Track B: Automata, Logic, Semantics, and Theory of Programming

Preface

This volume contains the papers presented at the *51st EATCS International Conference on Automata, Languages and Programming (**ICALP 2024**)*, held in Tallinn, Estonia, during July 8–12, 2024. ICALP is a series of annual conferences of the *European Association for Theoretical Computer Science (EATCS)*, which first took place in 1972. This year, ICALP was co-located with the 39th Annual ACM/IEEE Symposium on Logic in Computer Science (LICS) and the 9th International Conference on Formal Structures for Computation and Deduction (FSCD).

The ICALP 2024 program consisted of two tracks:

Track A: Algorithms, Complexity, and Games

Track B: Automata, Logic, Semantics, and Theory of Programming

In response to the call for papers, a total of 519 eligible, anonymous submissions were received: 404 for Track A and 115 for Track B. The committees decided to accept 153 papers for inclusion in the scientific program: 119 papers for Track A and 34 for Track B. The selection was made by the program committees based on originality, quality, and relevance to theoretical computer science. The quality of the submissions was very high, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper in each of the two tracks, selected by the program committees. The **best paper awards** were given to the following papers:

Track A: Yuda Feng and Shi Li. *A Note on Approximating Weighted Nash Social Welfare with Additive Valuations.*

Track B: Dmitry Chistikov, Alessio Mansutti, and Mikhail Starchak. *Integer Linear-Exponential Programming in NP by Quantifier Elimination.*

The **best student paper awards**, for papers that are solely authored by students, were given to the following papers:

Track A: Ce Jin and Hongxun Wu. *A Faster Algorithm for Pigeonhole Equal Sums.*

Track A: Kingsley Yung. *Limits of Sequential Local Algorithms on the Random k-XORSAT Problem.*

Track B: Roland Guttenberg. *Flattability of Priority Vector Addition Systems.*

ICALP 2024 included invited presentations by

- Anuj Dawar, University of Cambridge,
- Edith Elkind, University of Oxford (joint with LICS 2024),
- Danupon Nanongkai, MPI Saarbrücken,
- Merav Parter, Weizmann Institute,
- Stephanie Weirich, University of Pennsylvania (joint with LICS 2024 and FSCD 2024).

This volume contains all the contributed papers presented at the conference, and an abstract or paper accompanying some of the invited talks.

The program of ICALP 2024 also included presentations of

- the Gödel Prize 2024 (joint with ACM SIGACT) awarded to Ryan Williams (MIT) for the paper *Non-Uniform ACC Circuit Lower Bounds*: IEEE Conference on Computational Complexity (CCC) 2011. Journal of the ACM 61(1):1–32 (2014).
- the Alonzo Church Award 2024 (joint with LICS), awarded to Thomas Ehrhard (CNRS / IRIF) and Laurent Regnier (Université d'Aix-Marseille).

51st International Colloquium on Automata, Languages, and Programming (ICALP 2024).
Editors: Karl Bringmann, Martin Grohe, Gabriele Puppis, and Ola Svensson
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- the EATCS Award 2024 to Samson Abramsky (Department of Computer Science, Oxford University),
- the Presburger Award 2024, awarded jointly to Justin Hsu (Cornell University) and Pravesh Kothari (Princeton University).

The EATCS Distinguished Dissertation Award 2023 was awarded jointly to the following PhD dissertations:

- William Kuszmaul (MIT). *Randomized Algorithms that Achieve the Unexpected.*
- Nathan Klein (University of Washington). *Finding Structure in Entropy: Improved Approximation Algorithms for TSP and other Graph Problems.*
- Ruiwen Dong (University of Oxford). *Algorithmic Problems for Subsemigroups of Infinite Groups.*

There was also the announcement of the new EATCS Fellows for 2024, who are:

- Yossi Azar (Blavatnik School of Computer Science, Tel-Aviv University),
- Friedhelm Meyer auf der Heide (Heinz Nixdorf Institute and Department of Computer Science, Paderborn University).

The following workshops were held as satellite events of ICALP 2024, LICS 2024, and FSCD 2024 during July 6-9, 2024:

- Algorithmic Aspects of Temporal Graphs VII (AATG 2024)
- Geometric and Topological Methods in Computer Science (GETCO 2024)
- Intersection Types and Related Systems (ITRS 2024)
- International Workshop on Confluence (IWC 2024)
- Learning and Automata (LearnAut 2024)
- Logical Frameworks and Meta-Languages: Theory and Practice (LFMTP 2024)
- Logic Mentoring Workshop (LMW 2024)
- Mathematically Structured Functional Programming (MSFP 2024)
- Parameterized Approximation Algorithms Workshop (PAAW 2024)
- Parameterized Algorithms and Constraint Satisfaction (PACS 2024)
- Structure meets Power (SmP 2024)
- Trends in Arithmetic Theories (TAT 2024)
- Trends in Linear Logic and Applications (TLLA 2024)
- Women in Logic 2024

We wish to thank all authors who submitted extended abstracts for consideration, the program committees for their scholarly effort, and all the reviewers who assisted the program committees in the evaluation process.

We are very grateful to the Conference General Chair, Pawel Sobocinski, his colleagues from Tallinn University of Technology, and EATCS, for hosting ICALP 2024 in Tallinn.

Finally, we would like to thank Anca Muscholl, the Chair of the ICALP Steering Committee, for her continuous support, Artur Czumaj, the president of EATCS, for his generous advice on the organization of the conference, as well as the editorial office of LIPIcs for their support in editing these proceedings.

Organization

Program Committees

Track A

Nima Anari	Stanford University
Karl Bringmann (*co-chair*)	Saarland University
Parinya Chalermsook	Aalto University
Vincent Cohen-Addad	Google Research
Jose Correa	Universidad de Chile
Holger Dell	Goethe University Frankfurt
Ilias Diakonikolas	University of Wisconsin-Madison
Yuval Filmus	Technion
Arnold Filtser	Bar Ilan University
Naveen Garg	IIT Delhi
Pawel Gawrychowski	University of Wrocław
Anupam Gupta	Carnegie Mellon University
Samuel Hopkins	MIT
Sophie Huiberts	Columbia University
Giuseppe Italiano	LUISS University
Michael Kapralov	EPFL
Eun Jung Kim	Université Paris-Dauphine
Sándor Kisfaludi-Bak	Aalto University
Tomasz Kociumaka	Max-Planck-Institute for Informatics
Fabian Kuhn	University of Freiburg
Amit Kumar	IIT Delhi
William Kuszmaul	Harvard University
Rasmus Kyng	ETH Zurich
Kasper Green Larsen	Aarhus University
François Le Gall	Nagoya University
Pasin Manurangsi	Google Research
Daniel Marx	CISPA Helmholtz Center for Information Security
Yannic Maus	TU Graz
Nicole Megow	University of Bremen
Ruta Mehta	University of Illinois at Urbana-Champaign
Jakob Nordström	University of Copenhagen
Richard Peng	University of Waterloo
Seth Pettie	University of Michigan
Adam Polak	Bocconi University
Lars Rohwedder	Maastricht University
Eva Rotenberg	DTU Compute
Sushant Sachdeva	University of Toronto
Melanie Schmidt	University of Cologne
Sebastian Siebertz	University of Bremen
Shay Solomon	Tel Aviv University
Nick Spooner	University of Warwick

51st International Colloquium on Automata, Languages, and Programming (ICALP 2024).
Editors: Karl Bringmann, Martin Grohe, Gabriele Puppis, and Ola Svensson
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Clifford Stein	Columbia University
Ola Svensson (*co-chair*)	EPFL
Luca Trevisan	Bocconi University
Ali Vakilian	Toyota Technological Institute Chicago
Jan van den Brand	Georgia Tech
Erik Jan van Leeuwen	Utrecht University
Oren Weimann	University of Haifa
Nicole Wein	University of Michigan
Andreas Wiese	TU Munich
John Wright	UC Berkeley

Track B

Arnold Beckmann	Swansea University
Manuel Bodirsky	TU Dresden
Patricia Bouyer	CNRS, LMF
Yijia Chen	Shanghai Jiao Tong University
Victor Dalmau	Universitat Pompeu Fabra
Laurent Doyen	CNRS, LMF
Marcelo Fiore	Cambridge University
Stefan Göller	University of Kassel
Martin Grohe (*chair*)	RWTH Aachen University
Sandra Kiefer	Oxford University
Aleks Kissinger	Oxford University
Bartek Klin	Oxford University
Antonin Kucera	Masaryk University Brno
Carsten Lutz	University of Leipzig
Jerzy Marcinkowski	University of Wrocław
Annabelle McIver	Macquaire University Sydney
Andrzej Murawski	Oxford University
Paweł Parys	University of Warsaw
Michał Pilipczuk	University of Warsaw
Joel Ouaknine	Max Planck Institute for Software Systems
Christian Riveros	Pontificia Universidad Catolica de Chile
Alexandra Silva	Cornell University
Balder ten Cate	ILLC Amsterdam
Szymon Toruńczyk	University of Warsaw
Igor Walukiewicz	CNRS, University of Bordeaux
Sarah Winter	IRIF, University Paris Cité
Georg Zetzsche	Max Planck Institute for Software Systems
Martin Ziegler	KAIST

Organizing Committee

Pawel Sobocinski (*chair*)	Tallinn University of Technology
Niccolò Veltri	Tallinn University of Technology
Amar Hadzihasanovic	Tallinn University of Technology
Fosco Loregian	Tallinn University of Technology
Matt Earnshaw	Tallinn University of Technology
Diana Kessler	Tallinn University of Technology
Ekaterina Zhuchko	Tallinn University of Technology
Kristi Ainen	Tallinn University of Technology

ICALP Steering Committee

Luca Aceto	Reykjavik University and Gran Sasso Science Institute, L'Aquila
Artur Czumaj	University of Warwick
Kousha Etessami	University of Edinburgh
Uriel Feige	Weizmann Institute
Sevag Gharibian	University of Paderborn
Thore Husfeldt (co-chair)	Lund University and IT University of Copenhagen
Anca Muscholl (chair)	University of Bordeaux
Luke Ong	NTU Singapore
Yuval Rabani	Hebrew University
Eva Rotenberg	DTU Compute
Paul Spirakis	University of Liverpool and University of Patras
Ola Svensson	EPFL

Limits of Symmetric Computation

Anuj Dawar
Department of Computer Science and Technology, University of Cambridge, UK

Abstract

I survey recent work on symmetric computation. A number of strands of work, from logic, circuit complexity, combinatorial optimization and other areas have converged on similar notions of symmetry in computation. This write-up of an invited talk gives a whirlwind tour through the results and pointers to the relevant literature.

Introduction

In the 1980s, descriptive complexity was a new approach to the problems of complexity theory. It carried the hope that methods from logic, particularly finite model theory, could be deployed to settle the difficult questions of complexity. It was one of many promising approaches at the time but the hard problems of complexity proved resistant to all of them. An amusing article from ACM Sigact News in 1996 [24] imagines the many possible titles of a paper announcing a resolution of the P vs.NP question. One of them is through Immerman's approach to descriptive complexity which recasts the question of separting P from NP as the question of separating the expressive power of fixed point logic FP from existential second-order logic on *ordered structures*. This captures the essential gap between the promise of descriptive complexity and its delivery. The methods from finite model theory that it makes available for proving inexpressibility in logics such as FP work well on *unordered* structures. But, the correspondence with complexity classes works well on *ordered* structures.

A more recent viewpoint on this is that the inexpressibility results from finite model theory establish lower bounds for restricted, *symmetric* models of computation. This is exemplified by the results of [2, 21], which show that the logic FPC (fixed-point logic with counting) corresponds to a natural model of *symmetric circuits*. The logic FPC is a natural and powerful logic within P for which unconditional lower bounds have been proved (see [11] for an overview).

Understanding the inexpressibilty methods of descriptive complexity as lower bounds for symmetric models of computation leads to a number of interesting further directions of investigation, which I review in the present talk. In particular, I look at the following directions.

1. We can extend the expressive power of FPC by considering more powerful operations than counting, while remaining within P. These give rise to further notions of symmetric computation, essentially weakening the symmetry restriction. Recently lower bounds have been obtained for these as well.
2. We can investigate what efficient algorithms can be implemented within these symmetric models. It turns out that many natural algorithmic methods are symmetric and therefore subject to the lower bound methods of descriptive complexity.

3. We can look at symmetry as it arises in other models of computation, and see to what extent *asymmetry* is used as a resource. I illustrate this with two cases, that of linear programs and of arithmetic circuits.
4. We relate the lower bounds to other classifications of problems according to their symmetries. In particular, the very successful classification of constraint satisfaction problems into tractable and intractable ones is based on a different, but related notion of symmetry.

In the following, after a brief introduction of the relationship between FPC and symmetric circuits, I give a summary of each of the above directions. The main aim is to provide pointers to the relevant literature and to identify fertile directions for future work. Formal definitions, statements of the results and proofs may be found in the cited literature.

FPC and symmetric circuits

The symmetry restriction we are considering is most clearly explained in a circuit model of computation. Recall that any decision problem $L \subseteq \{0,1\}^*$ can be seen as a family of Boolean functions $(f_n)_{n\in\omega}$ where $f_n : \{0,1\}^n \to \{0,1\}$. Moreover, each function f_n can be described by a circuit C_n: a directed acyclic graph with n inputs and gates labelled by Boolean functions from some fixed basis, such as $\wedge$, $\vee$, $\neg$ or extensions with a majority gate or threshold gates. The language L is decidable in polynomial time if, and only if, it has such a family of circuits that is P-uniform. In other words, the circuit C_n can be constructed in poly(n) time. One fact to note here is that when we consider what Boolean functions we can use in the basis, we are restricted to *symmetric* functions. These are functions whose value depends only on the number of 1s and 0s in the input and not on the order in which the inputs appear. The functions $\wedge$, $\vee$, $\neg$, majority and threshold all have this property. This is necessary in order for the circuit to be defined as a DAG with no further structure on it, such as an order of the gates.

When we consider decision problems on structures such as graphs, we are typically interested in deciding properties that are invariant under graph isomorphisms. A key perspective of descriptive complexity is that we consider formalisms in which only such properties can be expressed. In the context of circuit complexity, we can consider a property P of (directed) graphs as being given by a family of Boolean functions $(p_n)_{n\in\omega}$ where $p_n : \{0,1\}^{n\times n} \to \{0,1\}$ takes the adjacency matrix of a graph and maps it to 1 just in case the graph has property P. Such Boolean functions have natural symmetries in the sense that for any permutation π of $[n]$, we have $p_n(x) = p_n(x^\pi)$ where the string x^π is defined to have $x^\pi_{ij} = x_{\pi(i)\pi(j)}$. We say that a circuit C computing p_n is *symmetric* if this action of permutations $\pi \in S_n$ on the inputs always extends to an automorphism of the circuit C itself.

The key result from [2] is that a graph property is definable in FPC (for a formal definition of FPC, I refer the reader to [11]) if, and only if, it is decidable by a P-uniform family of symmetric circuits. The result there is stated for circuits with threshold gates (indeed, just a majority gate would suffice) but, as observed in [21], adding further symmetric Boolean functions to the basis does not change it. Thus, we get quite a robust notion of symmetric polynomial-time computation and it corresponds exactly to definability in FPC. Moreover, while I have stated it here for graphs, it is proved more generally for finite relational structures.

The important aspect of the connection between FPC definability and decidability with symmetric circuits is that we have methods for proving inexpressibility results in FPC and these yield proofs of unconditional lower bounds for symmetric circuits. In particular, FPC definable classes of graphs exhibit stronger invariance conditions than just being closed under

isomorphism. This is made precise by considering the Weisfeiler-Leman (WL) equivalences. For a precise definition of the k-dimensional Weisfeiler-Leman equivalence, see [17, Sec. 2]. Here we just note that this is, for any fixed k, a coarser relation than graph isomorphism. The connection with FPC definability comes from the fact that for any property P of graphs that is definable by a formula of FPC, there is a constant k such that P is invariant under k-dimensional WL equivalence.

Cai et al. [10] first showed that there is no fixed value of k for which k-dimensional WL equivalence is the same as isomorphism, and this leads to a construction of a class of graphs in P which is not FPC definable. This fundamental construction has been at the heart of many lower bounds since. That is, most results showing that some property P is not definable in FPC and therefore not decidable by symmetric circuits proceed by showing that P is not invariant under k-dimensional WL for any fixed k. Graph properties for which this has been shown include Hamiltonicity and 3-colourability.

Symmetric algorithms

The fact that we can prove unconditional lower bounds for classes of symmetric circuits would not be so interesting if these classes formed a very weak model of computation. It turns out, however, that many natural algorithmic techniques are in fact symmetric. First of all, it is worth recalling some of the original motivation for the interest of finite model theory in computer science, which came from the study of database query languages (see [31]). Languages for querying relational databases, based on first-order logic and its extensions, naturally give rise to symmetric algorithms (in the precise sense of symmetric circuits considered above) when automatically compiled (see, for instance, the connection to circuits given in [23, 29]). In this sense, FPC provides a good formal model of database query languages that extend the relational calculus with recursion and counting mechanisms. When FPC was first introduced [27] it was proposed as a possible language in which all polynomial-time decidable queries could be expressed. Even after Cai et al. showed that this was not the case, it was often said that all *natural* polynomial-time decidable properties are expressible in FPC. One way to understand this is that problems for which the obvious algorithm is in polynomial time can usually be formulated in FPC. However, the power of FPC, and hence of symmetric computation, is surprising and a number of problems for which the polynomial-time algorithms are far from trivial have been shown nonetheless to admit symmetric algorithms. A few are worth highlighting.

The most significant one is Grohe's monumental work [26] showing that any polynomial-time decidable property of graphs excluding some fixed minor is in FPC, and so invariant under k-WL equivalence for some fixed k. In [3], my co-authors and I show that the ellipsoid method for optimizing linear programs can be expressed in FPC, and so many natural combinatorial optimization problems have bounded WL dimension. In particular this is true of the problem of determining the size of a maximum matching in a graph. The result can be further extended to hierarchies of semi-definite programs [19, 6]. This shows that some of our most powerful techniques for constructing efficient algorithms can be implemented in a way that is symmetry preserving.

Linear-algebraic extensions

While many powerful algorithmic techniques can be implemented symmetrically, there are some simple efficient algorithms that just cannot be symmetrized without an exponential blow-up. It has been observed that the construction of Cai et al. essentially shows that

the problem of solving systems of linear equations over a a finite field cannot be expressed in FPC [4]. It follows that the Gaussian elimination algorithm cannot be implemented symmetrically. Indeed, since linear algebra, and more generally equation-solving, provides a rich source of examples of problems that cannot be expressed in FPC [12], research in descriptive complexity has investigated extensions of this logic with linear-algebraic operators. The resultung logics are provably more expressive than FPC. Here I want to point to connections of these with symmetric circuits, and with approximations of isomorphism stronger than the WL equivalences.

The first proposed extension of FPC by means of linear-algebraic operators was *fixed-point logic with rank* (FPR), which allows for operators that compute the rank of a matrix over a finite field [14, 25]. The expressive power of this logic has been shown to be characterized by symmetric circuits with *rank gates* [21]. To make this work, we need to modify the definition of circuit. To be precise, the Boolean function computed by a rank gate is not a fully symmetric function and so we can no longer think of a circuit as a DAG. It needs to have additional structure to give a matrix structure to the inputs of a rank gate. This relaxed notion of circuit gives a weaker requirement of symmetry which can be formalized and used to give a circuit characterization of FPR.

In order to study the expressiveness of FPR, a strengthening of the family of WL equivalences was defined in [16] which we call the *invertible map* (IM) equivalences. The WL equivalences can be seen as giving, on a fixed graph G, a partition of the k-tuples of vertices that approximates the partition into orbits of the automorphism group. The k-WL partition is the coarsest partition of the k-tuples of G into classes $P_1, \ldots, P_t$ satisfying a natural *stability condition*. This condition says that two tuples $\mathbf{u}$ and $\mathbf{v}$ in the same class P_i cannot be distinguished by counting the number of substitutions we can make in them to get a tuple in class P_j. The k-IM equivalences (denoted $\equiv^k_{\mathrm{IM}}$) are similarly defined but with a different stability condition. This essentially amounts to saying that the partition $P_1, \ldots, P_t$ cannot be further refined using *linear algebraic operators* over fields of characteristic p where p is a prime from some fixed set Ω. Technical details of the definition and characterization in terms of linear algebraic operators can be found in [13].

In a breakthrough result, Lichter [28] has shown that there is no constant k for which $\equiv^k_{\mathrm{IM}}$ is the same as isomorphism. The implications of this construction for the expressive power of any extension of FPC with linear-algebraic operators are spelled out in [15].

Symmetry and asymmetry in other models

Once we recognize symmetry as a feature of algorithms, it makes sense to identify how it appears in other models of computation, beyond logic and circuits. It is, of course, built in as a natural feature in the logics we study in descriptive complexity. And we have identified the corresponding notion in the context of circuits. One aim of identifying meaningful restrictions by symmetry in various models of computation is to see how asymmetry (or symmetry-breaking) is a resource and how it trades off with other computational resources. In this section, I aim to provide pointers to two specific models where we have obtained interesting insights by analysing symmetric restrictions to natural known computational paradigms.

The first is that of linear programming. I noted above that the ellipsoid method for solving linear programs can be implemented symmetrically. Moreover, when combinatorial problems are formualted as linear programs, the programs have natural symmetries inherited from the problem. Symmetric linear programs in this sense were studied by Yannakakis [32]. The focus there was on linear programs, or *extended formulations*. For example, consider

graphs over the vertex set $[n]$. We can consider these as functions $G : X \to \{0,1\}$ where $X = \{x_{ij} \mid i,j \in [n]\}$ is the set of potential edges. Equivalently, we can think of G as a 0-1 valued vector in the Euclidean space $\mathbb{R}^X$. A collection of graphs is then a set $P \subseteq \{0,1\}^X$ and various graph optimization problems can be expressed as optimizing a linear function over P. If we can represent the convex hull $\text{conv}(P)$ as the projection of a polytope $Q \subseteq \mathbb{R}^{X \times Y}$ using additional variables Y, with a number of facets polynomial in n, we can solve these problems in polynomial time. Yannakakis proved that the travelling salesman and matching polytopes do not have such polynomial-size *symmetric* extended formulations. The notion of symmetry is the natural one. Any permutation of $[n]$ has a natural action on X and hence on $\mathbb{R}^X$. The symmetry requirement says that for any such permutation $\pi \in S_n$ we can find a permutation σ of Y such that for $\mathbf{xy} \in R^{X \times Y}$, $\mathbf{xy} \in Q$ if, and only if, $\pi(\mathbf{x})\sigma(\mathbf{y}) \in Q$. While the lower bound proof of Yannakakis relies heavily on the notion of symmetry, it turns out that this is not essential to the result as Rothvoß [30] obtains exponential lower bounds without the assumption.

We can consider another way of representing the set $P \subseteq \{0,1\}^X$ as a linear program. We say that a polytope $\mathcal{P} \subseteq \mathbb{R}^X$ *recognizes* P if $P \subseteq \mathcal{P}$ and $\{0,1\}^X \setminus P$ is disjoint from $\mathcal{P}$. Now, a class of graphs that is decidable in polynomial time necessarily is recognized by a polynomial-size family of extended formulations. But, what classes are recognized by *symmetric* such families? It turns out that they are exactly the classes of bounded WL dimension. In other words those that are recognized by (possibly non-uniform) families of polynomial-size symmetric circuits with threshold gates [5].

Another computational model where the assumption of symmetry has revealed remarkable structure is that of *arithmetic circuits*. Formally, an arithmetic circuit over a field K and a set of variables X is a directed acyclic graph where every input (i.e. node of indegree 0) is labelled by an element of X or an element of K, and every internal node is labelled either $+$ (a sum gate) or $\times$ (a product gate). A distinguished *output* gate can then be seen as computing a polynomial in the ring $K[X]$. Two polynomials (strictly speaking they are families of polynomials) that are much studied in the field are the *determinant* and the *permanent*. They are both defined on a set of variables X representing the entries of an $n \times n$ matrix, so $X = \{x_{ij} \mid 1 \leq i,j \leq n\}$. It is known that there are polynomial-size circuits for computing the determinant $\det(X)$ while it is conjectured that there are no polynomial-size circuits for computing the permanent $\text{perm}(X)$. Both $\det(X)$ and $\text{perm}(X)$ are invariant under permutations of the variables X which are induced by the natural action of S_n. So, it makes sense to ask whether these polynomials can be computed by polynomial-size *symmetric* circuits. It turns out [20] that this is the case for the determinant but provably not for the permanent. Furthermore, these polynomials have symmetries that go beyond the action of S_n simultaneously on rows and columns. For example, the permanent is invariant under *any* permutation of the rows and columns of the matrix and the determinant under separate permutations of the rows and columns that have the same sign. We are able to establish lower bounds for arithmetic circuits assuming these more stringent symmetry requirements [22]. This provides an interesting case study in the tradeoff between symmetry and other resources, in this case circuit size. The lower bounds are obtained by adapting proof methods from finite model theory, even though the connection to logic is now remote.

Constraint satisfaction problems

One of the great breakthroughs in theoretical computer science in recent years was the dichotomy theorem for constraint satisfaction problems (CSP) proved independently by Bulatov [8] and Zhuk [33]. A specific CSP is given by a finite relational structure $\mathbb{D}$: the

domain D along with a collection of relations $R_1, \ldots, R_m$ on it. An instance to be solved is specified by a similar relational structure $\mathbb{V}$: the set V of variables and for each relation R_i, a set of tuples from V whose interpretation must be in the relation. A solution is just a homomorphism from $\mathbb{V}$ to $\mathbb{D}$. It turns out that the computational complexity of determining whether a given instance is solvable is completely determined by the algebraic structure of the so-called *clone of polymorphisms* of $\mathbb{D}$ [9]. Looking at the polymorphism clones of a structure, rather than the automorphism groups is a different notion of symmetry which is more relevant when we are interested in the homomorphisms between structures. Nonetheless, there is a potentially intriguing relationship between the two notions of symmetry.

While the Bulatov-Zhuk dichotomy theorem classifies all CSP into two classes: those that are solvable in polynomial time and those that are NP-complete, for our purposes a trifurcation of CSP is interesting. That is, we can further subdivide the polynomial-time solvable problems into those that have *bounded width* and those that do not. The CSP of bounded width can be solved by means of a simple algorithm, known as *local consistency* [7]. This is parameterized by a natural number k. Since, for fixed k, the k-local consistency check is a polynomial-time algorithm, all bounded-width CSP admit a polynomial-time algorithm. However, the converse is not true. A number of CSP are known which are efficiently solvable, but do not have bounded width. It turns out that a CSP has bounded width if, and only if, the collection of satisfiable instances has bounded WL dimension (see [4, 7, 18]). Thus, there is apparently a close relationship between the k-dimensional WL approximation of isomorphism and the k-local consistency method for approximating homomorphism. This relationship is made precise in the category theoretic framework we developed in [1].

It remains an open question whether we can similarly characterize *all* tractable CSP, i.e. those with a near-unanimity polymorphism by some (perhaps tractable) approximation of isomorphism. Indeed, it is conceivable that the invertible map equivalences serve this purpose. Could it be that for every such CSP there is a k such that the collection of satisfiable instances is invariant under $\equiv^k_{\mathrm{IM}}$? Converesely, could it be that for every CSP that does not admit such a polymorphism (i.e. those that we know to be NP-complete) is not invariant under $\equiv^k_{\mathrm{IM}}$ for any k?

Conclusion

We have discovered that symmetry arises in many forms in the analysis of computation, and is an important property of structured data, such as graphs and also of algorithms that work on this data. Symmetry in algorithms arises naturally when algorithms are automatically generated from high-level specifications. At the same time, symmetry-breaking can be an important method to improve efficiency of algorithmic procedures, and this is demonstrated by the unconditional lower bounds we have for symmetric algorithms for some problems, where efficient symmetry-breaking algorithms are known. The emerging theory of upper and lower bounds for symmetric computation pulls together a number of distinct strands within theoretical computer science, and draws in diverse mathematical methods with many promising directions to follow.

Group Fairness: Multiwinner Voting and Beyond

Edith Elkind ✉
University of Oxford, UK
Alan Turing Institute, London, UK

Abstract

In multiwinner voting with approval ballots the agents are presented with a set of alternatives, each agent indicates which of these alternatives they approve, and the goal is to select a fixed-size subset of the alternatives, in a way that reflects the voters' preferences. This framework captures a variety of group decision-making scenarios, from choosing a list of speakers for an event to appointing a set of validators in a proof-of-stake blockchain. An important concern in many of these scenarios is group fairness: every sufficiently large group of agents with similar preferences should be represented in the winning set of alternatives. In this talk, we discuss how to formalise this idea and whether the resulting axioms can be satisfied by efficiently computable voting rules. We also discuss extensions of our framework to the more expressive setting of participatory budgeting, where the agents are presented with a slate of projects (which may have different costs) and the goal is to select a subset of projects subject to a budget constraint.

Cross-Paradigm Graph Algorithms

Danupon Nanongkai

Abstract

A goal of the theory of graph algorithms is algorithmic techniques that enable computing devices to process graph data with little resources (time, space, communication overhead, etc.). This led to extensive studies of graph algorithms in various models of computation (sequential algorithms, distributed algorithms, streaming algorithms, etc.) by many sub-communities. *Cross-paradigm graph algorithms* is an effort to attack the same problem in many models of computation *simultaneously*, with the goal to generate new insights that may not emerge from the isolated viewpoint of a single model and to ultimately develop techniques that can be used to solve graph problems near-optimally across many models of computation. In this talk, I will discuss some recent advances in graph algorithmic techniques for basic graph problems (e.g. minimum cut, shortest path, and maximum flow) in connection to this research program, especially some insights that led to cross-paradigm algorithms and to answering notorious open questions. No background will be assumed from the audience beyond familiarity with textbook graph algorithms.

Graphs Shortcuts: New Bounds and Algorithms

Merav Parter ✉
Weizmann Institute of Science, Rehovot, Israel

Abstract

For an n-vertex digraph $G = (V, E)$, a *shortcut set* is a (small) subset of edges H taken from the transitive closure of G that, when added to G guarantees that the diameter of $G \cup H$ is small. Shortcut sets, introduced by Thorup in 1993, have a wide range of applications in algorithm design, especially in the context of parallel, distributed and dynamic computation on directed graphs. A folklore result in this context shows that every n-vertex digraph admits a shortcut set of linear size (i.e., of $O(n)$ edges) that reduces the diameter to $\widetilde{O}(\sqrt{n})$. Despite extensive research over the years, the question of whether one can reduce the diameter to $o(\sqrt{n})$ with $\widetilde{O}(n)$ shortcut edges has been left open.

In this talk, I will present the first improved diameter-sparsity tradeoff for this problem, breaking the $\sqrt{n}$ diameter barrier. Specifically, we show an $O(n^\omega)$-time randomized algorithm for computing a linear shortcut set that reduces the diameter of the digraph to $\widetilde{O}(n^{1/3})$. I also present time efficient algorithms for computing these shortcuts and explain the limitations of the current approaches. Finally, I will draw some connections between shortcuts and several forms of graph sparsification (e.g., reachability preservers, spanners). Based on a joint work with Shimon Kogan (SODA 2022, ICALP 2022, FOCS 2022, SODA 2023).

Abstract

In the Submodular Facility Location problem (SFL) we are given a collection of n clients and m facilities in a metric space. A feasible solution consists of an assignment of each client to some facility. For each client, one has to pay the distance to the associated facility. Furthermore, for each facility f to which we assign the subset of clients S^f, one has to pay the opening cost $g(S^f)$, where $g(\cdot)$ is a monotone submodular function with $g(\emptyset) = 0$.

SFL is APX-hard since it includes the classical (metric uncapacitated) Facility Location problem (with uniform facility costs) as a special case. Svitkina and Tardos [35, SODA'06] gave the current-best $O(\log n)$ approximation algorithm for SFL. The same authors pose the open problem whether SFL admits a constant approximation and provide such an approximation for a very restricted special case of the problem.

We make some progress towards the solution of the above open problem by presenting an $O(\log \log n)$ approximation. Our approach is rather flexible and can be easily extended to generalizations and variants of SFL. In more detail, we achieve the same approximation factor for the natural generalizations of SFL where the opening cost of each facility f is of the form $p_f + g(S^f)$ or $w_f \cdot g(S^f)$, where $p_f, w_f \geq 0$ are input values.

We also obtain an improved approximation algorithm for the related Universal Stochastic Facility Location problem. In this problem one is given a classical (metric) facility location instance and has to a priori assign each client to some facility. Then a subset of active clients is sampled from some given distribution, and one has to pay (a posteriori) only the connection and opening costs induced by the active clients. The expected opening cost of each facility f can be modelled with a submodular function of the set of clients assigned to f.

We would also like to thank Neil Olver for inspiring discussions about applications of their technique in [5] to various covering problems over time.

1 Introduction

In the Submodular Facility Location problem (SFL), we are given a set C of n clients and set F of m facilities, with metric distances $d : (C \cup F) \times (C \cup F) \to \mathbb{R}_{\geq 0}$. Furthermore, we are given a monotone submodular[1] (opening cost) function $g : 2^C \to \mathbb{R}_{\geq 0}$ with $g(\emptyset) = 0$. Notice that $g(\cdot)$ is non-negative. A feasible solution consists of an assignment $\varphi : C \to F$ of each client to some facility (we also say that $\varphi(c)$ *serves* c). The opening cost of $f \in F$ in this solution is $g(\varphi^{-1}(f))$. The cost of the solution, that we wish to minimize, is the sum of the distances from each client to the corresponding facility plus the total opening cost of the facilities, in other words

$$\text{cost}(\varphi) = \sum_{c \in C} d(c, \varphi(c)) + \sum_{f \in F} g(\varphi^{-1}(f)).$$

SFL captures practical scenarios where the cost of opening a facility is a (non-linear, still "tractable") function of the set of served clients. For example, each client might have different types of needs, and satisfying such needs might have a submodular impact on the opening cost (regardless of the facility location). As we will discuss, SFL is also closely related to certain stochastic optimization problems which recently attracted a lot of attention (see, e.g, [2, 17, 19, 22, 24] and references therein). In particular, there are scenarios where one has to pay (a posteriori) the connection and opening costs related only to a random subset of *activated* clients, and this naturally induces objective functions with submodular opening costs.

SFL is APX-hard since it includes the classical Facility Location problem (with uniform facility costs) as a special case [21]. Hence the best we can hope for, in terms of approximation algorithms, is a constant approximation. Finding such an approximation algorithm is explicitly posed as an open problem, e.g., by Svitkina and Tardos [35, 36]. The same authors present an $O(\log n)$ approximation, based on a greedy approach, for a generalization of SFL where each facility f has a distinct monotone submodular function $g_f(\cdot)$ (and this result is tight for this generalization due to a reduction from Set Cover by Shmoys, Swamy and Levi [33]). Chekuri and Ene [10] obtain an alternative $O(\log n)$ approximation for the same generalization of SFL based on rounding a convex relaxation exploiting Lovász extensions (see also the related work on submodular partitioning problems [9, 13]). Svitkina and Tardos also present a constant approximation for a rather restrictive (still practically motivated) special case of SFL where $g(\cdot)$ is induced by certain subtrees of a node-weighted tree over the clients.

1.1 Our Results and Techniques

We make some progress towards the resolution of the mentioned open problem by presenting an improved approximation algorithm for SFL.

[1] We recall that $g(\cdot)$ is submodular iff, for every $S, T \subseteq C$, $g(S) + g(T) \geq g(S \cap T) + g(S \cup T)$. The function is also monotone if $g(T) \leq g(S)$ for every $T \subseteq S \subseteq C$. As usual in this framework, we assume to have an oracle access to $g(\cdot)$: given $S \subseteq C$, we can obtain the value of $g(S)$ in polynomial time.

▶ **Theorem 1.1.** *There is a polynomial-time $O(\log\log n)$-approximation algorithm for SFL.*

Our approach is surprisingly simple (modulo exploiting some non-trivial results in the literature). By standard reductions (see Section 1.4) we can assume that $N = n + m$ is polynomial in n, hence it is sufficient to provide an $O(\log\log N)$ approximation. Our starting point is a natural (configuration) LP relaxation for the problem:

$$\begin{aligned}
\min \quad & \sum_{f\in F}\sum_{R\subseteq C} g(R)\cdot x_R^f + \sum_{c\in C}\sum_{f\in F}\sum_{R\ni c} d(c,f)\cdot x_R^f && \text{(Conf-LP)}\\
\text{s.t.} \quad & \sum_{f\in F}\sum_{R\ni c} x_R^f = 1 && \forall c\in C;\\
& \sum_{R\subseteq C} x_R^f = 1 && \forall f\in F;\\
& x_R^f \geq 0 && \forall R\subseteq C,\ \forall f\in F.
\end{aligned}$$

In an integral solution, we interpret $x_R^f = 1$ as assigning exactly the set of clients R to the facility f. Notice that we impose $\sum_{R\subseteq C} x_R^f = 1$. This is w.l.o.g. since $g(\emptyset) = 0$ (intuitively, $x_\emptyset^f = 1$ means that no client is assigned to f). We can solve the above LP in polynomial time (see Appendix A for a proof).

▶ **Lemma 1.2.** *In* $\mathrm{poly}(N)$ *time one can find an optimal solution to* (Conf-LP) *with* $\mathrm{poly}(N)$ *non-zero entries.*

Given an optimal solution $\dot{x} = (\dot{x}_R^f)_{f\in F, R\subseteq C}$ to (Conf-LP) of cost $\mathrm{cost}(\dot{x})$ as in Lemma 1.2, we proceed with two main stages. In the first stage (discussed in Section 2) we simply sample partial assignments of clients to facilities with the distribution induced by $\dot{x}$ for $\ln\ln N$ many times. This cost at most $\ln\ln N$ times the optimal LP cost in expectation, and leads to a partial solution that covers a random subset $C_1 \subseteq C$ of clients.

In the second stage (discussed in Section 3) we take care of the remaining uncovered clients $C_2 = C \setminus C_1$. Let us consider the restriction $\ddot{x}$ of $\dot{x}$ to C_2. The opening cost of $\ddot{x}$ might be as large as the opening cost of $\dot{x}$. However, in expectation, the connection cost of $\ddot{x}$ is only a $1/\ln N$ fraction of the connection cost of $\dot{x}$ (as we will show).

At this point, using the probabilistic tree embedding algorithm in [14], we embed the original metric d into a (rooted) tree metric d^T over a hierarchically well-separated tree (HST) T (see Section 1.4 for the details). The opening cost of $\ddot{x}$ w.r.t. to the new tree instance does not change, while its connection cost grows by a factor at most $O(\log N)$ in expectation. Altogether we obtain a feasible fractional solution $\ddot{x}$ over the tree instance whose expected cost is at most $O(\mathrm{cost}(\dot{x}))$. Hence it is sufficient to develop an $O(\log\log N)$-approximate LP-rounding algorithm for the considered tree instance.

The next step is at the heart of our approach. Using the properties of HSTs and losing a constant factor in the approximation, we can further reduce our SFL tree instance to the following Descendant-Leaf Assignment problem (DLA): the facilities are leaves of T and the clients are arbitrary nodes of T. Each client c must be served by a facility contained in the subtree T_c rooted at c. The opening cost of each facility is given by $g(\cdot)$, and there are no connection costs at all. Bosman and Olver [5] describe a reduction of Submodular Joint Replenishment and Inventory Routing problems to the Nice Subadditive Cover Over Time problem. We critically observed that DLA has some similarities with the latter problem (though this connection might not be obvious at first sight, see the discussion in Section 1.3). In particular, we were able to adapt their approach to achieve the desired $O(\log\log N)$ approximation for our DLA problem.

We remark that we do not know how to get an $O(1)$ approximation for SFL on trees (even on HSTs). Though such approximation would not imply an $O(1)$ approximation for SFL with our approach (due to the first stage), finding it seems to be a natural intermediate problem to address.

The first stage of our construction might be helpful in other related problems, in particular to reduce the input problem to one on HSTs while introducing an additive $O(\log \log n)$ term in the approximation ratio.

1.2 Generalizations and Variants

Our basic approach is rather flexible, and it can be applied to generalizations and variants of SFL. We next describe some other applications of our approach, and we expect to see a few more ones in the future. For example, we can handle the case where the opening cost of the facility f is $g_f(S^f) = w_f \cdot g(S^f)$, where $w_f \geq 0$ is some input value: we call this the SFL WITH MULTIPLICATIVE OPENING COSTS problem (MULTSFL).

▶ **Theorem 1.3.** *There is a polynomial-time $O(\log \log n)$-approximation algorithm for* MULTSFL.

Similarly, we can address the SFL WITH ADDITIVE OPENING COSTS problem (ADDSFL), where $g_f(S^f) = p_f + g(S^f)$ for $S^f \neq \emptyset$, $g_f(\emptyset) = 0$, and $p_f \geq 0$ is some input value.

▶ **Theorem 1.4.** *There is a polynomial-time $O(\log \log n)$-approximation algorithm for* ADDSFL.

The above generalizations are discussed in Appendix B. We remark that we do not know how to obtain an $O(\log \log n)$-approximation for the AFFINE SFL case, where the opening costs are submodular functions of the form $g_f(S^f) = p_f + w_f \cdot g(S^f)$. Notice that this generalizes both ADDSFL and MULTSFL. This is left as an interesting open problem.

As mentioned earlier, SFL is closely related to stochastic variants of FACILITY LOCATION. In particular, our approach also extends to the following UNIVERSAL STOCHASTIC FACILITY LOCATION problem (UNIVFL). Here we are given clients C and facilities F with metric distances d like in SFL, plus an opening cost w_f for each $f \in F$. Furthermore, we have an oracle access to a probability distribution $\pi : 2^C \to \mathbb{R}_{\geq 0}$ specifying the probability $\pi(A)$ that a given subset of clients $A \subseteq C$ is activated. A feasible solution is an (universal) mapping $\varphi : C \to F$. The cost of φ w.r.t. clients $A \subseteq C$ is $\text{cost}_A(\varphi) = \sum_{c \in A} d(c, \varphi(c)) + \sum_{f \in F : \varphi^{-1}(f) \cap A \neq \emptyset} w_f$. In words, this is the cost of connecting clients in A to the corresponding facilities, plus the cost of opening the facilities that serve at least one client in A. Our goal is to minimize $\mathbb{E}_{A \sim \pi}[\text{cost}_A(\varphi)]$. The main motivation for *universal* problems of this type is to allow a very quick (possibly distributed) reaction to requests that arrive over time. Let $\text{opt} : C \to F$ minimize $\mathbb{E}_{A \sim \pi}[\text{cost}_A(\text{opt})]$, in other words opt is an optimal (universal) mapping. We say that an algorithm for UNIVFL is α-approximate[2] if it returns a universal mapping φ satisfying $\mathbb{E}_{A \sim \pi}[\text{cost}_A(\varphi)] \leq \alpha \cdot \mathbb{E}_{A \sim \pi}[\text{cost}_A(\text{opt})]$.

Notice that the objective function of UNIVFL can be rewritten as

$$\sum_{c \in C} d(c, \varphi(c)) \cdot \mathbb{P}_{A \sim \pi}[\{c\} \cap A \neq \emptyset] + \sum_{f \in F} w_f \cdot \mathbb{P}_{A \sim \pi}[\varphi^{-1}(f) \cap A \neq \emptyset].$$

[2] In Section 1.3 we describe alternative ways to define the approximation ratio.

Hence univFL is almost identical to SFL since $g(R) = \mathbb{P}_{A\sim\pi}[R \cap A \neq \emptyset]$ is a monotone submodular function of R which is 0 for $R = \emptyset$. We can therefore adapt our techniques to achieve the following result (see Section 4). Let $\pi_{\min} := \min_{c\in C}\{\mathbb{P}_{A\sim\pi}[c \in A]\}$ be the smallest probability of any client to be activated. W.l.o.g. we will assume $\pi_{\min} > 0$.

▶ **Theorem 1.5.** *There is a polynomial-time $O(\log\log \frac{n}{\pi_{\min}})$-approximation algorithm for the* Universal Stochastic Facility Location *problem.*

For a comparison, Adamczyk, Grandoni, Leonardi and Włodarczyk [2] obtain an $O(\log n)$ approximation which also holds for non-metric distances. In the case of metric distances, they obtain an $O(1)$ approximation but only in the *independent activation case*, i.e., when the sampled set A of active clients is obtained by independently sampling each client c according to some input probability $\pi'(c)$ for k times.

1.3 Related Work

As mentioned earlier, Bosman and Olver [5] consider the Nice Subadditive Cover Over Time problem: roughly speaking, here we are given a set V of items and a time interval $\{1,\dots,L\}$. Each item $v \in V$ is associated with a time window $F_v = \{s,\dots,t\}$, $1 \le s \le t \le L$. The time windows altogether have a special *left-aligned* structure whose definition we skip here. A feasible solution consists of a subset $S_t \subseteq V$ for each $t \in \{1,\dots,L\}$, such that, for each $v \in V$, one has $v \in S_r$ for some $r \in F_v$. The goal is to minimize $\sum_{t=1}^{L} g(S_t)$, where $g(\cdot)$ is a monotone submodular set function with $g(\emptyset) = 0$. For this problem they give a $O(\log\log L)$ approximation, using a clever rounding algorithm for a convex optimization problem involving the Lovász extension of $g(\cdot)$. Intuitively, in our DLA problem (defined in Section 3.1) the time interval is replaced by the leaves (associated with some facility) of the tree $\tilde{T}$, and the time window of $c \in \tilde{C}$ by the set $\tilde{F}_c$. Our time windows naturally induce a laminar family, which is a special case of the left-aligned structure mentioned before. The parameter $\log L$ in their construction is replaced by the depth D of $\tilde{T}$ in our case.

In the (Metric Uncapacitated) Facility Location problem (FL) we are given a set of clients and a set of facilities in a metric space d, where each facility has an opening cost o_f. One has to select a subset of facilities $F' \subseteq F$ and assign each client c to the closest facility $F'(c)$ in F' so as to minimize $\sum_{c\in C} d(c, F'(c)) + \sum_{f\in F'} o_f$. FL is a special case of both addSFL and multSFL (and of SFL in the case of uniform opening costs). FL is among the best-studied problems in the literature from the point of view of approximation algorithms (see, e.g., [8, 30, 34]). It is known to be APX-hard [21] and the current best-known 1.488-approximation algorithm [28] is a randomized combination of the greedy JMS algorithm [26] with an LP-rounding algorithm from [6]. Lagrangian-multiplier preserving algorithms for FL are at the heart of several approximation algorithms for fundamental clustering problems, including k-Median [3, 7, 11, 12, 18, 26, 27, 29] and k-Means [3, 11, 20].

Various variants of FL were studied in the literature and for most of them (at least with metric connection costs) a constant approximation was eventually discovered. A notable example is the Capacitated Facility Location problem in which the number of clients that can be served from a facility is restricted by a location-specific bound. A local-search-based constant approximation for the latter problem is given in [37] (see also [4] for a more recent LP-based result). SFL is one of the most natural generalizations of (metric) FL where a constant approximation is still not known.

Grandoni, Gupta, Leonardi, Miettinen, Sankowski, and Singh [19], among other universal stochastic problems, studied univFL in the independent activation case. However, they compare the cost of their solution with $\mathbb{E}_{A\sim\pi}[\text{cost}_A(\text{opt}(A))]$, where $\text{opt}(A)$ is the optimal

facility location solution restricted to clients A (while we compare with $\mathbb{E}_{A\sim\pi}[\text{cost}_A(\text{opt})]$). For this setting they obtain a $O(\log n)$ approximation, which also holds for non-metric connection costs.

Gupta, Pál, Ravi, and Sinha [22] consider a 2-stage stochastic version of FL. Here in a first stage, one buys some facilities, then a subset of active clients is sampled from a given distribution. Finally, one can buy some more facilities, however at an opening cost which is increased by a multiplicative *inflation factor* σ. For this setting they present a constant approximation.

Universal stochastic problems have a natural online stochastic counterpart. For example, in the Online Stochastic Facility Location problem clients are sampled one by one, and when client c is sampled one has to connect c to an already open facility or open a new facility f and connect c to f. Garg, Gupta, Leonardi and Sankowski [17] consider this problem in the independent activation case, i.e. when the next client to be served is sampled from a probability distribution $\pi : C \to \mathbb{R}_{\geq 0}$. For this setting, they present an $O(1)$ approximation. Meyerson [31] studied a variant of the problem where an adversary chooses the set of input clients, and then a random permutation of them is presented in input (*random order model*).

We believe that it is plausible that SFL admits a constant approximation. In particular, one might consider greedy algorithms. Gupta [23] considered a natural set-cover type greedy algorithm for SFL. The same algorithm gives a 1.861-approximation when applied to the classical Facility Location problem [26]. Gupta [23, Section 2.3] showed that this algorithm produces an $\Omega(\log n)$ approximate solutions for SFL. Hence our algorithm is provably better than that one.

1.4 Preliminaries and Notation

We use log for the logarithm with base 2 and ln for the natural logarithm. Define $X = C \cup F$, and $N = |X| = |C \cup F|$. Given a metric d over X, we let $d_{\min}$ be the smallest non-zero distance and $d_{\max}$ be the largest distance (that we assume to be positive w.l.o.g). We use $g(c)$ as a shortcut for $g(\{c\})$.

We sometimes express a feasible solution to SFL in the form $S = (S^f)_{f\in F}$, where $S^f \subseteq C$ specifies the clients $\varphi^{-1}(f)$ assigned to f. Notice that for each $c \in C$ there is precisely one $f \in F$ with $c \in S^f$. We define a *partial assignment* as $S = (S^f)_{f\in F}$, where $S^f \subseteq C$. We say that S covers the clients $C' = \cup_{f\in F} S^f \subseteq C$. Notice that, for technical reasons, in a partial assignment we allow $S^f \cap S^{f'} \neq \emptyset$ for two distinct $f, f' \in F$ (i.e. we allow to simultaneously assign a client to more than one facility). The cost of a (partial) assignment S of the above type is defined as $\text{cost}(S) \coloneqq \text{conn}(S) + \text{open}(S)$, where $\text{conn}(S) \coloneqq \sum_{f\in F}\sum_{c\in S^f} d(c, f)$ is the connection cost of S and $\text{open}(S) \coloneqq \sum_{f\in F} g(S^f)$ is the opening cost of S. Given a (possibly infeasible) fractional solution x for (Conf-LP), we analogously define $\text{cost}(x) = \text{conn}(x) + \text{open}(x)$, where $\text{conn}(x) = \sum_{c\in C}\sum_{f\in F}\sum_{R\ni c} d(c, f) \cdot x^f_R$, and $\text{open}(x) = \sum_{f\in F}\sum_{R\subseteq C} g(R) \cdot x^f_R$.

It is convenient to define the merge $S = S_1 + S_2$ of two partial assignments S_1 and S_2 naturally as follows: (1) for each facility $f \in F$, we initially set $S^f \coloneqq S^f_1 \cup S^f_2$; (2) while there exist two distinct facilities f and f' with $S^f \cap S^{f'} \neq \emptyset$, replace $S^{f'}$ with $S^{f'} \setminus S^f$ (intuitively this second step guarantees that each client is assigned to no more than one facility). We observe that merging two partial assignments cannot increase the total cost.

▶ **Lemma 1.6.** *For any two partial assignments S_1 and S_2,* $\text{cost}(S_1 + S_2) \leq \text{cost}(S_1) + \text{cost}(S_2)$.

Proof. Let $S = S_1 + S_2$, and S' be the intermediate value of S obtained by executing only step (1) of the merge operation. One has $\mathrm{conn}(S') = \mathrm{conn}(S_1) + \mathrm{conn}(S_2)$. Furthermore, by the submodularity (hence subadditivity) of $g(\cdot)$, $\mathrm{open}(S') \leq \mathrm{open}(S_1) + \mathrm{open}(S_2)$. Clearly $\mathrm{conn}(S) \leq \mathrm{conn}(S')$, and the monotonicity of $g(\cdot)$ implies that $\mathrm{open}(S) \leq \mathrm{open}(S')$. The claim follows. ◀

We will exploit the following fairly standard reductions (proofs in Appendix A), thanks to which in the following it will be sufficient to obtain an $O(\log \log N)$ approximation for SFL. In order to distinguish between distinct instances J of the problem, we use $\mathrm{cost}_J(\varphi)$ to denote the cost of φ w.r.t. J and define similarly $\mathrm{open}_J(\varphi)$ etc.

▶ **Lemma 1.7.** *There is a 3-approximate reduction from SFL to the special case where $m = n$.*

▶ **Lemma 1.8.** *For any constant $\varepsilon > 0$, There is a $(1 + 4\varepsilon)$-approximate reduction from SFL to the special case where the metric d satisfies $d_{\min} = 2$ and $d_{\max} \leq \frac{2nN}{\varepsilon}$.*

One of the key tools that we use is the notion of probabilistic tree embedding, which we use to map the input metric into a metric on a *hierarchically well-separated tree* (HST) while stretching the distances by a small enough factor. We recall that an HST is an edge weighted rooted tree where all the leaves are at the same distance from the root r. Furthermore, on every path from a leaf to r the edge weights are $1, 2, 4, \ldots$ In particular, edges at the same level have the same weight. We will use the following construction[3] by Fakcharoenphol, Rao and Talwar [14].

▶ **Theorem 1.9** (FRT metric tree embedding [14])**.** *For any finite metric space (M, d) with $d_{\min} > 1$, there exists a randomized polynomial-time algorithm returning an HST T such that:*

1. *Every $a \in M$ is mapped to some leaf $map(a)$ of T (with elements at distance zero being mapped to the same leaf);*
2. *Let $d^T(a, b) := d^T(map(a), map(b))$ be the length of the path between the leaves $map(a)$ and $map(b)$ of T. Then $d^T(a, b) \geq d(a, b)$ and $\mathbb{E}\left[d^T(a, b)\right] \leq 8 \log |M| \cdot d(a, b)$;*
3. *T has depth $O(\log d_{\max})$.*

For a given set C, let $h\colon 2^C \to \mathbb{R}$ be a monotone submodular function with $h(\emptyset) = 0$. The *Lovász extension* $\hat{h}\colon [0, 1]^C \to \mathbb{R}$ of $h(\cdot)$ is defined as

$$\hat{h}(y) := \min \Big\{ \sum_{R \subseteq C} h(R)\mu_R : \sum_{R \subseteq C} \sum_{R \ni c} \mu_R = y_c \ \forall c \in C,\ \sum_{R \subseteq C} \mu_R = 1,\ \mu \geq 0 \Big\}. \tag{1}$$

The function $\hat{h}(\cdot)$ is convex. We remark that $\hat{h}(y)$ can be alternatively defined as

$$\hat{h}(y) := \sum_{k=1}^{n-1} h\left(\{c_1, \ldots, c_k\}\right)\left(y_{c_k} - y_{c_{k+1}}\right) + h(C) y_{c_n}, \tag{2}$$

where the components of y are sorted in decreasing order, i.e. $y_{c_1} \geq y_{c_2} \geq \cdots \geq y_{c_n}$ [16, Section 6.3]. By the monotonicity of $h(\cdot)$, $\hat{h}(\cdot)$ is also non-decreasing in the sense that $\hat{h}(y) \geq \hat{h}(y')$ if $y \geq y'$.

[3] We slightly and trivially extend their claim to consider nodes at distance 0.

2 Reducing the Connection Cost

In this section, we show how to compute a random partial assignment $S_1 = (S_1^f)_{f \in F}$ covering a random subset of clients $C_1 \coloneqq \cup_{f \in F} S_1^f \subseteq C$ with the following high-level properties: the expected cost of S_1 is "small enough" and (2) each client belongs to C_1 with "large enough" probability. In the next section, we will describe a different partial assignment $S_2 = (S_2^f)_{f \in F}$, again of small enough cost, covering the remaining clients $C_2 \coloneqq C \setminus C_1$. By merging these two partial assignments we obtain a feasible solution for the input problem of small enough total cost.

Let $\dot{x}$ be an optimal solution to (Conf-LP) with at most poly(N) non-zero entries that can be computed via Lemma 1.2. The basic idea behind the next lemma is fairly standard: we sample partial assignments according to the distribution induced by $\dot{x}$ for $\ln \ln N$ times, and merge them together.

▶ **Lemma 2.1.** *In polynomial time one can compute a random partial assignment S_1 covering a random subset of clients C_1 such that: (1) $\mathbb{E}[\text{cost}(S_1)] \leq \ln \ln(N) \cdot \text{cost}(\dot{x})$ and (2) For each $c \in C$, $\mathbb{P}[c \in C_1] \geq 1 - \frac{1}{\ln N}$.*

Proof. For $i \in \{1, 2, \ldots, \ln \ln N\}$ and for every $R \subseteq C$, we define a partial assignment $S(i, R)$ by setting $S^f(i, R) = R$ independently with probability $\dot{x}_R^f$ and $S^f(i, R) = \emptyset$ otherwise. Let $S_1 = \sum_{i=1}^{\ln \ln N} \sum_{R \subseteq C} S(i, R)$ be obtained by merging all these solutions, and let $C_1 = \cup_{f \in F} S_1^f$. Observe that

$$\mathbb{P}[c \notin C_1] = \prod_{f \in F} \prod_{R \ni c} (1 - \dot{x}_R^f)^{\ln \ln N} \leq e^{-\ln \ln N \sum_{f \in F} \sum_{R \ni c} \dot{x}_R^f} \leq e^{-\ln \ln N} = \frac{1}{\ln N}.$$

Furthermore, by Lemma 1.6, $\mathbb{E}[\text{cost}(S_1)]$ is upper-bounded by

$$\sum_{i=1}^{\ln \ln N} \sum_{R \subseteq C} \mathbb{E}[\text{cost}(S(i, R))] = \ln \ln N \cdot \sum_{f \in F, R \subseteq C} \dot{x}_R^f \cdot \left(g(R) + \sum_{c \in R} d(c, f) \right) = \ln \ln N \cdot \text{cost}(\dot{x}). \quad \blacktriangleleft$$

Consider the partial assignment S_1 covering the random subset of clients C_1 as in the previous lemma. Let $C_2 \coloneqq C \setminus C_2$ be the remaining (uncovered) clients. Let also $\ddot{x}$ be $\dot{x}$ restricted to C_2, i.e. $\ddot{x}_R^f = \sum_{R' \subseteq C_1} \dot{x}_{R \cup R'}^f$ for $R \subseteq C_2$ and $f \in F$. The following lemma upper bounds the expected opening and connection cost of $\ddot{x}$.

▶ **Lemma 2.2.** *One has* $\text{open}(\ddot{x}) \leq \text{open}(\dot{x})$ *and* $\mathbb{E}[\text{conn}(\ddot{x})] \leq \frac{1}{\ln N} \text{conn}(\dot{x})$.

Proof. We have $\text{open}(\ddot{x}) \leq \text{open}(\dot{x})$ by the monotonicity of $g(\cdot)$. For the connection cost, notice that the probability of a client c being in C_2 is at most $1/\ln N$, and only in that case one has to pay the associated connection cost. Thus by linearity of expectation, the expected connection cost of $\ddot{x}$ is at most $\text{conn}(\dot{x})/\ln N$. The claim follows. ◀

Notice that $\ddot{x}$ is a feasible fractional solution for (Conf-LP) limited to C_2. In the following section, we show how to randomly round $\ddot{x}$ to a partial assignment S_2 which covers C_2 at expected cost $O(\log \log N) \cdot \text{cost}(\ddot{x})$. It will then follow that $S_1 + S_2$ is a feasible $O(\log \log N)$-approximate solution to the input SFL instance.

3 Approximating SFL on an HST

Given an SFL instance and a tree embedding of $(C \cup F, d)$ into an HST T as in Theorem 1.9, we say that $(C \cup F, d^T, g(\cdot), map(\cdot))$ is the corresponding HST-type instance. We remark that we allow multiple clients $C(v)$ and facilities $F(v)$ to be colocated at each leaf v of T. In this section we will describe an $O(\log \log N)$-approximate LP-rounding algorithm for the considered instances w.r.t. (Conf-LP).

▶ **Lemma 3.1.** *Given a feasible fractional solution x to* (Conf-LP) *for an HST-type SFL instance, in polynomial time one can compute a feasible (integral) solution for the same instance with cost at most $O(\log\log N)\cdot \mathrm{cost}(x)$.*

Theorem 1.1 directly follows.

Proof of Theorem 1.1. By Lemma 1.7 it is sufficient to describe an $O(\log\log N)$-approximation. Furthermore by Lemma 1.8, we can assume that $d_{\min}=2$ and $d_{\max}\le \frac{2nN}{\varepsilon}$.

By applying the construction of Section 2 we compute a random partial assignment $S_1=(S_1^f)_{f\in F}$ covering the clients $C_1=\cup_{f\in F}S_1^f$ with expected cost at most $O(\log\log N)\cdot\mathrm{cost}(\dot{x})$, where $\dot{x}$ is an optimal solution to (Conf-LP). Furthermore, by Lemma 2.2, we obtain a feasible solution $\ddot{x}$ to (Conf-LP) restricted to clients $C_2\coloneqq C\setminus C_1$ which satisfies $\mathrm{open}(\ddot{x})\le\mathrm{open}(\dot{x})$ and $\mathbb{E}[\mathrm{conn}(\ddot{x})]\le\frac{1}{\ln N}\mathrm{conn}(\dot{x})$. By applying the probabilistic tree embedding from Theorem 1.9 to the metric $(C_2\cup F,d)$, we obtain an HST-type SFL instance $(C_2\cup F,d^T,g(\cdot),map(\cdot))$ where the tree has depth $D=O(\log d_{\max})=O(\log N)$. Observe that $\ddot{x}$ is a feasible fractional solution for (Conf-LP) restricted to C_2 on the HST-type instance. Furthermore, let $\mathrm{conn}_T(\ddot{x})$ denote the connection cost of $\ddot{x}$ w.r.t. the HST-type instance, and define similarly $\mathrm{open}_T(\ddot{x})$ and $\mathrm{cost}_T(\ddot{x})$. Then one has

$$\mathbb{E}[\mathrm{cost}_T(\ddot{x})]=\mathrm{open}(\ddot{x})+\mathbb{E}[\mathrm{conn}_T(\ddot{x})]\le\mathrm{open}(\dot{x})+O(\log N)\cdot\mathbb{E}[\mathrm{conn}(\ddot{x})]\le O(\mathrm{cost}(\dot{x})).$$

By applying the LP-rounding algorithm from Lemma 3.1 to $\ddot{x}$ one obtains a partial assignment $(S_2^f)_{f\in F}$ covering the clients C_2 of cost at most $O(\log\log N)\,\mathrm{cost}(\dot{x})$. The same solution has no larger cost in the original problem (on a non-tree metric). Altogether S_1+S_2 is a feasible solution to the input SFL problem of expected cost at most $O(\log\log N)\cdot\mathrm{cost}(\dot{x})\le O(\log\log N)\cdot\mathrm{cost}(\mathrm{opt})$. ◀

In the rest of this section, we prove Lemma 3.1. To this aim, we will first present a reduction to a different problem that we call the Descendent-Leaf Assignment problem (DLA) (see Section 3.1). Then, we will present a good-enough approximation algorithm for DLA (see Section 3.2).

3.1 A Reduction to DLA

In the Descendent-Leaf Assignment problem (DLA) we are given a rooted tree $\tilde{T}$ with depth D, a set of facilities $\tilde{F}$ and a set of clients $\tilde{C}$. Each $x\in\tilde{F}\cup\tilde{C}$ is mapped to some node $v(x)$ of $\tilde{T}$, with the restriction that facilities are mapped to leaves of $\tilde{T}$. By $\tilde{F}_c$ we denote the facilities which are mapped to nodes that are descendants of $v(c)$ in T ($v(c)$ included if it is a leaf). A feasible solution consists of an assignment $\tilde{\varphi}:\tilde{C}\to\tilde{F}$ of each $c\in\tilde{C}$ to some $f\in\tilde{F}_c$. The cost of this solution is $\sum_{f\in\tilde{F}}h(\tilde{\varphi}^{-1}(f))$, where $h(\cdot)$ is a monotone submodular function over $\tilde{C}$ with $h(\emptyset)=0$. Similarly to SFL, we also express a feasible solution as $S=(S^f)_{f\in\tilde{F}}$, where $S^f=\tilde{\varphi}^{-1}(f)$, and let $\mathrm{cost}_{\mathrm{DLA}}(S)=\sum_{f\in\tilde{F}}h(S^f)$ be the associated cost. We define a convex-programming (CP) relaxation for DLA as follows:

$$\begin{aligned}
\min\quad & \sum_{f\in\tilde{F}}\hat{h}(z^f) && && \text{(DLA-CP)}\\
\text{s.t.}\quad & \sum_{f\in\tilde{F}_c}z_c^f=1 && \forall c\in\tilde{C};\\
& z_c^f\ge 0 && \forall c\in\tilde{C},\ \forall f\in\tilde{F}.
\end{aligned}$$

In a 0-1 integral solution we interpret $z_c^f = 1$ as c being assigned to f. Recall that $\hat{h}(\cdot)$ is convex, which makes (DLA-CP) a convex program. We also notice that each feasible assignment $S = (S^f)_{f\in\tilde{F}}$ corresponds to a feasible integral solution $z = (z^f)_{f\in\tilde{F}}$ to (DLA-CP) with $\text{cost}_{\text{DLA}}(S) = \text{cost}_{\text{DLA}}(z) \coloneqq \sum_{f\in\tilde{F}} \hat{h}(z^f)$ and vice versa. Hence indeed (DLA-CP) is a CP-relaxation of DLA.

The next lemma provides the claimed reduction from SFL on HST-type instances to DLA.

▶ **Lemma 3.2.** *Given a polynomial-time $O(\log D)$-approximate CP-rounding algorithm for DLA w.r.t.* (DLA-CP)*, where D is the depth of the tree, there is polynomial-time $O(\log\log N)$-approximate LP-rounding algorithm for SFL on HST-type instances with tree-depth $O(\log N)$ w.r.t.* (Conf-LP)*.*

Proof. Let $(C \cup F, d^T, g(\cdot), map(\cdot))$ be the considered HST-type instance of SFL over an HST T, and x be an input feasible fractional solution to (Conf-LP) for this instance.

We build an instance $(\tilde{C}\cup\tilde{F}, \tilde{T}, h(\cdot), v(\cdot))$ of DLA as follows. First, let $y_c^f \coloneqq \sum_{R\subseteq C: c\in R} x_R^f$: intuitively this is the fractional amount by which c is assigned to f in x. We set $h(\cdot) = g(\cdot)$ and $\tilde{T} = T$. Notice that $D = O(\log N)$. We set $\tilde{F} = F$ and $v(f) = map(f)$ for each $f \in \tilde{F}$. We associate to each $c \in C$ a new client $\tilde{c} \in \tilde{C}$. Let T_v be the subtree rooted at v (containing v and all its descendants) and F_v be the facilities located in the leaves of T_v according to $map(\cdot)$. We map $\tilde{c}$ into the lowest ancestor $v(\tilde{c})$ of $map(c)$ such that $\sum_{f\in F_{v(\tilde{c})}} y_c^f \geq 1/2$. Notice that $v(\tilde{c}) = map(c)$ is possible (in which case there is at least one facility f colocated with c in T).

We next define a feasible fractional solution z for (DLA-CP) w.r.t this DLA instance as follows. For each $\tilde{c} \in \tilde{C}$ we set $z_{\tilde{c}}^f = y_c^f/(\sum_{f'\in F_{v(\tilde{c})}} y_c^{f'})$ if $f \in F_{v(\tilde{c})}$, and otherwise $z_{\tilde{c}}^f = 0$. Let $\tilde{\varphi}$ be a solution to the DLA instance obtained with the CP-rounding algorithm in the claim w.r.t. z. We obtain a feasible solution φ for the input instance by simply setting $\varphi(c) = \tilde{\varphi}(\tilde{c})$.

It remains to analyze the cost of φ. Define $\bar{z}_{\tilde{c}}^f = y_c^f/(\sum_{f'\in F_{v(\tilde{c})}} y_c^{f'})$ for all $f \in F$. Notice that $\bar{z} \geq z$. By the definition of $\hat{h}(\cdot)$ and its monotonicity, $\hat{h}(z^f) \leq \hat{h}(\bar{z}^f) = \hat{h}(y^f/(\sum_{f'\in F_{v(\tilde{c})}} y_c^{f'})) \leq 2\hat{h}(y^f) = 2\hat{g}(y^f)$. Notice that by plugging in x_R^f for μ_R in the set in (1) and by how y is defined w.r.t. x above, we get $\hat{g}(y^f) \leq \sum_{R\subseteq C} g(R)\cdot x_R^f$ and in particular $\sum_{f\in F}\hat{g}(y^f) \leq \text{open}(x)$. Thus, we have $\text{cost}_{\text{DLA}}(z) \leq 2\,\text{open}(x)$ and

$$\text{open}(\varphi) = \text{cost}_{\text{DLA}}(\tilde{\varphi}) = O(\log D)\cdot\text{cost}_{\text{DLA}}(z) \leq O(\log\log N)\cdot 2\,\text{open}(x). \tag{3}$$

Consider next the connection cost of a given $c \in C$. If $v(\tilde{c}) = map(c)$, i.e $v(\tilde{c})$ has no child, then $d^T(c,\varphi(c)) = 0 \leq \sum_{f\in F} d^T(c,f)y_c^f$. Otherwise, let $w(c)$ be the child of $v(\tilde{c})$ along the $v(\tilde{c})$-$map(c)$ path in T. Let Δ be the weight of the edge between $v(\tilde{c})$ and $w(c)$. Observe that the distance between $v(\tilde{c})$ and the leaves in $T_{v(\tilde{c})}$ is exactly $2\Delta - 1$. Furthermore, both c and $\varphi(c)$ are located in the leaves of $T_{v(\tilde{c})}$ in the HST mapping $map(\cdot)$. Hence $d^T(c,\varphi(c)) \leq 2(2\Delta-1)$.

By the definition of $v(\tilde{c})$, it must be the case that $\sum_{f\in F_{w(c)}} y_c^f < \frac{1}{2}$, and consequently $\sum_{f\in F\setminus F_{w(c)}} y_c^f \geq \frac{1}{2}$. For each $f \in F \setminus F_{w(c)}$, the $map(f)$-$map(c)$ path in T has length at least $2(2\Delta-1)$. Thus

$$\sum_{f\in F} d^T(c,f)y_c^f \geq \sum_{f\in F\setminus F_{w(c)}} d^T(c,f)y_c^f \geq \frac{1}{2}2(2\Delta-1).$$

Therefore, the connection cost of c in φ is at most 2 times its connection cost in x. We conclude that $\text{conn}(\varphi) \leq 2\,\text{conn}(x)$. Altogether we have $\text{cost}(\varphi) \leq 2\,\text{conn}(x) + O(\log\log N) \cdot 2\,\text{open}(x) \leq O(\log\log N) \cdot \text{cost}(x)$. ◀

3.2 An Approximation Algorithm for DLA

In this section, we present a CP-rounding algorithm for DLA. Lemma 3.1 follows by chaining Lemmas 3.2 and 3.3.

▶ **Lemma 3.3.** *Given a feasible fractional solution z to* (DLA-CP) *on an instance of DLA with tree-depth D, in polynomial time one can compute a feasible (integral) solution to the same instance of cost at most $O(\log D) \cdot \text{cost}_{\text{DLA}}(z)$.*

The CP-rounding algorithm from Lemma 3.3 is essentially the algorithm by Bosman and Olver [5] with minor modifications that we introduced to simplify our correctness analysis. Also, the analysis of its approximation ratio is essentially identical to [5], but we reproduce it for the sake of completeness. In particular, we will exploit the following definitions and lemma from [5]. Let $h : 2^{\tilde{C}} \to \mathbb{R}_{\geq 0}$ be a monotone submodular function with $h(\emptyset) = 0$. For a given $f \in \tilde{F}$ and a (possibly infeasible) solution z to (DLA-CP), let $L_\theta(z^f) \coloneqq \{c \in \tilde{C} : z_c^f \geq \theta\}$ be the set of clients that are served fractionally by at least some value θ by f. Let also $z^{f|\theta}$ be obtained from z^f by rounding down to θ the values larger than θ, i.e. $z_c^{f|\theta} \coloneqq \min\{z_c^f, \theta\}$ for each $c \in \tilde{C}$. Given $\theta \in [0,1]$ and $z^f \in [0,1]^{\tilde{C}}$, we say that the set $L_\theta(z^f)$ is α-supported (w.r.t. h) if $\hat{h}(z^f) - \hat{h}(z^{f|\theta}) \geq \alpha h(L_\theta(z^f))$.

▶ **Lemma 3.4** (Lemma 5.2 from [5])**.** *Given $z^f \in [0,1]^{\tilde{C}}$ and $\alpha \in (0,1]$, at least one of the following holds: (1) there exists $\theta \in [0,1]$, which can be computed in polynomial time, such that $L_\theta(z^f)$ is $\frac{\alpha}{32}$-supported; (2) $2^{1/\alpha} h(L_1(z^f)) \leq \hat{h}(z^f)$.*

Our algorithm is Algorithm 1 in the figure. Recall that $\tilde{T}_v$ is the subtree rooted at node v, where $\tilde{T}_v$ includes v and all its descendants. Furthermore, $\tilde{F}_v$ is the set of facilities mapped to the leaves of $\tilde{T}_v$. As usual the level of a node is its hop-distance from the root.

Algorithm 1 An algorithm used to prove Lemma 3.3.

Input: Feasible solution z to (DLA-CP)

$S^f \leftarrow \emptyset$ for all $f \in F$
for $i = 0, \ldots, D$ **do**
  For every node v at level $D - i$, choose an arbitrary $f_v \in \tilde{F}_v$ and set $z^{f_v} \leftarrow \sum_{f' \in \tilde{F}_v} z^{f'}$ and $z^{f'} \leftarrow 0$ for all $f' \in \tilde{F}_v \setminus \{f_v\}$
  if there exists $\theta \in [0,1]$ such that $L_\theta(z^{f_v})$ is $\frac{1}{32\log(D+1)}$-supported **then**
    For an arbitrary such θ, set $S^{f_v} \leftarrow S^{f_v} \cup L_\theta(z^{f_v})$ and $z_c^{f_v} \leftarrow 0$ for all $c \in L_\theta(z^{f_v})$
  else
    Set $S^{f_v} \leftarrow S^{f_v} \cup L_1(z^{f_v})$ and $z_c^{f_v} \leftarrow 0$ for all $c \in L_1(z^{f_v})$
For every $c \in \tilde{C}$ choose $f \in \tilde{F}_c$ such that $c \in S^f$ and set $S^{f'} \leftarrow S^{f'} \setminus \{c\}$ for all $f' \in \tilde{F} \setminus \{f\}$
return $(S^f)_{f \in \tilde{F}}$

Clearly Algorithm 1 runs in polynomial time. The next two lemmas analyze the correctness and the approximation ratio of Algorithm 1, hence proving Lemma 3.3.

▶ **Lemma 3.5.** *Algorithm 1 computes a feasible DLA solution.*

Proof. Consider a given client $c \in \tilde{C}$ such that $v(c)$ is at level $D - i$ in $\tilde{T}$. Let us show that the following invariant holds at the beginning of each iteration $j \leq i$: either $\sum_{f \in \tilde{F}_c} z_c^f = 1$ or $c \in S^f$ for some $f \in \tilde{F}_c$. The invariant trivially holds for $j = 0$. Assume that it holds

up to the beginning of iteration $j < i$, and consider what happens during that iteration. Notice that for every node v at level $D - j > D - i$, we either have that every $f \in \tilde{F}_v$ is a descendant of $v(c)$ or every $f \in \tilde{F}_v$ is not in $\tilde{F}_c$. Therefore, in Step (3) the value of $\sum_{f \in \tilde{F}_c} z_c^f$ does not change. In more detail, it remains 1 by inductive hypothesis. The same value can decrease in Steps (5) or (7), however, this can only happen if c is added to S^{f_v} for some $f_v \in \tilde{F}_c$. Thus the invariant holds at the end of the j-th iteration, hence at the beginning of the next iteration $j + 1$.

Due to the invariant, during the iteration i, when one considers the node $v = v(c)$, one has that either c already belongs to some S^f with $f \in \tilde{F}_c$, or $\sum_{f \in \tilde{F}_c} z_c^f = 1$. In the latter case, after Step (3), $z_c^{f_v} = 1$ where $f_v \in \tilde{F}_c$, so c belongs to every set $L_\theta(z^{f_v})$ with $\theta \in [0, 1]$. As a consequence, c is added to S^{f_v} either in Step (5) or in Step (7).

It might happen that a client c is assigned *also* to a facility not in $\tilde{F}_c$. Step (8) guarantees that the final assignment of c is correct and unique. ◀

▶ **Lemma 3.6.** *Algorithm 1 outputs a solution of cost at most* $O(\log D) \cdot \mathrm{cost}_{\mathrm{DLA}}(z)$.

Proof. Recall that $\mathrm{cost}_{\mathrm{DLA}}(z) = \sum_{f \in \tilde{F}} \hat{h}(z^f)$. We start by observing that the value of $\mathrm{cost}_{\mathrm{DLA}}(z)$ can not increase over time when z changes during the execution of the algorithm. Indeed, Steps (5) and (7) can only decrease the entries of z, hence $\mathrm{cost}_{\mathrm{DLA}}(z)$ by the monotonicity of $\hat{h}(\cdot)$. The only other changes of z happen in Step (3). Let us interpret this step as iteratively decreasing to zero $z^{f'}$ for each $f' \in \tilde{F}_v \setminus \{f_v\}$ and increasing z^{f_v} by the same amount. The decrease of the cost at each step is $\hat{h}(z^{f_v}) + \hat{h}(z^{f'}) - \hat{h}(z^{f_v} + z^{f'})$. By the alternative definition of $\hat{h}(\cdot)$ as in (2) and its convexity, one has $\hat{h}(z^{f_v} + z^{f'}) = 2\hat{h}\left(\frac{z^{f_v} + z^{f'}}{2}\right) \leq 2\left(\frac{1}{2}\hat{h}(z^{f_v}) + \frac{1}{2}\hat{h}(z^{f'})\right) = \hat{h}(z^{f_v}) + \hat{h}(z^{f'})$. Hence the decrease of the cost is non-negative as required.

For each facility f and level i, let $\Delta_i^\theta(f)$ be the clients added to S^f in Step (5) during iteration i (possibly $\Delta_i^\theta(f) = \emptyset$). We define similarly $\Delta_i^1(f)$ w.r.t. Step (7). Notice that, by the submodularity (hence subadditivity) of $h(\cdot)$, the increase of the cost of the solution due to adding Δ to S^f is at most $h(\Delta)$. Therefore we can upper bound the cost of the final solution $S = (S^f)_{f \in \tilde{F}}$ by

$$\mathrm{cost}_{\mathrm{DLA}}(S) \coloneqq \sum_{f \in \tilde{F}} h(S^f) \leq \sum_{i=0}^{D} \sum_{f \in \tilde{F}} \Big(h(\Delta_i^\theta(f)) + h(\Delta_i^1(f)) \Big).$$

Let us upper bound the right-hand side of the above inequality. Let $z(i)$ denote the value of z at the beginning of iteration i. From the previous observation, we have $\hat{h}(z(i)) \leq \hat{h}(z)$ for every i. By Lemma 3.4 with $\alpha = \frac{1}{\log(D+1)}$, for any $\Delta_i^1(f)$ one has $h(\Delta_i^1(f)) \leq \frac{1}{D+1}\hat{h}(z^f(i))$. Thus

$$\sum_{i=0}^{D} \sum_{f \in \tilde{F}} h\big(\Delta_i^1(f)\big) \leq \sum_{i=0}^{D} \sum_{f \in \tilde{F}} \frac{1}{D+1} \hat{h}\big(z^f(i)\big) \leq \sum_{i=0}^{D} \frac{1}{D+1} \mathrm{cost}_{\mathrm{DLA}}(z(i)) \leq \mathrm{cost}_{\mathrm{DLA}}(z). \quad (4)$$

Let $z(D+1)$ be the value of z at the end of the D-th iteration, hence in particular $\mathrm{cost}_{\mathrm{DLA}}(z(D+1)) \geq 0$. Notice that $z = z(0)$. We can lower bound $\mathrm{cost}_{\mathrm{DLA}}(z)$ by

$$\mathrm{cost}_{\mathrm{DLA}}(z) \geq \sum_{i=0}^{D} \Big(\mathrm{cost}_{\mathrm{DLA}}(z(i)) - \mathrm{cost}_{\mathrm{DLA}}(z(i+1)) \Big).$$

Let $z_1(i)$ be the value of z obtained from $z(i)$ after applying Step (3) for all nodes of level $D-i$. Let also $z_2(i)$ be the value obtained from $z_1(i)$ if, for all the facilities F'_i where Step (5) is applied during iteration i, instead of setting $z^f_c = 0$ one sets $z^f_c = \theta$ for the corresponding value of θ. For the facilities not in F'_i we simply let $z^f_2(i) = z^f_1(i)$. Observe that $z(i+1) \le z_2(i) \le z_1(i) \le z(i)$. One has

$$\begin{aligned}
\mathrm{cost}_{\mathrm{DLA}}(z(i)) - \mathrm{cost}_{\mathrm{DLA}}(z(i+1)) &\ge \mathrm{cost}_{\mathrm{DLA}}(z_1(i)) - \mathrm{cost}_{\mathrm{DLA}}(z(i+1)) \\
&\ge \mathrm{cost}_{\mathrm{DLA}}(z_1(i)) - \mathrm{cost}_{\mathrm{DLA}}(z_2(i)) \\
&= \sum_{f\in\tilde{F}} \hat{h}\Big(z^f_1(i)\Big) - \hat{h}\Big(z^f_2(i)\Big) = \sum_{f\in F'_i} \hat{h}\Big(z^f_1(i)\Big) - \hat{h}\Big(z^f_2(i)\Big) \\
&\ge \frac{\sum_{f\in F'_i} h\big(\Delta^\theta_i(f)\big)}{32\log(D+1)} = \frac{\sum_{f\in\tilde{F}} h\big(\Delta^\theta_i(f)\big)}{32\log(D+1)}.
\end{aligned}$$

In the first two inequalities above we used the monotonicity of $\hat{h}(\cdot)$, while in the last inequality the definition of α-supported. Altogether

$$\begin{aligned}
\sum_{i=0}^{D}\sum_{f\in\tilde{F}} h\Big(\Delta^\theta_i(f)\Big) &\le 32\log(D+1)\cdot\sum_{i=0}^{D}\Big(\mathrm{cost}_{\mathrm{DLA}}(z(i)) - \mathrm{cost}_{\mathrm{DLA}}(z(i+1))\Big) \\
&\le O(\log D)\cdot\mathrm{cost}_{\mathrm{DLA}}(z). \qquad (5)
\end{aligned}$$

By the monotonicity of $h(\cdot)$, Step (8) cannot increase the cost of the solution, hence the claim. ◀

4 Universal Stochastic Facility Location

In this section we sketch our approximation algorithm for UNIVFL. We first present a weaker approximation factor $O(\log\log N + \log\log \frac{d_{\max}}{d_{\min}})$. Later we will show how to refine it.

Define $g(R) \coloneqq \mathbb{P}_{A\sim\pi}[R \cap A \neq \emptyset]$. We observe that this function is monotone submodular and $g(\emptyset) = 0$. Recall that $g(c) = g(\{c\})$ for every $c \in C$. W.l.o.g. we can assume $g(c) > 0$ since otherwise we can discard c. We can define the objective function of UNIVFL for a given assignment $\varphi : C \to F$ as

$$\mathrm{cost}(\varphi) = \mathrm{conn}(\varphi) + \mathrm{open}(\varphi) = \sum_{c\in C} d(c,\varphi(c))\cdot g(c) + \sum_{f\in F} w_f \cdot g(\varphi^{-1}(f)).$$

Notice that only the connection cost changes w.r.t. MULTSFL. In more detail, the connection cost of each client c is scaled by the factor $g(c)$.

We can similarly define a configuration LP for UNIVFL, and solve it by the same arguments as in Lemma 1.2. We next use an analogous notation as for SFL. Let $\dot{x}$ be an optimal solution to this LP with poly(N) many non-zero variables. We can apply the first stage of our algorithm for SFL (described in Section 2) with essentially no changes. This will lead to a partial assignment S_1 of expected cost $\mathbb{E}[\mathrm{cost}(S_1)] \le \ln\ln N \cdot \mathrm{cost}(\dot{x})$ and serving the clients C_1, where $\mathbb{P}[c \notin C_1] \le \frac{1}{\ln N}$. Mapping the metric over an HST T and considering the restriction $\ddot{x}$ of $\dot{x}$ to $C_2 \coloneqq C \setminus C_1$, we obtain that $\mathbb{E}[\mathrm{cost}_{HST}(\ddot{x})] = O(\mathrm{cost}(\dot{x}))$. A reduction similar to the one in Lemma 3.2 works also in this case (since the scaling of the fractional solution is done on a per-client base). However in this case $D = O(\log \frac{d_{\max}}{d_{\min}})$ (since we did not reduce the ratio $\frac{d_{\max}}{d_{\min}}$ in a preprocessing step). Hence we can apply the result from Lemma 3.3 to obtain an assignment covering C_2 of expected cost $O(\log\log \frac{d_{\max}}{d_{\min}})\cdot\mathrm{cost}(\dot{x})$. This concludes the sketch of the $O(\log\log N + \log\log \frac{d_{\max}}{d_{\min}})$ approximation.

We next improve this bound via a preprocessing step. Recall that $0 < \pi_{\min} := \min_{c \in C}\{g(c)\}$. We first scale the ratio $d_{\max}/d_{\min}$. Let us guess[4] the largest distance $L = \max_{c \in C}\{d(c, \mathrm{opt}(c))\}$ in some optimal (universal) solution opt. Notice that $\mathrm{cost}(\mathrm{opt}) \geq \pi_{\min} L$. We use essentially the same arguments as in Lemma 1.8, we can enforce that $d_{\max} \leq NL$ and $d_{\min} \geq \frac{\varepsilon}{n}\pi_{\min} L$. Hence we obtain $\frac{d_{\max}}{d_{\min}} \leq \frac{nN}{\varepsilon \pi_{\min}}$.

Now let us reduce the number of facilities m to $O(n + \log \frac{1}{\pi_{\min}})$ (hence N as well). Here we use essentially the same argument as in the proof of Lemma B.1 (with $p_f = 0$). In more detail, we can assume that $m \leq 2^n$. Indeed, otherwise we can reduce the input instance to a Weighted Set Cover instance (that we can solve exactly in polynomial time) in the same way as in the mentioned lemma, with the difference that now, for $R \neq \emptyset$, we set $\kappa_R = \min_{f \in F}\{w_f \cdot g(R) + \sum_{c \in R} d(c, f) \cdot g(c)\}$. By the rest of the construction in the same lemma, we can reduce (with a constant loss in the approximation factor) our instance to one where there are $O(\log \frac{d_{\max}}{d_{\min}}) = O(\log \frac{n2^n}{\varepsilon \pi_{\min}}) = O(n + \log \frac{1}{\pi_{\min}})$ facilities per client. Altogether we reduce N to $N' = O(n(n + \log \frac{1}{\pi_{\min}}))$. Now we can apply again the above scaling trick over the distances (with N replaced by N') to obtain distances d' which satisfy:

$$\frac{d'_{\max}}{d'_{\min}} \leq \frac{nN'}{\varepsilon \pi_{\min}} = O\left(\frac{n^3 + n^2 \log \frac{1}{\pi_{\min}}}{\pi_{\min}}\right).$$

This leads to the approximation factor

$$O\left(\log \log \frac{d'_{\max}}{d'_{\min}} + \log \log N'\right) = O\left(\log \log \frac{n}{\pi_{min}}\right).$$

A Some Omitted Proofs about SFL

Proof of Lemma 1.2. Considering the dual of (Conf-LP):

$$\max \Big\{ \sum_{c \in C} \alpha_c + \sum_{f \in F} \beta_f : \sum_{c \in R} \alpha_c + \beta_f \leq g(R) + \sum_{c \in R} d(c,f),\ \forall R \subseteq C,\ \forall f \in F \Big\}. \tag{Conf-DLP}$$

Notice that for fixed α and β, the functions $g_f(R) \coloneqq g(R) + \sum_{c \in R} d(c,f) - \sum_{c \in R} \alpha_c - \beta_f$ are submodular. Thus, a call of a separation oracle on (Conf-DLP) is equivalent to a minimization of all functions $g_f(\cdot)$, which can be done using polynomially many oracle calls of $g(\cdot)$ [25]. Therefore, an optimal primal solution with $\mathrm{poly}(N)$ many non-zero variables for (Conf-LP) can be found in polynomial time [32, Corollary 14.1g(v)]. ◀

Proof of Lemma 1.7. Let $I = (C, F, d, g(\cdot))$ be the considered instance of SFL. Consider the complete weighted graph on nodes $C \cup F$, with weights induced by d. For each client c, let $f(c)$ be the facility closest to c. We create a dummy facility $f'(c)$ and add a dummy edge $\{c, f'(c)\}$ of weight $d(c, f(c))$. Let F' be the set of newly created facilities. Observe

that $|F'| = n$. Finally we remove F and consider the metric d' over $C \cup F'$ induced by the distances over the resulting graph. Let $I' = (C, F', d', g(\cdot))$ be the obtained instance of SFL. Given a solution φ' for I', we obtain a solution φ for I by simply assigning to $f(c)$ each client c' assigned to $f'(c)$ in φ'.

Let us analyze the approximation factor introduced by this reduction. We first observe that $\mathrm{cost}_I(\varphi) \leq \mathrm{cost}_{I'}(\varphi')$. Indeed, $\mathrm{open}_I(\varphi) = \mathrm{open}_{I'}(\varphi')$. Furthermore, for each each client c' assigned to $f'(c)$ by φ', the associated connection cost w.r.t. I is $d(c', f(c)) \leq d(c', c) + d(c, f(c)) = d'(c', f'(c))$. Hence $\mathrm{conn}_I(\varphi) \leq \mathrm{conn}_{I'}(\varphi')$.

Next consider an optimal solution opt for I. For each facility f with $\mathrm{opt}^{-1}(f) \neq \emptyset$, let $c \in \mathrm{opt}^{-1}(f)$ be the client closest to f. We define a solution opt$'$ for I' by assigning all the clients in $\mathrm{opt}^{-1}(f)$ to $f'(c)$. Again, $\mathrm{open}_I(\varphi) = \mathrm{open}_{I'}(\varphi')$. For each client c' assigned to f in opt, its connection cost in I' is

$$d'(c', f'(c)) = d(c, c') + d(c, f(c)) \leq d(c', f) + d(c, f) + d(c, f(c)) \leq d(c', f) + 2d(c, f) \leq 3d(c', f).$$

Hence $\mathrm{conn}_{I'}(\mathrm{opt}') \leq 3\,\mathrm{conn}_I(\mathrm{opt})$. The claim follows. ◀

Proof of Lemma 1.8. Let us guess the value $L = \max_{c \in C} d(c, \mathrm{opt}(c))$ for some optimal solution opt. W.l.o.g. assume $L > 0$, otherwise the problem is trivial. Consider the complete weighted graph on nodes $C \cup F$ with weights induced by d. Remove the edges of weight larger than L. We next compute a feasible solution in each connected component of the resulting graph separately. Notice that this part of the reduction is approximation preserving since no client can be assigned to a facility in a different connected component in opt.

Let C' and F' be the clients and facilities, resp., in one such connected component G', $X' = C' \cup F'$, and d' be the metric induced by the distances in G'. Consider the corresponding SFL instance $I' = (C', F', d', g(\cdot))$. Notice that in each such instance I' one has $d'_{\max} \leq NL$. We next change the location of elements of X' as follows. We consider the ball $B(x) := \{y \in X' : d'(x, y) \leq \frac{\varepsilon}{2n} L\}$ of radius $\frac{\varepsilon}{2n} L$ around each $x \in X'$. Let $\mathcal{I}$ be a maximal (independent) set of such balls so that, if $B(x), B(y) \in \mathcal{I}$ for $x \neq y$, then $B(x) \cap B(y) = \emptyset$. For each y with $B(y) \notin \mathcal{I}$, we consider any $B(x) \in \mathcal{I}$ with $B(x) \cap B(y) \neq \emptyset$ (which must exist since $\mathcal{I}$ is maximal) and colocate y with x. Let $I'' = (C', F', d'', g(\cdot))$ be the resulting instance of SFL. Observe that $d''_{\max} \leq NL$ and $d''_{\min} \geq \frac{\varepsilon}{n} L$.

Let $\tilde{I}$ be the union of all the instances I'', and $\tilde{d}$ be the associated distances (where inter-component distances can be considered to be $+\infty$). Given a solution φ for $\tilde{I}$ (obtained by the union of all the solutions obtained for each instance I''), we return exactly the same solution φ for I.

Let us analyze the approximation factor. Notice that $\mathrm{open}_I(\varphi) = \mathrm{open}_{\tilde{I}}(\varphi)$. Furthermore, for each client c, $d(c, \varphi(c)) \leq \tilde{d}(c, \varphi(c)) + \frac{2\varepsilon}{n} L$, where in the latter term we consider the fact that each client and facility is moved at most at distance $\frac{\varepsilon}{n} L$ from the original location. Hence $\mathrm{conn}_I(\varphi) \leq \mathrm{conn}_{\tilde{I}}(\varphi) + 2\varepsilon L$. Given an optimum solution opt for I, by a symmetric argument one has $\mathrm{cost}_{\tilde{I}}(\mathrm{opt}) \leq \mathrm{cost}_I(\mathrm{opt}) + 2\varepsilon L \leq (1 + 2\varepsilon)\,\mathrm{cost}_I(\mathrm{opt})$, where we used the fact that $\mathrm{cost}_I(\mathrm{opt}) \geq L$. Altogether an $\alpha \geq 1$ approximation algorithm for each instance I'' implies an $\alpha(1 + 2\varepsilon) + 2\varepsilon \leq \alpha(1 + 4\varepsilon)$ approximation for I.

Finally, we scale the distance d'' and $g(\cdot)$ by the same factor $\frac{2n}{\varepsilon L}$ so that $d''_{\min} = 2$ and $d''_{\max} \leq \frac{2nN}{\varepsilon}$. Clearly this final scaling is approximation preserving. ◀

B Generalizations of SFL

In this section we discuss some generalizations of SFL.

B.1 Reduction of the Number of Facilities

In this section we consider the generalization of SFL, next called Affine SFL, where the opening cost of each facility f with assigned clients $R \neq \emptyset$ is $g_f(R) \coloneqq p_f + w_f \cdot g(R)$, where $p_f, w_f \geq 0$ are input values. Notice that this generalizes SFL with Additive (resp., Multiplicative) Opening Costs. We also observe that each $g_f(\cdot)$ is non-negative monotone submodular.

We show how to reduce to the case where $m = \text{poly}(n)$ (hence $N = \text{poly}(n)$) while loosing a constant factor in the approximation. We will use this reduction in the following sections to convert an $O(\log \log N)$ approximation into an $O(\log \log n)$ one.

▶ **Lemma B.1.** *For any constant $\varepsilon > 0$, there is a $(3 + 37\varepsilon)$-approximate reduction from* Affine *SFL to the special case where the number of facilities is $O_\varepsilon(n^3)$.*

Proof. First of all, consider the case $m \geq 2^n$. In this case we can solve the problem optimally in polynomial time via the following reduction to the Weighted Set Cover problem. For an instance $I = (C, F, d, g(\cdot))$ of Affine SFL, consider the instance $J = (\mathcal{U}, \mathcal{R}, \kappa)$ of Weighted Set Cover with universe $\mathcal{U} = C$, set collection $\mathcal{R} = 2^C$ and weight function κ given as $\kappa_R = 0$ if $R = \emptyset$ and $\kappa_R = \min_{f \in F}(p_f + w_f \cdot g(R) + \sum_{c \in R} d(c, f))$ for $R \in 2^C \setminus \{\emptyset\}$ (which can be computed in $\text{poly}(N)$ time). Notice that $2^{|\mathcal{U}|} = 2^n$ which is polynomially bounded in the input size of I. The optimal solution to J induces a solution of exactly the same cost to I and vice versa. There is a simple dynamic program which solves Weighted Set Cover in time $O(2^{|U|} \cdot |U| \cdot |\mathcal{R}|)$ [15, Lemma 2]. Applying this algorithm to J, one obtains an optimal solution for the input instance I in time $O(2^n \cdot \text{poly}(n, m))$, which is polynomial in m.

Hence it remains to consider the case $m \leq 2^n$. We show how to reduce the number of facilities to $O_\varepsilon(n^2 \log(nN)) = O_\varepsilon(n^3)$, while losing the approximation factor in the claim. By exactly the same reduction as in Lemma 1.8, we can assume that in the input metric d the maximum distance is $0 < d_{\max} \leq NL$ and the minimum non-zero distance is $d_{\min} \geq \frac{\varepsilon}{n} L$ while loosing a factor $(1 + 4\varepsilon)$ in the approximation. Here L is some value that lower bounds the cost of a given optimum solution opt. Let us guess the largest value P of p_f over the facilities with at least one assigned client in opt. We discard all the facilities f with $p_f > P$. Now, assuming $P > 0$, we replace each p_f with the value $p'_f \coloneqq \lceil \frac{p_f \cdot n}{\varepsilon P} \rceil \cdot \frac{\varepsilon P}{n}$ ($p'_f = p_f$ for $P = 0$). Notice that this can only increase the cost of a given solution φ, however this increase is upper bounded by $n \cdot \frac{\varepsilon P}{n} \leq \varepsilon \cdot \text{cost}_I(\text{opt})$, where I is the input instance of the problem. Hence this reduction preserves the approximation guarantee up to a factor $1 + \varepsilon$. After this reduction, the set $\mathcal{P}'$ of different possible values of p'_f has cardinality at most $\frac{n}{\varepsilon}$.

Let $I = (C, F, d, p', w, g(\cdot))$ be the instance of Affine SFL obtained after the above two reductions. Consider the complete edge-weighted graph on nodes $C \cup F$, with weights induced by d. We modify this graph as follows. For each client c and value $p' \in \mathcal{P}'$, we consider the set of facilities $F_{p'}$ with $p'_f = p'$. Let $F_{p'}(c, i)$, $i \geq 0$, be the facilities in $F_{p'}$ whose distances from c are in the range $[\frac{\varepsilon}{n} L \cdot (1 + \varepsilon)^i, \frac{\varepsilon}{n} L \cdot (1 + \varepsilon)^{i+1})$. We also define the set $F_{p'}(c, -1)$ of the facilities in $F_{p'}$ at distance 0 from c. Notice that there are at most $1 + \lceil \log_{1+\varepsilon} \frac{nN}{\varepsilon} \rceil$ sets $F_{p'}(c, i)$ which are non-empty. For each $F_{p'}(c, i) \neq \emptyset$, we choose a facility $f = f_{p'}(c, i)$ with minimum value of w_f. We create a dummy facility $f' = f'_{p'}(c, i)$ with opening cost $g'_{f'}(C') = p' + w_f \cdot g(C')$ for $C' \neq \emptyset$, and add a dummy edge $\{c, f'\}$ of weight $d(c, f)$. Let F'

be the set of dummy facilities. Notice that, considering also the previous reduction, one has $|F'| \leq n \cdot \frac{n}{\varepsilon} \cdot (1 + \lceil \log_{1+\varepsilon} \frac{nN}{\varepsilon} \rceil) = O(n^2 \log(nN))$. We remove the original facilities F, and let d' be the metric given by the distances in the resulting graph G' on nodes $C \cup F'$. We solve the problem on the resulting instance $I' = (C, F', d', p', w, g(\cdot))$. Given a solution φ' for I', we obtain a solution φ for I naturally as follows: if $\varphi'(c') = f'_{p'}(c, i)$, we assign c' to $f_{p'}(c, i)$.

Let us analyze the approximation factor of this final reduction. The opening costs of φ and φ' are identical. Furthermore, for each client c' assigned to $f = f_{p'}(c, i)$ in φ, and for $f' = f'_{p'}(c, i)$, one has $d(c', f) \leq d(c', c) + d(c, f) = d'(c', c) + d'(c, f') = d'(c', f')$. Hence $\mathrm{cost}_I(\varphi) = \mathrm{cost}_{I'}(\varphi')$.

Next consider an optimum solution opt for I. We construct a feasible solution opt$'$ for I' as follows. Let $S^f \neq \emptyset$ be the clients assigned to some $f \in F$ in opt. Recall that the opening cost of f is $g'_f(S^f) = p'_f + w_f \cdot g(S^f)$. Let $c \in S^f$ be the client at minimum distance $d(c, f)$ from f. Define i as -1 if $d(c, f) = 0$, and otherwise, i such that $d(c, f) \in [\frac{\varepsilon}{n} L \cdot (1+\varepsilon)^i, \frac{\varepsilon}{n} L \cdot (1+\varepsilon)^{i+1})$. In opt$'$ we reassign all the clients in S^f to $f' = f'_{p'_f}(c, i)$. The opening cost associated with f' in opt$'$ is no larger than the corresponding cost in opt since

$$p'_{f'} + w_{f'} \cdot g(S^{f'}) = p'_f + w_{f'} \cdot g(S^f) \leq p'_f + w_f \cdot g(S^f).$$

In the last inequality above we used the fact that $f \in F_{p'_f}(c, i)$ and $f_{p'_f}(c, i)$ is the facility in the latter set with minimum w_f value. The connection cost of each $c' \in S^f$ w.r.t. opt$'$ satisfies

$$\begin{aligned} d'(c', f') &= d'(c', c) + d'(c, f') = d(c, c') + d(c, f_{p'_f}(c, i)) \\ &\leq d(c', f) + d(c, f) + (1 + \varepsilon) d(c, f) \leq (3 + \varepsilon) d(c', f). \end{aligned}$$

Altogether, $\mathrm{cost}_{I'}(\mathrm{opt}') \leq (3 + \varepsilon)\, \mathrm{cost}_I(\mathrm{opt})$. Considering also the first two reductions, we obtain a global reduction which preserves the approximation guarantee up to a factor $(1 + 4\varepsilon)(1 + \varepsilon)(3 + \varepsilon) \leq 3 + 37\varepsilon$. ◀

B.2 SFL with Multiplicative Opening Costs

In this section we sketch the proof of Theorem 1.3. By Lemma B.1, it is sufficient to provide an $O(\log \log N)$ approximation.

For $f \in F$ and $R \subseteq C$ let $g_f(R) \coloneqq w_f \cdot g(R)$. Note that $g_f(\cdot)$ is submodular, monotone and has $g(\emptyset) = 0$ for every $f \in F$. For any (partial) assignment $S = (S^f)$ and any vector $(x^f_R)^{f \in F}_{R \subseteq C}$ let also $\mathrm{open}'(S) \coloneqq \sum_{f \in F} g_f(S^f)$, resp. $\mathrm{open}'(x) \coloneqq \sum_{f \in F} \sum_{R \subseteq C} g_f(R) \cdot x^f_R$ and $\mathrm{cost}'(S) \coloneqq \mathrm{open}'(S) + \mathrm{conn}(S)$ resp. $\mathrm{cost}'(x) \coloneqq \mathrm{open}'(x) + \mathrm{conn}(x)$.

By these definitions, the LP-relaxation of the MULTSFL is given by the constraints from (Conf-LP) and the objective $\mathrm{cost}'(\cdot)$. In particular, the LP-relaxation of MULTSFL can be solved with the approach from Lemma 1.2. We keep the merging rule defined in Section 1.4 and the sampling procedure from Section 2. It is easy to verify that the vector $\ddot{x}$ resulting from this procedure fulfills Lemma 2.2 w.r.t. open$'$ instead of open.

We reduce MULTSFL to a similar problem to DLA which we call DLA* which is the same problem as DLA and with the same input variables as DLA, additional inputs $\tilde{w}_f \geq 0$ for every $f \in \tilde{F}$ and cost $\mathrm{cost}^*_{\mathrm{DLA}}(\varphi) = \sum_{f \in \tilde{F}} h_f(\varphi^{-1}(f))$ where $h_f(\cdot) \coloneqq \tilde{w}_f h(\cdot)$ for every $f \in \tilde{F}$. Its convex relaxation is given by the constraints in (DLA-CP) with the cost function $\mathrm{cost}^*_{\mathrm{DLA}}(z) \coloneqq \sum_{f \in \tilde{F}} \hat{h}_f(z^f)$ (where $\hat{h}_f$ is the Lovász extension of h_f). The reduction described in Lemma 3.2 can be reproduced to reduce MULTSFL to DLA*. We define the input values

of DLA* w.r.t. MULTSFL in the same way we define the input values of DLA w.r.t. SFL, with additionally $\tilde{w}_f = w_f$ for every $f \in F$. Notice that $h_f(\cdot) = \tilde{w}_f h(\cdot) = g_f(\cdot) = w_f g(\cdot)$. Every reasoning made in the proof of Lemma 3.2 stays valid.

We now adjust Algorithm 1 for DLA* as follows: in Step 3, we select the facility $f_v \in \tilde{F}_v$ with minimum weight $\tilde{w}_{f_v}$. In the if-clause 4, we search and verify for supportedness w.r.t. h_{f_v} instead of h (which is equivalent unless $\tilde{w}_{f_v} = 0$, in which case $L_\theta(z^{f_v})$ is supported for every θ). Since the new algorithm functions exactly like Algorithm 1, except for an arbitrary selection step becoming determined (in particular, the new algorithm is a possible implementation of Algorithm 1), its correctness is implied by the correctness of Algorithm 1.

Notice that since f_v in Step 3 is now chosen to have minimal weight, we have for any $f' \in \tilde{F}_v \setminus \{f_v\}$

$$\hat{h}_{f_v}\big(z^{f_v} + z^{f'}\big) \leq \hat{h}_{f_v}\big(z^{f_v}\big) + \hat{h}_{f_v}\big(z^{f'}\big) \leq \hat{h}_{f_v}\big(z^{f_v}\big) + \hat{h}_{f'}\big(z^{f'}\big),$$

which means that the cost of z does not increase at any time by the arguments as before. Also, notice that since h_f is submodular, monotone and $h_f(\emptyset) = 0$ we can apply Lemma 3.4 with respect to h_{f_v} instead of h. Thus, the cost of the sets added at Step 5 and Step 7 is still bounded as in (4) and (5).

B.3 SFL with Additive Opening Costs

In this section we sketch the proof of Theorem 1.4. As in the previous section, by Lemma B.1, it is sufficient to provide an $O(\log \log N)$ approximation.

Similarly to the previous section, we define the set function $g_f(\cdot)$ as $g_f(R) = g(R) + p_f$ for $R \neq \emptyset$ and $g_f(\emptyset) = 0$. As argued in the previous section, we can find an optimum to the LP relaxation of ADDSFL and reduce it to the problem DLA* as defined in the last section, but with input weights $\tilde{p}_f$ instead of $\tilde{w}_f$ and $h_f(\cdot)$ as $h_f(R) \coloneqq h(R) + p_f$ for $R \neq \emptyset$, and $h_f(\emptyset) = 0$.

We adapt Algorithm 1 like in the previous section: in Step 3, we select the facility $f_v \in \tilde{F}_v$ with minimum weight $\tilde{p}_{f_v}$. In the if-clause 4, we search and verify for supportedness w.r.t. h_{f_v} instead of h. The correctness of the new algorithm here is given by the same argument as in the previous section. Notice that by (2) we have $\hat{h}_f(z) = \hat{h}(z) + p_f \cdot \max_{c \in \bar{C}} z_c$, which implies $\hat{h}_{f_v}(z^{f_v} + z^{f'}) \leq \hat{h}_{f_v}(z^{f_v}) + \hat{h}_{f'}(z^{f'})$ with f_v chosen as in Step 3 in Algorithm 1. The cost of z does therefore not increase throughout the algorithm. Bounding the cost of sets added to the solution at Step 5 and Step 7 can be done, like for MULTSFL, by applying Lemma 3.4 to h_{f_v}.

Parameterized Approximation For Robust Clustering in Discrete Geometric Spaces

Abstract

We consider the well-studied Robust (k, z)-Clustering problem, which generalizes the classic k-Median, k-Means, and k-Center problems and arises in the domains of robust optimization [Anthony, Goyal, Gupta, Nagarajan, Math. Oper. Res. 2010] and in algorithmic fairness [Abbasi, Bhaskara, Venkatasubramanian, 2021 & Ghadiri, Samadi, Vempala, 2022]. Given a constant $z \geq 1$, the input to Robust (k, z)-Clustering is a set P of n points in a metric space (M, δ), a weight function $w : P \to \mathbb{R}_{\geq 0}$ and a positive integer k. Further, each point belongs to one (or more) of the m many different groups $S_1, S_2, \ldots, S_m \subseteq P$. Our goal is to find a set X of k centers such that $\max_{i \in [m]} \sum_{p \in S_i} w(p)\delta(p, X)^z$ is minimized.

Complementing recent work on this problem, we give a comprehensive understanding of the parameterized approximability of the problem in geometric spaces where the parameter is the number k of centers. We prove the following results:

- **(i)** For a universal constant $\eta_0 > 0.0006$, we devise a $3^z(1-\eta_0)$-factor FPT approximation algorithm for Robust (k, z)-Clustering in *discrete* high-dimensional Euclidean spaces where the set of potential centers is finite. This shows that the lower bound of 3^z for general metrics [Goyal, Jaiswal, Inf. Proc. Letters, 2023] no longer holds when the metric has geometric structure.
- **(ii)** We show that Robust (k, z)-Clustering in discrete Euclidean spaces is $(\sqrt{3/2} - o(1))$-hard to approximate for FPT algorithms, even if we consider the special case k-Center in logarithmic dimensions. This rules out a $(1+\epsilon)$-approximation algorithm running in time $f(k, \epsilon)\mathsf{poly}(m, n)$ (also called efficient parameterized approximation scheme or EPAS), giving a striking contrast with the recent EPAS for the *continuous* setting where centers can be placed anywhere in the space [Abbasi et al., FOCS'23].
- **(iii)** However, we obtain an EPAS for Robust (k, z)-Clustering in discrete Euclidean spaces when the dimension is sublogarithmic (for the discrete problem, earlier work [Abbasi et al., FOCS'23] provides an EPAS only in dimension $o(\log \log n)$). Our EPAS works also for metrics of sub-logarithmic doubling dimension.

1 Introduction

Clustering is a crucial method in the analysis of massive datasets and has widespread applications in operations research and machine learning. As a consequence, optimization problems related to clustering have received significant attention from the theoretical computer science community over the years. Within the framework of center-based clustering, k-Center, k-Means, and k-Median [25, 26, 10, 4, 27] are widely regarded as the most fundamental problems.

A general notion that captures various classic clustering problems is referred to as (k, z)-Clustering in the literature, where $z \geq 1$ is a constant. In this type of problem, the input is a set P of data points (clients), a set F of centers (facilities), a metric δ on $P \cup F$, and a positive integer k. The goal is to find a set $C \subseteq F$ of k facilities that minimizes the following cost function:

$$cost(C) = \sum_{p \in P} cost(p, C)$$

where $cost(p, C) = \delta(p, C)^z$ and $\delta(p, C) = \min_{c \in C} \delta(p, c)$. Note that (k, z)-Clustering encapsulates the classical k-Median, and k-Means for $z = 1$ and $z = 2$, respectively .

Center-based clustering has cemented its place as an unsupervised learning method that has proven effective in modeling a variety of real-world problem. In most of the practical machine learning applications however, it is observed that the input data is rarely of high quality.

To tackle this challenge, we study a robust version of (k, z)-Clustering in this paper which can handle uncertainty in the input: Consider a situation where we do not have complete knowledge about the clients that will be served. In order to perform well despite this uncertainty, Anthony et al. [5] defined a concept of robustness for the k-Median problem, in which each possible scenario is represented by a group of clients and the goal is to find a solution that performs best possible even in the worst scenario. In this paper, we address the following robust version of the (k, z)-Clustering problem (called Robust (k, z)-Clustering):

Robust (k, z)-Clustering
Input: Instance (P, F, δ) with δ being a metric on $P \cup F$, positive integer k, a weight function $w\colon P \to \mathbb{R}_+$, and m groups $S_1, \ldots, S_m$ such that $S_i \subseteq P, P = \cup_{i \in [m]} S_i$.
Output: A k-element subset $X \subseteq F$ that minimizes $\max_{i \in [m]} \sum_{p \in S_i} w(p)\delta(p, X)^z$.

Let $n = |P|$. We remark that, in addition to generalizing k-Median and k-Means, the Robust (k, z)-Clustering problem encapsulates k-Center, when each group contains a distinct singleton. A similar objective has been studied in the context of *fairness*, in which

we aim to create a solution that will be appropriate for each of the specified groups of people. This problem is known in the literature as Socially Fair k-Median, recently introduced independently by Abbasi et al. [3] and Ghadiri et al. [20]. Notice that Abbasi et al. [3] introduce fair clustering with client weights being inversely proportional to the group size as a normalization. On the other hand, Anthony et al. [5] introduce robust clustering with unweighted clients. Since our definition allows arbitrary client weights, we capture both of these settings.

While k-Means, k-Median, and k-Center admit constant-factor approximations, it is not very surprising that Robust (k, z)-Clustering is harder due to its generality: Makarychev and Vakilian [29] design a polynomial-time $\mathcal{O}(\log m/\log\log m)$-approximation algorithm, which is tight under a plausible complexity assumption [8][1]. As this precludes the existence of efficient constant-factor approximation algorithms, recent works have focused on designing constant factor *parameterized* (FPT) approximation algorithms[2]. Along these lines, an FPT time $(3^z + \epsilon)$-approximation algorithm has been proposed and shown to be tight under the Gap Exponential-Time Hypothesis (Gap-ETH) [22]. When allowing a parameterization on the number of groups m (instead of k), Ghadiri et al. designed a $(5 + 2\sqrt{6} + \epsilon)^z$-approximation algorithm in $n^{\mathcal{O}(m^2)}$ time [21].

Motivated by the tight lower bounds for general discrete metrics, we focus on *geometric* spaces. Geometric spaces have a particular importance in real-world applications because data can often be represented via a (potentially large) collection of numerical attributes, that is, by vectors in a (possibly high-dimensional) geometric space. For example, in the bag-of-words model a document is represented by a vector where each coordinate specifies the frequency of a given word in that document. Such representations naturally lead to very high-dimensional data. A setting of particular interest is the high-dimensional *Euclidean space* where the metric is simply the Euclidean metric $\delta(x, y) = ||x - y||_2$.

The study of clustering problems in high-dimensional Euclidean space is an important line of research that has received significant attention in the algorithms community. It may seem intuitive to believe that it should generally (for almost any problem) be possible to algorithmically leverage the geometric structure to separate high-dimensional Euclidean from general metrics. For clustering, however, this turns out to be either false or highly non-trivial in many cases. For example, it is a long-standing open question [19] whether k-Center admits a polynomial time $(2 - \epsilon)$-approximation algorithm even in $\mathbb{R}^2$, improving the tight bound of 2 in general metrics. Interestingly enough, for the more general Euclidean k-Supplier problem, Nagarajan et al. [30] obtain an improvement over the tight bound of 3 in general metrics. The improved bounds for Euclidean k-Median and k-Means by Ahmadian et al. [4], Grandoni et al. [23], and recently by Cohen-Addad et al. [11] were breakthroughs. Concerning the more general Robust (k, z)-Clustering, the tight inapproximability bound of $\Omega(\log m/\log\log m)$ in general metric continues to hold even in the line metric [8].

Similarly, the regime of FPT approximation algorithms for Euclidean clustering problems has received significant attention. Classic works design an Efficient Parameterized Approximation Scheme (EPAS), that is, a $(1 + \epsilon)$-approximation in $f(k, \epsilon)\mathsf{poly}(n)$ time, for k-Center [6] as well as for k-Median and k-Means [28]. Recent research focuses on the design of so-called coresets [31, 16] whose existence implies an EPAS if their size only depends on k and the error parameter ϵ.

[1] Note that they proved this factor for Robust k-Median, and the hardness result holds even in the line metric, unless $\mathsf{NP} \subseteq \cap_{\delta>0}\mathsf{DTIME}(2^{n^\delta})$.

[2] Throughout the paper, parameterization refers to the natural parameter k.

In the real space $\mathbb{R}^d$, it is important to distinguish between the *discrete* and the *continuous* settings. In the discrete setting, both the point set P and the candidate center set F are finite subsets of $\mathbb{R}^d$ while in the continuous setting, centers can be chosen anywhere in the metric space, that is, $F = \mathbb{R}^d$. A separate line of research has studied the contrast between continuous and discrete versions. For example, while discrete clustering variants are clearly polynomial-time solvable for constant k by trivial enumeration, the continuous versions of k-Center and k-Median are known to be NP-hard even for $k = 2$ [18] in high-dimensional Euclidean space. Also in terms of polynomial-time approximability, stronger lower bounds were shown by Cohen-Addad et al. [14] for the continuous versions. Indeed, there have been systematic research efforts in understanding these geometric clustering problems [15, 13, 14]. A recent result [2] implies an EPAS for Robust (k, z)-Clustering in continuous Euclidean spaces (of any dimension), as well as in discrete Euclidean spaces in "relatively low" dimension, that is, dimension $o(\log \log n)$.

The main goal of this paper is to develop comprehensive understanding for Robust (k, z)-Clustering in high-dimensional discrete Euclidean spaces, in particular, when the dimension is at least $\Omega(\log \log n)$.

1.1 Our contributions

First, motivated by a factor-$(3^z - o(1))$ hardness of FPT approximation for Robust (k, z)-Clustering in general metrics [22], a natural question is whether the structures of Euclidean spaces can be leveraged to obtain better results in high dimensions. While it is intuitive to believe that such an improvement should generally (for almost any problem) be possible in geometric spaces, we note that this is sometimes not the case: The polynomial time inapproximability of Robust (k, z)-Clustering remains $\Omega(\log m / \log \log m)$ even in the line metric [8].

Our first result gives an affirmative answer to this question.

▶ **Theorem 1.1** (High-Dimensional Euclidean Space). *There exists a universal constant $\eta_0 > 0.0006$ such that for any constant positive integer z, there is a factor $3^z(1 - \eta_0)$ FPT approximation algorithm for Robust (k, z)-Clustering in discrete Euclidean space $\mathbb{R}^d$ that runs in time $2^{\mathcal{O}(k \log k)} \mathsf{poly}(m, n, d)$.*

We remark that, first, our running time has only a polynomial dependency on d. Secondly, the key take-home message for Theorem 1.1 is not about a concrete approximation factor, but rather a "proof of concept" that the factor of 3^z can be improved. Conceptually, this result shows that geometric spaces are indeed easier for Robust (k, z)-Clustering than general metric spaces in the FPT world, in contrast to the polynomial-time world, where they seem to be equally hard [8]. The proof of this theorem relies on a new geometric insight that leverages the properties of Euclidean spaces (that do not hold in general metric spaces). The analysis of our algorithms "reduces" the global analysis of approximation factor to a "local" geometric instance, in which it suffices to merely analyze the behavior of three points in the Euclidean spaces.

Next, we focus on obtaining a complete characterization of the existence of EPAS in discrete Euclidean spaces. Recall that an EPAS exists in continuous Euclidean spaces of any dimensions and in discrete Euclidean spaces of dimension $o(\log \log n)$ [2], so to complete the landscape, we need to understand the discrete Euclidean spaces of dimension $\Omega(\log \log n)$.

In the next theorem, we prove that even the special case of k-Center does not admit an EPAS. This hardness holds for any ℓ_q metric and even in dimension $O(k \log n)$. More formally, we prove the following theorem.

▶ **Theorem 1.2** (Hardness in Discrete Euclidean Space). *For any constant positive integer q and any positive constant $\eta > 0$, there exists a function $d(k,n) = O(k \log n)$ such that there is no factor-$(3/2-\eta)^{1/q}$ FPT approximation algorithm for the discrete k-Center problem in $\mathbb{R}^{d(k,n)}$ under the ℓ_q metric unless W[1]= FPT. Moreover, for the ℓ_2 metric this hardness holds even for some dimension $O(\log n)$, that is, independently of k.*

Our result therefore highlights the interesting contrast between the discrete and continuous settings in high-dimensional Euclidean spaces, which has been systematically studied in recent years [15, 13, 14]. As mentioned, the continuous setting admits an EPAS [2], so our hardness result implies that the discrete setting is harder than the continuous counterpart. This is contrast to the results Cohen-Addad et al. [14] mentioned earlier showing that continuous variants of k-Median and k-Means in geometric spaces are apparently harder to approximate (in polynomial time) than their discrete part as well as the different complexity status of continuous and discrete clustering in high-dimensional spaces even for $k = 2$ [18]. This shows a rather mysterious behavior of clustering problems in geometric spaces.

Our next theorem completes the FPT-approximability landscape by designing an EPAS for the problem in doubling metrics of dimension $d = o_k(\log n)$[3]. We remark that the doubling dimension of the d-dimensional discrete Euclidean metric is $\Theta(d)$, that is, we obtain an EPAS for discrete Euclidean $o_k(\log n)$-dimensional spaces in particular.

▶ **Theorem 1.3** (EPAS for Doubling Metric of Sub-Logarithmic Dimension). *There is an algorithm that computes $(1+\epsilon)$-approximate solution, for every $\epsilon > 0$, for Robust (k,z)-Clustering in the metric of doubling dimension d in time $f(k,d,\epsilon,z)\mathsf{poly}(m,n)$, where $f(k,d,\epsilon,z) = \left(\left(\frac{2^z}{\epsilon}\right)^d k \log k\right)^{\mathcal{O}(k)}$.*

Note that the above theorem yields an EPAS for Robust (k,z)-Clustering when $d = o_k(\log n)$. Together with Theorem 1.2, this theorem gives (almost) a dichotomy result for the existence of EPAS: An EPAS exists for Robust (k,z)-Clustering in $o_k(\log n)$ dimension, while obtaining an EPAS is W[1]-hard in $\Omega_k(\log n)$ dimension. This leads to an almost complete understanding on the existence of EPAS in continuous and discrete Euclidean spaces.

2 Overview of Techniques

Improved FPT Approximation in High-Dimensional Discrete Euclidean Space

Our algorithm underlying Theorem 1.1 is a slight modification of the factor-$(3^z+\epsilon)$ FPT approximation algorithm for general metrics by Goyal and Jaiswal [22]. Our main technical contribution lies in the improved analysis. A key component of the analysis by Goyal and Jaiswal is a simple projection property of metric spaces (see Lemma 2.1 below). We argue that under minor additional assumptions, this property can be strengthened in Euclidean space. The resulting *assigment lemma* (see Lemma 3.1) is at the heart of our analysis and its proof relies on several new ideas and technically involved ingredients.

We briefly review the algorithm by Goyal and Jaiswal [22]. Their algorithm consists of two main steps. First, they compute a (κ,λ)-bicriteria solution $B \subseteq F$, that is, the cost of B is bounded by $\kappa\mathsf{OPT}$ and the cardinality of B is bounded by λk. Specifically, they obtain guarantees $\kappa = 1+\epsilon$ and $\lambda = \mathcal{O}\left(\log^2 n/\epsilon^2\right)$ for sufficiently small $\epsilon > 0$. In the second step, they extract a feasible solution from the (infeasible) bi-criteria solution B by enumerating all k-subsets of B and outputting the one of minimum cost.

[3] We use notation $o_k(\cdot)$ to hide multiplicative factors depending only on k.

Their analysis is based on proving the existence of a k-subset of B whose cost is at most $(3^{z-1}(\kappa+2))\mathsf{OPT}$, which can be bounded by $(3^z+\epsilon)\mathsf{OPT}$ assuming z being constant. Since the algorithm enumerates all k-subsets, this provides an upper bound on the cost of the algorithm. The key component of their existential argument is the following simple property of metric spaces, which we call *projection lemma*. It is convenient to think of O as an optimal solution and B as a bicriteria solution with $|B| > |O|$ but the lemma holds for any sets B, O.

▶ **Lemma 2.1** (Projection Lemma). *Let (Y,δ) be a metric space, and $B \subseteq Y$. Then for any set $O \subseteq Y$, there exists an assignment $\sigma\colon O \to B$ such that, for all $o \in O$ and $y \in Y$, we have*

$$\delta(y,\sigma(o)) \leq 2\delta(y,o) + \delta(y,B)\,. \tag{1}$$

Intuitively, their lemma allows them to "project" the optimal solution O onto a k-subset $\sigma(O) \subseteq B$ of the bicriteria solution so that for any client $y \in Y$, the distance $\delta(y,\sigma(O))$ can be charged to $\delta(y,O)$ and $\delta(y,B)$. If fact, the number 3 in the approximation factor $3^z+\epsilon$ corresponds to the sum $(2+1)$ of the coefficients in front of $\delta(y,o)$ and $\delta(y,B)$.

In this paper, we study the setting where Y is a discrete Euclidean metric (P,F,δ), that is, where P, F are finite subsets of $\mathbb{R}^d$ and δ is the Euclidean distance. A natural attempt to improve the approximation factor in the Euclidean setting is to reduce the coefficients in front of the terms $\delta(y,o)$ and $\delta(y,B)$ in the projection lemma. Unfortunately, this straightforward approach fails: The projection lemma is tight even on the line metric; see Figure 1.

Figure 1 This example shows that the projection lemma is tight even for the 1-dimensional Euclidean space. Let $o = 0$ be the optimum facility located at the origin and serving client $p = 1/2$. Let $b' = 1$ be the facility in B that serves p and let $b = \sigma(o) = -1$ be the facility in B nearest to o. We have $\mathsf{OPT} = 1/2$, which also equals the cost of B. However $\delta(p,\sigma(o)) = 3/2 = 2\times\delta(p,o)+1\times\delta(p,b')$. Combining multiple such examples in orthogonal directions and sharing facility b shows that the approximation ratio of the algorithm of Goyal and Jaiswal [22] approaches 3 in the discrete Euclidean space.

It turns out that slightly enlarging the projection space is already sufficient to bypass this obstacle. More specifically, we project onto the *midpoint closure*

$$\mathsf{cl}(B) = B \cup \left\{ \pi_F\left(\frac{b+b'}{2}\right) : b, b' \in B \right\}, \tag{2}$$

of the bicriteria solution where $\pi_F(p)$ represents the closest facility in F to point p. This step exploits that the metric space is embedded into $\mathbb{R}^d$ (so that the midpoints exist).

While on the algorithmic side a slight modification of the original algorithm is sufficient for the improvement, the analysis requires several new ideas and technically involved ingredients. To prove a strengthened version of the projection lemma (called assignment lemma) we set up a factor-revealing geometric optimization problem in the plane; see (3) in Definition 3.2 below. We call the optimum objective γ_β of this problem *displacement ratio*. Roughly speaking, this ratio corresponds to the maximum ratio between the left-hand and the right-hand side of (1) in Lemma 2.1. However, we project to $\mathsf{cl}(B)$ rather than B and impose some additional minor restrictions. By a careful and technically involved analysis of this optimization problem we can upper bound the displacement ratio in the Euclidean setting by $1-\epsilon_0$ for some universal constant $\epsilon_0 > 0$ as long as two obstructions are avoided. The first obstruction occurs in any configuration similar to the one in Figure 1 above where the bi-criteria solution contains two

facilities b, b' so that o is near to the mid-point of b and b'. However, in such a configuration facility o certifies that $b'' = \pi_F((b + b')/2)$ must be close to o allowing us to assign o to b'' contained in the mid-point closure. The second obstruction arises if p is β-*near*, that is, within a small distance β from o (but there is no facility in B such as b' as in the first obstruction). For β approaching 0, the displacement ratio of β-near points can approach 1 even if when projecting to the mid-point closure of B. To account for β-near points, we therefore cannot resort to the assignment lemma. However, the overall contribution of β-near points to the cost of the projected solution can be shown to be very small. More details of the algorithm and its analysis are provided in Section 3.1. The full proof of the assignment lemma is technically more involved and can be found in the full version [1].

Hardness of Discrete k-Center

Our proof constructs an instance of the discrete k-Center from an instance of Multi-Colored Independent Set problem, which is known to be $W[1]$-hard. In Multi-Colored Independent Set, we are given a k-partite graph G with a k-partition of the vertices $V_1, \ldots, V_k$, and the goal is to determine if there is an independent set that contains precisely one node from each set V_i, $i \in [k]$. The gadget in our construction is a set of nearly equidistant binary code words. Such code words with relative Hamming distance roughly $1/2$ and logarithmic length are known to exist (see Ta-Shma [32]). The high level idea is as follows. We associate each vertex of G with a unique code word of suitable length t. Then, we generate a data point in P for each vertex and edge of G by using code word(s) associated with the corresponding vertices. The construction guarantees the following crucial properties: (i) The Hamming distance between the data points of vertices is roughly t. (ii) The Hamming distance between a data point of vertex $v \in V_i$ and a data point of an edge e is roughly t if e is incident on $V_i \setminus \{v\}$ and is roughly $3t/2$ otherwise. (iii) The Hamming distance between the data points of edges is at least (close to) $3t/2$. Thus, the construction forces us to pick data points of vertices as centers in our solution and guarantees that the optimum cost of the k-Center instance is roughly t if and only if there is an independent set in G. As a result, approximating the cost of the k-Center instance better than a (roughly) $(3/2)^{1/q}$ factor would imply $W[1] = \mathsf{FPT}$. That is because the cost of a k-Center instance is the maximum ℓ_q distance between a data point and its closest selected center, and hence, approximating this cost better than the mentioned factor allows us to distinguish between Yes and No cases of an arbitrary instance of Multi-Colored Independent Set.

Approximation Scheme for Metrics of Sub-Logarithmic Doubling Dimension

Our algorithm comprises two main components, both based on standard techniques from the literature: instance compression and decomposition of the doubling metric into smaller balls. However, it becomes evident that a natural construction based on these standard techniques for Robust (k, z)-Clustering faces serious information-theoretic limitations, as explained below. One natural idea for compressing a Robust (k, z)-Clustering instance is to reduce the number of groups, as each group can be further compressed using a (k, z)-Clustering coreset (such coresets exist [16]). This reduction yields a significantly smaller instance. If we could reduce the number of groups to $m' \ll m$ while approximately preserving the cost for every solution, we could obtain an EPAS as follows. First, apply a (k, z)-Clustering coreset to every group of the compressed instance to obtain another Robust (k, z)-Clustering instance with m' groups, each containing $g(k, \epsilon)$ points, where g is some function that represents the size of (k, z)-Clustering coreset. It is essential to note that this compression

is acceptable for obtaining an EPAS since the coreset of a group approximately preserves the (k, z)-Clustering cost of the group. Next, enumerate all k-partitions of the points within each group to find potential solutions. Finally, return the solution that has the minimum Robust (k, z)-Clustering cost. Unfortunately, because Robust (k, z)-Clustering captures k-Center (and consequently faces a coreset lower bound of $2^{\Omega(d)}$ in Euclidean space of dimension d [9]), the number of new groups must satisfy $m' \geq 2^{\Omega(d)}$. Consequently, the running time of this algorithm is $k^{2^{\Omega(d)}}\mathsf{poly}(n, m)$, which is doubly exponential in d. It is worth noting that this algorithm matches the running time of [2] and does not yield an EPAS for sub-logarithmic dimension.

Furthermore, if we explore an alternative approach and utilize the coreset of k-Center, it is not immediately clear how to extend the coreset of k-Center to reduce the number of groups in an instance of Robust (k, z)-Clustering. This is because, firstly, we would require a mapping between the old groups and the new groups, and secondly, this mapping should ideally approximately preserve the Robust (k, z)-Clustering cost for every solution.

Another potential method for compressing the instance involves reducing the number of points in set P, rather than altering the groups, with the hope of designing an EPAS that can exploit the smaller P (without concern for the number of groups). However, for this approach to succeed, it is essential to establish a bijection between the old and new groups. Yet, it remains uncertain whether such a bijection exists. In typical coreset constructions, each point in the coreset P' of P has a weight that is the sum of the weights of the points in its local neighborhood in P which it is supposed to represent in P'. However, these points in P could potentially belong to different groups, making it challenging to establish the mapping between groups.

The core idea of our approach is to work with an alternative and more general definition of groups that permits a point to participate in different groups with varying weights. In this revised definition, instead of viewing groups as subsets of points, we treat each group as a weight function that assigns non-negative real values to points. This flexibility allows different weights to be assigned to the same point by different groups, which can, in fact, be of practical interest. Utilizing this new definition, we can devise an approach for compressing the points such that each point in the compressed instance can have a weight for group g that represents the sum of the weights of nearby points in g that were filtered out during compression. Essentially, this enables us to approximately preserve the group costs. With this approach and additional technical work that leverages the standard ball decomposition technique for doubling metrics, we derive a coreset for Robust (k, z)-Clustering that can be employed to construct an EPAS for doubling metrics with sub-logarithmic dimension.

▶ Remark 2.2. Due to lack of space, we move some of the proofs to the full version [1]. The proofs of the Theorems and Lemmas with corresponding $(\star)$ marked are provided in the full version [1].

3 High-Dimensional Discrete Euclidean Space

3.1 FPT Approximation Algorithm for Robust (k, z)-Clustering

In this section, we exploit non-trivial properties of the Euclidean metric to prove the following result that breaches the barrier of 3^z-approximation for Robust (k, z)-Clustering in general metrics.

▶ **Theorem 1.1** (High-Dimensional Euclidean Space). *There exists a universal constant $\eta_0 > 0.0006$ such that for any constant positive integer z, there is a factor $3^z(1 - \eta_0)$ FPT approximation algorithm for Robust (k, z)-Clustering in discrete Euclidean space $\mathbb{R}^d$ that runs in time $2^{\mathcal{O}(k \log k)}\mathsf{poly}(m, n, d)$.*

Recall from Section 2 that our approach begins with computing a (κ, λ)-bicriteria solution B to the Robust (k, z)-Clustering instance employing the algorithm proposed by Goyal-Jaiswal [22]. As we argued, it is sufficient to prove the existence of a k-subset of B whose cost is within a constant factor of optimal. The result by Goyal and Jaiswal [22] is based on the following simple projection lemma for general metrics whose proof we state here for the sake of later reference.

▶ **Lemma 2.1** (Projection Lemma). *Let (Y, δ) be a metric space, and $B \subseteq Y$. Then for any set $O \subseteq Y$, there exists an assignment $\sigma\colon O \to B$ such that, for all $o \in O$ and $y \in Y$, we have*

$$\delta(y, \sigma(o)) \leq 2\delta(y, o) + \delta(y, B)\,. \tag{1}$$

Proof. For each $o \in O$, define $\sigma(o)$ as $\pi_B(o)$, the point in B closest in distance to o. Notice that for any $o \in O$, $y \in Y$, we have $\delta(y, \sigma(o)) \leq \delta(y, o) + \delta(o, \sigma(o))$ by triangle inequality. The lemma follows by combining this with $\delta(o, \sigma(o)) = \delta(o, B) \leq \delta(o, \pi_B(y)) \leq \delta(y, o) + \delta(y, B)$. ◀

This lemma itself is tight even in 1-dimensional Euclidean space (as we showed in Figure 1). In order to get around this issue, we make use of the property of our geometric space. Given the instance (P, F, δ) embedded into the Euclidean space and the bicriteria solution B, we project to the mid-point closure $\mathsf{cl}(B)$ as defined in (2).

Notice that $|\mathsf{cl}(B)| = \mathcal{O}\left(|B|^2\right)$. Let O be the optimal solution. For $\beta > 0$ we say that client $p \in P$ is *β-far* (from O w.r.t. B) if $\delta(p, O) \geq \beta \cdot \delta(p, B)$, and we say that client p is *β-near* otherwise. The key of our analysis is the following strengthening of the projection lemma for Euclidean space, which we call assignment lemma.

▶ **Lemma 3.1** (Assignment Lemma) (⋆). Let $\beta_0 = 0.05$ and let $B \subseteq \mathbb{R}^d$. Then, for any $O \subseteq \mathbb{R}^d$, there exists an assignment $\sigma\colon O \to \mathsf{cl}(B)$ such that, for all β_0-far points $p \in \mathbb{R}^d$, we have $\delta(p, \sigma(O)) \leq (1 - \epsilon_0)(2\delta(p, O) + \delta(p, B))$ where $\epsilon_0 > 0.002$.

Proof Sketch. We start with defining the assignment function σ. Take any facility $o \in O$ and let $b = \pi_B(o)$. We assume w.l.o.g. that the instance is rotated so that p, b, and o lie in the plane spanned by the first two coordinates. For the sake of easier notation, we identify p, b, o by points in $\mathbb{R}^2$. Further, by translation and scaling, we assume that o coincides with the origin and that $b = (-1, 0)$. Let $q = (0, 1)$ be the mirror image of b. Let α be a parameter to be fixed (we later set it to 0.6). We define $\sigma(o)$ based on the position of o relative to an α-ball. Specifically, $\sigma(o) = b$ if the α-ball centered at a point q contains no facility from B; otherwise, $\sigma(o)$ is the projection $\pi_{\mathsf{cl}(B)}(o)$ of o onto the mid-point closure of B.

Our goal is to analyze the displacement of a client p under the assignment rule σ. Recall from the proof of Lemma 2.1 that if $\sigma(o)$ is simply the projection onto B, then a client p, when served by facilities o and b' in sets O and B respectively, incurs a cost of at most $2||p - o|| + ||p - b'||$. We wish to show that the assignment cost in our algorithm is strictly smaller than this upper bound (under certain assumptions). We prove this by bounding the ratio of these two quantities.

▶ **Definition 3.2** (Displacement Ratio). *For a given small constant $\beta > 0$, let the* displacement ratio *be defined as*

$$\gamma_\beta = \max_{\substack{p \in \mathbb{R}^d \setminus \mathsf{ball}(o, \beta),\\ b' \in \mathbb{R}^d \setminus \mathsf{ball}(o, 1)}} \left\{ \frac{||p - \sigma(o)||}{2||p - o|| + ||p - b'||} \right\}. \tag{3}$$

Let S be the plane spanned by b, p, and o. After the appropriate rotations and translations we mentioned earlier, S would coincide with the x-y plane. In what follows, we also restrict b' to lie in $\mathbb{R}^2$ as well. We omit the argument why this assumption is without loss of generality from this sketch, and defer it to [1].

To show the lemma, we demonstrate that γ_β can be upper-bounded by $1 - f(\alpha, \beta)$ for some $f(\alpha, \beta) > 0$, where $f(\cdot)$ is a function dependent on α, β and the geometry of O and B. We distinguish two cases. First, suppose that B contains a facility b'' lying inside the α-ball around q. Recall that in this case $\sigma(o) = \pi_{\mathrm{cl}(B)}(o)$. Hence $\sigma(o)$ is no farther from o than the facility $\pi_F((b + b'')/2)$ nearest to the midpoint of b and b''. This allows us to bound the displacement ratio γ_β by $1 - \frac{1-\alpha}{2}$. See Figure 2 for an illustration. Notice that the optimal center o certifies the existence of a point in F nearby the mid-point of b and b''.

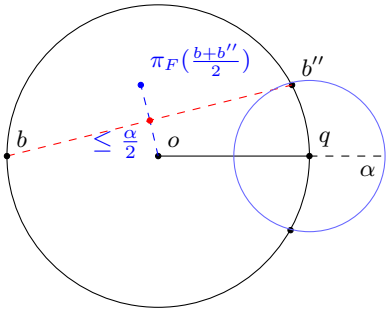

Figure 2 The midpoint of b and b'' is shown by red dot, $||(b + b'')/2 - o|| \leq \frac{\alpha}{2}$ and thus $||\sigma(o) - o|| \leq \alpha$.

In the second case, where the α-ball does not contain a facility from B, we argue that the points o, $\sigma(o) = b$, and b' are far enough from a co-linear position. This allows us to argue that the triangle inequality in the proof of Lemma 2.1 is not tight. Towards this, we divide the space into four regions R_1, R_2, R_3 and R_4 that could contain client p, we assume that p lies in the half plane above the x-axis (The case where p lies below the x-axis is symmetric.). Let q_1 be the intersection point of the surfaces of $\mathsf{ball}(o, 1)$ and $\mathsf{ball}(q, \alpha)$ above the x-axis. Let q_3 be the midpoint of q and q_1, the region H is defined as the area above the lines passing through (q_3, o) and (o, b), we define $R_1 = H \backslash \mathsf{ball}(o, \beta)$. Next, consider $(1 - \omega)$ and $(1 + \omega)$ balls around o, H' is defined as the area below the line passing through (o, q_3) and above the line passing through (o, q), we define $R_2 = (\mathsf{ball}(o, 1 - \omega) \backslash \mathsf{ball}(o, \beta)) \cap H'$, $R_3 = (\mathsf{ball}(o, 1 + \omega) \backslash \mathsf{ball}(o, 1 - \omega)) \cap H'$, and $R_4 = H' \backslash \mathsf{ball}(o, 1 + \omega)$, the regions are indicated in Figure 3. Below, we provide full proof for one of these regions.

Assume that client p lies in region R_1 (see Figure 4). Let b'' be the closest point to p not in the interior of $\mathsf{ball}(o, 1)$, and let p' be the point on the boundary of $\mathsf{ball}(o, \beta)$ that is closet to p. Let p'' be the point where the segment (o, q_3) intersects the boundary of $\mathsf{ball}(o, \beta)$, that is, $p'' = (\beta \cos\theta, \beta \sin\theta)$ where $\theta = \angle q_3 o q_1$. Notice that $\cos\theta = 1 - \frac{\alpha^2}{4}$. First, we assume p is inside $\mathsf{ball}(o, 1 + 2\beta)$ in the region of R_1.

▶ **Observation 3.3.** *For any* $\epsilon_1, \epsilon_2, X, Y \geq 0$ *:*

$$\frac{X - \epsilon_1 + Y}{X + Y} \leq \frac{X - \epsilon_1 + Y + \epsilon_2}{X + Y + \epsilon_2}$$

Consider assigning p via p' to b. We bound the displacement cost as follows:

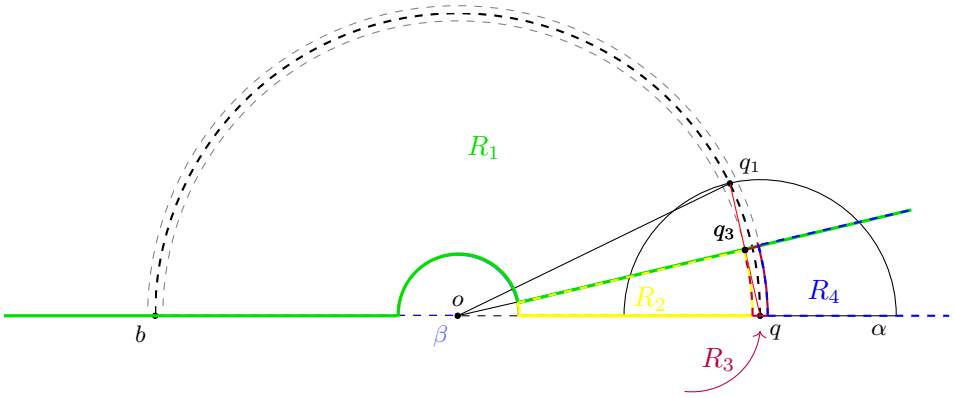

Figure 3 The dashed black circle depicts $\mathsf{ball}(o, 1)$, while the dashed gray circles represent $\mathsf{ball}(o, 1-\omega)$ and $\mathsf{ball}(o, 1+\omega)$. Regions R_1, R_2, R_3, and R_4 are outlined with green, yellow, purple, and blue borders respectively.

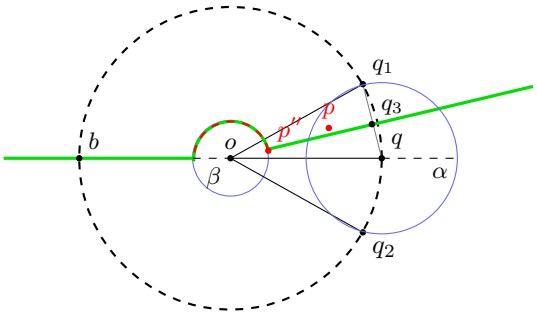

Figure 4 The dashed circle depicts $\mathsf{ball}(o, 1)$, α-ball around q and β-ball around o are shown in blue. The region R_1 is specified by green borders. The red dashed area represents the potential location of point p'.

$$\begin{aligned}
\gamma_\beta = \frac{||\sigma(o) - p||}{2||p-o|| + ||p-b'||} &\leq \frac{||b-p'|| + ||p-p'||}{2||p'-o|| + ||p'-b''|| + ||p-p'||} \\
&\leq \frac{||b-p''|| + ||p-p'||}{2\beta + 1 - \beta + ||p-p'||} \\
&\leq \frac{\sqrt{(\beta\cos(\theta)+1)^2 + (\beta\sin(\theta))^2} + ||p-p'||}{1+\beta+||p-p'||} \\
&= \frac{\sqrt{\beta^2 + 2\beta\cos\theta + 1} + ||p-p'||}{1+\beta+||p-p'||} \\
&= \frac{\sqrt{(1+\beta)^2 - \frac{\beta\alpha^2}{2}} + ||p-p'||}{1+\beta+||p-p'||}
\end{aligned}$$

We assume $||p - p'|| \leq 1 + \beta$, and by observation 3.3, we obtain:

$$\gamma_\beta \leq \frac{(1+\beta)(1+\sqrt{(1-\frac{\beta\alpha^2}{2})})}{2(1+\beta)} \leq \frac{1}{2} + \frac{\sqrt{1^2 - \frac{2\beta\alpha^2}{4} + \frac{\beta^2\alpha^4}{16}}}{2} \leq \frac{1}{2} + \frac{1 - \frac{\beta\alpha^2}{4}}{2}$$
$$= 1 - \frac{4 + \beta\alpha^2}{8}$$

Second, let's assume that the client p is distant from o and positioned within region R_1 outside $\mathsf{ball}(o, 1 + 2\beta)$, we can bound γ_β as follows:

$$\gamma_\beta \leq \frac{1 + ||o - p||}{2||o - p||} \leq \frac{1 + 1 + 2\beta}{2(1 + 2\beta)} = \frac{1 + \beta}{1 + 2\beta} = 1 - \frac{\beta}{1 + 2\beta}$$

Therefore, by examining the position of p in the regions, we establish that γ_β is upper-bounded by $1 - f(\alpha, \beta)$. Consequently, Lemma 3.1 is substantiated by showing the existence of an $\alpha_0 \leq 0.6$ and a sufficiently small $\beta_0 \leq 0.05$ such that $\gamma_{\beta_0} \leq 1 - f(\alpha_0, \beta_0) = 1 - \epsilon_0 \leq 0.9978$. The proofs for the other regions as well as the full details of the rest of the argument are provided in the full version [1]. ◀

In the proof of Theorem 1.1, we show that this new assignment property is enough to derive an improved FPT approximation for Robust (k, z)-Clustering in Euclidean space. Since the assignment σ maps every facility in O uniquely to a facility in $\mathsf{cl}(B)$, this implies that $\sigma(O)$ is a feasible solution of cost at most $(3^z \cdot (1 - \eta_0))\mathsf{OPT}$. This certifies the existence of a feasible solution being a subset of $\mathsf{cl}(B)$ with the desired approximation factor. Hence, we can find such a solution in FPT time by enumeration. The complete proof of Theorem 1.1 is provided in the full version [1].

3.2 Hardness of Discrete k-Center

For this section, we use the following explicit construction of the so-called *η-balanced error-correcting codes* from a recent result of Ta-Shma [32] which we rephrase for our purposes as follows:

▶ **Theorem 3.1.** *Let $\eta \in (0, 1/2)$ be a positive constant. Then there is an algorithm that computes, for any given number $s \in \mathbb{N}$, an s-element set $B \subseteq \{0,1\}^t$ of binary vectors of dimension $t = \mathcal{O}(\log s/\eta^{2+o(1)})$ such that for any $b \in B$, its Hamming weight $||b||_1$ and for any $b' \in B \setminus \{b\}$, the Hamming distance $||b - b'||_1$ both lie in the interval $[(1/2-\eta)t, (1/2+\eta)t]$. The running time of the algorithm is $\mathcal{O}(st)$.*

Proof. Ta-Shma [32] gives an explicit construction of a $t \times \lceil \log_2 s \rceil$ binary matrix generating a linear, binary, error-correcting code of message length $\lceil \log_2 s \rceil$, block length $t = \mathcal{O}(\log s/\eta^{2+o(1)})$, and pairwise Hamming distance between $(1/2 - \eta)t$ and $(1/2 + \eta)t$. Since the code is linear, it contains the zero code word. Hence each code word has Hamming weight in $[(1/2 - \eta)t, (1/2 + \eta)t]$. The time for constructing the matrix is polynomial in $\log s$ and t. Using the generating matrix, at least s many non-zero code words can be enumerated in time $\mathcal{O}(st)$, which dominates the time for computing the matrix. ◀

We leverage balanced error correcting codes as gadget in our hardness proof for discrete k-Center. For any binary vector $b \in \{0,1\}^t$, we denote by $\bar{b}$ the binary vector obtained by flipping each coordinate in b.

▶ **Theorem 1.2** (Hardness in Discrete Euclidean Space). *For any constant positive integer q and any positive constant $\eta > 0$, there exists a function $d(k,n) = O(k \log n)$ such that there is no factor-$(3/2-\eta)^{1/q}$ FPT approximation algorithm for the discrete k-Center problem in $\mathbb{R}^{d(k,n)}$ under the ℓ_q metric unless W[1]= FPT. Moreover, for the ℓ_2 metric this hardness holds even for some dimension $O(\log n)$, that is, independently of k.*

Proof. We show a reduction from Multi-Colored Independent Set, which is known to be $W[1]$-hard [17]. The input is a k-partite graph $G = (V, E)$ with k-partition $V_1, \ldots, V_k$. The question is if there is an independent set that is *multi-colored*, that is, it has precisely one node from each set V_i, $i \in [k]$. W.l.o.g. we assume that each V_i contains at least one node that is adjacent to all nodes $V \setminus V_i$. Adding such nodes, we can additionally assume that $|V_i| = n/k$ for each $i \in [k]$ where $n = |V|$.

Fix some constant $\eta \in (0, 1/2)$. Using Theorem 3.1, we construct a set $B \subseteq \{0,1\}^t$ of n nearly equidistant code words of dimension $t = \mathcal{O}(\log n/\eta^{2+o(1)})$. We map each node $u \in V$ uniquely to some non-zero code word $b(u) \in B$. We construct a k-Center instance in $\mathbb{R}^{k \cdot t}$ as follows. We subdivide the coordinates of each point in $\mathbb{R}^{k \cdot t}$ into k *blocks* each containing t consecutive coordinates. In our set P of data points, we introduce for each node $v_i \in V_i$, $i \in [k]$, the point $p(v_i) \in P$ in which the ith block equals $b(v_i)$ and all other coordinates are zero. For each edge $(v_i, v_j) \in E$, $v_i \in V_i$, $v_j \in V_j$ for distinct $i, j \in [k]$ we create a point $p(v_i, v_j) \in P$ in which the ith block equals $\overline{b(v_i)}$, the jth block equals $\overline{b(v_j)}$, and all other coordinates are zero. No further points are added to P. We set the number of centers to be k completing the construction of the k-Center instance.

Let $i \in [k]$ and $v_i, v_i' \in V_i$ be distinct vertices. We have that $||p(v_i) - p(v_i')||_q^q \leq ||b(v_i) - b(v_i')||_1 \leq (1/2 + \eta)t$ by Theorem 3.1. Let $v_j \in V_j$, $j \in [k]$ such that $(v_i, v_j) \in E$. By Theorem 3.1, we have that

$$\begin{aligned} ||p(v_i') - p(v_i, v_j)||_q^q &\leq ||b(v_i') - \overline{b(v_i)}||_1 + ||\overline{b(v_j)}||_1 \\ &\leq (t - ||b(v_i') - b(v_i)||_1) + (t - (1/2 - \eta)t) \\ &\leq (t - (1/2 - \eta)t) + (1/2 + \eta)t \\ &\leq (1 + 2\eta)t\,. \end{aligned}$$

Hence if there is a multi-colored independent set I for G then $X = \{\, p(u) \mid u \in I \,\}$ is a k-element set such that $\delta(p, X)^q \leq (1 + 2\eta)t$ for any $p \in P$ under the ℓ_q metric, which gives an upper bound of $(1 + 2\eta)t$ on the k-Center objective in the completeness case.

For analyzing the soundness case, assume that there is no multi-colored independent set for G. Consider an arbitrary k-element set $X \subseteq V$. We say that $x \in X$ *covers* $p \in P$ if $\delta(p, x)^q < (3/2 - 3\eta)t$. We claim that there is some $p \in P$ not covered by any center in X. The correctness of this claim implies that any parameterized approximation algorithm with approximation ratio strictly better than $((3/2 - 3\eta)/(1 + 2\eta))^{1/q}$ implies that $W[1] = \mathsf{FPT}$ and thus the theorem.

In order to prove this claim, we assume for the sake of contradiction, that all $p \in P$ are covered by some center in X. First, we argue that w.l.o.g. X contains no point of the form $p(v_i, v_j)$ where $(v_i, v_j) \in E$. In fact, for any $g \notin \{i, j\}$, we have that

$$\begin{aligned} ||p(v_g') - p(v_i, v_j)||_q^q &\geq ||b(v_g')||_1 + ||\overline{b(v_i)}||_1 + ||\overline{b(v_j)}||_1 \\ &\geq (1/2 - \eta)t + 2(t - (1/2 + \eta)t) \\ &= (3/2 - 3\eta)t\,. \end{aligned} \tag{4}$$

Hence $p(v_i, v_j)$ can cover $p(v_g')$ only if $g = i$ or $g = j$. Similarly, $p(v_i, v_j)$ can cover $p(v_g', v_h')$ only if $i = g$ and $j = h$. But then these points would be covered by $p(v_i)$ as well and hence we could replace $p(v_i, v_j)$ with $p(v_i)$. We therefore assume that X contains only points of the form $p(v_i)$.

We claim that X is multi-colored. Otherwise, there would be some V_i that contains no point from X. By our initial assumption, V_i contains some point v_i that is adjacent to all points $V \setminus V_i$. Assuming $k \geq 3$ there exists at least one V_j, $j \neq i$ that contains at most one node from X. If V_j intersects X then let $v_j \in V_j \cap X$, and otherwise let v_j be an arbitrary node in V_j. By our assumption $(v_i, v_j) \in E$. If $v_j \in X$ then

$$\begin{aligned} ||p(v_j, v_i) - p(v_j)||_q^q &\geq ||\overline{b(v_j)} - b(v_j)||_1 + ||\overline{b(v_i)}||_1 \\ &\geq t + (t - (1/2 + \eta)t) \\ &= (3/2 - \eta)t \end{aligned} \tag{5}$$

as the jth block of $p(v_j)$ equals $b(v_j)$ and the ith block of $p(v_j, v_i)$ equals $\overline{b(v_j)}$. If $v_j \notin X$ then for any it$v_h \in X$ we have $h \notin \{i, j\}$. Thus $||p(v_i, v_j) - p(v_h)||_q^q \geq (3/2 - 3\eta)t$, which follows as in (4). Hence $p(v_i, v_j)$ would not be covered showing that X is multi-colored. Since X is multi-colored it can not be an independent set. Hence there exists some edge (v_i, v_j) such that $v_i, v_j \in X$ but then $||p(v_i) - p(v_i, v_j)||_q^q \geq (3/2 - \eta)t$, $||p(v_j) - p(v_i, v_j)||_q^q \geq (3/2 - \eta)t$, and $||p(v_h) - p(v_i, v_j)||_q^q \geq (3/2 - 3\eta)t$ for any $v_h \in X$, $h \notin \{i, j\}$, which follows as in (5) and (4), respectively. Hence $\delta(p(v_i, v_j), X) \geq (3/2 - 3\eta)t$, implies that $p(v_i, v_j)$ is not covered.

We complete the proof by noting that the dimension of the instance can be reduced to $O(\log n)$ for Euclidean metrics by using the Johnson-Lindenstrauss transform with sufficiently small (constant) error parameter. ◀

4 EPAS for Metrics of Sub-Logarithmic Doubling Dimension

In this section, we show an EPAS for Robust (k, z)-Clustering in metrics of sub-logarithmic doubling dimension. This result complements the hardness result of Section 3 (Theorem 1.2). Towards our goal, we prove the following result.

▶ **Theorem 1.3** (EPAS for Doubling Metric of Sub-Logarithmic Dimension). *There is an algorithm that computes $(1 + \epsilon)$-approximate solution, for every $\epsilon > 0$, for Robust (k, z)-Clustering in the metric of doubling dimension d in time $f(k, d, \epsilon, z)\mathsf{poly}(m, n)$, where $f(k, d, \epsilon, z) = \left(\left(\frac{2^z}{\epsilon}\right)^d k \log k\right)^{\mathcal{O}(k)}$.*

Note that the above algorithm runs in FPT time for $d = o(\log n)$. We also remark that the above result can be extended to the continuous $\mathbb{R}^d$. Throughout this section, we assume that the weight aspect ratio $\frac{\max_{p \in P} w(p)}{\min_{p' \in P} w(p')}$ and the distance aspect ratio $\frac{\max_{p,p' \in P} \delta(p,p')}{\min_{p \neq p' \in P} \delta(p,p')}$ are bounded by $\mathsf{poly}(n)$, some polynomial in n. For $p \in P$ and any number $r \geq 0$, denote by $\mathsf{ball}(p, r)$ to be the closed ball centered at p of radius r. We prove the theorem in two steps: first, in Section 4.1 we show an algorithm to obtain a coreset for the problem, and then, in Section 4.2 we show how to use this coreset to get the algorithm of Theorem 1.3.

4.1 Coreset for Robust (k, z)-Clustering

The key idea for constructing coresets for Robust (k, z)-Clustering crucially relies on the following alternate but equivalent definition of the problem. In this definition, we are given $\mathcal{I} = (F, P \subset \mathcal{M}, \mathcal{W})$, where either $F = \mathcal{M}$ or $F \subseteq \mathcal{M}$, where $\mathcal{M}$ is doubling metric of dimension d, defined by the metric function δ. A *group* is a weight vector $\mathbf{w} \in \mathcal{W}$ such that $\mathbf{w} : P \to \mathbb{R}_{\geq 0}$. Given $X \subseteq F$, the distance vector $\boldsymbol{\delta}_P(X)$ is defined as $\boldsymbol{\delta}_P(X)[p] = \delta(p, X)^z$, for each $p \in P$. The cost of X for a group $\mathbf{w} \in \mathcal{W}$ is defined as $c(\mathbf{w}, X) = \mathbf{w} \cdot \boldsymbol{\delta}_P(X)$. For a Robust (k, z)-Clustering instance $\mathcal{I} = (F, P, \mathcal{W})$, the cost of X is defined as $\mathsf{cost}(\mathcal{I}, X) = \max_{\mathbf{w} \in \mathcal{W}} \mathsf{cost}(\mathbf{w}, X)$. The cost of the instance $\mathcal{I} = (F, P, \mathcal{W})$ is

$$\mathsf{OPT}(\mathcal{I}) = \min_{X \subseteq F, |X|=k} \max_{\mathbf{w} \in \mathcal{W}} \mathsf{cost}(\mathbf{w}, X)$$

Whenever the instance $\mathcal{I}$ is clear from context, we will just write OPT. Notice that, in the original Robust (k,z)-Clustering, a group is given by $S \subseteq P$, and this can be captured by weight vector $\mathbf{w}[p] = 0$ for $p \notin S$ and $w(p)$ otherwise. We prove the following coreset exists for Robust (k,z)-Clustering.

▶ **Theorem 4.1** (Coreset for Robust (k,z)-Clustering) $(\star)$**.** Given an instance $\mathcal{I} = (F, P, \mathcal{W})$ of Robust (k,z)-Clustering in doubling metric of dimension d and $0 < \epsilon \leq 1$, there is an algorithm that, in time $\left(\frac{2^z}{\epsilon}\right)^{\mathcal{O}(d)} \mathsf{poly}(n,m)$, computes another instance $\mathcal{I}' = (F, P', \mathcal{W}')$ of Robust (k,z)-Clustering with $P' \subseteq P : |P'| = \left(\frac{2^z}{\epsilon}\right)^{\mathcal{O}(d)} kz \log n$ such that for any $X \subseteq F$ with $|X| = k$,

$$(1-\epsilon)\mathsf{cost}(\mathcal{I}, X) \leq \mathsf{cost}(\mathcal{I}', X) \leq (1+\epsilon)\mathsf{cost}(\mathcal{I}, X).$$

We remark that the above theorem yields a coreset of clients, and not of groups, and hence, the total size of coreset is comparable to the original instance. However, we will show later that such coreset is sufficient to get a parameterized approximation scheme with parameters k and d. We would also like to point out that the exponential dependency on d on the point set size of the coreset is inevitable since Robust (k,z)-Clustering captures k-Center, for which such a lower bound is known [9, 7]. To see that our notion of coreset for Robust (k,z)-Clustering coincides with the regular notion of coreset for k-Center, note that in this setting each group contains a single distinct point.

In the next section, we describe the algorithm of Theorem 4.1. Due to space constraints, we defer the analysis of our algorithm to the full version [1].

The Algorithm

Our algorithm is inspired by the grid construction approach of [24] that yields coresets for k-Median and k-Means. Given an instance $\mathcal{I} = (F, P, \mathcal{W})$ of Robust (k,z)-Clustering, the first step is to start with an (α, β)-bicriteria solution $B = \{b_i\}_{i \in [\beta k]}$ that opens at most βk facilities with the guarantee that $\mathsf{cost}(\mathcal{I}, B) \leq \alpha \cdot \mathsf{OPT}$, for some constants $\alpha, \beta \geq 1$. Let $R = \sqrt[z]{\frac{\mathsf{cost}(\mathcal{I},B)}{\alpha\tau}}$, where $\tau := \max_{\mathbf{w} \in \mathcal{W}} ||\mathbf{w}||_1$. Let $\Delta = \frac{\max_{p \in P, \mathbf{w} \in \mathcal{W}} \mathbf{w}[p]}{\min_{p \in P, \mathbf{w} \in \mathcal{W}} \mathbf{w}[p]}$ be the weight aspect ratio of $\mathcal{I}$. Then, for each $b_i \in B$, consider the balls $\mathcal{B}_i^j := \mathsf{ball}(b_i, 2^j R)$, for $j \in \{0, \cdots, \lceil 2\log(\alpha n \Delta)\rceil\}$. Note that, for $\mathbf{w} \in \mathcal{W}$ and $p \in P$ with $\mathbf{w}[p] > 0$, it holds that $\delta(p, B) \leq R\sqrt[z]{\alpha n \tau}$, since $\delta(p,B) \leq \sqrt[z]{\frac{\mathsf{cost}(\mathcal{I},B)}{\mathbf{w}[p]}} \leq \sqrt[z]{\frac{\alpha\tau}{\mathbf{w}[p]}} R \leq R\sqrt[z]{\alpha n \Delta}$. Hence, we have that every point $p \in P$ is contained in some ball $\mathcal{B}_i^j$. For $b_i \in B$, let $\mathcal{Q}_i^j = \mathcal{B}_i^j - \mathcal{B}_i^{j-1}$, for $j = \{1, \cdots, \lceil 2\log(\alpha\Delta)\rceil\}$, be the ring between $\mathcal{B}_i^j$ and $\mathcal{B}_i^{j-1}$, with $\mathcal{Q}_i^0 = \mathcal{B}_i^0$. Decompose every ball $\mathcal{B}_i^j$ into smaller balls each of radius $\frac{\epsilon}{40\alpha} R 2^j$ using the fact that the metric is a doubling metric. These balls can intersect, so we assign every point $p \in P$ to exactly one ball (for example, by associating p to the smallest ball containing p, breaking ties arbitrarily). For every ball $\mathcal{B}_i^j$ and every smaller ball t of $\mathcal{B}_i^j$ with $|t \cap \mathcal{Q}_i^j| \neq \emptyset$, pick an arbitrary point $p' \in t \cap \mathcal{Q}_i^j$ as the *representative* of (the points in) $t \cap \mathcal{Q}_i^j$, and add p' to the coreset P' with group weight vectors as follows. Corresponding to every group vector $\mathbf{w} \in \mathcal{W}$, create a new group vector $\mathbf{w}' \in \mathcal{W}'$. Then,$\mathbf{w}'[p'] := \sum_{p \in t \cap Q_i^j} \mathbf{w}(p)$. Intuitively, $\mathbf{w}'[p']$ captures the total weight of points of $\mathbf{w}$ in $t \cap \mathcal{Q}_i^j$. This concludes the coreset construction. For detailed pseudocode of the algorithm, please refer to the full version of the paper [1].

The high-level idea above is to decompose each ball $\mathcal{B}_i^j$ into smaller balls and pick a distinct point as the representative of points in the non-empty decomposed ball. Additionally, such representative p' participates in the group $\mathbf{w}'$ with weight which is sum of the weights of points in $\mathbf{w}$ that are represented by p'. However, we want to decompose the ball $\mathcal{B}_i^j$ into smaller balls in a way that the total number of balls remains the same, irrespective of the radius of the ball. This is necessary as for higher values of j, this number would depend on n, if we are not careful. While this does not seem to help much, as the radius of the decomposed balls is much larger for higher values j, it actually does the trick: since the points in these balls are far from b_i, and hence their connection cost to b_i is also large. This allows us to represent the radii of larger balls in terms of the connection cost of its points to B, thus bounding the error in terms of the cost of B, which in turn is bounded by $\alpha\mathsf{OPT}$, which gives us the desired guarantee.

4.2 EPAS for Robust (k, z)-Clustering

In this section, we show how to use the coreset obtained from Theorem 4.1 to get a $(1+\epsilon)$-approximate solution to the Robust (k, z)-Clustering problem and provide an EPAS with respect to k and d, when $|P|$ is small. By scaling the distances in the instance of Robust (k, z)-Clustering, we assume that the distances are between 1 and Δ', for some number Δ'. Our algorithm (see Algorithm 1) uses the leader guessing idea of [12]. In the leader guessing approach, we guess the leader of every partition of a fixed optimal solution, where the leader of a partition is a closest point (client) in P to the corresponding optimal center. However, each point can participate in multiple groups, resulting in the total number of points being dependent on the number of groups, $|\mathcal{W}|$. In the full version [1], we show that guessing the leaders from P without considering the groups in $\mathcal{W}$ is, in fact, sufficient. Further, to get a $(1+\epsilon)$-approximate solution, we use a standard ball decomposition lemma (for e.g., see the full version [1]).

▶ **Theorem 4.2.** *For any $0 < \epsilon \leq 1$, Algorithm 1, on input $\mathcal{I} = (F, P, \mathcal{W})$, computes $X \subseteq F : |X| \leq k$ such that $\mathsf{cost}(\mathcal{I}, X) \leq (1+\epsilon)\mathsf{OPT}(\mathcal{I})$ in time $\left((\frac{z}{\epsilon})^d \log n\right)^{\mathcal{O}(k)} |P|^k \mathsf{poly}(n, m)$.*

We conclude this section by proving the main claim of this section (Theorem 1.3) by using the results of Theorem 4.1 and Theorem 4.2 as follows.

Proof of Theorem 1.3. Given an instance $\mathcal{I} = (F, P, \mathcal{W})$ of Robust (k, z)-Clustering, and the accuracy parameter $\epsilon > 0$, we invoke Theorem 4.1 on $\mathcal{I}$ with parameter $\epsilon/10$ to obtain an coreset $(P', \mathcal{W}')$ such that $P' \subseteq P : |P'| = \left(\frac{2^z}{\epsilon}\right)^{\mathcal{O}(d)} kz \log n$. Let $\mathcal{I}' = (F, P', \mathcal{W}')$ be the resulting instance. Then, we invoke Theorem 4.2 on $\mathcal{I}'$ with parameter $\epsilon/10$ to obtain $X \subseteq F : |X| \leq k$ such that $\mathsf{cost}(\mathcal{I}', X) \leq (1+\epsilon/10)\mathsf{OPT}(\mathcal{I}')$.

First, we analyze the overall running time. With $|P'| = \left(\frac{2^z}{\epsilon}\right)^{\mathcal{O}(d)} kz \log n$, Theorem 4.2 runs in time $\left(\left(\frac{2^z}{\epsilon}\right)^d kz \log n\right)^{\mathcal{O}(k)} \mathsf{poly}(n, m)$, leading to $\left(\left(\frac{2^z}{\epsilon}\right)^d zk \log k\right)^{\mathcal{O}(k)} \mathsf{poly}(n, m)$ as the overall running time as desired. For correctness, consider

$$\begin{aligned}
\mathsf{cost}(\mathcal{I}, X) &\leq (1+\epsilon/10)\mathsf{cost}(\mathcal{I}', X) && \text{by the coreset property} \\
&\leq (1+\epsilon/10)^2\mathsf{OPT}(\mathcal{I}') && \text{by Algorithm 1} \\
&\leq (1+\epsilon/10)^3\mathsf{OPT}(\mathcal{I}) && \text{by the coreset property} \\
&\leq (1+\epsilon)\mathsf{OPT}(\mathcal{I}). &&
\end{aligned}$$

◀

Algorithm 1 $(1+\epsilon)$-approximation algorithm for Robust (k,z)-Clustering.

Data: Instance $\mathcal{I} = (F, P, \mathcal{W})$ of Robust (k,z)-Clustering
Result: $(1+\epsilon)$-approximate solution $X \subseteq F$

Let $X \leftarrow \emptyset$;

Finer-Grained Reductions in Fine-Grained Hardness of Approximation

Elie Abboud

Abstract

We investigate the relation between δ and ϵ required for obtaining a $(1+\delta)$-approximation in time $N^{2-\epsilon}$ for closest pair problems under various distance metrics, and for other related problems in fine-grained complexity.

Specifically, our main result shows that if it is impossible to (exactly) solve the (bichromatic) inner product (IP) problem for vectors of dimension $c \log N$ in time $N^{2-\epsilon}$, then there is no $(1+\delta)$-approximation algorithm for (bichromatic) Euclidean Closest Pair running in time $N^{2-2\epsilon}$, where $\delta \approx (\epsilon/c)^2$ (where $\approx$ hides polylog factors). This improves on the prior result due to Chen and Williams (SODA 2019) which gave a smaller polynomial dependence of δ on ϵ, on the order of $\delta \approx (\epsilon/c)^6$. Our result implies in turn that no $(1+\delta)$-approximation algorithm exists for Euclidean closest pair for $\delta \approx \epsilon^4$, unless an algorithmic improvement for IP is obtained. This in turn is very close to the approximation guarantee of $\delta \approx \epsilon^3$ for Euclidean closest pair, given by the best known algorithm of Almam, Chan, and Williams (FOCS 2016). By known reductions, a similar result follows for a host of other related problems in fine-grained hardness of approximation.

Our reduction combines the hardness of approximation framework of Chen and Williams, together with an MA communication protocol for IP over a small alphabet, that is inspired by the MA protocol of Chen (Theory of Computing, 2020).

1 Introduction

Traditionally, the approach to determine whether a computational problem is tractable was to find out whether it has a polynomial-time algorithm. Finding such an algorithm implies that the problem is in P, and thus it was considered efficiently computable. Otherwise, if one is interested in proving that the problem is intractable, we usually lack the tools to

prove lower bounds; instead one relies on hardness assumptions which allow us to prove conditional lower-bounds. In the classical theory of NP-hardness, the hardness assumption is that P $\neq$ NP, which is known to imply that no polynomial-time algorithm exists for many central computational problems.

In fine-grained complexity, one is interested in pinning down the *precise* complexity of *tractable* computational problems. In particular, a central objective in fine-grained complexity is to determine the exact exponent in the time complexity of problems already known to be in P. More concretely, given a problem with input length n known to be solvable in $t(n)$-time, is it possible to solve the problem in time $t(n)^{1-\epsilon}$ for some $\epsilon > 0$? This is motivated by the fact that despite rigorous study of many central computational problems in P, we have failed to improve on the running time of their best-known algorithms (see for example the survey [21] for a list of such problems). This motivates the question of whether there is an inherent difficulty in the problem that prevents us from finding faster algorithms.

Once more, we typically lack the tools to prove lower bounds, and we thus instead rely on hardness assumptions to obtain conditional lower bounds for problems in P. One popular such conjecture has been the *Strong Exponential Time Hypothesis* (SETH), which postulates that for any $\epsilon > 0$, there exists an integer $k = k(\epsilon)$ so that it is impossible to solve k-SAT on n variables in time $2^{(1-\epsilon)n}$ [13].

Another popular conjecture is the *Orthogonal Vector Conjecture* (OVC) which in the low-dimensional regime posits that for any $\epsilon > 0$, there exists a $c_{\text{ov}} = c_{\text{ov}}(\epsilon)$ such that given a pair of sets $A, B \subseteq \{0,1\}^d$ of cardinality N each and of dimension $d = c_{\text{ov}} \cdot \log N$, it is impossible to determine whether there exists a pair $(a, b) \in A \times B$ satisfying that $\langle a, b\rangle = 0$ in $N^{2-\epsilon}$ time [11]. It is known that SETH implies OVC [20], and so OVC is at least as plausible as SETH. In terms of algorithms, it is known how to solve the OV problem in time $N^{2-\epsilon}$ with $c = \exp(1/\epsilon)$ [3, 7], which implies that $c_{\text{ov}} \geq \exp(1/\epsilon)$.

A related assumption is the *inner product* (IP) *assumption* which postulates that for any $\epsilon > 0$, there exists a $c_{\text{ip}} = c_{\text{ip}}(\epsilon)$ such that given a pair of sets $A, B \subseteq \{0,1\}^d$ of cardinality N each and of dimension $d = c_{\text{ip}} \cdot \log N$, and an integer $\sigma \in \{0, 1, \ldots, d\}$, it is impossible to determine whether there exists a pair $(a, b) \in A \times B$ satisfying that $\langle a, b\rangle = \sigma$ in $N^{2-\epsilon}$ time. Once more, since the OV problem is a special case of the IP problem, the IP assumption is at least as plausible as OVC[1]. Indeed, the best known algorithms for the IP problem are only able to solve this problem in time $N^{2-\epsilon}$ with $c \approx 1/\epsilon$ [5], and this only imposes that $c_{\text{ip}} \gtrapprox 1/\epsilon$.[2]

In recent years, there has been a flurry of work showing fine-grained lower bounds for many central computational problems in P, based on the above assumptions. A main challenge in showing such fine-grained lower bounds based on these assumptions is that one must carefully design the reductions so that they run fast enough as not to supersede the lower bound assumptions.

One fundamental problem for which such fine-grained reductions were shown is the *Closest Pair* (CP) *problem*. In this problem, given a distance metric $\text{dist} : \{0,1\}^d \times \{0,1\}^d \to \mathbb{R}^+$, and given a pair of sets $A, B \subseteq \{0,1\}^d$, the goal is to find a pair $(a, b) \in A \times B$ which minimizes $\text{dist}(a, b)$. This problem was studied for various metrics such as Hamming, ℓ_p, and edit distance, and it has many applications, for example in computational geometry, geographic information systems [12], clustering [24, 6], and matching problems [23], to name a few. For concreteness, in what follows we restrict our attention only to the Euclidean ℓ_2 metric, though many of the results we mention hold also for other metrics.

---

[1] The IP assumption is at least as plausible as OVC if we allow an arbitrary dependence of c_{ip} on epsilon.
[2] We use $\approx$, $\gtrsim$, $\lesssim$ to hide polylog factors.

One can naïvely solve the (Euclidean) Closest Pair problem in $O(N^2 d)$ time. On the other hand, algorithms have been developed which solve the problem in time $\approx N^{O(c)}$ in the low-dimensional regime $d = c \log N$, [16, 14]; Thus, a truly sub-quadratic algorithm is only known for smaller values of c. On the other hand, in [5] it was shown that assuming OVC, for any $\epsilon > 0$ there exists $c = c(\epsilon)$ so that no algorithm can solve this problem in time $N^{2-\epsilon}$.

1.1 Fine-grained hardness of approximation

Given the above state of affairs, it is natural to ask whether relaxing the requirements and settling for an approximate "close-enough" answer can help in designing faster fine-grained algorithms. For example, it is known that for the (Euclidean) CP problem, one can obtain a $(1+\delta)$-approximation with running time $N^{2-\epsilon}$ for $\delta \approx \epsilon^3$ (for any dimension $d \leq N^{1-\epsilon}$) [4], which is much faster than the best-known exact algorithm.

In terms of impossibility results, known fine-grained reductions can typically be adapted to the approximate setting, based on appropriate *gap assumptions*, such as Gap-SETH.[3] In the theory of NP-hardness, it is often possible to base hardness of gap-problems on hardness of exact problems using PCPs. However, a major barrier in applying this approach in the fine-grained setting (for example for the purpose of reducing SETH to Gap-SETH) is the large (super-constant) blow-up in the length of existing PCPs, which translates into a large (super-constant) blow-up in the number of variables n in the reduction.

Nevertheless, in a recent breakthrough, Abboud, Rubinstein, and Williams [2] have shown how to utilize PCP machinery (specifically, the sumcheck protocol) for showing fine-grained hardness of approximation results based on *non-gap assumptions*. Since then, many works have utilized this framework for showing fine-grained hardness of approximation results for many central problems in P, based on non-gap assumptions such as SETH or OVC (see the recent surveys [18, 10] for a description of this line of work).

In particular, for the CP problem, Rubinstein [17] has shown that assuming OVC, for any $\epsilon > 0$ there exists $\delta = \delta(\epsilon)$ such that there is no $(1+\delta)$-approximation algorithm for (Euclidean) CP running in time $N^{2-\epsilon}$. This rules out truly sub-quadratic approximation algorithms, running, say, in time $f(\delta) \cdot N^{1.99}$. However, the obtained dependence of δ on ϵ is far from optimal, specifically $\delta = \exp(-c_{\text{ov}}/\epsilon)$, where $c_{\text{ov}} = c_{\text{ov}}(\epsilon) \geq \exp(1/\epsilon)$ is the constant guaranteed by the OVC conjecture.

In a follow-up work, Chen and Williams [9] have shown an improved hardness of approximation result for CP in which δ only depends polynomially on ϵ. Specifically, they showed that if the IP assumption holds, then for any $\epsilon > 0$ there is no $(1+\delta)$-approximation algorithm for (Euclidean) CP running in time $N^{2-\epsilon}$, where $\delta = \text{poly}(\epsilon/c_{\text{ip}})$ and $c_{\text{ip}} = c_{\text{ip}}(\epsilon) \gtrapprox 1/\epsilon$ is the constant guaranteed by the IP assumption. However, the obtained dependence of δ on ϵ was still quite small, on the order of $\delta \approx (\epsilon/c_{\text{ip}})^6 \lessapprox \epsilon^{12}$. This is still quite far from the dependence obtained by the best known approximation algorithm for CP which gives an $(1+\delta)$-approximation in time $N^{2-\epsilon}$ for $\delta \approx \epsilon^3$.

In this work, we investigate the question of whether the dependence of δ on ϵ can even be further improved, potentially to match the best known approximation algorithm.

[3] The Gap-SETH assumption asserts that for any $\epsilon > 0$, there are k and $\delta > 0$, so that no $2^{(1-\epsilon)n}$-time algorithm can, given a k-CNF on n variables, distinguish between the case that it is satisfiable, and the case that any assignment satisfies at most an $(1-\delta)$-fraction of its clauses.

1.2 Our results

Recall that by the discussion above, the best known approximation algorithm for (Euclidean) CP gives an $(1+\delta)$-approximation in time $N^{2-\epsilon}$ for $\delta \approx \epsilon^3$, while the best-known hardness of approximation result shows that if the IP assumption holds, then no $(1+\delta)$-approximation algorithm running in time $N^{2-\epsilon}$ exists for $\delta \approx (\epsilon/c_{\text{ip}})^6 \lessapprox \epsilon^{12}$, where $c_{\text{ip}} = c_{\text{ip}}(\epsilon) \gtrapprox 1/\epsilon$ is the constant guaranteed by the IP assumption. Thus there remains a large polynomial gap between the upper and lower bounds, and our main result narrows this gap.

▶ **Theorem 1.1.** *Suppose that the IP assumption holds, i.e., for any $\epsilon' > 0$, there exists a $c_{\text{ip}} = c_{\text{ip}}(\epsilon')$ such that given a pair of sets $A, B \subseteq \{0,1\}^d$ of cardinality N each and of dimension $d = c_{ip}(\epsilon') \cdot logN$, and an integer $\sigma \in \{0, 1, \ldots, d\}$, it is impossible to find a pair $(a, b) \in A \times B$ satisfying that $\langle a, b\rangle = \sigma$ in $N^{2-\epsilon'}$ time.*

Then for any $\epsilon > 0$, there is $\delta = \tilde{\Theta}((\frac{\epsilon}{c_{\text{ip}}(\epsilon/2)})^2)$, so that any algorithm running in time $N^{2-\epsilon}$ cannot $(1+\delta)$-approximate Euclidean CP.

Recall that it is known how to solve the IP problem in time $N^{2-\epsilon}$ for dimension $d = c \log N$ with $c \approx 1/\epsilon$, and so it must hold that $c_{\text{ip}} \gtrapprox 1/\epsilon$. If we assume that $c_{\text{ip}} \approx 1/\epsilon$, then the above theorem gives a dependence of δ on ϵ of the form $\delta \approx \epsilon^4$, which is very close to the dependence of $\delta \approx \epsilon^3$ given by the best known algorithm. Moreover, improving the dependence in the above theorem to $\delta \approx \frac{\epsilon}{c_{\text{ip}}}$ would imply an algorithmic improvement on the IP problem. We leave the question of determining the exact dependence of δ on ϵ as an interesting open problem for future research.

By known reductions, the above theorem gives a similar improvement for a host of other problems in fine-grained hardness of approximation such as closest pair with respect to other metrics such as Hamming, ℓ_p-norm for any constant $p > 0$, and edit distance, Furthest Pair and approximate nearest neighbor in these metrics, and additive approximations to Max-IP and Min-IP, see Appendix A for more details.

Finally, we remark that the above theorem also holds under OVC (or SETH), but is less meaningful, since as discussed above, for the OV problem we have that $c_{\text{ov}} \geq \exp(1/\epsilon)$.

1.3 Proof overview

Next we give an overview of our proof method, and how it improves on prior work. To this end, we first describe the general framework presented in [2] for obtaining fine-grained hardness of approximation results based on MA communication protocols. Then we discuss the work of Rubinstein [17] who relied on this framework to give the first fine-grained hardness of approximation result for CP, albeit with an exponential dependence of δ on ϵ, and the work of Chen and Williams [9] who improved this dependence to polynomial. Following this, we turn to discuss our proof method that obtains a tighter polynomial relation.

Fine-grained hardness of approximation via MA communication [2]. In a Merlin-Arthur (MA) communication protocol for a function $f : \{0,1\}^d \times \{0,1\}^d \to \{0,1\}$, two players Alice and Bob wish to compute $f(a, b)$, where Alice is given as input only $a \in \{0,1\}^d$, and Bob is given as input only $b \in \{0,1\}^d$. To this end, Alice and Bob engage in a randomized (public coin) communication protocol, where their goal is to use as little communication as possible. To aid them with this task, there is also a (potentially malicious) prover Merlin who sees Alice's and Bob's inputs, and before any communication begins Merlin sends Alice a short message m, which can be thought of as a "proof" or "advice". The requirement is that if

$f(a,b)=1$, then there must exist some message m from Merlin on which Alice accepts with probability 1. Otherwise, if $f(a,b)=0$, then for any possible message $\tilde{m}$ from Merlin, Alice accepts with probability at most $\frac{1}{2}$ on $\tilde{m}$.[4]

In [2], it was shown that an efficient MA communication protocol for *set disjointness*[5] implies a fine-grained reduction from OV to an approximate version of Max-IP in which given two sets $A,B\subseteq\{0,1\}^d$ of cardinality N each, the goal is to output a number sufficiently close to $M:=\max_{a\in A,b\in B}\langle a,b\rangle$.

To see how a reduction as above can be constructed, suppose that there exists an MA communication protocol for set disjointness with Merlin's message length L, communication complexity cc between Alice and Bob, and randomness complexity R. Suppose furthermore that we are given an instance $A,B\subseteq\{0,1\}^d$ of OV, where $|A|=|B|=N$. Then for each possible Merlin's message $m\in\{0,1\}^L$, we construct an instance $A_m,B_m\subseteq\{0,1\}^{2^{\mathrm{cc}+R}}$ of Max-IP, where $|A_m|=|B_m|=N$.

Fix $m\in\{0,1\}^L$. Then the set A_m is obtained from A by mapping each element $a\in A$ to a binary vector a_m that contains an entry for each possible transcript $\Gamma\in\{0,1\}^{\mathrm{cc}}$ and randomness string $r\in\{0,1\}^R$ (so a_m has length $2^{\mathrm{cc}+R}$), and whose (Γ,r)-entry equals 1 if and only if Γ is consistent with r and a, and Alice accepts on input a, randomness string r, and transcript Γ. The set B_m is obtained analogously from B.

Then the main observation is that for some $m\in\{0,1\}^L$, we have that the (Γ,r)-entry of both a_m and b_m equals 1 if and only if Alice accepts on Merlin's message m, inputs a and b, and randomness string r. Consequently, if there exists $(a,b)\in A\times B$ so that $\langle a,b\rangle=0$ (i.e., $f(a,b)=1$), then there exists a Merlin's message m on which Alice accepts with probability 1 on inputs a and b, and consequently we have that the corresponding vectors $(a_m,b_m)\in A_m\times B_m$ satisfy that $\langle a_m,b_m\rangle=2^R$. On the other hand, if $\langle a,b\rangle\neq 0$ (i.e., $f(a,b)=0$) for any $(a,b)\in A\times B$, then for any Merlin's message $\tilde{m}$, and on any inputs $(a,b)\in A\times B$, Alice accepts with probability at most $\frac{1}{2}$, and so $\langle a_{\tilde{m}},b_{\tilde{m}}\rangle\leq\frac{1}{2}\cdot 2^R$ for any pair $(a_{\tilde{m}},b_{\tilde{m}})\in A_{\tilde{m}}\times B_{\tilde{m}}$. This gives the desired gap, showing that OV reduces to 2^L instances of approximate Max-IP.

To obtain a fine-grained reduction, one must make sure that cc, R and L are not too large, so that the total construction time of the reduction is at most N^ϵ. To achieve this, one can use the MA communication protocol of Aaronson and Wigderson [1] for set disjointness in which all these quantities are upper bounded by $\approx\sqrt{d}$.

For $d=c\log N$, this gives that 2^{cc}, 2^R, and 2^L are all upper bounded by $2^{\tilde{O}(\sqrt{\log N})}\ll N^\epsilon$, and so the reduction can be constructed in time N^ϵ. Next we describe the MA communication protocol of [1], as hardness of approximation results for CP (including ours) crucially rely on its properties.

MA communication protocol for set disjointness [1]. The MA communication protocol for set disjointness of Aaronson and Wigderson [1] relies on the influential sumcheck protocol of [15], and it proceeds as follows.

Let $a\in\{0,1\}^d$ be Alice's input. Slightly abusing notation, we view a as a $\sqrt{d}\times\sqrt{d}$ binary matrix in the natural way, and we let $\hat{a}$ denote the $p\times\sqrt{d}$ matrix obtained by encoding each column of a with a systematic Reed-Solomon code $\mathrm{RS}_{\sqrt{d},p}:\mathbb{F}_p^{\sqrt{d}}\to\mathbb{F}_p^p$ of degree $\sqrt{d}$ over a prime field of size $p\approx 4\sqrt{d}$.[6] Let $\hat{b}$ be defined analogously.

[4] The accept probability can be increased by executing the communication phase between Alice and Bob independently for multiple times and accepting if and only if all invocations accept.

[5] Recall that *set disjointness* is the function $\mathrm{disj}:\{0,1\}^d\times\{0,1\}^d\to\{0,1\}$ which satisfies that $\mathrm{disj}(a,b)=1$ if and only if the supports of a and b are disjoint, i.e., if $\langle a,b\rangle=0$.

[6] The systematic Reed-Solomon code $\mathrm{RS}_{d,p}:\mathbb{F}_p^d\to\mathbb{F}_p^p$ of degree d over a prime field of size $p>d$ is a linear

In the protocol, Merlin first computes the pointwise product $\hat{a} \star \hat{b} \in \mathbb{F}_p^{p \times \sqrt{d}}$, and then sends Alice the sum $m \in \mathbb{F}_p^p$ of the columns of $\hat{a} \star \hat{b}$ (where arithemtic is performed mod p). Alice first checks that m is a codeword of $\mathrm{RS}_{2\sqrt{d},p}$, and that the first $\sqrt{d}$ entries of m are all zero, otherwise she rejects and aborts. Then Alice and Bob jointly sample a random index $i \in [p]$, Bob sends Alice the i'th row of $\hat{b}$, Alice computes its inner product with the i'th row of $\hat{a}$, and accepts if and only if this product equals $m(i)$ (where once more, arithmetic is performed mod p).

To see that the protocol is complete, note first that if a and b are disjoint, then $a \star b$ is the all-zero matrix. Consequently, by the systematic property of the Reed-Solomon encoding, the first $\sqrt{d}$ rows of $\hat{a} \star \hat{b}$ are also identically zero, which implies in turn that the first $\sqrt{d}$ entries of m are identically zero. Furthermore, since the product of two polynomials of degree at most $\sqrt{d}$ is a polynomial of degree at most $2\sqrt{d}$, it follows that m is a codeword of $\mathrm{RS}_{2\sqrt{d},p}$. Thus, both Alice's checks will clearly pass. It can also be verified that by construction, the inner product of the i'th rows of $\hat{a}$ and $\hat{b}$ equals $m(i)$, and so Alice accepts with probability 1.

