable w.h.p. when $r > r_{sat}(k)$. (We say an event $\mathcal{E}_n$, depending on a number n, occurs **with high probability**, or shortened to **w.h.p.**, if the probability of the event $\mathcal{E}_n$ occurring converges to 1 as n goes to the infinity, that is, $\lim_{n\to\infty} \Pr[\mathcal{E}_n] = 1$.) Furthermore, Ibrahimi, Kanoria, Kraning and Montanari [25] obtained the sharp *clustering threshold* $r_{core}(k)$, which is less than $r_{sat}(k)$, of random k-

XORSAT for $k \geq 3$. When $r < r_{core}(k)$, w.h.p. the solution space of a random k-XORSAT instance is "well-connected". When $r_{core}(k) < r < r_{sat}(k)$, w.h.p. the solution space of a random k-XORSAT instance shatters into an exponential number of "well-separated clusters". In [25], They also provided a linear-time algorithm that can solve a random k-XORSAT instance w.h.p. for $r < r_{core}(k)$. On the other hand, no algorithm is known to be able to find a solution for a random k-XORSAT instance with non-vanishing probability in linear time, for $r_{core}(k) < r < r_{sat}(k)$ in which solutions exist with high probability.

In this work, we consider a natural class of algorithms, called *sequential local algorithms*. A sequential algorithm selects an unassigned variable randomly and assigns a value to it, iteratively, until every variable has an assigned value. In each iteration of the algorithm, to decide the assigned value, the algorithm runs some heuristic called *local rules* which return a value $p \in [0, 1]$, and decide the assigned value to be either 0 or 1 randomly, according to the Bernoulli distribution with parameter p. Ideally, if in each iteration the local rule can calculate the exact marginal probability of the selected variable over a randomly chosen solution for the instance conditioned on fixing all previously selected variables to their assigned values, the algorithm should be able to find a solution. However, we restrict the ability of the local rules by only providing *local* structure to the local rules. To explain the meaning of "local", we first construct a graphical representation for the k-XORSAT instances: the *factor graph*. The *factor graph* G of a k-XORSAT instance Φ is constructed in the following way: (1) each variable is represented by a *variable node*; (2) each equation is represented by an *equation node*; (3) add an undirected edge (v, e) if the variable v is involved in the equation e. Note that since there is a one-to-one correspondence between variables (equations) and variable nodes (equation nodes), in this paper, the terms *variables (equations)* and *variable nodes (equation nodes)* are interchangeable. The *distance* between any two nodes is the number of edges in the shortest path connecting the two nodes. For any integer $R \geq 0$, the *local neighborhood* $B_G(v, R)$ with radius R of a node v is the subgraph of G induced by all nodes with distances less than or equal to R from the node v. By "local" in the name of the algorithms, it means the local rules only takes the local neighborhood of the selected variable, of radius R, as its input.

The actual implementation of a sequential local algorithm depends on the choice for the local rules. To emphasize the choices for the local rules of the algorithms, the sequential local algorithm with the given local rule τ is called the *τ-decimation algorithm* $\texttt{DEC}_\tau$. The formal definitions of the sequential local algorithms, as well as the τ-decimation algorithms, will be given in Section 1.4. Note that if the local rule τ takes constant time, then the τ-decimation algorithm also takes linear time.

We introduce a notion of *freeness* to the sequential local algorithms. For any iteration in which the local rule returns $1/2$, we call it a *free step*. Intuitively, a free step means the local rule cannot obtain useful information from the local structure and let the algorithms make a random guess for the assigned value. We say a τ-decimation algorithm is *δ-free* if w.h.p. it has at least δn free steps. Moreover, we say a τ-decimation algorithm is *strictly δ-free* if it is δ'-free for some $\delta' > \delta$. If the τ-decimation algorithm is δ-free with large $\delta > 0$, it means the algorithm makes a lot of random guess on the assigned values, and it is likely that the local rule τ cannot extract useful information from the local structure to guide the algorithm. This leads to our contribution described in the next section.

1.2 Main contribution

The main contribution of this work consists of two parts. The first part is to show that as $n \to \infty$ if the τ-decimation algorithm is strictly $2\mu(k, r)$-free then w.h.p. it fails to find a solution for the random k-XORSAT instance, when the clause density r is beyond the

clustering threshold $r_{core}(k)$ but below the satisfiability threshold $r_{sat}(k)$. This can be formally written as Theorem 1. The value $\mu(k,r)$ given in Theorem 1 is an upper bound of the number of variables removed from the instance in order to obtain the sub-instance called *core instance*, which is crucial in our proof. We will discuss its meaning in detail in Section 2.

▶ **Theorem 1.** *For any $k \geq 3$ and $r \in (r_{core}(k), r_{sat}(k))$, if the τ-decimation algorithm $\mathtt{DEC}_\tau$ is strictly $2\mu(k,r)$-free on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$, then w.h.p. the output assignment $\mathtt{DEC}_\tau(\mathbf{\Phi})$ from the algorithm $\mathtt{DEC}_\tau$ on input $\mathbf{\Phi}$ is not in the solution space $\mathcal{S}(\mathbf{\Phi})$, that is,*

$$\lim_{n\to\infty} \Pr\left[\, \mathtt{DEC}_\tau(\mathbf{\Phi}) \in \mathcal{S}(\mathbf{\Phi}) \,\right] = 0,$$

where Q is the largest solution of the fixed point equation $Q = 1 - \exp(-krQ^{k-1})$, and $\mu(k,r)$ is the real-valued function given by $\mu(k,r) = \exp(-krQ^{k-1}) + krQ^{k-1}\exp(-krQ^{k-1})$.

Note. This theorem can also be applied to the *non-sequential local algorithms* in which the algorithms run their local rules and decide the assigned value for each variable, *in parallel*, without depending on the other assigned values. We will briefly discuss the reason at the end of Section 1.6 where we discuss the proof technique we used.

The best known linear algorithm of finding a solution for the random k-XORSAT instance succeeds w.h.p., for $k \geq 3$ and $r < r_{core}(k)$ [25]. That means these sequential local algorithms do not outperform the best known linear algorithm. Note that $r_{core}(k)$ is where the best known linear algorithm succeeds up to, and where the sequential local algorithms starts failing. These support the intuition that $r_{core}(k)$ is the sharp threshold of the existence of a linear-time algorithm for random k-XORSAT problem.

The second part of our contribution is to verify that the "freeness" condition in Theorem 1 is satisfied by the τ-decimation algorithm with certain local rules τ. One of them is the simplest local rule, the Unit Clause Propagation `UC`, which tries to satisfy the unit clause on the selected variable if exists, or make random guess otherwise. By using the Wormald's method of differential equations to count the number of free steps run by `UC`-decimation algorithm $\mathtt{DEC}_{\mathtt{UC}}$, we can show that it is strictly $2\mu(k,r)$-free on the random k-XORSAT instance $\mathbf{\Phi}$ for $k \geq 9$, which leads to the following theorem.

▶ **Theorem 2.** *For any $k \geq 9$, $r \in (r_{core}(k), r_{sat}(k))$, given a random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$, we denote by $\mathtt{DEC}_{\mathtt{UC}}(\mathbf{\Phi})$ the output assignment from the `UC`-decimation algorithm $\mathtt{DEC}_{\mathtt{UC}}$ on input $\mathbf{\Phi}$. Then, we have $\lim_{n\to\infty} \Pr\left[\, \mathtt{DEC}_{\mathtt{UC}}(\mathbf{\Phi}) \in \mathcal{S}(\mathbf{\Phi}) \,\right] = 0$.*

In each iteration, the role of the local rules is to calculate the marginal probability of the selected variable in the instance conditioned on fixing all previously selected variables to their assigned values. Belief Propagation `BP` and Survey Propagation `SP` are surprisingly good at approximating marginal probabilities of variables over randomly chosen solutions in many random constraint satisfaction problems empirically [29, 21, 7, 36, 27]. In particular, it is well-known that they can calculate the exact marginal probabilities of variables when the underlying factor graph is a tree, which is proved analytically. If Belief Propagation `BP` and Survey Propagation `SP` are used as the local rule τ, it is natural to expect that the τ-decimation algorithm can find a solution. However, we prove that even the local rule τ can give the exact marginal probabilities of variables over a randomly chosen solution for any instance whose factor graph is a tree, the τ-decimation algorithm still cannot find a solution w.h.p. for $k \geq 13$. We know that w.h.p. the local neighborhood of the factor graph of the random k-XORSAT instance is a tree. Therefore, running `BP` and `SP` on the

local neighborhood actually gives the exact marginal probabilities of the selected variables, with respect to the sub-instance induced by the local neighborhood. This implies that both BP-decimation algorithm $\texttt{DEC}_{\texttt{BP}}$ and SP-decimation algorithm $\texttt{DEC}_{\texttt{SP}}$ fail to find a solution w.h.p. for $k \geq 13$.

▶ **Theorem 3.** *For any $k \geq 13$, $r \in (r_{core}(k), r_{sat}(k))$, given a random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$, denote by $\texttt{DEC}_\tau(\mathbf{\Phi})$ the output assignment from the τ-decimation algorithm $\texttt{DEC}_{\texttt{UC}}$ on input $\mathbf{\Phi}$. Assume the local rule τ outputs the exact marginal probability of a selected variable for any instance whose factor graph is a tree. Then, we have* $\lim_{n\to\infty} \Pr\left[\,\texttt{DEC}_\tau(\mathbf{\Phi}) \in \mathcal{S}(\mathbf{\Phi})\,\right] = 0$.

To prove Theorem 2 and Theorem 3, we only need to calculate the number of free steps in $\texttt{DEC}_{\texttt{UC}}$ and the number of free steps in $\texttt{DEC}_\tau$ with the assumption on τ described in Theorem 3. If the number of free steps is strictly greater than $2\mu(k, r)n$ with high probability, we know that they are strictly $2\mu(k, r)$-free, and the results follow immediately by applying Theorem 1. Similarly, to obtain the same results for other τ-decimation algorithms, all we need to do is to calculate the number of free steps for those algorithms. If they are strictly $2\mu(k, r)$-free, we can obtain the same results by applying Theorem 1. Note that, due to certain limitations of our calculation, our results are limited to $k \geq 9$ in Theorem 2 and $k \geq 13$ in Theorem 3. We believe that the results hold for general $k \geq 3$, and can be proved by improving some subtle calculation in our argument.

Although we only show a few of implementations of the sequential local algorithms, we believe that the results are general across many sequential local algorithms with different local rules due to Theorem 3. In the framework of sequential local algorithms, the role of the local rules is to approximate the marginal probabilities of the selected variables over a random solution for the instance induced by the local neighborhood centered at the selected variables. Therefore, we believe that for any local rule that can make a good approximation on the marginals, it shall give similar results as Theorem 3. (Note that a more general definition of "δ-free" may be useful, for example, we can say a τ-decimation algorithm is (δ, ϵ)-*free* if we have $|p - 1/2| < \epsilon$, where p is the value returned by the local rule, for at least δn iterations.)

It is worth to mention the differences between these implementations of the sequential local algorithms and their well-known variants. Firstly, the UC-decimation algorithm is slightly different from the well-known Unit Clause algorithm. Under the framework of sequential local algorithm, the variables are selected in a random order. However, in the well-studied Unit Clause algorithm the variables in unit clauses are selected first [5]. The difference in the variable order could be crucial to the effectiveness of the Unit Clause algorithm. Secondly, the BP-decimation algorithm and the SP-decimation algorithm are slightly different from the Belief Propagation Guided Decimation Algorithm [12] and Survey Propagation Decimation Algorithm [8, 7, 28]. In the framework of sequential local algorithms, we only provide the local neighborhood to BP and SP. It is equivalent to bounding the number of messages passed in each decimation step by the constant $R \geq 0$ in BP-guided Decimation Algorithm and SP-guided Decimation Algorithm. It is in contrast to many empirical studies of BP-guided Decimation Algorithm and SP-guided Decimation Algorithm which allow the message passing iteration to continue until it converges.

Moreover, this work provides a new variant of the *overlap gap property method*, which was originally introduced by Gamarnik and Sudan [20]. Instead of considering the overlap gap property of the whole instance, we utilize that property of a sub-instance of the random k-XORSAT instance. In particular, the proof of this work is inspired by [20], which uses the overlap gap property method to rule out the class of balanced sequential local algorithms

from being able to solve random NAE-k-SAT problem when the clause density is close to the satisfiability threshold. Instead of directly applying the method on the whole instance, we focus on the sub-instance induced by the 2-core of the factor graph of the instance. This modification help us obtain tight bounds of algorithmic threshold unlike [20]. If we apply the original overlap gap property method and use the first moment method to obtain the property, we are able to show that the sequential local algorithms fail to solve the random k-XORSAT problem when the clause density is lower than a certain threshold $r_1(k)$. However, that threshold $r_1(k)$ is much higher than the $r_{core}(k)$. It only tells us that the algorithms fails when the density is very close to the satisfiability threshold $r_{sat}(k)$. With our modification, we can lower that threshold to exactly $r_{core}(k)$, namely, the algorithms fail in finding a solution when the clause density is as low as the clustering threshold. This opens a new possibility to improve other results which use the overlap gap property method on other random constraint satisfaction problems.

1.3 Phase transition of random k-XORSAT

Many random ensembles of constraint satisfaction problems CSPs such as random k-SAT and random NAE-k-SAT are closely related to the random k-XORSAT. For example, the well-known random k-SAT is analogous to the random k-XORSAT, in the sense that we can obtain a k-XORSAT instance from a k-SAT instance by replacing OR operators with XOR operators. We are particularly interested in the existences of some sharp thresholds on the clause density r in which the behaviors of a random instance changes sharply when the clause density r grows and passes through those thresholds. The following three thresholds are particularly of interest.

1. The *satisfiability threshold* separates the regime where w.h.p. the random instance is satisfiable and the regime where w.h.p. it is unsatisfiable.
2. The *clustering threshold* separates the regime where w.h.p. the solution space can be partitioned into well-separated subsets, each containing an exponential small fraction of solutions, and the regime where w.h.p. the solution space cannot be partitioned in this way.
3. The *algorithmic threshold* separates the regime where we have an efficient algorithm that can find a solution for a satisfiable random instance with non-vanishing probability, and the regime where no such algorithm exists.

Many random constraint satisfaction problems such as random k-SAT, random NAE-k-SAT and random graph coloring share the following phenomena related to these thresholds [3].

- There is an upper bound of the (conjectured) satisfiability threshold.
- There is a lower bound of the (conjectured) satisfiability threshold, from the non-constructive proof, and the lower bound is essentially tight.
- There are some polynomial time algorithms that can find a solution when the density is relatively low, but no polynomial time algorithm is known to succeed when the density is close to the satisfiability threshold. This leads to a conjectured algorithmic threshold, which is asymptotically below the (conjectured) satisfiability threshold.
- The clustering phenomenon takes place when the density is greater than a (conjectured) clustering threshold, and this threshold is close to or even asymptotically equal to the algorithmic threshold.

It is worth to mention that not every random constraint satisfaction problems share this set of phenomena. The most notable example is *symmetric binary perceptron* (SBP). Its satisfiability threshold $\alpha_{sat}(k) > 0$ was established by [33, 2]. They also showed that SBP exhibits clustering property and almost all clusters are singletons, for clause density $\alpha > 0$.

On the other hand, [1] gave a polynomial-time algorithm that can find solutions w.h.p., for low clause density. Therefore, there is a regime of low clause density in which SBP exhibits clustering property, and it is solvable in polynomial time, simultaneously. Its clustering phenomenon does not cause the hardness.