To show soundness, suppose that a and b intersect, and let $\tilde{m}$ denote Merlin's message. We may assume that $\tilde{m}$ is a codeword of $\mathrm{RS}_{2\sqrt{d},p}$, and that the first $\sqrt{d}$ entries of $\tilde{m}$ are all zero, since otherwise Alice clearly rejects. But on the other hand, since a and b intersect, then $a \star b$ has a 1-entry, say in the j-th row, and since $p > \sqrt{d}$, the sum of entries in the j'th row of $a \star b$ is non-zero mod p, which implies in turn that $m(j) \neq 0$. Thus, we conclude that $\tilde{m}$ and m are distinct codewords of $\mathrm{RS}_{2\sqrt{d},p}$ – a code of distance at least $\frac{p}{2}$ – and so they must differ by at least $\frac{1}{2}$ of their entries. But this implies in turn that with probability at least $\frac{1}{2}$ over the choice of i, it holds that $\tilde{m}(i) \neq m(i)$, in which case the inner product of the i'th row of $\hat{a}$ and $\hat{b}$ will be different than $\tilde{m}(i)$, which will cause Alice to reject.

Finally, it can also be verified that in this protocol, cc, R, and L are all upper bounded by $\approx \sqrt{d}$.

Hardness of approximation for CP with exponential dependence [17]. In [17], Rubinstein utilized the above framework to show fine-grained hardness of approximation for CP. The starting point of [17] is a simple linear-time reduction from δ-additive approximation for Max-IP[7] to an $(1+\Theta(\delta))$-approximation for (Euclidean) CP. Thus, to show that no algorithm can find an $(1+\Theta(\delta))$-approximation for (Euclidean) CP in time $N^{2-\epsilon}$, it suffices to show that no algorithm can find a δ-additive approximation for Max-IP in time $N^{2-\epsilon}$.

The [2] framework discussed above generates instances of Max-IP of dimension $2^{\mathrm{cc}+R}$ and additive gap of $\frac{1}{2} \cdot 2^R$, which gives $\delta := \Theta(2^{-\mathrm{cc}})$. However, the MA protocol of [1] described above only gives cc $\approx \sqrt{d}$ which is super-constant for a super-constant dimension d, and consequently only yields a *sub-constant* δ.

To deal with this, [17] first utilized the fact (previously utilized also in [2]) that the [1] protocol described above works equally well on skewed matrices of dimensions $\frac{d}{T} \times T$, in which case we have that $L = \frac{d}{T} \cdot \log p$ and $\mathrm{cc} = T \cdot \log p$. Thus, assuming $d = c \log N$, to achieve $2^L \leq N^\epsilon$, one can set $T = \frac{c}{\epsilon} \cdot \log p$, which gives in turn $\mathrm{cc} = \frac{c}{\epsilon} \cdot \log^2 p$.

---

map, defined as follows. To encode a message $m = (m(0), \ldots, m(d-1)) \in \mathbb{F}_p^d$, one finds the (unique) degree $d-1$ polynomial $P_m(X) \in \mathbb{F}_p[X]$ which satisfies that $P_m(i) = m(i)$ for any $i = 0, \ldots, d-1$, and lets $\mathrm{RS}_{d,p}(m) = (P_m(0), \ldots, P_m(p-1))$. The code is called *systematic* since the message is a prefix of its encodings. The code has distance at least $p-d+1$ since any pair of distinct degree $d-1$ polynomials can agree on at most $d-1$ points.

[7] In a *δ-additive approximation* for Max-IP, given $A, B \subseteq \{0,1\}^d$ of cardinality N each, the goal is to output a number in $[M - \delta \cdot d, M]$, where $M := \max_{a \in A, b \in B} \langle a, b \rangle$.

However, this is still not quite enough since the MA protocol of [1] requires setting $p > \sqrt{d}$ because of the use of Reed-Solomon codes that are only defined over a large alphabet, and consequently the communication complexity is still super-constant. However, the main observation in [1] is that the protocol can actually be executed using any error-correcting code with a *multiplication property*[8]. Relying on this observation, Rubinstein replaced the Reed-Solomon codes in the protocol of [1] with algebraic-geometric (AG) codes that satisfy the multiplication property over a constant-size alphabet. This reduced the communication complexity to $\approx c/\epsilon$, yielding in turn an approximation factor of $\delta = 2^{-\tilde{\Theta}(c/\epsilon)}$.

Polynomial dependence [9]. While [17] gave the first non-trivial hardness of approximation result for CP, a downside of this result was that the approximation factor δ depended exponentially on the running time parameter ϵ. In the follow-up work [9], Chen and Williams showed how to reduce this dependence to just polynomial.

The main observation of Chen and Williams was that instead of thinking of the output of the MA protocol of [17] as being just accept or reject, one can view the output as being *short vectors* $a', b' \in \mathbb{F}_p^T$ (namely, the i'th row of $\hat{a}, \hat{b}$, respectively), and $\sigma' \in \{0, 1, \ldots, T \cdot p^2\}$ (namely, the i'th entry of Merlin's message m), where a' only depends on Alice's input a and the randomness string, b' only depends on Bob's input b and the randomness string, and σ' only depends on Merlin's message and the randomness string. The requirement then is that if $\langle a, b\rangle = 0$ for some $(a, b) \in A \times B$, then for some Merlin's message m, $\langle a', b'\rangle = \sigma'$ with probability 1, while if $\langle a, b\rangle \neq 0$ for any $(a, b) \in A \times B$, then for any Merlin's message $\tilde{m}$, then $\langle a', b'\rangle \neq \sigma'$ with probability at least $\frac{1}{2}$.

Chen and Williams then suggested to create an instance A_m, B_m for any Merlin's message m, where the set A_m is obtained from A by simply mapping each element $a \in A$ to a vector $a_m \in \mathbb{F}_p^{T \times 2^R}$ that is the concatenation of all possible output vectors a' for all possible randomness strings, and analogously for B_m. The advantage is that now the dimension of the vectors in A_m and B_m is much shorter than in [17]. However, a disadvantage is that now the alphabet is not binary anymore, and an even more serious problem is that the soundness guarantee is only that $\langle a', b'\rangle \neq \sigma'$, so the reduction does not seem to produce any gap.

To deal with these issues, Chen and Williams use an *encoding lemma* which gives mappings g, h and a value Γ, where g, h, and Γ only depend on p and T, so that $g(a', \sigma')$ and $h(b', \sigma')$ are binary vectors of length $\text{poly}(p, T)$ satisfying that if $\langle a', b'\rangle = \sigma'$ then $\langle g(a', \sigma'), h(b', \sigma')\rangle = \Gamma$, while if $\langle a', b'\rangle \neq \sigma'$ then $\langle g(a', \sigma'), h(b', \sigma')\rangle < \Gamma$ (see Lemma 4.2 for a formal statement). This produces the desired additive gap, on the order of $\Omega(2^R)$. Since the encoding lemma increases the dimension of the vectors only by a factor of $\text{poly}(p, T)$, this yields an approximation factor of $\delta = \frac{1}{\text{poly}(p,T)} = \text{poly}(\frac{\epsilon}{c})$.

We note that a delicate issue that should be dealt with in the reduction is that the encoding lemma works over the integers, while the protocol works over finite fields, and in particular, over non-prime fields, as AG codes are only known to exist over non-prime fields. Additionally, Chen and Williams show that the reduction works equally well when using the IP problem instead of OV as its starting point, and using an MA communication protocol for IP similar to that of [1]. This can potentially allow for a smaller value of c as it is only known how to solve (exact) IP in time $N^{2-\epsilon}$ up to a dimension of $c \log N$ for $c \approx 1/\epsilon$.

[8] Informally, we say that a linear code $C : \mathbb{F}^k \to \mathbb{F}^n$ has a *multiplication property* if the set $\text{span}\{C(m) \star C(m') \mid m, m' \in \mathbb{F}^k\}$ has sufficiently large distance.

This work – tighter polynomial dependence. While [9] obtained a polynomial dependence of δ on ϵ, the dependence was quite small, on the order of $\delta \approx (\frac{\epsilon}{c})^6$, and in the current work we show how to improve the dependence to $\delta \approx (\frac{\epsilon}{c})^2$.

To this end, we first observe that one reason for the small polynomial dependence obtained in [9] was the large polynomial dependence of the dimension of the resulting vectors in the encoding lemma on the alphabet size p. While in the protocol of [17] the field size p can be made constant using AG codes, the field still needs to be of characteristic at least T, since otherwise the sum of entries in a non-zero row of $a \star b$ may sum to zero over $\mathbb{F}_p$, and consequently the soundness analysis will not go through.

To reduce the alphabet size, we first design a new MA protocol in which the alphabet size is only *polylogarithmic* in T (see Theorem 3.1). This protocol is inspired by the MA protocol of [8] for IP which achieved communication complexity $O(\sqrt{d \log d \log \log d})$, improving on the communication complexity of $O(\sqrt{d} \log d)$ of [1]. In a nutshell, Chen's idea was to execute the original MA protocol of [1] multiple times over different small prime fields, hoping that if $\langle a, b \rangle \neq 0$, then $\langle a, b \rangle$ is also non-zero modulo many of the primes, and so the protocol will be executed correctly. Chen showed that this is indeed possible to achieve using $O(\log d)$ distinct primes of cardinality at most polylog(d) each.

We observe that for skewed matrices of dimensions $\frac{d}{T} \times T$, it in fact suffices to execute the protocol with $O(\log T)$ distinct primes of cardinality at most polylog(T) each. While this choice does not necessarily guarantee the property above that if $\langle a, b \rangle \neq 0$, then $\langle a, b \rangle$ is also non-zero modulo many of the primes, this turns out to still suffice for a correct execution of the protocol.

We then further observe that such a protocol can be used in the framework of [9] to obtain an improved hardness of approximation result for Max-IP. Once more, a delicate issue is how to use the encoding lemma in the presence of many different non-prime fields.

To the best of our knowledge, this is the first use of the techniques underlying the improved MA protocol of [8] for showing a fine-grained hardness of approximation result.[9]

Paper organization. The rest of the paper is organized as follows. We begin in Section 2 below with the required notation and terminology with respect to fine-grained complexity problems and error-correcting codes. Then in Section 3 we present our improved MA protocol over a small alphabet, while in Section 4 we show how to use this protocol for obtaining an improved reduction from IP to approximate Max-IP. Finally, in Appendix A we show implications of our latter result to showing hardness of approximation results for closest pair, as well as other related problems in fine-grained complexity.

2 Preliminaries

We start by setting some general notation. For a positive integer d, we let $[d] := \{1, 2, \ldots, d\}$. For convenience, we often view a vector $a \in \Sigma^d$ as a function $a : [d] \to \Sigma$, and we let $a(i)$ denote the i-th entry of a. For a pair of vectors $a, b \in \mathbb{N}^d$, we let $\langle a, b \rangle := \sum_{i=1}^{d} a(i) \cdot b(i)$ denote their inner product, and we let $a \star b \in \mathbb{N}^d$ denote their pointwise product, given by $(a \star b)(i) = a(i) \cdot b(i)$ for $i \in [d]$. For $a, b \in \Sigma^d$, we let $\Delta(a, b) := |\{i \in [d] \mid a(i) \neq b(i)\}|$ denote their Hamming distance. For an $n \times k$ matrix A and $i \in [n]$ ($j \in [k]$, respectively), we let $\text{row}_i(A)$ ($\text{col}_j(A)$, respectively) denote the i-th row (j-th column, respectively) of A.

[9] The paper [8] contains various hardness of approximation results for Max-IP, as well as the improved MA protocol for IP. To the best of our knowledge, the improved MA protocol presented in this paper was not used in this paper or in any subsequent work as the basis for hardness of approximation results.

2.1 Problems in fine-grained complexity

Below we list the main fine-grained problems that we will be concerned with in this paper.

▶ **Definition 2.1** (Inner Product (IP)). *In the inner product* $\mathrm{IP}_{N,d}$ *problem, given two sets* $A, B \subseteq \{0,1\}^d$ *of cardinality* N *each, and an integer* $\sigma \in \{0,1,\ldots,d\}$*, the goal is to determine whether there exists a pair* $(a,b) \in A \times B$ *satisfying that* $\langle a,b\rangle = \sigma$*.*

▶ **Definition 2.2** (Maximum Inner Product (Max-IP)). *In the maximum inner product* Max-$\mathrm{IP}_{N,d}$ *problem, given two sets* $A, B \subseteq \{0,1\}^d$ *of cardinality* N *each, the goal is to compute* $M := \max_{a\in A, b\in B} \langle a,b\rangle$*.*

For the approximate version of Max-IP, defined next, we will consider the less standard *additive* approximation version that will be useful for obtaining hardness of approximation for the closest pair problem.

▶ **Definition 2.3** (Approximate Maximum Inner Product (Apx-Max-IP)). *Let* $\delta > 0$ *be a parameter. In the (additive) approximate maximum inner product* δ-Apx-Max-$\mathrm{IP}_{N,d}$ *problem, given two sets* $A, B \subseteq \{0,1\}^d$ *of cardinality* N *each, the goal is to output a number in* $[M - \delta \cdot d, M]$*, where* $M := \max_{a\in A, b\in B} \langle a,b\rangle$*.*

▶ **Definition 2.4** (Closest Pair (CP)). *Let* $\mathrm{dist} : \{0,1\}^d \times \{0,1\}^d \to \mathbb{R}^+$ *be a distance function. In the closest pair* $\mathrm{CP}_{N,d,\mathrm{dist}}$ *problem, given two sets* $A, B \subseteq \{0,1\}^d$ *of cardinality* N *each, the goal is to compute* $M := \min_{a\in A, b\in B} \mathrm{dist}(a,b)$*.*

▶ **Definition 2.5** (Approximate Closest Pair (Apx-CP)). *Let* $\mathrm{dist} : \{0,1\}^d \times \{0,1\}^d \to \mathbb{R}^+$ *be a distance function, and let* $\delta > 0$ *be a parameter. In the approximate closest pair* δ-Apx-$\mathrm{CP}_{N,d,\mathrm{dist}}$ *problem, given two sets* $A, B \subseteq \{0,1\}^d$ *of cardinality* N *each, the goal is to output a number in* $[M, (1+\delta)M]$*, where* $M := \min_{a\in A, b\in B} \mathrm{dist}(a,b)$*.*

2.2 Error-correcting codes

Our reduction will make use of error-correcting codes. In what follows, we first present some general notation and terminology with respect to error-correcting codes, and then describe the kind of codes we shall use for our reduction.

Let Σ be a finite alphabet, and k, n be positive integers (the message length and the codeword length, respectively). An (error-correcting) code is an injective map $C : \Sigma^k \to \Sigma^n$. The elements in the domain of C are called messages, and the elements in the image of C are called codewords. We say that C is systematic if the message is a prefix of the corresponding codeword, i.e., for every $x \in \Sigma^k$ there exists $z \in \Sigma^{n-k}$ such that $C(x) = (x,z)$. The rate of a code $C : \Sigma^k \to \Sigma^n$ is the ratio $\rho := \frac{k}{n}$. The relative distance $\mathrm{dist}(C)$ of C is the maximum $\delta > 0$ such that for every pair of distinct messages $x, y \in \Sigma^k$ it holds that $\Delta(C(x), C(y)) \geq \delta$.

If $\Sigma = \mathbb{F}$ for some finite field $\mathbb{F}$, and C is a linear map between the vector spaces $\mathbb{F}^k$ and $\mathbb{F}^n$ then we say that C is linear. The generating matrix of a linear code $C : \mathbb{F}^k \to \mathbb{F}^n$ is a matrix $G \in \mathbb{F}^{n\times k}$ such that $C(x) = G \cdot x$ for any $x \in \mathbb{F}^k$. We say that a linear code C is explicit if G can be generated in time $\mathrm{poly}(n)$.

For our reduction, we shall require linear codes over a small (constant-size, independent of the codeword length) alphabet, satisfying the *multiplication property*, which informally says that all pointwise products of pairs of codewords span a code of large distance. Such codes can be obtained from the AG codes of [19] (see also [17, Theorem 2.4]).

▶ **Theorem 2.6** ([19]; [17], Theorem 2.4). *There exists a constant integer* p_0 *so that for any prime* $p \geq p_0$*, there exist two explicit code families* $\mathcal{C} = \{C_k\}_{k\in\mathbb{N}}$ *and* $\mathcal{C}_\star = \{(C_\star)_k\}_{k\in\mathbb{N}}$ *so that the following hold for any* $k \in \mathbb{N}$*:*

- $C_k, (C_\star)_k$ *are systematic linear codes over* $\mathbb{F}_{p^2}$ *of relative distance at least* 0.1 *and rate at least* 0.1.
- C_k *has message length* k.
- *For any* $x, y \in (\mathbb{F}_{p^2})^k$, $C_k(x) \star C_k(y)$ *is a codeword of* $(C_\star)_k$.

3 MA protocol for IP over a small alphabet

In this section, we will provide an MA protocol for IP over a small alphabet. The protocol will be later used in Section 4 below to show a reduction from IP to Apx-Max-IP.

▶ **Theorem 3.1** (MA Protocol for IP over a small alphabet). *For any sufficiently large integer* T*, there is an integer* $q = O(\log^2 T)$*, so that for any integer* d *which is a multiple of* T *there is an* MA *Protocol which satisfies the following:*

1. *Alice is given as input a vector* $a \in \{0,1\}^d$ *and an integer* $\sigma \in \{0, 1, \ldots, d\}$*, Bob is given as input a vector* $b \in \{0,1\}^d$*, and Merlin is given as input* a*,* b*, and* σ*.*
2. *Merlin sends Alice a message* m *of (bit) length* $L = O(\frac{d}{T} \cdot \log^2 T)$*. Alice reads Merlin's message, and based on this message and* σ*, decides whether to reject and abort, or continue.*
3. *Alice and Bob sample a joint random string* r *of (bit) length* $R = \log(\frac{d}{T}) + \log\log T + O(1)$*.*
4. *Alice outputs a string* $a' \in \{0, 1, \ldots, q\}^T$ *and an integer* $\sigma' \in \{0, 1, \ldots, T \cdot q^2\}$*, where* a' *only depends on Alice's input* a *and the randomness string* r*, and* σ' *only depends on Merlin's message* m *and* r*, and Bob outputs a string* $b' \in \{0, 1, \ldots, q\}^T$*, which only depends on Bob's input* b *and* r*, so that the following hold:*
   - *(Completeness) If* $\langle a, b\rangle = \sigma$*, then on Merlin's message* m*, Alice and Bob output* a', b'*, and* σ' *so that* $\langle a', b'\rangle = \sigma'$ *with probability* 1*.*
   - *(Soundness) If* $\langle a, b\rangle \neq \sigma$*, then for any Merlin's message* $\tilde{m}$*, Alice and Bob output* a', b'*, and* σ' *so that* $\langle a', b'\rangle = \sigma'$ *with probability at most* 0.98*.*

   Moreover, the running time of both Alice and Bob is $\mathrm{poly}(d)$*.*

The main difference between the above protocol and that of [9], is that instead of working over a field of characteristic $\Theta(T)$, we perform the protocol of [9] simultaneously over $O(\log T)$ different fields of size $O(\log^2 T)$ each.

To this end, we start by fixing some notation. Let t be an integer such that $t^t = T$. By Lemma 2.4 in [8], for a large enough integer t, there exist $10t$ distinct primes $p_1 < p_2 < \cdots < p_{10t}$, where the value of each prime is bounded in the interval $[t, t^2]$. Let $q := t^2$, and note that $t = O(\log T)$ and $q = O(\log^2 T)$. For each $\ell \in [10t]$, let $C^{(\ell)}, C_\star^{(\ell)}$ be the systematic linear codes over $\mathbb{F}_{p_\ell^2}$ guaranteed by Theorem 2.6, where $C^{(\ell)}$ has message length $\frac{d}{T}$ and codeword length $n_\ell := O(\frac{d}{T})$. Finally, recall that the elements of $\mathbb{F}_{p_\ell^2}$ can be viewed as degree 1 polynomials over $\mathbb{F}_{p_\ell}$, where multiplication is performed modulo an irreducible polynomial Q_ℓ of degree 2 over $\mathbb{F}_{p_\ell}$.

Let $a \in \{0,1\}^d$ be Alice's input. Slightly abusing notation, we view a as a $\frac{d}{T} \times T$ binary matrix in the natural way. For $\ell \in [10t]$, let $a^{(\ell)}$ denote the $n_\ell \times T$ matrix over $\mathbb{F}_{p_\ell^2}$ obtained by encoding each column of a with the code $C^{(\ell)}$. View each entry of $a^{(\ell)}$ as a degree 1 polynomial over $\mathbb{F}_{p_\ell}$, and let $a^{(\ell,0)}, a^{(\ell,1)}$ denote the $n_\ell \times T$ matrices over $\mathbb{F}_{p_\ell}$, obtained from $a^{(\ell)}$ by keeping in each entry only the free coefficient and linear coefficient, respectively. Let $b, b^{(\ell)}, b^{(\ell,0)}, b^{(\ell,1)}$ be defined analogously for $\ell \in [10t]$. In what follows, all arithmetic operations are performed over the reals, unless otherwise stated.

The protocol. The protocol proceeds as follows:

1. **a.** Merlin sends

$$m_0 := \sum_{j=1}^{T} \mathrm{col}_j(a) \star \mathrm{col}_j(b) \in \{0,1,\ldots,T\}^{d/T}.$$

   b. For $\ell = 1,\ldots,10t$ and $\alpha,\beta \in \{0,1\}$, Merlin sends

$$m_{\ell,\alpha,\beta} := \sum_{j=1}^{T} \mathrm{col}_j(a^{(\ell,\alpha)}) \star \mathrm{col}_j(b^{(\ell,\beta)}) \in \{0,1,\ldots,T\cdot q^2\}^{n_\ell}.$$

2. **a.** Alice checks that $\sum_{i=1}^{d/T} m_0(i) = \sigma$.
   b. Alice checks that $m_{\ell,0,0}(i) = m_0(i)$ and $m_{\ell,0,1}(i) = m_{\ell,1,0}(i) = m_{\ell,1,1}(i) = 0$ for $\ell = 1,\ldots,10t$ and $i = 1,\ldots,\frac{d}{T}$.
   c. For $\ell = 1,\ldots,10t$, let $m_\ell \in (\mathbb{F}_{p_\ell^2})^{n_\ell}$ given by

$$m_\ell = m_{\ell,0,0} + (m_{\ell,0,1} + m_{\ell,1,0}) \cdot X + m_{\ell,1,1} \cdot X^2 \pmod{Q_\ell}.$$

   Alice checks that m_ℓ is a codeword of $C_\star^{(\ell)}$ for $\ell = 1,\ldots,10t$.
   If any of the checks is unsatisfied, then Alice rejects and aborts.
3. Alice and Bob jointly sample $\ell_* \in [10t]$, $i_* \in [n_{\ell_*}]$, and $\alpha_*,\beta_* \in \{0,1\}$.
4. Alice outputs $a' := \mathrm{row}_{i_*}(a^{(\ell_*,\alpha_*)}) \in \{0,1,\ldots,q\}^T$ and $\sigma' := m_{\ell_*,\alpha_*,\beta_*}(i_*) \in \{0,1,\ldots,T\cdot q^2\}$, and Bob outputs $b' := \mathrm{row}_{i_*}(b^{(\ell_*,\beta_*)}) \in \{0,1,\ldots,q\}^T$.

It can be verified that the protocol has the required structure, and that the running times of Alice and Bob are as claimed. Next we show completeness and soundness.

Completeness. Suppose that $\langle a,b\rangle = \sigma$, we shall show that in this case Alice and Bob output a', b', and σ' so that $\langle a',b'\rangle = \sigma'$ with probability 1.

We first show that in this case all of Alice's checks on Step 2 always pass.

To this end, first note that by assumption that $\langle a,b\rangle = \sigma$, we have that

$$\sum_{i=1}^{d/T} m_0(i) = \sum_{i=1}^{d/T}\sum_{j=1}^{T} a(i,j)\cdot b(i,j) = \langle a,b\rangle = \sigma, \tag{1}$$

so Alice's check on Step 2a will pass.

We now show that Alice's check on Step 2b passes. Fix $\ell \in [10t]$, and recall that $a^{(\ell)}$ is obtained by encoding each column of the matrix $a \in \{0,1\}^{\frac{d}{T}\times T}$ with a systematic linear code. Consequently, a is the restriction of $a^{(\ell)}$ to the first $\frac{d}{T}$ rows, and similarly for b. This implies in turn that for any $i \in [\frac{d}{T}]$, we have that

$$m_{\ell,0,0}(i) = \left\langle \mathrm{row}_i(a^{(\ell,0)}), \mathrm{row}_i(b^{(\ell,0)}) \right\rangle = \langle \mathrm{row}_i(a), \mathrm{row}_i(b)\rangle = m_0(i), \tag{2}$$

and

$$m_{\ell,0,1}(i) = m_{\ell,1,0}(i) = m_{\ell,1,1}(i) = 0. \tag{3}$$

So Alice's check on Step 2b will pass as well.

Finally, we show that Alice's check on Step 2c passes. Fix $\ell \in [10t]$, and note that

$$\begin{aligned} m_\ell &= m_{\ell,0,0} + (m_{\ell,0,1} + m_{\ell,1,0}) \cdot X + m_{\ell,1,1} \cdot X^2 \pmod{Q_\ell} \\ &= \sum_{j=1}^{T} \Big[\mathrm{col}_j(a^{(\ell,0)}) \star \mathrm{col}_j(b^{(\ell,0)}) \\ &\quad + \Big(col_j(a^{(\ell,0)}) \star \mathrm{col}_j(b^{(\ell,1)}) + col_j(a^{(\ell,1)}) \star \mathrm{col}_j(b^{(\ell,0)}) \Big) \cdot X \\ &\quad + col_j(a^{(\ell,1)}) \star \mathrm{col}_j(b^{(\ell,1)}) \cdot X^2 \Big] \pmod{Q_\ell} \\ &= \sum_{j=1}^{T} (\mathrm{col}_j(a^{(\ell,0)}) + \mathrm{col}_j(a^{(\ell,1)}) \cdot X) \star (\mathrm{col}_j(b^{(\ell,0)}) + \mathrm{col}_j(b^{(\ell,1)}) \cdot X) \pmod{Q_\ell} \\ &= \sum_{j=1}^{T} \mathrm{col}_j(a^{(\ell)}) \star \mathrm{col}_j(b^{(\ell)}) \pmod{Q_\ell}. \end{aligned} \tag{4}$$

Now, since each column of $a^{(\ell)}$ and $b^{(\ell)}$ is a codeword of $C^{(\ell)}$, we have that $\mathrm{col}_j(a^{(\ell)}) \star \mathrm{col}_j(b^{(\ell)}) \pmod{Q_\ell}$ is a codeword of $C_\star^{(\ell)}$ for any $j \in [T]$. By linearity of $C_\star^{(\ell)}$, this implies in turn that m_ℓ is a codeword of $C_\star^{(\ell)}$, and so Alice's check on Step 2c will also pass.

Thus, we conclude that all of Alice's checks on Step 2 pass. Furthermore, we clearly have that

$$\langle a', b' \rangle = \left\langle \mathrm{row}_{i_*}(a^{(\ell_*,\alpha_*)}), \mathrm{row}_{i_*}(b^{(\ell_*,\beta_*)}) \right\rangle = m_{\ell_*,\alpha_*,\beta_*}(i) = \sigma'.$$

We conclude that in the case that $\langle a, b \rangle = \sigma$, we have that $\langle a', b' \rangle = \sigma'$ with probability 1, as required.

Soundness. Assume that $\langle a, b \rangle \neq \sigma$, and let $\tilde{m}_0$ and $\tilde{m}_{\ell,\alpha,\beta}$ for $\ell = 1, \ldots, 10t$ and $\alpha, \beta \in \{0,1\}$ be Merlin's messages on Step 1. We shall show that in this case Alice and Bob output a', b', and σ' so that $\langle a', b' \rangle = \sigma'$ with probability at most 0.98.

To this end, first note that we may assume that $\sum_{i=1}^{d/T} \tilde{m}_0(i) = \sigma$, since otherwise Alice clearly rejects on Step 2a. On the other hand, by (1) and by assumption that $\langle a, b \rangle \neq \sigma$, we have that $\sum_{i=1}^{d/T} m_0(i) = \langle a, b \rangle \neq \sigma$. Consequently, there exists $i \in [\frac{d}{T}]$ so that $m_0(i) \neq \tilde{m}_0(i)$.

Moreover, since $m_0(i), \tilde{m}_0(i) \in \{0, 1, \ldots, T\}$, we have that $|m_0(i) - \tilde{m}_0(i)| \leq T$. Recalling that $t^t = T$, and that $p_\ell \geq t$ for any $\ell \in [10t]$, we conclude that at most t of the p_ℓ's can divide $|m_0(i) - \tilde{m}_0(i)|$. Thus, with probability at least 0.9 over the choice of ℓ_*, it holds that $p_{\ell *}$ does not divide $|m_0(i) \neq \tilde{m}_0(i)|$, and so $m_0(i) \neq \tilde{m}_0(i) \pmod{p_{\ell_*}}$. In what follows, assume that this event holds.

Let $\tilde{m}_{\ell_*} \in (\mathbb{F}_{p_{\ell_*}^2})^{n_{\ell *}}$ be given by

$$\tilde{m}_{\ell_*} = \tilde{m}_{\ell_*,0,0} + (\tilde{m}_{\ell_*,0,1} + \tilde{m}_{\ell^*,1,0}) \cdot X + \tilde{m}_{\ell^*,1,1} \cdot X^2 \pmod{Q_{\ell_*}}.$$

Next observe that we may assume that for any $i \in [\frac{d}{T}]$,

$$\tilde{m}_{\ell_*}(i) = \tilde{m}_{\ell_*,0,0}(i) + (\tilde{m}_{\ell_*,0,1}(i) + \tilde{m}_{\ell^*,1,0}(i)) \cdot X + \tilde{m}_{\ell^*,1,1}(i) \cdot X^2 \pmod{Q_{\ell_*}} = \tilde{m}_0(i) \pmod{p_{\ell_*}},$$

since otherwise Alice clearly rejects on Step 2b. On the other hand, by (2) and (3) we have that for any $i \in [\frac{d}{T}]$,

$$m_{\ell_*}(i) = m_{\ell_*,0,0}(i) + (m_{\ell_*,0,1}(i) + m_{\ell^*,1,0}(i)) \cdot X + m_{\ell^*,1,1}(i) \cdot X^2 \pmod{Q_{\ell_*}} = m_0(i) \pmod{p_{\ell_*}}.$$

Consequently, by assumption that $m_0(i) \neq \tilde{m}_0(i) \pmod{p_{\ell_*}}$ for some $i \in [\frac{d}{T}]$, we have that $\tilde{m}_{\ell_*}(i) \neq m_{\ell_*}(i)$.

Finally, note that we may assume that $\tilde{m}_{\ell_*}$ is a codeword of $C_\star^{(\ell_*)}$, since otherwise Alice clearly rejects on Step 2c. Moreover, by (4) we also have that m_{ℓ^*} is a codeword of $C_\star^{(\ell_*)}$. Since $C_\star^{(\ell_*)}$ has relative distance at least 0.1, and by assumption that $\tilde{m}_{\ell_*} \neq m_{\ell_*}$, we have that $\tilde{m}_{\ell^*}$ and m_{ℓ^*} differ on at least a 0.1-fraction of their entries, and so with probability at least 0.1 over the choice of i_* it holds that $\tilde{m}_{\ell_*}(i_*) \neq m_{\ell_*}(i_*)$. In what follows, assume that this event holds as well.

By assumption that $\tilde{m}_{\ell_*}(i_*) \neq m_{\ell_*}(i_*)$, there exist $\alpha, \beta \in \{0,1\}$ so that $\tilde{m}_{\ell_*,\alpha,\beta}(i_*) \neq m_{\ell_*,\alpha,\beta}(i_*)$. Consequently, with probability at least 0.25 over the choice of α_*, β_*, it holds that $\tilde{m}_{\ell_*,\alpha_*,\beta_*}(i_*) \neq m_{\ell_*,\alpha_*,\beta_*}(i_*)$. But assuming that this latter event holds, we have that

$$\langle a', b' \rangle = \left\langle \mathrm{row}_{i_*}(a^{(\ell_*,\alpha_*)}), \mathrm{row}_{i_*}(b^{(\ell_*,\beta_*)}) \right\rangle = m_{\ell_*,\alpha_*,\beta_*}(i_*) \neq \tilde{m}_{\ell_*,\alpha_*,\beta_*}(i_*) = \sigma'.$$

We conclude that in the case that $\langle a, b \rangle \neq \sigma$, for any Merlin's message, we have that Alice either rejects or $\langle a', b' \rangle \neq \sigma'$ with probability at least $0.9 \cdot 0.1 \cdot 0.25 \geq 0.02$ over the choice of ℓ_*, i_*, α_*, and β_*. So $\langle a', b' \rangle = \sigma'$ with probability at most 0.98 over the choice of ℓ_*, i_*, α_*, and β_*.

4 From IP to Apx-Max-IP

In this section we use Theorem 3.1 from the previous section which gives an MA protocol for IP over a small alphabet to give a fine-grained reduction from IP to Apx-Max-IP with a tighter polynomial dependence of the approximation parameter δ on the running time parameter ϵ.

▶ **Lemma 4.1** (From IP to Apx-Max-IP). *The following holds for any $\epsilon > 0$ and integer $c \geq 1$. Suppose that $\mathrm{IP}_{N,d}$ cannot be solved in time $N^{2-\epsilon}$ for $d = c \log N$. Then there exists d' such that δ-Apx-Max-$\mathrm{IP}_{N,d'}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta = \tilde{\Theta}((\frac{\epsilon}{c})^2)$.*

To prove the above lemma, we shall use the following encoding lemma from [9], which can be used to turn the (non-binary) vectors a', b' from the protocol given in Theorem 3.1 into (binary) vectors, whose inner product exhibits a gap.

▶ **Lemma 4.2** (Encoding Lemma, [9]). *For any non-negative integers T and q, there exist mappings $g, h : \{0,1,\ldots,q\}^T \times \{0,1,\ldots,T \cdot q^2\} \to \{0,1\}^{O(T^2 q^4)}$ and an integer $\Gamma \leq O(T^2 \cdot q^4)$, so that for any $a, b \in \{0,1,\ldots,q\}^T$ and $\sigma \in \{0,1,\ldots,T \cdot q^2\}$:*

- *If $\langle a, b \rangle = \sigma \Rightarrow \langle g(a,\sigma), h(b,\sigma) \rangle = \Gamma$.*
- *If $\langle a, b \rangle \neq \sigma \Rightarrow \langle g(a,\sigma), h(b,\sigma) \rangle < \Gamma$.*

Moreover, g, h can be computed in time $\mathrm{poly}(T, q)$.

The reduction. We shall show a reduction from IP to many instances of Apx-Max-IP, based on our MA protocol for IP over a small alphabet given in Theorem 3.1, and the above encoding Lemma 4.2.

Let $A, B \subseteq \{0,1\}^d$ and $\sigma \in \{0,1,\ldots,d\}$ be an instance of $\mathrm{IP}_{N,d}$. Let T be a sufficiently large integer, to be determined later on, and let π be the protocol guaranteed by Theorem 3.1 for T, $q = O(\log^2 T)$, and d (without loss of generality assume that T divides d). Let g, h, and Γ be the mappings and the integer guaranteed for T and q by Lemma 4.2.

Let $\mathrm{Rej} \subseteq \{0,1\}^L$ denote the subset of Merlin's messages $m \in \{0,1\}^L$ in π on which Alice rejects on input σ. For $b \in B$ and $r \in \{0,1\}^R$, let b'_r denote the string output by Bob in the protocol π on input b and randomness string r. Similarly, for $a \in A$ and $r \in \{0,1\}^R$, let a'_r denote the string output by Alice in the protocol π on input a and randomness string r. For $m \in \{0,1\}^L \setminus \mathrm{Rej}$ and $r \in \{0,1\}^R$, let $\sigma'_{m,r}$ denote the integer output by Alice on Merlin's message m and randomness string r.

For any $m \in \{0,1\}^L \setminus \text{Rej}$, we create an instance A_m, B_m of Apx-Max-IP$_{N,d'}$, given by

$$A_m := \{(g(a'_r, \sigma'_{m,r}))_{r\in\{0,1\}^R} \mid a \in A\},$$

and

$$B_m := \{(h(b'_r, \sigma'_{m,r}))_{r\in\{0,1\}^R} \mid b \in B\},$$

where

$$d' = O(2^R \cdot T^2 \cdot q^4).$$

Let $\delta := \frac{0.01\cdot 2^R}{d'}$. Given an algorithm $\mathcal{A}$ for δ-Apx-Max-IP$_{N,d'}$, we show an algorithm $\mathcal{A}'$ for IP$_{N,d}$: Given an instance A, B, σ for IP$_{N,d}$, the algorithm $\mathcal{A}'$ generates all instances A_m, B_m for $m \in \{0,1\}^L \setminus \text{Rej}$, and runs $\mathcal{A}$ on any of these instances. If on any of the instances the algorithm $\mathcal{A}$ outputs a value at least $2^R \cdot (\Gamma - 0.01)$ then the algorithm $\mathcal{A}'$ accepts, otherwise it rejects.

Correctness. Correctness relies on the following claim.

▷ Claim.

- If there exists $(a, b) \in A \times B$ so that $\langle a, b\rangle = \sigma$, then there exist $m \in \{0,1\}^L \setminus \text{Rej}$ and $(a'', b'') \in A_m \times B_m$ so that $\langle a'', b''\rangle = 2^R \cdot \Gamma$.
- If $\langle a, b\rangle \neq \sigma$ for any $(a, b) \in A \times B$, then $\langle a'', b''\rangle \leq 2^R \cdot (\Gamma - 0.02)$ for any $m \in \{0,1\}^L \setminus \text{Rej}$ and $(a'', b'') \in A_m \times B_m$.

Proof. For the first item, suppose that there exists $(a, b) \in A \times B$ so that $\langle a, b\rangle = \sigma$. Let m be Merlin's message in the protocol π on inputs a, b, and σ, and let $(a'', b'') \in A_m \times B_m$ be given by $a'' = (g(a'_r, \sigma'_{m,r}))_{r\in\{0,1\}^R}$ and $b'' = (h(b'_r, \sigma'_{m,r}))_{r\in\{0,1\}^R}$. By the completeness property of π, we have that $m \notin \text{Rej}$, and $\langle a'_r, b'_r\rangle = \sigma'_{m,r}$ for any $r \in \{0,1\}^R$. Consequently, by Lemma 4.2, $\left\langle g(a'_r, \sigma'_{m,r}), h(b'_r, \sigma'_{m,r})\right\rangle = \Gamma$ for any $r \in \{0,1\}^R$. But this implies in turn that

$$\langle a'', b''\rangle = \sum_{r\in\{0,1\}^R} \left\langle g(a'_r, \sigma'_{m,r}), h(b'_r, \sigma'_{m,r})\right\rangle = 2^R \cdot \Gamma.$$

For the second item, suppose that $\langle a, b\rangle \neq \sigma$ for any $(a, b) \in A \times B$. Fix $m \in \{0,1\}^L \setminus \text{Rej}$ and $(a'', b'') \in A_m \times B_m$. Then by construction, $a'' = (g(a'_r, \sigma'_{m,r}))_{r\in\{0,1\}^R}$ and $b'' = (h(b'_r, \sigma'_{m,r}))_{r\in\{0,1\}^R}$. By the soundness property of π, for at least a 0.02-fraction of the randomness strings $r \in \{0,1\}^R$, it holds that $\langle a'_r, b'_r\rangle \neq \sigma'_{m,r}$. Consequently, by Lemma 4.2 for at least a 0.02-fraction of the randomness strings $r \in \{0,1\}^R$, it holds that $\left\langle g(a'_r, \sigma'_{m,r}), h(b'_r, \sigma'_{m,r})\right\rangle \leq \Gamma - 1$. But this implies in turn that

$$\langle a'', b''\rangle = \sum_{r\in\{0,1\}^R} \left\langle g(a'_r, \sigma'_{m,r}), h(b'_r, \sigma'_{m,r})\right\rangle \leq 0.98\cdot 2^R\cdot\Gamma + 0.02\cdot 2^R\cdot(\Gamma-1) = 2^R\cdot(\Gamma-0.02).\triangleleft$$

Now, if there exists $(a, b) \in A \times B$ so that $\langle a, b\rangle = \sigma$, then by the above claim there exists $m \in \{0,1\}^L \setminus \text{Rej}$ so that $\max_{a''\in A_m, b''\in B_m} \langle a'', b''\rangle \geq 2^R \cdot \Gamma$. Consequently, the algorithm $\mathcal{A}$ will output a value greater than $2^R \cdot \Gamma - \delta \cdot d' = 2^R \cdot (\Gamma - 0.01)$ on the instance A_m, B_m, and so the algorithm $\mathcal{A}'$ will accept.

If on the other hand, $\langle a, b\rangle \neq \sigma$ for any $(a, b) \in A \times B$, then by the above claim $\max_{a''\in A_m, b''\in B_m} \langle a'', b''\rangle \leq 2^R \cdot (\Gamma - 0.02)$ for any $m \in \{0,1\}^L \setminus \text{Rej}$. Consequently, the algorithm $\mathcal{A}$ will output a value at most $2^R \cdot (\Gamma - 0.02) < 2^R \cdot (\Gamma - 0.01)$ on any of the instances, an so the algorithm $\mathcal{A}'$ will reject.

Running time. Suppose that the algorithm $\mathcal{A}$ for δ-Apx-Max-IP$_{N,d'}$ runs in time $N^{2-2\epsilon}$, we shall show that for an appropriate choice of T, the running time of the algorithm $\mathcal{A}'$ for IP$_{N,d}$ is at most $N^{2-\epsilon}$.

The algorithm $\mathcal{A}'$ enumerates over all possible Merlin's messages $m \in \{0,1\}^L$, and for each such message checks whether Alice rejects m in π, which takes time poly(d), and if she does not reject, it generates the instance A_m, B_m which takes time $N \cdot 2^R \cdot \text{poly}(d) \cdot \text{poly}(T,q) \leq N \cdot \text{poly}(d)$, and runs the algorithm $\mathcal{A}$ on A_m, B_m which takes time $N^{2-2\epsilon}$.

Hence the total running time of the algorithm $\mathcal{A}'$ is at most

$$\begin{aligned} 2^L \cdot (N \cdot \text{poly}(d) + N^{2-2\epsilon}) &\leq 2^{O(\frac{d}{T} \cdot \log^2 T)} \cdot (N \cdot \text{poly}(d) + N^{2-2\epsilon}) \\ &= 2^{O(\frac{c \log N}{T} \cdot \log^2 T)} \cdot (N \cdot \text{poly}(c \log N) + N^{2-2\epsilon}). \\ &\leq 2^{O(\frac{c \log N}{T} \cdot \log^2 T)} \cdot N^{2-2\epsilon}. \end{aligned}$$

Finally, it can be verified that the latter expression is at most $N^{2-\epsilon}$ for choice of $T = \tilde{\Theta}(c/\epsilon)$ which divides d.

Approximation parameter. By choice of $\delta = \frac{0.01 \cdot 2^R}{d'}$, $d' = O(2^R \cdot T^2 \cdot q^4)$, $T = \tilde{\Theta}(c/\epsilon)$, and $q = O(\log^2 T)$, we have that

$$\delta = \Theta\left(\frac{1}{T^2 q^4}\right) = \tilde{\Theta}\left(\left(\frac{\epsilon}{c}\right)^2\right).$$

A Applications

In this section we show a couple of consequences of Lemma 4.1 to obtaining tighter fine-grained hardness of approximation results based on the IP assumption.

Closest pair in Hamming metric. The following reduction from Max-IP to CP in the Hamming metric Δ is implicit in [17].

▶ **Lemma A.1** (From Apx-Max-IP to Apx-CP$_\Delta$, [17]). *Suppose that δ-Apx-Max-IP$_{N,d}$ cannot be solved in time $N^{2-\epsilon}$. Then δ'-Apx-CP$_{N,d',\Delta}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta' = \frac{\delta}{2}$.*

The above lemma and Lemma 4.1 readily imply the following.

▶ **Corollary A.2** (From IP to Apx-CP$_\Delta$). *Suppose that IP$_{N,d}$ cannot be solved in time $N^{2-\epsilon}$ for $d = c \log N$. Then δ-Apx-CP$_{N,d',\Delta}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta = \tilde{\Theta}((\frac{\epsilon}{c})^2)$.*

In contrast, it is known how to obtain an $(1+\delta)$-approximation for CP over the Hamming metric in time $N^{2-\epsilon}$ for $\delta = \tilde{\Theta}(\epsilon^3)$ [4].

Closest pair in ℓ_p metric. The following reduction from CP in the Hamming metric to CP in the ℓ_p metric is also implicit in [17].

▶ **Lemma A.3** (From Apx-CP$_\Delta$ to Apx-CP$_{\ell_p}$, [17]). *Suppose that δ-Apx-CP$_{N,d,\Delta}$ cannot be solved in time $N^{2-\epsilon}$. Then for any $p > 0$, δ'-Apx-CP$_{N,d,\ell_p}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta' = \Theta_p(\delta)$.*

The following corollary is a consequence of the above lemma and Corollary A.2, and implies Theorem 1.1.

▶ **Corollary A.4** (From IP to Apx-CP$_{\ell_p}$). *Suppose that* IP$_{N,d}$ *cannot be solved in time $N^{2-\epsilon}$ for $d = c \log N$. Then for any $p > 0$, δ-Apx-CP$_{N,d',\ell_p}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta = \tilde{\Theta}_p((\frac{\epsilon}{c})^2)$.*

In contrast, it is known how to obtain an $(1+\delta)$-approximation for CP over the ℓ_p metric in time $N^{2-\epsilon}$ for $\delta = \tilde{O}(\epsilon^3)$ and $p \in \{1, 2\}$ [4].

Closest pair in edit distance metric. For $a, b \in \Sigma^d$, we let $ED(a, b)$ denote their edit distance which is the minimum number of character deletion, insertion, and substitution operations needed to transform a into b. The following Lemma is also implicit in [17].

▶ **Lemma A.5** (From Apx-CP$_\Delta$ to Apx-CP$_{ED}$, [17]). *Suppose that δ-Apx-CP$_{N,d,\Delta}$ cannot be solved in time $N^{2-\epsilon}$. Then δ'-Apx-CP$_{N,d',ED}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta' = \Theta(\delta)$.*

The above lemma and Corollary A.2 imply the following corollary.

▶ **Corollary A.6** (From IP to Apx-CP$_{ED}$). *Suppose that* IP$_{N,d}$ *cannot be solved in time $N^{2-\epsilon}$ for $d = c \log N$. Then δ-Apx-CP$_{N,d',ED}$ cannot be solved in time $N^{2-2\epsilon}$ for $\delta' = \tilde{\Theta}((\frac{\epsilon}{c})^2)$.*

To the best of our knowledge, it is not known how to solve $(1+\delta)$-Apx-CP$_{\text{ED}}$ in sub-quadratic time.

▶ Remark (Apx-Min-IP and Furthest-Pair). It is not hard to show (see e.g., [9], Lemma 5.3) that there is a simple linear-time reduction from δ-Apx-Max-IP$_{N,d}$ to δ-Apx-Min-IP$_{N,d}$ (and vice versa), and so the same result as in Lemma 4.1 also holds for δ-Apx-Min-IP$_{N,d}$ (where the goal is to output a number in $[M, M + \delta \cdot d]$, where $M := \min_{a \in A, b \in B} \langle a, b \rangle$).

Using Apx-Min-IP as the starting point for the reductions cited above instead of Apx-Max-IP implies the same results as in Corollaries A.2, A.4, and A.6 for Furthest Pair (where the goal is to output a number in $[(1-\delta)M, M]$, where $M := \max_{a \in A, b \in B} dist(a, b)$).

Data structure setting. Our results extend to the data structure setting.

▶ **Definition A.7** (Approximate Nearest Neighbor (Apx-NN)). *Let* dist : $\{0,1\}^d \times \{0,1\}^d \to \mathbb{R}^+$ *be a distance function, and let $\delta > 0$ be a parameter. In the Approximate Nearest Neighbor δ-Apx-NN$_{N,d,dist}$ problem, given a set $A \subseteq \{0,1\}^d$ of cardinality N, the goal is to pre-process the set, so that given a vector $b \in \{0,1\}^d$ it is possible to quickly output a number in $[M, (1+\delta)M]$, where $M := \min_{a \in A}$* dist(a, b).

It is known that Apx-CP can be reduced to Apx-NN [22] (see also proof of Corollary 1.4 in [2]).

▶ **Lemma A.8** (From Apx-CP$_\Delta$ to Apx-NN, [22]). *Let* dist : $\{0,1\}^d \times \{0,1\}^d \to \mathbb{R}^+$ *be a distance function. Suppose that δ-Apx-CP$_{N,d,dist}$ cannot be solved in $N^{2-\epsilon}$ time. Then for any $r > 0$, δ-Apx-NN$_{N,d,dist}$ cannot be solved with N^r preprocessing time and $N^{1-2r\epsilon}$ time.*

▶ **Corollary A.9** (From IP to Apx-NN). *Suppose that* IP$_{N,d}$ *cannot be solved in time $N^{2-\epsilon}$ for $d = c \log N$. Then for any distance function* dist $\in \{\Delta, \ell_p, \text{ED}\}$ *and $r > 0$, δ-Apx-NN$_{N,d',dist}$ cannot be solved with N^r preprocessing time and $N^{1-3r\epsilon}$ query time for $\delta = \tilde{\Theta}((\frac{\epsilon}{c})^2)$.*

Approximation Schemes for Geometric Knapsack for Packing Spheres and Fat Objects

Abstract

We study the geometric knapsack problem in which we are given a set of d-dimensional objects (each with associated profits) and the goal is to find the maximum profit subset that can be packed non-overlappingly into a given d-dimensional (unit hypercube) knapsack. Even if $d = 2$ and all input objects are disks, this problem is known to be NP-hard [Demaine, Fekete, Lang, 2010]. In this paper, we give polynomial time $(1 + \varepsilon)$-approximation algorithms for the following types of input objects in any constant dimension d:

- disks and hyperspheres,
- a class of fat convex polygons that generalizes regular k-gons for $k \geq 5$ (formally, polygons with a constant number of edges, whose lengths are in a bounded range, and in which each angle is strictly larger than $\pi/2$),
- arbitrary fat convex objects that are sufficiently small compared to the knapsack.

We remark that in our PTAS for disks and hyperspheres, we output the computed set of objects, but for a $O_\varepsilon(1)$ of them we determine their coordinates only up to an exponentially small error. However, it is not clear whether there always exists a $(1 + \varepsilon)$-approximate solution that uses only rational coordinates for the disks' centers. We leave this as an open problem which is related to well-studied geometric questions in the realm of circle packing.

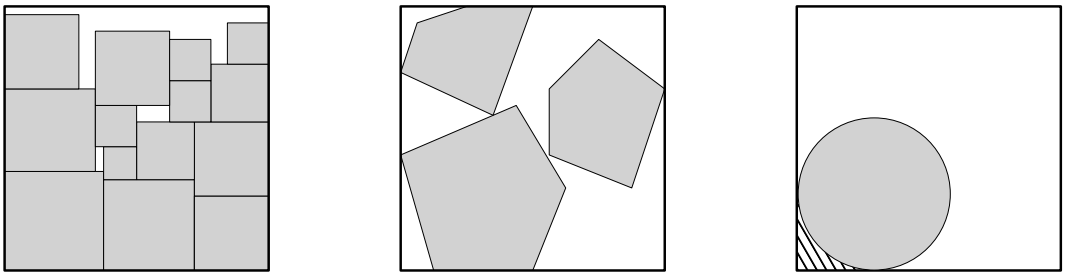

Figure 1 Left: The squares are stacked compactly inside the knapsack. Middle: The pentagons cannot be stacked as tightly inside the knapsack as the squares. Right: The space in the corner (striped area) cannot be covered by any large circle.

1 Introduction

One of the cornerstones of geometry is the problem of packing circles and spheres into a container, e.g., a square or a hypercube. It dates back to the 17th century when Kepler conjectured his famous bound on the average density of any packing of spheres in the three-dimensional Euclidean space [27]. The problem has been investigated, for example, by Lagrange [11] who solved it in the setting of two dimensions, by Hales and Ferguson [24] who proved Kepler's original conjecture, and by Viazovska [39] who studied the problem in dimension 8 and was awarded the Fields medal in 2022 for her work.

A natural corresponding optimization question is the *geometric knapsack problem*, where we are given a set of d-dimensional objects for some constant $d \in \mathbb{N}$, e.g., circles or (hyper-)spheres, but possibly also other shapes (like squares, pentagons, hexagons, etc. for the case of $d = 2$) with each of them having a given profit. The goal is to find the subset of maximum total profit that can be packed non-overlappingly into a given square or (hyper-)cube. In this work, we consider the translations of the objects but do not allow rotations.

Geometric knapsack is a natural mathematical problem and it is well-motivated by practical applications in several areas, including radio tower placement [38], origami design [30], cylinder pallet assembly [8, 17], tree plantation [38], cutting industry [38], bundling tubes or cables [40], layout of control panels [8], or design of digital modulation schemes [36].

The problem is known to be NP-hard, already for $d = 2$ and if all input objects are axis-aligned squares or disks [14, 2]. This motivates designing approximation algorithms for it. For hypercubes in any constant dimension d, there is a polynomial time $(1+\varepsilon)$-approximation algorithm known for any constant $\varepsilon > 0$ [26], i.e., a polynomial time approximation scheme (PTAS). Thus, this is the best possible approximation guarantee, unless P=NP.

However, for other classes of (fat) objects, the best known results either have approximation ratios that are (far) from their respective lower bounds or they require resource augmentation, i.e., increase in the size of the given knapsack. One intuitive reason for this is that axis-aligned squares and cubes can be stacked nicely without wasting space and the resulting coordinates are well-behaved, while for more general shapes this might not be the case, see Figure 1. For circles, the best known result is a $(3 + \varepsilon)$-approximation [35] but the best known lower bound is only NP-hardness. Still, the membership in NP is wide open for the following question: given a set of n circles of $O(1)$ number of different sizes, decide whether they can be packed into a unit square. It is also open whether packing circles into a square knapsack is $\exists\mathbb{R}$-complete or not [1]. Even for n unit circles. we do not know the exact value of the smallest size squares that can pack them. See [37] for the current status of upper and lower bounds for $n \leq 1000$.

There is a PTAS in any constant dimension d for this case, but it requires resource augmentation [9]. For triangles, there is a $O(1)$-approximation algorithm (assuming it is allowed to rotate the triangles arbitrarily) whose precise approximation ratio is not explicitly specified [33]. Also for this case, it is still possible that there is a PTAS. On the other hand, there are settings of geometric knapsack that do *not* admit a PTAS, e.g., axis-parallel cuboids in three dimensions [12].

Furthermore, in practical applications (e.g., loading cargo into a truck or cutting pieces out of raw material like cloth or metal) the objects do not necessarily all have the same shape. For example, Bennell and Oliveira [6] consider a mix of different shapes of objects (their primary objects are circles, rectangles, regular polygons, and convex polygons). However, the previous papers in the theoretical literature for geometric knapsack mostly assume that all input objects are of the same type, e.g., only squares, only circles, or only rectangles, etc. Thus, from a theoretical point of view, it is interesting to see how the problem behaves when the input objects might be of different types.

This raises the following natural question that we study in this paper:

What are the best approximation ratios we can achieve for the geometric knapsack problem, depending on the type of the input objects? For which type of objects does a PTAS exist?

1.1 Our contribution

In this paper, we present a polynomial time $(1+\varepsilon)$-approximation algorithm for geometric knapsack problem for packing d-dimensional spheres into d-dimensional hypercube knapsack, for any constant dimension $d \geq 2$. For spheres, there is a complication that possibly any (near-)optimal packing for a given instance require irrational coordinates. Therefore, our output consists of a set of spheres that can be packed non-overlappingly inside the given knapsack and whose profit is at least $(1+\varepsilon)^{-1}w(\mathrm{OPT})$, where $w(\mathrm{OPT})$ denotes the profit of the optimal solution OPT. Moreover, for all but at most $O_\varepsilon(1)$ spheres, our algorithm outputs the precise (rational) coordinates of the packing. [1] For the other $O_\varepsilon(1)$ spheres it outputs them up to an exponentially small error in each dimension. We remark that there are related packing problems for which it is known that irrational coordinates are sometimes necessary and that computing them is $\exists\mathbb{R}$-complete (and hence possibly even harder than NP-hardness) [1]. On the other hand, if we knew that there always exists a $(1+\varepsilon)$-approximate solution in which all coordinates are rational with only a polynomial number of bits, our algorithm would find such coordinates in polynomial time. We stress that our returned set of spheres is always guaranteed to fit into the given knapsack with appropriate (possibly irrational) coordinates but *without* resource augmentation.

Our second result is a polynomial time $(1+\varepsilon)$-approximation algorithm for the geometric knapsack problem for wide classes of convex geometric polygons. Our first result is a PTAS for a class of fat convex polygons which generalizes pentagons, hexagons, and regular k-gons for constant $k > 4$ (see Figure 2). Formally, we require for each polygon that the angle between any two adjacent edges is at least $\pi/2 + \delta$ for some constant $\delta > 0$ and that each polygon has a constant number of edges with similar lengths (up to a constant factor). Note that in contrast to many prior results, we allow that each input object has a different shape, e.g., with a different number of edges, different angles formed by them, and a different orientation. Also, the polygons may differ arbitrarily in size.

[1] The notation $O_\varepsilon(f(n))$ means that the implicit constant hidden in big-O notation can depend on ε.

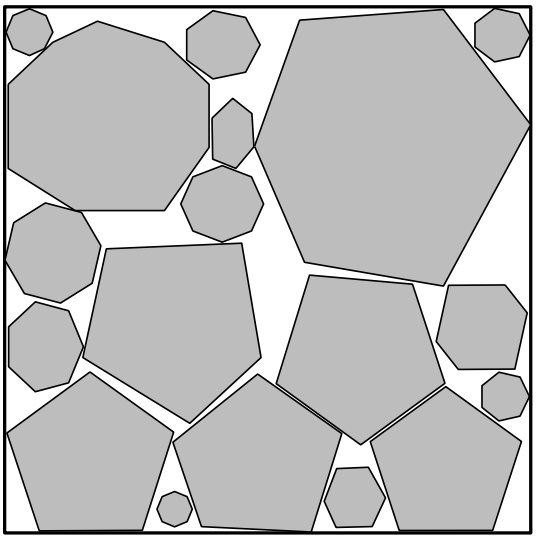

Figure 2 Packing of fat convex polygons in a knapsack.

If each input object is sufficiently small compared to the knapsack, we obtain even a polynomial time $(1+\varepsilon)$-approximation for *arbitrary* fat convex objects in any constant dimension d. We remark that for other packing problems like one-dimensional Knapsack or Bin Packing, near-optimal solutions can easily be achieved via greedy algorithms if the input objects are sufficiently small. Even for sufficiently small d-dimensional axis-aligned hypercuboids, it is known that simple algorithms like NFDH [13, 4] has negligible wasted space. However, for other geometric objects this is much harder since we might not be able to place the input objects compactly without wasting space. For example, classical result by Thue [11] showed that one can pack at most $\frac{\pi}{2\sqrt{3}} \approx 0.9069$ fraction of the total area, even in the case of packing of unit circles. Furthermore, for circles and other similar convex objects, irrational coordinates may arise in the packing and the optimal solution may use a very complicated packing to minimize the wasted space.

1.2 Our techniques

We discuss now the techniques of our results, starting with our PTAS for spheres. To compute our packing, we first enumerate all the large spheres in the optimal solution, i.e., the spheres whose radius is at least a constant fraction of the side length of the knapsack. Also, we guess their placement up to a polynomially small error, which yields a small range of possible placements for each of them. Note that we cannot guess these coordinates precisely, since we cannot even exclude that they are irrational. However, we guarantee that such coordinates *exist*, by solving a system of polynomial equations *exactly* in polynomial time.

Next, we want to place small spheres into the remaining part of the knapsack. Unfortunately, we do not know precisely which part of the knapsack is available for them since we do not know the precise coordinates of the large spheres. Thus, there is some area of the knapsack that is *maybe* used by the large spheres in our packing; however, potentially, the optimal solution uses it for placing small spheres. Our key insight is that this area is small compared to the area that is for sure *not* used by large spheres in the optimal solution. Using the fact that objects are spheres, we show that some area in each corner of the knapsack cannot be covered by any large sphere in *any* solution and whose size is at least a constant

fraction of the knapsack (see the bottom-left empty corner in Figure 1). We use this area to compensate the fact that we do not know the precise coordinates of our large spheres and we waste space because of this.

When we select and pack the small spheres, we define a constant number of (small) identical knapsacks that fit into the given knapsack together with the large spheres and into which we place our small spheres. For the remaining task of placing the small spheres, we argue that it is sufficient to have an algorithm that uses resource augmentation, i.e., that increases the size of each knapsack by a factor of $1 + \varepsilon$ (in each dimension). Thus, on a high level, we reduce the problem of packing arbitrary spheres into *one* knapsack to the problem of packing small spheres into a *constant number* of knapsacks *with resource augmentation*.

This remaining problem can be solved via an algorithm in [9]; however, we present a more general routine that works even for arbitrary convex fat objects. Also, it is arguably simpler than the corresponding algorithm in [9]. On a high level, we prove that there is a well-structured solution based on a hierarchical decomposition of the knapsacks into grid cells. The grid cells are partitioned such that each placed object P is contained in a constant number of grid cells whose size is comparable to P. Importantly, these grid cells are used *exclusively* by P and not by any other placed object (not even partially). This allows us to devise a dynamic program (DP) that computes the optimal structured packing of this type. Our DP has a subproblem for each combination of a level (corresponding to a size range of the input objects) and a number of available grid cells corresponding to this level. Given such a subproblem, it suffices to enumerate a polynomial number of possibilities for selecting and placing objects of this level, which reduces the given subproblem to a subproblem corresponding to the next level. This DP might have applications in other related packing problems.

In our algorithm for fat convex polygons (with the properties described above), we extend our algorithm for spheres as follows. For the guessed large polygons, we compute their coordinates *exactly* in polynomial time. Here, we use the (known) fact that there exists a placement for them that corresponds to an extreme point solution of a suitable linear program, which has rational coordinates. Then, intuitively we use the condition for the polygons' angles to ensure that the large objects leave a certain area of the knapsack empty. We use this empty area in a similar way as in the setting of circles. Again, we place the small objects into a constant number of knapsacks under resource augmentation, using our new subroutine described above.

If all input objects are sufficiently small compared to the size of the knapsack (formally, we assume that each of them fits in a smaller knapsack with side length $\Theta(\varepsilon)$) there are no large objects and, hence, we can omit the step of enumerating them. In particular, we do not need the conditions of the polygons' edges anymore. Since the input objects are so small, we can show that by losing a factor of $1 + \varepsilon$ in the approximation ratio, we may pretend that we have resource augmentation available. Hence, we can directly call our subroutine for small objects under resource augmentation.

We leave it as an open question to determine whether irrational coordinates are sometimes necessary for optimal or $(1 + \varepsilon)$-approximate solutions for geometric knapsack for spheres. If yes, it would be interesting to determine the best possible approximation ratio one can achieve with rational coordinates only. Note that this question is related to the well-studied problem of determining the size of the smallest knapsack needed to pack a given number of unit circles. For that problem, it is known that for some number of unit circles the smallest knapsack has irrational edge lengths [18]. On the other hand, recall that if rational coordinates with a polynomial number of bits always suffice, our algorithm for spheres can compute the coordinates of *all* returned spheres of our $(1 + \varepsilon)$-approximation algorithm *exactly*.

1.3 Other related work

For geometric knapsack for axis-parallel rectangles (i.e., when $d = 2$), the best known polynomial time algorithm has an approximation ratio of $17/9 + \varepsilon$ [19]. There is a pseudo-polynomial time algorithm with a ratio of $4/3 + \varepsilon$ [20] and a pseudo-polynomial time approximation scheme if we require guillotine-separable packing [28] . If it is allowed to rotate the rectangles by 90 degrees, there is also a polynomial time $(1.5 + \varepsilon)$-approximation algorithm known [19]. Moreover, the problem admits a QPTAS if the input data are quasi-polynomially bounded integers [3]. For the setting of packing circles, there is a PTAS under resource augmentation in one dimension, assuming that the profit of each circle equals its area, due to Lintzmayer, Miyazawa, and Xavier [31]. This was improved to the above mentioned PTAS under resource augmentation in one dimension for spheres with arbitrary profits in any constant dimension d, due to Chagas, Dell'Arriva, and Miyazawa [9]. In addition, there have been many attempts to develop heuristics and other optimization methods on circle packing, see e.g., [38, 25, 32].

A related problem is the geometric bin packing problem in which we want to place a given set of geometric objects into the smallest number of unit size bins. For the settings of squares or (hyper-)cubes [4] or skewed rectangles [29], the problem admits an asymptotic PTAS. In the case of general rectangles, the best known result is an asymptotic 1.405-approximation [5] but an asymptotic PTAS cannot exist unless $\mathsf{P} = \mathsf{NP}$ [12]. Maximum independent set in geometric intersection graphs [10, 34, 21] is another well-studied related problem.

In a recent paper, Abrahamsen, Miltzow, and Seiferth [1] developed a framework to show that for many combinations of allowed pieces, containers, and motions, the resulting packing problem is $\exists\mathbb{R}$-complete. For example, they showed that it is $\exists\mathbb{R}$-complete problem to decide if a set of convex polygons with at most seven corners each can be packed into a square if arbitrary rotations are allowed. However, it is not known if the setting of packing circles into a square knapsack is $\exists\mathbb{R}$-complete.

There is also a large body of work on questions about the optimal packings of unit circles into unit squares or equilateral triangles. We refer to [15, 16, 22, 25] for an overview.

1.4 Organization of this paper

In Section 2, we discuss the PTAS when the input items are sufficiently small fat convex objects. In Section 3, we give our algorithm for spheres. In Section 4, we consider the case of convex polygons. Finally, in Section 5 we end with conclusions. Due to space constraints, many proofs have been omitted. The corresponding lemmas and theorems are marked with $(\star)$. Please see the full version of the paper for the complete proofs.

2 PTAS under Resource Augmentation

In this section we present a PTAS when the input items are fat convex objects, and we are allowed to increase the size of the given knapsack by a factor of $1 + \varepsilon$ in each dimension. Chagas et al. [9] presented a PTAS for circles with resource augmentation in one dimension. Their result is based on a combination of multiple integer programs with variables for different configurations for packing parts of the given knapsack. Our result is arguably simpler and purely based on dynamic programming.

Let P_i be a two-dimensional convex object and let $r_i^{\text{out}}(P_i)$ and $r_i^{\text{in}}(P_i)$ be the radius of the smallest circle containing P_i and the radius of the largest circle contained in P_i, respectively. We will drop P_i when it is clear from the context. We say that P_i is *f-fat* if $r_i^{\text{out}}/r_i^{\text{in}} \leq f$ for some value $f \geq 1$. In the remainder of this section, we prove the following theorem.

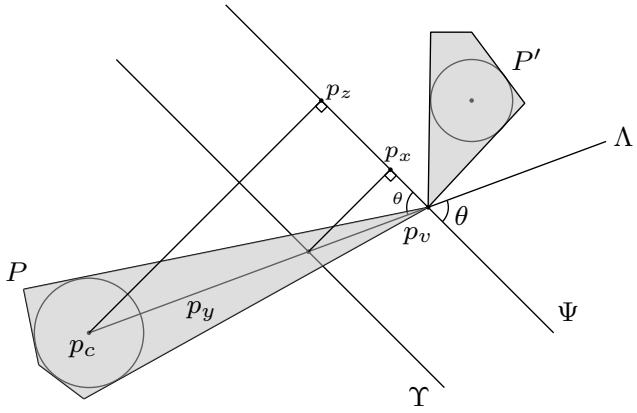

Figure 3 Line Ψ separates the two f-fat and convex objects P and P'. We construct line Υ such that it has intersects no common grid cells with line Ψ. We proceed to shrink the two objects P, P' by a factor of $1+\varepsilon$ such that they cannot intersect the space between lines Υ and Ψ.

▶ **Theorem 1.** *Let $f \geq 1$, $\varepsilon > 0$, and $d \in \mathbb{N}$ be constants. Given a set of d-dimensional f-fat convex input objects, there exists a polynomial time algorithm that can pack a subset of them with a total profit of $w(\mathsf{OPT})$ into a knapsack $K' := [0, 1+\varepsilon]^d$, where $w(\mathsf{OPT})$ is the optimal profit that can be packed into a knapsack $K := [0,1]^d$.*

For simplicity, we first describe our algorithm in the setting where $d = 2$. Given a packing of a set of f-fat objects $\mathcal{P} = \{P_1, P_2, \ldots, P_n\}$ in our knapsack $K = [0,1] \times [0,1]$, we want to show that there is also a structured packing of these objects into an augmented knapsack $K' = [0, 1+\varepsilon] \times [0, 1+\varepsilon]$, defined via a discrete grid. Let $\delta_{cell} > 0$ be a constant to be defined later such that $1/\delta_{cell} \in \mathbb{N}$. We place a two-dimensional grid inside K' such that each grid cell has an edge length of δ_{cell}. Let $\mathcal{G}$ denote the set of all resulting grid cells. We assume first that each object $P_i \in \mathcal{P}$ is δ_{large}-*large*, meaning that $r^{in}(P_i) \geq \delta_{large}$ for some given constant $\delta_{large} > 0$. We say that our given packing for $\mathcal{P}$ is *discretized* if there is a partition of $\mathcal{G}$ into sets $\{\mathcal{G}_{P_1}, \mathcal{G}_{P_2}, \ldots, \mathcal{G}_{P_n}\}$ such that for each $P_i \in \mathcal{P}$, we have that P_i is contained in the union of the cells in $\mathcal{G}_{P_i}$. Therefore, each object $P_i \in \mathcal{P}$ has "its own" set of grid cells $\mathcal{G}_{P_i}$ that contain P_i and that do not intersect with any other object $P_j \in \mathcal{P} \setminus \{P_i\}$.

We show that for an appropriate choice of δ_{cell}, there is a discretized packing for $\mathcal{P}$ in K', i.e., if we can increase the size of our knapsack K by a factor of $1+\varepsilon$ in each dimension.

▶ **Lemma 2.** *For each $f \geq 1$, $\varepsilon > 0$, and $\delta_{large} > 0$, there is a value $\delta_{cell} > 0$ such that for any set of δ_{large}-large f-fat convex objects $\mathcal{P}$ that can be placed nonoverlappingly inside a knapsack $K = [0,1] \times [0,1]$, there is a discretized packing for $\mathcal{P}$ inside knapsack $K' = [0, 1+\varepsilon] \times [0, 1+\varepsilon]$ based on a grid in which each edge of each grid cell has a length of δ_{cell}.*

Proof. Let $P, P' \in \mathcal{P}$ be two f-fat convex δ_{large}-large objects packed inside the knapsack. Then by *separating hyperplane theorem for convex objects* [7], we know that there is a line Ψ containing a point p_v on the boundary of P, and Ψ separates P from P' (see Figure 3). Now, intuitively, increasing the size of the knapsack by a factor of $1+\varepsilon$ is equivalent to shrinking the objects in $\mathcal{P}$ by a factor of $1+\varepsilon$. So, we want to find the right constraints such that after shrinking P and P' do not share any grid cell. Let the center of the incircle (of radius r^{in}) contained in P be p_c and the line joining p_c and p_v be Λ. Let the foot of the image of the point p_c on line Ψ be the point p_z. Now the length of line segment $\overline{p_c p_z} := |\overline{p_c p_z}| \geq r^{in}$

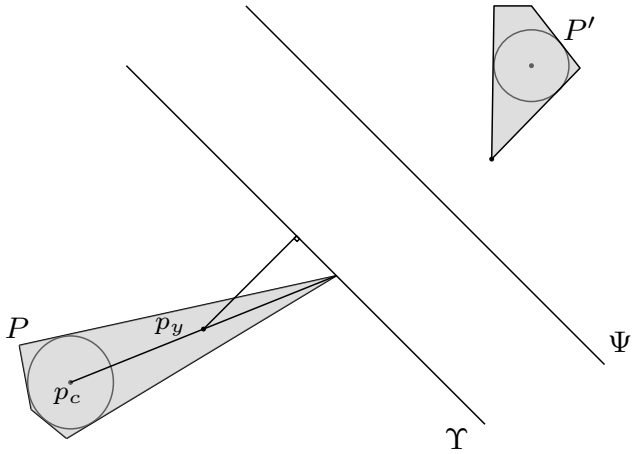

Figure 4 P, P' are shrunk so that they cannot intersect the space between the lines Υ and Ψ.

and $|\overline{p_c p_v}| \leq 2fr^{in}$, due to fatness. Hence, the angle θ between Ψ and Λ is at least $\sin^{-1}(\frac{1}{2f})$. Consider points p_x on Ψ and p_y on Λ such that $|\overline{p_x p_y}| = \sqrt{2}\delta_{cell}$ and the line Υ joining p_x, p_y is parallel to the line joining $p_c p_z$. Then any point on Ψ does not share a gridcell with any point on Υ. Also, $|\overline{p_y p_v}| \leq 2\sqrt{2}f\delta_{cell}$. Now we want to shrink P by $(1+\varepsilon)$ factor keeping p_c at the same position such that the shrunk version of P lies completely within one side of Υ (see Figure 4). After shrinking, $\overline{p_c p_v}$ gets smaller by $\varepsilon|\overline{p_c p_v}| \geq \varepsilon r^{in} \geq \varepsilon\delta_{large}$. Now we choose δ_{cell} such that $\delta_{cell} \leq \frac{\varepsilon}{2\sqrt{2}f} \cdot \delta_{large}$. Thus we satisfy $\varepsilon|\overline{p_c p_v}| \geq \varepsilon\delta_{large} \geq 2\sqrt{2}f\delta_{cell} \geq |\overline{p_y p_v}|$ and this ensures that the shrunk down version of P and P' do not share any grid cell. We assign each polygon to the grid cells that it intersects with. Hence this process leads to a discretization such that the no grid cell is intersected by two polygons. ◀

Next, we argue that there is also a structured packing for fat objects that are not necessarily all (relatively) large. Let $\delta_{large}, \delta_{cell}, \delta_{small} > 0$ be constants to be defined later (they will depend on ε which will denote the amount by which we increase the size of our knapsack). We place now a *hierarchical* two-dimensional grid with multiple levels. We define that the whole knapsack K is one grid cell of level 0 of side length $\delta_{c,0} := 1$. For each level $\ell \geq 1$, we define grid cells whose edges all have a length of $\delta_{c,\ell} := \delta_{cell}\delta_{c,(\ell-1)}$. Recursively, for each $\ell \geq 1$ we partition each grid cell of level $\ell - 1$ into $1/\delta_{cell}^2$ grid cells of level ℓ with side length $\delta_{c,\ell}$ each. Similarly as before, we want that there is a partition of the grid cells such that for each object $P \in \mathcal{P}$ there is a set of grid cells $\mathcal{G}_P$ that contain P and that are disjoint from the grid cells $\mathcal{G}_{P'}$ for each object $P' \in \mathcal{P} \setminus \{P\}$. Also, we want that all grid cells in $\mathcal{G}_P$ are of the same level, that their size is comparable to the size of P, and that the number of grid cells in $\mathcal{G}_P$ is bounded. To ensure this, we group the objects $P \in \mathcal{P}$ according to their respective values $r^{in}(P)$ which we use as a proxy for their sizes. Formally, we define $\delta_{small,0} := 1$ and for each level $\ell \geq 1$ we define $\delta_{large,\ell} := \delta_{large}\delta_{c,(\ell-1)}$ and $\delta_{small,\ell} := \delta_{small}\delta_{c,(\ell-1)}$. For each level ℓ we define

- L_ℓ to be all objects $P \in \mathcal{P}$ with $r^{in}(P) \in (\delta_{large,\ell}, \delta_{small,(\ell-1)}]$; intuitively, they are "large" for level ℓ,
- M_ℓ to be all objects $P \in \mathcal{P}$ with $r^{in}(P) \in (\delta_{small,\ell}, \delta_{large,\ell}]$.

Note that our grid and the sets L_ℓ and M_ℓ depend on the (initial) choice of $\delta_{large}, \delta_{small}$ and δ_{cell}. In the next lemma, we show via a shifting argument that there are choices for these values such that the total area of the objects in $\bigcup_\ell M_\ell$ is very small. This will allow us later to pack them separately via a simple greedy algorithm. In particular, these choices are from a set of $O_\varepsilon(1)$ candidate values D, and thus we will be able to guess them later easily.

▶ **Lemma 3** (⋆). *Let $f \geq 1$. There is a global set D with $|D| \leq O_\varepsilon(1)$ such that for any set of f-fat convex objects $\mathcal{P}$ that can be packed in a knapsack $K = [0,1] \times [0,1]$, there are values $\delta_{large}, \delta_{small}, \delta_{cell} > 0$ that are all contained in D such that for the resulting hierarchical grid and the corresponding sets $\{L_\ell, M_\ell\}_\ell$ we have that the total area of all objects in $\bigcup_\ell M_\ell$ is bounded by ε.*

We generalize now our notion of discretized packings. Intuitively, like before, we require that there is a partition of the grid cells such that for each object $P \in \mathcal{P}$ there is a set of grid cells $\mathcal{G}_P$ that contain P and that are disjoint from the grid cells $\mathcal{G}_{P'}$ for each object $P' \in \mathcal{P} \setminus \{P\}$. Formally, we define that our packing of $\mathcal{P}$ is *discretized* if

- for each level ℓ and for each object $P \in \mathcal{P} \cap L_\ell$ there is a set of $O(1/\delta_{cell}^2)$ grid cells $\mathcal{G}_P$ of level ℓ such that P is contained in $\mathcal{G}_P$, and there is a single grid cell of level $\ell - 1$ that contains all grid cells in $\mathcal{G}_P$, and
- for any two objects $P, P' \in \mathcal{P}$ (not necessarily of the same level) and for any two grid cells $C \in \mathcal{G}_P$ and $C' \in \mathcal{G}'_P$ their relative interiors are disjoint.

We show that by increasing the size of our knapsack by a factor of $1+\varepsilon$, there is a discretized packing for all objects in $\bigcup_\ell L_\ell$. As mentioned above, we will pack the objects in $\bigcup_\ell M_\ell$ separately later.

▶ **Lemma 4.** *Let each $f \geq 1$ and $\varepsilon > 0$. There is a global set D with $|D| \leq O_\varepsilon(1)$ such that for any set of f-fat objects $\mathcal{P}$ that can be placed non-overlappingly inside a knapsack $K = [0,1] \times [0,1]$, there is a choice for the grid with parameters $\delta_{large}, \delta_{small}, \delta_{cell} > 0$ such that all these values are contained in D and there is a discretized packing for $\mathcal{P} \cap (\bigcup_\ell L_\ell)$ inside an (augmented) knapsack $[0, 1 + O(\varepsilon)] \times [0, 1 + O(\varepsilon)]$.*

Proof. We start with the given packing of $\mathcal{P}$ in K and do a sequence of refinements which leads to our discretized packing for $\mathcal{P} \cap \bigcup_\ell L_\ell$. First, we use the increased size of the knapsack to ensure that for each level ℓ and any two objects $P, P' \in L_\ell$, the distance between P and P' is at least $2\delta_{c,\ell}$. Intuitively, increasing the size of the knapsack by a factor of $1+\varepsilon$ is equivalent to shrinking the objects in $\mathcal{P}$ by a factor of $1+\varepsilon$. Therefore, we can achieve this required minimum distance of $2\delta_{c,\ell}$ by choosing δ_{cell} appropriately according to the multiple constraints given in the proof of Lemma 2.

Next, we would like that for each level ℓ, each object in $\mathcal{P} \cap L_\ell$ is contained in a grid cell of level $\ell - 1$. This might not be the case, however, via a shifting argument (giving the grid a random shift) we can argue that this is the case for almost all objects in $\mathcal{P}$. The probability that an object in level ℓ intersects a grid line from level $\ell - 1$ is at most $8\delta_{small,\ell-1}/\delta_{cell,\ell-1} = 8\delta_{small}/\delta_{cell}$. Let this probability be smaller than $\varepsilon^2/2$, leading to a constraint $\delta_{small} \leq \varepsilon^2 \delta_{cell}/16$ on the choice of $\delta_{cell}, \delta_{small}$. Then the total area of intersecting objects must also be smaller than ε^2 as the area of all packed objects can be at most the area of the augmented knapsack. Thus we can easily pack these intersected objects into extra space that we gain via increasing the size of the knapsack (i.e., for a second time).

After this preparation, we process the objects $P \in \mathcal{P}$ level by level and define their corresponding sets $\mathcal{G}_P$, starting with the highest level. Consider a level ℓ. For each object $P \in \mathcal{P}$ of level ℓ we define $\mathcal{G}_P$ to be the set of all grid cells of level ℓ that intersect with P. Due to our minimum distance between any two objects in $\mathcal{P}$ of level ℓ, for any two different objects $P, P' \in \mathcal{P}$ of level ℓ we have that $\mathcal{G}_P \cap \mathcal{G}_{P'} = \emptyset$. Now it could be that a cell $\mathtt{C} \in \mathcal{G}_P$ for some $P \in \mathcal{P}$ intersects not only with P, but also with another object $P' \in \mathcal{P}$ of some deeper level $\ell' > \ell$. We call such a cell $\mathtt{C}$ *problematic*; recall that we wanted the cells in $\mathcal{G}_P$ to be used exclusively by P. Therefore, we move all objects $P' \in \mathcal{P}$ of some level $\ell' > \ell$ that intersect a problematic grid cell in $\mathcal{G}_P$. We pack them into extra space that we gain due to resource augmentation. We do this operation for all levels ℓ.

In the process above, we move objects that intersect problematic grid cells. We need to argue that the total area of these moved objects is small compared to the size of the knapsack and that, therefore, we can pack them into additional space that we gain due to our resource augmentation. In particular, we need to argue this globally, over all levels. The key insight is that if we define a set $\mathcal{G}_P$ for some object $P \in \mathcal{P}$ as above, then each problematic cell $\mathtt{C} \in \mathcal{G}_P$ must intersect the boundary of P and, since P is fat, the number of problematic cells $\mathtt{C} \in \mathcal{G}_P$ is very small compared to the number of cells $\mathtt{C}' \in \mathcal{G}_P$ that are contained in P and, thus, for sure *not* problematic.

By the classical *Barbier's theorem*, we know the perimeter of a convex set P of level ℓ is at most $\pi \cdot \text{diameter}(P) \leq 2\pi r^{out} \leq 2\pi f r^{in}$. A curve of length $\delta_{cell,\ell}$ is bound to be contained inside a circle of radius $\delta_{cell,\ell}$. This implies that this curve can intersect at most 9 grid cells as any circle of radius $\delta_{cell,\ell}$ can be bounded in a 3×3 grid square. Hence, the number of grid cells (of level ℓ) N_1 that the perimeter can intersect is at most $18\pi f r^{in}/\delta_{cell,\ell}$. On the other hand, P completely contains at least grid cells of area $\pi(r^{in} - 2\delta_{cell,\ell})^2$, i.e., the number of such gridcells N_2 is at least $\frac{\pi(r^{in}-2\delta_{cell,\ell})^2}{(\delta_{cell,\ell})^2}$. We need $N_1 \leq \varepsilon N_2$. Equivalently, we want to show, $\delta_{cell,\ell} \leq \frac{\varepsilon}{18f} \cdot \frac{(r^{in}-2\delta_{cell,\ell})^2}{r^{in}}$. For this we impose the condition that $\delta_{large} \geq \frac{72f}{\varepsilon}\delta_{cell}$. Then, $\frac{\varepsilon}{18f} \cdot \frac{(r^{in}-2\delta_{cell,\ell})^2}{r^{in}} \geq \frac{\varepsilon}{18f} \cdot \frac{(r^{in}/2)^2}{r^{in}} \geq \frac{\varepsilon}{18f} \cdot \frac{\delta_{large,\ell}}{4} \geq \delta_{cell,\ell}$.

Using this, we derive a *global* argumentation, stating that the total area of *all* problematic grid cells over all objects of all levels is at most an ε-fraction of the area of the knapsack. Also, if an object P' of some level ℓ' intersects a problematic grid cell $\mathtt{C}$ of some level $\ell < \ell'$, then P' is very small compared to $\mathtt{C}$. Thus, the total area of these objects intersecting a problematic grid cell $\mathtt{C}$ is essentially the same as the area of $\mathtt{C}$. Thus, we can pack all these objects into our additional space due to resource augmentation.

Finally, we can afford to increase the space of our knapsack such that this additional space is even by a constant factor larger than the total area of the objects we need to pack into it. Therefore, it is easy to find a discretized packing for them in this extra space. ◀

Algorithm. Now we describe our algorithm. First, we *correctly* guess (i.e., by brute-force enumeration of all possible cases) the values $\delta_{large}, \delta_{small}, \delta_{cell} > 0$ from set D due to Lemma 4. Note that we still do not know $\bigcup_\ell L_\ell$ or $\bigcup_\ell M_\ell$, i.e., which objects are there in the optimal packing. So, for each level ℓ we define $\tilde{L}_\ell$ to be all input objects P with $r^{in}(P) \in (\delta_{large,\ell}, \delta_{small,(\ell-1)}]$ and $\tilde{M}_\ell$ to be all input objects P with $r^{in}(P) \in (\delta_{small,\ell}, \delta_{large,\ell}]$.

Then, we compute an optimal discretized packing via a dynamic program. Intuitively, our DP computes an optimal subset of $\bigcup_\ell \tilde{L}_\ell$ for which there is a discretized packing. We introduce a DP-cell DP$[\ell, m]$ for each combination of a level ℓ and a value $m \in \{1, ..., n\}$. This cell corresponds to the subproblem of packing a maximum profit subset of the objects in $\tilde{L}_\ell, \tilde{L}_{\ell+1}, \tilde{L}_{\ell+2}, \ldots$. via a discretized packing into at most m grid cells of level $\ell - 1$, i.e., with side length $\delta_{c,(\ell-1)}$ each. Recall that each object in $\tilde{L}_\ell$ is relatively large compared to the grid cells of level $\ell - 1$. Therefore, we can pack only constantly many items from $\tilde{L}_\ell$ into each of these m grid cells of level $\ell - 1$. Therefore, there are only constantly many options how the set $\mathcal{G}_P$ of an object $P \in \tilde{L}_\ell$ in the optimal solution to our subproblem can look like. We say that a *configuration* is a partition of a grid cell of level $\ell - 1$ into sets of grid cells of level ℓ. Each grid cell of level $\ell - 1$ contains $O(1/\delta_{cell}^2)$ many grid cells of level ℓ. Hence, there are only constantly many configurations. We assume two configurations to be *equivalent* if they are identical up to translation by an integral multiple of $\delta_{c,(\ell-1)}$, i.e., by an integral multiple of the edge length of a grid cell of level $\ell - 1$. Denote by C the total number of resulting equivalence classes. We guess in time $m^{O(C)} \leq n^{O(C)}$ how many grid cells have each of the

at most C configurations (up to equivalences). Then, we assign the items in $\tilde{L}_\ell$ into the grid cells according to this guess. We can do this by weighted bipartite matching. For each object $P \in \tilde{L}_\ell$, each possible configuration $\mathcal{G}'$, and each set in the partition of $\mathcal{G}'$, we can check easily whether P fits into $\mathcal{G}'$. In the bipartite graph, one side will contain the objects in $\tilde{L}_\ell$ and other side will contain the sets in the partition of $\mathcal{G}'$. If P fits into set Q in the partition of $\mathcal{G}'$, then there is an edge with edge cost as $w(P)$. Our guess yields a certain number m' of empty grid cells of level $\ell+1$ into which we need to pack items in $\tilde{L}_{\ell+1}, \tilde{L}_{\ell+2}, \ldots$. We assign these items according to the solution in the DP-cell $\mathrm{DP}[\ell+1, \min\{m', n\}]$. Note that there are at most n items and, hence, we never need more than n grid cells of level $\ell+1$. Also, since our input data is polynomially bounded, the number of classes $\tilde{L}_i$ is bounded by $n^{O(1)}$. Thus, our DP runs in time $n^{O(C)}$.

Additionally, we pack medium objects from the set $\bigcup_\ell \tilde{M}_\ell$ separately in a strip of the form $[0,1] \times [1, 1+O(\varepsilon)]$. We select the most profitable subset of $\bigcup_\ell \tilde{M}_\ell$ (up to a factor of $1+\varepsilon$) whose total area is bounded by ε (see Lemma 3). We replace each of these objects by the smallest square that contains it, which increases its area only by a constant factor. We can pack these squares efficiently into a (slightly larger) strip $[0,1] \times [1, 1+O(\varepsilon)]$ using the `NFDH` algorithm [13]. This yields the following lemma.

▶ **Lemma 5.** ($\star$) *In polynomial time we can compute a set $\mathcal{P}' \subseteq \bigcup_\ell \tilde{M}_\ell$ and a non-overlapping placement of $\mathcal{P}'$ inside $[0,1] \times [1, 1+O(\varepsilon)]$ such that $w(\mathcal{P}')$ is at least the profit of any subset of $\bigcup_\ell \tilde{M}_\ell$ whose total area is at most ε.*

One can easily extend our algorithm above to any constant dimension d. This completes the proof of Theorem 1. A consequence is that we obtain a polynomial time $(1+\varepsilon)$-approximation *without* resource augmentation if all input objects are small, i.e., if $r^{out}(P) \leq \varepsilon$ for each given object $P \in \mathcal{P}$. Using this property, we can argue that there is a $(1+\varepsilon)$-approximate solution in which only the area $[0, 1-\Theta(\varepsilon)] \times [0, 1-\Theta(\varepsilon)]$ of the knapsack is used. Thus, we can use the free space for the resource augmentation that is required by our algorithm due to Theorem 1.

▶ **Theorem 6.** ($\star$) *Let $d \in \mathbb{N}$ be a constant. There is a polynomial time $(1+O(\varepsilon))$-approximation for the geometric knapsack problem if the set of input objects $\mathcal{P}$ consists of convex fat d-dimensional objects such that $r^{out}(P) \leq \varepsilon$ for each $P \in \mathcal{P}$.*

3 Spheres

In this section we present our $(1+\varepsilon)$-approximation algorithm for the case of d-dimensional spheres. Let $\mathcal{C} = \{C_1, C_2, \ldots, C_n\}$ be a set of n number of d-dimensional hyperspheres. We denote the radius and profit of each hypersphere $C_i \in \mathcal{C}$ by r_i and w_i. For an object C_i we denote its volume (or area in 2-dimension) to be $a(C_i)$. For a collection of objects $\mathcal{A}$, we define its volume and profit to be $a(\mathcal{A}) := \sum_{C_i \in A} a(C_i)$ and $w(\mathcal{A}) := \sum_{C_i \in A} w(C_i)$, respectively. We are given a unit knapsack $K := [0,1]^d$.

We first consider the case of circles, i.e., $d = 2$. Let OPT be an optimal solution and $\mathcal{C}_{\mathsf{OPT}}$ be the circles in OPT. Let $\varepsilon \in (0, 1/2]$ be a constant and assume that $1/\varepsilon \in \mathbb{N}$. First, we want to classify the input circles into *small* and *large* circles such that each large circle is much larger than any small circle. Due to the following lemma, we can do this such that we can ignore all circles that are neither large nor small by losing only a factor of $1+\varepsilon$. We will use this standard shifting argument throughout the paper.

▶ **Lemma 7** ($\star$)**.** *There is a set of global constants $\varepsilon^{(0)}, \ldots, \varepsilon^{(1/\varepsilon)} \geqslant 0$ such that $\varepsilon^{(j)} = (\varepsilon^{(j-1)})^{24}$ for each $j \in \{1, \ldots, 1/\varepsilon\}$ and a value $k \in \{1, \ldots, 1/\varepsilon - 1\}$ with the following property: if we define $\varepsilon_{large} := \varepsilon^{(k)}$ and $\varepsilon_{small} := \varepsilon^{(k+1)}$, then sum of profits of all circles C_i in OPT with radii $\varepsilon_{small} \leq r_i \leq \varepsilon_{large}$ is at most $\varepsilon \cdot w(\mathsf{OPT})$.*

We guess the value $k \in \{0, ..., 1/\varepsilon - 1\}$ due to Lemma 7. We define that a circle $C_i \in \mathcal{C}$ is *large* if $r_i > \varepsilon_{large}$ and *small* if $r_i \leqslant \varepsilon_{small}$. Also, note that $\varepsilon_{small} = \varepsilon_{large}^{24}$.

3.1 Guessing large circles

We observe that in OPT there can be only a constant number of large circles since each large circle covers a constant fraction of the available area in the knapsack.

▶ **Proposition 8** ($\star$). *Any feasible solution can contain at most* $(1/\varepsilon)^{O_k(1)}$ *large circles.*

We guess a feasible solution of the large circles in OPT that satisfy the packing constraints in time $n^{(1/\varepsilon)^{O_k(1)}}$, denote them by $\mathcal{C}_L^*$. In related problems, like the two-dimensional knapsack problem with squares or rectangles, one can easily guess the correct placement of the guessed large circles (assuming rational input data). For packing circles, it is not clear that if there is a packing in which the centers of the circles are placed at rational coordinates. However, in the following section, when we pack polygons, we can guarantee that there is an optimal solution in which the corner of each polygon has a rational coordinate.

Therefore, instead we first guess for each circle $C_i \in \mathcal{C}_L^*$ an *estimate* for its placement in OPT. Denote by $\hat{x}_i^{(1)}, \hat{x}_i^{(2)} \in [0, 1]$ the coordinates of the center of C_i in OPT. We guess values $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)} \in \{0, \frac{\varepsilon}{n}, \frac{2\varepsilon}{n}, ..., 1\}$ such that $\hat{x}_i^{(1)} \in [\tilde{x}_i^{(1)}, \tilde{x}_i^{(1)} + \frac{\varepsilon}{n})$ and $\hat{x}_i^{(2)} \in [\tilde{x}_i^{(2)}, \tilde{x}_i^{(2)} + \frac{\varepsilon}{n})$. Note that there are only $O(n^2/\varepsilon^2)$ possibilities for each $C_i \in \mathcal{C}_L^*$, and hence only $n^{(1/\varepsilon)^{O_k(1)}}$ possibilities overall for all circles $C_i \in \mathcal{C}_L^*$.

Given these guessed values $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ for each circle $C_i \in \mathcal{C}_L^*$, we verify that our guess was correct or not, i.e., confirm that there exists, indeed a corresponding placement for each circle $C_i \in \mathcal{C}_L^*$ such that the circles in $\mathcal{C}_L^*$ do not overlap. Therefore, we define a system of quadratic inequalities that describes the problem of finding such a placement. We require that this placement is consistent with our guesses $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ for each $C_i \in \mathcal{C}_L^*$.

$$\begin{aligned}
\max\{\tilde{x}_i^{(1)}, r_i\} \leqslant x_i^{(1)} &\leqslant \min\left\{\tilde{x}_i^{(1)} + \frac{\varepsilon}{n}, 1 - r_i\right\} && \forall C_i \in \mathcal{C}_L^* \\
\max\{\tilde{x}_i^{(2)}, r_i\} \leqslant x_i^{(2)} &\leqslant \min\left\{\tilde{x}_i^{(2)} + \frac{\varepsilon}{n}, 1 - r_i\right\} && \forall C_i \in \mathcal{C}_L^* \\
(x_i^{(1)} - x_j^{(1)})^2 + (x_i^{(2)} - x_j^{(2)})^2 &\geqslant (r_i + r_j)^2 && \forall C_i, C_j \in \mathcal{C}_L^* \\
x_i^{(1)}, x_i^{(2)} &\geqslant 0 && \forall C_i \in \mathcal{C}_L^*
\end{aligned} \tag{1}$$

Let $|\mathcal{C}_L^*| =: t$. Then, the above system has $2t$ variables and $k := O(t^2)$ constraints. It is not clear how to compute a solution to this system in polynomial time. It is not even clear whether it has a solution in which each variable has a rational value. However, in polynomial time, we can *decide* whether it has a solution (without computing the solution itself) using an algorithm from [23].

Note that the set of solutions satisfying system (1) is a semi-algebraic set in the field of real numbers. Thus, whether a given set of circles can be packed or not (the decision problem) reduces to a decision problem of whether this semi-algebraic set is nonempty or not. Here, each constraint $i \in [k]$ in (1) can be written as a function $f_i(x_1^{(1)}, x_1^{(2)}, \ldots, x_t^{(1)}, x_t^{(2)}) \geqslant 0$ where each $f_i \in \mathbb{Q}[x_1^{(1)}, x_1^{(2)}, \ldots, x_t^{(1)}, x_t^{(2)}]$ is a polynomial with rational coefficients of degree at most two. Thus deciding the circle packing problem is equivalent to deciding the truth of the following formula: $F := (\exists x_1^{(1)})(\exists x_1^{(2)}) \ldots (\exists x_t^{(1)})(\exists x_t^{(2)}) \wedge_{i=0}^{k} f_i(x_1^{(1)}, x_1^{(2)}, \ldots, x_t^{(1)}, x_t^{(2)}) \geqslant 0$. To solve this decision problem, we use the following result.

▶ **Theorem 9** ([23]). *Let $f_1, f_2, \ldots, f_k \in \mathbb{Q}[x_1^{(1)}, x_1^{(2)}, \ldots, x_t^{(1)}, x_t^{(2)}]$ be polynomials with absolute value of any coefficient to be represented by M bits and maximum degree Δ. There is an algorithm that decides whether the formula $F := (\exists x_1^{(1)})(\exists x_1^{(2)}) \ldots (\exists x_t^{(1)})(\exists x_t^{(2)}) \wedge_{i=0}^{k} f_i(x_1, y_1, \ldots, x_n, y_n) \geqslant 0$ is true, with a running time of $M^{O(1)}(k\Delta)^{O(t^2)}$.*

If it is true, the algorithm also returns polynomials $f, g_1, h_1, \ldots, g_t, h_t \in \mathbb{Q}[x]$ with coefficients of bit size at most $M^{O(1)}(k\Delta)^{O(t)}$ and maximum degree $k^{O(t)}$, such that for a root x of $f(x)$, the assignment $x_1^{(1)} = g_1(x), x_1^{(2)} = h_1(x), \ldots, x_t^{(1)} = g_n(x), x_t^{(2)} = h_n(x)$ satisfies the formula F.

Moreover, for any rational $\alpha > 0$, it returns values $\bar{x}_1^{(1)}, \bar{x}_1^{(2)} \ldots, \bar{x}_t^{(1)}, \bar{x}_t^{(2)} \in \mathbb{Q}$ such that $|\bar{x}_i^{(1)} - x_i^{(1)}| \leqslant \alpha$ and $|\bar{x}_i^{(2)} - x_i^{(2)}| \leqslant \alpha$, for $1 \leqslant i \leqslant t$, in time at most $(\log(1/\alpha)M)^{O(1)}(k\Delta)^{O(t^2)}$.

We crucially use here that our system has only constantly many variables and constraints, i.e., in (1), we have that Δ, k, t are constants and that M is polynomially bounded in n. From Theorem 9, we see that in polynomial time we can decide whether (1) has a solution.

If the system (1) does not have a solution, then we reject this guessed combination of $\mathcal{C}_L^*$ and values $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ for each circle $C_i \in \mathcal{C}_L^*$. We assume in the following that it has a solution. Observe that the guessed values $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ yield an estimate for $\hat{x}_i^{(1)}, \hat{x}_i^{(2)}$ up to a (polynomially small) error of ε/n.

3.2 Placing small circles

We want to select small circles from $\mathcal{C}$ and place them inside the knapsack, so that they do not overlap with each other or with the circles in $\mathcal{C}_L^*$. To this end, we define $\varepsilon_{cell} := \varepsilon_{large}^{12}$ (i.e., $\varepsilon_{small} = \varepsilon_{large}^{12}\varepsilon_{cell} = \varepsilon_{cell}^2$) to subdivide the knapsack into a grid with $1/\varepsilon_{cell}^2$ square grid cells of side length ε_{cell} . Our choice of parameters ensures that each small circle is small compared to each grid cell and each large circle is big compared to each grid cell. Formally, for each $\ell, \ell' \in \{0, 1, \ldots, \frac{1}{\varepsilon_{cell}} - 1\}$ we define a grid cell $G_{\ell,\ell'} := [\ell \cdot \varepsilon_{cell}, (\ell+1) \cdot \varepsilon_{cell}) \times [\ell' \cdot \varepsilon_{cell}, (\ell'+1) \cdot \varepsilon_{cell})$. We define the set of all grid cells by $\mathcal{G} := \{G_{\ell,\ell'} : \ell, \ell' \in \{0, 1, \ldots, 1/\varepsilon_{cell} - 1\}\}$.

We say that a placement of a circle $C_i \in \mathcal{C}_L^*$ is *legal* if its center is placed at a point $(x_i^{(1)}, x_i^{(2)})$ such that $\max\{\tilde{x}_i^{(s)}, r_i\} \leqslant x_i^{(s)} \leqslant \min\left\{\tilde{x}_i^{(s)} + \frac{\varepsilon}{n}, 1 - r_i\right\}$ for each $s \in \{1, 2\}$. We show that there is a structured packing with near-optimal profit in which each small circle is contained in a grid cell that does not intersect with any large circle in $\mathcal{C}_L^*$ in any legal packing of them. This will allow us to decouple the remaining problem for the small circles from the large circles, even though we do not know the exact placement for the latter. Moreover, in each grid cell the small circles use only a reduced area of size $(1-\varepsilon)\varepsilon_{cell} \times (1-\varepsilon)\varepsilon_{cell}$. Let $\mathcal{C}_S^*$ denote the small circles in OPT.

▶ **Lemma 10.** *In polynomial time, we can compute a set of grid cells $\mathcal{G}_w$ such that no grid cell in $\mathcal{G}_w$ intersects with any circle $C_i \in \mathcal{C}_L^*$ for any legal placement of C_i. Moreover, there is a set of small circles $\mathcal{C}_S \subseteq \mathcal{C}_S^*$ such that $w(\mathcal{C}_S) \geqslant (1-\varepsilon)w(\mathcal{C}_S^*)$ and the circles in $\mathcal{C}_S$ can be packed non-overlappingly inside $|\mathcal{G}_w|$ grid cells of size $(1-\varepsilon)\varepsilon_{cell} \times (1-\varepsilon)\varepsilon_{cell}$ each.*

We will prove Lemma 10 later in Section 3.3. Using it, we compute an approximation to the set $\mathcal{C}_S$ via Theorem 1.

We pack the computed circles into our grid cells $\mathcal{G}_w$, denote them by $\mathcal{C}_S'$. In particular, they do not intersect any of the large circles in $\mathcal{C}_L^*$ in any legal placement of them. Our solution (corresponding to the considered guesses) consists of $\mathcal{C}_L^* \cup \mathcal{C}_S'$. Recall that we can guarantee that these circles can be packed non-overlappingly inside the knapsack. Also, for the circles in $\mathcal{C}_S'$ we computed their placement *exactly* and for the circles in $\mathcal{C}_L^*$ we computed their placement up to our polynomially small error of ε/n. In Appendix A we show how to reduce this error to an exponentially small error.

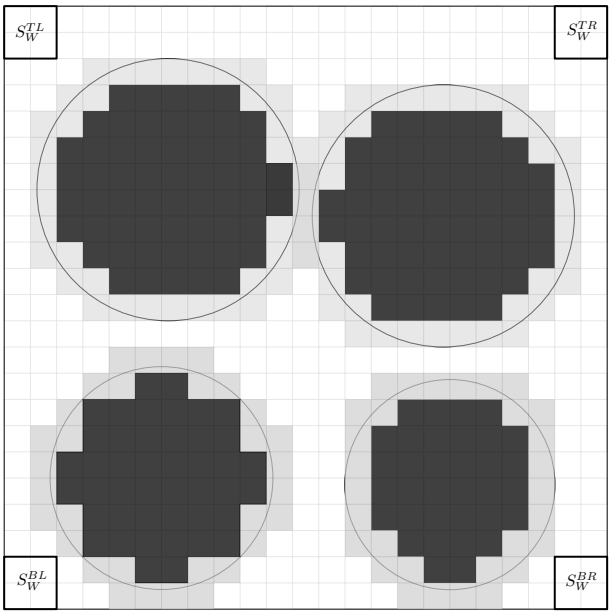

Figure 5 Partitioning grid cells into white, black and gray cells. Later corner regions $S_W^{BL}, S_W^{TL}, S_W^{BR}, S_W^{TR}$ are used to to pack items in gray cells.

3.3 Structural packing for small circles

In this section, we prove Lemma 10. First, we show that intuitively almost every small circle in $\mathcal{C}_S^*$ is contained inside some grid cell. Formally, we show that the total area of all other small circles in $\mathcal{C}_S^*$ is small. For any set $\mathcal{S}$ of circles or grid cells, we define $a(\mathcal{S})$ to be the total area of the elements in $\mathcal{S}$.

▶ **Lemma 11** ($\star$). *Let $\mathcal{C}_{cut} \subseteq \mathcal{C}_S^*$ be the set of all small circles in $\mathcal{C}_S^*$ that intersect more than one grid cell. We have that $a(\mathcal{C}_{cut}) \leqslant 8\varepsilon_{small}/\varepsilon_{cell} \leqslant \varepsilon\varepsilon_{large}^2/64$.*

We will repack the circles in $\mathcal{C}_{cut}$ later such that each of them is contained inside one single grid cell. Thus, for each small circle $C_i \in \mathcal{C}_{\mathsf{OPT}} \setminus \mathcal{C}_{cut}$ there is a grid cell $G_{\ell,\ell'}$ for some $\ell, \ell' \in \{0, 1, ..., 1/\varepsilon_{cell} - 1\}$ such that C_i is contained in $G_{\ell,\ell'}$ in OPT. When we select and place small circles, we must be careful that they do not intersect any large circles from $\mathcal{C}_L^*$. One difficulty for this is that we do not know the precise coordinates of the large circles. Therefore, we place small circles only into grid cells that do not overlap with any large circle from $\mathcal{C}_L^*$ in any legal placement of them. Formally, we partition the cells in $\mathcal{G}$ into three types: white, gray, and black cells (see Figure 5).

▶ **Definition 12.** Let $G_{\ell,\ell'} \in \mathcal{G}$ for some $\ell, \ell' \in \{0, 1, ..., 1/\varepsilon_{cell} - 1\}$. The cell $G_{\ell,\ell'}$ is

- *white* if $G_{\ell,\ell'}$ does not intersect with any circle $C_i \in \mathcal{C}_L^*$ for any legal placement of C_i,
- *black* if $G_{\ell,\ell'}$ is contained in some circle $C_i \in \mathcal{C}_L^*$ for any legal placement of C_i,
- *gray* if $G_{\ell,\ell'}$ is neither white nor black.

The gray cells are problematic for us since a gray cell might be (partially) covered by a large circle in $\mathcal{C}_L^*$ but we do not know by how much (and which part of the cell). Therefore, we do not place any small circles into gray cells. However, OPT might place small circles into these cells (and obtain the profit of these circles). On the other hand, we can show that the number of gray cells is very small, only a small fraction of all grid cells can be gray. In

order to do this, we use the fact that the values $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ for each circle $C_i \in \mathcal{C}_L^*$ estimate the placement of each large circle relatively accurately, and that the grid cells are relatively small. This allows us to prove that almost all cells are black or white. Also, we can compute all gray cells efficiently. Let $\mathcal{G}_g \subseteq \mathcal{G}$ denote the set of all gray grid cells in $\mathcal{G}$.

▶ **Lemma 13** (⋆). *The total area of gray cells $a(\mathcal{G}_g)$ is at most $\varepsilon\varepsilon_{large}^2/5$. We can compute $\mathcal{G}_g$ in polynomial time.*

Unfortunately, it is not sufficient for us that there are only few gray cells. It might be that almost all cells are either gray or black and, hence, we need to place most of the selected small circles into gray cells (in order to obtain an $(1+\varepsilon)$-approximate solution).

However, we can show that this is not the case. We prove that the number of white cells (which we can safely use for small circles) is at least by a factor $1/\varepsilon$ larger than the number of gray cells. To show this, we exploit the geometry of the circles. In each corner of the knapsack, there are cells that cannot intersect with any large circle, simply because the grid cells are small compared to the large circles and because of the shape of the large circles (see the corner regions in Figure 5). Hence, these grid cells are white. Let $\mathcal{G}_w \subseteq \mathcal{G}$ denote the set of all white grid cells in $\mathcal{G}$.

▶ **Lemma 14** (⋆). *The total area of white grid cells $a(\mathcal{G}_w)$ is at least $\varepsilon_{large}^2/4$. We can compute $\mathcal{G}_w$ in polynomial time.*

Using Lemmas 11, 13, and 14, we show that there is a $(1+\varepsilon)$-approximate solution in which each small circle is contained in some white cell; in particular, no small circle is placed inside a gray cell. To prove this, we delete all small circles in the $O(\varepsilon|\mathcal{G}_w|)$ white grid cells with the smallest total profit among all white cells and place all circles from gray cells and all circles from $\mathcal{C}_{cut}$ into those.

▶ **Lemma 15** (⋆). *There is a set $\mathcal{C}_S' \subseteq \mathcal{C}_S^*$ of small circles with $p(\mathcal{C}_S') \geqslant (1-\varepsilon)p(\mathcal{C}_S^*)$ such that there is a packing for $\mathcal{C}_S'$ using the grid cells in $\mathcal{G}_w$ only.*

We complete the proof of Lemma 10 by applying the following lemma to $\mathcal{C}_S := \mathcal{C}_S''$ which shows that we can sacrifice a factor of $1 + O(\varepsilon)$ to be able to use resource augmentation when we pack the small circles.

▶ **Lemma 16** (⋆). *There is a set of small circles $\mathcal{C}_S'' \subseteq \mathcal{C}_S'$ such that $w(\mathcal{C}_S'') \geq (1-\varepsilon)w(\mathcal{C}_S')$ and it is possible to place the circles in $\mathcal{C}_{\text{sml}}''$ non-overlappingly inside $|\mathcal{G}_w|$ square knapsacks of size $(1-\varepsilon)\varepsilon_{cell} \times (1-\varepsilon)\varepsilon_{cell}$ each.*

3.4 Higher dimensions

Our techniques from the previous section extend directly to the problem of packing hyperspheres in any (constant) dimension d which yields our main theorem for the setting of packing (hyper-)spheres.

▶ **Theorem 17** (⋆). *Let $d \in \mathbb{N}$ be a fixed constant. For the geometric knapsack problem with d-dimensional hyperspheres, there is a polynomial time algorithm that computes a set of hyperspheres $\tilde{\mathcal{C}}$ with $p(\tilde{\mathcal{C}}) \geqslant (1-\varepsilon)\mathsf{OPT}$ that can be placed non-overlappingly inside the knapsack. For all but $O_\varepsilon(1)$ hyperspheres in $\tilde{\mathcal{C}}$ we compute the precise coordinate of the corresponding packing; for the other $O_\varepsilon(1)$ circles we compute an estimate of the packing with an additive error of at most $\frac{1}{2^{n/\varepsilon}}$ in each dimension.*

4 Polygons

In this section, we adjust our techniques from the previous sections to obtain a PTAS for the case that each input object is a fat and convex polygon with at most a constant number of edges whose lengths differ by at most a constant factor, and such that each angle between adjacent edges is larger than $\pi/2$. These objects generalize regular polygons with greater than 4 sides.

Formally, we assume that we are given a set $\mathcal{P} = \{P_1, P_2, \dots, P_n\}$ of n polygons that are (f, α, q, t)-*well-behaved*, i.e., for each polygon $P_i \in \mathcal{P}$ we assume that

- P_i is fat, i.e., $r_i^{\text{out}}/r_i^{\text{in}} \leq f$ for some (global) constant $f \geq 1$, where r_i^{out} and r_i^{in} is the radius of the smallest circle containing P_i and the radius of the largest circle contained in P, respectively,
- the angle between any two consecutive edges of P_i is at least $\pi/2 + \alpha$, for some (global) constant $\alpha > 0$,
- P_i has at most q edges for some (global) constant q such that the lengths of any two of its edges differ at most by a factor of t.

For example, regular pentagons are $(2, \pi/10, 5, 1)$-well-behaved. For each polygon $P_i \in \mathcal{P}$ we denote by w_i its profit, and for a set of polygons $\mathcal{P}' \subseteq \mathcal{P}$ we denote by $w(\mathcal{P}') := \sum_{P_i \in \mathcal{P}'} w_i$ their total profit. For any object C we define its area to be $a(C)$, and for any collection of objects $\mathcal{A}$ we denote their total area by $a(\mathcal{A}) := \sum_{P_i \in A} a(P_i)$. We want to pack a subset of $\mathcal{P}$ non-overlappingly into the unit knapsack $K := [0,1]^2$. We do not allow rotations in our packing.

Let $\varepsilon > 0$. We require that $\varepsilon < g(f, \alpha, q, t)$ for a function g to be defined later. In contrast to the case with hyperspheres, we show that we can compute each coordinate of our packing exactly. We classify each polygon $P_i \in \mathcal{P}$ as large or small according to the respective value r_i^{in}. For this, we define values ε_{large} and ε_{small}. For technical reasons, we need that $\varepsilon_{small} \leq h(\varepsilon_{large})$ for some decreasing function $h : \mathbb{R} \to \mathbb{R}$ to be defined later.

▶ **Lemma 18.** ($\star$) *There is a set of global constants $\varepsilon^{(0)}, \dots, \varepsilon^{(1/\varepsilon)} \geqslant 0$ such that $\varepsilon^{(j)} = h(\varepsilon^{(j-1)})$ for each $j \in \{0, \dots, 1/\varepsilon - 1\}$ and a value $k \in \{0, \dots, 1/\varepsilon - 1\}$ with the following properties. If we define $\varepsilon_{large} := \varepsilon^{(k)}$ and $\varepsilon_{small} := \varepsilon^{(k+1)}$, then by losing a factor of $1 + \varepsilon$ in our approximation guarantee, we can assume that each polygon $P_i \in \mathcal{P}$ satisfies that $r_i^{\text{in}} \leq \varepsilon_{small}$ or $r_i^{\text{in}} > \varepsilon_{large}$.*

We guess the value $k \in \{0, \dots, 1/\varepsilon - 1\}$ due to Lemma 18 and define that a polygon $P \in \mathcal{P}$ is *large* if $r_i^{\text{in}} \geq \varepsilon^{(k-1)} = \varepsilon_{large}$ and *small* if $r_i^{\text{in}} < \varepsilon^{(k)} = \varepsilon_{small}$. We discard all input polygons that are neither large nor small. Similar to the case of hyperspheres, we guess the large polygons in OPT. Since they are fat, there can be only constantly many of them.

▶ **Proposition 19.** *Any feasible solution can contain at most $(1/\varepsilon)^{O(1)}$ large polygons.*

We now calculate the placement of the large polygons using a linear program. Define $\mathcal{P}_L^*$ to be the set of large polygons in OPT. Note that, since they are convex polygons instead of circles or hyperspheres, we can compute an *exact* placement of the polygons with *rational* coordinates. For this, we use the following approach, which was also noted by Abrahamsen et al. in [1]. Consider the placement of the polygons $\mathcal{P}_L^*$ in OPT. Each side e of each polygon $P_i \in \mathcal{P}_L^*$ is contained in a line $\{x : a_e x = b_e\}$ for some vector a_e and a scalar b_e. For each corner vertex v of each polygon $P_j \in \mathcal{P}_L^*$, we have that $a_e x \geq b_e$ or $a_e x \leq b_e$ (or both); we guess which of these cases applies. Let v_i be a special vertex for each polygon P_i defined as

a vertex with the least value of $x_i^{(1)}$. Then, the coordinates $(x_i^{(1)}, x_i^{(2)})$ of the special vertex v_i of each polygon $P_i \in \mathcal{P}_L^*$ satisfy a system of linear inequalities defined as follows. There are three types of inequalities:

- *Positivity constraints*: $x_i^{(1)}, x_i^{(2)} \geq 0, \forall P_i \in \mathcal{P}_L^*$
- *Packing constraints*: $\forall P_i, P_j \in \mathcal{P}_L^*$ any vertex v in polygon $P_j \neq P_i$ cannot lie inside P_i. A vertex v lies inside polygon P_i if it satisfies the inequalities described above.
- *Container constraints*: $\forall P_i \in \mathcal{P}_L^*$, $0 \leq x_i^{(1)} \leq a_i$ and $b_i \leq x_i^{(2)} \leq 1 - c_i$, where a_i, b_i, and c_i can be calculated exactly in constant time for a given polygon. They represent the maximum value of $x_{i,v}^{(1)} - x_i^{(1)}$, maximum value of $x_i^{(2)} - x_{i,v}^{(2)}$, and maximum value of $x_{i,v}^{(2)} - x_i^{(2)}$, where $x_{i,v}^{(1)}, x_{i,v}^{(2)}$ vary over all vertices v of polygon P_i.

From Proposition 19, we know that there can only be at most $(1/\varepsilon)^{O(1)}$ large polygons in OPT. We take all possible subsets $\mathcal{P}_L^*$ of this size and smaller from the set $\mathcal{P}$, which is polynomial in number. We compute a feasible solution of packing of these subsets P_L^* to it which is easy since it has only $O_{\varepsilon,k,f,\alpha,t,q}(1)$ variables and constraints for each subset for polynomially many subsets, by using the ellipsoid method.

Now for each guessed large subset P_L^*, we compute a near-optimal packing of the small polygons P_S^*. Our goal is to pack the small polygons in the bin with only a loss of ε-fraction of profit, corresponding to the guessed P_L^*. We then return the solution $P_L^* \cup P_S^*$ which has maximum weight over all guessed values of P_L^* initially and claim that this packing is near-optimal.

In order to pack small polygons, we need a corresponding version of Lemma 10. We define grid cells again similarly such that ε_{cell} is much smaller compared to ε_{large} and ε_{small} is much smaller compared to ε_{cell}. Intuitively, since our input polygons are well-behaved, we can prove that a certain amount of space is not used by the large polygons, similar to Lemma 14. To ensure this, we require that ε is sufficiently small, which in particular also yields a bound on ε_{cell}. Using this, we show that there are many grid cells that are disjoint from any large polygon (similarly as the white grid cells in Section 3).

▶ **Lemma 20.** ($\star$) *There is a function $g : \mathbb{R}^4_{\geq 0} \to \mathbb{R}_{\geq 0}$ such that if all given polygons are (f, α, q, t)-well-behaved and $\varepsilon < g(f, \alpha, q, t)$ then*

- *in polynomial time we can compute a set of grid cells $\mathcal{G}_w$ such that no grid cell in $\mathcal{G}_w$ intersects with any polygon $P_i \in \mathcal{P}_L^*$,*
- *there is a set of small polygons $\mathcal{P}_S \subseteq \mathcal{P}_S^*$ such that $w(\mathcal{P}_S) \geq (1 - O(\varepsilon))w(\mathcal{P}_S^*)$ for the optimal packing of large polygons, and*
- *the polygons in $\mathcal{P}_S$ can be packed non-overlappingly inside $|\mathcal{G}_w|$ grid cells that have size $(1-\varepsilon)\varepsilon_{cell} \times (1-\varepsilon)\varepsilon_{cell}$ each.*

We can prove Lemma 20 with similar techniques as we used in the proof of Lemma 10. In order to select and place the small polygons, we use the algorithm due to Theorem 1.

Let P_S^* denote our computed solution for the small polygons. We return the solution $\tilde{P} = P_L^* \cup P_S^*$ which has maximum weight over all initially guessed combinations for the polygons in P_L^* and their approximate coordinates.

▶ **Theorem 21.** *For any constants $f, q \geq 1$ and $t, \alpha > 0$ there is a PTAS for the geometric knapsack problem for (f, α, q, t)-*well-behaved *polygons.*

5 Conclusion

We almost settle the approximability of the geometric knapsack problem in the setting of packing spheres into a hypercube knapsack. However, it remains an open problem whether rational coordinates always suffice in an optimal packing. If not, it would be an interesting

question to determine the best approximation ratio one can obtain if we allow only rational coordinates for the centers of the circles (while the optimal packing has no such restrictions). It would be also interesting to obtain a PTAS for the case of d-dimensional fat convex objects. Another interesting but difficult open question is whether the case of convex but not necessarily fat input objects in the plane admits a PTAS. The best known result for this setting is only an $O(1)$-approximation in quasi-polynomial time (assuming polynomially bounded integral input data [33]). Already for the special case of axis-parallel rectangles, it is open whether a PTAS exists.

A Improving the precision of the large spheres

Recall that for each large circle $C_i \in \mathcal{C}_L^*$ we guessed its center in the optimal packing up to a polynomial error of $\frac{\varepsilon}{n}$. We improve this to only an exponential error of at most $\frac{1}{2^{n/\varepsilon}}$. To do this, we apply Theorem 9 with $\alpha := \Theta(\frac{1}{2^{n/\varepsilon}})$. This yields more precise estimates $\bar{x}_i^{(1)}, \bar{x}_i^{(2)}$ for each $C_i \in \mathcal{C}_L^*$. There is an important subtlety though: for our guessed coordinates $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ we can assume that they differ from the coordinates of OPT by at most our polynomial error of $\frac{\varepsilon}{n}$. For the new estimates $\bar{x}_i^{(1)}, \bar{x}_i^{(2)}$ we can *not* guarantee this: our subroutine from Theorem 9 possibly returns a solution that is (close to) feasible for the large circles, but not (close to) a solution that is feasible for the large and for the small circles. Because of this, we guessed the estimates $\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)}$ for each $C_i \in \mathcal{C}_L^*$, so that we can assume that these estimates really correspond to OPT and not just to some arbitrary solution to (1).

If it were true that there is always a $(1+\varepsilon)$-approximate solution in which the center of each circle has rational coordinates that can be encoded with a polynomially bounded number of bits, then we could choose α appropriately to compute it. More precisely, we could compute a range for each coordinate that contains only one rational number with a bounded number of bits, and we could compute this number afterward.

Detecting Disjoint Shortest Paths in Linear Time and More

Abstract

In the k-Disjoint Shortest Paths (k-DSP) problem, we are given a graph G (with positive edge weights) on n nodes and m edges with specified source vertices $s_1, \ldots, s_k$, and target vertices $t_1, \ldots, t_k$, and are tasked with determining if G contains vertex-disjoint (s_i, t_i)-shortest paths. For any constant k, it is known that k-DSP can be solved in polynomial time over undirected graphs and directed acyclic graphs (DAGs). However, the *exact* time complexity of k-DSP remains mysterious, with large gaps between the fastest known algorithms and best conditional lower bounds. In this paper, we obtain faster algorithms for important cases of k-DSP, and present better conditional lower bounds for k-DSP and its variants.

Previous work solved 2-DSP over weighted undirected graphs in $O(n^7)$ time, and weighted DAGs in $O(mn)$ time. For the main result of this paper, we present optimal *linear time* algorithms for solving 2-DSP on weighted undirected graphs and DAGs. Our linear time algorithms are algebraic however, and so only solve the detection rather than search version of 2-DSP (we show how to solve the search version in $O(mn)$ time, which is faster than the previous best runtime in weighted undirected graphs, but only matches the previous best runtime for DAGs).

We also obtain a faster algorithm for k-Edge Disjoint Shortest Paths (k-EDSP) in DAGs, the variant of k-DSP where one seeks edge-disjoint instead of vertex-disjoint paths between sources and their corresponding targets. Algorithms for k-EDSP on DAGs from previous work take $\Omega(m^k)$ time. We show that k-EDSP can be solved over DAGs in $O(mn^{k-1})$ time, matching the fastest known runtime for solving k-DSP over DAGs.

Previous work established conditional lower bounds for solving k-DSP and its variants via reductions from detecting cliques in graphs. Prior work implied that k-Clique can be reduced to $2k$-DSP in DAGs and undirected graphs with $O((kn)^2)$ nodes. We improve this reduction, by showing how to reduce from k-Clique to k-DSP in DAGs and undirected graphs with $O((kn)^2)$ nodes (halving the number of paths needed in the reduced instance). A variant of k-DSP is the k-Disjoint Paths (k-DP) problem, where the solution paths no longer need to be shortest paths. Previous work reduced from k-Clique to p-DP in DAGs with $O(kn)$ nodes, for $p = k + k(k-1)/2$. We improve this by showing a reduction from k-Clique to p-DP, for $p = k + \lfloor k^2/4 \rfloor$.

Under the k-Clique Hypothesis from fine-grained complexity, our results establish better conditional lower bounds for k-DSP for all $k \geq 4$, and better conditional lower bounds for p-DP for all $p \leq 4031$. Notably, our work gives the first nontrivial conditional lower bounds 4-DP in DAGs and 4-DSP in undirected graphs and DAGs. Before our work, nontrivial conditional lower bounds were only known for k-DP and k-DSP on such graphs when $k \geq 6$.

We thank Malte Renken and André Nichterlein for answering questions about previous work, as well as Matthias Bentert for telling us about his and his coauthors' work [3], which independently proves Theorem 6 from this paper. The first author additionally thanks Ryan Williams and Zixuan Xu for conversations about early versions of ideas presented here, and Yinzhan Xu for nice discussions about the arguments in this paper.

1 Introduction

Routing disjoint paths in graphs is a classical problem in computer science. For positive integer k, in the k-Disjoint Paths (k-DP) problem, we are given a graph G with n vertices and m edges, with specified source nodes $s_1, \ldots, s_k$ and target nodes $t_1, \ldots, t_k$, and are tasked with determining if G contains (s_i, t_i)-paths which are internally vertex-disjoint. Beyond being a natural graph theoretic problem to study, k-DP is important because of its deep connections with various computational tasks from the Graph Minors project [22].

Following a long line of research, the polynomial-time complexity of k-DP has essentially been settled: in directed graphs the 2-DP problem is NP-hard [18, Lemma 3], and so is unlikely to admit a polynomial time algorithm, while in undirected graphs k-DP can be solved in $\tilde{O}(m+n)$ time for $k = 2$ [24], and in $O(n^2)$ time or $m^{1+o(1)}$ time for any constant $k \geq 3$ [19, 20].

In this work we study an optimization variant of k-DP, the k-Disjoint Shortest Paths (k-DSP) problem. In k-DSP we are given the same input as in k-DP, but are now tasked with determining if the input contains (s_i, t_i)-*shortest* paths which are internally vertex-disjoint. This problem is interesting both because it is a natural graph algorithms question to investigate from the perspective of combinatorial optimization, and because understanding the complexity of k-DSP could lead to a deeper understanding of the interaction between shortest paths structures in graphs (analogous to how studying k-DP helped develop the rich theory surrounding forbidden minors in graphs).

Compared to k-DP, not much is known about the exact time complexity of k-DSP. In directed graphs, 2-DSP can be solved in polynomial time [6], but no polynomial-time algorithm (or NP-hardness proof) is known for k-DSP for *any* constant $k \geq 3$. In undirected graphs, it was recently shown that for any constant k, k-DSP can be solved in polynomial time [21]. However, the current best algorithms for k-DSP in undirected graphs run in $n^{O(k \cdot k!)}$ time, so in general this polynomial runtime is quite large for $k \geq 3$. For example, the current fastest algorithm for 3-DSP in undirected graphs takes $O(n^{292})$ time [4].

Significantly faster algorithms are known for detecting $k = 2$ disjoint shortest paths. The paper which first introduced the k-DSP problem in 1998 also presented an $O(n^8)$ time algorithm for solving 2-DSP in weighted[1] undirected graphs [15]. The first improvement for this problem came over twenty years later in [1], which presented an algorithm solving 2-DSP in weighted undirected graphs in $O(n^7)$ time, and in unweighted undirected graphs in $O(n^6)$

[1] Throughout, we assume that weighted graphs have positive edge weights.

time. Soon after, [4, Theorem 1] presented an even faster $O(mn)$ time algorithm for solving 2-DSP in the special case of unweighted undirected graphs.[2] The main result of our work is an optimal algorithm for 2-DSP in weighted undirected graphs.

▶ **Theorem 1.** *2-DSP can be solved in weighted undirected graphs in $O(m+n)$ time.*

This result pins down the true time complexity of 2-DSP in undirected graphs, and (up to certain limitations of our algorithm, which we discuss later) closes the line of research for this specific problem, initiated twenty-five years ago in [15].

As discussed previously, over directed graphs the 2-DP problem is NP-hard, and the complexity of k-DSP is open even for $k = 3$. This lack of algorithmic progress in general directed graphs has motivated researchers to characterize the complexity of disjoint path problems in restricted classes of directed graphs. In this context, studying algorithms for routing disjoint paths in directed acyclic graphs (DAGs) has proved to be particularly fruitful. For example, the only known polynomial time algorithm for 2-DSP on general directed graphs works by reducing to several instances of 2-DP on DAGs [6]. Similarly, the fastest known algorithm for k-DSP on undirected graphs works by reducing to several instances of disjoint paths on DAGs [4].

It is known that 2-DP in DAGs can be solved in linear time [25]. More generally, since 1980 it has been known that k-DP in DAGs can be solved in $O(mn^{k-1})$ time, and this remains the fastest known algorithm for these problems for all $k \geq 3$ [18, Theorem 3].

As observed in [6, Proposition 10], the algorithm of [18] for k-DP on DAGs can be modified to solve k-DSP in weighted DAGs in the same $O(mn^{k-1})$ runtime. This is the fastest known runtime for k-DSP in DAGs. In particular, the fastest algorithm for 2-DSP from previous work runs in $O(mn)$ time.

The second result of our work is an optimal algorithm for 2-DSP in weighted DAGs.

▶ **Theorem 2.** *2-DSP can be solved in weighted DAGs in $O(m+n)$ time.*

This settles the time complexity of 2-DSP in DAGs, and marks the first improvement over the $O(mn)$ time algorithm implied by [18] from over thirty years ago. The 2-DSP problem in weighted DAGs generalizes the 2-DP problem in DAGs, and so Theorem 2 also offers an alternate linear time algorithm for 2-DP in DAGs, which is arguably simpler than the previous approaches leading up to [25], many of which involved tricky case analyses and carefully constructed data structures.

Our algorithms for solving 2-DSP in undirected graphs and DAGs are algebraic, and work by testing whether certain polynomials, whose terms encode pairs of disjoint shortest paths in the input graph, are nonzero. As a consequence, the algorithms establishing Theorems 1 and 2 are randomized, and solve 2-DSP with high probability. Moreover, these algorithms determine whether the input graph has a solution, but do not explicitly return solution paths. So while our algorithms solve the decision problem 2-DSP, they do not solve the search problem of returning two disjoint shortest paths if they exist. This is a common limitation for algebraic graph algorithms.

The 2-DSP problem does admit a search to decision reduction – with $O(m)$ calls to an algorithm which detects whether a graph contains two disjoint shortest paths, we can actually find two disjoint shortest paths if they exist. Thanks to the algebraic nature of our algorithms, we can get a slightly better reduction, and find two disjoint shortest paths when they exist with only $O(n)$ calls to the algorithms from Theorems 1 and 2.

[2] It seems plausible that the method of [4] could be adapted to handle weighted undirected graphs as well, but such a generalization does not appear to currently be known.

▶ **Theorem 3.** *We can solve 2-DSP over weighted DAGs and undirected graphs, and find a solution if it exists, in $O(mn)$ time.*

So we can *find* two disjoint shortest paths in weighted undirected graphs in $O(mn)$ time (which still beats the previous fastest $O(n^7)$ time algorithm for weighted undirected graphs, and matches the previous fastest algorithm for *unweighted* undirected graphs), and in weighted DAGs in $O(mn)$ time (which only matches, rather than beats, the previous fastest runtime for 2-DSP in DAGs).

Finally, one can also consider *edge-disjoint* versions of all the problems discussed thus far. The k-Edge Disjoint Paths (k-EDP) and k-Edge Disjoint Shortest Paths (k-EDSP) problems are the same as the respective k-DP and k-DSP problems, except the solutions paths merely need to be edge-disjoint instead of internally vertex-disjoint.

For any constant k, there is a simple reduction from k-EDSP on n nodes and m edges to k-DSP on $O(m+n)$ nodes and $O(m)$ edges. Combining this reduction with Theorems 1 and 2, we get that we can solve 2-EDSP over weighted DAGs and undirected graphs in linear time as well.

▶ **Corollary 4.** *There is an algorithm solving 2-EDSP over weighted DAGs and undirected graphs in $O(m+n)$ time.*

More generally, for all $k \geq 3$ the fastest known algorithms for k-EDSP on DAGs in the literature work by reducing this problem to k-DSP using the reduction mentioned in the previous paragraph. Consequently, the current fastest algorithm for k-EDSP in DAGs runs in $O(m^k)$ time, which in dense graphs is much slower than the $O(mn^{k-1})$ time algorithm known for k-DSP. For the same reason, the fastest known algorithm for k-EDP in DAGs for $k \geq 3$ runs in $O(m^k)$ time.

Our final algorithmic result is that we can solve k-EDSP in weighted DAGs as quickly as the fastest known algorithms for k-DSP.

▶ **Theorem 5.** *The k-EDSP problem can be solved in weighted DAGs in $O(mn^{k-1})$ time.*

Since k-EDSP in weighted DAGs generalizes the k-EDP problem in DAGs, Theorem 5 also implies faster algorithms for this latter problem. Our algorithm is simple and employs the same general approach used by previous routines [18, 6] for this problem.

Lower Bounds

For $k \geq 3$, the known $O(mn^{k-1})$ algorithms for k-DP and k-DSP in DAGs have resisted any improvements over the past three decades. Thus, it is natural to wonder whether there is complexity theoretic evidence that solving these problems significantly faster would be difficult. Researchers have presented some evidence in this vein, in the form of reductions from the conjectured hard problem of detecting cliques in graphs.

Let $k = \Theta(1)$ be a positive integer. A *k-clique* is a collection of k mutually adjacent vertices in a graph. In the k-Clique problem,[3] we are given a k-partite graph G with vertex set $V_1 \sqcup \cdots \sqcup V_k$, where each part V_i has n vertices, and are tasked with determining if G contains a k-clique.

[3] This problem is sometimes referred to in the literature as k-Multicolored Clique. A folklore argument reduces from detecting a k-clique in an arbitrary n-node graph to the k-Clique problem as defined here, by making k copies of the input graph, and only including edges between different copies, e.g. as in [11, Proof of Theorem 13.7].

We can of course solve k-Clique in $O(n^k)$ time, just by trying out all possible k-tuples of vertices. Better algorithms for k-Clique are known, which employ fast matrix multiplication. Let ω denote the exponent of matrix multiplication (i.e., ω is the smallest real such that two $n \times n$ matrices can be multiplied in $n^{\omega+o(1)}$ time). Given positive reals a, b, c, we more generally write $\omega(a, b, c)$ to denote the smallest real such that we can compute the product of an $n^a \times n^b$ matrix and an $n^b \times n^c$ matrix in $n^{\omega(a,b,c)+o(1)}$ time. Then it is known that k-Clique can be solved in

$$C(n, k) = \Theta(n^{\omega(\lfloor k/3 \rfloor, \lceil (k-1)/3 \rceil, \lceil k/3 \rceil)})$$

time [16]. The current fastest matrix multiplication algorithms yield $\omega < 2.37156$ [28]. A popular fine-grained hardness hypothesis posits (e.g., in [27, 13]) that current algorithms for k-Clique are optimal.

▶ Hypothesis 1 (k-Clique Hypothesis). For any integer constant $k \geq 3$, solving k-Clique requires at least $C(n, k)^{1-o(1)}$ time.

In this context, previous work provided reductions from k-Clique to disjoint path problems. For example, [4] presents a reduction from k-Clique to $2k$-DSP on undirected graphs with $O((kn)^2)$ vertices (and this reduction easily extends to DAGs). Our first conditional lower bound improves this result for DAGs, by halving the number of paths needed in the reduction.

▶ **Theorem 6.** *There is a reduction from k-Clique to k-DSP on unweighted DAGs with $O((kn)^2)$ vertices, that runs in $O((kn)^2)$ time.*

▶ **Corollary 7.** *Assuming the k-Clique Hypothesis, k-DSP requires $C(n^{1/2}, k)^{1-o(1)}$ time to solve on unweighted DAGs.*

The previous reduction of [4] yields a weaker bound of $C(n^{1/2}, \lfloor k/2 \rfloor)^{1-o(1)}$ for the time needed to solve k-DSP, assuming the k-Clique Hypothesis. If $\omega > 2$, this earlier result only gives nontrivial (that is, superquadratic) lower bounds for $k \geq 10$, and if $\omega = 2$ is only nontrivial for $k \geq 14$. In comparison, if $\omega > 2$, Corollary 7 is nontrivial for $k \geq 5$, and if $\omega = 2$, Corollary 7 is still nontrivial for $k \geq 7$. See Table 1 for the concrete lower bounds we achieve for small k.

As mentioned before, the k-DSP problem in weighted DAGs generalizes k-DP in DAGs. However, the current fastest algorithms for k-DP have the same time complexity as the current best algorithms for the more general k-DSP problem. To explain this behavior, it is desirable to show conditional lower bounds for k-DP in DAGs, which are similar in quality to the known lower bounds for k-DSP in DAGs.

Such lower bounds have been shown by [10]. In particular, [10] together with standard reductions in parameterized complexity [11, Proofs of Theorems 14.28 and 14.30] implies that there is a reduction from k-Clique to $8k$-EDSP on graphs with $O((kn)^4)$ nodes. One can easily modify this reduction, using the idea in the construction from [5, Section 6], to instead reduce from k-Clique to $8k$-DSP on graphs with $O((kn)^4)$ nodes.

This reduction implies that k-DSP requires $C(n^{1/4}, \lfloor k/8 \rfloor)^{1-o(1)}$ time to solve on DAGs, assuming the k-Clique Hypothesis. For large k, this is the current best conditional lower bound for k-DP in DAGs. However, the blow-up in the graph size and parameter value in this reduction makes this lower bound irrelevant for small k (in fact, the reduction only yields nontrivial lower bounds under the k-Clique Hypothesis for $k \geq 96$).

For small values of k, better conditional lower bounds are known for k-DP. In particular, [23] presents reductions from k-Clique to p-DP and p-DSP on DAGs with $O(kn)$ vertices, for parameter value $p = k + \binom{k}{2}$. For our final conditional lower bound, we improve this reduction, by reducing the number of paths needed to $k + \lfloor k^2/4 \rfloor$.

▶ **Theorem 8.** *Let $k \geq 3$ be a constant integer, and set $p = k + \lfloor k^2/4 \rfloor$. There are $O((kn)^2)$ time reductions from k-Clique to p-DP and p-DSP on unweighted DAGs with $O(kn)$ vertices.*

Table 1 A list of lower bounds implied by Corollary 7 for k-DSP when $5 \leq k \leq 9$. Each row corresponds to a value of k. An entry of α in the left column of the row for a given k value indicates that solving k-DSP in $O(n^{\alpha-\delta})$ time for any constant $\delta > 0$ would require refuting the k-Clique Hypothesis or designing faster matrix multiplication algorithms. An entry of β in the right column in the row for a given k value indicates that assuming the k-Clique Hypothesis, k-DSP requires $n^{\beta-o(1)}$ time to solve. **The previous reduction of [4] gave no nontrivial lower bound for k-DSP for any value of k in this table**, and the reduction of [23] matches our lower bound for $k = 6$, but is worse everywhere else. Table entry values are based off rectangular matrix multiplication exponents from [28, Table 1].

k	k-DSP Exponent Lower Bound	
	(for current ω)	(if $\omega = 2$)
5	2.042	Trivial
6	2.371	Trivial
7	2.794	2.5
8	3.198	3
9	3.557	3

For each integer $p \geq 5$, we can find the largest integer $k \geq 3$ such that $k + \lfloor k^2/4 \rfloor \leq p$, and then apply Theorem 8 to obtain conditional lower bounds for p-DP and p-DSP on DAGs.

▶ **Corollary 9.** *Assuming the k-Clique Hypothesis, the p-DSP and p-DP problems require*

$$\max\left(C(n, k_{even}(p)), C(n, k_{odd}(p))\right)^{1-o(1)}$$

time to solve on unweighted DAGs for all integers $p \geq 5$, where

$$k_{even}(p) = 2\lfloor\sqrt{p+1}\rfloor - 2$$

and

$$k_{odd}(p) = 2\left\lfloor\frac{\sqrt{p+5}-1}{2}\right\rfloor - 1$$

are the largest even and odd integers k such that $k + \lfloor k^2/4 \rfloor \leq p$ respectively.

Assuming the k-Clique Hypothesis, Corollary 9 shows that 5-DSP requires at least $n^{\omega-o(1)}$ time and 8-DSP requires at least $C(n,4)^{1-o(1)}$ time to solve. For the current value of ω, these yield lower bounds of $n^{2.371-o(1)}$ for 5-DSP and $n^{3.198-o(1)}$ for 8-DSP, which are better than the lower bounds implied by Corollary 7 (see Table 1). If $\omega = 2$ however, Corollary 9 does not yield better lower bounds than Corollary 7 for k-DSP.

Previous reductions give nontrivial lower bounds for p-DP only when $p \geq 6$ if $\omega > 2$, and $p \geq 10$ if $\omega = 2$. In comparison, Corollary 9 yields nontrivial lower bounds for p-DP under the k-Clique Hypothesis for $p \geq 5$ if $\omega > 2$, and $p \geq 8$ if $\omega = 2$.

Previously, the reduction of [23] yielded the best lower bounds for p-DP for $p \leq 2016$, and otherwise the reduction of [10] yielded better lower bounds. In comparison, Corollary 9 yields lower bounds matching the reduction from [23] for $p \in \{6, 7, 10\}$, and otherwise, for $\omega > 2$, yields strictly better lower bounds for p-DP for all $p \geq 5$. Moreover, for $\omega = 2$, Corollary 9 yields the best lower bounds for p-DP for all $p \leq 4031$ (with [10] yielding better lower bounds only for larger p). To see quantitatively how Corollary 9 improves the best conditional lower bounds for p-DP from previous work at various concrete values of p, see Table 2.

Table 2 A list of lower bounds implied by Corollary 9 (and previous work) for p-DP at various values of p. Rows correspond to values of p. For a given such row, the entries α, β, γ in the three columns collected under the heading of "p-DP Exponent Lower Bound," read from left to right, indicate that Corollary 9, the reduction of [23], and the reduction of [10] imply that p-DP requires $n^{\alpha-o(1)}$, $n^{\beta-o(1)}$, and $n^{\gamma-o(1)}$ time to solve respectively, assuming the k-Clique Conecture.

1.1 Comparison with Previous Algorithms

Previous algorithms for 2-DSP and 2-DP in DAGs are combinatorial in nature: they observe certain structural properties of candidate solutions, and then leverage these observations to build up pairs of disjoint paths. In the special case of *unweighted* undirected graphs, [8] presented an algebraic algorithm for solving a generalization of 2-DSP, but all other prior algorithms for 2-DSP and 2-DP in undirected graphs are combinatorial. Our work is the first to employ algebraic methods to tackle the general weighted 2-DSP problem: our algorithms for 2-DSP on undirected graphs and DAGs work by checking that a certain polynomial, whose monomials correspond uniquely to pairs of disjoint shortest paths in the input graph, is nonzero. To obtain the fast runtimes in Theorems 1 and 2, we evaluate this polynomial over a field of characteristic two, and crucially exploit certain symmetries which make efficient evaluation possible when working modulo two.

Such "mod 2 vanishing" methods have appeared previously in the literature for algebraic graph algorithms, but the symmetries we exploit in our algorithms for 2-DSP differ in interesting ways from those of previous approaches. For example, previous methods tend to work exclusively in undirected graphs (relying on the ability to traverse cycles in both the forwards and backwards directions to produce terms in polynomials which cancel modulo 2), while our approach is able to handle 2-DSP in both undirected graphs and DAGs. It is also interesting that our algorithms solve 2-DSP in *weighted* graphs without any issue, since the previous algebraic graph algorithms we are aware of are efficient in unweighted graphs, but in weighted graphs have a runtime which depends polynomially on the value of the maximum edge weight.

Below, we compare our techniques to previous algebraic algorithms in the literature.

Two Disjoint Paths with Minimum Total Length

The most relevant examples of algebraic graph algorithms in the literature to our work are previous algorithms for the MinSum 2-DP problem: in this problem, we are given a graph G on n vertices, with specified sources s_1, s_2 and targets t_1, t_2, and are tasked with finding internally vertex-disjoint paths P_i from s_i to t_i, such that the sum of the lengths of P_1 and P_2 is minimized, or reporting that no such paths exists.

In *unweighted* undirected graphs, [7] showed that MinSum 2-DP can be solved in polynomial time, with [8, Section 6] providing a faster implementation of this approach running in $\tilde{O}(n^{4+\omega})$ time. Similar to our work, these algorithms check if a certain polynomial enumerating disjoint pairs of paths in G is nonzero or not. These methods rely on G being undirected, and are based off computing determinants of $n \times n$ matrices.

Our approach for 2-DSP differs from these arguments because we seek linear time algorithms, and so **avoid computing determinants** (which would yield $\Omega(n^\omega)$ runtimes). We instead directly enumerate pairs of intersecting paths and subtract them out. This alternate approach also allows us to obtain algorithms which apply to both undirected graphs and DAGs, whereas the cycle-reversing arguments of [8] do not appear to extend to DAGs.

Paths and Linkages with Satisfying Length Conditions

Given sets S and T of p source and target vertices respectively, an (S, T)-linkage is a set of p vertex-disjoint paths, beginning at different nodes in S and ending at different nodes in T. The length of such a linkage is the sum of the lengths of the paths it contains. Recent work has presented algorithms for the problem of finding (S, T)-linkages in undirected graphs of length at least k, fixed-parameter tractable in k. In particular, [17, Section 4] presents an algorithm solving this problem in $2^{k+p}\,\mathrm{poly}(n)$ time. Their algorithm enumerates collections of p walks beginning at different nodes in S and ending at different nodes in T. They then argue that all terms in this enumeration with intersecting walks cancel modulo 2, leaving only the (S, T)-linkages. One idea used in the above cancellation argument is that if two paths P and Q in a collection intersect at a vertex v, then we can pair this collection with a new collection obtained by swapping the suffixes of P and Q after vertex v.

In the 2-DSP problem, solution paths must connect sources s_i to corresponding targets t_i instead of to arbitrary targets, and so we cannot use the above suffix-swapping argument to get cancellation. So to enumerate disjoint shortest paths in our algorithms, we employ somewhat trickier cancellation arguments than what was previously used.

More recently, [14, Section 6] presented an algorithm solving the linkage problem discussed above in $2^k\,\mathrm{poly}(n)$ time (with runtime independent of p). Their approach uses determinants to enumerate (S, T)-linkages. As mentioned previously, we explicitly avoid using determinants so that we can obtain linear time algorithms.

Additional Related Work

There are many additional examples of algebraic graph algorithms in the literature. For example, [9] presents an efficient algorithm for finding shortest cycles through specified subsets of vertices, [12] presents algorithms for finding shortest cycles and perfect matchings in essentially matrix multiplication time, and [8] presents a polynomial time algorithm for finding a shortest cycle of even length in a directed graph. Even more examples of algebraic methods in parameterized algorithms are listed in [14, Table 1].

Bibliographic Remark

While the current paper was under submission, the work [3] of Bentert, Fomin, and Golovach was posted online. The reduction they use to establish [3, Theorem 1] is essentially the same as the reduction we use to prove Theorem 6, so this result was independently shown by [3].

Organization

In Section 2 we introduce notation and recall useful facts about graphs and polynomials used in our results. In Section 3 we provide some informal overviews for the proofs of our results. Full proofs of the results claimed in this paper can be found in the full version of this work [2]. We conclude in Section 4 by highlighting some open problems motivated by this work.

2 Preliminaries

General Notation

Given a positive integer a, we let $[a] = \{1, \ldots, a\}$ denote the set of the first a positive integers. Given positive integers a and b, we let $[a, b] = \{a, \ldots, b\}$ denote the set of consecutive integers from a to b inclusive (if $a > b$, then $[a, b]$ is the empty set).

Throughout, we let k denote a constant positive integer parameter.

Graph Notation and Assumptions

Throughout, we let G denote the input graph on n vertices and m edges. We let $s_1, \ldots, s_k$ denote the source vertices of G, and $t_1, \ldots, t_k$ denote the target vertices of G. A *terminal* is a source or target node. We assume without loss of generality that G is weakly connected (we can do this because we only care about solving disjoint path problems on G, and if terminals of G are in separate weakly connected components, we can solve smaller disjoint path problems on each component separately).

Given an edge $e = (u, v)$, we let $\ell(u, v)$ denote the weight of e in G. We assume all edge weights are positive. We let $\text{dist}(u, v)$ denote the distance of a shortest path (i.e., the sum of the weights of the edges used in a shortest path) from u to v. When we write "path P traverses edge (u, v)" we mean that P first enters u, then immediately goes to v.

We represent paths $P = \langle v_0, \ldots, v_r \rangle$ as sequences of vertices. If the path P passes through vertices u and v in that order, we let $P[u, v]$ denote the subpath of P which begins at u and ends at v. We let $\overleftarrow{P}$ denote the *reverse path* of P, which traverses the vertices of P in reverse order. Given two paths P and Q such that the final vertex of P is the same as the first vertex of Q, we let $P \diamond Q$ denote the concatenation of P and Q.

Shortest Path DAGs

Given a graph G and specified vertex s, the *s-shortest paths DAG of G* is the graph with the same vertex set as G, which includes edge (u, v) if and only if (u, v) is an edge traversed by an (s, v)-shortest path in G. From this definition, it is easy to see that a sequence of vertices is an (s, v)-shortest path of G if and only if it is an (s, v)-path in the s-shortest paths DAG of G. Indeed, every edge of an (s, v)-shortest path in G is contained in the s-shortest paths DAG by definition, and so forms a path in this graph. Conversely, if the sequence of vertices $P = \langle v_0, \ldots, v_r \rangle$ is an (s, v)-path in the s-shortest paths DAG of G, then we can inductively show that $P[s, v_i]$ is a shortest path in G for each index i.

We observe that shortest paths DAGs can be constructed in linear time.

▶ **Proposition 10** (Shortest Path DAGs). *Let G be a weighted DAG or undirected graph with distinguished vertex s. Then we can construct the s-shortest paths DAG of G in linear time.*

Proof. By definition, an edge (u, v) is in the s-shortest paths DAG of G if and only if (u, v) is the last edge of some (s, v)-shortest path in G. This is equivalent to the condition that (u, v) is an edge in G, and

$$\text{dist}(s, v) = \text{dist}(s, u) + \ell(u, v). \tag{1}$$

So, we can construct the s-shortest paths DAG of G by computing the values of $\text{dist}(s, v)$ for all vertices v, and then going through each edge (u, v) in G (if G is undirected, we try out both ordered pairs (u, v) and (v, u) of an edge $\{u, v\}$) and checking if Equation (1) holds.

So to prove the claim, it suffices to compute $\text{dist}(s, v)$ for all vertices v in linear time.

When G is a weighted DAG, we can compute a topological order of G in linear time, and then perform dynamic programming over the vertices in this order to compute $\text{dist}(s, v)$ for all vertices v in linear time (this procedure is just a modified breadth-first search routine).

When G is an undirected graph, we instead use Thorup's linear-time algorithm for single-source shortest paths in weighted undirected graphs [26] to compute $\text{dist}(s, v)$ for all vertices v. ◀

Finite Fields

Our algorithms for 2-DSP in undirected graphs and DAGs involve working over a finite field $\mathbb{F}_{2^q}$ of characteristic two, where $q = O(\log n)$. We work in the Word-RAM model with words of size $O(\log n)$, so that addition and multiplication over this field take constant time.

We make use of the following classical result, which shows that we can test if a polynomial is nonzero by evaluating it at a random point of a sufficiently large finite field.

▶ **Proposition 11** (Schwartz-Zippel Lemma)**.** *Let f be a nonzero polynomial of degree at most d. Then a uniform random evaluation of f over $\mathbb{F}$ is nonzero with probability at least $1 - d/|\mathbb{F}|$.*

3 Technical Overview

3.1 2-DSP Algorithms

We first outline a linear time algorithm solving 2-DP in DAGs. We then discuss the changes needed to solve the 2-DSP problem in weighted DAGs, and then the additional ideas used to solve 2-DSP in weighted undirected graphs.

Let G be the input DAG. For each edge (u, v) in G, we introduce an indeterminate x_{uv}. We assign each pair of paths in G a certain monomial over the x_{uv} variables, which records the pairs of consecutive vertices traversed by the paths. These monomials are constructed so that any pair of disjoint paths has a unique monomial.

Let F be the sum of monomials corresponding to all pairs of paths $\langle P_1, P_2 \rangle$ such that P_i is an (s_i, t_i)-path in G. Let F_{disj} and $F_{\cap}$ be the sums of monomials corresponding to all such pairs of paths which are disjoint and intersecting respectively. Since each disjoint pair of paths produces a distinct monomial, we can solve 2-DP by testing whether F_{disj} is a nonzero polynomial. We can perform this test by evaluating F_{disj} at a random point, by the Schwartz-Zippel lemma (Proposition 11).

Since every pair of paths is either disjoint or intersecting, we have

$$F = F_{\text{disj}} + F_{\cap}$$

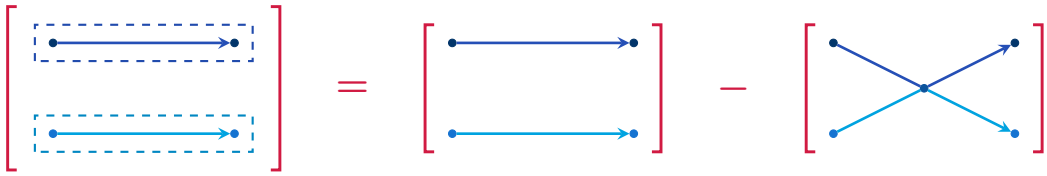

Figure 1 To enumerate the family of disjoint pairs of paths on the left (the dashed borders around the paths indicate that the paths do not intersect), it suffices to enumerate all pairs of paths and subtract out those pairs in the family which intersect at some point.

which implies that

$$F_{\text{disj}} = F - F_{\cap}.$$

This relationship is pictured in Figure 1.

Thus, in order to evaluate F_{disj}, it suffices to evaluate F and $F_{\cap}$. Since F enumerates pairs of paths from the sources to their corresponding targets with no constraints, it turns out that F is easy to evaluate. So solving 2-DP amounts to evaluating $F_{\cap}$ efficiently.

To evaluate $F_{\cap}$, we need a way of enumerating over all pairs of intersecting paths. Each pair of intersecting paths overlaps at a unique earliest vertex v (with respect to the topological order of G). Consequently, if we let F_v be the sum of monomials of pairs of intersecting paths with first intersection at v, we have

$$F_{\cap} = \sum_{v \in V} F_v \tag{2}$$

as depicted in Figure 3.

We evaluate each F_v by relating it to a seemingly simpler polynomial. Let $\tilde{F}_v$ be the polynomial enumerating pairs of paths $\langle P_1, P_2 \rangle$ where P_i is an (s_i, t_i)-path in G such that

1. P_1 and P_2 intersect at vertex v, and
2. the vertices appearing immediately before v on P_1 and P_2 are distinct.

We can think of property 2 as a relaxation of the condition that P_1 and P_2 have v as their earliest intersection point: instead of requiring that $P_1[s_1, v]$ and $P_2[s_2, v]$ never overlap before v, we merely require that these subpaths do not overlap at the position *immediately* before v. It turns out evaluating $\tilde{F}_v$ is easy, because we can enforce property 2 above by enumerating over all pairs of paths which intersect at v, and then subtracting out all such pairs which overlap at some edge ending at v. Simultaneously evaluating all $\tilde{F}_v$ can then be done in $O(m)$ time, roughly because we perform one subtraction for each possible edge the paths could overlap at.

So far, we have explained how to compute all $\tilde{F}_v$ values in linear time. Now comes the key idea behind our algorithm: over fields of characteristic two, the polynomials $\tilde{F}_v$ and F_v are actually identical! Indeed, consider a pair of paths $\langle P_1, P_2 \rangle$ enumerated by $\tilde{F}_v$, which intersects before v. Let the first intersection point of these paths be some vertex u. Then by condition 2 above, the subpaths $P_1[u, v]$ and $P_2[u, v]$ are distinct, because their penultimate vertices are distinct. So if we define new paths

$$Q_1 = P_1[s_1, u] \diamond P_2[u, v] \diamond P_1[v, t_1] \quad \text{and} \quad Q_2 = P_2[s_2, u] \diamond P_1[u, v] \diamond P_2[v, t_2]$$

obtained by swapping the u to v subpaths in P_1 and P_2, we get a new pair of paths $\langle Q_1, Q_2 \rangle$ satisfying conditions 1 and 2 from before, such that each Q_i is an (s_i, t_i)-path in G, which produces the same monomial as $\langle P_1, P_2 \rangle$. This subpath swapping operation is depicted in Figure 2, for $u = a$ and $v = b$. Then modulo two, the contributions of the pairs $\langle P_1, P_2 \rangle$

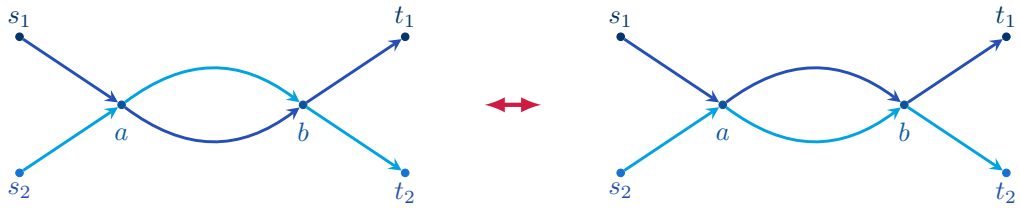

Figure 2 Given paths P_1 and P_2 which intersect at nodes $a = \alpha(P_1, P_2)$ and $b = \beta(P_1, P_2)$, such that a appears before b on both paths, if we swap the a to b subpaths of of P_1 and P_2 to produce new paths Q_1 and Q_2 respectively, then these pairs $f(P_1, P_2) = f(Q_1, Q_2)$ have the same monomials. Moreover, swapping the a to b subpaths of Q_1 and Q_2 recovers P_1 and P_2.

and $\langle Q_1, Q_2 \rangle$ to $\tilde{F}_v$ will cancel out. It follows that all pairs of paths which intersect before v have net zero contribution to $\tilde{F}_v$, and so $\tilde{F}_v = F_v$ as claimed. This congruence is depicted in Figure 4.

Given this observation, we can use our evaluations of $\tilde{F}_v$ in Equation (2) to evaluate $F_\cap$ and thus, by the previous discussion, solve the 2-DP problem.

From Disjoint Paths to Disjoint Shortest Paths

To solve 2-DSP in weighted DAGS, we can modify the 2-DP algorithm sketched above as follows. First, for $i \in [2]$, we compute G_i, the s_i-shortest paths DAG of G. We then construct polynomials as above, but with the additional constraint that they only enumerate pairs of paths $\langle P_1, P_2 \rangle$ with the property that every edge in path P_i lies in G_i. This ensures that we only enumerate pairs of paths which are shortest paths between their terminals.

With this change, the above algorithm for 2-DP generalizes to solving 2-DSP.

▶ Remark 12 (Enumeration Makes Generalization Easy). Previous near-linear time algorithms for 2-DP in DAGs and undirected graphs do not easily generalize to solving 2-DSP. In contrast, as outlined above, in our approach moving from 2-DP to 2-DSP is simple. Why is this?

Intuitively, this happens because our algorithms take an *enumerative* perspective on 2-DSP, rather than the detection-based strategy of previous algorithms. Older algorithms iteratively build up solutions to 2-DP or 2-DSP. Depending on the problem, this involves enforcing different sorts of constraints, since partial solutions to these problems may look quite different. In our approach, we just need to enumerate paths to solve 2-DP and enumerate shortest paths to solve 2-DSP. Enumerating paths and shortest paths are both easy in DAGs by dynamic programming. Hence algorithms for these two problems end up being essentially the same in our framework.

From DAGs to Undirected Graphs

When solving 2-DSP in DAGs, we used the fact that DAGs have a topological order, so that any pair of paths intersects at a unique earliest vertex v in this order. This simple decomposition does not apply to solving 2-DSP in undirected graphs, since we cannot rely on a fixed topological order.

Instead, we perform casework on the first vertex v in P_1 lying in $P_1 \cap P_2$. We observe that in undirected graphs, there are two possibilities: v is either the first vertex in P_2 lying in $P_1 \cap P_2$, or it is the final vertex in P_2 lying in $P_1 \cap P_2$. Intuitively, the paths either "agree" and go in the same direction, or "disagree" and go in opposite directions.

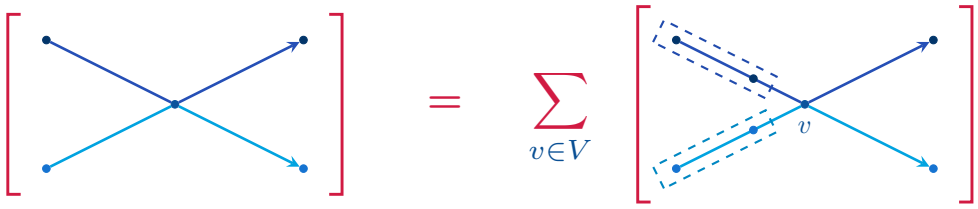

Figure 3 To enumerate the family of intersecting pairs of paths on the left, we can perform casework on the earliest intersection point v for the paths (the dashed border on the subpaths on the right indicates that the paths do not intersect before v).

We then argue that over a field of characteristic two, we can efficiently enumerate over pairs of paths in each of these cases. As with DAGs, we make this enumeration efficient by arguing that modulo 2 we can relax the (a priori difficult to check) condition of v being the first intersection point on P_1 to some simpler "local" condition. When the paths agree, this argument is similar to the reasoning used for solving 2-DSP in DAGs.

For the case where the paths disagree, this enumeration is more complicated, because there is no consistent linear ordering of the vertices neighboring v on the two shortest paths, but can still be implemented in linear time using a more sophisticated local condition. Specifically, if we let a_i and b_i denote the nodes appearing immediately before and after v on path P_i, then to enumerate the "disagreeing paths" modulo two, we prove that it suffices to enumerate paths P_1 and P_2 which intersect at v and have the properties that $a_1 \neq a_2$, $b_1 \neq b_2$, and $a_1 \neq b_2$. Intuitively, using the subpath swapping idea depicted in Figure 4, the conditions that $a_1 \neq a_2$ and $a_1 \neq b_2$ ensure that v is the first vertex of P_1 lying in $P_1 \cap P_2$, and the condition that $b_1 \neq b_2$ ensures that the paths disagree. To implement this idea, we need a slightly more complicated subpath swapping argument, which can also handle the case where two paths P_1 and P_2 intersect at vertices u and v, with u appearing before v on P_1 but u appearing after v on P_2 (this situation does not occur in DAGs, but can occur in undirected graphs). We do this by combining the previous subpath swapping idea with the observation that in undirected graphs we can also traverse subpaths in the reverse direction (so it is possible to swap the subpaths $P_1[u, v]$ and $P_2[v, u]$ in P_1 and P_2, even though u and v appear in different orders on P_1 and P_2).

By combining the enumerations for both cases, we can evaluate F_{disj}, and thus solve 2-DSP over undirected graphs.

3.2 k-EDSP Algorithm

The previous algorithm of [6, Proposition 10] for k-EDSP works by constructing a graph G' encoding information about k-tuples of edge-disjoint shortest paths in the original graph G. This new graph G' has special nodes $\vec{s}$ and $\vec{t}$, such that there is a path from $\vec{s}$ to $\vec{t}$ in G' if and only if G contains k edge-disjoint shortest paths connecting its terminals. The nodes of the new graph G' are k-tuples of edges $(e_1, \ldots, e_k)$ where each e_i is an edge in G. So constructing G' already takes $\Omega(m^k)$ time.

Our algorithm for k-EDSP uses the same general idea. We construct an alternate graph G' which still has the property that finding a single path between two specified vertices of G' solves the k-EDSP problem in G. However, we design G' to have nodes of the form $(v_1, \ldots, v_k)$, where each v_i is a *vertex* in G. Our construction produces a graph with n^k nodes and $O(mn^{k-1})$ edges, which yields the speed-up. We avoid the $\Omega(m^k)$ bottleneck of the previous algorithm by showing how to encode edge-disjointness information simply through the k-tuples of vertices, rather than edges, that the k potential solution paths in G traverse.

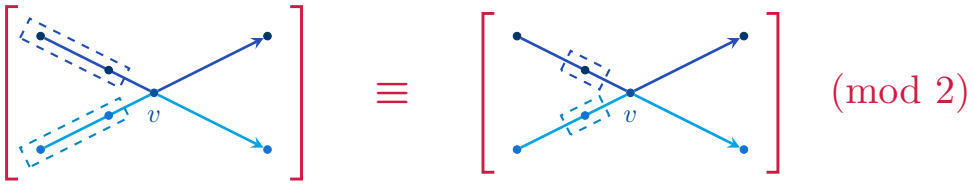

Figure 4 If we work modulo two, then we can enumerate pairs of paths which have common first intersection at node v by enumerating pairs of paths which intersect at v and have the property that the vertices appearing immediately before v on each path are distinct.

3.3 Lower Bounds

Disjoint Shortest Paths

Our proof of Theorem 6 is based on the reduction of [5, Proposition 1] from k-Clique to $2k$-DSP on undirected graphs, which also easily extends to DAGs. Our contribution is a transformation that reduces the number of paths in their reduction from $2k$ to k by exploiting the symmetry of the construction.

The reduction of [5] maps each vertex v in the k-Clique instance to a horizontal path P_v and a vertical path Q_v, each of length n. These paths are arranged so that for each pair of vertices (v, w) in the input graph, the paths P_v and Q_w intersect if and only if (v, w) is not an edge in the input graph. To achieve this, the paths are placed along a grid, and at the intersection point in the grid between paths P_v and Q_w, these two paths are modified to bypass each other to avoid intersection if (v, w) is an edge in the input graph.

The main idea of our transformation is the following. Since the known reduction is symmetric along the diagonal of the grid, it contains some redundancy. We remove this redundancy by only keeping the portion of the grid below the diagonal. To do this, we only have one path P_v for each vertex v in the input graph, and each such path has both a horizontal component and a vertical component. Each path turns from horizontal to vertical when it hits the diagonal. As a result, each pair of paths (P_v, P_w) has exactly one intersection point in the grid (which we bypass if (v, w) is an edge in the input graph). Since we produce only a single path P_v for each vertex v, we obtain a reduction to k-DSP instead of $2k$-DSP.

Disjoint Paths

The starting point for Theorem 8 is the work of [23], which reduces from k-Clique to p-EDP in a DAG with $O(kn)$ nodes, for $p = k + \binom{k}{2}$. The parameter blows up from k to p in this way because the reduction uses k solution paths to pick k vertices in the original graph, and then for each of the $\binom{k}{2}$ pairs of vertices chosen, uses an additional solution path to verify that the vertices in that pair are adjacent in the original graph.

We improve upon this by modifying the reduction graph to allow some solution paths to check multiple edges simultaneously. This lets us avoid using $\binom{k}{2}$ solution paths to separately check for edges between each pair of nodes in a candidate k-clique. Instead, we employ just $\lfloor k^2/4 \rfloor$ solution paths in the reduction, roughly halving the number of paths needed.

To do this, we need to precisely identify which paths can check for multiple edges without compromising the correctness of the reduction. To this end, we examine the structure of the reduction and define a notion of a *covering family* which characterizes which paths can safely check for multiple edges at once. Formally, a k-covering family is a collection $\mathcal{L}$ of increasing lists of positive integers, with the property that for all integers i, j with $1 \leq i < j \leq k$, some list in $\mathcal{L}$ contains i and j as consecutive members.

We show that for any k, the smallest number of lists in a k-covering family is $\lambda(k) = \lfloor k^2/4 \rfloor$ (note that merely obtaining asymptotically tight bounds would not suffice for designing interesting conditional lower bounds). We then insert this construction of a minimum size covering family into the framework of the reduction and prove that the reduction remains correct. Intuitively, given lists in a covering family, we can map each list L to a path which checks edges between vertex parts V_i and V_j for each (i, j) pair appearing as consecutive members of L.

The original reduction of [23] corresponds to implementing this strategy with the trivial k-covering family using $\binom{k}{2}$ lists, achieved by taking a single increasing list of two elements for each unordered pair of integers from $[k]$. Our improved reduction comes from implementing this framework with the optimal bound of $\lfloor k^2/4 \rfloor$ lists.

This yields reductions from k-Clique to p-DP and p-DSP for $p = k + \lambda(k) = k + \lfloor k^2/4 \rfloor$.

4 Conclusion

In this work, we obtained linear time algorithms for 2-DSP in undirected graphs and DAGs. These algorithms are based off algebraic methods, and as a consequence are *randomized* and only solve the *decision*, rather than search, version of 2-DSP. This motivates the following questions:

▶ Open 1. Is there a *deterministic* linear time algorithm solving 2-DSP?

▶ Open 2. Given a DAG or undirected graph G with sources s_1, s_2 and targets t_1, t_2, is there a linear time algorithm *finding* disjoint (s_i, t_i)-shortest paths in G for $i \in \{1, 2\}$?

It is also an interesting research direction to see if algebraic methods can help design faster algorithms for k-DSP in undirected graphs and DAGs when $k \geq 3$, or help tackle this problem in the case of general directed graphs.

In this work, we also established tighter reductions from finding cliques to disjoint path and shortest path problems. There still remain large gaps however, between the current best conditional lower bounds and current fastest algorithms for these problems.

▶ Open 3. Is there a fixed integer $k \geq 3$ and constant $\delta > 0$ such that k-DSP in DAGs can be solved in $O(n^{k+1-\delta})$ time? Or does some popular hypothesis rule out such an algorithm?

Since k-Clique admits nontrivial algorithms by reduction to matrix multiplication, it is possible that k-DSP can be solved faster using fast matrix multiplication algorithms. On the other hand, if we want to rule out this possibility and obtain better conditional lower bounds for k-DSP, we should design reductions from problems which are harder than k-Clique. In this context, a natural strategy would be to reduce from Negative k-Clique and 3-Uniform k-Hyperclique instead, since these problems are conjectured to require $n^{k-o(k)}$ time to solve (and it is not known how to leverage matrix multiplication to solve these problems faster than exhaustive search).

For all $k \geq 3$, the current fastest algorithm for k-DSP in undirected graphs takes $n^{O(k \cdot k!)}$ time, much slower than the $O(mn^{k-1})$ time algorithm known for the problem in DAGs. Despite this, every conditional lower bound that has been established for k-DSP in undirected graphs so far also extends to showing the same lower bound for the problem in DAGs. This is bizarre behavior, and suggests we should try establishing a lower bound which separates the complexities of k-DSP in undirected graphs and DAGs. If designing such a lower bound proves difficult, that would offer circumstantial evidence that far faster algorithms for k-DSP in undirected graphs exist.

▶ Open 4. Can we show a conditional lower bound for k-DSP in undirected graphs, which is stronger than any conditional lower bound known for k-DSP in DAGs?

Finally, for large k, the best conditional time lower bounds we have for k-DP in DAGs are far weaker than the analogous lower bounds we have for k-DSP in DAGs. This is despite the fact that the fastest algorithms we have for both problems run in the same time. It would nice to resolve this discrepancy, either by designing faster algorithms for the latter problem, or showing better lower bounds for the former problem.

▶ Open 5. Is there a fixed integer $k \geq 3$ such that we can solve k-DP in DAGs faster than we can solve k-DSP in weighted DAGs?

▶ Open 6. Can we show a conditional lower bound for k-DP in DAGs matching the best known conditional lower bound for k-DSP in DAGs?

Abstract

Many iterative algorithms in computer science require repeated computation of some algebraic expression whose input varies slightly from one iteration to the next. Although efficient data structures have been proposed for maintaining the solution of such algebraic expressions under low-rank updates, most of these results are only analyzed under exact arithmetic (real-RAM model and finite fields) which may not accurately reflect the more limited complexity guarantees of real computers. In this paper, we analyze the stability and bit complexity of such data structures for expressions that involve the inversion, multiplication, addition, and subtraction of matrices under the word-RAM model. We show that the bit complexity only increases linearly in the number of matrix operations in the expression. In addition, we consider the bit complexity of maintaining the determinant of a matrix expression. We show that the required bit complexity depends on the logarithm of the condition number of matrices instead of the logarithm of their determinant. Finally, we discuss rank maintenance and its connections to determinant maintenance. Our results have wide applications ranging from computational geometry (e.g., computing the volume of a polytope) to optimization (e.g., solving linear programs using the simplex algorithm).

1 Introduction

Computing algebraic expressions is a workhorse of many iterative algorithms in modern optimization, computational geometry, and dynamic algorithms. Examples include but are not limited to interior point methods for solving linear programs [30, 15, 29, 8, 10], iterative refinement for solving p-norm regression problems [13, 1, 2, 3, 28], semi-definite programming [26, 27], and many algorithmic graph theory problems [33, 11, 6, 14].

Such algebraic expressions are usually represented as matrix formulas involving matrices and operations such as inversion, multiplication, and addition/subtraction. In many iterative algorithms, the algebraic expression does not change over the course of the algorithm, and

only low-rank updates occur to the corresponding matrices from one iteration to the next. For example, for $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{n \times n}$, if we have $\mathbf{AB}$ from a previous iteration and one column of $\mathbf{B}$ changes in the next iteration, we can update $\mathbf{AB}$ in $O(n^2)$ time which is much faster than computing $\mathbf{AB}$ from scratch again. This has been exploited in many iterative algorithms to reduce the amortized cost of iteration and, therefore, the total running time of the algorithms.

A main component of this approach is the Sherman-Morrison-Woodbury (SMW) identity (see (1)), which informally states that the inverse of a rank-k perturbation of a matrix $\mathbf{A}$ can be obtained by a rank-k perturbation of $\mathbf{A}^{-1}$. Although this identity (also called *inverse maintenance*) has been used from the early days of optimization and control theory [31, 32], it was recently shown that *any matrix formula* involving only inversion, multiplication, and addition/subtraction operations can be maintained under low-rank updates with the Sherman-Morrison-Woodbury identity [9]. The main idea is to inductively construct a large matrix whose inverse contains a block that is precisely the output of the formula.

The result of [9] is under the *real-RAM model*, which assumes each arithmetic operation is carried over to infinite precision in constant time. Although this is a valid assumption for finite fields, it does not hold over real numbers. For example, in modern computers, floating-points are the number system of choice that only has a finite precision. Then, it is unclear whether such inverse maintenance techniques are sufficiently stable so that the downstream iterative algorithm outputs the correct solution (e.g., whether the iterative optimization algorithm converges).

Very recently, [24] analyzed the SMW identity over fixed-point arithmetic and showed that a bit complexity proportional to the logarithm of the condition number (ratio of the largest singular value to the smallest singular value) of the corresponding matrix is sufficient to guarantee the stability of the inverse maintenance over the *word-RAM model* in which the running time of arithmetic operations is proportional to the number of bits of corresponding numbers and only finite precision is guaranteed (and the precision itself depends on the number of utilized bits).

This implies that in order to show that the techniques of [9] also hold over the word-RAM model, we need to bound the condition number of the inductively constructed matrix for arbitrary matrix formulas. Indeed, we affirmatively show that the condition number of the constructed matrix is $\kappa^{O(s)}$, where κ is an upper bound for the condition numbers of the input matrices and s is the number of input matrices. This implies that a bit complexity of $O(s \log \kappa)$ is sufficient to guarantee the stability of dynamically updating the matrix formulas. We point out that a naive analysis would give a bound of $O(2^s \log \kappa)$ for the bit complexity, and our bound on the condition number is asymptotically tight since one can easily see that the product of s matrices each with condition number κ results in a matrix with condition number κ^s, e.g., consider $\mathbf{A}^s$.

In addition, we consider the stability and bit complexity of maintaining the determinant and rank of matrix formulas with inversion, multiplication, and addition/subtraction. An application of maintaining the determinant is in the faster computation of the volume of a polytope [22], and an application of the rank maintenance is in dynamic maximum matching [34].

To maintain the determinant of a matrix formula up to a multiplicative error of $(1 \pm \epsilon)$ for $0 < \epsilon < 1$, in addition to the inductively constructed matrix $\mathbf{N}$ of [9], we construct another matrix $\widehat{\mathbf{N}}$ and show that the determinant of the matrix formula is the ratio of $\det(\widehat{\mathbf{N}})$ to $\det(\mathbf{N})$. This then allows us to use the *matrix determinant lemma* (see (3)) to maintain the determinant. Although one might expect that we would require $\log \det(\mathbf{N})$ number of bits for determinant maintenance, we show that $O(s \log(\kappa/\epsilon))$ bits are sufficient. Note that

$\log \kappa$ is preferable to $\log \det$ since, for random matrices, the condition number is polynomial in the dimension of the matrix with high probability [19, 20] while the determinant is exponential [35].

We also consider rank maintenance over finite fields. This is because, under fixed-point arithmetic, we can multiply our matrices by a large number to obtain integer matrices and then perform all operations modulo a sufficiently large prime number ($\text{poly}(n)$ is sufficient). Then the rank of such matrix formula over $\mathbb{Z}_p$ is the same as the rank of the original matrix formula with high probability.

We believe optimizers and algorithm designers can use our results as black boxes to analyze their algorithms under the word-RAM model. The only additional part on their side is to analyze what error bounds can be tolerated in the corresponding algorithm while guaranteeing the returned outputs are correct. Then, our results provide the corresponding running time and bit complexity bounds for the required errors.

Our algorithmic results are presented as dynamic data structures in the next Section 1.1. They cover the most common update schemes occurring in iterative algorithms, such as updating one entry of the matrix and querying one entry or updating a column and querying a row.

Finally, to illustrate the effectiveness of our approach and results, we discuss two example applications. The first one, discussed in the full version, considers finding a basic solution of a set of linear constraints in the standard form $\mathbf{Ax} = \mathbf{b}$, $\mathbf{x} \geq 0$ where $\mathbf{A} \in \mathbb{R}^{d \times n}$ and $n \geq d$. The operations involved in this algorithm are similar to the simplex algorithm. Beling and Megiddo [5] presented two algorithms, a simple one with $O(d^2 n) = O(n^3)$ time, and a more complicated one with $O(d^{1.528} n) = O(n^{2.528})$ time. Both these algorithms assumed the real-RAM model ($O(1)$ time per arithmetic operation with infinite precision). We show that for $n = O(d)$, by simply plugging our data structures into the simple algorithm, the time complexity becomes $\widetilde{O}(n^{2.528} \log(\kappa \cdot \max \det))$ in bit complexity (i.e., number of bit operations). Here $\max \det$ is the maximum determinant over each square $d \times d$ submatrix, and κ is the maximum condition number over each $d \times d$ submatrix. In particular, for matrices with $\log \max \det = \text{poly} \log(n)$ (as is the case when modeling many combinatorial problems as linear programs), our worst-case running time (i.e., number of bit operations) is $\widetilde{O}(n^{2.528} \log \kappa)$. Thus, not only does the simple algorithm become competitive with the more complicated algorithm, but we also show that it can be efficiently implemented without the real-RAM assumptions.

The second example application is for dynamically maintaining the size of the maximum matching of a graph that goes through edge deletion, edge insertion, turning vertices on and off, and merging vertices. We show in the full-version that our rank maintenance data structure can be used for this purpose with a cost of $O(n^{1.405})$ arithmetic operations per update.

1.1 Our Results

Our first result is the following generic data structure that can maintain the value of any matrix formula. Here a matrix formula is any expression that can be written using the basic matrix operations of addition, subtraction, multiplication, and inversion.

▶ **Theorem 1.** *Suppose we are given a matrix formula $f(\mathbf{M}_1, \ldots, \mathbf{M}_s)$ with respective input matrices $\mathbf{M}_1, \ldots \mathbf{M}_s$, where $\|\mathbf{M}_i\|_{\mathrm{F}} \leq \kappa$ for all $i \in [s]$. Let n denote the sum of the number of rows and columns of all $\mathbf{M}_1, \ldots, \mathbf{M}_s$. We further assume that the result of each inversion within f also has Frobenius-norm bounded by κ: in other words, we assume that every*

internal inversion-node of the computation tree has a bounded condition number. Then, for $\epsilon > 0, \kappa > n$*, there exists data structures that are each initialized in time* $\widetilde{O}(n^\omega s \log(\kappa/\epsilon))$ *and have the following operations.*

The data structures have the following update and query operations (where each bullet is a different data structure)

- *Support entry updates and entry queries in* $\widetilde{O}(n^{1.405} s \log(\kappa/\epsilon))$ *time.*
- *Support entry updates in* $\widetilde{O}(n^{1.528} s \log(\kappa/\epsilon))$ *time and entry queries in* $O(n^{0.528} s \log(\kappa/\epsilon))$ *time.*
- *Support column updates and row queries in* $\widetilde{O}(n^{1.528} s \log(\kappa/\epsilon))$ *time.*
- *Support rank-1 updates and returning all entries of* $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ *in* $\widetilde{O}(n^2 s \log(\kappa/\epsilon))$ *time.*
- *Support column updates and row queries in the offline model (the entire sequence of column indices and row queries is given at the start) in* $\widetilde{O}(n^{\omega-1} s \log(\kappa/\epsilon))$ *update and query time.*

The outputs are all ϵ*-approximate, i.e. each entry is off by at most an additive* ϵ*. The stated time complexities depend on current bounds on fast matrix multiplication [37]. The precise dependencies are stated in Theorem 4.*

A similar result was previously proven in [9] using data structures from [33, 12], assuming $O(1)$ time per arithmetic operation and infinite precision. We extend this to the word-RAM model by analyzing the stability of this data structure under the fixed-point arithmetic.

In addition, we show that we can also maintain other properties of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ while receiving updates to the input matrices. We can maintain the determinant and the rank of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$. The following Theorem 2 and Theorem 3 are proven in the full version.

▶ **Theorem 2.** *Let* $\mathbf{M}_1 \in \mathbb{R}^{n_1 \times d_1}, ..., \mathbf{M}_s \in \mathbb{R}^{n_s \times d_s}$ *and* $n = \sum_{i=1}^{s} n_i + d_i$*. Then, there exists a dynamic determinant data structure that initializes in* $\widetilde{O}(n^\omega s \log(\kappa/\epsilon))$ *time on given accuracy parameters* $\epsilon > 0, \kappa > 2n$*, matrix formula* $f(\mathbf{M}_1, ..., \mathbf{M}_s)$*, and respective input matrices* $\mathbf{M}_1, \ldots, \mathbf{M}_s$*.*

The data structures support the maintenance of $\det(f(\mathbf{M}_1, ..., \mathbf{M}_s))$ *up to a multiplicative factor of* $1 \pm \epsilon$*. They have the following update operations (each bullet is a different data structure)*

- *Support entry updates to any* $\mathbf{M}_i$ *in* $\widetilde{O}(n^{1.405} s \log(\kappa/\epsilon))$ *time.*
- *Support column updates to any* $\mathbf{M}_i$ *in* $\widetilde{O}(n^{1.528} s \log(\kappa/\epsilon))$ *time.*
- *Support rank-1 updates to any* $\mathbf{M}_i$ *in* $\widetilde{O}(n^2 s \log(\kappa/\epsilon))$ *time.*

We assume that throughout all updates, $\|f(\mathbf{M}_1, ..., \mathbf{M}_s)\|_{\mathrm{F}} \leq \kappa$*,* $\|(f(\mathbf{M}_1, ..., \mathbf{M}_s))^{-1}\|_{\mathrm{F}} \leq \kappa$*, and* $\|\mathbf{M}_i\|_{\mathrm{F}} \leq \kappa$ *for all* i*, and the result of each inversion within* f *also has the Frobenius norm bounded by* κ*.*

▶ **Theorem 3.** *There exists a dynamic rank data structure that initializes in* $O(n^\omega)$ *arithmetic operations on given matrix formula* $f(\mathbf{M}_1, ..., \mathbf{M}_s)$*, and respective input matrices. Here,* n *is the sum of the number of rows and columns of all* $\mathbf{M}_1, ..., \mathbf{M}_s$*. The data structure maintains* $\mathrm{rank}(f(\mathbf{M}_1, ..., \mathbf{M}_s))$ *subject to entry updates to any* $\mathbf{M}_i$ *in* $O(n^{1.405})$ *arithmetic operations per update.*

This implies, for example, maintaining the size of the maximum matching in a dynamic graph undergoing edge insertions and deletions, turning vertices on/off, and also merging of vertices (see full version for details). Each such update to the graph takes $O(n^{1.405})$ time. This was previously achieved for edge insertions/deletions only [34, 12].

Theorem 3 gives bounds for rank maintenance over finite fields. It is usually assumed that operations over finite fields take $O(1)$ time. However, a more realistic running time is $\text{poly}\log(|\mathbb{F}|)$ if an isomorphism to polynomials of degree less than d over $\mathbb{Z}_p$ is given, where $|\mathbb{F}| = p^d$ is the size of the field. One approach to go beyond the finite fields for rank maintenance is to perform the operations modulo a random prime, which preserves the rank with constant probability. This has been leveraged in communication complexity literature [36, 23]. See Lemma 4.1 on [36].

1.2 Preliminaries

Notation. We denote matrices with bold uppercase letters and vectors with bold lowercase letters. We denote the Frobenius norm and the operator norm by $\|\cdot\|_{\text{F}}$ and $\|\cdot\|_2$, respectively. We define the condition number of an invertible matrix $\mathbf{M}$ as $\kappa(\mathbf{M}) := \|\mathbf{M}\|_2 \cdot \left\|\mathbf{M}^{-1}\right\|_2$. For simplicity of presentation, we use κ as an upper bound for the Frobenius norm of matrices and their inverses. However, since the condition number of matrices is scale-free, up to polynomial factors such an upper bound is equal to the condition number. When the corresponding matrix is clear from the context, we drop the argument and simply write κ. We denote entry (i, j) of $\mathbf{M}$ by $\mathbf{M}_{i,j}$, row i of $\mathbf{M}$ by $\mathbf{M}_{i:}$ and column j of $\mathbf{M}$ by $\mathbf{M}_{:j}$. For sets I and J, we write $(\mathbf{A})_{I,}$ to denote the rows with indices in I, $(\mathbf{A})_{,J}$ to denote the column with indices in J, and $(\mathbf{A})_{I,J}$ to denote the submatrix with rows with indices in I and columns with indices in J. We denote the $n \times n$ identity matrix by $\mathbf{I}^{(n)}$, and use $\mathbf{0}^{(i,j)}$ to denote the $i \times j$ all-zeros matrix. We denote the transposition of matrix $\mathbf{M}$ by $\mathbf{M}^\top$. We use $\widetilde{O}$ notation to omit polylogarithmic factors in n and polyloglog factors in κ/ϵ from the complexity, i.e., for function f, $\widetilde{O}(f) := O(f \cdot (\log n \cdot \log\log \frac{\kappa}{\epsilon})^c)$, where c is a constant. Further, we denote the set $\{1, \ldots, n\}$ by $[n]$. We denote the number of operations for multiplying an $n^a \times n^b$ matrix with an $n^b \times n^c$ matrix by $O(n^{\omega(a,b,c)})$ and use $O(n^\omega)$ as shorthand for $O(n^{\omega(1,1,1)})$. Finally, for $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $i \in [\min(m, n)]$, let σ_i denote the i'th largest singular value of $\mathbf{A}$.

Sherman-Morrison-Woodbury Identity [38]. Consider an invertible matrix $\mathbf{M} \in \mathbb{R}^{n \times n}$, and matrices $\mathbf{U} \in \mathbb{R}^{n \times r}, \mathbf{D} \in \mathbb{R}^{r \times r}, \mathbf{V} \in \mathbb{R}^{r \times n}$. If $\mathbf{D}$ and $(\mathbf{M} + \mathbf{UDV})^{-1}$ are invertible, then:

$$(\mathbf{M} + \mathbf{UDV})^{-1} = \mathbf{M}^{-1} - \mathbf{M}^{-1}\mathbf{U}(\mathbf{D}^{-1} + \mathbf{VM}^{-1}\mathbf{U})^{-1}\mathbf{VM}^{-1} \tag{1}$$

Schur complement. Consider the block matrix $\mathbf{M}$ given by:

$$\mathbf{M} = \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix},$$

where $\mathbf{A}$ and $\mathbf{D}$ are square matrices. Then if $\mathbf{D}$ is invertible, $\mathbf{M}/\mathbf{D} := \mathbf{A} - \mathbf{BD}^{-1}\mathbf{C}$ is called the *Schur complement* of block $\mathbf{D}$ of matrix $\mathbf{M}$. Similarly, if $\mathbf{A}$ is invertible, $\mathbf{M}/\mathbf{A} := \mathbf{D} - \mathbf{CA}^{-1}\mathbf{B}$ is the Schur complement of block $\mathbf{A}$ of $\mathbf{M}$. The Schur complement gives an inversion formula for block matrices. Particularly, we have the following fact:

Fact. If $\mathbf{A}$ and $\mathbf{M}/\mathbf{A}$ are invertible, then $\mathbf{M}$ is invertible and

$$\mathbf{M}^{-1} = \begin{bmatrix} \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{B}(\mathbf{M}/\mathbf{A})^{-1}\mathbf{CA}^{-1} & -\mathbf{A}^{-1}\mathbf{B}(\mathbf{M}/\mathbf{A})^{-1} \\ (\mathbf{M}/\mathbf{A})^{-1}\mathbf{CA}^{-1} & (\mathbf{M}/\mathbf{A})^{-1} \end{bmatrix}.$$

This can be easily verified by multiplication with $\mathbf{M}$.

The Frobenius norm over $\mathbb{R}$ satisfies non-negativity, homogeneity, and the triangle inequality. Specifically, we have that $\|\mathbf{A}\|_{\mathrm{F}} \geq 0$, $\|\beta\mathbf{A}\|_{\mathrm{F}} = |\beta| \|\mathbf{A}\|_{\mathrm{F}}$ and $\|\mathbf{A}+\mathbf{B}\|_{\mathrm{F}} \leq \|\mathbf{A}\|_{\mathrm{F}} + \|\mathbf{B}\|_{\mathrm{F}}$. Finally, when the product $\mathbf{AB}$ is defined, the Frobenius norm obeys the following sub-multiplicative property: $\|\mathbf{AB}\|_{\mathrm{F}} \leq \|\mathbf{A}\|_{\mathrm{F}} \|\mathbf{B}\|_{\mathrm{F}}$.

Our Computational Model. Our algorithms and analysis are under the fixed-point arithmetic. We present all of our analysis under fixed-point arithmetic except for the result of [17] for QR decomposition which is under floating-point arithmetic but we only use that result in a black-box way. In fixed-point arithmetic, each number is represented with a fixed number of bits before and after the decimal point, e.g., under fixed-point arithmetic with 6 bits, we can only present integer numbers less than 64. Addition/subtraction and multiplication of two numbers with n bits can be done in $\widetilde{O}(n)$ time in this model by using fast Fourier transform (FFT) – see [16, Chapter 30]. Division to an additive error of ϵ can also be performed in $\widetilde{O}(n + \log(1/\epsilon))$ time again with the help of FFT. In general, when we mention running time, we mean the number of bit operations. Otherwise, we specify the complexity is about the number of arithmetic operations.

Matrix Formula. Intuitively, a matrix formula is any formula involving matrices and the basic matrix operations of adding, subtracting, multiplying, or inverting matrices. E.g., $f(\mathbf{A},\mathbf{B},\mathbf{C},\mathbf{D}) = (\mathbf{AB}+\mathbf{C})^{-1}\mathbf{D}$ is a matrix formula.

Formally, a matrix formula $f(\mathbf{M}_1,...,\mathbf{M}_s)$ is a directed tree, where each input $\mathbf{M}_i$ is a leaf, and each matrix operation (addition, subtraction, multiplication, inversion) is an internal node. Nodes that represent addition, subtraction, or multiplication have two children, i.e. the two terms that are being added, subtracted, or multiplied. Inversion has only one child, the term being inverted. For example, for node v labeled "+", the subtree rooted at the left child and the subtree rooted at the right child represent formulas $g_{\text{left}}(\mathbf{M}_1,...,\mathbf{M}_k), g_{\text{right}}(\mathbf{M}_{k+1},...,\mathbf{M}_s)$, and the tree rooted at v represents $f(\mathbf{M}_1,...,\mathbf{M}_s) = g_{\text{left}}(\mathbf{M}_1,...,\mathbf{M}_k) + g_{\text{right}}(\mathbf{M}_{k+1},...,\mathbf{M}_s)$.

Note that since a formula is a tree, and not a DAG, and because there is no point in inverting something twice in succession, a formula (i.e., tree) with s input matrices (i.e., leaves) has at most $O(s)$ operations (i.e., internal nodes). Further, note that by formulas being trees, a leaf (input) can be used only once. For example, $(\mathbf{A}+\mathbf{B})\mathbf{A}$ is a formula with 3 inputs.

2 Technical Overview

Here we outline how we obtain our three main results Theorems 1–3. [9] proved a variant of Theorem 1 that assumed the "real-RAM model", i.e., exact arithmetic in only $O(1)$ time per operation. Modern computers do not provide this guarantee unless one uses up to $\Omega(n)$ bit, substantially slowing down each arithmetic operation and the overall algorithm. We show that the techniques by [9] also work with bounded accuracy and much smaller bit complexity. In particular, only $\widetilde{O}(s\log\kappa)$ bits are enough, as stated in Theorem 1.

Before we can outline how to obtain these results, we need to give a brief recap of [9]. This is done in Section 2.1. We outline in Section 2.2 how to prove that $\widetilde{O}(s\log\kappa)$-bit accuracy suffice, resulting in Theorem 1. At last, Section 2.3 outlines how to extend Theorem 1 to maintain determinant and rank of a matrix formula, i.e., prove Theorems 2 and 3.

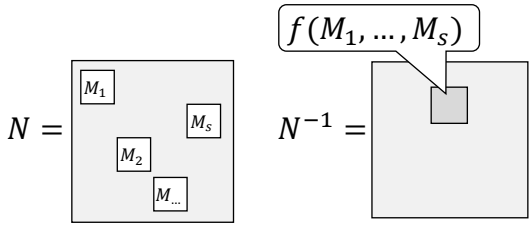

Figure 1 Maintaining $\mathbf{N}^{-1}$ allows us to maintain $f(\mathbf{M}_1, ..., \mathbf{M}_s)$.

2.1 Setting the Stage: How to Maintain Dynamic Algebraic Formulas

Dynamic Matrix Formula is the following data structures task: We are given a formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ and respective input matrices $\mathbf{M}_1, ..., \mathbf{M}_s$. The entries of these matrices change over time, and the data structure must maintain $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ (see Theorem 1). *Dynamic Matrix Inverse* is the special case $f(\mathbf{M}) = \mathbf{M}^{-1}$, i.e., given a matrix that changes over time, we must maintain information about its inverse. The latter problem has been studied in, e.g., [33, 12] and there exist several data structures for this task (see Theorem 7).

Previously, [9] showed that the dynamic matrix formula for any formula can be reduced to the special case of matrix inversion, i.e., dynamic matrix inverse. In particular, this means all the previous data structures for dynamic matrix inverse [33, 12] or simple application of the Sherman-Morrison-Woodbury identity (1), can also be used to maintain any general formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$. [9] shows that for any formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$, there is a large block matrix $\mathbf{N}$, where $\mathbf{M}_1, ..., \mathbf{M}_s$ occur as subblocks. Further, $\mathbf{N}^{-1}$ contains a block[1] that is precisely $f(\mathbf{M}_1, ..., \mathbf{M}_s)$. See Figure 1. When $\mathbf{M}_1, ..., \mathbf{M}_s$ change over time, matrix $\mathbf{N}$ changes over time, and running a dynamic matrix inverse data structures on this $\mathbf{N}$ allows us to maintain $\mathbf{N}^{-1}$ and its subblock containing $f(\mathbf{M}_1, ...\mathbf{M}_s)$.

The issue of the reduction is that we do not know if $\mathbf{N}$ is well-conditioned. Under which conditions to f and $\mathbf{M}_1, ..., \mathbf{M}_s$ can we guarantee that matrix $\mathbf{N}$ is well-conditioned? Once we can guarantee that $\mathbf{N}$ is well-conditioned, we can give good error guarantees for the dynamic matrix inverse data structures that maintain $\mathbf{N}^{-1}$ via the result of [24] regarding the numerical stability of SMW identity (see full version for details).

We will bound both $\|\mathbf{N}\|_{\mathrm{F}}$ and $\|\mathbf{N}^{-1}\|_{\mathrm{F}}$, which gives a bound on the condition number. In particular, we show that under reasonable assumptions on formula f and input $\mathbf{M}_1, ..., \mathbf{M}_s$, both Frobenius-norms are bounded by $\kappa^{O(s)}$ (Lemma 6). With the dynamic matrix inverse data structures' complexities scaling in the log of these Frobenius norms (see Theorem 7), this leads to the $\widetilde{O}(s \log \kappa)$ factors in Theorem 1.

2.2 Bounding the Frobenius Norms

As outlined in the previous subsection, when given a matrix formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$, [9] constructs a matrix $\mathbf{N}$ with the following properties. Matrix $\mathbf{N}$ contains $\mathbf{M}_1, ..., \mathbf{M}_s$ as subblock, and the inverse $\mathbf{N}^{-1}$ contains a subblock that is precisely $f(\mathbf{M}_1, ..., \mathbf{M}_s)$, see Figure 1. Our task is to bound the Frobenius-norm of both $\mathbf{N}$ and $\mathbf{N}^{-1}$, which then implies a bound on the condition number of $\mathbf{N}$. Further, data structures for maintaining $\mathbf{N}^{-1}$ have a runtime that scales in those norms (Theorem 7).

[1] The proof is constructive. Given $f, \mathbf{M}_1, ..., \mathbf{M}_s$, we know $\mathbf{N}$ and we know which submatrix of $\mathbf{N}^{-1}$ contains $f(\mathbf{M}_1, ..., \mathbf{M}_s)$, i.e., we do not have to search for the subblock.

Let us briefly recap how matrix $\mathbf{N}$ is constructed, so we can then analyze the Frobenius-norms of $\mathbf{N}$ and $\mathbf{N}^{-1}$.

Construction of N. The given formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ can be represented as a tree (where the operations like matrix product, sum, or inversion are nodes, the input matrices are leaves, and the output is the root). The construction of $\mathbf{N}$ follows by induction over the size of the tree: E.g., given some $f(\mathbf{M}_1, ..., \mathbf{M}_s) = g_1(\mathbf{M}_1, ..., \mathbf{M}_k) \cdot g_2(\mathbf{M}_{k+1}, ..., \mathbf{M}_s)$, by induction hypothesis there are matrices $\mathbf{N}_1, \mathbf{N}_2$ where $\mathbf{N}_i$ contains the input matrices of g_i as blocks, and a block of $\mathbf{N}_i^{-1}$ contains the evaluation of f_i. These two matrices are then combined into one larger matrix $\mathbf{N}$ (i.e., $\mathbf{N}$ contains $\mathbf{N}_1, \mathbf{N}_2$ as sub-blocks and thus $\mathbf{N}$ contains $\mathbf{M}_1, ..., \mathbf{M}_s$ as sub-blocks) with the property that $\mathbf{N}^{-1}$ contains a sub-block that is precisely $g_1(\mathbf{M}_1, ..., \mathbf{M}_k) \cdot g_2(\mathbf{M}_{k+1}, ...\mathbf{M}_s)$.

Here we will not go into the precise construction of $\mathbf{N}$ for the different arithmetic operations $f(\mathbf{M}_1, ..., \mathbf{M}_s) = g_1(\mathbf{M}_1, ..., \mathbf{M}_k) \circ g_2(\mathbf{M}_{k+1}, ..., \mathbf{M}_s)$. To follow the outline, it is only important to know that we perform induction by splitting the formula $f = g_1 \circ g_2$ at its root into g_1 and g_2 to obtain two smaller matrices $\mathbf{N}_1, \mathbf{N}_2$. If the root is an inversion, i.e., $f(\mathbf{M}_1, ..., \mathbf{M}_s) = (g(\mathbf{M}_1, ..., \mathbf{M}_s))^{-1}$, then we only have one matrix $\mathbf{N}'$ where $\mathbf{N}'^{-1}$ contains a sub-block that is $g(\mathbf{M}_1, ..., \mathbf{M}_s)$.

Bounding the Frobenius Norm (Section 3.1). For each possible operation $\circ \in \{+, -, \cdot\}$ at the root: $f(\mathbf{M}_1, ..., \mathbf{M}_s) = g_1(\mathbf{M}_1, ..., \mathbf{M}_k) \circ g_2(\mathbf{M}_{k+1}, ..., \mathbf{M}_s)$ there is a different construction for how to combine $\mathbf{N}_1, \mathbf{N}_2$ into a single $\mathbf{N}$, such that $\mathbf{N}^{-1}$ contains $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ as a submatrix. We bound the Frobenius-norm of $\mathbf{N}$ and $\mathbf{N}^{-1}$, with respect to the Frobenius-norms of $\mathbf{N}_1, \mathbf{N}_2$. This then implies a bound by induction. Since the construction of $\mathbf{N}$ differs depending on the operation $\circ \in \{+, -, \cdot\}$, we need slightly different proof for each operation. The proofs will all follow via simple applications of triangle inequalities. Since $\mathbf{N}$ is constructed so that $\mathbf{N}_1, \mathbf{N}_2$ are submatrices of $\mathbf{N}$, simple arguments via triangle inequality suffice. However, for the special case of $f(\mathbf{M}_1, ..., \mathbf{M}_s) = (g(\mathbf{M}_1, ..., \mathbf{M}_s))^{-1}$, a more careful analysis is required, which we outline below.

For $\mathbf{N}'$ being the matrix constructed for formula $g(\mathbf{M}_1, ..., \mathbf{M}_s)$, we have sets $I', J' \subset \mathbb{N}$ where $(\mathbf{N}'^{-1})_{I',J'} = g(\mathbf{M}_1, ..., \mathbf{M}_s)$ (i.e., this is the subblock that contains the evaluation of $g(\mathbf{M}_1, ..., \mathbf{M}_s)$). The reduction by [9] then constructs $\mathbf{N}$ as follows, and we state its inverse:

$$\mathbf{N} = \begin{bmatrix} \mathbf{N}' & -\mathbf{I}^{(n_{N'})}_{,J'} \\ \mathbf{I}^{(n_{N'})}_{I',} & \mathbf{0}^{(n_w, n_w)} \end{bmatrix}$$

$$\mathbf{N}^{-1} = \begin{bmatrix} \mathbf{N}'^{-1} - (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',} & (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'} \\ -(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',} & ((\mathbf{N}'^{-1})_{I',J'})^{-1} \end{bmatrix}$$

Note that the bottom right block of $\mathbf{N}^{-1}$ is precisely $g(\mathbf{M}_1, ..., \mathbf{M}_s)^{-1}$ since $(\mathbf{N}'^{-1})_{I',J'} = g(\mathbf{M}_1, ..., \mathbf{M}_s)$. To bound the Frobenius-norm of $\mathbf{N}$ and $\mathbf{N}^{-1}$, we apply the triangle inequality to

$$\begin{aligned} \|\mathbf{N}\|_{\mathrm{F}} &\leq \left\| \begin{bmatrix} \mathbf{N}' & 0 \\ 0 & 0 \end{bmatrix} \right\|_{\mathrm{F}} + \left\| \begin{bmatrix} 0 & -\mathbf{I}^{(n_{N'})}_{,J'} \\ \mathbf{I}^{(n_{N'})}_{I',} & 0 \end{bmatrix} \right\|_{\mathrm{F}} \\ &\leq \|\mathbf{N}'\|_F + \sqrt{|J'| + |I'|} \end{aligned}$$

We will have an upper bound on $\|\mathbf{N}'\|_{\mathrm{F}}$ by the inductive hypothesis, so this yields an upper bound on $\|\mathbf{N}\|_{\mathrm{F}}$ as well.

Using the triangle inequality similarly, we also can also bound $\|\mathbf{N}^{-1}\|_{\mathrm{F}}$ by

$$\begin{aligned}\|\mathbf{N}^{-1}\|_{\mathrm{F}} \leq &\left\|\mathbf{N}'^{-1} - (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',}\right\|_{\mathrm{F}} \\ &+ \left\|(\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'}\right\|_{\mathrm{F}} + \left\|(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',}\right\|_{\mathrm{F}} + \left\|(\mathbf{N}'^{-1})^{-1}_{I',J'}\right\|_{\mathrm{F}} \end{aligned} \tag{2}$$

We can split the sum by the triangle inequality, and products using $\|\mathbf{AB}\|_{\mathrm{F}} \leq \|\mathbf{A}\|_{\mathrm{F}}\|\mathbf{B}\|_{\mathrm{F}}$. If we naively upper bound $\|(\mathbf{N}'^{-1})_{I',}\|_{\mathrm{F}}$ and $\|(\mathbf{N}'^{-1})_{,J'}\|_{\mathrm{F}}$ using $\|(\mathbf{N}'^{-1})\|_{\mathrm{F}}$, we will get

$$\begin{aligned}&\|\mathbf{N}'^{-1} - (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',}\|_{\mathrm{F}} \\ &\quad\leq \|\mathbf{N}'^{-1}\|_{\mathrm{F}} + \|(\mathbf{N}'^{-1})_{,J'}\|_{\mathrm{F}}\|(\mathbf{N}'^{-1})^{-1}_{I',J'}\|_{\mathrm{F}}\|(\mathbf{N}'^{-1})_{I',}\|_{\mathrm{F}} \\ &\quad\leq \|\mathbf{N}'^{-1}\|_{\mathrm{F}} + \|(\mathbf{N}'^{-1})^{-1}_{I',J'}\|_{\mathrm{F}}\|(\mathbf{N}'^{-1})\|^2_{\mathrm{F}}\end{aligned}$$

and similarly for the other three terms of (2). This will yield an upper bound for $\|\mathbf{N}^{-1}\|_{\mathrm{F}}$, but it involves $\|(\mathbf{N}'^{-1})\|^2_{\mathrm{F}}$. In particular, the upper bound gets squared for every nested inverse gate, which will yield a bound that is in the order of κ^{2^s} (with $O(s)$ being a bound on the number of gates).

To improve this, we bound $\|(\mathbf{N}'^{-1})_{I',}\|_{\mathrm{F}}$ and $\|(\mathbf{N}'^{-1})_{,J'}\|_{\mathrm{F}}$ inductively as well. This removes the dependence on $\|(\mathbf{N}'^{-1})\|^2_{\mathrm{F}}$, so the upper bound no longer gets squared in every iteration, and becomes $\kappa^{O(s)}$ instead.

2.3 Dynamic Rank and Determinant of Matrix Formulas

So far, we outlined how to maintain $f(\mathbf{M}_1, ...\mathbf{M}_s)$ within finite precision. This is based on a reduction by [9] from the dynamic matrix formula to the dynamic matrix inverse. We now explain how to extend the reduction, allowing us to also maintain $\det(f(\mathbf{M}_1, ..., \mathbf{M}_s))$ and $\mathrm{rank}(f(\mathbf{M}_1, ..., \mathbf{M}_s))$.

Maintaining the Determinant. First, note that given a block matrix, we can represent its determinant as follows

$$\text{For } \mathbf{M} = \begin{bmatrix}\mathbf{A} & \mathbf{B}\\ \mathbf{C}^\top & \mathbf{D}\end{bmatrix} \text{ we have } \det(\mathbf{M}) = \det(\mathbf{A}) \cdot \det(\mathbf{D} - \mathbf{C}^\top\mathbf{A}^{-1}\mathbf{B}).$$

This allows for the following observation: Given $n \times n$ matrix $\mathbf{N}$ and sets $I, J \subset \mathbb{N}$ with $(\mathbf{N}^{-1})_{I,J} = f(\mathbf{M}_1, ..., \mathbf{M}_s)$, we have $(\mathbf{N}^{-1})_{I,J} = \mathbf{I}^{(n)}_{I,[n]}\mathbf{N}^{-1}\mathbf{I}^{(n)}_{[n],J}$ and thus

$$\widehat{\mathbf{N}} = \begin{bmatrix}\mathbf{N} & \mathbf{I}^{(n)}_{[n],J}\\ \mathbf{I}^{(n)}_{I,[n]} & \mathbf{0}\end{bmatrix} \text{ with } \det(f(\mathbf{M}_1, ..., \mathbf{M}_s)) = \det(\mathbf{I}^{(n)}_{I,[n]}\mathbf{N}^{-1}\mathbf{I}^{(n)}_{[n],J}) = \det(\widehat{\mathbf{N}})/\det(\mathbf{N}).$$

Thus, to maintain $\det(f(\mathbf{M}_1, ..., \mathbf{M}_s))$, we just need to maintain $\det(\widehat{\mathbf{N}})$ and $\det(\mathbf{N})$. Maintaining these determinants can be done via the determinant lemma, which states:

$$\det(\mathbf{N} + \mathbf{uv}^\top) = \det(\mathbf{N})(1 + \mathbf{v}^\top\mathbf{N}^{-1}\mathbf{u}). \tag{3}$$

Here adding $\mathbf{uv}^\top$ is a rank-1 update and can capture updates such as changing an entry of $\mathbf{N}$ (when $\mathbf{u}, \mathbf{v}$ have only 1 nonzero entry each) or changing a column of $\mathbf{N}$ (when v has only 1 nonzero entry). In particular, the task of maintaining $\det(\mathbf{N})$ reduces to the task of repeatedly computing $\mathbf{v}^\top\mathbf{N}^{-1}\mathbf{u}$. This is a dynamic matrix formula (since $\mathbf{u}, \mathbf{v}, \mathbf{N}$ change over time). For example, maintaining $\det(\mathbf{N})$ while $\mathbf{N}$ receives entry updates, requires us to

maintain $f(\mathbf{u}, \mathbf{v}, \mathbf{N}) = \mathbf{v}^\top \mathbf{N}^{-1}\mathbf{u}$ while $\mathbf{u}, \mathbf{v}, \mathbf{N}$ receive entry updates. Thus data structures for maintaining $\det(f(\mathbf{M}_1, ..., \mathbf{M}_s))$ (Theorem 2) are implied by data structures for dynamic matrix formula (Theorem 7), together with some additional error analysis performed in the full-version. A key observation in the error analysis is that the determinant is the product of the eigenvalues, and therefore, if we guarantee (with a sufficient number of bits) that the eigenvalues are preserved up to a multiplicative error factor of $1 \pm \frac{\epsilon}{10n}$, then we have determinant computation up to a multiplicative error factor of $1 \pm \epsilon$. We formalize this idea by bounding the determinant of a matrix perturbed by a small amount – see full version for details.

Maintaining the Rank. Let us assume that $\mathbf{M}_1, ..., \mathbf{M}_s$ are integer matrices, so $\mathbf{N}$ is an integer matrix as well. Note that w.h.p. $\text{rank}(\mathbf{N})$ is the same over $\mathbb{Z}$ and $\mathbb{Z}_p$ for prime $p \sim n^c$ and large enough constant c. So for the rank, we do not need to worry about rounding errors and can just focus on finite fields.

Sankowski [34] proved the following statement about matrix ranks. For any $n \times n$ matrix $\mathbf{M}$, and random $n \times n$ matrices $\mathbf{X}$ and $\mathbf{Y}$ (each entry is chosen uniformly at random from $\mathbb{Z}_p$), and $\mathbf{I}_k$ being a partial identity (the first k diagonal entries are 1, the remaining diagonal entries are 0), let

$$\overline{\mathbf{M}} = \begin{bmatrix} \mathbf{M} & \mathbf{X} & \mathbf{0} \\ \mathbf{Y} & \mathbf{0} & \mathbf{I}_n \\ \mathbf{0} & \mathbf{I}_n & \mathbf{I}_k \end{bmatrix}$$

Then with high probability, $\det(\overline{\mathbf{M}}) \neq 0 \iff \text{rank}(\mathbf{M}) \geq n - k$. In [34], this was used to maintain the rank of $\mathbf{M}$. We now generalize this to maintaining the rank of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$.

Given a formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$, let $g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k) = \mathbf{P} f(\mathbf{M}_1, ..., \mathbf{M}_s)\mathbf{Q} + \mathbf{R}_k$ where

$$\mathbf{P} = \mathbf{Q} = \begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \mathbf{R}_k = \begin{bmatrix} \mathbf{0} & \mathbf{X} & \mathbf{0} \\ \mathbf{Y} & \mathbf{0} & \mathbf{I} \\ \mathbf{0} & \mathbf{I} & \mathbf{I}_k \end{bmatrix},$$

we have

$$g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k) = \begin{bmatrix} f(\mathbf{M}_1, ..., \mathbf{M}_s) & \mathbf{X} & \mathbf{0} \\ \mathbf{Y} & \mathbf{0} & \mathbf{I}_n \\ \mathbf{0} & \mathbf{I}_n & \mathbf{I}_k \end{bmatrix}$$

Thus, $\det(g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k)) \neq 0 \iff \text{rank}(f(\mathbf{M}_1, ..., \mathbf{M}_s)) \geq n - k$. So we can track the rank of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ by finding and maintaining the smallest k where $\det(g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k)) \neq 0$. Note that with each changed entry to any $\mathbf{M}_i$, the rank can change by at most 1. So we can simply try increasing/decreasing k by performing a single entry update to $\mathbf{R}_k$ (and potentially reverting the update) to check if the $\det(g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k))$ becomes 0. Note that the determinant lemma (3) breaks once the matrix is no longer invertible.

Thus we must increase k whenever $\det(g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k)) = 0$. If an update causes the determinant to become 0, we must revert that update by reverting any internal changes of the data structure, then increase k, and then perform the reverted update again. This way, we always guarantee $\det(g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k)) \neq 0$ and that (3) never breaks. By always maintaining the largest k where $\det(g(\mathbf{M}_1, ..., \mathbf{M}_s, \mathbf{P}, \mathbf{Q}, \mathbf{R}_k)) \neq 0$, we know $n - k$ is the rank of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$.

3 Dynamic Matrix Formula

In this section, we prove the first main result: a generic data structure that can maintain the evaluation of any matrix formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ while supporting updates to the input matrices.

▶ **Theorem 4** (Detailed variant of Theorem 1). *Suppose we are given a matrix formula $f(\mathbf{M}_1, \ldots, \mathbf{M}_s)$ with respective input matrices $\mathbf{M}_1, \ldots \mathbf{M}_s$, where $\|\mathbf{M}_i\|_{\mathrm{F}} \leq \kappa$ for all $i \in [s]$. Let n denote the sum of the number of rows and columns of all $\mathbf{M}_1, \ldots, \mathbf{M}_s$. We further assume that the result of each inversion within f also has Frobenius-norm bounded by κ: in other words, we assume that every internal inversion-node of the computation tree has a bounded condition number. Then, for $\epsilon > 0, \kappa > n$ and any $0 \leq \nu \leq \mu \leq 1$, there exists data structures that are each initialized in time $\widetilde{O}(n^{\omega} s \log(\kappa/\epsilon))$ and have the following operations.*

The data structures have the following update and query operations (where each bullet is a different data structure)

- *Support entry updates and entry queries in $\widetilde{O}((n^{\omega(1,1,\mu)-\mu} + n^{\omega(1,\mu,\nu)-\nu} + n^{\mu+\nu}) s \log(\kappa/\epsilon))$ time. This is $\widetilde{O}(n^{1.405} s \log(\kappa/\epsilon))$ for $\nu \approx 0.543, \mu \approx 0.8612$.*
- *Support entry updates in $\widetilde{O}((n^{\omega(1,1,\mu)-\mu} + n^{1+\mu}) s \log(\kappa/\epsilon))$ time and entry queries in $O(n^{\mu} s \log(\kappa/\epsilon))$ time. This is $\widetilde{O}(n^{1.528} s \log(\kappa/\epsilon))$ and $O(n^{0.528} s \log(\kappa/\epsilon))$ for $\mu \approx 0.528$.*
- *Support column updates and row queries in $\widetilde{O}((n^{\omega(1,1,\mu)-\mu} + n^{1+\mu}) s \log(\kappa/\epsilon))$ time. This is $\widetilde{O}(n^{1.528} s \log(\kappa/\epsilon))$ for $\mu \approx 0.528$.*
- *Support rank-1 updates and returning all entries of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ in $\widetilde{O}(n^2 s \log(\kappa/\epsilon))$ time.*
- *Support column updates and row queries in the offline model (the entire sequence of column indices and row queries is given at the start) in $\widetilde{O}(n^{\omega-1} s \log(\kappa/\epsilon))$ update and query time.*

The outputs are all ϵ-approximate, i.e. each entry is off by at most an additive ϵ.

The explicit upper bound exponents were obtained via the tool of [7] and use the upper bounds on fast matrix multiplication by [37].

This result is obtained by reducing the task to the special case $g(\mathbf{N}) = \mathbf{N}^{-1}$, where the structure of matrix $\mathbf{N}$ depends on the formula f and its inputs $\mathbf{M}_1, ..., \mathbf{M}_s$.

We then run data structures (Theorem 7) that can maintain $\mathbf{N}^{-1}$ while supporting updates to $\mathbf{N}$. The accuracy of these data structures depends on $\|\mathbf{N}\|_F$ and $\|\mathbf{N}^{-1}\|_F$, so we must bound these Frobenius-norms. These bounds are given in Section 3.1. We then combine the bounds with the previous reduction to obtain Theorem 1 in Section 3.2.

3.1 Norm Bounds on Construction

In this section, we bound the Frobenius norm of the matrix produced by the reduction of [8], as well as its inverse. Formally, [8] has proven the following.

▶ **Theorem 5** (Theorem 3.1 of [9]). *Given a matrix formula $f(\mathbf{A}_1, ..., \mathbf{A}_p)$ over field $\mathbb{F}$, define $n := \sum_{i \in V} n_i + m_i$ where $n_i \times m_i$ is the dimension of $\mathbf{A}_i$.*

Then there exists a square matrix $\mathbf{N}$ of size at most $O(n) \times O(n)$, where each $\mathbf{A}_i$ is a block of $\mathbf{N}$. Further, if $f(\mathbf{A}_1, ..., \mathbf{A}_p)$ does not attempt to invert a non-invertible matrix then $(\mathbf{N}^{-1})_{I,J} = f(\mathbf{A}_1, \ldots, \mathbf{A}_p)$. Constructing $\mathbf{N}$ and I, J takes $O(n^2)$ time.

In the following Lemma 6 we retread the construction of matrix $\mathbf{N}$ and bound the Frobenius-norm.

▶ **Lemma 6.** *Let $f(\mathbf{A}_1, \ldots, \mathbf{A}_p)$ be a matrix formula over $\mathbb{R}$ using s gates. Suppose matrix $\mathbf{N}$, and index sets I, and J are constructed as in Theorem 5 so that $(\mathbf{N}^{-1})_{I,J} = f(\mathbf{A}_1, \ldots, \mathbf{A}_p)$. Let $\kappa \geq \max_i n_i + m_i \geq 2$, where $n_i \times m_i$ are the dimensions of $\mathbf{A}_i$.*

Then, if $\|\mathbf{A}_1\|_{\mathrm{F}}, \ldots, \|\mathbf{A}_p\|_{\mathrm{F}} \leq \kappa$, and the Frobenius norms of outputs of intermediate inverse gates are also bounded by κ, we have

$$\begin{aligned} \|\mathbf{N}\|_{\mathrm{F}} &\leq \kappa^s \\ \|\mathbf{N}^{-1}\|_{\mathrm{F}} &\leq (10\kappa)^{2s+1}. \end{aligned}$$

Proof. We bound $\|\mathbf{N}\|_{\mathrm{F}}$ and $\|\mathbf{N}^{-1}\|_{\mathrm{F}}$ by induction on the number of gates s. Note that the given formula f can be represented as a tree, where the input matrices are leaves and each operation is an internal node. For example $f(\mathbf{M}_1 ... \mathbf{M}_p) = g(\mathbf{M}_1, ..., \mathbf{M}_q) + h(\mathbf{M}_{q+1}, ..., \mathbf{M}_p)$ can be seen as a tree where the root node is a "+" with two subtrees for the formulas g and h. Each node that represents an operation has 2 children (or 1 child in case of inversion). We call the nodes also gates, e.g., inversion gate or addition gate, depending on what operation they represent.

Theorem 5 ([8]) constructs the matrix $\mathbf{N}$ by induction over the number of gates, i.e., for each gate w some matrix $\mathbf{N}_w$ is constructed. This $\mathbf{N}_w$ is constructed as a block matrix where some blocks are $\mathbf{N}_u, \mathbf{N}_v$ where u, v are the child gates of w. We also say that "$\mathbf{N}_w$ is returned by gate w".

Suppose matrix $\mathbf{N}$, and index sets I, and J are constructed as in Theorem 5 so that $(\mathbf{N}^{-1})_{I,J} = f(\mathbf{A}_1, \ldots, \mathbf{A}_p)$. We will show by induction on $s \geq 1$ (the number of gates in f) that:

$$\begin{aligned} \|\mathbf{N}\|_{\mathrm{F}} &\leq \kappa^s \\ \|(\mathbf{N}^{-1})_{I,J}\|_{\mathrm{F}} &\leq 2s\kappa \\ \|(\mathbf{N}^{-1})_{I,}\|_{\mathrm{F}} &\leq (5\kappa)^s \\ \|(\mathbf{N}^{-1})_{,J}\|_{\mathrm{F}} &\leq (5\kappa)^s \\ \|\mathbf{N}^{-1}\|_{\mathrm{F}} &\leq (10\kappa)^{2s+1} \end{aligned}$$

We now prove bounds on the output of our gates by assuming the induction hypothesis that their inputs have bounded norms. We start with the base case.

Input gate. The base case is when $s = 1$, in which case the formula $f(\mathbf{M}_v) = \mathbf{M}_v$ consists of a single input gate. The construction by [8] for Theorem 5 defines $\mathbf{N}$ as

$$\mathbf{N}^{-1} = \mathbf{N} = \begin{bmatrix} \mathbf{I}^{(n_v)} & \mathbf{M}_v \\ \mathbf{0}^{(m_v, n_v)} & -\mathbf{I}^{(m_v)} \end{bmatrix}$$

where $\mathbf{M}_v$ is the input matrix to the formula f and $n_v \times m_v$ are its dimensions. Selecting rows with indices in $I = \{1, ..., m_v\}$, and columns with indices in $J = \{n_v + 1, ..., n_v + m_v\}$, we get

$$\begin{aligned} (\mathbf{N}^{-1})_{,J} &= \begin{bmatrix} \mathbf{M}_v \\ -\mathbf{I}^{(m_v)} \end{bmatrix}, \\ (\mathbf{N}^{-1})_{I,} &= \begin{bmatrix} \mathbf{I}^{(n_v)} & \mathbf{M}_v \end{bmatrix}, \\ (\mathbf{N}^{-1})_{I,J} &= \begin{bmatrix} \mathbf{M}_v \end{bmatrix} \end{aligned}$$

Applying the triangle inequality to

$$\mathbf{N} = \begin{bmatrix} \mathbf{I}^{(n_v)} & \mathbf{0}^{(n_v,m_v)} \\ \mathbf{0}^{(m_v,n_v)} & -\mathbf{I}^{(m_v)} \end{bmatrix} + \begin{bmatrix} \mathbf{0}^{(n_v,n_v)} & \mathbf{M}_v \\ \mathbf{0}^{(m_v,n_v)} & \mathbf{0}^{(m_v,m_v)} \end{bmatrix}$$

and using the fact that $\sqrt{n_v + m_v} \leq \kappa$ and $\|\mathbf{M}_v\|_{\mathrm{F}} \leq \kappa$, we get

$$\begin{aligned} \|\mathbf{N}\|_{\mathrm{F}} &\leq \sqrt{n_v + m_v} + \|\mathbf{M}_v\|_{\mathrm{F}} \\ &\leq 2\kappa \end{aligned}$$

Similarly, we have that

$$\begin{aligned} \|(\mathbf{N}^{-1})_{I,J}\| &\leq \|\mathbf{M}_v\|_{\mathrm{F}} \leq \kappa^1 \\ \|(\mathbf{N}^{-1})_{I,}\| &\leq \|\mathbf{M}_v\|_{\mathrm{F}} + \sqrt{n_v} \leq 2\kappa \leq (5\kappa)^1 \\ \|(\mathbf{N}^{-1})_{,J}\| &\leq \|\mathbf{M}_v\|_{\mathrm{F}} + \sqrt{m_v} \leq 2\kappa \leq (5\kappa)^1 \\ \|\mathbf{N}^{-1}\|_{\mathrm{F}} &\leq \sqrt{n_v + m_v} + \|\mathbf{M}_v\|_{\mathrm{F}} \leq 2\kappa \leq (10\kappa)^3 \end{aligned}$$

We now consider the operation gates for the inductive step.

Inversion. Suppose the root gate is an inversion gate. Suppose $\mathbf{N}'$ is a $n_{N'} \times n_{N'}$ matrix and $I', J' \subset \mathbb{Z}$ are sets, such that $(\mathbf{N}'^{-1})_{I',J'}$ is the $n_w \times n_w$ matrix that the child gate w returns. The child gate is the root of a subtree with $a = s - 1 \geq 1$ gates, which implies bounds on the Frobenius-norm of $\mathbf{N}'$. The construction of Theorem 5 defines

$$\mathbf{N} = \begin{bmatrix} \mathbf{N}' & -\mathbf{I}^{(n_{N'})}_{,J'} \\ \mathbf{I}^{(n_{N'})}_{I',} & \mathbf{0}^{(n_w,n_w)} \end{bmatrix}$$

By block matrix inversion (Section 1.2), we have

$$\mathbf{N}^{-1} = \begin{bmatrix} \mathbf{N}'^{-1} - (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',} & (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'} \\ -(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',} & (\mathbf{N}'^{-1})^{-1}_{I',J'} \end{bmatrix}$$

Selecting the rows with indices in I, and columns with indices in J, we get

$$\begin{aligned} (\mathbf{N}^{-1})_{I,} &= \begin{bmatrix} -(\mathbf{N}'^{-1})^{-1}_{I',J'}(\mathbf{N}'^{-1})_{I',} & (\mathbf{N}'^{-1})^{-1}_{I',J'} \end{bmatrix} \\ (\mathbf{N}^{-1})_{,J} &= \begin{bmatrix} (\mathbf{N}'^{-1})_{,J'}(\mathbf{N}'^{-1})^{-1}_{I',J'} \\ (\mathbf{N}'^{-1})^{-1}_{I',J'} \end{bmatrix} \\ (\mathbf{N}^{-1})_{I,J} &= \begin{bmatrix} (\mathbf{N}'^{-1})^{-1}_{I',J'} \end{bmatrix} \end{aligned}$$

By the triangle inequality and the assumption that $\kappa \geq n_w \geq 1$,

$$\begin{aligned} \|\mathbf{N}\|_{\mathrm{F}} &\leq \|\mathbf{N}'\|_{\mathrm{F}} + \sqrt{2n_w} \\ &\leq 2a\kappa + 2\kappa \leq 2s\kappa \end{aligned}$$

By the assumption that the output of each inversion gate has Frobenius norm at most κ,

$$\|(\mathbf{N}^{-1})_{I,J}\|_{\mathrm{F}} = \|(\mathbf{N}'^{-1})^{-1}_{I',J'}\|_{\mathrm{F}} \leq \kappa \leq \kappa^s$$

For the remaining matrices, we can bound their Frobenius norms by the sum of Frobenius norms of their blocks, use the triangle inequality to split sums, and $\|\mathbf{AB}\|_{\mathrm{F}} \leq \|\mathbf{A}\|_{\mathrm{F}}\|\mathbf{B}\|_{\mathrm{F}}$ to split products, and then bound the resulting terms by the inductive hypothesis:

$$\begin{aligned}
\|(\mathbf{N}^{-1})_{I,}\|_{\mathrm{F}} &\leq \|(\mathbf{N}'^{-1})^{-1}_{I',J'}\|_{\mathrm{F}}(1 + \|(\mathbf{N}'^{-1})_{I',}\|_{\mathrm{F}}) \\
&\leq \kappa(1 + (5\kappa)^a) \leq \kappa \cdot 2(5\kappa)^a \leq (5\kappa)^{a+1} = (5\kappa)^s \\
\|(\mathbf{N}^{-1})_{,J}\|_{\mathrm{F}} &\leq \|(\mathbf{N}'^{-1})^{-1}_{I',J'}\|_{\mathrm{F}}(1 + \|(\mathbf{N}'^{-1})_{,J'}\|_{\mathrm{F}}) \\
&\leq \kappa(1 + (5\kappa)^a) \leq \kappa \cdot 2(5\kappa)^a \leq (5\kappa)^{a+1} = (5\kappa)^s \\
\|\mathbf{N}^{-1}\|_{\mathrm{F}} &\leq \|\mathbf{N}'^{-1}\|_{\mathrm{F}} + \|(\mathbf{N}'^{-1})^{-1}_{I',J'}\|_{\mathrm{F}}(\|(\mathbf{N}'^{-1})_{I',}\|_{\mathrm{F}} + 1)(\|(\mathbf{N}'^{-1})_{,J'}\|_{\mathrm{F}} + 1) \\
&\leq (10\kappa)^{2a+1} + \kappa((5\kappa)^a + 1)^2 \leq (10\kappa)^{2a+1} + \kappa(10\kappa)^{2a} \\
&\leq (10\kappa)^{2a+3} = (10\kappa)^{2s+1}
\end{aligned}$$

Addition and Subtraction. Suppose the root gate w is an addition gate, adding two $n_w \times m_w$ matrices. Suppose the subtree of the left child has $a \geq 1$ gates and the subtree of the right child has $b \geq 1$ gates, where $s = a + b + 1$. Let $\mathbf{L}$ be the $n_L \times n_L$ matrix and $\mathbf{R}$ be the a $n_R \times n_R$ matrix returned by the child gates, where $(\mathbf{L}^{-1})_{I_L,J_L}$ and $(\mathbf{R}^{-1})_{I_R,J_R}$ are $n_w \times m_w$ matrices. The matrix $\mathbf{N}$ for parent (addition) gate w is defined as

$$\mathbf{N} = \begin{bmatrix} \mathbf{L} & \mathbf{0} & \mathbf{I}^{(n_L)}_{,J_L} & \mathbf{0} \\ \mathbf{0} & \mathbf{R} & \mathbf{I}^{(n_R)}_{,J_R} & \mathbf{0} \\ \mathbf{I}^{(n_L)}_{I_L,} & \mathbf{I}^{(n_R)}_{I_R,} & \mathbf{0} & \mathbf{I}^{(n_w)} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}^{(m_w)} & \mathbf{0} \end{bmatrix}$$

$$\mathbf{N}^{-1} = \begin{bmatrix} \mathbf{L}^{-1} & \mathbf{0} & \mathbf{0} & -(\mathbf{L}^{-1})_{,J_L} \\ \mathbf{0} & \mathbf{R}^{-1} & \mathbf{0} & -(\mathbf{R}^{-1})_{,J_R} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}^{(m_w)} \\ -(\mathbf{L}^{-1})_{I_L,} & -(\mathbf{R}^{-1})_{I_R,} & \mathbf{I}^{(n_w)} & (\mathbf{L}^{-1})_{I_L,J_L} + (\mathbf{R}^{-1})_{I_R,J_R} \end{bmatrix}$$

Selecting the rows of $\mathbf{N}^{-1}$ with indices in I and columns with indices in J, we get

$$(\mathbf{N}^{-1})_{I,} = \begin{bmatrix} -(\mathbf{L}^{-1})_{I_L,} & -(\mathbf{R}^{-1})_{I_R,} & \mathbf{I}^{(n_w)} & (\mathbf{L}^{-1})_{I_L,J_L} + (\mathbf{R}^{-1})_{I_R,J_R} \end{bmatrix}$$

$$(\mathbf{N}^{-1})_{,J} = \begin{bmatrix} -(\mathbf{L}^{-1})_{,J_L} \\ -(\mathbf{R}^{-1})_{,J_R} \\ \mathbf{I}^{(m_w)} \\ (\mathbf{L}^{-1})_{I_L,J_L} + (\mathbf{R}^{-1})_{I_R,J_R} \end{bmatrix}$$

$$(\mathbf{N}^{-1})_{I,J} = \begin{bmatrix} (\mathbf{L}^{-1})_{I_L,J_L} + (\mathbf{R}^{-1})_{I_R,J_R} \end{bmatrix}$$

We now bound the Frobenius norms of these matrices using the bounds on $\|\mathbf{L}\|_{\mathrm{F}}$, $\|\mathbf{L}^{-1}\|_{\mathrm{F}}$, $\|(\mathbf{L}^{-1})_{I_L,}\|_{\mathrm{F}}$, $\|(\mathbf{L}^{-1})_{,J_L}\|_{\mathrm{F}}$, $\|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}}$, and similarly for $\mathbf{R}^{-1}$, that we get from the inductive hypothesis. Using the triangle inequality and the assumption that $\kappa \geq n_w + m_w$, and that $\|\mathbf{L}\|_{\mathrm{F}} \leq 2a\kappa$ and $\|\mathbf{R}\|_{\mathrm{F}} \leq 2b\kappa$ by the inductive hypothesis,

$$\begin{aligned}
\|\mathbf{N}\|_{\mathrm{F}} &\leq \|\mathbf{L}\|_{\mathrm{F}} + \|\mathbf{R}\|_{\mathrm{F}} + \sqrt{3n_w + 3m_w} \\
&\leq 2a\kappa + 2b\kappa + 2\kappa \leq 2(a + b + 1)\kappa = 2s\kappa
\end{aligned}$$

Similarly, we get:

$$\begin{aligned}
\|(\mathbf{N}^{-1})_{I,J}\|_{\mathrm{F}} &\le \|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{I_R,J_R}\|_{\mathrm{F}} \\
&\le \kappa^a + \kappa^b \le 2\kappa^{a+b} \le \kappa^{a+b+1} = \kappa^s \\
\|(\mathbf{N}^{-1})_{I,}\|_{\mathrm{F}} &\le \|(\mathbf{L}^{-1})_{I_L,}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{I_R,}\|_{\mathrm{F}} + \|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{I_R,J_R}\|_{\mathrm{F}} + \sqrt{n_w} \\
&\le (5\kappa)^a + (5\kappa)^b + \kappa^a + \kappa^b + \kappa \le 5(5\kappa)^{a+b} \le (5\kappa)^{a+b+1} = (5\kappa)^s \\
\|(\mathbf{N}^{-1})_{,J}\|_{\mathrm{F}} &\le \|(\mathbf{L}^{-1})_{,J_L}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{,J_R}\|_{\mathrm{F}} + \|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{I_R,J_R}\|_{\mathrm{F}} + \sqrt{m_w} \\
&\le (5\kappa)^a + (5\kappa)^b + \kappa^a + \kappa^b + \kappa \le 5(5\kappa)^{a+b} \le (5\kappa)^{a+b+1} = (5\kappa)^s
\end{aligned}$$

$$\begin{aligned}
\|\mathbf{N}^{-1}\|_{\mathrm{F}} &\le \|\mathbf{L}^{-1}\|_{\mathrm{F}} + \|\mathbf{R}^{-1}\|_{\mathrm{F}} + \|(\mathbf{L}^{-1})_{I_L,}\|_{\mathrm{F}} + \|(\mathbf{L}^{-1})_{,J_L}\|_{\mathrm{F}} \\
&\qquad + \|(\mathbf{R}^{-1})_{I_R,}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{,J_R}\|_{\mathrm{F}} + \sqrt{n_w + m_w} \\
&\le (10\kappa)^{2a+1} + (10\kappa)^{2b+1} + 2(5\kappa)^a + 2(5\kappa)^b + \kappa \\
&\le 7(10\kappa)^{2a+2b+1} \le (10\kappa)^{2a+2b+3} = (10\kappa)^{2s+1}
\end{aligned}$$

Subtraction gates are the same as addition gates except that the $\mathbf{I}^{(n_R)}_{,J_R}$ in the second row, third column of $\mathbf{N}$ is replaced by $-\mathbf{I}^{(n_R)}_{,J_R}$. The norm-bounding computations are then the same except for irrelevant sign changes.

Multiplication. Suppose the root gate is a multiplication gate. Suppose the left child has $a \ge 1$ gates and the right child has $b \ge 1$ gates, where $s = a + b + 1$. Let $\mathbf{L}$ be the $n_L \times n_L$ matrix and $\mathbf{R}$ be the $n_R \times n_R$ matrix such that the outputs of the child gates are $(\mathbf{L}^{-1})_{I_L,J_L}$ and $(\mathbf{R}^{-1})_{I_R,J_R}$.

$$\begin{aligned}
\mathbf{N} &= \begin{bmatrix} \mathbf{L} & -\mathbf{I}^{(n_L)}_{[n_L],J_L}\mathbf{I}^{(n_R)}_{I_R,[n_R]} \\ \mathbf{0}^{(n_R,n_L)} & \mathbf{R} \end{bmatrix} \\
\mathbf{N}^{-1} &= \begin{bmatrix} \mathbf{L}^{-1} & (\mathbf{L}^{-1})_{,J_L}(\mathbf{R}^{-1})_{I_R,} \\ \mathbf{0} & \mathbf{R}^{-1} \end{bmatrix}
\end{aligned}$$

Selecting the rows of $\mathbf{N}^{-1}$ with indices in I is the same as taking the first row of blocks and left-multiplying by $\mathbf{I}^{(n_L)}_{I_L,}$. Selecting columns with indices in J is the same as taking the second column of blocks and right-multiplying by $\mathbf{I}^{(n_R)}_{,J_R}$. Hence,

$$\begin{aligned}
(\mathbf{N}^{-1})_{I,} &= \begin{bmatrix} (\mathbf{L}^{-1})_{I_L,} & (\mathbf{L}^{-1})_{I_L,J_L}(\mathbf{R}^{-1})_{I_R,} \end{bmatrix} \\
(\mathbf{N}^{-1})_{,J} &= \begin{bmatrix} (\mathbf{L}^{-1})_{,J_L}(\mathbf{R}^{-1})_{I_R,J_R} \\ (\mathbf{R}^{-1})_{,J_R} \end{bmatrix} \\
(\mathbf{N}^{-1})_{I,J} &= \begin{bmatrix} (\mathbf{L}^{-1})_{I_L,J_L}(\mathbf{R}^{-1})_{I_R,J_R} \end{bmatrix}
\end{aligned}$$

We again bound the Frobenius norms of these matrices using the bounds on $\|\mathbf{L}\|_{\mathrm{F}}$, $\|\mathbf{L}^{-1}\|_{\mathrm{F}}$, $\|(\mathbf{L}^{-1})_{I_L,}\|_{\mathrm{F}}$, $\|(\mathbf{L}^{-1})_{,J_L}\|_{\mathrm{F}}$, $\|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}}$, and similarly for $\mathbf{R}^{-1}$, that we get from the inductive hypothesis. The Frobenius norm of each block matrix is bounded by the sum of the Frobenius norms of its blocks. Using this together with the fact that $\|\mathbf{AB}\|_{\mathrm{F}} \le \|\mathbf{A}\|_{\mathrm{F}}\|\mathbf{B}\|_{\mathrm{F}}$, we get

$$\begin{aligned}
\|\mathbf{N}\|_{\mathrm{F}} &\leq \|\mathbf{L}\|_{\mathrm{F}} + \|\mathbf{R}\|_{\mathrm{F}} + \sqrt{\min(n_L, n_R)} \\
&\leq 5a\kappa + 5b\kappa + \kappa \leq 5(a+b+1)\kappa = 5s\kappa \\
\|(\mathbf{N}^{-1})_{I,J}\|_{\mathrm{F}} &\leq \|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}}\|(\mathbf{R}^{-1})_{I_R,J_R}\|_{\mathrm{F}} \\
&\leq \kappa^a\kappa^b \leq \kappa^{a+b+1} = \kappa^s \\
\|(\mathbf{N}^{-1})_{I,}\|_{\mathrm{F}} &\leq \|(\mathbf{L}^{-1})_{I_L,}\|_{\mathrm{F}} + \|(\mathbf{L}^{-1})_{I_L,J_L}\|_{\mathrm{F}}\|(\mathbf{R}^{-1})_{I_R,}\|_{\mathrm{F}} \\
&\leq (5\kappa)^a + \kappa^a(5\kappa)^b \leq (5\kappa)^{a+b} + (5\kappa)^{a+b} \leq (5\kappa)^{a+b+1} = (5\kappa)^s \\
\|(\mathbf{N}^{-1})_{,J}\|_{\mathrm{F}} &\leq \|(\mathbf{R}^{-1})_{,J_R}\|_{\mathrm{F}} + \|(\mathbf{R}^{-1})_{I_R,J_R}\|_{\mathrm{F}}\|(\mathbf{L}^{-1})_{,J_L}\|_{\mathrm{F}} \\
&\leq (5\kappa)^b + \kappa^b(5\kappa)^a \leq (5\kappa)^{a+b} + (5\kappa)^{a+b} \leq (5\kappa)^{a+b+1} = (5\kappa)^s \\
\|\mathbf{N}^{-1}\|_{\mathrm{F}} &\leq \|\mathbf{L}^{-1}\|_{\mathrm{F}} + \|\mathbf{R}^{-1}\|_{\mathrm{F}} + \|(\mathbf{L}^{-1})_{,J_L}\|_{\mathrm{F}}\|(\mathbf{R}^{-1})_{I_R,}\|_{\mathrm{F}} \\
&\leq (10\kappa)^{2a+1} + (10\kappa)^{2b+1} + (5\kappa)^a(5\kappa)^b \\
&\leq 3(10\kappa)^{2a+2b+1} \leq (10\kappa)^{2a+2b+3} = (10\kappa)^{2s+1}
\end{aligned}$$

Then by the inductive hypothesis, the claim is proven. ◀

3.2 Proof of Theorem 1

To obtain Theorem 1, we will use the following data structures (Theorem 7) by Sankowski [33], v.d.Brand, Nanongkai and Saranurak [12]. This previous work only considered finite fields or the real-RAM model, i.e., infinite precision with $O(1)$ time per arithmetic operation. In the full version, we prove that these data structures also work with finite precision and $\widetilde{O}(\log(\kappa/\epsilon))$-bit fixed-point arithmetic, as stated in Theorem 7.

▶ **Theorem 7.** *There exist several dynamic matrix inverse algorithms with the following operations. For any update vs. query time trade-off parameters $0 \leq \nu \leq \mu \leq 1$, each data structure initializes in $O(n^\omega \log \kappa/\epsilon)$ time on given accuracy parameters $\epsilon > 0, \kappa > n$, and dynamic matrix $\mathbf{Z} \in \mathbb{R}^{n\times n}$ that is promised to stay invertible throughout all updates with $\|\mathbf{Z}\|_F, \|\mathbf{Z}^{-1}\|_F \leq \kappa$.*

The data structures have the following update/query operations

1. *Support entry updates and entry queries in $\widetilde{O}((n^{\omega(1,1,\mu)-\mu} + n^{\omega(1,\mu,\nu)-\nu} + n^{\mu+\nu})s\log(\kappa/\epsilon))$ time. This is $\widetilde{O}(n^{1.405}s\log(\kappa/\epsilon))$ for $\nu \approx 0.543, \mu \approx 0.8612$.*
2. *Support entry updates in $\widetilde{O}((n^{\omega(1,1,\mu)-\mu} + n^{1+\mu})s\log(\kappa/\epsilon))$ time and entry queries in $O(n^\mu s\log(\kappa/\epsilon))$ time. This is $\widetilde{O}(n^{1.528}s\log(\kappa/\epsilon))$ and $O(n^{0.528}s\log(\kappa/\epsilon))$ for $\mu \approx 0.528$.*
3. *Support rank-1 updates and returning all entries of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ in $\widetilde{O}(n^2 s\log(\kappa/\epsilon))$ time.*
4. *Support column updates and row queries in the offline model (the entire sequence of column indices and row queries is given at the start) in $\widetilde{O}(n^{\omega-1}s\log(\kappa/\epsilon))$ update and query time.*

The outputs are all ϵ-approximate, i.e., each entry is off by at most an additive $\pm\epsilon$.

By running the data structures of Theorem 7 on the matrix obtained from Theorem 5, we obtain Theorem 1.

Proof of Theorem 4 (Theorem 1). Given the formula $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ and its input matrices $\mathbf{M}_1, ..., \mathbf{M}_s$, where each $\mathbf{M}_i$ is of size $n_i \times m_i$, let $n = \sum_s n_i + m_i$.

Initialization. By Theorem 5, we can construct in $O(n^2)$ time a square $O(n) \times O(n)$ matrix, where each $\mathbf{M}_i$ is a sub-block of $\mathbf{N}$, and two sets $I, J \subset \mathbb{Z}$ with $(\mathbf{N}^{-1})_{I,J} = f(\mathbf{M}_1, ..., \mathbf{M}_s)$.

The assumption of Theorem 4 states that each $\|\mathbf{M}_i\|_F \leq \kappa$ and each result of an inversion gate within f also has Frobenius norm bounded by κ. Thus, by Lemma 6, we have $\log \|\mathbf{N}\|_F$ and $\log \|\mathbf{N}^{-1}\|_F$ bounded by $O(s \log \kappa)$.

Depending on the type of update and query that we want (i.e., entry, column, row, etc), we run the respective data structure from Theorem 7 on $\mathbf{N}$.

In total, the initialization takes $\widetilde{O}(n^\omega s \log(\kappa/\epsilon))$ time, dominated by the initialization of the data structure from Theorem 7.

Updates and Queries. Since each $\mathbf{M}_i$ is a submatrix of $\mathbf{N}$, entry, column, row, or rank-1 updates to any $\mathbf{M}_i$ can be modeled by an entry, column, row, or rank-1 update to $\mathbf{N}$.

Likewise, querying an entry, a row, or column of $f(\mathbf{M}_1, ..., \mathbf{M}_s)$ can be performed by querying an entry, or row, or column of $\mathbf{N}^{-1}$, because submatrix $(\mathbf{N}^{-1})_{I,J} = f(\mathbf{M}_1, ..., \mathbf{M}_s)$. Further, the queries all have accuracy ϵ by Theorem 7.

Thus, the update and query complexity of Theorem 1 is exactly as stated in Theorem 7. ◀

4 Conclusion

We discussed the bit complexity and stability of maintaining arbitrary matrix formulas (with inversion, multiplication, and addition/subtraction) and their determinants. In addition, we provided data structures for maintaining the rank of matrices under finite fields and discussed a few applications for these. We believe our data structures and analysis would provide a useful and easy-to-use toolbox for designing iterative algorithms under the word-RAM model. For example, to extend optimization algorithms to the word-RAM model, one is only required to provide an analysis of what amount of errors in each step can be tolerated without affecting the convergence. Some other applications are in computational geometry and computer algebra problems.

A compelling future direction is to analyze the bit complexity of more complex algorithms that use algebraic and matrix formulas and the required error bounds for these algorithms. One interesting example is the Gram-Schmidt walk introduced for discrepancy minimization [4] that has many applications including experimental design [25]. It is not clear how many bits are required to guarantee such a random walk constructs a good distribution.

Another compelling direction is to investigate whether our bit complexity bounds can be improved for certain problems. For example, in the basic solution application, we presented bounds that depend on both the maximum determinant and maximum condition number over all d-by-d submatrices. We know that the maximum determinant is small for combinatorial problems and the maximum condition number is small for random matrices with high probability. Therefore it would be interesting to investigate whether one of these terms can be eliminated from the bit complexity bound. Another case of special problems is in tensor Tucker decomposition, where linear regression problems with Kronecker structure are solved [18, 21]. Although the matrices involved have a condition number exponential in the order of the tensor, such matrices are usually not constructed explicitly.

Finally, our results hint that inverse maintenance approaches might not be as unstable as previously assumed. It would be interesting to investigate their performance in practice. This might require modifications to plain vanilla Sherman-Morrison-Woodbury identity.

Abstract

We present two randomised approximate counting algorithms with $\widetilde{O}(n^{2-c}/\varepsilon^2)$ running time for some constant $c > 0$ and accuracy ε:

1. for the hard-core model with fugacity λ on graphs with maximum degree Δ when $\lambda = O(\Delta^{-1.5-c_1})$ where $c_1 = c/(2-2c)$;
2. for spin systems with strong spatial mixing (SSM) on planar graphs with quadratic growth, such as $\mathbb{Z}^2$.

For the hard-core model, Weitz's algorithm (STOC, 2006) achieves sub-quadratic running time when correlation decays faster than the neighbourhood growth, namely when $\lambda = o(\Delta^{-2})$. Our first algorithm does not require this property and extends the range where sub-quadratic algorithms exist.

Our second algorithm appears to be the first to achieve sub-quadratic running time up to the SSM threshold, albeit on a restricted family of graphs. It also extends to (not necessarily planar) graphs with polynomial growth, such as $\mathbb{Z}^d$, but with a running time of the form $\widetilde{O}\left(n^2\varepsilon^{-2}/2^{c(\log n)^{1/d}}\right)$ where d is the exponent of the polynomial growth and $c > 0$ is some constant.

1 Introduction

The study of counting complexity was initiated by Valiant [33] with the introduction of the complexity class #**P**. An intriguing phenomenon emerging in counting complexity is that many #**P**-complete problems admit fully polynomial-time randomised approximation schemes (FPRAS), which output an ε-approximation in time polynomial in n and $1/\varepsilon$ with n being the input size. This is most commonly found for the so-called partition function of spin systems, as demonstrated by the pioneering work of Jerrum and Sinclair [23, 24]. Spin systems are physics models for nearest neighbour interactions, and the partition functions are the normalizing factors for their Gibbs distributions. This quantity can express the count of combinatorial objects such as the number of matchings, independent sets, or colourings in a graph, and is much more expressible by allowing real parameters of the system.

In this paper we are most interested in the fine-grained aspects of the complexity of estimating partition functions. While for most spin systems, exact counting is #**P**-hard [6], many of them admit efficient approximation schemes when strong spatial mixing (SSM) holds. Roughly speaking, SSM states that correlation or influence between vertices decays quickly as their distance increases (detailed definitions are given in Section 2 and Definition 7). When SSM fails, the partition function is usually **NP**-hard to approximate [31, 19, 18].

Efficient approximate counting was first enabled by the work of Jerrum, Valiant, and Vazirani [25] who gave self-reductions from approximate counting to sampling for a large class of problems. The sampling task is then most commonly solved via Markov chains. The efficiency of a Markov chain is measured by its mixing time (i.e. how long it takes to get close to the target distribution). For spin systems with SSM, in many situations, the standard chain, namely the Glauber dynamics, mixes in $O(n \log n)$ time [10, 2, 8, 9].

Another later technique, simulated annealing, provides a more efficient counting to sampling reduction [32, 22, 27]. Together with the $O(n \log n)$ mixing time mentioned above, this leads to $\widetilde{O}((n/\varepsilon)^2)$[1] approximate counting algorithms. These Markov chain Monte Carlo (MCMC) algorithms are the fastest for estimating partition functions in general, but $\Omega(n^2)$ appears to be a natural barrier to this approach. This is because generating a sample would take at least linear time (and there are $\Omega(n \log n)$ lower bounds for the mixing time of Markov chains [21] for many spin systems), and, restricted to the standard way of using the samples, the number of samples required for simulated annealing is at least $\Omega(n/\varepsilon^2)$ [27, Theorem 10].

On the other hand, when we relax the parameters, $\Omega(n^2)$ is no longer a barrier to algorithms. Let us take the hard-core gas model as an example. Here the Gibbs distribution μ is over the set $\mathcal{I}$ of independent sets of a graph G. For an independent set I, $\mu(I) := \lambda^{|I|}/Z(G)$, where λ is a parameter of the system (so-called fugacity), and $Z(G) := \sum_{I \in \mathcal{I}} \lambda^{|I|}$ is the partition function. For graphs with degree bound Δ, SSM holds when $\lambda < \lambda_c(\Delta) := \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta}} \approx \frac{e}{\Delta}$. The aforementioned MCMC results [10, 8, 9] imply FPRASes running in time $\widetilde{O}((n/\varepsilon)^2)$ as long as $\lambda < \lambda_c(\Delta)$. Yet much earlier, Weitz [34] gave the first fully polynomial-time approximation scheme (FPTAS, the deterministic counterpart to FPRAS) for the partition function of the hard-core model when $\lambda < \lambda_c(\Delta)$, which is not based on Markov chains. While Weitz's algorithm has a running time $n^{O(\log \Delta)}$ in general, it has an interesting feature that it gets faster as λ decreases. Roughly speaking, for $k > 0$ and $\lambda = O((1/\Delta)^{1+k})$, Weitz's FPTAS runs in time $O(n^{1+1/k}/\varepsilon^2)$. In particular, if $\lambda = o(\Delta^{-2})$, Weitz's algorithm passes the $\Omega(n^2)$ barrier, whereas the aforementioned MCMC method still takes $\Omega(n^2)$ time. This leads to an intriguing question:

When can we achieve sub-quadratic running time for approximate counting? (1)

[1] The notation $\widetilde{O}(\cdot)$ hides logarithmic factors.

In this paper we make some progress towards this question. For hard-core models, Weitz's algorithm uses the self-reduction [25] to reduce approximate counting to estimating marginal probabilities. We provide a quadratic speedup for the marginal estimation step for λ well below $\lambda_c(\Delta)$, albeit with the introduction of randomness. The result is summarized as follows.

▶ **Theorem 1.** *Fix a constant $k > 0$. Let $\Delta \geq 2$ be an integer and $\lambda < \frac{1}{\Delta^k(\Delta-1)}$. For graphs with maximum degree Δ, there exists an FPRAS for the partition function of the hard-core model with parameter λ in time $\widetilde{O}(n^{1+\frac{1}{2k}}/\varepsilon^2)$, where n is the number of vertices.*

▶ Remark 2 (Decay rate vs. neighbourhood growth). For a constant ε, the running time of Theorem 1 is sub-quadratic if $\lambda = o(\Delta^{-1.5})$, and $\widetilde{O}(n^{1.5})$ if $\lambda = O(\Delta^{-2})$. In contrast, to achieve sub-quadratic running-time, Weitz's algorithm requires $\lambda = o(\Delta^{-2})$, which is also the threshold when correlation decays faster than the growth of the neighbourhood. This threshold has algorithmic significance in other contexts [17, 1], but Theorem 1 implies that it is not essential to achieve sub-quadratic approximate counting.

Figure 1 is a sketch comparing the running times of MCMC,[2] Weitz's algorithm, and Theorem 1.[3] For the limiting case of $k = 0$, our algorithm works when $\lambda < \frac{1}{\Delta-1}$ and still presents a quadratic speedup comparing to Weitz's algorithm. However in this case the running time is $\left(\frac{n}{\varepsilon}\right)^{O(\log \Delta)}$ and thus our speedup is hidden in the big-O notation and is less significant. The parameter constraint $\frac{1}{\Delta-1}$ is imposed by the running-time tail bound of a subroutine we used, namely the recursive marginal sampler of Anand and Jerrum [1].

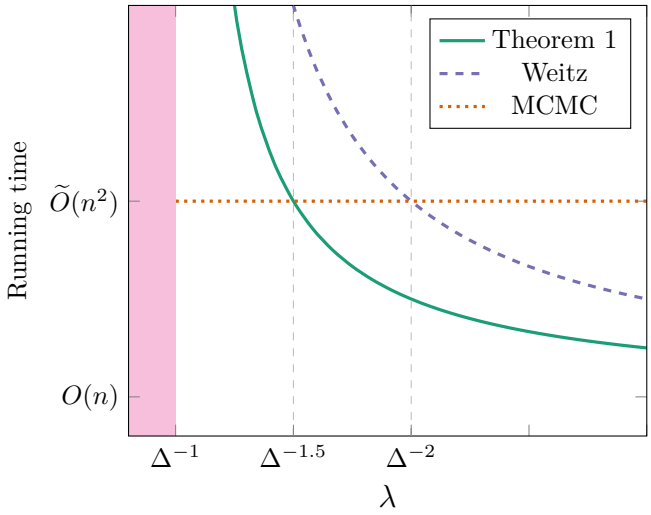

Figure 1 Running time comparison among MCMC, Weitz's algorithm, and Theorem 1.

The key to our method is to find a new estimator of the marginal probability that simultaneously has low variance and can be evaluated very fast. Our technique combines Weitz's self-avoiding walk (SAW) tree construction and the $\widetilde{O}(1)$ marginal sampler of Anand

[2] The running time of MCMC usually also depends on the parameter λ, but changing λ does not change the exponent of n. The effect of λ is usually a small polynomial factor hidden in the $\widetilde{O}(\cdot)$ notation, and the sketch in Figure 1 ignores this effect.

[3] Another notable FPTAS is via zeros of polynomials [3, 29]. It can achieve similar subquadratic running time when $\lambda = o(\Delta^{-2})$, but it is apparently no faster than Weitz's correlation decay algorithm.

and Jerrum [1]. The marginal of the root of the SAW tree preserves the desired marginal probability, and can be evaluated in time linear in the size of the tree via standard recursion. We use the marginal sampler to draw a random boundary condition at a suitable depth on the SAW tree, and compute the marginal of the root using recursion under this boundary condition. Both steps can be computed in time near-linear in the size of the sub-tree. The depth of our boundary condition is roughly half of where Weitz truncates the SAW tree, and yet we show that our estimator has $O(1/n)$ variance under SSM, which is essential to get an FPRAS. This leads to our quadratic improvement on the marginal estimation over Weitz's algorithm. This method also extends to other anti-ferromagnetic 2-spin systems.

Our second contribution is about graphs with polynomial growth. In particular, for planar graphs with quadratic growth, we provide $\widetilde{O}(n^{2-c}/\varepsilon^2)$ algorithms for some constant $c > 0$. An informal statement is as follows. (The detailed statement is Theorem 13.)

▶ **Theorem 3.** *Let $\mathbb{G}$ be a family of planar graphs with quadratic growth. For a spin system exhibiting SSM on $\mathbb{G}$, there exists an FPRAS for the partition function of $G \in \mathbb{G}$ with n vertices. The run-time is $\widetilde{O}(n^{2-c}/\varepsilon^2)$ for some constant $c > 0$.*

We note that one of the most important graph in statistical physics, the 2D integer grid $\mathbb{Z}^2$, indeed has quadratic growth. More generally, any planar graph with a bounded radius circle packing has quadratic growth. Thus Theorem 3 covers many important families of planar graphs, including most lattices. (A *non*-example would be the Cayley tree.) Specialized to the hard-core model, Theorem 3 works up to the critical threshold, which is at least $\lambda_c(\Delta)$,[4] when the graph satisfies the condition in the theorem and has maximum degree Δ.

The key to Theorem 3 is once again a suitable estimator for marginal probabilities. We choose a distance ℓ boundary around a vertex v in G with a carefully chosen ℓ, and our estimator is the marginal under random boundary conditions. This boundary condition is yet again sampled using the algorithm of Anand and Jerrum [1]. Our main observation is that due to quadratic growth, the number of possible boundary conditions do not grow very fast. It turns out to be more efficient to create a look-up table by enumerating all boundary conditions first, and instead of computing the marginal for each sample, we simply find it in this table. Since planar graphs have linear local tree-width, the table can be created efficiently. This last step is inspired by the work of Yin and Zhang [35].

This method extends to any (not necessarily planar) graph families with polynomial growth. Without planarity, we use brute-force enumeration instead to create the table. This makes our gain on the running time smaller. Again an informal statement is as follows, with the full version in Theorem 22.

▶ **Theorem 4.** *Let $\mathbb{G}$ be a family of graphs with polynomial growth. For a spin system exhibiting SSM on $\mathbb{G}$, there exists an FPRAS for the partition function of $G \in \mathbb{G}$ with n vertices. The run-time is $\widetilde{O}\left(\frac{n^2}{\varepsilon^2 2^{c(\log n)^{1/d}}}\right)$ where $c > 0$ is some constant and d is the exponent of the polynomial growth.*

An example of such graphs would be the d-dimensional integer lattice $\mathbb{Z}^d$. Note that Theorem 3 is better than Theorem 4 for $d = 2$ but requires the extra assumption of planarity. The speedup factor $2^{c(\log n)^{1/d}}$ in Theorem 4 is slower than any polynomial in n but faster than any polynomial in $\log n$.

We note an interesting related work by Chu, Gao, Peng, Sachdeva, Sawlani, and Wang [11], who give an approximate counting algorithm with running time $\widetilde{O}(m^{1+o(1)} + n^{1.875+o(1)}/\varepsilon^{1.75})$ for spanning trees of graphs, where m is the number of edges and n is the number of vertices.

[4] For a given graph family, such as subgraphs of $\mathbb{Z}^2$, the critical threshold may be well above $\lambda_c(\Delta)$.

Notice that the input size here is $O(m)$ and $m = \Omega(n)$. Thus their running time is also sub-quadratic. However, there are some key differences between this work and ours. Aside from not being a spin system, spanning trees can be counted exactly in polynomial time, thanks to Kirchhoff's matrix-tree theorem. This allows them to use various efficient exact counting subroutines, whereas the problems we consider are #**P**-hard in general and no such subroutine is likely to exist.

Another more recent related result is the sub-quadratic all-terminal unreliability estimation algorithm by Cen, He, Li, and Panigrahi [7], which runs in sub-quadratic time $m^{1+o(1)}\varepsilon^{-3} + \widetilde{O}(n^{1.5}\varepsilon^{-2})$. This problem, while #**P**-hard, is not a spin system either. Their method features a recursive Monte Carlo estimator that is very different from ours, and not applicable to spin systems.

A crucial ingredient of our algorithm is the recursive marginal sampler of Anand and Jerrum [1]. This type of local / marginal samplers allows us partial access to a large random object with substantially less information than traditional samplers. It has found applications in local computation algorithms [4], and in derandomising Markov chains [16]. Our results offer yet another application, namely to accelerate computation of the global partition function.

We hope that our results are just the first step towards answering the question (1). In particular, it is not clear whether an $O(n^{2-c}/\varepsilon^2)$ algorithm exists for the hard-core model when $\lambda = \Theta(1/\Delta)$ on graphs with maximum degree Δ, or if more efficient algorithms exist for graphs with polynomial or sub-exponential growth. We leave these questions as open problems.

2 Preliminaries

We are interested in spin systems which exhibit strong spatial mixing.

▶ **Definition 5.** *A q state spin system (or q-spin system for short) is given by a graph $G = (V, E)$, a q-by-q interaction matrix A, and a field $b : [q] \to \mathbb{R}$. A configuration of G is an assignment of states to vertices, $\sigma : V \to [q]$. The weight of a configuration σ is determined by the assignments to the vertices and the interactions between them,*

$$w(\sigma) := \prod_{(u,v)\in E} A_{\sigma(u),\sigma(v)} \prod_{v\in V} b_{\sigma(v)}.$$

The Gibbs distribution μ is one where the probability of each configuration is proportional to its weight, namely, $\mu(\sigma) := \frac{w(\sigma)}{Z(G)}$, where the partition function $Z(G) = \sum_\sigma w(\sigma)$ is a normalizing factor.

In this paper, we consider the following permissive spin system, which says any locally feasible configuration can be extended to a globally feasible configuration.

▶ **Definition 6.** *A q-spin system on $G = (V, E)$ is permissive if for any $\Lambda \subseteq V$, any $\sigma \in [q]^\Lambda$, if $b_{\sigma(v)} > 0$ for all $v \in \Lambda$ and $A_{\sigma(u),\sigma(v)} > 0$ for all $u, v \in \Lambda$ satisfying $(u, v) \in E$, then σ can be extended to a full configuration $\sigma' \in [q]^V$ such that $w(\sigma') > 0$.*

Many natural spin systems are permissive. Examples include the hard-core model, the graph q-colouring with $q \geq \Delta + 1$, where Δ is the maximum degree of the graph, and all spin systems with soft constraints (e.g. the Ising model and the Potts model).

We call the problem of evaluating Z the counting problem for the q-spin system. The standard algorithmic aim here is a *fully-polynomial randomised approximation scheme* (FPRAS), where given the spin system and an accuracy $\varepsilon > 0$, the algorithm outputs $\widetilde{Z}$

such that $1-\varepsilon \le \frac{\widetilde{Z}}{Z} \le 1+\varepsilon$ with probability at least $3/4$, and runs in time polynomial in the size of the system and $1/\varepsilon$. To understand the requirement of an FPRAS, note that the probability $3/4$ can be boosted arbitrarily close to 1 via standard means. The accuracy can also be boosted by taking many disjoint copies of the system. In fact, any polynomial accuracy can be boosted to an arbitrarily small ε in polynomial-time.

Also note that if G is disconnected, then $Z(G) = \prod_i Z(G_i)$ where $G_i's$ are the connected components of G. Thus, we always consider connected graphs in the paper.

Similar to $\mu(\sigma)$ for the probability of a configuration, for an $S \subseteq V$ and a partial configuration σ_S on S, we use $\mu(\sigma_S)$ for the marginal probability of σ_S under μ. We denote the marginal distribution induced by μ on S by μ_S. When $S = \{v\}$, we also write μ_v. For the distribution conditioned on a partial configuration σ_S, we use μ^{σ_S} or $\mu_v^{\sigma_S}$.

Strong spatial mixing is a property of the spin system where a partial configuration of G does not significantly influence the assignment of a distant vertex.

▶ **Definition 7** (SSM). *A q-spin system is said to have strong spatial mixing with decay rate $f(\ell)$ for a family of graphs if for any $G = (V, E)$ in the family, any $v \in V, S \subset V$, and two configurations σ_S, τ_S,*

$$d_{\mathrm{TV}}(\mu_v^{\sigma_S}, \mu_v^{\tau_S}) \le f(\ell),$$

where d_{TV} denotes the total variation distance, $T \subseteq S$ is the subset where the configurations are different, and $\ell = \mathrm{dist}(v, T)$ is the minimum distance from v to a vertex in T.

Strong spatial mixing is a very strong form of correlation decay. When $f(\ell) = \exp(-\Omega(\ell))$ we say we have strong spatial mixing with exponential decay.

2.1 Two-state spin systems

A spin system is symmetric if $A_{ij} = A_{ji}$ for all i, j. When $q = 2$ and the system is symmetric, we have states $\{0, 1\}$ and can normalize A and b so that the interaction between 0 and 1 and the contribution of 0 are 1, and $A = \begin{bmatrix} \beta & 1 \\ 1 & \gamma \end{bmatrix}$ and $b = (1, \lambda)$ for $\beta, \gamma \ge 0$, and $\lambda > 0$.

When $\beta = \gamma$ the system is an Ising model, and for $\beta = 1, \gamma = 0$ the system is a hard-core gas model. We call a system *anti-ferromagnetic* if disagreeing assignments of adjacent vertices are more heavily weighted, namely $\beta\gamma < 1$.

For a tree T rooted at v and a partial configuration σ_S we define the marginal ratio

$$R_T^{\sigma_S} := \frac{\mu_v^{\sigma_S}(1)}{\mu_v^{\sigma_S}(0)} = \frac{\mu_v^{\sigma_S}(1)}{1 - \mu_v^{\sigma_S}(1)},$$

or $R_T^{\sigma_S} := \infty$ if $\mu_v^{\sigma_S}(1) = 1$. These ratios satisfy a well-known recurrence relation:

$$R_T^{\sigma_S} = \lambda \prod_{i=1}^{d} \frac{\gamma R_{T_i}^{\sigma_S} + 1}{R_{T_i}^{\sigma_S} + \beta}, \tag{2}$$

where T_i is the ith subtree of T. Similarly, for a graph G we can define $R_{G,v}^{\sigma_S} = \mu_v^{\sigma_S}(1)/(1 - \mu_v^{\sigma_S}(1))$. While $R_{G,v}^{\sigma_S}$ does not exhibit a simple recursion, the self-avoiding walk (SAW) tree of G at v as constructed by Weitz [34] can be used to compute it.

▶ **Theorem 8** (Theorem 3.1 of [34]). *For any $G = (V, E)$, a configuration σ_S on $S \subset V$, and any $v \in V$, there exists a tree $T_{\mathrm{SAW}} = T_{\mathrm{SAW}}(G, v)$ such that*

$$R_{G,v}^{\sigma_S} = R_{T_{\mathrm{SAW}}}^{\sigma_S}.$$

The SAW tree is rooted at v. Each node corresponds to a self-avoiding walk starting from v. The length of the walk is the same as the distance between the node and the root v. When a walk is closed, the node is set to unoccupied or occupied according to if the penultimate vertex is before or after the starting vertex of the cycle in some pre-determined local ordering at the last vertex. For details, see [34].

The SAW tree can have depth up to n, so may be exponential in size. Marginals on the SAW tree are therefore difficult to compute, but using the recursion in Equation (2) we can approximate them by truncating the tree. This approximation is accurate when strong spatial mixing holds, and the time to compute the marginal is linear in the size of the truncated tree. To maintain a polynomial running time, Weitz [34] choose to truncate it at a suitable logarithmic depth.

3 Fast SSM regime for 2-spin systems

In this section we give a quadratic speedup of Weitz's Algorithm to estimate the marginal of a single vertex in 2-spin systems, albeit being randomised instead of deterministic. We use the hard-core model as our running example to illustrate the main ideas. The main result of the section is Theorem 1.

Let the hard-core model be described by $A = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$ and $b = (1, \lambda)$. The support of the Gibbs distribution is the set of independent sets of G. Let vertices assigned 0 not be in the independent set (unoccupied) and vertices assigned 1 be in the independent set (occupied). Our algorithm uses self-reduction [25] as follows. Since unoccupied vertices contribute 1 to the weight of a configuration, we can consider the all 0 configuration σ_0 where

$$\begin{aligned} \frac{1}{Z(G)} = \mu(\sigma_0) = \mu_{v_1}(0)\mu^{v_1 \leftarrow 0}_{V\setminus\{v_1\}}(\mathbf{0}) = \mu_{v_1}(0)\frac{1}{Z(G\setminus\{v_1\})} \\ = \mu_{G_1,v_1}(0)\mu_{G_2,v_2}(0)\cdots\mu_{G_n,v_n}(0), \end{aligned} \tag{3}$$

and where $G_i = G \setminus \{v_1, \ldots, v_{i-1}\}$ for all $i \in [n]$. This reduces the problem of computing $Z(G)$ to computing μ_{v_1} and recursively $Z(G \setminus \{v_1\})$. As the G_i's are subgraphs of G, they have the same degree bound and still exhibit SSM. The crux of our algorithm is to design a random variable that estimates μ_v in time $\widetilde{O}(n^{1/(2k)})$.

Another ingredient we need is the lazy single-site sampler by Anand and Jerrum [1], which allows us to rapidly sample a partial configuration vertex by vertex. The original setting of [1] requires sub-exponential neighbourhood growth in order to work up to the strong spatial mixing threshold, but in our parameter regime no sub-exponential growth is required. Moreover, only the expected running time is studied in [1], while we need a tail bound. A similar analysis is done in [16, Appendix B]. For completeness, we provide a proof specialised to our setting in Appendix A.

▶ **Lemma 9.** *Let $\Delta \geq 2$ be an integer and $\lambda < \frac{1}{\Delta-1}$. Let $G = (V, E)$ be a graph with maximum degree Δ. There exists an algorithm that, for any $v \in V$, draws a sample from μ_v and halts in time $O(\log \frac{1}{\varepsilon})$ with probability at least $1 - \varepsilon$.*

Our algorithm then combines the lazy sampler of Lemma 9 with the SAW tree of [34]. We expand the SAW tree, and then use Lemma 9 to sample a truncated boundary, from which we use the recursion in (2) to get our estimate. The depth of the truncation controls the variance of this estimator. In our algorithm, we only need to bound the variance from above by $1/n$. In contrast, Weitz's algorithm requires the error of the marginal incurred

by the truncation to be bounded from above by $O(1/n)$. As the variance of our estimator decays twice as fast as the marginal errors, our truncation depth is roughly half of that in Weitz's algorithm. Consequently, we achieved a quadratic speedup for estimating each term in (3).

▶ **Lemma 10.** *For a graph G with maximum degree Δ, if the hard-core model on G has strong spatial mixing with decay rate $C\Delta^{-k\ell}$ for some constant $C > 0$, there exists an algorithm that generates a random sample $\widetilde{p}_v$ and halts in time $O(n^{1/(2k)}(\log \frac{n}{\delta})^2)$ with probability at least $1 - \frac{\delta}{8}$. Furthermore, $\mathbb{E}[\widetilde{p}_v] = \mu_v(0)$ and $\mathrm{Var}\,(\widetilde{p}_v) \le 1/n$.*

Proof. Let T_{SAW} be the self-avoiding walk tree for G rooted at v as defined in Theorem 8, and let $S = \{u \in V | d_{T_{\mathrm{SAW}}}(v, u) = \ell\}$ where ℓ is a parameter we will fix later. We have

$$\mu_{T_{\mathrm{SAW}},v}(0) = \sum_{\sigma \in \{0,1\}^S} \mu_{T_{\mathrm{SAW}}}(\sigma)\mu^{\sigma}_{T_{\mathrm{SAW}},v}(0) = \mathbb{E}_{\sigma \sim \mu_{T_{\mathrm{SAW}},S}}[\mu^{\sigma}_{T_{\mathrm{SAW}},v}(0)].$$

We use Lemma 9 to sample σ. Fix an arbitrary order of $S = \{s_1, s_2, \ldots, s_{|S|}\}$. We sample first the marginal of s_1 with $\varepsilon := \frac{\delta}{8|S|}$. Then, conditioned on the result on s_1, we sample s_2 with the same ε, and so on and so forth. Note that whatever the result on s_1 is, it always reduces to a hard-core instance of a smaller graph. Thus, the condition of Lemma 9 is always satisfied until all of S are sampled. This gives a boundary condition σ_S in T_{SAW}.

As the full SAW tree may be exponential in size, a little care is required to implement the outline above. We first expand T_{SAW} up to level ℓ, denoted $T_{\mathrm{SAW},\ell}$. The algorithm in Lemma 9 (Algorithm 1 in Appendix A) is essentially an exploration process. When we apply it to sample the boundary condition σ_S, we expand the SAW tree below $T_{\mathrm{SAW},\ell}$ on the fly, only creating vertices that are explored by the algorithm. Note that the construction of the SAW tree imposes a boundary condition whenever a vertex in G is encountered again in a self-avoiding walk. We implement this pinning by remembering a list of all ancestors of a given node in the SAW tree and checking the next vertex to explore against this list. Since Lemma 9 halts in $O(\log \frac{1}{\varepsilon})$ time with probability at least $1 - \varepsilon$, this extra check incurs a multiplicative slowdown factor $O(\ell + \log \frac{1}{\varepsilon}) = O(\ell + \log \frac{|S|}{\delta})$ with probability at least $1 - \varepsilon$.

Given σ_S, we can compute $\mu^{\sigma_S}_v(0) = \widetilde{p}_v$ with the standard dynamic programming approach. By a union bound, the total running time of sampling the boundary is $O(|S| \log \frac{|S|}{\delta}(\ell + \log \frac{|S|}{\delta}))$ with probability at least $1 - \frac{\delta}{8}$, and the dynamic programming step uses time $O(|T_{\mathrm{SAW},\ell}|)$.

We choose $\ell := \left\lceil \frac{\log(n)/2 - \log C}{k \log(\Delta)} \right\rceil$ so that $C\Delta^{-k\ell} \le n^{-0.5}$ and $\Delta^{\ell} \le C' n^{1/(2k)}$ for some constant $C' > 0$. Note that $|S| \le (\Delta - 1)^{\ell}$ and $|T_{\mathrm{SAW},\ell}| \le \Delta^{\ell}$. Then the total runtime to draw a sample is $O(n^{1/(2k)}(\log \frac{n}{\delta})^2)$ with probability at least $1 - \frac{\delta}{8}$.

Finally, we analyze the variance. SSM implies that for any σ_S, $|\mu^{\sigma_S}_v(0) - \mu_v(0)| \le C\Delta^{-k\ell}$, so

$$\mathrm{Var}\,(\widetilde{p}_v) = \mathrm{Var}_{\sigma_S}\left(\mu^{\sigma_S}_v(0)\right) = \mathbb{E}_{\sigma_S \sim \mu_{T_{\mathrm{SAW}},S}}[|\mu^{\sigma_S}_v(0) - \mu_v(0)|^2] \le \left(C\Delta^{-k\ell}\right)^2 \le n^{-1}, \qquad (4)$$

which is what we desire. ◀

▶ **Lemma 11.** *For a graph G with maximum degree Δ, if $\lambda \le \frac{1}{\Delta^k(\Delta-1)}$ for some constant $k > 0$, the hard-core model on G exhibits strong spatial mixing with decay rate $C\Delta^{-k\ell}$.*

Proof. It is well-known that if $\lambda < \lambda_c(\Delta) = \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta}} \approx \frac{e}{\Delta}$, strong spatial mixing holds with exponential decay Cr^{ℓ} for some constant C and $r < 1$ [34]. Moreover, the decay rate r can be controlled by a quantity related to the recursion (2) [30]. For example, by [20,

Lemma 7.20], r is bounded by $r \le |f'(\widehat{x})|$, where $f(x) := \frac{\lambda}{(1+x)^{\Delta-1}}$ is the symmetric version of the recursion in (2) and $\widehat{x}$ is the unique positive fixed point of f. (Note that when the degree of G is at most Δ, all vertices but the root in T_{SAW} have branching number $\Delta - 1$.) Then we have

$$|f'(x)| = \left| -\frac{f(x)(\Delta-1)}{1+x} \right| < (\Delta-1)f(x).$$

As $\widehat{x} > 0$ and $\widehat{x}$ is a fixed point, it holds that $\widehat{x} < \widehat{x}(1+\widehat{x})^{\Delta-1} = \lambda$. Thus, as $\lambda \le \frac{1}{\Delta^k(\Delta-1)}$,

$$r \le |f'(\widehat{x})| < (\Delta-1)f(\widehat{x}) = (\Delta-1)\widehat{x} < \frac{1}{\Delta^k}. \qquad \blacktriangleleft$$

Now we are ready to prove Theorem 1.

Proof of Theorem 1. We will first give an algorithm whose running time has a tail bound. To have a fixed running time upper bound, we then truncate this algorithm.

Set $N := \lceil 8e^{(1+\lambda)^2}/\varepsilon_0^2 \rceil$ where $\varepsilon_0 = \varepsilon/2$. Let $X := \prod_{i=1}^{n} \widetilde{p}_{G_i,v_i}$ where $G_1 = G$ and $G_i = G_{i-1} \setminus \{v_{i-1}\}$. By Lemma 11, we can use Lemma 10 to draw N samples of X and take its average, where we set $\delta = \frac{1}{nN}$ in Lemma 10. Each $\widetilde{p}_{G_i,v_i}$ can be computed in time $O(n^{1/(2k)}(\log \frac{n}{\delta})^2)$ with probability at least $1 - \frac{\delta}{8}$, so computing one sample of X takes time $O(n^{1+1/(2k)}(\log \frac{n}{\delta})^2)$ time with probability at least $1 - \frac{n\delta}{8}$ by a union bound. By a union bound again, the overall running time of taking the average is $O(Nn^{1+1/(2k)}(\log \frac{n}{\delta})^2) = O\left(\frac{n^{1+1/(2k)}}{\varepsilon^2}(\log \frac{n}{\varepsilon})^2\right)$ with probability at least $1 - \frac{\delta}{8} \cdot nN = \frac{7}{8}$.

Since $\{\widetilde{p}_{G_i,v_i}\}$ are mutually independent, by Lemma 10,

$$\mathbb{E}[X] = \mathbb{E}\left[\prod_{i=1}^{n} \widetilde{p}_{G_i,v_i}\right] = \prod_{i=1}^{n} \mu_{G_i,v_i}(0) = \frac{1}{Z(G)}.$$

We bound $\mathrm{Var}\,(X)$ as follows

$$\begin{aligned}\frac{\mathrm{Var}\,(X)}{(\mathbb{E}[X])^2} &= \frac{\mathbb{E}[X^2]}{(\mathbb{E}[X])^2} - 1 = \frac{\prod_{i=1}^{n}\mathbb{E}[\widetilde{p}_{G_i,v_i}^2]}{\prod_{i=1}^{n}\mathbb{E}[\widetilde{p}_{G_i,v_i}]^2} - 1 = \prod_{i=1}^{n}\left(1 + \frac{\mathrm{Var}\,(\widetilde{p}_{G_i,v_i})}{(\mathbb{E}[\widetilde{p}_{G_i,v_i}])^2}\right) - 1 \\ &\le \left(1 + \frac{c}{n}\right)^n - 1 < e^c, \qquad \text{(by Lemma 10)}\end{aligned}$$

where $c = \max_i(1/\mu_{G_i,v_i}(0)^2)$. Note that as $\mu_{G_i,v_i}(0) \ge \frac{1}{1+\lambda}$, $c \le (1+\lambda)^2$ and is a constant.

Let $\widetilde{X}$ be the average of N samples of X. Then $\mathrm{Var}\left(\widetilde{X}\right) = \frac{\mathrm{Var}(X)}{N} \le \frac{e^c}{N \cdot Z(G)^2}$. By Chebyshev's inequality,

$$\Pr\left[\left|\widetilde{X} - \frac{1}{Z(G)}\right| \ge \frac{\varepsilon_0}{Z(G)}\right] \le \frac{\mathrm{Var}\left(\widetilde{X}\right)}{\frac{\varepsilon_0^2}{Z(G)^2}} \le \frac{e^c}{N \cdot Z(G)^2} \cdot \frac{Z(G)^2}{\varepsilon_0^2} \le \frac{1}{8}.$$

Thus, with probability at least $7/8$, we have that $\frac{1-\varepsilon_0}{Z(G)} \le \widetilde{X} \le \frac{1+\varepsilon_0}{Z(G)}$. Finally, we output $\widetilde{Z} = 1/\widetilde{X}$. To make sure that the algorithm runs within the desired time bound $O\left(\frac{n^{1+1/(2k)}}{\varepsilon^2}(\log \frac{n}{\varepsilon})^2\right)$, we truncate the algorithm if it runs overtime and output an arbitrary value in that case. This truncated version can be coupled with the untruncated algorithm with probability at least $7/8$, and its output $\widetilde{Z}$ satisfies $1 - \varepsilon \le \frac{\widetilde{Z}}{Z(G)} \le 1 + \varepsilon$ with probability at least $7/8 - 1/8 = 3/4$. $\blacktriangleleft$

Note that, Weitz's algorithm is faster if the correlation decay is faster, but in that case so is our algorithm. In Appendix B, Lemma 26 shows that the correlation decay cannot be much faster than the standard analysis in the parameter regimes of Theorem 1, and our speed-up, comparing to Weitz's algorithm, is always at least $\widetilde{O}(n^{1/2k-o(1/k^2)})$.

We also remark that Theorem 1 generalises to antiferromagnetic 2-spin systems. This is because all the key ingredients, namely correlation decay, Weitz's SAW tree, and the marginal sampler of Anand and Jerrum all generalise, except that the Anand-Jerrum algorithm would require the neighbourhood growth rate smaller than the decay rate (see Theorem 25). This is also the parameter regime where Weitz's algorithm is faster than $O(n^2)$. Thus, our speedup is still in the sub-quadratic regime. The self-reduction in (3) also generalises (as we will see in (5) in the next section). One needs to redo the calculations in Lemma 11 to get a precise statement, which we will omit here.

4 Speed-up on planar graphs

In this section we mainly consider (not necessarily two-state) spin systems on planar graphs. We show that for any planar graph with quadratic neighbourhood growth, when SSM holds with exponential decay, approximate counting can be done in sub-quadratic time. For example, this includes all subgraphs of the 2D lattice $\mathbb{Z}^2$. The circle-packing theorem asserts that any planar graph is the tangent graph of some circle packing. All planar graphs with bounded-radius circle packings have quadratic neighbourhood growth. Thus this is a substantial family of planar graphs. Moreover, in Section 4.2 we extend the result to (not necessarily planar) graphs with polynomial growth, but the speed up factor there is sub-polynomial yet faster than $(\log n)^k$ for any k.

▶ **Definition 12.** *A graph family $\mathbb{G}$ has* quadratic growth*, if there is a constant C_0 such that for any $G = (V, E) \in \mathbb{G}$, $v \in V$, and any integer $\ell > 0$, $|B_v(\ell)| \le C_0\ell^2$.*

Subgraphs of the 2D lattice $\mathbb{Z}^2$ satisfies Definition 12 with $C_0 = 5$. Note that by taking $\ell = 1$, Definition 12 implies that the maximum degree is no larger than C_0.

▶ **Theorem 13.** *Let $\mathbb{G}$ be a family of planar graphs with quadratic growth (assume the rate is $C_0\ell^2$). Let $\boldsymbol{A}$ and $\boldsymbol{b}$ specify a q-state spin system, which exhibits SSM with decay rate $Cr^{-\ell}$ on $\mathbb{G}$. Then there is a constant $c > 0$ such that there exists an FPRAS for the partition function of $G \in \mathbb{G}$ with n vertices with run-time $\widetilde{O}(n^{2-c}/\varepsilon^2)$. The constant c depends on C_0, q, and r.*

Theorem 13 is the detailed version of Theorem 3.

Essentially the idea is still to find an estimator for the marginal of an arbitrary vertex that can be evaluated very quickly. Let us first consider a $\sqrt{n}$-by-$\sqrt{n}$ grid. For any vertex v, we consider the sphere $S_v(\ell)$ of radius $\ell = O(\log n)$ centered at v, and a random configuration τ on $S_v(\ell)$. Let $B_v(\ell)$ be the ball of radius ℓ centered at v. Since any planar graph has linear local tree-width [12, 15], $B_v(\ell)$ has tree-width $O(\ell)$. Thus, given a configuration τ on S, the law of μ_v^τ can be computed in time $2^{O(\ell)}\mathrm{poly}(\ell)$ for a fixed τ (see, e.g. [35][5]). This step can be very efficient with a carefully chosen ℓ.

For a general bounded degree planar graph, $|S_v(\ell)|$ can be a polynomial in n, which makes the number of possible τ's exponential in n. However, for a $\sqrt{n}$-by-$\sqrt{n}$ grid, $|S_v(\ell)| \le 4\ell = O(\log n)$, and the number of possible τ's is much smaller and is a small polynomial in

[5] The algorithm in [35] uses the separator decomposition. Another possibility is to first find a constant approximation of the tree decomposition first [26], and then apply Courcelle's theorem.

n. Thus, it would be more efficient to first create a table to list all possibilities of τ, and then, instead of computing μ_v^τ each time, simply look up the answer from this table. We can do the same for any subgraph of $\mathbb{Z}^2$ by choosing a boundary based on distance in the original grid.

For a general $G \in \mathbb{G}$, we no longer have a linear bound on the size of the boundary. (In Appendix C of the arXiv version of this paper, we construct a subgraph of $\mathbb{Z}^2$ where the distance ℓ boundary has size $\Omega(\ell^2)$.) However, since $\mathbb{G}$ has quadratic growth, we know that $B_v(\ell) \le C_0\ell^2$ for some constant $C_0 > 0$. It implies that

$$\sum_{i=\ell/2}^{\ell} |S_v(\ell)| \le |B_v(\ell)| \le C_0\ell^2.$$

Thus, there must exist an $\ell' \in [\ell/2, \ell]$ such that $|S_v(\ell')| \le 2C_0\ell$. We will find this ℓ' and use $S_v(\ell')$ instead.

Once again, we use a self-reduction similar to (3). For q-spin systems, given a feasible configuration σ, we have the decomposition,

$$\frac{w(\sigma)}{Z_G} = \mu(\sigma) = \mu_{v_1}(\sigma_{v_1})\mu_{v_2}^{\sigma_{v_1}}(\sigma_{v_2})\mu_{v_3}^{\sigma_{v_1},\sigma_{v_2}}(\sigma_{v_3})\dots\mu_{v_n}^{\sigma_{v_1},\dots,\sigma_{v_{n-1}}}(\sigma_{v_n}). \tag{5}$$

When computing our table, we will have to condition on the already pinned vertices.

▶ **Lemma 14.** *Let $\boldsymbol{A}$, $\boldsymbol{b}$, q and G be as in Theorem 13. For $v \in V$, a partial configuration σ, and an integer ℓ, we can find an ℓ' such that $\ell' \in [\ell/2, \ell]$, and then construct a table of $\mu_v^{\sigma,\tau}$, indexed by every boundary configuration τ on unpinned vertices of $S_v(\ell')$. The total run-time is $2^{C_1\ell}$, where C_1 is a constant depending on C_0 and q.*

Proof. As discussed earlier, due to the quadratic growth of G, there must exist an ℓ such that $\ell' \in [\ell/2, \ell]$ and $|S_v(\ell')| \le 2C_0\ell$. To find this ℓ, we do a breadth-first-search to check $S_v(i)$ from $i = \ell/2$ to ℓ. The running time is at most $O(B_v(\ell)) = O(\ell^2)$.

Once ℓ' is found, $|S_v^\sigma(\ell')| \le |S_v(\ell')| \le 2C_0\ell$, and there are at most $q^{2C_0\ell}$ configurations τ in our table. As G is a planar graph, the tree-width of the ball $\mathrm{tw}(B_v(\ell')) = O(\ell') = O(\ell)$. Thus, using for example the algorithm of [35], each entry of the table can be computed in time $2^{O(\ell)}\mathrm{poly}\,(\ell)$. The total amount of time required is $O(\ell^2) + q^{2C_0\ell}2^{O(\ell)}\mathrm{poly}\,(\ell) \le 2^{C_1\ell}$, for some sufficiently large constant C_1. ◀

While we may construct this table very quickly, it is not clear how to compute or estimate the marginals of the boundary condition τ's rapidly. Instead, we sample a random one using the marginal sampler [1] that terminates in almost linear time with high probability. See Theorem 25.

▶ **Lemma 15.** *Let $\boldsymbol{A}$, $\boldsymbol{b}$, q and $G \in \mathbb{G}$ be as in Theorem 13. Let σ be a partial configuration. For any $v \in V$ not pinned under σ and any $k \in [q]$, there exists an algorithm that generates a random variable $\widetilde{Z}$ such that $\mathbb{E}[\widetilde{Z}] = \mu_v^\sigma(k)$ and $\mathrm{Var}\left(\widetilde{Z}\right) \le 1/n$. Moreover, its running time is $\widetilde{O}(n^{1-c})$ with high probability where c depends on C_0, q, and r.*

Proof. Let ℓ be a constant that we will choose later. Let $\ell' \in [\ell/2, \ell]$ be as in Lemma 14, and let τ be a boundary condition on the unpinned vertices of $S_v(\ell')$ under σ. Let $Z_v(\tau) = \mu_v^{\sigma,\tau}(k)$ so that $\mathbb{E}_\tau[Z_v(\tau)] = \mu_v^\sigma(k)$. Then, let

$$\widetilde{Z} := \frac{1}{m}\sum_{j=1}^{m} Z_v(\tau_j)$$

be the empirical mean over m random samples τ_j, where we will choose m later.

Since the spin system exhibits SSM with decay rate $Cr^{-\ell}$, similar to (4), we have $\mathrm{Var}\left(Z_v(\tau)\right) \le C^2 r^{-2\ell'} \le C^2 r^{-\ell}$. Then

$$\mathrm{Var}\left(\widetilde{Z}\right) = \mathrm{Var}\left(\frac{1}{m}\sum_{j=1}^{m} Z_v(\tau_j)\right) \le \frac{C^2}{mr^{\ell'}}.$$

Thus, we set $m = \lceil nC^2 r^{-\ell'} \rceil$ samples so that $\mathrm{Var}\left(\widetilde{Z}\right) \le 1/n$.

For the running time, we first construct the table as in Lemma 14. Then we take m samples of τ, each of which can be generated in time almost linear in $|S_v(\ell')|$ with high probability using Theorem 25. As $|S_v(\ell')| \le 2C_0\ell$, the runtime in total is at most $O(2^{C_1\ell} + n\ell r^{-\ell'} \log n)$ with high probability. We choose $\ell = \frac{1-c}{C_1}\log n$ for $c = \frac{\log r}{\log r + 2C_1} \in [0,1]$, so that $\ell' \ge \ell/2 = \frac{1-c}{2C_1}\log n$ and the total runtime is $O(n^{1-c} + n^{1-(1-c)\log r/(2C_1)}\log^2 n) = \widetilde{O}(n^{1-c})$. ◀

Now we are ready to prove Theorem 13.

Proof of Theorem 13. We are going to use (5) to do a self-reduction. First we construct the target configuration σ adaptively. Given σ on $v_1, \dots, v_{i-1}$, we want to choose σ_{v_i} to be $k \in [q]$ with the largest marginal. In other words, $\sigma_{v_i} = \mathrm{argmax}_{k\in[q]} \mu_{v_i}^{\sigma_i}(k)$ for each i, where σ_i is what has been constructed so far, namely $\sigma_{v_1}, \dots, \sigma_{v_{i-1}}$. Of course, this step cannot be done exactly. Instead, we may fix a constant $t = t(C, r, q)$ such that $Cr^{-t} \le \frac{1}{2q}$, fix an arbitrary boundary configuration τ on $S_{v_i}^{\sigma_i}(t)$ and then pick $k \in [q]$ that maximises $\mu_{v_i}^{\sigma_i,\tau}(k)$. SSM guarantees that $\mu_{v_i}^{\sigma_i}(\sigma_{v_i}) \ge 1/2q$, where $\sigma_{v_i} = k$. This step takes constant time as t is a constant.

The rest of the proof is very similar to that of Theorem 1. Set $N := \lceil 10e^{4q^2}/\varepsilon_0^2 \rceil$ where $\varepsilon_0 = \varepsilon/2$. We compute $X = \prod_{i=1}^n \widetilde{Z}_i$ where each $\widetilde{Z}_i$ is from Lemma 15 plugging in v_i and σ_i. Due to the decomposition (5) we have

$$\mathbb{E}[X] = \mathbb{E}\left[\prod_{i=1}^n \widetilde{Z}_i\right] = \prod_{i=1}^n \mathbb{E}\left[\widetilde{Z}_i\right] = \prod_{i=1}^n \mu_{v_i}^{\sigma_i}(\sigma_{v_i}) = \mu(\sigma).$$

We also compute $w(\sigma)$ which can be done in $O(n)$ on a planar graph with quadratic growth. By Lemma 15, the time to generate one X is $O(n^{2-c}\mathrm{polylog}\,(n))$ with high probability. We bound $\mathrm{Var}\,(X)$ as follows

$$\begin{aligned}\frac{\mathrm{Var}\,(X)}{(\mathbb{E}[X])^2} = \frac{\mathbb{E}[X^2]}{(\mathbb{E}[X])^2} - 1 = \frac{\prod_{i=1}^n \mathbb{E}[\widetilde{Z}_i^2]}{\prod_{i=1}^n \mathbb{E}[\widetilde{Z}_i]^2} - 1 &= \prod_{i=1}^n \left(1 + \frac{\mathrm{Var}\left(\widetilde{Z}_i\right)}{(\mathbb{E}[\widetilde{Z}_i])^2}\right) - 1 \\ &\le \left(1 + \frac{4q^2}{n}\right)^n - 1 \le e^{4q^2},\end{aligned}$$

where we use $\mu_{v_i}^{\sigma_i}(\sigma_{v_i}) \ge 1/2q$ for any $i \in [n]$. Let $\widetilde{X}$ be the average of N samples of X. Then $\mathrm{Var}\left(\widetilde{X}\right) = \frac{\mathrm{Var}(X)}{N} \le \frac{e^{4q^2}}{N \cdot Z(G)^2}$. By Chebyshev's inequality,

$$\Pr\left[\left|\widetilde{X} - \frac{1}{Z(G)}\right| \ge \frac{\varepsilon_0}{Z(G)}\right] \le \frac{\mathrm{Var}\left(\widetilde{X}\right)}{\frac{\varepsilon_0^2}{Z(G)^2}} \le \frac{e^{4q^2}}{N \cdot Z(G)^2} \cdot \frac{Z(G)^2}{\varepsilon_0^2} \le \frac{1}{10}.$$

Thus, with probability at least 9/10, we have that $\frac{1-\varepsilon_0}{Z(G)} \le \widetilde{X} \le \frac{1+\varepsilon_0}{Z(G)}$. Finally, we output $\widetilde{Z} = w(\sigma)/\widetilde{X}$. Since Definition 12 implies a constant degree bound, the graph is sparse and $w(\sigma)$ can be computed in $O(n)$ time. To make sure that the algorithm runs within the

Figure 2 Circle packings of some lattices. (a): $\mathbb{Z}^2$ grid, $R = 1$. (b): Kisrhombille tiling, $R = 2 - \sqrt{3}$. (c): degree-3 Bethe lattice, $R = 0$.

desired time bound $O\left(\frac{n^{2-c}}{\varepsilon^2}\right)$, we truncate the algorithm if it runs overtime and output an arbitrary value in that case. This truncated version can be coupled with the untruncated algorithm with probability at least 7/8, and its output $\widetilde{Z}$ satisfies $1 - \varepsilon \leq \frac{\widetilde{Z}}{Z(G)} \leq 1 + \varepsilon$ with probability at least 3/4. ◀

4.1 Bounded-radius circle packing

Here we show that Theorem 13 applies to any planar graph with bounded-radius circle packings. We begin with the definition of a circle packing.

▶ **Definition 16.** *A* circle packing *is a collection $\mathcal{C}$ of interior-disjoint circles over the 2-dimensional plane. A* tangency graph *of a circle packing is a graph having a vertex for each circle, and an edge between two vertices if and only if the two corresponding circles are tangent.*

The Koebe-Andreev-Thurston *circle packing theorem* states the following.

▶ **Theorem 17.** *For every connected locally finite simple planar graph $\mathbb{G}$, there exists a circle packing whose tangency graph is (isomorphic to) $\mathbb{G}$.*

We are concerned with the radius of the circles used in the packing, especially the ratio between the smallest and largest ones.

▶ **Definition 18.** *A locally finite simple planar graph $\mathbb{G}$ is said to have an R-*bounded-radius circle packing *(R-BRCP) for some constant $R > 0$, if there exists a circle packing $\mathcal{C}$ whose tangency graph is (isomorphic to) $\mathbb{G}$ such that*

$$\frac{\inf\limits_{\odot \in \mathcal{C}} r_{\odot}}{\sup\limits_{\odot \in \mathcal{C}} r_{\odot}} \geq R$$

where $r_{\odot}$ denotes the radius of a circle $\odot$ in the packing.

Three examples are given in Figure 2. The $\mathbb{Z}^2$ grid can be naturally packed by unit disks, leading to $R = 1$. Such a graph is called a "penny graph". The 3, 6-kisrhombille tiling is a tiling of the 2-dimensional plane by $\pi/6$-$\pi/3$-$\pi/2$ triangles. This lattice can be packed by

circles of radii $1, 2\sqrt{3}-3, 2-\sqrt{3}$, so $R = 2-\sqrt{3}$. The degree-3 Bethe lattice, also known as the infinite 3-regular tree, can be drawn as a planar graph on the 2-dimensional plane. However, the neighbourhood growth is so fast that $R = 0$.

Fix the underlying graph $\mathbb{G}$ and its R-BRCP $\mathcal{C}$. Without loss of generality, we assume the diameter of the largest circle in $\mathcal{C}$ is 1. Thus, the radius of an arbitrary circle in $\mathcal{C}$ is between $R/2$ and $1/2$. Let G be a finite subgraph of $\mathbb{G}$. Here we need to distinguish the graph distance in G and the geometric distance (the Euclidean distance $\|\cdot\|_2$ between the center of their corresponding disks on the 2-dimensional plane). For two vertices u and v, we use $\mathrm{dist}_G(u,v)$ to denote their graph distance, and use $\|u-v\|_2$ to denote their geometric distance. Note that $\mathrm{dist}_{\mathbb{G}}(u,v) \geq \|u-v\|_2$ and $\mathrm{dist}_G(u,v) \geq \mathrm{dist}_{\mathbb{G}}(u,v)$.

For any vertex v and u in the ℓ-ball $B_v(\ell)$ in G, $\|u-v\|_2 \leq \mathrm{dist}_G(u,v) \leq \ell$. The disk $\odot_u$ corresponding to u must be contained completely in the circle centered at u with radius $\ell + 1/2$. By considering the area they cover,

$$|B_v(\ell)| \leq \frac{\pi(\ell+1/2)^2}{\pi(R/2)^2} = O(\ell^2/R^2).$$

Thus, any family of subgraphs of $\mathbb{G}$ has quadratic growth, where the growth constant depends on R. Together with Theorem 13, we have the following corollary.

▶ **Corollary 19.** *Let $\mathbb{G}$ be a locally finite simple planar graph, together with an R-BRCP where $R > 0$ is a constant. Let $\mathcal{G}$ be a family of subgraphs of $\mathbb{G}$, and $\boldsymbol{A}, \boldsymbol{b}$ specify a q-spin system that exhibits SSM with exponential decay on $\mathcal{G}$. Then there exists an FPRAS that takes a graph $G \in \mathcal{G}$ as an input and estimates the partition function of the spin system on G in time $\widetilde{O}(n^{2-c}/\varepsilon^2)$. Here, $n = |V(G)|$, and $c > 0$ is a constant depending on q, decay rate of SSM, and R.*

▶ Remark 20. The algorithm does not need to know the circle packing, as long as an R-BRCP exists.

On a separate note, although a good approximation of the circle packing of a finite planar graph can be found in near linear time [13], its output does not optimise the radius ratio. It is not clear how to generate a circle packing with a constant approximation of the optimal radius ratio. In the extreme, it is **NP**-hard to decide if a given graph G (without geometric positions) is a penny graph, namely admitting a circle packing using unit circles [14], even if G is restricted to be a tree [5].

4.2 Polynomial-growth graphs

Our method goes beyond planar graphs with quadratic growth rate. For any graph with a polynomial growth rate, we have a speed-up that is faster than any polylog factors.

▶ **Definition 21.** *A graph family $\mathbb{G}$ has* polynomial growth*, if there are constants C and d such that for any $G = (V, E) \in \mathbb{G}$, $v \in V$, and any integer $\ell > 0$, $|B_v(\ell)| \leq C_0 \ell^d$.*

Examples of graphs with polynomial growth include finite subgraphs of the d-dimensional integer lattice $\mathbb{Z}^d$. Again, by taking $\ell = 1$, Definition 21 implies that the maximum degree is no larger than C_0.

▶ **Theorem 22.** *Let $\mathbb{G}$ be a family of graphs with polynomial growth (assume the rate is $C_0\ell^d$). Let $\boldsymbol{A}$ and $\boldsymbol{b}$ specify a q-state spin system, which exhibits SSM with decay rate $Cr^{-\ell}$ on $\mathbb{G}$. Then there is a constant $c > 0$ such that there exists an FPRAS for the partition function of $G \in \mathbb{G}$ with n vertices with run-time $\widetilde{O}\left(\frac{n^2}{\varepsilon^2 2^{c(\log n)^{1/d}}}\right)$. The constant c depends on C_0, q, and r.*

Theorem 22 is the detailed version of Theorem 4.

In comparison to Theorem 13, the proof of Theorem 22 needs only a few small tweaks. Let ℓ be a parameter we will choose later, and our estimator is still set by using a random boundary condition on $S_v(\ell)$ to estimate the marginal at v. Note that we no longer need to find ℓ' for a smaller boundary. The main difference is in Lemma 14, where we no longer have linear local tree-width. Instead, we have to create the table by brute-force enumeration. There are $q^{C_0\ell^d}$ possible boundary conditions, and the overall time cost for creating the table is $O(q^{2C_0\ell^d})$.

We use the same estimator as in Lemma 15. To reduce the variance of our estimator to $1/n$, we need $nC^2r^{-2\ell}$ samples, each of which can be looked up quickly using the table. Let $\ell = \frac{0.99(\log n)^{1/d}}{2C_0 \log q}$. The overall time cost is

$$\widetilde{O}\left(\frac{n}{\varepsilon^2}\left(q^{2C\ell^d} + nr^{-2\ell}\right)\right) = \widetilde{O}\left(\frac{n}{\varepsilon^2}\left(n^{0.99} + \frac{n}{2^{c(\log n)^{1/d}}}\right)\right) = \widetilde{O}\left(\frac{n^2}{\varepsilon^2 2^{c(\log n)^{1/d}}}\right),$$

where $c = \frac{0.99 \log r}{C_0 \log q}$. This shows Theorem 22. Note that the factor $2^{c(\log n)^{1/d}}$ grows faster than $(\log n)^k$ for any $k > 0$.

A Lazy marginal samplers

Lemma 9 is proved in this subsection. The single-site Anand-Jerrum algorithm adapts to the hard-core model as in Algorithm 1.

Algorithm 1 HardcoreSampler$(G, \lambda, (\Sigma, \sigma), v)$.

Input: a Δ-degree graph G, fugacity λ, a set of vertices $\Sigma \subseteq V$ with a configuration $\sigma \in \Omega_\Sigma$, and vertex to sample $v \notin \Sigma$
Output: the partial configuration passed in with a spin at v: $(\Sigma, \sigma) \oplus (v, i)$ for some $i \in \{0, 1\}$.

Decrease the global timer $T \leftarrow T - 1$;
if *there exists* $u \in \Sigma \cap N(v)$ *such that* $\sigma(u) = 1$ **then**
  return $((\Sigma, \sigma) \oplus (v, 0))$;
Sample random $X \in \{\perp, 0\}$ with $\Pr[X = \perp] = \lambda/(1 + \lambda)$ and $\Pr[X = 0] = 1/(1 + \lambda)$;
if $X = \perp$ **then**
  $(\Sigma', \sigma') \leftarrow (\Sigma, \sigma)$;
  $Y \leftarrow 1$;
  forall $u \in N(v) \backslash \Sigma$ **do**
    $(\Sigma', \sigma') \leftarrow$ HardcoreSampler$(G, \lambda, (\Sigma', \sigma'), u)$;
    if $\sigma'(u) = 1$ **then** $Y \leftarrow 0$;
  return $((\Sigma, \sigma) \oplus (v, Y))$;
else
  return $((\Sigma, \sigma) \oplus (v, 0))$;

The correctness of the algorithm is summarised by the following theorem, adapted to our setting.

▶ **Theorem 23** ([1, Theorem 5.3]). *Suppose G is a graph with maximum degree bounded by Δ, and $\lambda < \lambda_c(\Delta)$. If the untruncated algorithm* HardcoreSampler$_{+\infty}(G, \lambda, (\Sigma, \sigma), v)$ *terminates with probability 1, then it generates a spin of v according to the correct marginal distribution upon termination, provided that the partial configuration (Σ, σ) is feasible.*

We remark that the correctness does not rely on the graph's neighbourhood growth being sub-exponential. However, the algorithm given here is a special case of that in [1], where they look at an ℓ-distance neighbourhood. Fixing $\ell = 1$ as we do here results in the regime of fugacity λ being worse than the critical λ_c, as we will see very soon. The saving grace of [1] is that other ℓ's might be chosen in order to get to the critical regime, but this is at the cost of limiting the neighbourhood growth. Our main algorithm does not work up to the critical λ_c, so only the 1-hop neighbourhood is considered.

In [1], the expected running time is studied and turns out to be a constant depending on the parameters of the model. However, we further need an exponential tail bound of the algorithm. This is done by the same idea of [16, Section B.3], though we do not truncate this algorithm as is done there. As soon as an exponential tail bound of running time is established, the algorithm then terminates with probability 1 and hence is correct.

We treat the algorithm as a branching process. Each time the algorithm recurses into its neighbourhood, it creates at most $\Delta - 1$ new copies of the routine HardcoreSampler. Such branching happens with probability $p := \lambda/(1 + \lambda)$. This leads us to study the following Markovian process that stochastically dominates the actual branching process. Let $(X_t)_{t \in \mathbb{Z}_{\geq 0}}$ be a discrete Markov chain where $X_t \in \mathbb{Z}_{\geq 0}$ with initial state $X_0 = 1$. This chain has an absorbing barrier at 0, and for any other $X_t > 0$, the transition probability is given by

$$X_{t+1} \leftarrow \begin{cases} X_t + \Delta - 1 & \text{with probability } p; \\ X_t - 1 & \text{with probability } 1 - p. \end{cases} \tag{6}$$

In the general case, the tail bound of this process is proved in [16, Lemma B.12], and this requires $\lambda \le \frac{1}{2e\Delta-1}$ when specialised to the hard-core model. Here we provide a stronger analysis to remove the constant.

▶ **Lemma 24.** *Suppose $\lambda < \frac{1}{\Delta-1}$. For any $0 < \varepsilon < 1$, let $T = \frac{2\Delta^2}{\left(\frac{\lambda}{1+\lambda}\Delta-1\right)^2}\log\frac{1}{\varepsilon}$. Then with probability at most ε, the process (X_t) defined by (6) does not terminate in T rounds.*

Proof. Given $\{X_t\}_{t\in\mathbb{Z}_{\ge 0}}$, define an auxillary process $\{Y_t\}_{t\in\mathbb{Z}_{\ge 0}}$ in the following way. Let $Y_0 = 1$, and the transition probability is given by

$$Y_{t+1} \leftarrow \begin{cases} Y_t + \frac{1}{1+\lambda}\Delta & \text{with probability } \frac{\lambda}{1+\lambda}; \\ Y_t - \frac{\lambda}{1+\lambda}\Delta & \text{with probability } \frac{1}{1+\lambda}. \end{cases} \tag{7}$$

Then couple X_t with Y_t perfectly that, if X_t increases then so does Y_t, and vice versa, till X_t reaches the absorbing barrier. After this point, Y_t just performs the above transition independently.

Clearly, $\{Y_t\}$ is a martingale, and if $X_t > 0$ is not absorbed then $Y_t = X_t + \left(\frac{\lambda}{1+\lambda}\Delta - 1\right)t$. Also note that the regime on λ ensures $\frac{\lambda}{1+\lambda}\Delta - 1 > 0$. This allows us to bound the probability of $\{X_t\}$ not terminating after T rounds by by applying Azuma–Hoeffding inequality:

$$\Pr[X_T > 0] = \Pr[X_T \ge X_0] = \Pr\left[Y_T - Y_0 \ge T\left(\frac{\lambda}{1+\lambda}\Delta - 1\right)\right]$$

$$\le \exp\left\{-\frac{T^2\left(\frac{\lambda}{1+\lambda}\Delta - 1\right)^2}{2\Delta^2 T}\right\} = \varepsilon. \qquad \blacktriangleleft$$

Lemma 9 then follows by exactly the same argument as in [16, Proof of Lemma B.10], by noticing that the branching process (X_t) stochastically dominates the number of "active" instances of HardcoreSampler, and using Lemma 24.

If we want to cover the whole strong spatial mixing regime but only work on amenable graphs, then we can invoke the original Anand-Jerrum algorithm, allowing us to do recursion at farther vertices rather than one-hop neighbours. Its running time tail bound is shown in [16, Lemma B.10].

▶ **Theorem 25** ([16, Lemma B.10])**.** *Suppose a q-spin system $\mathcal{S} = (G, [q], \boldsymbol{b}, \boldsymbol{A})$ exhibits strong spatial mixing with decay rate $f(\ell)$, and there is a function $s(\ell)$ such that the neighbourhood growth of G satisfies $|\{u \mid \mathrm{dist}_G(u,v) = \ell\}| \le s(\ell)$ for all v. If there is some $r \in \mathbb{Z}_{\ge 1}$ such that $2eq(1+s(r))f(r) \le 1$, then for any feasible boundary configuration (Σ, σ), the Anand-Jerrum algorithm, on input $(\mathcal{S}, (\Sigma, \sigma), v, r)$, generates a sample of v subject to the correct marginal distribution, and halts in time $O(s(r)\log\frac{1}{\varepsilon})$ with probability at least $1-\varepsilon$.*

B A lower bound for Weitz's algorithm

In this section, we prove a lower bound for the running time of the standard implementation of Weitz's algorithm. Consider the hard-core model on $G = (V, E)$ with parameter λ. Suppose we want to estimate the partition function Z within a *constant* approximation error. Let $V = \{v_1, \ldots, v_n\}$ and $G_i = G \setminus \{v_1, \ldots, v_{i-1}\}$. Weitz's algorithm solves this task by estimating each $\mu_{G_i, v_i}(0)$ within an approximation error $O(\frac{1}{n})$. It first constructs the SAW tree of G_i rooted at v_i, then truncates the tree at level ℓ and applies dynamic programming on the truncated tree to estimate $\mu_{G_i, v_i}(0)$. The standard implementation

of Weitz's algorithm [34, 28] ensures that for any tree with maximum degree Δ, any two configurations σ, τ at level ℓ, $d_{\mathrm{TV}}(\mu_v^\sigma, \mu_v^\tau) = O(\frac{1}{n})$. Standard analysis bounds the total running time from above by $T_{\mathrm{Weitz}} = \Theta(n\Delta^\ell)$.

By the same correlation decay analysis as in Lemma 11, when the algorithm in Theorem 1 has running time $\widetilde{O}(n^{1+1/2k})$, we need to choose ℓ so that $T_{\mathrm{Weitz}} = O(n^{1+1/k})$. This analysis only gives an upper bound on the correlation decay rate. If the decay rate is faster, then Weitz's algorithm is faster, and so is the algorithm in Theorem 1. The speedup will depend on how much faster the decay rate becomes. Nevertheless, the next lemma shows that the analysis in Lemma 11 is almost sharp in the worst case. The speedup in Theorem 1 is at least $\widetilde{\Omega}\left(n^{\frac{1}{2k} - O(\frac{1}{k^2 \log \Delta})}\right)$.

▶ **Lemma 26.** *Let the real number $k > 0$ and the integer $\Delta \geq 2$ be two constants satisfying $\Delta^k \geq 4$. Let $\lambda = \frac{2}{(\Delta-1)\Delta^k}$. Let T be an infinite Δ-regular tree with root v. For any $\ell \geq 2$, let σ_0 and σ_1 be all-0 and all-1 configurations at level ℓ of T respectively. The Gibbs distribution μ of the hard-core model on T with parameter λ satisfies*

$$d_{\mathrm{TV}}(\mu_v^{\sigma_0}, \mu_v^{\sigma_1}) \geq \frac{1}{2}\left(\frac{1}{\Delta^k}\right)^\ell.$$

Let the parameters k, Δ, and λ be as in Lemma 26. Consider a family of hard-core instances where the graphs are indeed Δ-regular trees. In Weitz's algorithm, in order to ensure an $O(\frac{1}{n})$ truncation error, Lemma 26 implies that ℓ must satisfy $\frac{1}{2}\left(\frac{1}{\Delta^k}\right)^\ell = O(\frac{1}{n})$, namely,

$$\Delta^\ell = \Omega(n^{\frac{1}{k}}).$$

This makes the overall running time $T_{\mathrm{Weitz}} = \Omega(n^{1+\frac{1}{k}})$. In comparison, for these parameters, the algorithm in Theorem 1 has a running time upper bound $\widetilde{O}\left(n^{1+\frac{1}{2k}+O(\frac{1}{k^2 \log \Delta})}\right)$, which is faster by a factor of roughly $\widetilde{\Omega}(n^{1/2k})$.

Proof of Lemma 26. Let w be an arbitrary vertex at level $0 \leq t \leq \ell$. Let π denote the Gibbs distribution on the subtree rooted T_w at w. Recall that σ_0, σ_1 are pinnings on $T(\ell)$, where $T(\ell)$ is level ℓ of T. Let $p_t^0(c) = \pi_w^{\sigma_0}(c)$ and $p_t^1(c) = \pi_w^{\sigma_1}(c)$ for $c \in \{0, 1\}$, where we use σ_0 and σ_1 to denote all-0 and all-1 pinnings on $T_w \cap T(\ell)$. By symmetry, $p_t^0(\cdot)$ and $p_t^1(\cdot)$ depend only on t but not on w. In particular, $p_0^0 = \mu_v^{\sigma_0}$ and $p_0^1 = \mu_v^{\sigma_1}$ for the root v. For any $0 \leq t \leq \ell$, define

$$R_t^0 := \frac{p_t^0(1)}{p_t^0(0)}, \quad R_t^1 := \frac{p_t^1(1)}{p_t^1(0)}.$$

We next prove the following result holds for all $1 \leq t \leq \ell - 1$:

$$\left|R_t^0 - R_t^1\right| \geq \frac{1}{2}\left(\frac{1}{\Delta^k}\right)^{\ell-t-1}. \tag{8}$$

We need the following bound to prove (8). By considering the worst pinning on the neighbourhood, we have the following bound on both ratios R_s^0 and R_s^1

$$\forall 0 \leq s \leq \ell - 1, \quad R_s^0, R_s^1 \leq \lambda = \frac{2}{(\Delta-1)\Delta^k}. \tag{9}$$

We prove (8) by induction on t from $\ell-1$ to 1. The base case is $t=\ell-1$. Note that $\Delta^k \geq 4$. A straightforward calculation shows that

$$\left|R^0_{\ell-1} - R^1_{\ell-1}\right| = |1-\lambda| = 1 - \frac{2}{(\Delta-1)\Delta^k} \geq \frac{1}{2}.$$

For the induction step, fix $1 \leq t \leq \ell-2$. The recursion function in $(\Delta-1)$-ary tree is

$$f(x) = \lambda\left(\frac{1}{1+x}\right)^{\Delta-1}.$$

Note that $R^0_t = f(R^0_{t+1})$ and $R^1_t = f(R^1_{t+1})$. By the mean value theorem, there exists $\min(R^0_{t+1}, R^1_{t+1}) < \theta < \max(R^0_{t+1}, R^1_{t+1})$ such that

$$\left|R^0_t - R^1_t\right| = |f'(\theta)| \cdot \left|R^0_{t+1} - R^1_{t+1}\right|.$$

By (9) and the fact $\Delta^k \geq 4$, we have

$$\begin{aligned}|f'(\theta)| &= \lambda(\Delta-1)\left(\frac{1}{1+\theta}\right)^{\Delta} \geq \lambda(\Delta-1)\left(\frac{1}{1+\lambda}\right)^{\Delta} \geq \lambda(\Delta-1)\exp(-\lambda\Delta)\\ &= \frac{2}{\Delta^k}\exp\left(-\frac{2\Delta}{(\Delta-1)\Delta^k}\right) \geq \frac{2}{\Delta^k}\exp\left(-\frac{4}{\Delta^k}\right) \geq \frac{1}{\Delta^k}.\end{aligned}$$

By the induction hypothesis that $\left|R^0_{t+1} - R^1_{t+1}\right| \geq \frac{1}{2}(\frac{1}{\Delta^k})^{\ell-t-2}$, we can prove (8) for t. This finishes the induction step for $1 \leq t \leq \ell-3$.

Finally, we use (8) to bound $|R^0_0 - R^1_0|$. The proof is similar to the proof in the induction step. The only difference is that the recursion for root v becomes $g(x) = \lambda\left(\frac{1}{1+x}\right)^{\Delta}$. By a similar calculation, there exists $\min(R^0_1, R^1_1) < \theta < \max(R^0_1, R^1_1)$ such that

$$\begin{aligned}|R^0_0 - R^1_0| = |g'(\theta)| \cdot \left|R^0_1 - R^1_1\right| &\geq \Delta\lambda\left(\frac{1}{1+\theta}\right)^{\Delta+1} \cdot \frac{1}{2}\left(\frac{1}{\Delta^k}\right)^{\ell-2}\\ &= \frac{\Delta}{(\Delta-1)(1+\theta)} \cdot \lambda(\Delta-1)\left(\frac{1}{1+\theta}\right)^{\Delta} \cdot \frac{1}{2}\left(\frac{1}{\Delta^k}\right)^{\ell-2}\\ &\geq \frac{\Delta}{(\Delta-1)(1+\lambda)} \cdot \frac{1}{2}\left(\frac{1}{\Delta^k}\right)^{\ell-1} \geq \frac{1}{3}\left(\frac{1}{\Delta^k}\right)^{\ell-1}.\end{aligned}$$

By the definitions of R^0_0 and R^1_0 and the fact $\Delta^k \geq 4$, we have

$$\begin{aligned}d_{\mathrm{TV}}(\mu^{\sigma_0}_v, \mu^{\sigma_1}_v) = |\mu^{\sigma_0}_v(1) - \mu^{\sigma_1}_v(1)| &= \mu^{\sigma_0}_v(0)\mu^{\sigma_1}_v(0)|R^0_0 - R^1_0|\\ &\geq \left(\frac{1}{1+\lambda}\right)^2 \cdot \frac{1}{3}\left(\frac{1}{\Delta^k}\right)^{\ell-1} \geq \frac{4}{27}\left(\frac{1}{\Delta^k}\right)^{\ell-1} \geq \frac{1}{2}\left(\frac{1}{\Delta^k}\right)^{\ell}.\end{aligned}$$

Abstract

Folklore in complexity theory suspects that circuit lower bounds against $\mathbf{NC}^1$ or $\mathbf{P}/\text{poly}$, currently out of reach, are a necessary step towards proving strong proof complexity lower bounds for systems like Frege or Extended Frege. Establishing such a connection formally, however, is already daunting, as it would imply the breakthrough separation $\mathbf{NEXP} \not\subseteq \mathbf{P}/\text{poly}$, as recently observed by Pich and Santhanam [58].

We show such a connection conditionally for the Implicit Extended Frege proof system (iEF) introduced by Krajíček [45], capable of formalizing most of contemporary complexity theory. In particular, we show that if iEF proves efficiently the standard derandomization assumption that a concrete Boolean function is hard on average for subexponential-size circuits, then any superpolynomial lower bound on the length of iEF proofs implies $\#\mathbf{P} \not\subseteq \mathbf{FP}/\text{poly}$ (which would in turn imply, for example, $\mathbf{PSPACE} \not\subseteq \mathbf{P}/\text{poly}$). Our proof exploits the formalization inside iEF of the soundness of the sum-check protocol of Lund, Fortnow, Karloff, and Nisan [54]. This has consequences for the self-provability of circuit upper bounds in iEF. Interestingly, further improving our result seems to require progress in constructing interactive proof systems with more efficient provers.

1 Introduction

At a high level, both circuit complexity and proof complexity can be thought of as an approach towards the **P** versus **NP** question. The circuit complexity program, which met with considerable success in the 1980s, tries to prove lower bounds against gradually larger circuit classes, hoping to eventually show $\mathbf{NP} \not\subseteq \mathbf{P}/\text{poly}$. Proof complexity, often identified with the so-called Cook-Reckhow program, intends to show $\mathbf{NP} \neq \mathbf{coNP}$ and, in turn, $\mathbf{P} \neq \mathbf{NP}$, by proving lower bounds against gradually more powerful proof systems for propositional logic.

While both enterprises share the motivation to study *concrete* computational models of increasing power hoping to build up techniques to attack the long-sought separations, there exist notable differences. Circuit complexity looks at deterministic models of computation, while proof complexity deals with proof systems, which are inherently non-deterministic. Furthermore, while circuit complexity has a clear end-goal (lower bounds against general Boolean circuits), it remains wide open whether the Cook-Reckhow program can be realized even in principle. It is not known whether lower bounds against strong systems like Extended Frege can imply lower bounds for every other system and, as such, one could potentially keep proving lower bounds for ever-stronger systems without ever settling whether $\mathbf{NP} \neq \mathbf{coNP}$.

The parallels between circuit complexity and proof complexity are made clearer by Frege systems. For each circuit complexity class $\mathcal{C}$, one can define the proof system $\mathcal{C}$-Frege, in which proof lines are restricted to be circuits from $\mathcal{C}$. In this setting strong systems like Frege and Extended Frege correspond to $\mathbf{NC}^1$-Frege and $\mathbf{P}/\text{poly}$-Frege, respectively, and thus the natural question arises: Can we turn explicit lower bounds for $\mathcal{C}$ circuits into lower bounds for $\mathcal{C}$-Frege systems, and vice versa?

While the question is essentially open, work on weaker systems and circuit classes has proven successful. In one direction, the method of feasible interpolation [43, 65, 50] (see [51, §17.9.1] for the history of the method) has been extensively applied to obtain proof complexity lower bounds. The framework of feasible interpolation formalizes the idea of extracting computational content from proofs: given short proofs in a given system, one can extract a small Boolean circuit in some restricted classes for a related interpolant function. Contrapositively, circuit lower bounds for such functions (often coming from unconditional results such as lower bounds against monotone circuits [64, 4, 3]), turn into lower bounds for proofs systems like Resolution [50] or Cutting Planes [61] (and conditionally for other systems, such as Polynomial Calculus or Sum-of-Squares [32]). Unfortunately, this connection breaks for stronger proof systems: already $\mathbf{AC}^0$-Frege and $\mathbf{TC}^0$-Frege are known to lack feasible interpolation properties[1] under standard cryptographic hardness assumptions [52, 13, 12], and this holds even if we allow feasible interpolation by quantum circuits [6].

In the other direction (circuit complexity from proof complexity), the theory of lifting has unveiled deep connections between proofs, circuits and communication protocols. Here, so-called query-to-communication lifting theorems translate query complexity lower bounds (corresponding to weak systems, like Resolution) into communication complexity lower bounds (e.g. [63, 53]). The latter provide restricted circuit lower bounds, such as for monotone circuits (see e.g. [27, 24, 25] and references therein). It is, however, not known how to derive non-monotone lower bounds for unrestricted Boolean circuits by lifting proof complexity lower bounds.

[1] Some of these systems are known to admit some form of interpolation by stronger computational models, see e.g. [62, 23], but we are interested in Boolean circuits.

For proper Frege systems, the connection has worked mostly in one direction, from circuits to proofs, particularly at the level of techniques. The method of random restrictions and the celebrated switching lemmas used to show constant-depth circuit lower bounds in the 1980s [26, 1, 33] were successfully transferred into $\mathbf{AC}^0$-Frege lower bounds shortly after [2, 10, 43, 8, 59, 49]. This suggests that understanding what makes proof lines large might be necessary to understand why proofs are long. Intriguingly, understanding the proof lines alone does not seem to suffice: the $\mathbf{AC}^0[p]$ lower bounds of Razborov and Smolensky [66, 68] are yet to be successfuly translated to proof complexity, with lower bounds for $\mathbf{AC}^0[2]$-Frege being one of the prominent frontier problems in the field.

The current situation seems to suggest that in order to make progress towards proof complexity lower bounds, it is *necessary* (though seemingly not sufficient) to first obtain strong enough circuit lower bounds. In particular, under this folklore belief, circuit lower bounds against $\mathbf{NC}^1$ or $\mathbf{P}/\text{poly}$, currently out or reach, would be a necessary step towards proving strong proof complexity lower bounds for systems like Frege or Extended Frege. However, the suspicion remains unproven, and no generic way of deriving explicit circuit lower bounds for unrestricted Boolean circuits from proof complexity lower bounds for concrete propositional proof systems has been discovered[2].

The first result giving such a connection under relatively conventional assumptions which are presumably weaker than the conclusion of the connection itself was presented recently by Pich and Santhanam [58]. Specifically, they showed that any superpolynomial lower bound on the length of tautologies in the Extended Frege system EF implies $\mathbf{NP} \not\subseteq \mathbf{P}/\text{poly}$ assuming hypotheses (1) and (2) below:

(1) (*Provable circuit lower bound.*) EF proves efficiently that a concrete Boolean function in $\mathbf{E}$ is average-case hard for subexponential-size circuits.

(2) (*Provable reduction of OWFs to* $\mathbf{P} \neq \mathbf{NP}$.) EF proves efficiently that a polynomial-time function transforms circuits breaking one-way functions into circuits solving SAT.

We remark that Hypothesis (1) above presupposes $\mathbf{E} \not\subseteq \mathbf{P}/\text{poly}$, which is however believed to be a significantly weaker statement than $\mathbf{NP} \not\subseteq \mathbf{P}/\text{poly}$. Alternatively, Hypotheses (1) and (2) can be replaced by a single assumption on the feasible provability of the existence of antickeckers in EF. These results remain valid even if we replace EF by an essentially arbitrary proof system simulating EF.

Crucially, improving this and related results by dropping the hypotheses is surprisingly daunting. As noted by Pich and Santhanam [58, Prop. 1], if one unconditionally establishes the implication "if S is not polynomially bounded, then $\mathbf{NP} \not\subseteq \mathbf{P}/\text{poly}$" for a concrete proof system S, then the breakthrough separation $\mathbf{NP} \not\subseteq \mathbf{SIZE}[n^k]$, for every fixed k (and $\mathbf{NEXP} \not\subseteq \mathbf{P}/\text{poly}$) follows!

In short, proving a formal connection between proof complexity and circuit complexity provably requires breakthrough circuit lower bounds! Despite this setback, one can still hope to get evidence that points at these connections, possibly by shifting some of the components of the ingredients. Namely, one may try to (a) adopt some hardness assumption, in the style of [58]; (b) conclude lower bounds weaker than $\mathbf{NP} \not\subseteq \mathbf{P}/\text{poly}$; or (c) look at non-Cook-Reckhow proof systems (such as MA proof systems or proof systems for languages beyond $\mathbf{coNP}$).

[2] We note that the issue lies in establishing such a connection for a *concrete* system. Of course, the statement "there is a proof system S such that if S is not polynomially bounded, then $\mathbf{P} \neq \mathbf{NP}$" is true: if $\mathbf{NP} = \mathbf{coNP}$ the implication is vacuously true by taking a polynomially bounded proof system; if $\mathbf{NP} \neq \mathbf{coNP}$, then $\mathbf{P} \neq \mathbf{NP}$ and thus the statement holds for any proof system. It would be dramatically different to obtain such a connection for a concrete system.

In this style, Grochow and Pitassi [31] showed that the Ideal Proof System (IPS) does satisfy such a connection, to *algebraic* circuit complexity. Indeed, any superpolynomial lower bound in the length of proofs in $\mathsf{IPS}_{\mathbb{F}}$ implies $\mathbf{VP}_{\mathbb{F}} \neq \mathbf{VNP}_{\mathbb{F}}$. Grochow and Pitassi avoid the Pich-Santhanam barrier by means of (b) and (c) above: first, IPS is not known to be a Cook-Reckhow system, since proofs are verified by randomized machines via polynomial identity testing; second, the lower bounds are algebraic and not Boolean. Recall that while separating **VP** and **VNP** is a necessary step[3] towards $\mathbf{NP} \not\subseteq \mathbf{P}/\mathrm{poly}$ [14], the converse is not known.

Another interesting connection has been established in the realm of quantified Boolean formulas, where the connection can be made essentially optimal. Beyersdorff, Bonacina, Chew, and Pich [11] showed that for every circuit class $\mathcal{C}$, the quantified system $\mathcal{C}$-Frege + $\forall$red is not polynomially bounded if and only if either $\mathbf{PSPACE} \not\subseteq \mathcal{C}$ or $\mathcal{C}$-Frege is not polynomially bounded. Here, $\mathcal{C}$-Frege + $\forall$red stands for the natural quantified system obtained by extending $\mathcal{C}$-Frege with a universal reduction rule, which takes care of universal quantifiers by instantiating concrete values for its variables in the hope of refuting the formula. The reason this avoids the Pich-Santhanam barrier is the disjunct in the conclusion. That is, in the context of QBF the conclusion of the Pich-Santhanam barrier becomes that that either $\mathbf{NEXP} \not\subseteq \mathbf{P}/\mathrm{poly}$ or $\mathcal{C}$-Frege is not polynomially bounded. But this disjunction is no breakthrough, since it follows directly by a diagonalization argument anyway: if a propositional system is polynomially bounded, then **NEXP** is hard for $\mathbf{P}/\mathrm{poly}$ [44].

Contributions

We prove a new conditional connection between proof complexity and circuit complexity, giving further evidence that strong proof complexity lower bounds require circuit lower bounds. This constitutes the first example of a natural proof system that is conditionally Cook-Reckhow and whose lower bounds imply Boolean circuit lower bounds.

The system in question is (an extension of) the Implicit Extended Frege (iEF) proof system of Krajíček [45], capable of formalizing most of contemporary complexity theory. Our result can be informally stated as follows, where $\mathsf{iEF}^{\mathrm{tt}(h)}$ stands for the proof system extending iEF by axioms $\mathrm{tt}^{\mathrm{avg}}_{1/4}(h_n, 2^{n/4})$ claiming there are no circuits of size $2^{n/4}$ approximating a concrete function h on more than a $(1/2 + 1/2^{n/4})$-fraction of the inputs.[4]

▶ **Theorem 1** (Main theorem, informal). *Suppose there is a Boolean function $h \in \mathbf{NE} \cap \mathbf{coNE}$ that is hard on average for subexponential-size circuits. If the Cook-Reckhow proof system $\mathsf{iEF}^{\mathrm{tt}(h)}$ is not polynomially bounded, then $\#\mathbf{P} \not\subseteq \mathbf{FP}/\mathrm{poly}$.*

In the theorem above one could instead consider the system $\mathsf{iEF}^{\mathrm{tt}(h)}$ for some unconditionally hard function family h that is guaranteed to exist. The only problem in this case is that we might need non-uniform advice to verify the proofs, and so the system would not be Cook-Reckhow (we refer to Cook and Krajíček [19] for a systematic treatment of non-uniform proof systems).

One can interpret our theorem as improving on the connection of Pich and Santhanam [58] from proof complexity to circuit complexity. Our result improves that of Pich and Santhanam by completely dropping their second assumption (the one about EF proving the existence of one-way functions under $\mathbf{P} \neq \mathbf{NP}$). The price to pay for these changes is two-fold:

[3] Unconditionally over finite fields, and assuming the Generalized Riemann Hypothesis for infinite fields.
[4] For technical reasons, we define $\mathsf{iEF}^{\mathrm{tt}(h)}$ using a system which is polynomially equivalent to iEF instead of iEF itself, see Definition 17.

1. we need to replace EF by the seemingly stronger Implicit Extended Frege system (iEF). Informally, iEF extends EF with an extra rule allowing us to derive a formula φ after we have derived that a truth table of a given circuit encodes an EF-proof of φ. Such a circuit is called an *implicit* proof;
2. we can conclude only $\#\mathbf{P} \not\subseteq \mathbf{FP}/\text{poly}$ from iEF lower bounds, instead of $\mathbf{NP} \not\subseteq \mathbf{P}/\text{poly}$.

One may also compare our result to that of Grochow and Pitassi [31], who showed $\mathbf{VP} \neq \mathbf{VNP}$ (and hence hardness of computing the permanent) would follow from IPS lower bounds. Like our result, the IPS proof system is only conditionally Cook-Reckhow. Indeed, IPS is a Merlin-Arthur proof system which can be derandomized[5] under standard assumptions, like $\mathbf{E}$ being hard to approximate by subexponential-size circuits. Our result is in some sense stronger in that the lower bounds obtained are Boolean rather than algebraic. However, we seem to be getting to lower bounds for the same problem as Grochow and Pitassi, since computing the permanent is both $\mathbf{VNP}$-complete and $\#\mathbf{P}$-complete.

We note that the requirement that $h \in \mathbf{NE} \cap \mathbf{coNE}$ is not strictly needed and, in fact, one can phrase the result in a more general style (as we do in the technical part) in which the connection holds for any extension of iEF by truth table formulas for any hard function. Observe, however, that iEF is a very strong proof system, with its bounded arithmetic counterpart being the theory V^1_2 (or $\mathsf{S}^1_2 + \text{1-EXP}$, in the first-order setting), and so it is plausible that iEF already proves such a circuit lower bound. For example, already EF can prove efficiently the PCP theorem [57], $\mathbf{AC}^0$, $\mathbf{AC}^0[2]$ and monotone circuit lower bounds [67, 55], or the hardness amplification producing average-case hard functions in $\mathbf{E}$ from worst-case hard functions in $\mathbf{E}$ [36]. Furthermore, iEF proves efficiently the correctness of Zhuk's algorithm from a CSP dichotomy [28, 29]. Hence, it is plausible to imagine that if circuit lower bounds are at all provable, they may well be provable already in iEF. If that turned out to be the case, then the concrete proof system in our main theorem becomes iEF itself.

▶ **Corollary 2** (Main theorem, restated). *Assume that* iEF *proves efficiently* $\mathrm{tt}^{\mathrm{avg}}_{1/4}(h_n, 2^{n/4})$ *for some function family* h *and each sufficiently big* n*. Then, if* iEF *is not polynomially bounded,* $\#\mathbf{P} \not\subseteq \mathbf{FP}/\text{poly}$.

Let us note that one cannot make big improvements to this result without hitting the Pich-Santhanam barrier that implies $\mathbf{NEXP} \not\subseteq \mathbf{P}/\text{poly}$ unconditionally: if we managed to prove Theorem 1 for a Cook-Reckhow proof system, then $\mathbf{NEXP} \not\subseteq \mathbf{P}/\text{poly}$ would follow unconditionally. On the other hand, if our final goal is to prove $\mathbf{FP} \neq \#\mathbf{P}$, then the assumption of Theorem 1 is given to us for free even for some hard $h \in \mathbf{E}$, as otherwise, if $\mathbf{E}$ can be computed by subexponential-size circuits, it is not hard to show that $\mathbf{P} \neq \mathbf{NP}$ [44].

Consequences for self-provability of circuit upper bounds

Our result has consequences for the self-provability of circuit upper bounds. Suppose that $\#\mathbf{P} \subseteq \mathbf{FP}/\text{poly}$. Then, there is a sequence of polynomial-size circuits $\{C_n\}_{n\in\mathbb{N}}$ that on input a formula φ of size n, outputs a satisfying assignment if one exists. This means that the propositional formula $\mathrm{SAT}_n(\varphi, \alpha) \to \mathrm{SAT}_n(\varphi, C_n(\varphi))$ claiming the correctness of C_n as a SAT solver is tautological (where SAT_n is the satisfiability predicate, taking a formula φ and

[5] In fact, derandomizing IPS at all by simulating it by a Cook-Reckhow system implies a non-trivial derandomization of polynomial identity testing to $\mathbf{NP}$ [30]; this, in turn, implies some circuit lower bounds, as shown by Kabanets and Impagliazzo [38].

an assignment α and evaluating the formula). But by Theorem 1, $\mathsf{iEF}^{\mathrm{tt}}$ is now polynomially bounded, and so the proof system is able to efficiently argue for the correctness of the circuits. Namely, the mere validity of the upper bound $\#\mathbf{P} \subseteq \mathbf{FP}/\mathrm{poly}$ would imply the efficient propositional provability of $\mathrm{SAT} \in \mathbf{P}/\mathrm{poly}$.

Outline of the proof

Our main result follows from a derandomization of the known fact that $\mathbf{coNP} \not\subseteq \mathbf{MA}$ implies $\#\mathbf{P} \not\subseteq \mathbf{FP}/\mathrm{poly}$ (see, for example, [5, Thm. 8.22]), together with a formalization of the underlying MA system in a suitable theory of bounded arithmetic. The implication holds, actually, for the MA system given by the sum-check protocol of Lund, Fortnow, Karloff, and Nisan [54] in which proofs consist of a circuit simulating the moves of the Prover in the protocol, so that given such a circuit, the Verifier can simulate the entire protocol on their own with the aid of randomness. If $\#\mathbf{P} \subseteq \mathbf{FP}/\mathrm{poly}$, then the $\#\mathbf{P}$-powerful Prover in the sum-check protocol can be replaced by a polynomial-size circuit and thus the system is a polynomially bounded Merlin-Arthur system. Clearly, lower bounds on the length of proofs in this system are exactly circuit lower bounds against $\#\mathbf{P}$.

Since $\mathbf{MA}$ can be derandomized under standard hardness assumptions, assuming, for example, that $\mathbf{E}$ is hard for subexponential-size circuits, the proof system R based on the sum-check protocol above becomes a Cook-Reckhow system such that if R is not polynomially bounded, then $\#\mathbf{P} \not\subseteq \mathbf{FP}/\mathrm{poly}$. This is almost our goal. Our task now is to replace this system by a different more standard Cook-Reckhow system S. This can be achieved by proving efficiently the reflection principle of the system R in S, which essentially amounts to proving the soundness of the sum-check protocol in S. Here, we employ a recent work of Khaniki [40], in which the soundness of the sum-check protocol was formalized in $\mathsf{S}^1_2 + \mathsf{1\text{-}EXP}$.

In order to translate the formalization inside $\mathsf{S}^1_2 + \mathsf{1\text{-}EXP}$ into propositional logic, we need to express the soundness of the sum-check protocol by propositional formulas. This is achieved using the machinery of approximate counting of Jeřábek [37], which exploits Nisan-Wigderson generators based on a hard Boolean function.

Open problems

Improving our result seems to require significant conceptual work. Of course, simultaneously dropping the circuit lower bound assumption as well as getting the stronger separation $\mathbf{NP} \not\subseteq \mathbf{P}/\mathrm{poly}$ would already imply $\mathbf{NEXP} \not\subseteq \mathbf{P}/\mathrm{poly}$, but one may hope to improve the existing connection by improving on one of the two fronts only. Interestingly, this seems to require progress in some of the central open questions in the theory of interactive proof systems or in hardness magnification.

The power of the prover

Is it possible to strengthen the conclusion of the main theorem all the way down to $\mathbf{NP} \not\subseteq \mathbf{P}/\mathrm{poly}$? This would follow, for example, if we managed to design an interactive protocol for TAUT with a prover solving only $\mathbf{NP}$ problems and prove its correctness in iEF (unlike the current situation, where the prover is required to compute a $\#\mathbf{P}$-complete function). The general question of constructing a protocol for a language L where the prover's power is limited to $\mathbf{P}^L$ is a well-known open problem in the theory of interactive proof systems (see, for example, [5, §8.4]).

Note, of course, that the existence of such a protocol does not suffice, since its soundness must be provable inside iEF. In fact, the reason why we require iEF (or $\mathsf{S}^1_2 + \mathsf{1\text{-}EXP}$) to carry out the formalization of the existing sum-check protocol is that one cannot feasibly talk about #SAT directly in EF or S^1_2 (unless $\mathbf{FP} = \#\mathbf{P}$).

Hardness magnification

Is it possible to replace iEF in the main theorem by Gentzen's system G, or even by Extended Frege? One option would be to carry out the existing formalization inside EF, as mentioned above. The caveat would be, however, that we would then have to make the assumption on truth table tautologies for EF. Whether EF can prove general circuit lower bounds at all seems much less believable than for iEF, and so the plausibility of our hypotheses seems affected.

Instead, one may choose to keep everything in iEF and obtain the connection indirectly for EF via hardness magnification. Is there a natural class of formulas over which EF simulates iEF (and which are believably hard for EF)? If so, assuming hardness of these formulas for EF would imply iEF lower bounds. By our main theorem, $\#\mathbf{P} \not\subseteq \mathbf{P}/\mathrm{poly}$ would follow. To the best of our knowledge, no such type of hardness magnification is known for strong proof systems.

2 Preliminaries

We assume familiarity with the central concepts of computational complexity theory, propositional proof complexity and mathematical logic. Below we review the central concepts needed in this paper and fix some notation.

2.1 Proof complexity

Following Cook and Reckhow [22], a *propositional proof system* S for the language $\textsc{Taut}$ of propositional tautologies is a polynomial-time surjective function $S : \{0,1\}^* \to \textsc{Taut}$ taking as input a proof $\pi \in \{0,1\}^*$ and outputting $S(\pi) = \varphi$, the theorem that π proves. Soundness follows from the fact that the range is exactly $\textsc{Taut}$, and implicational completeness is guaranteed by the fact that S is surjective. We sometimes drop the term *proof* in *proof system* and use the term *system* alone to refer to a function S that is not guaranteed to be a Cook-Reckhow proof system (perhaps because it is unsound, or not deterministically computable).

We denote by $\mathsf{size}_S(\varphi)$ the *size* of the smallest S-proof of φ plus the size of φ. A proof system S is *polynomially-bounded* if for every $\varphi \in \textsc{Taut}$, $\mathsf{size}_S(\varphi) \leq |\varphi|^{O(1)}$. We say that a proof system S *polynomially simulates* a system Q, written $S \geq Q$, if for every $\varphi \in \textsc{Taut}$, $\mathsf{size}_S(\varphi) \leq \mathsf{size}_Q(\varphi)^{O(1)}$. Note that the notion of size and the definition of simulation do not exploit the soundness requirement of Cook-Reckhow systems. In particular, an unsound system can be polynomially bounded and simulate every other system. In some cases simulations hold only for some set T of tautologies, such as the set of tautologies written as 3DNFs, and not for all formulas, and then we say that S polynomially simulates Q over T. Given a family $\{\varphi_n\}_{n\in\mathbb{N}}$ of propositional tautologies, we write $S \vdash \varphi_n$ whenever $\mathsf{size}_S(\varphi_n) \leq |\varphi_n|^{O(1)}$.

2.1.1 Frege systems

Proof complexity studies a wide variety of proof systems. The most important ones for us are *Frege systems*. A Frege system is a finite set of axiom schemas and inference rules that are sound and implicationally complete for the language of propositional tautologies built from the Boolean connectives negation ($\neg$), conjunction ($\wedge$), and disjunction ($\vee$). A Frege proof is a sequence of formulas where each formula is obtained by either substitution of an axiom schema or by application of an inference rule on previously derived formulas. The specific choice of rules does not affect proof size up to polynomial factors, as long as there are only finitely many rules and these are sound and implicationally complete. Indeed, Frege systems polynomially simulate each other [51, Thm. 4.4.13]. Alternatively, one may choose to think of Frege systems as some variant of Natural Deduction or the Sequent Calculus for classical propositional logic.

Particularly important for us is the Extended Frege (EF) system, in which proof lines can be Boolean circuits and not just formulas, which would allow in principle for more succinct proofs. We shall often consider extensions of Extended Frege by sets of additional axioms. For a set $A \subseteq \textsc{Taut}$ of tautologies recognizable in polynomial time, the system $\mathsf{EF} + A$ refers to Extended Frege extended with substitution instances of any formula in A. Note that if A were to contain contingent formulas, then $\mathsf{EF} + A$ would not be sound; in particular, it would not be a Cook-Reckhow system, though it would be polynomially bounded.

A useful property of EF is the fact that $\mathsf{EF} + \mathrm{Ref}_S \geq S$ for every propositional system S [47]. Here Ref_S is the sequence of tautologies encoding the *reflection principle for* S, which states that S is sound. Namely, $\mathrm{Ref}_S \coloneqq \{\mathrm{Ref}_{S,n,m}\}_{n,m\in\mathbb{N}}$ where the formulas $\mathrm{Ref}_{S,n,m} \coloneqq \mathrm{Prf}_{S,n,m}(\pi,\varphi) \to \mathrm{Sat}_{n,m}(\varphi,\alpha)$ encode the soundness of S, and φ is a formula of size n, π is a purported S-proof of size m and α is an assignment to the variables in φ, which are all encoded by free variables. The formula $\mathrm{Prf}_{S,n,m}$ encodes that π is a correct S-proof of φ, and $\mathrm{Sat}_{n,m}(\varphi,\alpha)$ encodes the standard satisfaction relation for propositional formulas. Alternatively, one may exploit the same relation with respect to the *consistency* of S, $\mathrm{Con}_S \coloneqq \{\mathrm{Con}_{S,m}\}_{m\in\mathbb{N}}$, where $\mathrm{Con}_{S,m} \coloneqq \neg\,\mathrm{Prf}_{S,1,m}(\pi,\bot)$ and π encodes a purported proof of size m.

2.1.2 Quantified propositional systems

It is often convenient to operate on systems capable of reasoning with *quantified* Boolean formulas, where the quantification ranges over $\{0,1\}$. We denote by Σ^q_i (respectively, Π^q_i) the class of quantified Boolean formulas with i alternations between existential and universal quantifiers, starting with an existential (respectively, universal) one.

We are particularly interested in Gentzen's Sequent Calculus for quantified propositional logic. The system extends the usual propositional Sequent Calculus by four new rules to handle quantifiers (see [51, Def. 4.1.2] for a formal definition of the rules). We denote this system by G, and by G^* its tree-like counterpart. The system G_i, for $i \in \mathbb{N}$, corresponds to G where the quantified formulas appearing in the sequents can only be in the class $\Sigma^q_i \cup \Pi^q_i$. The tree-like counterpart of G_i is naturally denoted G^*_i. It is useful to know that EF and G^*_1 are polynomially equivalent with respect to Π^q_1 formulas [51, Thm. 4.1.3].

2.1.3 Implicit proof systems

Implicit proof systems constitute a systematic way of obtaining, for every proof system S, a potentially stronger system S', and were introduced by Krajíček [45]. The essential idea is to encode a given proof in the system S as a multi-output Boolean circuit taking

as input a number i in binary and outputting the i-th step of the proof. More formally, given propositional proof systems S and Q, a proof of a tautology φ in the *implicit system* $[S, Q]$ is a pair (π, C) consisting of a proof and a circuit, such that the truth table of C encodes a valid Q-proof of φ (the *implicit* proof), while π is an *explicit* S-proof of the formula $\mathrm{Correct}_Q(\varphi, C)$, which is the formula stating that the truth table of C is a correct Q-proof of φ. If S and Q are Cook-Reckhow proof systems, then so is $[S, Q]$.

For a system S, the implicit system $[S, S]$ is denoted by $\mathsf{i}S$. In particular, we shall work with the *Implicit Extended Frege* proof system, $\mathsf{iEF} \coloneqq [\mathsf{EF}, \mathsf{EF}]$. The system iEF is particularly strong, and it can in fact simulate all of Gentzen's G with respect to propositional tautologies [45, Cor. 2.4].

2.2 Bounded arithmetic

Our proofs exploit the connections between propositional proof complexity and theories of bounded arithmetic. Below we cover the essential preliminaries, which should be accessible to any reader with basic knowledge of first-order logic.

2.2.1 The theories S^1_2 and $\mathsf{S}^1_2 + \text{1-EXP}$

Theories of bounded arithmetic capture various levels of feasible reasoning and act as a uniform counterpart of propositional systems. Intuitively, feasibility is achieved by restricting the complexity of formulas over which one can apply general reasoning schemes like induction.

The central theory for us is Buss's S^1_2, which we think of as corresponding to polynomial-time reasoning. In this context, we work over the first-order language of bounded arithmetic, $\mathcal{L}_{\mathrm{BA}} \coloneqq \{0, S, +, \cdot, <, |x|, \lfloor x/2 \rfloor, x\#y\}$, which extends the language of Peano Arithmetic by the symbols $|x|$, $\lfloor x/2 \rfloor$ and $x\#y$. The standard interpretation of $\lfloor x/2 \rfloor$ is clear. The notation $|x|$ denotes the length of the binary encoding of the number x, $\lceil \log(x+1) \rceil$, while the *smash symbol* $x\#y$ stands for $2^{|x| \cdot |y|}$.

The definition of *bounded formulas* is analogous to the bounded quantification one encounters in the polynomial hierarchy. For a quantifier $Q \in \{\exists, \forall\}$ and a term t in the language of bounded arithmetic, a formula of the form $Qx < t.\varphi(x)$ stands for either $\forall x.(x < t \to \varphi(x))$ or $\exists x.(x < t \wedge \varphi(x))$. These are called *bounded quantifiers*. Whenever the bounded quantifier is of the form $Q < |s|$ for some term s, we talk about *sharply bounded quantifiers*. The hierarchy of *bounded formulas* consists of the classes Σ^b_n and Π^b_n, for $n \geq 1$, which are defined by counting the alternations of bounded quantifiers ignoring the sharply bounded ones, starting with an existential (respectively, universal) one. The class Δ^b_n consists of all formulas that admit an equivalent definition in both Σ^b_n and Π^b_n. In particular, the class Δ^b_0 stands for all formulas with sharply bounded quantifiers only.

The theory S^1_2 of Buss [15] extends Robinson's arithmetic Q by some basic axioms for the new function symbols and the polynomial induction scheme (PInd) for Σ^b_1-formulas: for every $\varphi \in \Sigma^b_1$, the theory contains the axiom

$$\varphi(0) \wedge \forall x(\varphi(\lfloor x/2 \rfloor) \to \varphi(x)) \to \forall x \varphi(x). \tag{PInd}$$

An alternative system intended to capture polynomial-time reasoning is Cook's equational theory PV [21]. In the formalism of PV one has some basic function symbols and introduces new ones recursively by composition and limited recursion on notation, in the style of Cobham's functional definition of **FP** [17]. In this way, the function symbols obtained in PV are precisely those of all polynomial-time functions over the naturals. The first-order version of PV is PV_1 [48, 16, 18]. Without loss of generality, we shall work in the theory $\mathsf{S}^1_2(\mathsf{PV})$,

which is the theory S^1_2 in the language of bounded arithmetic extended by all PV function symbols, meaning that we have a fresh symbol for each function in **FP**, and induction is now available for all $\Sigma^b_1(\mathsf{PV})$ formulas. We abuse notation and refer to this directly as S^1_2.

While S^1_2 is able to formalize a significant amount of complexity theory and some mathematics, it suffers from the drawback of being unable to even state the existence of exponentially large objects. For certain more elaborate arguments we shall work instead inside $\mathsf{S}^1_2 + \mathsf{1\text{-}EXP}$, which patches this issue. We follow here the definition of the theory given by Krajíček [45, Cor. 2.2]: we write $\mathsf{S}^1_2 + \mathsf{1\text{-}EXP} \vdash \forall x \varphi(x)$ for some arithmetic formula φ if there exists a term t such that

$$\mathsf{S}^1_2 \vdash \forall x \forall y (t(x) \leq |y| \to \varphi(x)).$$

The definition is somewhat indirect and may be hard to grasp at first glance. Intuitively, it allows one to derive properties about x under the assumption that $y = 2^x$ exists.

The theory S^1_2 corresponds to polynomial-time computations in the sense that the provably total relations in S^1_2 are precisely the polynomial-time-computable ones. The same relation holds for $\mathsf{S}^1_2 + \mathsf{1\text{-}EXP}$ and the complexity class **EXP**.

2.2.2 Approximate counting

Many of the formalizations carried out in bounded arithmetic require the ability to count. In some cases, small sets can be counted *exactly*, but one often requires more sophisticated machinery for *approximate counting*, needed to formalize many probabilistic arguments.

For $a \in \mathbb{N}$, a *bounded definable set* is a set of naturals $X = \{x < a \mid \varphi(x)\} \subseteq [0, a)$, where $\varphi \in \Sigma^b_\infty$ is some arithmetic formula. For $X \subseteq a$ and $Y \subseteq b$, we define $X \times Y \coloneqq \{bx + y \mid x \in X, y \in Y\} \subseteq ab$ and $X \dot\cup Y \coloneqq X \cup \{y + a \mid y \in Y\} \subseteq a + b$. Rational numbers are assumed to be represented by pairs of integers in the natural way. We also use the unfortunate but standard *Log-notation* widespread in bounded arithmetic, by which $n \in \mathrm{Log}$ stands for the formula $\exists x (n = |x|)$ and $n \in \mathrm{LogLog}$ stands for $\exists x (n = ||x||)$.

Intuitively, from the point of view of the theory, numbers in Log are "small" numbers. For a circuit $C : 2^k \to 2$, where we adopt the set-theoretic custom of identifying $\{0, 1\}$ with the number 2, we can consider the bounded definable set $X_C \coloneqq \{x < 2^k \mid C(x) = 1\}$, and ask about the task of counting the size of X_C.

There exists a PV-function $\mathrm{Count}(C, y) = |X_C \cap |y||$. This means that if $2^k \in \mathrm{Log}$, then one can do *exact counting* of $|X_C|$ efficiently. We use the notation $\Pr_{x<|y|}[C(x) = 1] \leq z/w$ for the PV-relation $w \cdot \mathrm{Count}(C, y) \leq |y| \cdot z$.

If $2^k \notin \mathrm{Log}$, exact counting becomes problematic. To avoid this, Jeřábek [36, 37] systematically developed the theory APC_1 capturing probabilistic polynomial-time reasoning by means of approximate counting. The theory APC_1 is defined as $\mathsf{PV}_1 + \mathrm{dWPHP}(\mathsf{PV})$ where $\mathrm{dWPHP}(\mathsf{PV})$ stands for the *dual (surjective) pigeonhole principle* for all PV-functions. That is, the set of all formulas

$$x > 0 \to \exists v < x(|y| + 1). \forall u < x|y|.\ f(u) \neq v, \tag{dWPHP}$$

where f is a PV-function which might involve other parameters not explicitly shown.

We write $C : X \twoheadrightarrow Y$ if C is a surjective mapping from X to Y. Let $X, Y \subseteq 2^n$ be definable sets, and $\epsilon \leq 1$. The size of X is *approximately less than the size of Y with error ϵ*, written as $X \preceq_\epsilon Y$, if there exists a circuit C, and $v \neq 0$ such that

$$C : v \times (Y \dot\cup \epsilon 2^n) \twoheadrightarrow v \times X.$$

In this context, the notation $X \approx_\epsilon Y$ stands for $X \preceq_\epsilon Y$ and $Y \preceq_\epsilon X$. As with exact counting, the notation $\Pr_{x<y}[C(x) = 1] \circ_\epsilon z/w$ stands for $w \cdot (X_C \cap y) \circ_\epsilon y \cdot z$, for $\circ \in \{\preceq, \approx\}$. Since a number s is identified with the interval $[0, s)$, $X \preceq_\epsilon s$ means that the size of X is at most s with error ϵ.

The definition of $X \preceq_\epsilon Y$ is an unbounded $\exists\Pi^b_2$ formula even if X and Y are defined by circuits, so it cannot be used freely in bounded induction. This problem can be solved by working in $\mathsf{sHARD}^{\mathrm{A}}$, defined as the relativized theory $\mathsf{S}^1_2(\alpha)$ extended with axioms postulating that $\alpha(x)$ is a truth table of a function on $||x||$ variables hard on average for circuits of size $2^{||x||/4}$. In $\mathsf{sHARD}^{\mathrm{A}}$ there is a $\mathsf{PV}(\alpha)$ function Size approximating the size of any set $X \subseteq 2^n$ defined by a circuit C so that $X \approx_\epsilon \mathrm{Size}(\alpha, C, 2^n, 2^{\epsilon^{-1}})$ for $\epsilon^{-1} \in \mathrm{Log}$ (by combination of [37, Lemma 2.14] and [35, Cor. 3.6]).

The following key definition allows us to express that a function is indeed hard on average.

▶ **Definition 3** ($\mathrm{Hard}^{\mathrm{A}}_\epsilon(f)$, in PV_1 [37]). *Let $f : 2^k \to 2$ be a truth table of a Boolean function with k inputs (with f encoded as a string of 2^k bits, and hence with $k \in \mathrm{LogLog}$). We say that f is* average-case ϵ-hard*, written as $\mathrm{Hard}^A_\epsilon(f)$, if for every circuit C of size at most $2^{\epsilon k}$,*

$$|\{u < 2^k \mid C(u) = f(u)\}| < (1/2 + 2^{-\epsilon k})2^k.$$

Note that $\mathrm{Hard}^A_\epsilon(f)$ is Π^b_1-definable in PV_1.

We write $\mathrm{tt}^{\mathrm{avg}}_\epsilon(f_k, 2^{\epsilon k}) := ||\,\mathrm{Hard}^{\mathrm{A}}_\epsilon(f)||_m$ for the propositional translation (see Section 2.2.3) of the formula $\mathrm{Hard}^{\mathrm{A}}_\epsilon(f)$ above and an appropriately chosen parameter m depending on k and ϵ. We also consider the polynomial-time function $\mathrm{CorrectFracTT}^\delta(s, n, C, f)$, that checks whether f is a string of length 2^n, C encodes a circuit of size at most s, and finally verifies whether the fraction of accepted inputs is larger than $(1/2 + 2^{-\delta n})2^n$.

The theory APC_1 is strong enough to show that hard-on-average functions do exist.

▶ **Proposition 4** (Jeřábek [35]). *For every rational constant $\epsilon < 1/3$, there exists a constant c such that APC_1 proves that for every $k \in \mathrm{LogLog}$ such that $k \geq c$, there exist a function $f : 2^k \to 2$ that is average-case ϵ-hard.*

The theory S^1_2 can be relativized to $\mathsf{S}^1_2(\alpha)$. This means, in particular, that the language of $\mathsf{S}^1_2(\alpha)$, denoted also $\mathsf{S}^1_2(\alpha)$, contains symbols for all polynomial-time machines with access to the oracle α.

▶ **Definition 5** ($\mathsf{sHARD}^{\mathrm{A}}$ [35]). *The theory sHARD^A is an extension of the theory $\mathsf{S}^1_2(\alpha)$ by the axioms stating*

1. *the number $\alpha(x)$ encodes the truth table of a Boolean function in $||x||$ variables;*
2. *$x \geq c \to \mathrm{Hard}^A_{1/4}(\alpha(x))$, where c is the constant from the previous proposition;*
3. *$||x|| = ||y|| \to \alpha(x) = \alpha(y)$.*

The key technical tool from the framework of approximate counting is the following theorem by Jeřábek.

▶ **Theorem 6** (Jeřábek [37]). *There is a $\mathsf{PV}(\alpha)$-function* Size *such that sHARD^A proves that if $X \subseteq 2^n$ is definable by a circuit C, then $X \approx_\epsilon \mathrm{Size}(\alpha, C, 2^n, e)$, where $\epsilon = |e|^{-1}$.*

For a circuit $C : 2^n \to 2$, we introduce the notation

$$\Pr_{x<y}[C(x) = 1] \preceq^f_\epsilon \frac{z}{w}$$

to mean $w \cdot \mathrm{Size}(f, C, 2^n, e) \leq y \cdot z$, where $\epsilon = |e|^{-1}$.

2.2.3 Correspondences and propositional translations

While our formalizations are comfortably carried out in the first-order theories presented above, we are able to transfer our results back to propositional logic thanks to the existence of *propositional translations*. Following Krajíček [51], we say that a theory T *corresponds* to a propositional proof system S if (i) T can prove the soundness of S and (ii) every universal consequence $\forall x\varphi(x)$ of T, where φ is quantifier-free, admits polynomial-size proofs in S when grounded into a sequence of propositional formulas. Pudlák alternatively says that S is the *weak system* of the theory T [62]. More formally, for such a universal formula φ, we denote by $||\varphi||_n$ the propositional translation for models of size n. Sometimes we abuse the notation and write $||\varphi||$ dropping the subscript n. We refer the reader to standard texts like those of Krajíček [51] or Cook and Nguyen [20] for formal definitions of the translation.

The key fact for us is that universal theorems of S^1_2 admit short propositional proofs in Extended Frege. More importantly, $\mathsf{S}^1_2 + \text{1-EXP}$ corresponds to Implicit Extended Frege.

▶ **Theorem 7** (Correspondence of $\mathsf{S}^1_2 + \text{1-EXP}$ and iEF [45, Thm. 2.1])**.** *The proof system* iEF *corresponds to* $\mathsf{S}^1_2 + \text{1-EXP}$*. That is,*

- **(i)** *the theory* $\mathsf{S}^1_2 + \text{1-EXP}$ *proves the soundness of* iEF*;*
- **(ii)** *whenever a* $\forall\Pi^b_1$*-sentence* $\forall x\varphi(x)$ *is provable in* $\mathsf{S}^1_2 + \text{1-EXP}$*, there are polynomial-size* iEF*-proofs of the sequence of tautologies* $\{||\varphi||_n\}_{n\in\mathbb{N}}$*;*
- **(iii)** *if* $\mathsf{S}^1_2 + \text{1-EXP}$ *proves the soundness of some propositional system* S*, then* $\text{iEF} \geq S$*.*

The translation also works for formulas beyond $\forall\Pi^b_1$ as long as we translate into a quantified propositional system. The definition of the translation is straightforward, and we note that Σ^b_1-consequences of S^1_2 translated as Σ^q_1 formulas admit polynomial-size proofs in G^*_1.

▶ **Theorem 8** (Correspondence of S^1_2 and G^*_1 [47])**.** *Whenever a* $\forall\Sigma^b_1$*-sentence* $\forall x\exists y \leq t.\varphi(x,y)$ *is provable in* S^1_2*, there are polynomial-size proofs of the sequence of* Σ^q_1*-formulas obtained by the translation,* $\{||\exists x\varphi(x,y)||_n\}_{n\in\mathbb{N}}$*, in* G^*_1*.*

2.3 Interactive proof systems and the sum-sheck protocol

While our focus is on propositional proof systems in the sense of Cook and Reckhow, our work exploits relations to more lax notions of provability. Following Babai [7], an *Merlin-Arthur proof system* or *Merlin-Arthur protocol* for a language $L \subseteq \{0,1\}^*$ is a polynomial-time function S together with some constant c such that the two following properties are satisfied for every $x \in \{0,1\}^*$. Namely,

1. if $x \in L$, then there exists some $\pi \in \{0,1\}^*$ such that $\Pr_{r\in\{0,1\}^{(|x|+|\pi|)^c}}[S(x,\pi,r) = 1] = 1$;
2. if $x \notin L$, then for every $\pi \in \{0,1\}^*$, $\Pr_{r\in\{0,1\}^{(|x|+|\pi|)^c}}[S(x,\pi,r) = 1] < 1/3$.

The first condition formalizes *completeness*, while the second corresponds to *soundness*. The complexity class **MA** contains all languages that admit a polynomially-bounded Merlin-Arthur protocol, meaning that there exists a constant d such that the completeness guarantee is strengthened to proofs $\pi \in \{0,1\}^{|x|^d}$. One should think of MA proof systems as Cook-Reckhow systems where the verifier is randomized and may thus accept some incorrect proofs with small probability.

We recall that, under the standard derandomization assumption that there exists a Boolean function family in **E** that is wort-case hard for subexponential-size circuits, every Merlin-Arthur system derandomizes into a Cook-Reckhow system and, in particular, **MA** = **NP** [56, 34].

Our proofs rely on a particular interactive protocol, the *Sum-Check Protocol* of Lund, Fortnow, Karloff, and Nisan [54] for the language of unsatisfiable 3CNFs. Unlike Merlin-Arthur protocols, this is an interactive protocol running for multiple rounds between a Prover and a Verifier, before the Verifier makes a decision. We now recall the details of the protocol.

The Sum-Check Protocol [54]

The protocol considers a 3CNF $\varphi(x_1, \dots, x_n)$ over m clauses, known to both the Verifier and the Prover.

1. The Prover generates a prime number[6] $p \in (2^{2n^3+n}, 2^{(2n^3+n)^{c_p}}]$ together with a Pratt certificate[7] on the primality of p and sends them to the Verifier, who checks for correctness of the certificate, and aborts if incorrect.
2. The Prover and the Verifier arithmetize φ into a polynomial $P_\varphi(x_1, \dots, x_n)$ of degree at most $3m$ over $\mathbb{F}_p$ in the usual way: a clause like $(x \vee \neg y \vee z)$ is turned into $1-(1-x)y(1-z)$, and one then takes the product of all such arithmetized clauses. In this way, for all $x \in \{0,1\}^n$, $\varphi(x) = 1$ if and only if $P_\varphi(x) = 1$.
3. The Verifier sets $(a_1, \dots, a_n) := (0, \dots, 0)$, $Q_0(a_0) := 0$ and for $i \in \{1, \dots, n\}$, the following interaction is carried out:
   a. Leaving x_i free, the Prover computes the coefficients of the following univariate polynomial over $\mathbb{F}_p$, $Q_i(x_i) := \sum_{x_{i+1} \in \{0,1\}} \cdots \sum_{x_n \in \{0,1\}} P_\varphi(a_1, \dots, a_{i-1}, x_i, x_{i+1}, \dots, x_n)$ and sends the $O(m)$ coefficients of Q_i to the Verifier.
   b. The Verifier checks whether $Q_i(0) + Q_i(1) = Q_{i-1}(a_{i-1})$. If the check fails, the Verifier rejects. Otherwise, it samples a random $a_i \in \mathbb{F}_p$ and sends it to the Prover.
   c. In the final round, instead of sending a_n to the Prover, the Verifier checks whether $P_\varphi(a_1, \dots, a_n) = Q_n(a_n)$ and accepts or rejects based on this.

3 Main result

Our proof exploits the known fact that if $\#\mathbf{P} \subseteq \mathbf{FP}/\text{poly}$, then $\mathbf{coNP} \subseteq \mathbf{MA}$. Indeed, if $\#\mathbf{P}$ has small circuits one can provide polynomial-size circuits that simulate the Prover's movements in the Sum-Check protocol for Unsat, since one can consider the MA proof system in which Arthur receives from Merlin a circuit claiming to be the circuit that the Prover used to carry out their strategy, and with the aid of randomness, Arthur can execute this on his own and decide based on the outcome of this simulation.

Let us make this formal.

▶ **Definition 9** (The SC proof system). *Let $V(p, u, \varphi, C, r)$ be the polynomial-time function carrying out the simulation of the Sum-Check protocol. Namely, p is intended to be a prime in $(2^{2n^3+n}, 2^{(2n^3+n)^{c_p}}]$, u a Pratt certificate for p, φ a 3CNF over n variables, r a string of random bits, and C a multi-output circuit providing the Prover's responses in the interactions with the Verifier in the Sum-Check protocol.*

The Sum-Check Proof System*, denoted by* SC*, is a Merlin-Arthur proof system for proving 3DNF tautologies. An* SC *proof of φ is a tuple $\langle p, u, C \rangle$ such that p is indeed a prime in the interval above, correctly certified by the Pratt certificate u, and such that* $\Pr_{r \in \mathbb{F}_p^n}\left[V(p, u, \neg\varphi, C, r) = 1\right] = 1$.

[6] The constant c_p in the exponent comes from the formalization of the soundness of the sum-check protocol inside $\mathsf{S}_2^1 + \text{1-EXP}$ in a recent work of Khaniki [40]; while we do not need such details in our proofs, we leave it here to be faithful to the formalization.

[7] A *Pratt certificate* is a succinct witness for primality checkable in polynomial time [60]. The details are not relevant for our results, but it is important that the Verifier can be convinced of p being a prime.

The following is just a rephrasing of the fact that $\#\mathbf{P} \subseteq \mathbf{FP}/\mathrm{poly}$ implies $\mathbf{coNP} \subseteq \mathbf{MA}$, in terms of the Merlin-Arthur system SC. We omit the proof, which can be be found in standard texts (see e.g. [5, Thm. 8.22]).

▶ **Lemma 10.** *If $\#\mathbf{P} \subseteq \mathbf{FP}/\mathrm{poly}$, then SC is polynomially bounded over 3DNF tautologies.*

Our goal is to extend the previous lemma from SC to the concrete and natural Cook-Reckhow system Implicit Extended Frege. The idea again is that iEF (or rather its first-order counterpart, $\mathsf{S}^1_2 + \text{1-EXP}$) can prove the soundness of this system and thus simulate it. We shall then derandomize the SC protocol inside iEF. Fortunately for us, the soundness of the Sum-Check protocol was recently proven by Khaniki in the right theory of bounded arithmetic.

▶ **Theorem 11** (Soundness of the sum-check protocol [39, Thm. 15.3])**.** *There are constants $c, k \in \mathbb{N}$ such that S^1_2 proves the following sentence: for every n, φ, a, p, u, C, if it holds that (i) φ is a 3CNF in n variables where $n \geq c$, and (ii) $\varphi(a) = 1$ and, (iii) $2^{2n^3+n} < p \leq 2^{(2n^3+n)^{c_p}}$ and, (iv) $n^k \in \mathrm{Log}\,\mathrm{Log}$, then*

$$\Pr_{r \in \mathbb{F}_p^n}\left[V(p, u, \varphi, C, r) = 1\right] \leq \frac{n\binom{2n}{3}}{p}.$$

We can now formalize the soundness of the SC proof system from Definition 9. The arguments that follow are a concrete application of more sophisticated techniques employed by Khaniki [40, 39], who has studied interactive protocols in the context of defining new jump operators in proof complexity.

▶ **Definition 12** (The $\mathrm{Sound}_c(\mathsf{SC})$ formula)**.** *We denote by $\mathrm{Sound}_c(\mathsf{SC})$ the following $\forall\Sigma^b_1$ sentence, claiming the soundness of SC: for all φ, a, p, u, C, f, where $|\varphi| > c$, there is a circuit D of size $\leq \lceil |f|^{1/4} \rceil$ such that if*

$$\neg\left(\Pr_{r \in \mathbb{F}_p^n}[V(p, u, \neg\varphi, C, r) = 1] \preceq^f_\epsilon \frac{3}{8}\right)$$

holds, then at least one of the following conditions holds:

- **(i)** $|f| \neq |C|^{k_a} + k'_a$ *or,*
- **(ii)** $\mathrm{CorrectFracTT}^{1/4}(\lceil |f|^{1/4} \rceil, ||f||, D, f) = 1$ *or,*
- **(iii)** $p \notin (2^{2n^3+n}, 2^{(2n^3+n)^{c_p}}]$ *or,*
- **(iv)** $\varphi(a) = 1$*,*

where k_a, k'_a are the constants from Theorem 6 making sure that Size *function works properly, $\epsilon = 1/16$ and n is the number of variables of φ. In the definition of the displayed probability, we assume that $y = p^n$ and that the circuit defining the set of strings accepted by V rejects all $r \geq p^n$.*

Note that even if V accepts with probability 1 on a given input, the approximating probability from Definition 12 can be significantly smaller because of the difference between p^n and the input-size of the circuit in the input of the Size function. Another relevant point is that for each $C, 2^n, e$, the function $\mathrm{Size}(\alpha, C, 2^n, e)$ calls α only once. In fact, it calls $\alpha(x)$ on an input x which depends only on $|C|, n, |e|$. This is needed for the formula $\mathrm{Sound}_c(\mathsf{SC})$ to be well-defined.

It now suffices to verify that the encoding of the soundness of SC is indeed provable in $\mathsf{S}^1_2 + \text{1-EXP}$.

▶ **Proposition 13** (Soundness of SC inside $\mathsf{S}^1_2 + \text{1-EXP}$). *There is a constant $c \in \mathbb{N}$ such that* $\mathsf{S}^1_2 + \text{1-EXP} \vdash \text{Sound}_c(\mathsf{SC})$.

Proof. Let $c \in \mathbb{N}$ be a big enough constant that can be computed from the rest of the argument and

$$\text{Sound}_c(\mathsf{SC}) := \forall \varphi, a, p, u, C, f \exists D \Phi(\varphi, a, p, u, C, f, D)$$

the soundness formula in Definition 12 above. Let φ be a 3DNF in n variables such that $|\varphi| > c$, and consider a, p, u, C, f. Then the following cases can happen:

(a) If $|f| \neq |C|^{k_a} + k'_a$ or $p \notin (2^{2n^3+n}, 2^{(2n^3+n)^{c_p}}]$, then $\Phi(\varphi, a, p, u, C, f, 0)$ is trivially true.

(b) If there is a circuit D of size $\leq \lceil |f|^{1/4} \rceil$ such that $\text{CorrectFracTT}^{1/4}(\lceil |f|^{1/4} \rceil, ||f||, D, f) = 1$, then $\Phi(\varphi, a, p, u, C, f, D)$ is trivially true.

(c) If the previous cases do not happen and moreover

$$\neg \left(\Pr_{r \in \mathbb{F}_p^n} [V(p, u, \neg\varphi, C, r) = 1] \preceq^f_\epsilon \frac{3}{8} \right)$$

holds, then we have that $8 \cdot \text{Size}(f, C^*, 2^m, e) > 3p^n$, where m is the smallest integer such that $2^m \geq p^n$, $\epsilon := |e|^{-1}$ and $C^*(r) := V(p, u, \neg\varphi, C, r)$. By the assumption $\text{Hard}^{\text{A}}_{1/4}(f)$ holds and by the fact that we are over S^1_2 and we can use f as a parameter in polynomial induction for Σ^b_1 formulas, we can do approximate counting using Theorem 6. Hence there is a circuit G and some $v \leq \text{poly}(m\epsilon^{-1}|C^*|)$ such that

$$G : v \times (X_{C^*} \dot\cup\ \epsilon 2^m) \twoheadrightarrow v \times \text{Size}(f, C^*, 2^m, e).$$

As we work in $\mathsf{S}^1_2 + \text{1-EXP}$ and G is surjective, we can find a subset $A \subseteq v \times (X_{C^*} \dot\cup\ \epsilon 2^m)$ such that G restricted to A is a one-to-one function from A to $v \times \text{Size}(f, C^*, 2^m, e)$. Now we can apply exact counting (as we have 1-EXP) and show that

$$\text{Size}(f, C^*, 2^m, e) \leq |X_{C^*}| + \epsilon 2^m.$$

By the fact that $8 \cdot \text{Size}(f, C^*, 2^m, e) > 3p^n > 3 \cdot 2^m/2$, we have $2^m/8 < |X_{C^*}|$. Now if $\varphi(a) = 0$, by Theorem 11 we get

$$\Pr_{r \in \mathbb{F}_p^n} \left[V(p, u, \neg\varphi, \pi, r) = 1 \right] \leq \frac{n\binom{2n}{3}}{p}.$$

Note that $|\varphi| > c$ which implies that n is big enough and as $p > 2^{2n^3+n}$ we get that $n\binom{2n}{3}/p \leq 1/8$, which implies

$$\Pr_{r \in \mathbb{F}_p^n} \left[V(p, u, \neg\varphi, \pi, r) = 1 \right] \leq \frac{1}{8}.$$

As C^* rejects all $r \geq p^n$, this implies that $|X_{C^*}| \leq 2^m/8$ which leads to a contradiction, so $\varphi(a) = 1$. ◀

The main technical issue now is that $\text{Sound}_c(\mathsf{SC})$ is a $\forall\Sigma^b_1$ sentence that does not translate into a propositional formula that iEF can reason about. Instead, we shall work on a quantified propositional system. For this to make sense we need to know the quantified propositional proof system associated with $\mathsf{S}^1_2 + \text{1-EXP}$.

We invoke the following known **TFNP** characterization of the Σ^b_1 consequences of $\mathsf{S}^1_2 + \text{1-EXP}$, which identifies a "complete" Σ^b_1 sentence Ψ such that any other Σ^b_1 consequence of $\mathsf{S}^1_2 + \text{1-EXP}$ reduces to it in G^*_1.

▶ **Theorem 14** ([42, 41, 46, 9]). *There is a $\forall\Sigma^b_1$ sentence $\Psi := \forall x \exists y \psi(x,y)$ (the bound on y is implicit in ψ) such that the following statements are true:*

(i) $\mathsf{S}^1_2 + \text{1-EXP} \vdash \forall x \exists y \psi(x,y)$*;*

(ii) *for any $\forall\Sigma^b_1$ sentence $\forall x \exists y \alpha(x,y)$ such that $\mathsf{S}^1_2 + \text{1-EXP} \vdash \forall x \exists y \alpha(x,y)$, there are* PV *functions f and g such that $\mathsf{S}^1_2 \vdash \forall x, y(\psi(f(x), y) \to \alpha(x, g(x, y)))$.*

In what follows, we shall work with Gentzen's system G extended with the propositional translation of the sentence Ψ in the theorem above. We denote this system by $\mathsf{G}_{\mathsf{EXP}} := \mathsf{G}^*_1 + ||\Psi||$ and use the following key properties about it. The full version of the paper contains explicit proofs of each of these items, but we shall omit these here.

▶ **Corollary 15.** *The following statements about $\mathsf{G}_{\mathsf{EXP}}$ hold:*

(i) $\mathsf{S}^1_2 + \text{1-EXP} \vdash \Sigma^q_1\text{-Ref}(\mathsf{G}_{\mathsf{EXP}})$*, i.e. the reflection principle for $\mathsf{G}_{\mathsf{EXP}}$ and Σ^q_1 formulas is provable in $\mathsf{S}^1_2 + \text{1-EXP}$;*

(ii) *for every $\forall\Sigma^b_1$-sentence $\forall x \exists y \alpha(x,y)$, if $\mathsf{S}^1_2 + \text{1-EXP} \vdash \forall x \exists y \alpha(x,y)$, then there are polynomial-size $\mathsf{G}_{\mathsf{EXP}}$-proofs of the sequence of Σ^q_1-tautologies $\{||\exists y \alpha(y)||_n\}_{n\in\mathbb{N}}$;*

(iii) *if $\mathsf{S}^1_2 + \text{1-EXP}$ proves the soundness of a propositional proof system S, then $\mathsf{G}_{\mathsf{EXP}} \geq S$.*

Let us observe that $\mathsf{G}_{\mathsf{EXP}}$ is in fact equivalent to iEF.