Being analogous to the random k-SAT problem, the random k-XORSAT problem shares those phenomena with other random constraint satisfaction problems. However, the story is slightly different in the random k-XORSAT problem. Since the k-XORSAT instances are equivalent to Boolean linear systems, their solution spaces are simply some affine subspaces in the Hamming hypercube $\{0,1\}^n$. Because of their algebraic structures, we are able to obtain the existence and the (n-independent) value of the satisfiability threshold of the random k-XORSAT problem. Dubois and Mandler [14] proved that there exists an n-independent satisfiability threshold $r_{sat}(k)$ for $k = 3$, and determined the exact value of the sharp threshold by the second moment argument. Pittel and Sorkin [34] further extended it for general $k \geq 3$. An independent work on cuckoo hashing from [13] also included an argument of the k-XORSAT satisfiability threshold for general $k \geq 3$. Those proofs consider the 2-core of the hypergraph associated with the random k-XORSAT instance. (In graph theory, a *k-core* of a (hyper)graph is a maximal subgraph in which all vertices have degree at least k.) Based on the 2-core, we can construct a sub-instance, called *2-core instance* or simply *core instance* of the original instance. One can prove that the original instance is satisfiable if and only if core instance is satisfiable. [10, 30] studied the core instance and determined the satisfiability threshold of the core instance, which can be converted to the satisfiability threshold of the random k-XORSAT instance.

Mézard, Ricci-Tersenghi and Zecchina [30] started the study of the clustering phenomenon of random k-XORSAT, and linked it to the existence of the non-empty 2-core instance. From [35, 32, 26], we know the non-empty 2-core of random hypergraphs suddenly emerges at a critical edge density $r_{core}(k)$. After that, Ibrahimi, Kanoria, Kraning and Montanari [25], and Achlioptas and Molloy [6] independently proved that there exists the clustering threshold $r_{clt}(k)$, which is equal to $r_{core}(k)$ and smaller than $r_{sat}(k)$, such that w.h.p. the solution space is a connected component for density $r < r_{core}(k)$, and w.h.p. the solution space shatters into exponentially many $\Theta(n)$-separated components for density $r > r_{core}(k)$, provided that we consider the solution space as a graph in which we add an edge between two solutions if their Hamming distance is $O(\log n)$.

As we mentioned before, the random k-XORSAT instance can be written as a random Boolean linear system, so it can be solved in polynomial time by using linear algebra method, regardless the clause density. For example, Gaussian elimination can solve it in $O(n^3)$ time. Since we do not have linear time algebraic method to solve linear system, we can still study the algorithmic phase transition if we only consider linear-time algorithms as efficient algorithms. In the proofs in [25], they provided an algorithm that can find a solution in linear time when $r < r_{core}(k)$, which implies that $r_{core}(k)$ is a lower bound of the (linear-time version of) algorithmic threshold $r_{alg}(k)$ of the random k-XORSAT problem. We conjecture that no algorithm can solve the random k-XORSAT problem in linear time with non-vanishing probability when $r > r_{core}(k)$, which implies $r_{core}(k)$ is an upper bound of $r_{alg}(k)$ and thus $r_{alg}(k) = r_{core}(k)$. This would lead to the intimate relation between the failure of linear time algorithms on random k-XORSAT and the clustering phenomenon of its solution space.

1.4 Sequential local algorithms

Sequential local algorithms are a class of algorithms parametrized by a local rule τ that specifies how values should be assigned to variables based on the "neighborhoods" of the variables. Given a local rule τ, the sequential local algorithm can be written as the following *τ-decimation algorithm*.

Given a fixed even number $R \geq 0$, we denote by $\mathcal{I}_R$ the set of all instances in which each of those instances has exactly one of its variables selected as *root*, and all nodes in its factor graph have distances from the root variable node at most R. A **local rule** is defined to be a function $\tau : \mathcal{I}_R \to [0,1] \in \mathbb{R}$, mapping from $\mathcal{I}_R$ to the interval $[0,1]$. Given an instance Φ, since the local neighborhood $B_\Phi(x^*, R)$ of a variable node x^* represents a sub-instance of Φ induced by all nodes having distance at most R from the root variable node x^*, we have $B_\Phi(x^*, R) \in \mathcal{I}_R$ and $\tau(B_\Phi(x^*, R))$ is well-defined. Then, the τ-decimation algorithm can be expressed as the followings.

Algorithm 1 τ-decimation algorithm.

Input: an instance of the k-XORSAT problem Φ,
an even number $R \geq 0$, and
a local rule $\tau : \mathcal{I}_R \to [0,1]$.
Set $\Phi_0 = \Phi$.
for $t = 0, ..., n-1$ **do**
Select an unassigned variable x^* from Φ_t, uniformly at random.
Set $\sigma(x^*) = \begin{cases} 1 & \text{with probability } \tau(B_{\Phi_t}(x^*, R)) \\ 0 & \text{with probability } 1 - \tau(B_{\Phi_t}(x^*, R)) \end{cases}$
Obtain Φ_{t+1} from Φ_t by:
(i) remove x^*;
(ii) for any clause having x^* before (i), add $\sigma(x^*)$ to its right-hand-side value;
(iii) remove all clauses that no longer contain any variable.
end for
Output: the assignment σ.

For any $t \in [n]$, if the value $\tau(B_{\Phi_t}(x^*, R))$ given by the local rule τ in the t-th iteration is $1/2$, then we call that iteration a **free step**. In a free step, the τ-decimation algorithm simply assigns a uniformly random Boolean value to the selected variable. On the contrary, if the value $\tau(B_{\Phi_t}(x^*, R))$ given by the local rule τ in the t-th iteration is either 0 or 1, then we call that iteration a **forced step**. In a forced step, the τ-decimation algorithm is forced to assign a particular value to the selected variable according to the value $\tau(B_{\Phi_t}(x^*, R))$. To simplify our discussion, we introduce the following definitions for those τ-decimation algorithms having certain numbers of free steps.

▶ **Definition 4.** *For any $\delta \in [0,1]$, we say a τ-decimation algorithm $\texttt{DEC}_\tau$ is **δ-free** on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$ if w.h.p the τ-decimation algorithm $\texttt{DEC}_\tau$ on input $\mathbf{\Phi}$ has at least δn free steps.*

▶ **Definition 5.** *For any $\delta \in [0,1]$, we say a τ-decimation algorithm $\texttt{DEC}_\tau$ is **strictly δ-free** on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$ if there exists $\delta' > \delta$ such that the τ-decimation algorithm $\texttt{DEC}_\tau$ is δ'-free on $\mathbf{\Phi}$.*

There are many choices for the local rules τ. The simplest one is the Unit Clause Propagation UC. In each iteration, after selecting the unassigned variable x^*, UC checks whether there exists a unit clause (clause with one variable) on the variable x^*. If yes, then UC sets $\tau(B_{\Phi_t}(x^*, R))$ to be the right-hand-side value of the unit clause, which can force the decimation algorithm to pick the suitable value to satisfy that clause. In this case, this iteration is a forced step. (If there are multiple unit clauses on the selected variable x^*, then only consider the one with the lowest index.) If there is no unit clause on the selected variable x^*, then UC sets $\tau(B_{\Phi_t}(x^*, R))$ to $1/2$, which let the algorithm choose the assigned value randomly. In this case, this iteration is a free step.

Algorithm 2 Unit Clause Propagation `UC`.

Input: the selected variable x^*, and its local neighborhood $B_{\Phi_t}(x^*, 2)$
if there exists any unit clause on the variable x^* **then**
    Pick the unit clause c on the variable x^* (with the lowest index if having multiple such clauses).
    Output: the right-hand-side value of the clause c.
else
    Output: $1/2$.
end if

1.5 Message passing algorithms

A new challenger to break the algorithmic threshold came out from statistical mechanics. In experiments [29, 21, 7, 36, 27], the *message passing algorithms* demonstrated their high efficiency on finding solutions of random k-SAT problem with the densities close to the satisfiability threshold. Those algorithms include *Belief Propagation Guided Decimation Algorithm* and *Survey Propagation Guided Decimation Algorithm*, which are based on the insightful but non-rigorous *cavity method* from statistical mechanics [7, 36]. Unfortunately, several analyses showed that they do not outperform the best known algorithms for some problems. Coja-Oghlan [12] showed that BP-guided Decimation fails to find solutions for random k-SAT w.h.p. for density above $\rho_0 2^k/k$ for a universal constant $\rho_0 > 0$, and thus does not outperform the best known algorithm from [11]. Hetterich [23] also gave the same conclusion for SP-guided Decimation by showing that it fails w.h.p. for density above $(1 + o_k(1))2^k \ln k/k$.

For random NAE-k-SAT, Gamarnik and Sudan [20] showed that the balanced sequential local algorithms fail to find solutions for density above $(1 + o_k(1))2^{k-1} \ln^2 k/k$ for sufficiently large k. This means the algorithms do not outperform the best known algorithm, Unit Clause algorithm, which can find solutions w.h.p. for density up to $\rho\, 2^{k-1}/k$ for some universal constant $\rho > 0$ for sufficiently large k [5]. The framework of balanced sequential local algorithms also covers BP-guided Decimation and SP-guided Decimation with the number of message passing iterations is bounded by $O((\ln \ln n)^{O(1)})$.

In our work, we obtain an analogous result. In Theorem 1, we show that w.h.p. strictly $2\mu(k, r)$-free sequential local algorithms fails to solve the random k-XORSAT problem when the clause density exceeds the clustering threshold. Then, in Theorem 3, we show that any sequential local algorithm with local rule that can compute the exact marginals are strictly $2\mu(k, r)$-free and thus fails to find a solution for random k-XORSAT problem. This theorem covers the sequential local algorithms with Belief Propagation `BP` and Survey Propagation `SP` as local rules.

1.6 Technique

The works from [3, 4] demonstrated the clustering phenomenon for several random CSPs, and conjectured that it could be an obstruction of solving those problems. [19, 20] and subsequent works leveraged a different notion of clustering, named *overlap gap property* (OGP) by [18], to link the clustering phenomenon to the hardness rigorously. Gamarnik gave a detailed survey on it [15].

This paper focuses on the vanilla version of the OGP. Given an instance Φ of the constraint satisfaction problem, we say it exhibits the overlap gap property with values $0 \le v_1 < v_2$ if every two solutions σ and σ' satisfy either $d(\sigma, \sigma') \le v_1$ or $d(\sigma, \sigma') \ge v_2$, where d is a

metric on its solution space. (We assume d is the Hamming distance throughout this paper.) Intuitively, it means every pair of solutions are either close to each other, or far from each other, and thus the solution space of the instance exhibits a topological discontinuity based on the proximity.

Now we illustrate how does the overlap gap property method. (Some details of the overlap gap property method is slightly different if we consider different variants of the OGP, but the overall idea of *topological barrier* stays the same.) Assume we have an algorithm $\mathcal{A}$ that takes a random instance $\mathbf{\Phi}$ as input and outputs an assignment σ for the instance. The output σ can be viewed as a random variable which depends on both the random instance $\mathbf{\Phi}$ and some internal random variables, represented by a random internal vector $\mathbf{I}$, of the algorithm. Let Φ and I be realizations of $\mathbf{\Phi}$ and $\mathbf{I}$ respectively, and denote the output assignment as $\sigma_0 = \sigma_{\Phi,I}$. We then re-randomize the components of the internal vector I *one-by-one*. After each re-randomizing a component of I, we run the algorithm again to generate a new output assignment. Then, we obtain a sequence of assignments $\sigma_0, \sigma_1, \cdots, \sigma_T$ for the instance Φ, where T is the number of components of the random vector I that we have re-randomized. Next, we show that the algorithm is *insensitive to its input* in the sense that when one of the components of the random internal vector $\mathbf{I}$ is re-randomized, the output assignment almost remains unchanged, In particular, $d(\sigma_i, \sigma_{i+1})$ is smaller than $v_2 - v_1$. We also show that the algorithm has certain *freeness* in the sense that when all components in the random internal are re-randomized the output assignment is expected to change a lot. In particular, $\mathbb{E}[d(\sigma_0, \sigma_T)]$ should be larger than v_2. These two properties together imply that the sequence of assignments cannot "jump" over the overlap gap, while two ends of the sequence probably lie in different clusters. Therefore, there should be an assignment σ_{T_0} that falls in the gap, namely, there exists $T_0 > 0$ such that $v_1 \leq d(\sigma_0, \sigma_{T_0}) \leq v_2$. If the probability that the algorithm successfully finds a solution is greater than some small value s_n slowly converging to 0, then there could be a very small probability that both σ_0 and σ_{T_0} are solutions of the instance Φ, with $v_1 \leq d(\sigma_0, \sigma_{T_0}) \leq v_2$. Even though this probability is very small, it still has the chance to violates the OGP of the instance. Then, by contradiction, we could conclude that the probability that the algorithm succeeds in finding a solution is smaller than $s_n = o(1)$, namely, w.h.p. the algorithm fails in finding a solution.

Instead of considering the overlap gap property of the entire instance $\mathbf{\Phi}$, we move our focus to the overlap gap property of a sub-instance of $\mathbf{\Phi}$. Indeed, the sub-instance we consider is the *2-core instance* $\mathbf{\Phi_c}$ induced by the 2-core of the factor graph representation of the random instance $\mathbf{\Phi}$. In [25, 6], they proved that the 2-core instance $\mathbf{\Phi_c}$ exhibits the overlap gap property with $v_1' = o(n)$ and $v_2' = \epsilon_k n$ for some constant $\epsilon_k > 0$ for clause density $r_{core}(k) < r < r_{sat}(k)$. We remove all variables not in the core instance from the sequence of assignments $\sigma_0, \sigma_1, \cdots, \sigma_T$ we obtained above, then it becomes a sequence of assignments $\sigma_0', \sigma_1', \cdots, \sigma_T'$ for the core instance. We also prove that the algorithm is *insensitive to its input* with respect to the core instance in the sense that $d(\sigma_i', \sigma_{i+1}') < v_2' - v_1'$, and has certain *freeness* so that $\mathbb{E}[d(\sigma_0', \sigma_T')] > v_2'$. By repeating the above argument of the overlap gap property method, we can conclude that w.h.p. the algorithm fails in find a solution.

Our proof can also be used for the non-sequential local algorithms. Since the local rule τ runs on the local neighborhood of each variable in parallel, the values assigned to variables do not depend on each other. Informally speaking, there is no long-range dependency among those assigned values. Therefore, re-randomizing one component of the internal vector I, say I_{i+1}, only affects the value $\sigma(x_{i+1})$ assigned to the corresponding variable x_{i+1}. So, we have $d(\sigma_i, \sigma_{i+1}) \leq 1 < v_2' - v_1'$. Hence, we can obtain the same result as Theorem 1 for non-sequential local algorithms with the same proof.

1.7 Related works

The vanilla version of OGP helps us rule out some large classes of algorithms on random CSPs for relatively high clause densities, but it is not sophisticated enough to close the *statistical-to-computational gap* in some cases such as random NAE-k-SAT discussed in [20] and random k-XORSAT discussed in this paper (more details in Section 2). There have been some recent works trying to improve the notion of OGP by developing different variants of OGP. The most notable one is *multi-OGP* [37, 9, 24, 17, 16], which succeeds in closing the statistical-to-computational gap in certain models. However, it is not clear about the relation between the clustering property and the multi-OGP.

2 Overlap Gap Property

We say that a k-XORSAT instance Φ exhibits the **overlap gap property** (or shortened as OGP) with the values $0 \le v_1 < v_2$ if for any two solutions $\sigma, \sigma' \in S(\Phi)$ we have either $d(\sigma,\sigma') \le v_1$ or $d(\sigma,\sigma') \ge v_2$. Informal speaking, any two solutions of the instance are either close to each other or far away from each other, and thus the solution space exhibits a topological discontinuity. Given a random k-XORSAT instance, we can prove that it exhibits the OGP when the clause density is greater than certain value, and obtain the following lemma.

▶ **Lemma 6.** *For any $k \ge 3$, there exists $r_1(k) > 0$ such that for $r > r_1(k)$ and any pair of solutions $\sigma, \sigma' \in S(\boldsymbol{\Phi})$ of the random k-XORSAT instance $\boldsymbol{\Phi} \sim \boldsymbol{\Phi}_n(k, rn)$, w.h.p. the distance $d(\sigma,\sigma')$ between the two solutions is either $\le u_1 n$ or $\ge u_2 n$ for some $0 \le u_1 < u_2$. In particular, the value of $r_1(k)$ is given by*

$$r_1(k) = \min_{0\le\alpha\le 1} \frac{1 + H(\alpha)}{2 - \log(1 + (1-2\alpha)^k)},$$

where H is the binary entropy function, that is, $H(x) = -x\log_2(x) - (1-x)\log_2(1-x)$.