▶ **Lemma 16.** *The proof systems $\mathsf{iEF}, \mathsf{EF} + \text{Ref}_{\mathsf{iEF}}$ and $\mathsf{G}_{\mathsf{EXP}}$ are polynomially equivalent over propositional tautologies.*

Proof. By item (iii) of Corollary 15 and item (iii) Theorem 7, iEF and $\mathsf{G}_{\mathsf{EXP}}$ polynomially simulate each other. As mentioned in Section 2.1.1, $\mathsf{EF} + \text{Ref}_{\mathsf{iEF}} \geq \mathsf{iEF}$. It is also easy to see that $\mathsf{S}^1_2 + \text{1-EXP}$ proves the soundness of $\mathsf{EF} + \text{Ref}_{\mathsf{iEF}}$, which by item (iii) of Theorem 7 gives us $\mathsf{iEF} \geq \mathsf{EF} + \text{Ref}_{\mathsf{iEF}}$. ◀

We are now ready to define the extension of iEF for which our main theorem holds. Recall that the propositional formulas $\text{tt}^{\text{avg}}_{1/4}(h_n, 2^{n/4})$ were defined in Section 2.2.2 and state the average-case hardness of a Boolean function h_n represented as a truth table.

▶ **Definition 17** (The systems iEF^{tt}). *Let $h = \{h_n\}_{n\in\mathbb{N}}$ be some family of Boolean functions, and let $n_0 \in \mathbb{N}$. We denote by $\mathsf{iEF}^{\text{tt}(h,n_0)} := \mathsf{G}_{\mathsf{EXP}} + \{\text{tt}^{avg}_{1/4}(h_n, 2^{n/4})\}_{n\geq n_0}$ the system that extends $\mathsf{G}_{\mathsf{EXP}}$ by the axioms claiming the hardness of h_n, for $n \geq n_0$.*

Note that $\mathsf{iEF}^{\text{tt}(h,n_0)}$ is a family of proof systems, parameterized by a Boolean function family h and some threshold parameter n_0. Observe that depending on the choice of h and n_0, the system $\mathsf{iEF}^{\text{tt}(h,n_0)}$ may not be a Cook-Reckhow system: if h is not a hard function, or n_0 is not large enough, we will be adding axioms which are not tautologies; and even if h is hard and n_0 is large enough, the system may require advice to verify the proofs. As we shall see, however, these degenerate instantiations of $\mathsf{iEF}^{\text{tt}(h,n_0)}$ are not a problem.

What is more important, the systems $\mathsf{iEF}^{\text{tt}(h,n_0)}$, regardless of their consistency, always simulate SC.

▶ **Lemma 18.** *Let h be family of Boolean functions and let $n_0 \in \mathbb{N}$. The system $\mathsf{iEF}^{\text{tt}(h,n_0)}$ polynomially simulates* SC *over 3DNF tautologies.*

Proof. If the system $\mathsf{iEF}^{\text{tt}(h,n_0)}$ is unsound because the added axioms are not tautologies, then the system is polynomially bounded and simulates every other proof system. So suppose the added axioms are indeed tautologies, meaning that the function h is indeed hard on average.

Let φ_1 be a 3DNF in n_1 variables and $\langle p_1, u_1, C_1\rangle$ be a SC-proof of φ_1. This means

$$2^{2n_1^3+n_1} < p_1 \leq 2^{(2n_1^3+n_1)^{c_p}} \wedge \Pr_{r\in\mathbb{F}_{p_1}^{n_1}}\left[V(p_1, u_1, \neg\varphi_1, C_1, r) = 1\right] = 1.$$

Note that by Theorem 11 and Corollary 15, there are PV functions l, g such that

$$\mathsf{S}_2^1 \vdash \forall\varphi, a, p, u, C, f\,(\psi(l(\varphi, a, p, u, C, f), y) \to \Phi(\varphi, a, p, u, C, f, g(\varphi, a, p, u, C, f, y)))\,,$$

where $\mathrm{Sound}_c(\mathsf{SC}) \coloneqq \forall\varphi, a, p, u, C, f\exists D\Phi(\varphi, a, p, u, C, f, D)$. Let $s \coloneqq |\,\langle p, u, C\rangle\,|$. Then by Theorem 8 there is a $s^{O(1)}$-size G_1^*-proof of

$$||\forall\varphi, a, p, u, C, f\,(\psi(l(\varphi, a, p, u, C, f), y) \to \Phi(\varphi, a, p, u, C, f, g(\varphi, a, p, u, C, f, y)))\,||_{s'},$$

where $s' \coloneqq \mathrm{poly}(s)$. Let us rewrite the previous quantified propositional formula as $||\Psi'|| \to ||\Phi'||$ with the right range of parameters such that p_1, u_1, φ_1, C_1 are substituted in the formula in their corresponding places. Now we take the substitution instance $\mathrm{tt}_{1/4}^{\mathrm{avg}}(h_{n'}, 2^{n'/4})$ where $|h_{n'}| \coloneqq |C_1|^{k_a} + k'_a$ and we substitute $h_{n'}$ to the variables corresponding to f and therefore the disjunct which corresponds to CorrectFracTT disappears from $||\Phi'||$ when we apply the rules of G_1^*. Moreover, it is not hard to verify that after the substitutions every other disjunct which corresponds to subformulas of $\mathrm{Sound}_c(\mathsf{SC})$ from Definition 12 disappears except φ_1. So what we have is G_1^*-proof of $||\Psi''||(\bar{x}, \bar{y}) \to \varphi_1(\bar{x})$ ($\bar{x}$ and $\bar{y}$ are disjoint variables) where $||\Psi''||$ is a substitution instance of $||\Psi'||$. Since we are working in $\mathsf{G}_{\mathsf{EXP}}$, we have the substitution instance $\exists\bar{y}||\Psi''||(\bar{x}, \bar{y})$ and therefore using the rules of G_1^* we get a short $\mathsf{G}_{\mathsf{EXP}}$-proof of $\varphi_1(\bar{x})$. ◀

Our main theorem now easily follows.

▶ **Theorem 19** (Main theorem). *Let h be a family of Boolean functions and let $n_0 \in \mathbb{N}$. If the system $\mathsf{iEF}^{\mathrm{tt}(h,n_0)}$ is not polynomially bounded, then $\#\mathbf{P} \not\subseteq \mathbf{FP}/\mathrm{poly}$.*

Proof. By Lemma 18 above, for every choice of h and n_0, the system $\mathsf{iEF}^{\mathrm{tt}(h,n_0)}$ polynomially simulates SC, so if $\mathsf{iEF}^{\mathrm{tt}(h,n_0)}$ is not polynomially bounded, then SC is not either. Then, by the contrapositive of Lemma 10, $\#\mathbf{P} \not\subseteq \mathbf{FP}/\mathrm{poly}$. ◀

As discussed, depending on the choice of h and n_0, the system $\mathsf{iEF}^{\mathrm{tt}(h,n_0)}$ may not be sound and thus possibly not Cook-Reckhow. However, for any fixed choice of a uniform candidate hard function, the system is concrete and exhibits the desired connection that proof complexity lower bounds for it imply strong circuit lower bounds. In particular, if there exist functions in $\mathbf{NE} \cap \mathbf{coNE}$ average-case hard for subexponential-size circuits, then we recover the version of the theorem presented in the introduction (Theorem 1).

We note that there is the possibility that iEF, given its strength, already proves such strong circuit lower bounds for some Boolean function. It is thus worth to mention the following corollary.

▶ **Corollary 20.** *Suppose there exists a sequence of Boolean functions $\{h_n\}_{n\in\mathbb{N}}$ for which iEF has polynomial-size proofs of the formula family $\{\mathrm{tt}_{1/4}^{\mathrm{avg}}(h_n, 2^{n/4})\}_{n\geq n_0}$ for some sufficiently large $n_0 \in \mathbb{N}$. If iEF is not polynomially bounded, then $\#\mathbf{P} \not\subseteq \mathbf{FP}/\mathrm{poly}$.*

Proof. If there is such a function h and threshold n_0, then $\mathsf{iEF}^{\mathrm{tt}(h,n_0)}$ is polynomially equivalent to iEF itself, so by Theorem 19 the corollary follows. ◀

Abstract

We consider the problem of learning low-degree quantum objects up to ε-error in ℓ_2-distance. We show the following results: (i) unknown n-qubit degree-d (in the Pauli basis) quantum channels and unitaries can be learned using $O(1/\varepsilon^d)$ queries (which is independent of n), (ii) polynomials $p : \{-1,1\}^n \to [-1,1]$ arising from d-query quantum algorithms can be learned from $O((1/\varepsilon)^d \cdot \log n)$ many random examples $(x, p(x))$ (which implies learnability even for $d = O(\log n)$), and (iii) degree-d polynomials $p : \{-1,1\}^n \to [-1,1]$ can be learned through $O(1/\varepsilon^d)$ queries to a quantum unitary U_p that block-encodes p. Our main technical contributions are new Bohnenblust-Hille inequalities for quantum channels and completely bounded polynomials.

1 Introduction

Computational learning theory refers to the mathematical framework for understanding machine learning models and quantifying their complexity. The seminal result of Leslie Valiant [54] (who introduced the Probably Approximately Correct (PAC) model) gives a complexity-theoretic definition of what it means for a class of functions $f : \{0,1\}^n \to \{0,1\}$ to be learnable information-theoretically and computationally.

One of the foundational results in computational learning theory is the one of Linial, Mansour and Nisan [39] who showed that AC_0, or constant-depth n-bit classical circuits consisting of AND, OR and NOT gates, can be learned in quasi-polynomial time. A crucial aspect of their proof is the following structural theorem: if a Boolean function f is computable by AC_0 then f can be approximated by a *low-degree polynomial*. Using this structural property, the learning algorithm approximates the coefficients of all the low-degree monomials of f in the PAC model and hence approximately learns the unknown AC_0 function. Since their work, the notion of Boolean functions being low-degree or being well-approximated by low-degree polynomials has been a central technique [16] in obtaining new learning algorithms. Furthermore, low-degree approximations have played a significant role in theoretical computer science topics such as quantum computing, circuit complexity, learning theory and cryptography.

In the last few years, there have been several works in quantum learning theory where the goal has been to learn an unknown object on a quantum computer under various access models. Motivated by classical learning theory, in this work our primary focus will be on learning objects that have the additional structure of being *low-degree*. Since we consider different objects, when presenting our results we will make the definition of being low-degree clear, but the main motivation of this work can be summarized by the following question:

Can we learn low-degree n-qubit quantum objects information-theoretically with complexity that scales only polynomial (or better polylogarithmic) in n?

We give a positive answer to this question for low-degree channels, unitaries, quantum query algorithms, polynomials, and states. The organization of the paper is as follows. In Section 2 we present our main technical contribution, then in Section 3 we describe our applications to learning, in Section 4 we prove the result for channels, and in Section 5 we prove the result for quantum query algorithms. Due to page restrictions, we defer the preliminaries of our paper as well as the remaining proofs to the extended version [6].

2 Technical contribution: New Bohnenblust-Hille inequalities

In 1931, Bohnenblust and Hille [13] (generalizing the classic theorem of Littlewood [40]) gave a solution to the famous *Bohr strip problem* of Dirichlet series [14]. To do that, they showed the following: let $T : ([-1,1]^n)^d \to [-1,1]$ be a d-tensor specifed by the coefficients $T = (\widehat{T}_{i_1,\ldots,i_d})_{i_1,\ldots,i_d \in [n]}$, then

$$\Big(\sum_{i_1,\ldots,i_d=1}^{n} |\widehat{T}_{i_1,\ldots,i_d}|^{2d/(d+1)} \Big)^{(d+1)/2d} \leq C(d), \tag{1}$$

where $C(d)$ is a universal constant independent of n.[1] Their work marked the birth of the Bohnenblust-Hille (BH) inequality, which has became a fundamental tool in functional analysis. Despite being studied over a century, the best known upper bound on $C(d)$ scales polynomially with d, while the best lower bound is a constant. Closing this gap has been an active area of research in mathematics. In 2011 Defant et. al [22] refined the BH inequality and found a striking application of the BH inequality: they determined the precise asymptotic behavior of the n-dimensional Bohr radius using the BH inequality. Since then,

[1] We remark that the inequality above is a simplified version of the original Bohnenblust-Hille inequality and we discuss this in more detail in the preliminaries.

there has been renewed interest in the BH inequality and has found several applications in theoretical computer science such as Fourier-Entropy influence conjecture [4], classical learning theory [26], non-local games [42], and quantum computing [33, 57].

Of particular relevance to our work, the BH inequality recently captured the attention of the computer science community when Eskenazis and Ivanisvili [26] used a version of it to prove a major improvement in the problem of classical learning bounded low-degree multilinear polynomials (which we discuss in detail below). The key insight of Eskenazis and Ivanisvili is that BH inequalities imply that for bounded operators the small coefficients have a low total contribution, so one does not have to learn them. Multiple extensions of the BH have been proved since then and applied to learning quantum objects [33, 50, 51, 57, 36]. In this work, we extend the BH inequality in two ways:

1. We consider a variant of the BH inequality, that can be regarded as a hybrid between the BH inequality and the celebrated Grothendieck inequality [30]. We show that degree-d completely bounded tensors $\widehat{T}$ (which are known to be the the output of d-query quantum algorithms [3]) satisfy

$$\Big(\sum_{i_1,\ldots,i_d=1}^{n} |\widehat{T}_{i_1,\ldots,i_d}|^{2d/d+1}\Big)^{(d+1)/2d} \leq 1.$$

   In other words, we improve the BH constant for completely bounded tensors from poly(d) to 1. See Theorem 15 for a precise statement.
2. More recently, the works of [33, 57] considered non-commutative variants of the BH inequality. They showed that the Pauli coefficients of n-qubit degree-d (i.e., d-local) observables that are bounded in operator norm, can be bounded in a similar fashion to Eq. (1), but with exp(d) instead of poly(d). Here, we prove another non-commutative version of the BH inequality for quantum *channels* (we in fact prove a stronger BH inequality for *maps* that are bounded in $S_1 \to S_1$ norm, and refer the reader to Theorem 11). In particular, if Φ is a quantum channel defined as $\Phi(\rho) := \sum_{x,y\in\{0,1,2,3\}^n} \widehat{\Phi}(x,y)\sigma_x\rho\sigma_y$ (where $\sigma_x = \otimes_i \sigma_{x_i}$ and $\sigma_0 = I, \sigma_1 = X, \sigma_2 = Y, \sigma_3 = Z$ are the usual single-qubit Pauli operators) where $\widehat{\Phi}(x,y) = 0$ if $|x|, |y| > d$, then the Pauli coefficients $\widehat{\Phi}(x,y)$ satisfy

$$\Big(\sum_{x,y} |\widehat{\Phi}(x,y)|^{2d/(d+1/2)}\Big)^{(d+1/2)/2d} \leq \exp(d). \tag{2}$$

   While exp(d) in Equation (2) might seem much higher than the factor poly(d) of Equation (1), this is not a fair comparison. Equation (1) corresponds to tensors, which are a very structured class of polynomials, while Equation (2) is a non-commutative analogue of the BH inequality for general polynomials, for which the best known upper bounds [23] are superpolynomial in d.

These BH inequalities might be of independent interest both for mathematicians and quantum computing; in this work we crucially use them for our learning algorithms.

3 Applications and main results

3.1 Result 1: Learning channels

Learning a quantum process is a fundamental task in quantum computing and this can be modelled as learning an unknown *quantum channel*, also referred to as *quantum process tomography*. On an experimental level, the dynamics of closed quantum systems can be modeled as a unitary transformation from the initial state to the final state. However, in

practice, quantum systems interact with the environment and must be treated as an open quantum system. To learn the behavior of these open quantum systems, it is convenient to model this map as a quantum channel [45]. Learning an n-qubit quantum channel is however challenging and is known to require $\Theta(4^n)$ queries to the channel [31]. This exponential sample complexity can be drastically improved when prior information on the structure of the channel is available. For example, a recent work of Bao and Yao [10] considered k-junta quantum channels, i.e., n-qubit channels that act non-trivially only on at most k of the n (unknown) qubits leaving rest of qubits unchanged. These channels were shown to be learnable using $\widetilde{\Theta}(4^k)$ queries to the channel [10]. In [21], it was shown that quantum channels that can be efficiently generated, can be learned efficiently, albeit in the PAC learning model. In this work, we consider learning n-qubit quantum channels which have a Pauli decomposition only involving low-degree Pauli operators.

General quantum channels. To describe our result, we first describe Pauli analysis for quantum channels. An n-qubit to n qubit quantum channel Φ can be expressed as

$$\Phi(\rho) = \sum_{x,y\in\{0,1,2,3\}^n} \widehat{\Phi}(x,y)\cdot\sigma_x\rho\sigma_y, \tag{3}$$

where $\sigma_x = \otimes_{i\in[n]}\sigma_{x_i}$ and σ_i for $i\in\{0,1,2,3\}$ are the Pauli matrices

$$\sigma_0 = \begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix},\ \sigma_1 = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix},\ \sigma_2 = \begin{pmatrix}0 & -i\\ i & 0\end{pmatrix},\ \sigma_3 = \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix};$$

and $\widehat{\Phi}(x,y)$ are the Pauli coefficients of the channel. Given $x\in\{0,1,2,3\}^n$, $|x|$ is the number of non-zero entries of x. The degree of a channel Φ is the minimum integer d such that $\widehat{\Phi}(x,y)=0$ if $|x|>d$ or $|y|>d$. Our first result is an efficient learning algorithm for low-degree channels. The learning model we consider is the same as the recent work of Bao and Yao [10]. Given a channel Φ, a learning algorithm is allowed to make *queries to* Φ as follows: it can apply Φ to an arbitrary ρ (or subsystem of ρ) of its choice and measure the resulting state in in any basis. From the measurement outcomes, the learner should output a classical description of a superoperator $\widetilde{\Phi}$ that is close to Φ in the ℓ_2-distance defined by the usual inner product for superoperators, i.e., $\langle\Phi,\widetilde{\Phi}\rangle = \mathrm{Tr}[J(\Phi),J(\widetilde{\Phi})]/4^n$, where $J(\Phi)$ is the Choi-Jaminkowski (CJ) representation of Φ.[2]

▶ **Theorem 1.** *Let Φ be a n-qubit degree-d quantum channel. There is an algorithm that (ε,δ)-learns Φ (in ℓ_2-distance) using $\exp\left(\widetilde{O}(d^2+d\log(1/\varepsilon))\right)\cdot\log(1/\delta)$ queries to Φ.*

We remark that the sample complexity of learning general quantum channels requires $\Omega(4^n)$ queries, but if we are promised the channel is *low-degree*, then our algorithm is much faster than the general algorithm. Additionally, observe that the sample complexity of our learning algorithm is independent of n, in contrast to the results [33, 57, 50, 51, 36] on quantum learning observables (which also are based on the BH inequality) that have a logarithmic dependence on n.

To prove the theorem, we first note the fact that the matrix $\widehat{\Phi}$ (whose entries are given by $\widehat{\Phi}_{x,y} = \widehat{\Phi}(x,y)$) is the density matrix of a state that is unitarily equivalent to the CJ state of the channel Φ [10, Lemma 8]. Hence, $\widehat{\Phi}$ can be prepared by applying Φ to the first n-qubits of n EPR pairs defined over $2n$ qubits, and $\{\widehat{\Phi}(x,x)\}_x$ is a probability distribution. The high-level idea behind the learning algorithm is the following.

[2] In this paper we say an algorithm (ε,δ)-learns a quantum object if it succeeds with probability $\geq 1-\delta$ and outputs an ε-approximation to the unknown quantum object in a metric that will be made clear.

1. Prepare T few copies of $\widehat{\Phi}$ and measure them in the computational basis, allowing the learner to sample from the distribution $\{\widehat{\Phi}(x,x)\}_x$.
2. Using a well-known result in distribution learning theory, we observe that $O(1/\alpha^2)$ many samples from $\{\widehat{\Phi}(x,x)\}_x$ suffices to obtain the xs such that $\Phi(x,x)$ is α-large.
3. Approximate all the large Pauli coefficients in the step above using a SWAP test for mixed states.
4. Output $\widetilde{\Phi}$ with coefficients that were estimated above and the remaining coefficients set to 0.

At this point, we use the BH inequality for quantum channels and show that, as long as $T \sim \exp(d^2/\varepsilon^d)$, then the output $\widetilde{\Phi}$ is ε-close to the target Φ in ℓ_2-distance.

Remark on learning Pauli channels. One can also consider a special case of quantum channels called *Pauli channels* Φ, motivated by the fact that Pauli channels are often the dominant noise on quantum devices and a practical noise model for analyzing fault-tolerance [52]. For these channels, the only non-zero terms in the Fourier expansion (3) are $\widehat{\Phi}(x,x)$ (i.e., $\widehat{\Phi}(x,y) = 0$ when $x \neq y$) and these coefficients are often called *error rates*. Since learning Pauli channels is an important task on near-term quantum devices for error mitigation [55] and analyzing error correction, it is desirable to avoid using entangled copies of a state and access to ancillary qubits as part of the learning algorithm. With this requirement, it was shown that, in order to ε-learn (in diamond norm) an unknown n-qubit Pauli channels using unentangled measurements, one needs to use the channel $\Omega(4^n/\varepsilon^2)$ many times [28]. In this work, we show that the subclass of low-degree Pauli channels are efficiently learnable.

Noise on current large-scale quantum devices is modeled as Pauli channels containing a sparse set of local Paulis [55], which is a subclass of low-degree Pauli channels. Such models are available from device physics and experiments used to characterize noise on quantum hardware. When non-local interactions but only over few qubits are included in the Pauli channel [53], the corresponding Paulis are still low-degree which fits into the class of Pauli channels considered. Our learning result is as follows.

▶ **Fact 2.** *Let Φ be an n-qubit degree-d Pauli channel. There is an algorithm that (ε,δ)-learns Φ (under the diamond norm) using $O\left(n^{2d}/\varepsilon^2 \cdot \log(n/\delta)\right)$ queries to Φ. The learning algorithm only requires preparation of product states and measurements in the Pauli basis.*

We remark that the dependence on n in our sample complexity matches the algorithm in [29] for learning low-degree Pauli channels under the diamond norm but our analysis differs from theirs; our result is obtained using a Fourier-analytic approach in contrast to the the result of [29] which uses ideas from population recovery.

3.2 Result 2: Learning unitaries

Apart from learning channels, in this paper we also consider the task of learning unknown n-qubit unitaries. Similar to the case for channels, it is well-known that learning an unstructured n-qubit unitary requires $\widetilde{\Theta}(4^n)$ applications of U [31]. This complexity can be significantly improved if structural information is available. For example, it has been show efficient learning is possible if the unitary corresponds to Clifford circuits [41], corresponds to Clifford circuits with few non-Clifford gates [38], or are the diagonal unitaries of the Clifford hierarchy [2].

In a recent work, Chen et al. [20] considered the task of learning unitaries U that are k-juntas and showed that this class can be learned querying the unitary $\widetilde{\Theta}(4^k)$ many times. In this work, we consider the scenario where the unitary is degree-d and show such an exponential saving (in comparison to naive tomography) is possible. This structured class of low-degree unitaries occur in many instances. For example, in nature, the dynamics of many physical

systems are governed by local Hamiltonians, whose unitary time evolution operators for short time evolution are close to being low-degree unitaries. Moreover, through the application of Lieb-Robinson bounds to structured many-body Hamiltonians, the corresponding unitary evolution operator can be seen to only have support only on low-degree Paulis [19]. In addition, the quantum unitaries corresponding to quantum circuits producing degree-d phase states containing all commuting diagonal quantum gates [2], are low-degree. The learning algorithm that we will present is thus applicable for learning and verifying such circuits.

Consider the Pauli decomposition of an n-qubit unitary as follows:

$$U = \sum_{x \in \{0,1,2,3\}^n} \widehat{U}(x)\sigma_x,$$

where $\widehat{U}(x)$ are its Pauli coefficients. The degree of U is the minimum integer d such that $|x| > d$ implies $\widehat{U}(x) = 0$. Our learning model is the one by Chen et al. [20]. Given an unitary U, a learning algorithm is allowed to make *queries to* U (and to control-U) as follows: it can choose a state ρ, apply U to the state to obtain $U\rho U^*$, and measure $U\rho U^*$ in a chosen basis. From the measurement outcomes, the learner should output a classical description of an operator $\widetilde{U}$ that is close to U in the ℓ_2-distance determined by the usual inner product for operators defined as $\langle U, V\rangle = \mathrm{Tr}[U^*V]/2^n$.

▶ **Theorem 3.** *Let U be a n-qubit degree-d unitary. There is an algorithm that (ε, δ)-learns U (in ℓ_2-distance) using the unitary U $\exp\left(\widetilde{O}(d^2 + d\log(1/\varepsilon))\right) \cdot \log(1/\delta)$ many times.*

The proof of Theorem 3 follows the same structure as that of Theorem 1, but now we learn the Pauli coefficients via an extension of the algorithm of Montanaro and Osborne [43], and the control on the contribution of the small coefficients relies on the non-commutative BH inequality of Volberg and Zhang [57].

The BH inequality of Volberg and Zhang [57] works for matrices with bounded operator norm, of which unitaries are a very special case. As argued by Montanaro and Osborne [43], matrices bounded on the operator norm are the quantum analogue of bounded functions $f : \{-1,1\}^n \to [-1,1]$, while unitaries are the analogue of Boolean functions[3] $f : \{-1,1\}^n \to \{-1,1\}$. These two families of classical functions differ a lot with respect to the BH inequalities: the best upper bound [23] for the BH constant for bounded functions is $\exp(d^{1/2})$, while for Boolean functions of degree d one can even prove that the *usually much bigger* quantity $\sum_s |\widehat{f}(s)|$ is at most 2^{d-1} [46, Exercise 1.11]. An open question is if this fact can be generalized to the quantum setting.

▶ **Question 4.** *Is there a constant $C(d)$ such that $\sum_{x\in\{0,1,2,3\}^n} |\widehat{U}(x)| \leq C(d)$ for every n-qubit degree-d unitary U?*

If Question 4 was answered positively, then one could improve the ε dependence of Theorem 3 to $(1/\varepsilon)^2$. Some evidence in favor of an affirmative answer to Question 4 is that if a conjecture of Montanaro and Osborne was true [43, Conjecture 4], then every degree-d hermitian unitary would be a 2^d-junta, which would imply an affirmative answer to Question 4 for the hermitian case.

Remark on learning low-degree quantum states. Learning quantum states has been an active line of research given its fundamental importance and applications to quantum system characterization, assessing quality of quantum gates, verification of quantum circuits and

[3] To be precise, they argue that unitary Hermitian matrices are the analogue of Boolean functions.

validating performance of quantum algorithms. Breakthrough results of Haah et al. [32] and O'Donnell and Wright [47] showed that the sample complexity of learning an unknown n-qubit state, up to trace distance ε is $\Theta(4^n/\varepsilon^2)$. A natural consideration is the task of learning *low-degree* quantum states. To describe this, we first write down the Pauli expansion of an n-qubit state ρ as

$$\rho = \sum_{x\in\{0,1,2,3\}^n} \widehat{\rho}(x)\sigma_x.$$

Then, we say that ρ has degree at most d if $\widehat{\rho}(x) = 0$ for all $|x|> d$. It is not too hard to see that one can use the formalism of classical shadows [34] to obtain a learning (in trace norm) algorithm that has a sample complexity of $\widetilde{O}(n^d/\varepsilon^2 \cdot \log(n/\delta))$. A similar result (with a different norm and with a bit more structure than just being low-degree) was noted in a recent work of Nadimpalli et al. [44], where they used the result to give efficient algorithms to learn QAC^0 circuits.

3.3 Result 3: Learning quantum query algorithms

Eskenazis and Ivanisvili [26] established a surprising connection between the BH inequality and learning theory. They considered the following question: suppose $f : \{-1,1\}^n \to [-1,1]$ is a bounded degree-d function, and a learner is given uniformly random x and $f(x)$, then how many $(x, f(x))$ suffices to learn f up to error ε in ℓ_2^2 error? The seminal low-degree algorithm of Linial, Mansour and Nisan uses[4] $O_{d,\varepsilon}(n^d)$ many such samples [39]. This was not improved until recently, when Iyer et al. [35] reduced this complexity to $O_{d,\varepsilon}(n^{d-1})$. In a surprising work, [26] showed that one can learn f in sample complexity $O_{d,\varepsilon}(\log n)$. For the particular case of bounded d-linear tensors $T : (\{-1,1\}^n)^d \to [-1,1]$ they showed that it suffices to use

$$(1/\varepsilon)^d \cdot \Big(\sum_{i_1,\ldots,i_d=1}^{n} |\widehat{T}_{i_1,\ldots,i_d}|^{2d/d+1} \Big)^{(d+1)/2d} \cdot \log n \tag{4}$$

samples $(x, T(x))$, where x is uniform from $(\{-1,1\}^n)^d$ and $\widehat{T}$ is the tensor of coefficients of T, i.e., $T(x) = \sum_{i_1,\ldots,i_d} \widehat{T}_{i_1,\ldots,i_d} x_1(i_1)\ldots x_d(i_d)$. Combining that with the upper bound of the BH constant for multilinear tensors [11], it yields

$$(d/\varepsilon)^{O(d)} \cdot O(\log n) \tag{5}$$

uniformly random samples are enough to learn T. Although this result is surprising since the complexity only scales polylogarithmic with n, observe that if $d = \omega(\log n)$, then the sample complexity is superpolynomial in n, motivating the natural question, are there classes of polynomials that can be learned using $\mathrm{poly}(n)$ samples for any $d = \omega(\log n)$? Below we show that the class of polynomials that arise from quantum query algorithms answers this question in the positive.

Quantum polynomials. The result of Equation (5) can be applied to learn the amplitudes of quantum algorithms that query different blocks of variables every time (see Figure 1), as they are multilinear tensors bounded on the supremum norm [12]. To be precise, we consider quantum query algorithms such that they prepare a state

$$|\psi_x\rangle = U_d(O_{x_d} \otimes \mathrm{Id}_m)U_{d-1}\ldots U_1(O_{x_1} \otimes \mathrm{Id}_m)U_0|u\rangle,$$

[4] Here and below, we use $O_{d,\varepsilon}$ to hide the factors that depend on $d, 1/\varepsilon$ and independent of n.

where m is an integer, x stands for $(x_1, \ldots, x_d)$, O_y is the n-dimensional unitary that maps $|i\rangle$ to $y_i|i\rangle$, $U_0, \ldots, U_d$ are $(n+m)$-dimensional unitaries and $|u\rangle$ is a $n+m$-dimensional unit vector. The algorithm succeeds according to a projective measurement that measures the projection of the final state onto some fixed $n+m$ dimensional unit vector $|v\rangle$. Hence, the amplitude of $|v\rangle$ is $T(x) = \langle v|\Psi_x\rangle$, so $|T(x)|^2$ is the acceptance probability of the algorithm. These quantum algorithms have been considered in the quantum computing literature. For

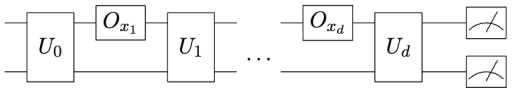

Figure 1 Quantum query algorithms considered in Theorem 5.

example, k-forrelation, that witnesses the biggest possible quantum-classical separation, has this structure [1, 8]. Also, for these algorithms the Aaronson and Ambainis conjecture is known to be true, so they can be classically and efficiently simulated almost everywhere [9, 25]. In addition, Arunachalam et al. showed that those amplitudes are not only bounded, but also completely bounded [3]. Our main contribution regarding these algorithms is showing that for d-linear tensors T that are *completely bounded*, we can improve the BH inequality to

$$\Big(\sum_{i_1,\ldots,i_d=1}^{n} |\widehat{T}_{i_1,\ldots,i_d}|^{2d/d+1} \Big)^{(d+1)/2d} \leq 1.$$

Using this upper bound, we show the following.

▶ **Theorem 5.** *For a quantum algorithm that makes d-queries as in Figure 1, its amplitudes can be learned up to error ε in ℓ_2^2 accuracy using $O\left((1/\varepsilon)^d \cdot \log n\right)$ uniformly random samples.*

This exponentially improves the complexity of [26], as stated in Eq. (5) for the natural class of polynomials arising from quantum query algorithms. In particular, for $d = \omega(\log n)$ and contant ε, one can learn this class of polynomials with sample complexity that is polynomial in n.

3.4 Result 4: Quantum learning of classical polynomials

3.4.1 Boolean functions

Quantum learning not only concerns quantum objects, but also classical ones. For instance, Boolean functions $f : \{-1,1\}^n \to \{-1,1\}$ can be accessed using a *quantum example*, given by

$$|\psi_f\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \{-1,1\}^n} |x, f(x)\rangle.$$

This data access model has been vastly studied in the literature, where several notable quantum speedups have been proven [15, 7, 5]. Many of these speedups are analyzed trough the Fourier transform, that allows to identify every function via $f : \{-1,1\}^n \to \mathbb{R}$ with a multilinear polynomial $f = \sum_{s \in \{0,1\}^n} \widehat{f}(s)\chi_s$, where $\widehat{f}(s) \in \mathbb{R}$ are the Fourier coefficients and χ_s are the character functions $\chi_s(x) = \prod_{i \in [n]} x_i^{s_i}$. The degree for these functions is the minimum integer d such that if $|s| > d$ then $\widehat{f}(s) = 0$. It is a well-known fact that Boolean functions $f : \{-1,1\}^n \to \{-1,1\}$ of degree d are 2^{1-d}-granular, meaning that their Fourier coefficients lie in $2^{1-d}\mathbb{Z}$. This has immediate consequences for both learning theory and BH inequalities.

▶ **Fact 6.** *Let $f : \{-1,1\}^n \to \{-1,1\}$ be a degree-d function. There is a quantum algorithm that $(0,\delta)$ learns f using $O\left(4^d d \log(1/\delta)\right)$ quantum examples. However, a classical algorithm can learn it using $O\left(4^d d \log(n/\delta)\right)$ uniform examples and requires $\Omega(2^d + \log n)$ examples.*

Despite the simplicity of the proof of Fact 6, we state it for completeness and because it seems not to be well-known (see for instance [44, Corollary 34], which proposes a quantum algorithm for the same problem that requires $O(n^d)$ samples, or [27, Corollary 4] that proposes a classical algorithm that requires $O(2^{d^2} \log n)$ samples). Furthermore, we observe a BH-type inequality for Boolean functions.

▶ **Fact 7.** *Let $f : \{-1,1\}^n \to \{-1,1\}$ of degree at most d. Then,*

$$\Big(\sum_{s\in\{0,1\}^n} |\widehat{f}(s)|^{\frac{2d}{d+1}} \Big)^{\frac{d+1}{2d}} \leq 2^{\frac{d-1}{d}}.$$

The equality it is witnessed by the address function.

Fact 7 might be of interest in functional analysis for two reasons: (i) it is conjectured that the value of the BH constant for d-linear tensors is $2^{\frac{d-1}{d}}$ [48], so this fact proves the conjecture for particular case of d-linear Boolean tensors, (ii) the address function[5], that saturates the inequality, is a d-linear form that gives a lower bound for the BH constant for multilinear tensors of $2^{\frac{d}{d-1}}$, which matches the best lower bound known so far [24].

3.4.2 Real-valued polynomials

For bounded functions $f : \{-1,1\}^n \to [-1,1]$ the definition of quantum uniform examples $|\psi_f\rangle$ is unclear. Given that bounded polynomials have received attention in a few works [39, 35, 26], we propose a way learning them quantumly by accessing these polynomials through a block encoding [18], i.e., a learning algorithm has access to a block encoding of the 2^n-dimensional diagonal matrix whose diagonal entries all equal f. To this end, we prove the following theorem.

▶ **Proposition 8.** *Let $f : \{-1,1\}^n \to [-1,1]$ be a degree-d polynomial. There is an algorithm that (ε,δ)-learns f (in ℓ_2-distance) using $\exp(\widetilde{O}(\sqrt{d^3} + d\log(1/\varepsilon))\log(1/\delta))$ copies of a block-encoding of f.*

The proof of Proposition 8 is a combination of the ideas of Eskenazis and Ivanisvili [26] with the Fourier sampling and block-encoding quantum primitives. We remind the reader that the merit of Eskenazis and Ivanisvili [26] was to bring down the classical complexity of the problem from $O_{d,\varepsilon}(n^d)$ to $O_{d,\varepsilon}(\log n)$. Proposition 8 shows that the quantum complexity this could be even reduced to $O_{d,\varepsilon}(1)$. Proposition 8 also implies a quantum speedup (with respect to n), as the lower bound of $\Omega(2^d + \log n)$ also holds for membership queries[6], which are the classical analogue of accessing a unitary block-encoding of f.

[5] For $d \in \mathbb{N}$, the address function $f : (\{-1,1\}^2)^{d-1} \times \{-1,1\}^{2^{d-1}} \to \{-1,1\}$ is defined as $f(x,y) = \sum_{a\in\{-1,1\}^{d-1}} g_a(x)y(a)$, where we identify $\{-1,1\}^{d-1}$ with $[2^{d-1}]$ and $g_a(x)$ is 0 unless $x_i(1) = a_i x_i(2)$ for every $i \in [n]$, in which case it takes the value $\prod_{i\in[n]} x_i(1)$.

[6] Making a membership query to f consists on accessing one pair $(x, f(x))$ where x is chosen by the learner, not necessarily uniformly at random. If f is a Boolean function and U_f is the unitary defined by $U_f|x\rangle = f(x)|x\rangle$, then a membership query $(x, f(x))$ can be simulated by applying $(H\otimes \mathrm{Id}_n)CU_f(H\otimes \mathrm{Id}_n)$ to $|0\rangle|x\rangle$ and measuring the first qubit in the computational basis. Note that U_f can be regarded as a block-encoding of f.

Remarkably, we highlight that although our results are about sample complexity, the time complexity of our quantum algorithm of Proposition 8 scales as $\mathrm{poly}(n, \exp(d^{1.5}))$, while the current state-of-the-art classical algorithm [26] approximates the $\binom{n}{d}$ Fourier coefficients, so it requires $\mathrm{poly}(n^d)$ time. In particular, for $d = (\log n)^{2/3}$, constant ε, δ, our quantum algorithm has a time complexity of $\mathrm{poly}(n)$ time, while the state-of-the-art classical algorithm runs in time $n^{\mathrm{polylog} n}$.

4 Learning algorithm for low-degree quantum channels

In this section we give our learning algorithm for quantum channels, i.e., prove Theorem 1. To do that, we first need to prove a new BH inequality for quantum channels.

4.1 Bohnenblust-Hille inequality for quantum channels

In this section, we prove a Bohnenblust-Hille inequality for n-qubit quantum channels. In fact, it is a result for superoperators which are bounded in the S_1 to S_1 norm (defined below), of which quantum channels are a particular example. Hence, we will treat Φ as a linear map from $\mathcal{M}_N$ to $\mathcal{M}_N$, the space of N-dimensional matrices with $N = 2^n$. In particular, we will evaluate Φ on matrices that are not states. The S_1 to S_1 norm of superoperator is defined by

$$\|\Phi\|_{S_1 \to S_1} = \sup_{M \neq 0} \frac{\|\Phi(M)\|_{S_1}}{\|M\|_{S_1}},$$

where $\|M\|_{S_1}$ is the Schatten 1-norm of M, i.e., the sum of the singular values of M.

To prove our theorem will reduce to the classical case of functions $f : \{-1,1\}^n \to \mathbb{R}$.

▶ **Theorem 9** ([23]). *Let $p : \{-1,1\}^n \to \mathbb{R}$ of degree at most d. Then,*

$$\|\widehat{p}\|_{\frac{2d}{d+1}} \leq C^{\sqrt{d \log d}} \|p\|_\infty,$$

where $C > 0$ is a constant.

To achieve this reduction, for every superoperator $\Phi : \mathcal{M}_M \to \mathcal{M}_N$, we assign it a function $f_\Phi : \{-1,1\}^{3n} \times \{-1,1\}^{3n} \to \mathbb{C}$ defined as follows. For $a = (a^1, a^2, a^3)$, $b = (b^1, b^2, b^3) \in \{-1,1\}^n \times \{-1,1\}^n \times \{-1,1\}^n$ and $s, t \in \{1,2,3\}^n$, define the following matrices (which are not necessarily states)

$$|a^s\rangle\langle b^t| = \bigotimes_{i \in [n]} |\chi^{s(i)}_{a^s(i)}\rangle\langle\chi^{t(i)}_{b^t(i)}|,$$

where $|\chi^s_{\pm 1}\rangle$ are the ± 1 eigenstates of the single-qubit Pauli operators σ_s. The function $f_\Phi : \{-1,1\}^{3n} \times \{-1,1\}^{3n} \to \mathbb{C}$ is then given by

$$f_\Phi(a,b) = \frac{1}{9^n} \sum_{s,t \in \{1,2,3\}^n} \mathrm{Tr}[\Phi\left(|a^s\rangle\langle b^t|\right) |b^t\rangle\langle a^s|],$$

where f_Φ has the following properties, allowing us to reduce to the classical BH inequality.

▶ **Lemma 10.** *Let Φ be a degree-d superoperator. Then, $|f_\Phi(a,b)| \leq \|\Phi\|_{S_1 \to S_1}$ for all a, b and $\left\|\widehat{\Phi}\right\|_p \leq 9^d \left\|\widehat{f_\Phi}\right\|_p$. The degree of f_Φ as a multilinear polynomials is $2d$.*

Proof. We first show the bound on $|f_\Phi|$. Given that $(|a^s\rangle\langle b^t|)(|a^s\rangle\langle b^t|)^* = |a^s\rangle\langle a^s|$, we have that

$$\left\||a^s\rangle\langle b^t|\right\|_{S_1} = \left\||a^s\rangle\langle b^t|\right\|_{S_\infty} = 1. \tag{6}$$

Thus, we have that f_Φ is bounded:

$$\begin{aligned}
|f_\Phi(a,b)| &\leq \frac{1}{9^n} \sum_{s,t\in\{1,2,3\}^n} |\mathrm{Tr}[\Phi\left(|a^s\rangle\langle b^t|\right)|b^t\rangle\langle a^s|]| \\
&\leq \frac{1}{9^n} \sum_{s,t\in\{1,2,3\}^n} \left\|\Phi\left(|a^s\rangle\langle b^t|\right)\right\|_{S_1} \left\||b^t\rangle\langle a^s|\right\|_{S_\infty} \\
&\leq \frac{1}{9^n} \sum_{s,t\in\{1,2,3\}^n} \|\Phi\|_{S_1\to S_1} \left\||a^s\rangle\langle b^t|\right\|_{S_1} \left\||b^t\rangle\langle a^s|\right\|_{S_\infty} \\
&\leq \frac{1}{9^n} \sum_{s,t\in\{1,2,3\}^n} \|\Phi\|_{S_1\to S_1} = \|\Phi\|_{S_1\to S_1},
\end{aligned}$$

where in the first inequality we have used the triangle inequality, in the second inequality Riesz theorem, in the third the definition of $S_1 \to S_1$ norm and in the fourth Equation (6). We now prove that $\left\|\widehat{\Phi}\right\|_p \leq 9^{-d}\left\|\widehat{f_\Phi}\right\|_p$ and that the degree of f_Φ is $2d$. It suffices to show that

$$f_\Phi(a,b) = \sum_{x,y\in\{0,1,2,3\}^n} \frac{\widehat{\Phi}(x,y)}{3^{|x|+|y|}} \prod_{i\in\mathrm{supp}(x)} \prod_{j\in\mathrm{supp}(y)} a_i^{x(i)} b_j^{y(j)}, \tag{7}$$

where $\mathrm{supp}(x) = \{i \in [n] : x_i \neq 0\}$ and $|x|$ is the size of $\mathrm{supp}(x)$. To prove Equation (7) the key is observing that for every $s,t \in \{1,2,3\}$, $x,y \in \{0,1,2,3\}$ and $a,b \in \{-1,1\}$ we have that

$$\mathrm{Tr}[\sigma_x|\chi_a^s\rangle\langle\chi_b^t|\sigma_y|\chi_b^t\rangle\langle\chi_a^s|] = \begin{cases} 0 & \text{if } (s\neq x \text{ and } x\neq 0) \text{ or } (t\neq y \text{ and } y\neq 0), \\ 1 & \text{if } x=0 \text{ and } y=0, \\ a & \text{if } s=x \text{ and } y=0, \\ b & \text{if } x=0 \text{ and } t=y, \\ ab & \text{if } s=x \text{ and } y=t. \end{cases}$$

After taking tensor products, we observe that for every $s,t \in \{1,2,3\}^n$, $x,y \in \{0,1,2,3\}^n$ and $a=(a^1,a^2,a^3)$, $b=(b^1,b^2,b^3) \in \{-1,1\}^n \times \{-1,1\}^n \times \{-1,1\}^n$, it holds that

$$\mathrm{Tr}[\sigma_x|a^s\rangle\langle b^t|\sigma_y|b^t\rangle\langle a^s|] = \prod_{i\in\mathrm{supp}\,x} \prod_{j\in\mathrm{supp}\,y} a_i^{x(i)} b_j^{y(j)} \delta_{x(i),s(i)} \delta_{y(j),t(j)},$$

where $\delta_{x,y}$ is the delta function taking value of 1 when $x=y$, and 0 otherwise. In particular, from this follows that

$$f_{\Phi_{x,y}}(a,b) = \frac{1}{9^n} \sum_{s,t\in\{1,2,3\}^n} \mathrm{Tr}[\sigma_x|a^s\rangle\langle b^t|\sigma_y|b^t\rangle\langle a^s|] = \frac{1}{9^n} \prod_{i\in\mathrm{supp}\,x} \prod_{j\in\mathrm{supp}\,y} a_i^{x(i)} b_j^{y(j)} \sum_{s\in\mathcal{X},t\in\mathcal{Y}} 1,$$

where $\mathcal{X} = \{s \in \{1,2,3\}^n : s(i) = x(i)\ \forall\ i \in \mathrm{supp}(x)\}$. Hence, as $|\mathcal{X}| = 3^{n-|x|}$, Equation (7) follows for the case of $\Phi_{x,y}$. By linearity, Equation (7) follows for every superoperator. ◀

▶ **Theorem 11** (Bohnenblust-Hille inequality for $S_1 \to S_1$ maps). *Let Φ be a super-operator of degree at most d. Then there exists a constant C such that*

$$\left\|\widehat{\Phi}\right\|_{\frac{2d}{d+1/2}} \leq C^d \|\Phi\|_{S_1\to S_1}.$$

In particular, if Φ is a quantum channel, then there exists a constant C such that

$$\left\|\widehat{\Phi}\right\|_{\frac{2d}{d+1/2}} \leq C^d.$$

Proof. Let $\Re f_\Phi : \{-1,1\}^n \to \mathbb{R}$ be defined as taking the real part of f_Φ i.e., $(\Re f_\phi)(x) = \Re(f_\Phi(x))$ and $\Im f_\Phi : \{-1,1\}^n \to \mathbb{R}$ as taking the imaginary part of f_Φ i.e., $(\Im f_\phi)(x) = \Im(f_\Phi(x))$. Note that we have that $\widehat{f}_\phi = \widehat{\Re f}_\Phi + i\widehat{\Im f}_\Phi$. By Lemma 10, $|(\Re f_\phi)(x)|, |(\Im f_\phi)(x)| \leq |f_\Phi(x)| \leq \|\Phi\|_{S_1\to S_1}$ and that the degree of both the real and imaginary part is at most $2d$. Hence, by the triangle inequality and Theorem 9 we have

$$\left\|\widehat{f}_\Phi\right\|_{\frac{4d}{2d+1}} \leq \left\|\widehat{\Re f}_\Phi\right\|_{\frac{4d}{2d+1}} + \left\|\widehat{\Im f}_\Phi\right\|_{\frac{4d}{2d+1}} \leq C\sqrt{d\log d}\,\|\Phi\|_{S_1\to S_1}\,.$$

Thus, using that $\left\|\widehat{\Phi}\right\|_{2d/(d+1)} \leq 9^d \left\|\widehat{f}_\Phi\right\|_{2d/(d+1)}$ it follows that $\left\|\widehat{\Phi}\right\|_{2d/(d+1)} \leq C^d \|\Phi\|_{S_1\to S_1}$. This proves the first part of the statement.

For the second we just have to show that if Φ is a quantum channel, then $\|\Phi\|_{S_1\to S_1}$ is bounded by a constant. Indeed, if M is self-adjoint, we can write it as $M = M^+ - M^-$, with M^+ and M^- being positive semidefinite, so

$$\frac{\|\Phi(M)\|_{S_1}}{\|M\|_{S_1}} \leq \frac{\mathrm{Tr}[\Phi(M^+)] + \mathrm{Tr}[\Phi(M^-)]}{\mathrm{Tr}[M^+] + \mathrm{Tr}[M^-]} = 1, \tag{8}$$

where in the first equality we have used that Φ is positive and in the second that is trace perserving. Finally, any matrix M can be written as $M = \Re M + i\Im M$, where $\Re M = (M + M^*)/2$ and $\Im M = (M - M^*)/2$ are self-adjoint. Hence,

$$\frac{\|\Phi(M)\|_{S_1}}{\|M\|_{S_1}} \leq \frac{\|\Phi(\Re M)\|_{S_1} + \|\Phi(\Im M)\|_{S_1}}{\|M\|_{S_1}} \leq \frac{\|\Re M\|_{S_1} + \|\Im M\|_{S_1}}{\|M\|_{S_1}} \leq \frac{\|M\|_{S_1} + \|M\|_{S_1}}{\|M\|_{S_1}} = 2,$$

where in the first inequality we have used the triangle inequality, in the second inequality we have used Equation (8) and in the third inequality that $\|\Re M\|_{S_1}, \|\Im M\|_{S_1} \leq \|M\|_{S_1}$. ◀

4.2 Learning low-degree quantum channels

Before we prove the main theorem of the section, we show that for given $x, y \in \{0,1,2,3\}^n$, the corresponding Fourier coefficient $\widehat{\Phi}(x,y)$ can be efficiently learned. This is accomplished through the combination of a few SWAP tests.

▶ **Fact 12** (SWAP test for mixed states [37]). *Let ρ, ρ' be two states. Then, one can estimate $\mathrm{Tr}[\rho\rho']$ up to error ε with probability $1-\delta$ using $O((1/\varepsilon)^2 \log(1/\delta))$ copies of ρ and ρ'.*

▶ **Lemma 13** (Pauli coefficient estimation for channels). *Let $x, y \in \{0,1,2,3\}^n$. Then, $\widehat{\Phi}(x,y)$ can be estimated with error ε and probability $1-\delta$ using $O((1/\varepsilon)^2 \log(1/\delta))$ queries to Φ.*

Proof. If $x = y$, we just have to prepare $\widehat{\Phi}$ (which can be done by preparing the Choi state $J(\Phi)$ following by a unitary transformation) and apply Fact 12 to $\widehat{\Phi}$ and the state $\rho = |x\rangle\langle x|$. If $x \neq y$, one first learns $\widehat{\Phi}(x,x)$ and $\widehat{\Phi}(y,y)$ with error ε as before. One the one hand, one can learn $\widehat{\Phi}(x,x) + \widehat{\Phi}(x,x) + 2\Re\widehat{\Phi}(x,y)$, with error ε by applying Fact 12 to $\widehat{\Phi}$ and $1/2\sum_{z,t\in\{x,y\}} |z\rangle\langle t|$. Hence, one learns $\Re\widehat{\Phi}(x,y)$ with error $3\varepsilon/2$. On the other hand, one can learn $\widehat{\Phi}(x,x) + \widehat{\Phi}(y,y) + 2\Im\widehat{\Phi}(x,y)$, with error ε by applying Fact 12 to $\widehat{\Phi}$ and $1/2(|x\rangle\langle x| + i|x\rangle\langle y| - i|y\rangle\langle x| + |y\rangle\langle y|)$, and thus one can learn $\Im\widehat{\Phi}(x,y)$ with error $3\varepsilon/2$. ◀

We will also need the following well-known result on learning discrete probability distributions. See [17, Theorem 9] for a proof.

▶ **Lemma 14.** *Let $p = \{p(x)\}_x$ be a probability distribution over some set $\mathcal{X}$. Let $p' = (p'(x))_x$ the empirical probability distribution obtained after sampling T times from p. Then, for $T = O((1/\varepsilon)^2 \log(1/\delta))$ with probability $1-\delta$ we have that $|p(x) - p'(x)| \leq \varepsilon$ for every $x \in \mathcal{X}$.*

Now, we are ready to prove Theorem 1, which we restate for the convenience of the reader.

▶ **Theorem 1.** *Let Φ be a n-qubit degree-d quantum channel. There is an algorithm that (ε, δ)-learns Φ (in ℓ_2-distance) using $\exp\left(\widetilde{O}(d^2 + d\log(1/\varepsilon))\right) \cdot \log(1/\delta)$ queries to Φ.*

Proof. We first state the algorithm.

Algorithm 1 Learning low-degree channels via BH inequality.

Input: A quantum channel Φ of degree at most d, and error ε and a failure probability δ

1: Let $c = \varepsilon^{2d+1} C^{-d^2}$
2: Prepare $T_1 = O((1/c)^2 \log(1/\delta))$ copies of $\widehat{\Phi}$ to sample from $(\widehat{\Phi}(x,x))_x$. Let $(\widehat{\Phi}'(x,x))_x$ be the associated empirical distribution
3: **for** $x, y \in \mathcal{X}_c = \{x : |\widehat{\Phi}'(x,x)| \geq c\}$ **do**
4: Prepare $O((1/c)^2 (1/\varepsilon)^2 \log((1/c)^2 (1/\delta)))$ copies of $\widehat{\Phi}$ and use them to approximate $\widehat{\Phi}(x,y)$ with $\widehat{\Phi}''(x,y)$ using Lemma 13.
5: **end for**

Output: $\sum_{x,y \in \mathcal{X}_c} \widehat{\Phi}''(x,y) \Phi_{x,y}$

Let $c > 0$ to be determined later. In the first part of the algorithm we prepare $\widehat{\Phi}$ and measure, i.e., we sample from $(\widehat{\Phi}(x,x))_{x \in \{0,1,2,3\}^n}$. Let $(\widehat{\Phi}'(x,x))_{x \in \{0,1,2,3\}^n}$ be the empirical distribution one obtains after T_1 samples. $\mathcal{E} = \{|\widehat{\Phi}(x,x) - \widehat{\Phi}'(x,x)| \leq c \ \forall x \in \{0,1,2,3\}^n\}$. By Lemma 14, taking T_1 to be $O((1/c)^2 \log(1/\delta))$ ensures that

$$\Pr[\mathcal{E}] \geq 1 - \delta.$$

Let $\mathcal{X}_c = \{x : \ |\widehat{\Phi}'(x,x)| \geq c\}$. Note that, as $\sum_{x \in \mathcal{X}_c} \Phi(x,x) \leq 1$,

$$|\mathcal{X}_c| \leq c^{-1}, \tag{9}$$

and in the event of $\mathcal{E}$ we have that

$$x \notin \mathcal{X}_c \implies |\widehat{\Phi}(x,x)| \leq |\widehat{\Phi}'(x,x)| + ||\widehat{\Phi}(x,x)| - |\widehat{\Phi}'(x,x)|| \leq 2c. \tag{10}$$

In particular, it follows that

$$x \notin \mathcal{X}_c \implies |\widehat{\Phi}(x,y)| \leq \sqrt{|\widehat{\Phi}(x,x)||\widehat{\Phi}(y,y)|} \leq \sqrt{2c} \quad \forall\, y \in \{0,1,2,3\}^n, \tag{11}$$

where in the first inequality we have used that $\widehat{\Phi}$ is positive semidefinite and in the second inequality Equation (10) and that $\widehat{\Phi}(y,y) \leq 1$. We assume that the first part of the algorithm succeeds, meaning that $\mathcal{E}$ happens. In the second part of the algorithm we approximate all the Pauli coefficients of $\mathcal{X}_c \times \mathcal{X}_c$ with error $c\varepsilon$ and probability $1 - \delta$ querying Φ just

$$T_2 = O((1/c)^4 (1/\varepsilon)^2 \log((1/c)^2 (1/\delta)))$$

times from Lemma 13. Note that $T_2 > T_1$, so this complexity dominates the one of the first part of the algorithm. Let $\widehat{\Phi}''(x,y)$ be these approximations and let $\Phi_c = \sum_{x,y \in \mathcal{X}_c} \widehat{\Phi}''(x,y) \sigma_x \cdot \sigma_y$. Now, we have that

$$\begin{aligned}\|\Phi - \Phi_c\|_2^2 &= \sum_{x,y\in\mathcal{X}_c} |\widehat{\Phi}(x,y) - \widehat{\Phi}''(x,y)|^2 + \sum_{x\vee y\notin\mathcal{X}_c} |\widehat{\Phi}(x,y)|^2 \\ &\leq \varepsilon^2 + \sum_{x\vee y\notin\mathcal{X}_c} |\widehat{\Phi}(x,y)|^{\frac{1}{d+1/2}} |\widehat{\Phi}(x,y)|^{\frac{2d}{d+1/2}} \\ &\leq \varepsilon^2 + (2c)^{\frac{1/2}{d+1/2}} \left\|\widehat{\Phi}\right\|_{\frac{2d}{d+1/2}}^{\frac{2d}{d+1/2}} \\ &\leq \varepsilon^2 + c^{\frac{1/2}{d+1/2}} C^d,\end{aligned}$$

where in the equality we have used Parseval's identity; in the first inequality we used Equation (9), the learning guarantees of the second part of the algorithm and that $2 = 1/(d+1/2) + 2d/(d+1/2)$; in the second inequality we have used Equation (11); and in the third inequality we used the Bohnenblust-Hille inequality for channels (Theorem 11). Hence, by choosing

$$c = \varepsilon^{4d+2} C^{-d^2}$$

we obtain the desired result. ◀

5 Learning quantum query algorithms

In this section, our goal will be to prove Theorem 5, restated below for the reader's convenience.

▶ **Theorem 5.** *For a quantum algorithm that makes d-queries as in Figure 1, its amplitudes can be learned up to error ε in ℓ_2^2 accuracy using $O\left((1/\varepsilon)^d \cdot \log n\right)$ uniformly random samples.*

Proof. Eskenazis and Ivanishvili [26] showed that a function $f : \{-1,1\}^n \to [-1,1]$ with degree at most d and $\left\|\widehat{f}\right\|_{\frac{2d}{d+1}} \leq C$, can be learned with success probablity $1-\delta$ and error ε in ℓ_2^2 accuracy using $O(\varepsilon^{-(d+1)} C^{2d} \log(n/\delta))$ samples $(x, f(x))$, where x is drawn uniformly at random from $x \in \{-1,1\}^n$. Arunachalam et al. [3] showed that the amplitudes of quantum algorithms that d queries as in Figure 1 are completely bounded d-tensors. Hence, using Theorem 15 (which we prove below) we can let $C = 1$, and obtain the desired result. ◀

5.1 The constant of the completely bounded BH inequality is 1

In this section we determine that the exact value of the constant of the completely bounded BH inequality is 1. Before that, we first define the completely bounded norm. For d-linear tensors, the completely bounded norm is defined as

$$\|T\|_{\text{cb}} = \sup \left\| \sum_{\mathbf{i}\in[n]^d} \widehat{T}_{\mathbf{i}} X_1(i_1) \dots X_t(i_t) \right\|_{\text{op}}, \tag{12}$$

where $X_s(i_s)$ are matrices of size $m \times m$ that have operator norm at most 1 and $m \in \mathbb{N}$.

▶ **Theorem 15.** *Let $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}\}$. Let $T : (\mathbb{K}^n)^d \to \mathbb{K}$ be a d-linear form. Then,*

$$\left\|\widehat{T}\right\|_{\frac{2d}{d+1}} \leq \|T\|_{\text{cb}},$$

and the inequality can be saturated.

Theorem 15 establishes that the best constant for the completely bounded BH inequality is exactly 1. This sharply contrasts with the current knowledge about the BH constants, where only poly(d) upper bounds are known. We thus *close* one of the edges of comparison of the three norms that appear in Grothendieck and Bohnenblust-Hille inequalities (see Figure 2).

Figure 2 Triangles of norm comparisons. In the left triangle, we display the norm comparisons implied by the Littlewood [40] and Grothendieck inequalities [30] and our Theorem 15 for real bilinear maps. In the right triangle, we depict the best upper bound for the BH constant [11], the no extension of the Grothendieck inequality [49], and our Theorem 15 for d-linear tensors.

The main ingredient of the proof of Theorem 15 is a general lower bound for the completely bounded norm, Lemma 17. This technique is inspired by the idea of Varoupoulos to rule out a generalization of von Neumann's inequality [56] and was recently used by Escudero-Gutiérrez to show a particular case of the famous Aaronson and Ambainis conjecture of quantum query complexity [25]. Theorem 15 follows from combining Lemma 17 with Blei's inequality Lemma 16. See [11, Theorem 2.1] for a proof of Blei´s inequality.

▶ **Lemma 16** (Blei's inequality). *Let $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}\}$ and let $\widehat{T} \in (\mathbb{K})^{n^d}$. Then,*

$$\Big(\prod_{s\in[d]}\sum_{i_s\in[n]}\sqrt{\sum_{i_1,\ldots,i_{s-1},i_{s+1},\ldots,i_d\in[n]}|\widehat{T}_{\mathbf{i}}|^2}\Big)^{\frac{1}{d}} \geq \left\|\widehat{T}\right\|_{\frac{2d}{d+1}}.$$

▶ **Lemma 17.** *Let $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}\}$, let $T : (\mathbb{K}^n)^d \to \mathbb{K}$ be a d-linear form, and let $s \in [d]$. Then,*

$$\|T\|_{\mathrm{cb}} \geq \sum_{i_s\in[n]}\sqrt{\sum_{i_1,\ldots,i_{s-1},i_{s+1},\ldots,i_d\in[n]}|\widehat{T}_{\mathbf{i}}|^2}.$$

Proof. The proof involves evaluating Equation (12) on an explicit set of contractions (matrices with operator norm at most 1). Let $m = \sum_{r=0}^{s-1} n^r + \sum_{r=0}^{d-r} n^r$ and let $\{e_{\mathbf{i}}, f_{\mathbf{j}} : \mathbf{i} \in [n]^r, r \in \{0\} \cup [d-s], \mathbf{j} \in [n]^t, t \in \{0\} \cup [s-1]\}$ be an orthonormal basis of $\ell_2^m(\mathbb{K})$, where we identify $[n]^0$ with $\emptyset$. We define $m \times m$ matrices $X(i)$ for $i \in [n]$ by

$$X(i)e_{\mathbf{j}} = e_{(i,\mathbf{j})}, \text{ if } \mathbf{j} \in [n]^r,\ r \in \{0\} \cup [d-s-1],$$
$$X(i)e_{\mathbf{j}} = \frac{\sum_{\mathbf{k}\in[n]^{s-1}} \widehat{T}^*_{\mathbf{k}i\mathbf{j}} f_{\mathbf{k}}}{\sqrt{\sum_{k_1,\ldots,k_{s-1},k_{s+1},\ldots,k_d\in[n]}|\widehat{T}|^2_{(k_1,\ldots,k_{s-1},i,k_{s+1},\ldots,k_d)}}}, \text{ if } \mathbf{j} \in [n]^{d-s},$$
$$X(i)f_{\mathbf{j}} = \delta_{i,j_s} f_{(i_1,\ldots,i_{s-1})}, \text{ if } \mathbf{j} \in [n]^{d-s},\ r \in \{0\} \cup [d-1].$$

For some intuition of the behaviour of these matrices, one may interpret the first $d-s$ applications of the matrices $X(i)$ as *creation* operators and the last $s-1$ as *destruction* operators. Assume for the moment that $X(i)$ are contractions. Given that,

$$\langle f_\emptyset, X(i_1)\ldots X(i_d)e_\emptyset\rangle = \frac{\widehat{T}_{\mathbf{i}^*}}{\sqrt{\sum_{i_1,\ldots,i_{s-1},i_{s+1},\ldots,i_d\in[n]}|\widehat{T}_{\mathbf{i}}|^2}},$$

it would then follow that

$$\begin{aligned}\|T\|_{\mathrm{cb}} &\geq \left\| \sum_{\mathbf{i}\in[n]^d} \widehat{T}_{\mathbf{i}} X(i_1)\dots X(i_d) \right\|_{\mathrm{op}} \\ &\geq \sum_{\mathbf{i}\in[n]^d} \widehat{T}_{\mathbf{i}} \frac{\widehat{T}^*_{\mathbf{i}}}{\sqrt{\sum_{k_1,\dots,k_{s-1},k_{s+1},\dots,k_d\in[n]} |\widehat{T}|^2_{(k_1,\dots,k_{s-1},i_s,k_{s+1},\dots,k_d)}}} \\ &= \sum_{i_s\in[n]} \sqrt{\sum_{i_1,\dots,i_{s-1},i_{s+1},\dots,i_d\in[n]} |\widehat{T}_{\mathbf{i}}|^2},\end{aligned}$$

as desired. It then remains to prove that the matrices $X(i)$ are contractions. Given that $X(i)$ maps $\{e_{\mathbf{i}} : \mathbf{i}\in[n]^r,\, r\in\{0\}\cup[d-s-1]\}$, $\{e_{\mathbf{i}} : \mathbf{i}\in[n]^{d-s}\}$ and $\{f_{\mathbf{i}} : \mathbf{i}\in[n]^r,\, r\in\{0\}\cup[s]\}$ to orthogonal subspaces, it suffices to show that the $X(i)$ are contractions when restricted to those subspaces. For the first and third sets, this is true because $X(i)$ maps each basis vector of these sets to a different basis vector or to 0. For the second set, is also true because for every $\lambda\in\mathbb{K}^{n^{d-s}}$

$$\begin{aligned}\left\| X(i) \sum_{\mathbf{j}\in[n]^{d-s}} \lambda_{\mathbf{j}} e_{\mathbf{j}} \right\|_2 &= \left\| \frac{\sum_{\mathbf{k}\in[n]^{s-1}} (\sum_{\mathbf{j}\in[n]^{d-s}} \lambda_{\mathbf{j}} \widehat{T}^*_{\mathbf{k}i\mathbf{j}}) f_{\mathbf{k}}}{\sqrt{\sum_{k_1,\dots,k_{s-1},k_{s+1},\dots,k_d\in[n]} |\widehat{T}|^2_{(k_1,\dots,k_{s-1},i,k_{s+1},\dots,k_d)}}} \right\|_2 \\ &= \frac{\sqrt{\sum_{\mathbf{k}\in[n]^{s-1}} |\sum_{\mathbf{j}\in[n]^{d-s}} \lambda_{\mathbf{j}} \widehat{T}^*_{\mathbf{k}i\mathbf{j}}|^2}}{\sqrt{\sum_{k_1,\dots,k_{s-1},k_{s+1},\dots,k_d\in[n]} |\widehat{T}|^2_{(k_1,\dots,k_{s-1},i,k_{s+1},\dots,k_d)}}} \\ &\leq \frac{\sqrt{\sum_{\mathbf{k}\in[n]^{s-1}} \sum_{\mathbf{j}\in[n]^{d-s}} |\widehat{T}^*_{\mathbf{k}i\mathbf{j}}|^2} \sqrt{\sum_{\mathbf{j}\in[n]^{d-s}} |\lambda_{\mathbf{j}}|^2}}{\sqrt{\sum_{k_1,\dots,k_{s-1},k_{s+1},\dots,k_d\in[n]} |\widehat{T}|^2_{(k_1,\dots,k_{s-1},i,k_{s+1},\dots,k_d)}}} \\ &= \|\lambda\|_2 ,\end{aligned}$$

where in the inequality we have used Cauchy-Schwarz for the sum over $\mathbf{j}$. ◀

Proof of Theorem 15. The inequality $\|\widehat{T}\|_{\frac{2d}{d+1}} \leq \|T\|_{\mathrm{cb}}$ follows from Lemmas 16 and 17. The inequality is saturated by the form $T(x_1,\dots,x_d) = x_1(1)$. ◀

Abstract

We study the *noncommutative rank* problem, ncRANK, of computing the rank of matrices with linear entries in n noncommuting variables and the problem of *noncommutative Rational Identity Testing*, RIT, which is to decide if a given rational formula in n noncommuting variables is zero on its domain of definition.

Motivated by the question whether these problems have *deterministic* NC algorithms, we revisit their interrelationship from a parallel complexity point of view. We show the following results:

1. Based on Cohn's embedding theorem [14, 15] we show deterministic NC reductions from multivariate ncRANK to bivariate ncRANK and from multivariate RIT to bivariate RIT.
2. We obtain a deterministic NC-Turing reduction from bivariate RIT to bivariate ncRANK, thereby proving that a deterministic NC algorithm for bivariate ncRANK would imply that both multivariate RIT and multivariate ncRANK are in deterministic NC.

1 Introduction

There are two main algorithmic problems of interest in this paper. These are the *noncommutative Rational Identity Testing problem* (RIT) and the *noncommutative rank* (ncRANK) problem for matrices with linear entries.

The RIT problem is a generalization of multivariate polynomial identity testing to identity testing of multivariate rational expressions. When the variables are commuting, rational identity testing and polynomial identity testing are equivalent problems. On the other hand, if the variables are all noncommuting, the RIT problem needs different algorithmic techniques as rational expressions in noncommuting variables are more complicated. Mathematically, rational expressions over noncommuting variables are quite well studied. They arise in the construction of the so-called free skew fields [15]. Hrubes and Wigderson [21] initiated the algorithmic study of RIT for *rational formulas* and gave a deterministic polynomial time reduction from RIT to ncRANK. Subsequently, deterministic polynomial-time algorithms were obtained independently by Ivanyos et al [23, 22] and by Garg et al [18, 19] for the RIT problem, in fact they obtain deterministic polynomial time algorithms for ncRANK, and

using Hrubes-Wigderson reduction from RIT to ncRANK get a polynomial time algorithm for RIT. The Ivanyos et al algorithm is algebraic and works for fields of all characteristics. The Garg et al algorithm has an analytic flavor and is for the characteristic zero case.

The Edmonds' Problem and ncRANK

The ncRANK problem is essentially the noncommutative version of the well-known Edmonds' problem: determine the rank of a matrix M whose entries are linear forms in commuting variables (see [23, 19, 7, 10] for more details). A special case of it is to determine if a square matrix M with linear entries in commuting variables is *singular*. This is also known as the symbolic determinant identity testing problem, SDIT. There is an easy randomized NC algorithm for it, based on the Polynomial Identity Lemma [5, 28, 30, 16], by randomly substituting scalar values for the variables from the field (or a suitable extension of it) and evaluating the determinant using a standard NC algorithm. However, a deterministic polynomial-time algorithm for SDIT is an outstanding open problem [7].

Recently, for the RIT problem the first deterministic quasi-NC algorithm has been obtained [2]. Another recent development – building on the connection between the noncommutative Edmonds' problem and identity testing for noncommutative algebraic branching programs [10] – is a generalization of the Edmond's problem to a partially commutative setting with application to the weighted k-tape automata equivalence problem [3].

1.1 This paper: overview of results and proofs

With this background, the natural algorithmic questions are whether RIT for noncommutative rational formulas and ncRANK have deterministic NC algorithms. We revisit the problems from this perspective and obtain the following new results.

1. We show that multivariate RIT for formulas is deterministic NC reducible to bivariate RIT for formulas. More precisely, given a rational formula $\Phi(x_1, x_2, \ldots, x_n)$, computing an element of the skew field $\mathbb{F}\langle\langle X\rangle\rangle$, where $X = \{x_1, x_2, \ldots, x_n\}$, the deterministic NC reduction replaces each x_i by a formula $\Phi_i(x, y)$ computing a polynomial in $\mathbb{F}\langle x, y\rangle$. Then the resulting rational formula

   $$\Psi(x, y) = \Phi(\Phi_1(x, y), \Phi_2(x, y), \ldots, \Phi_n(x, y))$$

   has the property that

   $$\Phi(x_1, x_2, \ldots, x_n) \neq 0 \text{ iff } \Psi(x, y) \neq 0.$$

2. We next show that multivariate ncRANK is deterministic NC reducible to bivariate ncRANK. More precisely, given a $d \times d$ linear matrix $A = A_0 + \sum_{i=1}^{n} A_i x_i$ in noncommuting variables $X = \{x_1, x_2, \ldots, x_n\}$, where the A_i are matrices over the scalar field $\mathbb{F}$, we first give a deterministic NC reduction that transforms A to a $d \times d$ matrix B whose entries are bivariate polynomials in $\mathbb{F}\langle x, y\rangle$, where x and y are two noncommuting variables, where its entries $B[i, j]$ are given by *polynomial size noncommutative formulas*, with the property that $\text{ncrk}(A) = \text{ncrk}(B)$. Then we examine the Higman linearization process [21] that transforms B into a matrix B' with linear entries in x and y such that the noncommutative rank $\text{ncrk}(B)$ of B can be easily recovered from $\text{ncrk}(B')$. We show that this process can be implemented in deterministic NC (the earlier works [21, 22, 23, 19] only consider its polynomial-time computability).
   Additionally, we consider the more general problem ncRANK_{poly} of computing the noncommutative rank of a matrix whose entries are noncommutative formulas computing polynomials. We show using our parallel Higman linearization algorithm that ncRANK_{poly} is also deterministic NC reducible to bivariate ncRANK.

Both the multivariate to bivariate reductions, stated above, are crucially based on a theorem of Cohn [14] (also see [15, Theorem 4.7.3]) which we will refer to as Cohn's embedding theorem and describe it later in the introduction.

3. Finally, obtaining a deterministic NC reduction from RIT to ncRANK turns out to be quite subtle. From the work of Hrubes and Wigderson [21], who initiated this line of research on RIT, we can only obtain a sequential deterministic polynomial-time reduction from RIT to ncRANK. However, for our result we require an NC reduction. If the given rational formula has logarithmic depth, then their result already implies an NC reduction. Now, in the same paper [21], Hrubes and Wigderson have also shown a *depth reduction* result for multivariate noncommutative rational formulas: every rational formulas of size s is equivalent to a logarithmic depth rational formula of size $\text{poly}(s)$. Their construction is based on Brent's depth reduction result for commutative arithmetic formulas. However, due to noncommutativity and the presence of inversion gates, the formula constructed in their proof needs to be different based on whether certain rational subformulas, arising in the construction procedure, are identically zero or not. To algorithmize such steps in the construction we need to use RIT as a subroutine. As RIT has a polynomial-time algorithm [23, 19], the depth-reduction in [21] also has a polynomial time algorithm.[1]
   As the third result of this paper, building on the Hrubes-Wigderson depth-reduction construction, we are able to show that, with oracle access to RIT, rational formula depth reduction can be done in deterministic NC. Using this we are able to obtain a deterministic NC-Turing reduction from RIT to ncRANK. Hence, if bivariate ncRANK is in deterministic NC we will obtain a deterministic NC algorithm also for RIT. We leave open the question whether depth reduction of noncommutative rational formulas is unconditionally in NC.

2 Preliminaries

In this section we recall the essential basic definitions and fix the notation.

Let $\mathbb{F}$ be a (commutative) field[2] and $X = \{x_1, x_2, \ldots, x_n\}$ be n free noncommuting variables. The free monoid X^* is the set of all monomials in the variables X. A *noncommutative polynomial* $f(X)$ is a finite $\mathbb{F}$-linear combination of monomials in X^*, and the *free noncommutative ring* $\mathbb{F}\langle X\rangle$ consists of all noncommutative polynomials.

Noncommutative Rational Formulas

An *arithmetic circuit* computing an element of $\mathbb{F}\langle X\rangle$ is a directed acyclic graph with each indegree 0 node labeled by either an input variable $x_i \in X$ or some scalar $c \in \mathbb{F}$. Each internal node g has indegree 2 and is either a $+$ gate or a $\times$ gate: it computes the sum (resp. left to right product) of its inputs. Thus, each gate of the circuit computes a polynomial in $\mathbb{F}\langle X\rangle$ and the polynomial computed by the circuit is the polynomial computed at the *output gate*. A *formula* is restricted to have fanout 1 or 0.

[1] In the commutative case, Brent's result is parallelizable to yield an NC algorithm. For noncommutative formulas without inversion gates we can obtain the depth-reduced formula in NC, as we will observe later in the paper.

[2] In this paper, $\mathbb{F}$ will either be the field of rationals or a finite field.

When we allow the formulas/circuits to have *inversion gates* we get *rational formulas and rational circuits*.

The Free Skew Field

We now briefly explain the free skew field construction. The elements of the free skew field are noncommutative rational functions which are more complicated than their commutative counterparts. Rational formulas in the commutative setting can be canonically expressed as ratios of two polynomials. There is no such canonical representation for noncommutative rational formulas.

Following Hrubes-Wigderson [21], we use Amitsur's approach [1] for formally defining skew fields.[3]

It involves defining appropriate notion of equivalence of formulas (intuitively, two formulas are equivalent if they agree on their *domain of definition*). The equivalence classes under this equivalence relation are the elements of the free skew field. We give the formal definitions below.

Let $\mathbb{M}_k(\mathbb{F})$ denote the ring of $k \times k$ matrices with entries from field $\mathbb{F}$. Note that a rational formula Φ defines a partial function

$$\hat{\Phi} : \mathbb{M}_k(\mathbb{F})^n \mapsto \mathbb{M}_k(\mathbb{F})$$

that on input $(a_1, a_2, \ldots, a_n) \in \mathbb{M}_k(\mathbb{F})^n$ evaluates Φ by substituting $x_i \leftarrow a_i$ for $i \in [n]$. $\hat{\Phi}(a_1, \ldots, a_n)$ is undefined if the input to some inversion gate in Φ is not invertible in $\mathbb{M}_k(\mathbb{F})$.

▶ **Definition 1.** *Let Φ be a rational formula in variables X. For each $k \in \mathbb{N}$, let $\mathcal{D}_{k,\Phi}$ be the set of all matrix tuples $(a_1, a_2, \ldots, a_n) \in \mathbb{M}_k(\mathbb{F})^n$ such that $\hat{\Phi}(a_1, a_2, \ldots, a_n)$ is defined. The* domain of definition *of Φ is the union $\mathcal{D}_\Phi = \bigcup_k \mathcal{D}_{k,\Phi}$.*

▶ **Definition 2** ([21])**.**

- *A rational formula Φ is called* correct *if for every gate u of Φ the subformula Φ_u has a nonempty domain of definition.*
- *Correct rational formulas Φ_1, Φ_2 are said to be* equivalent *(denoted $\Phi_1 \equiv \Phi_2$) if the intersection $\mathcal{D}_{\Phi_1} \cap \mathcal{D}_{\Phi_2}$ of their domains of definitions is nonempty and they agree on all the points in the intersection.*

We note that equivalent formulas need not have the same domain of definition. For example, $\Phi_1 = z_1 z_2 z_3$ and $\Phi_2 = (z_1 z_2 z_3 \cdot (z_2 z_3 - z_3 z_2)^{-1}) \cdot (z_2 z_3 - z_3 z_2)$ are equivalent. However, the domain of definition of Φ_1 includes all matrix tuples, whereas the domain of definition of Φ_2 contains only matrix tuples (Z_1, Z_2, Z_3) such that $\det(Z_2 Z_3 - Z_3 Z_2) \neq 0$.

The relation $\equiv$ as defined above is an equivalence relation on rational formulas and the equivalence classes, called *rational functions*, are the elements of the skew field $\mathbb{F}\langle\langle X \rangle\rangle$ [21, 1].

Noncommutative Rank

We now recall the notion of rank for matrices over the noncommutative ring $\mathbb{F}\langle X \rangle$.

▶ **Definition 3** (inner rank)**.** *Let M be a matrix over $\mathbb{F}\langle X \rangle$. Its* inner rank *is the least r such that M can be written as a matrix product $M = PQ$ where Q has r rows (and P has r columns).*

[3] There are other ways to defining free skew fields [1, 6, 27, 11, 12, 13, 15].

▶ **Definition 4** (full matrices). *An $n \times n$ square matrix M over $\mathbb{F}\langle X\rangle$ is* full *if it cannot be decomposed as a matrix product $M = PQ$ where P is $n \times r$ and Q is $r \times n$ for $r < n$. In other words, an $n \times n$ matrix is called full precisely when its inner rank is n.*

We can also define the rank of a matrix M to be the maximum r such that M contains an $r \times r$ full submatrix. For matrices over $\mathbb{F}\langle X\rangle$ these notions of *noncommutative rank* coincide as summarized below.[4]

▶ **Proposition 5** ([15]). *Let M be an $n \times n$ matrix over the ring $\mathbb{F}\langle X\rangle$. Then*

- *M is a full matrix (that is, M has inner rank n) iff it is invertible over the skew field $\mathbb{F}\langle\langle X\rangle\rangle$.*
- *More generally, M has inner rank r iff the largest full submatrix of M is $r \times r$.*

The Algorithmic Problems of Interest

At this point we formally define the problems of interest in this paper.

1. The multivariate RIT problem takes as input a rational formula Φ, computing a rational function $\hat{\Phi}$ in $\mathbb{F}\langle\langle X\rangle\rangle$, and the problem is to check if Φ is equivalent to 0? In the bivariate RIT problem Φ computes a rational function in $\mathbb{F}\langle\langle x, y\rangle\rangle$.
2. The multivariate ncRANK problem takes as input a matrix M with affine linear form entries over X and the problem is to determine its noncommutative rank $\mathrm{ncrk}(M)$. Bivariate ncRANK is similarly defined.
3. A more general version of ncRANK is ncRANK_{poly} in which the matrix entries are allowed to be polynomials in $\mathbb{F}\langle X\rangle$ computed by noncommutative formulas. A closely related problem is SINGULAR where the problem is to test if a square matrix M over $\mathbb{F}\langle X\rangle$ with entries computed by formulas is singular or not.

The complexity class NC and NC reductions

The class NC consists of decision problems that can be solved in $\mathrm{polylog}(n)$ time with $\mathrm{poly}(n)$ many processors.[5] For two decision problems A and B we say A is many-one NC reducible to B if there is a reduction from A to B that is NC computable. Similarly, A is NC-Turing reducible to B if there is an oracle NC algorithm for A that has oracle access to B.

It turns out that SINGULAR and ncRANK are equivalent even under deterministic NC reductions.[6]

Cohn's Embedding Theorem

We now give an outline of Cohn's embedding theorem and how it gives us the desired reduction from multivariate to bivariate RIT and also from multivariate to bivariate ncRANK. However, for multivariate to bivariate reduction for ncRANK we will require additional NC algorithms for formula depth reduction and Higman linearization.

Let $X = \{x_1, x_2, \ldots, x_n\}$ be a set of n noncommuting variables, and let x, y be a pair of noncommuting variables. We first recall the following well-known fact, observed in the early papers on noncommutative polynomial identity testing [8, 26]: for noncommutative

[4] For a ring R in general, a full matrix R need not be invertible (see [21] for an example).
[5] This model is widely accepted as the right theoretical notion for efficient parallel algorithms.
[6] As for $M \in \mathbb{F}\langle X\rangle^{m\times n}$, $\mathrm{ncrk}(M) = r$ iff r is a size of a largest sized invertible minor of M, so to compute $\mathrm{ncrk}(M)$, it suffices to test singularity of matrix UMV, where U, V are generic $r \times m, n \times r$ matrices respectively with entries as fresh noncommuting variables for $r \leq \min(m, n)$. See e.g. [19, Lemma A.3] for details.

polynomials in $\mathbb{F}\langle X\rangle$, the problem of polynomial identity testing (PIT) is easily reducible to PIT for bivariate noncommutative polynomials in $\mathbb{F}\langle x, y\rangle$. Indeed, more formally, we have the following easy to check fact.

▶ **Proposition 6.** *The map*

$$x_i \mapsto x^{i-1}y, 1 \leq i \leq n$$

extends to an injective homomorphism (i.e. a homomorphic embedding*) from the ring* $\mathbb{F}\langle X\rangle$ *to the ring* $\mathbb{F}\langle x, y\rangle$*.*

However, in order to obtain our multivariate to bivariate reductions, we need a mapping $\beta : X \to \mathbb{F}\langle x, y\rangle$ which has the following properties:

- For each i, there is a small noncommutative arithmetic formula that computes $\beta(x_i)$.
- β extends to an injective homomorphism[7], not just from the ring $\mathbb{F}\langle X\rangle$ to $\mathbb{F}\langle x, y\rangle$, but also to an injective homomorphism from the skew field $\mathbb{F}\langle\langle X\rangle\rangle$ to the skew field $\mathbb{F}\langle\langle x, y\rangle\rangle$. This will guarantee that for two rational formulas Φ_1, Φ_2 computing inequivalent rational functions in $\mathbb{F}\langle\langle X\rangle\rangle$ their images $\beta(\Phi_1)$ and $\beta(\Phi_2)$ also compute inequivalent rational functions in $\mathbb{F}\langle x, y\rangle$.
- Furthermore, in order to get the multivariate to bivariate reduction for ncRANK, we will additionally require of the map β that for any matrix M over $\mathbb{F}\langle X\rangle$ its image $\beta(M)$, which is a matrix over $\mathbb{F}\langle x, y\rangle$ obtained by applying β to each entry of M, has the same rank as M. Such a homomorphic embedding is called an *honest embedding* [14]. Here we note that, full matrices over $\mathbb{F}\langle X\rangle$ are invertible over $\mathbb{F}\langle\langle X\rangle\rangle$ [15]. Consequently if one can lift embedding β to one between the corresponding free skew fields, it enforces β to be an honest embedding.

The mapping $x_i \mapsto x^{i-1}y$ actually *does not* extend to an honest embedding as observed in [14]. Indeed, the rank 2 matrix $\begin{pmatrix} x_1 & x_2 \\ x_3 & x_4 \end{pmatrix}$ has image

$$\begin{pmatrix} y & xy \\ x^2y & x^3y \end{pmatrix} = \begin{pmatrix} 1 \\ x^2 \end{pmatrix} \begin{pmatrix} y & xy \end{pmatrix}$$

which is rank 1. In general, a homomorphic embedding from a ring R to a ring R' is an *honest embedding* if it maps full matrices over R to full matrices over R'. We now state Cohn's embedding theorem.

For polynomials $f, g \in \mathbb{F}\langle x, y\rangle$ let $[f, g]$ denotes the commutator polynomial $fg - gf$. Cohn's embedding map $\beta : \mathbb{F}\langle X\rangle \to \mathbb{F}\langle x, y\rangle$ is defined as follows.

- Let $\beta(x_1) = y$. For $i \geq 2$, define $\beta(x_i) = [\beta(x_{i-1}), x]$.
- We can then naturally extend β to a homomorphism from $\mathbb{F}\langle X\rangle$ to $\mathbb{F}\langle y, x\rangle$, and it is easy to check that it is injective. In fact, we can even assume $|X|$ to be countably infinite.

▶ **Theorem 7** (Cohn's embedding theorem [15, Theorem 7.5.19])**.** *The embedding map* $\beta : \mathbb{F}\langle X\rangle \to \mathbb{F}\langle x, y\rangle$ *defined above extends to an embedding between the corresponding skew fields* $\beta : \mathbb{F}\langle\langle Z\rangle\rangle \to \mathbb{F}\langle\langle x, y\rangle\rangle$ *and hence is an honest embedding.*

Cohn's construction is based on skew polynomial rings, which explains the appearance of the iterated commutators $\beta(x_i) = [\beta(x_{i-1}), x]$. We briefly explain the underlying ideas in the arxiv version [4]. For more details see [14, 15].

[7] That is, a homomorphic embedding.

3 The Reduction from multivariate RIT to bivariate RIT

The reduction follows quite easily from Theorem 7. However, we present some complexity details in this section showing that it is actually a deterministic NC reduction. The following lemma is useful to describe the reduction.

▶ **Lemma 8.** *Recall the embedding map β defined above. $\beta(z_0) = y$ and $\beta(z_{i+1}) = [\beta(z_i), x]$ are polynomials in $\mathbb{F}\langle x, y\rangle$ for each $i \geq 0$. Then, for $n \geq 1$ we have*

$$\beta(z_n) = \sum_{i=0}^{n} (-1)^i \binom{n}{i} x^i y x^{n-i}.$$

As a consequence, there is a deterministic NC *algorithm that constructs a* poly(n)*-sized formula for $\beta(z_n)$.*

Proof. We will use induction on n. The base case follows from the fact that $\beta(z_1) = yx - xy$. Inductively assume the claim is true for all n. Now, $\beta(z_{n+1}) = [\beta(z_n), x]$

$$\begin{aligned}
&= \sum_{i=0}^{n} (-1)^i \binom{n}{i} x^i y x^{n-i+1} - \sum_{j=0}^{n} (-1)^j \binom{n}{j} x^{j+1} y x^{n-j} \text{ by induction hypothesis} \\
&= yx^{n+1} + \sum_{i=1}^{n} (-1)^i \binom{n}{i} x^i y x^{n-i+1} + \sum_{i=1}^{n+1} (-1)^i \binom{n+1-1}{i-1} x^i y x^{n+1-i} \\
&= yx^{n+1} + \sum_{i=1}^{n} (-1)^i \left[\binom{n+1-1}{i} + \binom{n+1-1}{i-1} \right] x^i y x^{n-i+1} + (-1)^{n+1} x^{n+1} y \\
&= yx^{n+1} + (-1)^{n+1} x^{n+1} y + \sum_{i=1}^{n} (-1)^i \binom{n+1}{i} x^i y x^{n+1-i} \text{ from Pascal's identity} \\
&= \sum_{i=0}^{n+1} (-1)^i \binom{n+1}{i} x^i y x^{n+1-i}
\end{aligned}$$

This completes the inductive proof.

As the binomial coefficients can be computed in NC using Pascal's identity, the expression for $\beta(z_n)$ obtained above immediately implies an NC algorithm for construction of a poly(n) sized formula for $\beta(z_n)$. ◀

▶ **Theorem 9.** *The multivariate RIT problem is deterministic* NC *(in fact, logspace) reducible to bivariate RIT. More precisely, given as input a rational formula Φ computing an element of $\mathbb{F}\langle\langle X\rangle\rangle$, $X = \{x_1, x_2, \ldots, x_n\}$ there is a deterministic* NC *algorithm that computes a rational formula Ψ computing an element of $\mathbb{F}\langle\langle x, y\rangle\rangle$ such that Φ is nonzero in its domain of definition iff Ψ is nonzero in its domain of definition.*

Proof. We can identify $\mathbb{F}\langle\langle X\rangle\rangle$ with $\mathbb{F}\langle\langle z_0, z_1, \ldots, z_{n-1}\rangle\rangle$. Let $\Phi_i(x, y)$ be the poly(i) size noncommutative formula computing the nested commutator $\beta(z_i)$ for each i. In the rational formula Φ, for each i we replace the input z_i to Φ by $\Phi_i(x, y)$. The new formula we obtain is

$$\Psi(x, y) = \Phi(\Phi_1(x, y), \Phi_2(x, y), \ldots, \Phi_{n-1}(x, y)).$$

By Theorem 7, $\Psi(x, y) \neq 0$ on its domain of definition iff $\Phi(z_0, z_1, \ldots, z_{n-1})$ is nonzero on its domain of definition. Furthermore, because β is an embedding, it is guaranteed that if Φ has a nontrivial domain of definition then Ψ also has a nontrivial domain of definition.

As computation of Ψ from Φ involves only replacing the z_i by Φ_i, the reduction is clearly logspace computable. ◀

4 Reduction from n-variate ncRANK_{poly} to 2-variate ncRANK

In this section we give a deterministic NC reduction from n-variate ncRANK_{poly} to bivariate ncRANK. The basic idea of the reduction is as follows. Given a polynomial matrix[8] $M \in \mathbb{F}\langle X\rangle^{m\times m}$ such that each entry of M is computed by formula of size at most s. We will use Cohn's embedding theorem 7 to get a matrix M_1 with *bivariate* polynomial entries such that each entry of M_1 is computed by a $\mathrm{poly}(n,s)$ size noncommutative formula and $\mathrm{ncrk}(M) = \mathrm{ncrk}(M_1)$. Notice that M_1 is an instance of bivariate ncRANK_{poly}. Next, we need to give an NC reduction transforming M_1 to an instance of bivariate ncRANK (which will be a matrix with linear entries in x and y).

In order to do this transformation in NC, we will first apply the depth-reduction algorithm of Lemma 10 to get matrix M_2 whose entries are $\mathrm{poly}(n,s)$ size log-depth formulas that compute the same polynomials as the corresponding entries of M_1. Then we apply Higman Linearization to M_2 to obtain a bivariate linear matrix M_3. For this we will use our parallel algorithm for Higman Linearization described in Theorem 13. From the properties of Higman linearization we can easily recover $\mathrm{ncrk}(M_2)$ from $\mathrm{ncrk}(M_3)$. In what follows, first we give a deterministic NC algorithm for the depth reduction of noncommutative formulas and Higman linearization process. We conclude the section by giving an NC reduction from multivariate to bivariate ncRANK using above NC algorithms combined with Cohn's embedding theorem 7.

4.1 Depth reduction for noncommutative formulas without divisions

In the commutative setting Brent [9] obtained a deterministic NC algorithm to transform a given *rational* formula (which may have division gates) to a log-depth rational formula. In the noncommutative setting, Hrubes and Wigderson [21] proved the *existence* of log-depth *rational* formula equivalent to any given rational formula. Their proof is based on [9]. However, it is not directly algorithmic as explained in the introduction. We will discuss it in more detail in Section 5. However, it turns out that, if the noncommutative formula doesn't have division gates then the depth reduction is quite easy and we obtain a simple deterministic NC algorithm for it that computes a log-depth noncommutative formula equivalent to the given noncommutative formula. The proof is based Brent's commutative version. We highlight the distinctive points arising in the noncommutative version.

We introducing some notation. Let Φ be a noncommutative arithmetic formula computing a polynomial in $\mathbb{F}\langle x_1, x_2, \ldots, x_n\rangle$. Let $\hat{\Phi}$ denote the polynomial computed by Φ. For a node $v \in \Phi$, let Φ_v denote the subformula of Φ rooted at node v, so $\hat{\Phi_v}$ is the polynomial computed by the subformula rooted at v. For a node $v \in \Phi$, let $\Phi_{v\leftarrow z}$ be a formula obtained from Φ by replacing the sub-formula Φ_v by single variable z. For a node $v \in \Phi$, let $wt(v) = |\Phi_v|$ denote the number of nodes in the subformula rooted at v. By size of formula Φ we refer to number of gates in Φ.

▶ **Lemma 10.** *Given a formula Φ of size s computing a noncommutative polynomial $f \in \mathbb{F}\langle x_1, x_2, \ldots, x_n\rangle$ there is an NC algorithm to obtain an equivalent formula Φ' for f with depth $O(\log s)$.*

Proof. First we describe a recursive construction to compute a formula Φ' equivalent to Φ and inductively prove that the depth of Φ' is $c\log_2 s$ for an absolute constant c. Then we analyze the parallel time complexity of the construction and prove that it can be implemented in NC.

[8] We can assume it is a square matrix without loss of generality.

Let A_Φ be $s \times s$ matrix such that for gates $u, v \in \Phi$, $(u,v)^{th}$ entry of A_Φ is 1 if gate v is a descendent of gate u. Using the well-known pointer doubling strategy (see e.g. [29, 25]) we can compute matrix A_Φ in NC. So by adding elements in each row of A_Φ, we can compute $wt(u)$ (that is the number of descendants of gate $u \in \Phi$) in NC. Let v be a gate in Φ such that $\frac{s}{3} \leq wt(v) < \frac{2s}{3}$. Such a gate always exists by a standard argument. Since we can compute the number of descendants of a gate in NC, we can also find such a gate v in NC, by simply having a processor associated to each gate to check the above inequalities. Now we are ready to describe recursive construction of Φ'.

1. In NC find a gate v in Φ such that $\frac{s}{3} \leq wt(v) < \frac{2s}{3}$.
2. Let $r = v_0$ be the root of Φ and $v_1, v_2, \ldots, v_{\ell-1}$ be gates on r to v path in Φ. Let $v = v_\ell$. For $1 \leq i \leq \ell$, let u_i denote a sibling of v_i. Let S_1 be collection of all indices j such that $1 \leq j \leq \ell$, v_j is a product gate and is a right child of its parent. Similarly let S_2 be collection of all indices j such that $1 \leq j \leq \ell$, v_j is a product gate and is a left child of its parent. Define formula $\Psi_1 = \prod_{j \in S_1} \Phi_{u_j}$. The product is computed using sequence of multiplication gates, starting with Φ_{u_j} for the first u_j (one with smallest index $j \in S_1$) each multiplication gate multiplies the product so far from right by Φ_{u_j} for the next gate u_j, $j \in S_1$, along the root to v path. Similarly define formula $\Psi_2 = \prod_{j \in S_2} \Phi_{u_j}$. Let Ψ_3 be a formula obtained from Φ by replacing subformula Φ_v by zero.
3. Recursively in parallel compute log-depth formulas $\Psi_1', \Psi_2', \Psi_3', \Phi_v'$ equivalent to Ψ_1, Ψ_2, Ψ_3 and Φ_v respectively.
4. Define formula Φ' as $(\Psi_1' \cdot \Phi_v') \cdot \Psi_2' + \Psi_3$.

From the definitions of Ψ_1, Ψ_2 and Ψ_3 it is clear that the polynomial computed by Φ equals $(\hat{\Psi}_1 \cdot \hat{\Phi}_v) \cdot \hat{\Psi}_2 + \hat{\Psi}_3$, where $\hat{\Psi}_1, \hat{\Psi}_1, \hat{\Psi}_1, \hat{\Phi}_v$ are the polynomials computed by Ψ_1, Ψ_2, Ψ_3 and Φ_v respectively. Hence, Φ', defined in Step 4, is equivalent to Φ.

Let $d(s)$ denote the upper bound on the depth of the formula output by the above procedure if size s formula is given to it as input. We use induction on the size s to prove that $d(s) \leq c \log_2 s$. As Ψ_1, Ψ_2 are disjoint subformulas of $\Phi_{v \leftarrow z}$, clearly we have $|\Psi_1| + |\Psi_2| \leq |\Phi_{v \leftarrow z}|$. Since $|\Phi_v| \geq \frac{s}{3}$, it implies $|\Psi_1|, |\Psi_2| \leq |\Phi_{v \leftarrow z}| \leq \frac{2s}{3}$. From the definition of Ψ_3, it is clear that $|\Psi_3| \leq |\Phi_{v \leftarrow z}| \leq \frac{2s}{3}$. So the size of each formula Ψ_1, Ψ_2, Ψ_3 and Φ_v is upper bounded by $\frac{2s}{3}$. Hence, inductively, for each of the formulas $\Psi_1', \Psi_2', \Psi_3', \Phi_v'$ the depth is upper bounded by $c \log_2 \frac{2s}{3}$. As Φ' is obtained from $\Psi_1', \Psi_2', \Psi_3', \Phi_v'$ using two multiplications and an addition as in Step 4, it follows that the depth of $\Phi' = d(s) \leq c \log_2 \frac{2s}{3} + 3$. Choosing $c \geq \frac{3}{(\log_2 3 - 1)}$ we get $d(s) \leq c \log_2 \frac{2s}{3} + 3 \leq c \log_2 s$. This completes the induction, proving that the depth of Φ' is at most $c \log_2 s$.

Let $t(s)$ denotes parallel time complexity of the above procedure. Since Steps 1, 2, 4 can be implemented in NC they together take $(\log s)^k$ parallel time for an absolute constant k. As all the recursive calls in Step 3 are processed in parallel, we have the recurrence $t(s) \leq t(2s/3) + (\log s)^k$. Hence, $t(s) \leq (\log s)^{(k+1)}$. This shows that the above procedure can be implemented in NC, completing the proof of the theorem. ◀

▶ Remark 11. In Lemma 10, we avoid using the depth-reduction approach for noncommutative rational formulas that is used in [21]. This is because it can introduce inversion gates even if the original formula has no inversion gates. Instead, we directly adapt ideas from Brent's construction for commutative formulas to obtain the NC algorithm. We note here that Nisan's seminal work [24] also briefly mentions noncommutative formula depth reduction (but not its parallel complexity or even in an algorithmic context).

Higman linearization which is sometimes called Higman's trick was first used by Higman in [20]. Cohn extensively used Higman Linearization in his factorization theory of free ideal rings. Given a matrix with noncommutative polynomials as its entries, Higman linearization

process transforms it into a matrix with linear entries. This transformation process has several nice properties such as: it preserves fullness of the matrix (that is the input polynomial matrix is full rank iff final linear matrix is full rank), it preserves irreducibility of the matrix, etc.

We first describe a single step of the linearization process applied to a single noncommutative polynomial, which easily generalizes to matrices with polynomial entries. Given an $m \times m$ matrix M over $\mathbb{F}\langle X\rangle$ such that $M[m,m] = f + g \times h$, apply the following:

- Expand M to an $(m+1) \times (m+1)$ matrix by adding a new last row and last column with diagonal entry 1 and remaining new entries zero:

$$\left[\begin{array}{c|c} M & 0 \\ \hline 0 & 1 \end{array}\right].$$

- Then the bottom right 2×2 submatrix is transformed as follows by elementary row and column operations

$$\begin{pmatrix} f+gh & 0 \\ 0 & 1 \end{pmatrix} \to \begin{pmatrix} f+gh & g \\ 0 & 1 \end{pmatrix} \to \begin{pmatrix} f & g \\ -h & 1 \end{pmatrix}$$

Given a polynomial $f \in \mathbb{F}\langle X\rangle$ by repeated application of the above step we will finally obtain a *linear matrix* $L = A_0 + \sum_{i=1}^{n} A_i x_i$, where each $A_i, 0 \le i \le n$ is an $\ell \times \ell$ over $\mathbb{F}$, for some ℓ. The following theorem summarizes its properties.

▶ **Theorem 12** (Higman Linearization [15]). *Given a polynomial $f \in \mathbb{F}\langle X\rangle$, there are matrices $P, Q \in \mathbb{F}\langle X\rangle^{\ell\times\ell}$ and a linear matrix $L \in \mathbb{F}\langle X\rangle^{\ell\times\ell}$ such that*

$$P \left(\begin{array}{c|c} f & 0 \\ \hline 0 & I_{\ell-1} \end{array}\right) Q = L \tag{1}$$

with P upper triangular, Q lower triangular, and the diagonal entries of both P and Q are all 1's. (Hence, P and Q are both invertible over $\mathbb{F}\langle\langle X\rangle\rangle$, moreover entries of P^{-1} and Q^{-1} are in $\mathbb{F}\langle X\rangle$).

Instead of a single f, we can apply Higman linearization to a matrix of polynomials $M \in \mathbb{F}\langle X\rangle^{m\times m}$ to obtain a linear matrix L such that $P(M \oplus I_k)Q = L$ for invertible matrices P, Q. Garg et al. [19] gave polynomial time algorithm to carry out Higman linearization for polynomial matrix whose entries are given by noncommutative formulas. We will give an NC algorithm to implement this transformation.

▶ **Theorem 13.** *Let $A \in \mathbb{F}\langle X\rangle^{n\times n}$ be a polynomial matrix such that each entry of A is given by a noncommutative formula of size at most s. Then there is a deterministic* NC *algorithm (with parallel time complexity* $\mathrm{poly}(\log s, \log n)$*) to compute invertible upper and lower triangular matrices $P, Q \in \mathbb{F}\langle X\rangle^{\ell\times\ell}$ with all diagonal entries 1 and a linear matrix $L \in \mathbb{F}\langle X\rangle^{\ell\times\ell}$ such that $P \left(\begin{array}{c|c} A & 0 \\ \hline 0 & I_k \end{array}\right) Q = L$, where $\ell = n + k$ and k is $O(n^2 \cdot s)$. All the entries of P, Q are computable by algebraic branching programs of size* $\mathrm{poly}(n, s)$*. Moreover $ncrk(A) + k = ncrk(L)$, hence the rank of A is easily computable from the rank of L.*

The proof of the above theorem can be found in the arXiv version [4].

Using Theorem 7, Lemma 10 and Theorem 13 we get a deterministic NC reduction from multivariate ncRANK to bivariate ncRANK.

▶ **Theorem 14.** *There is a deterministic* NC *reduction from the multivariate ncRANK problem to the bivariate ncRANK problem.*

5 NC Reduction from RIT to bivariate ncRANK

In this section we give an NC-Turing reduction from RIT to bivariate ncRANK. That is, we design an NC algorithm for RIT assuming we have an oracle for bivariate ncRANK. Hrubes and Wigderson in [21] give a polynomial time reduction from RIT to ncRANK problem [21, Theorem 2.6]. Also they show that for any given rational formula Φ there is a log-depth rational formula that is equivalent to Φ [21, Proposition 4.1].

Our key contribution here is to use Cohn's embedding theorem to transform RIT problem to the *bivariate* case. Then we parallelize the Hrubes-Wigderson reduction from RIT to ncRANK. In fact, if the input rational formula is already logarithmic depth then the Hrubes-Wigderson reduction from RIT to ncRANK can be implemented in NC. In this section we design an NC algorithm for depth reduction of rational formulas (possibly with division gates) assuming NC oracle for bivariate ncRANK.[9] Indeed, the construction of an equivalent log-depth rational formula, as described in [21], does not appear to be directly parallelizable, as its description crucially requires rational formula identity testing.[10]

We show that, indeed, the depth-reduction proof in [21] can be parallelized step by step. However, there are some key points where our algorithmic proof is different. Firstly, to solve the RIT instance arising in the depth-reduction proof, we need to recursively depth-reduce the corresponding subformula and then apply Hrubes-Wigderson reduction from RIT to ncRANK on the constructed log-depth subformula. Secondly, we need to handle an important case arising in the proof (namely, the case (2) in the description of the Normal-Form procedure in the proof of the Lemma 17) which was not significant for the existential argument in [21]. In fact to handle this case, we require an argument based on Brent's commutative formula depth reduction [9].

In the detailed proof of Lemma 17, we first sketch our NC algorithm for depth reduction of rational formula assuming oracle access to bivariate ncRANK. We highlight and elaborate the key steps where our proof differs from [21]. We need to reproduce some parts of their proof for completeness, for these parts we just sketch the argument and refer to [21] for the details. Using this depth reduction algorithm we give an NC Turing reduction from RIT to bivariate ncRANK, which is a main result of this section.

5.1 Depth reduction for noncommutative formulas with inversion gates

The following is a consequence of results in [21] and [17].

▶ **Theorem 15** ([21, 17]). *Let Φ be a rational formula of size s computing a* non-zero *rational function in $\mathbb{F}\langle\langle X\rangle\rangle$. If the field $\mathbb{F}$ is sufficiently large and $k > 2s$ then, at a matrix tuple $(M_1, M_2, \ldots, M_n)$ chosen uniformly at random from $M_{k\times k}(\mathbb{F})^n$, the matrix $\hat{\Phi}(M_1, \ldots, M_n)$ is nonsingular with "high" probability.*

If $\mathbb{F}$ is small then we can pick the random matrices over a suitable extension field, and by "high" probability we mean, say, $1 - 2^{-\Omega(s+n)}$.

[9] It is an interesting problem to devise an NC algorithm for rational formula depth reduction without oracle access to singularity test.

[10] The overall proof in [21] is based on the Brent's depth-reduction of commutative rational formulas [9]. In the commutative case addressed by Brent, it turns out that the construction procedure does not require oracle access to identity testing and he obtains an NC algorithm for obtaining the depth-reduced formula.

Let Φ_1 and Φ_2 be correct rational formulas of size at most s computing rational functions in $\mathbb{F}\langle\langle X\rangle\rangle$. By Theorem 15 and a union bound argument, for a random matrix substitution $(M_1, M_2, \ldots, M_n)$ from $M_{k\times k}(\mathbb{F})^n$, inputs to all the inversion gates in Φ_1 and Φ_2 simultaneously evaluate to non-singular matrices with "high" probability. Hence, for k sufficiently large we have $\mathcal{D}_{k,\Phi_1} \cap \mathcal{D}_{k,\Phi_2} \neq \emptyset$. It follows that a random matrix tuple is in $\mathcal{D}_{k,\Phi_1} \cap \mathcal{D}_{k,\Phi_2}$ with high probability.

By Theorem 15 and the definition of correct rational formulas (Definition 2), it follows that if Φ_1 and Φ_2 are size s correct formulas that are *not* equivalent then for a random matrix substitution of dimension $k > 2s$ both Φ_1 and Φ_2 are defined and they disagree with high probability. As noted in Section 2, equivalent formulas need not have the same domain of definition.

Lemma 17 is the main technical result of this section. It describes an NC algorithm for depth-reduction of correct formulas assuming an oracle for bivariate ncRANK. The next lemma is useful for establishing equivalences of formulas arising in the proof of Lemma 17. Suppose Φ is a rational formula computing the rational function $\hat{\Phi}$. For a gate v in formula Φ, Φ_v denotes the subformula rooted at v. The formula $\Phi_{v\leftarrow z} \in \mathbb{F}\langle\langle X \cup \{z\}\rangle\rangle$ is obtained from Φ by replacing subformula Φ_v with fresh variable z.

▶ **Lemma 16** (local surgery). *Let Φ be a correct rational formula and v be a gate in Φ. Suppose Ψ is a correct rational formula equivalent to Φ_v. Let $\Psi' = (A\cdot z+B)\cdot(C\cdot z+D)^{-1}$ is a formula equivalent to $\Phi_{v\leftarrow z}$ such that A, B, C, D are correct formulas which do not depend upon z and $\hat{C}\cdot\hat{\Delta}+\hat{D} \neq 0$ for any formula Δ such that $\Phi_{v\leftarrow\Delta}$ is correct. Let Φ' denote the rational formula obtained by replacing z in Ψ' by Ψ. Then Φ' is correct and it is equivalent to Φ.*

Proof. From the definitions of Φ_v and $\Phi_{v\leftarrow z}$ it follows that $\Phi = \Phi_{v\leftarrow\Phi_v}$. As Φ is correct, from the properties of formulas C, D as stated in the lemma it follows that $\hat{C}\hat{\Phi}_v + \hat{D} \neq 0$. Which implies $\hat{C}\hat{\Psi} + \hat{D} \neq 0$ as $\Psi \equiv \Phi_v$. This shows that the formula $\Phi' = (A\cdot\Psi+B)\cdot(C\cdot\Psi+D)^{-1}$ is correct. Now let $\tau = (M_1, \ldots, M_n)$ is a matrix tuple in $\mathcal{D}_\Phi \cap \mathcal{D}_{\Phi'}$, the intersection of domains of definition of Φ and Φ'. This implies $\tau \in \mathcal{D}_{\Phi_v}$ as $\mathcal{D}_\Phi \subseteq \mathcal{D}_{\Phi_v}$, Φ_v being subformula of Φ. Similarly, $\tau \in \mathcal{D}_\Psi$ as $\mathcal{D}_{\Phi'} \subseteq \mathcal{D}_\Psi$, Ψ being a subformula of Φ'. So $\tau \in \mathcal{D}_{\Phi_v} \cap \mathcal{D}_\Psi$. As $\Phi_v \equiv \Psi$, it follows that $\Phi_v(\tau) = \Psi(\tau)$. As $\tau \in \mathcal{D}_\Phi$. It implies that $(M_1, M_2, \ldots, M_n, \Phi_v(\tau)) = (\tau, \Phi_v(\tau)) \in \mathcal{D}_{\Phi_{v\leftarrow z}}$. Similarly, as $\tau \in \mathcal{D}_{\Phi'}$, it follows that $(\tau, \Psi(\tau)) \in \mathcal{D}_{\Psi'}$. As $\Phi_v(\tau) = \Psi(\tau)$, it implies

$$(\tau, \Phi_v(\tau)) = (\tau, \Psi(\tau)) \in \mathcal{D}_{\Phi_{v\leftarrow z}} \cap \mathcal{D}_{\Psi'}$$

As $\Phi_{v\leftarrow z} \equiv \Psi'$, this implies $\Phi_{v\leftarrow z}(\tau, \Phi_v(\tau)) = \Psi'(\tau, \Psi(\tau))$. But $\Phi_{v\leftarrow z}(\tau, \Phi_v(\tau)) = \Phi(\tau)$ and $\Psi'(\tau, \Psi(\tau)) = \Phi'(\tau)$. So we get $\Phi(\tau) = \Phi'(\tau)$ for any $\tau \in \mathcal{D}_\Phi \cap \mathcal{D}_{\Phi'}$. Thus proving $\Phi \equiv \Phi'$. ◀

▶ **Lemma 17.** *Given a* correct *formula Φ of size s computing a rational function $f \in \mathbb{F}\langle\langle X\rangle\rangle$, for sufficiently large s and absolute constants c, b*

1. *we give an* NC *algorithm, with oracle access to bivariate ncRANK, that outputs a correct formula Φ' of depth at most $c\log_2 s$ which is equivalent to Φ.*
2. *If a variable z occurs in Φ at most once then we give an* NC *algorithm, with bivariate ncRANK as oracle, that constructs* correct *rational formulas A, B, C, D which do not depend on z with depth at most $c\log_2 s + b$ and the formula $\Phi' = (A\cdot z+B)\cdot(C\cdot z+D)^{-1}$ is equivalent to Φ. Moreover, the rational function $\hat{C}\hat{\Psi} + \hat{D} \neq 0$ for any formula Ψ such that $\Phi_{z\leftarrow\Psi}$ is correct.*

Proof. We give a recursive construction for both the parts and prove the correctness by induction on s, the size of the formula Φ.

Depth-reduce(Φ).
Input: A correct formula Φ of size s computing a rational function in $\mathbb{F}\langle\langle X\rangle\rangle$.
Output: A correct formula Φ' of depth at most $c\log_2 s$ such that $\Phi \equiv \Phi'$.

1. Find a gate $v \in \Phi$ such that $\frac{s}{3} < wt(v) \leq \frac{2s}{3}$.
2. In Parallel construct formulas Ψ, Δ such that Ψ = Depth-Reduce(Φ_v) and Δ = Normal-Form($\Phi_{v\leftarrow z}, z$).
3. Obtain formula Φ' from Δ by replacing z in Δ by Ψ.
4. Output Φ'.

Normal-Form(Φ, z).
Input: A correct formula Φ of size s computing a rational function in $\mathbb{F}\langle\langle X\rangle\rangle$ and a variable $z \in \Phi$ which appears at most once in Φ
Output: A correct formula Φ' which is of the form

$$\Phi' = (Az + B)(Cz + D)^{-1}$$

where A, B, C and D are correct rational formulas which do not depend on z with depth at most $c\log_2 s + b$. Moreover, the rational function $\hat{C}\hat{\Psi} + \hat{D} \neq 0$ for any formula Ψ such that $\Phi_{z\leftarrow\Psi}$ is correct.

Let $v_1, v_2, \ldots, v_\ell = z$ be gates on the path from root r of Φ to the leaf gate z, such that v_j is not an inverse gate. So parent of each v_j has two children, and let u_i denote the sibling of v_i. Use pointer doubling based parallel algorithm (as mentioned in the proof of Lemma 10) to compute $wt(u_i)$ and $wt(v_i)$ for all $i \in [\ell]$. We call gate v_i for $i \in [\ell]$ as a *balanced* gate if $wt(\Phi_{v_i}), wt(\Phi_{v_i\leftarrow z'}) \leq \frac{5s}{6}$. Now we consider two cases.

1. There exist a balanced gate v_i:
   a. Let $v = v_i$. In parallel compute formulas Ψ_1, Ψ_2 such that
   $$\Psi_1 = (A_1z' + B_1)(C_1z' + D_1)^{-1} = \text{Normal-Form}(\Phi_{v\leftarrow z'}, z')$$
   $$\Psi_2 = (A_2z + B_2)(C_2z + D_2)^{-1} = \text{Normal-Form}(\Phi_v, z)$$
   b. Define formulas A, B, C, D as $A_1 \cdot A_2 + B_1 \cdot C_2$, $A_1 \cdot B_2 + B_1 \cdot D_2$, $C_1 \cdot A_2 + D_1 \cdot C_2$ and $C_1 \cdot B_2 + D_1 \cdot D_2$ respectively.
   c. Let $\Phi' = (A \cdot z + B) \cdot (C \cdot z + D)^{-1}$
   d. Output Φ' and halt
2. There does not exist a balanced gate:
   In this case, we can prove that there is a unique $i \in [\ell]$ such that $wt(u_i) > \frac{s}{6}$.
   a. Let v be parent of the gate v_i.
   b. In Parallel find formulae $\Psi_1, \Psi_2, \Psi_3, \Psi_4$ such that
   $$\Psi_1 = (A_1z' + B_1)(C_1z' + D_1)^{-1} = \text{Normal-Form}(\Phi_{v\leftarrow z'}, z')$$
   $$\Psi_2 = (A_2z + B_2)(C_2z + D_2)^{-1} = \text{Normal-Form}(\Phi_{v_i}, z)$$
   $$\Psi_3 = \text{Depth-Reduce}(\Phi_{u_i})$$
   $$\Psi_4 = (Az + B)(Cz + D)^{-1} = \text{Normal-Form}(\Phi'', z)$$
   where Φ'' is obtained by replacing sub-tree rooted at u_i by 0 in Φ.
   c. Using the algorithm of Theorem 19 check if $\hat{\Psi}_3 \equiv 0$ in NC with oracle access to bivariate ncRANK. If $\hat{\Psi}_3 \equiv 0$ then output Ψ_4 and halt.

d. If $\hat{\Psi_3} \not\equiv 0$ then let $\Phi' = (A \cdot z + B) \cdot (C \cdot z + D)^{-1}$, where

$$A = \begin{cases} A_1A_2 + B_1C_2 + A_1\hat{\Psi_3}C_2 & \text{if } v_i \text{ is a } +\text{-gate} \\ A_1\hat{\Psi_3}A_2 + B_1C_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a right child of } v \\ A_1A_2 + B_1\hat{\Psi_3}^{-1}C_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a left child of } v \end{cases}$$

$$B = \begin{cases} A_1B_2 + B_1D_2 + A_1\hat{\Psi_3}D_2 & \text{if } v_i \text{ is a } +\text{-gate} \\ A_1\hat{\Psi_3}B_2 + B_1D_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a right child of } v \\ A_1B_2 + B_1\hat{\Psi_3}^{-1}D_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a left child of } v \end{cases}$$

$$C = \begin{cases} C_1A_2 + D_1C_2 + C_1\hat{\Psi_3}C_2 & \text{if } v_i \text{ is a } +\text{-gate} \\ C_1\hat{\Psi_3}A_2 + D_1C_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a right child of } v \\ C_1A_2 + D_1\hat{\Psi_3}^{-1}C_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a left child of } v \end{cases}$$

$$D = \begin{cases} C_1B_2 + D_1D_2 + C_1\hat{\Psi_3}D_2 & \text{if } v_i \text{ is a } +\text{-gate} \\ C_1\hat{\Psi_3}B_2 + D_1D_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a right child of } v \\ C_1B_2 + D_1\hat{\Psi_3}^{-1}D_2 & \text{if } v_i \text{ is a } \times\text{-gate and is a left child of } v \end{cases}$$

e. Output Φ' and halt.

Case 2 above is not explicitly dealt with in [21] as their focus is on the *existence* of a log-depth formula equivalent to Φ. In contrast to that, in our case we want to *algorithmically construct* log-depth formula Φ' equivalent to Φ. This makes the details of Case 2 crucial as the construction of Φ' in Case 2 depends on whether $\hat{\Phi_{u_i}} \equiv 0$ or not. To solve this RIT instance we need to recursively compute log-depth formula Ψ_3 equivalent to Φ_{u_i} and then invoke algorithm of theorem 19 to carry out RIT test in NC with oracle access to bivariate ncRANK, as in Step (c).

We first prove the correctness of both the algorithms described above using induction on s, then we analyze the parallel complexity of both the algorithms. We will choose appropriate constants c, b during the proof.

Correctness of the algorithm Depth-Reduce. We know that there exists a gate $v \in \Phi$ such that $\frac{s}{3} < wt(v) \leq \frac{2s}{3}$. As in proof of Lemma 10 we can find such a gate v as required by Step 1 of the Depth-Reduce algorithm. Clearly, the formulas Φ_v and $\Phi_{v \leftarrow z}$ are of size at most $2s/3$. Using inductive assumption, we can construct a correct formula Ψ such that depth of Ψ is at most $c \log_2 \frac{2s}{3}$ and $\Psi \equiv \Phi_v$. Again using inductive assumption we can construct correct formulas A, B, C, D (which do not depend on z) of depth at most $c \log_2 \frac{2s}{3} + b$ such that the formula $\Delta = (A \cdot z + B) \cdot (C \cdot z + D)^{-1}$ is equivalent to $\Phi_{v \leftarrow z}$. Since Φ is equal to the formula obtained from $\Phi_{v \leftarrow z}$ by replacing z by Φ_v and Φ is correct so from inductive assumption it follows that $\hat{C}\hat{\Phi_v} + \hat{D} \neq 0$.

As $\Psi \equiv \Phi_v$, $\Delta \equiv \Phi_{v \leftarrow z}$ and $\hat{C}\hat{\Phi_v} + \hat{D} \neq 0$ from Lemma 16 it follows that Φ' is correct and $\Phi' \equiv \Phi$. Since $\Phi' = (A \cdot \Psi + B) \cdot (C \cdot \Psi + D)^{-1}$ we get that depth of Φ' is at most $c \log_2 \frac{2s}{3} + b + 4$. By choosing constant $c \geq \frac{b+4}{(\log_2 3 - 1)}$, we get that the depth of Φ' is at most $c \log_2 s$. Completing the inductive argument for the correctness proof of the algorithm Depth-Reduce.

Correctness of the algorithm Normal-Form. In case (1) we know that there exists a balanced gate $v = v_i$. We have $wt(\Phi_v), wt(\Phi_{v\leftarrow z'}) \leq \frac{5s}{6}$. So by inductive assumption we know that the formulas A_j, B_j, C_j, D_j for $j \in \{1,2\}$ are correct, and their depths are at most $c\log_2 \frac{5s}{6} + b$. Now using compositionality of the z-normal forms as in Proposition 4.1 of [21] it follows that the formula $\Phi' = (A\cdot z + B)\cdot(C\cdot z + D)^{-1}$ is equivalent to Φ where A, B, C, D are $A_1\cdot A_2 + B_1\cdot C_2$, $A_1\cdot B_2 + B_1\cdot D_2$, $C_1\cdot A_2 + D_1\cdot C_2$ and $C_1\cdot B_2 + D_1\cdot D_2$ respectively. Also, clearly the depth of A, B, C, D is at most $c\log_2 \frac{5s}{6} + b + 2$. By choosing $c \geq \frac{2}{(\log_2 6 - \log_2 5)}$ it follows that the depths of formulas A, B, C, D are at most $c\log_2 s + b$. To complete the inductive proof we need to prove that $\hat{C}\hat{\pi} + \hat{D} \neq 0$ for any formula π such that $\Phi_{z\leftarrow\pi}$ is correct. Let π be such that $\Phi_{z\leftarrow\pi}$ is correct. For simplicity lets denote formulas Φ_v and $\Phi_{v\leftarrow z'}$ by α and β respectively. Since $\Phi_{z\leftarrow\pi}$ is correct, it implies $\alpha_{z\leftarrow\pi}$ is correct as α is a subformula of Φ. So by inductive assumption $\hat{C}_2\hat{\pi} + \hat{D}_2 \neq 0$. Since $\Phi_{z\leftarrow\pi}$ is correct, β being a subformula of Φ it also implies $\beta_{z'\leftarrow\gamma}$ is correct where $\gamma = (A_2\cdot\pi + B_2)\cdot(C_2\cdot\pi + D_2)^{-1}$. By inductive assumption we get

$$\begin{aligned}
\hat{C}_1\hat{\gamma} + D_1 &\neq 0 \text{ which implies} \\
\hat{C}_1[(\hat{A}_2\cdot\hat{\pi} + \hat{B}_2)\cdot(\hat{C}_2\cdot\hat{\pi} + \hat{D}_2)^{-1}] + D_1 &\neq 0 \text{ which implies} \\
\hat{C}_1(\hat{A}_2\cdot\hat{\pi} + \hat{B}_2) + \hat{D}_1(\hat{C}_2\cdot\hat{\pi} + \hat{D}_2) &\neq 0 \text{ as } \hat{C}_2\hat{\pi} + \hat{D}_2 \neq 0 \\
\text{So } (\hat{C}_1\hat{A}_2 + \hat{D}_1\hat{C}_2)\hat{\pi} + (\hat{C}_1\hat{B}_2 + \hat{D}_1\hat{D}_2) &\neq 0 \text{ which implies} \\
\hat{C}\hat{\pi} + \hat{D} &\neq 0
\end{aligned}$$

This completes the proof for case 1.

Next we argue that case 1 and case 2 together cover all the possibilities. To see this, we will argue that if there does not exist a unique u_i with $wt(u_i) \geq \frac{s}{6}$ then there must exist a balanced gate. There are two possibilities: either for every gate u_i, $wt(u_i) \leq \frac{s}{6}$ or there are two or more gates u_i's with $wt(u_i) > \frac{s}{6}$ If for every $i \in [\ell]$, $wt(u_i) \leq \frac{s}{6}$, we find smallest j such that $\sum_{i=1}^{j} wt(u_i) > \frac{s}{6}$. Clearly $\sum_{i=1}^{j} wt(u_i) \leq \frac{2s}{6}$, which implies $wt(\Phi_v), wt(\Phi_{v\leftarrow z'}) \leq \frac{5s}{6}$ for $v = v_{i+1}$. So v is balanced. If there are two or more u_i's such that $wt(u_i) > \frac{s}{6}$ then v be parent of gate u_i such that i is a largest index with $wt(u_i) > \frac{s}{6}$. Clearly v is a balanced gate. This proves that case 1, 2 together cover all possibilities.

Assume that there is a unique $i \in [\ell]$ such that $wt(u_i) > \frac{s}{6}$. We first apply Depth-Reduce on formula Φ_{u_i} and get a log-depth formula Ψ_3 equivalent to Φ_{u_i}, we carry out this depth reduction to efficiently test if $\Phi_{u_i} \equiv 0$?. We will give details on this later when we figure out the parallel time complexity of the algorithm. Now when $\Phi_{u_i} \equiv \Psi_3 \equiv 0$, clearly formula $\Phi \equiv \Phi''$ where Φ'' is a formula obtained from Φ by replacing sub-formula rooted at u_i by 0. As $wt(u_i) > \frac{s}{6}$, we have $|\Phi''| \leq \frac{5s}{6}$. So by inductive assumption, the correct sub-formulas A, B, C, D of Ψ_4 obtained by recursive call Normal-Form(Φ'', z) have depth at most $c\log_2 \frac{5s}{6} + b \leq c\log_2 s + b$ and $\Psi_4 \equiv \Phi'' \equiv \Phi$. So it follows, $\Phi_{z\leftarrow\pi} \equiv \Phi''_{z\leftarrow\pi}$. Consequently $\Phi_{z\leftarrow\pi}$ is correct iff $\Phi''_{z\leftarrow\pi}$ is correct. So from inductive hypothesis it follows that $\hat{C}\hat{\pi} + \hat{D} \neq 0$ for any formula π such that $\Phi_{z\leftarrow\pi}$ is correct. This proves the correctness of Normal-form procedure when $\Phi_{u_i} \equiv 0$.

Now let $\Phi_{u_i} \not\equiv 0$. Let v be the parent of u_i. Below we discuss the case when v is $\times$-gate and u_i is a right child of v.

We have $\Psi_2 \equiv \Phi_{v_i} \equiv (A_2\cdot z + B_2)\cdot(C_2\cdot z + D_2)^{-1}$. Let $h_1 = A_2\cdot z + B_2$ and $h_2 = C_2\cdot z + D_2$). So $\Phi_{v_i} \equiv h_1\cdot h_2^{-1}$. Now as v is $\times$-gate and v_i, u_i are left and right children of v respectively. So we get $\Phi_v \equiv h_1h_2^{-1}\Phi_{u_i} \equiv h_1h_2^{-1}\Psi_3$. We have $\Psi_1 \equiv \Phi_{v\leftarrow z'} = (A_1z' + B_1)(C_1z' + D_1)^{-1}$. So we get

$$\begin{aligned}
\Phi &\equiv (\ A_1 \cdot (h_1 h_2^{-1}\Psi_3) + B_1) \cdot (\ C_1 \cdot (h_1 h_2^{-1}\Psi_3) + D_1)^{-1} \\
&\equiv (A_1 \cdot h_1 + B_1 \cdot \Psi_3^{-1} h_2) \cdot h_2^{-1}\Psi_3 \cdot [\ (C_1 \cdot h_1 + D_1 \cdot \Psi_3^{-1} h_2) \cdot h_2^{-1}\Psi_3\ ]^{-1} \\
&\equiv (A_1 \cdot h_1 + B_1 \cdot \Psi_3^{-1} h_2) \cdot h_2^{-1}\Psi_3 \cdot \Psi_3^{-1} h_2\ \cdot (C_1 \cdot h_1 + D_1 \cdot \Psi_3^{-1} h_2)^{-1} \\
&\equiv (A_1 \cdot h_1 + B_1 \cdot \Psi_3^{-1} h_2) \cdot (C_1 \cdot h_1 + D_1 \cdot \Psi_3^{-1} h_2)^{-1}
\end{aligned}$$

By substituting values of h_1, h_2 and simplifying we get that $\Phi \equiv (A \cdot z + B) \cdot (C \cdot z + D)^{-1}$ where A, B, C, D are $A_1 \cdot A_2 + B_1 \cdot \Psi_3^{-1} \cdot C_2$, $A_1 \cdot B_2 + B_1 \cdot \Psi_3^{-1} \cdot D_2$, $C_1 \cdot A_2 + D_1 \cdot \Psi_3^{-1} \cdot C_2$ and $C_1 \cdot B_2 + D_1 \cdot \Psi_3^{-1} \cdot D_2$ respectively as defined in Step 2(d).

As $wt(u_i) > \frac{s}{6}$, clearly $|\Phi_{v_i}|, |\Phi_{v \leftarrow z'}| \leq \frac{5s}{6}$. Since

$$\begin{aligned}
\Psi_1 &= (A_1 z' + B_1)(C_1 z' + D_1)^{-1} = \text{Normal-Form}(\Phi_{v \leftarrow z'}, z') \\
\Psi_2 &= (A_2 z + B_2)(C_2 z + D_2)^{-1} = \text{Normal-Form}(\Phi_{v_i}, z)
\end{aligned}$$

So by inductive assumptions the sub-formulas A_1, B_1, C_1, D_1 of Ψ_1 and the sub-formulas A_2, B_2, C_2, D_2 of Ψ_2 are correct and have depths at most $c \log_2 \frac{5s}{6} + b$. As $\Psi_3 = \text{Depth-Reduce}(\Phi_{u_i})$ and $|\Phi_{u_i}| < s$ by inductive assumption we get that the depth of Ψ_3 is at most $c \log_2 s$. Clearly $c \log_2 \frac{5s}{6} + b \leq c \log_2 s$ for $c \geq \frac{b}{\log_2 6 - \log_2 5)}$. So from expressions for A, B, C, D it follows that the depth of A, B, C, D is at most depth of Ψ_3 plus 4. Which implies that the depth of A, B, C, D is at most $c \log_2 s + 4 \leq c \log_2 s + b$ if the constant $b \geq 4$. This gives us the desired bound on the depth of A, B, C, D. To summarize if we choose constant $b \geq 4$ and choose constant c such that it satisfies all the lower bounds required in different steps of the above proof, we will get the desired bound on the depth of A, B, C, D. We can show that $\hat{C}\hat{\pi} + \hat{D} \neq 0$ for any formula π such that $\Phi_{z \leftarrow \pi}$ is correct. The proof is similar to one for Case (1), we additionally need to take into account $\times$-gate at v while composing z-Normal forms Ψ_1 and Ψ_2. We skip the details.

When v is a v is a $\times$-gate and u_i is a left child of v, the composition of z-normal forms is easy as we do not need an oracle access for RIT as in the case discussed above when u_i is the right child. In the commutative case we can by default assume that u_i is the left child. Precisely for this reason Brent's construction [9] is independent of whether $\Phi_{u_i} \equiv 0$ or not. We skip the details of cases when v is a $+$-gate or v is $\times$-gate and u_i is the left child which can be handled similar to case (1). This proves the correctness of the procedure Normal-Form.

Next we analyze the parallel time complexity of both the procedures. Let $t_1(s), t_2(s)$ denote the parallel time complexities of the procedures Depth-Reduce and Normal-Form respectively. The step (1) of the Depth reduce procedure can be implemented in NC so it has parallel time complexity $(\log_2 s)^k$ for some absolute constant k. As both the formulas Φ_v and $\Phi_{v \leftarrow z}$ have sizes at most $2s/3$, the parallel time complexity of step (2) is at most $\max(t_1(2s/3), t_2(2s/3))$. So we get the following recurrence for $t_1(s)$.

$$t_1(s) \leq (\log_2 s)^a + \max\left(\ t_1\left(\frac{2s}{3}\right)\ ,\ t_2\left(\frac{2s}{3}\ \right)\right)$$

where a is an absolute constant. Now we obtain recurrence for $t_2(s)$. In Case (1) of Normal-Form when there exist a balanced gate v_i, we can find such a gate in NC. Both the formulas Φ_v and $\Phi_{v \leftarrow z'}$ have the sizes at most $5s/6$ so step 1(a) takes parallel time $\max(t_1(5s/6), t_2(5s/6))$. In case (2) the formulas $\Phi_{v \leftarrow z'}$, Φ_{v_i} and Φ'' all have sizes at most $5s/6$ and formula Φ_{u_i} has size at most $s - 1$. So collectively we get the following recurrence for $t_2(s)$

$$\begin{aligned} t_2(s) &\leq (\log_2 s)^b + \max\left(t_1\left(\frac{5s}{6}\right) \ , \ t_2\left(\frac{5s}{6}\right) \ , \ t_1(s-1)\right) \\ &\leq (\log_2 s)^b + \max\left(t_2\left(\frac{5s}{6}\right) \ , \ t_1(s)\right) \end{aligned}$$

for an absolute constant b. The upper bound $t_1(s), t_2(s) \leq (\log_2 s)^c$ for sufficiently large constant c follows from an easy induction. Hence both the procedures can be implemented in deterministic NC. ◀

Hrubes-Wigderson reduction from RIT to ncRANK

Now we recall the polynomial-time reduction from RIT to ncRANK from [21, Theorem 2.6]. Given a rational formula Φ their reduction outputs an invertible linear matrix M in the variables X.[11] Their reduction ensures that the top right entry of M^{-1} is $\hat{\Phi}$, the rational function computed by the formula Φ. It turns out that if Φ is already of logarithmic depth then their reduction can be implemented in NC.

▶ **Theorem 18** ([21]). *Let Φ be a rational formula of size s and depth $O(\log s)$ computing a rational expression in $\mathbb{F}\langle\langle X\rangle\rangle$ there is an* NC *algorithm to construct an invertible linear matrix M_Φ such that the top right entry of M_Φ^{-1} is $\hat{\Phi}$.*

Proof. We only briefly sketch the NC algorithm. Their reduction recursively constructs the matrix M_Φ, using the formula structure of Φ.

Given a formula Φ we can compute the sizes of all its subformulas in NC using a standard pointer doubling algorithm. This allows us to estimate the dimensions of matrices M_{Φ_v} for subformulas Φ_v for each gate v of Φ. We can also compute in NC the precise location for placement of the sub-matrices M_{Φ_v} inside the matrix M_Φ following their construction. Assuming that Φ is already of logarithmic depth, there are only $O(\log s)$ nested recursive calls for this recursive procedure. This ensures that the overall process can be implemented in NC. ◀

After constructing linear matrix M_Φ such that the top right entry of M_Φ^{-1} is $\hat{\Phi}$, define matrix M' as $M' = \begin{pmatrix} v^T & M_\Phi \\ 0 & -u \end{pmatrix}$

where u, v are $1 \times k$ vectors, such that $u = (1, 0, \ldots, 0)$ and $v = (0, 0, \ldots, 0, 1)$ where k is the dimension of the matrix M_Φ. It follows that $\hat{\Phi} \neq 0$ iff M' is invertible in the skew field $\mathbb{F}\langle\langle X\rangle\rangle$ (see e.g. [18, Proposition 3.29]). So we have the following theorem.

▶ **Theorem 19** ([21]). *Let Φ be a rational formula of size s and depth $O(\log s)$ computing a rational expression in $\mathbb{F}\langle\langle X\rangle\rangle$ then there is an* NC *algorithm to construct a linear matrix M such that $\hat{\Phi} \neq 0$ iff M is invertible in the skew field $\mathbb{F}\langle\langle X\rangle\rangle$.*

Now, from Lemma 17, Theorem 19, and Theorem 9, we obtain an NC Turing reduction from multivariate RIT to bivariate ncRANK.

▶ **Theorem 20.** *There is a deterministic* NC *Turing reduction from RIT problem to ncRANK problem for bivariate linear matrices.*

[11] Notice that the entries of M^{-1} are elements of the skew field $\mathbb{F}\langle\langle X\rangle\rangle$

Concluding Remarks

Motivated by the question whether RIT and ncRANK have deterministic NC algorithms, we show that multivariate RIT is NC-reducible to bivariate RIT and multivariate ncRANK is NC-reducible to bivariate ncRANK. RIT is known to be polynomial-time reducible to ncRANK, and indeed that is how the polynomial-time algorithm for RIT works, by reducing to ncRANK and solving ncRANK. We show that RIT is deterministic NC-Turing reducible to ncRANK. We prove this by showing that noncommutative rational formula depth reduction is NC-Turing reducible to ncRANK. The main open problem is to obtain deterministic NC algorithms for bivariate ncRANK and bivariate RIT. We also leave open finding an unconditional NC algorithm for depth-reduction of noncommutative rational formulas.

Abstract

We address the problem of **List Update**, which is considered one of the fundamental problems in online algorithms and competitive analysis. In this context, we are presented with a list of elements and receive requests for these elements over time. Our objective is to fulfill these requests, incurring a cost proportional to their position in the list. Additionally, we can swap any two consecutive elements at a cost of 1. The renowned "Move to Front" algorithm, introduced by Sleator and Tarjan, immediately moves any requested element to the front of the list. They demonstrated that this algorithm achieves a competitive ratio of 2. While this bound is impressive, the actual cost of the algorithm's solution can be excessively high. For example, if we request the last half of the list, the resulting solution cost becomes quadratic in the list's length.

To address this issue, we consider a more generalized problem called **List Update with Time Windows**. In this variant, each request arrives with a specific deadline by which it must be served, rather than being served immediately. Moreover, we allow the algorithm to process multiple requests simultaneously, accessing the corresponding elements in a single pass. The cost incurred in this case is determined by the position of the furthest element accessed, leading to a significant reduction in the total solution cost. We introduce this problem to explore lower solution costs, but it necessitates the development of new algorithms. For instance, Move-to-Front fails when handling the simple scenario of requesting the last half of the list with overlapping time windows. In our work, we present a natural $O(1)$ competitive algorithm for this problem. While the algorithm itself is intuitive, its analysis is intricate, requiring the use of a novel potential function.

Additionally, we delve into a more general problem called **List Update with Delays**, where the fixed deadlines are replaced with arbitrary delay functions. In this case, the cost includes not only the access and swapping costs, but also penalties for the delays incurred until the requests are served. This problem encompasses a special case known as the prize collecting version, where a request may go unserved up to a given deadline, resulting in a specified penalty. For this more comprehensive problem, we establish an $O(1)$ competitive algorithm. However, the algorithm for the delay version is more complex, and its analysis involves significantly more intricate considerations.

1 Introduction

One of the fundamental problems in online algorithms is the **List Update** problem. In this problem we are given an ordered list of elements and requests for these elements that arrive over time. Upon the arrival of a request, the algorithm must serve it immediately by accessing the required element. The cost of accessing an element is equal to its position in

the list. Finally, any two consecutive elements in the list may be swapped at a cost of 1. The goal in this problem is to devise an algorithm so as to minimize the total cost of accesses and swaps. Note that it is an online algorithm and hence does not have any knowledge of future requests and must decide what elements to swap only based on requests that have already arrived.

Although the list update problem is a fundamental and simple problem, its solutions may be costly. Consider the following example. Assume that we are given requests to each of the elements in the farther half of the list. Serving these requests sequentially results in quadratic cost (quadratic in the length of the list). However, in many scenarios, while the requests arrive simultaneously, they do not have to be served immediately. Instead, they arrive with some deadline such that they must be served some time in the (maybe near) future. If this is the case, and the requests' deadlines are further in the future than their arrival, they may be jointly served; thereby incurring a linear (rather than quadratic) cost in the former example. This example motivates the following definition of List Update with Time Windows problem which may improve the algorithms' costs significantly.

The **List Update with Time Windows** problem is an extension of the classical List Update problem. Requests are once again defined as requests that arrive over time for elements in the list. However, in this problem they arrive with future deadlines. Requests must be served during their time window which is defined as the time between the corresponding request's arrival and deadline. This grants some flexibility, allowing an algorithm to serve multiple requests jointly at a point in time which lies in the intersection of their time windows. The cost of serving a set of requests is defined as the current position of the farthest of those elements (i.e. serving a request for the i-th item in the list causes all the other active requests for the first i elements in the list to be served as well in this access operation). In addition, as in the classical problem, swaps between any two consecutive elements may be performed at a cost of 1. Note that both accessing elements (or, serving requests) and swapping consecutive elements is done instantaneously (i.e., time does not advance during these actions). The goal is then to devise an online algorithm so as to minimize the total cost of serving requests and swapping elements. Also note that this problem encapsulates the original List Update problem. In particular, the List Update problem can be viewed as List Update with Time Windows where each time window consist of a unique single point.

We also consider a generalization of the time-window version – **List Update with Delays**. In this problem each request is associated with an arbitrary delay function, such that an algorithm accumulates delay cost while the request remains pending (i.e., unserved). The goal is to minimize the cost of serving the requests plus the total delay. This provides an incentive for the algorithm to serve the requests early.

Another interesting and related variant is the prize collecting variant, which has been heavily researched in other fields as well. The price collecting problem is a special case of List Update with Delay and a generalization of List Update with Time Windows. In the context of List Update, the prize collecting problem is defined such that a request must be either served until some deadline or incur some penalty. Note that List Update with Delays encapsulates this variant by defining a delay function that incurs 0 cost and thereafter (at the deadline) immediately jumps to the penalty cost. The prize collecting problem encapsulates List Update with Time Windows when the penalty is arbitrarily large.

While the flexibility introduced in the list update with time windows or delays problems allow for lower cost solutions, it also introduces complexity in the considered algorithms. In particular, the added lenience will force us to compare different algorithms (our online algorithm compared to an optimal algorithm, for instance) at different time points in the

input sequence. Since the problem definition allows for serving requests at different time points, this results in different sets of unserved requests when comparing the algorithms – this divergence will prove to be the crux of the problem and will result in significant added complexity compared to the classical List Update problem.

Originally, the List Update problem was defined to allow for free swaps to the accessed element: i.e., immediately after serving an element e, the algorithm may move e towards the head of the list - free of charge. All other swaps between consecutive elements still incur a cost of 1. In our work, it will be convenient for us to consider the version of the problem where these free swaps are not allowed and all swaps between two consecutive elements incur a cost of 1. We would like to stress that while these two settings may seem different, this is not the case. One may easily observe that the difference in costs between a given solution in the two models is at most a multiplicative factor of 2. This can be seen to be true since the cost of the free swaps may be attributed to the cost of accessing the corresponding element (that was swapped) which is always at least as large. Thus, our results extend easily to the model with free swaps to the accessed element (by losing a factor of 2 in the competitive ratio). In particular, an algorithm which is constant competitive for one of the models is also constant-competitive for the other.

Using the standard definitions an **offline algorithm** sees the entire sequence of requests in advance and thus may leverage this knowledge for better solutions. Conversely, an **online algorithm** only sees a request (i.e., its corresponding element and entire time window or a delay function) upon its arrival and thus must make decisions based only on requests that have already arrived[1]. To analyze the performance of our algorithms we use the classical notion of **competitive ratio**. An online algorithm is said to be c-competitive (for $c \geq 1$) if for every input, the cost of the online algorithm is at most c times the cost of the optimal offline algorithm[2].

1.1 Our Results

In this paper, we show the following results:

- For the List Update with Time Windows problem we provide a 24-competitive algorithm.
- For the List Update with Delays we provide a 336-competitive algorithm.

For the **time windows** version the algorithm is natural. Upon a deadline of a request for an element, the algorithm serves all requests up to twice the element's position and then moves that element to the beginning of the list. Note that the algorithm does not use the fact that the deadline is known when the request arrives. I.e. our result holds even if the deadline is unknown until it is reached (as in non-clairvoyant models). Also note that while the algorithm is deceptively straightforward - its resulting analysis is tremendously more involved.

In the **delay** version the algorithm is more sophisticated. (See the full version [12] for counter examples to some simpler algorithms). The algorithm maintains two types of counters: request counters and element counters. For every request, its request counter increases over time at a rate proportional to the delay cost the request incurred. The request

[1] In principle the time when a request arrives (i.e., is revealed to the online algorithm) need not be the same as the time when its time window or delay begins (i.e., when the algorithm may serve the request). Note however that the change makes no difference with respect to the offline algorithms but only allows for greater flexibility of the online algorithms. Therefore, any competitiveness results for our problem will transcend to instances with this change.

[2] We note that the lists of both the online algorithm and the optimum offline algorithm are identical at the beginning.

counter will be deleted at some point in time after the request has been served (it may not happen immediately after the request is served, but rather further in the future). Unlike the request counters, an element counter's scope is the entire time horizon. The element counter increases over time at a rate that is proportional to the sum of delay costs of unserved requests to that element. Once the requests are served, the element counter ceases to increase. There are two types of events that cause the algorithm to take action: prefix-request-counter events and element-counter events. A prefix-request-counter event takes place when the sum of the request counters of the first ℓ elements reaches a value of ℓ. This event causes the algorithm to access the first 2ℓ elements in the list and delete the request counters for requests to the first ℓ elements. The request counters of the elements in positions $\ell + 1$ up to 2ℓ remain undeleted but cease to increase (Note that this will also result in the first 2ℓ element counters to also cease to increase). An element-counter event takes place when an element counter's value reaches the element's position. Let ℓ be that position. This event causes the algorithm to access the first 2ℓ elements in the list. Thereafter, the algorithm deletes all request counters of requests to that element. Finally, the element's counter is zeroed and the algorithm moves the element to the front.

It is interesting to note that List Update with Delay in the clairvoyant case can be reduced to the special case of prize collecting List Update (which is a generalization of List Update with Time Windows) by creating multiple requests with appropriate penalties. However, neither our algorithm for Delay nor our proof are getting simplified for this case, therefore we present our algorithm and proof for the general case (i.e. for List Update with Delay). Moreover, the reduction from List Update with Delay to prize collecting holds only for the clairvoyant case while our algorithm works on the non-clairvoyant model as well. The full version of this paper contains all the omitted proofs, figures and additional counter examples, and appears in [12].

1.2 Previous Work

We begin by reviewing previous work relating to the classical List Update problem. Sleator and Tarjan [27] began this line of work by introducing the deterministic online algorithm Move to Front (i.e. MTF). Upon a request for an element e, this algorithm accesses e and then moves e to the beginning of the list. They proved that MTF is 2-competitive in a model where free swaps to the accessed element are allowed. The proof uses a potential function defined as the number of inversions between MTF's list and OPT's list. An inversion between two lists is two elements such that their order in the first list is opposite to their order in the second list. A simple lower bound of 2 for the competitive ratio of deterministic online algorithms is achieved when the adversary always requests the last element in the online algorithm's list and OPT orders the elements in its list according to the number of times they were requested in the sequence. Since the model with no free swaps differs in the cost by at most a factor of 2 this immediately yields that MTF is 4-competitive for the model with no free swaps. The simple 2 lower bound also holds for this model. Previous work regarding randomized upper bounds for the competitive ratio have been done by many others [25, 26, 2, 1, 5]. Currently, the best known competitiveness was given by Albers, Von Stengel, and Werchner [3], who presented a random online algorithm and proved it is 1.6 competitive. Previous work regarding lower bounds for this problem have also been made [28, 26, 5]. The highest of which was achieved by Ambühl, Gartner and Von Stengel [6], who proved a lower bound of 1.50084 on the competitive ratio for the classical problem. With regards to the offline classical problem: Ambühl proved this problem is NP-hard [4].

Problems with time windows have been considered for various online problems. Gupta, Kumar and Panigrahi [24] considered the problem of paging (caching) with time windows. Bienkowski et al. [16] considered the problem of online multilevel aggregation. Here, the problem is defined via a weighted rooted tree. Requests arrive on the tree's leaves with corresponding time windows. The requests must be served during their time window. Finally, the cost of serving a set of requests is defined as the weight of the subtree spanning the nodes that contain the requests. Bienkowski et al. [16] showed a $O(D^4 2^D)$ competitive algorithm where D denotes the depth of the tree. Buchbinder et al. [21] improved this to $O(D)$ competitiveness. Later, Azar and Touitou [14, 15] provided a framework for designing and analyzing algorithms for these types of metric optimization problems.

In addition, set cover with deadline [9] was also considered as well as online service in a metric space [20, 11]. To all these problems poly-logarithmic competitive algorithms were designed. It is interesting to note that in contrast to all these problems we show that for our list update problem constant competitive algorithms are achievable. We note that problems with deadline can be also extended to problems with delay where there is a monotone penalty function for each request that is increasing over time until the request is served (and is added to the original cost). Many of the results mentioned above can be extended to arbitrary penalty function. The main exception is matching with delays that can be efficiently solved (i.e. with poly-logarithmic competitive ratio) only for linear functions [22, 8, 7] as well as for concave functions [13]. For other problems that tackle deadlines and delays see: [17, 23, 10, 18, 19].

1.3 Our Techniques

While introducing delays or time windows introduces the option of serving multiple requests simultaneously thereby drastically improving the solution costs, this lenience requires the algorithms and their analyses to be much more intricate.

The "freedom" given to the algorithm compared with the classical List Update problem requires more decisions to be made: for example, in the time windows version assume there are currently two active requests: a request for an element e_1 which just reached its deadline and a request for a further element in the list, e_2 but its deadline has not been reached yet. Should the algorithm access only e_1, pay its position in the list and leave the request for e_2 to be served later or access both e_1 and e_2 together and pay the position of e_2 in the list? If no more requests arrive until the deadline of the second active request, the latter option is better. However, requests that might arrive before the deadline of the second active request might cause the former option to be better after all. In the delay version the decision is more complicated since it may be the case that there are various requests for elements, each request accumulated a small or medium delay but their total is large. Hence, we need to decide at what stage and to what extend serving these requests. Moreover it is more tricky to decide which element to move to the front of the list and at which point in time.

As for the analysis, we need to handle the fact that the online algorithm and the optimal algorithm serve requests at different times. Further, since both algorithms may serve different sets of requests at different times, we may encounter situations wherein a given request at a given time would have been served by the online algorithm and not the optimal algorithm (and vice versa). This, combined with the fact that the algorithms' lists may be ordered differently at any given time, will prove to be the crux of our problem and its analysis.

To overcome these problems, we introduce new potential functions (one for the time windows case and one for the delays case). We note that the original List Update problem was also solved using a potential function [27], however, due to the aforementioned issues,

the original function failed to capture the resulting intricacies and we had to introduce novel (and more involved) functions. Ultimately, this resulted in constant competitiveness for both settings.

List Update with Time Windows. Here, the potential function consists of three terms. The first accounts for the difference (i.e., number of inversions) between the online and optimal algorithms' lists at any given time (similar to that of Sleator and Tarjan [27]). The second term accounts for the difference in the set of served requests between the two algorithms. Specifically, whenever the optimal algorithm serves a request not yet served by the online algorithm, we add value to this term which will be subtracted once the online algorithm serves the request. The third term accounts for the movement costs made by the online algorithm incurred by requests that were already served by the optimal algorithm.

At any given time point, our proof considers separately elements that are positioned (significantly) further in the list in the online algorithm compared to the optimal algorithm, as opposed to all other elements (which we will refer to as "the closer" elements). To understand the flavor of our proofs, e.g., the incurred costs of "the further" elements is charged to the first term of the potential function. In contrast, the change in the first term is not be enough to cover the incurred costs of "the closer" elements (the term may even increase). Fortunately, the second term is indeed enough to cover both the incurred costs and the (possible) increase in the first term. Specifically, the added value is of the same order of magnitude as the access cost incurred by the optimal algorithm for serving the corresponding requests. This follows from (a) only requests for elements in ALG which are located at a position which is of the same order of magnitude as the location in OPT get "gifts" in the second term. (b) The fact that the number of trigger elements and their positions in ALGs list is bounded because upon a deadline of a trigger, ALG serves all the elements located up to twice the position of the trigger in its list. The definition of the term "trigger" appears in the beginning of Section 3.

Note however that the analysis above holds only as long as the optimal algorithm does not move an element further in the list between the time it serves it and the time the online algorithm serves it. In such a case, the third term will offset the costs.

List Update with Delays. Here, the potential function consists of five terms. The first term is similar to that of the time windows setting with the caveat that defining the distance between the online and optimal algorithms' lists should depend on the values of the element counters as well. Consider the following example. Assume that the ordering of i, j is reversed when comparing it between the online and optimal algorithms and assume it is ordered (i, j) in the online algorithm. As we defined our algorithm, once the element counter of j is filled, it is moved to the front and therefore the ordering will be reversed. Therefore, intuitively, if j element counter is almost filled we consider the distance between this pair smaller than the case where its element counter is completely empty. Therefore, we would like the contribution to the potential function to be smaller in the former case.

Note that the contribution of the inversion (i, j) depends on the element counter of j but not on the element counter of i (i.e. the contribution is asymmetric). Even if the element counter of j is very close to its position in the online algorithm's list, we still need a big contribution of the pair (i, j) in order to pay for the next element counter event on j. However, if the element counter of j is far from its position in the online algorithm's list, we will need even more contribution of the pair (i, j) to the potential function in order to also cover future delay penalty which the algorithm may suffer on the element j that will not cause an element counter event on j to occur in the short term.

The second part of the potential function consists of the delay cost that both the online and optimal algorithms incurred for requests which were active in both algorithms. This term is used to cover the next element counter events for the elements required in these requests. The third part of the potential function offsets the requests which have been served by the optimal algorithm but not by the online algorithm. This part is very similar to the gifts in the second term of the potential function in time windows and the ideas behind it are similar. Again, the gifts are only given to requests which are located by the online algorithm at a position which is of the same order of magnitude as the location in the optimal algorithm. The gift is of the same order of magnitude as the total delay the online algorithm pays for the request (including the delay it will pay in the future). This is used in order to offset the next element counter event in the online algorithm on the element. However, this gift also decreases as the online algorithm suffers more delay for the request because we want this term in the potential function to also cover the future delay penalty the online algorithm will pay for the request.

The fourth and fifth terms in the potential function are very similar to the third term in the potential function of time windows but each one of them has its own purposes: The fourth term should cover the next element counter event on the element while the fifth term should cover the scenario in which the optimal algorithm served a request and then moved the element further in its list but the online algorithm will suffer more delay penalty for this request in the future. The fifth term should cover this delay cost that the online algorithm pays and thus it is proportional to the fraction between the future delay the online algorithm pays for the request and the position of the element in the online algorithm's list.

2 The Model for Time Windows and Delays

Given an input σ and algorithm ALG we denote by $ALG(\sigma)$ the cost of its solution. Recall that in the **time windows** setting $ALG(\sigma)$ is defined as the sum of (1) the algorithm's access cost: the algorithm may serve multiple requests at a single time point and then the access cost is defined as the position of the farthest element in this set of requests. $ALG(\sigma)$ also accounts for (2) the total number of element swaps performed by ALG. In total, $ALG(\sigma)$ is equal to the sum of access costs and swaps. In the **delay** setting $ALG(\sigma)$ accounts (1) and (2) as above in addition to (3) the sum of the delay incurred by all requests. The delay is defined via a delay function that is associated with each request. The delay functions may be different per request and are each a monotone non-decreasing non-negative function. In total, $ALG(\sigma)$ is equal to the sum of access costs, swaps and delay costs. As is traditional when analysing online algorithms, we denote by $OPT(\sigma)$ the cost of the optimal solution to input σ. Furthermore, we say that ALG is c-competitive (for $c \geq 1$) if for every input σ, $ALG(\sigma) \leq c \cdot OPT(\sigma)$. Throughout our work, when clear from context, we use $ALG(\sigma)$ to denote both the cost of the solution and the solution itself. Our algorithms work also in the non-clairvoyant case: In the time windows version we only know the deadline of a request upon its deadline (and not upon its arrival). In the delay version we know the various delay functions of the requests only up to the current time. Next we introduce several notations that will aid us in our proofs.

▶ **Definition 1.** *Let $\mathbb{E}$ be the set of the elements.*

- *Let n denote the number of elements in our list ($|\mathbb{E}| = n$) and m the number of requests.*
- *Let r_k denote the kth request and e_k the requested element by r_k.*
- *Let $y_k \in [n]$ denote the position of e_k in OPTs list at the time OPT served r_k. Let $x_k \in [n]$ denote the position of e_k in ALGs list at the time OPT (and not ALG) served r_k*[3].

[3] In the delay version, x_k and y_k are defined only in case OPT indeed served the request r_k at some time.

Throughout our work, given an element in the list, we oftentimes consider its neighboring elements in the list. We therefore introduce the following conventions to avoid confusion. Given an element in the list we refer to its **previous** element as its neighbor which is closer to the head of the list and its **next** element as its neighbor which is further from the head of the list.

3 The Algorithm for Time Windows

Prior to defining our algorithm, we need the following definitions.

▶ **Definition 2.** *We define the* ***triggering element****, when a deadline of a request is reached, as the farthest element in the list such that there exists an active request for it which just reached its deadline. We define the* ***triggering request*** *as one of the active requests for the triggering element that just reached its deadline - arbitrary.*

When clear from context we will use the term "trigger" instead of "triggering request" or "triggering element". Next, we define the algorithm.

Algorithm 1 Algorithm for Time Windows (i.e. Deadlines).

```
1 Upon deadline of a request do:
2     i ← triggering element's position
3     Serve the set of requests in the first 2i − 1 elements in the list
4     Move-to-front the triggering element
```

We prove the following theorem for the above algorithm in Appendix A.

▶ **Theorem 3.** *For each sequence of requests σ, we have that*

$$ALG(\sigma) \leq 24 \cdot OPT(\sigma).$$

4 The Algorithm for Delays

Our algorithm maintains two types of counters in order to process the input: requests counters and element counters. We begin by defining the **request counters**. The algorithm maintains a separate request counter for every incoming request. For a given request r_k we denote its corresponding counter as RC_k. The counter is initialized to 0 the moment the request arrives and increases at the same rate that the request incurs delay. Once the request is served, the counter ceases to increase. Finally, our algorithm deletes the request counters - it will do so at some point in the future after the request is served (but not necessarily immediately when the request is served).

Next we define the **element counters**. Unlike the request counters, element counters exist throughout the entire input (i.e., they are initialized at the start of the input and do not get deleted). We define an element counter EC_e for every element $e \in \mathbb{E}$. These counters are initialized to 0 and increase at a rate equal to the total delay incurred by requests to the specific element.

We define two types of events that cause the algorithm to act: prefix-request-counter events and element-counter events. A **prefix request counters event on ℓ** for $\ell \in [n]$ occurs when the sum of all the request counters of requests for the first ℓ elements in the list reaches the value of ℓ. When this type of event takes place, the algorithm performs the

following two actions. First, it serves the requests of the first 2ℓ elements. Second, it deletes the request counters that belong to the first ℓ elements. Note that these are the request elements that contributed to this event and are therefore deleted. Also note that the request counters of the elements $\ell+1$ to 2ℓ and the element counters of the first 2ℓ elements cease to increase since their requests have been served.

An **element counter event on e** for $e \in \mathbb{E}$ occurs when EC_e reaches the value of ℓ, where $\ell \in [n]$ is the position of the element e in the list, currently. When this type of event takes place, the algorithm performs the following three actions. First, it serves the requests on the first 2ℓ elements. Second, it deletes all request counters of requests to the element e. Third, it sets EC_e to 0 and perform move-to-front to e.

Note that the increase in an element counter equals to the sum of the increase of all the request counters to this element. In particular, the value of the element counter is at least the sum of the non-deleted request counters for the element (It may be larger since request counters may be deleted in request counters events while the element counter maintains its value). Hence when we zero an element counter, we also delete the request counters of requests for this element in order to maintain this invariant.

Next, we present the algorithm.

Algorithm 2 Algorithm for Delay.

Initialization:
  For each $e \in \mathbb{E}$ **do**:
    $EC_e \leftarrow 0$
Upon arrival of a new request r_k **do**:
  $RC_k \leftarrow 0$
Upon prefix-request-counters event on $\ell \in [n]$ **do**:
  Serve the set of requests in the first 2ℓ elements in the list
  Delete the request counters for the first ℓ elements in the list
Upon element-counter event on e (let ℓ denote e's current position) **do**:
  Serve the set of requests in the first 2ℓ elements in the list
  Delete all the request counters of requests for the element e
  $EC_e \leftarrow 0$
  Move-to-front the element e

We prove the following theorem for the above algorithm in the full version.

▶ **Theorem 4.** *For each sequence of requests σ, we have that*

$$ALG(\sigma) \leq 336 \cdot OPT(\sigma).$$

5 Potential Functions for Time Windows and Delay

Our proofs use potential functions. In particular we prove for each possible event that

$$\Delta ALG + \Delta\Phi \leq c \cdot \Delta OPT$$

where Φ is the potential and c is the competitive ratio. In this section we describe the potential functions. The detailed proofs that use these potential functions appear in the full version.

5.1 Time Windows

As mentioned earlier, our potential function used for the time windows setting consists of three terms. We will define them separately. We begin with the first term that aims to capture the difference between ALG and OPT's lists at any given moment.

▶ **Definition 5.** *Let $\phi(t)$ denote the number of **inversions** between ALG's and OPT's lists at time t. Specifically,*

$$\phi(t) = |\{(i,j) \in \mathbb{E}^2 | \text{ At time } t, \text{ } i \text{ is before } j \text{ in ALG's list and after } j \text{ in OPT's list}\}|.$$

The second term accounts for the difference in the set of served requests between the two algorithms. Specifically, whenever the optimal algorithm serves a request not yet served by the online algorithm, we add value to this term which will be subtracted once the online algorithm serves the request. Before defining this term, we need the following definition.

▶ **Definition 6.** *For each time t, let $\lambda(t) \subseteq [m]$ be the set of all the request indices k such that the request r_k arrived and was served by OPT but was not served by ALG at time t.*

Recall that for request r_k we denote by y_k the position of e_k in OPT's list at the time that OPT served r_k. Furthermore, we denote by x_k the position of e_k in ALG's list at the time OPT (and not ALG) served r_k. We are now ready to define the second term in our potential function.

▶ **Definition 7.** *For $k \in \lambda(t)$ we define $\psi(x_k, y_k) \geq 0$ as*

$$\psi(x,y) = \begin{cases} 7x & \text{if } 1 \leq x \leq y \\ 8y - x & \text{if } y \leq x \leq 8y \\ 0 & \text{if } 8y \leq x \end{cases}$$

Next, we define the third term of our potential function.

▶ **Definition 8.** *We define $\mu_k(t)$ as the number of swaps OPT performed between e_k and its next element in the list from the time OPT served the request r_k until time t.*

Finally, we combine the terms and define our potential function.

▶ **Definition 9.** *We define our potential function for Time Windows as*

$$\Phi(t) = 4 \cdot \phi(t) + \sum_{k \in \lambda(t)} \psi(x_k, y_k) + 4 \cdot \sum_{k \in \lambda(t)} \mu_k(t).$$

5.2 Delay

In the delays setting, we define a different potential function that is comprised of five terms. We will define the terms separately first and thereafter use them to compose our potential function. We begin with the first term.

As mentioned in Our Techniques, the first term also aim to capture the distance between ALG's and OPT's lists. In the time windows setting, we defined this term as the number of element inversions. In the delays case this does not suffice; we have to take into the account the elements' counters as well. To gain some intuition as to why this addition is needed, consider the following example. Assume that elements i, j are ordered (i, j) in ALG and reversed in OPT. Recall that ALG is defined such that when j' element counter is filled,

then we move it to the front (thereby changing the ALG's ordering to (j,i)). Therefore, if it is the case that j's element counter is nearly filled, intuitively we may say that i,j's ordering in ALG and OPT are closer to each other than if j's element counter would have been empty. Therefore, we would like the contribution to the potential function to be smaller in the former case.

Note that the contribution of the inversion (i,j) depends on the element counter of j but not on the element counter of i (i.e. the contribution is asymmetric). Even if the element counter of j is very close to its position in the online algorithm's list, we still need a big contribution of the pair (i,j) in order to pay for the next element counter event on j. However, if the element counter of j is far from its position in the online algorithm's list, we need even more contribution of the pair (i,j) to the potential function in order to also cover future delay penalty which the algorithm may suffer on the element j that does not cause an element counter event on j to occur in the short term. Before formally defining this term, we define the following.

▶ **Definition 10.** *For a time t and an element $e \in \mathbb{E}$ we define:*
- *EC_e^t to be the value of the element counter EC_e at time t.*
- *$x_e^t \in [n]$ ($y_e^t \in [n]$ resp) to be the position of e in ALGs (OPTs resp) list at time t.*
- *$I_e^t = \{i \in \mathbb{E} | i$ is before e in ALGs list and after e in OPTs list at time $t\}$.*

▶ **Definition 11.** *For element $e \in \mathbb{E}$ we define $\rho_e(t) = |I_e^t| \cdot (28 - 8 \cdot \frac{EC_e^t}{x_e^t})$*

Observe that each $i \in I_e^t$ contributes $20 + 8 \cdot (1 - \frac{EC_e^t}{x_e^t})$ to $\rho_e(t)$. The additive term of 20 is used in order to cover the next element counter event for e while the second term is used to cover the delay penalty ALG will pay in the future for requests for e. Note that the term $1 - \frac{EC_e^t}{x_e^t}$ is the fraction of EC_e which is not "filled" yet. If this term is very low, ALG is very close to have an element counter event on e, which causes the order of i and e in ALGs list and OPTs list to be the same, thus it makes sense that the contribution of i to $\rho_e(t)$ is lower compared with the case where $1 - \frac{EC_e^t}{x_e^t}$ would be higher.

Next, we consider the second term. First, we denote the total incurred delay by a request as $d_k(t)$. Formally, this is defined as follows.

▶ **Definition 12.** *For a given request r_k and time t let $d_k(t)$ denote the total delay incurred by the request by ALG up to time t. (Note that it is defined as 0 before the request arrived and remains unchanged after the request is served). Let $d_k = \sup_t d_k(t)$. Note that this is a supremum and not maximum for the case that r_k is never served. Note that $d_k \leq n$ because ALG always serves r_k before $d_k > n$.*

Our second term is a sum of incurred delay costs of specific elements.

▶ **Definition 13.** *For each $k \in [m]$, the request r_k is considered:*
- ***active** in ALG (resp. OPT) from the time it arrives until it is served by ALG (resp. OPT).*
- ***frozen** from the time it is served by ALG until EC_{e_k} is zeroed in an e_k element counter event.*

▶ **Definition 14.** *For time t we define $\lambda(t) \subseteq [m]$ as the set of requests (request indices) which are either active **or** frozen in ALG at time t. We define $\lambda_1(t) \subseteq \lambda(t)$ as the set of requests that are also active in OPT at time t and $\lambda_2(t) \subseteq \lambda(t)$ as the set of requests that are also not active in OPT at time t.*

Finally, we define our second term.

▶ **Definition 15.** *We define the second term of the Delays potential function as* $\sum_{k\in\lambda_1(t)} d_k(t)$.

The third term is defined as follows (we use x_k and y_k as previously defined).

▶ **Definition 16.** *We define the third term as* $\sum_{k\in\lambda_2(t)}(42d_k - 6d_k(t)) \cdot 1[x_k \leq 4y_k]$.

Note that $42d_k - 6d_k(t) = 36d_k + 6 \cdot (d_k - d_k(t))$. Therefore each request index $k \in \lambda_2(t)$ contributes two terms to Φ: $36d_k$ is used to cover the next element counter on e_k while the second term is 6 times the delay ALG will pay for r_k in the future, which will be used to cover this exact delay penalty that ALG will pay in the future for r_k.

The fourth term is defined to cover the next element counter event on a given element as follows.

▶ **Definition 17.** *Let $\mu_e(t)$, for $e \in \mathbb{E}$, be the number of swaps OPT performed between e and its next element in its list ever since the last element counter event before time t on e by ALG (or the beginning of the time horizon if there was not such an event).*

Finally, we define the fifth term. The fifth term should cover the scenario in which the optimal algorithm served a request and then moved the element further in its list but the online algorithm will suffer more delay penalty for this request in the future. It will also cover the delay cost that the online algorithm will pay and thus it is proportional to the fraction between the future delay the online algorithm will pay for the request and the position of the element in the online algorithm's list.

▶ **Definition 18.** *Let $\mu_k(t)$, for $k \in \lambda_2(t)$, be the number of swaps OPT performed between e_k and its next element in its list ever since OPT served the request r_k (by accessing e_k).*

▶ **Definition 19.** *We define the fifth term of the Delays potential function as*

$$8 \cdot \sum_{k\in\lambda_2(t)} \frac{d_k - d_k(t)}{x^t_{e_k}} \cdot \mu_k(t).$$

We are now ready to define our potential function.

▶ **Definition 20.** *We define our potential function for the delays setting as*

$$\Phi(t) = \sum_{e\in\mathbb{E}} \rho_e(t) + 36 \cdot \sum_{k\in\lambda_1(t)} d_k(t) + \sum_{k\in\lambda_2(t)} (42d_k - 6d_k(t)) \cdot 1[x_k \leq 4y_k] +$$
$$+ 48 \cdot \sum_{e\in\mathbb{E}} \mu_e(t) + 8 \cdot \sum_{k\in\lambda_2(t)} \frac{d_k - d_k(t)}{x^t_{e_k}} \cdot \mu_k(t)$$

6 Conclusion and Open Problems

In this paper, we presented the List Update with Time Windows and Delay, which generalize the classical List Update problem.

- We presented a 24-competitive ratio algorithm for the List Update with Time Windows problem.
- We presented a 336-competitive ratio algorithm for the List Update with Delays problem.
- Open problems: The main issue left unsolved is the gap between the upper and lower bounds. Currently, the best lower bound for both problems considered is 2. Note that this is the same lower bound given to the original List Update problem. An interesting followup would be to improve upon this result and show a better lower bound. On the other hand, one may improve the upper bound - our algorithms are non-clairvoyant in the

sense that our proofs and algorithms hold even when the deadlines/delays are unknown. It would be interesting to understand whether clairvoyance may improve the upper bound. Another interesting direction would be to consider randomization as a way of improving our bounds.

A The Analysis for the Algorithm for Time Windows

In this section we will prove Theorem 3. Throughout we will denote Algorithm 1 as *ALG*.

▶ **Definition 21.** *For each $k \in [m]$ we use a_k and q_k to denote the arrival time and deadline of the request r_k.*

As a first step towards proving Theorem 3 we prove in Lemma 22 that it is enough to consider inputs that only contain triggering requests. The proof appears in the full version [12].

▶ **Lemma 22.** *Let σ be a sequence of requests and let σ' be σ after omitting all the non-triggering requests (with respect to ALG). Then*

$$\frac{ALG(\sigma)}{OPT(\sigma)} \leq \frac{ALG(\sigma')}{OPT(\sigma')}.$$

▶ **Corollary 23.** *We may assume w.l.o.g. that the input σ only contains triggering requests (with respect to ALG).*

The following lemma is simple but will be very useful later. Recall that k refers to the index of the k'th request in the input σ and that e_k denotes its requested element.

▶ **Lemma 24.** *For every $k \in [m]$, the position of e_k in ALG's list remains unchanged throughout the time interval $[a_k, q_k)$. Hence x_k denotes the location of e_k in ALGs list during the time interval $[a_k, q_k)$.*

Proof. During the time interval between a_k and q_k, *ALG* did not access the element e_k and did not access any element located after e_k in its list, because otherwise it would be a contradiction to our assumption that r_k is a trigger request. Therefore, during the time interval mentioned above, *ALG* only accessed (served) elements which were before e_k in its list and performed move-to-fronts on them. But these move-to-fronts did not change the position of e_k in *ALG*'s list. ◀

▶ **Definition 25.** *Let z_k denote the position of the farthest element OPT accesses at the time it served r_k.*

Note that z_k defines the cost *OPT* pays for serving the set of requests that contain r_k.

Recall that *ALG* serves all requests separately (since all requests are triggering requests - Corollary 23). *OPT*, on the other hand, may serve multiple requests simultaneously. Note that at the time *OPT* serves the request r_k, it pays access cost of z_k (and it is guaranteed that $z_k \geq y_k$). The strict inequality $z_k > y_k$ occurs in case *OPT* serves a request for an element located further than e_k in its list and by accessing this far element, *OPT* also accesses e_k, thus serving r_k.

▶ **Lemma 26.** *The cost of ALG is bounded by*

$$ALG(\sigma) \leq 3 \cdot \sum_{k=1}^{m} x_k$$

Proof. For each $k \in [m]$, e_k is located at position x_k at the time when *ALG* serves r_k. *ALG* pays an access cost of at most $2x_k - 1$ when it serves the request r_k (Observe that *ALG* may pay an access cost of less than $2x_k - 1$ in case $n < 2x_k - 1$). *ALG* also pays a cost of $x_k - 1$ for performing move-to-front on e_k. Therefore, *ALG* suffers a total cost of at most $(2x_k - 1) + (x_k - 1) \leq 3x_k$ for serving this request. If we sum for all the requests, we get that $ALG(\sigma) \leq 3 \cdot \sum_{k=1}^{m} x_k$. ◀

▶ **Lemma 27.** *Let t be a time when the active request indices in ALG are $R = \{k_1, k_2, ..., k_d\}$ where $1 \leq x_{k_1} < x_{k_2} < ... < x_{k_d} \leq n$. We have:*

1. *For each $\ell \in [d-1]$, we have $q_{k_\ell} \leq q_{k_{\ell+1}}$, i.e., ALG serves the request r_{k_ℓ} before it serves $r_{k_{\ell+1}}$.*

2. *For each* $\ell \in [d-1]$ *we have that* $2x_{k_\ell} \leq x_{k_{\ell+1}}$.
3. $d \leq \log n + 1$*, i.e., at any time, there are at most* $\log n + 1$ *active requests in ALG.*

Proof. If ALG serves $r_{k_{\ell+1}}$ before it serves r_{k_ℓ}, it serves also r_{k_ℓ} by passing through e_{k_ℓ} when it accesses $e_{k_{\ell+1}}$, contradicting our assumption that r_{k_ℓ} is a trigger request (Observation 23).

If we have $x_{k_{\ell+1}} \leq 2x_{k_\ell} - 1$, then when ALG serves r_{k_ℓ}, it will also access $e_{k_{\ell+1}}$, thus serving $r_{k_{\ell+1}}$, contradicting our assumption that $r_{k_{\ell+1}}$ is a trigger request (Observation 23).

Using what we have already proved, a simple induction can be used in order to prove that for each $\ell \in [|R_t^{OPT}|]$, we have that $2^{\ell-1}x_{k_1^t} \leq x_{k_\ell^t}$. Therefore, we have that $2^{|R_t^{OPT}|-1}x_{k_1^t} \leq x_{k^t_{|R_t^{OPT}|}}$. We also have that $1 \leq x_{k_1^t}$ and $x_{k^t_{|R_t^{OPT}|}} \leq n$. These three inequalities yield to $|R_t^{OPT}| \leq \log n + 1$. ◀

Next we consider OPT's solution.

▶ **Definition 28.** *Let* T_{OPT} *be the set of times when* OPT *served requests. We then define:*

- *For each time* $t \in T_{OPT}$*, let* $R_t^{OPT} = \{k_1^t, k_2^t, ..., k^t_{|R_t^{OPT}|}\}$ *be the non-empty set of request indices that* OPT *served at time* t *where* $1 \leq x_{k_1^t} < x_{k_2^t} < ... < x_{k^t_{|R_t^{OPT}|}} \leq n$.
- *Let* $J(t) = \arg\max_{k \in R_t^{OPT}} \{y_k\}$.

By definition for each $t \in T_{OPT}$, we have

$$1 \leq y_{J(t)} = z_{k_1^t} = z_{k_2^t} = ... = z_{k^t_{|R_t^{OPT}|-1}} = z_{k^t_{|R_t^{OPT}|}} \leq n$$

Observe that at time $t \in T_{OPT}$, OPT serves the requests R_t^{OPT} together by accessing the $y_{J(t)}$'s element in its list. Therefore, OPT pays an access cost of $y_{J(t)}$ at time t.

▶ **Observation 29.** *For any* $t \in T_{OPT}$*, the total cost* OPT *pays for accessing elements at time* t *is* $y_{J(t)}$.

▶ **Lemma 30.** *Let* $t \in T_{OPT}$*. We have:*

1. *For each* $\ell \in [|R_t^{OPT}| - 1]$ *we have that* $2x_{k_\ell^t} \leq x_{k_{\ell+1}^t}$.
2. $|R_t^{OPT}| \leq \log n + 1$*, i.e,* OPT *serves at most* $\log n + 1$ *triggers at the same time.*

Proof. Since OPT served the requests R_t^{OPT} at time t, all these requests arrived at time t or before it. Therefore, from Observation 32 we get that all the requests R_t^{OPT} were active in ALG at time t. Therefore, we get that this lemma holds due to Lemma 27. Note that there may be additional requests which were active in ALG at time t but OPT did not serve at time t (meaning they were not in R_t^{OPT}), but this does not contradict the conclusion. ◀

The following lemma allows us to consider from now on only algorithms such that if they serve requests at time t, then at least one of these requests has a deadline at t. In particular, we can assume that OPT has this property. Observe that ALG also has this property.

▶ **Lemma 31.** *For every algorithm* A*, there exists an algorithm* B *such that for each sequence of request* σ *we are guaranteed that:*

1. B *only serves requests upon some deadline.*
2. $B(\sigma) \leq A(\sigma)$.

For convenience, we assume that when both ALG and OPT are serving σ, in case both OPT and ALG perform access or swapping operations at the same time - we first let OPT perform its operations and only then ALG will perform its operations.

On the other hand, for elements which are not served at the same time by OPT and ALG, by combining the fact that ALG serves requests at their deadline (see Corollary 23) with the fact that OPT must serve requests before the deadline, we get that again OPT serves the request before ALG. Combining the two cases yields Observation 32.

▶ **Observation 32.** *For each $k \in [m]$, OPT serves the request r_k before ALG serves r_k.*

▶ **Definition 33.** *We define the set of **events** P which contains the following 3 types of events:*

1. *ALG serves the request r_k at time q_k.*
2. *OPT serves the requests R_t^{OPT} at time t.*
3. *OPT swaps two elements.*

Recall that the potential function Φ is defined in Section 5.1 as follows:

$$\Phi(t) = 4 \cdot \phi(t) + \sum_{k \in \lambda(t)} \psi(x_k, y_k) + 4 \cdot \sum_{k \in \lambda(t)} \mu_k(t)$$

where the terms ϕ, λ, ψ and μ_k are also defined in that section.

▶ **Definition 34.** *For each event $p \in P$, we define:*

- *ALG^p (OPT^p) to be the cost ALG (OPT) pays during p.*
- *For any parameter z, Δz^p to be the value of z after p minus the value of z before p.*

Clearly, we have $ALG(\sigma) = \sum_{p \in P} ALG^p$ and $OPT(\sigma) = \sum_{p \in P} OPT^p$. Observe that Φ starts with 0 (since at the beginning, the lists of ALG and OPT are identical) and is always non-negative. Therefore, if we prove that for each event $p \in P$, we have

$$ALG^p + \Delta\Phi^p \leq 24 \cdot OPT^p$$

then, by summing it up for over all the events, we will be able to prove Theorem 3. Note that we do not care about the actual value $\Phi(t)$ by itself, for any time t. We will only measure the change of Φ as a result of each type of event in order to prove that the inequality mentioned above indeed holds. The three types of events that we will discuss are:

1. The event where ALG serves the request r_k at time q_k (event type 1) is analyzed in Lemma 35.
2. The event where OPT serves the requests R_t^{OPT} at time t (event type 2) is analyzed in Lemma 39.
3. The event where OPT swaps two elements (event type 3) is analyzed in Lemma 40.

We begin by analyzing the event where ALG served a request.

▶ **Lemma 35.** *Let $p \in P$ be the event where ALG served the request r_k (where $k \in [m]$) at time q_k. We have*

$$ALG^p + \Delta\Phi^p \leq 0 \ (= OPT^p)$$

In order to prove Lemma 35, we separate the movement of ALG versus the movement of OPT. The final proof is the superposition of the two movements. Firstly we assume that OPT did not increase the position of e_k in its list ever since it served the request r_k until ALG served it, then we remove this assumption.

▶ **Lemma 36.** *Let $p \in P$ be the event where ALG served the request r_k (where $k \in [m]$) at time q_k. Assume that ever since OPT served r_k until ALG served r_k, OPT did not increase the position of e_k in its list. We have that*

$$3x_k + 4 \cdot \Delta\phi^p - \psi(x_k, y_k) \leq 0$$

Proof. The assumption means that at time q_k, the position of e_k in OPT's list is at most y_k (it may be even lower, due to movements which may be performed by OPT to e_k towards the beginning of its list, after OPT served r_k). Recall that after ALG serves r_k, the position of e_k in ALG's list changes from x_k to 1, as a result of the move-to-front ALG performs on e_k. In order to prove the required inequality, we consider the following cases, depending on the value of y_k:

- The case $1 \leq x_k \leq y_k$. We have $\psi(x_k, y_k) = 7x_k$.
  Therefore, observe that it is sufficient to prove that $\Delta\phi^p \leq x_k$.
  This is indeed the case, because moving e_k from position x_k to position 1 in ALG's list required ALG to perform $x_k - 1$ swaps, each one of those caused ϕ to either increase by 1 or decrease by 1. Therefore, all these $x_k - 1$ swaps cause ϕ to increase by at most $x_k - 1$.
- The case $y_k \leq x_k \leq n$.
  On one hand, there are at least $x_k - y_k$ elements which were before e_k in ALG's list and after e_k in OPT's list before the move-to-front ALG performed on e_k, but they will be after e_k in ALG's list after this move-to-front. This causes ϕ to decrease by at least $x_k - y_k$. On the other hand, there are at most $y_k - 1$ elements which were before e_k in both OPT's list and ALG's list before the move-to-front ALG performed on e_k, but they will be after e_k in ALG's list after this move-to-front. This causes ϕ to increase by at most $y_k - 1$. Therefore, we have that

  $$\Delta\phi^p \leq -(x_k - y_k) + (y_k - 1) = 2y_k - x_k - 1$$

  Hence,

  $$3x_k + 4 \cdot \Delta\phi^p \leq 3x_k + 4 \cdot (2y_k - x_k - 1) \leq 8y_k - x_k$$

  Now we distinguish between these two following cases, depending on the value of y_k:
  - The case $y_k \leq x_k \leq 8y_k$. We have that $\psi(x_k, y_k) = 8y_k - x_k$. Hence

    $$3x_k + 4 \cdot \Delta\phi^p - \psi(x_k, y_k) \leq 8y_k - x_k - \psi(x_k, y_k) = 8y_k - x_k - (8y_k - x_k) = 0$$

  - The case $8y_k \leq x_k \leq n$. We have that $\psi(x_k, y_k) = 0$. Hence

    $$3x_k + 4 \cdot \Delta\phi^p - \psi(x_k, y_k) \leq 8y_k - x_k - \psi(x_k, y_k) = 8y_k - x_k \leq 8y_k - 8y_k = 0$$

◀

Now we are ready to complete the proof of Lemma 35.

Proof of Lemma 35. Since OPT has already served this request, we have $OPT^p = 0$. As explained in the proof of Lemma 26, we have $ALG^p \leq 3x_k$. Therefore, we are left with the task to prove that

$$3x_k + \Delta\Phi^p \leq 0$$

Observe that $\psi(x_k, y_k)$ and $\mu_k(t)$ are dropped (and thus are subtracted) from Φ as a result of ALG serving r_k. Therefore, we are left with the task to prove that

$$3x_k + 4 \cdot \Delta\phi^p - \psi(x_k, y_k) - 4 \cdot \mu_k(t) \leq 0$$

We first assume that ever since OPT served r_k until ALG served r_k, OPT did not increase the position of e_k in its list (later we remove this assumption). This assumption means that $\mu_k(t) = 0$. Therefore, due to Lemma 36, we have that the above inequality holds. We are left with the task to prove that the above inequality continues to hold even without this assumption.

Assume that ever since OPT served r_k until ALG served r_k, OPT performed a swap between e_k and another element where e_k's position has been increased as a result of this swap. We shall prove that the above inequality continues to hold nonetheless.

On one hand, this swap causes either an increase of 1 or a decrease of 1 to $\Delta\phi^p$. Therefore, the left term of the inequality will be increased by at most 4. On the other hand, the left term of the inequality will certainty be decreased by 4 as a result of this swap, because μ_k will certainty be increased by 1. To conclude, a decrease of at least $4 - 4 = 0$ will be applied to the left term of the inequality, thus the inequality will continue to hold after this swap as well.

By using the argument above for each swap of the type mentioned above, we get that the above inequality continues to hold even without the assumption that OPT did not increase the position of e_k in its list since it served r_k until ALG served r_k, thus the lemma has been proven. ◀

Now that we analyzed the event when ALG serves a request, the next target is to analyze the event where OPT serves multiple request together. The following observation contains useful properties of ψ that will be used later on. The reader may prove them algebraically.

▶ **Observation 37.** *For each $x, x', y, y' \in [1, \infty)$ such that $x \leq x'$ and $y \leq y'$, the function ψ satisfies the following claims:*

1. $0 \leq \psi(x, y) \leq 7x$.
2. *If $y \leq x \leq x'$ then $\psi(x', y) \leq \psi(x, y)$.*
3. $\psi(x, y) \leq \psi(x, y')$.

The target now is to analyze the event when OPT serves the requests R_t^{OPT} together at time t. Recall that when OPT serves a request r_k, the value $\psi(x_k, y_k)$ is added to Φ. The following lemma will be needed in order to analyze this event.

▶ **Lemma 38.** *Let $a > 0$ and let $f : [0, \infty) \to [0, \infty)$ be the function defined as follows:*

$$f(x) = \begin{cases} 7x & \text{if } 0 \leq x \leq a \\ 8a - x & \text{if } a \leq x \leq 8a \\ 0 & \text{if } 8a \leq x \end{cases}$$

Consider the optimization problem Q of choosing a (possibly infinite) subset $U \subseteq (0, 8a)$ that will maximize $\sum_{x \in U} f(x)$ with the requirement $\forall x, y \in U : x < y \implies 2x \leq y$. Then the optimal value of Q is $24a$.

Now we can use Lemma 38 in order to analyze the event when OPT serves multiple requests together. The proofs of Lemmas 38 and 39 appear in the full version [12].

▶ **Lemma 39.** *Let $p \in P$ be the event where OPT served the requests R_t^{OPT} at time t. We have*

$$ALG^p + \Delta\Phi^p \leq 24 \cdot OPT^p$$

We analyzed the event where ALG serves a request and the event when OPT serves multiple requests together. The only event which is left to be analyzed is the event when OPT performs a swap. We analyze it in the lemma below. The proof is in the full version [12].

▶ **Lemma 40.** *Let $p \in P$ be the event where OPT performed a swap at time t. We have*

$$ALG^p + \Delta\Phi^p \leq 8 \cdot OPT^p$$

We are now ready to prove Theorem 3.

Proof of Theorem 3. Due to Lemma 35, Lemma 39 and Lemma 40, we have for each event $p \in P$ that

$$ALG^p + \Delta\Phi^p \leq 24 \cdot OPT^p$$

The theorem follows by summing it up for over all events and use the fact that Φ starts with 0 and is always non-negative. ◀

NP-Hardness of Testing Equivalence to Sparse Polynomials and to Constant-Support Polynomials

Abstract

An s-sparse polynomial has at most s monomials with nonzero coefficients. The Equivalence Testing problem for sparse polynomials (ETsparse) asks to decide if a given polynomial f is equivalent to (i.e., in the orbit of) some s-sparse polynomial. In other words, given $f \in \mathbb{F}[\mathbf{x}]$ and $s \in \mathbb{N}$, ETsparse asks to check if there exist $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ and $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$ such that $f(A\mathbf{x} + \mathbf{b})$ is s-sparse. We show that ETsparse is NP-hard over any field $\mathbb{F}$, if f is given in the sparse representation, i.e., as a list of nonzero coefficients and exponent vectors. This answers a question posed by Gupta, Saha and Thankey (SODA 2023) and also, more explicitly, by Baraskar, Dewan and Saha (STACS 2024). The result implies that the Minimum Circuit Size Problem (MCSP) is NP-hard for a *dense* subclass of depth-3 arithmetic circuits if the input is given in sparse representation. We also show that approximating the smallest s_0 such that a given s-sparse polynomial f is in the orbit of some s_0-sparse polynomial to within a factor of $s^{\frac{1}{3}-\epsilon}$ is NP-hard for any $\epsilon > 0$; observe that s-factor approximation is trivial as the input is s-sparse. Finally, we show that for any constant $\sigma \geq 6$, checking if a polynomial (given in sparse representation) is in the orbit of some support-σ polynomial is NP-hard. Support of a polynomial f is the maximum number of variables present in any monomial of f. These results are obtained via direct reductions from the 3-SAT problem.