Instead of considering the random k-XORSAT instance $\boldsymbol{\Phi}$ itself, we focus on the sub-instance, called the *core instance* (defined below), of the random k-XORSAT instance $\boldsymbol{\Phi}$, and show that core instance also exhibits the overlap gap property, even when the clause density is much lower. (See Table 1.)

Table 1 Compare $r_{core}(k)$ with $r_1(k)$ for different k. The numeric values in the table are rounded off to 6 decimal places.

k	3	4	5	6	7	8	9
$r_{core}(k)$	0.818470	0.772280	0.701780	0.637081	0.581775	0.534997	0.495255
$r_1(k)$	0.984516	0.943723	0.905812	0.874349	0.848314	0.826470	0.807862

We start from defining the **peeling algorithm** and the **core instances**. Given an XORSAT instance Φ, suppose there exists a variable x of degree 1, which means it is involved in exactly one clause e. We remove the variable x and the only clause c involving x, to obtain a modified instance Φ'. If we have a solution σ' for the modified instance Φ', we can always choose a suitable value for the variable x to satisfy the clause c, and extend the solution σ' to a solution σ for the original instance Φ. Similarly, we can also do the same thing if the variable x is of degree 0, since it does not involve in any equation, and we are free to choose any value for it. By doing this, solving the original instance Φ is reduced to solving the modified instance Φ'.

We can repeat this process until there is no variable of degree at most 1. This process is named the **peeling algorithm** on an instance as its input (Algorithm 3). We call the resultant instance the **2-core instance** (or simply the **core instance**) of the instance Φ, denoted by Φ_c. This name is borrowed from the graph theory. In graph theory, the *k-core* of a graph is the maximal subgraph with minimum degree at least k. It is known that the factor graph of the core instance Φ_c is exactly the maximal subgraph of the factor graph G_Φ of the instance Φ, with minimum variable degree at least 2.

Algorithm 3 Peeling algorithm.

Input: an instance Φ.
while There exists ≥ 1 variable of degree ≤ 1. **do**
    Select a variable x of degree ≤ 1.
    (Pick x with the lowest index if there are > 1 such variables.)
    Update Φ by removing the variable x_i and its only involved clause (if exists).
end while
Output: the resultant instance Φ.

Mézard and Montanari [31] gave a detailed description on the structure of the core instance. Reader can find more details about the core instance in their book. The following theorem is a short summary of some known facts about the core instances we needed in the paper.

▶ **Theorem 7.** *For any $k \geq 3$, there exists $r_{core}(k) > 0$ given by*

$$r_{core}(k) \equiv \sup\{r \in [0,1] : Q > 1 - e^{-krQ^{k-1}} \ \forall Q \in (0,1)\}$$

such that the factor graph G_c of the core instance $\mathbf{\Phi}_c$ of the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_n(k, rn)$ have the following properties.

1. *For $r < r_{core}(k)$, w.h.p. the factor graph G_c of the core instance $\mathbf{\Phi}_c$ is an empty graph.*
2. *For $r > r_{core}(k)$, w.h.p. the factor graph G_c of the core instance $\mathbf{\Phi}_c$ have $V(k,r)n + o(n)$ variable nodes, where*

$$V(k,r) = 1 - \exp(-krQ^{k-1}) - krQ^{k-1}\exp(-krQ^{k-1})$$

and Q is the largest solution of the fixed point equation $Q = 1 - \exp(-krQ^{k-1})$. In particular, the fraction of variable nodes of degree l is between $\widehat{\Lambda}_l - \epsilon$ and $\widehat{\Lambda}_l + \epsilon$ with probability greater than $1 - e^{-\Theta(n)}$, where $\widehat{\Lambda}_0 = \widehat{\Lambda}_1 = 0$ and

$$\widehat{\Lambda}_l = \frac{1}{e^{krQ^{k-1}} - 1 - krQ^{k-1}} \frac{1}{l!} (krQ^{k-1})^l \quad \text{for } l \geq 2.$$

3. *Conditioning on the number of variable nodes $V(k,r)n + o(n)$ and the degree profile $\widehat{\Lambda}$, the factor graph G_c of the core instance $\mathbf{\Phi}_c$ is distributed according to the ensemble containing all possible factor graphs of k-XORSAT instances of $V(k,r)n + o(n)$ variables and variable degree distribution Λ.*

Theorem 7 shows that there exists a threshold $r_{core}(k)$ below the satisfiability threshold $r_{sat}(k)$ of random k-XORSAT problem. When the clause density r is below the threshold $r_{core}(k)$, w.h.p. the instance $\mathbf{\Phi}$ does not have a core instance. When the clause density r is above the threshold $r_{core}(k)$, w.h.p. the core instance $\mathbf{\Phi}_c$ emerges. In particular, the variable degree distribution is a Poisson distribution with mean krQ^{k-1} conditioning on $\Lambda_0 = \Lambda_1 = 0$. [31] also showed that the core instance exhibits the OGP.

▶ **Lemma 8.** *For $k \geq 3$ and $r_{core}(k) < r < r_{sat}(k)$, there exists $\epsilon(k,r) > 0$ such that w.h.p. the distance between any two solutions for the core instance $\mathbf{\Phi}_c$ of a random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_n(k, rn)$ is either $o(n)$ or greater than $\epsilon(k,r)n$.*

Now, we know that w.h.p. the core instance of a random k-XORSAT instance has the overlap gap property with the values $v_1 = o(n)$ and $v_2 = \epsilon(k,r)n$. With OGP, we can partition the solution space of the core instance into multiple groups, each called a **core cluster**, such that the distance between any pair of core solutions in the same core cluster is at most $o(n)$, and the distance between any pair of core solutions in different core clusters is at least $\epsilon(k,r)n$.

Suppose we have a k-XORSAT instance Φ. We first define a binary relation on the solution space of a core instance Φ_c by: for $\sigma_c, \sigma_c' \in \mathcal{S}(\Phi_c)$, we write $\sigma_c \simeq \sigma_c'$ if and only if $d(\sigma_c, \sigma_c') = o(n)$. It is easy to see it is an equivalence relation. Then, we can partition the solution space by the equivalence classes of $\simeq$. We can denote those equivalence classes by $\mathcal{S}_{c,1}, \mathcal{S}_{c,2}, ..., \mathcal{S}_{c,n_c}$. Thus, we have $\mathcal{S}_{c,1} \sqcup \mathcal{S}_{c,2} \sqcup ... \sqcup \mathcal{S}_{c,n_c} = \mathcal{S}(\Phi_c)$ where $\sqcup$ is the disjoint union. Then, we have

$$\begin{aligned} &d(\sigma_c, \sigma_c') = o(n) && \text{if } \ \sigma_c, \sigma_c' \in \mathcal{S}_{c,i}, \quad \text{and} \\ &d(\sigma_c, \sigma_c') \geq \epsilon(k,r)n && \text{if } \ \sigma_c \in \mathcal{S}_{c,i},\ \sigma_c' \in \mathcal{S}_{c,j} \text{ and } \mathcal{S}_{c,i} \neq \mathcal{S}_{c,j} \end{aligned}$$

Now we can partition the solution space $\mathcal{S}(\Phi)$ of the original instance Φ into clusters based on the partition of the solution space of core instance. We set

$$\mathcal{S}(\Phi) = \bigsqcup_{i=1}^{n_c} \mathcal{S}_i \quad \text{and} \quad \mathcal{S}_i = \{\sigma \in \mathcal{S}(\Phi) : \pi(\sigma) \in \mathcal{S}_{c,i}\} \quad \text{for } i = 1, 2, ..., n_c$$

where π is defined to be the **projection** mapping assignments for the instance Φ to assignments for the core instance Φ_c by removing all variables not in the core instance Φ_c. Each $\mathcal{S}_i$ is called a **cluster** in the solutions space $\mathcal{S}(\Phi)$. We can then prove that these clusters are well-separated from each other.

▶ **Lemma 9.** *Let $k \geq 3$ and $r_{core}(k) < r < r_{sat}(k)$. Suppose $\mathbf{\Phi} \sim \mathbf{\Phi}_n(k, rn)$ is a random k-XORSAT instance. Then, w.h.p. there exists a partition $\mathcal{S}(\mathbf{\Phi}) = \mathcal{S}_1 \sqcup \mathcal{S}_1 \sqcup ... \sqcup \mathcal{S}_{n_c}$ for the solutions space $S(\mathbf{\Phi})$ of the random instance $\mathbf{\Phi}$ such that the following statements hold.*

1. *If $\sigma, \sigma' \in \mathcal{S}_i$ for some $i \in [n_c]$, then we have $d(\sigma, \sigma') \leq \mu(k,r)n + o(n)$, where the real-valued function $\mu(k,r)$ is given by $\mu(k,r) = \exp(-krQ^{k-1}) + krQ^{k-1}\exp(-krQ^{k-1})$ and Q is the largest solution of the fixed point equation $Q = 1 - \exp(-krQ^{k-1})$.*
2. *If $\sigma \in \mathcal{S}_i, \sigma' \in \mathcal{S}_j$ and $\mathcal{S}_i \neq \mathcal{S}_j$ for some $i, j \in [n_c]$, then we have $d(\sigma, \sigma') \geq \epsilon(k,r)n$.*

Proof. Assume the instance $\mathbf{\Phi}$ has a non-empty core instance $\mathbf{\Phi}_c$, which exists with high probability according to Theorem 7. We also assume the core instance $\mathbf{\Phi}_c$ exhibits the OGP with $v_1 = o(n)$ and $v_2 = \epsilon(k,r)n$, which occurs with high probability according to Lemma 8. Let σ and σ' be two solutions of the random k-XORSAT instance $\mathbf{\Phi}$, and let $\sigma_c = \pi(\sigma)$ and $\sigma_c' = \pi(\sigma')$ be the projection of σ and σ' on the core solution space $\mathcal{S}(\mathbf{\Phi})$, respectively.

To prove the first part of the lemma, we assume that σ and σ' are in the same cluster, that is, $\sigma, \sigma' \in \mathcal{S}_i$ for some $i \in [n_c]$. By the definition of cluster, we have $d(\sigma_c, \sigma_c') = o(n)$. Therefore, $d(\sigma, \tau)$ is upper bounded by the number of variables not in the core instance, plus $o(n)$. By Theorem 7, the number of variables outside the core instance is given by $(1 - V(k,r))n + o(n)$. Hence, we have $d(\sigma, \tau) \leq (1 - V(k,r))n + o(n) = \left(\exp(-krQ^{k-1}) + krQ^{k-1}\exp(-krQ^{k-1})\right)n + o(n)$.

To prove the second part of the lemma, we assume that σ and τ are in the different clusters, that is, $\sigma \in \mathcal{S}_i$, $\sigma' \in \mathcal{S}_j$ and $\mathcal{S}_i \neq \mathcal{S}_j$ for some $i, j \in [n_c]$. By the definition of cluster and Lemma 8, we have $d(\sigma_c, \sigma_c') \geq \epsilon(k,r)n$ Therefore, we have $d(\sigma, \sigma') \geq d(\pi(\sigma), \pi(\sigma')) = d(\sigma_c, \sigma_c') \geq \epsilon(k,r)n$. ◀

3 Preparation of OGP method

In this section, we introduce some notions and obtain some preliminary results needed by the overlap gap property method to prove the main results.

3.1 Sequence of output assignments

The random k-XORSAT instance $\mathbf{\Phi}$ is a random variable, and the τ-decimation algorithm $\mathtt{DEC}_\tau$ is a randomized algorithm. Therefore, the assignment output by the τ-decimation algorithm $\mathtt{DEC}_\tau$ on input $\mathbf{\Phi}$ is also a random variable. The outcomes of the output assignment depend on the random instance $\mathbf{\Phi}$, the order of variables being chosen, and the value selection based on the output from the local rule τ. Now we introduce two random variables to explicitly represent the order of variables and the value selection so that we can have a more concrete language to discuss how the randomness from both the instance and the algorithm affects the output assignment. We adopt the notation from [20] in the following discussion.

The order of variables can be represented by a random vector $\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n)$ whose entries are n i.i.d. random variables with uniform distribution over the interval $[0,1] \subset \mathbb{R}$, independent of the random instance $\mathbf{\Phi}$. We call $\mathbf{Z}$ the **ordering vector** of the algorithm. For all $i \in [n]$, the variable x_i in the instance $\mathbf{\Phi}$ is associated with the random variable $\mathbf{Z}_i$. In each iteration of the algorithm, the unassigned variable x_i with the largest value $\mathbf{Z}_i$, among all other unassigned variables, is selected. In the other words, we can construct the permutation $s : [n] \to [n]$ such that $\mathbf{Z}_{s(1)} > \mathbf{Z}_{s(2)} > \cdots > \mathbf{Z}_{s(n)}$, and for all $t \in [n]$ the variable $x_{s(t)}$ is selected in the t-th iteration. The value selection based the output from the local rule τ can be represented by a random vector $\mathbf{U} = (\mathbf{U}_1, \mathbf{U}_2, ..., \mathbf{U}_n)$ whose entries are n i.i.d. random variables with uniform distribution over the interval $[0,1] \subset \mathbb{R}$. We call $\mathbf{U}$ the **internal vector** of the algorithm. In the t-th iteration of the algorithm, the value $\sigma(x_{s(t)})$ assigned to the selected variable $x_{s(t)}$ is set to be 1 if $\mathbf{U}_t < \tau(B_{\mathbf{\Phi}_t}(x_{s(t)}, R))$, and 0 otherwise. Conditioning on $\mathbf{\Phi}$, $\mathbf{Z}$ and $\mathbf{U}$, the output assignment σ can be uniquely determined. Therefore, we can view the τ-decimation algorithm $\mathtt{DEC}_\tau$ as a deterministic algorithm on random input $(\mathbf{\Phi}, \mathbf{Z}, \mathbf{U})$, and denote by $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U}}$ the output of the algorithm.

With this notion of the deterministic algorithm, we can construct a sequence of output assignments which will be used in the argument of the overlap gap property method. The sequence of output assignments is generated by applying the τ-decimation algorithm $\mathtt{DEC}_\tau$ on a random k-XORSAT instance $\mathbf{\Phi}$ multiple times in the following way: First, given a random k-XORSAT instance $\mathbf{\Phi}$, we sample an ordering vector $\mathbf{Z}$ and an internal vector $\mathbf{U}$. Then, we run the τ-decimation algorithm $\mathtt{DEC}_\tau$ on input $\mathbf{\Phi}$ with the ordering vector $\mathbf{Z}$ and the internal vector $\mathbf{U}$ to get the first output assignment σ_0. After that, we re-randomize (i.e. sample again) the entries of the internal vector $\mathbf{U}$ one by one from $\mathbf{U}_1$ to $\mathbf{U}_n$. Right after each re-randomization we run the algorithm again to get a new output assignment. By doing this, we obtain a sequence of $n+1$ output assignments for the instance $\mathbf{\Phi}$ in total. We denote by σ_i the output assignment generated after re-randomizing the first i entries of $\mathbf{U}$, for $i = 0, 1, 2, ..., n$. Precisely speaking, let $\mathbf{V} = (\mathbf{V}_1, \mathbf{V}_2, ..., \mathbf{V}_n)$ and $\mathbf{W} = (\mathbf{W}_1, \mathbf{W}_2, ..., \mathbf{W}_n)$ be two independent random internal vectors with the uniform distribution over $[0,1]^n$, and set $\mathbf{U^i} = (\mathbf{W}_1, ..., \mathbf{W}_i, \mathbf{V}_{i+1}, ..., \mathbf{V}_n)$ for $i = 0, 1, 2, ..., n$. Note that $\mathbf{U^0} = \mathbf{V}$ and $\mathbf{U^n} = \mathbf{W}$.

Then, the sequence of output assignments $\{\sigma_i\}_{i=0}^n$ can be written as $\{\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^i}}\}_{i=0}^n$, which is equivalent to the sequence of output assignment obtained by running the τ-decimation algorithm $\mathtt{DEC}_\tau$ (for $n+1$ times in total) on input $(\mathbf{\Phi},\mathbf{Z},\mathbf{U^i})$ for all $i=0,1,...,n$.