Acknowledgements We thank the anonymous reviewers for their detailed and constructive feedback, which has helped us improve the presentation of this work. In particular, we thank one of the reviewers for pointing out some inaccuracies in the original proofs of Lemmas 50 and 51; simpler proofs for both lemmas came up in the process of fixing these inaccuracies.

1 Introduction

The Polynomial Equivalence (PE) problem asks to decide if two polynomials, given as lists of coefficients, are equivalent. Polynomials $f, g \in \mathbb{F}[\mathbf{x}]$ are *equivalent*, denoted as $f \sim g$, if there is an $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ and a $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$ such that $f = g(A\mathbf{x} + \mathbf{b})$. Equivalent polynomials

represent the same function up to a change of the coordinate system.[1] The PE problem is thus regarded as the algebraic analog of the graph isomorphism (GI) problem. PE is at least as hard as GI [2, 36], but we do not know if it is much harder than GI. There is, in fact, a cryptographic authentication scheme based on the presumed average-case hardness of PE [46]. Is PE NP-hard? Over finite fields, PE is not NP-hard unless the polynomial hierarchy collapses [51, 55]. In contrast, PE is not even known to be decidable over $\mathbb{Q}$. With the aim of gaining more insight into the complexity of testing polynomial equivalence, a natural variant of PE has been studied in the literature. This variant is known as *equivalence testing*.

In the following discussion, whenever we write "circuit(s)" and "formula(s)", we mean arithmetic circuit(s) and arithmetic formula(s), respectively, unless mentioned otherwise.[2]

Equivalence testing. Equivalence testing (ET) comes in two flavors – ET for polynomial families and ET for circuit classes. ET for a polynomial family $\mathcal{F}$ is defined as follows: given a *single* polynomial f, check if it is equivalent to some $g \in \mathcal{F}$. This variant of PE was introduced in [37, 36], wherein randomized polynomial-time ET algorithms were provided for the permanent, determinant, and elementary and power symmetric polynomial families. Subsequently, efficient ET algorithms were given for various other important polynomial families, such as the iterated matrix multiplication (IMM) family [39] (see the Related Works section in the full version). These algorithms are efficient even if f is provided as a circuit or a black-box.[3] ET for a circuit class $\mathcal{C}$ (a.k.a testing equivalence to $\mathcal{C}$) is defined similarly: given a polynomial f, decide if it is equivalent to some polynomial g that is computable by a circuit in $\mathcal{C}$. Recently, efficient ET algorithms have been given for read-once formulas [24] and a special subclass of sparse polynomials, namely t-design polynomials for constant t [8]. Sparse polynomials are depth-2 circuits.[4] It is natural to ask whether or not ET can be solved efficiently for *general* sparse polynomials. This question was posed in [24] and also, more explicitly, in [8].

Before proceeding to discuss ET for sparse polynomials, we point out a subtle difference between ET for polynomial families and that for circuit classes. The polynomial families for which ET has been studied so far are such that if f is equivalent to some g in the family, then g is unique and it can be readily identified from f. For example, if f is equivalent to some determinant polynomial[5], then we know which one simply from the number of variables of f. Moreover, polynomials in most of these families admit well-known polynomial-size circuits. So, a circuit for g can be derived once it is identified. Thus, if f is also given as a circuit, then ET for such a family reduces to PE with the input polynomials given as circuits. Over finite fields, this version of PE is in $\mathsf{AM} \cap \mathsf{coAM}$ and hence unlikely to be NP-hard. On the other hand, in the case of ET for a circuit class, if f is equivalent to some circuit C in the class, then C need *not* be unique, and further, C may not be easily deducible from f. This leaves us with the prospect of proving that ET is hard for some natural circuit class. Do sparse polynomials form such a class?

---

[1] Over $\mathbb{R}$, an invertible map $\mathbf{x} \mapsto A\mathbf{x} + \mathbf{b}$ is simply a combination of rotation, reflection, scaling, and translation.

[2] An *arithmetic circuit* is like a Boolean circuit but with AND and OR replaced by $\times$ and $+$ gates, and with edges labelled by $\mathbb{F}$-elements. It computes a polynomial over $\mathbb{F}$. A *formula* is a circuit whose underlying graph is a tree.

[3] Black-box access to f means oracle access to f, we get $f(\mathbf{a})$ from a query point $\mathbf{a}$ in unit time. It is as if f is given as a "hidden" circuit, and the only operation we are allowed is to evaluate the circuit at chosen points.

[4] We assume that a depth-2 circuit has a $+$ gate on top and a bottom layer of $\times$ gates. If the top gate is a $\times$ gate, then ET can be solved efficiently using polynomial factorization algorithms [35].

[5] The n^2-variate determinant polynomial is the determinant of the matrix $(x_{i,j})_{i,j\in[n]}$ of formal variables.

ET for sparse polynomials. An n-variate, degree-d polynomial is *s-sparse* if it has at most s monomials with nonzero coefficients. An s-sparse polynomial is computable by a depth-2 circuit having top fan-in s. Sparse polynomials have been extensively studied in algebraic complexity, particularly with regard to identity testing [41, 43], interpolation [10, 21, 41, 12], and factorization [56, 11] (see the tutorial [49] and the references therein for more algorithms involving sparse polynomials). ET provides yet another avenue to understand these "basic" polynomials better. ET for sparse polynomials asks to check if a given polynomial is sparse in some coordinate system. More formally, given a polynomial f as an arithmetic circuit and an $s \in \mathbb{N}$, decide if there is an s-sparse polynomial g such that $f \sim g$. This problem was studied in [20] over $\mathbb{Q}$, wherein an exponential in n^4 time algorithm was provided. There has not been any significant progress on this problem since that work. The lack of improvements in the complexity for over three decades makes one wonder:

Is ET for sparse polynomials NP-hard?

In this work, we answer this question in the affirmative over *any* field (see the first part of Theorem 2) even if the input f is provided as a depth-2 circuit. The result answers the question posed in [24, 8]. To our knowledge, the theorem gives the first example of a natural circuit class for which ET is provably hard.

Although ET for sparse polynomials (ETsparse) is a fairly natural problem, there is a deeper reason to study ETsparse originating from the expressive power of affine projections of sparse polynomials and the *Minimum Circuit Size Problem* (MCSP) for depth-3 circuits. We discuss this reason below to motivate ETsparse when the input is a *homogeneous* polynomial.

1.1 ETsparse and MCSP for depth-3 circuits

First, we need a few definitions: A polynomial g is an *affine projection* of f if $g = f(A\mathbf{x} + \mathbf{b})$ for some $A \in \mathbb{F}^{|\mathbf{x}|\times|\mathbf{x}|}$ and $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$. If $\mathbf{b} = 0$, we say g is a *linear projection* of f; additionally, if $A \in \mathrm{GL}(|\mathbf{x}|)$, we say g is in the *orbit* of f, denoted as $\mathrm{orb}(f)$. Depth-3 circuits form a highly expressive class [23, 54]. A depth-3 ($\Sigma\Pi\Sigma$) circuit is a circuit with a $+$ gate on top, a middle layer of $\times$ gates, and a bottom layer of $+$ gates. A depth-3 circuit with a top fan-in of s is an affine projection of an s-sparse polynomial. Thus, the problem of deciding if a given f is an affine projection of an s-sparse polynomial is closely related to MCSP for depth-3 circuits. We say "closely related to" instead of "the same as" because the size of a depth-3 circuit is determined by not only its top fan-in but also its formal degree.

MCSP. The complexity of MCSP for Boolean circuits has baffled researchers for over six decades. MCSP for a Boolean circuit class $\mathcal{C}$ ($\mathcal{C}$-MCSP) takes input the truth table of an n-variate Boolean function f and a parameter $s \in \mathbb{N}$ and asks to check if f is computable by a circuit in $\mathcal{C}$ of size at most s. There are intriguing connections between MCSP and several other areas such as cryptography [34, 3], learning theory [14], average-case complexity [27], and proof complexity [47]. Whether or not MCSP for general Boolean circuits is NP-hard is a long-standing open question. It is known that MCSP is NP-hard for DNF [44, 4] and DNF $\circ$ XOR formulas [29]. But no NP-hardness result is known (under deterministic polynomial-time reductions) for more general circuit models such as AC^0 circuits.[6] This is not too surprising

[6] However, strong hardness results are known for several powerful circuit models under randomized or quasi-polynomial time or subexponential time reductions [30, 32, 31, 28].

as [34] showed that NP-hardness of $\mathcal{C}$-MCSP under *natural*[7] deterministic polynomial-time reductions implies a $2^{\Omega(n)}$ lower bound for $\mathcal{C}$, unless NP $\subseteq$ SUBEXP. Unfortunately, such strong lower bounds are not known even for depth-3 Boolean circuits. However, a $2^{\Omega(n)}$ lower bound is known for XOR $\circ$ AND $\circ$ XOR formulas [48], which are depth-3 arithmetic circuits over $\mathbb{F}_2$ and are like DNF $\circ$ XOR formulas but with the top OR gate replaced by an XOR gate. In fact, a $2^{\Omega(n)}$ lower bound is known for depth-3 arithmetic circuits over any fixed finite field [22]. This raises hope that we will be able to prove the hardness of MCSP for depth-3 arithmetic circuits over finite fields. But how is the input given in the case of MCSP for arithmetic circuits? And what about depth-3 circuits over fields of characteristic 0?

MCSP for arithmetic circuits: Input representation and model of computation. In the Boolean setting of MCSP, one of the main reasons to assume the input to be a truth table is that the assumption puts MCSP in NP. Analogously, in the algebraic setting, we could assume that the polynomial is given in the dense representation as a list of $\binom{n+d}{n}$ coefficients. But observe that even if the input is given as an arithmetic circuit, MCSP is in the complexity class MA over finite fields. This is because verifying if two circuits compute the same polynomial is the polynomial identity testing problem, which admits a randomized polynomial-time algorithm [16, 57, 52]. Furthermore, class MA equals NP, assuming a widely believed circuit lower bound [33]. A succinct input representation also opens up the possibility of proving NP-hardness of MCSP for models, such as depth-3 circuits over fields of characteristic 0, for which strong exponential lower bounds are unknown (the MCSP hardness to lower bound implication in [34] needs the input in the dense format). The current best lower bound for depth-3 circuits over fields of characteristic 0 is quasi-polynomial in n [42, 5].

It is, therefore, reasonable to assume that the input polynomial is given succinctly as a circuit which should only facilitate our efforts in proving NP-hardness of MCSP for arithmetic circuit classes. For example, there is an instance in the Boolean setting wherein succinct representation of the input helped prove NP-hardness of MCSP long before such a hardness result was shown with respect to the dense representation – it is the case of the *partial* MCSP problem [25, 28]. In this work, we assume that the input is given as a depth-2 circuit, i.e., as a list of nonzero coefficients, and exponent vectors in unary – this is the *sparse representation*.[8]

A few remarks are in order concerning the model of computation. Over finite fields, we assume the Turing machine model. However, over arbitrary fields of characteristic 0, it is natural to consider an arithmetic model of computation (similar to the Blum-Shub-Smale machine model [13]) that allows us to store a field element in unit space and perform an arithmetic operation in unit time. Over $\mathbb{Q}$, it is not clear if MCSP for arithmetic circuits is even decidable in the Turing machine model. But, if we confine our search to size-s circuits whose field constants are $s^{O(1)}$ bit rational numbers, then we can work with the Turing machine model.

MCSP for homogeneous depth-3 circuits. The size of a $\Sigma\Pi\Sigma$ circuit is primarily determined by its formal degree and its top fan-in, whereas the size of a homogeneous depth-3 (hom-$\Sigma\Pi\Sigma$) circuit is mainly decided by its top fan-in (the formal degree of a $\Sigma\Pi\Sigma$ circuit is the maximum

[7] i.e., the size of the output of the reduction and the output parameter s depend only on the size of the input instance. Almost all reductions that show NP-hardness of problems are natural.

[8] Sparse representations of polynomials are also used in computer algebra systems wherein the exponent vector is given in binary. As the degree is $n^{O(1)}$ in this work (except on one occasion; see the remark following Theorem 16), whether the exponent vector is given in unary or binary makes little difference.

fan-in of the middle layer of $\times$ gates). MCSP for $\Sigma\Pi\Sigma$ circuits can be defined as follows: given f and $D, s \in \mathbb{N}$, decide if there is a $\Sigma\Pi\Sigma$ circuit with formal degree bounded by D and top fan-in bounded by s that computes f. Similarly, MCSP for hom-$\Sigma\Pi\Sigma$ circuits is defined as: given a homogeneous f and $s \in \mathbb{N}$, check if there is a hom-$\Sigma\Pi\Sigma$ circuit with top fan-in at most s that computes f. In order to prove NP-hardness of $\Sigma\Pi\Sigma$-MCSP, it is *necessary* to prove NP-hardness of hom-$\Sigma\Pi\Sigma$-MCSP. The reason is: a polynomial $f(x_1, x_2, \ldots, x_n)$ has a $\Sigma\Pi\Sigma$ circuit with formal degree bounded by D and top fan-in bounded by s if and only if the homogeneous polynomial $z^D f(x_1 z^{-1}, x_2 z^{-1}, \ldots, x_n z^{-1})$ has a hom-$\Sigma\Pi\Sigma$ circuit with top fan-in bounded by s. Moreover, if the reduction in a hypothetical proof of NP-hardness of hom-$\Sigma\Pi\Sigma$-MCSP has a certain simple feature, then it would imply NP-hardness of $\Sigma\Pi\Sigma$-MCSP (see the second remark following Proposition 39). Hence, it is natural to study the hardness of hom-$\Sigma\Pi\Sigma$-MCSP first.

NP-hardness of MCSP is known for two interesting subclasses of hom-$\Sigma\Pi\Sigma$ circuits, namely depth-3 powering circuits [53] and set-multilinear $\Sigma\Pi\Sigma$ circuits [26]; the top fan-in's of circuits in these two classes correspond to Waring rank and tensor rank, respectively. Perhaps an appealing evidence in favor of NP-hardness of hom-$\Sigma\Pi\Sigma$-MCSP is a proof of NP-hardness of MCSP for a "dense" subclass of hom-$\Sigma\Pi\Sigma$ circuits. Intuitively, $\mathcal{C}$ is a *dense* subclass of hom-$\Sigma\Pi\Sigma$ circuits if every hom-$\Sigma\Pi\Sigma$ circuit can be approximated "infinitesimally closely" by circuits in $\mathcal{C}$.[9] Unfortunately, depth-3 powering circuits and set-multilinear $\Sigma\Pi\Sigma$ circuits are *not* dense inside hom-$\Sigma\Pi\Sigma$ circuits.[10] On the other hand, *orbits of homogeneous sparse polynomials* form a dense subclass of hom-$\Sigma\Pi\Sigma$ circuits.[11] It is natural to ask:

Is MCSP for orbits of homogeneous sparse polynomials NP-hard?

MCSP for orbits of homogeneous sparse polynomials is exactly the ETsparse problem on inputs that are homogeneous polynomials. The second part of Theorem 2 answers the question positively over fields of characteristic 0.

Approximating the sparse-orbit complexity. Call the smallest s_0 such that f is in the orbit of an s_0-sparse polynomial, the *sparse-orbit complexity* of f. Theorem 2 shows that sparse-orbit complexity is hard to compute in the worst case.

Is sparse-orbit complexity easy to approximate?

In Theorem 8, we show that it is NP-hard to approximate the sparse-orbit complexity of a given s-sparse polynomial (homogeneous or not) to within a $s^{\frac{1}{3}-\epsilon}$ factor for any $\epsilon \in (0, 1/3)$. For s-sparse inputs, a within s factor approximation of the sparse-orbit complexity is trivial.

[9] Formally, a subclass $\mathcal{C}$ of hom-$\Sigma\Pi\Sigma$ circuits is *dense* if there are polynomial functions $p, q : \mathbb{N} \to \mathbb{N}$ such that the following holds: For $n, d, s \in \mathbb{N}$, the coefficient vector of every n-variate degree-d polynomial computable by a size-s hom-$\Sigma\Pi\Sigma$ circuit is in the *Zariski closure* of the set of coefficient vectors of $p(nds)$-variate degree-d polynomials computable by size-$q(nds)$ circuits in $\mathcal{C}$. Here, "size" means "top fan-in".

[10] Circuits of these two classes have small read-once algebraic branching programs (ROABPs), and the class ROABP is closed under Zariski closure [18]. So, the closures of these two classes are also contained inside ROABPs. But, there are explicit $O(n)$ size hom-$\Sigma\Pi\Sigma$ circuits that require $2^{\Omega(n)}$ size ROABPs [50, 38].

[11] Every n-variate degree-d size-s hom-$\Sigma\Pi\Sigma$ circuit is a linear projection of an s-sparse degree-d homogeneous polynomial in at most sd variables. It is well known that linear projections of f are contained in the Zariski closure of the orbit of f over fields of characteristic 0 (see [50] for a proof of this fact).

1.2 ET for constant-support polynomials

ET is efficiently solvable for two special sparse polynomial families, namely the power symmetric polynomial $\mathsf{PSym} := x_1^d + \ldots + x_n^d$ [36] and the sum-product polynomial $\mathsf{SP} := \sum_{i\in[s]} \prod_{j\in[d]} x_{i,j}$ [45, 36]. What makes ET easy for these sparse polynomials? Explanations were provided in [24, 8]: SP is a read-once formula; it is also a 1-design polynomial. PSym is a 1-design polynomial, but it is also a support-1 polynomial.

Is ET easy for constant-support polynomials?

In Theorem 16, we show that checking if a given f is in the orbit of a support-6 polynomial is NP-hard; this answers the question in the negative.

1.3 Our results

We now state our results formally. The ETsparse problem is defined as follows.

▶ **Problem 1** (ETsparse)**.** *Given a polynomial $f \in \mathbb{F}[\mathbf{x}]$ in its sparse representation and an $s \in \mathbb{Z}$, check if there exists an $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ and a $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$ such that $f(A\mathbf{x}+\mathbf{b})$ is s-sparse.*

Our first result, Theorem 2, shows the NP-hardness of ETsparse over any field.

▶ **Theorem 2** (ETsparse is NP-hard)**.**
1. *Let $\mathbb{F}$ be any field. There exists a deterministic polynomial-time many-one reduction from* 3-SAT *to* ETsparse *over $\mathbb{F}$.*
2. *Let* $\mathrm{char}(\mathbb{F}) = 0$*. There exists a deterministic polynomial-time many-one reduction from* 3-SAT *to* ETsparse *over $\mathbb{F}$ where the input polynomial in* ETsparse *is homogeneous.*

▶ Remark 3. The reduction is *natural*[12] and has the feature that a satisfying assignment can be mapped to a sparsifying invertible $A \in \{-1, 0, 1\}^{|\mathbf{x}|\times|\mathbf{x}|}$ and vice versa. So, ETsparse is NP-hard even when A is restricted to having only $\{-1, 0, 1\}$ entries.

▶ Remark 4. The authors of [15] showed the undecidability over $\mathbb{Z}$ of testing if a given f is shift equivalent to some sparse polynomial (f is shift equivalent to a polynomial g, if there exists a $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$ s.t $f = g(\mathbf{x}+\mathbf{b})$). However, their result does not imply the intractability of ETsparse as testing shift equivalence to a sparse polynomial is a special case of ETsparse when A is the identity map.

▶ Remark 5. Depth-3 power circuits, set-multilinear depth-3 circuits, and shifted sparse polynomials are all contained inside ROABPs. So, these models admit polynomial-time (improper) learning algorithms [9, 40] and quasi-polynomial-time hitting sets [1, 19]. Orbits of sparse polynomials require exponential size ROABPs [50]; we cannot expect to improperly learn them via ROABPs. Theorem 2 suggests that proper learning orbits of sparse polynomials is likely hard. Nonetheless, there is a quasi-polynomial time hitting set for orbits of sparse polynomials [45, 50].

▶ Remark 6. We believe that with some more effort, the second part of Theorem 2 can be proven over fields of finite characteristics as well. See the last remark in Section 3.4.
We prove Theorem 2 in Section 3. Next, we define the gap version of ETsparse.

▶ **Problem 7** (α-gap-ETsparse)**.** *Let $\alpha > 1$ be a parameter. Given a polynomial $f \in \mathbb{F}[\mathbf{x}]$ in its sparse representation and an integer s_0, output:*
- *YES, if there exist an $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ and $\mathbf{b} \in \mathbb{F}$ such that $f(A\mathbf{x}+\mathbf{b})$ is s_0-sparse.*
- *NO, if for all $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ and $\mathbf{b} \in \mathbb{F}$, $f(A\mathbf{x}+\mathbf{b})$ has sparsity at least αs_0.*

[12] unless $\mathrm{char}(\mathbb{F}) = 2$. See the full version for details.

Our second result, Theorem 8, shows that α-gap-ETsparse is NP-hard for $\alpha = s^{\frac{1}{3}-\epsilon}$, where s is the sparsity of the input polynomial f and $\epsilon \in (0, \frac{1}{3})$ is an arbitrary constant. Theorem 8 is proven in Section 4. From Theorem 8, we get Corollary 11 which states that $s^{\frac{1}{3}-\epsilon}$ factor approximation of the sparse-orbit complexity of an s-sparse polynomial is NP-hard.

▶ **Theorem 8** ($s^{\frac{1}{3}}$-gap-ETsparse is NP-hard). *Let $\epsilon \in (0, \frac{1}{3})$ be an arbitrary constant.*

1. *Let $\mathbb{F}$ be any field. There exists a deterministic polynomial-time many-one reduction from* 3-SAT *to* $s^{\frac{1}{3}-\epsilon}$-gap-ETsparse *over $\mathbb{F}$ where the input polynomial in* $s^{\frac{1}{3}-\epsilon}$-gap-ETsparse *is s-sparse.*
2. *Let* $\mathrm{char}(\mathbb{F}) = 0$. *There exists a deterministic polynomial-time many-one reduction from* 3-SAT *to* $s^{\frac{1}{3}-\epsilon}$-gap-ETsparse *over $\mathbb{F}$ where the input polynomial in* $s^{\frac{1}{3}-\epsilon}$-gap-ETsparse *is homogeneous and s-sparse.*

▶ Remark 9. With a more careful analysis, the constant $\frac{1}{3}$ in $s^{\frac{1}{3}-\epsilon}$ may be improved.

▶ Remark 10. Interestingly, the above results are obtained without invoking the celebrated PCP theorem [7, 6, 17].

▶ **Corollary 11.** *Let $0 < \epsilon < \frac{1}{3}$ be an arbitrary constant.*

1. *Let $\mathbb{F}$ be any field. It is NP-hard to compute $s^{\frac{1}{3}-\epsilon}$ factor approximation of the sparse-orbit complexity when the input is an s-sparse polynomial over $\mathbb{F}$.*
2. *Let* $\mathrm{char}(\mathbb{F}) = 0$. *It is NP-hard to compute $s^{\frac{1}{3}-\epsilon}$ factor approximation of the sparse-orbit complexity when the input is an s-sparse homogeneous polynomial over $\mathbb{F}$.*

Now, we formally define the support of a polynomial.

▶ **Definition 12** (Support of a polynomial). *For a monomial $\mathbf{x}^{\boldsymbol{\alpha}}$, where $\boldsymbol{\alpha}$ is the exponent vector, the support of $\mathbf{x}^{\boldsymbol{\alpha}}$,* $\mathrm{Supp}(\mathbf{x}^{\boldsymbol{\alpha}})$*, is the number of variables with non-zero exponent. The support of a polynomial f,* $\mathrm{Supp}(f)$*, is the maximum support size over all the monomials of f.*

Thus, a polynomial has support σ if there exists a monomial with support σ and no other monomial has support $> \sigma$. The ET problem for constant-support polynomials and a stronger version of it are defined next (henceforth, σ is assumed to be a constant).

▶ **Problem 13** (ETsupport). *Given a polynomial $f \in \mathbb{F}[\mathbf{x}]$ in its sparse representation and an integer σ, check if there exists an $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ such that* $\mathrm{Supp}(f(A\mathbf{x})) \leq \sigma$.

▶ **Problem 14** ($(\sigma+1)$-to-σ ETsupport). *Given a polynomial $f \in \mathbb{F}[\mathbf{x}]$ with support $\sigma+1$ in its sparse representation, check if there exists an $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ such that* $\mathrm{Supp}(f(A\mathbf{x})) \leq \sigma$.

▶ Remark 15. Unlike ETsparse, checking if f is in the *orbit* of a constant-support polynomial is the same as checking if f is equivalent to a constant-support polynomial. This follows from the observation that $\mathrm{Supp}(f(\mathbf{x})) = \mathrm{Supp}(f(\mathbf{x}+\mathbf{b}))$ for any $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$.

Our third and last result, Theorem 16, shows that ETsupport and $(\sigma+1)$-to-σ ETsupport are NP-hard. We prove Theorem 16 in Section 5.

▶ **Theorem 16** (ETsupport is NP-hard). *Let $\sigma \geq 6$ be a constant and $\mathbb{F}$ be a field with* $\mathrm{char}(\mathbb{F}) = 0$ *or* $> \sigma + 1$. *There is a deterministic polynomial-time many-one reduction from* 3-SAT *to* ETsupport *over $\mathbb{F}$. In particular,* 3-SAT *reduces to* $(\sigma+1)$-to-σ ETsupport *in deterministic polynomial time.*

▶ Remark 17. Over fields of finite characteristic, it is assumed that the exponent vectors corresponding to the monomials of the input polynomial are given in binary.

We prove Theorems 2, 8 and 16 by direct reductions from 3-SAT, and at the beginning of Sections 3, 4 and 5, we give proof sketches of the respective reductions.

2 Preliminaries

2.1 Definitions and notations

For $n, a, b \in \mathbb{N}$, $[n]$ denotes the set $\{1, 2 \ldots, n\}$ and $[a, b]$ denotes the integers from a to b, both inclusive. A polynomial is *homogeneous* if all its monomials have the same total degree. The set of invertible linear transforms in n variables over a field $\mathbb{F}$ is denoted by $\mathrm{GL}(n, \mathbb{F})$. For a polynomial $f \in \mathbb{F}[\mathbf{x}]$, the action of a linear transform $A \in \mathbb{F}^{|\mathbf{x}|\times|\mathbf{x}|}$ on its variables is denoted by $f(A\mathbf{x})$ as well as by $A(f)$. The sparsity of a polynomial f, denoted as $\mathcal{S}(f)$, is the number of monomials in f with non-zero coefficients. For a polynomial f, $\mathrm{var}(f)$ denotes the set of variables that occur in at least one monomial of f. We have used the notation $f \sim g$ earlier to denote $f = g(A\mathbf{x} + \mathbf{b})$. Henceforth, we will ignore the translation vector $\mathbf{b}$ in the main body of the discussion for simplicity but mention the necessary changes in the proofs or point to appropriate sections when translations are involved. Thus, for polynomials f and g, $f \sim g$ will mean $f(\mathbf{x}) = g(A\mathbf{x})$ where $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$.[13] Similarly, the orbit of a polynomial f will now denote the set $\{f(A\mathbf{x}), A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})\}$.

▶ **Definition 18** (Degree separated polynomials)**.** *Polynomials f and g are **degree separated** if no monomial of f has the same degree as a monomial of g. Similarly, f and g are **degree separated with respect to a variable** x if no monomial of f has the same x-degree as a monomial of g.*[14]

2.2 Algebraic preliminaries

The proofs of the observations and claims in this section can be found in the full version.

▶ **Observation 19.** *Let f and g be polynomials such that $f \sim g$. Then, f and g have the same set of degrees*[15] *for the monomials. Thus, if f and g are degree separated, then $f \not\sim g$.*

▶ **Observation 20.** *If f and g are degree separated (or degree separated with respect to some variable), then $\mathcal{S}(f + g) = \mathcal{S}(f) + \mathcal{S}(g)$.*

▶ **Observation 21.** *If f and g are degree separated, $f_1 \sim f$ and $g_1 \sim g$, then $\mathcal{S}(f_1 + g_1) = \mathcal{S}(f_1) + \mathcal{S}(g_1)$.*

Observation 22 analyzes the sparsity of powers of linear forms. Observation 23 is a special case of Observation 22 and is stated separately because it is simpler and is invoked many times. Observation 24 analyzes the sparsity of powers of affine forms.

▶ **Observation 22.** *Let ℓ be a m-variate linear form*[16] *and $d \in \mathbb{N}$. If $\mathrm{char}(\mathbb{F}) = 0$, $\mathcal{S}(\ell^d) = \binom{d+m-1}{m-1}$ and if $\mathrm{char}(\mathbb{F}) = p$, $\mathcal{S}(\ell^d) = \prod_{i=0}^{k} \binom{e_i+m-1}{m-1}$, where $d = \sum_{i=0}^{k} e_i p^i$, $e_i \in [0, p-1]$.*

▶ **Observation 23.** *If $\mathrm{char}(\mathbb{F}) = 0$ and ℓ is a linear form in exactly two variables, then $\mathcal{S}(\ell^d) = d+1$. The result holds for $\mathrm{char}(\mathbb{F}) = p$ fields if $p > d$ or if $d = p^k - 1$ for some $k \in \mathbb{N}$. Further, if ℓ is a linear form in at least two variables and d is as before, then $\mathcal{S}(\ell^d) \geq d + 1$.*

---

[13] Note $\sim$ is an equivalence relation under this definition.

[14] The degree of a monomial means its total degree and the degree of a polynomial f is the maximum degree amongst all monomials in f. The x-degree of a monomial is the degree of the variable x in the monomial.

[15] The set of degrees is the set of distinct degrees of all the monomials in the polynomial. For example, the set of degrees of $f(x_1, x_2) = x_1^2 + x_1x_2 + 4x_2$ is $\{2, 1\}$.

[16] A linear form is a homogeneous degree one polynomial. An affine form is a degree one polynomial.

▶ **Observation 24.** *Let $h = \ell + c_0$, where ℓ is a linear form in at least one variable and $c_0 \in \mathbb{F}\setminus\{0\}$, then $\mathcal{S}(h^d) \geq \mathcal{S}(\ell^d) + 1$. More precisely, $\mathcal{S}(h^d) \geq d + 1$ holds if $\mathrm{char}(\mathbb{F}) = 0$ or if $\mathrm{char}(\mathbb{F}) = p$ and $p > d$ or $d = p^k - 1$ for some $k \in \mathbb{N}$.*

Claim 25 analyzes the sparsity of polynomials divisible by a power of some linear form in at least two variables and is used to prove part two of Theorems 2 and 8. Claim 26 analyzes the support of monomials under invertible linear transforms and is used to prove Theorem 16.

▷ Claim 25. Let $\mathrm{char}(\mathbb{F}) = 0$. If $f \in \mathbb{F}[\mathbf{x}]$ is a non-zero polynomial divisible by ℓ^d for some linear form ℓ in at least two variables, then $\mathcal{S}(f) \geq d + 1$.

▷ Claim 26. Let $\sigma, d, n \in \mathbb{N}$, $d \geq \sigma$, $f = (x_1 \cdots x_n)^d$, and $\ell_1, \ldots, \ell_n$ be linearly independent linear forms in $x_1, \ldots, x_n$. If $|\cup_{i=1}^n \mathrm{var}(\ell_i)| \geq \sigma$ and $g := f(\ell_1 \cdots \ell_n)$, then $\mathrm{Supp}(g) \geq \sigma$. The claim holds if $\mathrm{char}(\mathbb{F}) = 0$, or $\mathrm{char}(\mathbb{F}) = p$ with $p > d$, or $p > \sigma$ and $d = p^k - 1$ for some $k \in \mathbb{N}$.

3 NP-hardness of ETsparse

In this section, we prove Theorem 2 over $\mathrm{char}(\mathbb{F}) = 0$ fields without translations for easy understanding.[17] The full version contains the proofs of the lemmas and the observations in this section, and the reduction over $\mathrm{char}(\mathbb{F}) > 0$ fields and also when translations are allowed.

Proof sketch. The reduction maps each variable and clause of a 3-CNF[18] ψ to distinct degree separated polynomials which, summed together, give the polynomial f. As the summands are degree separated, the sparsity of f under invertible transforms can be analyzed by doing so for individual polynomials. The degrees are chosen such that f is equivalent to an s-sparse polynomial (for a suitable sparsity parameter s) if and only if $\psi \in$ 3-SAT.

3.1 Constructing f and s

Let ψ be a 3-CNF in variables $\mathbf{x} := \{x_1, x_2 \ldots x_n\}$ and m clauses:

$$\psi = \wedge_{k=1}^{m} \vee_{j \in C_k} (x_j \oplus a_{k,j}),$$

where C_k denotes the set of indices of the variables in the k^{th} clause and $a_{k,j} \in \{0, 1\}$. Let $\mathbf{y} := \{y_1, y_2 \ldots y_n\}$, x_0 be a new variable and $\mathbf{z} := \{x_0\} \sqcup \mathbf{x} \sqcup \mathbf{y}$. For $d_1, d_2, d_3, d_4 \in \mathbb{N}$, consider the following polynomials:

- Corresponding to variable x_i, where $i \in [n]$, define $Q_i(\mathbf{z})$ as:

$$Q_i(\mathbf{z}) := Q_{i,1}(\mathbf{z}) + Q_{i,2}(\mathbf{z}) + Q_{i,3}(\mathbf{z}), \text{ where}$$
$$Q_{i,1}(\mathbf{z}) := x_0^{(3i-2)d_1} x_i^{d_2},\ Q_{i,2}(\mathbf{z}) := x_0^{(3i-1)d_1}(y_i + x_i)^{d_3} \text{ and } Q_{i,3}(\mathbf{z}) := x_0^{3id_1}(y_i - x_i)^{d_3}.$$

- For the k^{th} clause, $k \in [m]$, define $R_k(\mathbf{z}) := x_0^{(3n+k)d_1} \prod_{j \in C_k} (y_j + (-1)^{a_{k,j}} x_j)^{d_4}$.

[17] Note that for f and g two homogeneous polynomials, $f(\mathbf{x}) = g(A\mathbf{x} + \mathbf{b})$ implies $f(\mathbf{x}) = g(A\mathbf{x})$, where $A \in \mathrm{GL}(|\mathbf{x}|, \mathbb{F})$ and $\mathbf{b} \in \mathbb{F}^{|\mathbf{x}|}$. Hence, it suffices to prove part 2 of Theorem 2 without translations.

[18] We assume, without loss of generality, that each clause of a 3-CNF has 3 distinct variables. This can be achieved by introducing extra variables for clauses with < 3 variables.

Define $s := 1 + n(3 + d_3) + m(d_4 + 1)^2$ and the polynomial f as:

$$f(\mathbf{z}) := x_0^{d_1} + \sum_{i=1}^{n} Q_i(\mathbf{z}) + \sum_{k=1}^{m} R_k(\mathbf{z}). \tag{1}$$

The following conditions are imposed on the d_i's:

$$d_1 \geq \max(s, d_2 + 1),\ d_2 \geq 2d_3,\ d_3 \geq m(d_4 + 1)^2 + 1,\ \text{and } d_4 \geq m. \tag{2}$$

Set $d_4 := m$, $d_3 := m(m+1)^2 + 1 = O(m^3)$, $d_2 = 2m(m+1)^2 + 2 = O(m^3)$ and $d_1 = 1 + n(4 + m(m+1)^2) + m(m+1)^2 = O(nm^3)$. Then $s = O(nm^3)$ and the d_i's satisfy the conditions of (2), under which the following observations hold.

▶ **Observation 27.** *For $i \in [n]$, $k \in [m]$, the polynomials $x_0^{d_1}$, $Q_{i,1}(\mathbf{z})$, $Q_{i,2}(\mathbf{z})$, $Q_{i,3}(\mathbf{z})$ and $R_k(\mathbf{z})$ are degree separated from one another. Also, $Q_i(\mathbf{z})$ is degree separated from $Q_j(\mathbf{z})$, for $i, j \in [n]$ and $i \neq j$. Similarly, $R_k(\mathbf{z})$ is degree separated from $R_l(\mathbf{z})$ for $k, l \in [m]$ and $k \neq l$.*

▶ **Observation 28.** *The degree of f is $(3n + m)d_1 + 3d_4 = (mn)^{O(1)}$, $\mathcal{S}(f(\mathbf{z})) = 1 + n(2d_3 + 3) + m(d_4 + 1)^3$ and $\mathrm{Supp}(f) = 7$.*

3.2 The forward direction

Proposition 29 shows how a satisfiable ψ implies the existence of an invertible A, such that $\mathcal{S}(f(A\mathbf{z})) \leq s$ by constructing A from a satisfying assignment $\mathbf{u} \in \{0,1\}^n$ of ψ.

▶ **Proposition 29.** *Let $\mathbf{u} \in \{0,1\}^n$ be such that $\psi(\mathbf{u}) = 1$. Then $\mathcal{S}(f(A\mathbf{z})) \leq s$ for A as:*

$$A : x_0 \mapsto x_0, x_i \mapsto x_i, y_i \mapsto y_i + (-1)^{u_i} x_i, \quad \forall i \in [n]. \tag{3}$$

Proof. It follows from the definition of f in (1), Observations 27 and 21 that

$$\mathcal{S}(f(A\mathbf{z})) = \mathcal{S}(A(x_0^{d_1})) + \sum_{i=1}^{n} \mathcal{S}(Q_i(A\mathbf{z})) + \sum_{k=1}^{m} \mathcal{S}(R_k(A\mathbf{z})).$$

Thus, it suffices to analyze the sparsity of $A(x_0^{d_1}), Q_i(A\mathbf{z})$'s and $R_k(A\mathbf{z})$'s. Now, $\mathcal{S}(A(x_0^{d_1})) = 1$ as $A(x_0^{d_1}) = x_0^{d_1}$. We now analyze $\mathcal{S}(Q_i(A\mathbf{z}))$ for $i \in [n]$. If $u_i = 0$, then

$$Q_{i,1}(A\mathbf{z}) = x_0^{(3i-2)d_1} x_i^{d_2},\ Q_{i,2}(A\mathbf{z}) = x_0^{(3i-1)d_1}(y_i + 2x_i)^{d_3} \text{ and } Q_{i,3}(A\mathbf{z}) = x_0^{3id_1} y_i^{d_3}.$$

If $u_i = 1$, then

$$Q_{i,1}(A\mathbf{z}) = x_0^{(3i-2)d_1} x_i^{d_2},\ Q_{i,2}(A\mathbf{z}) = x_0^{(3i-1)d_1} y_i^{d_3} \text{ and } Q_{i,3}(A\mathbf{z}) = x_0^{3id_1}(y_i - 2x_i)^{d_3}.$$

By Observation 23 (for linear forms in two variables over $\mathrm{char}(\mathbb{F}) = 0$ fields), if $u_i = 0$ then $\mathcal{S}(Q_{i,2}(A\mathbf{z})) = d_3 + 1$ and $\mathcal{S}(Q_{i,3}(A\mathbf{z})) = 1$ and, if $u_i = 1$ then $\mathcal{S}(Q_{i,2}(A\mathbf{z})) = 1$ and $\mathcal{S}(Q_{i,3}(A\mathbf{z})) = d_3 + 1$. In either case, by Observations 27 and 21,

$$\mathcal{S}(Q_i(A\mathbf{z})) = \mathcal{S}(Q_{i,1}(A\mathbf{z})) + \mathcal{S}(Q_{i,2}(A\mathbf{z})) + \mathcal{S}(Q_{i,3}(A\mathbf{z})) = d_3 + 3.$$

For the k^{th} clause, $k \in [m]$, the action of A on the corresponding polynomial R_k is:

$$R_k(A\mathbf{z}) = x_0^{(3n+k)d_1} \prod_{j \in C_k} (y_j + ((-1)^{a_{k,j}} + (-1)^{u_j}) x_j)^{d_4}.$$

As the multiplicands in $R_k(A\mathbf{z})$ do not share any variables, $\mathcal{S}(R_k(A\mathbf{z}))$ is the product of the sparsity of the multiplicands. Since $\psi(\mathbf{u}) = 1$, therefore in the k^{th} clause there exists $j \in C_k$ such that $a_{k,j} \neq u_j$. For that j, $(y_j + ((-1)^{a_{k,j}} + (-1)^{u_j})x_j)^{d_4} = y_j^{d_4}$. As at least one literal is true in every clause under $\mathbf{u}$, $\mathcal{S}(R_k(A\mathbf{z})) \leq (d_4+1)^2$ using Observation 23. Thus,

$$\begin{aligned}\mathcal{S}(f(A\mathbf{z})) &= \mathcal{S}(A(x_0^{d_1})) + \sum_{i=1}^{n} \mathcal{S}(Q_i(A\mathbf{z})) + \sum_{k=1}^{m} \mathcal{S}(R_k(A\mathbf{z})) \\ &\leq 1 + n(d_3+3) + m(d_4+1)^2 = s.\end{aligned}$$

◀

3.3 The reverse direction

Now, we show that $(f, s) \in$ ETsparse implies $\psi \in$ 3-SAT by showing that the permuted and scaled versions of the transform of (3) form all the viable sparsifying invertible linear transforms. This is where the constraints on the d_i's are used. So, let $A \in \mathrm{GL}(|\mathbf{z}|, \mathbb{F})$ be such that $\mathcal{S}(f(A\mathbf{z})) \leq s$. Lemma 30 shows that $A(x_0)$ is just a variable by leveraging $d_1 \geq s$.

▶ **Lemma 30.** *Without loss of generality,* $A(x_0) = x_0$.

The proof of Lemma 31 uses $d_2 \geq 2d_3$ while that of Lemma 32 uses $d_3 \geq m(d_4+1)^2 + 1$.

▶ **Lemma 31.** *For any invertible* A *and* $i \in [n]$*:*

$$\mathcal{S}(Q_i(A\mathbf{z})) = \mathcal{S}(Q_{i,1}(A\mathbf{z})) + \mathcal{S}(Q_{i,2}(A\mathbf{z})) + \mathcal{S}(Q_{i,3}(A\mathbf{z})) \geq d_3 + 3,$$

where Q_i, $Q_{i,1}$, $Q_{i,2}$ *and* $Q_{i,3}$ *are as defined in Section 3.1. Equality holds if and only if* $A(x_i) = X_i$ *and* $A(y_i) = Y_i + (-1)^{u_i} X_i$ *for some scaled variables* $X_i, Y_i \in \mathbf{z}$ *and* $u_i \in \{0,1\}$*. Further, if* $\mathcal{S}(Q_i(A\mathbf{z})) \neq d_3 + 3$*, then* $\mathcal{S}(Q_i(A\mathbf{z})) \geq 2d_3 + 3$.

▶ **Lemma 32.** *Under the given* A, $\mathcal{S}(Q_i(A\mathbf{z})) = d_3 + 3$ *holds for all* $i \in [n]$.

Lemmas 30, 31 and 32 together show that A is a permuted scaled version of the transform of (3). We can assume A to be as described in (3) without loss of generality as permutation and non-zero scaling of variables do not affect the sparsity of a polynomial. Proposition 33 shows how a satisfying assignment can be formed from A using $d_4 \geq m$.

▶ **Proposition 33.** *For* A *as given in* (3), $\mathbf{u} = (u_1, \ldots, u_n)$ *is a satisfying assignment for* ψ.

Proof. Suppose not; then there exists $k \in [m]$ such that the k^{th} clause, $\vee_{j \in C_k}(x_j \oplus a_{k,j})$, in ψ is unsatisfied. Since this clause is unsatisfied, $u_j = a_{k,j}$ for all $j \in C_k$. Thus, $R_k(A\mathbf{z}) = x_0^{(3n+k)d_1} \prod_{j \in C_k}(y_j \pm 2x_j)^{d_4}$, where R_k is as defined in Section 3.1, and $\mathcal{S}(R_k(A\mathbf{z})) = (d_4+1)^3 \geq (m+1)(d_4+1)^2$ by Observation 23, the fact that $R_k(A\mathbf{z})$ is a product of linear forms not sharing variables, and the condition $d_4 \geq m$. By the definition of f and s in Section 3.1, Observations 27 and 21, it holds that

$$\begin{aligned}\mathcal{S}(f(A\mathbf{z})) &\geq \mathcal{S}(A(x_0)^{d_1}) + \sum_{i=1}^{n} \mathcal{S}(Q_i(A\mathbf{z})) + \mathcal{S}(R_k(A\mathbf{z})) \\ &\geq 1 + n(3+d_3) + m(d_4+1)^2 + (d_4+1)^2 = s + (d_4+1)^2 > s,\end{aligned}$$

a contradiction. Thus, $\mathbf{u}$ is a satisfying assignment for ψ. ◀

3.4 Homogeneous case: Proof of Part 2 of Theorem 2

We show a modification of the construction in Section 3.1 which, along with arguments similar to those in Sections 3.2 and 3.3, can be used to prove Theorem 2 for homogeneous polynomials over $\text{char}(\mathbb{F}) = 0$ fields. Because the polynomials are homogeneous, we cannot use degree separation like in the non-homogeneous case. Instead, we introduce a new variable y_0 and redefine $Q_i(\mathbf{z})$ and $R_k(\mathbf{z})$ of Section 3.1 so that:

1. Each polynomial is homogeneous with the same degree and is divisible by $x_0^{d_1}$ and $y_0^{d_1}$.
2. Each polynomial has distinct y_0-degree and if P_1 and P_2 are polynomials where P_1 has a higher y_0-degree than P_2, then the y_0-degree of P_1 is greater than the degree of any variable (except possibly x_0) in P_2.

The divisibility condition ensures that both x_0 and y_0 map to scaled variables (see Lemma 37 and its proof), and the second condition induces a degree separation of the polynomials with respect to y_0 (see Observation 34 and Lemma 38). Formally, let x_0, $\mathbf{x}$ and $\mathbf{y}$ be as defined in Section 3.1 and y_0 be a new variable. Define $\mathbf{z} := \mathbf{x} \sqcup \mathbf{y} \sqcup \{x_0\} \sqcup \{y_0\}$. Let $d_1, d_2, d_3, d_4 \in \mathbb{N}$. Consider the following polynomials:

1. For each variable x_i, $i \in [n]$, let $Q_i(\mathbf{z}) := Q_{i,1}(\mathbf{z}) + Q_{i,2}(\mathbf{z}) + Q_{i,3}(\mathbf{z})$, where

$$Q_{i,1}(\mathbf{z}) := x_0^{d_1(3n-3i+6)-d_2} y_0^{d_1(3i+m-2)} x_i^{d_2},\ Q_{i,2}(\mathbf{z}) := x_0^{d_1(3n-3i+5)-d_3} y_0^{d_1(3i+m-1)} (y_i + x_i)^{d_3}$$
$$Q_{i,3}(\mathbf{z}) := x_0^{d_1(3n-3i+4)-d_3} y_0^{d_1(3i+m)} (y_i - x_i)^{d_3}.$$

2. For the k^{th} clause, $k \in [m]$, let $R_k(\mathbf{z}) := x_0^{d_1(3n+m+4-k)-3d_4} y_0^{d_1 k} \prod_{j \in C_k} (y_j + (-1)^{a_{k,j}} x_j)^{d_4}$.

Define $s := 1 + n(d_3 + 3) + m(d_4 + 1)^2$ as before and impose the conditions of (2) on the d_i's. Using the conditions on the d_i's, it is easy to verify that the individual degrees of x_0 and y_0 in every polynomial defined above is at least d_1. Define f as:

$$f(\mathbf{z}) := x_0^{3d_1} y_0^{d_1(3n+m+1)} + \sum_{i=1}^{n} Q_i(\mathbf{z}) + \sum_{k=1}^{m} R_k(\mathbf{z}). \tag{4}$$

Clearly, f is a homogeneous polynomial of degree $(3n + m + 4)d_1$ and is divisible by $x_0^{d_1}$ and $y_0^{d_1}$. Further, we have the following observations under the constraints of (2).

▶ **Observation 34.** *For all $i \in [n]$, $k \in [m]$, the polynomials $x_0^{3d_1} y_0^{d_1(3n+m+1)}$, $Q_{i,1}(\mathbf{z})$, $Q_{i,2}(\mathbf{z})$, $Q_{i,3}(\mathbf{z})$ and $R_k(\mathbf{z})$ are degree separated with respect to y_0 from one another. Also, $Q_i(\mathbf{z})$ is degree separated with respect to y_0 from other $Q_j(\mathbf{z})$'s, for $i, j \in [n]$ and $i \neq j$. Similarly, $R_k(\mathbf{z})$ is degree separated with respect to y_0 from $R_l(\mathbf{z})$ for $k, l \in [m]$ and $k \neq l$.*

▶ **Observation 35.** $\mathcal{S}(f(\mathbf{z})) = 1 + n(2d_3 + 3) + m(d_4 + 1)^3$ *and* $\text{Supp}(f) = 8$.

The forward direction. Let $\mathbf{u} \in \{0,1\}^n$ be such that $\psi(\mathbf{u}) = 1$ and f, as described in (4), be the polynomial corresponding to ψ. Proposition 36 shows how to construct a sparsifying transform from $\mathbf{u}$. The proof of Proposition 36 is very similar to that of Proposition 29.

▶ **Proposition 36.** $\mathcal{S}(f(A\mathbf{z})) \leq s$ *where* $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$ *is as follows:*

$$A : y_0 \mapsto y_0,\ x_0 \mapsto x_0,\ x_i \mapsto x_i,\ y_i \mapsto y_i + (-1)^{u_i} x_i \quad i \in [n]. \tag{5}$$

The reverse direction. Let $\mathcal{S}(f(A\mathbf{z})) \leq s$ for some $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$. Lemma 37, the proof of which requires Claim 25, shows that $A(x_0)$ and $A(y_0)$ have only one variable. With this, Lemma 38 shows that the summands of $f(A\mathbf{z})$ must be degree separated with respect to y_0.

▶ **Lemma 37.** *Without loss of generality,* $A(x_0) = x_0$ *and* $A(y_0) = y_0$.

▶ **Lemma 38.** *For all* $i \in [n]$, $k \in [m]$, *the polynomials* $x_0^{3d_1} y_0^{d_1(3n+m+1)}$, $Q_{i,1}(A\mathbf{z})$, $Q_{i,2}(A\mathbf{z})$, $Q_{i,3}(A\mathbf{z})$ *and* $R_k(A\mathbf{z})$ *are degree separated from one another with respect to* y_0. *Also,* $Q_i(A\mathbf{z})$ *is degree separated with respect to* y_0 *from other* $Q_j(A\mathbf{z})$*'s, for* $i, j \in [n]$ *and* $i \neq j$. *Similarly,* $R_k(A\mathbf{z})$ *is degree separated with respect to* y_0 *from* $R_l(A\mathbf{z})$ *for* $k, l \in [m]$ *and* $k \neq l$.

$$\therefore \quad \mathcal{S}(f(A\mathbf{z})) = \mathcal{S}(x_0^{3d_1} y_0^{d_1(3n+m+1)}) + \sum_{i=1}^{n} \mathcal{S}(Q_i(A\mathbf{z})) + \sum_{k=1}^{m} \mathcal{S}(R_k(A\mathbf{z})), \text{ by Lemma 38.}$$

Lemmas 31 and 32 then hold with slight modification to their proofs, which, along with Lemma 37, show that A is a permuted scaled version of the transform of (5). Proposition 39 then holds and can be proven similarly to Proposition 33.

▶ **Proposition 39.** *For* A *as given in* (5), $\mathbf{u} = (u_1, \ldots, u_n)$ *is a satisfying assignment for* ψ.

▶ Remark 40. In the definition of f in Section 3.1 and this section, an extra summand is present besides Q_i's and R_k's. If $\text{char}(\mathbb{F}) = 0$, we can drop the summand by using Claim 25 and suitably modifying f, the current parameters and arguments to make the reduction work. We preserve the extra summand here for two reasons: One, for ease of understanding, because the definition of f in (1) is similar to that in (4). Two, in the non-homogeneous case, the extra summand proves useful in showing the reduction over finite characteristic fields, where Claim 25 does not hold, and thus it may also prove useful in showing the reduction for homogeneous polynomials over such fields.

▶ Remark 41. A feature of the reduction is that we can assume that the output polynomial is of the form $w^D f(\mathbf{z})$, where $w \notin \mathbf{z}$. This can be achieved by multiplying the output polynomial f of the current reduction by w^D, where D is greater than the sparsity parameter s in the reduction. If a proof of NP-hardness of hom-ΣΠΣ-MCSP has this feature, then it would imply NP-hardness of ΣΠΣ-MCSP (via a homogenization trick).

▶ Remark 42. We believe Claim 25 (used to prove Lemma 37) can be modified for finite characteristic fields, using which the argument in this section can be extended to such fields.

4 NP-hardness of α-gap-ETsparse

In this section, we prove parts 1 and 2 of Theorem 8 over $\text{char}(\mathbb{F}) = 0$ fields when no translations are involved. The full version contains the proofs of the lemmas in this section and that of the finite characteristic case with translations allowed for part 1 of Theorem 8.

Proof sketch. For a 3-CNF ψ, we carefully analyze the sparsity of the corresponding polynomial f, as defined in (1) with the constraints of (2) and (6), under all $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$. For $\psi \in \overline{\text{3-SAT}}$, Lemma 43 shows lower bounds on $\mathcal{S}(f(A\mathbf{z}))$ for any $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$. For $\psi \in$ 3-SAT, by Proposition 29, there exists $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$ such that $\mathcal{S}(f(A\mathbf{z})) \leq s_0 := 1 + n(d_3 + 3) + m(d_4 + 1)^2$. Proposition 44 compares the sparsities for satisfiable and unsatisfiable ψ's and shows α-gap-ETsparse is NP-hard using Lemma 43 and the conditions in (6).

$$d_1 = d_2 + 1, \; d_2 = d_3^2 + 1, \; d_3 = m(d_4 + 1)^2 + 1, \; d_4 \geq 4mn. \tag{6}$$

▶ **Lemma 43.** *Let $\psi \in \overline{\text{3-SAT}}$, f be as defined in (1) corresponding to ψ and $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$.*
1. *If $A(x_0)$ is a linear form in at least 2 variables, $\mathcal{S}(f(A\mathbf{z})) \geq d_1 + 1$.*
2. *If A is not as in item 1 and $A(x_j)$ is a linear form in at least 2 variables for some $j \in [n]$, then $\mathcal{S}(f(A\mathbf{z})) \geq d_2 + 1$.*
3. *If A is not as in items 1 and 2 and $\mathcal{S}(A(y_j + x_j)) \geq 3$ or $\mathcal{S}(A(y_j - x_j)) \geq 3$ for some $j \in [n]$, then $\mathcal{S}(f(A\mathbf{z})) \geq \frac{d_3^2+3d_3+2}{2}$.*
4. *If A is not of the form described in the previous three cases, then $\mathcal{S}(f(A\mathbf{z})) \geq (d_4+1)^3$.*

▶ **Proposition 44.** *α-gap-ETsparse is NP-hard for s-sparse polynomial inputs over $\mathbb{F}$ and $\alpha = s^{1/3-\epsilon}$, where $\epsilon \in (0, 1/3)$ is an arbitrary constant.*

Proof. If $\psi \in$ 3-SAT, then $\mathcal{S}(f(A\mathbf{z})) \leq s_0$ where A is as described in (3). If $\psi \in \overline{\text{3-SAT}}$, then it follows from Lemma 43 that for any $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$:

$$\mathcal{S}(f(A\mathbf{z})) \geq \min\left(d_1 + 1, d_2 + 1, \frac{d_3^2 + 3d_3 + 2}{2}, (d_4+1)^3\right).$$

The constraints imposed in (6) ensure that $(d_4+1)^3$ is the minimum. As $d_3 = m(d_4+1)^2+1$, therefore $s_0 = 1 + n(d_3+3) + m(d_4+1)^2 \leq 3nd_3 = 3mn(d_4+1)^2 + 3n \leq 4mn(d_4+1)^2$. Thus, the gap in the sparsities of the YES instances and the NO instances is

$$\frac{(d_4+1)^3}{s_0} \geq \frac{(d_4+1)^3}{4mn(d_4+1)^2} = \frac{d_4+1}{4mn}.$$

Also, as $d_4 \geq 4mn$, $\mathcal{S}(f) = s \leq 2m(d_4+1)^3 \implies d_4 + 1 \geq (\frac{s}{2m})^{1/3}$. Then, the gap is

$$\frac{(d_4+1)^3}{s_0} \geq \frac{d_4+1}{4mn} \geq \frac{s^{1/3}}{2^{1/3}4m^{4/3}n}.$$

Let $\epsilon \in (0, 1/3)$ be an arbitrary constant. The parameter d_4, which determines s, can be chosen a sufficiently large polynomial function in m and n such that $2^{1/3}4m^{4/3}n \leq s^{\epsilon}$. Hence, the gap is at least $s^{1/3-\epsilon}$. Thus, 3-SAT reduces to α-gap-ETsparse for $\alpha = s^{1/3-\epsilon}$. ◀

Homogeneous polynomials over $\text{char}(\mathbb{F}) = 0$ fields. We now consider the polynomial f as defined in (4) for ψ with the constraints of (6). For $\psi \in$ 3-SAT, $\mathcal{S}(f(A\mathbf{z})) \leq s_0$ where A is as described in (5) and s_0 is as defined earlier. For $\psi \in \overline{\text{3-SAT}}$, Lemma 45, proved using Claim 25, shows lower bounds on $\mathcal{S}(f(A\mathbf{z}))$, for all $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$. Proposition 46 proves α-gap-ETsparse is NP-hard using Lemma 45 and has the same proof as Proposition 44.

▶ **Lemma 45.** *Let $\psi \in \overline{\text{3-SAT}}$, f be as defined in (4) corresponding to ψ and $A \in \text{GL}(|\mathbf{z}|, \mathbb{F})$.*
1. *If $A(x_0)$ or $A(y_0)$ is a linear form in at least 2 variables, then $\mathcal{S}(f(A\mathbf{z})) \geq d_1 + 1$.*
2. *If A is not as in item 1 and if $A(x_j)$ is a linear form in at least 2 variables for some $j \in [n]$, then $\mathcal{S}(f(A\mathbf{z})) \geq d_2 + 1$.*
3. *If A is not as in items 1 and 2 and $\mathcal{S}(A(y_j + x_j)) \geq 3$ or $\mathcal{S}(A(y_j - x_j)) \geq 3$ for some $j \in [n]$, then $\mathcal{S}(f(A\mathbf{z})) \geq \frac{d_3^2+3d_3+2}{2}$.*
4. *If A is not of the form described in the previous three cases, then $\mathcal{S}(f(A\mathbf{z})) \geq (d_4+1)^3$.*

▶ **Proposition 46.** *Let $\text{char}(\mathbb{F}) = 0$. Then, α-gap-ETsparse is NP-hard for s-sparse homogeneous polynomial inputs over $\mathbb{F}$ and $\alpha = s^{\frac{1}{3}-\epsilon}$, where $\epsilon \in (0, \frac{1}{3})$ is an arbitrary constant.*

▶ Remark 47. The proof of Lemma 45 uses Claim 25, which works over $\text{char}(\mathbb{F}) = 0$ fields. We believe that Claim 25 can be modified for finite characteristic fields, using which the argument in this section can be extended over such fields.

5 NP-hardness of ETsupport

In this section, we prove Theorem 16 for characteristic 0 fields. The full version contains the proofs of the lemmas and the reduction for the finite characteristic case.

Proof sketch. We map ψ, a 3-CNF, to a polynomial f, which is the sum of degree separated polynomials with at least one polynomial of support $\sigma+1$ (σ is a constant integer) and the rest of support σ. As the summands are degree separated, $\text{Supp}(f) = \sigma+1$ and for any invertible linear transform A, $\text{Supp}(A(f))$ is the maximum support size over all the transformed summands. Claim 26 is used to show $\psi \in$ 3-SAT iff there exists an invertible linear transform A, such that $\text{Supp}(A(f)) \leq \sigma$. Thus, the reduction also holds for $(\sigma+1)$-to-σ ETsupport.

5.1 Construction of f and σ

Let $\sigma \geq 6$ be an even integer constant and ψ be as denoted in Section 3.1. Assume $n \geq \sigma+4$ and that in the first clause of ψ all the variables are complemented.[19] Let $\mathbf{x} := \{x_1, \ldots, x_n\}$, $\mathbf{y} := \{y_1, \ldots, y_n\}$ and $\mathbf{z} := \{z_1, \ldots, z_{\sigma-5}\}$ and $\mathbf{w} := \mathbf{x} \sqcup \mathbf{y} \sqcup \mathbf{z}$. Consider the polynomials:

- First, introduce $\binom{n+\sigma-5}{\sigma}$ many monomials defined by the set

$$P := \{(w_{i_1} \cdots w_{i_\sigma})^\star \mid w_{i_1}, \ldots, w_{i_\sigma} \in \mathbf{z} \sqcup \mathbf{x} \text{ and are pairwise distinct}\}.$$

- Then, introduce $\binom{n}{\frac{\sigma}{2}}$ many monomials defined by the set

$$Q := \{((x_{i_1} y_{i_1}) \cdots (x_{i_{\frac{\sigma}{2}}} y_{i_{\frac{\sigma}{2}}}))^\star \mid i_1, \ldots, i_{\frac{\sigma}{2}} \in [n] \text{ and are pairwise distinct}\}.$$

- Let $R := \{R_k(\mathbf{w}) \mid k \in [m]\}$, where $R_k(\mathbf{w})$ is defined corresponding to the k^{th} clause as:

$$R_k(\mathbf{w}) := (\prod_{j \in C_k} (y_j - a_{k,j} x_j))^2 (z_1 \cdots z_{\sigma-5})^\star.$$

Define $f(\mathbf{w}) := \sum_{g \in P} g(\mathbf{w}) + \sum_{h \in Q} h(\mathbf{w}) + \sum_{k=1}^{m} R_k(\mathbf{w})$. The degrees, denoted by $\star$, are of form $\sigma + i$ where $i \in [N]$ and $N = \binom{n+\sigma-5}{\sigma} + \binom{n}{\sigma/2} + m$ to ensure all polynomials in $P \sqcup Q \sqcup R$ are degree separated with degrees $\geq \sigma+1$. Based on this, Observation 48 holds.

▶ **Observation 48.** *$\mathcal{S}(f(\mathbf{w})) = O(n^\sigma + m)$ and $\text{Supp}(f(\mathbf{w})) = \sigma+1$.*

5.2 The forward direction

Proposition 49 shows how a satisfying assignment for ψ implies the existence of an invertible A, such that $\text{Supp}(f(A\mathbf{w})) = \sigma$ by constructing A from the satisfying assignment.

▶ **Proposition 49.** *Let $\psi \in$ 3-SAT with $(u_1, \ldots, u_n) \in \{0,1\}^n$ a satisfying assignment. Then, $\text{Supp}(f(A\mathbf{w})) = \sigma$, where the transform A is defined as*

$$A : z_j \mapsto z_j,\ x_i \mapsto x_i,\ y_i \mapsto y_i + (1-u_i)x_i \quad i \in [n], j \in [\sigma-5]. \tag{7}$$

[19] To achieve $n \geq \sigma+4$, add fresh variables and clauses in these variables to ψ. To ensure that the first clause contains only complemented variables, every uncomplemented variable x in the first clause is replaced by $\neg x$ followed by complementing each occurrence of x in the remaining clauses of ψ.

Proof. As all polynomials in $P \sqcup Q \sqcup R$ are degree separated, analysing the action of A on individual polynomials suffices. For $g \in P$, $g(A\mathbf{w}) = g$. On each monomial of Q, A acts as:

$$A : ((x_{i_1}y_{i_1}) \cdots (x_{i_{\frac{s}{2}}}y_{i_{\frac{\sigma}{2}}}))^\star \mapsto ((x_{i_1})(y_{i_1} + (1-u_{i_1})x_{i_1}) \cdots (x_{i_{\frac{\sigma}{2}}})(y_{i_{\frac{\sigma}{2}}} + (1-u_{i_{\frac{s}{2}}})x_{i_{\frac{\sigma}{2}}}))^\star.$$

Under A, each monomial of Q has support σ by Claim 26. For $k \in [m]$, A acts on $R_k(\mathbf{w})$ as:

$$A : (\prod_{j \in C_k}(y_j - a_{k,j}x_j))^2 \cdot (z_1 \cdots z_{\sigma-5})^\star \mapsto (\prod_{j \in C_k}(y_j + (1-a_{k,j}-u_j)x_j)^2 \cdot (z_1 \cdots z_{\sigma-5})^\star.$$

If $a_{k,j} \neq u_j$, then $a_{k,j} = 1 - u_j$. Since ψ is satisfiable, therefore for all $k \in [m]$, $a_{k,j} \neq u_j$ for some $j \in C_k$. Hence, $\mathrm{Supp}(R_k(A\mathbf{w})) \leq (\sigma - 5) + 5 = \sigma$ for all $k \in [m]$. ◀

5.3 The reverse direction

Now, we show that if $\mathrm{Supp}(f(A\mathbf{w})) \leq \sigma$ for $A \in \mathrm{GL}(|\mathbf{w}|, \mathbb{F})$, then a satisfying assignment can be obtained for ψ. Lemmas 50 and 51, proved using Claim 26, together show that A is as:

$$A : z_j \mapsto z_j,\ x_i \mapsto x_i,\ y_i \mapsto y_i + c_i x_i \quad c_i \in \mathbb{F},\ j \in [\sigma - 5], i \in [n]$$

without loss of generality.[20] Proposition 52 constructs a satisfying assignment for ψ from A.

▶ **Lemma 50.** *If* $\mathrm{Supp}(f(A\mathbf{w})) \leq \sigma$*, then* $\forall w \in \mathbf{z} \sqcup \mathbf{x}$*,* $A(w) = W$*, for scaled variable* $W \in \mathbf{w}$*.*

▶ **Lemma 51.** *If* $\mathrm{Supp}(f(A\mathbf{w})) \leq \sigma$*, then* $A(x_i) = X_i$ *and* $A(y_i) = Y_i + c_i X_i$*, for scaled variables* $Y_i, X_i \in \mathbf{w}$*.*

▶ **Proposition 52.** *A satisfying assignment* $\mathbf{u}$ *for* ψ *can be constructed from* A*.*

Proof. The action of A on R_k, where $k \in [m]$, is:

$$(\prod_{j \in C_k}(y_j - a_{k,j}x_j))^2 \cdot (z_1 \cdots z_{\sigma-5})^\star \mapsto (\prod_{j \in C_k}(y_j + (c_j - a_{k,j})x_j))^2 \cdot (z_1 \cdots z_{\sigma-5})^\star.$$

Thus, $\mathrm{Supp}(R_k(A\mathbf{w})) \leq \sigma$ iff for some $j \in C_k$, $c_j = a_{k,j}$. By assumption $\mathrm{Supp}(R_k(A\mathbf{w})) \leq \sigma$ for all $k \in [m]$. Hence, for each $R_k(\mathbf{w})$, there exists $j \in C_k$ such that $c_j \in \{0, 1\}$. Construct $\mathbf{u} \in \{0,1\}^n$ by setting $u_j := 1 - c_j$, for appropriate $j \in C_k$ and the remaining u_i's to arbitrary values in $\{0, 1\}$. From the definition of $\mathbf{u}$, it follows that for all $k \in [m]$, there exists $j \in C_k$ such that $u_j \neq a_{k,j}$. As k is arbitrary, all clauses are satisfied. ◀

6 Conclusion

In this work, we show that ET for sparse polynomials is NP-hard. Particularly, we show the NP-hardness of MCSP for orbits of homogeneous sparse polynomials (a dense subclass of hom-ΣΠΣ circuits) over characteristic 0 fields. We also define a gap version of ET for sparse polynomials and show it is NP-hard, which implies the NP-hardness of $s^{\frac{1}{3}-\epsilon}$-factor approximation of the sparse-orbit complexity of s-sparse polynomials. Lastly, we show that ET for constant-support polynomials is NP-hard. In all three cases, we reduce 3-SAT to the respective problems. We end by listing some problems whose solutions we do not know:

[20] as permutation and non-zero scaling of variables do not affect the support.

1. **Hardness of ETsparse for constant degree polynomials:** In the reduction of Theorem 2, can the degree of the output polynomial be made constant? Currently, the degree is polynomial in the number of clauses and variables.
2. **Improving the gap in Theorem 8:** Can α-gap-ETsparse be shown NP-hard for $\alpha = s^{1-\epsilon}$, where the input polynomial has sparsity s and $\epsilon > 0$ is an arbitrary constant?
3. **Hardness of ETsupport for $\sigma = 2$:** Is checking if a given polynomial is in the orbit of a support-2 polynomial NP-hard? Theorem 16 shows ETsupport is NP-hard for $\sigma \geq 6$.
4. **Hardness of MCSP for hom-$\Sigma\Pi\Sigma$ circuits:** Is MCSP for hom-$\Sigma\Pi\Sigma$ circuits NP-hard?

Vital Edges for (s,t)-Mincut: Efficient Algorithms, Compact Structures, & Optimal Sensitivity Oracles

Surender Baswana
Department of Computer Science & Engineering, IIT Kanpur, India

Koustav Bhanja
Department of Computer Science & Engineering, IIT Kanpur, India

Abstract

Let G be a directed weighted graph on n vertices and m edges with designated source and sink vertices s and t. An edge in G is vital if its removal reduces the capacity of (s,t)-mincut. Since the seminal work of Ford and Fulkerson [CJM 1956], a long line of work has been done on computing the *most vital edge* and *all vital edges* of G. However, even after 60 years, the existing results are for either undirected or unweighted graphs. We present the following result for *directed weighted graphs* that also solves an open problem by Ausiello, Franciosa, Lari, and Ribichini [NETWORKS 2019].

1. **Algorithmic Results:** There is an algorithm that computes all vital edges as well as the most vital edge of G using $\mathcal{O}(n)$ maximum (s,t)-flow computations.

   Vital edges play a crucial role in the design of *sensitivity oracle* for (s,t)-mincut – a compact data structure for reporting (s,t)-mincut after insertion/failure of any edge. For directed graphs, the only existing sensitivity oracle is for unweighted graphs by Picard and Queyranne [MPS 1982]. We present the first and optimal sensitivity oracle for *directed weighted graphs* as follows.
2. **Sensitivity Oracles:**
   - **(a)** There is an optimal $\mathcal{O}(n^2)$ space data structure that can report an (s,t)-mincut C in $\mathcal{O}(|C|)$ time after the failure/insertion of any edge.
   - **(b)** There is an $\mathcal{O}(n)$ space data structure that can report the capacity of (s,t)-mincut after failure or insertion of any edge e in $\mathcal{O}(1)$ time if the capacity of edge e is known.

   A *mincut for a vital edge* e is an (s,t)-cut of the least capacity in which edge e is outgoing. For unweighted graphs, in a classical work, Picard and Queyranne [MPS 1982] designed an $\mathcal{O}(m)$ space directed acyclic graph (DAG) that stores and characterizes all mincuts for all vital edges. Conversely, there is a set containing at most $n-1$ (s,t)-cuts such that at least one mincut for every vital edge belongs to the set. We generalize these results for *directed weighted graphs* as follows.
3. **Structural & Combinatorial Results:**
   - **(a)** There is a set $\mathcal{M}$ containing at most $n-1$ (s,t)-cuts such that at least one mincut for every vital edge belongs to the set. This bound is tight as well. We also show that set $\mathcal{M}$ can be computed using $\mathcal{O}(n)$ maximum (s,t)-flow computations.
   - **(b)** We design two compact structures for storing and characterizing all mincuts for all vital edges – (i) an $\mathcal{O}(m)$ space DAG for *partial* and (ii) an $\mathcal{O}(mn)$ space structure for *complete* characterization.

To arrive at our results, we develop new techniques, especially a generalization of *maxflow-mincut* Theorem by Ford and Fulkerson [CJM 1956], which might be of independent interest.

1 Introduction

For any graph problem, there are edges whose removal affects the solution of the given problem. These edges are called *vital* edges for the problem. There has been extensive research on the vital edges for various fundamental problems – shortest paths/distance [32, 34, 23, 28, 19], minimum spanning trees [15, 26, 33], strongly connected components (SCC) [16]. The concept of vital edge for (s,t)-mincut has existed ever since the seminal work of Ford and Fulkerson [14] on maximum (s,t)-flow. In this article, for directed weighted graphs, we present the following two main results – (1) an efficient *algorithm* for computing all vital edges, and (2) optimal *sensitivity oracles* for (s,t)-mincut. The algorithm in (1) is the first nontrivial algorithm for computing all vital edges in directed weighted graphs, which also answers an open question in [3]. Our optimal sensitivity oracle in (2) is the first sensitivity oracle for directed weighted graphs in the area of minimum cuts. In order to arrive at these results, we present interesting *structural* & optimal *combinatorial* results on mincuts for vital edges. These results provide a generalization of the classical work of Picard and Queyranne [30] and the recent work of Baswana, Bhanja, and Pandey [4].

Let $G=(V,E)$ be a directed graph on $n=|V|$ vertices and $m=|E|$ edges. Each edge $e \in E$ has a capacity, denoted by $w(e)$, which is a positive real number. Let s be a designated source vertex and t be a designated sink vertex in G.

A set $C \subset V$ is said to be a cut if $C \neq \emptyset$. The outgoing edges from C are called *contributing* edges of C. The *capacity* of cut C, denoted by $c(C)$, is defined as the sum of the capacities of all contributing edges of C. A cut C is said to be an (s,t)-cut if $s \in C$ and $t \in \overline{C} = V \setminus C$. An (s,t)-cut C with the least capacity is called an (s,t)-*mincut*. We denote the capacity of (s,t)-mincut by f^*. The (s,t)-mincut of a graph is a fundamental concept in graph theory and is used to design efficient algorithms for numerous real-world problems [1]. Now we formally define the vital edges for (s,t)-micuts.

▶ **Definition 1** (vital edge). *An edge $e \in E$ is said to be a vital edge if the removal of e decreases the capacity of (s,t)-mincut in G. E_{vit} denotes the set of all vital edges in G.*

Observe that each edge that contributes to an (s,t)-mincut is definitely a vital edge. However, a vital edge might not necessarily contribute to any (s,t)-mincut (e.g., edge (v_1,v_4) in Figure 1)(i). An edge that is not vital is called a *nonvital* edge. At first glance, it may appear that we may remove all nonvital edges from the graph without affecting the (s,t)-mincut. But it is not true, as stated in the following note.

▶ Note 2. Although the removal of any single nonvital edge does not decrease the capacity of (s,t)-mincut, the removal of a set of nonvital edges might lead to the reduction in the capacity of (s,t)-mincut (e.g., edges (v_2,v_6) and (v_3,v_5) in Figure 1(i)).

The design of efficient algorithms for various problems [31, 35, 27, 29] related to vital edges started just a few years after the seminal work of Ford and Fulkerson [14]. The *vitality of an edge* e is the reduction in the capacity of (s,t)-mincut after the removal of edge e. Observe that one maximum (s,t)-flow computation is sufficient for computing the vitality of any edge. So, for computing all vital edges and their vitality, there is a trivial algorithm that requires $\mathcal{O}(m)$ maximum (s,t)-flow computations. An edge having the maximum vitality is

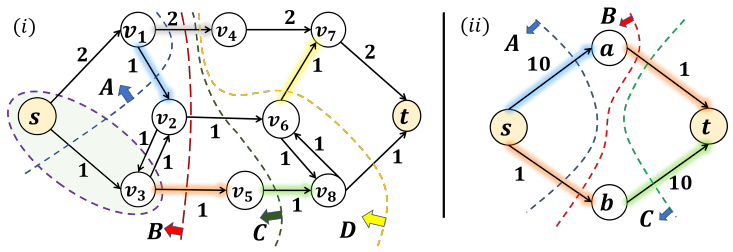

Figure 1 (i) Each mincut for vital edge (v_1, v_4) contains a nonvital edge (shown in the same color). (ii) A mincut cover fails to include mincut B for edges (a, t) and (s, b) if property $\mathcal{P}$ is not ensured in the construction. An edge and the mincut for the edge are shown in the same color.

said to be the *most vital edge*. Aneja, Chandrasekaran, and Nair [2] designed an algorithm that performs $\mathcal{O}(n)$ maximum (s,t)-flow computations to compute the most vital edge in an undirected graph. Ausiello, Franciosa, Lari, and Ribichini [3] showed that $\mathcal{O}(n)$ maximum (s,t)-flow computations are sufficient even for computing all vital edges and their vitality in an undirected graph. Unfortunately, even after 60 years, the following question has remained unanswered, which is also posed as an open problem in [3].

▶ **Question 1.** *For directed weighted graph G, does there exist an algorithm that can compute all vital edges along with their vitality using $\mathcal{O}(n)$ maximum (s,t)-flow computations?*

We can generalize the notion of (s,t)-mincut to *"mincut for an edge"* as follows.

▶ **Definition 3** (mincut for an edge). *Let e be a contributing edge of an (s,t)-cut C. C is a mincut for edge e if $c(C) \leq c(C')$ for each (s,t)-cut C' in which edge e appears as a contributing edge.*

Not only the study of mincuts for vital edges is important from a graph theoretic perspective but it also plays a crucial role in designing sensitivity oracle for (s,t)-mincuts – a compact data structure that efficiently reports an (s,t)-mincut after the failure/insertion of any edge.

The minimum cuts in a graph can be quite large in number – $\Omega(n^2)$ global mincuts [11], $\Omega(2^n)$ (s,t)-mincuts [30]. Interestingly, compact structures have been invented that compactly store and *characterize* various types of minimum cuts and cuts of capacity near minimum [13, 12, 30, 11, 4]. A compact structure G' is said to characterize a set $\mathcal{C}$ of cuts using a property $\mathcal{P}$ if the following holds. A cut C belongs to $\mathcal{C}$ if and only if cut C satisfies property $\mathcal{P}$ in graph G'. Specifically for (s,t)-mincuts in any directed weighted graph G, Picard and Queyranne [30] showed that there exists a directed acyclic graph (DAG), denoted by $\mathcal{D}_{PQ}(G)$, occupying $\mathcal{O}(m)$ space that compactly stores all (s,t)-mincuts. In addition, it provides the following characterization for each (s,t)-mincut.

An (s,t)-cut C is an (s,t)-mincut in G if and only if C is a 1-transversal cut in $\mathcal{D}_{PQ}(G)$.

An (s,t)-cut is said to be 1-transversal if its edges intersect any simple path at most *once*; e.g., cut A is 1-transversal but cut $\{s, v_3\}$ is not 1-transversal in Figure 1(i). The 1-transversality property also plays a crucial role in designing sensitivity oracles for (s,t)-mincuts in unweighted graphs [30, 4]. Observe that $\mathcal{D}_{PQ}(G)$ stores all mincuts for all edges that contribute to (s,t)-mincuts. However, edges contributing to (s,t)-mincuts may constitute a small subset of the set of all vital edges. Therefore, $\mathcal{D}_{PQ}(G)$ may fail to preserve all mincuts for all vital edges. This raises the following question.

▶ **Question 2.** *Does there exist a compact graph structure that stores and characterizes all mincuts for all vital edges in directed weighted graph G?*

Constructing the smallest set storing a minimum cut for every edge or every pair of vertices has been addressed extensively [22, 11, 9, 18, 20, 21] since the remarkable work of Gomory and Hu [18]. The smallest set of (s,t)-cuts that has at least one mincut for every edge is called a *mincut cover*. For directed unweighted graphs, Baswana, Bhanja, and Pandey [4], exploiting the DAG structure in [30], showed that there is a mincut cover of cardinality at most $n-1$ for all vital edges. For undirected weighted graphs, it is shown in [3] that there is a mincut cover of cardinality at most $n-1$ for all edges, and hence for all vital edges. Unfortunately, for directed weighted graphs, we establish that it is not possible to have a mincut cover of cardinality $o(n^2)$ for all edges (Theorem 37). Therefore, the following question naturally arises.

▶ **Question 3.** *Does there exist a mincut cover of cardinality $o(n^2)$ for all vital edges in directed weighted graph G?*

Design of sensitivity oracles have been studied quite extensively for various fundamental problems in both unweighted and weighted graphs – shortest paths/distances [8, 19], reachability [24, 10], strongly connected components [5, 16], all-pairs mincuts [6]. In weighted graphs, the concept of failures/insertions of edges is, interestingly, more generic. Here, the aim is to report the solution to the given problem given that the capacities of a *small* set of edges are decreased/increased by an amount $\Delta > 0$.

For (s,t)-mincuts in directed graphs, the existing sensitivity oracles are only for unweighted graphs and completely based on DAG $\mathcal{D}_{PQ}(G)$ [30], which dates back to 1982. Firstly, there is an $\mathcal{O}(m)$ space sensitivity oracle given in [30]. After the failure/insertion of an edge, the oracle takes $\mathcal{O}(1)$ time for reporting the capacity and $\mathcal{O}(m)$ time for reporting the corresponding (s,t)-mincut. Assuming the edge of the query exists in the graph, an $\mathcal{O}(n)$ space data structure can be designed [4]. This data structure can report the capacity of (s,t)-mincut in $\mathcal{O}(1)$ time and an (s,t)-mincut C in $\mathcal{O}(|C|)$ time after the failure/insertion of an edge. For various problems related to sensitivity analysis, it is also important to efficiently report a compact structure that stores and characterizes *all* (s,t)-mincuts after the failure of any edge, as shown in [30]. For unweighted graphs, DAG $\mathcal{D}_{PQ}$ for the resulting graph can be reported in $\mathcal{O}(m)$ time [30]. All these results crucially exploit the property that, in unweighted graphs, a mincut for a vital edge is also an (s,t)-mincut; hence, every contributing edge is also vital. However, for weighted graphs, this property no longer holds. In fact, nonvital edges may contribute to all mincuts for a vital edge (e.g., all mincuts $\{A,B,C,D\}$ for edge (v_1,v_4) in Figure 1(i)). So, the following question arises.

▶ **Question 4.** *For directed weighted graph G, does there exist*
1. *an $\mathcal{O}(n)$ space data structure that can report the capacity of (s,t)-mincut in $\mathcal{O}(1)$ time,*
2. *a compact data structure that can report an (s,t)-mincut C in $\mathcal{O}(|C|)$ time, and*
3. *a compact data structure that can report DAG $\mathcal{D}_{PQ}$ in $\mathcal{O}(m)$ time for the resulting graph after increasing/decreasing the capacity of any given edge?*

▶ Note 4. It is a simple exercise to design an $\mathcal{O}(n^2)$ space data structure and an $\mathcal{O}(n)$ space data structure that, after increasing the capacity of any edge, can report an (s,t)-mincut C in $\mathcal{O}(|C|)$ time and its capacity in $\mathcal{O}(1)$ time, respectively. Henceforth, while addressing sensitivity oracles, we focus only on handling the decrease in the capacity of an edge.

1.1 Our contribution and the organization of the results

We provide an affirmative answer to all the four questions raised above. We present basic notations and terminologies in the following section. Thereafter, we present a generalization of *maxflow-mincut* Theorem by Ford and Fulkerson [14] in Section 3. This property, which

might be of independent interest, plays a key role in establishing various results in this article. Mincut cover for all vital edges and sensitivity oracles for (s,t)-mincut are presented in Section 4 and 5 respectively. Algorithm for computing all vital edges is presented in Section 6. Compact structures for storing and characterizing all mincuts for all vital edges are described in Section 7. We present various lower bounds in Section 8.

2 Preliminaries

For any directed weighted graph H with a designated source vertex s and a designated sink vertex t, we define the following notations to be used throughout the article.

- $H \setminus \{e\}$: Graph after the failure of an edge e in H.
- value(f,H): value of an (s,t)-flow f in graph H. We denote value(f,G) by f^*.
- $f(e,H)$: value of (s,t)-flow f along edge e in H.
- $f_{in}(C,H)$: For any (s,t)-flow f and an (s,t)-cut C in H, $f_{in}(C,H)$ is the sum of the flow through all edges that leave $\overline{C}$ and enter C.
- $f_{out}(C,H)$: For any (s,t)-flow f and an (s,t)-cut C in H, $f_{out}(C,H)$ is the sum of the flow through all edges that leave C and enter $\overline{C}$.

Without causing any ambiguity, we use $f_{in}(C)$ and $f_{out}(C)$ to denote $f_{in}(C,G)$ and $f_{out}(C,G)$ respectively.

The following lemma can be proved easily using the conservation of an (s,t)-flow.

▶ **Lemma 5.** *For any (s,t)-cut C in H, $f_{out}(C,H) - f_{in}(C,H) = value(f,H)$.*

For a set $U \subseteq V$, $E_{vit}(U)$ denotes the set of vital edges whose both endpoints belong to U. We now introduce a notation that quantitatively captures the *vitality* of an edge.

- $w_{min}(e)$: the reduction in the capacity of (s,t)-mincut in G after the failure of edge e.

The following observation is immediate from Definition 1.

▶ **Observation 6.** *For any vital edge e, $w_{min}(e) > 0$.*

▶ **Definition 7** (A mincut cover for a set of edges)**.** *A set $\mathcal{A}$ consisting of (s,t)-cuts is said to be a mincut cover for a set of edges E' if, for each edge $e \in E'$, at least one mincut for e is present in $\mathcal{A}$, and $|\mathcal{A}|$ is the smallest.*

The following lemma provides a maximum (s,t)-flow based characterization for a vital edge.

▶ **Lemma 8.** *An edge e is vital if and only if $f(e) > 0$ in every maximum (s,t)-flow f in G.*

Lemma 8 can be proved easily using the strong duality between maximum (s,t)-flow and (s,t)-mincut [14].

▶ **Definition 9** (Edge-set of a cut)**.** *A cut C is said to* separate *a pair of vertices $u,v \in V$ if either $u \in C$ and $v \in \overline{C}$ or $v \in C$ and $u \in \overline{C}$. The edge-set of C is the set of all those edges whose endpoints are separated by C.*

For an undirected graph, the set of contributing edges of a cut is the edge-set of the cut. In a seminal work, Gomory and Hu [17] established the following two results for an undirected graph. (1) There is a set of $n-1$ cuts such that the cut of the least capacity separating each pair of vertices is present in this set. (2) Each of these $n-1$ cuts appears as a cut in a spanning tree on the vertex set V. This tree is widely-known as Gomory-Hu tree.

The construction of Gomory-Hu tree crucially exploits that the capacity of each cut in graph is defined as the sum of the capacities of all contributing edges of the cut. Suppose capacity of each cut is defined by any arbitrary real-valued function F. Even for this generic

setting, Cheng and Hu [9] showed that there exists a set consisting of $n-1$ cuts such that a cut of the least capacity (F-value) separating any pair of vertices is present in the set. Furthermore, Cheng and Hu [9] showed that all these cuts can be stored in a suitably augmented rooted full binary tree, called *ancestor tree* as follows. Every vertex of the given graph is mapped to a unique leaf node in the ancestor tree, and the cut of the least capacity separating any pair of vertices is stored at their lowest common ancestor (LCA) in the tree. The ancestor tree occupies $\mathcal{O}(n^2)$ space and, Cheng and Hu [9] also designed an efficient algorithm to construct the tree – It performs only $\mathcal{O}(n)$ calls to an algorithm that, given any pair of vertices, can report a cut of the least capacity separating them.

Ausiello, Franciosa, Lari, and Ribichini [3] showed that the ancestor tree of Cheng and Hu [9] can be constructed for (s,t)-cuts as well if function F is defined as follows.

$$\text{For a set } C \subset V,\ F(C) = \begin{cases} c(C), & \text{if } s \in C \text{ and } t \in \overline{C} \\ \infty, & \text{otherwise.} \end{cases} \tag{1}$$

This insight played a crucial role in the computation of all vital edges in an undirected graph using $\mathcal{O}(n)$ maximum (s,t)-flow computations [3].

3 A Generalization of FlowCut Property

Let $E_{min} \subseteq E$ be the set of all edges contributing to any (s,t)-mincut. Ford and Fulkerson [14] established a strong duality between (s,t)-mincut and maximum (s,t)-flow. Exploiting this, the following property provides a maximum (s,t)-flow based characterization for mincut for any edge $e \in E_{min}$.

FlowCut: *Let C be an (s,t)-cut and $e \in E_{min}$ is a contributing edge of C. C is a mincut for edge e if and only if for any maximum (s,t)-flow, each contributing edge of C is fully saturated and each incoming edge of C carries no flow.*

For directed weighted graphs, we know that E_{min} maybe only a proper subset of the set of all vital edges. We now present a generalization of FlowCut property that provides a maximum (s,t)-flow based characterization for each mincut $C(e)$, $\forall e \in E_{vit}$.

▶ **Theorem 10** (GenFlowCut). *Let C be an (s,t)-cut and a vital edge $e=(u,v)$ contributes to C in G. C is a mincut for e if and only if there is a maximum (s,t)-flow f such that*

1. *$f_{in}(C) = 0$.*
2. *e carries exactly $w_{min}(e)$ amount of (s,t)-flow and every other contributing edge e' in C is fully saturated, that is, $f(e') = w(e')$.*

Proof. Suppose C is a mincut for vital edge e in G. After the removal of edge e, the capacity of (s,t)-cut C is related to f^* as follows.

$$\text{In graph } G \setminus \{e\},\ c(C) = f^* - w_{min}(e) \tag{2}$$

Let G' be the graph obtained from G after reducing the capacity of edge e from $w(e)$ to $w_{min}(e)$. Therefore, using Equation 2, the capacity of C in G' is $(f^* - w_{min}(e)) + w_{min}(e) = f^*$. Let $\mathcal{C}_{u,v}$ be the set of all (s,t)-cuts that keep u on the side of s and v on the side of t. The capacity of each cut in $\mathcal{C}_{u,v}$ gets reduced by the same amount due to reduction in the capacity of e. Therefore, C is a mincut for edge e in G' as well. Hence the capacity of every cut belonging to $\mathcal{C}_{u,v}$ in G' is at least f^*. Capacity of any (s,t)-cut in G', that does not belong to $\mathcal{C}_{u,v}$, is at least f^* since it remains unaffected by the reduction in the capacity of

edge e. These facts imply that f^* is the capacity of (s,t)-mincut in G'. Thus, using the strong duality between maximum (s,t)-flow and (s,t)-mincut, it follows that there exists a maximum (s,t)-flow f in G' such that value$(f,G') = f^*$. Using Lemma 5 for C in G', we get the following equality.

$$f_{out}(C,G') - f_{in}(C,G') = f^* \tag{3}$$

It follows from the capacity constraint that $f_{out}(C,G') \leq c(C)$. So, Equation 3 implies that $f_{in}(C,G') \leq c(C) - f^*$. Since $c(C) = f^*$ in G' as shown above, we arrive at the following.

$$f_{in}(C,G') = 0 \qquad \text{and} \qquad f_{out}(C,G') = f^* \tag{4}$$

This implies that, in G', each outgoing edge of C is fully saturated and each incoming edge does not carry any amount of flow. f is also a valid maximum (s,t)-flow for graph G because f^* is the value of maximum (s,t)-flow in G and $f((u,v)) \leq w((u,v))$ in G. Therefore, it follows from Equation 4 that in graph G, $f_{in}(C) = 0$, each outgoing edge of C is fully saturated, and edge e carries exactly $w_{min}(e)$ amount of (s,t)-flow.

We now prove the converse part. Suppose there is a maximum (s,t)-flow in G such that each outgoing edge of C, except e, is fully saturated and each incoming edge carries no flow. Therefore, $c(C)$ in G is $f^* - w_{min}(e) + w(e)$. So, in graph $G \setminus \{e\}$, capacity of C is $f^* - w_{min}(e)$. Since e is a vital edge, it follows from definition that $f^* - w_{min}(e)$ is the capacity of (s,t)-mincut in $G \setminus \{e\}$. Therefore, C is an (s,t)-mincut in $G \setminus \{e\}$. Hence, each (s,t)-cut in G that keeps u on the side of s and v on the side of t has a capacity at least $f^* - w_{min}(e) + w(e)$. This implies that C is a mincut for edge e. ◀

▶ Remark 11. Theorem 10 crucially exploits Equation 2 which holds for vital edges only. Note that $w_{min}(e) = 0$ for a nonvital edge e. So, if C is a mincut for e, C might have capacity $> f^*$ even after removing nonvital edge e from G.

4 A Mincut Cover for All Vital Edges

For any subset $\mathcal{E}$ of vital edges, let $V(\mathcal{E})$ denote the smallest set of vertices such that for each edge $(u,v) \in \mathcal{E}$, both u and v belong to $V(\mathcal{E})$. We establish an upper bound on the cardinality of the mincut cover of $\mathcal{E}$ in terms of $|V(\mathcal{E})|$.

Let e be a vital edge, and let C be a mincut for e. In undirected graphs, recall that each edge belonging to the edge-set of C is a contributing edge of C. However, in directed graphs, there may exist edges incoming to C. Any such incoming edge, say e', is not a contributing edge of C, and certainly, any mincut for edge e' is different from C. Can e' be a vital edge? The following lemma answers this question in negation. It crucially exploits the properties of (s,t)-maxflow across C as stated in GenFlowCut Property (Theorem 10).

▶ **Lemma 12.** *If C is a mincut for a vital edge, each incoming edge of C must be a nonvital edge.*

Proof. Let e' be an incoming edge of C. It follows from Theorem 10(1) that there is a maximum (s,t)-flow f such that $f_{in}(C) = 0$. So e' does not carry any flow in maximum (s,t)-flow f. Hence, it follows from Lemma 8 that e' is not a vital edge in G. ◀

The following lemma, which can be seen as a corollary of Lemma 12, establishes that a mincut for a vital edge partitions all the vital edges into three sets.

▶ **Lemma 13.** *Let $G = (V, E)$ be a directed weighted graph with a designated source vertex s and a designated sink vertex t. Let $\mathcal{E}$ be a subset of vital edges. For any edge $e \in \mathcal{E}$, let C be a mincut for e. C partitions the entire set $\mathcal{E}$ into three subsets – (i) $\mathcal{E}_C$: edges that are contributing to C, (ii) $\mathcal{E}_L$: edges whose both endpoints belong to C, and (iii) $\mathcal{E}_R$: edges whose both endpoints belong to $\overline{C}$.*

Let $\mathcal{M}(\mathcal{E})$ denote the mincut cover for a subset $\mathcal{E}$ of vital edges. Suppose Lemma 13 additionally guarantees the following property.

$\mathcal{P}$: *For each vital edge $e' \in \mathcal{E}$ that contributes to C, C is a mincut for e' as well.*

Property $\mathcal{P}$ ensures that C is a mincut for all vital edges that belong to $\mathcal{E}_C$. This implies that $\mathcal{M}(\mathcal{E}_L) \cup \mathcal{M}(\mathcal{E}_R) \cup \{C\}$ is a mincut cover for $\mathcal{E}$ as well. Therefore, the cardinality of mincut cover for set $\mathcal{E}$ can be bounded as follows.

$$|\mathcal{M}(\mathcal{E})| \leq |\mathcal{M}(\mathcal{E}_L)| + |\mathcal{M}(\mathcal{E}_R)| + 1 \tag{5}$$

Let $\mathcal{N}(\mu)$ denote the cardinality of a mincut cover for any set $\mathcal{E}$ of vital edges with $\mu = |V(\mathcal{E})|$. Note that $\mathcal{E} = \emptyset$ implies $\mu = 0$, and $\mathcal{E} \neq \emptyset$ implies $\mu \geq 2$. Equation 5, Lemma 13, and Property $\mathcal{P}$ lead to the following recurrence for $\mathcal{N}(\mu)$.

$$\text{Base case:} \qquad \mathcal{N}(0) = 0.$$

$$\text{For any } \mu \geq 2, \qquad \mathcal{N}(\mu) \leq 1 + \mathcal{N}(\mu_1) + \mathcal{N}(\mu_2), \quad \text{where } \mu_1 = |V(\mathcal{E}_L)|,\ \mu_2 = |V(\mathcal{E}_R)| \tag{6}$$

Note that $\mu_1, \mu_2 < \mu$, and $\mu_1 + \mu_2 \leq \mu$. Using induction on μ, it is a simple exercise to show that $\mathcal{N}(\mu) \leq \mu - 1$ for all $\mu \geq 2$.

Though property $\mathcal{P}$ is crucially used in establishing an upper bound on the mincut cover of a set of vital edges, Lemma 13, in its current form, does not guarantee it. However, we can enforce $\mathcal{P}$ easily as follows. In Lemma 13, the mincut for edge e is of the least capacity among mincuts for all edges in $\mathcal{E}$.

Using Recurrence 6 for the entire set of vital edges, we get an upper bound of $n-1$ on the cardinality of the mincut cover for all vital edges in G. This leads to the following theorem that answers Question 3 in the affirmative.

▶ **Theorem 14** (Mincut Cover)**.** *For any directed weighted graph G on n vertices with a designated source vertex s and a designated sink vertex t, there exists a set $\mathcal{C}_{min}$ containing at most $n-1$ (s,t)-cuts such that, for any vital edge e in G, at least one mincut for edge e is present in set $\mathcal{C}_{min}$.*

The following note emphasizes the need of property $\mathcal{P}$ in establishing the upper bound derived above.

▶ Note 15. Selecting any arbitrary edge $e \in \mathcal{E}$ might skip some mincuts for vital edges. Refer to Figure 1(ii) on Page 3. The set of vital edges, denoted by $\mathcal{E}$, contains four vital edges (s,a), (s,b), (a,t), and (b,t). Suppose we first select vital edge (s,a) and mincut $A = \{s\}$ for edge (s,a). It follows from Lemma 13 that $\mathcal{E}$ is partitioned into $\mathcal{E}_L$, $\mathcal{E}_R$ and $\mathcal{E}_A$. Observe that $\mathcal{E}_L$ does not contain any vital edge, vital edges (a,t) and (b,t) belong to $\mathcal{E}_R$, and (s,b) belongs to $\mathcal{E}_A$. We now recurse on set $\mathcal{E} = \mathcal{E}_R$ and select the vital edge (b,t). Mincut $C = \{s,a,b\}$ partitions $\mathcal{E}$ into $\mathcal{E}_L$, $\mathcal{E}_R$, and $\mathcal{E}_C$. Observe that both $\mathcal{E}_L$ and $\mathcal{E}_R$ do not contain any vital edge, and vital edge (a,t) belongs to $\mathcal{E}_C$. The process terminates as $V(\mathcal{E}_L)$ and $V(\mathcal{E}_R)$ are empty. We get a pair of (s,t)-cuts A and C as mincut cover for $\mathcal{E}$. Unfortunately, it does not contain mincut $B = \{s,a\}$ for edges (a,t) and (s,b).

5 Optimal Sensitivity Oracles for (s,t)-mincut

Let $e = (u, v)$ be an edge in G, and we wish to determine the impact of the failure of e on (s, t)-mincut. We begin with a brief overview of $\mathcal{O}(n)$ space sensitivity oracle [4] for (s, t)-mincuts in unweighted graphs. By construction of $\mathcal{D}_{PQ}(G)$ [30], there is a mapping from the vertices of G to the nodes of $\mathcal{D}_{PQ}(G)$ such that the following assertion holds – u and v are mapped to the same node of $\mathcal{D}_{PQ}(G)$ if and only if there is no (s, t)-mincut in G that separates u and v. In $\mathcal{D}_{PQ}(G)$, each 1-transversal cut is an (s, t)-mincut in G. Exploiting this property, it is shown in [4] that there is an (s, t)-mincut to which edge (u, v) contributes if and only if the node containing u succeeds the node containing v in any topological ordering of $\mathcal{D}_{PQ}(G)$. If u and v are mapped to the same node of $\mathcal{D}_{PQ}(G)$, it follows that the mincut for edge (u, v) has a capacity strictly larger than that of the (s, t)-mincut. Therefore, if G is unweighted, the failure of edge (u, v) does not reduce the capacity of the (s, t)-mincut; so (u, v) is not a vital edge. Thus, the mapping from V to the nodes of $\mathcal{D}_{PQ}(G)$ along with its topological ordering serves as an $\mathcal{O}(n)$ space sensitivity oracle in unweighted graphs.

If G is weighted, it is still possible that though u and v mapped to the same node of $\mathcal{D}_{PQ}(G)$, yet the failure of edge (u, v) reduces (s, t)-mincut. In other words, if G is weighted, there may be many vital edges internal to the nodes of $\mathcal{D}_{PQ}(G)$ (refer to Figure 2). Thus $\mathcal{D}_{PQ}(G)$ fails to serve as sensitivity oracle for a weighted graph G; hence we need to explore the *structure* of cuts *internal* to a node of $\mathcal{D}_{PQ}(G)$.

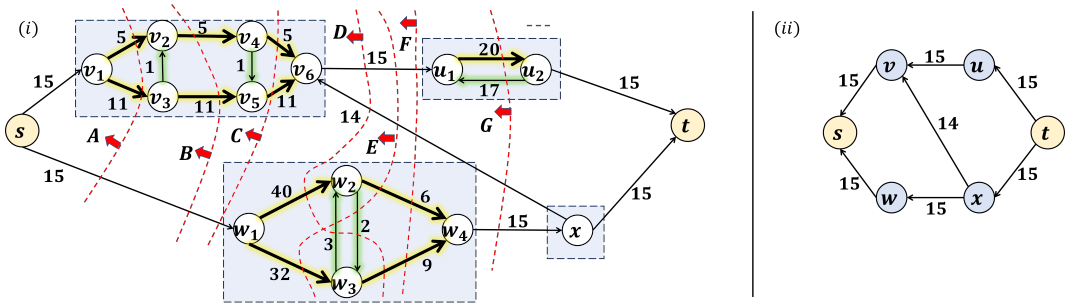

Figure 2 (i) A graph H and (ii) $\mathcal{D}_{PQ}(H)$. Thick edges in (i) represent the vital edges of H that are internal to the nodes of $\mathcal{D}_{PQ}(H)$. A mincut for them is represented by dashed curves.

Let $\textsc{cap}(e, \Delta)$ denote the query for reporting the capacity of (s, t)-mincut after reducing the capacity of $e \in E$ by Δ such that $0 \leq \Delta \leq w(e)$. We now address the design of a compact data structure that can efficiently answer query $\textsc{cap}(e, \Delta)$ for G.

Let us first consider only the set of vital edges. There may exist $\Omega(n^2)$ vital edges in a graph (refer to Figure 4(ii) on Page 17). Therefore, explicitly storing the capacity of a mincut for each vital edge would occupy $\Omega(n^2)$ space. To design an $\mathcal{O}(n)$ space data structure, we use the following lemma for vital edges. This lemma follows from Lemma 13 and the discussion we used for bounding the size of mincut cover for vital edges.

▶ **Lemma 16.** *Let $U \subseteq V$ and an edge $e \in E_{vit}(U)$. If mincut for e, say C, has the least capacity among the mincuts for all vital edges from $E_{vit}(U)$, then, for any edge $e' \in E_{vit}(U)$, either C is a mincut for e' or both endpoints of e' belong to $U \cap C$ or $U \cap \overline{C}$.*

Using Lemma 16, we design a divide and conquer based algorithm to build a data structure that compactly stores the capacity of mincut for each vital edge as follows.

Let e^* be an edge in $E_{vit}(V)$ such that the capacity of mincut for e^* is less than or equal to the capacity of mincut for each vital edge in G. Let C be a mincut for e^*. C serves as the mincut for each vital edge contributing to C. For the mincuts of the remaining vital edges, we recursively process $E_{vit}(V \cap C)$ and $E_{vit}(V \cap \overline{C})$. Refer to Algorithm 1 for the pseudocode of this recursive algorithm.

It can be observed that the data structure resulting from Algorithm 1 is a rooted binary tree. We refer to it as $\mathcal{T}_{vit}(G)$ henceforth. Its leaves are associated with disjoint subsets of the entire vertex set V – for each vertex $v \in V$, $\mathcal{L}(v)$ stores the pointer to the leaf to which v is mapped. Each internal node ν in $\mathcal{T}_{vit}(G)$ has the following three fields.

- $\nu.cap$ is the capacity of mincut for the vital edge selected during the recursive call in which node ν is created.
- $\nu.left$ is the left child of ν and $\nu.right$ is the right child of ν.

Algorithm 1 : TreeConstruction(V) computes $\mathcal{T}_{vit}(G)$.

```
1:  procedure TreeConstruction(U)
2:      Create a node ν;
3:      if E_vit(U) = ∅ then
4:          for each x ∈ U do L(x) ← ν;
5:          end for
6:      else
7:          Let C(e) denote a mincut for edge e;
8:          Select an edge e* ∈ E_vit(U) such that c(C(e*)) ≤ c(C(e')) ∀e' ∈ E_vit(U);
9:          Assign ν.cap ← c(C(e*));
10:         ν.left ← TreeConstruction(U ∩ C(e*));
11:         ν.right ← TreeConstruction(U ∩ C̄(e*));
12:     end if
13:     return ν;
14: end procedure
```

The following observation is immediate from the construction of $\mathcal{T}_{vit}(G)$.

▶ **Observation 17.** *Let ν be an internal node in $\mathcal{T}_{vit}(G)$ and C be the (s,t)-cut associated with node ν (chosen in Step 8 of Algorithm 1). For a vertex u, $\mathcal{L}(u)$ belongs to the subtree rooted at $\nu.left$ if and only if $u \in C$.*

Observe that $\mathcal{T}_{vit}(G)$ is a full binary tree with at most n leaves. So the number of internal nodes is at most $n-1$. Moreover, every internal node of $\mathcal{T}_{vit}(G)$ stores $\mathcal{O}(1)$ information. Hence, we can state the following theorem.

▶ **Theorem 18.** *Let $G = (V, E)$ be a directed weighted graph on $n = |V|$ vertices with designated source vertex s and designated sink vertex t. There is a rooted full binary tree occupying $\mathcal{O}(n)$ space that stores the capacity of mincut for each vital edge.*

Let $e = (x, y)$ be a query edge. If e is a vital edge, it follows from the construction of tree $\mathcal{T}_{vit}(G)$ in Theorem 18 that the LCA of $\mathcal{L}(x)$ and $\mathcal{L}(y)$ stores the capacity of mincut for (x, y). So, using the efficient data structure for LCA [7], it takes $\mathcal{O}(1)$ time to answer CAP(e, Δ) for any vital edge e. However, what if the query edge is a nonvital edge? Although there is no impact on (s,t)-mincut capacity due to the reduction in the capacity of a nonvital edge, tree $\mathcal{T}_{vit}(G)$ stores no information explicitly about nonvital edges. Therefore, in order to answer CAP(e, Δ) for any edge, it seems a classification of all edges as vital or nonvital is required. Unfortunately, any such explicit classification would require $\Omega(m)$ space, which is also trivial for answering query CAP as discussed above.

Interestingly, $\mathcal{T}_{vit}(G)$ can answer CAP(e, Δ) for any edge e without any such classification. This is because, as shown in the following lemma, it is already capable of classifying an edge to be vital or nonvital.

▶ **Lemma 19.** *Let $e = (x, y)$ be any edge in G such that $\mathcal{L}(x) \neq \mathcal{L}(y)$. Let ν be the* LCA *of $\mathcal{L}(x)$ and $\mathcal{L}(y)$ in $\mathcal{T}_{vit}(G)$, and let C be the (s,t)-cut associated with node ν in $\mathcal{T}_{vit}(G)$. Edge (x, y) is a nonvital edge if and only if exactly one of the following two conditions is satisfied.*

1. *$\mathcal{L}(x) \in \nu.right$ and $\mathcal{L}(y) \in \nu.left$.*
2. *$\mathcal{L}(x) \in \nu.left$, $\mathcal{L}(y) \in \nu.right$, and $c(C) - w(e) \geq f^*$.*

Proof. Suppose edge (x, y) is a nonvital edge. Observe that $\mathcal{L}(x)$ and $\mathcal{L}(y)$ belong to the subtree rooted at ν in $\mathcal{T}_{vit}(G)$ because ν is the LCA of $\mathcal{L}(x)$ and $\mathcal{L}(y)$. It follows from the construction of $\mathcal{T}_{vit}(G)$ (Algorithm 1) that edge (x, y) either contributes to C or is an incoming edge to C. Suppose (x, y) is a contributing edge to C. So using Observation 17, $\mathcal{L}(x) \in \nu.left$ and $\mathcal{L}(y) \in \nu.right$. If $c(C)$ falls below f^* upon removal of edge (x, y), (x, y) would be a vital edge by Definition 1. Hence, $c(C) - w(e) \geq f^*$. So condition (2) is satisfied. Suppose (x, y) is an incoming edge to C, that is, $x \notin C$ and $y \in C$. It follows from Observation 17 that $\mathcal{L}(x)$ must belong to the right subtree and $\mathcal{L}(y)$ must belong to the left subtree of ν. So condition (1) is satisfied.

We now prove the converse part. Suppose condition (1) is satisfied, that is, $\mathcal{L}(x) \in \nu.right$ and $\mathcal{L}(y) \in \nu.left$. Observation 17 implies that $x \in \overline{C}$ and $y \in C$. Hence, edge (x, y) is an incoming edge of C. It follows from the construction of $\mathcal{T}_{vit}(G)$ that C is a mincut for some vital edge. So, by Theorem 10(1), there exists a maximum (s,t)-flow f such that $f_{in}(C) = 0$. Hence $f(x, y) = 0$. So it follows from Lemma 8 that (x, y) is a nonvital edge. Suppose condition (2) is satisfied. Hence (x, y) is an outgoing edge of C. Assume to the contrary that e is a vital edge. It follows from the construction of $\mathcal{T}_{vit}(G)$ that C is a mincut for e. Since e is a vital edge, by Definition 1, $c(C) - w(e) < f^*$, a contradiction. ◀

For any edge $e \in E$ and $0 \leq \Delta \leq w(e)$, Algorithm 2 verifies conditions of Lemma 19 to answer query CAP(e, Δ) in $\mathcal{O}(1)$ time using $\mathcal{T}_{vit}(G)$. So we can state the following Theorem.

Algorithm 2 Reporting the capacity of (s,t)-mincut after decreasing the capacity of an edge.

```
1:  procedure CAP((x, y), Δ)
2:      if L(x)==L(y) then
3:          return f*
4:      else
5:          ν ← LCA of L(x) and L(y) in T_vit(G).
6:      end if
7:      NewCapacity ← ν.cap − Δ
8:      if (L(x) ∈ ν.left ∧ L(y) ∈ ν.right ) ∧ NewCapacity < f* then
9:          return NewCapacity.
10:     else
11:         return f*.
12:     end if
13: end procedure
```

▶ **Theorem 20** (Sensitivity Oracle for Reporting Capacity)**.** *Let G be a directed weighted graph on n vertices with a designated source vertex s and a designated sink vertex t. There is an $\mathcal{O}(n)$ space data structure that, given any edge $e \in E$ and a value Δ satisfying $0 \leq \Delta \leq w(e)$, can report in $\mathcal{O}(1)$ time the capacity of (s,t)-mincut after reducing the capacity of e by Δ.*

Reporting an (s,t)-mincut. An internal node, say ν, of $\mathcal{T}_{vit}(G)$ stores only the capacity of the mincut for a vital edge. We augment ν with a mincut for the edge that was picked by Algorithm 1 in Step 8. The size of the resulting data structure is $\mathcal{O}(n^2)$. Observe that the condition $\Delta \leq w(e)$ can be verified for any edge e in $\mathcal{O}(1)$ time if we store the capacity of all edges of G. This will require only additional $\mathcal{O}(m) = \mathcal{O}(n^2)$ space. So we can state the following theorem.

▶ **Theorem 21** (Sensitivity Oracle)**.** *Let G be a directed weighted graph on n vertices with a designated source vertex s and a designated sink vertex t. There is an $\mathcal{O}(n^2)$ space data structure that, given any edge e and any value $\Delta \geq 0$, can report*
1. *the capacity of (s,t)-mincut in $\mathcal{O}(1)$ time, and*
2. *an (s,t)-mincut C in $\mathcal{O}(|C|)$ time for the resulting graph*
3. *the DAG $\mathcal{D}_{PQ}$ occupying $\mathcal{O}(m)$ space in $\mathcal{O}(m)$ time (proof is in the full version)*

after reducing the capacity of the edge e by Δ.

▶ Remark 22. It is a simple exercise to show that our data structure in Theorem 21(1) and (2) can be extended to handle a vertex failure using the standard technique of vertex splitting.

Lower Bound. We complement the result in Theorem 21 by a matching lower bound, which holds even for undirected graphs as follows (refer to Section 8 for the proof).

▶ **Theorem 23.** *Any data structure for reporting the capacity of (s,t)-mincut after the failure of an edge in an (un)directed graph on n vertices with positive edge capacities must require $\Omega(n^2 \log\ n)$ bits of space in the worst case, irrespective of the query time.*

▶ Remark 24. The $\mathcal{O}(n)$ space upper bound in Theorem 20 does not violate the $\Omega(n^2)$ space lower bound in Theorem 23. This is because Theorem 20 assumes that the query edge e belongs to E and the reduction in capacity of e is at most $w(e)$. However, this assumption seems practically justified since, in real world, the capacity of an edge can decrease only if the edge *actually* exists, and furthermore, it can decrease by an amount at most the capacity of the edge.

Labeling Scheme. Let f be any function defined on the vertex/edge set of the graph. A labeling scheme of f assigns small labels to each vertex/edge of the graph in such a way that, for any given subset A of edges/vertices, $f(A)$ can be computed only by using the labels of vertices/edges in A. A labeling scheme of $\mathcal{O}(\log^2\ n + \log\ n \log\ W)$ bits can be designed for reporting capacity of (s,t)-mincut after decreasing capacity of any edge in G using Theorem 20 and a labeling scheme for LCA query [25]. Here W is the maximum capacity of any edge in G. The proof is in the full version.

6 An Algorithm for Computing All Vital Edges

The existing algorithms [2, 3] that compute the most vital edge or all vital edges in undirected graphs take *cut-based* approaches as follows. For computing the most vital edge in an undirected graph, Aneja, Chandrasekaran, and Nair [2] establish that there exists an (s,t)-cut such that the most vital edge is the maximum capacity edge among all the edges that contribute to the cut. Ausiello, Franciosa, Lari, and Ribichini [3] define function F on cuts as in Equation 1 in order to use the ancestor tree of Cheng and Hu [9]. To compute all vital edges efficiently in a directed weighted graph, we take a *flow-based* approach that analyzes flow along a set of edges in a maximum (s,t)-flow. We first classify all vital edges into two types based on the maximum flow that an edge can carry in any maximum (s,t)-flow.

A classification of vital edges. In graph G, there may exist multiple (s,t)-flows attaining value f^*. The flow along an edge may be different in these multiple maximum (s,t)-flows. A vital edge is a *tight* edge if it carries flow equal to its capacity in at least one maximum (s,t)-flow; otherwise, it is a *loose* edge.

Our algorithm for computing all vital edges makes use of the classification of vital edges, and employs two results that were derived for solving two seemingly *unrelated* problems.

To compute all the loose edges, we crucially exploit the following result on maximum (s,t)-flow, which has been used for solving *mincost maximum* (s,t)*-flow problem.*

▶ **Lemma 25** (Theorem 11.1 and Theorem 11.2 in [1]). *For any directed weighted graph G, there exists a maximum (s,t)-flow $f^{\#}$ such that the edges that carry nonzero flow but not fully saturated are at most $n-1$.*

For any maximum (s,t)-flow, by definition, the set of all loose edges is a subset of all edges that carry nonzero flow but are not fully saturated. So, by Lemma 25, the number of loose edges can be at most $n-1$. Moreover, there is an algorithm that, given any maximum (s,t)-flow, can compute $f^{\#}$ of Lemma 25 in $\mathcal{O}(mn)$ time [1]. As a result, all the loose edges of G can be computed using $\mathcal{O}(n)$ maximum (s,t)-flow computations.

Observe that the efficient computation of the set of loose edges crucially exploits the fact that there can be at most $n-1$ loose edges. However, there can be $\Omega(n^2)$ tight edges in a graph (refer to Figure 4(*ii*) on page 17). Hence, to compute all the vital edges, the main challenge arises in computing all the tight edges of G. We now state a property of tight edges that plays a crucial role in their efficient computation.

A property satisfied by tight edges

Let E_{min} be the set of all edges that contribute to (s,t)-mincuts. Set E_{min} is a subset of all the tight edges since all edges in E_{min} are fully saturated in every maximum (s,t)-flow. Exploiting the strong duality between maximum (s,t)-flow & (s,t)-mincut and Lemma 5, it can be observed that each edge $(u,v) \in E_{min}$ satisfies the following property. If C is any (s,t)-cut such that $v \in C$ and $u \in \overline{C}$, then $c(C)$ is strictly greater than f^*. The following lemma shows that this property is satisfied by each tight edge as well.

▶ **Lemma 26.** *Let $e=(u,v)$ be a tight edge. Let C be a mincut for edge e and $C_{v,u}$ be an (s,t)-cut of the least capacity that keeps v on the side of s and u on the side of t. Then, $c(C) < c(C_{v,u})$.*

Proof. Edge (u,v) is a tight edge, so by definition, there is a maximum (s,t)-flow f such that $f(e)$ is equal to $w(e)$. This would imply that $f_{in}(C_{v,u})$ is at least $w(e)$ since edge (u,v) is an incoming edge for cut $C_{v,u}$. It follows from Lemma 5 that $f_{out}(C_{v,u}) - f_{in}(C_{v,u}) = f^*$. Therefore, $f_{out}(C_{v,u}) - w(e) \geq f^*$. Since the capacity of an (s,t)-cut is an upper bound on the value of any outgoing flow of the (s,t)-cut, therefore, $f_{out}(C_{v,u}) \leq c(C_{v,u})$. Hence we arrive at the following inequality.

$$c(C_{v,u}) \geq f^* + w(e) \tag{7}$$

It follows from Theorem 10(2) that $w_{min}(e)$ is the minimum amount of flow that must pass through edge (u,v) to get a maximum flow of value f^*. Let f' be the value of maximum (s,t)-flow in graph $G \setminus \{e\}$. Thus we arrive at the following equality.

$$f^* = f^{'} + w_{min}(e) \tag{8}$$

We now add $(w(e) - w_{min}(e))$ on both sides of Equation 8 and get the following equation.

$$f^* + w(e) - w_{min}(e) = f^{'} + w(e) \tag{9}$$

It follows from Theorem 10(2) that $f^{'}$ is also equal to the sum of capacities of all edges contributing to C except edge (u, v). Therefore, $f^{'} + w(e)$ is equal to the capacity of C in G. So it follows from Equation 9 that $f^* + w(e) - w_{min}(e) = c(C)$. Since (u, v) is a vital edge, therefore, $w_{min}(e) > 0$ using Observation 6. Hence,

$$f^* + w(e) > c(C) \tag{10}$$

It follows from Inequality 7 and Inequality 10 that $c(C_{v,u}) > c(C)$. ◀

For any tight edge (u, v), let C be an (s, t)-cut of the least capacity that separates vertex u and vertex v. It follows from Lemma 26 that C is also a mincut for edge (u, v). So we can state the following theorem.

▶ **Theorem 27.** *Let G be a directed weighted graph with a designated source vertex s and a designated sink vertex t. For any tight edge $e = (u, v)$ in G, a mincut for edge e is identical to an (s, t)-cut of the least capacity that separates vertex u and vertex v.*

Algorithm for computing tight edges

For the given directed weighted graph G, we define function F as in Equation 1 and then compute the Ancestor tree of Cheng and Hu [9] for (s, t)-cuts. For each pair of vertices, $\mathcal{T}_{(s,t)}$ stores an (s, t)-cut of the least capacity separating them at their LCA. This tree, denoted by $\mathcal{T}_{(s,t)}$, can be built using $\mathcal{O}(n)$ maximum (s, t)-flow computations [9]. We augment $\mathcal{T}_{(s,t)}$ with a data structure for LCA queries [7].

To compute all tight edges, we process $\mathcal{T}_{(s,t)}$ and the edges of G as follows. Let (u, v) be an edge in G. We perform LCA query on $\mathcal{T}_{(s,t)}$ for u and v to get the (s, t)-cut, say C, of the least capacity that separates u and v. We determine whether C satisfies the following two conditions.

1. Edge (u, v) contributes to C.
2. $c(C) - w((u, v)) < f^*$

If both conditions are satisfied, by Definition 1, (u, v) is a vital edge. Observe that there may be vital edges that do not satisfy Condition (1); refer to Figure 3(i). However, it follows from Theorem 27 that each tight edge does satisfy these two conditions. After processing all edges of G, let S be the resulting set of vital edges that satisfy both these conditions. We eliminate from S all the loose edges to get all the tight edges.

▶ Remark 28. In an undirected graph, observe that a mincut for an edge (u, v) is always an (s, t)-cut of the least capacity that separates u and v. Therefore, computing all vital edges in an undirected graph amounts to just verifying condition (2) for each edge as shown by Ausiello, Lari, Franciosa, and Ribichini [3].

Thus we can state the following theorem.

▶ **Theorem 29.** *For any directed weighted graph G on n vertices with a designated source vertex s and a designated sink vertex t, there is an algorithm that computes all tight edges of G using $\mathcal{O}(n)$ maximum (s, t)-flow computations.*

Theorem 29 and the discussion on computing the loose edges lead to Theorem 30.

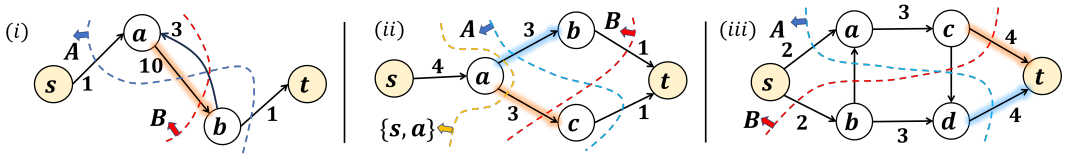

Figure 3 (i) A is the (s,t)-cut of least capacity that separates a and b. Edge (a,b) is a vital edge, and it is incoming to A. (ii) $\mathcal{D}_{vit}(G)$=G. $\{s,a\}$ is a 1-transversal cut, but not a mincut for any vital edge. (iii) mincuts A and B for vital edges (c,t) and (d,t), respectively, are not closed under union. Moreover, edge (b,a) (likewise edge (c,d)) contributes to A (likewise to B) and is incoming to B (likewise to A).

▶ **Theorem 30** (Computing All Vital Edges). *For any directed weighted graph on n vertices with a designated source vertex s and designated sink vertex t, there is an algorithm that computes all vital edges and their vitality using $\mathcal{O}(n)$ maximum (s,t)-flow computations.*

▶ Note 31. We present the following applications of our algorithm in Theorem 30 (refer to the full version).

1. Observe that data structure $\mathcal{T}_{(s,t)}$ also stores a mincut for every tight edge. Therefore, an (s,t)-mincut in graph $G\setminus\{e\}$ for every tight edge e can be computed using $\mathcal{O}(n)$ maximum (s,t)-flow computations. Moreover, since loose edges are at most $n-1$, therefore, using $\mathcal{O}(n)$ maximum (s,t)-flow computations, we can compute an (s,t)-mincut in graph $G\setminus\{e\}$ for every vital edge e of G.
2. Given a mincut for all vital edges, using Algorithm 1, the process of constructing $\mathcal{T}_{vit}(G)$ and the data structure in Theorem 21(2) requires $\mathcal{O}(m \log\ n + n^2)$ time. As a byproduct, data structure in Theorem 21(2) provides a mincut cover for all vital edges.
3. As stated in (2), we can construct $\mathcal{T}_{vit}(G)$ using $\mathcal{O}(n)$ maximum (s,t)-flow computations. Given any $k \in [m]$, using $T_{vit}(G)$ and a maxheap data structure, the k most vital edges can be reported in $\mathcal{O}(m + k \log\ k)$ time.

▶ Note 32. Given any edge e and its capacity $w(e)$, the data structure in Theorem 20 can be used to report the vitality of e in $\mathcal{O}(1)$ time by assigning $\Delta = w(e)$.

7 Compact Structures for all Mincuts for all Vital Edges

The set containing all (s,t)-mincuts satisfies two important properties – (i) closed under both intersection and union and (ii) an edge contributing to an (s,t)-mincut can never be an incoming edge to another (s,t)-mincut. These two properties are exploited crucially in the design of DAG structures for compactly storing and characterizing all (s,t)-mincuts [30, 4] using 1-transversal cuts. Unfortunately, none of these properties holds for the set of all mincuts for all vital edges (refer to Figure 3(iii)). This makes the problem of designing compact structures for mincuts for all vital edges challenging. We present two structures for storing and characterizing all mincuts for all vital edges – one is a single DAG that provides a *partial* characterization and the other consists of a set of $\mathcal{O}(n)$ DAGs that provides a complete characterization.

(a) An $\mathcal{O}(m)$ Space DAG for Partial Characterization. We first show that the approaches taken in [30, 4] are not sufficient for designing a compact structure for all mincuts for all vital edges. In particular, the resulting graph $Q'(G)$, obtained from G after applying the techniques from [30, 4], is still not acyclic. Moreover, a mincut for a vital edge can have

unbounded transversality (refer to the full version) in $Q'(G)$. It turns out that the source of this problem is the set of all edges that are contributing to a mincut for a vital edge as well as incoming to a mincut for another vital edge. The set of such edges is denoted by Γ-*edges*. Exploiting GenFlowCut property crucially, we show that all edges in Γ-edges are nonvital. Thereafter, counter intuitive to Note 2, we show that the graph obtained after the removal of all Γ-edges from G still preserves all (s,t)-mincuts of G, and provides a partial characterization for all mincuts for all vital edges as follows.

▶ **Theorem 33** (Partial Characterization). *For a directed weighted graph G on m edges with a designated source vertex s and a designated sink vertex t, there is an $\mathcal{O}(m)$ space directed acyclic graph $\mathcal{D}_{vit}(G)$ that preserves the capacity of (s,t)-mincut, and for each vital edge e in G, (1) Every mincut for edge e in G is a 1-transversal cut in $\mathcal{D}_{vit}(G)$ and (2) A mincut C for e in G appears as a relevant cut in $\mathcal{D}_{vit}(G)$, that is, $c(C) - w(e) < f^*$ in $\mathcal{D}_{vit}(G)$.*

▶ Note 34. Existing DAG structures for (s,t)-mincuts [30, 4] turn out to be just a special case of DAG $\mathcal{D}_{vit}(G)$ in Theorem 33. Moreover, $\mathcal{D}_{vit}(G)$ additionally guarantees the property (2) in Theorem 33, which does not hold in the existing DAGs [30, 4] (refer to full version).

(b) An $\mathcal{O}(mn)$ Space Structure for Complete Characterization. Although each mincut for every vital edge is a 1-transversal cut in $\mathcal{D}_{vit}(G)$, it is not necessary that each 1-transversal cut in $\mathcal{D}_{vit}(G)$ is a mincut for a vital edge (refer to Figure 3(ii)). Hence, $\mathcal{D}_{vit}(G)$ could provide only a partial characterization. Let $e = (u,v)$ be any vital edge, and H_e denote the graph obtained by adding two infinite weight edges, (s,u) and (v,t), in graph G. Observe that all mincuts for (u,v) are compactly stored in the DAG for (s,t)-mincuts [30] built on graph H_e. We denote this DAG by $\mathcal{D}_{PQ}(H_e)$. It can be seen that keeping $\mathcal{D}_{PQ}(H_e)$ for each vital edge e serves as a compact structure for storing all mincuts for all vital edges and characterizing them in terms of 1-transversal cuts. However, this structure may take $\mathcal{O}(m^2)$ space in the worst case. We present an $\mathcal{O}(mn)$ space structure $S_{vit}(G)$. This structure consists of $\mathcal{O}(n)$ DAGs for storing and characterizing all mincuts for all vital edges in terms of 1-transversal cuts. To build the structure $\mathcal{S}_{vit}(G)$, the main challenge turns out to be designing a compact structure for storing and characterizing all mincuts for all tight edges. It follows from Theorem 27 that any tight edge $e = (u,v)$ contributes to the (s,t)-cut of the least capacity separating u and v. Therefore, a solution to the following problem would suffice to overcome the challenge.

▶ **Problem 1.** *Given a directed weighted graph G with a designated source s and a designated sink t, build a compact structure that, for each pair of vertices a and b in G, stores and characterizes all the (s,t)-cuts of the least capacity that separate a and b in G.*

To solve Problem 1, we address the problem of designing a compact structure for storing and characterizing all Steiner (s,t)-mincuts for a given Steiner set, which is of independent interest.

Compact Structure for all Steiner (s,t)-mincuts. Let $S \subseteq V$ be a Steiner set. An (s,t)-cut C is a *Steiner (s,t)-cut* if $C \cap S$ and $\overline{C} \cap S$ are nonempty. A Steiner (s,t)-cut with the least capacity is a *Steiner (s,t)-mincut*. The main hurdle in designing a compact structure for Steiner (s,t)-mincuts is that, unlike (s,t)-mincuts, they are not closed under intersection/union. We overcome this hurdle by generalizing the *covering* technique from [4] to directed weighted graphs and obtain a structure occupying $\mathcal{O}(|S|m)$ space.

Finally, we design a hierarchy tree, which is a generalization of the hierarchy tree of [25], and augment it with the structure for Steiner (s,t)-mincuts. It leads to the following result.

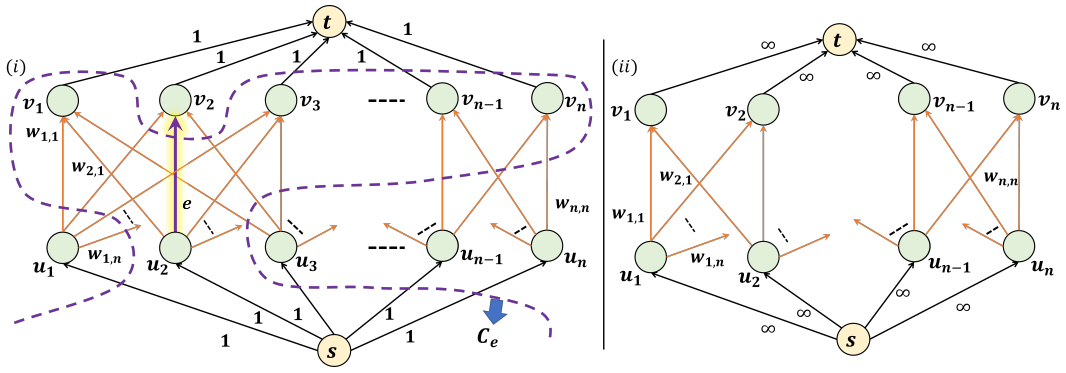

Figure 4 (i) Graph $\mathcal{G}$. The dashed curve represents the mincut for edge (u_2, v_2). (ii) Graph $G(M)$. Each edge (u_i, v_j), $1 \leq i, j \leq n$, is a vital as well as tight edge.

▶ **Theorem 35** (Complete Characterization). *For any directed weighted graph G on n vertices and m edges with a designated source vertex s and a designated sink vertex t, there is an $\mathcal{O}(mn)$ space structure $\mathcal{S}_{vit}(G)$ consisting of $\mathcal{O}(n)$ DAGs such that for any vital edge e,*
1. There exists at most two DAGs, $\mathcal{D}^s(e)$ and $\mathcal{D}^t(e)$, that store all mincuts for edge e.
2. An (s,t)-cut C in G is a mincut for edge e if and only if C is a 1-transversal cut in either $\mathcal{D}^s(e)$ or $\mathcal{D}^t(e)$ and e is a contributing edge of C.

▶ Note 36. Problem 1 is addressed in [4] for unweighted graphs and only for those pair of vertices for which the capacity of (s,t)-cut of the least capacity separating them is minimum+1. An $\mathcal{O}(mn)$ space structure is designed in [4] for this special case of Problem 1. Hence, Theorem 35 provides a generalization of the result in [4] for weighted graphs while matching the space bound. An important application of structure $\mathcal{S}_{vit}(G)$ is Theorem 21(3) (refer to the full version).

8 Lower Bounds

In this section, we first provide a lower bound on the worst case size of mincut cover for all edges. Later, we give a lower bound on the space for any data structure that can report the capacity of (s,t)-mincut after the failure of any edge in both undirected and directed graphs.

8.1 Mincut Cover for All Edges

In this section, we establish the following theorem.

▶ **Theorem 37.** *There exists a directed weighted graph $G = (V, E)$ on $n = |V|$ vertices such that the number of mincuts for all edges in G is $\Omega(n^2)$.*

In order to prove Theorem 37, we construct a graph $\mathcal{G}$ on $2n + 2$ vertices with a set of $\Omega(n^2)$ edges E' that has the following property. For each pair of edges $e, e' \in E'$, the capacity of mincut for edge e is different from the capacity of mincut for edge e' (refer to Figure 4(i)).

Construction of $\mathcal{G}$. The vertex set consists of two disjoint sets $A = \{u_1, u_2, \ldots, u_n\}$ and $B = \{u_1, u_2, \ldots, u_n\}$ of n vertices each, along with a source vertex s and a sink vertex t. The edges are defined as follows. There is an edge with unit capacity from vertex s to each vertex in A. Likewise, there is a unit capacity edge from each vertex in B to sink t. For each $u \in A$ and $v \in B$, there is an edge (u, v). Let E' be the set of all edges from A to B. Each edge in E' is assigned a unique capacity from $[n^2, 2n^2]$. It can be observed that $w(e_1) \neq w(e_2)$ for every pair of edges $e_1, e_2 \in E'$.

▶ **Lemma 38.** *For every pair of edges e_1 and e_2 from E', the capacity of mincut for e_1 is different from the capacity of mincut for e_2.*

Proof. Let $e = (u, v)$ be an edge from E'. Let us define an (s, t)-cut C_e in which edge e contributes. C_e keeps each vertex $x \in A \setminus \{u\}$ on the side of t. Similarly, C_e keeps each vertex $x \in B \setminus \{v\}$ on the side of s. Therefore, the contributing edges of (s, t)-cut C_e are edge e, the edges from s to each vertex $x \in A \setminus \{u\}$, and the edges from each vertex $x \in B \setminus \{v\}$ to t. Hence the capacity of C_e is $w(e) + (n-1) + (n-1) = w(e) + 2n - 2$. Any other (s, t)-cut in which edge e contributes must have at least one more contributing edge e' from E'. Since $w(e')$ is at least n^2, therefore, C_e is the mincut for edge e. For any other edge e'' from E', in a similar way, the capacity of the mincut for e'' is $w(e'') + 2n - 2$, which is different from the capacity of C_e since $w(e) \neq w(e'')$. This completes the proof. ◀

Since $|E'| = \Omega(n^2)$, it follows from Lemma 38 that graph $\mathcal{G}$ has $\Omega(n^2)$ different capacities of mincuts for edges in E'. This completes the proof of Theorem 37.

8.2 Fault-tolerant (s,t)-mincut

In this section, we provide a lower bound on the space for any data structure that can report the capacity of (s, t)-mincut after the failure of any edge. Let M be a $n \times n$ matrix where for any $i, j \in [n]$, $M[i, j]$ stores an integer in the range $[1, n^c]$ for some constant $c > 0$. Given any instance of the matrix M, we construct the following undirected graph $G(M)$ (refer to Figure 4(*ii*)).

Description of $G(M)$. The vertex set is defined as follows. There is a source vertex s and a sink vertex t. For all the n rows of matrix M, there is a set R of n vertices $\{u_1, u_2, \ldots, u_n\}$. Similarly, For all the n columns of matrix M, there is a set C of n vertices $\{v_1, v_2, \ldots, v_n\}$. For each $i, j \in [n]$, there is an edge e_{ij} of capacity $w_{i,j} = M[i, j]$ between vertex u_i and v_j. For each $i \in [n]$, there is an edge of infinite capacity between source s and vertex u_i and there is an edge of infinite capacity between vertex v_i and sink t. Let λ be the capacity of (s, t)-mincut in $G(M)$.

We now establish a relation between the graph $G(M)$ and matrix M in the following lemma.

▶ **Lemma 39.** *For any $i, j \in [n]$, the capacity of (s, t)-mincut in $G(M)$ after the failure of edge (u_i, v_j) is $\lambda - M[i, j]$.*

Proof. In graph $G(M)$, $C = \{s\} \cup R$ is the only (s, t)-cut of finite capacity. Therefore, C is the (s, t)-mincut in graph $G(M)$. Observe that only edges (u_i, v_j) for any $0 < i, j \leq n$ contribute to C. Hence $\lambda = \sum_{i,j \in [n]} w((u_i, v_j))$. Therefore, upon failure of edge $e_{ij} = (u_i, v_j)$, the reduction in the capacity of (s, t)-mincut is the same as $w(e_{ij})$, which is $M[i, j]$ as follows from the construction of $G(M)$ described above. ◀

Let $F(G(M))$ be any data structure that can report the (s, t)-mincut after the failure of an edge in the graph $G(M)$. We use the data structure $F(G(M))$ and Lemma 39 to report $M[i, j]$ for any $0 < i, j \leq n$ as follows.

return $(\lambda - \lambda')$ where λ' is the value returned by $F(G(M))$ after failure of edge (u_i, v_j).

Note that there are $2^{n^2 c \log\ n}$ different instances of the matrix M. It follows from Lemma 39 that for any pair of distinct instances of matrix M, the encoding of the corresponding data structures must differ. Therefore, there is an instance of matrix M for which the data structure $F(G(M))$ must occupy $\Omega(n^2 \log\ n)$ bits of space.

For directed graphs, a lower bound of $\Omega(n^2 \log\ n)$ bits of space can be achieved by orienting each undirected edge of $G(M)$ as follows. For each $i, j \in [n]$, orient edge (u_i, v_j) from vertex u_i to vertex v_j. For each $i \in [n]$, orient edge (s, u_i) from source s to vertex u_i. Similarly, for each $j \in [n]$, orient edge (v_j, t) from vertex v_j to sink t. The rest of the proof is the same as the case of undirected graphs. This completes the proof of Theorem 23.

By exploiting Theorem 37, the following data structure lower bound can also be established along similar lines to the proof of Theorem 23.

▶ **Theorem 40.** *Any data structure that, given a pair of vertices $\{u, v\}$, can report the capacity of an (s,t)-cut C of the least capacity such that $u \in C$ and $v \in \overline{C}$ in a directed weighted graph on n vertices must occupy $\Omega(n^2 \log\ n)$ bits of space.*

Abstract

Average linkage Hierarchical Agglomerative Clustering (HAC) is an extensively studied and applied method for hierarchical clustering. Recent applications to massive datasets have driven significant interest in near-linear-time and efficient parallel algorithms for average linkage HAC.

We provide hardness results that rule out such algorithms. On the sequential side, we establish a runtime lower bound of $n^{3/2-\epsilon}$ on n node graphs for sequential combinatorial algorithms under standard fine-grained complexity assumptions. This essentially matches the best-known running time for average linkage HAC. On the parallel side, we prove that average linkage HAC likely cannot be parallelized even on simple graphs by showing that it is CC-hard on trees of diameter 4. On the possibility side, we demonstrate that average linkage HAC can be efficiently parallelized (i.e., it is in NC) on paths and can be solved in near-linear time when the height of the output cluster hierarchy is small.

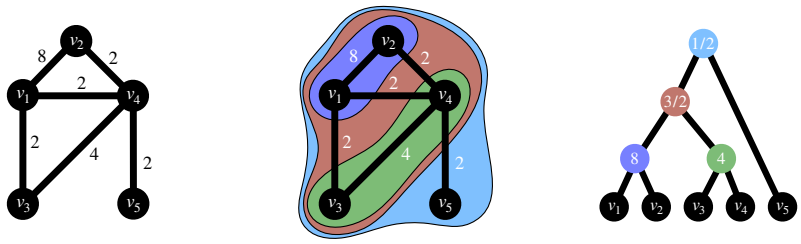
1 Introduction

Hierarchical clustering is a fundamental method for data analysis which organizes data points into a hierarchical structure so that similar points appear closer in the hierarchy. Unlike other common clustering methods, such as k-means, hierarchical clustering does not require the the number of clusters to be fixed ahead of time. This allows it to capture structures that are inherently hierarchical – such as phylogenies [18] and brain structure [11]. One of the most widely used and studied methods for hierarchical clustering is Hierarchical Agglomerative

Clustering (HAC) [22, 24, 37]. HAC produces a hierarchy by first placing each point in its own cluster and then iteratively merging the two *most similar* clusters until all points are aggregated into a single cluster. The similarity of two clusters is given by a *linkage function*. HAC is included in many popular scientific computing libraries such as scikit-learn [35], SciPy [40], ALGLIB [36], Julia, R, MATLAB, Mathematica and many more [33, 34]. This cluster hierarchy is often equivalently understood as a binary tree – a.k.a. dendrogram – whose internal nodes correspond to cluster merges.

The proliferation of massive datasets with billions of points has driven the need for more efficient HAC algorithms that can overcome the inherent $\Theta(n^2)$ complexity required to read all pairwise distances [16, 17, 29]. Finer-grained running time bounds for HAC were recently obtained by assuming that only $m = o(n^2)$ pairs of points have nonzero similarity, and analyzing the running time as a function of both n and m. This is a natural assumption in practice, as in large datasets of billions of datapoints, typically a small fraction of pairs exhibit nonnegligible similarity. In this case, the input to HAC is an edge-weighted graph, where each vertex represents an input point and each edge weight specifies the similarity between its endpoints. This approach is convenient for large-scale applications since (1) very large clustering instances can be compactly represented as sparse weighted graphs and (2) the running time of HAC can be decoupled from the running time of nearest-neighbor search.

A particularly common linkage function for HAC is *average linkage*, which both optimizes reasonable global objectives [31] and exhibits good empirical performance [5, 12, 20, 23, 27, 29, 30, 32, 44]. Here, the similarity of two clusters is the average edge weight between them (non-present edges are treated as having weight 0). In other words, average linkage HAC repeatedly merges the two clusters with the highest average edge weight between them (see Figure 1 for an example).



(a) Input G. **(b)** HAC Output. **(c)** Dendrogram.

Figure 1 An example of average linkage HAC run on an input graph G. Edges labeled with weights. 1a gives G. 1b gives the cluster hierarchy output by HAC. 1c gives the corresponding dendrogram with internal nodes labeled with the weight of their corresponding merge.

A natural algorithmic question then is how quickly can we solve average linkage HAC on n node and m edge graphs? Recent work has provided a partial answer to this basic question in sequential and parallel models of computation. In particular, [15] showed that average linkage HAC can be solved in $\tilde{O}(n\sqrt{m})$ time, thus providing a sub-quadratic time algorithm for sufficiently sparse graphs. A follow-up paper studied average linkage HAC in the parallel setting and showed that the problem is P-complete and so likely does not admit NC algorithms [16]. However, the P-completeness result of [16] holds for worst case graphs whereas typical applications of HAC are on highly structured graphs – namely those which are meant to capture relevant properties of an underlying metric – and so there is still hope for parallelizing average linkage HAC on more structured instances.

In fact, such structured instances of average linkage HAC are known to admit much faster algorithms in the sequential setting: the sequential algorithm of [15] implies that if the input graph is planar (or, more generally, minor-free) average linkage HAC can be solved in time $\tilde{O}(m)$. More generally, if each graph obtained by contracting all clusters at each step of average linkage HAC has $O(1)$ arboricity[1], then it is possible to solve average linkage HAC in time $\tilde{O}(m)$; it follows that average linkage HAC can be solved in sequential time $\tilde{O}(m)$ on trees or planar graphs. In light of these improved sequential results for highly structured graphs, it becomes natural to hope for efficient parallel algorithms on structured graphs such as low arboricity graphs or, even, just trees.

1.1 Our Contributions

In this work, we continue the line of work which studied the computational complexity of different variants of HAC [1, 15, 16, 19, 39] and perform a careful investigation into the complexity of average linkage HAC. In particular, we study HAC on n node and m edge graphs and investigate whether near-linear time algorithms, or more efficient parallel algorithms are possible, namely:

1. **Near-Linear Time Algorithms:** Can we improve over the best known $\tilde{O}(n\sqrt{m})$ upper bound for average linkage HAC and obtain near-linear time sequential algorithms?
2. **NC Algorithms:** are there $\mathsf{polylog}(n)$ depth parallel algorithms for average linkage HAC with $\mathsf{poly}(n)$ work for highly structured instances, e.g., trees, or minor-closed graphs?

We give both new lower bounds which (conditionally) rule out near-linear time and NC algorithms, and provide conditions under which these impossibility results can be bypassed.

First, we demonstrate that near-linear time algorithms are impossible under standard fine-grained complexity assumptions.

▶ **Theorem 1.** *If average linkage HAC can be solved by a combinatorial algorithm in $O(n^{3/2-\epsilon})$ time for any $\epsilon > 0$, then the Combinatorial Boolean Matrix Multiplication (Combinatorial BMM) Conjecture is false.*

Our reduction also implies a second (weaker) conditional lower bound that also holds for non-combinatorial algorithms (e.g., algebraic algorithms) based on the running time of matrix multiplication. In particular, for two $n \times n$ binary matrices, it is well known that matrix multiplication can be solved in time $O(n^\omega)$ where $2 \leq \omega < 2.3716$ [43]. In this setting, we obtain the following result:

▶ **Theorem 2.** *If average linkage HAC can be solved by an algorithm in $O(n^{\omega/2-\epsilon})$ time for some $\epsilon > 0$, then boolean matrix multiplication can be solved in $O(n^{\omega-\epsilon'})$ time for some $\epsilon' > 0$.*

Notably, Theorem 1 shows that the prior running time of $\tilde{O}(n\sqrt{m})$ of [15] is *optimal* up to logarithmic factors under standard fine-grained complexity assumptions, at least for graphs consisting of $O(n)$ many edges. We obtain this conditional lower bound by showing that a carefully constructed instance of HAC can be used to solve the triangle detection problem, which is sub-cubically equivalent to Boolean Matrix Multiplication [42]. We obtain a bound of (essentially) $\Omega(n^{3/2})$ since our reduction incurs a quadratic time and space blowup when transforming an input triangle detection instance to an instance of average linkage HAC.

[1] A graph has arboricity at most α if all of its edges can be covered by at most α trees.

We next turn to the parallel setting. Here, we show that HAC – *even on trees* – is unlikely to admit efficient parallel algorithms. More formally, we show that average linkage HAC on low diameter trees is as hard as any problem in the complexity class Comparator Circuit (CC) [13, 38]. It is believed that CC is incomparable with NC and that CC-hardness is evidence that a problem is not parallelizable [13, 28].

▶ **Theorem 3.** *Average linkage HAC is CC-hard, even on trees of diameter* 4*.*

We note that it is known that CC $\subseteq$ P and so the P-hardness of [16] already suggests the impossibility of efficient parallel algorithms on *general graphs*. However, our result suggests the impossibility of efficient parallel algorithms *even on very simple graphs* (trees of diameter 4). We obtain this result by reducing from the lexicographically first maximal matching (LFM Matching) problem and an intermediate problem which we call Adaptive Minimum, which captures some of what makes HAC intrinsically difficult to parallelize.

On the positive side, we demonstrate that average linkage HAC on path graphs is in NC, under the mild assumption that the aspect ratio is polynomial. While the class of path graphs is restrictive, even on paths average linkage is highly non-trivial and naively running HAC requires resolving chains of $\Omega(n)$ sequential dependencies. For example, consider a path of vertices $(v_1, v_2, \ldots, v_n)$ where the edge $\{v_i, v_{i+1}\}$ has weight $1 + i \cdot \epsilon$ for some small $\epsilon > 0$ and initially each vertex is in its own cluster. Initially, v_n's most similar neighbor is v_{n-1} and so v_n would like to merge with v_{n-1} but v_{n-1}'s most similar neighbor is v_{n-2} and so on. Thus, whether or not v_n gets to merge with v_{n-1} depends on the merge behavior of $\Theta(n)$ other clusters and so it is not at all clear that NC algorithms should be possible for this setting. Nonetheless, we show the following.

▶ **Theorem 4.** *Average linkage HAC on paths is in NC. In particular, there is an algorithm for average linkage HAC that runs in $O(\log^2 n \log\log n)$ depth with $O(n \log n \log\log n)$ work.*

The above algorithm leverages the fact that in average linkage HAC the maximum edge similarity monotonically decreases. In particular, it works in $O(\log n)$ phases where each phase consists of merges of equal similarity up to constants. The goal then becomes to efficiently perform merges until every edge is no longer within a constant of the starting maximum similarity of the phase. The starting point of the algorithm is to observe that $\Omega(n)$ sequential dependencies of clusters of equal size can be resolved efficiently in parallel in a phase by noting that in this phase only the odd-indexed edges merge in the chain. Thus, each edge can decide if it is odd-indexed in parallel by, e.g., using prefix-sum, which is well known to be solvable in linear work in NC.

For chains with clusters of general weights, we decompose dependency chains into short ($(O(\log n)$-length) subchains where resolving dependencies within the subchain must be done sequentially but in the current phase each subchain's merge behavior only depends on whether or not its closest neighboring subchains merges into it or not. Thus, each subchain can compute its merge behavior for these two cases and then, similar to the equal weights setting, we propagate merge behavior across subchains efficiently in parallel.

To complement our sequential lower bound with a positive result, we demonstrate that it is possible to achieve near-linear running time, provided the dendrogram has low height. Thus, if the output dendrogram is a relatively balanced tree, then near-linear time algorithms are possible.

▶ **Theorem 5.** *There is an implementation of the nearest-neighbor chain algorithm for average linkage HAC that runs in $O(m \cdot h \log n)$ time where h is the height of the output dendrogram.*

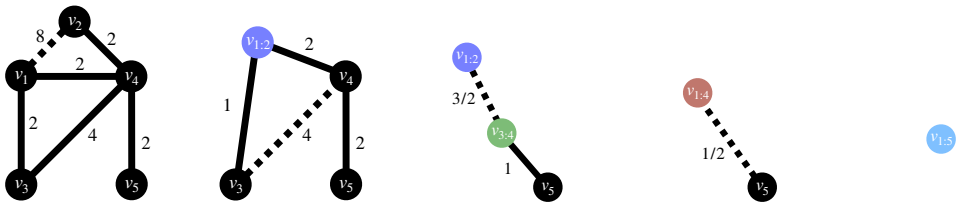
The above result is in fact obtained by a relatively simple (but to the best of our knowledge, new) analysis of *existing* classic HAC algorithms. In particular, we show that the nearest-neighbor chain [7, 21] and heap-based algorithms [27] for HAC, which were developed over 40 years ago achieve this bound. Due to space constraints, we prove Theorem 5 in the full version [6].

2 Preliminaries

The input to the HAC algorithm is an undirected weighted graph $G = (V, E, w)$, where $w : V \times V \to \mathbb{R}_+ \cup \{0\}$ is a function assigning nonnegative weights to the edges. For convenience we assume $w(x, y) = 0$ when $xy \notin E$. The vanilla version of average linkage HAC is given as Algorithm 1. It starts by putting each vertex in a cluster of size 1 and then repeats the following step. While there is a pair of clusters of positive similarity, find two most similar clusters and merge them together, that is, replace them by their union. The similarity between two clusters is the total edge weight between them divided by the product of the cluster sizes. We refer to this version as the *static graph* version, since the graph is not changed throughout the run of the algorithm.

Throughout the paper we usually work with a different (equivalent) way of presenting the same algorithm which is given as Algorithm 2. In this version we maintain a graph G whose vertices are clusters. The *size* of the vertex is the size of the cluster it represents. The *normalized* weight of an edge xy in G is $w(x, y)$ divided by the product of the sizes of x and y.

Whenever two clusters merge, their corresponding vertices are merged into one, i.e., the edge between them is contracted and the size of the new vertex is the sum of the sizes of the vertices that merged. In the following we sometimes say that a vertex x merges into vertex y. In this case we simply assume that the name of the resulting vertex is y and the size of y is increased by the size of x. See Figure 2.



(a) Input G. **(b)** 1 merge. **(c)** 2 merges. **(d)** 3 merges. **(e)** 4 merges.

Figure 2 An example of average linkage HAC run on an input graph G where we imagine we contract merged clusters. Intermediate vertices labeled with the vertices of G their corresponding cluster contains. Edges labeled with their weight and next merged edge is dashed.

The output of HAC is a *dendrogram* – a rooted binary tree representing the cluster merges performed by the algorithm. Every node of the dendrogram is a cluster built by the algorithm. There are exactly $|V|$ leaves corresponding to the single-element clusters that are formed in the beginning of the algorithm. Whenever two clusters C_1 and C_2 are merged, we add to the dendrogram a new node $C_1 \cup C_2$ whose children are C_1 and C_2. See Figure 1c for the dendrogram of Figure 2.

We use the classic multithreaded model [4, 9, 10] (formally, the MP-RAM [9]) to analyze the parallel algorithms. We assume a set of threads that share the memory. Each thread acts like a sequential RAM plus a `fork` instruction that forks two new child threads. When a

    Set $S(z) := S(x) + S(y)$

thread performs a fork, the two child threads can both start by running their next instructions, and the original thread is suspended until both children terminate. A computation starts with a single root thread and finishes when that root thread finishes. A parallel for-loop can be viewed as executing `fork`s for a logarithmic number of levels. A computation can thus be viewed as a DAG (directed acyclic graph). We say the *work* is the total number of operations in this DAG and *span (depth)* is equal to the longest path in the DAG. We note that computations in this model can be cross-simulated in standard variants of the PRAM model in the same work (asymptotically), and losing at most a single logarithmic factor in the depth [9].

3 An $\Omega(n^{3/2-\epsilon})$ Conditional Lower Bound for Average Linkage HAC

In this section, we show an $\Omega(n^{3/2-\epsilon})$ conditional lower bound on the time required to solve average linkage HAC on general weighted graphs. Specifically, we show this lower bound assuming the Combinatorial Boolean Matrix Multiplication (BMM) conjecture, a central conjecture in fine-grained complexity about the time required to multiply two $n \times n$ boolean matrices [2, 42].

▶ **Conjecture 6** (Combinatorial BMM). *Combinatorial algorithms cannot solve Boolean Matrix Multiplication in time $O(n^{3-\epsilon})$ for $\epsilon > 0$.*

We refer to [2] for an in-depth discussion of the somewhat informal notion of "combinatorial" algorithms and more on Conjecture 6 and its history.

In this work we will make use of an equivalent characterization of the BMM conjecture due to [42]. Specifically, [42] shows that the BMM problem is sub-cubically equivalent to the Triangle Detection problem: the problem of deciding whether or not an input graph G contains a triangle (i.e., cycle of 3 vertices). The following summarizes this result.

▶ **Theorem 7** (Theorem 1.3 of [42]). *Combinatorial algorithms cannot solve Triangle Detection in time $O(n^{3-\epsilon})$ for $\epsilon > 0$ unless Conjecture 6 is false.*

Thus, we give a reduction from Triangle Detection to average linkage HAC. Our reduction will quadratically increase the number of vertices of the input Triangle Detection instance, and therefore give an $\Omega(n^{3/2-\epsilon})$ lower bound for average linkage HAC. In the rest of this section, we show the following quadratic-blowup reduction from Triangle Detection to average linkage HAC.

▶ **Theorem 8.** *Given a Triangle Detection instance on graph G with t vertices and m edges, there is a reduction that runs in $O(t^2)$ time and constructs an instance of average linkage HAC on graph G' with $t + t^2$ vertices and $t^2 + m$ edges. Furthermore, given the sequence of merges performed by average linkage HAC on G', we can solve Triangle Detection on G in time $O(t^2)$.*

As a corollary of this reduction and Theorem 7, we obtain the following conditional lower-bound on the running time of HAC.

▶ **Theorem 1.** *If average linkage HAC can be solved by a combinatorial algorithm in $O(n^{3/2-\epsilon})$ time for any $\epsilon > 0$, then the Combinatorial Boolean Matrix Multiplication (Combinatorial BMM) Conjecture is false.*

As a second corollary, we obtain a conditional lower-bound in terms of the optimal running time of matrix multiplication for two $n \times n$ binary matrices. Matrix multiplication can be solved in time $O(n^\omega)$ where $2 \leq \omega < 2.3716$ [43]. An extensive line of research on matrix multiplication over the past thirty years has only improved ω from 2.376 to 2.3716, with the current state-of-the-art being due to a very recent result of Williams et al. [43] (for a subset of the historical advances in this area see, e.g., [3, 14, 26, 41]). The fastest known algorithm for triangle detection works by simply reducing the problem to matrix multiplication and therefore runs in $O(n^\omega)$ time. Surprisingly, despite triangle detection only returning a single bit (whether a triangle exists or not in G), the problem can be used to give a sub-cubic reduction for boolean matrix multiplication (where the output is n^2 bits). In particular, an algorithm for triangle detection running in time $O(n^{3-\delta})$ for some $\delta > 0$ yields an algorithm for matrix multiplication in time $O(n^{3-\delta/3})$ [42]. Using this fact, we can derive a conditional lower bound based on the value of ω.

▶ **Theorem 2.** *If average linkage HAC can be solved by an algorithm in $O(n^{\omega/2-\epsilon})$ time for some $\epsilon > 0$, then boolean matrix multiplication can be solved in $O(n^{\omega-\epsilon'})$ time for some $\epsilon' > 0$.*

An interesting open question is whether there are faster non-combinatorial algorithms that can leverage fast matrix multiplication or Strassen-like techniques and improve over the $\Omega(n^{3/2-\epsilon})$ barrier for combinatorial algorithms for average linkage HAC.

3.1 Reduction

We now prove Theorem 8 by giving a quadratic-time reduction from triangle detection to average linkage HAC. The reduction is loosely inspired by a recent lower-bound result for multidimensional range queries [25]. The input to the reduction is an unweighted graph G

on t vertices with m edges; the problem is to detect whether G has a triangle. To do this, we will construct a HAC instance on an edge-weighted graph G' with $t + t^2$ vertices and $t^2 + m$ edges. We will show that the specific way in which an exact HAC algorithm merges the edges in this instance reveals whether or not G has a triangle.

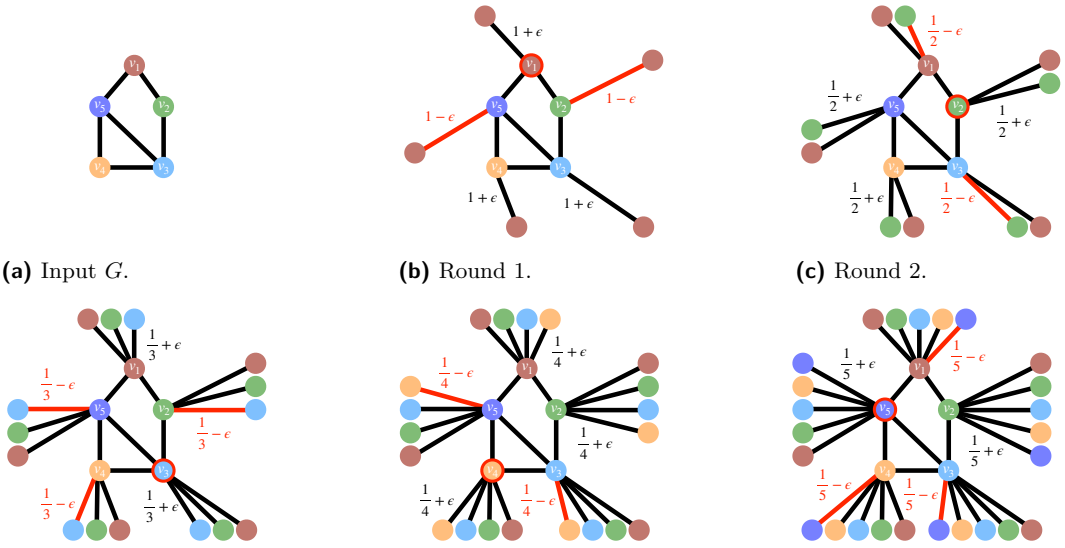
Constructing G'

Let $N_G(v)$ denote the neighbors of a vertex $v \in G$ (note that $v \notin N_G(v)$). We define G' as follows. We start by adding all vertices and edges from G, that is the t vertices $v_1, \ldots, v_t$ from G, including all of their incident edges $N_G(v_i)$. We call these the *core* vertices. The initail weight of the edges between any two core vertices is set to 1.

In addition to the core vertices, we add an additional t^2 *leaf* vertices that we connect to the core vertices with specific edge weights. We add the t^2 leaf vertices over a sequence of t *rounds* where the i-th round connects one new leaf vertex to every core vertex. The weights to the newly added leaves depend on the neighbors of the node v_i in the original graph G, and are set as follows:

(1) A core vertex v_j is connected to its new leaf with an edge of weight $(1/i) - \epsilon$ if $v_j \in N_G(v_i)$.
(2) A core vertex v_j is connected to its new leaf with an edge of weight $(1/i) + \epsilon$ if $v_j \notin N_G(v_i)$.

See Figure 3 for an illustration of our reduction.



(a) Input G. **(b)** Round 1. **(c)** Round 2.

(d) Round 3. **(e)** Round 4. **(f)** Round 5.

Figure 3 Our triangle detection reduction where we compute G' from G by adding $t = 5$ nodes over t rounds. 3f gives G'. Each node labeled according to its round and corresponding vertex in G. Edges labelled with their weight in the round they are added (edges of G have weight 1). For the ith round we highlight in red v_i and the edges added with weight $1/i - \epsilon$.

Running HAC on G'

Having defined G', let us consider the merges that the exact HAC algorithm will make on this instance. In this section, for succinctness we use *weight* to refer to the normalized (i.e., average linkage) weight. HAC will begin by merging the maximum weight edges. The maximum weight initially depends on the structure of $N_G(v_1)$. First, all core vertices that

are not in $N_G(v_1)$ will merge with their round 1 leaves (since these edges have weight $1+\epsilon$) increasing their cluster size to 2. This leaves all core vertices in $N_G(v_1)$. Any edge in G' between two such core vertices will have weight 1, and will be merged next. Crucially, any merge in this round with a weight of 1 indicates a triangle incident on v_1 since the two core vertex endpoints of the edge must be contained in $N_G(v_1)$, hence connected by edges to v_1. If no edges of weight 1 merge, the remaining leaves that we added to core vertices in $N_G(v_1)$ merge into their neighboring core vertex.

Assuming we did not merge any weight 1 edges in the first round, at this point the cluster size of each core vertex is 2, and so the weight of any edge originally in G (between two core vertices) will be $1/4$. The edge weights to leaves in round 2 will be $((1/2)\pm\epsilon)/2 = 1/4 \pm (\epsilon/2)$, which is larger than $1/4$ for edges of Type 2. Therefore, the same argument for how edges merge in round 1 can be inductively applied to the next round. The edge weights in round i for edges between core vertices will be $1/i^2$, and by the same argument as before, the Type 2 (Type 1) edges will be larger (smaller) by ϵ/i. As a result of how an exact average linkage HAC will merge the edges of G', we obtain the following lemma:

▶ **Lemma 9.** *Consider the sequence of merges performed by the HAC algorithm on G'. If the merge sequence consists of t^2 merges, which first merge all leaf vertices, and only then makes merges between core vertices, then G does not contain any triangles. If the merge sequence merges any edge between two core vertices in the first t^2 merges, then G contains a triangle.*

Completing the Reduction

We will now complete the proof of Theorem 8. Suppose we are given an instance of Triangle Detection on n vertices. Conjecture 6 implies that this instance cannot be solved by combinatorial algorithms in $O(n^{3-\epsilon})$ time for any $\epsilon > 0$.

Let the time complexity of HAC on a graph G with n vertices and m edges be $T_{\mathsf{HAC}}(n, m)$. Suppose HAC can be solved combinatorially in $O(n^{3/2-\epsilon})$ time. Given a Triangle Detection instance on n vertices we create a graph G' with $O(n^2)$ vertices and $O(n^2)$ edges, and run HAC on G'. The running time of the reduction is $O(n^2)$, and the running time of HAC on G' is $O((n^{2\cdot(3/2-\epsilon)}) = O(n^{3-2\epsilon})$, which will falsify Conjecture 6 by Theorem 7. Thus, conditional on Conjecture 6, there is no algorithm for HAC running in time $T_{\mathsf{HAC}}(n, m) = O(n^{3/2-\epsilon})$ for any constant $\epsilon > 0$, completing the proof of Theorems 8 and 1. The same argument, under the assumption that triangle detection cannot be solved in $O(n^{\omega-\epsilon})$ time for any constant $\epsilon > 0$ implies Theorem 2.

4 Average Linkage HAC is Hard to Parallelize Even on Trees

In this section we prove that average linkage HAC is likely hard to parallelize by showing it is CC-hard even on low depth trees. We begin with some preliminaries. The formal definition of CC-hardness we will use is as follows.

▶ **Definition 10** (CC-Hard). *A problem is CC-hard if all problems of CC are logspace-reducible to it.*

For our purposes we will not need to define the class CC. Rather, we only need the above definition of CC-hardness and a single CC-hard problem, LFM Matching. Recall that a matching of a graph $G = (V, E)$ is a subset of edges $M \subseteq E$ if each vertex is incident to at most one edge of M. A matching is said to be maximal if each $e = \{u, v\} \notin M$ satisfies the property that either u or v is incident to an edge of M. The greedy algorithm for maximal matching initializes M as $\emptyset$ and then simply iterates over the edges of E in some order and adds the current edge e to M if the result of doing so is a matching.

▶ **Problem 1** (LFM Matching). *An instance of lexicographically first maximal matching (LFM Matching) consists of a bipartite graph $G = (V = L \sqcup R, E)$ with vertices ordered as $L = (l_0, l_1, \ldots, l_{n-1})$ and $R = (r_0, r_1, \ldots, r_{n-1})$. The lexicographically first maximal matching is the matching obtained by running the greedy algorithm for maximal matching on edges ordered first by their endpoint in L and then by their endpoint in R. That is, in this ordering $e = \{l_i, r_j\}$ precedes $e' = \{l_{i'}, r_{j'}\}$ iff (1) $i < i'$ or (2) $i = i'$ and $j < j'$. Our goal is to decide if a designated input edge is in the LFM Matching.*

The following summarizes known hardness of LFM Matching.

▶ **Theorem 11** ([28, 38]). *LFM Matching is CC-hard.*

Next, we introduce the search variant of the HAC problem whose CC-hardness we will prove.

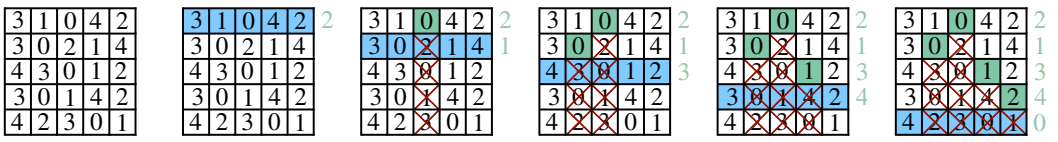
▶ **Problem 2** (Average Linkage HAC). *An instance of Average Linkage HAC consists an undirected graph $G = (V, E)$, along with edge weights $w : E \to \mathbb{R}_{\geq 0}$. Consider the sequence $(C_1, C_1'), (C_2, C_2'), \ldots$ of cluster merges produced by the procedure* `HAC(G)` *from Algorithm 1. Given any pair of vertices $u, v \in G$, the goal of the Average Linkage HAC problem is to output the index i such that u, v first merge together at step i, namely $u \in C_i$ and $v \in C_i'$ (or $u \in C_i'$ and $v \in C_i$).*

To prove the hardness of Average Linkage HAC, we will first prove the hardness of an intermediate problem, called Adaptive Minimum. The construction of the Adaptive Minimum problem will be more amenable to our reductions, and therefore simplify the following exposition. See Figure 4 for an illustration of Adaptive Minimum.

▶ **Problem 3** (Adaptive Minimum). *An instance of Adaptive Minimum consists of a (0-based indexed) $n \times n$ matrix A where each row contains a permutation of $\{0, \ldots, n-1\}$ and some index $x \in [0, n)$. The goal is to simulate the following algorithm. Start with $I = \{0, \ldots, n-1\}$ and execute the following steps for $i = 0, \ldots, x$:*

1. *Let $k_i = \arg\min_{j \in I} A[i, j]$.*
2. *Set $I := I \setminus \{k_i\}$.*

Our goal is to compute k_x.



(a) Input A. **(b)** Step 1. **(c)** Step 2. **(d)** Step 3. **(e)** Step 4. **(f)** Step 5.

Figure 4 Adaptive Minimum on matrix A. The row considered in each step is shown in blue. k_i for the i-th row written to the right of A in green with witnessing entry of A also in green. Indices removed from I in relevant rows crossed out in red.

Observe that both problems 2 and 3 are defined as having an algorithm output an index $i \in \{1, 2, \ldots\}$. Thus, these can be considered search problems instead of decision problems. We choose to work with the search versions of these problems for simplicity of our reductions, however, our reduction naturally extends to the decision variants (e.g., where the algorithm is given $u, v \in V$ and an index i and asked if u, v merge on step i).

We first prove the CC-hardness of this intermediate problem. See Figure 5 for an illustration of our reduction from LFM Matching to Adaptive Minimum.

▶ **Lemma 12.** *Adaptive Minimum is CC-hard.*

Proof. By Theorem 11 and the definition of CC-hardness (Definition 10), it suffices to argue that LFM Matching (Problem 1) is logspace reducible to Adaptive Minimum (Problem 3). We begin by describing our reduction and then observe that it only requires logarithmic space. The basic idea of the reduction is to associate with each vertex on the left side of our instance of LFM Matching a row of the matrix of Adaptive Minimum and each vertex on the right side of LFM Matching a column of the matrix of Adaptive Minimum.

More formally, consider an instance of LFM Matching on graph $G = (V = L \sqcup R, E)$ where our goal is to decide if a given edge e is in the LFM matching. We consider the following instance of Adaptive Minimum to solve this on a $2n \times 2n$ size matrix A. We will refer to an index i as a *dummy index* if $i \geq n - 1$.

Consider a vertex $l_i \in L$ connected to vertices $R_i \subseteq R$ in G, for some $i \leq n - 1$. We will construct the ith row of A to correspond to a permutation π_i that first gives the indices of all neighbors of l_i in R sorted according to the ordering of R then gives all dummy indices then gives the indices of non-neighbors of l_i in R. Specifically, the first $|R_i|$ indices of π_i will be the indices of R_i (sorted by their order in R), the next n indices will be dummy indices $n, n+1, \ldots 2n-1$ and the remaining $n - |R_i|$ indices will be the indices of vertices in $R \setminus R_i$ (sorted, say, by their order in R). For $i \geq n$ we can construct our permutation arbitrarily. Lastly, let x (the index for which we would like to compute k_x in our instance of Adaptive Minimum) be the index of the endpoint of e in L. Once Adaptive Minimum computes k_x, we verify whether or not it corresponds to the endpoint of e in R to determine the final output of the LFM Matching instance. Again, see Figure 5.

We now argue correctness of the reduction. A straightforward proof by induction on i demonstrates that at the beginning of the ith round of the Adaptive Minimum algorithm we have that I consists of at least $n - i$ dummy indices and $j < n$ is not in I only if r_j is in the LFM Matching and is matched to some $l_{i'}$ for $i' < i$. It follows that $e = (l_i, r_j)$ is in the LFM Matching iff $k_i = j$, showing correctness of our reduction.

It remains to show that the above reduction can be done with logspace. In order to do so, we must argue that $A[i, j]$ can be computed with logspace for every i and j. Doing so is trivial if i is a dummy index, so consider $i < n$.

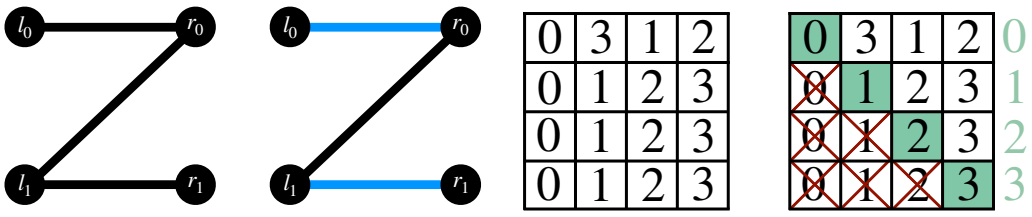
- If $j \leq |R_i|$ then $A[i, j]$ is just the index of the jth vertex of R_i (i.e., neighbor of l_i) in the ordering given by R.
- If $j \in [|R_i|, |R_i| + n]$ then $A[i, j]$ just is $j - |R_j| + n$.
- If $j > |R_i| + n$ then $A[i, j]$ is the index of the $(j - |R_i| - n)$th vertex in $R \setminus R_i$ (i.e., non-neighbors of l_i) when vertices of $R \setminus R_i$ are sorted according to the ordering on R.

All three of the above quantities can easily be computed in logspace. ◀

Concluding, we use the CC-hardness of Adaptive Minimum to prove the CC-hardness of Average Linkage HAC.

▶ **Theorem 3.** *Average linkage HAC is CC-hard, even on trees of diameter* 4.

Proof. Our reduction shows how to reduce an instance of Adaptive Minimum (Problem 3) of size n to an instance of average linkage HAC on a tree. We build a rooted tree, in which each root-to-leaf path has length 2 (i.e., the tree has depth 2). We call the neighbors of the root *internal* nodes. Observe that each node is either the root, an internal node or a leaf. The fact that the tree is rooted is only for the convenience of the description. In the construction, we will begin by assigning each node an initial size (see the definition of *size* in Section 2) which is possibly larger than 1 (but at most $\mathsf{poly}(n)$). We will later show how to remove these variable sizes, and reduce to the case where all nodes have initial size 1 (as in the original definition of HAC).



(a) LFM Matching. **(b)** Solution. **(c)** Adaptive Minimum. **(d)** Solution.

Figure 5 Reduction from LFM Matching to Adaptive Minimum. 5a gives the LFM Matching instance and 5b its solution. 5c gives the Adaptive Minimum instance from the reduction and 5d its solution.

The basic idea of our construction is as follows. Our HAC instance will consist of a rooted tree where each child of the root corresponds to a column of A in our Adaptive Minimum instance. HAC merges will then happen in phases where each phase corresponds to a row of A. In a given phase, exactly one internal node will merge with the root which will correspond to this internal node's column being minimum for the corresponding row of A. In order to guarantee this, each child of the root will have its own carefully selected children such that merging with these children guarantees the desired behavior in every phase.

More formally, the tree is constructed as follows. The root r of the tree has initial size n^8. It has n children, each of initial size n^4 – we denote them by $v_0, \ldots, v_{n-1}$. The root is connected to its children using edges of weight 1, i.e., $w(r, v_i) = 1$ for all $i = 0, 1, \ldots, n-1$ (thus, the normalized weight of the edges $\{rv_i\}_{i=0}^{n-1}$ are each $\frac{1}{n^{12}}$ at the start). Each internal node has $n(n+1)$ children (leaf nodes) grouped into n groups of $n+1$ leaves each. We write $C_{i,j} = \{v_{i,j,0}, v_{i,j,1}, \ldots, v_{i,j,n}\}$ to denote the j-th group of children of the i-th internal vertex. All the leaves $v_{i,j,k}$ have initial size 1. Thus, the vertices in the full graph in our construction consists of the root r, internal nodes $\{v_0, v_1, \ldots, v_{n-1}\}$ and leaves $\cup_{i=0}^{n-1} \cup_{j=0}^{n-1} \cup_{k=0}^{n} \{v_{i,j,k}\}$

Let $r_i = n^8 + i \cdot n^4$ (for $0 \le i < n$). For each pair of an internal node and each of its groups there are only two distinct edge weights for edges between the internal node and the leaves in the group. Specifically, for an internal node v_j and group $C_{j,i}$ of its children we have $A[i,j]+1$ edges of weight $\frac{1}{r_i - 1}$ and $n - A[i,j]$ edges of weight $\frac{1}{r_i + i \cdot n^3}$. Specifically, we set

$$w(v_j, v_{j,i,k}) = \begin{cases} \frac{1}{r_i - 1} & \text{if } 0 \le k \le A[i,j] \\ \frac{1}{r_i + i \cdot n^3} & \text{if } A[i,j] < k \le n \end{cases}$$

We call the two weights *high-weight* and *low-weight* edges, respectively. Note that their normalized weights are $\frac{1}{n^4(r_i - 1)}$ and $\frac{1}{n^4(r_i + i \cdot n^3)}$ respectively. Observe that the setting of *high-weight* and *low-weight* edges is independent of the internal node v_j, although the number of high versus low-weight edges depends on $A[i,j]$. Moreover, note that even low-weight edges of any group $C_{j,i}$ have higher weights than high-weight edges of group $C_{j,i+1}$:

$$\begin{aligned} \frac{1}{n^4(r_i + i \cdot n^3)} &> \frac{1}{n^4(r_{i+1} + (i+1) \cdot n^3)} \iff \\ \frac{1}{n^8 + i \cdot n^4 + i \cdot n^3} &> \frac{1}{n^8 + (i+1)n^4 - 1} \iff \\ i \cdot n^3 &< n^4 - 1. \end{aligned}$$

which follows from the fact that $i \leq n-1$. We now demonstrate that the average linkage HAC on this instance works in n phases numbered from 0 to $n-1$, where in each phase i,

- $n-1$ internal nodes contract all of their incident group i edges, and
- one internal node contracts all of its high-weight edges to group i, after which it merges with the root.

Because of the internal node merging with the root, the root has incident leaves, but they are connected with edges of (normalized) edge weights $\leq \frac{1}{n^{15}}$ and so they will be irrelevant until all phases have been completed. We show that if we denote by k_i the index of the internal node which merges with the root in phase i, the sequence $k_0, \ldots, k_{n-1}$ is a correct solution to the Adaptive Minimum problem.

In order to analyze the algorithm, we prove the following claim. For convenience, let us define $w_i = n^4 + i \cdot (n+1)$.

▷ Claim 13. In the beginning of phase i, the graph is as follows:

1. The size of the root node is $r_i + i^2 \cdot \Delta_i$ for some $\Delta_i \in [0, n+1]$.
2. Exactly i internal nodes have been merged with the root, and the corresponding values $k_0, \ldots, k_{i-1}$ have been computed correctly.
3. The size of each of the $n-i$ remaining internal nodes is w_i.
4. For all remaining internal nodes, *all* leaves in groups $0, \ldots, i-1$ have been merged into their parents, and no leaves in groups $i, \ldots, n-1$ have been merged.
5. The root may have incident leaves (resulting from internal nodes contracting into it) connected to the root with edges of normalized weights $\leq \frac{1}{n^{15}}$.

Proof. We prove the above claim using induction on i. The base case of $i = 0$ follows directly from how the tree is constructed.

We now simulate a single phase. The edges between the root and the internal nodes have (normalized) weights $\frac{1}{w_i(r_i + i^2 \cdot \Delta_i)} > \frac{1}{n^{15}}$. Hence, the additional leaf nodes incident to the root (see Item 5 of the Claim) are irrelevant. Thus, the highest weight edge in the graph is surely incident to one of the internal nodes. Observe that the relative order of edge weights between an internal node v and its children does not change as the leaves are merged into v. Therefore, given that groups $0, \ldots, i-1$ do not exist anymore, among edges between the internal nodes and leaves, the edges of group i have the highest weights. In the beginning of a phase the high-weight edges in that group have normalized weights $\frac{1}{w_i(r_i - 1)}$ and the low-weight edges have weight $\frac{1}{w_i(r_i + i \cdot n^2)}$.

Hence, we have that if we sort the edges by their normalized weights, the top 3 classes of edges are, starting from the highest weight:

1. High-weight edges between internal nodes and leaves of group i.
2. Edges between the root and the internal nodes.
3. Low-weight edges between internal nodes and leaves of group i.

We will show that the phase consists of the following sub-phases.

1. First, there is some number of subphases, where each of $n-i$ internal nodes contract one incident high-weight edge.
2. Then, there is exactly one subphase, where $n-i-1$ nodes contract an incident high-weight edge and one internal node merges with the root.
3. Then, the remaining $n-i-1$ internal nodes merge with all of their group i leaves (we do not analyze the order in this subphase, as it is irrelevant).

Assume that each internal node has at least one high-weight edge in group i. Then, the algorithm will execute a Type 1 subphase: the first $n-i$ steps of the algorithm would merge exactly one high-weight edge incident to each internal node. Note that when an edge incident to an internal node v merges, the weight of v increases, and so the incident edge weights decrease. This guarantees that in the considered $n-i$ steps exactly one merge per internal node happens.

Type 1 subphases of $n-i$ steps continue as long as each each internal node has at least one high-weight group i edge in the beginning of the subphase. Each Type 1 subphase also causes the weight of each internal node to increase by 1. Clearly, since nodes are being merged into internal nodes, the ordering of edge weights incident to any internal node does not change.

At some point, in the beginning of a subphase there is an internal node that does not have any incident high-weight edge in group i. Assume that this happened after p Type 1 subphases have completed. Thus, the size of each internal node is $w_i + p$. Since by the construction each internal node had a different number of high-weight edges in group i, there is exactly one node v with no high-weight incident edges and that node merges with the root. This is when Type 2 subphase happens. First, $n-i-1$ internal nodes contract with a high-weight incident group i edge. At this point the edge weights are as follows. The weight of an edge between v and the root is $\frac{1}{(w_i+p)(r_i+i^2\cdot\Delta_i)}$ and the weight of a high-weight edge in group i is $\frac{1}{(w_i+p+1)(r_i-1)}$. We have that the former is larger since

$$\begin{aligned}
(w_i+p)(r_i+i^2\cdot\Delta_i) &< (w_i+p+1)(r_i-1) \iff \\
(w_i+p)\cdot i^2\cdot\Delta_i &< r_i - 1 \iff \\
(n^4+i\cdot(n+1)+p)\cdot i^2\cdot\Delta_i &< n^8+i\cdot n^4-1 \Leftarrow \\
(n^4+n\cdot(n+1)+n)\cdot n\cdot n^2 &< n^8+i\cdot n^3-1.
\end{aligned}$$

Thus, the internal node with no incident high-weight edges in group i merges with the root. Observe that this is exactly the internal node which had the lowest number of high-weight edges in group i among all remaining internal nodes. This immediately implies that k_i is computed correctly, proving Item 2.

We now show that in the remaining part of the phase the $n-i-1$ remaining internal nodes contract their incident group i edges. First, observe that the new size of the root node is

$$r_i + w_i + p + i^2\cdot\Delta_i = \left(n^8 + i\cdot n^4 + n^4\right) + \left(i\cdot(n+1) + i^2\cdot\Delta_i + p\right) = r_{i+1} + (i+1)^2\Delta_{i+1}$$

for some $\Delta_{i+1} \in [0, n+1]$. Note that we use the fact that both Δ_i and p are upper bounded by $n+1$, which implies $i\cdot(n+1) + i^2\cdot\Delta_i + p \le (i+1)^2(n+1)$. This proves Item 1. Thus for an internal node of weight w, the weight of its edge to the root is

$$\frac{1}{w\cdot(r_{i+1}+(i+1)^2\Delta_{i+1})} \le \frac{1}{w\cdot r_{i+1}} = \frac{1}{w\cdot(n^8+(i+1)\cdot n^4)}.$$

On the other hand, its low-weight edges to group i leaves have weight

$$\frac{1}{w(n^8+i(n^4+n^2))}.$$

As a result, in the remaining part of the current phase all internal nodes will contract all their incident group i edges. This implies Item 4. Thus, the size of each internal node within the phase increases to $w_i + (n+1) = n^4 + i\cdot(n+1) + n + 1 = n^4 + (i+1)(n+1)$, as required. This proves Item 3 and completes the proof. ◁

Finally, we now claim that, given an instance of Adaptive Minimum with input index $x \in [0, n)$ and an algorithm which can compute the solutions to Problem 2, we can compute the solution k_x to Problem 3 in logspace. To see this, note that it suffices to determine the value k_x as defined above given an algorithm for Average Linkage HAC. To see this, note that for any internal node i, we can query the Average Linkage HAC algorithm to determine which time step t_i it merged with the root. This does not directly tell us which phase i merged with the root, but for a given i we can determine if it merged in phase x by comparing t_i with t_j for all $j \in \{0, 1, \ldots, n-1\} \setminus \{i\}$, and checking if there are exactly $x - 1$ values of t_j smaller than t_i. This clearly can be verified in log-space. Repeating for all $i \in \{0, 1, \ldots, n-1\}$ allows us to correctly determine the identity of the internal node that merged with the root in phase x, and therefore the value of k_x, in logspace as required.

To complete the proof of the Lemma it remains to show how to drop the assumption on the node sizes being initially not all equal to 1. In order to obtain a node of size w it suffices to create a node of weight 1 and initially connect it to $w - 1$ auxiliary nodes using very high weight edges. This will force the algorithm to merge all these auxiliary nodes and increase the size of that node to w. Since the auxiliary leaves are connected only to the root and internal nodes (the leaves in our construction have weight 1), the diameter of the tree does not increase. ◀

5 Average Linkage HAC on Paths in NC

In this section, we present an $\tilde{O}(n)$ work and $O(\mathsf{polylog}(n))$ depth algorithm for solving average linkage HAC on path graphs, provided that the aspect ratio of the input instance is bounded by $\mathsf{poly}(n)$. The *aspect ratio* is defined as $\mathcal{A} = W_{\max}/W_{\min}$, where $W_{\max} = \arg\max_{e \in E} w(e)$ and $W_{\min} = \arg\min_{e \in E} w(e)$ (note that this definition excludes all non-edges, which implicitly have a weight of 0).

In average linkage HAC, the weight (i.e., similarity) of edges monotonically decreases over time. Thus, our idea is to partition the edges into *buckets* where the edges in any bucket have the same similarity, up to constant factors. Next, we process these buckets in *phases*, from the highest similarity bucket to the lowest. In each phase, we perform a modified version of the classic nearest-neighbor chain algorithm, wherein we compute the nearest-neighbor chains for the graph induced on the edges in that bucket, and process each chain independently. We note that when we use the terminology *nearest neighbor* of a vertex in what follows, we refer to the neighbor along the *highest weight edge* incident to the vertex.

Initially, each cluster is a singleton, and we might end up with $\Omega(n)$ sequential dependencies to resolve. However, we observe that in this special case when the size of every cluster is equal, starting with the reciprocal pair, every *alternate* edge in this chain can be merged independently, and the rest of the edges will be moved to a later bucket. We can compute the edges that will be merged easily via a simple prefix-sum routine [8]. However, when the cluster sizes are arbitrary, this observation no longer holds. Nonetheless, we show that we can partition each chain further into $O(\log n)$-sized subchains such that, even though the dependencies within a subchain must be resolved sequentially, the dependencies across subchains can be resolved in parallel using a similar application of prefix-sum.

We state the following theorems showing (1) that our parallel algorithm is highly efficient (it runs near-linear time in the number of nodes) and runs in poly-logarithmic depth and (2) that our algorithm implies that the dendrogram height of a path input with polynomial aspect ratio is always poly-logarithmic. Due to space constraints, we defer the proofs and the details of the algorithm to the full version [6].

▶ **Theorem 4.** *Average linkage HAC on paths is in NC. In particular, there is an algorithm for average linkage HAC that runs in* $O(\log^2 n \log\log n)$ *depth with* $O(n \log n \log\log n)$ *work.*

▶ **Theorem 14.** *Average linkage HAC on path graphs with* $\mathsf{poly}(n)$ *aspect-ratio returns a dendrogram with height at most* $O(\log^2 n)$.

6 Conclusion

In this paper, we studied the parallel and sequential complexity of hierarchical graph clustering. We gave new classic and fine-grained reductions for Hierarchical Agglomerative Clustering (HAC) under the average linkage measure that likely rule out efficient algorithms for *exact* average linkage, parallel or otherwise. We also showed that such impossibility results can be circumvented if the output dendrogram has low height or is a path. An interesting question is whether such structure can be leveraged for other variants of interest of average linkage HAC: for example, can we can obtain dynamic algorithms for HAC that are also parameterized by the height?

Abstract

We study sublinear time algorithms for the *traveling salesman problem* (TSP). First, we focus on the closely related *maximum path cover* problem, which asks for a collection of vertex disjoint paths that include the maximum number of edges. We show that for any fixed $\varepsilon > 0$, there is an algorithm that $(1/2 - \varepsilon)$-approximates the maximum path cover size of an n-vertex graph in $\widetilde{O}(n)$ time. This improves upon a $(3/8 - \varepsilon)$-approximate $\widetilde{O}(n\sqrt{n})$-time algorithm of Chen, Kannan, and Khanna [ICALP'20].

Equipped with our path cover algorithm, we give an $\widetilde{O}(n)$ time algorithm that estimates the cost of $(1, 2)$-TSP within a factor of $(1.5 + \varepsilon)$ which is an improvement over a folklore $(1.75 + \varepsilon)$-approximate $\widetilde{O}(n)$-time algorithm, as well as a $(1.625 + \varepsilon)$-approximate $\widetilde{O}(n\sqrt{n})$-time algorithm of [CHK ICALP'20]. For graphic TSP, we present an $\widetilde{O}(n)$ algorithm that estimates the cost of graphic TSP within a factor of 1.83 which is an improvement over a 1.92-approximate $\widetilde{O}(n)$ time algorithm due to [CHK ICALP'20, Behnezhad FOCS'21]. We show that the approximation can be further improved to 1.66 using $n^{2-\Omega(1)}$ time.

All of our $\widetilde{O}(n)$ time algorithms are information-theoretically time-optimal up to $\operatorname{poly}\log n$ factors. Additionally, we show that our approximation guarantees for path cover and $(1, 2)$-TSP hit a natural barrier: We show better approximations require better sublinear time algorithms for the well-studied maximum matching problem.

1 Introduction

The *traveling salesman problem* (TSP) is a central problem in combinatorial optimization. Given a set V of n vertices and their pairwise distances, it asks for a Hamiltonian cycle of the minimum cost. In this paper, we study *sublinear time* algorithms for TSP. The algorithm is given query access to the distance pairs, and the goal is to estimate the solution cost in time sublinear in the input size (which is $\Theta(n^2)$).

TSP is NP-hard to approximate within a polynomial factor for an arbitrary distance function. As such, much of the work in the literature has been on more specific distance functions. Some notable examples include *graphic TSP* [15, 22, 23, 25, 10] where the distances are the shortest paths over an arbitrary unweighted undirected graph, $(1,2)$-*TSP* [1, 10, 7, 18, 21] where the distances are 1 or 2, and more generally *metric TSP* [17, 14, 12, 26] where the distances satsify triangle inequality.

In 2003, Czumaj and Sohler [13, 14] showed that for any fixed $\varepsilon > 0$, a $(1+\varepsilon)$-approximation of the cost of metric minimum spanning tree (MST) and thus a $(2+\varepsilon)$-approximation of the cost of metric TSP can be found in $\widetilde{O}(n)$ time. Twenty years later, it still remains a major open problem to either break two-approximation in $n^{2-\Omega(1)}$ time or prove a lower bound.[1] However, better bounds are known for both graphic TSP and $(1,2)$-TSP. In this paper, we present improved algorithms for these two well-studied variants of TSP. Our main tool to achieve this is an improved algorithm for the closely related *maximum path cover* problem which might be of independent interest.

Maximum Path Cover. The maximum path cover in a graph is a collection of vertex disjoint paths with the maximum number of edges in it. The (almost) 1/2-approximate maximum matching size estimator of Behnezhad [2] immediately implies an (almost) 1/4-approximation for the maximum path cover problem in $\widetilde{O}(n)$ time.[2] This can be improved to an (almost) $(3/8 = .375)$-approximation using the *matching-pair* idea of Chen, Kannan, and Khanna [10] in $\widetilde{O}(n\sqrt{n})$-time.[3] Our first main contribution is an improvement over both of these results:

▶ **Result 1** (Formally as Theorem 17). *For any $\varepsilon > 0$, there is a randomized algorithm that w.h.p. $(1/2-\varepsilon)$-approximates the size of maximum path cover in $\widetilde{O}(n \cdot \text{poly}(1/\varepsilon))$ time.*

Besides quantitavely improving prior work both in the running time and the approximation ratio, Result 1 reaches a qualitatively important milestone as well. First, the running time of Result 1 is information-theoretically optimal up to $\text{poly}\log n$ factors (the lower bound holds for any constant approximation – see the arXiv version of the paper). Second, its approximation ratio hits a rather important barrier. We give a non-trivial reduction that shows a $(1/2+\Omega(1))$-approximation in $\widetilde{O}(n)$ time for maximum path cover would imply the same bound for maximum matching in bipartite graphs. Such a result has remained elusive for matching, which is one of the most extensively studied problems in the literature of sublinear time algorithms. See the arXiv version of the paper for the lower bound details.

It is also worth noting that in bounding the running time of our algorithm in Result 1, we use connections to parallel algorithms. Such a connection was previously only used for matchings [2].

$(1,2)$-TSP. The $(1,2)$-TSP problem has been studied extensively in the classical setting. In his landmark paper, Karp [18] showed that $(1,2)$-TSP is NP-hard. Papadimitriou and Yannakakis [24] then proved its APX-hardness. Since then there has been a significant amount of work on $(1,2)$-TSP in the classical setting. The current best known inapproximability bound for $(1,2)$-TSP is 535/534 [19]. After a series of works, the best known polynomial

[1] See e.g. Open Problem 71 on sublinear.info [16].

[2] The application of sublinear time maximum matching algorithms for approximating maximum path cover was first proposed by Gupta and Onak. See [16].

[3] We note that even though a subsequent result of Behnezhad [2] improved the running time for maximal matchings and graphic TSP from $O(n\sqrt{n})$ in [10] to $\widetilde{O}(n)$, it is not immediately clear whether the same holds for path cover and $(1,2)$-TSP as they rely on a different notion of a matching pair.

Table 1 Comparison of running time and approximation ratio of our TSP algorithms and lower bounds with prior work.

Running Time	Approximation Ratio	Metric	Reference
$\widetilde{O}(n)$	$1.75+\varepsilon$	(1,2)	Folklore
$\widetilde{O}(n\sqrt{n})$	$1.625+\varepsilon$	(1,2)	Chen, Kannan, and Khanna [10]
$\widetilde{O}(n)$	$1.5+\varepsilon$	(1,2)	**This work** (Result 2)
$\widetilde{O}(n)$	1.929	Graphic	Chen, Kannan, and Khanna [10]
$\widetilde{O}(n)$	1.834	Graphic	**This work** (Result 3)
$n^{2-\Omega(1)}$	1.667	Graphic	**This work** (Result 4)
$\Omega(n^2)$	$1+\varepsilon$	(1,2) & Graphic	Chen, Kannan, and Khanna [10]
$n^{1+\Omega(1)}$ (Conditional)	$1.5-\varepsilon$	(1,2) & Graphic	**This work** (arXiv version)

time approximation is 8/7 [7] which can be implemented in $O(n^3)$ time [1]. For sublinear time algorithms, an $\widetilde{O}(n)$-time (almost) 1.75-approximation is folklore [16]. Chen, Kannan, and Khanna [10] improved the approximation to (almost) 1.625 in $\widetilde{O}(n\sqrt{n})$ time.

It is not hard to see that up to a small additive error of 1, $(1,2)$-TSP is equivalent to finding a maximum path cover on the weight-1 edges and then connecting their endpoints via weight-2 edges. A simple calculation shows that any α-approximation for the maximum path cover problem leads to a $(2-\alpha)$-approximation for $(1,2)$-TSP. Our path cover algorithm of Result 1 immediately implies the following result as a corollary:

▶ **Result 2.** *For any $\varepsilon > 0$, there is a randomized algorithm that w.h.p. $(1.5+\varepsilon)$-approximates the cost of $(1,2)$-TSP in $\widetilde{O}(n \cdot \text{poly}(1/\varepsilon))$ time.*

Similar to Result 1, the running time of Result 2 is information-theoretically optimal up to $\text{poly}\log n$ factors, and its approximation ratio hits a natural barrier due to a connection to sublinear time matching that we establish in this work.

Graphic TSP. The graphic TSP problem is equivalent to finding a tour of the minimium size that visits all the vertices. This is an important instance of TSP that has received a lot of attention over the years. For polynomial time algorithms, a 1.5-approximation of Christofides [12] (which also works more generally for metric TSP) had remained the best known until a series of works over the last decade improved it to $(1.5-\varepsilon_0)$ [15], 1.461 [22], 1.444 [23], and finally to 1.4 [25]. For sublinear time algorithms, Chen, Kannan, and Khanna [10] showed that an (almost) $(27/14 \approx 1.928)$-approximation of graphic TSP can be obtained in $\widetilde{O}(n\sqrt{n})$ time. The running time was subsequently improved to $\widetilde{O}(n)$ by Behnezhad [2].

We first show that plugging Result 1 into the framework of [10] immediately improves their approximation from 1.928 to (almost) 1.9 while keeping the running time $\widetilde{O}(n)$. We then give a more fine tuned algorithm that obtains a much improved approximation ratio of $(11/6 \approx 1.833)$.

▶ **Result 3.** *For any $\varepsilon > 0$, there is a randomized algorithm that w.h.p. $(1+\varepsilon)(\frac{11}{6} \approx 1.833)$-approximates the cost of graphic TSP in $\widetilde{O}(n \cdot \text{poly}(1/\varepsilon))$ time.*

Over the past few years, significant advancements have been made in the development of sublinear matching algorithms and lower bounds. Several recent results [3, 4, 5, 6, 8, 9] have led to the creation of a $(1, \varepsilon n)$-approximation algorithm for maximum matching, with running time of $n^{2-\Omega_\varepsilon(n)}$. Leveraging these sublinear algorithms, we have devised a slightly subquadratic algorithm that provides a more accurate estimation of the size of graphic TSP.

▶ **Result 4.** *For any $\varepsilon > 0$, there is a randomized algorithm that w.h.p. $(1+\varepsilon)(\frac{5}{3} \approx 1.666)$-approximates the cost of graphic TSP in $n^{2-\Omega_\varepsilon(1)}$ time.*

We contrast our results with prior sublinear TSP algorithms in Table 1.

Further related work. Finally, we note that in a recent paper, Chen, Khanna, and Tan [11] show that assuming that the metric has a spanning tree supported on weight 1 edges, one can obtain a $(2 - \varepsilon_0)$-approximation with $\widetilde{O}(n\sqrt{n})$ queries for some small unspecified constant $\varepsilon_0 > 0$. While this is a more general metric than graphic TSP and (1,2)-TSP that we study in this paper, we note that the two papers are orthogonal and their results are incomparable. In particular, the techniques developed in this paper are specifically designed to improve the approximation to much below 2, whereas [11] focuses on generalizing the distance function while beating 2.

2 Technical Overview

In this section, we give an overview of our algorithms, especially our sublinear time maximum path cover algorithm of Result 1 which is the key to the other results as well.

Let us start with using matchings to approximate maximum path cover. Consider a graph that has a Hamiltonian path. Here, the optimal maximum path cover has size $n - 1$. On the other hand, any maximum matching can have at most $n/2$ edges, which is by a factor 2 smaller than our optimal path cover. On top of this, we only know close to 1/2 approximations for maximum matching if we restrict the running to be close to linear in n [2, 6], thus can only achieve an approximation close to 1/4.

Instead of a single matching, Chen, Kannan, and Khanna [10] showed how to estimate the number of edges in a *maximal matching pair* in $\widetilde{O}(n\sqrt{n})$ time, where a matching pair is simply two edge disjoint matchings. It is not hard to see that the number of edges in a maximal matching pair is at least half the number of edges in a maximum path cover. The problem, however, is that a maximal matching pair is not a collection of paths! In particular, the two matchings can form cycles of length as small as four. Therefore, one may only be able to use 3/4 fraction of the edges of a matching pair in a path cover. This is precisely why the algorithm of [10] only obtains a $\frac{1}{2} \times \frac{3}{4} = \frac{3}{8}$ approximation for path cover, and a $2 - \frac{3}{8} = 1.625$ approximation for $(1, 2)$-TSP.

If we could modify the matching pair algorithm of [10], and avoid cycles by manually excluding edges whose endpoints are the endpoints of a path in the current matching pair, then we could avoid the 3/4 factor loss discussed above and achieve a 1/2-approximation. Unfortunately, checking whether the endpoints of an edge are endpoints of a path requires knowledge about whether a series of other edges belong to the solution, which seems hard to implement in sublinear time.

Instead of checking for cycles manually, we introduce the following Algorithm 1 which avoids cycles more naturally. While our final algorithm is a modified variant of Algorithm 1 described below, we start with Algorithm 1 as we believe it provides the right intuition.

Algorithm 1 A new algorithm for path cover.

1. Initialize $P \leftarrow \emptyset$.
2. Each vertex v has two *ports* that we denote by v^0 and v^1. Each of these ports throughout the algorithm will be either *free* or *occupied*. Initially, all ports are free.
3. Iterate over the edges in some ordering π. Upon visiting an edge $e = (u, v)$:
   - If v^0 and u^0 are free, add e to P, mark both as occupied, and skip to the next edge.
   - If v^1 and u^0 are free, add e to P, mark both as occupied, and skip to the next edge.
   - If v^0 and u^1 are free, add e to P, mark both as occupied, and skip to the next edge.
4. Return P.

Two properties of Algorithm 1 are crucial. First, it prioritizes occupying (u^0, v^0) (compared to (u^1, v^0) or (u^0, v^1)) which in particular implies that any component in P must have a (u^0, v^0) edge. Second, it never occupies (u^1, v^1) with an edge (u, v). While it is easy to see that the output of Algorithm 1 has maximum degree 2, and is thus a collection of paths or cycles, the two properties above actually guarantee that it never includes any cycle. See Figure 1. We provide the formal proof of this later in Section 4. Additionally, we show that the output of Algorithm 1 must be at least half the size of a maximum path cover, as we prove next. Hence, if we manage to estimate the size of the output P of Algorithm 1, then we have proved Result 1.

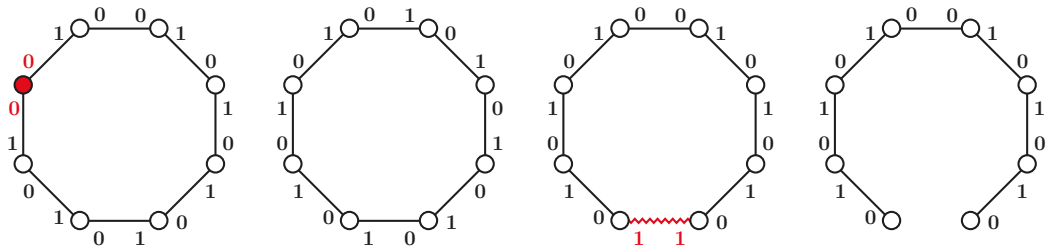

Figure 1 Examples of why the output of Algorithm 1 will not have cycles.

Our final algorithm is slightly different from Algorithm 1 discussed above. In particular, we slightly relax it – see Algorithm 2 – so that it can be solved via a randomized greedy maximal independent set (RGMIS), for which we have a rich toolkit of sublinear time estimators. Existing approaches (particularly the algorithm of Yoshida, Yamamoto, and Ito [27] and its two-step implementation by Chen, Kannan, and Khanna [10]) can be employed to estimate the value of this modified Algorithm 2 in $\widetilde{O}(n\sqrt{n})$ time. We achieve the improved, and near tight, $\widetilde{O}(n)$ time bound guarantee of Result 1 by building on the analysis of Behnezhad [2] for maximal independent set on the line graphs (i.e., maximal matchings). Though we note that several new ideas are needed, because the MIS graph in our case will not be exactly a line graph. We defer more discussions about this to Sections 4 and 5.

Implications for TSP. By having an α-approximate maximum path cover algorithm, we immediately obtain a $(2-\alpha)$-approximation for $(1,2)$-TSP. Therefore, the algorithm above immediately proves Result 2 that we can (almost) 1.5-approximate $(1,2)$-TSP in $\widetilde{O}(n)$ time. For our Result 3 for graphic TSP, we first observe that our improved path cover algorithm can be employed to provide a better lower bound for the optimal TSP solution. This improves the 1.92-approximation of [10] as black-box to 1.9-approximation (see the arXiv version of the paper). However, the final improvement to 1.83 requires more ideas, in particular, on how to better estimate the number of certain *bridges* in the graph. See Section 8 for more details about this.

3 Preliminaries

Problem Definition. In the sublinear TSP problem, we have a set V of n vertices and a distance function $d : V \times V \to \mathbb{R}_+$. The algorithm has query access to this distance function. Namely, for any pair (u,v) of the vertices of its choice, the algorithm may query the value of $d(u,v)$. The goal is to design an algorithm that runs in sublinear time in the input size, which is $\Theta(n^2)$ (all the distance pairs), and produces an estimate of the size of the optimal TSP solution. Denoting the optimal TSP value by $\tau(V)$, we say an estimate $\widetilde{\tau}(V)$ provides an α-approximation for $\alpha \geq 1$ if

$$\tau(V) \leq \widetilde{\tau}(V) \leq \alpha \cdot \tau(V).$$

We focus specifically on *graph TSP* and $(1,2)$-*TSP* problems. In graphic TSP, the distance function d is the shortest path metric on an unweighted undirected graph G that is unknown to the algorithm. Note, however, that the distance queries essentially provide *adjacency matrix* access to this graph G. In $(1,2)$-TSP, the assumption is that $d(u,v) \in \{1,2\}$ for every pair u,v. In the case of $(1,2)$-TSP we may use G to refer to the subgraph induced on the pairs with distance 1.

Defining graph G as above, we use n to denote the number of its vertices, m to denote the number of its edges, Δ to denote its maximum degree, $\mu(G)$ to denote its maximum matching size, $\nu(G)$ to denote its minimum vertex cover size, and $\bar{d}$ to denote its average degree.

Path Cover Definitions. Given an unweighted graph G, a path cover in G is a collection of vertex disjoint paths in G. A maximum path cover is a path cover of G with the maximum number of edges in it (note that we are not counting the number of paths, but rather the total number of edges in them). We use $\rho(G)$ to denote the size of the maximum path cover in G. We say an estimate $\widetilde{\rho}(G)$ for $\rho(G)$ provides an (α,ε)-approximation for $\alpha,\varepsilon \in [0,1]$ if

$$\alpha \cdot \rho(G) - \varepsilon n \leq \widetilde{\rho}(G) \leq \rho(G).$$

We may also use α-approximation instead of $(\alpha,0)$-approximation.

Graph Theory Definitions/Tools. A *bridge (cut edge)* in a graph is an edge whose deletion increases the number of connected components. Similarly, a *cut vertex* is a vertex whose deletion (along with its edges) increases the number of connected components. A *biconnected graph* is a connected graph with no cut vertex. Also, a *biconnected component (block)* of a graph is a maximal biconnected subgraph of the original graph. A non-trivial biconnected component is a block that is not a bridge. We say a graph is *2-edge-connected* if there is no bridge in the graph. A *2-edge-connected component* of a graph is maximal 2-edge-connected

subgraph of the original graph. The *bridge-block tree* of a graph is a tree obtained by contracting the 2-edge-connected components; note that the edge set of a bridge-block tree correspond to the bridges in the original graph.

We use the following classic theorem of König [20] that the size of the minimum vertex cover is equal to the size of maximum matching in bipartite graphs. Namely:

▶ **Proposition 1** (König's Theorem). *In any bipartite graph G, $\mu(G) = \nu(G)$.*

Probabilistic Tools. In our proofs, we use the following standard concentration inequalities.

▶ **Proposition 2** (Chernoff Bound). *Let $X_1, X_2, \ldots, X_n$ be independent Bernoulli random variables. Let $X = \sum_{i=1}^{n} X_i$. For any $t > 0$, $\Pr[|X - \mathbf{E}[X]| \geq t] \leq 2\exp\left(-\frac{t^2}{3\,\mathbf{E}[X]}\right)$.*

▶ **Proposition 3** (Hoeffding's Inequality). *Let $X_1, X_2, \ldots, X_n$ be independent random variables such that $a \leq X_i \leq b$. Let $\bar{X} = (\sum_{i=1}^{n} X_i)/n$. For any $t > 0$, $\Pr[|\bar{X} - \mathbf{E}[X]| \geq t] \leq 2\exp\left(-\frac{2nt}{(b-a)^2}\right)$.*

4 New Meta Algorithms for Maximum Path Cover

In this section, we present a new meta algorithm for maximum path cover that obtains a 1/2-approximation. The algorithm, as we will state it in this section, will not be particularly in the sublinear time model. We discuss its sublinear time implementation later in Sections 5 and 6.

Our starting point is the Algorithm 1 described in Section 2. Let us first formally prove that it obtains a 1/2-approximation, and that no component in it is a cycle.

▷ Claim 4. The output of Algorithm 1 is a collection of disjoint paths.

Proof. Since P has maximum degree two, it suffices to show none of its connected components are cycles. Property (i) above implies that at any point during the algorithm, any degree one vertex v has its port v^0 occupied. Now take an edge $e = (u, v)$ that forms a cycle if added to P. Both u and v must have degree one and so u^0 and v^0 are occupied. Since by property (ii) edge e does not occupy both v^1 and u^1, the algorithm does not add e to P thus not completing a cycle. ◁

▷ Claim 5. Let $P^\star$ be *any* path cover using weight one edges. Then the output of Algorithm 1 has size at least $\frac{1}{2}|P^\star|$.

Proof. For any edge $e = (u, v) \in P^\star$ define $\phi(e) = \frac{1}{4}(\deg_P(u) + \deg_P(v))$. We first claim that for every edge $e = (u, v)$ in G, we have $\phi(e) \geq 1/2$ (or, equivalently, $\deg_P(u) + \deg_P(v) \geq 2$). This is clear for edges $e \in P$ due to the contribution of e itself to its endpoints' degrees, so fix $e \notin P$. Consider the time that we process $e = (u, v)$ in the algorithm and decide not to add it to P. We claim that out of v^0, v^1, u^0, u^1 at least two ports must be occupied. Suppose w.l.o.g. and for contradiction that only v^x is occupied for $x \in \{0, 1\}$. Then (u, v) can occupy v^{1-x} and u^x and be added to P. This contradicts (u, v) not being added to P and proves our claim that $\phi(e) \geq 1/2$.

From the discussion above, we get that

$$\sum_{e \in P^\star} \phi(e) \geq \sum_{e \in P^\star} 1/2 = |P^\star|/2.$$

Moreover, because every vertex has degree at most two in $P^\star$, we get

$$\sum_{e \in P^\star} \phi(e) = \frac{1}{4} \sum_{(u,v) \in P^\star} \deg_P(u) + \deg_P(v) \leq \frac{1}{4} \cdot 2 \sum_{v \in V} \deg_P(v) = |P|.$$

The two inequalities above combined imply that $|P| \geq |P^\star|/2$. ◁

As discussed, our final algorithm is different from Algorithm 1 discussed above. One problem with Algorithm 1 is that it cannot be cast as an instance of the randomized greedy maximal independent set (RGMIS) algorithm for which there is a rich toolkit of sublinear time estimators. To remedy this, we present a modified variant of Algorithm 1 whose output is (almost) as good, but in addition can be modeled as an instance of RGMIS. We denote the output of RGMIS on a graph G with a permutation π on its vertices by $\text{RGMIS}(G, \pi)$.

The algorithm is stated below as Algorithm 2. Similar to the output of Algorithm 1, the output of Algorithm 2 can be verified to have maximum degree two. Thus, it is a collection of paths and cycles. But unlike Algorithm 1, the output of Algorithm 2 can have cycles. This happens since, unlike Algorithm 1, each connected component of the output of Algorithm 2 is not guaranteed to have an edge (u, v) occupying both u^0 and v^0. Nonetheless, we are able to show that this bad event only happens for a small fraction of connected components of the output of Algorithm 2 in expectation, and so once we remove one edge of each of these cycles, the resulting collection of disjoint paths has almost the same size.

Algorithm 2 A modification of Algorithm 1 that uses RGMIS.

1. **Parameter:** K (think of it as a large constant integer).
2. Let $G = (V, E)$ be the subgraph of weight one edges. We construct a graph $H = (V_H, E_H)$ from G on which we run RGMIS.
3. Each vertex in H corresponds to an edge e in G and two *ports* (as in Algorithm 1) of the endpoints of e that it occupies. Formally, for any $(u, v) \in E$ we have $K + 2$ vertices in H:
   - One vertex that corresponds to occuping u^0 and v^1.
   - One vertex that corresponds to occuping u^1 and v^0.
   - K vertices that each corresponds to occuping u^0 and v^0.
4. Consider two distinct vertices a and b in H corresponding to edges e_a and e_b in G:
   - If $e_a = e_b$ then we add an edge between a and b in H.
   - If e_a and e_b share exactly one endpoint v and both a and b occupy the same port of v, we add an edge between a and b in H.
5. Find a randomized greedy maximal independent set I of H.
6. Let P be the set of edges in G corresponding to the vertices in I.
7. Return P.

▶ **Observation 6.** *Let C be a connected component in the output of Algorithm 2. If C is a cycle, then every edge in C occupies one 0-port and one 1-port (that is, no edge occupies two 0-ports).*

Proof. Suppose that C has n' vertices. Since each vertex in a cycle has degree two, both ports of each vertex in C must be occupied. Hence, n' 0-ports and n' 1-ports of C are occupied in total. Given that any edge occupies at least one 0-port by the algorithm, we cannot have an edge that occupies two 0-ports, or else we should occupy more 0-ports than 1-ports of C, which is a contradiction. ◀

Next, we show that up to a factor of $(1+2/k)$ which is negligible for K in the order $1/\varepsilon$, the output of Algorithm 2 is an (almost) 1/2-approximation of the maximum path cover value.

▶ **Observation 7.** *Let C be a connected component in the output of Algorithm 2. If C is a path, then it contains at most one edge that occupies two 0-ports.*

Proof. Let C be the path $(v_1, v_2, \ldots, v_r)$. Since the degree of any vertex v_i for $1 < i < r$ is two in the path, both ports of v_i must be occupied. For v_1 and v_r, on the other hand, only one port is occupied. Hence, the total number of 0-ports that are occupied by C minus the number of 1-ports occupied by it is at most two. This means that there is at most one edge that occupies two 0-ports since all other types of edges occupy exactly one 0-port and one 1-port. ◀

▶ **Lemma 8.** *let P be the output of Algorithm 2 on graph G. Then*

$$\frac{1}{2}\rho(G) \leq \mathbf{E}\,|P| \leq \left(1+\frac{2}{K}\right)\rho(G),$$

where the expectation is taken over the randomization of computing RGMIS in Algorithm 2.

Proof. Let P^* be a maximum path cover. For any edge $e = (u, v) \in P^\star$ define $\phi(e) = \frac{1}{4}(\deg_P(u) + \deg_P(v))$. With the exact same argument as in the proof of Claim 5, we get that $\phi(e) \geq 1/2$, which implies

$$\sum_{e\in P^\star} \phi(e) \geq \sum_{e\in P^\star} 1/2 = \rho(G)/2.$$

Since the degree of each vertex in P is at most two, we get

$$\sum_{e\in P^\star} \phi(e) = \frac{1}{4}\sum_{(u,v)\in P^\star} \deg_P(u) + \deg_P(v) \leq \frac{1}{4}\cdot 2\sum_{v\in V}\deg_P(v) = |P|.$$

By combining above inequalities we get $\frac{1}{2}\rho(G) \leq |P|$. Note that we do not need the randomization for the proof of the lower bound.

By construction of P, every vertex has degree at most two in P. Hence, all connected components of P are cycles and paths. We claim that at most $\frac{2}{K+2}$ fraction of connected components are cycles in expectation. Since the expected number of connected components is at most $\mathbf{E}\,|P|$, from this we get that the expected number of cycles is at most $2\,\mathbf{E}\,|P|/(K+2)$. By removing one edge from each cycle, we obtain a valid solution for maximum path cover problem. Thus,

$$\mathbf{E}\,|P| - \frac{2\,\mathbf{E}\,|P|}{K+2} = \frac{K}{K+2}\,\mathbf{E}\,|P| \leq \rho(G) \qquad \Rightarrow \qquad \mathbf{E}\,|P| \leq \left(1+\frac{2}{K}\right)\cdot\rho(G).$$

So it remains to show that at most $\frac{2}{K+2}$ fraction of connected components are cycles in expectation. As we process edges one by one according to the ordering of RGMIS, let A be the set of edges that none of their incident edges are added to the solution of Algorithm 2. By definition of A, if one copy of edge (u, v) is in A, then all other copies of (u, v) are also in A. Therefore, at any point during running RGMIS, if a new component is added to the solution, the edge (u, v) that gets added to the solution occupies (u^0, v^0) with probability at least $\frac{K}{K+2}$ since K copies out of the $K+2$ copies are for (u^0, v^0). Let C_0 be the number of times that the newly added component is an edge occupying two 0-ports, and C_1 be the number of times that the newly added component is an edge occupying one 0-port and one 1-port. By the above argument, we have

$$\frac{\mathbf{E}[C_0]}{\mathbf{E}[C_0]+\mathbf{E}[C_1]} = \frac{K}{K+2}. \tag{1}$$

Note that after running Algorithm 2, it is possible that the number of connected components is actually smaller than $C_0 + C_1$, since some of the components may merge as the algorithm proceeds. However, by Observation 7, two components that their first edge occupies two 0-ports will not merge together. Also, by Observation 6, none of the cycle components have an edge that occupies two 0-ports. Therefore, in the end, there exists at most $\mathbf{E}[C_0] + \mathbf{E}[C_1]$ connected components and at least $\mathbf{E}[C_0]$ of them will not be cycles. This completes the proof. ◀

5 A Local Query Process for Algorithm 2 and its Complexity

In this section, we define a query process to estimate the size of the output of Algorithm 2.

In graph H of Algorithm 2, each vertex corresponds to an edge in the original graph. More precisely, we make $K+2$ copies of each edge (u, v) such that one of the copies corresponds to an edge occupying (u^0, v^1), one for (u^1, v^0), and K for (u^0, v^0). We use $G' = (V, E')$ to show the new graph with these parallel edges. During the course of Algorithm 2, two different edges that share the same endpoint and port cannot appear in the solution together. We use the following definition to formalize this notion.

▶ **Definition 9** (Conflicting Pair of Edges). *Two edges $e, e' \in E'$ that share an endpoint v are* conflicting *if both e and e' correspond to same port v^i for $i \in \{0, 1\}$. We call (e, e') a conflicting pair of edges.*

In order to estimate the size of the output of Algorithm 2, we define a vertex oracle that given a vertex v and a permutation π on E', returns the degree of vertex v in the output of Algorithm 2. These are akin to the query processes used before in the works of [2, 27], but are specific to our Algorithm 2.

Algorithm 3 "vertex oracle" $\text{VO}(u, \pi)$ to determine the degree of vertex u in $\text{RGMIS}(G', \pi)$.

```
1 Let e_1 = (u, v_1), ..., e_r = (u, v_r) be the edges incident to u with π(e_1) < ... < π(e_r).
2 d ← 0
3 for i in 1...r do
4     if EO(e_i, v_i, π) = TRUE then d ← d + 1;
5 return d
```

Note that in Line 2 of the Algorithm 4 we only recursively call the function on edges that their label, conflict with edge e since if other edges appear in the RMGIS subgraph, we can still have e in the RGMIS subgraph. Before analyzing the query complexity of the vertex oracle, we prove the correctness of the vertex oracle.

▷ Claim 10. For any edge $e = (u, z) \in E'$ that is occupying ports u^i and z^j, if $\text{EO}(e, u, \pi)$ is called while computing $\text{VO}(v, \pi)$, then $\text{EO}(e, u, \pi) = \text{TRUE}$ iff $e \in \text{RGMIS}(G', \pi)$.

Proof. We prove the claim using induction on ranking of edge e. Assume that the claim is true for all edges with ranking smaller than $\pi(e)$. If $\text{EO}(e, u, \pi)$ is called by $\text{EO}(e' = (w, z), z, \pi)$ or directly by $\text{VO}(v, \pi)$, then by definition of Algorithm 4 and Algorithm 3, all edges $e'' = (w', z)$ with $\pi(e'') < \pi(e')$ that are occupying z^j are queried before e' which means that

Algorithm 4 "edge oracle" $\text{EO}(e, u, \pi)$ to determine an edge e is in $\text{RGMIS}(G', \pi)$. Also, u must be an endpoint of e.

```
if EO(e, u, π) computed before then return the computed result.;
Let e_1 = (u, v_1), ..., e_r = (u, v_r) be the edges incident to e such that
  π(e_1) < ... < π(e_r) < π(e). Also, (e, e_i) is a conflicting pair for all 1 ≤ i ≤ r.
for i in 1...r do
    if EO(e_i, v_i, π) = True then return False;
return True
```

none of them return True. Hence, by induction hypothesis, none of the edges incident to z that are occupying z^j with lower rank are in the $\text{RGMIS}(G', \pi)$. Moreover, $\text{EO}(e, u, \pi)$ calls all incident edges to u with lower rank that are occupying u^i and return Trueif none of them are in the $\text{RGMIS}(G', \pi)$ by induction hypothesis. Therefore, $\text{EO}(e, u, \pi) = \text{True}$ iff $e \in \text{RGMIS}(G', \pi)$. ◁

▷ Claim 11. Let $v \in V$ and d be the output of $\text{VO}(v, \pi)$. Then d is equal to the degree of vertex v in the subgraph outputted by $\text{RGMIS}(G', \pi)$.

Proof. The observation follows by combining the fact that the vertex oracle queries edges in increasing order and Claim 10. ◁

Let $T(v, \pi)$ denote the number of recursive calls to the edge oracle during the execution of $\text{VO}(v, \pi)$.

▶ **Theorem 12.** *For a randomly chosen vertex v and permutation π on E', we have that*

$$\mathbf{E}_{v,\pi}[T(v, \pi)] = O(\bar{d} \cdot \log^2 n)$$

where $\bar{d}$ is the average degree of the graph G.

Let $Q(e, v, \pi)$ be the number of $\text{EO}(e, \cdot, \pi)$ calls during the execution of $\text{VO}(v, \pi)$. Moreover, let $Q(e, \pi)$ be the number of $\text{EO}(e, \cdot, \pi)$ calls starting from any vertex. In other words, we have that $Q(e, \pi) = \sum_{v \in V} Q(e, v, \pi)$.

▶ **Observation 13.** *For every edge e and permutation π, $Q(e, \pi) \leq O(n^2)$.*

Proof. Let $e = \{x, y\}$. For a fixed vertex u, either the vertex oracle $\text{VO}(u, \pi)$ queries the edge oracle for e directly, or through some incident edge e'. Hence, the edge oracle of e is called through at most $(K+2)(\deg(x)-1)+(K+2)(\deg(y)-1)$ of its incident edges ($K+2$ appears since each edge has $K+2$ copies), which implies that $Q(e, u, \pi) \leq (2K+4)(n-1)+1$. Therefore,

$$Q(e, \pi) \leq \sum_{u \in V} Q(e, u, \pi) \leq n\left((2K+4)(n-1)+1\right) \leq O(n^2).$$ ◀

The main contribution of this section is to show that the expected number of $\text{EO}(e, \pi)$ calls over all permutations π is $O(\log^2 n)$, which is formalized in the following lemma.

▶ **Lemma 14.** *For any edge $e \in E'$, we have $\mathbf{E}_{\pi}[Q(e, \cdot, \pi)] = O(\log^2 n)$.*

Assuming the correctness of Lemma 14, we can complete the proof of Theorem 12.

Proof of Theorem 12.

$$\begin{aligned}
\mathbf{E}_{v,\pi}[T(v,\pi)] = \frac{1}{n}\,\mathbf{E}_{\pi}\Big[\sum_{v\in V} T(v,\pi)\Big] &= \frac{1}{n}\,\mathbf{E}_{\pi}\Big[\sum_{v\in V}\sum_{e\in E'} Q(e,v,\pi)\Big] \\
&= \frac{1}{n}\,\mathbf{E}_{\pi}\Big[\sum_{e\in E'}\sum_{v\in V} Q(e,v,\pi)\Big] = \frac{1}{n}\,\mathbf{E}_{\pi}\Big[\sum_{e\in E'} Q(e,\pi)\Big] \\
&= \frac{1}{n}\sum_{e\in E'}\mathbf{E}_{\pi}[Q(e,\pi)] = \frac{1}{n}\sum_{e\in E'} O(\log^2 n) \\
&= \frac{1}{n}O(|E'|\cdot\log^2 n) = O(\bar{d}\cdot\log^2 n).
\end{aligned}$$

◀

We defer the proof of Lemma 14 to the arXiv version of the paper due to the page limit.

6 Our Estimator for Maximum Path Cover

In this section, we use the oracle of the previous section to estimate the number of edges in the output of Algorithm 2. In Section 5, we provide a lower bound on the number of recursive calls to our local query process. Note that this bound does not necessarily imply the same running time algorithm. For example, if we generate the whole permutation over all copies of edges before running the algorithm, it takes $\Theta(m)$ which is no longer sublinear. Using by now standard ideas of the literature, we show how we can implement the query process in almost the same running time (multiplied by a polylogarithmic factor) which is formalized in the following lemma (see the arXiv version of the paper).

▶ **Lemma 15.** *There exists a data structure that given a graph G in the adjacency list format, (implicitly) fixes a random permutation π over its edges. Then for any vertex v, the data structure returns the degree of vertex v in the subgraph P produced by Algorithm 2 according to a random permutation π. Each query v to the data structure is answered in $\tilde{O}(T(v,\pi))$ time w.h.p. where $T(v,\pi)$ is as defined in Section 5.*

Note that in our local query process, we need access to the adjacency list of weight-one edges. So the challenge that arises here is how to estimate the size of the output of Algorithm 2 in the adjacency matrix model. We present a reduction from adjacency matrix to adjacency list that appeared in the literature [2]. In this reduction, each query to the adjacency list can be implemented with $O(1)$ queries to the adjacency matrix and still we are able to estimate the maximum path cover with some additive error.

Let $\gamma = 16Kn$. We construct a graph $\hat{G} = (V_{\hat{G}}, E_{\hat{G}})$ for weight-one edges of graph G as follows:

- $V_{\hat{G}}$ is the union of V_1, V_2 and $U_1, U_2, \ldots, U_n$ such that:
  - V_1 and V_2 are two copies of the vertex set of the original graph G.
  - U_i is a vertex set of size γ for each $i \in [n]$.
- We define the edge set such that degree of each vertex is in $\{1, n, n+\gamma\}$:
  - Degree of each vertex $v \in V_1$ is n. The i-th neighbor of v is the i-th vertex in V_1 if $(v,i) \in E$, otherwise its i-th neighbor is the i-th vertex in V_2 for $i \le n$. Note that graph $(V_1, E_H \cap (V_1 \times V_1))$ is isomorphic to G.
  - Degree of each vertex $v \in V_2$ is $n+\gamma$. The i-th neighbor of v is the i-th vertex in V_2 if $(v,i) \in E$, otherwise, its i-th neighbor is the i-th vertex in V_1 for $i \le n$. For all $n < i \le n+\gamma$, the i-th neighbor of v is i-th vertex in U_v.
  - Degree of each vertex $u \in U_i$ is one for $i \in [n]$. The only neighbor of u is the i-th vertex of V_2.

By the construction of $\hat{G}$, the only neighbor of $v \in \bigcup_{i=1}^{n} U_i$ can be determined without any query to the adjacency matrix. Also, the i-th neighbor of each vertex in $V_1 \cup V_2$ can be determined with one query.

▶ **Observation 16.** *For each vertex $v \in V_{\hat{G}}$ and $i \in [\deg_{\hat{G}}(v)]$, the i-th neighbor of vertex v can be determined using at most one query to the adjacency matrix.*

Fix a vertex $v \in V_2$. When we run Algorithm 2, intuitively with high probability the first edge that is incident to v and occupies port v^0 is between v and $u \in U_v$. Furthermore, with high probability, the first two edges that are incident to v and occupies port v^1 are between v and $u \in U_v$. A vertex $v \in V_2$ is an *abnormal* vertex if the above properties do not hold for v. Let $R \in V_2$ be the set of abnormal vertices. We can show that there are few abnormal vertices exist in V_2, which implies that most of the incident edges to vertices of V_1 in the output of Algorithm 2 are in $\hat{G}[V_1]$ (only those between V_1 and R violate this property). Therefore, a natural way to estimate the number of edges in the output of Algorithm 2 on G, is to estimate the number of edges in $\hat{G}[V_1]$ in the output of Algorithm 2 on $\hat{G}$.

Algorithm 5 Final algorithm for maximum path cover.

1 Let $\hat{G} = (V_{\hat{G}}, E_{\hat{G}})$ as described above.
2 $r \leftarrow 192 \cdot K^2 \cdot \log n$.
3 Sample r vertices $u_1, u_2, \ldots, u_r$ uniformly at random from V_1 with replacement.
4 Sample r ports $p_1, p_2, \ldots, p_r$ uniformly at random from $\{0, 1\}$.
5 Run vertex oracle for each u_i and let X_i be the indicator if port $u_i^{p_i}$ is occupied with an edge in $\hat{G}[V_1]$ in output of Algorithm 2.
6 Let $X = \sum_{i \in [r]} X_i$ and $f = X/r$.
7 Let $\tilde{\rho} = \frac{K}{2(K+2)} \cdot (f \cdot n - \frac{n}{4K})$.
8 **return** $\tilde{\rho}$

▶ **Theorem 17.** *Given an adjacency matrix access for input graph G, there exists a randomized algorithm that w.h.p. runs in $\widetilde{O}(n)$ time and produces an estimate $\tilde{\rho}$, such that*

$$\left(\frac{1}{2} - \varepsilon\right) \cdot \rho(G) - \varepsilon n \leq \tilde{\rho} \leq \rho(G).$$

7 Our Estimator for (1,2)-TSP

In this section, we use the algorithm for estimating the size of maximum path cover as a black box to estimate the size of (1,2)-TSP. First, note that if there is no Hamiltonian cycle with weight one edges of the graph, then the set of weight-one edges of the graph (1,2)-TSP is a solution for maximum path cover of graph G. Also, in the case that there exists a Hamiltonian cycle, then the size of maximum path cover is $n - 1$. Moreover, if P^* is the maximum path cover of a graph G, then it is possible to create a TSP by connecting these paths using edges with weight two. This intuition helps to formalize the following observation.

▶ **Observation 18.** *Let $\tau(V)$ be the cost of (1,2)-TSP of graph $G = (V, E)$. Then, we have*

$$2n - \rho(G) - 1 \leq \tau(V) \leq 2n - \rho(G).$$

Now we are ready to present the final algorithm for estimating (1,2)-TSP.

Algorithm 6 Final algorithm for (1,2)-TSP.

1 Construct $\hat{G} = (V_{\hat{G}}, E_{\hat{G}})$ implicitly as desribed in Section 6.
2 Let $\tilde{\rho}$ be the output of Algorithm 5 on $\hat{G}$.
3 $\tilde{\tau} = 2n - \tilde{\rho}$
4 **return** $\tilde{\tau}$

▶ **Theorem 19.** *Let $\tau(V)$ be the cost of (1,2)-TSP of graph $G = (V, E)$. For any $\varepsilon > 0$, there exists an algorithm that estimate the cost of (1,2)-TSP, $\tilde{\tau}$, such that*

$$\tau(V) \leq \tilde{\tau} \leq (\frac{3}{2} + \varepsilon) \cdot \tau(V),$$

w.h.p in $\tilde{O}(n)$ running time.

8 Our Estimator for Graphic TSP

In this section, we use our algorithm for estimating the size of maximum path cover to estimate the size of graphic TSP. In a recent work, Chen et al. [10] showed that it is possible to obtain a (27/14)-approximate algorithm for graphic TSP by estimating the matching size and the number of biconnected components in the graph. Since the size of graphic TSP is at most $2n$ (the cost of MST is $n - 1$), they proved that if a graph has large matching and a few biconnected components, the cost of graphic TSP is significantly lower than $2n$. Since estimating the number of biconnected components is not an easy task in sublinear time, they use a proxy quantity that can be estimated in sublinear time.

In the full version of the paper, we show that if we use our estimator for maximum path cover as a black-box instead of matching estimator in algorithm of [10], we can improve the approximation ratio to 19/10. Moreover, we show that we can estimate the number of bridges in $\tilde{O}(n)$. We exploit this estimation for further improvement to get a 11/6-approximate algorithm for graphic TSP. We use the following algorithm for estimating the size of graphic TSP.

Algorithm 7 Improved algorithm for graphic TSP.

1 Construct $\hat{G} = (V_{\hat{G}}, E_{\hat{G}})$ implicitly as described in Section 6.
2 Let $\tilde{\rho}$ be the output of Algorithm 5 on $\hat{G}$.
3 Let $\tilde{B}$ be the estimate of the number of bridges.
4 $\tilde{\tau} = 2n - \frac{1}{3}(\tilde{\rho} - \tilde{B})$
5 **return** $\tilde{\tau}$

▶ **Theorem 20.** *Let $\tau(V)$ be the cost of graphic TSP of graph $G = (V, E)$. For any $\varepsilon > 0$, there exists an algorithm that estimate the cost of graphic TSP, $\tilde{\tau}$, such that*

$$\tau(V) \leq \tilde{\tau} \leq (\frac{11}{6} + \varepsilon) \cdot \tau(V),$$

w.h.p in $\tilde{O}(n)$ running time.

Abstract

We consider the problem of reconstructing the symmetric difference between similar sets from their representations (sketches) of size linear in the number of differences. Exact solutions to this problem are based on error-correcting coding techniques and suffer from a large decoding time. Existing probabilistic solutions based on Invertible Bloom Lookup Tables (IBLTs) are time-efficient but offer insufficient success guarantees for many applications. Here we propose a tunable trade-off between the two approaches combining the efficiency of IBLTs with exponentially decreasing failure probability. The proof relies on a refined analysis of IBLTs proposed in (Bæk Tejs Houen et al. SOSA 2023) which has an independent interest. We also propose a modification of our algorithm that enables telling apart the elements of each set in the symmetric difference.

1 Introduction

The problem of *set reconciliation* (or *database reconciliation* [12]) lies at the intersection of several lines of algorithmic research. One intuitive way to define it is in terms of communication protocols: assume that two parties Alice and Bob hold similar sets S and T, respectively, that they seek to reconcile (i.e. identify differences) using low communication overhead. Rather than exchanging representations of entire sets, they exchange their small *sketches* holding enough information to identify differences of S and T provided that their number does not exceed a pre-defined parameter D.

In this paper, we study the version of the problem where the differences $S \triangle T := (S \setminus T) \cup (T \setminus S)$ should be recovered from the sketches of S and T rather than from the sketch of one of them and the entire other set. This opens a way to the setting, relevant to some applications, when only sketches of sets are stored in a database, and for each pair of sets, items proper to one of them can be retrieved from the corresponding sketches. As an example, consider a vast database of highly similar genomic sequences, such as those of SARS-Cov-2 genomes[1], that are stored in the form of sketches, rather than raw sequences, still supporting retrieval of differences between any two of them. Beyond this example, set reconciliation

[1] More than 16M SARS-Cov-2 are available in GISAID database at the time of writing, which typically differ one from another by just a few characters, over about 30,000 characters of length.

problem occurs in many other scenarios in distributed systems, where information needs to be synchronized between computational units. Those include blockchain systems, P2P systems, ad-hoc networks, synchronizing information across devices or data centers, and others.

The set reconciliation problem is also raised in the streaming framework. It is a common and natural requirement that the sketch can be efficiently updated when a new key is added to or deleted from the set. For example, [6] considers the *straggler identification* problem defined on a stream of insertions and deletions of keys modeling a stream of people entering and leaving a building. In this model, the sketch summarizes information about people currently in the building and if their number does not exceed D, is capable of listing them.

1.1 Prior work

Solutions to set reconciliation can be categorized into probabilistic and exact ones (although there exists an interplay between these two classes of algorithms) [25]. Probabilistic algorithms are based on Invertible Bloom Lookup Tables (IBLTs), also known as Invertible Bloom Filters, based on random hash functions. Originally proposed in [6] where they were applied to the problem of *subset reconciliation* (set reconciliation assuming $S \subseteq T$), they (in a slightly different version) were more systematically studied in [12]. Earlier a related data structure, called *k-set data structure*, was proposed in [10]. Set reconciliation by computing a difference of IBLTs (called *difference digest*) was studied in [7]. Work [21] further applies IBLTs to *multi-party* set reconciliation. The idea of "subtracting" IBLTs has also been applied in [9], where the emphasis is to store in an IBLT carefully defined hash values obtained using cryptography techniques. Very recent work [1] studies a simplified version of IBLTs that also applies to set reconciliation. We rely on this construction in the present paper.

An exact solution of the set reconciliation problem uses algebraic techniques, in particular *error-correcting codes* [7, 3, 4]. Work [20] proposes an exact solution based on characteristic polynomials to both subset and set reconciliation problems using $(D+1)\log U$ bits of space (i.e. essentially the space needed to store D differences). [11] studies the straggler identification problem with multiplicities and proposes an $\mathcal{O}(D\log(Um))$-bit solution based on polynomials over finite field, where each key occurs at most m times. A somewhat similar solution to subset reconciliation was proposed in [6], based on Newton polynomials. [3] surveys code-theoretic techniques for space recovery many of which apply to set reconciliation as well. Set reconciliation with BCH codes has been implemented in Minsketch software [19], leveraging an efficient syndrome decoding algorithm for BCH codes [5]. [4] proposes a method for sparse recovery based on expander codes; the construction of [4] can be interpreted as a table somewhat similar to IBLT but with a different decoding mechanism. Recent papers [23, 2] apply algebraic techniques to construct specific "hash functions" that guarantee successful decoding for IBLTs. The general downside of exact solutions is a larger decoding time, typically growing at least quadratically in D and relying on finite field arithmetic. Note also that the relationship between codes and set reconciliation is two-way: [22] proposes a construction of codes based on set reconciliation with IBLTs.

1.2 Our contribution: overview

The IBLT solution to set reconciliation is very efficient but provides a poor success guarantee. For example, if we have to compute similarity joins by performing all pairwise reconciliations of the objects in our database, then a significant fraction of comparisons may fail. On the other hand, techniques based on error-correcting codes are exact but have a high cost of

decoding. Here we propose a family of solutions to set reconciliation offering a trade-off between these two approaches, that is having significantly smaller error rate compared to IBLT at the price of an asymptotically vanishing increase of space and time bounds.

Our solution is based on the space-efficient IBLT from [1] complemented by an additional *stash* data structure supporting recovery in case of failure of the main IBLT. The analysis of [1] provides no guarantee in the case when the IBLT decoding fails. Therefore, here we enhance the analysis of [1] and prove a probability bound on the number of missing and extraneous elements reported by the data structure, in the event that the correct decoding fails. This is a key argument of our construction and its proof constitutes the main technical contribution of this paper.

The algorithm we obtain is parametrized and provides a tunable trade-off between the failure probability and space and time consumption. In the table below, we provide an overview of how our solution relates to the existing approaches surveyed in Section 1.1.

Table 1 Comparison of main techniques of set reconciliation to the results of the present work. r is a parameter assumed to verify $r = \min\left(\mathcal{O}(D/\log^2 U), \mathcal{O}(\log U)\right)$. For our algorithm, decoding time given is expected.

Method	Sketch size (bits)	Insertion time	Decoding time	Failure probability
IBLT [1]	$(c_3+\epsilon)D\log U$	$\mathcal{O}(1)$	$\mathcal{O}(D)$	$\mathcal{O}(D^{-1})$
IBLT with t-bit hashsum field	$(c_3+\epsilon)D(\log U + t)$	$\mathcal{O}(1+t/\log U)$	$\mathcal{O}(D(1+t/\log U))$	$\min(\mathcal{O}(D^{-1}), \mathcal{O}(D/2^t))$
BCH	$D\log U$	$\mathcal{O}(D\log U)$	$\mathcal{O}(D^2\log^2 U)$	0
expander code [4]	$\mathcal{O}(D\log^2 U)$	$\mathcal{O}(\log U)$	$\mathcal{O}(D\log U)$	0
this paper	$(c_3+\epsilon)D\log U + r\log U$	$\mathcal{O}(r\log U)$	$\mathcal{O}(D)$	$2^{-\Omega(r)}$

The paper is organized as follows. In Section 2, we introduce our version of IBLT, which is a slightly modified set sketch from [1]. This data structure is very space-efficient, however its compactness has a price: the decoding process can "go wrong" triggering undesirable *anomalous* steps [1]. In Section 3.2, we provide a refined analysis of anomalies and prove the following fundamental property: if the sketch stores a set S, the decoding produces a set S_{dec} with $|S \triangle S_{dec}| \leq r$, with a failure probability of $2^{-\Omega(r)}$. Section 4 introduces a solution to set reconciliation based on BCH error-correcting codes. Relying on that result, in Section 5, we extend the IBLT with a backup data structure (stash) to obtain an efficient solution to set reconciliation. The algorithm resorts to the stash when the decoding with the main IBLT is not completed, leaving out a small number of keys. The stash is defined using error-correcting codes. In Section 6, we discuss how to extend our algorithm in order to identify the original set of the keys of the set difference.

2 Set reconciliation with Invertible Bloom Lookup Tables

Definition of IBLT. An Invertible Bloom Lookup Table (IBLT) is an array $A[1:n]$ equipped with k random hash functions $h_1, \ldots, h_k : \mathcal{U} \to [n]$, from the key universe $\mathcal{U}$ to $[n] = \{1, \ldots, n\}$. We assume h_i's to be fully random and denote $h(x) = \{h_1(x), \ldots, h_k(x)\}$.

Several variants of IBLTs have been considered, which differ in how entries $A[i]$ are configured. In all of them, $A[i]$ contains a keysum field that holds either bitwise XOR [12, 7, 21, 1] or arithmetic sum [6, 12] of all current keys hashed to i. XOR provides a more elegant and space-efficient option whereas arithmetic sum becomes necessary when multi-sets are considered. In this work, the keysum field is defined with XOR and is set to contain $\log U$ bits ($U = |\mathcal{U}|$).

Algorithm `initialise`**:**
$A[1:n] = (0, \dots, 0)$

Algorithm `toggle`(x)**:**
for $i \in h(x)$ **do**
$A[i] \leftarrow A[i] \oplus x$

Algorithm `merge`$(A[1:n], A'[1:n])$**:**
for $i \in [n]$ **do**
$B[i] \leftarrow A[i] \oplus A'[i]$
return B

Algorithm `looksPure`$(i \in [n])$**:**
return $A[i] \neq 0 \wedge i \in h(A[i])$

Algorithm `decode`**:**
$S_{\text{dec}} \leftarrow \varnothing$
$Q \leftarrow \{i \in [n] \mid \mathsf{looksPure}(i)\}$
$(t, t_{\max}) \leftarrow (0, 2n)$ // time limit $2n$
while $Q \neq \varnothing$ **do**
$Q_{\text{next}} \leftarrow \varnothing$
for $i \in Q$ **if** $\mathsf{looksPure}(i)$ **do**
$x \leftarrow A[i]$ // *detected* key x
$\mathsf{toggle}(x)$
$S_{\text{dec}} \leftarrow S_{\text{dec}} \triangle \{x\}$
$Q_{\text{next}} \leftarrow Q_{\text{next}}$
$\cup \{i \in h(x) \mid \mathsf{looksPure}(i)\}$
$t \leftarrow t + 1$
if $t \geq t_{\max}$ **then**
return S_{dec}
$Q \leftarrow Q_{\text{next}}$
return S_{dec}

Figure 1 IBLT implementation from [1] with added time limit in decode.

Besides the keysum, $A[i]$ can include a hashsum field that holds a hash sum of the keys in $A[i]$ and/or a counter field that tracks the current number of keys in $A[i]$. These are used for enforcing proper functioning and integrity of the data structure at the price of using additional space. In this work, we use the most compact IBLT configuration with three hash functions ($k = 3$) and $A[i]$ storing the keysum field only. This variant was introduced and analysed in recent paper [1] that we rely on in this work. Later in Section 6 we consider an extension introducing a restricted counter field.

Our IBLT implementation is defined in Figure 1. Initially, all entries $A[i]$ are set to zero with `initialise`. Both insertion and deletion of a key x is done by performing `toggle`(x).

Decoding the keys stored in an IBLT resembles the *peeling* process of the k-hypergraph, where n IBLT entries correspond to hypergraph vertices and each stored key corresponds to a hyperedge defined as the set of entries the key is hashed to. Peeling a hypergraph iterates the following operation: for any vertex of degree 1, delete the incident hyperedge. If the peeling results in the empty graph with no hyperedges, the input graph is called *peelable*; otherwise the process yields the largest subhypergraph with every vertex of degree at least 2, which is called the 2-*core* (hereafter simply *core*). It is known that peelability of random k-hypergraphs ($k \geq 3$) with n vertices and m hyperedges undergoes a phase transition: if $n > c_k m$, then the hypergraph is peelable with high probability (hereafter, *whp*), whereas if $n < c_k m$, the hypergraph is not peelable whp. Here constant c_k is the peelability threshold, in particular $c_3 = 1.22179\dots$ is the smallest of c_k for $k \geq 3$. The following results is shown in [12].

▶ **Theorem 1.** *Whenever $n > c_k m$, a random k-hypergraph is peelable except with probability $\mathcal{O}(1/n^{k-2})$.*

Set reconciliation using difference IBLT. Consider two sets S and T stored in IBLTs $A_S[1:n]$ and $A_T[1:n]$ respectively, using the same hash functions. If S and T have a bounded symmetric difference, that is $|S \Delta T| \leq D$, and $n > c_k D$, then the keys of $S \Delta T$ can

be recovered whp from the *difference IBLT* $A_{ST}[1:n] = \texttt{merge}(A_S, A_T)$. It is immediate to see that common keys of S and T are canceled out and A_{ST} stores exactly the keys $S \Delta T$. Thus, the difference IBLT can solve set reconciliation except with probability $\mathcal{O}(1/D)$.

Note that A_{ST} does not allow distinguishing keys of $S \setminus T$ and $T \setminus S$; below in Section 6 we will extend the construction to make this possible. Note also that for the reconciliation to be possible, the size n of IBLTs only depends on the size of the symmetric difference and does not depend on the sizes of S and T.

3 Improved Guarantees for IBLTs

Consider the IBLT implementation as given in Figure 1. It uses only the keysum field in its buckets and was studied, modulo slight changes stated below, in [1] under the name "simple set sketch". In this section we enhance the analysis given in [1] (reproduced as (i) in Theorem 2 below) by also probabilistically bounding the magnitude of the error of decode in its failure cases (given as (ii)). Note that we restrict our attention to three hash functions ($k = 3$) as this yields the best threshold value.[2]

▶ **Theorem 2.** *Let $\varepsilon > 0$ and $n > (c_3 + \varepsilon)|S|$. Let S_{dec} be the set returned by decode.*
(i) $\Pr[S_{\text{dec}} = S] = 1 - \widetilde{\mathcal{O}}(1/n)$.
(ii) *For any $r = o(n)$ we have* $\Pr[|S \triangle S_{\text{dec}}| > r] = 2^{-\Omega(r)}$.

Changes made to decode. Our version of decode differs from that in [1] in two minor ways. First, we have introduced a *time limit* of $2n$ to the number of peeling steps that are performed and return the current state of S_{dec} when the time limit is reached[3]. The result from [1] still applies with this change, since the authors proved that decode terminates in $n + \text{poly}\log(n)$ peeling steps with $S_{\text{dec}} = S$ with probability $1 - \mathcal{O}(1/n)$. Second, we insist that Q and Q_{next} are implemented as set data structures, e.g. using hash tables, whereas [1] pointed out that Q and Q_{next} can be implemented as multiset data structures, e.g. using FIFO queues.[4]

It should be clear that our version of decode can be implemented such that it has running time $\mathcal{O}(n)$, both in expectation and with high probability.

3.1 The issue of anomalies

Decode checks if the ith *bucket* of A contains a single key using the function $\texttt{looksPure}(i)$ that checks if $h_j(A[i]) = i$ for some $j \in \{1, 2, 3\}$. Importantly, $\texttt{looksPure}(i)$ may produce a false positive result when $A[i] = x_1 \oplus x_2 \oplus \ldots \oplus x_{\ell-1}$ is the sum of several keys hashing to i and $y = A[i]$ also happens to hash to i, i.e. $h_\sigma(y) = i$ for some $\sigma \in \{1, 2, 3\}$. Such an occurence $\{x_1, \ldots, x_{\ell-1}, y\}$ is called an *anomaly* (of size ℓ) in [1] and causes the key y to be toggled and thus inserted into the data structure. Anomalies corrupt the decoding process and may cause decode to fail or even to run in an infinite loop if no time limit is set [1].

[2] In [1] any $k \geq 3$ was considered and our analysis here could likewise be extended.
[3] In practice a dynamic time limit could be considered. For instance: Abort if a round of decode only toggles keys that have already been toggled in a previous round.
[4] At no point did the analysis from [1] actually *rely* on Q or Q_{next} being multisets. The motivation was merely that FIFO queues are the more lightweight data structure. We revert this simplification here because an argument from [1] showing that the impact of duplicated elements is negligible no longer applies. In fact, with a FIFO implementation of Q and Q_{next} we could see 2^R copies of the same element in Q in the Rth iteration of the while loop with small but non-negligible probability $n^{-\mathcal{O}(1)}$.

Dealing with anomalies is a challenging issue. In [1], it was proved that certain kinds of anomalies and certain interactions of several anomalies do not occur except with probability $\tilde{O}(1/n)$. Since $\mathcal{O}(1/n)$ is the probability for the existence of a non-empty core (see Theorem 1 for $k = 3$), which also causes decoding to fail, anomalies do not increase the failure probability significantly.

In this section we will go further, proving that *even in the unlikely cases where decoding produces an incorrect result*, e.g. due to problematic anomalies, the magnitude of the error is likely to be small.

3.2 Proof Outline

We quantify the effect of anomalies by considering two sets. First, the set F of all *foreign keys*, which are keys from $\mathcal{U} \setminus S$ that are added to the sketch at least once during the decoding process. Second, the set N of all centres of certain anomalies we call *internal anomalies* (defined in Section 3.4). Our proof of Theorem 2 rests on the following arguments.

- In Section 3.3 we bound the size of F. Intuitively, the heuristic looksPure is used $\mathcal{O}(n)$ times and fails each time with probability $\mathcal{O}(1/n)$. Each failure can cause one foreign key to be added, suggesting $\mathbb{E}[|F|] = \mathcal{O}(1)$. The precise argument, including a concentration bound for $|F|$, is more subtle since failures do not happen independently.
- In Section 3.4 we import a tail bound on $|N|$ from [1].
- In Section 3.5 we reframe the decoding process as the well-understood *peeling process* on a random hypergraph. Since peeling follows a local rule, the corruption due to anomalies spreads locally as well. This already implies that the majority of keys are correctly decoded if anomalies are rare.
- In Section 3.6 we prove a claim regarding the maximum hyperedge density of any subhypergraph of a given random hypergraph. Its intuitive role is to show that the size of the queue Q in late rounds of decode would always be, in the absense of anomalies, at least linear in the number of remaining keys. This implies that the anomalies only have the potential to stall progress in a significant way if they affect a number of buckets that is linear in the number of remaining keys.
- In Section 3.7 we stitch everything together: The effect of anomalies as quantified by $|F|$ and $|N|$ is probabilistically bounded. Peeling is likely to proceed largely unhindered in its early rounds. In its later rounds it proceeds until the number of remaining keys is linear in $|F| + |N|$.

3.3 Bounding Foreign Keys

Let $y \in \mathcal{U} \setminus S$ be any foreign key. In order for y to be added to the IBLT, y must occur as the sum of several keys in one of the buckets $h_1(y), h_2(y), h_3(y)$. Since $h_1(y), h_2(y), h_3(y)$ are uniformly random in $[n]$ and independent of the initial state of the data structure, decode would have to effectively "guess" a hash of y. We argue that decode is, in this sense, a player in a corresponding guessing game that, even if played optimally, rarely allows a player to guess a lot of hashes correctly.

A guessing game. Let $(X_{j,\sigma})_{j\in\mathbb{N},\sigma\in[3]}$ be a family of i.i.d. random variables with uniformly random values in $[n]$. Consider a game in which the player does not know the random variables. She may issue queries of the form $(i, j) \in [n] \times \mathbb{N}$ and is told whether or not $i \in \{X_{j,\sigma} \mid \sigma \in [3]\}$. If she gets a positive answer, we say she has *solved* group j and she is told the values $X_{j,1}$,$X_{j,2}$ and $X_{j,3}$.

▶ **Lemma 3.** *Assume a player is given* $6n$ *queries. She solves more than* r *groups with probability* $\mathcal{O}(2^{-r})$.

Proof. Consider a query $(i, j) \in [n] \times \mathbb{N}$ that is the kth query of the form $(\cdot, j)$ where j is an unsolved group. We distinguish two cases.

Case 1: $k \geq n/2$. We generously grant group j as solved. This affects at most $6n/(n/2) = 12$ groups.

Case 2: $k \leq n/2$. Up to $k-1$ values are already excluded for the variables $X_{j,1}$, $X_{j,2}$ and $X_{j,3}$. All other values are equally likely. The probability of solving group j with this query is at most $1 - (1 - \frac{1}{n-k+1})^3 < 1 - (1 - \frac{2}{n})^3 \leq \frac{6}{n}$.

Let Y be the number of successes due to Case 2. A simple coupling yields a random variable Z with $Y \leq Z$ and $Z \sim \mathrm{Bin}(6n, \frac{6}{n})$. We can think of Z as the sum of the outcomes of $6n$ Bernoulli trials. In order for Z to attain a value of at least $\ell = r - 12$ there must exist a set $T \subseteq [6n]$ of size ℓ such that the corresponding Bernoulli trials are all successes. A union bound over all choices of T yields:

$$\begin{aligned}\Pr[Y \geq \ell] \leq \Pr[Z \geq \ell] &\leq \binom{6n}{\ell}\left(\frac{6}{n}\right)^{\ell} \leq \left(\frac{6ne}{\ell}\right)^{\ell}\left(\frac{6}{n}\right)^{\ell} \\ &\leq \left(\frac{36e}{\ell}\right)^{\ell} = \left(\frac{36e}{r-12}\right)^{r-12} \leq 2^{-r+12},\end{aligned}$$

where the last step assumes $r \geq 72e + 12$.

Overall, if $r \geq 72e + 12$ then the number of successes is bounded by r, except with probability $\mathcal{O}(2^{-r})$. ◀

How this relates to the foreign keys. Let $F \subseteq \mathcal{U} \setminus S$ be the set of all foreign keys that are added to S_{dec} at least once during the execution of decode.

▶ **Lemma 4.** *For any $r \in \mathbb{N}$ we have $\Pr[|F| > r] = \mathcal{O}(2^{-r})$.*

Proof. Before decoding begins, the family $(h_\sigma(y))_{y \in \mathcal{U} \setminus S, \sigma \in [3]}$ of hashes of foreign keys are independent and uniformly random in $[n]$ just as is required in the guessing game above. We interpret decode as a player. Whenever decode executes the looksPure operation for a bucket i containing $A[i] = y \in \mathcal{U} \setminus S$, then we interpret this as the player issuing the query (y, i). He learns whether $i \in \{h_1(y), h_2(y), h_3(y)\}$ and, on a positive answer, he also learns the values $h_1(y), h_2(y), h_3(y)$. This is sufficient to continue the execution of decode, in particular decode amounts to a valid player respecting the access limitation to the relevant random variables.

The crucial observation is that any $y \in F$ is solved by decode. Indeed, if $y \in F$ then y was added to S_{dec} at some point during the execution of decode and this addition was immediately preceeded by a corresponding successful looksPure check.

The number q of queries issued by decode is by definition the number of calls to looksPure. Every time a bucket i is considered to be added to Q or Q_{next} there is one such call, and, if i is added, there can be another call when i is removed from Q. Due to the time limit we have $q \leq 2(n + t_{\max}) \leq 6n$. Therefore Lemma 3 implies our claim. ◀

3.4 Bounding Centres of Internal Anomalies

It is worthwhile to clarify the notion of anomalies by giving a precise definition of the set $\mathcal{A}$ of all anomalies.

$$\mathcal{A} = \left\{ \varnothing \neq A \subseteq \mathcal{U} \,\middle|\, \bigoplus_{x \in A} x = 0, \bigcap_{x \in A} h(x) \neq \varnothing \right\}$$

If $A = \{x_1, \ldots, x_\ell\}$ is an anomaly then the presence of any $\ell - 1$ keys from A can be mistaken as the presence of the missing ℓth key (because of $x_1 \oplus \ldots \oplus x_{\ell-1} = x_\ell$). A value $i \in \bigcap_{x \in A} h(x)$ is a centre of the anomaly A (in principle a single anomaly could have multiple centres). The set $\mathcal{A}$ makes no mention of S and contains many anomalies that are unlikely to become relevant during decoding. Immediately threatening is, however, the set of *native anomalies* $\mathcal{A}_{\text{nat}}$ define as

$$\mathcal{A}_{\text{nat}} = \{A \in \mathcal{A} \mid |A \setminus S| \leq 1\}.$$

For a native anomaly A, all but at most 1 key from A are present in the beginning, enough to cause trouble right away. In what follows, a subset of the native anomalies, namely the *internal* anomalies $\mathcal{A}_{\text{int}}$ and the set N of its centres play a role. They are defined as

$$\mathcal{A}_{\text{int}} = \{A \in \mathcal{A} \mid A \subseteq S\} \text{ and } N = \bigcup_{A \in \mathcal{A}_{\text{int}}} \bigcap_{x \in A} h(x).$$

▶ **Lemma 5.** *For any $r \in \mathbb{N}$ we have $\Pr[|N| > r] = \mathcal{O}(2^{-r})$.*

Proof. The authors of [1] show in their Lemma 2.2 that the set $N_{\text{nat}} = \bigcup_{A \in \mathcal{A}_{\text{nat}}} \bigcap_{x \in A} h(x)$ of centres of native anomalies satisfies $\Pr[N' \geq r] \leq \left(\frac{3e^4}{r}\right)^r$. For $r \geq 6e^4$ this is at most 2^{-r}. Since $N_{\text{nat}} \supseteq N$ the claim follows. ◀

3.5 Early Rounds of the Peeling Process

We will use a result by Molloy who analysed cores of random hypergraphs [24]. The hypergraph H arising in our setting has vertex set is $[n]$ and the m hyperedges $\{\{h_\sigma(x) \mid \sigma \in [k]\} \mid x \in S\}$. By the *parallel peeling* process we mean an algorithm on a hypergraph. In each round, all vertices of degree 0 or 1 are determined (simultaneously) and then all of these vertices are removed, including all incident hyperedges. When no vertex of degree 0 or 1 remains, the core of the hypergraph is reached, which may be empty. Note that decode implements this peeling process, except that anomalies may occur.

Early Peeling Without Anomalies. A lemma by Molloy is the following.

▶ **Lemma 6** ([24, Lemma 3])**.** *For any $\varepsilon, \delta > 0$, there exists $R \in \mathbb{N}$ such that after peeling a k-uniform hypergraph with $\frac{n}{m} > c_3 + \varepsilon$ for R rounds then at most δn vertices remain in expectation.*[5]

In the following we assume that constants $\varepsilon, \delta > 0$ are given and $R \in \mathbb{N}$ is the corresponding constant from Lemma 6.

By the R-neighbourhood of a vertex v or hyperedge e we mean the subhypergraph of H induced by all vertices that can be reached from v or e by traversing at most R hyperedges.

It is a well-known fact (and a consequence of the Poisson limit theorem) that the degree distribution of H converges to a Poisson distribution with parameter $3/c_3$ for $n \to \infty$. More generally, the distribution of the R-neighbourhoods of the vertices in H converges (see e.g. [15, 16]). This implies that we can choose a constant $D = D(\varepsilon, \delta, R)$ large enough such the probability that a given vertex has a vertex of degree at least D in its R-neighbourhood is at most δ.

[5] Molloy's Lemma is slightly stronger in that it claims that at most δn vertices remain with probability $1 - o(1)$. Since we need a much stronger concentration bound, we will redo a corresponding step ourselves.

In this context call a vertex v *good* if

(a) v is removed by the R-round peeling process

(b) the R-neighbourhood of v does not contain a vertex of degree at least D.

Since the first condition is met by at least $(1-\delta)n$ vertices in expectation by Lemma 6 and the second condition by at least $(1-\delta)n$ vertices in expectation by choice of D, the set G of good vertices has expectation at least $(1-2\delta)n$.

We will now use the bounded difference inequality by McDiarmid [18].

▶ **Lemma 7** (McDiarmid's inequality [18]). *Let $\mathcal{X}$ be some set, $d \in \mathbb{N}$ and $f : \mathcal{X}^n \to \mathbb{R}$ a function such that changing any one argument of f can affect the function value by at most d. Let $X_1, \dots, X_n$ be i.i.d. random variables with values in $\mathcal{X}$. Then*

$$\Pr[|f(X_1,\dots,X_n) - \mathbb{E}[f(X_1,\dots,X_n)]| > \varepsilon] \leq \exp(-\varepsilon^2/(nd^2)).$$

This gives us a concentration bound on the number of good vertices.

▶ **Lemma 8.** *In the above context there exists a constant $\gamma = \gamma(\varepsilon, \delta, R, D) > 0$ such that*

$$\Pr[|G| < (1-3\delta)n] \leq \exp(-\gamma n).$$

Proof. Note that whether or not a vertex is good is a *local* property in the sense that it only depends on its R-neighbourhood. This gives us a bounded difference property of $|G|$ as follows.

The set G (and therefore $|G|$) is a function of the $3m$ hash values defining the m hyperedges. Assume we change a single hash value from v to $v' \neq v$. A previously non-good vertex might become good only if it was in the vicinity of v and a previously good vertex might become non-good only if it ends up in the vicinity of v'. More precisely, a vertex w might be affected if prior to the change, v or v' (or both) were reachable from w via a path of length at most R that only traverses vertices of degree at most D (vertices reachable through vertices of higher degree are non-good anyway). To bound the number of such paths, note that in every step we can first choose among $\leq D$ incident hyperedges and then among $3-1$ endpoints of the chosen hyperedge, or we can choose to end the path at the current vertex. In particular, changing a single incidence affects the number of good vertices by at most $2(2D+1)^R$. We can therefore apply McDiarmid's inequality (Lemma 7) to conclude that

$$\begin{aligned}\Pr[n - |G| > 3\delta n] &\leq \Pr\left[(n-|G|) - \mathbb{E}[n-|G|] > \delta n\right] \\ &\leq \exp(-(\delta n)^2/(n \cdot (4(2D-1)^{2R})) = \exp(-\gamma n)\end{aligned}$$

when defining $\gamma = \delta^2/(4(2D+1)^{2R})$. ◀

Early Peeling With Anomalies. We now get back to the analysis of decode. Let S^R_{dec} be the state of S_{dec} after R rounds of the while-loop are executed (ignoring the time limit). Let $S^R := S^R_{\text{dec}} \triangle S$ be the set of elements stored in the IBLT at that time and $I^R := \bigcup_{x \in S^R} h(x)$ the set of buckets touched by S^R.

▶ **Lemma 9.** *For any $\varepsilon > 0$ and $\delta > 0$ there exist constants R and β such that*

$$\Pr[|I^R| > 7\delta n] \leq \mathcal{O}(2^{-\beta n}).$$

Proof. Given ε and δ, let $R = R(\varepsilon, \delta)$, $D = D(\varepsilon, \delta, R)$ and $\gamma = \gamma(\varepsilon, \delta, R, D)$, be the corresponding constants from the discussion of the discussion above. Recall from Lemmas 4, 5, and 8 that F is the set of foreign keys added to S at least once, N is the set of centres of internal anomalies and G is the set of good vertices. We know:

$$
\begin{array}{rll}
|F| \leq \frac{\delta n}{(2D+1)^R} & \text{except with probability } \mathcal{O}\left(2^{-\frac{\delta n}{(2D+1)^R}}\right) & \text{by Lemma 4} \\
|N| \leq \frac{\delta n}{(2D+1)^R} & \text{except with probability } \mathcal{O}\left(2^{-\frac{\delta n}{(2D+1)^R}}\right) & \text{by Lemma 5} \\
|G| \geq (1-3\delta)n & \text{except with probability } \exp(-\gamma n) & \text{by Lemma 8}
\end{array}
$$

The sum of the error probabilities is $\mathcal{O}(2^{-\beta n})$ where $\beta = \delta/(2D+1)^R + \gamma \log_2(e)$. Thus we may assume that all three stated events occur.

We now upper bound $|I^R|$. We pessimistically assume that each $i \in [n]$ that is not good is in I^R, which accounts for at most $3\delta n$ vertices. Any good $i \in [n]$ would be removed by the proper peeling process, so if $i \in I^R$ then an anomaly must have interfered. Therefore, the R-neighbourhood of i must include the centre of an internal anomaly or a vertex incident to a key from F. In other words, the R-neighbourhood of i must include a vertex from $|N \cup h(F)|$. At most $|N \cup h(F)| \cdot (2D+1)^R$ good vertices can be affected in this way, namely those reachable from a vertex in $N \cup h(F)$ via a path of length at most R traversing only vertices of degree at most D. Taken together the size of I_R is bounded by

$$
|I_R| \leq 3\delta n + |N \cup h(F)| \cdot (2D+1)^R \leq 3\delta n + \frac{4\delta}{(2D+1)^R} n \cdot (2D+1)^R \leq 7\delta n. \qquad \blacktriangleleft
$$

3.6 Late Rounds of the Peeling Process

▶ **Lemma 10.** *There exists a constant δ such that for any $1 \leq r \leq n$ there is an event E with probability $\mathcal{O}(2^{-r})$ such that, when E occurs, then*

$$
\forall I \subseteq [n] \text{ with } 5r \leq |I| \leq \delta n : |S[I]| \leq \tfrac{3}{5}|I|.
$$

Proof. We use a union bound over all possible sizes i of I and all possible sets of size i. Let p_i be the probability that a violating set of size i exists and $j := \frac{3}{5}i$. Multiplying the number $\binom{n}{i}$ of choices for I, the number $\binom{m}{j}$ of choices for $T \subseteq S$ of size j and the probability for $T \subseteq S[I]$ (i.e. the probability that all $x \in T$ satisfy $h(x) \subseteq I$) gives

$$
\begin{aligned}
p_i &\leq \binom{n}{i}\binom{m}{j}\left(\frac{i}{n}\right)^{3j} \leq \left(\frac{ne}{i}\right)^i \left(\frac{ne}{j}\right)^j \left(\frac{i}{n}\right)^{3j} \\
&= e^{i+j}\left(\frac{i}{j}\right)^j \left(\frac{i}{n}\right)^{-i+2j} \leq e^{3i}\left(\frac{i}{n}\right)^{i/5} = \left(\frac{e^{15}i}{n}\right)^{i/5}.
\end{aligned}
$$

Setting $\delta = 1/(2e^{15})$ we can bound the overall failure probability p as

$$
\begin{aligned}
p &\leq \sum_{i=5r}^{\delta n} p_i \leq \sum_{i=5r}^{\delta n} \left(\frac{e^{15}i}{n}\right)^{i/5} \leq \sum_{i=5r}^{\delta n} \left(\frac{e^{15}\cdot \delta n}{n}\right)^{i/5} \leq \sum_{i=5r}^{\delta n} (\tfrac{1}{2})^{i/5} \\
&= \sum_{i=5r}^{\delta n} \left((\tfrac{1}{2})^{1/5}\right)^i \leq 2^{-r} \cdot \sum_{i=0}^{\infty} \left((\tfrac{1}{2})^{1/5}\right)^i = 2^{-r} \cdot \Theta(1) = \mathcal{O}(2^{-r}).
\end{aligned}
\qquad \blacktriangleleft
$$

3.7 Proof of Theorem 2

We now assemble the previous Lemmas into a proof of Theorem 2. Note that we only claimed an error probability of $2^{-\Omega(r)}$, not $\mathcal{O}(2^{-r})$. By a change of parameters it therefore suffices that we show $\Pr[|S_{\text{dec}} \triangle S| > 185r] = \mathcal{O}(2^{-r})$.

The parameter $\varepsilon > 0$ and $r = o(n)$ are given. We use the absolute constant $\delta > 0$ from Lemma 10. We apply Lemma 9 for ε and $\delta' = \delta/7$ which gives us $R \in \mathbb{N}$ and $\beta > 0$. For convenience, let us summarise the statements used in the following. Since each holds with probability $1 - \mathcal{O}(2^{-r})$ we need only show that they imply $|S_{\text{dec}} \triangle S| \leq 185r$.

$$|I^R| < \delta n \quad \text{by Lemma 9} \tag{1}$$
$$\forall I \subseteq [n] \text{ with } 5r \le |I| \le \delta n : |S[I]| \le \tfrac{3}{5}|I| \quad \text{by Lemma 10} \tag{2}$$
$$|N| \le r \text{ and } |F| \le r \quad \text{by Lemmas 4 and 5} \tag{3}$$

Recall that *anomalous decoding steps* are those that add a key rather than removing a key.

▷ Claim 11. There are at most $|N| + 3|F| \le 4r$ anomalous decoding steps per round.

Proof. There are at most $3|F|$ buckets in which a key from F might be placed. We may conservatively assume that there is an anomalous decoding step in each round for each of these buckets. Anomalous decoding steps where no foreign key is involved can arise, by definition, only in centres of internal anomalies, hence there can be at most $|N|$ per round. ◁

We are most interested in the first $\hat{\rho}$ rounds of decode where $\hat{\rho} := R + \log_{\frac{20}{19}}(\frac{n}{300r}) = \Theta(\log \frac{n}{r})$. We now make sure that we are referring to well-defined rounds. Execution might end due to $Q = \varnothing$, or due to the time limit. If execution ends prior to round $\hat{\rho}$ due to $Q = \varnothing$, just pretend the loop is executed for a suitable number of additional rounds. Note that an additional round does not perform any steps when $Q = \varnothing$. Let us now deal with the time limit.

▷ Claim 12. The limit $t_{\max} = 2n$ on steps does not take effect within the first $\hat{\rho}$ rounds.

Proof. We use a potential argument. There are n keys in the beginning. Each non-anomalous decoding step removes a key and each anomalous decoding step adds a key. Hence, if a denotes the number of anomalous decoding steps in the first $\hat{\rho}$ rounds then the total number of decoding steps is at most $n + 2a$. The previous claim gives $a \le 4r\hat{\rho}$. We can therefore bound the number of decoding steps in the first $\hat{\rho}$ rounds by

$$n + 2a \le n + 8r\hat{\rho} = n(1 + \Theta(\tfrac{r}{n} \log \tfrac{n}{r})) = n(1 + o(1)) \le 2n.$$

The last step uses $r = o(n)$ and $\lim_{x \to 0} x \log \frac{1}{x} = 0$. ◁

We can now safely refer to each round $\rho \in \{1, \dots, \hat{\rho}\}$. Let S^ρ be the set of keys stored in the IBLT after ρ rounds, $I^\rho = h(S^\rho)$ the set of buckets touched by these keys and $S_0^\rho = S^\rho \setminus F$.

▷ Claim 13. If $300r \le |I^\rho| \le \delta n$ then $|I^{\rho+1}| \le \frac{19}{20}|I^\rho|$.

Proof. Since $S_0^\rho \subseteq S[I^\rho]$ we know $|S_0^\rho| \le \frac{3}{5}|I^\rho|$ from Equation (2). The number of incidences due to the keys from S_0^ρ is $3|S_0^\rho| \le \frac{9}{5}|I^\rho| = \frac{9}{10} \cdot 2|I^\rho|$. Thus at most a $\frac{9}{10}$-fraction of the buckets in I^ρ have two or more incidences to keys from S_0^ρ. This leaves at least $\frac{1}{10}|I^\rho|$ buckets with at most one incidence to S_0^ρ. If i is such a bucket, we would normally expect $i \notin I^{\rho+1}$.

There are only two exceptions. A foreign key might be stored in i at some point during round $\rho + 1$ or a key from S is added back into bucket i at some point during round $\rho + 1$. Each foreign key and each anomalous decoding step affects at most 3 buckets. Hence, by an earlier claim, at most $3(|F| + 4r) \le 15r$ buckets are exceptional in this sense. Together we get

$$|I^{\rho+1}| \le |I^\rho| - \tfrac{1}{10}|I^\rho| + 15r \le \tfrac{9}{10}|I^\rho| + 15r \le \tfrac{19}{20}|I^\rho|.$$

where the last step uses $|I^\rho| \ge 300r$. ◁

▷ Claim 14. If $|I^\rho| \leq 300r$ then $|I^{\rho+1}| \leq 300r$.

Proof. Assume w.l.o.g. that $|I^\rho| \geq 5r$ and modify the last step of the previous claim:

$$\tfrac{9}{10}|I^\rho| + 15r \leq \tfrac{9}{10} \cdot 300r + 15r = 285r < 300r. \qquad \triangleleft$$

Let now $\rho_{\max}$ be the last round that is fully executed.

▷ Claim 15. $|I^{\rho_{\max}}| \leq 300r$.

Proof. We have $|I^R| < \delta n$ by Equation (1). In subsequent rounds $\rho \in \{R+1, R+2, \dots\}$, the size of I^ρ decreases by at least a factor of $\frac{19}{20}$ until being at most $300r$ by Claim 13. By choice of $\hat{\rho}$ we have $I^\rho \leq 300r$ for some $\rho \leq \hat{\rho}$. By Claim 14 $|I^\rho|$ will subsequently not rise above $300r$ for larger values of ρ. $\triangleleft$

By the last claim and Equation (2) we have

$$|S_0^{\rho_{\max}}| \leq S[|I^{\rho_{\max}}|] \leq \tfrac{3}{5} \cdot (\max(5r, |I^{\rho_{\max}}|)) \leq \tfrac{3}{5} \cdot 300r = 180r.$$

The set $S^{\rho_{\max}}$ of all keys after round $\rho_{\max}$ might additionally include up to $|F| \leq r$ foreign keys. Since an additional round might be started but cut short due to the time limit, another $4r$ keys might be added due to anomalous decoding steps. Overall the set $S \triangle S_{\text{dec}}$ of keys returned in the end has size at most $180r + r + 4r = 185r$. This concludes the proof.

4 Set reconciliation with error-correcting codes

The set reconciliation problem can be modeled by encoding a set as a binary string of length U which is then sent through a channel inflicting up to D errors (bitflips). Recovering the errors is then equivalent to reporting the keys inserted to or deleted from the set. This reduction immediately implies that the problem can be solved by an appropriate application of error-correcting codes, in particular a linear code such as BCH, Reed-Solomon or expander code (see [14]). This reduction, in turn, highlights the relationship of set reconciliation to the problem of *sparse recovery*: reconstructing a sparse vector from a set of linear measurements (see e.g. [4]).

We will use a BCH code over the field $GF(2^w)$ with $U = 2^w - 1$. It is known (see e.g. [17]) that if up to D errors have to be corrected, the binary parity-check matrix $\mathcal{H}$ for BCH has dimensions $Dw \times U$. Let each set S be conceptually represented by a binary vector of size U. Denote $\mathcal{H}(S)$ the image of S by $\mathcal{H}$. Then for two sets S, T, $\mathcal{H}(S) \oplus \mathcal{H}(T) = \mathcal{H}(S \triangle T)$. That is, if $|S \triangle T| \leq D$, then $\mathcal{H}(S \triangle T)$, called *syndrome*, encodes the differences between S and T and can be reconstructed by a syndrome decoding algorithm. This implies that $\mathcal{H}(S)$ can be defined as a sketch of S of Dw bits so that the differences between two sets can be recovered from the XOR of their sketches, provided that there are at most D of them.

From the algorithmic viewpoint, inserting a key amounts to XORing the sketch with the corresponding column of $\mathcal{H}$ composed of D blocks of w bits (elements of $GF(2^w)$). Computing each block amounts to D multiplications in $GF(2^w)$[6]. A multiplication in $GF(2^w)$ can be done with $\mathcal{O}(w \log w)$ bit operations [13], but only with $\mathcal{O}(w)$ operations in the RAM model (see Appendix). Thus, an insertion of a key takes time $\mathcal{O}(Dw) = \mathcal{O}(D \log U)$.

[6] We refer to [5] for details on how keys of $\mathcal{U}$ are represented as elements of $GF(2^w)$.

Algorithm `insert`$(x, \mathcal{S})$**:**
- `toggle`(x) in $\mathcal{S}.A$
- $\mathcal{S}.H \leftarrow \mathcal{S}.H \oplus h(x)$
- `toggle_BCH`$(x, \mathcal{S}.C)$

Algorithm `diff`$(\mathcal{S}_1, \mathcal{S}_2)$**:**
- $\hat{\mathcal{S}}.A \leftarrow$ `merge`$(\mathcal{S}_1.A, \mathcal{S}_2.A)$
- $\hat{\mathcal{S}}.H \leftarrow \mathcal{S}_1.H \oplus \mathcal{S}_2.H$
- $\hat{\mathcal{S}}.C \leftarrow$ `merge_BCH`$(\mathcal{S}_1.C, \mathcal{S}_2.C)$
- **return** $\hat{\mathcal{S}}$

Algorithm `report`$(\mathcal{S})$**:**
- $S_{\text{dec}} \leftarrow$ `decode`$(\mathcal{S}.A)$
- **for** $x \in S_{\text{dec}}$ **do**
  - $\mathcal{S}.H \leftarrow \mathcal{S}.H \oplus h(x)$
- **if** $\mathcal{S}.H \neq 0$ **then**
  - **for** $x \in S_{\text{dec}}$ **do**
    - `toggle_BCH`$(x, \mathcal{S}.C)$ // delete x from $\mathcal{S}.C$
  - $S'_{\text{dec}} \leftarrow$ `decode_BCH`$(\mathcal{S}.C)$
- **return** $S_{\text{dec}} \triangle S'_{\text{dec}}$

Figure 2 Sketch operations. `insert`$(x, \mathcal{S})$ inserts key x to sketch $\mathcal{S}$, `diff`$(\mathcal{S}_1, \mathcal{S}_2)$ computes the difference of sketches $\mathcal{S}_1$ and $\mathcal{S}_2$, `report`$(\mathcal{S})$ reports keys stored in $\mathcal{S}$.

Decoding is a more complex operation. The efficient syndrome decoding algorithm of [5] requires $\mathcal{O}(D^2 w)$ multiplications in $GF(2^w)$ resulting in $\mathcal{O}(D^2 w^2) = \mathcal{O}(D^2 \log^2 U)$ time for decoding. Note that if the number $d < D$ of errors is known, then by properties of syndromes, it is sufficient to decode the first dw bits of the sketch, and the decoding complexity becomes $\mathcal{O}(d^2 \log^2 U)$.

Denote `toggle_BCH`(x, C) and `decode_BCH`(C) the operation of inserting/deleting a key x to/from a BCH sketch C and decoding a BCH sketch C, respectively. Complexity of BCH sketches is summarized in the following theorem.

▶ **Theorem 16.** *Consider a set S containing no more than D keys from U. Let S be stored in a BCH sketch C of $D \log(U+1)$ bits of space. Then*
- `toggle_BCH`(x, C) *takes $\mathcal{O}(D \log U)$ time,*
- `decode_BCH`(C) *decodes keys of S with no error in $\mathcal{O}(D^2 \log^2 U)$ time.*

Reconciliation of two sets is done by simply XORing their sketches C_1 and C_2, which can be trivially sped up by packing bits in words. We denote this operation by `merge_BCH`(C_1, C_2). A software implementation of a BCH sketch for set reconciliation is available [19].

5 IBLT with stash

Our goal is to enhance the IBLT in order to solve set reconciliation with a much stronger success guarantee than that provided by IBLT alone ([1], Table 1) while keeping small space and fast decoding time provided by the IBLT approach. Given an upper bound D on the size of set differences, our sketch $\mathcal{S}$ consists of three components depending on a parameter r:
- an IBLT $\mathcal{S}.A$ of size $n = (c_3 + \varepsilon)D$ with three hash functions, as defined in Section 2,
- a control checksum $\mathcal{S}.H$ of r bits,
- a *stash* data structure $\mathcal{S}.C$ defined as a BCH syndrome of $r \log U$ bits (see Section 4).

The control checksum $\mathcal{S}.H$ is used to check if the decoding of the main IBLT $\mathcal{S}.A$ succeeded. Before the decoding, $\mathcal{S}.H = \bigoplus_{x \in S} h(x)$ where $h : \mathcal{U} \to 2^r$ is a random hash function and S is the currently stored key set.

The stash $\mathcal{S}.C$ is configured so that it can decode up to r keys with no error, as described in Section 4. The entire sketch takes $(c_3 + \varepsilon)D \log U + r(1 + \log U) = (c_3 + \varepsilon)D \log U + o(D)$ bits.

Figure 2 shows Algorithms for inserting a key to a sketch, computing a sketch difference, and reporting keys.

A run of `report`($\mathcal{S}$) (Figure 2) can follow two scenarios. If the number of keys in the sketched set is no more than D, the main IBLT recovers those keys with probability $1 - \tilde{O}(1/D)$ (Theorem 2). With probability $\tilde{O}(1/D)$, however, the recovery may fail by "getting stuck", by resulting in a "falsely empty" IBLT (see [1]), or by being aborted after $2n$ steps. Checking the checksum ensures that an incorrect decoding will be recognized except with probability $\mathcal{O}(1/2^r)$. By Theorem 2, with probability $2^{-\Omega(r)}$, the output S_{dec} differs from S by no more than r missing or foreign keys. The algorithm resorts then to the stash in order to correct the output, i.e. to recover the missing/superfluous keys, under assumption that there are at most r of them. In this case, the stash reports those keys with no error.

The execution time of `report` depends on whether the correction step is triggered or not. If the decoding of the main IBLT is deemed to be successful by the checksum, the time taken will be $\mathcal{O}(D(1 + \frac{r}{w}))$, where w is the wordsize. Here we assume that updating the checksum is done by bit packing and takes $\mathcal{O}(\frac{r}{w})$ time. Otherwise the algorithm will spend additional $\mathcal{O}(r \log U)$ time on performing `toggle_BCH` on each of $\mathcal{O}(D)$ key in S_{dec}, followed by the decoding taking additional $\mathcal{O}(r^2 \log^2 U)$ time. Since the stash is activated with probability $\tilde{O}(1/D)$, the expected time is $\mathcal{O}(D(1 + \frac{r}{w}) + r \log U + \frac{r^2 \log^2 U}{D})$. Assuming $r = \min\left(\mathcal{O}(D/\log^2 U), \mathcal{O}(\log U)\right)$, the time of `report` is $\mathcal{O}(D)$.

We summarize the properties of `report` in the following theorem.

▶ **Theorem 17.** *Let $\mathcal{S}$ be a sketch built for a key set S and $r = \min\left(\mathcal{O}(D/\log^2 U), \mathcal{O}(\log U)\right)$. Then*

- *$\mathcal{S}$ takes $(c_3 + \varepsilon)D \log U + r(1 + \log U) = (c_3 + \varepsilon)D \log U + o(D)$ bits,*
- *inserting an element to $\mathcal{S}$ takes time $\mathcal{O}(r \log U)$,*
- *when $|S| \leq D$, `report`($\mathcal{S}$) correctly recovers S with probability $1 - 2^{-\Omega(r)}$,*
- *`report`($\mathcal{S}$) takes $\mathcal{O}(D)$ expected time.*

Note that if $r = \omega(\log D)$, the failure probability for `report` to recover a set of up to D keys is $o(1/D)$, as opposed to $\tilde{O}(1/D)$ for recovery without stash [1].

For two sets S and T represented by their respective sketches $\mathcal{S}_S$ and $\mathcal{S}_T$, `diff`$(\mathcal{S}_S, \mathcal{S}_T)$ is the sketch of symmetric difference $S \Delta T$. Therefore, Theorem 17 applies directly to the set reconciliation problem. In particular, if $|S \Delta T| \leq D$, then $S \Delta T$ can be recovered with guarantees stated in Theorem 17.

6 Distinguishing $S \setminus T$ and $T \setminus S$

The algorithm we presented computes symmetric difference $S \Delta T$ but is not capable of distinguishing elements of S and T in the output. However, the latter is desirable for many applications. Here we outline how our sketch and set reconciliation protocol (Figure 2) can be modified in order to make this possible. The general idea is to assign a "sign" to keys depending on whether they come from S or T and to keep track of it in a consistent manner. Formal proofs are left to the full version of the paper.

Modified IBLT. We modify our IBLT (Section 2) as follows. IBLT entries will now be *ternary* strings of $\{0, 1, 2\}^\nu$ seen as elements of group $\mathbb{Z}_3^\nu$ (additive group of $GF(3^\nu)$). The first *trit* encodes a *sign* and the other $\nu - 1$ trits encode a keysum. We use an appropriate encoding of $\mathcal{U}$ into strings $\{0, 1, 2\}^{\nu-1}$ and denote by $\widetilde{x}$ the encoding of x.

Toggling a key x is replaced by two operations: insertion and deletion. Inserting x into an IBLT is done by adding (in $\mathbb{Z}_3^\nu$) $1\widetilde{x}$ to each of the three entries at $h(x)$, and deleting x is done by subtracting $1\widetilde{x}$ from each of the three entries at $h(x)$ or, equivalently, adding

$2(-\widetilde{x}) \equiv (-1)(-\widetilde{x})$ where $-\widetilde{x}$ is the inverse of $\widetilde{x}$ in $\mathbb{Z}_3^{\nu-1}$. Observe that insertion and deletion of x cancel each other out, and that inserting twice the same key x is equivalent to deleting x and vice versa.

IBLT operations (Figure 1) are modified as follows. Operation `looksPure` checks if the first trit equals 1 or $2 \equiv -1$. If it is 2, the key assumed to sit in this entry is the inverse of the retrieved key value. `toggle`(x) deletes or inserts x from/to each of the three entries at $h(x)$ depending on whether x has been identified as *pure* with the first trit 1 or 2, respectively. Merging two IBLTs `merge`(A, A') now becomes non-commutative and is done by subtracting (in $\mathbb{Z}_3^{\nu}$) A' from A entry-wise.

Consider a sketch resulting from `merge`(A, A'). When reporting a set difference (modified Algorithm `report` in Figure 2) the algorithm now outputs *signed elements*, where elements annotated with 1 (i.e. those with the first trit equal to 1 at the moment of toggling) are interpreted as belonging to the first set, while those annotated with 2 are interpreted as belonging to the second. The symmetric difference operation Δ in both `decode` and `report` is also modified as follows. When computing $S_1 \Delta S_2$, an element is canceled only if it occurs in S_1 and S_2 with opposite signs. If an element occurs in S_1 and S_2 with the same sign, it is reported in the resulting set with the opposite sign.

Observe that the modified structure does not prevent anomalies to occur but only makes them less likely: an anomaly can still occur if the first trit is 1 or 2 but the entry actually contains more than one key. On the other hand, our analysis of Section 3 carries over to the signed case. The difference in S_{dec} compared to the original decoding is due to repeated reportings of the same key with different sign combinations, which does not affect the proof ideas of the main Theorem 2.

Modified control hashsum. Here the hashsum uses arithmetic summation instead of XOR. We assume that overflow is implemented in a consistent way, that is $(x + y) - y = x$ even if $x + y$ results in overflow. Toggling x entails subtracting $h(x)$ from the hashsum if x is annotated with 1, and adding if it is annotated -1. The hashsum of `diff`$(\mathcal{S}_1, \mathcal{S}_2)$ is now defined as $\mathcal{S}_1.H - \mathcal{S}_2.H$.

Modified BCH sketch. In order to deal with signed elements, we use BCH code over field $GF(3^{\nu-1})$. The BCH sketch of a set is still defined as the syndrome vector under assumption that each set element is encoded by value 1 in the error vector. The `merge_BCH` operation will now subtract the syndromes (in $GF(3)$) instead of XORing them. By linearity of the code, the "positive" and "negative" elements will correspond to positions with 1 and $2 \equiv -1$ respectively in the recovered error vector.

Given a BCH sketch resulting from the difference of sketches of input sets S and T, algorithm `report` will subtract the syndrome corresponding to the set S_{dec} of signed elements decoded by the IBLT. Naturally, positive and negative elements are encoded respectively by values 1 and 2 as well. Again, by linearity, the resulting syndrome will encode exactly the elements S'_{dec} so that $S_{\text{dec}} \Delta S'_{\text{dec}} = S \Delta T$, where positive (resp. negative) elements are those belonging to S (resp. T) only.

Observe that, in general, S_{dec} will contain a subset of $S \Delta T$ as well as possibly some foreign keys, however our modified definition of Δ will ensure a correct recovery of the original set. As an example, assume $x \in S \setminus T$ and assume x has been reported by the IBLT as positive, followed by another reporting of x (produced by an anomaly) as positive as well. From our definition of Δ, x will become negative in S_{dec} and will be added (rather than subtracted) to the BCH sketch. This will result in reporting x as negative again by the BCH sketch, and, by our definition of Δ, will be eventually correctly reported as positive in the final output.

The syndrome of the BCH code over $GF(3^{\nu-1})$ consists of at most $2D$ elements of $GF(3^{\nu-1})$ i.e. at most $4D \log_3 U$ bits by a straightforward encoding. Using ternary representation of keys and arithmetic operations in $GF(3^{\nu})$ instead of $GF(2^w)$ introduces only a constant factor change in time complexities of both insertion and decoding (see Appendix). In conclusion, time and robustness guarantees of Theorem 17 remain valid.

7 Concluding remarks

The presented solution to set reconciliation uses asymptotically negligible additional space and additional time for decoding compared to the IBLT-only solution, but provides a drastic improvement in robustness. The decoding time of our algorithm is small in expectation, however it becomes substantial in worst case. More precisely, when the BCH correction is activated, the decoding time becomes $O(D\, r\, \mathrm{polylog}(U))$ which can approach $O(D^2)$. We believe however this can be overcome by implementing the stash with expander codes which have much smaller insertion and decoding times. We leave details for future work.

Very recently, we learned about paper [8] that proposes a modified construction of IBLT and applies hash functions of restricted independence, rather than assuming them fully random. As a result, the construction takes a smaller space (compared to the original IBLT with the same error guarantee) and requires less randomness for hash functions. However, space is measured in terms of the number of IBLT buckets rather than in bits, which leads to a much larger multiplicative constant compared to our result. The decoding time of [8] appears to be larger than ours as well (not specified in the paper). On the other hand, an emphasis of [8] is to using hash functions of restricted randomness, the issue that we don't deal with in this work.

A Appendix

Below we describe how to perform multiplication in $GF(2^w)$ and $GF(3^\nu)$ in RAM model in times $O(w)$ and $O(\nu)$ respectively.

A.1 Multiplications in $GF(2^w)$ in RAM model in $O(w)$ time

The algorithm we describe is folklore, but since we did not find a reference we briefly sketch it here. The multiplication of two elements x and y in $GF(2^w)$ proceeds in two phases. In the first phase, one computes the product $z = x \cdot y$, where $\cdot$ refers to a carry-less multiplication of the binary representation of x and y. Thus, z will be a bitstring of length $2w - 1$. This phase can be easily implemented in $O(w)$ time using $O(w)$ XOR and shift operation (the result is the XOR of copies of y right-shifted by bit-positions of x that are equal to one) [7]. The second phase is the polynomial euclidean division of z by an irreducible polynomial P of degree w. The remainder of the division will be the final result of the multiplication and can also be easily implemented in $O(w)$ time using $O(w)$ XOR and shift operations: successively for decreasing positions i of z starting from position $2w - 1$ check whether the bit at that position is equal to one and if so, do $z \leftarrow (z \oplus (P \ll (i - w))$.

A.2 Multiplications in $GF(3^\nu)$ in RAM model in $O(\nu)$ time

Likewise, multiplication in $GF(3^\nu)$ can be implemented in $O(\nu)$ time. For that we can use a representation of an element using 2ν bits, where each element from the base field $GF(3)$ is represented using 2 bits. Note that any integer in the range $[0..3^\nu - 1]$ can be converted to this representation in $O(\nu)$ time, by doing successive euclidean divisions by 3. Notice that a division by 3 can be simulated using multiplications and other elementary operations. For a technical reason that will become clear later, we will instead use 4 bits to represent each element of the base field, resulting in a representation that uses 4ν bits. Let G be the function that transforms integers of $[0..3^\nu - 1]$ into binary representation of 4ν bits. Let G^{-1} be the inverse of G. Now assume that given two elements x and y represented as integers, we want to compute $z = x \cdot y$. We will first convert x and y into their binary representations $x' = G(x)$ and $y' = G(y)$, then compute the product $z' = x' \cdot y'$, and finally convert z' back into an integer z using function G^{-1}. We now describe how we do multiplication in the 4ν-bit representation. For that, we successively extract the quadbits (4-bit units) of x', multiply each of them with y', and aggregate all of them. The reason we use 4 bits instead of 2 to represent each digit is to accomodate the temporary result of the multiplication of two digits (numbers in $[0..2]$) which will be in the range $[0..4]$ (before doing Modulo 3 operation). Finally, the remainder of euclidean division by an irreducible polynomial can also be done in time $O(\nu)$ using $O(\nu)$ operations. Figure 3 shows the pseudocode of all steps of the algorithm.

[7] Note that in practice, most modern processors natively support carry-less multiplication in constant time using much less complex hardware implementation than standard multiplication, but is not part of the standard RAM operations.

Oracle Separation of QMA and QCMA with Bounded Adaptivity

Shalev Ben-David
Institute for Quantum Computing, University of Waterloo, Canada

Srijita Kundu
Institute for Quantum Computing, University of Waterloo, Canada

Abstract

We give an oracle separation between QMA and QCMA for quantum algorithms that have bounded adaptivity in their oracle queries; that is, the number of rounds of oracle calls is small, though each round may involve polynomially many queries in parallel. Our oracle construction is a simplified version of the construction used recently by Li, Liu, Pelecanos, and Yamakawa (2023), who showed an oracle separation between QMA and QCMA when the quantum algorithms are only allowed to access the oracle classically. To prove our results, we introduce a property of relations called *slipperiness*, which may be useful for getting a fully general classical oracle separation between QMA and QCMA.

1 Introduction

It is a long-standing open problem in quantum complexity theory whether the two possible quantum analogs of the complexity class NP are equivalent. QMA is defined as the class of decision problems that are solvable by a polynomial-time quantum algorithm that has access to a polynomial-sized *quantum* witness, whereas QCMA is the class of decision problems that are solvable by a polynomial-time quantum algorithm that only has access to the polynomial-sized *classical* witness. In other words, the question asks: are quantum proofs more powerful than classical proofs?

While the inclusion QCMA $\subseteq$ QMA is easy to see, the question of whether these two classes are actually equal, which was first posed by Aharonov and Naveh [3], remains unanswered. Indeed, an unconditional separation between these classes is beyond currently known techniques.

An easier, but still unsolved, problem is to show an oracle separation between QMA and QCMA. This is because oracle separations in the Turing machine model can be shown by means of separations in the much simpler model of *query complexity*, where similar

separations between complexity classes are routinely shown (for example, a recent oracle separation between BQP and PH was provided in [12]). The problem of finding an oracle separation between QMA and QCMA has been a longstanding focus of the quantum computing community; it boils down to asking whether quantum proofs are more powerful than classical proofs in the query model.

1.1 Previous work

The first progress on the question of an oracle separation of QMA and QCMA was made by Aaronson and Kuperberg [2], who showed that there is a quantum oracle, i.e., a blackbox unitary, relative to which QMA $\neq$ QCMA. Later, Fefferman and Kimmel [7] showed that the separation also holds under what they called an "in-place permutation oracle", which is still inherently quantum. Ideally, we would like to get these separations in the standard model of classical oracles: classical functions that a quantum algorithm may query in superposition. [4] showed separations between QMA and QCMA in other non-standard oracle models.

Very recently, there has been some progress on this question, with two different variations of the standard classical oracle model. Natarajan and Nirkhe [11] showed an oracle separation relative to a "distributional oracle". This essentially means that the classical oracle is drawn from a distribution, which the prover knows, but the specific instance drawn is not known to the prover. Therefore, the witness only depends on the distribution over the oracles, which makes it easier to show QCMA lower bounds. Following this, [9] showed a separation with a classical oracle that is fully known to the prover, but assuming the verifier is only allowed to access this classical oracle classically, i.e., the verifier is not allowed to make superposition queries (this makes the class similar to MA in terms of its query power and witness type). This model is also simpler to analyze because whatever information the verifier gets from the oracle by classically querying it, could also have been provided as the classical QCMA witness. [9] also gave an alternate construction of a distributional oracle separation, with a simpler proof than [11]. Their constructions are based on the relational problem used by Yamakawa and Zhandry [14], in their result on quantum advantage without structure.

Closely related to the QMA vs QCMA question is the $\mathsf{BQP}_{/\mathrm{qpoly}}$ vs $\mathsf{BQP}_{/\mathrm{poly}}$ question. $\mathsf{BQP}_{/\mathrm{qpoly}}$ is the class of decision problems that are solvable by a polynomial-time quantum algorithm with access to polynomial-sized quantum *advice*, which depends non-uniformly on the length of inputs, but nothing else. $\mathsf{BQP}_{/\mathrm{qpoly}}$ is the class of decision problems solvable by a polynomial-time quantum algorithm with access to polynomial-sized classical advice. Most works which have found oracle separations for QMA vs QCMA in various oracle models, such as [2, 11, 9], have also found oracle separations between $\mathsf{BQP}_{/\mathrm{qpoly}}$ and $\mathsf{BQP}_{/\mathrm{poly}}$ with related constructions in the same oracle models.

The question of the relative power of classical vs quantum advice was recently resolved unconditionally (without oracles) for relational problems by Aaronson, Buhrman and Kretschmer [1], who showed an unconditional separation between $\mathsf{FBQP}_{/\mathrm{qpoly}}$ and $\mathsf{FBQP}_{/\mathrm{poly}}$. $\mathsf{FBQP}_{/\mathrm{qpoly}}$ and $\mathsf{FBQP}_{/\mathrm{poly}}$ are the classes of relational problems analogous to $\mathsf{BQP}_{/\mathrm{qpoly}}$ and $\mathsf{BQP}_{/\mathrm{poly}}$ respectively. Their result was based on observing that separations between quantum and classical one-way communication complexity can be used to show separations between classical and quantum advice. The reason their result only works for the relation classes is that a separation in one-way communication complexity which satisfies the necessary conditions can only hold for relational problems. The specific relational problem used in [1] is known as the Hidden Matching problem. But as was observed in [9], the Yamakawa-Zhandry problem [14] also achieves the required communication separation, and could have been used instead. In light of this, the constructions in [14] can viewed as a way to convert relational

separations in one-way communication complexity, which correspond to relational separations for quantum vs classical advice, to separations for decision QMA vs QCMA, and $\mathsf{BQP}_{/\mathrm{qpoly}}$ vs $\mathsf{BQP}_{/\mathrm{poly}}$, relative to classically accessible oracles. The construction is not blackbox – it does not work if the Hidden Matching Problem is used instead of the Yamakawa-Zhandry problem, though it plausibly might work with a parallel repetition of the former.

1.2 Our results

Unlike previous work, we prove an oracle separation between QMA and QCMA relative to a *bona fide* regular oracle with regular (quantum) queries. Our catch is, instead, that we only allow the algorithms *bounded adaptivity*.

Bounded adaptivity means that the number of rounds of queries made by the algorithms is small, although there can be polynomially many queries in each round. Although our result is not formally stronger than those of [11] and [9], we feel our result is intuitively closer to a full QMA-QCMA separation, as it allows the full power of classical proofs and some of the power of quantum queries. Our main result is formally stated below.

▶ **Theorem 1.** *There is an oracle* $\mathcal{O}\colon \{0,1\}^* \to \{0,1\}$ *such that* $\mathsf{QCMA}^{\mathcal{O},r} \neq \mathsf{QMA}^{\mathcal{O},r}$*, for* $r = o(\log n/\log\log n)$.

In the above statement, $\mathsf{QMA}^{\mathcal{O},r}$ is the class of decision problems solvable by QMA algorithms that have oracle access to $\mathcal{O}$, and make at most r batches of parallel queries to $\mathcal{O}$; $\mathsf{QCMA}^{\mathcal{O},r}$ is defined analogously. The parameter n is the efficiency parameter (so the number of queries is $\mathrm{poly}(n)$).

▶ **Theorem 2.** *There is a function family* $F = \{F_N\}_{N\in I}$ *which is efficiently computable in 1-round query* QMA*, but with the property that the growth rate of* $\mathrm{QCMA}^r(F_N)$ *for* $r = o(\log\log N/\log\log\log N)$ *as* $N \to \infty$ *is not in* $O(\mathrm{polylog}(N))$.

We shall formally define the query versions of QMA and QCMA, and the r-round QCMA query complexity QCMA^r, which are used in this theorem statement, in Section 2.1.

Our construction for the query complexity separation is a somewhat simplified version of the construction in [9], which is based on the Yamakawa-Zhandry problem. [14] and [10] showed that there exists a relational problem R_f, indexed by functions $f : [n] \times \{0,1\}^m \to \{0,1\}$, for $m = \Theta(n)$, such that given oracle access to a quantum advice $|z_f\rangle$, a quantum algorithm on any input $x \in \{0,1\}^n$, and on average over f, can find a u such that $(x,u) \in R_f$[2]. On the other hand, no quantum algorithm can find such an u for most x, when given only a classical advice z_f, and classical query access to f. Using this relation R_f, for a subset $E \subseteq \{0,1\}^n$, we construct the following oracle:

$$O[f,E](x,u) = \begin{cases} 1 & \text{if } (x,u) \in R_f \wedge x \notin E \\ 0 & \text{otherwise.} \end{cases}$$

The 1-instances of the problem F_N that will separate QMA and QCMA in the query complexity model will be $O[f,\emptyset]$, and the 0-instances will be $O[f,E]$ for $|E| \geq \frac{2}{3}\cdot 2^n$, for a large subset of all functions f. This is essentially the same construction that is used in [9], except they also use an additional oracle G for a random function from $\{0,1\}^n$ to $\{0,1\}^n$, which O also depends on.

[2] The Yamakawa-Zhandry relation is a TFNP relation, which means that the u-s are of $\mathrm{poly}(n)$ length, and a u such that $(x,u) \in R_f$ exists for every x.

Note that the query complexity lower bound we obtain for QCMA is of a different nature than the one obtained in [9]: we need to lower bound (bounded-round) quantum query algorithms instead of only classical query algorithms, and we focus on the worst-case rather than average-case setting. In order to get an oracle separation for Turing machines from a separation in query complexity, one needs to use a diagonalization argument; because our result is set up a bit differently than in previous work, we reprove the diagonalization argument for our setting in. This can be found in Appendix A of the full version of this paper on arXiv.

Finally, we emphasize that the bounded adaptivity limitation of our result is because we allow the full power of classical proofs and also quantum queries. If one were to drop the power of classical proofs (resulting in the class BQP), or if one were to drop the power of quantum queries (resulting in, essentially, MA), it would follow from [9] that close variants of F_N cannot be solved even without the bounded-round restriction. We conjecture their lower bounds apply to F_N as well.

1.3 Our techniques

We briefly describe the techniques used to obtain the query complexity result. We start by observing that the oracle $O[f, \emptyset]$ is essentially just a verification oracle for the Yamakawa-Zhandry relation. Therefore, there is a quantum witness and a quantum algorithm that can distinguish $O[f, \emptyset]$ and $O[f, E]$ by using this witness, with only one query, with probability $1 - 2^{-\Omega(n)}$ over f. The witness for the yes instance $O[f, \emptyset]$ is simply the quantum advice for the Yamakawa-Zhandry problem, which finds a u for any x with probability $1 - 2^{-\Omega(n)}$ over f. The quantum algorithm finds a u for a random x using the witness, and queries the oracle. Since the no instances return 0 on any (x, u) for most x, this algorithm can distinguish $O[f, \emptyset]$ and $O[f, E]$ for $1 - 2^{-\Omega(n)}$ fraction of the f-s.

We now consider the uniform distribution over these good f-s (for which we can distinguish $O[f, \emptyset]$ and $O[f, E]$ with quantum advice), which has $2^{\Omega(n)}$ min-entropy. If there was a classical witness function depending on f, of size k, that made a quantum algorithm accept $O[f, \emptyset]$ for these f-s, then there would exist a fixed witness string w that would make $O[f, \emptyset]$ accept for 2^{-k} fraction of f-s. The quantum algorithm depends on the witness, but if we fix the witness string w, the algorithm is fixed, and we can then ignore the dependence of the algorithm on the witness.

We now attempt to remove rounds of the quantum query algorithm, starting with the first round, while keeping the behavior of the algorithm the same on as many oracles as possible. Every time we remove a round, we restrict our attention to a smaller set of oracles, all of which are consistent with a growing partial assignment we assume is given to us. At the end, the quantum algorithm will have no rounds left, and hence will make no queries; we want the set of oracles $O[f, \emptyset]$ on which the behavior is preserved to be non-empty, because then we can conclude that the algorithm cannot distinguish $O[f, \emptyset]$ and $O[f, E]$ for some large erased set E (since it now makes no queries).

To remove the first round of the query algorithm, we start by considering the the uniform distribution over the 2^{-k} fraction of good f-s such that $O[f, \emptyset]$ is accepted by w. This distribution has $2^{\Omega(n)} - k$ min-entropy, and therefore, by a result of [8, 6], it can be written as a convex combination of finitely many dense distributions. Dense distributions are a concept that was first introduced in the context of communication complexity: in a dense distribution, some coordinates are fixed, and the rest of the coordinates have high min-entropy in every subset. In fact we will not need the full convex combination of dense distributions – we restrict our attention to one such distribution in the convex combination, and try to preserve the behavior of the quantum algorithm only within a subset of its support.

Since some coordinates are fixed in our dense distribution, the probability over this distribution of the event $(x, u) \in R_f$ non-negligible, for some (x, u) pairs (this probability is exactly 2^{-n} over uniform f). The quantum algorithm can potentially learn a lot about f by querying the oracle $O[f, \emptyset]$ for these pairs. Therefore, we shall fix the coordinates of f that are fixed by (x, u) being in R_f. Here is where we use the fact that the Yamakawa-Zhandry relation is what we shall call *slippery*. This essentially means that given a small number of fixed coordinates for f, the number (x, u) pairs that have non-negligible probability is not too high, and the number of extra coordinates fixed by these (x, u) pairs being in R_f is also not too high. The Yamakawa-Zhandry relation being slippery essentially follows from it using a code that has good list recoverability properties. (The Hidden Matching relation, or its parallel repetition, are not slippery by this definition, and so our construction does not work with these.)

Using the slippery property, we can increase the size of the partial assignment by not too much, and via a hybrid-like argument [5], we can ensure that the first round of the quantum algorithm does not learn much from queries outside this partial assignment. We then restrict our attention to oracles consistent with this partial assignment; on those, we can simulate the first round of the algorithm without making real queries (we simply use the known partial assignment and guess "0" on the rest of the oracle positions, which are highly unlikely to be 1). This way, we get a quantum algorithm with one fewer round, which mimics the original algorithm on a small (but not too small) set of oracles.

Continuing this way, we eliminate all rounds of the algorithm while still maintaining a non-empty set of oracles on which the behavior is preserved. Each such oracle can be "erased", turning a 1-input into a 0-input, so we only need the final 0-round algorithm to preserve the behavior of the original algorithm on at least one input. Using this technique, we can handle up to $o(\log n / \log \log n)$ rounds of $O(\operatorname{poly} n)$ non-adaptive quantum queries each.

1.4 Discussion and further work

We expect our techniques for the QMA vs QCMA separation may also work for a $\mathsf{BQP}_{/\mathrm{qpoly}}$ vs $\mathsf{BQP}_{/\mathrm{poly}}$ separation with boundedly adaptive oracle queries, using the same problem that is described in [9]. Their oracle in the query complexity setting is given by a random function G, which the BQP algorithm has to compute given oracle access to

$$O[f, G](x, u) = \begin{cases} G(x) & \text{if } (x, u) \in R'_f \\ \perp & \text{otherwise,} \end{cases}$$

and a quantum or classical advice. Here R'_f is a modified 1-out-of-n version of the Yamakawa-Zhandry problem, which has better completeness properties, but is similar to the original problem otherwise. Clearly this problem can be solved in $\mathsf{BQP}_{/\mathrm{qpoly}}$ by using the quantum advice for the Yamakawa-Zhandry problem. It cannot be solved on input x with any classical advice and with access to an oracle that outputs $\perp$ for every (x, u). In order to show a $\mathsf{BQP}_{/\mathrm{poly}}$ lower bound for this problem, one needs that there exist many x-s such that a quantum algorithm with classical advice cannot distinguish $O[f, G]$ from a version of $O[f, G]$ that is erased on those x-s. Since $O[f, G]$ essentially serves as a verification oracle for the relation just as $O[f, \emptyset]$ does in the QMA vs QCMA construction, we expect that when the quantum algorithm has bounded rounds, a proof very similar to our QCMA lower bound will work.[3]

[3] R'_f, being a 1-out-of-n version of R_f, has worse slipperiness properties than R_f, which gets in the way of applying our techniques. But instead of using R'_f for better completeness, we can focus on the (large enough) subset of x, f for which the BQP algorithm with quantum advice works for R_f with high probability, and have $O[f, G]$ give $G(x)$ for free outside of this set. This would make the analysis very similar to the QMA vs QCMA case.

The final goal is, of course, to be able to show both these results without a bound on the number of rounds of oracle queries the quantum algorithm makes. As mentioned earlier, we fail to do this because the slipperiness parameters of the relation we picked are not good enough, and our methods would work to separate QMA and QCMA with an analogous problem definition where the Yamakawa-Zhandry relation is replaced by a different relation R_f that has the appropriate slipperiness property.

We now expand more on the required strong slipperiness property. Let R_f be a family of TFNP relations on $\{0,1\}^n \times \{0,1\}^m$ indexed by $f \in \{0,1\}^N$, where $m = \text{poly}(n)$ and $N = \Omega(2^n)$. We further assume R_f satisfies the property that if $(x,u) \in R_f$, then there is a polynomial-sized partial assignment p for f which certifies this, i.e., $(x,u) \in R_f \ \forall f \supseteq p$. Let $\mathcal{P} \subseteq \{0,1,*\}^N$ denote the set of polynomial-sized partial assignments for f. We define the extended version $\widetilde{R}$ of the family of relations R_f as follows:

$$\widetilde{R} = \{(p,x,u) : p \text{ is the minimal partial assignment s.t. } (x,u) \in R_f \, \forall f \supseteq p\}.$$

Since p is polynomial-sized, if we consider the uniform distribution over $\{0,1\}^N$, $\Pr[p \subseteq f]$ is exponentially small. Now consider a partial assignment q for f with size at most $s(n)$; we fix the bits in q and generate the other bits of f uniformly at random, which can make the probability of some other partial assignments p non-negligible. The slipperiness property is concerned with the total additional support (outside of q) of all partial assignments p such that $\Pr[p \subseteq f | q \subseteq f]$ is non-negligible, and $(p,x,u) \in \widetilde{R}$. We say $\widetilde{R}$ is $(\eta, s(n), t(n))$-slippery if for all $s(n)$-sized q, the total additional support of all p-s such that $\Pr[p \subseteq f | q \subseteq f] \geq \eta$ and $(p,x,u) \in \widetilde{R}$ is at most $t(n)$. See Definition 13 for a more formal definition.

Our techniques show that the following conjecture implies an oracle separation between QMA and QCMA.

▶ **Conjecture 3.** *There exists a family of* TFNP *relations R_f such that*

1. *There exists a polynomial-time algorithm $\mathcal{A}$, and for each f, a* poly(n)*-sized quantum state $|z_f\rangle$ such that, given access to x and $|z_f\rangle$, $\mathcal{A}$ can find u such that $(x,u) \in R_f$, with probability at least $1 - 2^{-\Omega(n)}$ over a product distribution $\mu_X \mu_F$ on x, f. Moreover, μ_X and μ_F are required to respectively have min-entropy $2^{\Omega(n)}$ and $\Omega(n)$.*
2. *There exists a function $s(n) = 2^{o(n)}$ such that for all polynomial functions $p(n)$, the extended relation $\widetilde{R}$ is $(1/p(n), s(n), t(n))$-slippery for some $t(n)$ such that $\log(t(n)) = o(\log(s(n)))$.*

Assuming Conjecture 3 is true, the oracle function separating QMA and QCMA would be distinguishing $O[f, \emptyset]$ and $O[f, E]$, for $|E| \geq \frac{2}{3} \cdot 2^n$, which we have defined earlier, using a relation R_f that satisfies the conjecture. (We can only prove the Yamakawa-Zhandry relation is $(\eta, s(n), t(n))$-slippery, with $t(n)$ bigger than $s(n)$, though it is possible that is satisfies the conjecture under finer analysis.)

We further note that any family of relations R_f that satisfies Conjecture 3 must give an exponential separation between quantum and randomized one-way communication complexity, with the communication setting being that Alice gets input f, Bob gets input x, and Bob has to output u such that $(x,u) \in R_f$.[4] This is because, if there was a polynomial-sized classical message w_f that Alice could send to Bob in the communication setting, then w_f could also serve as a QCMA proof. Therefore, it seems that the slipperiness condition could also be used for lower-bounding one-way randomized communication complexity (although weaker slipperiness parameters than in the conjecture would also suffice for this).

[4] Strictly speaking, condition 1 of the conjecture only implies that there exists a one-way communication protocol, in which Alice sends the state $|z_f\rangle$, which works on average over x and f, whereas we usually require worst-case success in communication complexity. However, we can restrict to the set of x and f for which the algorithm $\mathcal{A}$ works, in order to get the communication problem.

2 Preliminaries

2.1 QMA and QCMA in query complexity

In this section, we review the formal definitions of QMA, QCMA, computationally-efficient QMA, and bounded-round QCMA in the context of query complexity.

▶ **Definition 4** (Bounded-round quantum query algorithm). *For $r, T, n \in \mathbb{N}$, give the following definition of a quantum query algorithm Q acting on n bits, using r rounds, with T queries in each round. The algorithm will be a tuple of $r+1$ unitary matrices, $Q = (U_0, U_1, \ldots, U_r)$. These unitary matrices will each act on T "query-input" registers of dimension n, T "query-output" registers of dimension 2, an "output" register of dimension 2, and a work register of arbitrary dimension.*

For each $x \in \{0,1\}^n$, let U^x be the oracle unitary, which acts on the query-input and query-output registers by mapping

$$|i_1\rangle |b_1\rangle |i_2\rangle |b_2\rangle \ldots |i_T\rangle |b_T\rangle \to |i_1\rangle |b_1 \oplus x_{i_1}\rangle |i_2\rangle |b_2 \oplus x_{i_2}\rangle \ldots |i_T\rangle |b_T \oplus x_{i_T}\rangle$$

for all $i_1, \ldots, i_T \in [n]$ and all $b_1, \ldots, b_T \in \{0,1\}$. We extend U^x to other registers via a Kronecker product with identity, so that U^x ignores the other registers.

The action of the algorithm Q on input $x \in \{0,1\}^n$, denoted by the Bernoulli random variable $Q(x)$, will be the result of measuring the output register of the state

$$U_r U^x U_{r-1} U^x \ldots U^x U_1 U^x U_0 |\psi_{init}\rangle ,$$

where $|\psi_{init}\rangle$ is a fixed initial state.

We will use the term "T-query quantum algorithm" without referring to the number of rounds to indicate T rounds with 1 query in each.

▶ **Definition 5** (Query algorithm with witness). *Let Q be a r-query quantum algorithm on n bits with T queries in each round. For any quantum state $|\phi\rangle$ and any $x \in \{0,1\}^n$, let $Q(x, |\phi\rangle)$ be the random variable corresponding to the measured output register after the algorithm terminates, assuming the initial state contained $|\phi\rangle$ in the work register (with ancilla padding) instead of being $|\psi_{init}\rangle$. That is, $Q(x, |\phi\rangle)$ is a Bernoulli random variable corresponding to the measurement outcome of the output register of the final state*

$$U_r U^x U_{r-1} U^x \ldots U_1 U^x U_0 |\phi\rangle |pad\rangle ,$$

where $|pad\rangle$ is the ancilla padding.

▶ **Definition 6** (Query QMA and QCMA). *Let f be a possibly partial Boolean function on n bits, and let Q be a quantum query algorithm on n bits with T total queries. We say that Q is a QMA algorithm for f with witness size k if the following holds:*

1. (Soundness). *For every $x \in f^{-1}(0)$ and every k-qubit state $|\phi\rangle$, we have $\Pr[Q(x, |\phi\rangle) = 1] \leq \epsilon$.*
2. (Completeness). *For every $x \in f^{-1}(1)$, there exists a k-qubit state $|\phi\rangle$ such that $\Pr[Q(x, |\phi\rangle) = 1] \geq 1 - \delta$.*

Here, ϵ and δ govern the soundness and completeness of Q; by default, we take them both to be $1/3$. We denote the QMA query complexity of f by $\mathrm{QMA}_{\epsilon,\delta}(f)$, which is the minimum possible value of $T + k$ over any QMA algorithm for f with the specified soundness and completeness.

We say that Q is a QCMA algorithm for f if the same conditions hold, except with the witness state $|\phi\rangle$ quantifying over only classical k-bit strings in both the soundness and completeness conditions. We define $\mathrm{QCMA}_{\epsilon,\delta}(f)$ *analogously to* $\mathrm{QMA}_{\epsilon,\delta}(f)$*, and we omit the subscripts when they are both* $1/3$*.*

▶ **Definition 7** (Bounded round query QMA and QCMA)**.** *We define r-round QMA and QCMA in exactly the same way as the above definition, except the query algorithms are required to have at most r rounds. We use* $\mathrm{QMA}^r_{\varepsilon,\delta}(f)$ *and* $\mathrm{QCMA}^r_{\varepsilon,\delta}(f)$ *to denote the r-round QMA and QCMA query complexities of f respectively.*

▶ **Definition 8** (Function family)**.** *A* function family *is an indexed set $F = \{f_n\}_{n\in I}$ where $I \subseteq \mathbb{N}$ is an infinite set and where each f_n is a partial Boolean function $f_n\colon \mathrm{Dom}(f_n) \to \{0,1\}$ with $\mathrm{Dom}(f_n) \subseteq \{0,1\}^n$.*

▶ **Definition 9** (Efficiently computable QMA)**.** *Let $F = \{f_n\}_{n\in I}$ be a function family. We say that F is in* efficiently computable query QMA *if there is a polynomial-time Turing machine which takes in the binary encoding $\langle n\rangle$ of a number $n \in I$ and outputs a QMA verifier Q by explicitly writing out the unitaries of Q as quantum circuits (with a fixed universal gate set). The verifier Q must be sound and complete for f_n. Efficiently computable bounded-round QMA is defined analogously.*

In other words, $\mathrm{QMA}(f_n)$ *must be* $O(\mathrm{polylog}(n))$*, and moreover, the different algorithms for f_n must be uniformly generated by a single polynomial-time Turing machine.*

With these definitions, we show in the full version that Theorem 2 implies Theorem 1.

2.2 Error-correcting codes

A Reed-Solomon error-correcting code $\mathrm{RS}_{q,\gamma,k}$ over $\mathbb{F}_q$, with degree parameter $0 < k < q-1$ and generator $\gamma \in \mathbb{F}_q^*$, is defined as

$$\mathrm{RS}_{q,\gamma,k} = \{(f(\gamma), \dots f(\gamma^q)) : f \in \mathbb{F}_q[x]_{\deg\le k}\},$$

where $\mathbb{F}_q[x]_{\deg\le k}$ is the set of polynomials over $\mathbb{F}_q$ of degree at most k.

Let $q-1 = mn$, for some integers m and n. The m-folded version $\mathrm{RS}^{(m)}_{q,\gamma,k}$ of $\mathrm{RS}_{q,\gamma,k}$ is a mapping of the code to the larger alphabet $\mathbb{F}_q^m$ as follows:

$$\mathrm{RS}^{(m)}_{q,\gamma,k} = \{((x_1,\dots,x_m),\dots,(x_{q-m},\dots,x_q)) : (x_1,\dots,x_q) \in \mathrm{RS}_{q,\gamma,k}\}.$$

Note that the alphabet of $\mathrm{RS}^{(m)}_{q,\gamma,k}$ is $\mathbb{F}_q^m$.

▶ **Definition 10.** *We say that a code $C \subseteq \Sigma^n$ is combinatorially (ζ,ℓ,L)-list recoverable if for any subsets $S_i \subseteq \Sigma$ such that $|S_i| \le \ell$, we have,*

$$|\{(x_1,\dots,x_n) \in C : |\{i : x_i \in S_i\}| \ge (1-\zeta)n\}| \le L.$$

▶ **Lemma 11** ([13, 14])**.** *For a prime power q such that $mn = q-1$, any generator $\gamma \in \mathbb{F}_q^*$, and degree $k < q-1$, $\mathrm{RS}^{(m)}_{q,\gamma,k}$ is (ζ,ℓ,q^s)-list recoverable for some $s \le m$ if there exists an integer r such that the following inequalities hold:*

$$(1-\zeta)n(m-s+1) \ge \left(1+\frac{s}{r}\right)(mn\ell k^s)^{1/(s+1)} \tag{1}$$

$$(r+s)\left(\frac{mn\ell}{k}\right)^{1/(s+1)} < q. \tag{2}$$

▶ **Corollary 12.** *Let m be $\Theta(n)$ integer such that $nm+1=q$ is a prime power. Let $k=\frac{5}{6}mn$ and let c,d be constants. Then $\mathrm{RS}^{(m)}_{q,\gamma,k}$ is $(c\log n/n, 2^{(\log n)^d}, 2^{(\log n)^{d+2}})$-list recoverable.*

This corollary is proved simply by checking that the equations (1)–(2) are satisfied with this choice of parameters. The choice of parameters is in fact the same as those as [14]. Therefore, the above code satisfies the other conditions required for the [14] quantum algorithm to succeed in evaluating the relation $R_{C,f}$ defined in the next section.

3 The Yamakawa-Zhandry problem

For a function $f:[n]\times\{0,1\}^m\to\{0,1\}$ and a linear code $C\subseteq\{0,1\}^{nm}$, define the relation $R_{C,f}\subseteq\{0,1\}^n\times\{0,1\}^{nm}$

$$R_{C,f}=\{(x,u)=(x_1\dots x_n,u_1\dots u_n):(u_1\dots u_n\in C)\wedge(\forall i\, f(i,u_i)=x_i)\}.$$

We shall typically work with $m=\Theta(n)$. We shall usually work with a fixed code C, in which case we shall omit the subscript C from $R_{C,f}$.

Let $\mathcal{P}\subseteq\{0,1,*\}^{n2^m}$ denote the set of polynomial-sized partial assignments for functions $f:[n]\times\{0,1\}^m\to\{0,1\}$. We define the extended version $\widetilde{R}_C$ of $\{R_{C,f}\}_f$ over $\mathcal{P}\times\{0,1\}^n\times\{0,1\}^{nm}$ as follows:

$$\widetilde{R}_C=\{(p,x,u):p\text{ is the minimal partial assignment s.t. }(x,u)\in R_{C,f}\,\forall f\supseteq p\}.$$

In particular, (p,x,u) is in $\widetilde{R}_C$ when p is the partial assignment $(f(i,u_i)=x_i)_i$, which is n bits.

▶ **Definition 13.** *Let $\widetilde{R}_n$ be a sequence of relations on $\mathcal{P}_n\times\{0,1\}^n\times\{0,1\}^{\mathrm{poly}(n)}$, where $\mathcal{P}_n$ consists of fixed polynomial-sized partial assignments for $N=2^{\Omega(n)}$-bit strings, and $\mathrm{poly}(n)$ is some fixed polynomial. We say $\widetilde{R}_n$ is $(\eta,s(n),t(n))$-slippery w.r.t. distribution μ on f if for any partial assignment q on N bits with size at most $s(n)$, if we fix the bits of q in f and generate the other bits of f according to μ (conditioned on q), we will have*

$$\left|\bigcup_{\substack{(p,x,u)\in\widetilde{R}_n,\\ \Pr_{f\sim\mu}[p\subseteq f|q\subseteq f]\geq\eta}}\mathrm{supp}(p)\setminus\mathrm{supp}(q)\right|\leq t(n).$$

We omit mentioning the distribution μ explicitly if it is the uniform distribution.

▶ **Lemma 14.** *When C is a code with parameters from Corollary 12, then for $c=\mathrm{polylog}(n)$ and $d=o(\log n/\log\log n)$, $\widetilde{R}_C$ is $(\frac{1}{n^c},2^{(\log n)^d},c\log n\cdot 2^{(\log n)^{d+2}})$-slippery.*

Proof. Let q be a partial assignment of size $2^{(\log n)^d}$. For each $i\in[n]$, let $S_i=\{v:(i,v)\text{ is fixed in }q\}$. Clearly for each i, $|S_i|\leq 2^{(\log n)^d}$. By Corollary 12,

$$C_q=|\{u_1\dots u_n\in C:|\{i:u_i\in S_i\}|\geq n-c\log n\}|\leq 2^{(\log n)^{d+2}}.$$

A tuple (p,x,u) can satisfy $(p,x,u)\in\widetilde{R}_C$ and $\Pr_{f\sim U}[p\subseteq f|q\subseteq f]$ only if $u\in C_q$, so we only need to compute $|\bigcup\mathrm{supp}(p)|$ for such tuples. In fact we only need to worry about the number of (x,u) pairs that could be in $R_{C,f}$, since p is completely fixed by x and u. Each u has at most $c\log n$ many locations that are not fixed by q, and x can take any value in those $c\log n$ locations. The x-s taking different values in these locations have overlapping

p-s (i.e., the same bits are fixed to different values for the different x-s), and since we only care about $|\bigcup \mathrm{supp}(p)|$, we need not count these x-s separately. Therefore, the number of unique indices fixed by such p-s is determined only by the number of u-s in C_q.

Since the total support of each p is outside of q is $c \log n$, we have,

$$\left| \bigcup_{\substack{(p,x,u)\in \widetilde{R}_n, \\ \Pr_f[p\subseteq f | q \subseteq f] \geq \frac{1}{n^c}}} \mathrm{supp}(p) \setminus \mathrm{supp}(q) \right| \leq 2^{(\log n)^{d+2}} \cdot c \log n. \quad \blacktriangleleft$$

▶ **Corollary 15.** *If μ is a distribution such that for all partial assignments p with $|p| = n$, we have $\mu|_q[p] \leq k \cdot u|_q[p]$ (where $\mu|_q[p]$ is the probability mass of strings consistent with p under μ conditioned on q, and $u|_q[p]$ is the same with the uniform distribution), then $\widetilde{R}_C$ from Lemma 14 is also $(\frac{k}{n^c}, 2^{(\log n)^d}, c \log n \cdot 2^{(\log n)^{d+2}})$-slippery w.r.t. μ.*

Proof. Since $\mu[p] \leq k \cdot u|_q[p]$ for all p, partial assignments that have probability at least $\frac{k}{n^c}$ against μ conditioned on q have probability at least $\frac{1}{n^c}$ against the uniform distribution conditioned on q. Now we can apply Lemma 14. $\blacktriangleleft$

▶ **Theorem 16.** *There exists a code C such that*

1. *$\widetilde{R}_C$ is $(\frac{1}{n^c}, 2^{(\log n)^d}, c \log n \cdot 2^{(\log n)^{d+2}})$-slippery for $c = \mathrm{polylog}(n)$ and $d = o(\log n / \log\log n)$.*
2. *There exists a quantum advice $|z_f\rangle$ with polynomially many qubits, and a polynomial-time quantum algorithm $\mathcal{A}$ that has access to $|z_f\rangle, x$, and makes no queries to any oracle, such that for any $x \in \{0,1\}^n$,*

$$\Pr_{f\sim U}[(u \leftarrow \mathcal{A}(|z_f\rangle, x)) \wedge ((x,u) \in R_{C,f})] \geq 1 - 2^{-\Omega(n)},$$

where the probability is over uniformly random functions $f : [n] \times \{0,1\}^m \to \{0,1\}$, and the internal randomness of $\mathcal{A}$.

Proof. Item 1 is due to Lemma 14. As stated before, the problem $\widetilde{R}_C$, and the choice of parameters for the code C in Lemma 14, is the same as [14]. Therefore, item 2 is due to [14, 10].[5] $\blacktriangleleft$

4 Techniques for bounded-round quantum query algorithms

In this section, we prove some results about bounded-round quantum query algorithms that will be useful in proving our QCMA lower bound.

Recall that a non-adaptive quantum algorithm works on T query-input registers and T query-output registers plus an additional work register W, so that its basis states look like

$$|i_1\rangle |b_1\rangle |i_2\rangle |b_2\rangle \ldots |i_T\rangle |b_T\rangle |W\rangle .$$

To clear up notational clutter, we will use $\vec{i} \in [N]^T$ to represent a tuple of T indices in $[N]$. Moreover, for a string $x \in \{0,1\}^N$ and for $\vec{i} \in [N]^T$, we will define $x_{\vec{i}} := (x_{\vec{i}_1}, x_{\vec{i}_2}, \ldots, x_{\vec{i}_T})$.

[5] The quantum algorithm in [14] makes some non-adaptive quantum queries (not depending on x), and does not take an advice state. The modified algorithm, which instead takes an advice state (which is essentially the state of the algorithm in [14] after its non-adaptive queries) and makes no queries, was described in [10].

The basis states can then be written $|\vec{i}\rangle\,|\vec{b}\rangle\,|W\rangle$, and the action of the query unitary U^x to the string x is to map $|\vec{i}\rangle\,|\vec{b}\rangle\,|W\rangle \to |\vec{i}\rangle\,|\vec{b} \oplus x_{\vec{i}}\rangle\,|W\rangle$, extended linearly to the rest of the space. (Here $\oplus$ denotes the bitwise XOR of the two strings of length T.)

Define $\Pi_{\vec{i}} := |\vec{i}\rangle\langle\vec{i}| \otimes I_{\vec{b},W}$ to be the projection onto basis states with $\vec{i}$ in the query-input registers. For $i \in [N]$, define $\Pi_i := \sum_{\vec{i} \ni i} \Pi_{\vec{i}}$ to be the projection onto basis states with i occurring in one of the query-input registers. The projections $\Pi_{\vec{i}}$ are onto orthogonal spaces, though the projections Π_i are not. Observe that $\sum_{\vec{i}} \Pi_{\vec{i}} = I$, and that $\sum_i \Pi_i = \sum_i \sum_{\vec{i} \ni i} \Pi_{\vec{i}} = \sum_{\vec{i}} \sum_{i \in \vec{i}} \Pi_{\vec{i}} = T \cdot I$. Moreover, since the oracle unitary U^x does not change the query-input registers, U^x commutes with both $\Pi_{\vec{i}}$ and Π_i. Another convenient property is that if $x_{\vec{i}} = y_{\vec{i}}$ for two strings $x, y \in \{0,1\}^N$, then $\Pi_{\vec{i}}(U^x - U^y) = 0$; this holds because both U^x and U^y map $|\vec{i}\rangle\,|\vec{b}\rangle\,|W\rangle$ to the same vector when $x_{\vec{i}} = y_{\vec{i}}$. Using these properties, we have the following lemma.

▶ **Lemma 17** (Hybrid argument for nonadaptive queries). *For any strings $x, y \in \{0,1\}^N$ and any quantum state $|\psi\rangle = \sum_{\vec{i},\vec{b},W} \alpha_{\vec{i},\vec{b},W}\,|\vec{i}\rangle\,|\vec{b}\rangle\,|W\rangle$, we have*

$$\| U^x\,|\psi\rangle - U^y\,|\psi\rangle \,\|_2^2 \le 4 \sum_{i : x_i \neq y_i} \| \Pi_i\,|\psi\rangle \,\|_2^2.$$

Proof. We write the following, with justification afterwards.

$$\begin{aligned}
\| U^x\,|\psi\rangle - U^y\,|\psi\rangle \,\|_2^2 &= \left\| \sum_{\vec{i}} \Pi_{\vec{i}}(U^x - U^y)\,|\psi\rangle \right\|_2^2 \\
&= \sum_{\vec{i}} \| \Pi_{\vec{i}}(U^x - U^y)\,|\psi\rangle \,\|_2^2 \\
&= \sum_{\vec{i} : x_{\vec{i}} \neq y_{\vec{i}}} \| \Pi_{\vec{i}}(U^x - U^y)\,|\psi\rangle \,\|_2^2 \\
&\le \sum_{\vec{i}} \sum_{i \in \vec{i} : x_i \neq y_i} \| \Pi_{\vec{i}}(U^x - U^y)\,|\psi\rangle \,\|_2^2 \\
&= \sum_{i : x_i \neq y_i} \sum_{\vec{i} \ni i} \| \Pi_{\vec{i}}(U^x - U^y)\,|\psi\rangle \,\|_2^2 \\
&= \sum_{i : x_i \neq y_i} \left\| \sum_{\vec{i} \ni i} \Pi_{\vec{i}}(U^x - U^y)\,|\psi\rangle \right\|_2^2 \\
&= \sum_{i : x_i \neq y_i} \| \Pi_i(U^x - U^y)\,|\psi\rangle \,\|_2^2 \\
&= \sum_{i : x_i \neq y_i} \| (U^x - U^y)\Pi_i\,|\psi\rangle \,\|_2^2 \\
&\le 4 \sum_{i : x_i \neq y_i} \| \Pi_i\,|\psi\rangle \,\|_2^2.
\end{aligned}$$

In the first line, we used $\sum_{\vec{i}} \Pi_{\vec{i}} = I$. In the second, we used the orthogonality of the images of the projections $\Pi_{\vec{i}}$. In the third, we used $\Pi_{\vec{i}}(U^x - U^y) = 0$ when $x_{\vec{i}} = y_{\vec{i}}$.

In the fourth line, we replaced the sum over $\vec{i}$ containing at least one i with $x_i \neq y_i$ with a weighted sum, where the weight of $\vec{i}$ is the number of $i \in \vec{i}$ such that $x_i \neq y_i$; this weight is 0 when $x_{\vec{i}} = y_{\vec{i}}$ and at least 1 when $x_{\vec{i}} \neq y_{\vec{i}}$. This weight can be represented as a sum over $i \in \vec{i}$ with $x_i \neq y_i$, since we are counting $\vec{i}$ once for each such i in the tuple.

The fifth line flips the order of the sums, and the sixth uses orthogonality of the images of $\Pi_{\vec{i}}$ to put the sum back inside the squared norm. The seventh line is the definition of Π_i, and the eighth holds since Π_i commutes with U^x and U^y. Finally, the last line follows either from the triangle inequality, or from the fact that the spectral norm of $(U^x - U^y)$ is at most 2 (since U^x and U^y are unitary). ◀

For an oracle $x \in \{0,1\}^n$ and a block $B \subseteq [N]$, use $x[B]$ to denote the string x with queries in B erased; that is, $x[B]_i = x_i$ if $i \notin B$, and $x[B]_i = 0$ for $i \in B$. Next, we use this hybrid argument in combination with a Markov inequality to show that if a distribution μ over $\{0,1\}^n$ has a set of queries $B \in [N]$ that nearly always return zero for oracles sampled from μ, then for any non-adaptive quantum algorithm, there exists a large set of oracles (measured against μ) such that the algorithm does not detect whether any subset of B is erased.

▶ **Lemma 18** (Nonadaptive algorithms don't detect oracle erasures)**.** *Fix $|\psi\rangle$ representing the state of a quantum algorithm before a batch of non-adaptive queries. Let μ be a distribution over $\{0,1\}^N$, and let $\epsilon > 0$. Let $B = \{i \in [N] : \Pr_{x\sim\mu}[x_i = 1] \leq \epsilon\}$. Then there exists a set $S \subseteq \{0,1\}^N$ such that $\mu[S] \geq 1/2$ and for all $x \in S$ and all subsets $B_1, B_2 \subseteq B$, we have*

$$\| U^{x[B_1]} |\psi\rangle - U^{x[B_2]} |\psi\rangle \|_2 \leq \sqrt{8\epsilon T}.$$

Proof. We write the following, with justification afterwards.

$$\begin{aligned}
\mathop{\mathbb{E}}_{x\sim\mu}\left[\sum_{i:x_i\neq x[B]_i} \|\Pi_i |\psi\rangle\|_2^2\right] &= \mathop{\mathbb{E}}_{x\sim\mu}\left[\sum_{i\in B} x_i \|\Pi_i |\psi\rangle\|_2^2\right] \\
&= \sum_{i\in B} \|\Pi_i |\psi\rangle\|_2^2 \mathop{\mathbb{E}}_{x\sim\mu}[x_i] \\
&\leq \epsilon \sum_{i\in B} \|\Pi_i |\psi\rangle\|_2^2 \\
&\leq \epsilon \sum_{i\in[N]} \|\Pi_i |\psi\rangle\|_2^2 \\
&= \epsilon \sum_{i\in[N]} \sum_{\vec{i}\ni i} \|\Pi_{\vec{i}} |\psi\rangle\|_2^2 \\
&= \epsilon T \sum_{\vec{i}} \|\Pi_{\vec{i}} |\psi\rangle\|_2^2 \\
&= \epsilon T.
\end{aligned}$$

The first line follows by noting that $x_i \neq x[B]_i$ can only happen if both $i \in B$ and $x_i = 1$; we replace the sum over $i : x_i \neq x[B]_i$ with the sum over $i \in B$, and multiply the summand by the indicator for $x_i = 1$, which is x_i itself.

The second line is the result of pushing the expectation inside the sum, and observing that the norm does not depend on x and can be factored out of the expectation. The third line follows from the definition of B: we know that for all $i \in B$, the probability of $x_i = 1$ is at most ϵ. The fourth replaces the sum over B with that over $[N]$. The fifth uses the definition of Π_i, and exchanges the sum over $\vec{i}$ with the squared norm using orthogonality. The sixth line follows by noting that each $\vec{i}$ appears exactly T times in this double sum. Finally, the last line follows by pushing the sum inside the squared norm (using orthogonality), and recalling that $\sum_{\vec{i}} \Pi_{\vec{i}} = I$, together with the fact that $|\psi\rangle$ is a unit vector.

Given this bound on the expectation, we can apply Markov's inequality to conclude that at least half the strings x (weighted by μ) must satisfy $\sum_{i:x_i \neq x[B]_i} \|\Pi_i |\psi\rangle\|_2^2 \leq 2\epsilon T$. Let S be the set of such strings x; then $\mu[S] \geq 1/2$. Observe that for any $x \in S$ and any $B_1, B_2 \subseteq B$, the set $\{i : x[B_1]_i \neq x[B_2]_i\}$ is a subset of $\{i : x_i \neq x[B]_i\}$. We now apply Lemma 17 to get

$$\|U^{x[B_1]} |\psi\rangle - U^{x[B_2]} |\psi\rangle\|_2^2 \leq 4 \sum_{i:x[B_1]_i \neq x[B_2]_i} \|\Pi_i |\psi\rangle\|_2^2 \leq 4 \sum_{i:x_i \neq x[B]_i} \|\Pi_i |\psi\rangle\|_2^2 \leq 8\epsilon T.$$

The desired result follows by taking square roots. ◀

5 QMA vs QCMA

In this section, we prove Theorem 2. Theorem 19 will define the function F_N and show that it is in QMA, and Theorem 21 will show that it is not in QCMA.

5.1 Construction and QMA protocol

Fix a code C for which Theorem 16 holds, with $c = \log n$. We shall henceforth refer to $R_{C,f}$ as only R_f for this C. For a subset $E \subseteq \{0,1\}^n$, define the oracle $O[f, E]\colon \{0,1\}^n \times \{0,1\}^{nm} \to \{0,1\}$ as

$$O[f,E](x,u) = \begin{cases} 1 & \text{if } (x,u) \in R_f \wedge x \notin E \\ 0 & \text{otherwise.} \end{cases}$$

▶ **Theorem 19.** *There exists an efficient uniform collection of query QMA protocols (generated uniformly by a polynomial time Turing machine) which uses 1 query and polynomial witness size, and which outputs 0 on all oracles $O[f, E]$ with $|E| \geq (2/3) \cdot 2^n$, and outputs 1 on $O[f, \emptyset]$ for $1 - 2^{-\Omega(n)}$ fraction of f-s.*

Proof. The quantum witness for the algorithm will be quantum advice state for R_f from Theorem 16. The quantum algorithm works as follows: it samples a uniformly random $x \in \{0,1\}^n$, and runs the procedure from Theorem 16 to find a u such that $(x,u) \in R_f$. Note that this requires no queries to the oracle. Then it queries the oracle at (x,u) and returns the query output. If the oracle is $O[f,\emptyset]$ and the actual state $|z_f\rangle$ from Theorem 16 is provided as witness, then due to Theorem 16 we have,

$$\Pr_{f \sim U}[\mathcal{A}^{O[f,\emptyset]}(|z_f\rangle) = 1] \geq 1 - 2^{-\Omega(n)}.$$

On the other hand, if the oracle is $O[f,E]$ for $|E| \geq \frac{2}{3} \cdot 2^n$, no matter what witness is provided, and what u is obtained from this witness, the oracle outputs 0 on (x,u) for $\frac{2}{3}$ of the x-s. Since the algorithm samples a uniformly random x and queries it with some u for every f, we have for every f,

$$\Pr[\mathcal{A}^{O[f,E]}(|z_f\rangle) = 1] \leq \frac{1}{3}.$$ ◀

Defining the function F_N. We now define the following partial query function with input size $2^n \times 2^{mn}$: its 1-inputs are all the oracles $O[f,\emptyset]$ for which the algorithm from Theorem 19 accepts with probability at least $2/3$, and its 0-inputs are $O[f,E]$ for which $O[f,\emptyset]$ is a 1-input and $|E| \geq (2/3) \cdot 2^n$. Note that these oracles correspond to the inputs "x" of the query problem. This defines a family F_N of query tasks with $N = 2^n \times 2^{mn}$, and Theorem 19 showed that this family is in efficiently-computable QMA.

5.2 Densification of probability distributions

To prove our QCMA lower bound, we will need some properties of distributions on $\{0,1\}^N$. For such a distribution μ, let $\mathrm{RU}(\mu) \coloneqq \max_{x\in\{0,1\}^N} \log_2(2^N\mu[x])$ be the max relative entropy of μ relative to the uniform distribution. We will generally be interested in distributions μ such that $\mathrm{RU}(\mu)$ is small (say, $\mathrm{polylog}\, N$), which means that no input $x \in \{0,1\}^N$ has probability $\mu[x]$ much larger than 2^{-N}.

For a partial assignment p, let $\mu[p]$ be the probability mass of strings in $\{0,1\}^N$ which are consistent with p. Let $|p|$ be the size of p (the number of revealed bits in p). We define the density of μ to be $\mathrm{density}(\mu) \coloneqq 1 - \max_p \frac{\log_2(2^{|p|}\mu[p])}{|p|}$, with the maximum taken over partial assignments p. The density of the uniform distribution is 1.

For a partial assignment p, we let $\mu|_p$ denote the distribution μ conditioned on the sampled input being consistent with p. Items 1 and 3 of the following lemma essentially follow from results in [8, 6]. We produce a proof here because the version of the lemma we need is simpler than what was shown in [8, 6].

▶ **Lemma 20** (Densification). *Let μ be a distribution over $\{0,1\}^N$, and let $\delta \in (0,1)$. Then there exists a partial assignment p such that*

1. $|p| \le \mathrm{RU}(\mu)/\delta$
2. $\mathrm{RU}(\mu|_p) \le \mathrm{RU}(\mu)/\delta$
3. $\mathrm{density}(\mu|_p) > 1-\delta$, *where the density is measured on the bits not fixed by p.*

Proof. Let p be the largest partial assignment (we can pick the lexicographically first one according to some ordering, if there is a tie) for which $\mu[p] \ge 2^{-(1-\delta)|p|}$. Then

$$2^{-(1-\delta)|p|} \le \mu[p] = \sum_{x\supseteq p} \mu[x] \le 2^{N-|p|}\cdot 2^{-(N-\mathrm{RU}(\mu))} = 2^{\mathrm{RU}(\mu)-|p|},$$

so $\delta|p| \le \mathrm{RU}(\mu)$, from which the first item follows. Next,

$$\mathrm{RU}(\mu|_p) = \max_x \log_2(2^N\mu|_p[x]) = \max_{x\supseteq p} \log_2(2^N\mu[x]/\mu[p]) \le \mathrm{RU}(\mu) + \log_2(1/\mu[p])$$

$$\le \mathrm{RU}(\mu) + \log_2(2^{(1-\delta)|p|}) = \mathrm{RU}(\mu) + (1-\delta)|p| \le \mathrm{RU}(\mu) + (1-\delta)\,\mathrm{RU}(\mu)/\delta = \mathrm{RU}(\mu)/\delta,$$

which gives the second item. Finally, to upper bound the density of $\mu|_p$, let q be a partial assignment on a set of indices disjoint from that of p. By the maximality of p, we must have $\mu[p\cup q] < 2^{-(1-\delta)(|p|+|q|)}$. Now,

$$\log_2(2^{|q|}\mu|_p[q]) = \log_2(2^{|q|}\mu[q\cup p]/\mu[p]) < \log_2(2^{|q|}2^{-(1-\delta)(|p|+|q|)}/2^{-(1-\delta)|p|}) = \delta|q|.$$

From this it follows that $\mathrm{density}(\mu|_p) > 1-\delta$, as desired. ◀

5.3 QCMA lower bound

▶ **Theorem 21.** *There is no bounded-round, polynomial-cost QCMA protocol for the family F_N defined in Section 5.1. More formally, consider any family of QCMA protocols for the query problems F_N. If the number of rounds for these QCMA protocols grows slower than $o(\log\log N/\log\log\log N)$, then either the number of queries or the witness size must grow like $\log^{\omega(1)} N$.*

We will prove this theorem by a sequence of claims. The idea of the proof will be to remove the rounds of the algorithm one by one. We start by moving from QCMA to BQP via the following claim.

▷ Claim 22. If there is a QCMA protocol for F_N with witness size $k = k(N)$, then there is a quantum algorithm Q and a large set of functions S such that Q accepts all oracles $O[f, \emptyset]$ for $f \in S$ and rejects all oracles $O[f, E]$ for $f \in S$ and $|E| \geq (2/3)2^n$. The set S is large enough that the uniform distribution μ over S has $\mathrm{RU}(\mu) \leq 2k$. The algorithm Q makes the same number of rounds and number of queries as the QCMA protocol. By "accepting" and "rejecting", we mean with probability at least 2/3.

Proof. The idea is just to take a witness w that works for as many 1-inputs as possible, and hard-code this witness into the quantum algorithm. S will correspond to the set of 1-inputs on which this witness works.

More explicitly, since the witness is a classical string, there are only 2^k witnesses over which we quantify. Since each 1-input $O[f, \emptyset]$ has some witness accepting it, we conclude that at least one witness w of size k is a valid witness for at least a 2^{-k} fraction of the 1-inputs, and hence also for at least a $2^{-k}(1 - 2^{-\Omega(n)})$ fraction of all oracles $O[f, \emptyset]$ (including those not in the domain of F_N). This is because the fraction of f-s for which the quantum algorithm does not succeed with probability at least 2/3 is at most $2^{-\Omega(n)}$. We can assume $2^{-k}(1 - 2^{-\Omega(n)}) \geq 2^{-2k}$.

Let S be the set of f such that $O[f, \emptyset]$ is accepted by the algorithm given witness w. Let μ be the uniform distribution over S, and observe that $\mathrm{RU}(\mu) \leq 2k$. Let Q be the quantum algorithm which hard-codes the witness w into the verifier; then Q accepts all oracles $O[f, \emptyset]$ for $f \in \mathrm{supp}(\mu)$ and rejects all oracles $O[f, E]$ if $|E| \geq (2/3)2^n$. ◁

Defining the round reduction. Given a pair (Q, μ) of a quantum algorithm and a distribution over functions, we wish to define a pair $(\tilde{Q}, \tilde{\mu})$ such that $\tilde{Q}$ has one less round than Q, $\mathrm{supp}(\tilde{\mu})$ is a subset of $\mathrm{supp}(\mu)$ but "not by much" (i.e. $\mathrm{RU}(\tilde{\mu})$ is not much larger than $\mathrm{RU}(\mu)$), and the two algorithms behave similarly on $\tilde{\mu}$.

To define $(\tilde{Q}, \tilde{\mu})$ given (Q, μ), we proceed in several steps.

1. First, use Lemma 20 with $\delta = 1/n$ to find a partial assignment q with $|q| \leq n\,\mathrm{RU}(\mu)$, $\mathrm{RU}(\mu|_q) \leq n\,\mathrm{RU}(\mu)$, and with $\mu|_q$ being $(1 - \delta)$-dense on the bits not used by q.
2. Second, use Lemma 18 with $\epsilon = 1/3200r^2T$ on the distributions of oracles $O[f, \emptyset]$ when f is sampled from $\mu|_q$. The state $|\psi\rangle$ in the lemma will be the state of the algorithm Q just before the first batch of T queries. The lemma gives a set $S \subseteq \mathrm{supp}(\mu|_q)$ with $\mu|_q[S] \geq 1/2$. It has the property that for all $f \in S$ and all sets B_1, B_2 containing pairs (x, u) with $\Pr_{f \sim \mu|_q}[O[f, \emptyset](x, u) = 1] \leq \epsilon$, we have $\| U^{O[f,B_1]} |\psi\rangle - U^{O[f,B_2]} |\psi\rangle \|_2 \leq 1/20r$. Condition $\mu|_q$ on the set S to get a distribution μ'.
   Note that $O[f, B_1]$ is an abuse of notation, since normally we erase inputs x to f from the oracle, yet B_1 is a set of pairs (x, u). We will use this abuse of notation throughout; if we write $O[f, B]$ where B is a set of pairs, we mean to erase those pairs from the oracle, while if B is a subset of $\mathrm{Dom}(f)$, we mean to erase the pairs (x, u) for $x \in B$ and all u from the oracle.
3. Third, use the slippery property from Corollary 15 on q to conclude that the number of bits used by partial assignments p for which $(p, x, u) \in \tilde{R}_C$ and $\Pr_{f \sim \mu'}[p \subseteq f | q \subseteq f] \geq \epsilon/4$ is small. Recall that $(p, x, u) \in \tilde{R}_C$ means that the condition $O[f, \emptyset](x, u) = 1$ is equivalent to $p \subseteq f$ for all f; such certifying p have $|p| = n$. Corollary 15 can be applied because $\epsilon/4$ is larger than $1/n^c$ for $c = \log n$, since we are choosing $r = o(\log n / \log\log n)$ and $T \leq O(2^{\log^2 n} / \log n)$. Now, since $\mu|_q$ is $(1 - \delta)$-dense outside of q, the probability of a partial assignment p against $\mu|_q$ is at most $2^{\delta|p|}$ times the probability against the uniform distribution conditioned on q. Here $|p| = n$ and $\delta = 1/n$, so the probability against

$\mu|_q$ is at most twice that against the uniform distribution conditioned on q. Moving from $\mu|_q$ to μ' conditions on a set S of probability at least $1/2$, so it can increase the probability of p by at most a factor of 2. Hence the probability of p against μ' is overall at most 4 times its probability against the uniform distribution conditioned on q. By Corollary 15, we conclude the total number of bits used by partial assignments p for which $\Pr_{f\sim\mu'}[O[f,\emptyset](x,u)=1] \geq \epsilon$ is small. Let Z be the set of all such bits.

Our final modification to μ' will be to fix the bits in Z to the highest-probability partial assignment (measured against μ'), and let $\tilde{\mu}$ be μ' conditioned on this partial assignment.

4. Set $\tilde{Q}$ to be the quantum algorithm which is the same as Q, except that the first batch of queries is made to a fake oracle instead of a real one. The fake oracle is defined as follows: on queries (x,u) for which $O[f,\emptyset](x,u)$ is fixed for all $f \in \mathrm{supp}(\tilde{\mu})$, return this value $O[f,\emptyset](x,u)$; on queries (x,u) for which this value is not fixed for $f \in \mathrm{supp}(\tilde{\mu})$, return 0. Note that the fake oracle does not depend on the true input oracle $O[f,\emptyset]$, so queries to it can be implemented by $\tilde{Q}$ without making queries to the real oracle. This replaces the first round of Q, so $\tilde{Q}$ has one less round.

▷ Claim 23. Let Q and μ be as in Claim 22 (with μ the uniform distribution over S). Let $(Q_0,\mu_0)=(Q,\mu)$, and iteratively define $(Q_\ell,\mu_\ell)=(\tilde{Q}_{\ell-1},\tilde{\mu}_{\ell-1})$ for $\ell=1,2,\ldots,r$, where r is the number of rounds of Q.

Then Q_r makes no queries and μ_r "has large support": $\log \mathrm{RU}(\mu_r) \leq (2\log n)^{2r}\log 2k$ (assuming n is sufficiently large).

Proof. That Q_r makes no queries is clear, since each Q_ℓ in the chain makes one less round of queries than $Q_{\ell-1}$, and since the first algorithm $Q_0=Q$ makes r rounds.

To bound $\mathrm{RU}(\mu_r)$, we need to show that $\log \mathrm{RU}(\mu_{\ell+1})$ is at most a factor of $2\log^2 n$ more than $\log \mathrm{RU}(\mu_\ell)$.

Recall the construction of $\mu_{\ell+1}$ from μ_ℓ. The first step moved from μ_ℓ to $\mu_\ell|_q$ with $\mathrm{RU}(\mu_\ell|_q) \leq n\,\mathrm{RU}(\mu_\ell)$. The second step conditioned the latter distribution on a set S of probability mass at least $1/2$, which can only increase $\mathrm{RU}(\cdot)$ by 1, so $\mathrm{RU}(\mu'_\ell) \leq n\,\mathrm{RU}(\mu_\ell)+1$.

The third step found the set of all bits fixed in partial assignments p which certify some (x,u) as evaluating to 1, and picked the highest-probability partial assignment on those bits. The maximum increase in $\mathrm{RU}(\cdot)$ is the number of bits that were fixed in this way. This number comes from Theorem 16, and depends on the number of bits fixed in q; when $|q| = 2^{(\log n)^d}$, the number we are looking for is $c\log n \cdot 2^{(\log n)^{d+2}}$, so we can express this as $c\log n \cdot 2^{(\log^2 n)(\log|q|)}$. We had $|q| \leq n\,\mathrm{RU}(\mu_\ell)$ and $c=\log n$. It is not hard to see that this additive increase dominates $n\,\mathrm{RU}(\mu_\ell)+1$; assuming everything is large enough (e.g. $\log n$ is sufficiently large, and $\mathrm{RU}(\mu_\ell)$ is at least n^2, which is without loss of generality by restricting the original μ_0 to a smaller set if necessary), we can get the upper bound $\mathrm{RU}(\mu_{\ell+1}) \leq 2^{2\log^2 n \log \mathrm{RU}(\mu_\ell)}$, as desired. ◁

▷ Claim 24. Assume the witness size k is $O(\mathrm{poly}(n))$ and the number of rounds r is $o(\log n/\log\log n)$, and let n be large enough. With notation as in Claim 23, there exists $\hat{f} \in \mathrm{supp}(\mu_r)$ and a large set E (with $|E| \geq (2/3)2^n$) of inputs x such that for every $x \in E$ and every u, the pair (x,u) is "not fixed to 1 by μ_r" (that is, there exists $f \in \mathrm{supp}(\mu_r)$ such that $O[f,\emptyset](x,u)=0$).

Proof. We essentially apply another round-reduction iteration (without the second step) to μ_r. Using Lemma 20, we find a partial assignment q' such that $\mu_r|_{q'}$ is $(1-\delta)$-dense outside of q', with $\delta = 1/n$. We then apply Theorem 16 to conclude there are few pairs (x,u) with $\Pr_f[O[f,\emptyset](x,u)=1] \geq 1/2$, and hence few pairs (x,u) with $\Pr_f[O[f,\emptyset](x,u)=1] = 1$

when f is sampled from $\mu_r|_{q'}$; the number of such pairs is at most $2^{(2\log n)^{2r+2}\log k}$. Using $k = O(\text{poly}(n))$ and $r = o(\log n/\log\log n)$, this means that there are at most $2^{o(n)}$ pairs (x,u) that are fixed to 1 for all the oracles $O[f,\emptyset]$ for $f \in \text{supp}(\mu_r|_{q'})$. Therefore, there are $2^{n-o(n)}$ many inputs x such that for all u, the pair (x,u) is not fixed to 1 by $\text{supp}(\mu_r|_{q'})$. Let E be the set of such x; then $|E| \geq (2/3)2^n$. Let $\hat{f} \in \text{supp}(\mu_r|_{q'})$ be arbitrary, and the desired result follows. ◁

Proof of Theorem 21. Start with a QCMA protocol for f_N, and use Claim 22 to get a Q and μ; to get a contradiction, we just need to find $f \in \text{supp}(\mu)$ and a large set E of inputs x such that Q fails to distinguish the oracle $O[f,\emptyset]$ from the oracle $O[f,E]$.

Let (Q_ℓ, μ_ℓ) be as in Claim 23, and let $\hat{f}$ and E be as in Claim 24. To complete the proof, we just need show that $Q = Q_0$ fails to distinguish $O[\hat{f},\emptyset]$ and $O[\hat{f},E]$.

Let $B = \{(x,u) : x \in E, O[\hat{f},\emptyset](x,u) = 1\}$. Moreover, let B_ℓ be the set of pairs (x,u) which had $\Pr_{f\sim\mu_{\ell-1}|_q}[O[f,\emptyset](x,u) = 1] \leq \epsilon$ in iteration ℓ (where q is the partial assignment from step 1 of iteration ℓ). Note that the pairs not in B_ℓ are all fixed in all the oracles in the support of μ_ℓ, because we choose values for the bits used by their proving partial assignments p. This means that $B \subseteq B_\ell$ for all ℓ. Also, let O_ℓ be the oracle used by Q_ℓ to simulate the first query batch of $Q_{\ell-1}$. Recall that $O_\ell(x,u)$ returns 0 unless (x,u) is fixed to 1 in all $O[f,\emptyset]$ for $f \in \text{supp}(\mu_\ell)$. Since the support of μ_ℓ decreases as a subset in each iteration, the bits fixed in μ_ℓ are also fixed in μ_r, and hence also agree with $\hat{f}$. This means that O_ℓ can be written as an erased oracle $O[\hat{f},A_\ell]$ for some set A_ℓ of pairs (x,u) that were not fixed in μ_ℓ; in other words, $A_\ell \subseteq B_\ell$.

We now note the oracle $O[\hat{f},E]$ is the same as $O[\hat{f},B]$. Additionally, since $B, A_\ell \subseteq B_\ell$, we have by Lemma 18,

$$\|U^{O[\hat{f},B]}|\psi\rangle - U^{O[\hat{f},A_\ell]}|\psi\rangle\|_2 \leq 1/20r$$

where $|\psi\rangle$ is the state right before the first query of the algorithm $Q_{\ell-1}$. This can also be written

$$\|U^{O[\hat{f},E]}|\psi\rangle - U^{O_\ell}|\psi\rangle\|_2 \leq 1/20r.$$

Now, applying additional unitary matrices does not change the 2-norm, and Q_ℓ replaces only the first query of $Q_{\ell-1}$ with O_ℓ and applies the same unitaries as $Q_{\ell-1}$ in all other rounds. If we use $Q_\ell(O)$ to denote the final state of Q_ℓ on the oracle O, we therefore get

$$\|Q_\ell(O[\hat{f},E]) - Q_{\ell-1}(O[\hat{f},E])\|_2 \leq 1/20r.$$

By triangle inequality, we then get

$$\|Q(O[\hat{f},E]) - Q_r(O[\hat{f},E])\|_2 \leq 1/20.$$

Since $\emptyset \subseteq B_\ell$ for all ℓ, the same argument also works to show that

$$\|Q(O[\hat{f},\emptyset]) - Q_r(O[\hat{f},\emptyset])\|_2 \leq 1/20,$$

and of course we also have $Q_r(O[\hat{f},\emptyset]) = Q_r(O[\hat{f},E])$ since Q_r makes no queries. A final application of the triangle inequality gives us

$$\|Q(O[\hat{f},E]) - Q(O[\hat{f},\emptyset])\|_2 \leq 1/10.$$

This gives the desired contradiction, as Q failed to sufficiently distinguish these two oracles (it must accept one with probability at least 2/3 and the other with probability at most 1/3; converting this to a lower bound on the 2-norm distance is a straightforward exercise). ◀

Abstract

We study Two-Sets Cut-Uncut on planar graphs. Therein, one is given an undirected planar graph G and two disjoint sets S and T of vertices as input. The question is, what is the minimum number of edges to remove from G, such that all vertices in S are separated from all vertices in T, while maintaining that every vertex in S, and respectively in T, stays in the same connected component. We show that this problem can be solved in $2^{|S|+|T|}n^{\mathcal{O}(1)}$ time with a one-sided-error randomized algorithm. Our algorithm implies a polynomial-time algorithm for the network diversion problem on planar graphs, which resolves an open question from the literature. More generally, we show that Two-Sets Cut-Uncut is fixed-parameter tractable when parameterized by the number r of faces in a planar embedding covering the terminals $S \cup T$, by providing a $2^{\mathcal{O}(r)}n^{\mathcal{O}(1)}$-time algorithm.

1 Introduction

A *cut* in a graph $G = (V, E)$ is a partitioning (A, B) of V, and we denote by $\text{cut}_G(A)$ the *cut-set*, that is, the set of edges with one endpoint in A and the other in $B = V \setminus A$. For two disjoint sets of vertices S and T, (A, B) is an *S-T-cut* if $S \subseteq A$ and $T \subseteq B$. We study the following variant of the *cut-uncut problem*.

Two-Sets Cut-Uncut

Input:	A graph G, two disjoint terminal sets $S, T \subseteq V(G)$, and an integer $k \geq 0$.
Task:	Decide whether there exists an S-T-cut (A, B) of G with $\lvert\text{cut}_G(A)\rvert \leq k$ such that the vertices of S are in the same connected component of $G[A]$ and the vertices of T are in the same connected component of $G[B]$.

Our interest in Two-Sets Cut-Uncut is two-fold. First, Two-Sets Cut-Uncut is a natural optimization variant of the 2-Disjoint Connected Subgraphs problem that received considerable attention from the graph-algorithms and computational-geometry communities [14, 25, 30, 40, 43, 44]. In this problem, one asks whether, for two given disjoint sets $S, T \subseteq V(G)$, one can find disjoint sets $A_1 \supseteq S$ and $A_2 \supseteq T$ such that the subgraphs of G induced by A_i, $i = 1, 2$, are connected. In Two-Sets Cut-Uncut we not only want to decide whether there are disjoint connected sets containing terminal sets S and T, but also minimize the size of the corresponding cut (if it exists). Van 't Hof et al. [44] showed that 2-Disjoint Connected Subgraphs is NP-complete in general graphs, even if $|S| = 2$, and Gray et al. [25] proved that the problem is NP-complete on planar graphs. This implies that Two-Sets Cut-Uncut is also NP-complete on planar graphs.

Second, Two-Sets Cut-Uncut is closely related to the Network Diversion problem, which has been studied extensively by the operations research and networks communities [10, 11, 19, 22, 29, 36]. In this problem, we are given an undirected graph G, two terminal vertices s and t, an edge $b = uv$, and an integer k. The task is to decide whether it is possible to delete at most k edges such that the edge b will become a bridge with s on one side and t on the other. Equivalently, the task is to decide whether there exists a *minimal* s-t-cut of size at most $k + 1$ containing b. While this problem seems very similar to the classic s-t-Minimum Cut problem, the complexity status of this problem (P vs. NP) is widely open. Let us observe that a polynomial-time algorithm for the special case of Two-Sets Cut-Uncut with $|S| = |T| = 2$ implies a polynomial time algorithm for Network Diversion: There are two cases, either s is in the same component as u, or s is in the same component as v, and these correspond to instances of Two-Sets Cut-Uncut with $S = \{s, u\}$ and $T = \{t, v\}$ and $S = \{s, v\}$ and $T = \{t, u\}$, respectively.

Network Diversion has important applications in transportation networks and has therefore also been studied on planar graphs. Cullenbine et al. [10] gave a polynomial-time algorithm for Network Diversion on planar graphs for the special case when both terminals s and t are located on the same face. They posed as an open problem whether this polynomial-time algorithm can be generalized to work on arbitrary planar graphs [10]. Duan et al. put out a preprint [18], which among other results, claims an algorithm resolving Network Diversion on planar graphs in polynomial time, but without a description of the algorithm. We were not able to verify the correctness of the result due to several missing details. The result, however, is an immediate consequence of our main contribution, Theorem 1, establishing the fixed-parameter tractability of Two-Sets Cut-Uncut on planar graphs parameterized by $|S| + |T|$. Theorem 1 also establishes a more general result about fixed-parameter tractability of the problem parameterized by the minimum number of faces r of the graph containing all terminals. (Notice that r never exceeds $|S| + |T|$.)

▶ **Theorem 1.** *There is a one-sided-error randomized algorithm solving Two-Sets Cut-Uncut on planar graphs in $2^{|S|+|T|} \cdot n^{\mathcal{O}(1)}$ time. Moreover, there is a one-sided-error randomized algorithm solving the problem in $2^{\mathcal{O}(r)} \cdot n^{\mathcal{O}(1)}$ time, where r is the number of faces needed to cover $S \cup T$ in a planar embedding.*

Theorem 1 provides the first polynomial-time algorithm for Two-Sets Cut-Uncut on planar graphs for non-singleton S and T. Duan and Xu [19] showed how to solve Two-Sets Cut-Uncut on planar graphs for $|S| = 1$ and $|T| = 2$. This was later extended by Bezáková and Langley [4], who present an $O(n^4)$-time algorithm for $|S| = 1$ and arbitrary T on planar graphs. However, the polynomial time solvability of the case $|S| = |T| = 2$ (which is a generalization of Network Diversion) remained open.

The main tool we develop for showing Theorem 1 is a new algorithmic result about computing shortest paths in group-labeled graphs. We believe this new result to be of independent interest. The group that we consider is the *Boolean group* $(\mathbb{Z}_2^d, +)$, consisting of length-d binary vectors, where the operation $+$ is the component-wise exclusive or (xor). Our algorithm finds a shortest s-t-path in a graph, whose edges are labeled by elements of $(\mathbb{Z}_2^d, +)$ such that the sum of the labels assigned to the edges of the path equals a given value. Furthermore, we impose the constraint that the path can visit certain sets of vertices only once. Formally, we consider the following problem.

Xor-Constrained Shortest Path

Input: A graph G, two vertices s and t, an edge labeling function $g\colon E(G) \to \mathbb{Z}_2^d$, a value $c \in \mathbb{Z}_2^d$, and p sets of vertices $X_1, \ldots, X_p \subseteq V$.

Task: Find an s-t-path P in G that satisfies

(i) $\sum_{e \in E(P)} g(e) = c$, and

(ii) for each $i \in [p]$, $|V(P) \cap X_i| \leq 1$,

and among all such paths minimizes the length.

In Section 3, we give an algorithm for Xor-Constrained Shortest Path that in fact works for general graphs instead of only planar graphs. The result is the following theorem.

▶ **Theorem 2.** *Xor-Constrained Shortest Path can be solved in* $2^{d+p} \cdot (n+m)^{\mathcal{O}(1)}$ *time by a one-sided-error randomized algorithm.*

We call the problem variant where we replace path by cycle in the above problem definition Xor-Constrained Shortest Cycle. We will later show that Theorem 2 directly implies an algorithm for Xor-Constrained Shortest Cycle with the same running time.

The proof of Theorem 2 is based on enhancing the technique introduced by Björklund, Husfeldt, and Taslaman [7] for the T-cycle problem. In T-cycle, the task is to find a shortest cycle that visits a list of specified vertices $T \subseteq V(G)$[1], and Björklund et al. gave a $2^{|T|}n^{\mathcal{O}(1)}$-time algorithm for it. Our algorithm generalizes the algorithm of Björklund et al., because T-cycle can be reduced to Xor-Constrained Shortest Cycle with $d = |T|$ and $p = 0$ as follows. We assign each vertex $v \in T$ to one dimension of $\mathbb{Z}_2^d$, and to enforce that the cycle passes through v, we add a true twin u of v, that is, a vertex adjacent to v with the same neighborhood as v to the graph and assign the edge uv the vector in $\mathbb{Z}_2^d$ that has 1 at only the dimension assigned to v. All other edges are assigned the zero vector $\mathbf{0}$. A cycle evaluating to the all-one vector corresponds to a cycle that visits all vertices in T.

Related work. Besides the closely related work on Network Diversion, 2-Disjoint Connected Subgraphs, and Two-Sets Cut-Uncut that we already mentioned above, let us briefly go through other relevant work.

Two-Sets Cut-Uncut is a special case of Multiway Cut-Uncut, where for a given equivalence relation on the set of terminals, the task is to find a cut (or node-cut) separating terminals according to the relation. This problem is well-studied in parameterized complexity [8, 13, 41]. However, all previous work on parameterized algorithms for Multiway Cut-Uncut has focused on parameterizing by the size of the cut.

[1] The algorithm can also take a list of edges as input by subdividing each target edge and add the new vertex to T.

Multiway Cut is also one of the closest relatives of our problem. Here for a given set of k terminals, one looks for a minimum number of edges separating *all* terminals. On planar graph, the seminal paper of Dahlhaus et al. [15] provides an algorithm of running time $n^{\mathcal{O}(k)}$. Klein and Marx [32] improve the running time to $n^{\mathcal{O}(\sqrt{k})}$ and Marx [37] shows that this running time is optimal (assuming the Exponential Time Hypothesis (ETH)).

The second part of Theorem 1 concerns the parameterization by the number of faces covering the terminal vertices. Such parameterization comes naturally for optimization problems about connecting or separating terminals in planar graphs. In particular, parameterization by the face cover was investigated for Multiway Cut [39], Steiner Tree [3, 31], and various flow problems [21, 23, 35].

Our Theorem 2 belongs to the intersection of two areas around paths in graphs. The first area is about polynomial-time algorithms computing shortest paths in group-labeled graphs [16, 26, 33]. Recently, Iwata and Yamaguchi [28] gave an algorithm for shortest *non-zero* paths in arbitrary group-labeled paths. However, for our purposes, we need an algorithm computing a shortest path whose labels sum to a *specific* element of the group.

The second area is about FPT algorithms for finding paths in graphs satisfying certain properties [6, 7, 24, 20, 34, 45]. As mentioned above, our algorithm for Xor-Constrained Shortest Path can be seen as an extension of the algorithm of Björklund, Husfeldt, and Taslaman [7] for the T-cycle problem to a group-labeled setting.

Organization. The remainder of the article is organized as follows. We start with a general overview of how we achieve our two main results. We then present some notation and necessary definitions in Section 2. Afterwards, we show how to solve Xor-Constrained Shortest Path in Section 3. In Section 4, we apply this algorithm to show Theorem 1 by developing a (randomized) FPT-time algorithm for Two-Sets Cut-Uncut parameterized by the minimum number of faces such that each terminal vertex is incident to at least one such face. Section 5 is devoted to showing that Two-Sets Cut-Uncut is W[1]-hard on general graphs when parameterized by the number of terminals. We conclude in Section 6 with several open problems. Due to space constraints, proofs of some statements are omitted in this extended abstract. These statements are marked ($\star$). The detailed proofs can be found in the full arXiv version of the paper [2]. In the full version, we also present two applications of our FPT-time algorithm to generalize known results from the literature.

1.1 Outline of the Proofs for Theorems 1 and 2

In this section, we outline the proofs of Theorems 1 and 2. For Theorem 1, we first outline the $2^{|S|+|T|} \cdot n^{\mathcal{O}(1)}$-time algorithm for planar Two-Sets Cut-Uncut and then discuss the setting when $S \cup T$ can be covered by at most r faces. Then we consider Theorem 2.

We observe that any optimal solution to Two-Sets Cut-Uncut is an (inclusion-wise) minimal cut in the graph G. Our algorithm is based on the relation between minimal cuts in a planar graph and cycles in its dual graph (see Figure 1). In particular, a set of edges $C \subseteq E(G)$ is a cut-set of a minimal cut in G if and only if in the dual graph G^*, the corresponding set $C^* \subseteq E(G^*)$ is a (simple) cycle. Now, to translate Two-Sets Cut-Uncut into a problem about finding a cycle C^* in G^*, we wish to understand, based on C^*, whether two terminal vertices u and v are on the same side of the cut C in G or on different sides. For this, we observe that if $P \subseteq E(G)$ is the set of edges of an (arbitrary) u-v-path in G and P^* is the corresponding set of edges in G^*, then u and v are on different sides of C if and only if $|C^* \cap P^*|$ is odd.

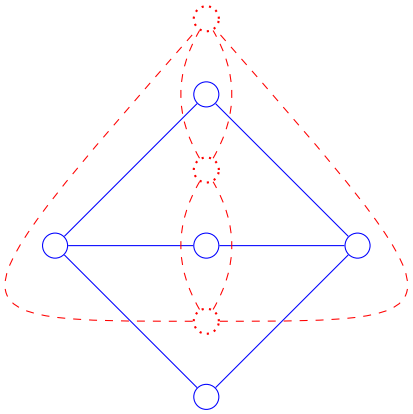

Figure 1 An example of a plane graph (blue) and its dual (multi)graph (dashed/red). Notice that there are bijections between the faces and the vertices, and also between the edges, that is, there is exactly one blue vertex in each red face, one red vertex in each blue face, and each red edge intersects exactly one blue edge and vice versa.

It follows that a constraint stating that u_i and v_i should be on the same/different side of the cut C in G can be expressed as a constraint stating that $|C^* \cap P_i^*|$ should be even/odd for some $P_i^* \subseteq E(G^*)$. By selecting one vertex v in the set of terminals S and writing a "same side" constraint with every other terminal vertex in S and a "different side" constraint with every terminal vertex in T, the Two-Sets Cut-Uncut problem reduces to the problem of finding a shortest cycle C^* in G^* that satisfies $|S| + |T| - 1$ given constraints, each requiring that $|C^* \cap P_i^*| \equiv b_i \pmod 2$ for some $P_i^* \subseteq E(G^*)$ and $b_i \in \{0, 1\}$.

This problem can be equivalently phrased as the Xor-Constrained Shortest Cycle problem with $d = |S| + |T| - 1$, and therefore Theorem 2 indeed implies a $2^{|S|+|T|} \cdot n^{\mathcal{O}(1)}$-time algorithm for Two-Sets Cut-Uncut on planar graphs. Note that here we did not use the condition (ii) in the statement of the Xor-Constrained Shortest Path problem; this condition will be used only for the algorithm utilizing the face cover.

Next, we turn to the more general setting when $S \cup T$ can be covered by at most r faces in a planar embedding of G. First, we observe that by the results of Bienstock and Monma [5], we can decide in $2^{\mathcal{O}(r)} \cdot n$ time whether the input graph has a planar embedding such that the terminals can be covered by at most r faces. Thus, we can assume that G is a plane graph and we are given a face cover of $S \cup T$. Further, we observe that it can be assumed without loss of generality that the input graph is 2-connected. This assumption simplifies arguments because the boundary of each face of a plane 2-connected graph is a cycle [17].

Suppose that f is a face of G that covers some terminals and let C' be the cycle forming the frontier of f. We use the following crucial observation: for the cut-set $C \subseteq E(G)$ of any minimal cut in G separating S and T, it holds that (i) if C' contains vertices of both sets of terminals, then $C \cap E(C')$ separates C' into two connected components (paths) such that each component contains the vertices of exactly one set of terminals, and (ii) if C' contains vertices of one set, then either $C \cap E(C') = \emptyset$ or $C \cap E(C')$ separates C' into two connected components (paths) such that the terminals are in the same component. We use this observation to restrict the behavior of the cycle C^* in G^* corresponding to a potential solution cut-set C. In case (i), we simply delete the edges of G^* that correspond to the edges of C' that should not participate in C (see Figure 2 (a) in the proof of Theorem 1). Case (ii) is more complicated. Suppose that C' contains q terminals. We find q internally vertex disjoint paths $P_1, \ldots, P_q$ in C' whose end-vertices are the terminals. Then we "split"

the vertex f of G^* into q vertices $f_1, \ldots, f_q$ in such a way that each f_i is incident to the edges of G^* corresponding to the edges of P_i (see Figure 2 (b)). However, this splitting would allow a cycle in the dual graph to visit the face f several times. To forbid this, we define $X_f = \{f_1, \ldots, f_q\}$ as used in constraint (ii) of Xor-Constrained Shortest Path and this is the reason why we need constraint (ii) in the problem definition.

We perform the modifications of G^* for all the faces in the cover. This allows us to restrict the number of terminals that we should separate. We pick representatives for each face f in the cover. If the frontier cycle C' of f contains terminals from both sets, we chose one representative from each set from the terminals on C'. If C' contains terminals from one set, we choose one representative. We then apply the same algorithm as for the parameterization by $|S| + |T|$. The difference is that we work only with the representatives and add constraint (ii) to the auxiliary instance of Xor-Constrained Shortest Path given by the sets constructed for the faces from the cover.

We conclude by sketching the main ideas of the algorithm from Theorem 2 for Xor-Constrained Shortest Path. This algorithm works not only on planar graphs but also on general graphs, and it is a generalization of the algorithm by Björklund, Husfeldt, and Taslaman [7] for the T-cycle problem. Our algorithm, like many previous parameterized algorithms for finding paths in graphs [6, 7, 24, 34, 45], exploits the cancellation of monomials in polynomials over fields of characteristic two and randomized polynomial identity testing [42, 46].

The idea of our algorithm is to associate with the input a polynomial over a finite field of characteristic two, and argue that (1) this polynomial is non-zero if and only if a solution exists, and (2) given an assignment of values to variables of the polynomial, the value of the polynomial can be evaluated in $2^{d+p} \cdot n^{\mathcal{O}(1)}$ time.[2] By the DeMillo–Lipton–Schwartz–Zippel lemma [42, 46], the problem can then be solved in $2^{d+p} \cdot n^{\mathcal{O}(1)}$ time by evaluating the polynomial for a random assignment of values. Note that solving the decision version also allows to recover the solution by self-reduction.

In more detail, the polynomial associated with the input is defined as follows. Let us assume that the input graph is a simple graph, as the problem on multigraphs can easily be reduced to simple graphs. For each edge $e \in E(G)$ of the input graph, we associate a variable $f(e)$, and then, for an s-t-walk $W = (e_1, e_2, \ldots, e_\ell)$ of length ℓ, we associate a monomial $f(W) = \prod_{i=1}^{\ell} f(e_i)$. For an integer ℓ, we let $\mathcal{C}_\ell$ denote the set of all s-t-walks of length ℓ that satisfy the conditions (i) and (ii) of the statement of Xor-Constrained Shortest Path, and finally let $f(\mathcal{C}_\ell) = \sum_{W \in \mathcal{C}_\ell} f(W)$ be the polynomial associated with the input. As the monomials of $f(\mathcal{C}_\ell)$ correspond to walks instead of paths, it is not complicated to design a $2^{d+p} \cdot n^{\mathcal{O}(1)}$-time dynamic program for evaluating the value of $f(\mathcal{C}_\ell)$. A more technical part of the proof is to argue that the polynomial $f(\mathcal{C}_\ell)$ is non-zero if and only if a solution exists, in particular, that monomials corresponding to walks that are not paths cancel each other out. This argument is a generalization of the argument used by Björklund et al. [7].

2 Preliminaries

For integers a and b, we use $[a, b]$ to denote the set $\{a, a+1, \ldots, b\}$ and $[b]$ to denote the set $[1, b]$.

[2] Recall that p is the number of constraints for condition (ii) in the Xor-Constrained Shortest Path problem.