Recall the projection π mapping assignments for the instance $\mathbf{\Phi}$ to assignments for the core instance $\mathbf{\Phi}_c$, by removing all variables not in the core instance. We can further obtain a sequence of assignments for the core instance $\mathbf{\Phi}_c$ by applying the projection on the output assignments σ_i, that is, we set $\{\sigma_i' = \pi(\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^i}})\}_{i=0}^n$.

3.2 Insensitive to internal vector

In this section, we show that the τ-decimation algorithm $\mathtt{DEC}_\tau$ is *insensitive* to its internal vector. By *insensitive*, it means when the value of an entry in the internal vector $\mathbf{U}$ is changed, only a small portion of the assigned values in the output assignment $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U}}$ change accordingly. If so, every two consecutive output assignments in the sequence $\{\sigma_i = \sigma_{\Phi,\mathbf{Z},\mathbf{U^i}}\}_{i=0}^n$ should only differ from each other in only a small portion of assigned values.

Consider the sequence of output assignment $\{\sigma_i = \sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^i}}\}_{i=0}^n$ from Section 3.1. Note that the i-th output assignment σ_i in the sequence is the output of the algorithm on input $(\mathbf{\Phi},\mathbf{Z},\mathbf{U^i})$. For any $i\in[n]$, the only difference between the input $(\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i-1}})$ and the input $(\mathbf{\Phi},\mathbf{Z},\mathbf{U^i})$ is the i-th entries of the internal vectors $\mathbf{U^{i-1}}$ and $\mathbf{U^i}$. We can immediately see that the insensitivity of the algorithm implies that every two consecutive output assignments in the sequence are close to each other. Gamarnik and Sudan [20] proved the insensitivity of the τ-decimation algorithm in their works, using the notion of *influence range*. Although their works [20] focused on the random NAE-k-SAT problem, the proof for the insensitivity of the τ-decimation algorithm is independent of the type of clauses in the random constraint satisfaction framework. So, we can directly use the result here.

▶ **Definition 10.** *Given a random instance $\mathbf{\Phi}$ and a random ordering vector $\mathbf{Z}$, we say that x_i **influences** x_j if either $x_i = x_j$ or in the variable-to-variable graph of the instance $\mathbf{\Phi}$ there exists a sequence of variable nodes $y_0, y_1, ..., y_t \in \{x_1, x_2, ..., x_n\}$ such that the following statements hold.*

1. *$y_0 = x_i$ and $y_t = x_j$.*
2. *There exists a path from y_l to y_{l+1}, of length at most r, in the variable-to-variable graph G, for $l = 0, 1, ..., t-1$.*
3. *$\mathbf{Z}_{y_{l-1}} > \mathbf{Z}_{y_l}$ for $l = 1, 2, ..., t$. In particular, $\mathbf{Z}_{x_i} > \mathbf{Z}_{x_j}$.*

*We define the **influence range** of x_i to be the set of all variables x_j influenced by x_i, denoted by $\mathcal{IR}_{x_i}$.*

▶ **Lemma 11.** *Given an instance Φ, a vector $Z\in[0,1]^n$, and two vectors $U, U'\in[0,1]^n$, we assume there exists $i\in\{1,2,...,n\}$ such that $U_i \neq U_i'$ and $U_j = U_j'$ for all $j\neq i$. Then, $\sigma_{\Phi,Z,U}(x) = \sigma_{\Phi,Z,U'}(x)$ for all variables $x_j \notin \mathcal{IR}_{x_i}$.*

▶ **Lemma 12.** *For any $\xi\in(0,1)$ and sufficiently large n,*

$$\Pr\left[\max_{1\le i\le n} |\mathcal{IR}_{x_i}| \ge n^{1/6}\right] \le \exp\left(-\ln n(\ln\ln n)^{\xi/4}\right).$$

They first showed that changing the value of only one entry, say U_i, in the internal vector U only affects the values assigned to the variables in the influence range of the variable x_i (Lemma 11). They further showed that w.h.p. the size of the influence range of variables is sublinear for all variables (Lemma 12). Note that in the original statement of Lemma 12 in [20], the index 1/6 in the inequality above can be any real number between 0 and 1/5.

Here, we pick a fixed value $1/6$ for simplicity. Combining these two lemmas, we can show that w.h.p. the differences between $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i-1}}}$ and $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i}}}$ is upper bounded by $n^{1/6}$ for all $i \in [n]$.

▶ **Lemma 13.** *For any $\xi \in (0,1)$ and sufficiently large n,*

$$\Pr\left[\, d(\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i-1}}}, \sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i}}}) \geq n^{1/6} \text{ for some } i \in [n] \,\right] \leq \exp\left(-\ln n (\ln\ln n)^{\xi/4}\right).$$

Proof. Fix an arbitrary $i \in [n]$. We know that $\mathbf{U_j^{i-1}} = \mathbf{U_j^{i}}$ for all $j \neq i$, and $\mathbf{U_i^{i-1}} \neq \mathbf{U_i^{i}}$. By Lemma 11, we have $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i-1}}}(x_j) = \sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i}}}(x_j)$ for all variables $x_j \notin \mathcal{IR}_{x_i}$. If $d(\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i-1}}}, \sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i}}}) \geq n^{1/6}$ for some $i \in [n]$, we have $|\mathcal{IR}_{x_i}| \geq n^{1/6}$. Hence, by Lemma 12, the result follows. ◀

3.3 Freeness

Recall the definition of *free steps*. An iteration of the τ-decimation algorithm $\mathtt{DEC}_\tau$ is called a free step if the local rule τ gives the value $1/2$ in that iteration. In this case, the value chosen by the τ-decimation algorithm for the selected variable is either 0 or 1 with even probability. Intuitively, it means that the local rule τ cannot capture useful information from the local structure to guide the τ-decimation algorithm choosing value for the selected variable, and thus the τ-decimation algorithm simply make a random guess for the assigned value. We also recall the definition of a τ-decimation algorithm being δ-free. A τ-decimation algorithm $\mathtt{DEC}_\tau$ is δ-free on the random k-XORSAT instance $\mathbf{\Phi}$ if w.h.p. the algorithm has at least δn free steps, on input $\mathbf{\Phi}$. Informal speaking, the more free the τ-decimation algorithm, the less the information captured by the local rule.

By using the Wormald's method of differential equations, we can calculate the degree profile of the remaining factor graph after t steps of the τ-decimation algorithm, for all $0 \leq t \leq n$. With the degree profiles, we can calculate the probability of each step being free, and thus approximate how free the τ-decimation algorithm is. The probability of having free steps depends on the choice of the local rules. Lemma 14 shows the freeness of the $\mathtt{UC}$-decimation algorithm.

▶ **Lemma 14.** *For $k \geq 3$ and $r > 0$, the $\mathtt{UC}$-decimation algorithm $\mathtt{DEC}_{\mathtt{UC}}$ is $w_1(k,r)$-free on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$, where*

$$w_1(k,r) = \frac{(kr)^{\frac{1}{1-k}}}{k-1}\,\gamma\left(\frac{1}{k-1}, kr\right)$$

and γ is the lower incomplete gamma function given by $\gamma(a,x) \equiv \int_0^x t^{a-1}e^{-t}dt$.

The role of the local rules is to approximate the marginal probability of the selected variable over a randomly chosen solution for the sub-instance induced by the local neighborhood of the selected variable. Interestingly, even we have a local rule τ that is capable to give the exact marginals when the factor graph is a tree, it still cannot provide enough useful information to guide the τ-decimation algorithm making good decision for the assigned value. With such a local rule, the τ-decimation algorithm still has a certain level of freeness.

▶ **Lemma 15.** *Assume the local rule τ can give the exact marginal probabilities of variables on any factor graph that is a tree. For $k \geq 3$ and $r > 0$, the τ-decimation algorithm $\mathtt{DEC}_\tau$ is $w_e(k,r)$-free on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$, where*

$$w_e(k,r) = \int_0^1 S_R(x)dx,$$

$S_0(x) = 1$ and $S_l(x) = \exp\left(-kr[(1-x)(1-S_{l-1}(x)) + x]^{k-1}\right)$ for any $l \geq 1$ and $x \in \mathbb{R}$.