Graphs. In this paper, we consider undirected multigraphs, that is, we allow multiple edges and self-loops. We use standard graph-theoretic notation and refer to the textbook by Diestel [17] for undefined notions. Let $G = (V, E)$ be an undirected graph. We use $V(G)$ and $E(G)$ to denote the set of vertices and the set of edges of G, respectively. We use n and m to denote the number of vertices and edges in G, respectively. A *path* P is a graph with vertex set $\{v_0, v_1, \ldots, v_\ell\}$ and edge set $\{v_{i-1}v_i \mid i \in [\ell]\}$. The vertices v_0 and v_ℓ are called the endpoints of P. A *cycle* C is a path with an additional edge between the two endpoints. The length of a path or a cycle is the number of edges in it. For a vertex subset $U \subseteq V$, we use $G[U]$ to denote the subgraph of G induced by the vertices in U and $G - U$ to denote $G[V \setminus V']$. For a set of edges $S \subseteq E$, we write $G - S$ to denote the graph obtained from G by deleting the edges of S.

We are mostly interested in *planar* input graphs. We refer the reader to the textbooks of Diestel [17] and Agnarsson and Greenlaw [1] for rigorous introductions. Informally speaking, a graph is planar if it can be drawn on the plane such that its edges do not cross each other. Such a drawing is called a *planar embedding* of the graph and a planar graph with a planar embedding is called a *plane* graph. We note that checking whether a graph is planar and finding a planar embedding can be done in linear time by the classic algorithm of Hopcroft and Tarjan [27]. The *faces* of a plane graph are the regions bounded by a set of edges and that do not contain any other vertices or edges. The vertices and edges on the boundary of a face form its *frontier*.

Given a plane graph $G = (V, E)$ with faces F, its *dual* graph $G^* = (F, E^*)$ (see Figure 1) is defined as follows. The vertices of G^* are the faces of G and for each $e \in E(G)$, G^* has the *dual* edge e^* whose endpoints are either two faces having e on their frontiers or e^* is a self-loop at f if e is in the frontier of exactly one face f (i.e., e is a bridge of G). Observe that G^* is not necessarily simple even if G is a simple graph as the example in Figure 1 shows. We note that G^* is a planar graph that has a plane embedding where each vertex of G^* corresponding to a face f of G is drawn inside f and each dual edge e^* intersects e only once and e^* does not intersect any other edge of G. Throughout this paper, we assume that G^* has such an embedding.

It is crucial for our results that for a connected plane graph G, each minimal cut in G has a one-to-one correspondence to a cycle in G^*. To be more precise, recall that each cycle on the plane has exactly two faces. Then (A, B) is a minimal cut of a plane graph G if and only if there is a cycle C^* in G^* such that the vertices of A are inside one face of C^* and the vertices of B are inside the other face. Furthermore, C^* is formed by the edges e^* that are dual to the edges $e \in \operatorname{cut}(A)$ and the length of C^* is $|\operatorname{cut}(A)|$.

Let G be a plane graph and let G^* be its dual. We say that a path P (a cycle C) in G *crosses* a cycle C^* of G^* in $e \in E(P)$ ($e \in E(C)$, respectively) if C^* contains the edge $e^* \in E^*$ that is dual to e. The *number of crosses* of P and C^* is the number of edges of P where P and C^* cross. We use the following observation.

▶ **Observation 3.** *Let G be a plane graph, let $s, t \in V$, and let P be an s-t-path. For any cycle C^* of G^*, s and t are in distinct faces of C^* if and only if the number of crosses of P and C^* is odd.*

Lastly, given a subset $U \subseteq V$ of vertices in a plane graph G with faces F, a *face cover* of U is a subset $F' \subseteq F$ of faces such that each vertex in U is on the frontier of a face in F'.

Groups. The group $(\mathbb{Z}_2^d, +)$ consists of the set of all length-d binary strings, and the sum of two strings is defined as the bitwise xor of the strings (or addition without carry over). In this regards, it can be seen as the d-dimensional *bitwise xor vector space* $\mathbb{F}_2^d$. It is easy

to see that this is indeed an (abelian) group: (1) The closure property is trivial, since it by definition contains every length-d binary string. (2) Associativity can be seen by a simple case analysis, i.e., $(a \oplus b) \oplus c = a \oplus (b \oplus c)$ is bitwise 1 if and only if there is an odd number of 1s in the bit's position. (3) The identity element is the all $\mathbf{0}$ vector, i.e. $a \oplus \mathbf{0} = a$. (4) The inverse element of a is a itself, i.e., $a \oplus a = \mathbf{0}$.

3 Shortest Paths under Xor Constraints

In Xor-Constrained Shortest Path, we are given a graph G, two vertices s and t, an edge-labeling function $g\colon E(G) \to \mathbb{Z}_2^d$, a value $c \in \mathbb{Z}_2^d$, and p sets of vertices $X_1, \ldots, X_p \subseteq V(G)$. The problem is to find an s-t-path P that satisfies (i) $\sum_{e \in E(P)} g(e) = c$ and (ii) for each $i \in [p]$, $|V(P) \cap X_i| \leq 1$, and among such paths minimizes the number of edges in P. In this section we prove Theorem 2, which we restate here.

▶ **Theorem 2.** *Xor-Constrained Shortest Path can be solved in $2^{d+p} \cdot (n+m)^{\mathcal{O}(1)}$ time by a one-sided-error randomized algorithm.*

As a corollary, we obtain an algorithm for Xor-Constrained Shortest Cycle by guessing one vertex v in a solution, adding a false twin u of v, that is, a non-neighbor of v with the same neighborhood as v to the input graph such that all edges incident to u are assigned value zero, and then asking for a shortest u-v-path satisfying conditions (i) and (ii).

▶ **Corollary 4.** *Xor-Constrained Shortest Cycle can be solved in $2^{d+p} \cdot (n+m)^{\mathcal{O}(1)}$ time by a one-sided-error randomized algorithm.*

3.1 The Algorithm

In the remainder of this section, we assume that the input graph G is a simple graph. Note that an input n-vertex m-edge multigraph can be turned into an $(n+m)$-vertex $2m$-edge simple graph by first removing self-loops, and then subdividing each edge once, giving the label of the edge to one of the subdivision edges and labeling the other subdivision edge with zero. This exactly doubles the length of the solution. We also assume without loss of generality that $s \neq t$.

Let us next introduce some notation. We say that a sequence $(v_0, v_1, \ldots, v_{\ell-1}, v_\ell)$ of $\ell+1$ vertices is an s-t-walk of length ℓ if $v_0 = s$, $v_\ell = t$, and $v_{i-1}v_i \in E(G)$ for each $i \in [\ell]$. Note that unlike a path, a walk can contain a vertex more than once. We say that an s-t-walk is *feasible* if it satisfies analogies of the contraints (i) and (ii), in particular, if

1. $\sum_{i=1}^{\ell} g(v_{i-1}v_i) = c$, and
2. for each $i \in [p]$, there is at most one $j \in [0, \ell]$ such that $v_j \in X_i$.

For an integer $\ell \geq 1$, let $\mathcal{C}_\ell$ denote the set of all feasible s-t-walks of length (exactly) ℓ. We associate with $\mathcal{C}_\ell$ a polynomial as follows.

Let $q = 2^{\lceil \log_2 n \rceil + 1}$, and recall that $\mathrm{GF}(q)$ is a finite field of characteristic 2 and order q. We define a polynomial over $\mathrm{GF}(q)$ as follows. For each edge $uv \in E(G)$ we associate a variable $f(uv)$. Then, for an s-t-walk $W = (v_0, \ldots, v_\ell)$ of length ℓ, we associate the monomial

$$f(W) = \prod_{i=1}^{\ell} f(v_{i-1}v_i), \tag{1}$$

and for the set $\mathcal{C}_\ell$ of all feasible s-t-walks of length ℓ, we associate the polynomial

$$f(\mathcal{C}_\ell) = \sum_{W \in \mathcal{C}_\ell} f(W).$$

Note that the degree of $f(\mathcal{C}_\ell)$ is ℓ. Our algorithm will be based on the following lemma, which will be proven in Section 3.2.

▶ **Lemma 5.** *The length of a shortest s-t-path satisfying (i) and (ii) is equal to the smallest integer ℓ such that $f(\mathcal{C}_\ell)$ is a non-zero polynomial. If no such ℓ exists, then no such s-t-path exists.*

Given Lemma 5, it remains to design an algorithm for testing if $f(\mathcal{C}_\ell)$ is a non-zero polynomial. For this, we use the DeMillo–Lipton–Schwartz–Zippel lemma.

▶ **Lemma 6** ([42, 46])**.** *Let $f(x_1, \ldots, x_n)$ be a non-zero polynomial of degree d over a field $\mathbb{F}$, and let S be a subset of $\mathbb{F}$. If each x_i is independently assigned a uniformly random value from S, then $f(x_1, \ldots, x_n) = 0$ with probability at most $d/|S|$.*

By Lemma 6 to probabilistically test if $f(\mathcal{C}_\ell)$ is non-zero it suffices to evaluate $f(\mathcal{C}_\ell)$ on a random assignment of values from $\mathrm{GF}(q)$ to the variables $f(uv)$. Because the degree of $f(\mathcal{C}_\ell)$ is $\ell \leq n$ and the order of $\mathrm{GF}(q)$ is $q \geq 2n$, this test is correct with probability at least 0.5 whenever $f(\mathcal{C}_\ell)$ is non-zero. Note that if $f(\mathcal{C}_\ell)$ is the zero polynomial, this test is always correct. Next we show that this evaluation can be done efficiently.

▶ **Lemma 7.** *Given an assignment of values to the variables $f(uv)$ for all $uv \in E(G)$, the value of the polynomial $f(\mathcal{C}_\ell)$ can be evaluated in $\mathcal{O}(2^{d+p}n^2\ell)$ time.*

Proof. We evaluate the polynomial by dynamic programming on walks. For $u \in V(G)$, $l \in [0, \ell]$, $y \in \mathbb{Z}_2^d$, and $T \subseteq [p]$, let $\mathcal{C}(u, l, y, T)$ denote the set of s-u-walks $(s = v_0, v_1, \ldots, v_l = u)$ of length l where

- $\sum_{i=1}^{l} g(v_{i-1}v_i) = y$,
- for each $i \in [p] \setminus T$, it holds that $\{v_0, v_1, \ldots, v_l\} \cap X_i = \emptyset$, and
- for each $i \in T$, there exists exactly one $j \in [0, l]$ such that $v_j \in X_i$.

We denote by $f(\mathcal{C}(u, l, y, T))$ the value $\sum_{W \in \mathcal{C}(u,l,y,T)} f(W)$, where $f(W)$ is defined as in Equation (1), with the empty product interpreted as being equal to 1. Now, we have that $f(\mathcal{C}_\ell) = \sum_{T \subseteq [p]} f(\mathcal{C}(t, \ell, c, T))$. It remains to show that the values $f(\mathcal{C}(u, l, y, T))$ can be computed by dynamic programming.

Let $T_v = \{i \in [p] \mid v \in X_i\}$ for each $v \in V(G)$. Then, the values for $l = 0$ are computed by setting $f(\mathcal{C}(s, 0, 0, T_s)) = 1$ and all other values with $l = 0$ to 0. When $l \geq 1$, the values $f(\mathcal{C}(u, l, y, T))$ are computed by dynamic programming from the values for smaller l as follows.

- If $T_u \subseteq T$, then $f(\mathcal{C}(u, l, y, T)) = \sum_{uw \in E(G)} f(uw) \cdot f(\mathcal{C}(w, l-1, y - g(\{u, w\}), T \setminus T_u))$.
- Otherwise, $f(\mathcal{C}(u, l, y, T)) = 0$.

This clearly computes the values correctly, and runs in overall $\mathcal{O}(2^{d+p}n^2\ell)$ time. ◀

Now, our algorithm works by using Lemma 7 to evaluate $f(\mathcal{C}_\ell)$ for random assignments of values to variables $f(uv)$ for increasing values of $\ell \leq n$, and once it evaluates to non-zero, reports that ℓ is the length of the shortest s-t-path satisfying (i) and (ii). If no such $\ell \leq n$ is found, the algorithm reports that no such s-t-path exists. Note that the correctness of the algorithm depends only on the randomness on the evaluation with the correct ℓ, and therefore the algorithm is correct with probability at least 0.5, and never reports a length shorter than the length of a shortest solution. This probability can be exponentially improved by running the algorithm multiple times. To recover the solution, it suffices to use the algorithm to test which edges can be removed from the graph G until G turns into an s-t-path. Clearly, to both recover the solution and to have an exponentially small error probability it suffices to run the algorithm a polynomial number of times, so this finishes the proof of Theorem 2, modulo the proof of Lemma 5 that will be given in the next subsection.

3.2 Proof of Correctness

This section is devoted to the proof of Lemma 5. We first prove the direction that the existence of a solution of length ℓ implies that $f(\mathcal{C}_\ell)$ is non-zero.

▶ **Lemma 8.** *If an s-t-path of length ℓ satisfying (i) and (ii) exists, then $f(\mathcal{C}_\ell)$ is a non-zero polynomial.*

Proof. Let $W = (s = v_0, v_1, \ldots, v_\ell = t)$ be the sequence of vertices on an s-t-path of length ℓ satisfying conditions (i) and (ii). Note that W is a feasible s-t-walk and $W \in \mathcal{C}_\ell$. Since each vertex occurs in the walk W at most once, we observe that W can be determined uniquely from its set of edges, and W is therefore the only walk in $\mathcal{C}_\ell$ with the monomial $f(W) = \prod_{i=1}^{\ell} f(v_{i-1}v_i)$. Thus, the monomial $f(W)$ occurs in the polynomial $f(\mathcal{C}_\ell)$ with coefficient 1, and therefore $f(\mathcal{C}_\ell)$ is non-zero. ◀

It remains to prove that if no solutions of length at most ℓ exists, then $f(\mathcal{C}_\ell)$ is the zero polynomial. For this, let us state our main lemma, but delay its proof for a bit.

▶ **Lemma 9.** *If no s-t-path of length at most ℓ satisfying conditions (i) and (ii) exists, then there exists a function $\phi : \mathcal{C}_\ell \to \mathcal{C}_\ell$ such that for every $W \in \mathcal{C}_\ell$ it holds that*

1. $\phi(\phi(W)) = W$,
2. $\phi(W) \neq W$, *and*
3. $f(\phi(W)) = f(W)$.

Now, assuming Lemma 9, the proof of Lemma 5 can be finished as follows.

▶ **Lemma 10.** *If no s-t-path of length at most ℓ satisfying conditions (i) and (ii) exists, then $f(\mathcal{C}_\ell)$ is the zero polynomial.*

Proof. Let ϕ be the function given by Lemma 9. By properties 1 and 2, the set $\mathcal{C}_\ell$ can be partitioned into pairs $\{W, \phi(W)\}$. Now, property 3 states that $f(W) = f(\phi(W))$ and since $\mathrm{GF}(q)$ is a field of characteristic 2, it holds that $f(W) + f(\phi(W)) = 0$. Thus, $\sum_{W \in \mathcal{C}_\ell} f(W) = 0$. ◀

Putting Lemmas 8 and 10 together implies Lemma 5. It remains to prove Lemma 9.

Proof of Lemma 9. Assume that no s-t-path of length at most ℓ satisfying (i) and (ii) exists. We will define the function $\phi : \mathcal{C}_\ell \to \mathcal{C}_\ell$ explicitly and show that it satisfies all of the required properties. Let $W = (v_0, v_1, \ldots, v_\ell)$ be an s-t-walk in $\mathcal{C}_\ell$. The idea of the definition of ϕ will be to locate a *subwalk* $(v_i, v_{i+1}, \ldots, v_{j-1}, v_j)$ of W where $0 \leq i < j \leq \ell$, and reverse the subwalk, i.e., map the walk

$$W = (v_0, v_1, \ldots, v_{i-1}, v_i, v_{i+1}, \ldots, v_{j-1}, v_j, v_{j+1}, \ldots, v_\ell)$$

into the walk

$$W\overleftarrow{[i,j]} = (v_0, v_1, \ldots, v_{i-1}, v_j, v_{j-1}, \ldots, v_{i+1}, v_i, v_{j+1}, \ldots, v_\ell).$$

In particular, we will have that $\phi(W) = W\overleftarrow{[i,j]}$ for a carefully chosen pair i, j with $0 \leq i < j \leq \ell$. This pair will be chosen so that $v_i = v_j$, which ensures that $W\overleftarrow{[i,j]} \in \mathcal{C}_\ell$ and $f(W\overleftarrow{[i,j]}) = f(W)$ since the multiset of pairs of adjacent vertices in the walk does not change.

It remains to argue that such a pair i, j can be chosen so that the properties $\phi(\phi(W)) = W$ and $\phi(W) \neq W$ hold. Observe that the property $\phi(W) \neq W$ holds if and only if the subwalk from i to j is not a *palindrome*, i.e., a sequence that is the same when reversed. Now we define a process that outputs a pair i, j so that $0 \leq i < j \leq \ell$, $v_i = v_j$, and the subwalk from i to j is not a palindrome.

The process starts by setting $i = j = 0$. Then, it repeats the following: It first selects i to be the smallest integer $i > j$ so that the vertex v_i occurs in the walk in the indices greater than j more than once. If no such i exists, it outputs FAIL. Then, it sets j to be the largest integer so that $v_i = v_j$, in particular, the index of the last occurrence of v_i in the walk. At this point, it is guaranteed that $0 \leq i < j \leq \ell$ and $v_i = v_j$. Now, if the subwalk from i to j is not a palindrome, it outputs the pair i, j. Otherwise, the process repeats.

Observe that the process always outputs either FAIL or a pair i, j with $0 \leq i < j \leq \ell$ and $v_i = v_j$ such that the subwalk from i to j is not a palindrome. We prove that it actually never outputs FAIL.

▷ Claim 11. The process defined above never outputs FAIL.

Proof of Claim 11. Suppose that the process output FAIL and let $i_1 < j_1 < i_2 < \ldots < j_t$ be the sequence of pairs i, j considered during the process. We define the *contracted walk* W' to be the subsequence of $W = (v_0, \ldots, v_\ell)$ obtained by removing the vertices on the indices in $[i_1 + 1, j_1] \cup [i_2 + 1, j_2] \cup \ldots \cup [i_t + 1, j_t]$ from W. In particular, W' is obtained from W by contracting each palindrome $v_{i_k}, \ldots, v_{j_k}$ considered in the process into a single vertex v_{i_k}.

Now, we claim that W' is a feasible s-t-walk of length at most ℓ, and moreover that no vertex occurs more than once in W'. This is a contradiction, because in that case W' would be in fact an s-t-path of length at most ℓ that satisfies conditions (i) and (ii), but we assumed that no such s-t-path exists. We observe that the contracted walk W' is indeed an s-t-walk, because it was obtained from an s-t-walk by contracting subwalks that each start and end in a same vertex. It also clearly has length at most ℓ, and it satisfies the condition (ii) because the multiset of vertices in W' is a subset of the multiset of vertices in W. For condition (i), we observe that if a subwalk $v_i, \ldots, v_j$ is a palindrome, then $\sum_{k=i+1}^{j} g(v_{k-1}v_k) = 0$ because each pair of adjacent vertices occurs an even number of times as G is a simple graph and we are working in the group $\mathbb{Z}_2^d$. Thus, contracting the palindromes does not change the sum of the edge labels on W, and thus W' satisfies condition (i).

Lastly, we argue that no vertex occurs more than once in W'. For the sake of contradiction, suppose that some vertex occurs more than once in W', which in particular implies that there are indices i',j' with $0 \leq i' < j' \leq \ell$ and $v_{i'} = v_{j'}$ that are not in $[i_1 + 1, j_1] \cup [i_2 + 1, j_2] \cup \ldots \cup [i_t + 1, j_t]$. If $i' < i_1$, then this would contradict the choice of i_1, and if $i' = i_1$, then this would contradict the choice of j_1. Similarly, if $j_k < i' \leq i_{k+1}$ for some $1 \leq k < t$, then this would contradict either the choice of i_{k+1} or j_{k+1}, and if $i' > j_t$, then this would contradict the fact that i_t, j_t was the last pair considered by the algorithm. ◁

Now, the function $\phi : \mathcal{C}_\ell \to \mathcal{C}_\ell$ is defined as $\phi(W) = W\overleftarrow{[i, j]}$, where i, j is the pair output by the process described above. We have already proven that $\phi(W) \neq W$ and $f(\phi(W)) = f(W)$, so it remains to prove that $\phi(\phi(W)) = W$. For this, it remains to observe that the operation $W\overleftarrow{[i, j]}$ does not change how the process for selecting i,j behaves, because it does not change the walk before the index i and it does not change the fact that the last occurrence of v_i is at the index j. ◀

This finishes the proof of Theorem 2.

4 Two-Sets Cut-Uncut Parameterized by the Face Cover Number

In this section, we show that Two-Sets Cut-Uncut is FPT when parameterized by the minimum number of faces in a planar embedding of the input graph covering the terminals. We use the following result by Bienstock and Monma [5] showing that a minimum face cover can be found in FPT time when parameterized by the size of a cover.

▶ **Proposition 12** ([5]). *It can be decided in $2^{\mathcal{O}(r)} \cdot n$ time whether for a set of vertices U of a planar graph G and a positive integer r, there is a planar embedding of G such that at most r faces cover U. Furthermore, if such an embedding exists, it can be found together with the face cover of U in the same time.*

By Proposition 12, we can assume that the input graph is plane, that is, we are given its planar embedding and, furthermore, we are given a face cover of the terminals.

Next, we note that we can consider only minimal cuts.

▶ **Observation 13** ($\star$). *Let (G, S, T, k) be an instance of Two-Sets Cut-Uncut where G is a connected graph. Then, (G, S, T, k) is a yes-instance if and only if there is a minimal cut (A, B) of G with $|\mathrm{cut}(A)| \leq k$ such that $S \subseteq A$ and $T \subseteq B$.*

This observation implies that to solve Two-Sets Cut-Uncut on a plane graph G, we have to find a shortest cycle C^* in the dual graph G^* such that the vertices of S and T are in distinct faces of C^*. First, we prove that we can assume without loss of generality that the input graph is 2-connected. This assumption simplifies arguments because the frontier of each face of a plane 2-connected graph is a cycle [17].

▶ **Lemma 14** ($\star$). *There is a polynomial-time algorithm that, given an instance (G, S, T, k) of Two-Sets Cut-Uncut, solves the problem or outputs an equivalent instance (G', S', T', k) of Two-Sets Cut-Uncut where G' is a 2-connected induced subgraph of G. Furthermore, given a planar embedding of G such that $S \cup T$ can be covered by at most r faces, $S' \cup T'$ can be covered in the induced embedding of G' by at most r faces.*

From now on, we assume that the graph of the considered instances of Two-Sets Cut-Uncut is 2-connected. Hence, the dual graph G^* has no loops. Also, since loops are irrelevant for Two-Sets Cut-Uncut, we assume that the input graph has no loops.

We use the following two separation properties for vertices on the frontier of the same face of a graph.

▶ **Lemma 15.** *Let G be a plane graph, let C be the cycle formed by the frontier of a face f of G, and let X and Y be disjoint nonempty sets of vertices in C. Let C^* be any cycle in G^*. Then, the vertices of X and the vertices of Y are in distinct faces of C^* if and only if $f \in V(C^*)$ and C crosses C^* in two edges e_1 and e_2 such that (i) the vertices of X are in the same connected component of $C - \{e_1, e_2\}$, (ii) the vertices of Y are in the same connected component of $C - \{e_1, e_2\}$, and (iii) the vertices of X and the vertices of Y are in distinct connected components of $C - \{e_1, e_2\}$.*

Proof. Suppose that the vertices of X and the vertices of Y are in distinct faces of C^*. Then, f is a vertex of C^*. Let e_1^* and e_2^* be the edges of C^* incident to f and let e_1 and e_2 be the dual edges of e_1^* and e_2^*, respectively. Note that C contains both e_1 and e_2 and C crosses C^* only in these two edges. We have that $C - \{e_1, e_2\}$ has two connected components P_1 and P_2 that are paths. Since C^* separates X and Y, we have that X is fully contained in P_1 or fully contained in P_2 and Y is fully contained in the respective other path. Thus, conditions (i)–(iii) are fulfilled.

For the opposite direction, assume that C crosses C^* in two edges e_1 and e_2 such that conditions (i)–(iii) are fulfilled. Consider an x-y-path P in C for arbitrary $x \in X$ and $y \in Y$ containing e_1 and excluding e_2 that exists by (i)–(iii). The number of crosses of P and C^* is one. Hence, x and y are in distinct faces of C^* by Observation 3. This concludes the proof. ◀

▶ **Lemma 16.** *Let G be a plane graph, let C be the cycle formed by the frontier of a face f of G, and let X be a nonempty sets of vertices in C. Let C^* be any cycle in G^*. Then, the vertices of X are in the same face of C^* if and only if either $f \notin V(C^*)$ and C does not cross C^* or $f \in V(C^*)$ and C crosses C^* in two edges e_1 and e_2 such that the vertices of X are in the same connected component of $C - \{e_1, e_2\}$.*

Proof. Suppose that the vertices of X are in the same face of C^* and assume that C crosses C^*. Then, f is a vertex of C^* and C^* has two edges e_1^* and e_2^* incident to f. We have that C crosses C^* in the edges e_1 and e_2 that are dual to e_1^* and e_2^*, respectively. Since C is a cycle, $C - \{e_1, e_2\}$ has two connected components P_1 and P_2 that are both paths. We show that either $X \subseteq V(P_1)$ or $X \subseteq V(P_2)$. For the sake of contradiction, assume that there are $x, y \in X$ such that $x \in V(P_1)$ and $y \in V(P_2)$. Then, there is an x-y-path P in C that contains e_1 but excludes e_2. The number of crosses of P and C^* is one and x and y are therefore in distinct faces of C^* by Observation 3; a contradiction. Hence, the vertices of X are in the same connected component of $C - \{e_1, e_2\}$.

For the opposite direction, assume that either C does not cross C^* or C crosses C^* in two edges e_1 and e_2 such that the vertices of X are in the same connected component of $C - \{e_1, e_2\}$. In both cases, for any two vertices $x, y \in X$, there is an x-y-path P that does not cross C^*. Then by Observation 3, the vertices of X are in the same face of C^*. This concludes the proof. ◀

We are now in a position to present the main result of this section.

▶ **Theorem 1.** *There is a one-sided-error randomized algorithm solving* Two-Sets Cut-Uncut *on planar graphs in $2^{|S|+|T|} \cdot n^{\mathcal{O}(1)}$ time. Moreover, there is a one-sided-error randomized algorithm solving the problem in $2^{\mathcal{O}(r)} \cdot n^{\mathcal{O}(1)}$ time, where r is the number of faces needed to cover $S \cup T$ in a planar embedding.*

Proof. We show the claim for the parameterization by the size of a face cover of the terminals and then explain how a simplified version of the algorithm can be used for the parameterization by the number of terminals.

Let (G, S, T, k) be an instance of Two-Sets Cut-Uncut where G is planar. We use Proposition 12 to decide whether there is a planar embedding of G such that the set of terminals $S \cup T$ can be covered by at most r faces. When the algorithm reports that such an embedding does not exist, we stop. Otherwise, we obtain an embedding of G in the plane and a set of faces F' of size at most r covering $S \cup T$. From now on, we assume that G is a plane graph. We remind that G can be assumed to be 2-connected by Lemma 14. We use the embedding of G to construct the dual graph G^* together with its embedding. By Observation 13 and duality, our task is to find a cycle C^* in G^* of length at most k such that S and T are in distinct faces of C^*. We find such a cycle using the algorithm for Xor-Constrained Shortest Cycle from Corollary 4.

We partition F' into two sets where $F_1 \subseteq F'$ is the set of faces having vertices from both S and T on their frontiers and $F_2 \subseteq F'$ consists of the faces $f \in F'$ such that the frontier of f contains either only vertices of S or only vertices of T. We modify G^* by analyzing each face $f \in F'$. The ultimate aim of the modification is to reduce the number of considered terminals.

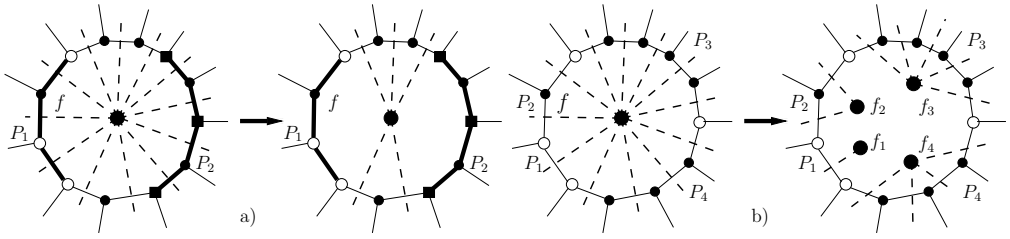

Figure 2 (a) The modification for $f \in F_1$. The vertices of S' are shown by white circles, the vertices of T' are shown by black squares, and the other vertices of G are shown by black circles. The edges of G^* are shown by dashed lines. The paths P_1 and P_2 are shown by thick lines. (b) The modification for $f \in F_2$. The vertices of $L \in \{S, T\}$ are shown by white circles and the other vertices of G are shown by small black circles. The vertex f of G^* and the vertices $f_1, f_2 \ldots, f_4$ are shown by large black circles and the edges of G^* and the constructed new edges are shown by dashed lines.

Modifications for F_1. Let $f \in F_1$ and let C be the cycle of G forming the frontier of f. Recall that $S' = S \cap V(C) \neq \emptyset$ and $T' = T \cap V(C) \neq \emptyset$. If there are no two edges $e_1, e_2 \in E(C)$ such that the vertices of S' and T' are in distinct connected components of $C - \{e_1, e_2\}$, then by Lemma 15, there is no cycle C^* such that the vertices of S' and the vertices of T' are in distinct faces of C^*. This implies that (G, S, T, k) is a no-instance. Hence, we assume that this is not the case and select two inclusion-minimal disjoint paths P_1 and P_2 in C such that $S' \subseteq V(P_1)$ and $T' \subseteq V(P_2)$. We modify G^* by deleting each edge e^* incident to f that is dual to an edge $e \in E(P_1) \cup E(P_2)$ (see Figure 2 (a)).

Modifications for F_2. Let $f \in F_2$, let C be the cycle of G forming the frontier of f, and let $L = V(C) \cap (S \cup T)$. Note that by definition of F_2, either $L \subseteq S$ or $L \subseteq T$. We split the vertex f of G^* into $q = |L|$ vertices $f_1, f_2, \ldots, f_q$ as follows. If $q \geq 2$, then C contains q internally vertex disjoint paths $P_1, P_2, \ldots, P_q$ whose end-vertices are in L (and whose internal vertices are not in L). We then

- delete f and construct a set $X_f = \{f_1, f_2, \ldots, f_q\}$ of q new vertices,
- for each $j \in [q]$ and edge e in P_j, we replace the dual edge e^* of G^* by an edge incident to f_j whose second endpoint is the same as for e^* unless e^* was deleted by some modification for F_1.

For $q = 1$, we set $X_f = \{f\}$ and $f_1 = f$, that is, we do not perform any modification. The construction is shown in Figure 2 (b). Note that the vertices $f_1, f_2, \ldots, f_q$ can be embedded in the face f of G such that the resulting graph H^* is plane. For each edge $e^* \in E(H^*)$, there is an edge $e \in E(G^*)$ such that e^* was constructed from the edge that is dual to e in G^*. Slightly abusing notation, we do not distinguish between the edges of H^* and G^*. In particular, we say that e^* is dual to e.

Next, we assign labels to the edges of H^* from $\mathbb{Z}_2^d$ for some appropriate d. For this, we greedily pick a set R of *representatives* from $S \cup T$ for each $f \in F'$. From each $f \in F_1$, we select two terminals from S and T, respectively, that are on the frontier of the face f of G. For each $f \in F_2$, we pick one terminal from the frontier of the face of f. We then construct an arbitrary inclusion minimal tree Q in G that spans R. This can be done in linear time using standard tools (see, e.g., [9]). We select an arbitrary vertex $u \in R \cap S$ and set $d = |R| - 1$. Observe that $|R| \leq 2|F_1| + |F_2|$ and $d \leq 2|F_1| + |F_2| - 1$. Denote by $v_1, \ldots, v_d$ the vertices of $L \setminus \{u\}$ and let Q_i be the u-v_i-path in Q for each $i \in [d]$. We define $g\colon E(G) \to \mathbb{Z}_2^d$ by setting $g(e) = (\delta_1, \ldots, \delta_d)^\intercal$ where for each $i \in [d]$, $\delta_i = \begin{cases} 1 & \text{if } e \in E(Q_i), \\ 0 & \text{if } e \notin E(Q_i). \end{cases}$

Moreover, let $g^*\colon E(H^*) \to \mathbb{Z}_2^d$ be defined by setting $g^*(e^*) = g(e)$ for each $e^* \in E(H^*)$ that is dual to $e \in E(G)$ and let $c = (c_1, \ldots, c_d)^\intercal \in \mathbb{Z}_2^d$ where

$$c_i = \begin{cases} 0 & \text{if } v_i \in S, \\ 1 & \text{if } v_i \in T \end{cases} \quad \text{for } i \in [d].$$

We show the following claim using Lemma 15 and Lemma 16.

▷ Claim 17 (⋆). The graph G^* contains a cycle C^* of length at most k such that the vertices of S and the vertices of T are in distinct faces of C^* if and only if the instance $(H^*, g^*, c, \{X_f \mid f \in F_2\})$ of Xor-Constrained Shortest Cycle has a solution and the length of a solution cycle is at most k.

By Claim 17, solving Two-Sets Cut-Uncut for (G, S, T, k) is equivalent to solving Xor-Constrained Shortest Cycle for $(H^*, g^*, c, \{X_f \mid f \in F_2\})$. For this, we use the algorithm from Corollary 4.

For the running time, observe that a face cover F' of size r can be constructed in $2^{\mathcal{O}(r)}n$ time by Proposition 12. Given such a cover, the graph H^* together with the sets X_f for $f \in F_2$ can be constructed in polynomial time. Since $d \leq 2|F_1| + |F_2| - 1 \leq 2r$, the labeling g^* and $c \in \mathbb{Z}_2^d$ can also be constructed in polynomial time. Finally, since $d \leq 2|F_1| + |F_2| - 1$ and $p = |\{X_i \mid f \in F_2\}| = |F_2|$, we have that $p + d \leq 2r - 1$ and the algorithm from Corollary 4 runs in $4^r n^{\mathcal{O}(1)}$ time. We conclude that the overall running time is in $2^{\mathcal{O}(r)}n^{\mathcal{O}(1)}$. This concludes the proof.

If we parameterize Two-Sets Cut-Uncut by $\ell = |S| + |T|$, then we can use a simplified variant of the algorithm. Given an instance (G, S, T, k) of Two-Sets Cut-Uncut where G is a planar graph, we use the classic algorithm of Hopcroft and Tarjan [27] to find a plane embedding of G. We then use the variant of the algorithm where we do not modify G^*, that is, we set $H^* = G^*$, and where we assume that all the terminals are representatives, that is, we set $R = S \cup T$. The labeling $g^*\colon E(H^*) \to \mathbb{Z}_2^d$ and c are defined in the same way as in the algorithm for the parameterization by the size of a face cover. By Observation 3, solving Two-Sets Cut-Uncut for (G, S, T, k) is equivalent to solving Xor-Constrained Shortest Cycle for $(H^*, g^*, c, \emptyset)$. Since $d = |R| - 1 = |S| + |T| - 1$, we conclude that we can solve the problem in $2^{|S|+|T|} \cdot n^{\mathcal{O}(1)}$ time using Corollary 4. ◀

5 Hardness

It is known that Two-Sets Cut-Uncut is NP-complete [25] in planar graphs and that it is NP-complete in general graphs even if $|S| = 2$ [44]. We strengthen the latter result by showing that Two-Sets Cut-Uncut remains W[1]-hard parameterized by $|T|$ even if $|S| = 1$ by providing a polynomial-time reduction from Regular Multicolored Clique parameterized by solution size k – a variant of Multicolored Clique where each vertex has the same degree d – such that $|T| = k$. This problem is known to be W[1]-hard and assuming ETH, it cannot be solved in $f(k) \cdot n^{o(k)}$ time [38, 12].

▶ **Proposition 18** (⋆). *Two-Sets Cut-Uncut is* W[1]*-hard when parameterized by* $|T|$ *even if* $|S| = 1$*. Moreover, this restricted version cannot be solved in* $f(|T|) \cdot n^{o(k)}$ *time unless the ETH breaks.*

6 Conclusion

In this paper, we have shown that Two-Sets Cut-Uncut is FPT on planar graphs parameterized by the number of terminals. We have also proven a more general result that the problem remains FPT parameterized by the minimum number of faces required to cover the terminals. Our result implies a polynomial-time algorithm for Network Diversion on planar graphs. We complement this result by showing that Two-Sets Cut-Uncut parameterized by the number of terminals ($|S| + |T|$) is W[1]-hard in general graphs even when $|S| = 1$.

We conclude with a few open problems.

1. First, we repeat the long-standing open question, whether Network Diversion is polynomial-time solvable in general graphs. Even the case for graphs embeddable on a torus remains open.
2. A natural extension of the Two-Sets Cut-Uncut is to extend it to a larger number of sets. Since on general graphs, 3-Way Cut is NP-complete [15], the same holds for Three-Sets Cut-Uncut even when all sets are of size one. However, for planar graphs, k-Way Cut is solvable in polynomial time for fixed k [15, 32, 39]. As a very concrete open question, we ask whether Three-Sets Cut-Uncut is solvable in polynomial time on planar graphs when two sets are of size one and one set is of size two.
3. Our algorithm is randomized and works only on unweighted graphs; can we get rid of either of these restrictions?
4. Finally, is it possible to solve Two-Sets Cut-Uncut in *subexponential* time (in $|S|+|T|$)? In our opinion, this could be a challenging problem. In particular, it is already an open question whether it is possible to find a cycle in a planar graph containing a given set of k terminals in subexponential time (in k).

Abstract

The splitting-off operation in undirected graphs is a fundamental reduction operation that detaches all edges incident to a given vertex and adds new edges between the neighbors of that vertex while preserving their degrees. Lovász [45, 47] and Mader [48] showed the existence of this operation while preserving global and local connectivities respectively in graphs under certain conditions. These results have far-reaching applications in graph algorithms literature [2, 7, 8, 12, 17, 22, 23, 24, 25, 26, 29, 30, 32, 33, 35, 38, 40, 41, 46, 48, 49, 50, 51]. In this work, we introduce a splitting-off operation in hypergraphs. We show that there exists a local connectivity preserving complete splitting-off in hypergraphs and give a strongly polynomial-time algorithm to compute it in weighted hypergraphs. We illustrate the usefulness of our splitting-off operation in hypergraphs by showing two applications: (1) we give a constructive characterization of k-hyperedge-connected hypergraphs and (2) we give an alternate proof of an approximate min-max relation for max Steiner rooted-connected orientation of graphs and hypergraphs (due to Király and Lau [38]). Our proof of the approximate min-max relation for graphs circumvents the Nash-Williams' strong orientation theorem and uses tools developed for hypergraphs.

1 Introduction

The splitting-off operation in undirected graphs is a simple yet powerful operation in graph theory. It is a reduction operation that detaches all edges incident to a given vertex and adds new edges between the neighbors of that vertex while preserving their degrees. Equivalently, it enables a vertex to exit the network by informing its neighbors how to reconfigure the lost links among themselves in order to preserve their degrees. Lovász [45, 47] introduced the splitting-off operation and showed the existence of the operation to preserve global edge-connectivity under certain conditions. Mader [48] showed the existence of the splitting-off operation to preserve local edge-connectivity (i.e., all pairwise edge-connectivities) under certain conditions. Both Lovász's and Mader's results also admit strongly polynomial-time algorithms [24, 27, 49]. Owing to the inductive nature of the splitting-off operation, Lovász's and Mader's results have enabled fundamental results in graph theory as well as efficient algorithms and min-max relations for numerous graph optimization problems. In fact, Mader [48] illustrated the power of his local edge-connectivity preserving splitting-off result by deriving Nash-Williams' strong orientation theorem [52] (also see Frank's exposition of this derivation [26]). Subsequently, the splitting-off operation has been used to give a constructive characterization of k-edge-connected graphs [24] and to address problems in edge-connectivity augmentation [2, 22, 23, 24, 49], graph orientation [25, 38], minimum cuts enumeration [29, 32, 50], network design [12, 30, 35], tree packing [7, 41], congruency-constrained cuts [51], and approximation algorithms for TSP [8,30]. Designing fast algorithms for global/local edge-connectivity preserving splitting-off remains an active area of research (e.g., see recent works [9, 10, 11, 42]) due to these far-reaching applications. In this work, we introduce a splitting-off operation in *hypergraphs*, show the existence of local-connectivity preserving splitting-off operation and design a strongly polynomial-time algorithm to compute it in weighted hypergraphs, and illustrate its usefulness by showing two applications.

Hypergraphs. Hypergraphs offer a richer and more accurate model than graphs for several applications. Consequently, hypergraphs have found applications in several modern areas (e.g., see [44, 54, 57, 60]) and these applications have, in turn, driven exciting recent progress in algorithms for hypergraph optimization problems [1, 4, 13, 14, 15, 18, 19, 21, 28, 31, 34, 36, 37, 39, 43, 55, 58]. A hypergraph $G = (V, E)$ consists of a finite set V of vertices and a set E of hyperedges, where every hyperedge $e \in E$ is a subset of V. We will denote a hypergraph $G = (V, E)$ with hyperedge weights $w : E \to \mathbb{Z}_+$ by the tuple (G, w) and use G_w to denote the unweighted multi-hypergraph over vertex set V containing $w(e)$ copies of every hyperedge $e \in E$. Throughout this work, we will be interested only in hypergraphs with positive integral weights and for algorithmic problems where the input/output is a hypergraph, we will require that the weights are represented in binary. If all hyperedges have size at most 2, then the hyperedges are known as edges and we call such a hypergraph as a graph. We emphasize a subtle but important distinction between hypergraphs and graphs: the number of hyperedges in a hypergraph could be exponential in the number of vertices. This is in sharp contrast to graphs where the number of edges is at most the square of the number of vertices. Consequently, in hypergraph network design problems where the goal is to construct a hypergraph with certain properties, one needs to be mindful of the number of hyperedges in the hypergraph returned by the algorithm. Recent works in hypergraph algorithms literature have focused on this issue in the context of cut/spectral sparsification of hypergraphs [4, 18, 19, 34, 36, 37, 39, 43, 55, 58].

Notation. Let $(G = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph. For $X \subseteq V$, let $\delta_G(X) := \{e \in E : e \cap X \neq \emptyset, e \setminus X \neq \emptyset\}$. We define the cut function $d_{(G,w)} : 2^V \to \mathbb{Z}_{\geq 0}$ by $d_{(G,w)}(X) := \sum_{e \in \delta_G(X)} w(e)$ for every $X \subseteq V$. For a vertex $v \in V$, we use $d_{(G,w)}(v)$ to denote $d_{(G,w)}(\{v\})$. We define the degree of a vertex v to be the sum of the weights of hyperedges containing v – we note that the degree of a vertex is not necessarily equal to $d_{(G,w)}(v)$ since we could have $\{v\}$ itself as a hyperedge (i.e., a singleton hyperedge that contains only the vertex v). For distinct vertices $u, v \in V$, let $\lambda_{(G,w)}(u, v) := \min\{d_{(G,w)}(X) : u \in X \subseteq V \setminus \{v\}\}$ – i.e., $\lambda_{(G,w)}(u, v)$ is the value of a minimum $\{u, v\}$-cut in the hypergraph. If all hyperedge weights are unit, then we drop w from the subscript and simply use d_G and λ_G.

Hypergraph Splitting-off. We now introduce our definition of splitting-off in hypergraphs. To compare and contrast our definition of splitting-off for hypergraphs with the classical definition of splitting-off for graphs, we include both our definition and the classical definition and distinguish them by identifying them as h-splitting-off and g-splitting-off. In the definitions below, we encourage the reader to consider the input hypergraph (G, w) to be a graph while considering g-splitting-off terminology and to be a hypergraph while considering h-splitting-off terminology. We encourage the reader to also assume unit weights during first read. See Figure 1 for an example.

▶ **Definition 1.** *Let $(G = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph and $s \in V$.*

1. *In* merge almost-disjoint hyperedges*, we pick a pair of hyperedges $e, f \in \delta_G(s)$ such that $e \cap f = \{s\}$, pick a positive integer $\alpha \in \mathbb{Z}_+$ such that $\alpha \leq \min\{w(e), w(f)\}$, reduce the weights of hyperedges e and f by α, and increase the weight of a hyperedge g by α. Here,*
   - **a.** *if we choose $g := e \cup f$, then the associated operation will be called as* h-merge almost-disjoint hyperedges operation.
   - **b.** *if we choose $g := (e \cup f) \setminus \{s\}$, then the associated operation will be called as* g-merge almost-disjoint hyperedges operation.

   In the above, if $\alpha = w(e)$ (resp. if $\alpha = w(f)$), then we discard the hyperedge e (resp. hyperedge f) from the hypergraph obtained after the operation; if the hyperedge $g \notin E$, then we introduce g as a new hyperedge with weight $w(g) := 0$ before performing the weight increase on the hyperedge g.
2. *In* trim hyperedge operation*, we pick a hyperedge $e \in \delta_G(s)$, pick a positive integer $\alpha \in \mathbb{Z}_+$, reduce the weight of the hyperedge e and increase the weight of the hyperedge $g := e \setminus \{s\}$. Here,*
   - **a.** *if we choose $\alpha \leq w(e)$, reduce the weight of the hyperedge e by α, and increase the weight of the hyperedge g by α, then the associated operation will be called as* h-trim operation *(if $\alpha = w(e)$, then we discard e from the hypergraph obtained after the operation; if $g \notin E$, then we add g as a new hyperedge with weight $w(g) := 0$ before performing the weight increase on the hyperedge g).*
   - **b.** *if we choose $\alpha \leq w(e)/2$, reduce the weight of the hyperedge e by 2α, and increase the weight of the hyperedge g by 2α, then the associated operation will be called as* g-trim operation *(if $\alpha = w(e)/2$, then we discard e from the hypergraph obtained after the operation; if $g \notin E$, then we add g as a new hyperedge with weight $w(g) := 0$ before performing the weight increase on the hyperedge g).*
3. *We say that a hypergraph $(H = (V, E_H), w_H : E_H \to \mathbb{Z}_+)$ is obtained by applying a*
   - **a.** h-splitting-off operation at s from (G, w) *if (H, w_H) is obtained from (G, w) by either the h-merge almost-disjoint hyperedges operation or the h-trim hyperedge operation.*
   - **b.** g-splitting-off operation at s from (G, w) *if (H, w_H) is obtained from (G, w) by either the g-merge almost-disjoint hyperedges operation or the g-trim hyperedge operation.*

Certain remarks regarding the definitions are in order. Firstly, the trim operation is valuable and unique to hypergraphs. It has been used in the hypergraph literature to obtain small-sized certificates for hypergraph connectivity [18] and for certain notions of directed hypergraph connectivity [24]. We note that the trim operation has limited value in graphs – trimming an edge leads to a singleton edge and singleton edges contribute only to the degree but not to the cut value of any set. Secondly, all operations mentioned above are degree preserving for vertices $u \in V \setminus \{s\}$: both h-trim and g-trim operations preserve degrees by definition; both h-merge and g-merge *almost-disjoint* hyperedges operations preserve degrees due to the almost-disjoint property of the chosen hyperedges. Thirdly, all operations mentioned above *do not* increase the cut values of subsets $X \subseteq V \setminus \{s\}$. Thus, the relevant goal with these operations is ensuring that the cut values do not decrease too much – i.e., preserving global/local connectivity. We will be interested in repeated application of h-splitting-off operations at a vertex from a given hypergraph to isolate that vertex while preserving global/local connectivity. We define these formally next.

▶ **Definition 2.** *Let $(G = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph and $s \in V$.*

1. *We say that a hypergraph $(G^* = (V, E^*), w^* : E^* \to \mathbb{Z}_+)$ is a*
   - **a.** complete h-splitting-off at s from (G, w) *if $d_{(G^*,w^*)}(s) = 0$ and (G^*, w^*) is obtained from (G, w) by repeatedly applying h-splitting-off operations at s from the current hypergraph.*
   - **b.** complete g-splitting-off at s from (G, w) *if $d_{(G^*,w^*)}(s) = 0$ and (G^*, w^*) is obtained from (G, w) by repeatedly applying g-splitting-off operations at s from the current hypergraph.*
2. *Let (G^*, w^*) be a complete h-splitting-off/g-splitting-off at s from (G, w). We say that (G^*, w^*)*
   - **a.** *preserves local connectivity if $\lambda_{(G^*,w^*)}(u, v) = \lambda_{(G,w)}(u, v)$ for every distinct $u, v \in V \setminus \{s\}$ and*
   - **b.** *preserves global connectivity if* $\min\{\lambda_{(G^*,w^*)}(u, v) : u, v \in V \setminus \{s\}, u \neq v\} = \min\{\lambda_{(G,w)}(u, v) : u, v \in V \setminus \{s\}, u \neq v\}$.

Our first contribution in this work is the definition of h-splitting-off operations at a vertex from a hypergraph. To the best of our knowledge, this definition has not appeared in the literature before. A notion of hypergraph splitting-off motivated by hypergraph connectivity augmentation applications has been studied in the literature before [3, 6, 20]. These works have explored local connectivity preserving complete g-splitting-off at a vertex s from a hypergraph under the assumption that *all hyperedges incident to the vertex s are edges (i.e., have size at most 2)*. In contrast, our focus is on local connectivity preserving complete h-splitting-off at a vertex s from a hypergraph without any assumption on the size of the hyperedges incident to the vertex s (i.e., the vertex s could have arbitrary-sized hyperedges incident to it). We refer the reader to Figure 1 for an example of complete h-splitting-off at a vertex from a hypergraph.

We will primarily be concerned with complete *h-splitting-off* at a vertex from a *hypergraph* and complete *g-splitting-off* at a vertex from a *graph*. Complete g-splitting-off at a vertex from a *graph* is equivalent to the classical and well-studied notion of complete splitting-off at a vertex from a graph (for the definition of the classical notion in graphs, see [24, 49]). We cast the results of Lovász [45, 47] and Mader [48] in the framework of our definitions now. Let (G, w) be a *graph* and let s be a vertex in G. Lovász [45, 47] showed that if $d_{(G,w)}(\{s\})$ is even and $\min\{\lambda_{(G,w)}(u, v) : u, v \in V \setminus \{s\}\} \geq K$ for some $K \geq 2$, then there exists a *global* connectivity preserving complete g-splitting-off at the vertex s from (G, w).

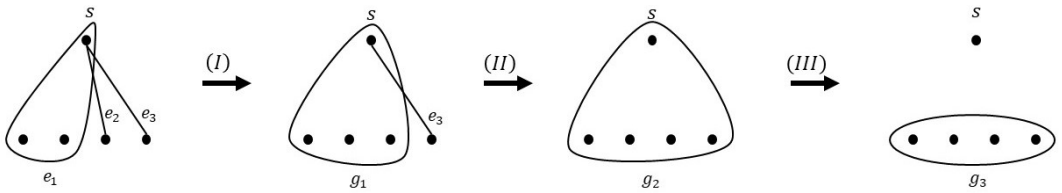

Figure 1 Example of (local connectivity preserving) complete h-splitting-off at a vertex s from a hypergraph. Consider the leftmost hypergraph where all hyperedge weights are one and the vertex s is as labeled. Operations (I) and (II) correspond to h-merge almost-disjoint hyperedges operations and Operation (III) corresponds to an h-trim hyperedge operation.

Mader [48] showed that if $d_{(G,w)}(\{s\})$ is even, there is no cut-edge[1] incident to s, and (G, w) is connected, then there exists a *local* connectivity preserving complete g-splitting-off at the vertex s from (G, w).

We compare and contrast complete h-splitting-off at a vertex from a hypergraph and complete g-splitting-off at a vertex from a graph. Complete h-splitting-off at a vertex s from a hypergraph enables the vertex s to exit the hypergraph by informing its incident hyperedges about how to merge and trim themselves in order to preserve degrees. In this sense, the definition of complete h-splitting-off at a vertex from a hypergraph serves the same role as complete g-splitting-off at a vertex from a graph. On the other hand, there are important differences between the two notions. Firstly, complete h-splitting-off at a vertex from a *graph* may not necessarily be a graph (owing to the creation of hyperedges of size at least 3) while it is an easy exercise to show that complete g-splitting-off at a vertex from a *graph* will necessarily be a graph. Secondly, local/global connectivity preserving complete g-splitting-off at a vertex from a graph may not exist – see Figure 2.

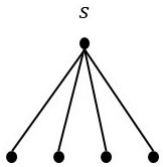

Figure 2 An example showing that global connectivity preserving complete g-splitting-off at a vertex from a graph may not exist. All edge weights are one and the vertex s is as labeled.

As our second main contribution, we show that local connectivity preserving complete h-splitting-off at a vertex from a hypergraph always exists and can be computed in strongly polynomial time (the rightmost hypergraph in Figure 1 is a local connectivity preserving complete h-splitting-off at the vertex s from the hypergraph in Figure 2).

▶ **Theorem 3.** *Given a hypergraph $(G = (V, E), w_G : E \to \mathbb{Z}_+)$ and a vertex $s \in V$, there exists a strongly polynomial-time algorithm to find a local connectivity preserving complete h-splitting-off at s from (G, w_G).*

A difference between Theorem 3 and the graph splitting-off results of Lovász and Mader is that Theorem 3 shows the existence of a local connectivity preserving complete h-splitting-off at a vertex from a hypergraph *without any assumptions on the hypergraph* whereas Lovász's

[1] Equivalently, for every edge $e \in \delta_G(s)$ with $w(e) = 1$, the removal of that edge does not disconnect the graph.

and Mader's results hold only under certain technical assumptions on the graph. In several applications of their results, additional arguments are needed to address cases where those technical assumptions do not hold. For this reason, we believe that Theorem 3 could be useful in simplifying the arguments involved in some of the applications of Lovász's and Mader's graph splitting-off results (e.g., we will later see that the edge version of Menger's theorem in undirected *graphs* follows in a straightforward fashion from Theorem 3).

A crude run-time of our algorithm that proves Theorem 3 is $O(|V|^6(|V|+|E|)^3)$. We understand that this run-time is impractical for applications. Nevertheless, we mention it here explicitly for the sake of completeness and as a potential starting point for future work: it would be interesting to design a near-linear time algorithm to find a local connectivity preserving complete h-splitting-off at a vertex from a weighted hypergraph.

▶ Remark 4. We note that existence of a local/global connectivity preserving complete h-splitting-off at a vertex from a hypergraph does not necessarily imply a polynomial-time algorithm to find it. This is because, a local/global connectivity preserving complete h-splitting-off at a vertex from a hypergraph (G, w_G) could contain exponential number of hyperedges although G contains only polynomial number of hyperedges. We give an example to illustrate this issue. Consider the graph $(G = (V, E), w_G)$ where G is the star graph on $n+1$ vertices with s being the center of the star and all edge weights are $2^{n-1}-1$. Consider the hypergraph $(H = (V, E_H), w_H)$ such that $E_H := \{e : e \subseteq V \setminus \{s\}$ and $|e| \geq 2\}$ with all hyperedge weights being one. The hypergraph (H, w_H) is a local connectivity preserving complete h-splitting-off at s from (G, w_G), but (H, w_H) has exponential number of hyperedges although (G, w_G) has only n edges. In order to design a polynomial-time algorithm to find a local connectivity preserving complete h-splitting-off at a vertex from a hypergraph, a necessary step is to show the existence of a local connectivity preserving complete h-splitting-off at a vertex from a hypergraph that contains only polynomially many *additional* hyperedges. For the star graph (G, w_G) with edge weights $2^{n-1}-1$ mentioned above, the hypergraph $(H' = (V, E_{H'}), w_{H'})$ containing only one hyperedge, namely $E_{H'} := \{V \setminus \{s\}\}$ with the weight of that hyperedge being $2^{n-1}-1$ is also a local connectivity preserving complete h-splitting-off at s from (G, w_G). One of the features of our algorithmic proof of Theorem 3 is the existence of a local connectivity preserving complete h-splitting-off at a vertex from a hypergraph that contains only polynomially many additional hyperedges.

As our third main contribution, we present two applications of Theorem 3.

Application 1: Constructive characterization of k-hyperedge-connected hypergraphs. For the purposes of this application, graphs and hypergraphs will refer to multi-graphs and multi-hypergraphs, respectively. Let k be a positive integer. A graph $G = (V, E)$ is *k-edge-connected* if $d_G(X) \geq k$ for every non-empty proper subset $X \subsetneq V$. Constructive characterization of k-edge-connected graphs is a central problem in graph theory. It is well-known that a graph is 1-edge-connected if and only if it containss a spanning tree. Robbins' [56] showed that a graph is 2-edge-connected if and only if it admits an ear decomposition (see [24] for definition of ear decomposition). Generalizing Robbins' result, Lovász [45, 47] gave a constructive characterization of k-edge-connected graphs for *even* k using his result on global connectivity preserving complete g-splitting-off at a vertex from a graph. Mader [48] gave a constructive characterization of k-edge-connected graphs for *odd* k using his result on local connectivity preserving complete g-splitting-off at a vertex from a graph. Motivated by these results, we present a constructive characterization of k-hyperedge-connected hypergraphs using our splitting-off result in Theorem 3. A hypergraph $G = (V, E)$ is defined to be *k-hyperedge-connected* if $d_G(X) \geq k$ for every non-empty proper subset $X \subsetneq V$.

Both Lovász's and Mader's constructive characterizations of k-edge-connected graphs are based on a pinching operation in graphs. Our constructive characterization of k-hyperedge-connected hypergraphs is also based on a pinching operation, but our pinching operation is defined for hypergraphs. We define this operation now (see Figure 3 for an example).

▶ **Definition 5.** *Let $G = (V, E)$ be a hypergraph and $p, k \in \mathbb{Z}_+$ be positive integers such that $p \leq k$. In* (k, p)-pinching *hyperedges of G, we obtain a new hypergraph by performing the following sequence of operations:*

1. *pick p distinct hyperedges $e_1, \ldots, e_p \in E$,*
2. *pick p positive integers $t_1, \ldots, t_p \in \mathbb{Z}_+$ such that $\sum_{i=1}^{p} t_i = k$,*
3. *for each $i \in [p]$, choose a partition of the hyperedge e_i into t_i non-empty parts $e_i = \biguplus_{j \in [t_i]} f_i^j$,*
4. *remove the hyperedges $e_1, \ldots, e_p$ from the hypergraph G,*
5. *add a new vertex s and hyperedges $\{f_i^j \cup \{s\} : j \in [t_i], i \in [p]\}$ to the hypergraph G.*

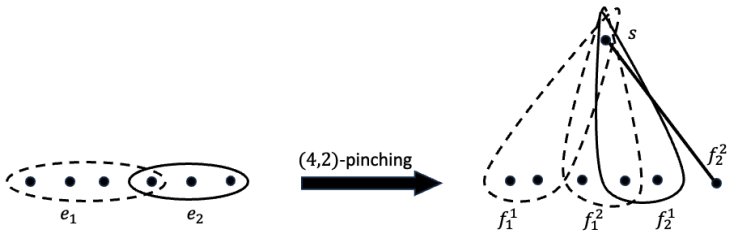

Figure 3 An example of a $(4, 2)$-pinching operation. Here, $t_1 = t_2 = 2$.

With this definition of pinching, we show the following constructive characterization of k-hyperedge-connected hypergraphs.

▶ **Theorem 6.** *Let $k \in \mathbb{Z}_+$ be a positive integer. A hypergraph $G = (V, E)$ is k-hyperedge-connected if and only if G can be obtained by starting from the single vertex hypergraph with no hyperedges and repeatedly applying one of the following two operations:*

1. *add a new hyperedge over a subset of vertices of the existing hypergraph, and*
2. *(k, p)-pinching hyperedges of the existing hypergraph for some positive integer $p \leq k$.*

Our proof of Theorem 6 is constructive: i.e., given a k-hyperedge-connected hypergraph G, our proof gives a polynomial-time algorithm to construct a sequence of hypergraphs $G_0, G_1, G_2, \ldots, G_t$, where G_0 is the single vertex hypergraph with no hyperedges, $G_t = G$ and for each $i \in [t]$, the hypergraph G_i is obtained from G_{i-1} by either adding a new hyperedge over a subset of vertices in G_{i-1} or by (k, p)-pinching hyperedges in G_{i-1} for some positive integer $p \leq k$.

▶ Remark 7. Robbins' constructive characterization of 2-edge-connected graphs and Lovász's constructive characterization of $2k$-edge-connected graphs find applications in graph orientation problems – e.g., Robbins' result leads to an algorithm to find a strongly connected orientation of 2-edge-connected graphs and Lovász's result leads to an algorithm to find a strongly k-arc-connected orientation of $2k$-edge-connected graphs. In fact, the latter leads to an alternative proof of Nash-Williams' *weak orientation theorem* [52]. Along the same vein, we hope that our above characterization of k-edge-connected hypergraphs might find applications in hypergraph orientation problems.

Application 2.1: Steiner Rooted k-arc-connected Orientation of Graphs. Orienting a graph to achieve high connectivity is a fundamental area in graph theory, combinatorial optimization, and algorithms. Let $G = (V, E)$ be an undirected graph. An *orientation* $\overrightarrow{G}$ of G is a directed graph obtained by assigning a direction to each edge of G. Let $G = (V, E)$ be an undirected graph, $T \subseteq V$ be a set of terminals, $r \in T$ be a root vertex, and k be a positive integer. An orientation $\overrightarrow{G}$ of G is defined to be *Steiner rooted k-arc-connected* if there exist k arc-disjoint paths in $\overrightarrow{G}$ from t to r for every terminal $t \in T \setminus \{r\}$. In Max Steiner Rooted-Connected Orientation problem, the goal is to find the maximum integer k and an orientation $\overrightarrow{G}$ of G such that $\overrightarrow{G}$ is Steiner rooted k-arc-connected. Max Steiner Rooted-Connected Orientation generalizes two classic problems in graph theory: The case of $|T| = 2$ is the max edge-disjoint $\{r, v\}$-paths problem and is solved via Menger's theorem. The case of $T = V$ is the max edge-disjoint spanning trees problem and is solved via Tutte and Nash-Williams' theorem [53, 59]. We mention that both these problems are also generalized by the Steiner Tree Packing problem and the associated Kriesell's conjecture [33, 40, 41], but we will not focus on that generalization.

Király and Lau [38] introduced the Max Steiner Rooted-Connected Orientation, showed that it is NP-hard, and gave a 2-approximation via an approximate min-max relation. We state their approximate min-max relation now. An undirected graph G is *Steiner k-edge-connected* if $\lambda_G(u, v) \geq k$ for every pair of distinct terminals $u, v \in T$. It is clear that if the graph G has a Steiner rooted k-arc-connected orientation, then G should be Steiner k-edge-connected. However, the converse is not necessarily true. Király and Lau observed that if the graph is Steiner $2k$-edge-connected, then it has a Steiner rooted k-arc-connected orientation.

▶ **Theorem 8** (Király and Lau [38]). *Let $G = (V, E)$ be an undirected graph, $T \subseteq V$ be a subset of terminals, $r \in T$ be the root vertex, and k be a positive integer. If G is Steiner $2k$-edge-connected, then it has a Steiner rooted k-arc-connected orientation.*

Király and Lau observed that Theorem 8 follows immediately from Nash-Williams' *strong orientation* theorem. Nash-Williams' *strong orientation* theorem [52] states that every undirected graph $G = (V, E)$ admits an orientation $\overrightarrow{G}$ such that $\lambda_{\overrightarrow{G}}(u, v) \geq \lfloor \lambda_G(u, v)/2 \rfloor$ for every distinct $u, v \in V$, where $\lambda_{\overrightarrow{G}}(u, v)$ is the maximum number of arc-disjoint directed paths from u to v in $\overrightarrow{G}$. In this work, we give an alternative proof of Theorem 8 that does not rely on Nash-Williams' strong orientation theorem. Instead, we use Theorem 3. Our proof strategy is unique since it proves an orientation result for *graphs* using tools developed for *hypergraphs*.

▶ Remark 9. Nash-Williams' proof of the strong orientation theorem [52] is a sophisticated inductive argument. Giving a simple and more insightful proof of the strong orientation theorem has been a central topic of interest in graph theory and combinatorial optimization (see [26]). Mader [48] gave a different proof of the strong orientation theorem using his local connectivity preserving splitting-off theorem, but his proof also involved sophisticated technical arguments. Frank [26] condensed the ideas of both Nash-Williams and Mader to present a proof of the strong orientation theorem using Mader's local connectivity preserving splitting-off, but it is still technically complicated. The technical complication in using Mader's local connectivity preserving splitting-off result arises from the assumptions that need to be satisfied by the vertex to be split-off. In contrast, our splitting-off result for hypergraphs (namely, Theorem 3) does not need any assumptions on the vertex to be split-off. In light of these considerations, our proof of Theorem 8 using Theorem 3 provides hope that Theorem 3 (or the ideas therein) could be used to give a conceptually simpler proof of Nash-Williams' strong orientation theorem.

Application 2.2: Steiner Rooted k-hyperarc-connected Orientation of Hypergraphs. Orienting *hypergraphs* is also a fundamental area in graph theory and combinatorial optimization (see Frank's book [24]) with far reaching implications. For example, Woodall's conjecture can be reformulated as a hypergraph orientation problem (see Conjecture 9.4.15 in [24]); moreover, hypergraph orientation results have recently been used in coding theory [1]. Király and Lau [38] showed that the approximate min-max relation in Theorem 8 also holds for hypergraphs. To state their result, we need some terminology in hypergraph orientations.

Let $G = (V, E)$ be a hypergraph. An *orientation* $\overrightarrow{G} = (V, E, \texttt{head} : E \to V)$ of G is a directed hypergraph obtained by assigning a unique head vertex $\texttt{head}(e) \in e$ for each $e \in E$. A pair $(e, \texttt{head}(e))$ is denoted as a *hyperarc* with the head of the hyperarc being $\texttt{head}(e)$ and the tails of the hyperarc being $e \setminus \texttt{head}(e)$. Let $G = (V, E)$ be a hypergraph, $T \subseteq V$ be a set of terminals, $r \in T$ be a root vertex, and k be a positive integer. An orientation $\overrightarrow{G}$ of G is defined to be *Steiner rooted k-hyperarc-connected* if there exist k hyperarc-disjoint paths in $\overrightarrow{G}$ from t to r for every terminal $t \in T \setminus \{r\}$. Here, a path from t to r in a directed hypergraph is an alternating sequence of distinct vertices and hyperarcs $t = v_1, a_1, v_2, a_2, ..., a_{\ell-1}, v_\ell = r$ such that v_i is a tail of a_i and v_{i+1} is the head of a_i for every $i \in [\ell - 1]$. We say that a hypergraph G is *Steiner k-hyperedge-connected* if $\lambda_G(u, v) \geq k$ for every pair of distinct terminals $u, v \in T$. It is clear that if the hypergraph G has a Steiner rooted k-hyperarc-connected orientation, then G should be Steiner k-hyperedge-connected. However, the converse is not necessarily true. Király and Lau [38] showed that if the hypergraph is Steiner $2k$-hyperedge-connected, then it has a Steiner rooted k-hyperarc-connected orientation.

▶ **Theorem 10** (Király and Lau [38]). *Let $G = (V, E)$ be a hypergraph, $T \subseteq V$ be a subset of terminals, $r \in T$ be the root vertex, and k be a positive integer. If G is Steiner $2k$-hyperedge-connected, then it has a Steiner rooted k-hyperarc-connected orientation.*

Király and Lau's proof of Theorem 10 was based on careful uncrossing and contractions. In this work, we give an alternative proof of Theorem 10 using Theorem 3. Our proof of Theorem 10 reveals the source of the 2-factor gap in the approximate min-max relation of Király and Lau for Max Steiner Rooted-Connected Orientation Problem: it arises from the 2-factor gap between connectivity and weak-partition-connectivity of hypergraphs (see Definition 5.1 for the definition of weak-partition-connectivity and Lemma 5.2 in the full version).

▶ Remark 11. Our proof technique for Theorems 8 and 10 using Theorem 3 – i.e., via the local-connectivity preserving splitting-off operation in hypergraphs – also leads to an alternate proof of Menger's theorem in *undirected* graphs and hypergraphs (edge-disjoint version). For details, we refer the reader to Section 5 of the full version where we discuss a proof of Menger's theorem using Theorem 3 as a warm-up towards a proof of Theorems 8 and 10.

Both Theorems 8 and 10 can be extended to weighted graphs/hypergraphs (by considering parallel copies of edges/hyperedges). The weighted version of Theorems 8 and 10 can also be shown to admit strongly polynomial-time algorithms using our proof strategy as well as the proof strategy of Király and Lau. We avoid stating the weighted versions in the interests of brevity.

1.1 Proof Technique for Theorem 6

We outline the proof technique for Theorem 6. The reverse direction follows by observing that if a hypergraph is k-hyperedge-connected, then both operations in the statement of the theorem preserve k-hyperedge-connectivity. We sketch a proof of the forward direction. The

proof is by induction on the number of hyperedges plus the number of vertices. First, suppose that there exists a hyperedge $e \in E$ such that $G - e$ is still k-hyperedge-connected. We note that deleting the hyperedge e is the inverse of operation (1). Consequently, the proof follows by deleting the hyperedge e, using the induction hypothesis on the resulting hypergraph H, and then noting that the hypergraph G is obtained from H by operation (1). Next, suppose that there does not exist a hyperedge $e \in E$ such that $G - e$ is k-hyperedge-connected. We call such a hypergraph to be minimally k-hyperedge-connected. In Lemma 4.1 of the full version, we show that a minimally k-hyperedge-connected hypergraph contains a vertex u with degree exactly k. By Theorem 3, there exists a global-connectivity preserving complete h-splitting-off at the vertex u from the hypergraph G. Let H be a global-connectivity preserving complete h-splitting-off at the vertex u from the hypergraph G. We note that complete h-splitting-off at u followed by deletion of the vertex u is the inverse of operation (2) at u. Consequently, the proof follows by using the induction hypothesis on the hypergraph $H - u$ and then noting that the hypergraph G is obtained from $H - u$ by operation (2).

1.2 Proof Technique for Theorems 8 and 10

We outline the proof technique for Theorem 10 and will remark after the proof about how it also implies a proof for Theorem 8. Our proof of Theorem 10 will be in three steps. Let us denote the set of non-terminals as *Steiner vertices*. Our first step is to obtain a hypergraph $H = (T, E_H)$ by applying our local connectivity preserving complete h-splitting-off at each Steiner vertex of G (sequentially, in arbitrary order of the Steiner vertices) and deleting the isolated vertices. We note that deleting the isolated vertices ensures that the vertex set of H is the set of terminals T. Moreover, our local connectivity preserving complete h-splitting-off ensures that the hypergraph H is $2k$-hyperedge-connected since the hypergraph G is Steiner $2k$-hyperedge-connected. Our second step is to show that this hypergraph $H = (T, E_H)$ admits a rooted k-hyperarc-connected orientation. A known characterization for the existence of a rooted k-hyperarc-connected orientation of a hypergraph is that the hypergraph is k-*weak-partition-connected* (see Definition 5.1 for the definition of weak-partition-connectivity and Theorem 5.1 for the characterization in the full version). We mention that the notion of weak-partition-connectivity in hypergraphs has been used recently in the context of coding theory [1, 31]. In order to use the characterization for the existence of a rooted k-hyperarc-connected orientation of a hypergraph, we relate the connectivity of a hypergraph to its *weak-partition-connectivity* and conclude that if H is $2k$-hyperedge-connected, then it is k-weak-partition-connected (see Lemma 5.2 in the full version). Consequently, the hypergraph H admits a rooted k-hyperarc-connected orientation. We note that such an orientation of H is equivalent to a Steiner rooted k-hyperarc-connected orientation of H since the vertex set of H is the set T of terminals. Our third step is to use this Steiner rooted k-hyperarc-connected orientation of H to obtain a Steiner rooted k-hyperarc-connected orientation of the hypergraph G: we will see that there is a natural way to extend the orientation of hyperedges while reversing the h-splitting-off operations to preserve Steiner rooted k-hyperarc-connected property (see Lemma 5.1 in the full version). This would complete the proof of Theorem 10.

We note that if the hypergraph G is a graph, then the same proof above obtains the required graph orientation, thus proving Theorem 8. In particular, to prove Theorem 8, we start from a graph $G = (V, E)$ that is Steiner $2k$-edge-connected, but our local connectivity preserving complete h-splitting-off operations at Steiner vertices results in a hypergraph $H = (T, E_H)$ that is $2k$-hyperedge-connected; by Lemma 5.2 in the full version, the hypergraph H is k-weak-partition-connected; now Theorem 5.1 in the full version gives a

rooted k-hyperarc-connected orientation of the resulting hypergraph. Such an orientation is extended to a Steiner rooted k-hyperarc-connected orientation of the *graph* $G = (V, E)$ using Lemma 5.1 in the full version. Essentially, the proof starts from the given graph, obtains a related hypergraph, orients that hypergraph, and extends that orientation of the hypergraph back into a desired orientation of the given graph.

Our proof technique for Theorems 8 and 10 also leads to an alternate proof of Menger's theorem in *undirected* graphs and hypergraphs (edge-disjoint version) – see Section 5 in the full version.

1.3 Proof Technique for Theorem 3

We prove a more general statement that implies Theorem 3. We begin with the definitions needed for the more general statement.

▶ **Definition 12.** *Let V be a finite set, $p : 2^V \to \mathbb{Z}$ be a set function, and $(H = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph.*

1. *The set function p*
   a. *is* symmetric *if $p(X) = p(V - X)$ for every $X \subseteq V$, and*
   b. *is* skew-supermodular *if for every $X, Y \subseteq V$, at least one of the following inequalities hold:*
      i. $p(X) + p(Y) \leq p(X \cap Y) + p(X \cup Y)$.
      ii. $p(X) + p(Y) \leq p(X - Y) + p(Y - X)$.
2. *The coverage function $b_{(H,w)} : 2^V \to \mathbb{Z}_{\geq 0}$ is defined by $b_{(H,w)}(X) := \sum_{e \in B_H(X)} w(e)$ for every $X \subseteq V$, where $B_H(X) := \{e \in E : e \cap X \neq \emptyset\}$ for every $X \subseteq V$.*
3. *The hypergraph (H, w)* weakly covers *the function p if $b_{(H,w)}(X) \geq p(X)$ for every $X \subseteq V$.*
4. *The hypergraph (H, w)* strongly covers *the function p if $d_{(H,w)}(X) \geq p(X)$ for every $X \subseteq V$.*

If a hypergraph (H, w) strongly covers a function $p : 2^V \to \mathbb{Z}$, then it also weakly covers the function p. However, the converse is false – i.e., a weak cover is not necessarily a strong cover[2]. Bernáth and Király [5] showed that a weak cover of a *symmetric skew-supermodular* function can be converted to a strong cover of the same function by repeated *merging of disjoint hyperedges*. We recall their definition of the merging operation, discuss their result, and its significance now.

▶ **Definition 13.** *Let $(H = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph. We use H_w to denote the unweighted multi-hypergraph over vertex set V containing $w(e)$ copies of every hyperedge $e \in E$. By* merging two disjoint hyperedges *of H_w, we refer to the operation of replacing them by their union in H_w. We will say that a hypergraph $(G = (V, E_G), c : E_G \to \mathbb{Z}_+)$ is obtained from (H, w) by* merging hyperedges *if the multi-hypergraph G_c is obtained from the multi-hypergraph H_w by repeatedly merging two disjoint hyperedges in the current hypergraph.*

Bernáth and Király showed the following result:

▶ **Theorem 14** (Bernáth and Király [5])**.** *Let $(H = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph and $p : 2^V \to \mathbb{Z}$ be a symmetric skew-supermodular function such that $b_{(H,w)}(X) \geq p(X)$ for every $X \subseteq V$. Then, there exists a hypergraph $\left(H^* = (V, E^*), w^* : E^* \to \mathbb{Z}_+\right)$ such that*
(1) *$d_{(H^*,w^*)}(X) \geq p(X)$ for every $X \subseteq V$ and*
(2) *the hypergraph (H^*, w^*) is obtained by merging hyperedges of the hypergraph (H, w).*

[2] For example, consider the function $p : 2^V \to \mathbb{Z}$ defined by $p(X) := 1$ for every non-empty proper subset $X \subsetneq V$ and $p(\emptyset) := p(V) := 0$, and the hypergraph $(H = (V, E := \{\{u\} : u \in V\}), w : E \to \{1\})$.

We observe that Theorem 14 can be used to prove the existential version of Theorem 3: namely, for every hypergraph $(G = (V, E), w_G : E \to \mathbb{Z}_+)$ and a vertex $s \in V$, *there exists* a local connectivity preserving complete h-splitting-off at s from (G, w_G). This can be shown by setting up the hypergraph (H, w) and the function p suitably based on (G, w_G) and using Theorem 14 (see the first two paragraphs of the proof of Theorem 3.1 in Section 3 of the full version). We emphasize that this conclusion regarding hypergraph splitting-off from Bernáth and Király's result was not known before in the literature and is one of our contributions.

▶ Remark 15. We were also able to prove the existential version of Theorem 3 using *element-connectivity preserving reduction operations* (see [16] for the definition of element-connectivity and the notion of element-connectivity preserving reduction operations) – we omit the details of this alternate proof in the interests of brevity. The alternate proof does not seem to be helpful for the purposes of a strongly polynomial time algorithm. In fact, it remains open to design a strongly polynomial-time algorithm to perform *complete* element-connectivity preserving reduction operations in the weighted setting [16].

We recall that existence of a local connectivity preserving complete h-splitting-off at a vertex from a hypergraph does not immediately imply a polynomial-time algorithm – see the example in Remark 4. However, the above-mentioned proof of existence of a local-connectivity preserving complete splitting-off at an arbitrary vertex from a hypergraph (i.e., existential version of Theorem 3) via Theorem 14 suggests a natural approach towards designing a strongly polynomial time algorithm to find a local-connectivity preserving complete splitting-off at a given vertex from a given hypergraph: it suffices to prove a constructive version of Theorem 14 via a strongly polynomial-time algorithm. Towards this end, the example in Remark 4 suggests a necessary structural step towards a strongly polynomial-time algorithmic version of Theorem 14: we need to show Theorem 14 with the extra conclusion that the number of additional hyperedges in H^* is polynomial in the number of hyperedges and vertices in H.

Bernáth and Király proved Theorem 14 in the context of a reduction between certain hypergraph connectivity augmentation problems. For that reduction, the existential version of Theorem 14 is sufficient. However, for the purposes of our application to hypergraph splitting-off, we need an algorithmic version of Theorem 14. Bernáth and Király's proof of Theorem 14 is in fact algorithmic, but the run-time of the associated algorithm is not necessarily polynomial. Their proof implies that the number of additional hyperedges in the hypergraph (H^*, c^*) returned by their algorithm is at most $\sum_{e \in E} w(e)$ (i.e., $|E^*| - |E| \leq \sum_{e \in E} w(e)$) and the run-time of the algorithm is $O(\sum_{e \in E}(|e| + w(e))$. In particular, their run-time is polynomial only if the input weights are given in unary. Moreover, the exponential-sized hypergraph from Remark 4 could indeed arise as a consequence of their algorithm.

We address both the structural and the algorithmic issues mentioned above by proving a stronger algorithmic version of Theorem 14. In order to phrase an algorithmic version of Theorem 14, we need suitable access to the function p. Bernáth and Király [5] suggested access to a certain function maximization oracle associated with the function p that we describe below.

▶ **Definition 16.** *Let $p : 2^V \to \mathbb{Z}$ be a set function. p-*`max-sc-Oracle`$\left((G_0, c_0), S_0, T_0\right)$ *takes as input a hypergraph $(G_0 = (V, E_0), c_0 : E_0 \to \mathbb{Z}_+)$ and disjoint sets $S_0, T_0 \subseteq V$, and returns a tuple $(Z, p(Z))$, where Z is an optimum solution to the following problem:*

$$\max \left\{ p(Z) - d_{(G_0, c_0)}(Z) : S_0 \subseteq Z \subseteq V - T_0 \right\}. \qquad (p\text{-}\texttt{max-sc-Oracle})$$

For the purposes of our application (namely local connectivity preserving complete h-splitting-off at a vertex from a hypergraph), the above-mentioned function maximization oracle can be implemented to run in strongly polynomial time (see Lemma 3.1 in the full version). Using the above mentioned oracle, we prove the following algorithmic version of Theorem 14.

▶ **Theorem 17.** *Let $(H = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph and $p : 2^V \to \mathbb{Z}$ be a symmetric skew-supermodular function such that $b_{(H,w)}(X) \geq p(X)$ for every $X \subseteq V$. Then, there exists a hypergraph $\left(H^* = (V, E^*), w^* : E^* \to \mathbb{Z}_+\right)$ such that*
(1) *$d_{(H^*,w^*)}(X) \geq p(X)$ for every $X \subseteq V$,*
(2) *the hypergraph (H^*, w^*) is obtained by merging hyperedges of the hypergraph (H, w), and*
(3) *$|E^*| - |E| = O(|V|)$.*
Furthermore, given a hypergraph $(H = (V, E), w : E \to \mathbb{Z}_+)$ and access to p-`max-sc-Oracle` of a symmetric skew-supermodular function $p : 2^V \to \mathbb{Z}$ where $b_{(H,w)}(X) \geq p(X)$ for every $X \subseteq V$, there exists an algorithm that runs in $O(|V|^3(|V| + |E|)^2)$ time using $O(|V|^3(|V| + |E|))$ queries to p-`max-sc-Oracle` and returns a hypergraph $\left(H^* = (V, E^*), w^* : E^* \to \mathbb{Z}_+\right)$ satisfying the above three properties. The run-time includes the time to construct the hypergraphs used as input to the queries to p-`max-sc-Oracle`. Moreover, for each query to p-`max-sc-Oracle`, the hypergraph (G_0, c_0) used as input to the query has $O(|V|)$ vertices and $O(|V| + |E|)$ hyperedges.

Theorem 17 is a strengthening of Theorem 14 in two ways. Firstly, our theorem shows the existence of a hypergraph that not only satisfies properties (1) and (2), but also satisfies property (3) – i.e., the number of additional hyperedges in the returned hypergraph is *linear* in the size of the vertex set. Secondly, our Theorem 17 shows the existence of a strongly polynomial-time algorithm that returns a hypergraph satisfying the three properties. Our main contribution is modifying Bernáth and Király's algorithm and analyzing the modified algorithm to bound the number of additional hyperedges and the run-time. We mention that property (3) cannot be tightened to guarantee that $|E^* - E| = O(|V|)$ – we were able to construct an example where $|E^* - E| = \Omega(|V|^2)$ (see Appendix A of the full version).

Theorem 17 immediately leads to a proof of Theorem 3 (see Theorem 3.1 and its proof in Section 3 of the full version). Instead of using Theorem 17 as a black-box, if we delve into the proof of it in the context of the proof of Theorem 3, we obtain the following theorem:

▶ **Theorem 18.** *Let $(G = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph and $s \in V$. Then, there exists a hypergraph $(G' = (V, E'), w' : E' \to \mathbb{Z}_+)$ obtained by applying a h-splitting-off operation at s from (G, w) such that $\lambda_{(G',w')}(u, v) = \lambda_{(G,w)}(u, v)$ for every distinct $u, v \in V \setminus \{s\}$.*

We omit the proof of Theorem 18 in the interests of brevity. Theorem 18 closely resembles the *existential edge splitting-off* results of Lovász [45, 47] and Mader [48] for graphs. Lovász's and Mader's existential edge splitting-off results for graphs are important since they have been used to simplify the proofs of fundamental results in graph theory – e.g., Nash-Williams' Strong Orientation Theorem. On the other hand, Theorem 18 does not immediately imply a strongly polynomial-time algorithm for finding a local connectivity preserving complete h-splitting off at a vertex from a given weighted hypergraph. So, Theorem 3 may be useful in algorithmic contexts while Theorem 18 may be useful in graph-theoretical contexts.

1.4 Proof Technique for Theorem 17

In this section, we describe our proof technique for the existential result in Theorem 17. The algorithmic results in that theorem follow from the existential result using standard algorithmic tools for submodular functions, so we focus only on outlining a proof of the

existential result. Let $(H = (V, E), w : E \to \mathbb{Z}_+)$ be a hypergraph and $p : 2^V \to \mathbb{Z}_+$ be a symmetric skew-supermodular function such that (H, w) weakly covers the function p. Our goal is to show that there exists a hypergraph $(H^* = (V, E^*), w^* : E \to \mathbb{Z}_+)$ such that

(1) (H^*, w^*) strongly covers the function p,

(2) (H^*, w^*) is obtained by merging hyperedges of the hypergraph (H, w), and

(3) $|E^*| - |E| = O(|V|)$.

Preliminaries. We define a set $X \subseteq V$ to be (p, H, w)-tight if $b_{(H,w)}(X) = p(X)$. For a function p and hypergraph (H, w), let $T_{p,H,w}$ denote the family of (p, H, w)-tight sets and let $\mathcal{T}_{p,H,w}$ be the family of inclusionwise maximal sets in $T_{p,H,w}$. We will need the following two operations:

(i) For hyperedges $e, f \in E$ and a positive integer $\alpha \leq \min\{w(e), w(f)\}$, the operation Merge $((H, w), e, f, \alpha))$ returns the hypergraph obtained from (H, w) by decreasing the weight of hyperedges e and f by α and increasing the weight of the hyperedge $e \cup f$ by α. All hyperedges with zero weight are discarded.

(ii) For a hyperedge $e \in E$ and a positive integer $\alpha \leq w(e)$, the operation Reduce $((H, w), e, \alpha)$ returns the hypergraph obtained by decreasing the weight of the hyperedge e by α. All hyperedges with zero weight are discarded.

Algorithm of [5]. Our proof of the existential result builds on the techniques of Bernáth and Király [5] who proved the existence of a hypergraph $(H^* = (V, E^*), w^* : E^* \to \mathbb{Z}_+)$ satisfying properties (1) and (2), so we briefly recall their techniques. We present the algorithmic version of their proof since it will be useful for our purposes.

The proof in [5] is inductive, and consequently, the algorithm implicit in their proof is recursive. The algorithm takes as input a hypergraph $((H = (V, E), w : E \to \mathbb{Z}_+)$ and a symmetric skew-supermodular function $p : 2^V \to \mathbb{Z}$ such that the hypergraph (H, w) weakly covers the function p. If $w(E) = 0$, then the algorithm is in its base case and returns the empty hypergraph. Otherwise, $w(E) > 0$; the algorithm chooses an arbitrary hyperedge $e \in E$ and defines hypergraphs (H_0, w_0) and (H', w') and the function p' by considering two cases. First, suppose that the hyperedge e is not contained in any set of the family $\mathcal{T}_{p,H,w}$. In this case, the algorithm defines (H_0, w_0) to be the hypergraph on vertex set V consisting of a single hyperedge e with $w_0(e) = 1$, constructs the hypergraph $(H', w') := \text{Reduce}((H, w), e, 1)$, and defines the function $p' := p - d_{(H_0,w_0)}$. Second, suppose that the hyperedge e is contained in some set $X \in \mathcal{T}_{p,H,w}$. It can be shown that there exists a hyperedge $f \in E$ such that $f \subseteq V - X$. In this case, the algorithm defines (H_0, w_0) to be the empty hypergraph on vertex set V, constructs the hypergraph $(H', w') := \text{Merge}((H, w), e, f, 1)$, and defines the function $p' := p$. In both cases, the algorithm recurses on the inputs (H', w') and p' to obtain a hypergraph (H_0^*, w_0^*) and returns the hypergraph $(H^*, w^*) = (H_0^* + H_0, w_0^* + w_0)$. Here, the hyperedges of H^* are the union of the hyperedges of H_0^* and H_0 with the weight $w^*(e)$ of a hyperedge e being the sum of the weights $w_0^*(e) + w_0(e)$ if the hyperedge e is present in both H_0^* and H_0, being $w_0^*(e)$ if the hyperedge e is present only in H_0^*, and being $w_0(e)$ if the hyperedge e is present only in H_0.

We note that $w'(E') = w(E) - 1$. Furthermore, it can be shown that the function p' is symmetric skew-supermodular and the hypergraph (H', w') weakly covers the function p'. Consequently, by induction on $w(E)$, the algorithm can be shown to terminate in $w(E)$ recursive calls and returns a hypergraph satisfying properties (1) and (2). Moreover, the number of additional hyperedges in the returned hypergraph is at most the number of recursive calls where the Merge operation is performed, which is also at most $w(E)$. Thus,

in order to reduce the number of additional hyperedges and to design a strongly polynomial-time algorithm, our goal is to reduce the recursion depth of the algorithm. We emphasize that the recursion depth of Bernáth and Király's algorithm could indeed be exponential (the exponential sized example mentioned in Remark 4 could arise in the execution of their algorithm), so we need to necessarily modify their algorithm.

Preprocessing for Additional Structure. Similar to Bernáth and Király's algorithm, our algorithm also takes as input a hypergraph $(H = (V, E), w : E \to \mathbb{Z}_+)$ and a symmetric skew-supermodular function $p : 2^V \to \mathbb{Z}$ such that the hypergraph (H, w) weakly covers the function p. However, unlike Bernáth and Király's algorithm, our algorithm performs a preprocessing step so that the inputs (H, w) and p satisfy the following two additional conditions:

(a) every hyperedge $e \in E$ is contained in some set of $\mathcal{T}_{p,H,w}$ and

(b) the degree of every vertex in (H, w) is non-zero.

As a consequence of these additional conditions, the family $\mathcal{T}_{p,H,w}$ will be a *disjoint family*, a property that we leverage heavily throughout our analysis. Furthermore, we modify Bernáth and Király's algorithm to ensure that these conditions hold during every recursive call.

Our Algorithm. We now describe our modification of the above-mentioned Bernáth and Király's algorithm to reduce the recursion depth. Our algorithm is also recursive and its base case is the same as that of Bernáth and Király's algorithm (i.e., $w(E) = 0$). During recursive cases (i.e., if $w(E) > 0$), instead of performing one of the two (i.e., Merge or Reduce) operations, our algorithm performs both operations in a sequential fashion. In particular, we find a pair of disjoint hyperedges $e, f \in E$ contained in distinct sets of $\mathcal{T}_{p,H,w}$ (such a pair exists by condition (a) and the arguments of Bernáth and Király mentioned above). Next, instead of performing one Merge operation (as was done by Bernáth and Király's algorithm), we perform as many Merge operations as possible using the hyperedges e and f. Formally, let

$$\alpha^M := \max\left\{\alpha \in \mathbb{Z}_+ : \text{hypergraph returned by } \textsc{Merge}((H, w), e, f, \alpha) \text{ weakly covers } p\right\}.$$

We let $(H^M, w^M) := \textsc{Merge}((H, w), e, f, \alpha^M)$ and $p^M := p$. Next, instead of recursing on $((H^M, w^M), p^M)$ (as was done by Bernáth and Király's algorithm), we perform as many Reduce operations as possible on the newly created hyperedge $e \cup f$. Formally, let

$$\alpha^R := \max\left\{\alpha \in \mathbb{Z}_{\geq 0} : \begin{array}{c}\text{Hypergraph returned by } \textsc{Reduce}((H^M, w^M), e \cup f, \alpha) \\ \text{weakly covers the function } (p^M - d_{(H_0^\alpha, w_0^\alpha)})\end{array}\right\}$$

where (H_0^α, w_0^α) denotes the hypergraph on vertex set V consisting of a single hyperedge $e \cup f$ with $w_0^\alpha(e \cup f) = \alpha$. We construct the hypergraph $(H_0, w_0) := (H_0^{\alpha^R}, w_0^{\alpha^R})$, the hypergraph $(H^R, w^R) := \textsc{Reduce}((H^M, w^M), e \cup f, \alpha^R)$ and define the function $p^R := p^M - d_{(H_0^{\alpha^R}, w_0^{\alpha^R})}$. This immediate reduce step ensures that the hypergraph (H^R, w^R) and the function p^R satisfy condition (a) – i.e., every hyperedge in (H^R, w^R) is contained in some set of $\mathcal{T}_{p^R,H^R,w^R}$. Finally, we compute sets $\mathcal{Z} := \{u \in V : b_{(H^R,w^R)}(u) = 0\}$ and $V' := V - \mathcal{Z}$, hypergraph $(H' := (V', E' := E^R), w' := w^R)$, and define the function $p' : 2^{V'} \to \mathbb{Z}$ by $p'(X) := \max\{p(X \cup R) : R \subseteq \mathcal{Z}\}$ for every $X \subseteq V'$ – this final step can be viewed as a clean up step since it gets rid of vertices that are not incident to any hyperedges (and revises the function p appropriately). This clean up step ensures that the hypergraph (H', w') satisfies condition (b) – i.e., the degree of every vertex in (H', w') is non-zero. It can be shown that

the function p' is symmetric skew-supermodular and the hypergraph (H', w') weakly covers the function p'. Furthermore, the function p' and hypergraph (H', w') satisfy conditions (a) and (b). We recursively call the algorithm on input $((H', w'), p')$ to obtain a hypergraph (H_0^*, w_0^*). We obtain the hypergraph (G, c) from (H_0^*, w_0^*) by adding the vertices $\mathcal{Z}$ and return the hypergraph $(G + H_0, c + w_0)$. By induction on the total weight of hyperedges in the input hypergraph, it can be shown that our algorithm returns a hypergraph satisfying properties (1) and (2) and also terminates within a finite number of recursive calls.

Recursion Depth and Potential Functions. We now sketch our proof to show that the recursion depth of our algorithm is $|E| + O(|V|)$. We note that this also bounds the number of additional hyperedges in the hypergraph returned by the algorithm, and consequently this hypergraph also satisfies property (3). Let ℓ be the number of recursive calls made by the algorithm on the input instance $((H, w), p)$. We partition the set $[\ell]$ of recursive calls into two parts: let $P_1 \subseteq [\ell]$ be the set of recursive calls during which the merged hyperedge $e \cup f$ survives in the hypergraph (H', w') that is input to the subsequent recursive call and $P_2 \subseteq [\ell]$ be the recursive calls during which the merged hyperedge $e \cup f$ does not survive in the hypergraph (H', w') that is input to the subsequent recursive call. We note that $[\ell] = P_1 \uplus P_2$. We bound $|P_1|$ and $|P_2|$ separately using certain carefully designed potential functions.

First, we show that $|P_1| = O(|V|)$ as follows: for $i \in [\ell]$, consider the maximal tight set family $\mathcal{T}_i = \mathcal{T}_{p_i, H_i, w_i}$ where $((H_i, w_i), p_i)$ is the input to the i^{th} recursive call. Also, let $\mathcal{T}_{\leq 1} := \mathcal{T}_1$ and $\mathcal{T}_{\leq i} := \mathcal{T}_i \cup \{X \cap V_i : X \in \mathcal{T}_{\leq i-1}\}$ for integers i where $2 \leq i \leq \ell$ and V_i is the ground set of the input to the i^{th} recursive call. Thus, $\mathcal{T}_{\leq i}$ is the *projection* of all the maximal tight sets encountered in the first i recursive calls of the algorithm onto the ground set of the inputs at the i^{th} recursive call. We show that $\mathcal{T}_{\leq i}$ is laminar for every $i \in [\ell]$ (Lemma 6.11 in the full version). However, $|\mathcal{T}_{\leq i}|$ is not necessarily non-decreasing with i since projection of a set family to a subset could result in the loss of sets from the family. Consequently, $|\mathcal{T}_{\leq i}|$ is not suitable as a potential function to measure progress. Instead, we use the potential function $\phi(i) := |\mathcal{T}_{\leq i}| + 3|\mathcal{Z}_{\leq i-1}|$, where $\mathcal{Z}_{\leq i}$ is the union of the sets $\mathcal{Z}$ computed up to the i^{th} recursive call. We show that $\phi(i)$ is non-decreasing and strictly increases if $i \in P_1$ (Claim 6.4 in Lemma 6.12 of the full version). Consequently, $|P_1| = O(|V|)$.

Secondly, we bound $|P_2|$ as follows. We use a lookahead-potential function: let $\Phi_1(i)$ be the number of recursive calls between i and ℓ during which the merged hyperedge $e \cup f$ survives in the hypergraph (H', w') that is input to the subsequent recursive call and let $\Phi(i) := |E_i| + \Phi_1(i)$, where E_i is the set of hyperedges in the hypergraph (H_i, w_i) input to the i^{th} recursive call. We show that $\Phi(i)$ is non-increasing and strictly decreases if $i \in P_2$ (Claim 6.5 in Lemma 6.12 of the full version). Hence, $|P_2| \leq \Phi(1) - \Phi(\ell) \leq \Phi(1) \leq |E_1| + |P_1| = |E| + O(|V|)$, where the last equality is because of the bound on $|P_1|$ from the previous paragraph.

▶ Remark 19. Our key technical contributions are twofold. Our first key technical contribution is identifying conditions (a) and (b) under which $\mathcal{T}_{p,H,w}$ becomes a disjoint family. We ensure that conditions (a) and (b) hold in every recursive call by performing *immediate* reduction and clean-up steps in the algorithm. Our second key technical contribution is identifying appropriate potential functions to measure progress of the algorithm. The disjointness of $\mathcal{T}_{p,H,w}$ was crucial for identifying the laminar structure of the family of projected maximal tight sets across recursive calls, which was subsequently helpful in bounding the number of recursive calls corresponding to P_1. Moreover, we bound the number of recursive calls corresponding to P_2 using a lookahead-potential function that relates $|P_2|$ to $|P_1|$. As discussed above, the additive $|E|$ in the recursion depth comes from the bound on $|P_2|$.

2 Conclusion

We introduced a splitting-off operation in (weighted) hypergraphs. Our contribution on this front is conceptualizing an appropriate notion of splitting-off in hypergraphs. Next, we proved that for every hypergraph there exists a local-connectivity preserving complete h-splitting-off at an arbitrary vertex from the hypergraph. Although our proof of existence follows from previously known existential results of Bernáth and Király [5] for an abstract function cover problem, our main contribution is identifying that our newly introduced notion of hypergraph splitting-off falls within their framework. Next, we designed a strongly polynomial-time algorithm to find a local-connectivity preserving complete splitting-off at a vertex. This involved substantial technical challenges to overcome. In particular, our main contribution towards the strongly polynomial-time algorithm is a strengthening of the above-mentioned existential result: we showed that there exists a local connectivity preserving complete h-splitting-off at an arbitrary vertex from the hypergraph *in which the number of additional hyperedges is polynomial in the number of vertices*. The strongly polynomial-time algorithm follows from our techniques to achieve this stronger existential result via standard algorithmic tools in submodularity. Finally, we illustrated the usefulness of the existence of local connectivity preserving complete h-splitting-off at an arbitrary vertex from a hypergraph by presenting two applications. Our first application is to give a constructive characterization of k-hyperedge-connected hypergraphs. Our second application is to give an alternative proof of an approximate min-max relation for the max Steiner rooted-connected orientation problem in graphs and hypergraphs. Two notable features of our proof of this relation for *graphs* are that (1) it avoids the strong orientation theorem of Nash-Williams and (2) it proves a result for graphs using tools developed for hypergraphs.

Local and global connectivity preserving complete splitting-off at a vertex from a graph is a powerful operation for graphs. It finds applications in a variety of graph problems including graph orientation [25, 26, 38, 48], connectivity augmentation [2, 22, 23, 24, 49], minimum cuts enumeration [29, 32, 50], network design [12, 17, 35, 46], tree packing [7, 33, 40, 41], congruency-constrained cuts [51], and approximation algorithms for TSP [8, 30]. We believe that our local connectivity preserving complete splitting-off results for hypergraphs is likely to find future applications akin to its counterpart in graphs. We mention some of the open questions raised by our work:

1. Our work focused on local connectivity preserving complete *h-splitting-off* at a vertex from a hypergraph. We gave an example showing that local/global connectivity preserving complete *g-splitting-off* at a vertex from a hypergraph may not exist (Figure 2). Are there sufficient conditions to guarantee local/global connectivity preserving complete *g-splitting-off* at a vertex from a hypergraph? We recall that Lovász's [45, 47] and Mader's [48] results give sufficient conditions to guarantee local and global connectivity preserving complete g-splitting-off at a vertex from a *graph*.
2. As one of the applications of our splitting-off result, we presented an alternative proof of an approximate min-max relation for the max Steiner *rooted*-connected orientation problem in hypergraphs. The computational complexity of a closely related hypergraph orientation problem is open: In max Steiner connected orientation problem in hypergraphs, the input is a hypergraph $G = (V, E)$ and a subset T of terminals. The goal is to find the maximum k and an orientation $\overrightarrow{G}$ of G such that $\overrightarrow{G}$ contains k hyperarc-disjoint paths from u to v for every pair of distinct terminals $u, v \in T$. Max Steiner connected orientation problem in *graphs* is solvable in polynomial time via the Nash-Williams' strong orientation theorem. Is max Steiner connected orientation problem in *hypergraphs* solvable in polynomial time?

Abstract

Valiant's famous VP vs. VNP conjecture states that the symbolic permanent polynomial does not have polynomial-size algebraic circuits. However, the best upper bound on the size of the circuits computing the permanent is exponential. Informally, VNP is an exponential sum of VP-circuits. In this paper we study whether, in general, exponential sums (of algebraic circuits) *require* exponential-size algebraic circuits. We show that the famous Shub-Smale τ-conjecture indeed implies such an exponential lower bound for an exponential sum. Our main tools come from parameterized complexity. Along the way, we also prove an exponential fpt (fixed-parameter tractable) lower bound for the parameterized algebraic complexity class $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}]$, assuming the same conjecture. $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}]$ can be thought of as the weighted sums of (unbounded-degree) circuits, where only ± 1 constants are *cost-free*. To the best of our knowledge, this is the *first* time the Shub-Smale τ-conjecture has been applied to prove explicit exponential lower bounds.

Furthermore, we prove that when this class is fpt, then a variant of the counting hierarchy, namely the *linear counting hierarchy* collapses. Moreover, if a certain type of parameterized exponential sums is fpt, then integers, as well as polynomials with coefficients being *definable* in the linear counting hierarchy have subpolynomial τ-complexity.

Finally, we characterize a related class $\mathsf{VW}[\mathsf{F}]$, in terms of permanents, where we consider an exponential sum of algebraic formulas instead of circuits. We show that when we sum over cycle covers that have one long cycle and all other cycles have constant length, then the resulting family of polynomials is *complete* for $\mathsf{VW}[\mathsf{F}]$ on certain types of graphs.

1 Introduction

Valiant [23] proposed an algebraic version of the P versus NP question and defined the class VP, the algebraic analogue of P, which contains polynomial families computable by polynomial sized algebraic circuits. An *algebraic circuit* (or, arithmetic circuit) C is a directed acyclic graph such that (1) every node has either in-degree (*fan-in*) 0 (the *input gates*) or 2 (the *computational gates*), (2) every input gate is labeled by elements from a field $\mathbb{K}$ or variables from $\mathbf{X} = \{X_1, \cdots, X_n\}$, (3) every computational gate is labeled by either $+$

(addition gate) or $\times$ (multiplication gate), with the obvious syntactic meaning, and (4) there is a unique gate of out-degree 0, the *output gate*. Clearly, every gate in a circuit computes a polynomial in $\mathbb{K}[\mathbf{X}]$. We say that the circuit C computes $P(\mathbf{X}) \in \mathbb{K}[\mathbf{X}]$ if the output gate of C computes $P(\mathbf{X})$. The *size* of C, denoted by $\text{size}(C)$, is the number of nodes in the circuit. An algebraic circuit is an *algebraic formula* if every gate in the circuit has out-degree 1 except for the output gate. The class VNP, the algebraic analogue of NP, is definable by taking *exponential sums* of the form

$$f(\mathbf{X}) = \sum_{e \in \{0,1\}^\ell} g(\mathbf{X}, e) \,, \tag{1}$$

where g is computable by a polynomial-size circuit and ℓ is polynomial in the number of variables. It is known that one can also replace algebraic circuits by algebraic formulas, and still get the same class VNP [23, 18]. Valiant further proved that the permanent family is complete for VNP (over fields of characteristic not two). Recall that the permanent of a matrix $(X_{i,j})$ is defined as

$$\operatorname{per} \mathbf{X} = \sum_{\pi \in S_n} X_{1,\pi(1)} \cdots X_{n,\pi(n)}. \tag{2}$$

The famous Valiant's conjecture $\mathsf{VP} \neq \mathsf{VNP}$ is equivalent to the fact that the permanent does not have polynomial-size circuits. The representation of the permanent in (2), although it looks very natural, is not *optimal*. Ryser's formula [19] yields an algebraic formula of size $O(2^n n^2)$. A formula of similar size was later found by Glynn [11]. Ryser's formula is now over sixty years old and has not been improved since. This gives rise to the interesting question whether there is a formula or circuit of subexponential-size (in n) for the permanent? More generally, we can now ask the following question.

▶ **Question 1.** *Is an exponential sum f (as in Eq. (1)) always computable by an algebraic circuit or formulas of size subexponential in ℓ, that is, size $2^{o(\ell)}$? Or are there instances for which exponential-size is necessary?*

Note that exponential-size being necessary is a much *stronger* claim than $\mathsf{VP} \neq \mathsf{VNP}$. It could well be that $\mathsf{VP} \neq \mathsf{VNP}$ but still exponential sums like in (1) have subxponential size circuits! In this paper, we shed some light on the question what happens if exponential sums would always have *subexponential* size circuits.

Question 1 works as driving force between the famous Shub-Smale τ-conjecture [20] and *exponential* lower bounds on exponential sums. The τ-complexity $\tau(f)$ of an integer polynomial is the size of a smallest division-free circuit that computes f starting from the constants ± 1. The *τ-conjecture* states the the number of integer zeroes of f is polynomially bounded in $\tau(f)$, see [20]. [20] shows that the τ-conjecture implies $\mathsf{P}_{\mathbb{C}} \neq \mathsf{NP}_{\mathbb{C}}$, in the Blum–Shub–Smale (BSS) model of computation over the complex numbers [5, 4].

Super-polynomial lower bounds assuming the τ-conjecture. Bürgisser [6] connected the τ-complexity of the permanent to various other conjectures. He showed that the τ-conjecture implies a *superpolynomial* lower bound on $\tau(\text{per}_n)$, implying the constant-free version of $\mathsf{VP} \neq \mathsf{VNP}$, namely $\mathsf{VP}^0 \neq \mathsf{VNP}^0$; for definitions, see Section 2.1. The proof strategy of [6] is as follows: assume $\tau(\text{per}_n) = \mathsf{poly}(n)$, and conclude a complexity-theoretic "collapse" that the counting hierarchy CH (for a definition, see Section 3) is in $\mathsf{P/poly}$. Consider the Pochhammer–Wilkinson polynomial $f_n(x) := \prod_{i=1}^{n}(x-i)$, and construct a unique $O(\log n)$-variate multilinear polynomial B_n such that under a "suitable" substitution, one gets back f_n.

The coefficients of f_n as well as B_n, are efficiently computable (since $\mathsf{CH} \subseteq \mathsf{P/poly}$), implying $B_n \in \mathsf{VNP}^0$. An inspection of Valiant's completeness result reveals that if $B_n \in \mathsf{VNP}^0$, then there is a polynomially bounded sequence $p(n)$ such that $\tau(2^{p(n)}B_n) = \mathsf{poly}(\log n)$, which implies $\tau(2^{p(n)}f_n) = \mathsf{poly}(\log n)$, contradicting the τ-conjecture.

In [6], the superpolynomial lower bound on $\tau(\mathrm{per}_n)$ was also implied by any of the quantities $\tau(n!)$, $\tau(\sum_{k=0}^{n} \frac{1}{k!}T^k)$, or $\tau(\sum_{k=0}^{n} k^r T^k)$ (for any fixed negative integer r) not being poly-logarithmically bounded as a function of n. Here, we remark that the separation proof of VP^0 and VNP^0, even assuming *strong* bounds on the τ-conjecture, is merely *superpolynomial*: we *do not* get the (possibly) desirable exponential separation between VP^0 and VNP^0. This leads to the following question.

▶ **Question 2.** *Does the τ-conjecture imply exponential algebraic lower bounds?*

Here, we mention that there are variants of the τ-conjecture, e.g., the *real τ-conjecture* [15, 21] or *SOS-τ-conjecture* [8], which also give strong algebraic lower bounds. There is also super polynomial lower bound known from a proof complexity theoretic view due to [1] from the original Shub-Smale τ-conjecture. However, the Shub-Smale τ-conjecture is *not known* to give an exponential lower bound for the permanent.

1.1 Our results

The results of our paper revolve around answering both Question 1-2 positively. The main result is the following.

▶ **Theorem 1** (Informal). *The τ-conjecture implies an exponential lower bound for some explicit exponential sum.*

Remarks.

(1) Although the existence of *some* polynomial requiring exponential circuits is clear from dimension/counting, the existence of an (even non-explicit) exponential sum polynomial requiring exponential-size circuits is *unclear*. Explicit here means that the family is in VNP.

(2) One can also think of an exponential sum f in Equation (1), as $f = \sum_{e\in\{0,1\}^{\ell(n)}} U(\mathbf{X}, y, e)$, where $U(\mathbf{X}, \mathbf{Y}, \mathbf{Z})$ is a *universal circuit* of size $\mathrm{size}(U) = \mathsf{poly}(\mathrm{size}(g))$ with $\mathbf{Y} = (Y_1, \ldots, Y_r)$ and $\mathbf{Z} = (Z_1, \ldots, Z_{\ell(n)})$ and $y \in \mathbb{F}^r$ is chosen such that $U(\mathbf{X}, y, e) = g(\mathbf{X}, e)$; and the number of variables $\ell(n)$ is linear in n.

(3) Since there's a polynomial (non-linear) blowup in the reduction of the exponential sum on the universal circuit from the permanent, we will only get a subexponential lower bound on the permanent polynomial assuming the τ-conjecture. We leave it as an open question to achieve an exponential lower bound on the permanent assuming the τ-conjecture.

The proof of Theorem 1 is rather indirect, and goes via *exponential sums*, which is our main object of study (and bridge between many results and classes).

log-variate exponential sum polynomial. Let $g(\mathbf{X}, \mathbf{Y})$ be some polynomial in n-many $\mathbf{X}$-variables and $\ell(n)$-many $\mathbf{Y}$-variables, where $\ell(n) = O(n)$. Assume that g is computed by a circuit of size m. Then we define

$$\mathsf{p\text{-}log\text{-}Expsum}_{m,k}(g) := \sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y) ,$$

where $k = n/\log m$. The size of the exponential is measured in the number $\ell(n)$ of $\mathbf{Y}$-variables. In the end, we want to measure in the input size, the number n of $\mathbf{X}$-variables. To talk about subexponential complexity, $\ell(n)$ should be linearly bounded. g will be typically computed by a circuit (of unbounded degree). We want to view $\mathsf{p\text{-}log\text{-}Expsum}_{m,k}$ as a parameterized problem, the parameter will be k. Our definition of p-log-Expsum, as a polynomial-sum, is motivated by the *log-parameterizations* which are used in the definition of the so-called M-hierarchy in the Boolean setting, see [9, 10].

We show that p-log-Expsum is most likely *not* fixed-parameter tractable (fpt). A polynomial family $p_{n,k}$ is fpt if both its size and degree are fpt bounded, i.e., of the form $f(k)q(n)$, for $q \leq \mathsf{poly}(n)$, and $f : \mathbb{N} \to \mathbb{N}$ being *any* computable function. We connect p-log-Expsum with – (1) a linear variant of the counting hierarchy (we denote it by $\mathsf{CH}_{\mathrm{lin}}$), where the size of the oracle calls are bounded linearly in the size of the input; for definition see Section 3; and (2) integers definable in $\mathsf{CH}_{\mathrm{lin}}$, similar to Bürgisser [6]. Informally, an integer is definable in $\mathsf{CH}_{\mathrm{lin}}$, if its sign and bits are computable in the same class.

▶ **Theorem 2** (Informal). *If* p-log-Expsum *is fixed-parameter tractable, then the following results hold.*

1. *The linear counting hierarchy (*$\mathsf{CH}_{\mathrm{lin}}$*) collapses.*
2. *Any sequence $a(n)$ definable in the linear counting hierarchy, as well as univariate polynomials with coefficients being definable in the linear counting hierarchy, have subpolynomial τ-complexity.*

For formal statements, see Theorem 13 and 21.

Finally, many algebraic complexity classes can be defined in terms of permanents. Most prominently, the "regular" permanent family (per_n) is complete for VNP. The class VW[1] is an important class in parameterized complexity. It is defined as a bounded sum over constant depth weft-1 circuits. Bounded sum means that we sum over $\{0,1\}$-vectors with k ones and k is the parameter. Bläser and Engels [3] prove that VW[1] is described by so-called k-permanents with k being the parameter. In a k-permanent, we only sum over permutations with $n-k$ self-loops. The crucial parameterized class of this work is VW[P]: it is defined as a bounded exponential sum over polynomially-sized arithmetic circuits computing a polynomial of degree that is polynomially bounded. While we do not characterise VW[P] in terms of permanents, we characterize the related class VW[F]: Here instead of summing over circuits, we sum over *formulas*.[1] The permutations that we sum over for defining our permanent family will have one cycle of length k and all other cycles bounded by 4. Again, k is the parameter. We call the corresponding polynomials $(k,4)$-restricted permanents. It turns out that we also need to restrict the graph classes. We call a graph $G = (V,E)$ $(4,b)$-nice if we can partition the set $V = V_1 \cup V_2$ disjointly, such that in the induced graph $G[V_1]$, every cycle is either a self-loop or has length > 4 and in the induced graph $G[V_2]$ has tree-width bounded by b. While this looks artificial at a first glance, it turns out that there is a constant b such that $(k,4)$-restricted permanent on $(4,b)$-nice graphs describes the natural class VW[F]. There is a family of $(4,b)$-nice graphs such that the corresponding family of $(k,4)$-restricted permanents is VW[F]-hard. On the other hand, the $(k,4)$-restricted permanent family is in VW[F] for every family of $(4,b)$-nice graphs. Together, this implies:

▶ **Theorem 3** (VW[F]-Completeness). *$(k,4)$-restricted permanent family on $(4,b)$-nice graphs is* VW[F]*-complete.*

[1] Maybe an explanation of the naming convention is helpful: In VW[P], we sum of polynomial-size circuits, which describe the class VP. In VW[F], we sum over polynomial size formulas, which define the class VF, the modern name for VP_e.

We also prove strong separations of algebraic complexity classes and parameterized algebraic complexity classes (Theorem 30), and exponential lower bounds in the parameterized setting (Theorem 36).
For VNP it is known that it does not matter whether we sum over formulas or circuits, that is, $\mathsf{VNP} = \mathsf{VNP}_e$. Whether $\mathsf{VW[P]} = \mathsf{VW[F]}$ remains an open questions for future research.

1.2 Proof ideas

In this section, we briefly sketch the proof ideas. The omitted proofs of the paper can be found in the longer arxiv version of the paper. We first present the proofs of Theorem 2, because the techniques and lemmas involved in proving them are the backbone of Theorem 1.

Proof idea of Theorem 2. We prove them in two parts.
Proof of Part (1): We prove even a stronger statement for the subexponential version of the linear counting hierarchy. The proof goes via induction on the level of the counting hierarchy. The criteria for some language B being in the $(k+1)$-th level is that there should be some language A in the k-th level such that $|\{y \in \{0,1\}^n : \langle x, y\rangle \in A\}| > 2^{n-1}$. Essentially, for a language A in the k-th level, we express $|\{y \in \{0,1\}^n : \langle x, y\rangle \in A\}| > 2^{n-1}$ as an exponential sum over an algebraic circuit $\chi_A(x, y)$, which captures the characteristic function of A. Furthermore, one can show that p-log-Expsum is fpt (in an unbounded constant-free setting) iff $\sum_y g(\mathbf{X}, y)$ has $2^{o(n)}\mathsf{poly}(m)$ size circuits, where g has a circuit of size m; see Theorem 15 and 16. Putting these together, one gets that the exponential sum has a subexponential-size constant-free circuit. Lastly, we want to get the information about the highest bit of the sum (which is equivalent to looking at it mod 2^n), which can be efficiently *arithmetized*. In every step there is polynomial blowup in the size, and hence the size remains subexponential, yielding the desired result. For details, see Theorem 13.
Proof of Part (2): This proof is an adaption of [6, 14] in our context. Take a sequence $(a_n)_n \in \mathsf{CH}_{\mathsf{lin}}\mathsf{P}$. We define a multilinear polynomial $A(\mathbf{Y})$ such that the coefficient of $\mathbf{Y}^{\mathbf{j}}$ is the j-th bit of $a(n)$, where $\mathbf{j}$ is the binary representation of j. Furthermore, checking $a(n, j) = b$ can be done by a subexponential circuit $C(\mathbf{N}, \mathbf{J})$, where $\mathbf{N}$ and $\mathbf{J}$ have $\log n$ and $\mathsf{bit}(n)$-many variables capturing n and j respectively. Moreover, one can define $F(\mathbf{N}, \mathbf{Y}, \mathbf{J}) = C(\mathbf{N}, \mathbf{J}) \cdot \prod_i (J_i Y_i + 1 - J_i)$ and show that A can be expressed as an exponential sum over $F(j, \mathbf{N}, \mathbf{Y})$! This is clearly a p-log-Expsum instance, which finally yields that the τ-complexity of $a(n)$ is subpolynomial. A similar proof strategy also holds for the polynomials with coefficients being definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$. For details, see Section 6.

Proof idea of Theorem 1. Take the Pochhammer polynomial $p_n(X) = \prod_{i=1}^{n}(X + i)$. The coefficient of X^{n-k} in p_n will be $\sigma_k(1, \ldots, n)$, where $\sigma_k(z_1, \ldots, z_n)$ is the k-th elementary symmetric polynomial in variables $z_1, \ldots, z_n$. It is not hard to show that $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ is closed under polynomially-many additions and multiplications (Theorem 19). Therefore, $(\sigma_k(1, \ldots, n))_{n\in\mathbb{N}, k\le n}$ is definable in the linear counting hierarchy (see Corollary 20). And by Theorem 21, $(p_n)_{n\in\mathbb{N}}$ has $n^{o(1)}$-sized constant-free circuits if p-log-Expsum is fixed-parameter tractable. But p_n has n distinct integer roots. Assuming the τ-conjecture, p-log-Expsum is not *fpt*. On the other hand, one can show that when exponential sums over circuits of size m have circuits have size $2^{o(n)}\mathsf{poly}(m)$, then the p-log-Expsum is fpt, by Theorem 16; in other words, p-log-Expsum is not fpt implies an exponential lower bound on an exponential sum. This finishes the proof.

Proof idea of Theorem 3. The hardness proof is *gadget* based (Theorem 42). The details are however quite complicated since we have to cleverly keep track of the cycle lengths. For the upper bound, we work along a tree decomposition. While it is known that the permanent can be computed in fpt time on graphs of bounded treewidth, we cannot simply adapt these algorithms, since we have to produce a formula. This can be achieved using a *balanced tree decomposition*.

1.3 Previous results

To prove (conditional) exponential lower bounds, the standard assumptions that $\mathsf{P} \neq \mathsf{NP}$ or $\mathsf{VP} \neq \mathsf{VNP}$ are not enough. It is consistent with our current knowledge that for instance $\mathsf{P} \neq \mathsf{NP}$, but NP-hard problems can have subexponential time algorithms. What we need is a complexity assumption stating that certain problems can only be solved in exponential time. This is the exponential time hypothesis (ETH) in the Boolean setting. Dell et al. [7] studied the exponential time complexity of the permanent, they prove that when there is an algorithm for computing the permanent in time $2^{o(n)}$, then this violates the counting version of the exponential time hypothesis #ETH. #ETH states that there is a constant c such that no deterministic algorithm can count the number of satisfying assignments of a formula in 3-CNF in time 2^{cn}. For connections between parameterized and subexponential complexity in the Boolean setting, we refer to [9, 10].

Bläser and Engels [3] transfer the important definitions and results from parameterized complexity in the Boolean world to define a theory of parameterized algebraic complexity classes. In particular, they define the VW-hierarchy and prove that the clique polynomial and the k-permanent are $\mathsf{VW}[1]$-complete (under so-called fpt-substitutions). They also claim the hardness of the restricted permanent for the class $\mathsf{VW}[t]$ for every constant t and sketch a proof. Note that $\mathsf{VW}[\mathsf{F}]$ contains each $\mathsf{VW}[t]$. So we strengthen the hardness proof in [3] and complement it with an upper bound.

The main tool used by Bürgisser [6] to prove the results above is the counting hierarchy. The polynomial counting hierarchy was introduced by Wagner [24] to classify the complexity of Boolean counting problems. The fact that small circuits for the permanent collapses the counting hierarchy is used by Bürgisser to prove the results mentioned above.

Finally, there have been quite a few works [6, 14, 16, 15], where we have conditional separations on the constant-free version of VP and VNP, namely VP^0 and VNP^0, or their variants, depending on the strength of the conjecture. But this is the first time that we are separating algebraic classes and proving exponential lower bounds, assuming the τ-conjecture.

1.4 Structure of the paper

In Section 2, we defined the basics of constant-free Valiant's model and the unbounded and parameterized setting. In Section 3, we introduce the linear counting hierarchy ($\mathsf{CH}_{\mathrm{lin}}$) and its basic properties. Section 4 connects Valiant's model to the counting hierarchy. Here, we formally introduce exponential sums and investigate their relation to the parameterized classes. The main result is that the fixed-parameter tractability of exponential sums collapses the counting hierarchy. The proofs are quite similar to [6], however, we need to pay special attention to the fact the witness size is linear. Section 5 introduces the definability (computability) of integers in the linear counting hierarchy, and some closure properties of the same. Section 6 proves the exponential lower bound on exponential sum assuming τ-conjecture. Section 7 introduces the parameterized VW-classes and its basic properties. In Section 8 we prove some easy conditional collapse results of the VW-hierarchy in various circuit models.

2 Preliminaries I

2.1 Constant-free and unbounded models

Constant-free Valiant's classes. We will say that an algebraic circuit is *constant-free*, if no field elements other than $\{-1, 0, 1\}$ are used for labeling in the circuit. Clearly, constant-free circuits can *only* compute polynomials in $\mathbb{Z}[\mathbf{X}]$. For $f(X) \in \mathbb{Z}[\mathbf{X}]$, $\tau(f)$ is the size of a minimum size constant-free circuit that computes f, while $L(f)$ denotes the minimum size circuit that computes f. It is noteworthy to observe that, *unlike* Valiant's classical models, computing integers in the constant-free model can be costly; e.g., $\tau(2^{2^n}X^n) = \Omega(n)$, while $L(2^{2^n}X^n) = \Theta(\log n)$. On the other hand, for any $f \in \mathbb{Z}[\mathbf{X}]$, $L(f) \leq \tau(f)$.

Before defining the constant-free Valiant classes, we formalize the notion of *formal degree* of a node, denoted formal-deg$(\cdot)$. It is defined recursively as follows: (1) the formal degree of an input gate is 1, (2) if $u = v + w$, then formal-deg$(u) = \max($formal-deg$(v),$ formal-deg$(w))$, and (3) if $u = v \times w$, then formal-deg$(u) =$ formal-deg$(v) +$ formal-deg(w). The formal degree of a circuit is defined as the formal degree of its output node.

The class *constant-free Valiant's* P, denoted by VP^0, contains all p-$\mathsf{families}$ (f) in $\mathbb{Z}[\mathbf{X}]$, such that formal-deg(f) and $\tau(f)$ are both p-$\mathsf{bounded}$. Analogously, VNP^0 contains all p-$\mathsf{families}$ (f_n), such that there exists a p-$\mathsf{bounded}$ function $q(n)$ and $(g_n) \in \mathsf{VP}^0$, where

$$f_n(\mathbf{X}) = \sum_{\overline{y} \in \{0,1\}^{q(n)}} g_n(\mathbf{X}, y_1, \ldots, y_{q(n)}) .$$

It is not clear whether showing $\mathsf{VP}^0 \neq \mathsf{VNP}^0$ implies $\mathsf{VP} \neq \mathsf{VNP}$, it is *not even clear* whether $\mathsf{VP}^0 \neq \mathsf{VNP}^0 \implies \tau(\mathrm{per}_n) = n^{\omega(1)}$. The *subtlety* here is that in the algebraic completeness proof for the permanent, *divisions by two* occur! However, a partial implication is known due to [6, Theorem 2.10]: Showing $\tau(2^{p(n)}f_n) = n^{\omega(1)}$, for some $f_n \in \mathsf{VNP}^0$ and all p-$\mathsf{bounded}$ $p(n)$ would imply that $\tau(\mathrm{per}_n) = n^{\omega(1)}$.

Arithmetization is a well-known technique in complexity theory. To arithmetize a Boolean circuit C computing a Boolean function φ, we use the arithmetization technique wherein we map $\varphi(x_1, \ldots, x_n)$ to a polynomial $p(x_1, \ldots, x_n)$ such that for any assignment of Boolean values $v_i \in \{0, 1\}$ to the x_i, $\varphi(v_1, \ldots, v_n) = p(v_1, \ldots, v_n)$ holds.

We define the arithmetization map Γ for variables x_i, and clauses $c_1, \ldots, c_m$, as follows:

1. $x_i \mapsto x_i$,
2. $\neg x_i \mapsto 1 - x_i$,
3. $c_1 \vee \cdots \vee c_m \mapsto 1 - \prod_{i \in [m]}(1 - \Gamma(c_i))$,
4. $c_1 \wedge \cdots \wedge c_m \mapsto \prod_{i \in [m]} \Gamma(c_i)$.

This map allows us to transform C into an arithmetic circuit for p. For a Boolean circuit C, we denote the arithmetized circuit by $\mathsf{arithmetize}(C)$. Here, we remark that the degree of $\mathsf{arithmetize}(C)$ can become *exponentially* large; this is because there is no known depth-reduction for Boolean circuits, and hence the degree may double at each step, owing to an exponential blowup in the degree.

Valiant's classes in the unbounded setting. It is well-known that an algebraic circuit of size s, can compute polynomials of degree $\exp(s)$; e.g., $f(x) = x^{2^s}$, and $L(f) = O(s)$. This brings us to the next definition, the class $\mathsf{VP}_{\mathrm{nb}}$, originally defined in [17]. A sequence of polynomials $(f) = (f_n)_n \in \mathsf{VP}_{\mathrm{nb}}$, if the number of variables in f_n and $L(f_n)$ are both p-$\mathsf{bounded}$ (the degree *may be* exponentially large). The subscript "nb" signifies the *"not bounded"* phenomenon on the degree of the polynomial, in contrast to the original class VP. Similarly, a sequence of polynomials $(f) = (f_n)_n \in \mathsf{VNP}_{\mathrm{nb}}$, if there exists a p-$\mathsf{bounded}$ function $q(n)$ and $g_n(\mathbf{X}, Y_1, \ldots, Y_{q(n)}) \in \mathsf{VP}_{\mathrm{nb}}$ where

$$f_n(\mathbf{X}) \;=\; \sum_{\overline{y}\in\{0,1\}^{q(n)}} g_n(\mathbf{X}, y_1, \ldots, y_{q(n)}) \;.$$

One can analogously define $\mathsf{VP}^0_{\mathrm{nb}}$ and $\mathsf{VNP}^0_{\mathrm{nb}}$, in the constant-free setting. It is obvious that $\mathsf{VP}_{\mathrm{nb}} = \mathsf{VNP}_{\mathrm{nb}}$ implies $\mathsf{VP} = \mathsf{VNP}$, but the converse is *unclear*. However, [17] showed that over a ring of positive characteristic, the converse holds, i.e., $\mathsf{VP} = \mathsf{VNP}$ implies $\mathsf{VP}_{\mathrm{nb}} = \mathsf{VNP}_{\mathrm{nb}}$! On the other hand, [16] showed that $\mathsf{VP}^0 = \mathsf{VNP}^0$ implies that $\mathsf{VP}^0_{\mathrm{nb}} = \mathsf{VNP}^0_{\mathrm{nb}}$, and the converse is unclear because it seems difficult to rule out the possibility that some polynomial family in VNP^0 does not lie in VP^0, but still in VP (i.e., computable by polynomial-size algebraic circuits using *exponentially large-bit* integers).

2.2 Parameterized Valiant's classes

Parameterized Valiant's classes were introduced in [3]. We will briefly review the definitions and results there and extend them to the constant-free and unbounded setting. We first start with the fixed-parameter tractable classes. The W-hierarchies will be introduced later since we only need them in the second part of this work.

Our families of polynomials will now have two indices. They will be of the form $(p_{n,k})$. Here, n is the index of the family and k is the parameter. We will say a polynomial family $(p_{n,k})$ is a *parameterized* p-family if the number of variables is p-bounded in n and the degree is p-bounded in n, k. If there is no bound on the degree, we say it is *parameterized* family.

The most natural parameterization is by the degree: Let (p_n) be any p-family then we get a parameterized family $(p_{n,k})$ by setting $p_{n,k} :=$ the homogeneous part of degree k of p_n. For more details, we will refer the reader to [3].

We now define fixed-parameter variants of Valiant's classes with the constant-free version.

▶ **Definition 4** (Algebraic FPT classes)**.**

1. *A parameterized* p-family $(p_{n,k})$ *is in* VFPT *iff* $L(p_{n,k})$ *is upper bounded by* $f(k)q(n)$ *for some* p-bounded *function* q *and some function* $f : \mathbb{N} \to \mathbb{N}$ *(such bound will be called an fpt bound). If one removes the requirement of* p-family *on* $p_{n,k}$*, and imposes only that the number of variables is* p-bounded*, one gets the class* $\mathsf{VFPT}_{\mathrm{nb}}$*.*
2. *A parameterized* p-family $p_{n,k}$ *is in* VFPT^0 *iff* $\tau(p_{n,k})$ *is upper bounded by* $f(k)q(n)$ *for some* p-bounded *function* q *and some function* $f : \mathbb{N} \to \mathbb{N}$*. Similarly, one gets* $\mathsf{VFPT}^0_{\mathrm{nb}}$*, if one removes the requirement of* p-family*, and imposes only that the number of variables is* p-bounded*.*

We remark that in the above, f need not be computable as Valiant's model is non-uniform.

▶ **Definition 5** (Fpt-projection)**.** *A parameterized family* $f = (f_{n,k})$ *is an fpt-projection of another parameterized family* $g = (g_{n,k})$ *if there are functions* $r, s, t : \mathbb{N} \to \mathbb{N}$ *such that* r *is* p-bounded*,* s, t *are functions and* $f_{n,k}$ *is a projection of* $g_{r(n)s(k),k'}$ *for some* $k' \leq t(k)$*,*[2]*. We write* $f \leq^{\mathrm{fpt}}_p g$*.*

However p-projection in Valiant's world seems to be *weaker* compared to parsimonious poly-time reduction in the Boolean world; therefore we need a stronger notion of reduction for defining algebraic models of the Boolean $\#W$-classes, see [3]. That's why we are defining substitutions. We will analogously define it for constant-free model as well.

[2] k' might depend on n, but its size is bounded by a function in k. There are examples in the Boolean world, where this dependence on n is used.

▶ **Definition 6** (Fpt-substitution).

1. *A parameterized family $f = (f_{n,k})$ is an fpt-substitution of another parameterized family $g = (g_{n,k})$ if there are functions $r, s, t, u : \mathbb{N} \to \mathbb{N}$ and polynomials $h_1, \ldots, h_{u(r(n)s(k))} \in \mathbb{K}[\mathbf{X}]$ with both $L(h_i)$ and $deg(h_i)$ fpt-bounded such that r, u are p-bounded, s, t are functions, and $f_{n,k}(\mathbf{X}) = g_{r(n)s(k),k'}(h_1, \ldots, h_{u(r(n)s(k))})$ for some $k' \leq t(k)$. We write $f \leq_s^{\text{fpt}} g$. When we allow* **unbounded** *degree substitution of h_i (i.e. only $L(h_i)$ is fpt-bounded), we say that f is an fpt_{nb}-substitution of g. We denote this as $f \leq_s^{\text{fpt}_{\text{nb}}} g$.*
2. *A parameterized family $f = (f_{n,k})$ is a constant-free fpt-substitution of another parameterized family $g = (g_{n,k})$ if there are functions $r, s, t, u : \mathbb{N} \to \mathbb{N}$ and polynomials $h_1, \ldots, h_{u(r(n)s(k))} \in \mathbb{K}[\mathbf{X}]$ with both $\tau(h_i)$ and $deg(h_i)$ are fpt-bounded such that r, u are p-bounded, s, t are functions and $f_{n,k}(\mathbf{X}) = g_{r(n)s(k),k'}(h_1, \ldots, h_{u(r(n)s(k))})$ for some $k' \leq t(k)$. We write $f \leq_s^{\tau\text{-fpt}} g$. If we remove the degree condition, we get fpt_{nb}-substitutions, denoted as $f \leq_s^{\tau\text{-fpt}_{\text{nb}}} g$.*

One can define constant-free fpt-projections analogously. The following lemma should be immediate from the definitions, see [3] for a proof in the case of VFPT.

▶ **Lemma 7.** $\mathsf{VFPT}, \mathsf{VFPT}_{\text{nb}}$ *and their constant-free versions (*VFPT^0, $\mathsf{VFPT}^0_{\text{nb}}$*) are* closed *under fpt-projections and fpt-substitutions (constant-free fpt-projections and constant-free fpt-substitutions, respectively).*

3 Linear counting hierarchy

In this section, we define the linear counting hierarchy, a variant of the counting hierarchy, which will allow us to talk about subexponential complexity. The original counting hierarchy was defined by Wagner [24]. We here restrict the witness length to be linear, which is important when dealing with exponential complexity. Allender et al. [2] also define a linear counting hierarchy. Their definition is not comparable to ours. We use an operator-based definition: The base class is deterministic polynomial time and the witness length is linearly bounded. Allender et al. use an oracle TM definition: The oracle Turing machine is probabilistic and linear time bounded, which automatically bounds the query lengths.

▶ **Definition 8.** *Given a complexity class K, we define $\mathbf{C}.K$ to be the class of all languages A such that there is some $B \in K$ and a function $p : \mathbb{N} \to \mathbb{N}$, $p(n) = O(n^c)$ for some constant c, and some polynomial time computable function $f : \{0,1\}^* \to \mathbb{N}$ such that,*

$$x \in A \iff |\{y \in \{0,1\}^{p(|x|)} : \langle x, y\rangle \in B\}| > f(x).$$

We start from $\mathsf{C}_0\mathsf{P} := \mathsf{P}$ and for all $k \in \mathbb{N}$, $\mathsf{C}_{k+1}\mathsf{P} := \mathbf{C}.\mathsf{C}_k\mathsf{P}$. Then the *counting hierarchy* is defined as $\mathsf{CH} := \bigcup_{k \geq 0} \mathsf{C}_k\mathsf{P}$. We now define our linear counting hierarchy:

▶ **Definition 9.** *Given a complexity class K, we define $\mathbf{C}_{\mathsf{lin}}.K$ to be the class of all languages A such that there is some $B \in K$ and a function $\ell : \mathbb{N} \to \mathbb{N}$, $\ell(n) = O(n)$, and some polynomial time computable function $f : \{0,1\}^* \to \mathbb{N}$ such that,*

$$x \in A \iff |\{y \in \{0,1\}^{\ell(|x|)} : \langle x, y\rangle \in B\}| > f(x).$$

We define $\mathsf{C\text{-}lin}_0\mathsf{P} := \mathsf{P}$ and for all $k \in \mathbb{N}$, $\mathsf{C\text{-}lin}_{k+1}\mathsf{P} := \mathbf{C}_{\mathsf{lin}}.\mathsf{C\text{-}lin}_k\mathsf{P}$. The *linear counting hierarchy* is $\mathsf{CH}_{\mathsf{lin}}\mathsf{P} := \bigcup_{k \geq 0} \mathsf{C\text{-}lin}_k\mathsf{P}$.

Now, we slightly modify the above definition to get $\exists_{\mathsf{lin}}.K$ and $\forall_{\mathsf{lin}}.K$ in the following way: $x \in A \iff \exists y \in \{0,1\}^{\ell(|x|)} : \langle x, y\rangle \in B$ and $x \in A \iff \forall y \in \{0,1\}^{\ell(|x|)} : \langle x, y\rangle \in B$, respectively. Clearly, it can be said that $K \subseteq \exists_{\mathsf{lin}}.K \subseteq \mathbf{C}_{\mathsf{lin}}.K$ and $K \subseteq \forall_{\mathsf{lin}}.K \subseteq \mathbf{C}_{\mathsf{lin}}.K$.

We can define the linear counting hierarchy in a slightly easier manner.

▶ **Definition 10.** *Given a complexity class K, we define $\mathbf{C}'_{\mathsf{lin}}.K$ to be the class of all languages A such that there is some $B \in K$ and a function $\ell : \mathbb{N} \to \mathbb{N}$, $\ell(n) = O(n)$, such that*

$$x \in A \iff |\{y \in \{0,1\}^{\ell(|x|)} : \langle x, y\rangle \in B\}| > 2^{\ell(|x|)-1}.$$

It is clear that $\mathbf{C}'_{\mathsf{lin}}.K \subseteq \mathbf{C}_{\mathsf{lin}}.K$ for any class K. Moreover, by an easy adaption of the proof of [22, Lemma 3.3], for any language $K \in \mathsf{CH}$, $\mathbf{C}_{\mathsf{lin}}.K \subseteq \mathbf{C}'_{\mathsf{lin}}.K$. Also, from the definition, we can say that $\mathsf{CH}_{\mathsf{lin}}\mathsf{P} \subseteq \mathsf{CH}$. Therefore, the following holds.

▶ **Fact 11.** $\mathsf{C\text{-}lin}_{k+1}\mathsf{P} = \mathbf{C}'_{\mathsf{lin}}.\mathsf{C\text{-}lin}_k\mathsf{P}$.

We also need a subexponential version of the counting hierarchy. Let $\mathsf{SUBEXP} = \mathsf{DTime}(2^{o(n)})$. Then we set $\mathsf{C\text{-}lin}_0\mathsf{SUBEXP} = \mathsf{SUBEXP}$ and for all $k \in \mathbb{N}$, $\mathsf{C\text{-}lin}_{k+1}\mathsf{SUBEXP} := \mathbf{C}_{\mathsf{lin}}.\mathsf{C\text{-}lin}_k\mathsf{SUBEXP}$. Moreover, $\mathsf{CH}_{\mathsf{lin}}\mathsf{SUBEXP} = \bigcup_{k\geq 0} \mathsf{C\text{-}lin}_k\mathsf{SUBEXP}$.

Here we define a few more terms that we shall use later in Section 5. We set $\mathsf{NP}_{\mathsf{lin}} = \exists_{\mathsf{lin}}.\mathsf{P}$, NP with linear witness size. In the same way, we can define the levels of the linear polynomial time hierarchy, Σ_i^{lin} and Π_i^{lin}, by applying the operators $\exists_{\mathsf{lin}}$ and $\forall_{\mathsf{lin}}$ in an alternating fashion to P. The linear polynomial hierarchy $\mathsf{PH}_{\mathsf{lin}}$ is the union over all Σ_i^{lin}.

From the above definitions, we get the following conclusion.

▶ **Fact 12.** $\mathsf{NP}_{\mathsf{lin}} \subseteq \mathsf{PH}_{\mathsf{lin}} \subseteq \mathsf{CH}_{\mathsf{lin}}$.

4 Connecting Valiant's model to the counting hierarchy

In this section, we aim to prove that subexponential upper bounds for exponential sums imply a collapse of the linear counting hierarchy (for a definition, see Section 3). To show this, we will define a polynomial family p-log-Expsum and show that p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}}$ is equivalent to exponential sums having subexponential circuits (Corollary 34). p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}}$ will imply a collapse of the linear counting hierarchy (Theorem 13).

4.1 log-variate exponential sum polynomial family

In this section, we will define a parameterized log-variate exponential sum polynomial family,

$$\mathsf{p\text{-}log\text{-}Expsum}_{m,k}(g) := \sum_{y\in\{0,1\}^{\ell(n)}} g_n(\mathbf{X}, y)\ ,$$

where $\mathbf{X}$ has n variables, $\ell(n) = O(n)$, and g_n has circuits of size m ($n = \Omega(\log m)$), and the parameter is $k = \frac{n}{\log m}$. m and k are functions of n. Note that the running parameter of the family is m. When we write p-log-Expsum $\in \mathsf{VFPT}$, we mean that $\{\mathsf{p\text{-}log\text{-}Expsum}_{m,k}(g)\}_{m,k} \in \mathsf{VFPT}$ for all families g. We are allowing g to have *unbounded* degree, i.e., g may not necessarily be a *p*-family. We will also be using constant-free circuits computing g in the constant-free context.

4.2 Collapsing of $\mathsf{CH}_{\mathsf{lin}}\mathsf{SUBEXP}$

The main theorem of the section is the following:

▶ **Theorem 13.** *If* p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}}$, *then for every language L in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{SUBEXP}$, *we have a constant-free algebraic circuit χ_L so that $x \in L \implies \chi_L(x) = 1$, $x \notin L \implies \chi_L(x) = 0$ and χ_L has size $2^{o(n)}$.*

Proof. We prove the above statement by induction on the level of $\mathsf{CH}_{\mathsf{lin}}\mathsf{SUBEXP}$. By definition, $\mathsf{CH}_{\mathsf{lin}}\mathsf{SUBEXP} = \bigcup_{k\geq 0} \mathsf{C\text{-}lin}_k\mathsf{SUBEXP}$. For $k = 0$, $\mathsf{C\text{-}lin}_k\mathsf{SUBEXP} = \mathsf{SUBEXP}$. Now by standard arithmetization, we can get a $2^{o(n)}$ size, unbounded degree constant-free circuit for each $L \in \mathsf{SUBEXP}$, so that the above-mentioned condition holds.

Now, by induction hypothesis say, it is true up to k-th level of the hierarchy. We will prove that it is true for the $(k+1)$-th level. Take any $B \in \mathsf{C\text{-}lin}_{k+1}\mathsf{SUBEXP}$. By Fact 11 and Definition 10, there exists $A \in \mathsf{C\text{-}lin}_k\mathsf{SUBEXP}$ such that

$$x \in B \iff |\{y \in \{0,1\}^{\ell(|x|)} : \langle x, y\rangle \in A\}| > 2^{\ell(|x|)-1},$$

where ℓ is some linear polynomial. By slight abuse of notation, let χ_A denote an algebraic circuit capturing the characteristic function for A, i.e.,

$$\chi_A(x, y) = 1 \iff \langle x, y\rangle \in A .$$

By the induction hypothesis, we can assume that χ_A has size $2^{o(|x|)}$. Now, one can equivalently write the following:

$$x \in B \iff \sum_{y\in\{0,1\}^{\ell(|x|)}} \chi_A(x, y) > 2^{\ell(|x|)-1} .$$

In this way, we get an instance of $\mathsf{p\text{-}log\text{-}Expsum}$, $\sum_{y\in\{0,1\}^{\ell(|x|)}} \chi_A(x, y)$, where the size of χ_A is $m = 2^{o(|x|)}$ and it computes a polynomial of *unbounded degree* (there is no depth-reduction known for Boolean circuits and thus, it cannot be reduced).

As $\mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathsf{nb}}$, there is an algebraic circuit C such that $C(x) := \sum_{y\in\{0,1\}^{\ell(|x|)}} \chi_A(x, y)$ and C has subexponential-size by Theorem 15.

Trivially, $\tau(2^{\ell(|x|)-1}) \leq \mathsf{poly}(|x|)$. So, we can make C first constant-free and then Boolean by the standard procedure of computing on the binary representation modulo $2^{\ell(n)}$. Let $\tilde{C}$ is the Boolean circuit that computes the highest bit. We just arithmetize $\tilde{C}$ and take $\chi_B = \mathsf{arithmetize}(\tilde{C})$. Each time we convert the arithmetic circuit to a Boolean one and arithmetize the Boolean circuit, we incur only a small polynomial blow-up in size. Therefore, χ_B has subexponential-size, as desired. ◀

▶ Remark 14. Clearly, $\mathsf{CH}_{\mathsf{lin}}\mathsf{P} \subseteq \mathsf{CH}_{\mathsf{lin}}\mathsf{SUBEXP}$ and hence, $\mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathrm{nb}}$ implies that every language in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ has subexponential-size constant-free algebraic circuits.

▶ **Theorem 15.** *If* $\mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathrm{nb}}$, *then* $\sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$ *has circuits of size* $2^{o(n)}\mathsf{poly}(m)$.

Proof. Assume that $\mathsf{p\text{-}log\text{-}Expsum}$ has circuits of size $f(n/\log m)\mathsf{poly}(m)$. We can assume that f is an increasing function. Let $i(n) = \max(\{1\} \cup \{j \mid f(j) \leq n\})$. $i(n)$ is nondecreasing and unbounded. Moreover, $f(i(n)) \leq n$ for all but finitely many n.

We will prove that $\sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$ has circuits of size $2^{n/i(n)}\mathsf{poly}(m)$. If $m \geq 2^{n/i(n)}$, then $f(n/\log m) \leq f(i(n)) \leq n$, thus there are circuits of size $n \cdot \mathsf{poly}(m) = \mathsf{poly}(m)$. If $m < 2^{n/i(n)}$, then let $\hat{m} = 2^{n/i(n)}$. We can take a circuit C for g and pad it to a circuit $\hat{C}$ of size s with $\hat{m} \leq s \leq O(\hat{m})$, such that $\hat{C}$ has the same variables as C. Then let $\hat{k} = n/\log \hat{m}$. Thus, $\sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$ has circuits of size $f(\hat{k})\mathsf{poly}(\hat{m}) = n \cdot \mathsf{poly}(2^{n/i(n)})$. ◀

We will need the unbounded version as stated above, but a similar proof also works for the bounded case. The same is true of the non-constant-free version. We will also need the following converse direction:

▶ **Theorem 16.** *Let* $\sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$ *have circuits of size* $2^{o(n)}\mathsf{poly}(m)$ *for each* g *of size* m. *Then* p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}}$.

Proof. Let C_n be a circuit for $\sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$ of size $2^{O(n/i(n))}\mathsf{poly}(m)$ for some non-decreasing and unbounded function i. Let f be a nondecreasing function such that $f(i(n)) \geq 2^n$. We claim that p-log-Expsum has circuits of size $f(k)\mathsf{poly}(m)$ with $k = n/\log m$. If $m \geq 2^{n/i(n)}$, then C_n has size $\mathsf{poly}(m) \leq f(k)\mathsf{poly}(m)$. Otherwise, $k = n/\log m \geq i(n)$ and therefore $f(k) \geq 2^n$. Thus, the trivial circuit for $\sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$ has size $f(k)\mathsf{poly}(m)$. ◀

5 Integers definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$

In [6, Section 3], integers are studied that are definable in the counting hierarchy. We adapt this notation to the *linear* counting hierarchy. Formally, we are given a sequence of integers $(a(n,k))_{n\in\mathbb{N},k\leq q(n)}$ for some p-bounded function $q : \mathbb{N} \to \mathbb{N}$. We can assume that $|a(n,k)| \leq 2^{n^c}$ for some constant c. In other words, the bit-size of $a(n,k)$ is at most *exponential*, as we think n, k has been represented in binary by $O(\log n)$ bits. Now consider two languages,

$$\mathsf{sgn}(a) := \{(n,k) : a(n,k) \geq 0\} \text{ and}$$
$$\mathsf{Bit}(|a|) := \{(n,k,j,b) : j\text{th bit of } |a(n,k)| \text{ is } b\} .$$

Here in both of these two languages, n, k, j are given in binary representation.

▶ **Definition 17.** *We say an integer sequence* $(a(n,k))_{n\in\mathbb{N},k\leq q(n)}$ *for some* p-bounded *function* q *is definable in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ *whenever both of* $\mathsf{sgn}(a)$ *and* $\mathsf{Bit}(|a|)$ *are in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$.

Chinese remainder language. Now, we define another language and make a connection to the definition of an integer sequence to be definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$, via the *Chinese remainder representation*. Given that the bit-size of $a(n,k)$ is at most n^c, we consider the set of all primes $p < n^{2c}$. The product of all such primes is $> 2^{n^c}$. Therefore, from $a(n,k) \bmod p$, for all primes $p < n^{2c}$, we can recover $a(n,k)$. Consider

$$\mathsf{CR}(a) := \left\{(n,k,p,j,b) : p \text{ prime}, p < n^{2c}, j\text{-th bit of } (a(n,k) \bmod p) \text{ is } b\right\} .$$

Now we show an essential criterion for a sequence to be in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$. It is an adaption with some additional modifications and observations from [12], which were further implemented in [6, Theorem 3.5].

▶ **Theorem 18.** *Let* $(a(n,k))_{n\in\mathbb{N},k\leq q(n)}$ *be a integer sequence of exponential bit-size* $(|a(n,k)| < 2^{n^c})$. *Then,* $(a(n,k))$ *is definable in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ *iff both* $\mathsf{sgn}(a)$ *and* $\mathsf{CR}(a)$ *are in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$.

Now, we can prove an important *closure* property of non-negative integers definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$, which we shall use later.

▶ **Theorem 19** (Closure properties). *Let* $(a(n,k))_{n\in\mathbb{N},k\leq q(n)}$ *be a non-negative integer sequence for some* p-bounded *function* $q : \mathbb{N} \to \mathbb{N}$ *with* $a(n,k)$ *having bit-size* $< n^c$ *and it is definable in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$. *Consider the sum and product of* $a(n,k)$ *defined as follows:*

$$b(n) := \sum_{k=0}^{q(n)} a(n,k) \quad \text{and} \quad c(n) := \prod_{k=0}^{q(n)} a(n,k) .$$

Then, both of $(b(n))_{n\in\mathbb{N}}$ *and* $(c(n))_{n\in\mathbb{N}}$ *are definable in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$.

▶ **Corollary 20.** *Take* $a(n,k) := \sigma_{n,k}(1,\ldots,n)$, $k \leq n$, *where* $\sigma_{n,k}(z_1,\ldots,z_n)$ *is the* k*-th elementary symmetric polynomial on variables* $z_1,\ldots,z_n$. *Then,* $(a(n,k))_{n\in\mathbb{N},k\leq n}$ *is definable in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$.

6 Connecting the counting hierarchy to the τ-conjecture

In this section, we connect the τ-conjecture to the counting hierarchy. Specifically, we show that the collapse of $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ implies that some explicit polynomial, whose coefficients are definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$, is "easy". Formally, we prove the following theorem:

▶ **Theorem 21.** *Say,* $(a(n))_{n\in\mathbb{N}}$ *and* $(b(n,k))_{k\leq q(n),n\in\mathbb{N}}$ *are both definable in* $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$. *Here* q *is some* p-bounded *function. If* $\mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathrm{nb}}$ *then the following holds:*

1. $\tau(a(n)) = n^{o(1)}$,
2. *If* $f_n(X) := \sum_{k=1}^{q(n)} b(n,k)X^k$ *then* $\tau(f_n) = n^{o(1)}$.

Proof. We can assume that if $a(n)$ is definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$, $|a(n)| \leq 2^{n^c}$, that is, the bit-size of any integer definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ is polynomially bounded. Furthermore, if $\mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathrm{nb}}$, then every language in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$ has subexponential-size circuits by Theorem 13. We will use both facts below.

Proof of part (1). Let $a(n) = \sum_{j=1}^{p(n)} a(n,j)2^j$ be the binary decomposition of $a(n)$ and $p(n) = O(n^c)$. Define a new polynomial:

$$A_{\lceil \log n\rceil}(Y_1,\ldots,Y_{\mathsf{bit}(n)}) := \sum_{j=0}^{p(n)} a(n,j)Y_1^{j_1}\ldots Y_{\mathsf{bit}(n)}^{j_{\mathsf{bit}(n)}},$$

where $\mathsf{bit}(n) := \lceil \log(p(n))\rceil$. By our assumption, we can decide if $a(n,j) = b$ by a subexponential-size circuit, given input n and j in binary. Say, $C_r(\mathbf{N},\mathbf{J})$ is the corresponding circuit, where $r = \lfloor \log n\rfloor$. We have $C_r(n_1,\ldots,n_{\lfloor \log n\rfloor+1},j_1,\ldots,j_{\mathsf{bit}(n)}) = a(n,j)$, where the n_i's and the j_i's are the bits of n and j, respectively. Consider the polynomial

$$F_r(J_1,\ldots,J_{cr+1},N_1,\ldots,N_{r+1},Y_1,\ldots,Y_{cr+1}) := C_r(\mathbf{N},\mathbf{J})\cdot\prod_{i=1}^{cr+1}(J_iY_i+1-J_i).$$

Now, by our assumption and Theorem 13, we can say that F_r has $2^{o(r)}$ size constant-free algebraic circuits (of unbounded degree). Consider the exponential sum

$$\tilde{F}_r(\mathbf{N},\mathbf{Y}) := \sum_{j\in\{0,1\}^{cr+1}} F_r(j,\mathbf{N},\mathbf{Y}).$$

It is an instance of $\mathsf{p\text{-}log\text{-}Expsum}$ with $\tau(F_r) = 2^{o(r)}$. By assumption, this implies that $\tau(\tilde{F}_r) = 2^{o(r)}$. Finally, note that $A_{\lceil \log n\rceil}(\mathbf{Y}) = \tilde{F}_r(n_1,\ldots,n_{r+1},\mathbf{Y})$, and $a(n) = A_{\lceil \log n\rceil}(2^{2^0},\ldots,2^{2^{\mathsf{bit}(n)-1}})$. Therefore,

$$\tau(a(n)) \leq \tau(\tilde{F}_r) + \tau(2^{2^{\mathsf{bit}(n)-1}}) \leq n^{o(1)},$$

as desired.

Proof of part (2). Again we can assume that $|b(n,k)|$ has polynomially many bits. Let $b(n,k) = \sum_{j=1}^{p(n)} b(n,k,j)2^j$ be the binary decomposition with $p(n) = O(n^{c'})$ and $q(n) = O(n^c)$. Define

$$B_{\lceil \log n \rceil}(Y_1, \ldots, Y_{\mu(n)}, Z_1, \ldots, Z_{\lambda(n)}) \;:=\; \sum_{k=0}^{q(n)} \sum_{j=0}^{p(n)} b(n,k,j) Y_1^{j_1} \ldots Y_{\mu(n)}^{j_{\mu(n)}} Z_1^{k_1} \ldots Z_{\lambda(n)}^{k_{\lambda(n)}} .$$

Here $\mu(n) := \lceil \log(p(n)) \rceil$ and $\lambda(n) := \lceil \log(q(n)) \rceil$. Let the variable sets be $\mathbf{J} = (J_1, \ldots, J_{c'r+1}), \mathbf{N} = (N_1, \ldots, N_{r+1}), \mathbf{K} = (K_1, \ldots, K_{cr+1}), \mathbf{Y} = (Y_1, \ldots, Y_{c'r+1}), \mathbf{Z} = (Z_1, \ldots, Z_{cr+1})$, where again $r = \lfloor \log n \rfloor$. Define a new polynomial F_r as follows:

$$F_r(\mathbf{J}, \mathbf{K}, \mathbf{N}, \mathbf{Y}, \mathbf{Z}) \;:=\; D_r(\mathbf{N}, \mathbf{J}, \mathbf{K}) \cdot \prod_{m=1}^{c'r+1} (J_m Y_m + 1 - J_m) \prod_{s=1}^{cr+1} (K_s Z_s + 1 - Z_s) .$$

Like in the previous part of the proof, $(D_r(\mathbf{N}, \mathbf{J}, \mathbf{K}))_r$ is the circuit family for computing $(b(n,k,j))$. In particular,

$$D_r(n_1, \ldots, n_{r+1}, j_1, \ldots, j_{\mu(n)}, k_1, \ldots, k_{\lambda(n)}) \;=\; b(n,k,j) .$$

By our assumption, D_r has $2^{o(r)}$ size constant-free algebraic circuits (of unbounded degree). Consider,

$$\tilde{F}_r(\mathbf{N}, \mathbf{Y}, \mathbf{Z}) = \sum_{j \in \{0,1\}^{c'r+1}} \sum_{k \in \{0,1\}^{cr+1}} F_r(j, k, \mathbf{N}, \mathbf{Y}, \mathbf{Z}).$$

It is an instance of p-log-Expsum with $\tau(F_r)$ is $2^{o(r)}$. Since p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}} \implies \tau(\tilde{F}_r) = 2^{o(r)}$. Now, $B_{\lceil \log n \rceil}(\mathbf{Y}, \mathbf{Z}) = F_r(n_1, \ldots, n_{r+1}, \mathbf{Y}, \mathbf{Z})$ and

$$f_n(X) \;=\; B_{\lceil \log n \rceil}(2^{2^0}, \ldots, 2^{2^{\mu(n)-1}}, X^{2^0}, \ldots, X^{2^{\lambda(n)-1}}) .$$

Therefore, $\tau(f_n) \;\leq\; \tau(B_{\lceil \log n \rceil}) + \tau(2^{2^{\mu(n)}}) + \tau(X^{2^{\lambda(n)}}) \;\leq\; n^{o(1)}$, as desired. ◀

▶ **Theorem 22.** *If the τ-conjecture is true, then* p-log-Expsum $\notin \mathsf{VFPT}^0_{\mathrm{nb}}$.

Proof. Take the Pochhammer polynomial $p_n(X) = \prod_{i=1}^{n}(X+i)$. The coefficient of X^{n-k} in p_n will be $\sigma_k(1, \ldots, n)$, where $\sigma_k(z_1, \ldots, z_n)$ is the k-th elementary symmetric polynomial in variables $z_1, \ldots, z_n$. And $(\sigma_k(1, \ldots, n))_{n \in \mathbb{N}, k \leq n}$ is definable in linear counting hierarchy by Corollary 20. By Theorem 21, $(p_n)_{n \in \mathbb{N}}$ has $n^{o(1)}$ size constant-free circuit if p-log-Expsum is fixed-parameter tractable. But p_n has distinct n many integer roots. So, assuming the τ-conjecture, p-log-Expsum is not *fpt*. ◀

▶ Remark 23. Instead of taking the Pochhammer polynomial, there are many other possible choices for some explicit polynomial, see [6].

Finally, we prove the exponential lower bound for an exponential sum, proving Theorem 1.

▶ **Theorem 24** (Exponential algebraic lower bound)**.** *If the τ-conjecture is true, then there exists an n-variate polynomial family $\sum_{y \in \{0,1\}^n} g_n(X, y)$, which requires $2^{\Omega(n)}$-size circuits.*

Proof. If the τ-conjecture is true, then Theorem 22 shows that p-log-Expsum $\notin \mathsf{VFPT}^0_{\mathrm{nb}}$. By the contrapositive statement of Theorem 16, the existence of such a hard exponential sum follows. ◀

▶ Remark 25. The family g_n simply is a universal circuit of size polynomial in n, where the polynomial is large enough to simulate the computation of the Turing machine that shows that the n-th Pochhammer polynomial is definable in $\mathsf{CH}_{\mathsf{lin}}\mathsf{P}$.

7 Preliminaries II: The VW-hierarchy

In this section, we define different variants of the VW-hierarchy, which will be analogous to $\#W$-hierarchy, see [3]. We will consider circuits that can have unbounded fanin gates.

▶ **Definition 26** (Weft). *For an algebraic circuit C, the weft of C is the maximum number of unbounded fan-in gates on any path from a leaf to the root.*

For $n \geq k \in \mathbb{N}$, let $\langle {n \atop k} \rangle$ be the set of all vectors in $\{0,1\}^n$ which have exactly k many 1s.

▶ **Definition 27.**

1. *A parameterized p-*family $f_{n,k}(\mathbf{X})$ *is in* $\mathsf{VW}[\mathsf{F}]$ *iff there exists a p-*bounded *function $q(n)$ and p-*family $g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ *such that* $f_{n,k} \leq_s^{\text{fpt}} \sum_{\overline{y} \in \langle {q(n) \atop k} \rangle} g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ *and g_n can be computed by a polynomial-size formula.*
2. *A parameterized family $f_{n,k}(\mathbf{X})$ is in* $\mathsf{VW}_{\text{nb}}[\mathsf{F}]$ *iff there exists a p-*bounded *function $q(n)$ and family $g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ such that* $f_{n,k} \leq_s^{\text{fpt}_{\text{nb}}} \sum_{\overline{y} \in \langle {q(n) \atop k} \rangle} g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ *and g_n can be computed by a polynomial-size formula.*
3. *A parameterized p-*family $f_{n,k}(\mathbf{X})$ *is in* $\mathsf{VW}^0[\mathsf{F}]$ *iff there exists a p-*bounded *function $q(n)$ and p-*family $g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ *such that* $f_{n,k} \leq_s^{\tau\text{-fpt}} \sum_{\overline{y} \in \langle {q(n) \atop k} \rangle} g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ *and g_n can be computed by a constant-free, polynomial-size formula.*
4. *A parameterized family $f_{n,k}(\mathbf{X})$ is in* $\mathsf{VW}^0_{\text{nb}}[\mathsf{F}]$ *iff there exists a p-*bounded *function $q(n)$ and family $g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ such that* $f_{n,k} \leq_s^{\tau\text{-fpt}_{\text{nb}}} \sum_{\overline{y} \in \langle {q(n) \atop k} \rangle} g_n(\mathbf{X}, y_1, \ldots, y_{q(n)})$ *and g_n can be computed by a constant-free, polynomial-size formula.*

In some sense, $\mathsf{VW}[\mathsf{F}]$ is a substitution of a *weighted sum* of formulas. We will define $\mathsf{VW}[\mathsf{P}]$ as a weighted sum as above, but summing over an arbitrary circuit of polynomial-size. Similarly, we can define $\mathsf{VW}^0[\mathsf{P}]$, and its counterpart in the unbounded setting, i.e. $\mathsf{VW}_{\text{nb}}[\mathsf{P}]$, and $\mathsf{VW}^0_{\text{nb}}[\mathsf{P}]$.

Finally, we will define the completeness notion:

▶ **Definition 28.** *We will say a parameterized p-*family $f_{n,k}$ *is* $\mathsf{VW}[\mathsf{F}]$*-hard if every* $g_{n,k} \in \mathsf{VW}[\mathsf{F}]$, $g_{n,k} \leq_s^{\text{fpt}} f_{n,q}$. *Similarly, we can define completeness for* $\mathsf{VW}[\mathsf{P}]$.

We can also define completeness and hardness in the constant-free and unbounded models.

8 Conditional collapsing of VW-hierarchy and applications

Let us recall the definition of k-degree n-variate ($n \geq k$) *elementary symmetric polynomial* $\sigma_{n,k}(\mathbf{X}) := \sum_{y \in \langle {n \atop k} \rangle} X_1^{y_1} X_2^{y_2} \ldots X_n^{y_n}$. It is known that $(\sigma_{n,k})_n \in \mathsf{VP}^0$, with a simple dynamic programming algorithm; see [13, Section 4]. Let us define a new polynomial family $B_{n,k}(\mathbf{X})$, which will be important in the latter part of the section: $B_{n,k}(\mathbf{X}) := \sum_{t=0}^{n-k} (-1)^t \binom{k+t}{k} \cdot \sigma_{n,k+t}(\mathbf{X})$. The following claim is crucial:

▷ Claim 29. For $y \in \{0,1\}^n$, $B_{n,k}(y) = \begin{cases} 1, & \text{if } y \in \langle {n \atop k} \rangle, \\ 0, & \text{otherwise.} \end{cases}$

Proof. For a string $y \in \{0,1\}^n$, we will call the *weight* of y, denoted $\text{wt}(y)$, the number of 1's present in y. Note that if $\text{wt}(y) < k$, then $\sigma_{n,k}(y) = 0$ implying $B_{n,k}(y) = 0$. Similarly if $\text{wt}(y) = k$, then $B_{n,k}(y) = \sigma_{n,k}(y)$, which will be exactly equal to 1. Now if $\text{wt}(y) = k + r$ where $r > 0$, then

$$B_{n,k}(y) \;=\; \sum_{t=0}^{n-k}(-1)^t\binom{k+t}{k}\cdot\sigma_{n,k+t}(y) \;=\; \sum_{t=0}^{r}(-1)^t\binom{k+t}{k}\cdot\sigma_{n,k+t}(y)$$
$$= \sum_{t=0}^{r}(-1)^t\binom{k+t}{k}\cdot\binom{k+r}{k+t}$$
$$= \sum_{t=0}^{r}(-1)^t\frac{(k+r)!}{k!t!(r-t)!}\,.$$

Let us further define the tri-variate polynomial $Q(x,y,z) := (x+y-z)^{k+r} \in \mathbb{Z}[x,y,z]$. Note that the coefficient of x^k in $Q(x,y,z)$ is

$$\sum_{t=0}^{r} y^{r-t}z^t(-1)^t\cdot\frac{(k+r)!}{k!t!(r-t)!}\,.$$

Now putting $y=z=1$, we get the coefficient exactly equal to $B_{n,k}(y)$; since $r\neq 0$, we can say that the coefficient of x^k in $Q(x,1,1)$ is 0, which finally implies that $B_{n,k}(y)=0$. ◁

Now we are ready to prove the following transfer theorem from the parameterized Valiant's classes to Valiant's algebraic models.

▶ **Theorem 30.** $\mathsf{VW}^0[\mathsf{P}] \neq \mathsf{VFPT}^0 \implies \mathsf{VP}^0 \neq \mathsf{VNP}^0$. *Similarly,* $\mathsf{VW}[\mathsf{P}] \neq \mathsf{VFPT} \implies \mathsf{VP} \neq \mathsf{VNP}$.

Proof. We will prove the contraposition. Assume that $\mathsf{VP}^0 = \mathsf{VNP}^0$. As mentioned before, we know that $(\sigma_{n,k})_n \in \mathsf{VP}^0$. Further, since $k \in [n]$, for $t \leq n-k$, it is trivial to see that $\tau(\binom{k+t}{k}) = n^{O(1)}$. Therefore, for each $0 \leq t \leq n-k$, $(-1)^t\binom{k+t}{k}\cdot\sigma_{n,k+t}(\mathbf{X})$ has a VP^0-circuit. Since VP^0 is closed under polynomially many additions, it follows that $(B_{n,k})_n \in \mathsf{VP}^0$.

Let $q_{n,k} \in \mathsf{VW}^0[\mathsf{P}]$. By definition, there is a polynomial family $p_{n,k}$ of the above form $p_{n,k}(\mathbf{X}) := \sum_{y\in\langle{n \atop k}\rangle} g_n(\mathbf{X},y)$, where $g_n(\mathbf{X},\mathbf{Y})$ is in VP^0, such that $q_{n,k} \leq_s^{fpt} p_{n,k}$. By Claim 29, it follows that

$$p_{n,k} \;=\; \sum_{y\in\{0,1\}^n} g_n(\mathbf{X},y)\cdot B_{n,k}(y)\,.$$

We have already proved above that $B_{n,k}$ has $\mathsf{poly}(n)$ sized constant-free circuits. Hence, $g_n(\mathbf{X},y)B_{n,k}(y)$ has constant-free $\mathsf{poly}(n)$-size circuit. Therefore, by definition and our primary assumption, it follows that $p_{n,k} \in \mathsf{VNP}^0 = \mathsf{VP}^0 \subseteq \mathsf{VFPT}^0$. Since, VFPT^0 is *closed* under constant-free fpt-substitution (Lemma 7), it follows that $q_{n,k} \in \mathsf{VFPT}^0$, implying $\mathsf{VW}^0[\mathsf{P}] \subseteq \mathsf{VFPT}^0$.

The proof in the usual (not constant-free) model also follows essentially along the same line as above. ◀

▶ Remark 31. The above theorem holds in the unbounded regime as well, i.e., $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}] \neq \mathsf{VFPT}^0_{\mathrm{nb}} \implies \mathsf{VP}^0_{\mathrm{nb}} \neq \mathsf{VNP}^0_{\mathrm{nb}}$ (which further implies $\mathsf{VP}^0 \neq \mathsf{VNP}^0$, see [16]). Similarly, $\mathsf{VW}_{\mathrm{nb}}[\mathsf{P}] \neq \mathsf{VFPT}_{\mathrm{nb}} \implies \mathsf{VP}_{\mathrm{nb}} \neq \mathsf{VNP}_{\mathrm{nb}}$.

We now aim to prove a *conditional separation* of $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}]$ and $\mathsf{VFPT}^0_{\mathrm{nb}}$, by showing that $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}] = \mathsf{VFPT}^0_{\mathrm{nb}}$ implies a collapse of the linear counting hierarchy. To show this, we will show that $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}] = \mathsf{VFPT}^0_{\mathrm{nb}} \implies \mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathrm{nb}}$ (Corollary 34) from which the collapse of the linear counting hierarchy follows.

▶ **Theorem 32.** *Let* $f(\mathbf{X}) = \sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X}, y)$, *where* $\ell(\cdot)$ *is a linear function and* g *is computed by an arithmetic circuit of size* $m = 2^{O(n^c)}$ *for some constant* c. *Then,* $f(\mathbf{X})$ *can be written as*

$$f(\mathbf{X}) = \sum_{e\in\langle {b(m) \atop k}\rangle} G(\mathbf{X}, e)\,,$$

for some p-bounded *function* b *and* $k = \ell(n)/\log m$ *and* G *has* poly(m) *size circuits.*

Proof. Let $f(\mathbf{X})$ be an instance of p-log-Expsum, i.e., $f(\mathbf{X}) = \sum_{y\in\{0,1\}^n} g(\mathbf{X}, y)$, where $g(\mathbf{X}, \mathbf{Y})$ has size m constant-free circuit. Here we mention that, although we just take sum over n *variables* here for the ease of presentation, the same proof also works if we sum over $\ell(n)$ many variables for some linear function ℓ.

Let us partition the variable set $\mathbf{Y} = \{Y_1, \ldots, Y_n\} = E_1 \sqcup \cdots \sqcup E_k$. Here $k = n/\log m$, and for all i, $|E_i| = \log m$. For each $S \subseteq E_i$, we take a *new variable* Z_i^S and we do this for all i. Define $\overline{Z_i} := \{Z_i^S : S \subseteq E_i\}$ and $\mathbf{Z} = \bigcup_i \overline{Z_i}$. The number of $\mathbf{Z}$-variables is $2^{\log m} \cdot k$, which is polynomial in m.

Let us call an assignment of $\mathbf{Z}$ variables a *good assignment*, if *exactly* one variable in each set $\overline{Z_i}$ is set to be 1. Below we show that there is a one-to-one correspondence between $\{0,1\}$ assignments to the $\mathbf{Y}$ variables and *good assignments* to the $\mathbf{Z}$ variables.

Let φ be a homomorphism from $R[\mathbf{Y}] \to R[\mathbf{Z}]$, where $R := \mathbb{F}[\mathbf{X}]$, such that $\varphi : Y_i \mapsto \prod_{S\subseteq E_i,\ Y_j\notin S}(1 - Z_i^S)$. Let us define $\tilde{g}(\mathbf{X}, \mathbf{Z}) := \varphi(g)$. Now let us fix an assignment $y \in \{0,1\}^n$ to the $\mathbf{Y}$ variables. We construct a corresponding good assignment of $\mathbf{Z}$. For each E_i of $\mathbf{Y}$, we have some $S_i \subseteq E_i$ such that *each* variable of E_i, which is in S_i, gets value 1. The remaining variables in $E_i \setminus S_i$ get value 0 (so that it corresponds to y). Pick this particular $S_i \subseteq E_i$. Note that this S_i is *unique* (it can be the empty set). Now set $Z_i^{S_i} = 1$ and $Z_i^S = 0$, if $S \neq S_i$, for all $i \in [k]$.

Each variable in $\bigcup_i S_i$ gets the value 1 and variables in $\bigcup_i (E_i \setminus S_i)$ are assigned 0. Under the map φ, any $Y_j \in E_1 \setminus S_1$ is replaced by $\prod_{S\subseteq E_1,\ Y_j\notin S}(1 - Z_1^S)$. Since, $S_1 \subseteq E_1$ and $Y_j \notin S_1$, $(1 - Z_1^{S_1})$ occurs in the product. And, hence the product becomes 0. Now, let $Y_\ell \in S_1$ and $\varphi(Y_\ell) = \prod_{S\subseteq E_1,\ Y_\ell\notin S}(1 - Z_1^S)$. As $Y_\ell \in S_1$, $(1 - Z_1^{S_1})$ does not contribute to the product. Thus, under the assignment defined before, $\varphi(Y_\ell)$ becomes 1. This argument holds for any E_i. Therefore, one can conclude that

$$f = \sum_{e:\ e \text{ is a } good \text{ assignment}} \tilde{g}(\mathbf{X}, e)\,.$$

Note that the weft of the circuit for $\tilde{g}$ has increased by 1 (from that of g), and the size has also increased by a polynomial (in m) factor. To capture a k-weight good assignment exactly, define a new polynomial $p(\mathbf{Z}) \in \mathbb{F}[\mathbf{Z}]$ as follows:

$$p(\mathbf{Z}) := \prod_{i=1}^{k} \left(\sum_{S\subseteq E_i} Z_j^S \right).$$

Clearly, p has a weft-2 circuit of size poly(m). Further, it is simple to see that for any k-weight $\{0,1\}$ assignment e to the $\mathbf{Z}$ variables, $p(e) = 1$ iff e is a *good* assignment because from each of the product terms, only one variable will survive. Therefore,

$$f = \sum_{e\in\langle {b(m) \atop k}\rangle} p(e) \cdot \tilde{g}(\mathbf{X}, e)\,, \qquad \text{where } b(m) = |\mathbf{Z}|\,.$$

We set $G(\mathbf{X},\mathbf{Z}) := p(\mathbf{Z})\tilde{g}(\mathbf{X},\mathbf{Z})$. By the construction, $\tilde{g}$ has weft $\leq t+1$, p has weft ≤ 2, and $\tilde{g}, p$ have $\mathsf{poly}(m)$ size circuits. So, this ends our proof. ◀

▶ Remark 33. The construction above increases the weft by one.

▶ **Corollary 34.** $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}] = \mathsf{VFPT}^0_{\mathrm{nb}} \implies \mathsf{p\text{-}log\text{-}Expsum} \in \mathsf{VFPT}^0_{\mathrm{nb}}$.

Proof. In Theorem 32 we have reduced an instance of p-log-Expsum to an instance of $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}]$ with parameter $k = \ell(n)/\log m$. By our assumption $\mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}] = \mathsf{VFPT}^0_{\mathrm{nb}}$ and thus we can say that p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}}$. ◀

▶ Remark 35. If one restricts p-log-Expsum to exponential sums over g, where g is a p-family (i.e., it has polynomial degree and size), denoted $\mathsf{p\text{-}log\text{-}Expsum}_{bd}$ (bd for bounded-degree), then the above proof similarly implies that $\mathsf{VW}^0[\mathsf{P}] = \mathsf{VFPT}^0 \implies \mathsf{p\text{-}log\text{-}Expsum}_{bd} \in \mathsf{VFPT}^0$.

Similarly, we also prove a lower bound for the class $\mathsf{VW}_{\mathrm{nb}}[\mathsf{P}]$, assuming an fpt lower bound on p-log-Expsum.

▶ **Theorem 36.** *Say that any family* $F_{m,k}(\mathbf{X}) = \sum_{e\in\langle {b(m) \atop k}\rangle} G(\mathbf{X},e) \in \mathsf{VW}^0_{\mathrm{nb}}[\mathsf{P}]$ *has* $2^{o(n)}\mathsf{poly}(m)$ *size constant-free circuits where* $\tau(G) \leq m$, $n := k\log m/c$, *for some constant* c *and* b *is some* p-bounded *function. Then,* p-log-Expsum $\in \mathsf{VFPT}^0_{\mathrm{nb}}$.

Proof. Take an instance of p-log-Expsum, $f(\mathbf{X}) = \sum_{y\in\{0,1\}^{\ell(n)}} g(\mathbf{X},y)$, for some $\ell(n) = O(n)$. And g has a constant-free circuit of size m. By Theorem 32, we can make it an instance of $\mathsf{VW}^0[\mathsf{P}]$ and say,

$$f = \sum_{e\in\langle {b(m) \atop k}\rangle} \tilde{g}(\mathbf{X},e)\,, \qquad \text{where } b \text{ is } p\text{-bounded}, \;\; k = \ell(n)/\log m$$

By our assumption, f has a constant-free circuit of size $2^{o(n)}\mathsf{poly}(m) = 2^{O(n/i(n))}\mathsf{poly}(m)$ for some unbounded and non-decreasing function $i : \mathbb{N} \to \mathbb{N}$. Let h be a non-decreasing function, so that $h(i(n)) \geq 2^n$. We shall prove that f has $h(k)\mathsf{poly}(m)$ size constant-free circuit. If $m \geq 2^{n/i(n)}$, clearly, f has $\mathsf{poly}(m)$ size constant-free circuit. Otherwise, if $m < 2^{n/i(n)}$, this will imply $i(n) \leq n/\log m = k$. And hence, $h(k) \geq 2^n$. So, f has $h(k)\mathsf{poly}(m)$ size constant-free circuit. ◀

9 Restricted permanent

A *cycle cover* of a directed graph is a collection of node-disjoint directed cycles such that each node is contained in exactly one cycle. Cycle covers of a directed graph stand in one-to-one relation with permutations of the nodes.

▶ **Definition 37.** *A cycle cover is* (k,c)*-restricted, if it contains one cycle of length* k *and all other cycles have length* $\leq c$.

Let $G = (V,E)$ be directed graph and $w : E \to R$ be a weight function. Here R is a ring and typically the ring of polynomials. The weight of a cycle cover C of G is the product of the weights of the edges in it, that is, $w(C) = \prod_{e\in C} w(e)$.

▶ **Definition 38.** *The* (k,c)*-restricted permanent of an edge-weighted directed graph* G *is*

$$\mathrm{per}^{(k,\leq c)}(G) = \sum_C w(C),$$

where the sum is over all (k,c)*-restricted cycle covers.*

If $X = (X_{i,j})$ is a variable matrix, then $\mathrm{per}_n(X)$ is the permanent of the complete directed graph with the edge weights $w(i,j) = X_{i,j}$. The (k,c)-restricted permanent family $\mathrm{per}^{(k,\leq c)} = (\mathrm{per}_n^{(k,\leq c)}(X_n))$, where X_n is an $n \times n$-variables matrix. $\mathrm{per}^{(k,\leq c)}$ is a parameterized family, n is the input size, k is the parameter, and c will be some constant to be determined later.

On general graphs, the restricted permanent is very powerful, even if we keep the parameter fixed.

▶ **Proposition 39.** *The $(2,2)$-restricted permanent family is* VNP*-complete.*

If we restrict the underlying graph appropriately, then the restricted permanent is complete for the class VW[F]. Recall that the girth of an undirected graph is the length of a shortest cycle in the graph. When we talk of the girth of a directed graph, we mean the girth of the graph when we disregard the direction of edges. Furthermore, when we talk about the treewidth of a directed graph, we mean the treewidth of the underlying undirected graph.

▶ **Definition 40.** *A directed graph $G = (V,E)$ is* (c,b)-nice *if we can partition the nodes $V = V_1 \cup V_2$ into two disjoint sets, such that*

1. *the graph induced by V_1 has girth $> c$ (not counting self-loops),*
2. *every node in V_1 has a self-loop, and*
3. *the graph induced by V_2 has tree-width bounded by b.*
4. *every cycle that contains vertices from V_1 and V_2 has length $> c$.*

Our main result is the following completeness result.

▶ **Theorem 41.** *Let c and b be constants. Let (G_n) be a family of (c,b)-nice graphs. Then the (k,c)-restricted permanent is in* VW[F].

▶ **Theorem 42.** *Let the underlying field have characteristic 0. There is a constant b and a family of $(4,b)$-nice graphs (H_n) such that the $(3k,4)$-restricted permanent of H_n forms a family of* VW[F]*-hard polynomials.*

Abstract

The Separating Hyperplane theorem is a fundamental result in Convex Geometry with myriad applications. The theorem asserts that for a point a not in a closed convex set K, there is a hyperplane with K on one side and a strictly on the other side. Our first result, Random Separating Hyperplane Theorem (RSH), is a strengthening of this for polytopes. RSH asserts that if the distance between a and a polytope K with k vertices and unit diameter in $\Re^d$ is at least δ, where δ is a fixed constant in $(0, 1)$, then a randomly chosen hyperplane separates a and K with probability at least $1/\operatorname{poly}(k)$ and margin at least $\Omega\left(\delta/\sqrt{d}\right)$.

RSH has algorithmic applications in learning polytopes. We consider a fundamental problem, denoted the "Hausdorff problem", of learning a unit diameter polytope K within Hausdorff distance δ, given an optimization oracle for K. Using RSH, we show that with polynomially many random queries to the optimization oracle, K can be approximated within error $O(\delta)$. To our knowledge, this is the first provable algorithm for the Hausdorff Problem in this setting. Building on this result, we show that if the vertices of K are well-separated, then an optimization oracle can be used to generate a list of points, each within distance $O(\delta)$ of K, with the property that the list contains a point close to each vertex of K. Further, we show how to prune this list to generate a (unique) approximation to each vertex of the polytope. We prove that in many latent variable settings, e.g., topic modeling, LDA, optimization oracles do exist provided we project to a suitable SVD subspace. Thus, our work yields the first efficient algorithm for finding approximations to the vertices of the latent polytope under the well-separatedness assumption. This assumption states that each vertex of K is far from the convex hull of the remaining vertices of K, and is much weaker than other assumptions behind algorithms in the literature which find vertices of the latent polytope.

1 Introduction

The Separating Hyperplane theorem is a fundamental result in Convex Geometry with myriad applications (see e.g. [6]). The theorem asserts that for a point a not in a closed convex set K, there is a hyperplane with K on one side and a strictly on the other side.

This paper makes two main contributions. Our theoretical contribution, which is an extension of the classical Separating Hyperplane Theorem, is what we call the Random Separating Hyperplane Theorem (RSH). Our main algorithmic contribution is to use RSH to prove that a natural algorithm, which we call the k-OLP algorithm, can learn (vertices of) latent polytopes arising in a number of problems in Latent Variable Models including

Clustering, Mixture Learning , LDA (linear discriminant analysis), Topic Models. The algorithmic result is shown by reducing the problem of learning latent polytopes in a variety of settings to that of constructing approximate optimization oracles for the corresponding polytopes. Bulk of our algorithmic contribution is in proving this reduction and the existence of such oracles.

1.1 Random Separating Hyperplane Theorem (RSH)

RSH draws its motivation mainly from the Separating Hyperplane Theorem of Convex Geometry. It also has connections to the Johnson-Lindenstrauss Random Projection theorem [15]. The Separating Hyperplane Theorem formally states that given a closed convex set K and a point $a \notin K$, there exists a vector u such that

$$u \cdot a > \text{Max}_{y \in K}\, u \cdot y.$$

The following question arises: Does a randomly picked u separate a from K? Taking into account some necessary conditions for a positive answer, we can ask if the following inequality holds for a randomly chosen u: (here Δ is the diameter of K, a is at distance at least $\delta\Delta$ from K, where $\delta \in (0,1)$):

$$\mathbf{Pr}\left(u \cdot a \geq \text{Max}_{y \in K} u \cdot y + |u|\alpha\delta\Delta\right) \geq 1/\text{poly}_{\delta},^{1} \tag{1}$$

with α being as high as possible.

The question (1) is also motivated from the Johnson-Lindenstrauss Random Projection theorem (JL theorem) [15] which states that if a, b are points in $\mathbf{R}^d$ and U is a random subspace of dimension s, then with probability bounded away from 0, the distance between the projection of a and b on U is at least $\Omega(|a-b|\sqrt{s}/\sqrt{d})$. The following natural generalization of this is interesting already for $s = 1$:

Instead of b being a point, if it is now a polytope K, does a similar lower bound on the distance of a to K in the projection onto a random line hold?

It is easy to see that in spirit, this is the same question as whether (1) holds. It is also easy (see below) to see that the projection shrinks the distance between a and K by a factor of $\Omega^*(\sqrt{d})$. The RSH theorem proves that the shrinkage is $O(\sqrt{d})$ thus making this parameter nearly (within log factors) tight. We now state the RSH theorem:

▶ **Theorem 1** (Random Separating Hyperplane Theorem(RSH): Informal version)**.** *Suppose K is a k vertex polytope with diameter $\Delta(K)$ and a is a point at distance at least $\delta\Delta(K)$, $\delta \in (0,1)$, from K. Let V be an $m-$dimensional subspace containing $K \cup \{a\}$. For a random Gaussian vector $u \in V$, the following event happens with probability at least 1/poly$_\delta(k)$:*

$$u \cdot a \geq Max_{y \in K} u \cdot y + \frac{\delta\Delta(K)|u|}{10\sqrt{m}}. \tag{2}$$

We provide a simple example where K is a line segment (see Appendix A) to show that the factor $\sqrt{m}$ cannot be improved. It is also interesting to note that the success probability of the event in (2) needs to depend on k. (see Appendix A). In particular, RSH does not hold for general convex sets (where k is not necessarily finite.)

[1] poly$_\delta(z)$ denotes $z^{\text{poly}(1/\delta)}$.

1.2 Algorithmic application of RSH

We now discuss the second main contribution of our work, i.e., applications of RSH to learning vertices of a latent polytope. We begin with the definition of an approximate optimization oracle.

▶ **Definition 2.** *For a non-empty convex set $K \subseteq \Re^d$ and $\varepsilon \in (0,1)$, an Optimization oracle for K with error ε, denoted $\mathsf{OptOr}_\varepsilon(K)$ oracle, takes as input any $u \in \Re^d, |u| = 1$, and returns a point $x(u)$ satisfying* both *these conditions :*

- $x(u) \in K + \varepsilon\Delta(K)B_d$, *where B_d is the unit ball, i.e., $\{x \in \Re^d : |x| \leq 1\}$, and*
- $u \cdot x(u) \geq Max_{y \in K} u \cdot y - \varepsilon\Delta(K)$

Problem Formulation. Several latent variable problems including Clustering, LDA, MMBM can be reduced (See Section 6 for details) to a problem that we call k-OLP: given an ε-optimization oracle for a k vertex polytope $K \subseteq \mathbf{R}^d$, learn the vertices of K (approximately). We define two simpler (than k-OLP) problems – ListLearn and Hausdorff, that are related to k-OLP, and then we define k-OLP.

The first problem, Hausdorff, seeks to find an approximation to a polytope K when we are given an approximate optimization oracle for the polytope.

▶ **Definition 3** ((ε,δ)-Hausdorff-Problem)**.** *Given an $\mathsf{OptOr}_\varepsilon(K)$ oracle for a polytope K in $\mathbf{R}^d$ with k vertices, find a set P of $m = \mathrm{poly}_\delta(dk)$ points such that $\mathsf{Haus}(\mathsf{CH}(P), K) \leq \delta\Delta(K)$, where, Haus denotes Hausdorff distance (see Definition 20 for a formal definition), and $\mathsf{CH}(P)$ is the convex hull of P.*

In the problem ListLearn, we also wish to find a small list of points, such that each vertex of K is close to at least one point in this list.

▶ **Definition 4** ((ε,δ)-ListLearn Problem)**.** *Given an $\mathsf{OptOr}_\varepsilon(K)$ oracle for a polytope K in $\Re^d$ with k vertices, each separated from the convex hull of the other $k-1$ vertices by at least $\delta\Delta(K)$, find a list $P \subseteq K + \delta\Delta(K)B_d$ of $m = \mathrm{poly}_\delta(dk)$ points such that for every vertex v of K, there is some $v' \in P$ with $|v - v'| \leq \delta\Delta(K)/10$.*

When the parameters ε, δ will be clear from the context, we shall abbreviate the above two problems as Hausdorff and ListLearn problems respectively. It is not difficult to see that any solution P to ListLearn is also a solution to Hausdorff, but, the converse need not hold: $\mathrm{CH}(P)$ may nearly contain K without P having any point close to some vertex of K. Our technical results (see below for the informal versions) show that if $\varepsilon \in O_\delta(1/\sqrt{d})$ [2], then we can solve the above-mentioned problems efficiently and indeed then, the following simple algorithm gives the desired answers (the proof crucially uses RSH):

Random Probes Algorithm

- Pick uniformly at random unit vectors $u_1, u_2, \ldots u_m$, where $m = \mathrm{poly}_\delta(dk)$.
- Return P, which is the set of m answers of the $\mathsf{OptOr}_\varepsilon(K)$ oracle to the queries $u_1, u_2, \ldots u_m$.

The first result (see Theorem 21 for a formal statement) states that the convex hull of answers to polynomially many random queries to the approximate optimization oracle approximates K well.

[2] $O_\delta(x)$ stands for $f(\delta)x$ for some function f.

▶ **Theorem 5** (Hausdorff Approximation from oracle (Informal)). *Consider an instance of the* (ε, δ)-Hausdorff *problem for a polytope* $K \subseteq \Re^d$. *Assume that* $\varepsilon \in O_\delta(1/\sqrt{d})$, *and let* P *be the set of points returned by the* **Random Probes Algorithm** *above. Then with high probability,*

$$\mathsf{Haus}(CH(P), K) \leq \delta\Delta(K).$$

The second result (see Theorem 28 for a formal statement) shows that as long as each vertex of K is *well-separated* from the convex hull of the other vertices of K, the set P constructed by the **Random Probes Algorithm** contains an approximation to each of the vertices. Thus, answers to polynomially many random queries list-learns the polytope.