4 Proof of main theorems

We denote by α_n the *success probability* of the τ-decimation algorithm $\texttt{DEC}_\tau$, namely, α_n is the probability that the assignment output by the τ-decimation algorithm $\texttt{DEC}_\tau$ on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$ with n variables and rn clauses is a solution for $\mathbf{\Phi}$. Formally, we define α_n by the following expression $\alpha_n \equiv \Pr\left[\, \sigma_{\mathbf{\Phi}\sim\mathbf{\Phi}_k(n,rn),\mathbf{Z},\mathbf{U}} \in \mathcal{S}(\mathbf{\Phi}) \,\right]$, where $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$ is the random k-XORSAT instance, $\mathbf{Z}$ is the random ordering vector, and $\mathbf{U}$ is the random internal vector, as mentioned in Section 3.1. Now, we consider the sequence of output assignments $\{\sigma_i = \sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^i}}\}_{i=0}^n$ generated by the procedure in Section 3.1. We first prove that if the algorithm $\texttt{DEC}_\tau$ is δ-free, then the expected distance $\mathbb{E}\left[d(\sigma_0, \sigma_n)\right]$ between the first and the last assignments in the sequence is at least $(\delta/2)n + o(n)$.

▶ **Lemma 16.** *If the τ-decimation algorithm $\texttt{DEC}_\tau$ is δ-free on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$ for some $\delta > 0$, then we have $\mathbb{E}\left[d(\sigma_0, \sigma_n)\right] \geq (\delta/2)n + o(n)$.*

Next, we will show that, if the τ-decimation algorithm is "free enough", namely, strictly $2\mu(k, r)$-free, then we can pick a pair of output assignments and project them to the core instance $\mathbf{\Phi}_c$ so that the distance between the two corresponding core assignments falls in the *forbidden range* from the overlap gap property of the core instance $\mathbf{\Phi}_c$.

▶ **Lemma 17.** *For any $k \geq 3$ and $r \in (r_{core}(k), r_{sat}(k))$, if the τ-decimation algorithm $\texttt{DEC}_\tau$ is strictly $2\mu(k, r)$-free on the random k-XORSAT instance $\mathbf{\Phi} \sim \mathbf{\Phi}_k(n, rn)$, then there exist $0 \leq i_0 \leq n$ and $0 < \epsilon' < \epsilon(k, r)$ such that w.h.p. we have $\left|d(\pi(\sigma_0), \pi(\sigma_{i_0})) - \frac{1}{2}\epsilon' n\right| < \frac{1}{4}\epsilon' n$, where $\epsilon(k, r)$ is given in Lemma 8.*

The following lemma shows that the probability of both the output assignments $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^o}}$ and $\sigma_{\mathbf{\Phi},\mathbf{Z},\mathbf{U^{i_o}}}$ being solutions for the instance $\mathbf{\Phi}$ is lower bounded by α_n^2.

▶ **Lemma 18.** *For any $i \in [n]$, we have $\Pr\left[\, \sigma_0 \in \mathcal{S}(\Phi) \text{ and } \sigma_i \in \mathcal{S}(\Phi) \,\right] \geq \alpha_n^2$.*

Finally, we can combine all above lemmas in this section to give the proof of Theorem 1.

Proof of Theorem 1. We denote by $\mathcal{A}$ the event of $\left|d(\pi(\sigma_0), \pi(\sigma_{i_0})) - \frac{1}{2}\epsilon' n\right| < \frac{1}{4}\epsilon' n$, and we have $\Pr\left[\,\mathcal{A}\,\right] = 1 - o(1)$ by Lemma 17. On the other hand, we pick $i = i_0$ for the inequality in Lemma 18. We denote by $\mathcal{B}$ the event of $\sigma_0 \in \mathcal{S}(\Phi)$ and $\sigma_{i_0} \in \mathcal{S}(\Phi)$, and $\Pr\left[\,\mathcal{B}\,\right] \geq \alpha_n^2$. Note that we have $\Pr\left[\,\mathcal{A} \cap \mathcal{B}\,\right] \geq 1 - \Pr\left[\,\text{Not } \mathcal{A}\,\right] - \Pr\left[\,\text{Not } \mathcal{B}\,\right] \geq 1 - o(1) - (1 - \alpha_n^2) = \alpha_n^2 - o(1)$. Thus, we have $\alpha_n \leq \Pr\left[\,\mathcal{A} \cap \mathcal{B}\,\right]^{1/2} + o(1)$.

Now assume both $\mathcal{A}$ and $\mathcal{B}$ take places. Since both σ_0 and σ_{i_0} are solutions for the random instance $\mathbf{\Phi}$, both $\pi(\sigma_0)$ and $\pi(\sigma_{i_0})$ are solutions for the core instance $\mathbf{\Phi}_c$. Moreover, the distance $d(\pi(\sigma_0), \pi(\sigma_{i_0}))$ falls in the interval $((1/4)\epsilon' n, (3/4)\epsilon' n) \subsetneq (o(n), \epsilon n)$, which takes place with probability at most $o(1)$ by Lemma 8. So, we have $\Pr\left[\,\mathcal{A} \cap \mathcal{B}\,\right] \leq o(1)$, and thus $\alpha_n \leq o(1)$. ◀

To prove Theorem 2 and 3, all we need to do is to show that $\texttt{DEC}_{\texttt{UC}}$ and $\texttt{DEC}_\tau$ with the exact marginal assumption are strictly $2\mu(k, r)$-free. The results immediately follow by applying Theorem 1. From Lemma 14 and 15, we know that $\texttt{DEC}_{\texttt{UC}}$ and $\texttt{DEC}_\tau$ are $w_1(k, r)$-free and $w_e(k, r)$-free, respectively. So, we only need to show that $w_1(k, r) > 2\mu(k, r)$ and $w_e(k, r) > 2\mu(k, r)$. It can be done with the following lemmas, which give an upper bound of $\mu(k, r)$ in Lemma 19, a lower bound of $w_1(k, r)$ in Lemma 20, and a lower bound of and $w_e(k, r)$ in Lemma 21.

▶ **Lemma 19.** *For any $k \geq 4$ and $r \in (r_{core}(k), r_{sat}(k))$, we have $\mu(k, r) < \mu_u(k)$, where*

$$\mu_u(k) = (1 - e^{-1/k}) - (1 - e^{-1/k}) \ln(1 - e^{-1/k}).$$

▶ **Lemma 20.** *For any $k \geq k_0 \geq 3$ and $r \in (r_{core}(k), r_{sat}(k))$, $w_1(k,r) \geq w_1^*(k_0)$, where*

$$w_1^*(k) = \frac{k^{\frac{1}{1-k}}}{k-1}\gamma\left(\frac{1}{k-1}, k\left(\frac{k}{k+1}\right)^{k-1}\right)$$

▶ **Lemma 21.** *For any $k \geq k_0 \geq 3$ and $r \in (r_{core}(k), r_{sat}(k))$, we have $w_e(k,r) \geq w_e^*(k_0, r_{sat}(k_0))$, where $w_e^*(k,r) = x^-(k,r) - kr^2(x^-(k,r))^k$ and*

$$x^{\pm}(k,r) = \left(\frac{1 \pm \sqrt{1 - 4(kr)^{-2}[(kr)^{\frac{1}{k-1}} - 1]}}{2}\right)^{\frac{1}{k-2}}. \tag{1}$$

Proof of Theorem 2. Let $k \geq 9$ and $r \in (r_{core}(k), r_{sat}(k))$. By Lemma 19 and 20, we have $2\mu(k,r) < 2\mu_u(9) \leq 0.3420 < 0.3575 \leq w_1^*(9) \leq w_1(k,r)$. Then, by Lemma 14, $\texttt{DEC}_{\texttt{UC}}$ is strictly $2\mu(k,r)$-free. The result follows. ◀

Proof of Theorem 3. Let $k \geq 13$ and $r \in (r_{core}(k), r_{sat}(k))$. By Lemma 19 and 21, we have $2\mu(k,r) < 2\mu_u(13) \leq 0.2668 < 0.2725 \leq w_e^*(13) \leq w_e(k,r)$. Then, by Lemma 15, $\texttt{DEC}_{\tau}$ is strictly $2\mu(k,r)$-free. The result follows. ◀