▶ **Theorem 6** (List-Learning from Oracle (Informal)). *Consider an instance of the* ListLearn *problem for a polytope* $K \subseteq \Re^d$, *and assume that* $\varepsilon \in O_\delta(1/\sqrt{d})$. *Then, with high probability, the set* P *output by the* **Random Probes Algorithm** *above has the following property: for every vertex* a *of* K, *there is a point* $a' \in P$ *with*

$$|a' - a| \leq \delta\Delta(K)/10.$$

The $\sqrt{d}$ factor in both the above theorems is near-optimal (within a $\log d$ factor). Indeed, we shall prove:

▶ **Theorem 7** (Oracle Lower Bound). *The problem where, one is required to output a point which is within* $\Delta(K)/10$ *of some vertex of* K, *given only by an* $\mathsf{OptOr}_\varepsilon(K)$ *oracle, cannot be solved in deterministic polynomial time when* $\varepsilon \geq 8 \ln d/\sqrt{d}$.

We now define the k-OLP problem (the parameters ε, δ in the definition will often be clear from the context and may not be mentioned explicitly). The problem statement is similar to that of ListLearn, but we want to output a list of exactly k points.

▶ **Definition 8** ((ε, δ)-k-OLP Problem). *Under the same hypothesis as for the* ListLearn *problem, find a set of points* P, $|P| = k$, *satisfying the following condition: for each vertex* v *of* K, *there is a (unique) point* $v' \in P$ *such that* $|v - v'| \leq \delta\Delta(K)/10$.

Our next result gives a strengthening of Theorem 6.

▶ **Theorem 9.** *Consider an instance of the* k-OLP *problem on a polytope* $K \subseteq \Re^d$, *and assume* $\varepsilon \in O_\delta(1/\sqrt{d})$ *in a* k-OLP *problem. Let* P *be the set of points returned by the* **Random Probes Algorithm**. *Then, in polynomial time, we can find a* $Q \subseteq P, |Q| = k$ *satisfying the following condition: for each vertex* v *of* K, *there is a (unique)* $v' \in P, |v - v'| \leq \delta\Delta(K)/10$.

The algorithm for finding Q from P is likely of independent interest. We call this problem the "Soft Convex Hull" problem and it is described in Section 6.1.

Do Approximate Optimization Oracles exist?

The answer to this question is a qualified Yes. They exist, but unfortunately, as we point out below, for many latent variable problems including the simple mixture of two Gaussians with means separated by $\Omega(1)$ standard deviations, we do not get $\varepsilon \in O_\delta(1/\sqrt{d})$, when, $k < d$. Thus, we do not satisfy the hypothesis of the results mentioned in Theorem 5,Theorem 6, and Theorem 9. But we are able to tackle this hurdle by projecting to the k-SVD subspace (of the input data points which satisfy conditions discussed below) where, we do get the necessary $\varepsilon \in O_\delta(1/\sqrt{k})$.

First we observe that approximate optimization oracles arise in a natural setting – that of latent variable models. [7] show that these models can be reduced to a geometric problem called LkP described below. [We will not reproduce the reduction here.] LkP is the following problem: Let K be a k vertex polytope in $\Re^d$. Let $M_{\cdot,1}, \ldots, M_{\cdot,k}$ denote the vertices of K. Assume that there are latent (hidden) points $P_{\cdot,j}, j = 1, 2, \ldots, n$, in K. The observed data points $A_{\cdot,j}, j = 1, 2, \ldots, n$ are generated (not necessarily under any stochastic assumptions) by adding *displacements* $A_{\cdot,j} - P_{\cdot,j}$ respectively to $P_{\cdot,j}$. Let[3]

$$\sigma_0 := \frac{||\mathbf{P} - \mathbf{A}||}{\sqrt{n}}.$$

We assume that there is a certain w_0 fraction of latent points close to every vertex of K, i.e., for all $\ell \in [k]$,

$$C_\ell := \{j : |P_{\cdot,j} - M_{\cdot,\ell}| \leq \frac{\sigma_0}{\sqrt{w_0}}\} \text{ satisfies } |C_\ell| \geq w_0 n.$$

▶ **Theorem 10** (From Data to Oracles). *Using the above notation, the following "Subset Smoothing algorithm" gives us a polynomial time* $\mathsf{OptOr}_{\frac{4\sigma_0}{\Delta\sqrt{w_0}}}(K)$ *oracle..*

> **Subset Smoothing Algorithm**
> Given query u, let S be the set of the $w_0 n$ j's with the highest $u \cdot A_{\cdot,j}$ values.
> Return $A_{\cdot,S} := \frac{1}{w_0 n} \sum_{j \in S} A_{\cdot,j}$.

The Subset Smoothing algorithm was used in [7]. It is also reminiscent of Super-quantiles [18], though our use here is not directly related to them. While this theorem helps us get optimization oracles, the error guarantee of $O(\sigma_0/\Delta\sqrt{w_0})$ is not good enough in many applications. An elementary example illustrates this issue:

Consider a mixture of two equal weight standard Gaussians centered at $-v$ and v, where, v is a vector of length 10. [This fits the paradigm "means separated by $\Omega(1)$ standard deviations".] Then, data generated by the mixture model fits our data generation process with $K = \{\lambda v, \lambda \in [-1, 1]\}$, and each $P_{\cdot,j}$ is either v or $-v$ depending on the Gaussian from which the point has been sampled. Here $A_{\cdot,j}$ denotes the actual sampled point from the mixture. Now, $\Delta = 20$ and it can be seen from Random Matrix Theorems (see e.g., [19]) that $\sigma_0 = O(1)$ with high probability. So, $\sigma_0/\Delta\sqrt{w_0} \in O(1)$ with high probability, and hence, the Theorem above yields an $\mathsf{OptOr}_\varepsilon(K)$ oracle with $\varepsilon \in \Omega(1)$. But d can be arbitrarily large and so we do not have the required $\mathsf{OptOr}_{O(1/\sqrt{d})}(K)$ oracle.

This elementary example can be tackled in several ways. Our algorithm which we call the "k-OLP algorithm" is simply stated and works in general settings (including on this toy example) for several Latent Variable problems (see Section 6 for details). The main idea is to first project the input points on a suitable SVD subspace and then use the approximate optimization oracle in the projection.

SVD and the k-OLP Algorithm

We now state the result (see Theorem 39 for a formal version) for k-OLP in the setting of LkP. As mentioned above, this uses SVD followed by subset smoothing.

[3] By the standard definition of spectral norm, it is easy to see that σ_0^2 is the maximum mean squared displacement in any direction.

▶ **Theorem 11.** *Recall the notation and assumptions of Theorem 10. In addition, we assume that each vertex of K is $\delta\Delta(K)$ far from the convex hull of other vertices of K, where, δ satisfies:*

$$\sigma_0 \leq c\delta^2\Delta\sqrt{w_0}/\sqrt{k}.$$

Then, the set of points P returned by the following k-OLP algorithm list learns the vertices of K. Further, we can find a subset Q of P with $|Q| = k$ and for each v, vertex of K, Q contains a v' with $|v - v'| \leq \delta\Delta/10$:

Algorithm k-OLP

1. Project to the k-dim SVD subspace V corresponding to the points $A_{\cdot,j}$.
2. Pick $m = \text{poly}_\delta(k)$ random vectors $u_1, u_2, \ldots, u_m$ in V.
3. For each u_i, take the mean of the $A_{\cdot,j}$ with the $w_0 n/2$ highest values of $u_i \cdot A_{\cdot,j}$.
4. Let P be the set of m means computed in the step above.
5. Output a subset Q of P, $|Q| = k$, using Theorem 9.

We sketch here the steps in the proof (the details are contained in the proof of Theorem 39.)

Sketch. Let $\widehat{K}$ denote projection of K onto V. By Theorem 10 , Step 3 of Algorithm k-OLP is an $\mathsf{OptOr}_\varepsilon(\widehat{K})$ oracle, where $\varepsilon = O\left(\frac{\sigma_0}{\Delta\sqrt{w_0}}\right)$. Also, each $\widehat{M}_{\cdot,\ell}$, which is the projection of $\widehat{M}_{\cdot,\ell}$ on V, is $O(\delta\Delta(K))$ far from the convex hull of the other vertices of $\widehat{K}$. Now, Theorem 9 applied to $\widehat{K}$ in the subspace V implies the desired result. ◀

It is worth noting that data obtained from several generative models are known to satisfy the LkP condition stated in Theorem 11, e.g., Stochastic Mixture models with k components, Topic Models, Mixed membership community models.

From List Learning to k-OLP

As outlined above, the k-OLP algorithm works in two stages: (i) Project the data points on the SVD subspace V of dimension k, and (ii) make polynomially calls to the $\mathsf{OptOr}_\varepsilon(K)$ oracle, where each query is given by a randomly chosen unit vector in the subspace V (as in the statement of Theorem 5) – let P be the set of points returned by the oracle. The first statement in Theorem 11 shows that the convex hull of P is close to K.

Obtaining approximations to the vertices of K from P requires addressing a new problem: given a set of points W, find a small subset T of W, such that their convex hulls are close. We call this the *soft convex hull* problem. A similar problem was addressed by [12]; however they gave a bi-criteria approximation algorithm for this problem. Under stronger assumptions, where we assume that there in the optimal solution $T^\star$, each point of $T^\star$ is well-separated from the convex hull of the rest of the points of $T^\star$, we show that one can recover approximations to each of the points in $T^\star$. Applying this result to the set of points P returned by the optimization oracle, we get a set of k points Q, each of which approximates a unique vertex of the polytope K.

The algorithm for obtaining soft convex hull proceeds as follows. We first prune points $w \in W$ which have the following property: consider the subset X of points in W which are sufficiently far from w. Then w is close the convex hull of X. After pruning such points from W, we pick a subset of points which are sufficiently far-apart from each other. The main technical result shows that this procedure outputs the desired set T.

1.3 Related Work

The well known result of [15] shows that given a set of n points in $\Re^d$, projection to a random subspace of dimension $O(\log n/\varepsilon^2)$ preserves all pair-wise distances up to $(1+\varepsilon)$-factor with high probability. Further, this bound on the dimension on which the points are projected is known to be tight [2, 16]. Note that in our setting, there are $k+1$ points "of interest", namely, the k vertices of K and a point $a \notin K$ and by the above, a random projection to $O^*(\log k)$ dimensional space preserves all pairwise distances among them. But this is not sufficient for our problems. We need separation of a not just from the vertices of K, but from all of K in the projection. We achieve this by projecting to a set of random 1-dimensional subspaces, and show that the distance between a point and a polytope does not scale down by more than $O(\sqrt{d})$ factor for at least one of them with high probability (this is an immediate corollary of the RSH Theorem).

The problem of learning vertices of a polytope arises in many settings where data is assumed to be generated by a stochastic process parameterized by a model. Examples include topic models [10], stochastic block models [1], latent Dirichlet allocation [11]. A variety of techniques have been developed for these specific problems (see e.g. [3, 4, 14]). [7] (see also [5]) proposed the latent k-polytope (LkP) model which seeks to unify all of these latent variable models. In this model, there is *latent* polytope with k vertices, and data is generated in a two step process: first we pick *latent* points from this polytope, and then the observed points are obtained by perturbing these latent points in an adversarial manner. They showed that under suitable assumptions on this deterministic setting, one can capture the above-mentioned latent variable problems. Assuming strong separability conditions on the vertices of the polytope (i.e., each vertex of K is far from the *affine* hull of other vertices of K), they showed that one can efficiently recover good approximations to the vertices of the polytope from the input data points. In comparison, our assumption on K is that each vertex of K is far from the convex hull of the remaining vertices of K. This is a much milder condition, e.g., it allows a polytope with more than 2 vertices in a plane. [8] showed how to infer the parameter k from data in the LkP setting (under the strong separation condition).

[12] addressed a problem similar to the Hausdorff problem: instead of an ε-optimization oracle for a polytope K, we are given an explicit set P of points, whose convex hull is within Hausdorff distance at most $\delta\Delta(K)$ from K. They are able to get better dependencies on the parameters k, δ, ε than Theorem 21 under these stronger assumptions.

2 Preliminaries

For two points $x, y \in \Re^d$, $|x-y|$ denotes the Euclidean distance between the points. Given a point $x \in \Re^d$ and a subset $X \subseteq \Re^d$, define $\mathsf{dist}(x, X)$ as the minimum distance between x and a point in X, i.e., $\inf_{y\in X}|x-y|$. For a set of points X, $\Delta(X)$ denotes the diameter of X, i.e., $\sup_{x,y\in X}|x-y|$. We denote the convex hull of X by $\mathsf{CH}(X)$. For two subsets A, B of $\Re^d$, define their Minkowski sum $A+B$ as $\{x+y : x \in A, y \in B\}$. Similarly, define λA, where $\lambda \in \Re$, as $\{\lambda x : x \in A\}$. For an $m \times n$ matrix B, we use $B_{\cdot,j}$ to denote the j^{th} column of B. For a subset $S \subseteq [n]$ of columns of B, $B_{\cdot,S}$ denotes $\frac{1}{|S|}\sum_{j\in S} B_{\cdot,j}$. Often, we represent the vertices of a polytope K in $\Re^d$ by a $d \times k$ matrix M, and so the columns $M_{\cdot,1}, \ldots, M_{\cdot,k}$ would represent the vertices of K. We shall use the notation $\mathrm{poly}_\delta(z)$ to denote a quantity which is $z^{\mathrm{poly}(1/\delta)}$. Further the notation $O_\delta(z)$ shall denote a quantity which is $f(\delta)z$, where $f(\delta)$ is a function depending on δ only (and hence, is constant if δ is constant).

We now give an outline of rest of the paper. In Section 3, we prove the Random Separating Hyperplane theorem. In Section 4, we prove Theorem 5 by showing that an $\mathsf{OptOr}_\varepsilon(K)$ oracle leads to efficient constructions of approximation to K. In Section 5 we give an algorithm

for the ListLearn problem under the stronger assumption that the vertices of K are well separated. We also prove the lower bound result Theorem 7 in this section. In Section 6, we extend the algorithm for ListLearn to the k-OLP problem. This requires the concept of soft convex hulls. The algorithm for constructing soft convex hulls in given in Section 6.1. Finally, in Section 7, we apply the k-OLP algorithm for the latent polytope problem. As note earlier, in the setting of latent polytopes K, we can only guarantee $\mathsf{OptOr}_\varepsilon(K)$ oracles with ε being $O(1/\sqrt{k})$, whereas our algorithm for k-OLP requires ε to be $O(1/\sqrt{d})$. We handle this issue by projecting to a suitable SVD subspace and executing the k-OLP algorithm in this subspace. We conclude with some open problems in Section 8.

3 Random Separating Hyperplane (RSH) Theorem

In this section, we prove RSH for polytopes: If a point p point is at a distance from a polytope K, then, the Gaussian measure of the set of *well-separating* hyperplanes has a positive lower bound depending on the number of vertices in K. More specifically, we show:

▶ **Theorem 12.** *Suppose K is a polytope in $\Re^d$ with k vertices and diameter $\Delta(K)$. Suppose a is a point in $\mathbf{R}^d$ and $\delta \in (0,1]$ with*

$$\min_{y\in K} |a-y| \geq \delta\Delta(K). \tag{3}$$

Let V be an m-dimensional subspace containing $\mathsf{Span}(K \cup \{a\})$ and let u be a random vector drawn from the normal distribution $N(0, I_m)$ in V. Then,

$$\mathbf{Pr}_u\left[(u\cdot a - \max_{y\in K} u\cdot y) \geq |u|\cdot\delta\Delta(K)\cdot\frac{\sqrt{\log k}}{3\sqrt{\log k}+4\delta\sqrt{m}}\right] \geq \frac{1}{40}k^{-10/\delta^2}.$$

Proof Overview

We give an informal overview of the proof. A naive, though incorrect, idea would be the following: let ζ be the closest vertex of K to a. We can argue that with reasonable probability (i.e., $\Omega(k^{-1/\delta^2})$) that $|(\zeta-a)\cdot u|$ is at least $\frac{2\sqrt{\log k}\cdot|\zeta-a|}{\delta\sqrt{m}} \geq \frac{2\sqrt{\log k}\cdot\Delta(K)}{\sqrt{m}}$. Call this event $\mathcal{E}_1$. Now consider a line segment joining two distinct vertices, say ζ_i, ζ_j, of K. The length of such a line segment is at most $\Delta(K)$, and hence there is high probability that $|(\zeta_i-\zeta_j)\cdot u| \leq \frac{1.5\sqrt{\log k}\cdot\Delta(K)}{\sqrt{m}}$. In fact, we can apply union bound, and show that this property holds for all pairs of vertices of K – call this event $\mathcal{E}_2$. If both $\mathcal{E}_1$ and $\mathcal{E}_2$ occur, then it is easy to see that along the direction u, a is separated from all the vertices of K. However, the events $\mathcal{E}_1$ and $\mathcal{E}_2$ are not independent, and hence, we cannot argue that both events will occur with non-trivial probability. Here one could use the union bound, but a calculation shows that for this we need $\delta > 1$. But $\delta < 1$ in our applications, so we cannot use this approach.

Instead, we rely on the following more nuanced idea. Let w be the unit direction along the line joining a and the closest point b of K. As argued above, we can show that $|(b-a)\cdot u|$ is at least $\frac{\Omega(\sqrt{\log k}\cdot|b-a|}{\delta\sqrt{m}} \geq \frac{\Omega(\sqrt{\log k})\cdot\Delta(K)}{\sqrt{m}}$ – this only requires arguing about the component of u along w; let $\mathcal{E}_1'$ denote this event. Now we show that the following event, say $\mathcal{E}_2'$, occurs with high probability: along the component of u orthogonal to w, the projections of the line segments joining any two vertices of K is at most $\frac{O(\sqrt{\log k})\Delta(K)}{\sqrt{m}}$. Since $\mathcal{E}_1'$ and $\mathcal{E}_2'$ are concerned with orthogonal directions, they are independent using properties of the Gaussian. Thus we can show that both of these events happen with non-trivial probability. This suffices

to show the desired result. We now give the formal proof of this result. First, we state the following well-known concentration bound for Gaussian random variables (see e.g. [19]):

▶ **Theorem 13** (Gaussian Concentration Bounds). *Let X be an $N(0,1)$ Gaussian random variable, i.e., with mean 0 and variance 1. Then, for any $t > 0$,*

$$e^{-t^2/4}/2 \leq \Pr[|X| \geq t] \leq 2e^{-t^2}.$$

We shall also need the following result on the sum of squares of i.i.d. normal random variables.

▶ **Theorem 14** ([17]). *Let $X_1, \ldots, X_n$ be n i.i.d. $N(0,1)$ Gaussian random variables. Then,*

$$\Pr[\sum_{i=1}^{n} X_i^2 > 4n] \leq e^{-\sqrt{n}}.$$

We now proceed with the proof of Theorem 12.

Proof of Theorem 12. Let $\zeta_1, \zeta_2, \ldots, \zeta_k$ be the k vertices of K. Let b be the closest point in K to a, and define

$$w = \frac{a-b}{|a-b|}.$$

Then by standard results on separation between a point and a closed convex set (see e.g. [13]), we know that for all points $y \in K$:

$$w \cdot y \leq w \cdot b. \tag{4}$$

Now, we extend w to an orthonormal basis $w_1 := w, w_2, \ldots, w_m$ of the subspace V. The random vector u can be generated as follows: sample m i.i.d. $N(0,1)$ random variables $\lambda_1, \ldots, \lambda_m$, and define $u := \sum_{i=1}^{m} \lambda_i w_i$. We first observe that it is enough to argue that the projection of a along u is well separated from that for each vertex ζ_ℓ of K. Indeed, we can express $(u \cdot a - \max_{y \in K} u \cdot y)$ as

$$u \cdot (a-b) - \max_{y \in K} u \cdot (y-b) = u \cdot (a-b) - \max_{\ell=1,\ldots,k} u \cdot (\zeta_\ell - b) \tag{5}$$

It suffices to show that with reasonably high probability, there is a lower bound on $u \cdot (a-b)$ and an upper bound on $u \cdot (\zeta_\ell - b)$ for all ℓ. We proceed with the latter goal first. Observe that along the direction w, K lies *below* b. Thus, it suffices to argue that the projection of $(\zeta_\ell - b)$ along the direction orthogonal to w is not large for any vertex ζ_ℓ of K. Let z denote $\lambda_2 w_2 + \ldots + \lambda_m w_m$. Then u can be expressed as $\lambda_1 w + z$. We now define events upper bounding $z \cdot (\zeta_\ell - b)$ for all vertices ζ_ℓ of K.

▶ **Definition 15.** *For $\ell = 1, 2, \ldots, k$, define the event $\mathcal{E}_\ell$ as $[|z \cdot (\zeta_\ell - b)| \leq 2\sqrt{\ln k}\Delta(K)]$.*

▶ **Proposition 16.** *Suppose the events $\mathcal{E}_\ell$ occur for all $\ell = 1, \ldots, k$. Then, for any $\ell \in [k]$,*

$$u \cdot (\zeta_\ell - b) \leq 2\sqrt{\ln k}\Delta(K).$$

Proof. Observe that

$$u \cdot (\zeta_\ell - b) = \lambda_1 w \cdot (\zeta_\ell - b) + z \cdot (\zeta_\ell - b) \overset{(4)}{\leq} z \cdot (\zeta_\ell - b).$$

The desired result now follows from the definition of the event $\mathcal{E}_\ell$. ◀

We now define events to lower bound $u \cdot (a-b)$. Observe that $(a-b)$ is along w, and hence, is orthogonal to z. Therefore $u \cdot (a-b) = \lambda_1 w \dot{(}a-b) = \lambda_1 |a-b|$. Therefore, we define an event that lower bounds λ_1. We also define an event that upper bounds $|z|$.

▶ **Definition 17.** *Define $\mathcal{E}_0$ as the event $[|z| \leq 4\sqrt{m}]$. Also define $\mathcal{E}_{k+1}$ as the event $[\lambda \geq 3\sqrt{\ln k}/\delta]$.*

▶ **Proposition 18.** *Suppose the events $\mathcal{E}_0, \ldots, \mathcal{E}_{k+1}$ happen. Then,*

$$u \cdot a - \max_{y \in K} u \cdot y \geq \frac{\lambda \delta \Delta(K)|u|}{3(\lambda + 4\sqrt{m})} \geq \frac{\delta\sqrt{\ln k}\Delta(K)|u|}{3\sqrt{\ln k} + 4\delta\sqrt{m}}.$$

Proof. As observed above, $u \cdot (a-b) = \lambda_1 |a-b|$. Now observe that for any vertex ζ_ℓ of K, Proposition 16 shows that

$$u \cdot (\zeta_\ell - b) \leq 2\sqrt{\ln k}\Delta(K) \overset{(3)}{\leq} 2\sqrt{\ln k}|a-b|/\delta \leq 2\lambda_1|a-b|/3,$$

where the last inequality follows from the definition of of event $\mathcal{E}_{k+1}$. Thus, we see from the above two inequalities and (5) that

$$u \cdot a - \max_{y \in K} u \cdot y \geq \lambda_1 |a-b|/3 \overset{(3)}{\geq} \lambda_1 \delta |\Delta(K)|/3. \tag{6}$$

It remains to upper bound $|u|$. Recall that $u = \lambda_1 w + z$, and hence, $|u| \leq |\lambda_1| + |z| \leq \lambda_1 + 4\sqrt{m}$, where we have used the definition of the event $\mathcal{E}_{k+1}$ and the fact that $\lambda_1 > 0$ because of event $\mathcal{E}_0$. Using this in (6) yields the first inequality in the desired claim. The second desired inequality follows from the fact that $\lambda_1 \delta \geq 3\sqrt{\ln k}$ (definition of event $\mathcal{E}_{k+1}$). ◀

It remains to show that the events $\mathcal{E}_0, \ldots, \mathcal{E}_{k+1}$ occur with reasonable probability.

▶ **Proposition 19.** $\mathbf{Pr}\left[\wedge_{\ell=0}^{k+1} \mathcal{E}_\ell\right] \geq \frac{1}{40} k^{-10/\delta^2}$.

Proof. Consider any $\ell \in [k]$. Observe that $z \cdot (\zeta_\ell - b)$ is a 1-dimensional Gaussian random variable with zero mean and with variance $|\zeta_\ell - b|^2 \leq \Delta(K)^2$. Thus, $\frac{z \cdot (\zeta_\ell - b)}{\Delta(K)}$ is an $N(0,1)$ normal random variable. Therefore, Theorem 13 shows that

$$\Pr[\neg \mathcal{E}_\ell] = \Pr\left[\frac{z \cdot (\zeta_\ell - b)}{\Delta(K)} \geq 2\sqrt{\ln k}\right] \leq \frac{1}{2k^2}.$$

By definition of z, $|z|^2 = \lambda_2 + \ldots + \lambda_m^2$. By Theorem 14,

$$\Pr[\neg \mathcal{E}_0] = \Pr[|z|^2 > 16m] \leq e^{-\sqrt{m}} \leq 1/20,$$

for large enough m. Applying union bound to the above two inequalities, we get

$$\mathbf{Pr}\left(\wedge_{\ell=0}^{k} \mathcal{E}_\ell\right) \geq 1 - \sum_{\ell=0}^{k} \mathbf{Pr}(\neg \mathcal{E}_\ell) \geq 1/4 \tag{7}$$

Finally we consider event $\mathcal{E}_{k+1}$. Observe that λ_1 is $N(0,1)$ Gaussian random variable. Applying Theorem 13 to λ_1, we see that

$$\Pr[\mathcal{E}_{k+1}] = \Pr\left[\lambda_1 \geq 3\sqrt{\ln k}/\delta\right] \geq \frac{1}{10} k^{-10/\delta^2}. \tag{8}$$

Observe that the event $\wedge_{\ell=0}^{k} \mathcal{E}_\ell$ depends on the random variables $\lambda_2, \ldots, \lambda_k$, and hence, is independent of the event $\mathcal{E}_{k+1}$. The desired result now follows from the (7) and (8). ◀

The theorem now follows from Proposition 18 and Proposition 19. ◀

4 From $\mathsf{OptOr}_\varepsilon(K)$ oracles to the Hausdorff Problem

We prove Theorem 5 in this section. We begin by defining Hausdorff distance formally.

▶ **Definition 20.** *The* Hausdorff-distance, $\mathsf{Haus}(K, K')$, *between two polytopes* K *and* K' *is the infimum over all values* α *such that the following condition is satisfied: for every point* $x \in K$, *there is a point* $y \in K'$ *such that* $|x - y| \leq \alpha$, *and vice versa.*

We now give the formal version of Theorem 5:

▶ **Theorem 21.** *Suppose* ε, δ *are reals in* $[0, 1]$ *with*

$$\delta > c\varepsilon\sqrt{d}, \delta > c/\sqrt{d}, \tag{9}$$

where c *is a large enough constant. Let* K *be a* k*-vertex polytope with* $\Delta(K)$ *denoting the diameter of* K. *Suppose we are also given an* $\mathsf{OptOr}_\varepsilon(K)$ *oracle* $\mathcal{O}$. *Let* P *be the set of answers from the oracle on* $m := k^{10+c\delta^{-2}}$ *independent random queries. Then,* $\mathsf{Haus}(K, \mathsf{CH}(P)) \leq \delta \cdot \Delta(K)$.

Before giving the proof, we highlight the main ideas here. Let the random queries correspond to unit directions $u^1, \ldots, u^m$, and for each of these queries u^j, the oracle $\mathcal{O}$ returns a near-optimal point $x(u^j)$. Let P^j denote the subset $\{x(u^1), \ldots, x(u^j)\}$. Let v be a vertex of K. The non-triviality in the proof lies in showing that there is a point in $\mathsf{CH}(P)$ close to v. Suppose there is no such point in $\mathsf{CH}(P^j)$, and let b the closest point in $\mathsf{CH}(P^j)$ to v. Then we show that with constant probability the following events happen: (i) the unit vector u^{j+1} has a non-trivial component along the direction joining b and v, and (ii) its component along the orthogonal direction is not too large. If both of these events happen, we show that $\mathsf{dist}(v, \mathsf{CH}(P^{j+1})) \leq (1 - O(\delta^2))\mathsf{dist}(v, \mathsf{CH}(P^j))$. We now give details of the proof.

Proof. We describe the algorithm for obtaining the desired set S (referred as **Random Probes Algorithm** in Section 1.2) in Algorithm 1. The set P is constructed as follows: we pick a set of m random unit vectors. For each such unit vector u, we add the corresponding point $x(u)$ returned by the oracle $\mathcal{O}$ to the set P.

Algorithm 1 Algorithm for finding the set P such that $\mathsf{CH}(P)$ approximates K.

Input: An $\mathsf{OptOr}_\varepsilon(K)$ oracle $\mathcal{O}$.
Initialize a set P to $\varnothing$
Repeat m times:
  Let u be a random unit vector in $\Re^d$.
  Call $\mathcal{O}$ on u to get a vector $x(u)$.
  Add $x(u)$ to P.
Output P.

One side of the desired result is easy to show:

▷ Claim 22. For each $x \in \mathsf{CH}(P)$, there is a $y \in K$ such that $|x - y| \leq \delta\Delta(K)$.

Proof. For a point $x(u) \in P$, we know by the definition of $\mathsf{OptOr}_\varepsilon(K)$ oracle that there is a point $y \in K$ such that $|x(u) - y| \leq \varepsilon\Delta(K) \leq \delta\Delta(K)$, where $\varepsilon \leq \delta$ follows from (9). The desired result now follows from the convexity of K. ◁

It remains to show that for any vertex v of K, there is a point $y \in \mathsf{CH}(P)$ such that $|v - y| \leq \delta\Delta(K)$. Fix such a vertex v of K for rest of the discussion. Let the random unit vectors considered in Algorithm 1 (in the order they get generated) be $u^1, \ldots, u^m$. Let P^j denote the subset $\{x(u^1), \ldots, x(u^j)\}$ of P. Define an event $\mathcal{E}_j$ as follows:

$$\mathsf{dist}(v, \mathsf{CH}(P^j)) \leq \delta \cdot \Delta(K) \quad \text{or} \quad \mathsf{dist}(v, \mathsf{CH}(P^{j+1})) \leq \left(1 - \frac{\delta^2}{c'}\right) \mathsf{dist}(v, \mathsf{CH}(P^j)),$$

where c' is a large enough constant. Our main technical result is to show that conditioned on *any* choice of $u^1, \ldots, u^j$ the event $\mathcal{E}_j$ happens with reasonably high probability (where the probability is over the choice of u^{j+1}):

▶ **Lemma 23.** *For any index $j \in [m-1]$,*

$$\Pr_{u^{j+1}} \left[\mathcal{E}_j | u^1, \ldots, u^j\right] \geq \frac{1}{100}.$$

Proof. Fix the vectors $u^1, \ldots, u^j$. If $\mathsf{dist}(v, \mathsf{CH}(P^j)) \leq \delta \cdot \Delta(K)$, then we are done. So assume this is not the case. Let b be the closest point in $\mathsf{CH}(P^j)$ to v. Thus,

$$|v - b| \geq \delta \cdot \Delta(K). \tag{10}$$

Define w as

$$w := \frac{v - b}{|v - b|}.$$

We can now express the vector u^{j+1} as $\lambda w + z$, where $\langle z, w \rangle = 0$. We first show the following useful properties of these vectors.

▷ Claim 24. With probability at least $\frac{1}{100}$, the following three events happen:

$$|z| \leq 4\sqrt{d} \tag{11}$$

$$\max_{y \in K} |z \cdot (v - y)| \leq 2\sqrt{\ln k}\Delta(K) \tag{12}$$

$$\lambda \geq \frac{100}{\delta}\sqrt{\ln k} \tag{13}$$

Proof. The proofs of these three inequalities are same as the arguments in Proposition 19 (in order to prove (12), it suffices to show it for points y which are vertices of K). ◁

The following fact is also easy to show:

▶ **Proposition 25.**

$$|v - x(u^{j+1})| \leq 2\Delta(K).$$

Proof. By the definition of $\mathsf{OptOr}_\varepsilon(K)$ oracle, there is a point $p \in K$ such that $|p - x(u^{j+1})| \leq \delta \cdot \Delta(K) \leq \Delta(K)$. The desired result now follows by triangle inequality. ◀

Let δ_1 denote $\frac{\delta^2}{100}$. Let b_1 denote the vector

$$\delta_1 x(u^{j+1}) + (1 - \delta_1)b.$$

Since $b_1 \in \mathsf{CH}(P^{j+1})$, the desired result will follow if we prove the following:

$$|v - b_1|^2 \leq \left(1 - \frac{\delta^2}{100}\right) |v - b|^2. \tag{14}$$

Now,

$$
\begin{aligned}
|v-b_1|^2 &= \delta_1^2|v-x(u^{j+1})|^2 + (1-\delta_1)^2|v-b|^2 + 2\delta_1(1-\delta_1)(v-x(u^{j+1}))\cdot(v-b)\\
&\overset{\text{Prop. 25}}{\leq} 4\delta_1^2\Delta(K)^2 + (1-2\delta_1)|v-b|^2 + \delta_1^2\Delta(K)^2 + 2\delta_1(1-\delta_1)(v-x(u^{j+1}))\cdot(v-b)\\
&\overset{(10)}{\leq} \left(1-\frac{3\delta_1}{2}\right)|v-b|^2 + +2\delta_1(1-\delta_1)|v-b|\cdot(v-x(u^{j+1}))\cdot w\\
&= \left(1-\frac{3\delta_1}{2}\right)|v-b|^2 + +2\delta_1(1-\delta_1)\Bigg(\underbrace{\frac{|v-b|}{\lambda}\cdot(v-x(u^{j+1}))\cdot u^{j+1}}_{:=A}\\
&\qquad \underbrace{-\frac{|v-b|}{\lambda}\cdot(v-x(u^{j+1}))\cdot z}_{:=B}\Bigg) \qquad (15)
\end{aligned}
$$

We now bound each of the terms A and B above. Now,

$$A \leq \frac{|v-b|}{\lambda}\varepsilon\Delta(K) \overset{(9)}{\leq} \frac{|v-b|\delta\Delta(K)}{c\lambda} \overset{(10)}{\leq} \frac{|v-b|^2}{c\lambda} \overset{(13)}{\leq} \frac{|v-b|^2\delta}{c},$$

where the first inequality follows from the definition of $\mathsf{OptOr}_\varepsilon(K)$ oracle. We now bound the quantity B. Let y be the point in K closest to $x(u^{j+1})$. We know that $|y-x(u^{j+1})| \leq \varepsilon\Delta(K)$. Therefore,

$$
\begin{aligned}
B &\leq \frac{|v-b|}{\lambda}\left(|(v-y)\cdot z| + |z|\varepsilon\Delta(K)\right)\\
&\overset{(11),(12)}{\leq} \frac{|v-b|}{\lambda}\left(2\sqrt{\ln k}\Delta(K) + 4\varepsilon\sqrt{d}\Delta(K)\right)\\
&\overset{(9),(13)}{\leq} \frac{\delta|v-b|\Delta(K)}{10} \overset{(10)}{\leq} \frac{|v-b|^2}{10}.
\end{aligned}
$$

Substituting the above bound on A and B in (15) yields the desired result. ◀

We are now almost done. As the following result shows, it suffices to argue that enough number of events $\mathcal{E}_j$ happen:

▷ Claim 26. If at least $\frac{c'}{\delta^2}\ln(2/\varepsilon)$ of the events $\mathcal{E}_j, j \in [m-1]$ happen, then $\mathsf{dist}(v, \mathsf{CH}(P)) \leq \delta\Delta(K)$.

Proof. Assume, for the sake of contradiction, that $\mathsf{dist}(v, \mathsf{CH}(P)) > \varepsilon\Delta(K)$. Assume that events $\mathcal{E}_{j_1}, \ldots, \mathcal{E}_{j_h}$ happen, where $h := \frac{c'}{\delta^2}\ln(2/\varepsilon)$. Now, for any index $i \in [h-1]$, the definition of $\mathcal{E}_{j_{i+1}}$ implies that

$$\mathsf{dist}(v, \mathsf{CH}(P^{j_{i+1}})) \leq \left(1-\frac{\delta^2}{c'}\right)\mathsf{dist}(v, \mathsf{CH}(P^{j_{i+1}-1}) \leq \mathsf{dist}(v, \mathsf{CH}(P^{j_i})).$$

Therefore,

$$\mathsf{dist}(v, \mathsf{CH}(P^{j_h})) \leq \left(1-\frac{\delta^2}{c'}\right)^h \mathsf{dist}(v, P^1) \overset{\text{Proposition 25}}{\leq} \left(1-\frac{\delta^2}{c'}\right)^h 2\Delta(K) \leq \delta\Delta(K). \quad \triangleleft$$

It remains to show that with high probability at least $h := \frac{c'}{\delta^2}\ln(2/\varepsilon)$ of the events happen. In order to prove this, we divide the sequence $[m]$ into $[h]$ subsequences, each of length m/h. Call these subsequences $C_1, \ldots, C_h$. It follows from Lemma 23 that for any $i \in [h]$,

$$\Pr\left[\wedge_{j\in C_i}\neg\mathcal{E}_j\right] \leq 0.99^{m/h} \leq \frac{1}{h^2}.$$

A simple union bound now shows that with probability at least $1 - 1/h$, at least one event $\mathcal{E}_j$ happens during each of the subsequences $C_1, \ldots, C_h$. Claim 26 now proves the theorem. ◀

5 From $\mathsf{OptOr}_\varepsilon(K)$ oracles to ListLearn

We first define the notion of well-separatedness.

▶ **Definition 27.** *We say that a polytope K with vertex set V is* δ-well-separated *if for every vertex $v \in V$, we have* $\mathsf{dist}(v, \mathsf{CH}(V \setminus \{v\})) \geq \delta \cdot \Delta(K)$.

Recall that Theorem 7 states that given access to only an $\mathsf{OptOr}_\varepsilon(K)$ oracle, ε must be $\Omega(\ln d/\sqrt{d})$ for any deterministic algorithm to output a point within $\Delta(K)/10$ of K. We show this result in the full version [9]. We now prove Theorem 6, which gives such an algorithm for the ListLearn problem.

▶ **Theorem 28.** *Suppose ε, δ are reals in $[0, 1]$ with $\delta^2 \geq c\varepsilon\sqrt{d}, \delta^3 \geq c\,\varepsilon$, where c is a large enough constant. Let K be a δ-well-separated k-vertex polytope. Suppose we are also given $\mathsf{OptOr}_\varepsilon(K)$ oracle $\mathcal{O}$. Let W be the set of answers of the oracle to $m = poly(d) \cdot k^{\Omega(1/\delta^2)}$ independent random queries. Then for each vertex v of K, there is a point $v' \in W$ such that $|v - v'| \leq O(\delta^2\Delta(K)/c)$.*

Proof. The algorithm chooses a set U of $k^{\Omega(1/\delta^2)}$ unit length i.i.d. Gaussian vectors. For each $u \in U$, it calls the oracle $\mathcal{O}$ to find a vector $x(u)$. Let W denote the set $\{x(u) : u \in U\}$. We first show that for every vertex of K, there is a direction u in U along which the projection of this vertex is higher than the projection of the remaining vertices by a large enough margin. Let $M_{\cdot,1}, \ldots, M_{\cdot,k}$ be the vertices of K. The proof of the following result is deferred to the full version [9].

▷ Claim 29. With high probability, the following event happens: for each $\ell \in [k]$, there is a vector $u^{(\ell)} \in U$ such that for all $\ell' \in [k], \ell' \neq \ell$, we have

$$u^{(\ell)} \cdot M_{\cdot,\ell} > u^{(\ell)} \cdot M_{\cdot,\ell'} + \frac{c\,\varepsilon \cdot \Delta(K)}{8\delta^2} \tag{16}$$

For rest of the proof, assume that the statement in Claim 29 holds true, i.e., there are directions $u^{(1)}, \ldots, u^{(k)} \in U$ satisfying (16). We now show that for every vertex of $M_{\cdot,\ell}$ of K, the corresponding point $x(u^\ell)$ is close to $M_{\cdot,\ell}$.

▷ Claim 30. For every $\ell \in [k]$, $|x(u^{(\ell)}) - M_{\cdot,\ell}| \leq 17\delta^2\Delta(K)/c$.

Proof. By the definition of $\mathcal{O}$, we know that $x(u^{(\ell)})$ can be written as $y(u^\ell) + z(u^{(\ell)})$, where $y(u^{(\ell)}) \in K$ and $|z(u^{(\ell)})| \leq \varepsilon\Delta(K)$. Thus, there is a convex combination $\lambda_{\ell'}, \ell' \in [k]$, of the vertices $M_{\cdot,\ell'}$ of K such that $x(u^{(\ell)}) = \sum_{\ell'\in[k]} \lambda_{\ell'} M_{\cdot,\ell'} + z(u^{(\ell)})$.

By the definition of $\mathcal{O}$, $x(u^{(\ell)}) \cdot u^{(\ell)} \geq M_{\cdot,\ell} \cdot u^{(\ell)} - \varepsilon\Delta(K)$ and $|z(u^{(\ell)}) \cdot u^{(\ell)}| \leq \varepsilon\Delta(K)$. So, we get

$$M_{\cdot,\ell} \cdot u^{(\ell)} - \varepsilon\Delta(K) \leq \sum_{\ell'\in[k]} \lambda_{\ell'} M_{\cdot,\ell'} \cdot u^{(\ell')} + \varepsilon\Delta(K),$$

which implies (after subtracting $\lambda_\ell M_{\cdot,\ell} \cdot u^{(\ell)}$ from both sides):

$$(1-\lambda_\ell)M_{\cdot,\ell}u^{(\ell)} \leq \sum_{\ell' \neq \ell} \lambda_{\ell'} M_{\cdot,\ell'} \cdot u^{(\ell')} + 2\varepsilon\Delta(K)$$

which, using Claim 29, yields:

$$(1-\lambda_\ell)M_{\cdot,\ell}u^{(\ell)} \leq (1-\lambda_\ell)M_{\cdot,\ell}u^{(\ell)} - (1-\lambda_\ell)\frac{c\varepsilon\Delta(K)}{8\delta^2} + 2\varepsilon\Delta(K).$$

It follows from the above inequality that $1-\lambda_\ell \leq \frac{16\delta^2}{c}$. Therefore,

$$|x(u^{(\ell)}) - M_{\cdot,\ell}| = \left|\sum_{\ell' \neq \ell} \lambda_{\ell'}(M_{\cdot,\ell} - M_{\cdot,\ell'})\right| + \varepsilon\Delta(K) \tag{17}$$

$$\leq \sum_{\ell' \neq \ell} \lambda_{\ell'}\Delta(K) + \varepsilon\Delta(K) \leq \frac{17\delta^2\Delta(K)}{c}.$$ ◁

This completes proof of the Theorem. ◀

6 From ListLearn to the k-OLP Problem

In this section, we show that for well-separated polytopes, a solution for the ListLearn problem can be used to solve the k-OLP problem as well. This algorithm uses the notion of soft convex hulls. We first describe the algorithm for constructing soft convex hulls, and then use it to solve the k-OLP problem.

6.1 Soft Convex Hulls

Let W be a finite set of points in $\Re^d$, and T be the vertices of $\mathsf{CH}(W)$. The subset T of W is the unique subset of W with the following properties:
(P1) $W \subseteq \mathsf{CH}(T)$
(P2) $\forall w \in W$, if $w \notin \mathsf{CH}(W \setminus \{w\})$, then $w \in T$.

We now define a natural notion of *soft* convex hull.

▶ **Definition 31.** *For an $\varepsilon \geq 0$, and $S \subseteq W$, define the ε-convex hull of S, ε-$\mathsf{CH}(S)$, as $\mathsf{CH}(S) + \varepsilon\Delta(W)B$, where B is the unit ball of the Euclidean norm.*

The intuition behind the above definition is that $\mathsf{CH}(W)$ can have many vertices, but there may be a small set of points whose soft convex hull contains W. This is defined more formally as follows:

▶ **Definition 32.** *We call a subset $T \subseteq W$ an ε-envelope of W, written ε-$\mathsf{ENV}(W)$, if $W \subseteq \varepsilon$-$\mathsf{CH}(T)$.*

Remarks. The following observations about the set ε-$\mathsf{ENV}(W)$ are easy to see:
(a) There are several distinct sets T which could qualify as ε-$\mathsf{ENV}(W)$. For example, let W consist of the following set of points in $\Re^2$: a set of points W_1 close to $(0,0)$ and a set of points W_2 close to $(1,0)$. Let T be a pair of points $\{x,y\}$ with $x \in W_1, y \in W_2$. Then it is easy to check that T is an ε-$\mathsf{ENV}(W)$; and (b) Let T be ε-$\mathsf{ENV}(W)$. Unlike property (P2) above, it is not necessary that if $w \in W$ is such that $w \notin \varepsilon$-$\mathsf{CH}(W \setminus \{w\})$, then $w \in T$.

Since the set ε-$\mathsf{ENV}(W)$ is not uniquely determined, we will impose one more condition on it to make it unique (if it exists) and polynomial time computable. This condition requires the points of T to be "far apart" from each other. More precisely:

▶ **Definition 33.** *For $\varepsilon, \delta \in [0,1]$, a set T is called a (ε,δ)-$\mathsf{ENV}(W)$ if it is an ε-$\mathsf{ENV}(W)$ and*

$$\forall w \in T, \mathsf{dist}(w, \mathsf{CH}(T \setminus \{w\})) > \delta\Delta(W) \tag{18}$$

The proof of the following result follows from standard arguments and is deferred to the appendix.

Given a subset T of W, we can check in polynomial time whether T is an (ε,δ)-$\mathsf{ENV}(W)$.

For rest of the section, we address the following question: given the set W, and parameters ε, δ, is there a (ε,δ)-$\mathsf{ENV}(W)$, and if so, can we find in polynomial time an approximation to this set? In the full version [9], we argue that several "natural" greedy strategies do not work. If $\varepsilon = 0$, the above question is easy to answer in polynomial time. The answer is yes iff the set T of vertices of $\mathsf{CH}(W)$ satisfies (18). Also, if $\delta = 1$, T has to be a singleton to satisfy (18).

In rest of this section, we consider the following problenm: For what pairs of values of ε, δ, can we prove that there is *essentially* at most one (ε,δ)-$\mathsf{ENV}(W)$, and if so, can we determine this set efficiently? We do not know the exact answer to this, but our main result here (which suffices for the applications) is (verbally stated) an affirmative answer to the question if the following condition is satisfied: $\delta \in \Omega(\sqrt{\varepsilon})$. This will follow as a corollary of our main result:

▶ **Theorem 34.** *Let $\delta, \varepsilon, \varepsilon_3$ be reals in $(0, 1/8)$ satisfying*

$$\delta > \max\left(\frac{2\varepsilon}{\varepsilon_3 - \varepsilon}, 4\varepsilon_3\right) \tag{19}$$

Let W be a finite set of points in $\Re^d$. We can determine in polynomial time whether exists a set T in (ε,δ)-$\mathsf{ENV}(W)$, and if so, we can efficiently find a subset Q of W such that

$$|Q| = |T| \tag{20}$$

$$\forall w \in T, \exists x \in Q : |w - x| \leq 2\varepsilon_3\Delta(W) \tag{21}$$

▶ **Corollary 35.** *Let δ, ε be reals in $(0, 1/8)$ satisfying $\delta > 16\sqrt{\varepsilon}$ Let W be a finite set of points in $\Re^d$. We can determine in polynomial time whether exists a set T forming a (ε,δ)-$\mathsf{ENV}(W)$, and if so, we can efficiently find a subset Q of W such that*

$$|Q| = |T| \tag{22}$$

$$\forall w \in T, \exists x \in Q : |w - x| \leq 8\sqrt{\varepsilon}\Delta(W) \tag{23}$$

Proof. The Corollary follows from Theorem (34) by taking $\varepsilon_3 = 4\sqrt{\varepsilon}$ ◀

We defer the proof of Theorem 34 to the full version [9]. The procedure for computing the set Q is as follows: We first compute a subset Q'' of W consisting of points $w \in W$ which do not lie in the soft convex hull of the points in W which are "far" from w – this can be done in polynomial time by using arguments similar to those in the proof of Section 6.1. Then Q is defined as a maximal subset of points in Q'' such that the pair-wise distance between the points in it is large.

6.2 Algorithm for k-OLP

We now show how soft convex hulls can be used to generate a solution for the k-OLP problem. The following result, which formalizes Theorem 9, uses the same setting as that in Theorem 28:

▶ **Theorem 36.** *Suppose ε, δ are reals in $[0,1]$ with $\delta^2 \geq c\varepsilon\sqrt{d}, \delta^3 \geq c\,\varepsilon$, where c is a large enough constant. Let K be a δ-well-separated k-vertex polytope. Suppose we are also given an $\mathsf{OptOr}_\varepsilon(K)$ oracle $\mathcal{O}$. Let W be the set of answers of the oracle $\mathcal{O}$ to $m = poly(d) \cdot k^{\Omega(1/\delta^2)}$ independent random queries. We can find $Q \subseteq W, |Q| = k$ in randomized $poly(d) \cdot k^{\Omega(1/\delta^2)}$-time which satisfies the following condition w.h.p.: for every vertex v of K, there is a point v' in Q with $|v - v'| \leq \delta\Delta(K)/10$.*

Proof. The proof of Theorem 28 shows that for every vertex $M_{\cdot,\ell}$ of K, there is a point $x(u^\ell) \in W$ such that

$$|x(u^{(\ell)}) - M_{\cdot,\ell}| \leq 17\delta^2\Delta(K)/c. \tag{24}$$

Let T denote $\{x(u^{(\ell)}) : \ell \in [k]\}$. Our first claim is that the points of T are also well-separated.

▷ Claim 37. For any $\ell \in [k]$, $\mathsf{dist}(x(u^{(\ell)}), \mathsf{CH}(T \setminus \{x(u^{(\ell)})\})) \geq \delta\Delta(K)/2$. Further, the diameter of $\mathsf{CH}(T)$ is at most $2\Delta(K)$.

Proof. Fix an index $\ell \in [k]$ and a point $y \in \mathsf{CH}(T \setminus \{x(u^{(\ell)})\})$. We can express y as a convex combination of points in $T \setminus \{x(u^{(\ell)})\}$, i.e., $y = \sum_{\ell' \neq \ell} \lambda_{\ell'} \cdot x(u^{(\ell')})$, where $\sum_{\ell' \neq \ell} \lambda_{\ell'} = 1$. Now,

$$\begin{aligned} |x(u^{(\ell)}) - y| &\geq \left| M_{\cdot,\ell} - \sum_{\ell' \neq \ell} \lambda_{\ell'} \cdot M_{\cdot,\ell'} \right| - |x(u^{(\ell)}) - M_{\cdot,\ell}| - \sum_{\ell' \neq \ell} \lambda_{\ell'} \cdot |x(u^{(\ell')}) - M_{\cdot,\ell'}| \\ &\geq \left(\delta - \frac{34\delta^2}{c}\right)\Delta(K) \geq \delta\Delta(K)/2, \end{aligned}$$

where the second last inequality follows from (24) and the fact that K is δ-well-separated. Since $\mathsf{dist}(x(u^{(\ell)}), K) \leq \varepsilon\Delta(K)$, it follows that $\Delta(\mathsf{CH}(T)) \leq 2\Delta(K)$. ◁

Recall that W denotes the set $\{x(u) : u \in U\}$. We now show that $\mathsf{CH}(T)$ closely approximates $\mathsf{CH}(W)$.

▷ Claim 38. $W \subseteq \varepsilon'\text{-}\mathsf{CH}(T)$, where $\varepsilon' = \frac{32\delta^2}{c}$.

Proof. Fix a point $x(u) \in W$. We know that $x(u)$ can be written as $x(u) = y(u) + z(u)$, $y(u) \in K, |z(u)| \leq \varepsilon$. Let $y(u) = \sum_{\ell \in [k]} \lambda_\ell \cdot M_{\cdot,\ell}$, where the coefficients λ_ℓ form a convex combination. Then

$$\left| x(u) - \sum_{\ell \in [k]} \lambda_\ell x(u^{(\ell)}) \right| \leq \sum_{\ell \in [k]} \lambda_\ell \cdot |x(u^{(\ell)}) - M_{\cdot,\ell}| + |z(u)| \leq \frac{17\delta^2\Delta(K)}{c} + \varepsilon\Delta(K) \leq \frac{32\delta^2\Delta(K)}{c},$$

where the second last inequality follows from (24) and the last inequality by the assumption in. ◁

Claim 37 and Claim 38 imply that T is (ε', δ')-$\mathsf{ENV}(W)$ with $\delta' = \delta/4, \varepsilon' = \frac{32\delta^2}{c}$. We can now apply Corollary 35 to get approximations to $x(u^{(\ell)})$ within distance $17\sqrt{\varepsilon'}\Delta(K)$. Claim 38 now implies that we can get approximations to $M_{\cdot,\ell}$ within distance

$$17\sqrt{\varepsilon'}\Delta(K) + \frac{16\delta^2\Delta(K)}{c} \leq \frac{\delta\Delta(K)}{10}.$$

This proves the desired result. ◀

7 k-OLP algorithm for Latent Polytopes using Singular Value Decomposition

Theorem 7 showed that a solution to k-OLP problem requires the error parameter ε to be $O^*(1/\sqrt{d})$. Theorem 28 gives an algorithm achieving this bound. However, for many polytopes with k vertices, we can solve the k-OLP problem with ε being $O^*(1/\sqrt{k})$. However, if $k < d$, this error is too high. To tackle this, we find a good approximation to the subspace spanned by the vertices of K, then we project to this subspace and use the result in Theorem 28. One such example is the "Latent $k-$ Polytope" (abbreviated LkP) problem which we now describe.

The LkP problem has been studied in [7]. Certain assumptions were made on the model, namely, the hidden polytope K as well as on the (hidden) process for generating observed data from latent points in K. These assumptions are (a) shown to hold in several important Latent Variable models and (b) are sufficient to enable one to get polynomial time learning algorithms.

Here, we formulate assumptions which are similar, but, weaker in one important aspect. Whereas [7] assumed that each vertex of K has a separation from the **affine hull** of the other vertices (thus, in particular, each vertex is affinely independent of other vertices), we assume here that each vertex is separated only from the convex hull of the others. Under this weaker assumption, the algorithm of [7] does not work. We give a different algorithm which we prove works. It is also simpler to state and carry out and its proof is based on a new general tool we introduce here - the Random Separating Hyperplane theorem (Theorem 12).

Assumptions on data in the LkP problem. Let $M_{.,1}, \ldots, M_{.,k}$ denote the vertices of K and $\mathbf{M}$ be the $d \times k$ matrix with columns representing the vertices of K. We assume there are latent (hidden) points $P_{.,j}, j = 1, 2, \ldots, n$ in K and observed data points $A_{.,j}, j = 1, 2, \ldots, n$ are generated (not necessarily under any stochastic assumptions) by adding *displacements* $A_{.,j} - P_{.,j}$ respectively to $P_{.,j}$. Clearly if the displacements are arbitrary, it is not possible to learn K given only the observed data. So we need some bound on the displacements.

Secondly, if all (or almost all) latent points lie in (or close to) the convex hull of a subset of $k-1$ or fewer vertices of K, the missing vertex cannot be learnt. To avoid this, we will assume that there is a certain w_0 fraction of latent points close to every vertex of K.

Let [4] $\sigma_0 := \frac{||\mathbf{P}-\mathbf{A}||}{\sqrt{n}}$. We now show that the k-OLP-**Algorithm** mentioned in Section 1.2 has the desired properties:

▶ **Theorem 39.** *Suppose K is a latent poytope with k vertices $M_{.,1}, M_{.,2}, \ldots, M_{.,k}$ and $\mathbf{P}, \mathbf{A}$ are latent points (all in K) and observed data respectively. Assume*

$$\text{For all } \ell \in [k]\ ,\ C_\ell := \{j : |P_{.,j} - M_{.,\ell}| \leq \frac{\sigma_0}{\sqrt{w_0}}\} \text{ satisfies } |C_\ell| \geq w_0 n. \tag{25}$$

Suppose $(\sqrt{\log k}/\sqrt{c_0 k}) \leq \delta \leq 1$ and c_0 is a large constant satisfying

$$\sigma_0 \leq \frac{\delta^2 \Delta(K)}{100 c_0} \frac{\sqrt{w_0}}{\sqrt{k}}. \tag{26}$$

Let V be the k-dimensional SVD subspace of $\mathbf{A}$, and $\widehat{K}$ denote the projection of K on V.

[4] By the standard definition of spectral norm, it is easy to see that σ_0^2 is the maximum mean squared displacement in any direction.

- *There is an* $\mathsf{OptOr}_{\frac{10\sigma_0}{\sqrt{w_0}\Delta}}(\widehat{K})$ *oracle* $\mathcal{O}$.
- *The algorithm* k-OLP **Algorithm** *in Section 1.2 outputs a set* Q *of* k *points such that the following condition is satisfied w.h.p.: for every vertex* v *of* K*, there is a point* v' *in* Q *with* $|v - v'| \leq \delta\Delta(K)/5$.

In the Theorem above, (26) implies an upper bound on σ_0 of $\Delta(K)\sqrt{w_0}/(c_0\sqrt{k})$ and so the oracle $\mathcal{O}$ used by the Theorem lies in $\mathsf{opt}_\varepsilon(\widehat{K})$ for $\varepsilon \leq 1/(c_0\sqrt{k})$. Thus, we get around the lower bound result Theorem 7 by working in the k-dimensional SVD subspace of $\mathbf{A}$. The proof of this result is deferred to the full version [9].

8 Open Problems

We now mention some problems that remain open in our work:

(i) In the statement of RSH, the success probability of the desired event is $O\left(1/k^{O(1/\delta^2)}\right)$. Can we improve the exponential dependence of the success probability on $1/\delta$?

(ii) Theorem 21 on the Haus problem returns exponentially many points whose convex hull approximates K. Can this be improved, either via an improvement mentioned in the first open problem above or by feeding the exponentially many points to the algorithm of [12]?

(iii) RSH asserts that if a point is sufficiently far from a k vertex polytope, then, a random hyperplane separates them, where, "sufficienlty" is measured with respect to the diameter of the polytope. An interesting question is whether there is a "dual" statement. The dual of points are facets, so, intuitively, a dual statement might assert that if for a polytope with k facets, there is a sufficiently deep cut, then, a random cut cuts reasonably deep into the polytope. But it is not obvious how to measure "deep" (and reasonably deep) . We leave a dual statement of RSH as an open question.

A Some Examples

The first example shows that the factor $1/\sqrt{m}$ in the statement of RSH (Theorem 1) cannot be improved, even for a simple polytope K consisting of just one line segment.

▶ **Example 1.** Suppose K is a polytope in $\Re^d$ with just two vertices Δ distance apart and $V = \Re^d, \delta = 1$. It is easy to verify from standard results on random projection on a line that the additive term in inequality (2) is tight up to constant factors.

The next example shows that the success probability of the desired event (2) in Theorem 1 needs to depend on k, the number of vertices of the polytope K.

▶ **Example 2.** Consider the Euclidean space $\Re^d$ and the $d-1$ dimensional sphere $K := \{x \in \Re^d : |x| \leq 1, x_1 = 0\}$. Observe that the diameter Δ of K is 1. Let a denote the point $(1, 0, 0, \ldots, 0)$. It is at distance 1 from K, and so the parameter δ in the statement of Theorem 1 can be set to 1. But, with high probability, a random unit length vector u has $u \cdot a \approx \frac{c}{\sqrt{d}}$ for some constant c, whereas the maximum of $v \cdot x$ over all points x in the sphere K is about 1. Therefore the probability of the event (2) is exponentially small in d.

Another Hamiltonian Cycle in Bipartite Pfaffian Graphs

Jesper Nederlof
Utrecht University, The Netherlands

Abstract

Finding a Hamiltonian cycle in a given graph is computationally challenging, and in general remains so even when one is further given one Hamiltonian cycle in the graph and asked to find another. In fact, no significantly faster algorithms are known for finding another Hamiltonian cycle than for finding a first one even in the setting where another Hamiltonian cycle is structurally guaranteed to exist, such as for odd-degree graphs. We identify a graph class – the bipartite Pfaffian graphs of minimum degree three – where it is NP-complete to decide whether a given graph in the class is Hamiltonian, but when presented with a Hamiltonian cycle as part of the input, another Hamiltonian cycle can be found efficiently.

We prove that Thomason's lollipop method [Ann. Discrete Math., 1978], a well-known algorithm for finding another Hamiltonian cycle, runs in a linear number of steps in cubic bipartite Pfaffian graphs. This was conjectured for cubic bipartite planar graphs by Haddadan [MSc thesis, Waterloo, 2015]; in contrast, examples are known of both cubic bipartite graphs and cubic planar graphs where the lollipop method takes exponential time.

Beyond the reach of the lollipop method, we address a slightly more general graph class and present two algorithms, one running in linear-time and one operating in logarithmic space, that take as input (i) a bipartite Pfaffian graph G of minimum degree three, (ii) a Hamiltonian cycle H in G, and (iii) an edge e in H, and output at least three other Hamiltonian cycles through the edge e in G.

We also present further improved algorithms for finding optimal traveling salesperson tours and counting Hamiltonian cycles in bipartite planar graphs with running times that are not achieved yet in general planar graphs.

Our technique also has purely graph-theoretical consequences; for example, we show that every cubic bipartite Pfaffian graph has either zero or at least six distinct Hamiltonian cycles; the latter case is tight for the cube graph.

1 Introduction

Finding a Hamiltonian cycle in a given undirected graph is a well-known, well-researched, and hard problem. This paper studies the question whether knowledge of one Hamiltonian cycle helps in finding another one. More precisely, the Another Hamiltonian Cycle problem asks, given as input (i) a graph[1] G, (ii) a Hamiltonian cycle H in G, and (iii) an edge $e \in E(H)$, to find another Hamiltonian cycle $H' \neq H$ in G with $e \in E(H')$.

Our interest is in the class of bipartite *Pfaffian*[2] graphs, a superclass of the bipartite planar graphs. This focus is partly motivated by the fact that both in cubic bipartite graphs and cubic planar graphs, a well-known general algorithm for finding another Hamiltonian cycle, Thomason's lollipop method [27], requires exponential time in the worst case, cf. Section 1.1. Also, the problem of deciding if the graph contains a Hamiltonian cycle at all remains NP-hard in the family of cubic bipartite planar graphs, as proved by Akiyama, Nishizeki, and Saito [1].

As our main result, we show that Another Hamiltonian Cycle admits both a linear-time algorithm as well as a logarithmic-space algorithm in bipartite Pfaffian graphs of minimum degree three. Further restricted to cubic bipartite Pfaffian graphs, we prove that Thomason's lollipop method runs in a linear number of steps and can be implemented to run in linear time. This is to our knowledge a first example of a nontrivial graph class where Another Hamiltonian Cycle is efficiently solvable; such an example was solicited by Kintali [18]. By trivial we here intend a graph class in which Hamiltonicity detection is NP-hard but is artificially constructed to ensure a simple local rerouting of any Hamiltonian cycle. Rather, in our case the global properties of bipartiteness, Pfaffianity, and the everywhere-local property of minimum-degree three, interplay to enable an efficient algorithm. Without the minimum-degree constraint, the problem is NP-hard (see the full version [4]).

Our techniques have also purely graph-theoretic consequences. We show that every cubic bipartite Pfaffian graph has at least three other Hamiltonian cycles through any edge of a Hamiltonian cycle. All three Hamiltonian cycles can be found in linear time. We also show that such Hamiltonian graphs must have at least six Hamiltonian cycles. The 8-vertex cube graph (), the canonical example in this class, is an extremal example to both results. It has precisely six distinct Hamiltonian cycles with every graph edge in exactly four of them.

1.1 Motivation and earlier work

While a graph need not be Hamiltonian, and a Hamiltonian graph need not admit another Hamiltonian cycle, there exist graph families with Hamiltonian members where another Hamiltonian cycle is always known to exist. Perhaps the most prominent such family are the odd-degree graphs, which via Smith's Theorem (see [30]) have an even number of Hamiltonian cycles through any given edge. Thomason [27] gave a constructive proof by describing an algorithm that solves for another Hamiltonian cycle in cubic graphs. The algorithm is often called Thomason's lollipop method as it transforms a Hamiltonian cycle to another one by a sequence of lollipop graphs, see Section 3.3 for a precise description of the algorithm. Dropping the requirement that the Hamiltonian cycle should go through a specific edge,

[1] We tacitly work with undirected simple loopless graphs unless mentioned otherwise, as well as assume knowledge of standard graph-theoretic terminology [32]. Our conventions with graphs can be found in Section 1.6.

[2] We postpone a precise definition and motivation of Pfaffian graphs to Section 1.5. Planar graphs are Pfaffian.

Bosák [5] proved that every cubic bipartite graph has an even number of Hamiltonian cycles. Thomassen [28, 29] showed that no bipartite graph in which every vertex in one of the two parts of the bipartition has degree at least three, has a unique Hamiltonian cycle. A famous conjecture due to Sheehan [26] claims that no 4-regular graph can have a unique Hamiltonian cycle; Thomassen's result proves Sheehan's conjecture for bipartite graphs.

Papadimitriou [24] popularized the Another Hamiltonian Cycle problem and Thomason's algorithm by introducing the complexity class PPA and showed the containment of the problem in odd-degree graphs; completeness for PPA remains open. It is also open whether the problem can be solved in polynomial time – indeed, the drawback of Thomason's algorithm is that it may run for a very long time; Krawczyk [19] and Cameron [8] showed that Thomason's algorithm requires exponential time for a family of cubic planar graphs. Later this was shown by Zhong [33] also for cubic bipartite graphs. The best bound to date is the recent result of Briański and Szady [6], which shows that there are cubic 3-connected planar graphs on n vertices, in which Thomason's lollipop algorithm runs in $\Omega(1.18^n)$ time.

The above papers reason about Thomason's algorithm specifically, but it may of course be other algorithms that solve the problem more efficiently. Some progress in this direction was provided by Bazgan, Santha, and Tuza [2] that showed that one given a cubic graph on n vertices and one of its Hamiltonian cycles can find another cycle of length $(1-\epsilon)n$ for any fixed constant $\epsilon > 0$ in polynomial time. Deligkas, Mertzios, Spirakis, and Zamaraev [12] derived an exponential-time polynomial-space deterministic algorithm that given a cubic graph along with one of its Hamiltonian cycles finds another Hamiltonian cycle; the algorithm is shown to be faster than the fastest known exponential-time polynomial-space deterministic algorithm for finding a Hamiltonian cycle in cubic graphs.

1.2 Main results for bipartite Pfaffian graphs

Let us now review our main results for bipartite Pfaffian graphs and the underlying techniques in more detail. Our main theorems are as follows.

▶ **Theorem 1** (Main; Linear–time Another Hamiltonian Cycle in minimum degree three). *There exists a deterministic linear-time algorithm that, given as input (i) a bipartite Pfaffian graph G with minimum degree three, (ii) a Hamiltonian cycle H in G, and (iii) an edge $e \in E(H)$, outputs a Hamiltonian cycle $H' \neq H$ in G with $e \in E(H')$.*

▶ **Theorem 2** (Main; Logarithmic–space Another Hamiltonian Cycle in minimum degree three). *There exists a deterministic logarithmic-space algorithm that, given as input (i) a bipartite Pfaffian graph G with minimum degree three, (ii) a Hamiltonian cycle H in G, and (iii) an edge $e \in E(H)$, outputs a Hamiltonian cycle $H' \neq H$ in G with $e \in E(H')$.*

The framework underlying our main theorems can be used to prove an upper bound on the number of steps needed for Thomason's lollipop method to terminate.

▶ **Theorem 3** (Thomason's lollipop method in cubic bipartite Pfaffian graphs). *Thomason's lollipop method starting from any Hamiltonian cycle H and any edge $e \in E(H)$ in an n-vertex cubic bipartite Pfaffian graph G, terminates after at most n steps.*

It was conjectured in a master thesis at Waterloo by Haddadan [14] that Thomason's lollipop method runs in a linear number of steps in cubic bipartite planar graphs. It was there also proven to hold for the subfamily of such graphs that does not have the wheel graph on six vertices as a minor. However, as the author himself points out, finding a first Hamiltonian cycle in this limited graph family does not seem intractable. We are not aware of any other papers providing a polynomial time bound on Thomason's lollipop method in any graph class.

Our framework also can be used to prove the following structural results for Hamiltonian cycles. Their proofs appear in the full version [4] of this paper.

▶ **Corollary 4** (Non-uniqueness in minimum degree three)**.** *For every bipartite Pfaffian graph G of minimum degree three and for every edge $e \in E(G)$, it holds that G has either zero or at least four distinct Hamiltonian cycles H with $e \in E(H)$.*

The cube graph is a cubic bipartite Pfaffian graph with six distinct Hamiltonian cycles. We show that no Hamiltonian graph in this class can have fewer Hamiltonian cycles.

▶ **Corollary 5** (Cubic tight lower bound)**.** *Every cubic bipartite Pfaffian graph has either zero or at least six distinct Hamiltonian cycles.*

Chia and Ong [9] (in the paragraph after Theorem 10) asked whether there exists cubic bipartite planar graphs with exactly four Hamiltonian cycles. The above Corollary rules out that possibility.

Remarks. One consequence of Theorem 1 is that if the Another Hamiltonian Cycle problem in general odd degree graphs is PPA-complete as hypothesized by Papadimitriou [24, Open Problem (4)], then any proof cannot carry over to cubic bipartite planar graphs unless also PPA = FP. Our result also seems related to another well-known conjecture, namely Barnette's conjecture (cf. Tutte [31, Unsolved Problem V]), which states that every cubic 3-connected bipartite planar graph (*Barnette graph*) has a Hamiltonian cycle. Gorsky, Steiner, and Wiederrecht [13] recently extended the conjecture by showing that if Barnette's conjecture is true, it also holds that every cubic bipartite 3-connected Pfaffian graph has a Hamiltonian cycle. It is known that if Barnette's conjecture is true, then there is a Hamiltonian cycle through every edge in every such graph, see Kelmans [17]. Moreover, it was indirectly shown by Holton, Manvel, and McKay [15] that any Barnette graph larger than the smallest such graph – namely the cube graph – can be reduced to a smaller Barnette graph in such a way that if the smaller graph has a Hamiltonian cycle through every edge, then the larger one must also have a Hamiltonian cycle. This means that if it was possible given any single Hamiltonian cycle in a Barnette graph to generate a Hamiltonian cycle through any specific edge *not* on the initial cycle, then Barnette's conjecture would be constructively true. We remark that our algorithm is not known to be able to do this, not even indirectly by applying it several times in a chain of Hamiltonian cycle transformations. We do note however, that our algorithms in Theorems 1 and 2 not only make sure the edge $e = \{s, t\}$ is part of both Hamiltonian cycles, they also retain the other edge incident to s on H; this can be observed by Lemma 10, that is, no edge incident to s is changed by the algorithms since it is not on the alternating cycle we use. In particular this makes it possible given H and any given edge $f \in E(G)$ *not* on H, to find another Hamiltonian cycle H' such that f is also not part of H'.

1.3 Overview of techniques

At the heart of our algorithms and structural results is what we believe to be a new framework for efficiently witnessing a Hamiltonian cycle H through an arbitrary *anchor* edge e in a bipartite Pfaffian graph G. We associate a (not necessarily proper) two-coloring $\chi_H : V(G) \to \{0, 1\}$ to H that is unique to H (but dependent on a fixed but arbitrary Pfaffian orientation of G as well as e) and that defines a unique *acyclic* Hamiltonian[3] orientation of

[3] In precise terms, the orientation is a directed acyclic graph that contains as a directed subgraph a directed Hamiltonian *path* from one end of e to the other.

$G \setminus e$. We will refer to such an χ_H as a *good coloring*. This acyclicity in particular enables the unique recovery of H in linear time by standard topological sorting when given χ_H as advice. The reader may want to consult Figure 1 (on page 9) for an advance illustration at this point; the framework itself is developed in Section 2.

We also show that it suffices to know χ_H in only one of the parts of a bipartition of G to efficiently extend to a Hamiltonian cycle, which is not necessarily equal to H however. More precisely, we show that a coloring λ of one of the parts leads to an auxiliary bipartite graph F_λ whose perfect matchings correspond to the good colorings χ_H extending λ, which in turn each define a unique Hamiltonian cycle H. We refer to Figure 2 (on page 11) for an advance illustration of this setting.

Finally, when G has minimum degree three, we observe that we can use F_λ to efficiently switch from one Hamiltonian cycle H in G (described by a perfect matching M_H in F_λ) to another Hamiltonian cycle $H' \neq H$ in G by switching along an alternating cycle in F_λ which can be discovered through a directed cycle in an auxiliary directed graph $D_{\lambda,H}$. Moreover, we show that this construction and discovery can be executed in deterministic linear time – we refer to Figure 3 (on page 14) for an advance illustration; the switching construction itself is developed in Section 3.

1.4 Further results

Our framework for witnessing Hamiltonicity should be contrasted with the Cut&Count approach for detecting Hamiltonian cycles by Cygan, Nederlof, Pilipczuk, Pilipczuk, Van Rooij, and Wojtaszczyk [10], which reduces the Hamiltonian cycle problem to a local problem by showing that a cycle cover of the input graph is Hamiltonian if and only if the number of the exponentially many vertex partitions that are consistent (defined in a certain local way) with it is *odd*. This approach therefore necessarily reduces the original decision problem to a parity counting problem, which has several disadvantages that seem inherent to the approach, including the need for randomization and a running time factor that is pseudo-polynomial in the integer weights for edge-weighted problem variants. Our framework shows that for bipartite Pfaffian graphs there is a more natural way to witness that a cycle cover is Hamiltonian using only a *single* vertex partition; that is, χ_H.

We explore the algorithmic consequences of our technique in the context of counting Hamiltonian cycles and in the context of the Traveling Salesperson Problem (TSP) in bipartite Pfaffian/planar graphs. For reasons of space, we postpone a detailed statement of these results, a discussion of pertinent earlier work, as well as the proofs, to the full version [4] of this paper.

1.5 Pfaffian graphs

Let us now define and motivate Pfaffian graphs in more detail. An *orientation* of a graph G replaces every edge $\{u, v\} \in E(G)$ with either the directed arc (u, v) or the directed arc (v, u), thereby obtaining a directed graph $\vec{G}$. A cycle C in G is *central* if the graph $G \setminus V(C)$ admits a perfect matching. We say that an orientation of a cycle is *consistent* if it is strongly connected. An orientation $\vec{G}$ of G is *Pfaffian* if for every central cycle C in G it holds that both consistent orientations of C have an odd number of arcs in common with $\vec{G}$. A graph is *Pfaffian* if it admits a Pfaffian orientation.

The bipartite Pfaffian graphs are most famous as the graph class in which Pólya's permanent problem has a solution, the bipartite graphs in which one can compute the number of perfect matchings efficiently by reduction to a matrix determinant, see e.g. Robertson,

Seymour, and Thomas [25] and McCuaig [22]. This brings us to one of our motivations to study the complexity of the detection (and counting) of Hamiltonian cycles on this graph class: Previous algorithms for Hamiltonian cycles (such as the one by Björklund [3]) use determinant-based methods previously designed for counting matchings (modulo 2) in polynomial time; given this close connection between the two problems it is natural to ask whether Pfaffianity can be exploited for detecting and counting Hamiltonian cycles, similarly as for counting perfect matchings.

The bipartite Pfaffian graphs were characterized by Little [21] as those graphs G that do not have a vertex set $U \subseteq V(G)$ such that $G \setminus U$ has a perfect matching and the induced subgraph $G[U]$ admits an even subdivision of $K_{3,3}$ as a subgraph. McCuaig [22] and Robertson, Seymour, and Thomas [25] gave a structural characterization of bipartite Pfaffian graphs and the latter also outlined an $O(n^3)$ time algorithm for their recognition; this algorithm can also produce a Pfaffian orientation when one exists.

A general Pfaffian graph, as opposed to a bipartite one, can be very dense as observed by Norine [23]: there is an infinite family of n-vertex Pfaffian graphs with $\Omega(n^2)$ edges. This construction in particular poses obstacles to find characterizations as the ones mentioned above for bipartite graphs. Indeed, it is not known how to efficiently recognize a general Pfaffian graph.

The most famous Pfaffian graphs are the *planar* ones, graphs whose vertices can be embedded in the plane with straight lines connecting the vertices of every edge without line crossings except at endpoints. That planar graphs are Pfaffian was discovered by Kasteleyn [16]; there is also a linear-time algorithm that finds a Pfaffian orientation given a planar graph by Little [20].

1.6 Conventions and organization

We assume knowledge of standard graph-theoretic terminology; see e.g. West [32]. Graphs in this paper are undirected unless otherwise mentioned; this in particular also applies to subgraphs such as paths, cycles, and Hamiltonian cycles. No graph or directed graph in this paper has loops or multiple edges. For a graph or directed graph G, we write $V(G)$ for the vertex set of G and $E(G)$ for the edge set of G. We identify the *edges* of a graph with two-subsets $\{u, w\}$ where u and w are distinct vertices. We call the edges of a directed graph *arcs* in what follows, and identify each arc with a two-tuple (u, w) where u and w are distinct vertices. We recall our conventions with orientations and Pfaffian graphs from Section 1.5.

We work with Iverson's bracket notation – for a logical proposition P, we define

$$[\![P]\!] = \begin{cases} 1 & \text{if } P \text{ is true}\,; \\ 0 & \text{if } P \text{ is false}\,. \end{cases}$$

The rest of this paper is organized as follows. Section 2 presents our novel witnessing technique for Hamiltonian cycles in bipartite Pfaffian graphs. We prove our main theorems and their indirect structural corollaries in Section 3. Proofs of Lemmas, Theorems, and Corollaries that are omitted due to space constraints can be found in the full version [4] of this paper. In the full version we also prove the NP-hardness of Another Hamiltonian Cycle in bipartite Pfaffian graphs without constrained vertex degrees, and state, motivate, and prove further results on counting Hamiltonian cycles as well as on TSP.

2 Hamiltonian cycles in bipartite Pfaffian graphs

This section presents what we believe to be a novel technique to efficiently witness Hamiltonian cycles in bipartite Pfaffian graphs via (not necessarily proper) two-colorings of the vertices. We also show how to efficiently construct a Pfaffian orientation from a known Hamiltonian cycle in a bipartite Pfaffian graph, as well as show how to efficiently find a witness by extending a given partial witness defined on only one of the parts of a bipartition.

Throughout this section G is an n-vertex bipartite Pfaffian graph and $\vec{G}$ is a fixed but otherwise arbitrary Pfaffian orientation of G. Since we are interested in whether G is Hamiltonian, without loss of generality we may assume that n is even and $n \geq 4$ in what follows.

Select an arbitrary edge $e \in E(G)$ and call it the *anchor* edge.

2.1 Preliminaries: The structure of Pfaffian orientations

We start by recalling the known structure of Pfaffian orientations of G. Namely, de Carvalho, Lucchesi, and Murty [11] observed that all Pfaffian orientations of G are obtainable from each other by reversals of arcs across vertex cuts. More precisely, for any Pfaffian orientation $\vec{G}$ and any vertex $u \in V(G)$, it holds that reversing the arcs incident to u in $\vec{G}$ results in another Pfaffian orientation; furthermore, every Pfaffian orientation of G can be obtained by starting with an arbitrary Pfaffian orientation of G and repeating such operations for different vertices [11].

2.2 The two-coloring defined by an anchored Hamiltonian cycle

We are interested in characterising each Hamiltonian cycle H in G that traverses the selected anchor edge e – we say that such an H is *anchored* – using a function $\chi_H : V(G) \to \{0,1\}$ that is unique[4] to H and from which we will (in the next subsection) see H can be efficiently constructed.

Towards this end, let us study the Pfaffian orientation $\vec{G}$ at the anchor e. Let $(s,t) \in E(\vec{G})$ be the arc in $\vec{G}$ whose underlying edge in G is the anchor edge $e = \{s,t\}$. Construct from the Pfaffian orientation $\vec{G}$ a new orientation $\vec{G}_e$ of G that is otherwise identical to $\vec{G}$ except that the arc (s,t) has been replaced with the arc (t,s). That is, by definition we have $(t,s) \in E(\vec{G}_e)$.

Now consider an arbitrary anchored Hamiltonian cycle H in G. Since $e \in E(H)$, there is a unique consistent orientation $\vec{H}$ of H such that $(t,s) \in E(\vec{H})$. Let us write $v_0, v_1, \ldots, v_{n-1}$ for the vertices of G indexed in the directed $\vec{H}$-path order from s to t; that is,

$$v_0 = s\,, \quad v_{n-1} = t\,, \quad \text{and} \quad (v_i, v_{(i+1) \bmod n}) \in E(\vec{H}) \quad \text{for all } i = 0, 1, \ldots, n-1\,. \tag{1}$$

Associate with H the (not necessarily proper) vertex-coloring function $\chi_H : V(G) \to \{0,1\}$ defined by setting

$$\begin{aligned} &\chi_H(v_0) = 0 \quad \text{and} \\ &\chi_H(v_{i+1}) \equiv \chi_H(v_i) + [\![(v_i, v_{i+1}) \in E(\vec{G}_e)]\!] \pmod 2 \quad \text{for all } i = 0, 1, \ldots, n-2\,. \end{aligned} \tag{2}$$

[4] Unique but not canonical; as we will see, the function χ_H will depend not only on the Hamiltonian cycle H but also on the choice of our assumed fixed but arbitrary Pfaffian orientation $\vec{G}$ of G.

Because $\vec{G}$ is a Pfaffian orientation and H is a central cycle of G, we have

$$|E(\vec{H}) \cap E(\vec{G})| = \sum_{i=0}^{n-1} [\![(v_i, v_{(i+1) \bmod n}) \in E(\vec{G})]\!] \equiv 1 \pmod 2 . \tag{3}$$

Since $\vec{G}$ and $\vec{G}_e$ differ only in the orientation of $e \in E(H)$, from (3) we immediately have

$$|E(\vec{H}) \cap E(\vec{G}_e)| = \sum_{i=0}^{n-1} [\![(v_i, v_{(i+1) \bmod n}) \in E(\vec{G}_e)]\!] \equiv 0 \pmod 2 . \tag{4}$$

We thus conclude

$$\begin{aligned} \chi_H(v_0) \overset{(2)}{=} 0 \overset{(4)}{\equiv} |E(\vec{H}) \cap E(\vec{G}_e)| &= \sum_{i=0}^{n-2} [\![(v_i, v_{i+1}) \in E(\vec{G}_e)]\!] + [\![(v_{n-1}, v_0) \in E(\vec{G}_e)]\!] \\ &\overset{(2)}{\equiv} \chi_H(v_{n-1}) + [\![(v_{n-1}, v_0) \in E(\vec{G}_e)]\!] \pmod 2 . \end{aligned} \tag{5}$$

Since by definition of $\vec{G}_e$ we have $(t, s) \in E(\vec{G}_e)$, from (1) and (5) we conclude that $\chi_H(t) = 1$. Furthermore, from (2) and (5) we have for all $(u, w) \in E(\vec{H})$ that

$$\chi_H(w) \equiv \chi_H(u) + [\![(u, w) \in E(\vec{G}_e)]\!] \pmod 2 . \tag{6}$$

That is, each arc $(u, w) \in E(\vec{H})$ is χ_H-monochromatic (i.e. both endpoints are assigned the same value by χ_H) if and only if $(w, u) \in E(\vec{G}_e)$.

2.3 The orientation induced by a good coloring

Suppose now that we do not know anything about the (anchored) Hamiltonian cycles of G, if any, and have access only to the Pfaffian orientation $\vec{G}$ and the orientation $\vec{G}_e$; the latter is easily obtainable from $\vec{G}$, cf. Section 2.2.

Consider an arbitrary vertex coloring $\chi : V(G) \to \{0, 1\}$ with $\chi(s) = 0$ and $\chi(t) = 1$. The last observation in Section 2.2 suggests that we should explore reversing exactly the χ-monochromatic arcs in $\vec{G}_e$. Let us make this formal as follows. Let the orientation $\vec{G}_e^{\chi}$ *induced* by the coloring χ be the unique orientation of G that for each edge $\{u, w\} \in E(G)$ satisfies

$$(u, w) \in E(\vec{G}_e^{\chi}) \quad \text{if and only if} \quad \chi(w) \equiv \chi(u) + [\![(u, w) \in E(\vec{G}_e)]\!] \pmod 2 . \tag{7}$$

To witness the serendipity of (7), suppose that G admits an anchored Hamiltonian cycle H; it follows immediately from (6) and (7) that $E(\vec{H}) \subseteq E(\vec{G}_e^{\chi_H})$. Thus, if we know only the coloring χ_H but not H, we can search for $E(\vec{H})$ in $E(\vec{G}_e^{\chi_H})$; let us next analyse this situation in more detail from the standpoint of our arbitrary χ.

Call the coloring χ *good* if there exists an anchored Hamiltonian cycle H in G with $\chi = \chi_H$; otherwise call χ *bad*. The following lemma shows that the orientation $\vec{G}_e^{\chi}$ for a good χ enables *linear-time* and unique algorithmic recovery of H by standard longest-path search in a directed acyclic graph (DAG); in fact, mere topological sorting suffices, as is apparent from the proof. See also Figure 1 for an illustration of the concepts involved in a Hamiltonian planar graph.

▶ **Lemma 6** (Acyclic Hamiltonicity of good-coloring-induced orientations). *Let χ be good. Then, the orientation $\vec{G}_e^{\chi} \setminus (t, s)$ of $G \setminus e$ is acyclic with the unique source vertex s and the unique sink vertex t. Moreover, the longest directed path in $\vec{G}_e^{\chi} \setminus (t, s)$ is unique and a directed Hamiltonian path.*

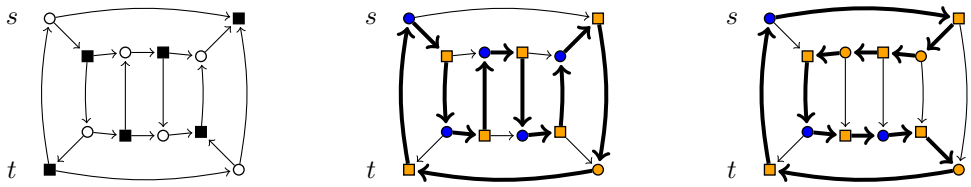

Figure 1 Illustration of orientations induced by good colorings. Left: an undirected bipartite planar graph G drawn in one of its orientations $\vec{G}_e$ with $e = \{s, t\}$, one arc reversal away from a Pfaffian orientation $\vec{G}$. Middle and right: two vertex colorings χ_H and coloring-induced orientations $\vec{G}_e^{\chi_H}$ for two different Hamiltonian cycles H, with the arcs of $\vec{H}$ drawn in bold in each case. Observe that every monochromatic arc reverses its orientation with respect to $\vec{G}_e$, whereas bichromatic arcs keep their orientation. Observe also that the removal of the arc (t, s) from $\vec{G}_e^{\chi_H}$ leaves an acyclic Hamiltonian directed graph, whereby the directed Hamiltonian path and hence H can be found, for example, by topological sorting; cf. Lemma 6.

Proof. Since χ is good, there exists an anchored Hamiltonian cycle H with $\chi = \chi_H$. Furthermore, we can follow the notational conventions in Section 2.2 with respect to this H, including the vertex-indexing $v_0, v_1, \ldots, v_{n-1}$ for G and (1) in particular. From $E(\vec{H}) \subseteq E(\vec{G}_e^{\chi})$ we thus conclude that the sequence $v_0, v_1, \ldots, v_{n-1}$ defines a longest directed path (which is also a directed Hamiltonian path from s to t) in the directed graph $\vec{G}_e^{\chi} \setminus (t, s)$. It follows immediately that s is the only possible source vertex and t is the only possible sink vertex in $\vec{G}_e^{\chi} \setminus (t, s)$.

Let us next show that $\vec{G}_e^{\chi} \setminus (t, s)$ is acyclic as a directed graph. To reach a contradiction, suppose that $\vec{D}$ is a directed cycle in $\vec{G}_e^{\chi} \setminus (t, s)$. Since $(t, s) = (v_{n-1}, v_0) \notin E(\vec{D})$ and $\vec{D}$ is a directed cycle with $V(\vec{D}) \subseteq \{v_0, v_1, \ldots, v_{n-1}\}$, there must exist $0 \leq i < j \leq n-1$ with at least two proper inequalities among the three such that $(v_j, v_i) \in E(\vec{D})$ and thus $(v_j, v_i) \in E(\vec{G}_e^{\chi})$. Let $\vec{C}$ be the directed cycle with $V(\vec{C}) = \{v_i, v_{i+1}, \ldots, v_j\}$ and $E(\vec{C}) = \{(v_i, v_{i+1}), (v_{i+1}, v_{i+2}), \ldots, (v_{j-1}, v_j), (v_j, v_i)\}$. In particular, $\vec{C} \neq \vec{H}$ since $(t, s) \notin E(\vec{C})$. Let C be the underlying undirected cycle of $\vec{C}$, and observe that C is a cycle of G. Since G is bipartite, C is even and has at least four vertices. Thus, the edges of $H \setminus V(C)$ contain a perfect matching of $G \setminus V(C)$, implying that C is central. Since C avoids e and $\vec{C}$ is a consistent orientation of C, we conclude by Pfaffianity that

$$|E(\vec{C}) \cap E(\vec{G}_e)| = |E(\vec{C}) \cap E(\vec{G})| \equiv 1 \pmod 2 .$$

But this is a contradiction since for all $(u, w) \in E(\vec{C})$ we have $(u, w) \in E(\vec{G}_e^{\chi})$, and thus by (7) it holds that $\chi(w) \equiv \chi(u) + [\![(u, w) \in E(\vec{G}_e)]\!] \pmod 2$; take the sum of these congruences over all arcs $(u, w) \in E(\vec{C})$ to conclude that $|E(\vec{C}) \cap E(\vec{G}_e)| \equiv 0 \pmod 2$, a contradiction. Thus, $\vec{G}_e^{\chi} \setminus (t, s)$ is acyclic as a directed graph.

From acyclicity it also immediately follows that s is a source vertex and t is a sink vertex of $\vec{G}_e^{\chi} \setminus (t, s)$; indeed, any arc into s or any arc out of t would complete a directed cycle together with an appropriate proper segment of the directed Hamiltonian path $s = v_0, v_1, \ldots, v_{n-1} = t$. This longest path (of n vertices) is also seen to be unique in $\vec{G}_e^{\chi} \setminus (t, s)$; indeed, the existence of any other such path would again imply an arc that would complete a directed cycle together with an appropriate proper segment of $v_0, v_1, \ldots, v_{n-1}$. ◀

An immediate corollary of the proof Lemma 6 is that there are at most 2^{n-2} Hamiltonian cycles through any fixed edge in an n-vertex bipartite Pfaffian graph. For comparison, there are planar graphs with at least 2.08^n Hamiltonian cycles, see [7].

2.4 Constructing a Pfaffian orientation from a Hamiltonian cycle

Next we address the task of constructing a Pfaffian orientation if we know one Hamiltonian cycle, with the intent of constructing possible further Hamiltonian cycles with the help of the Pfaffian orientation obtained.

▶ **Lemma 7** (Constructing a Pfaffian orientation from a Hamiltonian cycle)**.** *There exists a linear-time algorithm that, given as input a bipartite Pfaffian graph G and a Hamiltonian cycle H in G, outputs a Pfaffian orientation $\vec{G}$ of G.* ⋆*See full version [4] for proof*⋆

2.5 Finding a good coloring

Let us now study the task of finding a good coloring χ given the bipartite Pfaffian graph G, the Pfaffian orientation $\vec{G}$, and the anchor edge e as input; also recall the conventions and further notation – in particular, the vertices s and t – from Sections 2.2 and 2.3. In this setting, a natural question to ask is how much one needs to reveal from a good coloring χ to enable efficient completion to a good coloring. We now show that it suffices to reveal χ in one of the parts of the bipartition of G by a reduction to bipartite perfect matching in an auxiliary bipartite graph.

More precisely, let the sets L ("left") and R ("right") form a partition of the vertices of G such that $s \in L$, $t \in R$, and every edge of G has one end in L and the other end in R.[5] Let $\lambda : L \to \{0,1\}$ with $\lambda(s) = 0$ be a given further input. Our task is to find whether there exists a good coloring $\chi : V(G) \to \{0,1\}$ with $\chi(\ell) = \lambda(\ell)$ for all $\ell \in L \subseteq V(G)$; that is, whether there exists a good coloring that extends the partial coloring λ.

Construct an auxiliary bipartite graph F_λ as follows. Let the vertex set $V(F_\lambda) = V(G) \times \{0,1\}$. To avoid notational confusion between arcs and vertices of F_λ, we will use bracketed notation $[u,k]$ for vertices of F_λ with $u \in V(G)$ and $k \in \{0,1\}$. The edge set $E(F_\lambda)$ is defined by the following rule. For all $\ell \in L$, $r \in R$, $p \in \{0,1\}$, and $\rho \in \{0,1\}$ with $\{\ell, r\} \in E(G)$, we have

$$\{[\ell,p],[r,\rho]\} \in E(F_\lambda) \tag{8}$$

if and only if both

$$\rho \equiv \lambda(\ell) + [\![(\ell,r) \in \vec{G}_e]\!] \pmod 2 \tag{9}$$

and

$$\ell \neq s \quad \text{or} \quad p \neq 0 \quad \text{or} \quad r = t\,. \tag{10}$$

For an edge $\{[\ell,p],[r,\rho]\} \in E(F_\lambda)$, we say that the edge $\{\ell, r\} \in E(G)$ is the *projection* of the edge (to G) and call p the *port* at ℓ and ρ the *parity* at r, stressing that port and parity have asymmetric roles in our construction even though both range in $\{0,1\}$.

Let us now start analysing the structure of F_λ in more detail. First, the parts $L \times \{0,1\}$ and $R \times \{0,1\}$ witness by (8) that F_λ is bipartite. In particular, F_λ has $2n$ vertices with $|L| = |R| = n/2$, where we recall that $n \geq 4$ is the number of vertices in G with n even. Second, recalling that $s \in L$ and $t \in R$, the constraint (10) effectively states that $[s,0]$ is adjacent only to $[t,0]$ in F_λ; indeed, recalling that $\lambda(s) = 0$ and $(s,t) \notin \vec{G}_e$, from (9) we

[5] This bipartition (L,R) of G is in fact unique unless G is not Hamiltonian. Moreover, (L,R) is computable in linear time from the given input.

have that $[s,0]$ is not adjacent to $[t,1]$. Third, for all $\ell \in L \setminus \{s\}$, we observe from (9) and (10), the latter being trivially true, that the vertices $[\ell,0]$ and $[\ell,1]$ have identical vertex neighborhoods in F_λ.

We are now ready for our next key lemma. Recall the coloring χ_H associated to an anchored Hamiltonian cycle H of G from Section 2.2. The first lemma shows that every perfect matching in F_λ gives rise to an anchored Hamiltonian cycle; different perfect matchings may give rise to the same anchored Hamiltonian cycle however. This structure is illustrated in Figure 2.

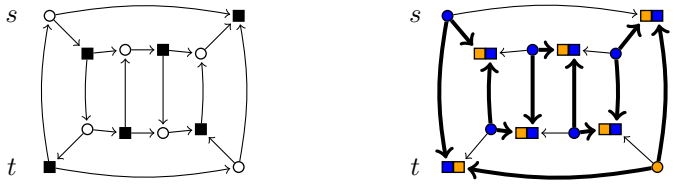

Figure 2 Illustration of a perfect matching in the graph F_λ. Left: The graph G drawn in one of its orientations $\vec{G}_e$ with $e = \{s,t\}$ and the bipartition (L,R) with vertices in L drawn as white circles and the vertices in R drawn as black boxes. Right: The graph F_λ and the coloring λ drawn as an oriented overlay of G. Observe that each vertex $r \in R$ has two copies $[r,\rho]$ in F_λ, one for each parity $\rho \in \{0,1\}$, with a blue square indicating parity 0 and an orange square indicating parity 1. Although each vertex $\ell \in L$ has two copies $[\ell,p]$ in F_λ, one copy for each port $p \in \{0,1\}$, we contract these two copies into one vertex (circle) in the drawing, and display for each vertex its color $\lambda(\ell) \in \{0,1\}$ (blue or orange) instead. Each arc in the drawing is oriented from L to R and represents two edges of F_λ with opposite ports. A perfect matching M in F_λ is represented by the bold arcs. In particular, observe that each circle is incident to two bold arcs; these two bold arcs represent two edges in M with opposite ports. These opposite ports are otherwise arbitrary except for the edge of M that projects to $\{s,t\}$, which must have port 0. Also observe that from the drawn M it is visually intuitive how to obtain a Hamiltonian cycle in G corresponding to M by turning the bold arcs into the edges of a Hamiltonian cycle in G; this intuition is made rigorous in Lemma 8 by the Hamiltonian cycle $\mathrm{H}[M]$ of G obtained from M.

▶ **Lemma 8** (Perfect matchings witness good extensions)**.** *For every perfect matching M in F_λ, there exists a Hamiltonian cycle $\mathrm{H}[M]$ in G with $\chi_{\mathrm{H}[M]}(\ell) = \lambda(\ell)$ for all $\ell \in L$.*

Proof. Let M be an arbitrary perfect matching in F_λ. For $[\ell,p] \in L \times \{0,1\}$ and $[r,\rho] \in L \times \{0,1\}$, let us use functional notation $M([\ell,p]) = [r,\rho]$ or $M([r,\rho]) = [\ell,p]$ to signal that the vertices $[\ell,p]$ and $[r,\rho]$ are matched by M in F_λ. We construct the anchored Hamiltonian cycle $\mathrm{H}[M]$ as well as the coloring $\chi = \chi_{\mathrm{H}[M]}$ with $\chi(\ell) = \lambda(\ell)$ for all $\ell \in L$ by traversing all the vertices of F_λ in an order determined by M to yield the Hamiltonian cycle $\mathrm{H}[M]$. In particular, we will define $\mathrm{H}[M]$ in steps by introducing, one vertex at a time, a vertex order $v_0, v_1, \ldots, v_{n-1}$ for the vertices of G with $v_0 = s$, $v_{n-1} = t$, and $(v_i, v_{(i+1) \bmod n}) \in E(\overrightarrow{\mathrm{H}[M]}) \subseteq E(\vec{G}_e^\chi)$ for all $i = 0,1,\ldots,n-1$.

Our traversal starts from the vertex $[\ell_0,p_0]$ of F_λ defined by $\ell_0 = s$ and $p_0 = 1$. The traversal then follows edges in the perfect matching M, changing parity (at vertices in $R \times \{0,1\}$) and port (at vertices in $L \times \{0,1\}$) to arrive at subsequent edges; for these changes, for $z \in \{0,1\}$ it is convenient to write $\overline{z} = (z+1) \bmod 2$ for notational brevity; that is, $\overline{0} = 1$ and $\overline{1} = 0$.

In precise terms, the traversal is as follows. Assuming we have defined $\ell_j \in L$ and $p_j \in \{0,1\}$ for all $j \in \{0,1,\ldots,i\}$ with $i \geq 0$, we proceed to define $\ell_{i+1} \in L$ and $p_{i+1} \in \{0,1\}$ as follows. Set $v_{2i} = \ell_i$ and $\chi(\ell_i) = \lambda(\ell_i)$. Define $r_i \in R$ and $\rho_i \in \{0,1\}$ by $M([\ell_i,p_i]) = [r_i,\rho_i]$.

Set $v_{2i+1} = r_i$ and $\chi(r_i) = \rho_i$. Define $\ell'_i \in L$ and $p'_i \in \{0,1\}$ by $M([r_i, \overline{\rho_i}]) = [\ell'_i, p'_i]$. Set $\ell_{i+1} = \ell'_i$ and $p_{i+1} = \overline{p'_i}$ as well as $\chi(\ell_{i+1}) = \lambda(\ell_{i+1})$ and $v_{2(i+1)} = \ell_{i+1}$. We continue this process for $i = 0, 1, \ldots$ and claim that eventually $\ell_{i+1} = \ell_0$ and $p_{i+1} = p_0$ with $i+1 = n/2$, at which point $\{v_0, v_1, \ldots, v_{n-1}\} = V(G)$ and $\mathrm{H}[M]$ is a Hamiltonian cycle in G with $\chi_{\mathrm{H}[M]} = \chi$ with $\chi(\ell) = \lambda(\ell)$ for all $\ell \in L$.

Let us now analyse the traversal process in more detail. First, we observe that $\ell_{i+1} \neq \ell_i$; indeed, suppose that $\ell_{i+1} = \ell_i$ and observe that the traversal step from ℓ_i to ℓ_{i+1} changes parity from ρ_i to $\bar{\rho}_i$ at r_i, yet from (9) we observe that every edge of F_λ that projects to the edge $\{\ell_i, r_i\} = \{\ell_{i+1}, r_i\}$ has the same parity at r_i, a contradiction. Next, let us observe that $(v_{2i}, v_{2i+1}) = (\ell_i, r_i) \in E(\vec{G}_e^\chi)$. Indeed, the identity is immediate, and membership holds by (7) and

$$\chi(r_i) = \rho_i \overset{(9)}{\equiv} \lambda(\ell_i) + [\![(\ell_i, r_i) \in \vec{G}_e]\!] = \chi(\ell_i) + [\![(\ell_i, r_i) \in \vec{G}_e]\!] \pmod 2 .$$

Let us then observe that $(v_{2i+1}, v_{2i+2}) = (r_i, \ell_{i+1}) \in E(\vec{G}_e^\chi)$. Again the identity is immediate, and membership holds by (7), the fact that $\vec{G}_e^\chi$ orients $\{\ell_{i+1}, r_i\} \in E(G)$ in one of two possible orientations, and

$$\chi(r_i) = \rho_i \neq \bar{\rho}_i \overset{(9)}{\equiv} \lambda(\ell_{i+1}) + [\![(\ell_{i+1}, r_i) \in \vec{G}_e]\!] = \chi(\ell_{i+1}) + [\![(\ell_{i+1}, r_i) \in \vec{G}_e]\!] \pmod 2 .$$

Next let us show that all the vertices ℓ_i and r_i traversed by the process are distinct, until $\ell_{i+1} = \ell_0$ for some $i \geq 1$, noting that the case $i = 0$ has already been excluded earlier. Suppose $\ell_1, \ell_2, \ldots, \ell_i$ are distinct; since M contains exactly two edges (of opposite parities) that project to edges incident to any fixed $r \in R$, we observe that these two edges of M have been each traversed once by the process for each $r_0, r_1, \ldots, r_i$ since $\ell_0, \ell_1, \ldots, \ell_i$ are distinct, implying that $r_0, r_1, \ldots, r_i$ are distinct, and thus that $v_0, v_1, \ldots, v_{2i+1}$ are distinct. So suppose that $\ell_{i+1} = \ell_j$ for some $0 \leq j \leq i$; also note that this must happen for some $i < |L| = n/2$. If $j \geq 1$, we have a contradiction since M contains exactly two edges (of opposite ports) that project to edges incident to any fixed $\ell \in L$, and for $\ell = \ell_j$ these two edges (projecting to $\{\ell_j, r_{j-1}\}$ and $\{\ell_j, r_j\}$) have already been traversed; so there is no edge in M that projects to $\{\ell_j, r_i\} = \{\ell_{i+1}, r_i\}$, a contradiction. So we must have $j = 0$. This implies in particular that $(v_k, v_{(k+1) \bmod (2i+2)}) \in E(\vec{G}_e^\chi)$ for all $k = 0, 1, \ldots, 2i+1$. Furthermore, since the edge of M that is incident to $[\ell_0, p_0] = [s, 1]$ has already been traversed, we have that the edge $\{[\ell_{i+1}, \overline{p_{i+1}}], [r_i, \bar{\rho}_i]\}$ in M must be the edge $\{[s,0], [t,0]\}$ (recall our analysis earlier that $[s,0]$ is adjacent only to $[t,0]$ in F_λ); thus we conclude that $\chi(t) = \chi(r_i) = \rho_i \neq \bar{\rho}_i = 0$; that is, $\chi(t) = 1$.

Let us next show that $i = n/2 - 1$. So to reach a contradiction, suppose that $i < n/2 - 1$. In particular, the edges of G underlying the arcs $(v_k, v_{(k+1) \bmod (2i+2)}) \in E(\vec{G}_e^\chi)$ for $k = 0, 1, \ldots, 2i+1$ trace a cycle of even length $2i + 2 < n$ in G. This leaves some of the vertices in G, and thus all corresponding vertices of F_λ regardless of port/parity, unvisited by the traversal process. By starting the traversal process again from an arbitrary unvisited vertex in $L \times \{0,1\}$, we end up tracing a further even-length cycle in G, and repeating the process until all vertices of G are visited, we obtain a vertex-disjoint union of even-length cycles that together cover the vertices of G, as well as a coloring χ such that all the cycles (in their consistently oriented form as they were traversed) occur as directed subgraphs of $\vec{G}_e^\chi$. Since $2i + 2 < n$, this cycle cover thus contains a cycle C that does not contain the anchor edge e and whose consistent orientation $\vec{C}$ is a subgraph of $\vec{G}_e^\chi$; observing that C is central – indeed, use every other edge from each even cycle other than C in the cover to witness a perfect matching in $G \setminus V(C)$ – this leads to a contradiction via Pfaffianity by the same argument as was used in the proof of Lemma 6; thus, $i = n/2 - 1$.

Since $i = n/2 - 1$, it follows from $(v_k, v_{(k+1) \bmod n}) \in E(\vec{G}_e^{\chi})$ for all $k = 0, 1, \ldots, n-1$ and from Lemma 6 we conclude that $\chi = \chi_{\mathrm{H}[M]}$ for the anchored Hamiltonian cycle $\mathrm{H}[M]$ in G defined by $V(\mathrm{H}[M]) = \{v_0, v_1, \ldots, v_{n-1}\}$ and $E(\mathrm{H}[M]) = \{\{v_k, v_{(k+1) \bmod n}\} : k = 0, 1, \ldots, n-1\}$. ◀

Conversely, we show that good extensions of λ are witnessed by perfect matchings in F_λ.

▶ **Lemma 9** (Good extensions witness perfect matchings). *For every anchored Hamiltonian cycle H in G with $\chi_H(\ell) = \lambda(\ell)$ for all $\ell \in L$, there exists a perfect matching M_H in F_λ with $\mathrm{H}[M_H] = H$.* ⋆*See full version [4] for proof*⋆

Thus, F_λ has a perfect matching if and only if λ has a good extension. Moreover, from the proofs of Lemma 8 and Lemma 9 we observe that the transformations $M \mapsto \mathrm{H}[M]$ and $H \mapsto M_H$ are computable in linear time. We also observe that for every anchored Hamiltonian cycle H in G there are exactly $2^{n/2-1}$ perfect matchings M in F_λ with $\mathrm{H}[M] = H$; these M are all obtainable from each other by transposing ports at zero or more vertices $\ell \in L \setminus \{s\}$.

3 Another Hamiltonian cycle in bipartite Pfaffian graphs

This section studies the problem of finding another Hamiltonian cycle when given as input (i) a bipartite Pfaffian graph G and (ii) a Hamiltonian cycle H in G. Recall from Lemma 7 that we can in linear time construct a Pfaffian orientation $\vec{G}$ from this input. In what follows we thus tacitly assume that such a $\vec{G}$ is available and fixed together with an arbitrary anchor edge $e \in E(H)$.

3.1 Linear-time solvability in minimum degree three

Our first objective in this section is our main theorem, which we restate below for convenience.

▶ **Theorem 1** (Main; Linear–time Another Hamiltonian Cycle in minimum degree three). *There exists a deterministic linear-time algorithm that, given as input (i) a bipartite Pfaffian graph G with minimum degree three, (ii) a Hamiltonian cycle H in G, and (iii) an edge $e \in E(H)$, outputs a Hamiltonian cycle $H' \neq H$ in G with $e \in E(H')$.*

We now proceed to prove Theorem 1. Recall and assume the setting of Section 2.5. Observe that from the given input, we can in linear total time (a) find a Pfaffian orientation $\vec{G}$ using H, (b) compute the orientation $\vec{G}_e$, (c) compute the coloring χ_H, (d) compute the vertex bipartition (L, R) of G, (e) restrict χ_H to L to obtain the coloring λ, (f) construct the graph F_λ, as well as (g) construct the perfect matching M_H in F_λ.

Using M_H and F_λ, introduce the directed graph $D_{\lambda,H}$ with the vertex set $V(D_{\lambda,H}) = L$ and the arc set defined for all distinct $\ell, \ell' \in L$ by the rule $(\ell, \ell') \in E(D_{\lambda,H})$ if and only if there exist $p, p' \in \{0, 1\}$, $r \in R$, and $\rho \in \{0, 1\}$ such that

$$\{[\ell, p], [r, \rho]\} \in E(F_\lambda) \setminus M_H \quad \text{and} \quad \{[\ell', p'], [r, \rho]\} \in M_H\,. \tag{11}$$

That is, an arc $(\ell, \ell') \in E(D_{\lambda,H})$ indicates that (disregarding ports p and p') we can walk from ℓ to ℓ' in F_λ by traversing first an edge not in M_H, followed by an edge in M_H. We stress that the traversal (11) *preserves* the parity ρ for consecutive edges, whereas the traversal in the proof of Lemma 8 *changes* parity for consecutive edges; the latter also uses edges only in M_H.

We recall that G has minimum degree at least three; this enables us to find a Hamiltonian cycle other than H in G with the help of a directed cycle in $D_{\lambda,H}$ revealed in the following lemma.

▶ **Lemma 10** (Existence of an s-avoiding directed cycle in $D_{\lambda,H}$). *Suppose that every vertex of G has degree at least three. Then, the directed graph $D_{\lambda,H}$ contains at least one directed cycle that avoids the vertex s.* ⋆*See full version [4] for proof*⋆

By the previous lemma we thus know that $D_{\lambda,H}$ contains an s-avoiding directed cycle $\vec{Q}$ with $V(\vec{Q}) = \{\ell_0, \ell_1, \ldots, \ell_{k-1}\} \subseteq L$ and $(\ell_j, \ell_{(j+1) \bmod k}) \in E(\vec{Q})$ for each $j = 0, 1, \ldots, k-1$ and $k \geq 2$. We will use $\vec{Q}$ to construct from M_H another Hamiltonian cycle $H' \neq H$ in G. Figure 3 illustrates the construction.

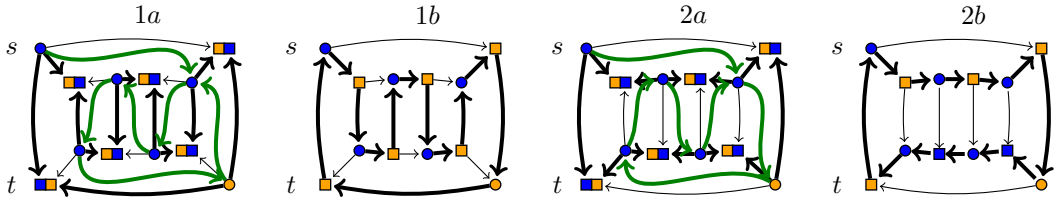

Figure 3 Obtaining another Hamiltonian cycle using a directed cycle in $D_{\lambda,H}$. $1a, 2a$: Two perfect matchings M_H in F_λ drawn as oriented overlays of G (cf. Figure 2), with further overlaying drawn in green and constituting the arcs of $D_{\lambda,H}$. $1b, 2b$: The corresponding two orientations $\vec{G}_e^{\chi_H}$ and colorings χ_H. In both cases we have that $D_{\lambda,H}$ contains a unique s-avoiding directed cycle $\vec{Q}$. Using $\vec{Q}$ in each case we can switch between the left and right Hamiltonian cycles in G. Note in particular that the two vertex colorings agree in L but differ in R.

From (11) applied to each arc of $\vec{Q}$ in turn we conclude that for $j = 0, 1, \ldots, k-1$ there exist $r_j \in R$ and $\rho_j, p_j \in \{0, 1\}$ with

$$\{[\ell_j, p_j], [r_j, \rho_j]\} \in E(F_\lambda) \setminus M_H \quad \text{and} \quad \{[\ell_{(j+1) \bmod k}, p'_j], [r_j, \rho_j]\} \in M_H\,. \tag{12}$$

We observe that the vertices $[r_j, \rho_j]$ for $j = 0, 1, \ldots, k-1$ are distinct because M_H is a perfect matching and $\ell_{(j+1) \bmod k}$ for $j = 0, 1, \ldots, k-1$ are distinct. In spite of this, the edges (12) for $j = 0, 1, 2, \ldots, k-1$ need *not* form a cycle in F_λ because we can have $p'_j \neq p_{(j+1) \bmod k}$. Here is where the fact that $\vec{Q}$ is s-avoiding pays off. Let $M = M_H$ and recall that the vertices $[\ell, 0]$ and $[\ell, 1]$ for each $\ell \in L \setminus \{s\}$ have identical vertex neighborhoods in F_λ. Thus, whenever we have $p'_j \neq p_{(j+1) \bmod k}$, we can modify M by transposing the vertices $[\ell_{(j+1) \bmod k}, 0]$ and $[\ell_{(j+1) \bmod k}, 1]$ in the edges of M; by the identical vertex neighborhoods property, the resulting M will still be a perfect matching in F_λ. Moreover, we have $H = \mathrm{H}[M_H] = \mathrm{H}[M]$; indeed, the traversal construction in Lemma 8 is insensitive to the specific values of the (opposite) ports. For $j = 0, 1, \ldots, k-1$ we thus now have

$$\{[\ell_j, p_j], [r_j, \rho_j]\} \in E(F_\lambda) \setminus M \quad \text{and} \quad \{[\ell_{(j+1) \bmod k}, p_{(j+1) \bmod k}], [r_j, \rho_j]\} \in M\,; \tag{13}$$

that is, these edges now form a $2k$-vertex cycle in F_λ. Let us write A for this cycle in F_λ.

Observe in particular from (13) that the edges of A alternate between edges in M and edges not in M. Thus, we have that the symmetric difference $M' = (M \setminus E(A)) \cup (E(A) \setminus M)$ is a perfect matching in F_λ. Furthermore, M' and M project to a different set of edges of G; indeed, from (13) we have that r_j changes adjacency from $\ell_{(j+1) \bmod k}$ in $\mathrm{H}[M]$ to ℓ_j in $\mathrm{H}[M']$ for $j = 0, 1, \ldots, k-1$. It follows that $H' = \mathrm{H}[M'] \neq \mathrm{H}[M] = H$. Thus, we have constructed a Hamiltonian cycle H' in G that is different from H. Moreover, this construction is computable in deterministic linear time. This completes the proof of Theorem 1. ◀

3.2 Logarithmic-space solvability in minimum degree three

We can implement the ideas of the previous section in an algorithm that uses little space. We consider as input a bipartite Pfaffian graph G of minimum degree three, a consistently oriented Hamiltonian cycle $\vec{H}$ in G, and an arc $(t,s) \in \vec{H}$. More precisely, we assume both graphs G and $\vec{H}$ are given in the input as a list of adjacency lists for each vertex. We seek to output a list of edges of another Hamiltonian cycle $H' \neq H$ with $\{s,t\} \in E(H')$. We assume that the vertices of G are represented as $O(\log n)$-bit integers in the input, where n is the number of vertices in G.

▶ **Theorem 2** (Main; Logarithmic–space Another Hamiltonian Cycle in minimum degree three). *There exists a deterministic logarithmic-space algorithm that, given as input (i) a bipartite Pfaffian graph G with minimum degree three, (ii) a Hamiltonian cycle H in G, and (iii) an edge $e \in E(H)$, outputs a Hamiltonian cycle $H' \neq H$ in G with $e \in E(H')$.*

⋆See full version [4] for proof⋆

3.3 Thomason's lollipop method in cubic bipartite Pfaffian graphs

In this section we prove that Thomason's lollipop method runs in linear time in cubic bipartite Pfaffian graphs. Let us first set up some preliminaries and then describe Thomason's lollipop method.

Let G be a Hamiltonian cubic graph and let H be a Hamiltonian cycle in G. Select an edge $e = \{s,t\}$ in the Hamiltonian cycle H. Let us call e the *anchor* edge. A *lollipop* is a connected graph with one vertex of degree one, one vertex of degree three, and all other vertices of degree two. All lollipops considered in what follows are subgraphs of G such that t is the unique degree-one vertex and e is the edge incident to t on the lollipop.

The lollipop method is best described as operating on a family of Hamiltonian paths in G. We say that a Hamiltonian path in G that starts at the vertex t and continues via the anchor edge e is an *e-anchored* Hamiltonian path. Now recall that G is cubic, so the vertex t is adjacent to s (via the anchor edge e) and to two other vertices a and b. The lollipop method transforms a given e-anchored Hamiltonian path P_e that ends at either a or b into an e-anchored Hamiltonian path $P'_e \neq P_e$ that ends at either a or b. Observe in particular that both Hamiltonian paths P_e and P'_e can be completed into e-anchored Hamiltonian cycles by adding the missing edge $\{a,t\}$ or $\{b,t\}$ into the respective path.

The transformation from P_e to P'_e is via a sequence of *lollipop steps*. A lollipop step consists of adding one edge to an e-anchored Hamiltonian path and removing another one, so that another e-anchored Hamiltonian path is formed. More precisely, let Q be an e-anchored Hamiltonian path ending at some vertex u. Since G is cubic, u is adjacent to two other vertices, x and y, such that the edges $\{u,x\}$ and $\{u,y\}$ of G are not in Q. Assume that $x \neq t$. Add the edge $\{u,x\}$ into Q to obtain a lollipop Ω where the unique degree-three vertex is x. Now observe that among the three adjacent vertices to x there is a unique vertex $v \notin \{u,t\}$ such that both $\{v,x\} \in E(\Omega)$ and removing $\{v,x\}$ from Ω leaves an e-anchored Hamiltonian path Q' ending at v. The transformation from Q to Q' now constitutes one lollipop step. Observe also that lollipop steps are *reversible*; that is, we can go back to Q from Q' by performing a lollipop step starting from Q'.

The *lollipop state graph* $\mathcal{L}(G,s,t)$ has as its vertices the e-anchored Hamiltonian paths in G and two vertices are joined by an edge if and only if it is possible to transform between the e-anchored Hamiltonian paths by one lollipop step. We observe immediately that $\mathcal{L}(G,s,t)$ has no isolated vertices – indeed, from any vertex Q we can arrive at another vertex $Q' \neq Q$ by a lollipop step – and the degree-one vertices are exactly the e-anchored Hamiltonian paths

Q that end at a vertex u adjacent to t in G; that is, $u \in \{a, b\}$; moreover, all other vertices have degree two. Thus, we can transform from P_e to $P'_e \neq P_e$ by tracing a path in $\mathcal{L}(G, s, t)$ from P_e to P'_e.

We now proceed to prove an upper bound on the maximum length of a path in $\mathcal{L}(G, s, t)$ on a cubic bipartite Pfaffian graph G. An example of the lollipop method applied to a cubic bipartite planar graph using the terminology in the subsequent proof is given in Figure 4.

▶ **Theorem 3** (Thomason's lollipop method in cubic bipartite Pfaffian graphs). *Thomason's lollipop method starting from any Hamiltonian cycle H and any edge $e \in E(H)$ in an n-vertex cubic bipartite Pfaffian graph G, terminates after at most n steps.*

Proof. To analyze the lollipop method in cubic bipartite Pfaffian graphs, let a cubic bipartite Pfaffian graph G, a Hamiltonian cycle H in G, and $e = \{s, t\} \in E(H)$ be given as input. This input enables us to work in the setting of Section 3.1; let the vertex bipartition (L, R) of G, the coloring λ of L, the graph F_λ, the perfect matching M_H in F_λ, and the directed graph $D_{\lambda,H}$ be constructed accordingly. Recall that $s \in L$ and $t \in R$.

The lollipop method starts by removing the edge $\{t, u\}$ with $u \neq s$ from H to obtain e-anchored Hamiltonian path P_e. Let $Q_0, Q_1, \ldots, Q_h$ be the sequence of e-anchored Hamiltonian paths traversed by consecutive lollipop steps in $\mathcal{L}(G, s, t)$ with $P_e = Q_0$ and $Q_h = P'_e$. We will show that P'_e ends at u and thus we can obtain a Hamiltonian cycle $H' \neq H$ by inserting the edge $\{t, u\}$ into P'_e. Moreover and crucially, we will show that $h \leq n$.

Our analysis of the lollipop method is based on the directed graph $D_{\lambda,H}$. We recommend consulting Figure 4 for intuition at this point. Recall from the proof of Lemma 10 that, in the directed graph $D_{\lambda,H}$, the vertex s has in-degree zero and every vertex has out-degree at least one. In particular, by traversing out-arcs from the vertex u in $D_{\lambda,H}$, and traversing the eventual directed cycle encountered, as well as traversing backwards to u from the directed cycle, in precise terms we observe that there exist vertices $w_0, w_1, \ldots, w_{d-1}$ with $(w_j, w_{(j+1) \bmod d}) \in E(D_{\lambda,H})$ for $j = 0, 1, \ldots, d-1$ as well as vertices $w'_0, w'_1, \ldots, w'_{d'}$ with $w_0 = w'_{d'}$, $w'_0 = u$, $\{w_0, w_1, \ldots, w_{d-1}\} \cap \{w'_0, w'_1, \ldots, w'_{d'-1}\} = \emptyset$, and $(w'_j, w'_{j+1}) \in E(D_{\lambda,H})$ for $j = 0, 1, \ldots, d'-1$. That is, the sequence $w'_0, w'_1, \ldots, w'_{d'}$ forms a directed path starting at the vertex $u = w'_0$ and ending at the vertex $w_{d'} = w_0$, which is on the directed cycle formed by the vertices $w_0, w_1, \ldots, w_{d-1}$ in $D_{\lambda,H}$; the directed cycle and the directed path intersect exactly at the vertex $w_{d'} = w_0$. In particular $d + d' \leq |L| = n/2$.

It will be convenient to introduce the following sequence of vertices visited on the traversal of $D_{\lambda,H}$ from u. For $i = 0, 1, \ldots, 2d' + d$, define

$$v_i = \begin{cases} w'_i & \text{for } i = 0, 1, \ldots, d'-1\,; \\ w_{i-d'} & \text{for } i = d', d'+1, \ldots, d'+d-1\,; \\ w'_{2d'+d-i} & \text{for } i = d'+d, d'+d+1, \ldots, 2d'+d\,. \end{cases} \tag{14}$$

We have $(v_i, v_{i+1}) \in E(D_{\lambda,H})$ for $i = 0, 1, \ldots, d'+d-1$; these arcs are precisely the arcs traversed forward. We have $(v_{i+1}, v_i) \in E(D_{\lambda,H})$ for $i = d'+d, d'+d+1, \ldots, 2d'+d-1$; these arcs are precisely the arcs traversed backward. For an arc $(\ell, \ell') \in E(D_{\lambda,H})$, let us write $r(\ell, \ell')$, $\rho(\ell, \ell')$, and $p'(\ell, \ell')$, respectively, for the unique $r \in R$, $\rho \in \{0, 1\}$, and $p' \in \{0, 1\}$ such that (11) holds. Also, let us write $p(\ell, \ell')$ for the minimum $p \in \{0, 1\}$ such that that (11) holds.

Let M^- be a matching with $n-1$ edges in F_λ such that the vertex $[t, 1]$ is left unmatched by M^-; we call such matchings *almost perfect* – indeed, any perfect matching M in F_λ has n edges. Also observe that the other vertex left unmatched by M^- is $[\ell, p]$ for some $\ell \in L$ and $p \in \{0, 1\}$. Recall the parity-and-port-changing traversal of M in the proof of Lemma 8 resulting in the Hamiltonian cycle $\mathrm{H}[M]$. Define a similar parity-and-port-changing traversal

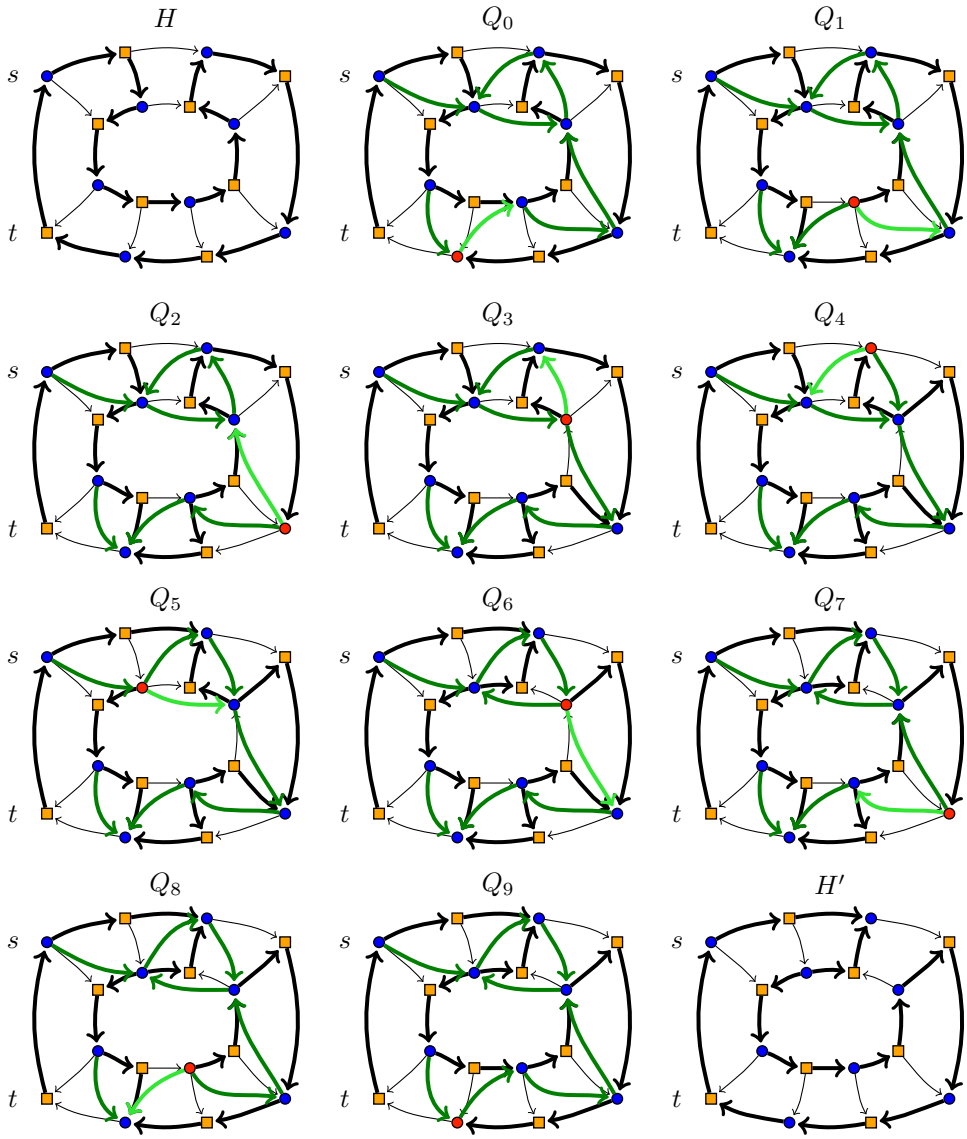

Figure 4 An example of the sequence of steps of Thomason's lollipop method in an n-vertex cubic bipartite planar graph viewed as a sequence of arc reversals in the directed graph $D_{\lambda,H}$. The given input G and H together with $e = \{s, t\}$ is displayed in the top left; the black arcs are oriented as in $\vec{G}_e$ obtained from Lemma 7 on input H. We display the initial Hamiltonian cycle H (top left) and the final Hamiltonian cycle H' (bottom right) obtained by the method, as well as the intermediate e-anchored Hamiltonian paths $Q_0, Q_1, \ldots, Q_9$ obtained in consecutive lollipop steps; the end-vertex of each Q_i is highlighted with red. The green arcs in Q_0 are the arcs of $D_{\lambda,H}$. Observe that each lollipop step from Q_i to Q_{i+1} can be understood as reversing the light-green arc in Q_i; the method terminates when the end-vertices of Q_0 and Q_{i+1} agree. By the structure of $D_{\lambda,H}$, we must have $i \leq n$; cf. Theorem 3.

of M^- by starting at the vertex $[\ell, \vec{p}]$ and observe by a similar argument as in the proof of Lemma 8 that this traversal defines an e-anchored Hamiltonian path $\mathrm{P}[M^-]$ from the vertex ℓ to the vertex t in G; in particular, observe that $\mathrm{P}[M^-]$ is e-anchored since by the structure of F_λ the almost perfect M^- must contain the edge $\{[s,0],[t,0]\}$.

We now proceed to characterize the e-anchored Hamiltonian paths $Q_0, Q_1, \ldots, Q_h$ using corresponding almost perfect matchings $M_0^-, M_1^-, \ldots, M_h^-$, and conclude that $h = 2d'+d \leq n$ in the process. For $i = 0, 1, \ldots, h$, let us write u_i for the end-vertex of Q_i other than t. Recalling that $Q_0 = P_e$ is constructed by deleting the edge $\{u,t\}$ from the Hamiltonian cycle H, let $p \in \{0,1\}$ be the port and $f \in E(F_\lambda)$ the edge with $f = \{[u,p],[t,1]\} \in M_H$. Take $M_0^- = M_H \setminus \{f\}$. In particular, we have $Q_0 = P_e = \mathrm{P}[M_0^-]$ and $u_0 = v_0 = u$. Let $p_0 = p$; we will fix values $p_i \in \{0,1\}$ for $i = 1, 2, \ldots, h$ as we progress in what follows.

We split the analysis into two ranges based on the parameter i. The first range corresponds to the forward-traversal of arcs in $D_{\lambda,H}$. For $i = 0, 1, \ldots, d' + d - 1$, we say an almost perfect matching M^- has *property* i if

- **(i)** $[v_i, p_i]$ is left unmatched by M^-; and
- **(ii)** we have $\{[v_j, p(v_j, v_{j+1})], [r(v_j, v_{j+1}), \rho(v_j, v_{j+1})]\} \in M^-$ and $\{[r(v_j, v_{j+1}), \rho(v_j, v_{j+1})], [v_{j+1}, p'(v_j, v_{j+1})]\} \notin M^-$ for all $0 \leq j \leq i-1$; and
- **(iii)** we have $\{[v_j, p(v_j, v_{j+1})], [r(v_j, v_{j+1}), \rho(v_j, v_{j+1})]\} \notin M^-$ and $\{[r(v_j, v_{j+1}), \rho(v_j, v_{j+1})], [v_{j+1}, p'(v_j, v_{j+1})]\} \in M^-$ for all $i \leq j \leq d' + d$.

The second range corresponds to the backward-traversal of arcs in $D_{\lambda,H}$. For $i = d'+d, d'+d+1, \ldots, 2d'+d$, we we say an almost perfect matching M^- has *property* i if

- **(i')** $[v_i, p_i]$ is left unmatched by M^-; and
- **(ii')** we have $\{[v_j, p(v_j, v_{j+1})], [r(v_j, v_{j+1}), \rho(v_j, v_{j+1})]\} \in M^-$ and $\{[r(v_j, v_{j+1}), \rho(v_j, v_{j+1})], [v_{j+1}, p'(v_j, v_{j+1})]\} \notin M^-$ for all $d' \leq j \leq d' + d - 1$ as well as for all $0 \leq j \leq 2d' + d - 1 - i$; and
- **(iii')** we have $\{[v_j, p(v_j, v_{j+1})], [r(v_j, v_{j+1}), \rho(v_j, v_{j+1})]\} \notin M^-$ and $\{[r(v_j, v_{j+1}), \rho(v_j, v_{j+1})], [v_{j+1}, p'(v_j, v_{j+1})]\} \in M^-$ for all $2d' + d - i \leq j \leq d' - 1$.

From previous observations and (11) we have that M_0^- satisfies property 0.

Let us now analyse the lollipop step mapping Q_i to Q_{i+1} one value $i = 0, 1, \ldots, d' + d - 1$ at a time. Suppose that there is an almost perfect matching M_i^- of F_λ that satisfies property i and that $Q_i = \mathrm{P}[M_i^-]$. In particular, we have $u_i = v_i$ by (i) and $Q_i = \mathrm{P}[M_i^-]$. We claim that the vertex $r(v_i, v_{i+1})$ is the unique degree-three vertex in the lollipop formed by the lollipop step transforming Q_i to Q_{i+1}. Observe by (iii) that $\{[r(v_i, v_{i+1}), \rho(v_i, v_{i+1})], [v_{i+1}, p'(v_i, v_{i+1})]\} \in M_i^-$, implying that $\{r(v_i, v_{i+1}), v_{i+1}\}$ is an edge in $Q_i = \mathrm{P}[M_i^-]$. Recalling that M_i^- is almost perfect, all vertices in $R \times \{0,1\}$ are matched, so $r(v_i, v_{i+1}) \in R$ is in fact adjacent to another vertex $\omega_i \neq v_{i+1}$ along an edge in $Q_i = \mathrm{P}[M_i^-]$. By (iii) and (11) we have $\{v_i, r(v_i, v_{i+1})\}$ is an edge in G but not in $Q_i = \mathrm{P}[M_i^-]$, and Q_i ends at v_i. Thus, $r(v_i, v_{i+1})$ is the unique degree-three vertex in the lollipop. Next, the lollipop step proceeds to delete an edge adjacent to the degree-three vertex $r(v_i, v_{i+1})$ in the lollipop. This edge is $\{v_{i+1}, r(v_i, v_{i+1})\}$ by the previous analysis. It follows that Q_{i+1} is obtained from Q_i by deleting $\{v_{i+1}, r(v_i, v_{i+1})\}$ and inserting $\{v_i, r(v_i, v_{i+1})\}$. Thus, Q_{i+1} ends at $u_{i+1} = v_{i+1}$. Define M_{i+1}^- by starting with M_i^- and deleting the edge $\{[r(v_i, v_{i+1}), \rho(v_i, v_{i+1})], [v_{i+1}, p'(v_i, v_{i+1})]\}$ as well as inserting the edge $\{[v_i, p(v_i, v_{i+1})], [r(v_i, v_{i+1}), \rho(v_i, v_{i+1})]\}$. Fix $p_{i+1} = p'(v_i, v_{i+1})$. From (i), (ii), and (iii) we have that M_{i+1}^- is an almost perfect matching that satisfies property $i+1$. Furthermore, $Q_{i+1} = \mathrm{P}[M_{i+1}^-]$.

The analysis of the lollipop step mapping Q_i to Q_{i+1} for $i = d'+d, d'+d+1, \ldots, 2d'+d-1$ is now similar, but relying on properties (i'), (ii'), (iii') instead. From the existence of an almost perfect matching M_i^- of F_λ that satisfies property i and $Q_i = \mathrm{P}[M_i^-]$, by a similar

analysis we conclude that there exists an almost perfect matching M^-_{i+1} of F_λ that satisfies property $i+1$ and $Q_{i+1} = \mathrm{P}[M^-_{i+1}]$. Since $v_{2d'+d} = u$ and u is adjacent to t in G, from (i') we conclude in particular that $P'_e = Q_{2d'+d}$ and thus $h = 2d' + d$. Since $2d' + d \leq n$, we have shown that the lollipop method terminates in at most n lollipop steps. ◀

We note that the algorithm implicit in the proof not only uses at most a linear number of lollipop steps, but also can be implemented with the guidance of $D_{\lambda,H}$ to run in linear time.

Abstract

The *hereditary discrepancy* of a set system is a quantitative measure of the pseudorandom properties of the system. Roughly speaking, hereditary discrepancy measures how well one can 2-color the elements of the system so that each set contains approximately the same number of elements of each color. Hereditary discrepancy has numerous applications in computational geometry, communication complexity and derandomization. More recently, the hereditary discrepancy of the set system of *shortest paths* has found applications in differential privacy [Chen et al. SODA 23].

The contribution of this paper is to improve the upper and lower bounds on the hereditary discrepancy of set systems of unique shortest paths in graphs. In particular, we show that any system of unique shortest paths in an undirected weighted graph has hereditary discrepancy $O(n^{1/4})$, and we construct lower bound examples demonstrating that this bound is tight up to polylog n factors. Our lower bounds hold even for planar graphs and bipartite graphs, and improve a previous lower bound of $\Omega(n^{1/6})$ obtained by applying the trace bound of Chazelle and Lvov [SoCG'00] to a classical point-line system of Erdős.

As applications, we improve the lower bound on the additive error for differentially-private all pairs shortest distances from $\Omega(n^{1/6})$ [Chen et al. SODA 23] to $\widetilde{\Omega}(n^{1/4})$, and we improve the lower bound on additive error for the differentially-private all sets range queries problem to $\widetilde{\Omega}(n^{1/4})$, which is tight up to polylog n factors [Deng et al. WADS 23].

1 Introduction

In graph algorithms, a fundamental problem is to efficiently compute distance or shortest path information of a given input graph. Over the last decade or so, the community has increasingly sought a principled understanding of the *combinatorial structure* of shortest paths, with the goal to exploit this structure in algorithm design. That is, in various graph settings, we can ask:

> *What notable structural properties hold for* ***shortest*** *path systems, that do not necessarily hold for* ***arbitrary*** *path systems?*

The following are a few of the major successes of this line of work:

- An extremely popular strategy in the literature is to use *hitting sets*, in which we (often randomly) generate a set of nodes S and argue that it will hit a shortest path for every pair of nodes that are sufficiently far apart. Hitting sets rarely exploit any structure of shortest paths, as evidenced by the fact that most hitting set algorithms generalize immediately to arbitrary set systems. However, they have inspired a successful line of work into graphs of bounded *highway dimension* [1, 6, 7]; very roughly, these are graphs whose shortest paths admit unusually efficient hitting sets of a certain kind.
- Shortest paths exhibit the notable structural property of *consistency*, i.e., any subpath of a shortest path is itself a shortest path. This fact is used throughout the literature on graph algorithms [21, 22, 8], including e.g. in the classic Floyd-Warshall algorithm for All-Pairs Shortest Paths. A recent line of work has sought to characterize the additional structure exhibited by shortest path systems, beyond consistency [8, 21, 19, 20, 17, 4, 2].
- Planar graphs have received special attention within this research program, and planar shortest path systems carry some notable additional structure. For example, it is known that planar shortest paths have unusually efficient tree coverings [5, 11], and that their shortest paths can be compressed into surprisingly small space [12, 13]. Shortest path algorithms also often benefit from more general structural facts about planar graphs, such as separator theorems [29, 28].

The main result of this paper is a new structural separation between shortest path systems and arbitrary path systems, expressed through the lens of *discrepancy theory*. We will come to formal definitions of discrepancy in just a moment, but at a high level, discrepancy has been described as a quantitative measure of the combinatorial pseudorandomness of a discrete system [18], and it has widespread applications in discrete and computational geometry, random sampling and derandomization, communication complexity, and much more[1]. We will show the following:

▶ **Theorem 1** (Main Result, Informal). *The discrepancy of unique shortest path systems in weighted graphs is inherently smaller than the discrepancy of arbitrary path systems in graphs.*

This separation between unique shortest paths and arbitrary paths is due to the structural property of *consistency* of unique shortest path systems, which is well-studied in the literature [21, 22, 8].

[1] We refer to the excellent textbooks of Alexander, Beck, and Chen [3], Chazelle [14], Matoušek [33] for discussion and further applications.

Our results can be placed within a larger context of prior work in computational geometry. A classical topic in this area is to determine the discrepancy of incidence structures between points and geometric range spaces such as axis-parallel rectangles, half-spaces, lines, and curves (cf. [14, Section 1.5]). These results have been used to show lower bounds for geometric range searching [37, 34].

Indeed, systems of unique shortest paths in graphs capture some of the geometric range spaces studied in prior work. For instance, arrangements of straight lines in Euclidean space can be interpreted as systems of unique shortest paths in an associated graph, implying a relation between the discrepancies of these two set systems. This connection has recently found applications in the study of differential privacy on shortest path distance and range query algorithms [16, 23].

More generally, discrepancy on graphs have also found applications in proving tight lower bounds on answering cut queries on graphs [26, 32]. We provide a detailed literature review for discrepancy on graphs in the full version of our paper [9]. The full version of our paper further discusses the connection between our results and the discrepancy of arrangements of curves.

1.1 Formal Definitions of Discrepancy

We first collect the basic definitions needed to understand this paper.

▶ **Definition 2** (Edge and Vertex Incidence Matrices). *Given a graph $G = (V, E)$ and a set of paths Π in G, the associated* vertex incidence matrix *is given by $A \in \mathbb{R}^{|\Pi| \times |V|}$, where for each $v \in V$ and $\pi \in \Pi$ the corresponding entry is*

$$A_{\pi,v} = \begin{cases} 1 & \text{if } v \in \pi \\ 0 & \text{if } v \notin \pi. \end{cases}$$

The associated edge incidence matrix *is given by $A \in \mathbb{R}^{|\Pi| \times |E|}$, where for each $e \in E$ and $\pi \in \Pi$ the corresponding entry is*

$$A_{\pi,e} = \begin{cases} 1 & \text{if } e \in \pi \\ 0 & \text{if } e \notin \pi. \end{cases}$$

▶ **Definition 3** (Discrepancy and Hereditary Discrepancy). *Given a matrix $A \in \mathbb{R}^{m \times n}$, its discrepancy is the quantity*

$$\operatorname{disc}(A) = \min_{x \in \{1,-1\}^n} \|Ax\|_\infty.$$

Its hereditary discrepancy is the maximum discrepancy of any submatrix A_Y obtained by keeping all rows but only a subset $Y \subseteq [n]$ of the columns; that is,

$$\operatorname{herdisc}(A) = \max_{Y \subseteq [n]} \operatorname{disc}_v(A_Y).$$

For a system of paths Π in a graph G, we will write $\operatorname{disc}_v(\Pi), \operatorname{herdisc}_v(\Pi)$ to denote the (hereditary) discrepancy of its vertex incidence matrix, and $\operatorname{disc}_e(\Pi), \operatorname{herdisc}_e(\Pi)$ to denote the (hereditary) discrepancy of its edge incidence matrix.

For intuition, the vertex discrepancy of a system of paths Π can be equivalently understood as follows. Suppose that we color each node in G either red or blue, with the goal to balance the red and blue nodes on each path as evenly as possible. The discrepancy associated to that particular coloring is the quantity

$$\max_{\pi \in \Pi} \Big| \; |\{v \in \pi \;\mid\; v \text{ colored red}\}| - |\{v \in \pi \;\mid\; v \text{ colored blue}\}| \; \Big|.$$

The discrepancy of the system Π is the minimum possible discrepancy over all colorings. The hereditary discrepancy is the maximum discrepancy taken over all *induced path subsystems* Π' of Π; that is, Π' is obtained from Π by selecting zero or more vertices from G, deleting these vertices, and deleting all instances of these vertices from all paths.[2] We may delete nodes from the middle of some paths $\pi \in \Pi$, in which case Π' may no longer be a system of paths in G, but rather a system of paths in some other graph G' with fewer nodes and some additional edges. Nonetheless, its vertex incidence matrix and therefore $\text{herdisc}_v(\Pi')$ remain well-defined with respect to this new graph G'. Edge discrepancy can be understood in a similar way, coloring edges rather than vertices.

1.2 Our Results

Our main result is an upper and lower bound on the hereditary discrepancy of unique shortest path systems in weighted graphs, which match up to hidden polylog n factors.

▶ **Theorem 4** (Main Result).

- **(Upper Bound).** *For any n-node undirected weighted graph G with a unique shortest path between each pair of nodes, there exists a polynomial-time algorithm that finds a coloring for the system of shortest paths Π such that:*

$$\text{herdisc}_v(\Pi) \leq \widetilde{O}(n^{1/4}) \qquad \textit{and} \qquad \text{herdisc}_e(\Pi) \leq \widetilde{O}(n^{1/4}).$$

- **(Lower Bound).** *There are examples of n-node undirected weighted graphs G with a unique shortest path between each pair of nodes in which this system of shortest paths Π has $\text{herdisc}_v(\Pi) \geq \widetilde{\Omega}(n^{1/4})$ and $\text{herdisc}_e(\Pi) \geq \widetilde{\Omega}(n^{1/4})$. In fact, in these lower bound examples we can take G to be planar or bipartite.*

This theorem has immediate applications in differential privacy; we refer to Theorem 6 discussed below. We can strengthen the hereditary discrepancy lower bound into a vertex (non-hereditary) discrepancy lower bound in the undirected and directed settings. We leave open whether our lower bound extends to (non-hereditary) edge discrepancy as well, and to vertex or edge discrepancy of planar graphs. We refer to Table 1 for a list of our results in these settings.

Table 1 Overview of vertex/edge (hereditary) discrepancy on general graphs and special families of graph: tree, bipartite and planar graphs. Here n is the number of vertices of the graph and m is the number of edges. D is the graph diameter or the longest number of hops of paths considered.

		Tree	Bipartite	Planar	Undirected Graph	Directed Graph
V	disc	$\Theta(1)$	$\Theta(1)$	$O(n^{1/4})$	$\widetilde{\Theta}(n^{1/4})$	$\widetilde{\Theta}(n^{1/4})$
	herdisc	$\Theta(1)$	$\widetilde{\Theta}(n^{1/4})$	$\widetilde{\Theta}(n^{1/4})$	$\Omega(n^{1/6})$[15] $\rightarrow \widetilde{\Theta}(n^{1/4})$	$\widetilde{\Theta}(n^{1/4})$
E	disc	$\Theta(1)$	$\Theta(1)$	$O(n^{1/4})$	$O(n^{1/4})$	$\min\left\{O(m^{1/4}), \widetilde{O}(D^{1/2})\right\}$
	herdisc	$\Theta(1)$	$\widetilde{\Theta}(n^{1/4})$	$\widetilde{\Theta}(n^{1/4})$	$\Omega(n^{1/6})$[15] $\rightarrow \widetilde{\Theta}(n^{1/4})$	$\widetilde{\Omega}(n^{1/4})$

[2] In the coloring interpretation, hereditary discrepancy allows a different choice of coloring for each subsystem Π', rather than fixing a coloring for Π and considering the induced coloring on each Π'.

The upper bound in Theorem 4 is constructive and algorithmic; that is, we provide an algorithm that colors vertices (resp. edges) of the input graph to achieve vertex (resp. edge) discrepancy $\widetilde{O}(n^{1/4})$ on its shortest paths (or on a given subsystem of its shortest paths). Notably, Theorem 4 should be contrasted with the fact that the maximum possible discrepancy of *any* simple path system of polynomial size in a general graph is known to be $\widetilde{\Theta}(n^{1/2})$.[3] In fact, the lower bound on discrepancy (as well as hereditary discrepancy) for a grid graph for a polynomial number of *simple* paths can be $\Omega(\sqrt{n})$ (see the full version of our paper [9] for a proof and more discussion on grid graphs). Thus, Theorem 4 represents a concrete separation between unique shortest path systems and general path systems.

The main open question that we leave in this work is on the hereditary edge discrepancy of shortest paths in *directed* weighted graphs. We show the following:

▶ **Theorem 5.** *For any n-node, m-edge directed weighted graph G with a unique shortest path between each pair of nodes, the system of shortest paths Π satisfies*

$$\text{herdisc}_v(\Pi) \leq O(n^{1/4}) \qquad \textit{and} \qquad \text{herdisc}_e(\Pi) \leq O(m^{1/4}).$$

Lower bounds in the undirected setting immediately apply to the directed setting as well, and so this essentially closes the problem for directed hereditary *vertex* discrepancy. It is an interesting open problem whether the bound for directed hereditary *edge* discrepancy can be improved to $\widetilde{O}(n^{1/4})$ as well.

Applications to Differential Privacy. One application of our discrepancy lower bound on unique shortest paths is in differential privacy (DP) [24, 25]. An algorithm is differentially private if its output distributions are relatively close regardless of whether an individual's data is present in the data set. More formally, for two databases Y and Y' that are identical except for one data entry, a randomized algorithm $\mathcal{M}$ is (ε, δ) differentially private if for any measurable set A in the range of $\mathcal{M}$, $\Pr[\mathcal{M}(Y) \in A] \leq e^{\varepsilon} \Pr[\mathcal{M}(Y') \in A] + \delta$.

The topic of discrepancy of paths on a graph is related to two problems already studied in differential privacy: *All Pairs Shortest Distances (APSD)* ([16, 27, 36]) and *All Sets Range Queries (ASRQ)* ([23]), both assuming the graph topology is public. In APSD problem, the edge weights are not publicly known. A query in APSD is a pair of vertices $(u, v) \in V \times V$ and the answer is the shortest distance between u and v. In contrast, in ASRQ problem, the edge weights are assumed to be known, and every edge also has a private *attribute*. Here, the range is defined by the shortest path between two vertices (based on publicly known edge weights). The answer to the query $(u, v) \in V \times V$ then is the sum of private attributes along the shortest path. In what follows, we give a high-level argument for the lower bound on DP-APSD problem; the lower bound of $\widetilde{\Omega}(n^{1/4})$ for the DP-ASRQ problem also follows nearly the same arguement (see the full version of our paper [9] for details).

Chen et al. [16] showed that DP-APSD can be formulated as a linear query problem. In this setting, we are given a vertex incidence matrix A of the $\binom{n}{2}$ shortest paths of a graph and a vector x of length n and asked to output Ax. They show that the hereditary discrepancy of the matrix A provides a lower bound on the ℓ_∞ error for any (ε, δ)-DP mechanism for this problem. With this argument, our new discrepancy lower bound immediately implies:

[3] A path system is *simple* if no individual path repeats nodes. The upper bound of $\widetilde{O}(n^{1/2})$ follows by coloring the nodes randomly and applying standard Chernoff bounds. The lower bound is nontrivial and follows from an analysis of the Hadamard matrix; see [14], Section 1.5.

▶ **Theorem 6** (Informal version of Corollaries 7.1 and F.1 in [9]). *The (ε, δ)-DP APSD problem and (ε, δ)-DP ASRQ problem require additive error at least $\widetilde{\Omega}(n^{1/4})$.*

The best known additive error bound for the DP-ASRQ problem is $\widetilde{O}(n^{1/4})$ [23], which, by Theorem 6, is tight up to a polylog(n) factor. Prior to this work, the only known lower bounds for DP-ASRQ and DP-APSD were from a point-line system with hereditary discrepancy of $\Omega(n^{1/6})$ [16]. The best known additive error upper bound for DP-APSD is $\widetilde{O}(n^{1/2})$ [16, 27]. Closing this gap remains an interesting open problem.

In addition to differential privacy, our hereditary discrepancy results also have implications for matrix analysis. In short, we can show that the factorization norm of the shortest path incidence matrix is $\widetilde{\Theta}(n^{1/4})$. We delay a detailed discussion to the full version of our paper [9].

1.3 Our Techniques

We will overview our upper and lower bounds on discrepancy separately.

Upper Bound Techniques. A folklore structural property of unique shortest paths is *consistency*. Formally, a system of undirected paths Π is consistent if for any two paths π_1, π_2, their intersection $\pi_1 \cap \pi_2$ is a (possibly empty) contiguous subpath of each. It is well known that, for any undirected graph $G = (V, E, w)$ with unique shortest paths, its system of shortest paths Π is consistent. An analogous fact holds for directed graphs. Our discrepancy upper bounds will actually apply to *any* consistent system of paths – not just those that arise as unique shortest paths in a graph.

We give our upper bounds on the discrepancy of consistent systems in two steps. First, we prove the existence of a low-discrepancy coloring using a standard application of *primal shatter functions* (see the the full version of our paper [9] for a definition). For consistent paths, the primal shatter function has degree two in both directed and undirected graphs. This immediately gives us an upper bound of $O(n^{1/4})$ for vertex discrepancy and $O(m^{1/4})$ for edge discrepancy (since edge discrepancy is defined on a ground set of m edges in the graph G).

When the graph is dense, this upper bound on edge discrepancy deteriorates, becoming trivial when $m = \Theta(n^2)$. We thus present a second proof of $\tilde{O}(n^{1/4})$ for *both* vertex and edge discrepancy, which explicitly constructs a low-discrepancy coloring. This improves the bound for vertex discrepancy by polylogarithmic factors and edge discrepancy by polynomial factors. The main idea in this construction is to adapt the *path cover* technique, used in the recent breakthrough on shortcut sets [30]. That is, we start by finding a small base set of roughly $n^{1/2}$ node-disjoint shortest paths in the distance closure of the graph. These paths have the property that any other shortest path π in the graph contains at most $O(n^{1/2})$ nodes that are not in any paths in the base set. We then color *randomly*, as follows:

- For every node that is not contained in any path in the base set, we assign its color randomly. Thus, applying concentration bounds, the contribution of these nodes to the discrepancy of π will be bounded by $\pm\widetilde{O}(n^{1/4})$.
- For every path in the base set, we choose the color of the first node in the path at random, and then alternate colors along the path after that. Then we can argue that by consistency, the nodes in each base path randomly contribute $+1$ or -1 (or 0) to the discrepancy of π (see Figure 1 for a visualization). Since there are only $n^{1/2}$ paths in the base set, we may again apply concentration bounds to argue that the contribution to discrepancy from these base paths will only be $\pm\widetilde{O}(n^{1/4})$.

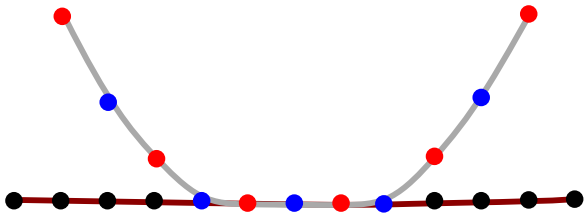

Figure 1 If we color the nodes of a unique shortest path with alternating colors, then its nodes will contribute discrepancy 0, +1, or −1 to all unique shortest paths that intersect it.

Summing together these two parts, we obtain a bound of $\widetilde{O}(n^{1/4})$ on discrepancy, which holds with high probability. We can translate this to a bound on *hereditary* discrepancy using the fact that consistency is a hereditary property of path systems.

Lower Bound Techniques. For lower bounds, we apply the trace bound of [15] on hereditary discrepancy together with an explicit graph construction [10] that was recently proposed as a lower bound against *hopsets* in graphs. An (exact) hopset of a graph G with hopbound β is a small set of additional edges H in the distance closure of G, such that every pair of nodes has a shortest path in $G \cup H$ containing at most β edges.

Until recently, the state-of-the-art hopset lower bounds were achieved using a point-line construction of Erdős [35], which had n points and n lines in $\mathbb{R}^2$ with each point staying on $\Theta(n^{1/3})$ lines and each line going through $\Theta(n^{1/3})$ points. This point-line system also implies tight lower bounds for the Szemerédi-Trotter theorem and the discrepancy of arrangements of lines in the plane [15], as well as the previous state-of-the-art lower bound on the discrepancy of unique shortest paths.

This point-line construction can be associated with a graph that possesses useful properties derived from geometry. If edges in this graph are weighted by Euclidean distance, then the paths in the graph corresponding to straight lines are unique shortest paths by design. On the other hand, two such shortest paths (along straight lines) only intersect at most once.

Recently, a construction in Bodwin and Hoppenworth [10] obtained stronger hopset lower bounds with a different geometric graph construction, which still took place in $\mathbb{R}^2$ but allowed shortest paths to have many vertices/edges in common. We show that this construction can be repurposed to derive a stronger lower bound of $\widetilde{\Omega}(n^{1/4})$ on vertex hereditary discrepancy, by applying the trace bound of [15]. Combined with our upper bounds, this substantially improves our understanding of the discrepancy of unique shortest paths.

The above upper and lower bounds are for general graphs. Naturally, one can ask if we have better bounds for special families of graphs. We further show that the lower bounds remain the same for two interesting families: planar graphs and bipartite graphs. The lower bound construction mentioned above is not planar, and so this requires some additional work. A natural attempt is to restore planarity by adding vertices to the construction wherever two edges cross. However, this comes at a cost of an increase in the number of vertices, and also with a potential danger of altering the shortest paths. In the full version of our paper [9], we first show that the number of crossings is not too much higher than n. Then, by carefully changing the weights of the edges and by exploiting the geometric properties of the construction, we show that the topology and incidence of shortest paths are not altered. For bipartite graphs, although the vertex discrepancy can be made very low – by coloring the vertices on one side +1 and vertices on the other side −1 – the hereditary discrepancy can be as high as the general graph setting. Specifically, we show a 2-lift of any graph G to a bipartite graph which essentially keeps the same hereditary discrepancy. Details can be found in the full version of our paper [9].

2 Preliminaries

A *path system* is a pair $S = (V, \Pi)$ where V is a ground set of nodes and Π is a set of vertex sequences called *paths*. Each path may contain at most one instance of each node. We now formally define consistency, a structural property of unique shortest paths that will be useful.

▶ **Definition 7.** *A path system $S = (V, \Pi)$ is consistent if no two paths in S intersect, split apart, and then intersect again later. Formally:*

- *In the undirected setting, consistency means that for all $u, v \in V$ and all $\pi_1, \pi_2 \in \Pi$ such that $u, v \in \pi_1 \cap \pi_2$, we have that $\pi_1[u, v] = \pi_2[u, v]$, i.e., the intersection of π_1 and π_2 is a contiguous subpath (subsequence) of π_1 and π_2.*
- *In the directed setting, consistency means that for all $u, v \in V$ and all $\pi_1, \pi_2 \in \Pi$ such that u **precedes** v in both π_1 and π_2, we have that $\pi_1[u, v] = \pi_2[u, v]$.*

In every weighted graph for which all pairs shortest paths exist (i.e. no negative cycles), we can represent all-pairs shortest paths using a consistent path system. In particular, if all shortest paths are *unique*, then consistency is implied immediately.

We will investigate the combinatorial discrepancy of path systems (V, Π). Usually, we will assume that $|V| = n$ and $|\Pi|$ is polynomial in n. We define a vertex coloring $\chi : V \mapsto \{-1, 1\}$ and define the *discrepancy* of Π as

$$\operatorname{disc}(\Pi) = \min_{\chi} \chi(\Pi), \quad \text{where } \chi(\Pi) = \max_{\pi \in \Pi} |\chi(\pi)|, \ \chi(\pi) = \sum_{v \in \pi} \chi(v).$$

Using a random coloring χ, we can guarantee that for all paths $\pi \in \Pi$ [14]:

$$|\chi(\pi)| \leq \sqrt{2|\pi| \ln(4|\Pi|)}.$$

This immediately provides a few observations.

▶ **Observation 8.** *When Π is a set of paths with size polynomial in n, then $\operatorname{disc}(\Pi) = O(\sqrt{n \log n})$. This bound is true even for paths that are possibly non-consistent.*

▶ **Observation 9.** *When the longest path in Π has D vertices we have $\operatorname{disc}(\Pi) = O(\sqrt{D \log n})$. Thus, for graphs that have a small diameter (e.g., small world graphs), the discrepancy of shortest paths is automatically small.*

Hereditary discrepancy is a more robust measure of the complexity of a path system (V, Π), defined as $\operatorname{herdisc}(\Pi) = \max_{Y \subseteq V} \operatorname{disc}(\Pi|_Y)$, where $\Pi|_Y$ is the collection of sets of the form $\pi \cap Y$ with $\pi \in \Pi$. Clearly, $\operatorname{herdisc}(\Pi) \geq \operatorname{disc}(\Pi)$. Sometimes the discrepancy of a set system may be small while the hereditary discrepancy is large [14]. Thus in the literature, we often talk about lower bounds on the hereditary discrepancy.

Now that we have defined vertex and edge (hereditary) discrepancy, one may wonder if there is an underlying relationship between vertex and edge (hereditary) discrepancy since they share the same bounds in most settings presented in Table 1. The following observation shows that vertex discrepancy bounds directly imply bounds on edge discrepancy.

▶ **Observation 10.** *Denote by $\operatorname{disc}(n)$ (and $\operatorname{herdisc}(n)$) the maximum discrepancy (minimum hereditary discrepancy, respectively) of a consistent path system of a (undirected or directed) graph of n vertices. We have that*

1. *Let $g(x)$ be a non-decreasing function. If $\operatorname{herdisc}_v(n) \geq g(n)$, then $\operatorname{herdisc}_e(n) \geq g(n/2)$.*
2. *Let $f(x)$ be a non-decreasing function. If $\operatorname{disc}_v(n) \leq f(n)$, then $\operatorname{disc}_e(m) \leq f(m)$.*

The proof of Observation 10 is deferred to the full version of our paper [9]. We also use some technical tools from discrepancy theory and statistics. For details please refer to the full version of our paper [9].

3 Undirected Graphs: Lower Bound and Explicit Colorings

We now discuss the main result (Theorem 4). We first show in Section 3.1 a hereditary discrepancy lower bound of $\Omega(n^{1/4}/\sqrt{\log n})$ for both edge and vertex discrepancy in general undirected graphs. Then in Section 3.2 we present a vertex coloring achieving hereditary discrepancy of $\widetilde{O}(n^{1/4})$. Finally, we present an explicit edge coloring with the same hereditary discrepancy bound in Section 3.3.

3.1 Lower Bound

As suggested by Observation 10, we focus on the vertex hereditary discrepancy, and our goal is to prove the following statement (Theorem 11). In Theorem 10 of the full version of our paper [9], we show that this theorem implies the same lower bound on (non-hereditary) vertex discrepancy as well.

▶ **Theorem 11.** *There are examples of n-vertex undirected weighted graphs G with a unique shortest path between each pair of vertices in which this system of shortest paths Π has*

$$\text{herdisc}_v(\Pi) \geq \Omega(n^{1/4}/\sqrt{\log n}).$$

To obtain the lower bound, we employ the new graph construction by [10], which shows that any exact hopset with $O(n)$ edges must have at least $\widetilde{\Omega}(n^{1/2})$ hop diameter. Despite seeming unrelated, this construction also sheds light on our problem. Another technique we use to show the hereditary discrepancy lower bound is the trace bound [31] (and restated in the full version of our paper [9]). In the following proof section, we first summarize the construction related to our objective, then show the calculation using the trace bound that leads to our lower bound.

Proof. The key properties of the graph construction in [10] (see also Section 5 of [9]) that we need can be summarized in the following lemma.

▶ **Lemma 12** (Lemma 1 of [10]). *For any $p \in [1, n^2]$, there is an infinite family of n-node undirected weighted graphs $G = (V, E, w)$ and sets Π of p paths in G such that*

- *G has $\ell = \Theta\left(\frac{n}{\sqrt{p \log n}}\right)$ layers. Each path in Π starts in the first layer, ends in the last layer, and contains exactly one node in each layer.*
- *Each path in Π is the unique shortest path between its endpoints in G.*
- *For any two nodes $u, v \in V$, there are at most $\frac{\ell}{h(u,v)}$ paths in Π that contain both u and v, where $h(u, v)$ is the hopdistance (number of edges on the shortest path) between u and v in G and $1 \leq h(u, v) \leq \ell$.*
- *Each node $v \in V$ lies on at most $O\left(\frac{\ell p}{n}\right)$ distinct paths in Π.*

We will make use of the shortest path vertex incidence matrix of this graph. Recall that hereditary discrepancy considers the sub-incidence matrix induced by columns corresponding to a set of vertices. We select the set of vertices occurring in the paths in Π, and show it leads to hereditary discrepancy at least $\Omega(n^{1/4}/\sqrt{\log n})$. Specifically, take A as the incidence matrix such that each row corresponds to one path in Π. A has dimension $p \times n$ where n is the number of vertices in G and the (i, j)-th entry of A is 1 is the vertex j is in the path i.

Now define $M = A^T A$. Recall that $\text{tr}(M)$ is the number of 1s in the matrix A. Since by construction, every path has length ℓ, we have $\text{tr}(M) = p\ell$. Furthermore, let m_{ij} be the (i, j)-th element of matrix M, and observe that it is exactly the number of paths that contain vertices i and j. (Note that $m_{ij} = m_{ji}$.) Additionally, $\text{tr}(M^2)$ is the number of length 4 closed walks in the bipartite graph representing the incidence matrix A. This implies that

$$\mathrm{tr}(M^2) = \sum_{j=1}^{p} \sum_{\substack{u,v \in P_j, \\ u \neq v}} m_{u,v} + \sum_{i=1}^{n} m_{ii}^2 = \sum_{j=1}^{p} \sum_{i=1}^{\ell} \sum_{\substack{u,v \in P_j, \\ h(u,v)=i}} m_{u,v} + n \cdot O\left(\frac{p\ell}{n}\right)^2$$

$$\leq \sum_{j=1}^{p} \sum_{i=1}^{\ell} \ell \cdot \frac{\ell}{i} + O\left(\frac{p^2\ell^2}{n}\right) \leq p\ell^2 \log \ell + O\left(\frac{p^2\ell^2}{n}\right) = \frac{np\ell^2 \log(\ell) + O(p^2\ell^2)}{n}. \quad (1)$$

By setting $p = n \log n$, it follows that $\ell = \Theta(\sqrt{n}/\log n)$ and $\mathrm{tr}(M) = p\ell$. Further,

$$np\ell^2 \log \ell = O(n \cdot n \log n \cdot \frac{n}{\log^2 n} \cdot \log n) = O(n^3) = O(p^2\ell^2).$$

By Equation (1), we have $\mathrm{tr}(M^2) = O(p^2\ell^2/n)$. Using this and $\mathrm{tr}(M) = p\ell$ in the trace bound of [31] gives us

$$\mathrm{herdisc}(A) \geq \frac{(\mathrm{tr}(M))^2}{8e \min\{p,n\} \cdot \mathrm{tr}(M^2)} \sqrt{\frac{\mathrm{tr}(M)}{\max\{p,n\}}} = \frac{(\mathrm{tr}(M))^2}{8en \cdot \mathrm{tr}(M^2)} \sqrt{\frac{\mathrm{tr}(M)}{p}}$$

$$\geq \Omega\left(\frac{p^2\ell^2}{p^2\ell^2}\sqrt{\ell}\right) = \Omega(\sqrt{\ell}) = \Omega\left(\frac{n^{1/4}}{\sqrt{\log n}}\right).$$

The trace bound is formally stated in the full version of our paper [9]. ◀

3.2 Vertex Discrepancy Upper Bound – Explicit Coloring

In this subsection, we will upper bound the discrepancy $\chi(\Pi)$ of a consistent path system (V, Π) with $|V| = n$ and $|\Pi| = \mathrm{poly}(n)$. This will immediately imply an upper bound for the hereditary vertex discrepancy of unique shortest paths in undirected graphs.

▶ **Theorem 13.** *For a consistent path system $S = (V, \Pi)$ where $|V| = n$ and $|\Pi| = \mathrm{poly}(n)$, there exists a labeling χ such that $\chi(\Pi) = O(n^{1/4} \log^{1/2} n)$. Consequently, every n-vertex undirected graph has hereditary vertex discrepancy $O(n^{1/4} \log^{1/2} n)$.*

Let $S = (V, \Pi)$ be a consistent path system with $|V| = n$ and $|\Pi| = \mathrm{poly}(n)$. As the first step towards constructing our labeling $\chi : V \mapsto \{-1, 1\}$, we will construct a collection of paths Π' on V that will have a useful covering property over the paths in Π.

Constructing path cover Π'. Initially, we let $\Pi' = \emptyset$. We define V' to be the set of all nodes in V belonging to a path in Π', i.e., $V' := \bigcup_{\pi' \in \Pi'} \pi'$. While $|\pi \setminus V'| \geq n^{1/2}$ for some $\pi \in \Pi$, find a (possibly non-contiguous) subpath of π of length $n^{1/2}$ that is vertex-disjoint from all paths in Π'. Formally, find a subpath $\pi' \subseteq \pi$ such that $|\pi'| = n^{1/2}$ and $\pi' \cap V' = \emptyset$. Add path π' to path cover Π' and update V'. Repeatedly add paths to path cover Π' in this manner until $|\pi \setminus V'| < n^{1/2}$ for all $\pi \in \Pi$.

▶ **Proposition 14.** *Path cover Π' satisfies the following properties:*

1. *for all $\pi \in \Pi'$, $|\pi| = n^{1/2}$,*
2. *the number of paths in Π' is $|\Pi'| \leq n^{1/2}$,*
3. (Disjointness Property). *The paths in Π' are pairwise vertex-disjoint,*
4. (Covering Property). *For all $\pi \in \Pi$, the number of nodes in π that do not lie in any path in path cover Π' is at most $n^{1/2}$. Formally, let $V' = \cup_{\pi' \in \Pi'} \pi'$. Then $\forall \pi \in \Pi, |\pi \setminus V'| \leq n^{1/2}$,*
5. (Consistency Property). *For all $\pi \in \Pi$ and $\pi' \in \Pi'$, the intersection $\pi \cap \pi'$ is a (possibly empty) contiguous subpath of π'.*[4]

[4] Note that it may not be true that $\pi \cap \pi'$ is a contiguous subpath of π.

Proof. Properties 1, 3, and 4 follows from the construction of Π'. Property 2 follows from Properties 1 and 3 and the fact that $|V| = n$. The Consistency Property of Π' is inherited from the consistency of path system S. Specifically, by the construction of Π', path $\pi' \in \Pi'$ is a subpath of a path $\pi'' \in \Pi$. Recall that by the consistency of path system S, the intersection $\pi \cap \pi''$ is a (possibly empty) contiguous subpath of π''. Then $\pi \cap \pi'$ is a contiguous subpath of π' since $\pi' \subseteq \pi''$. This concludes the proof. ◀

Constructing labeling χ. Let $\pi' = (v_1, \ldots, v_k) \in \Pi'$ be a path in our path cover. We will label the nodes of π' using the following random process. With probability $1/2$ we define $\chi : \pi' \mapsto \{-1, 1\}$ to be

$$\chi(v_i) = \begin{cases} 1 & i \equiv 0 \mod 2 \text{ and } i \in [1, k] \\ -1 & i \equiv 1 \mod 2 \text{ and } i \in [1, k] \end{cases},$$

and with probability $1/2$ we define $\chi : \pi' \mapsto \{-1, 1\}$ to be

$$\chi(v_i) = \begin{cases} -1 & i \equiv 0 \mod 2 \text{ and } i \in [1, k] \\ 1 & i \equiv 1 \mod 2 \text{ and } i \in [1, k] \end{cases}.$$

The labels of consecutive nodes in π' alternate between 1 and -1, with vertex v_1 taking labels 1 and -1 with equal probability. Since the paths in path cover Π' are pairwise vertex-disjoint, the labeling χ is well-defined over $V' := \cup_{\pi' \in \Pi'} \pi'$. We choose a random labeling for all nodes in $V \setminus V'$, i.e., we independently label each node $v \in V \setminus V'$ with $\chi(v) = -1$ with probability $1/2$ and $\chi(v) = 1$ with probability $1/2$. An illustration can be found in Figure 2.

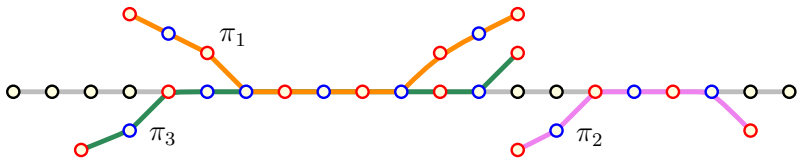

Figure 2 In this figure, paths $\pi_1, \pi_2, \pi_3 \in \Pi'$ from the path cover are intersecting a path $\pi \in \Pi$. Paths in the path cover are pairwise vertex-disjoint, and each path in the cover contributes discrepancy 0, -1, or $+1$ to π.

Bounding the discrepancy $\chi(\Pi)$. Fix a path $\pi \in \Pi$. We will show that $\left|\sum_{v \in \pi} \chi(v)\right| = O(n^{1/4} \log^{1/2} n)$ with high probability. Theorem 13 will follow as $|\Pi| = \text{poly}(n)$.

▶ **Proposition 15.** *For each path π' in path cover Π',*

$$\sum_{v \in \pi \cap \pi'} \chi(v) \in \{-1, 0, 1\}.$$

If $|\pi \cap \pi'| \equiv 0 \mod 2$, then $\sum_{v \in \pi \cap \pi'} \chi(v) = 0$. Moreover,

$$\Pr\left[\sum_{v \in \pi \cap \pi'} \chi(v) = -1\right] = \Pr\left[\sum_{v \in \pi \cap \pi'} \chi(v) = 1\right].$$

Proof. By the Consistency Property of Π' (as proven in Proposition 14), path $\pi \cap \pi'$ is a (possibly empty) contiguous subpath of π'. Then since consecutive nodes in π' alternate between -1 and 1, it follows that $\sum_{v \in \pi \cap \pi'} \chi(v) \in \{-1, 0, 1\}$.

Now note that $\sum_{v \in \pi \cap \pi'} \chi(v) \neq 0$ iff $|\pi \cap \pi'|$ is odd. Moreover, the first vertex of $\pi \cap \pi'$ takes labels 1 and -1 with equal probability. This concludes the proof of Proposition 15. ◀

We are now ready to bound the discrepancy of π.

▶ **Proposition 16.** *With high probability,* $\chi(\pi) = O(n^{1/4}\log^{1/2} n)$.

Proof. We partition the nodes of π into two sources of discrepancy that we will bound separately. Let $V' := \cup_{\pi' \in \Pi'} \pi'$.

Discrepancy of $\pi \cap V'$. For each path $\pi' \in \Pi'$, let $X_{\pi'}$ be the random variable defined as

$$X_{\pi'} := \sum_{v \in \pi \cap \pi'} \chi(v).$$

We can restate the discrepancy of $\pi \cap V'$ as

$$\left| \sum_{v \in \pi \cap V'} \chi(v) \right| = \left| \sum_{\pi' \in \Pi'} X_{\pi'} \right|.$$

By Proposition 15, if $|\pi \cap \pi'| \equiv 0 \mod 2$, then $X_{\pi'} = 0$, so we may assume without any loss of generality that $|\pi \cap \pi'|$ is odd for all $\pi' \in \Pi'$. In this case, $\Pr[X_{\pi'} = -1] = \Pr[X_{\pi'} = 1] = 1/2$, implying that $\mathbb{E}[\sum_{\pi' \in \Pi'} X_{\pi'}] = 0$. Then by Proposition 14 and Chernoff, it follows that for any constant $c \geq 1$,

$$\Pr\left[\left| \sum_{\pi' \in \Pi'} X_{\pi'} \right| \geq c \cdot n^{1/4}\log^{1/2} n\right] \leq e^{-c^2 \frac{n^{1/2}\log n}{2|\Pi'|}} \leq e^{-c^2/(2\cdot\log(n))} = n^{-c^2/2}.$$

Discrepancy of $\pi \setminus V'$. Note that by the Covering Property of the path cover (as proven in Proposition 14), $|\pi \setminus V'| \leq n^{1/2}$. Moreover, the nodes in $V \setminus V'$ are labeled independently at random, implying that $\mathbb{E}[\sum_{v \in \pi \setminus V'} \chi(v)] = 0$. Then we may apply a Chernoff bound to argue that for any constant $c \geq 1$,

$$\Pr\left[\left| \sum_{v \in \pi \setminus V'} \chi(v) \right| \geq c \cdot n^{1/4}\log^{1/2} n\right] \leq \exp\{-c^2 \frac{n^{1/2}\log n}{2|\pi \setminus V'|}\} \leq e^{-c^2/(2\cdot\log(n))} = n^{-c^2/2}.$$

We have shown that with high probability, the discrepancy of our labeling is $O(n^{1/4}\log^{1/2} n)$ for $\pi \cap V'$ and $O(n^{1/4}\log^{1/2} n)$ for $\pi \setminus V'$, so we conclude that the total discrepancy of π is $O(n^{1/4}\log^{1/2} n)$, completing the proof of Proposition 16. ◀

Extending to hereditary discrepancy. Let A be the vertex incidence matrix of a path system $S = (V, \Pi)$ on n nodes, and let A_Y be the submatrix of A obtained by taking all of its rows but only a subset Y of its columns. Then there exists a subset $V_Y \subseteq V$ of the nodes in V such that A_Y is the vertex incidence matrix of the path system $S[V_Y]$ (path system S induced on V_Y). Moreover, if path system S is consistent, then $S[V_Y]$ is also consistent. Then we may apply our explicit vertex discrepancy upper bound to $S[V_Y]$. We conclude that the hereditary vertex discrepancy of S is $O(n^{1/4}\log^{1/2} n)$.

3.3 Edge Discrepancy Upper Bound – Explicit Coloring

By Theorem 5, the edge discrepancy of the unique shortest paths of a (possibly directed) graph on m edges is $O(m^{1/4})$. However, in the case of undirected graphs and DAGs, we can improve the edge discrepancy to $O(n^{1/4}\log^{1/2} n)$, where n is the number of vertices

in the graph, by modifying the explicit construction for vertex discrepancy in Section 3.2. Our proof strategy will follow the same framework as the explicit construction for vertex discrepancy, but with some added complications in the construction and analysis.

We first introduce some new notation that will be useful in this section. Given a path π and nodes $u, v \in \pi$, we say that $u <_\pi v$ if u occurs before v on path π. Additionally, given a path system $S = (V, \Pi)$, we define the edge set $E \subseteq V \times V$ of the path system as the set of all pairs of nodes $u, v \in V$ that appear consecutively in some path in Π. Likewise, for any path π over the vertex set V, we define the edge set of π, $E(\pi) \subseteq \pi \times \pi$, as the set of all pairs of nodes $u, v \in \pi$ such that u, v appear consecutively in π and $(u, v) \in E$. Note that if path system S corresponds to paths in a graph G, then E will be precisely the edge set of G.

Recall that we wish to construct an edge labeling $\chi : E \mapsto \{-1, 1\}$ so that

$$\chi(\Pi) = \max_{\pi \in \Pi} \left| \sum_{e \in E(\pi)} \chi(e) \right|$$

is minimized. We will upper bound the discrepancy $\chi(\Pi)$ of consistent path systems such that $|V| = n$ and $|\Pi| = \text{ poly}(n)$. This will immediately imply an upper bound on the edge discrepancy of unique shortest paths in undirected graphs.

▶ **Theorem 17.** *For all consistent path systems $S = (V, \Pi)$ where $|V| = n$ and $|\Pi| = \text{poly}(n)$ with edge set E, there exists a labeling $\chi : E \to \{-1, 1\}$ such that*

$$\chi(\Pi) = O(n^{1/4} \log^{1/2} n).$$

Consequently, every n-vertex undirected graph has hereditary edge discrepancy $O(n^{1/4} \log^{1/2} n)$.

Let $S = (V, \Pi)$ be a consistent path system with $|V| = n$ and $|\Pi| = \text{poly}(n)$. As the first step towards constructing our labeling $\chi : E \mapsto \{-1, 1\}$, we will construct a collection of paths Π' on V that will have a useful covering property over the paths in Π.

3.3.1 Constructing path cover Π'

Initially, we let $\Pi' = \emptyset$. We define V' to be the set of all nodes in V belonging to a path in Π', i.e.,

$$V' := \bigcup_{\pi' \in \Pi'} \pi'.$$

While there exists a path $\pi \in \Pi$ such that $|\pi \setminus V'| \geq n^{1/2}$, find a (possibly non-contiguous) subpath of π of length $n^{1/2}$ that is vertex-disjoint from all paths in Π'. Specifically, let $\pi' \subseteq \pi$ be a (possibly non-contiguous) subpath of π containing exactly the first $n^{1/2}$ nodes in $\pi \setminus V'$. Add path π' to path cover Π' and update V'. Repeatedly add paths to path cover Π' in this manner until $|\pi \setminus V'| < n^{1/2}$ for all $\pi \in \Pi$.

Note that our path cover Π' is very similar to the path cover used in the explicit vertex discrepancy upper bound. Indeed, path cover Π' inherits all properties of the path cover defined in Subsection 3.2. The key difference here is that we require subpaths $\pi' \subseteq \pi$ in Π' to contain the *first* $n^{1/2}$ nodes in $\pi \setminus V'$. This will imply an additional property of our path cover, which we call the No Repeats Property.

▶ **Proposition 18.** *Path cover Π' satisfies all properties of Proposition 14, as well as the following additional properties:*

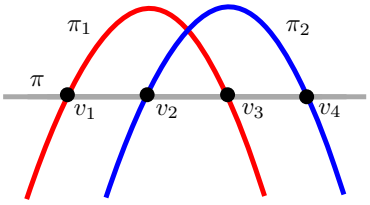

Figure 3 In this figure, paths $\pi_1, \pi_2 \in \Pi'$ are intersecting a path $\pi \in \Pi$. This arrangement of paths is forbidden by the No Repeats Property of Proposition 18.

- (Edge Covering Property). *For all $\pi \in \Pi$, the number of edges in π that are not incident to any node lying in a path in path cover Π' is at most $n^{1/2}$. Formally, let $V' = \cup_{\pi' \in \Pi'} \pi'$. For all $\pi \in \Pi$,*

  $$|\{(u, v) \in E(\pi) \mid u \notin V' \text{ and } v \notin V'\}| \leq n^{1/2},$$

- (No Repeats Property). *For all paths $\pi \in \Pi$, $\pi_1, \pi_2 \in \Pi'$, and nodes $v_1, v_2, v_3, v_4 \in \pi$ such that $v_1, v_3 \in \pi_1$ and $v_2, v_4 \in \pi_2$, the following ordering of the vertices in Π is impossible:*

  $$v_1 <_\pi v_2 <_\pi v_3 <_\pi v_4,$$

  where $x <_\pi y$ indicates that node x occurs in π before node y.

Proof. All properties from Proposition 14 follow from an identical argument as in the original proof. The Edge Covering Property follows immediately from the Covering Property of Proposition 14. What remains is to prove the No Repeats Property.

Suppose for the sake of contradiction that there exist paths $\pi \in \Pi$, $\pi_1, \pi_2 \in \Pi'$, and nodes $v_1, v_2, v_3, v_4 \in \pi$ such that $v_1, v_3 \in \pi_1$ and $v_2, v_4 \in \pi_2$, where $v_1 <_\pi v_2 <_\pi v_3 <_\pi v_4$. We will assume that path π_1 was added to Π' before path π_2 (the case where π_2 was added to Π' first is symmetric). By the construction of Π', path $\pi_1 \in \Pi'$ is a (possibly non-contiguous) subpath of a path $\pi_1'' \in \Pi$ that it was constructed from. Additionally, by the consistency of the path system S, the intersection $\pi \cap \pi_1''$ is a contiguous subpath of π. Then $v_2 \in \pi \cap \pi_1''$, and specifically, $v_2 \in \pi_1''$.

We assumed that $v_2 \in \pi_2$, which implies that $v_2 \notin \pi_1$, since paths in Π' are pairwise vertex-disjoint. Since path π_1 was added to Π' before path π_2, this means that when π_1 was added to Π', node v_2 did not belong to any path in Π' (i.e., v_2 was not in V'). Recall that in our construction of Π', we constructed subpath $\pi_1 \subseteq \pi_1''$ so that it contained exactly the *first* $n^{1/2}$ nodes in $\pi_1'' \setminus V'$. However, $v_2 \notin \pi_1$, but $v_3 \in \pi_1$, and v_2 comes before v_3 in π_1''. This contradicts our construction of path π_1 in path cover Π'. ◀

3.3.2 Constructing labeling χ

Let $\pi' \in \Pi'$ be a path of length k in our path cover. Let $e_1, \ldots, e_k \in E(\pi')$ be the edges in π' listed in the order they appear in π'. Note that since π' is a possibly non-contiguous subpath of a path in Π, pairs of nodes $u, v \in V$ that appear consecutively in π do not necessarily correspond to edges in edge set E.

We will label the edges in $E(\pi')$ using the following random process. With probability $1/2$ we define $\chi : E(\pi') \mapsto \{-1, 1\}$ to be

$$\chi(e_i) = \begin{cases} 1 & i \equiv 0 \mod 2 \text{ and } i \in [1, k] \\ -1 & i \equiv 1 \mod 2 \text{ and } i \in [1, k] \end{cases},$$

and with probability 1/2 we define $\chi : E(\pi') \mapsto \{-1, 1\}$ to be

$$\chi(e_i) = \begin{cases} -1 & i \equiv 0 \mod 2 \text{ and } i \in [1, k] \\ 1 & i \equiv 1 \mod 2 \text{ and } i \in [1, k] \end{cases}.$$

Note that the labels of consecutive edges e_i, e_{i+1} in π' alternate between 1 and -1, with edge e_1 taking labels 1 and -1 with equal probability.

Since the paths in path cover Π' are pairwise vertex-disjoint, the labeling χ is well-defined over $E' := \cup_{\pi' \in \Pi'} E(\pi')$. We take a random labeling for all edges in $E \setminus E'$, i.e., we independently label each edge $e \in E \setminus E'$ with $\chi(e) = -1$ with probability 1/2 and $\chi(e) = 1$ with probability 1/2.

3.3.3 Bounding the discrepancy ϕ

Fix a path $\pi := \pi[s, t] \in \Pi$. We will show that

$$\left| \sum_{e \in E(\pi)} \chi(e) \right| = O(n^{1/4} \log^{1/2} n)$$

with high probability. This will complete the proof of Lemma 17 since $|\Pi| = \text{poly}(n)$. The proof of the following proposition follows from an argument identical to Proposition 15 and hence omitted.

▶ **Proposition 19.** *For each path π' in path cover Π',*

$$\sum_{e \in E(\pi) \cap E(\pi')} \chi(e) \in \{-1, 0, 1\}.$$

If $|E(\pi) \cap E(\pi')| \equiv 0 \mod 2$, then $\sum_{e \in E(\pi) \cap E(\pi')} \chi(e) = 0$. Moreover,

$$\Pr\left[\sum_{e \in E(\pi) \cap E(\pi')} \chi(e) = -1 \right] = \Pr\left[\sum_{e \in E(\pi) \cap E(\pi')} \chi(e) = 1 \right].$$

We are now ready to bound the edge discrepancy of π. Define

$$V' := \bigcup_{\pi' \in \Pi'} \pi' \quad \text{and} \quad E' := \bigcup_{\pi' \in \Pi'} E(\pi').$$

We partition the edges of the path π into three sources of discrepancy that we will bound separately. Specifically, we split $E(\pi) \subseteq \pi \times \pi$ into the following sets E_1, E_2, E_3:

- $E_1 := E(\pi) \cap E'$,
- $E_2 := E(\pi) \cap ((V \setminus V') \times (V \setminus V'))$, and
- $E_3 := E(\pi) \setminus (E_1 \cup E_2)$.

Sets E_1 and E_2 roughly correspond to the two sources of discrepancy considered in the vertex discrepancy upper bound, while set E_3 corresponds to a new source of discrepancy that will require new arguments to bound. We begin with set E_1.

▶ **Proposition 20** (Discrepancy of E_1). *With high probability, $\left|\sum_{e \in E_1} \chi(e)\right| = O(n^{1/4} \log^{1/2} n)$.*

Proof. The proposition follow from an argument similar to Proposition 16. For each path $\pi' \in \Pi'$, let $X_{\pi'}$ be the random variable defined as

$$X_{\pi'} := \sum_{e \in E(\pi) \cap E(\pi')} \chi(e).$$

We can restate the discrepancy of E_1 as

$$\left| \sum_{e \in E_1} \chi(e) \right| = \left| \sum_{\pi' \in \Pi'} X_{\pi'} \right|.$$

By Proposition 19, if $|E(\pi) \cap E(\pi')| \equiv 0 \mod 2$, then $X_{\pi'} = 0$, so without any loss of generality, we may assume that $|E(\pi) \cap E(\pi')|$ is odd for all $\pi' \in \Pi'$. In this case,

$$\Pr[X_{\pi'} = -1] = \Pr[X_{\pi'} = 1] = 1/2,$$

implying that $\mathbb{E}[\sum_{\pi' \in \Pi'} X_{\pi'}] = 0$. Then by Proposition 18 and the Chernoff bound, it follows that for any constant $c \geq 1$,

$$\Pr\left[\left| \sum_{\pi' \in \Pi'} X_{\pi'} \right| \geq c \cdot n^{1/4} \log^{1/2} n \right] \leq e^{-c^2 \frac{n^{1/2} \log n}{2|\Pi'|}} \leq e^{-c^2/2 \cdot \log n} \leq n^{-c^2/2}. \quad \blacktriangleleft$$

We now bound the discrepancy of E_2.

▶ **Proposition 21** (Discrepancy of E_2). *With high probability,* $\left|\sum_{e \in E_2} \chi(e)\right| = O(n^{1/4} \log^{1/2} n)$.

Proof. The proposition follow from an argument similar to Proposition 16. Note that by the Edge Covering Property of the path cover (Proposition 18),

$$|E_2| = |\{(u, v) \in E(\pi) \mid u, v \notin V'\}| \leq n^{1/2}.$$

Moreover, the edges in $E \setminus E'$ are labeled independently at random, so we may apply a Chernoff bound to argue that for any constant $c \geq 1$,

$$\Pr\left[\left| \sum_{e \in E_2} \chi(e) \right| \geq c \cdot n^{1/4} \log^{1/2} n \right] \leq e^{-c^2 \frac{n^{1/2} \log n}{2|E_2|}} \leq e^{-c^2/2 \cdot \log n} \leq n^{-c^2/2}.$$

completing the proof. ◀

Finally, we upper bound the discrepancy of E_3.

▶ **Proposition 22** (Discrepancy of E_3). *With high probability,* $\left|\sum_{e \in E_3} \chi(e)\right| = O(n^{1/4} \log^{1/2} n)$.

Proof. Let

$$k := |\{\pi' \in \Pi' \mid \pi \cap \pi' \neq \emptyset\}|$$

denote the number of paths in our path cover that intersect π. We define a function $f : \mathbb{Z}_{\geq 0} \mapsto \mathbb{Z}_{\geq 0}$ such that $f(\phi)$ equals the largest possible value of $|E_3|$ when $\phi = k$. Note that f is well-defined since $0 \leq |E_3| \leq |E|$. We will prove that $f(\phi) \leq 4\phi$, by recursively decomposing path π.

When $\phi = 1$, there is only one path $\pi' \in \Pi'$ that intersects π. Then the only edges in E_3 are of the form

$$E(\pi) \cap ((V' \times (V \setminus V')) \cup ((V \setminus V') \times V')) = E(\pi) \cap ((\pi' \times (V \setminus \pi')) \cup ((V \setminus \pi') \times \pi')).$$

By the Consistency Property of Proposition 18, path π' can intersect π and then split apart at most once. Then

$$f(1) = |E_3| = |E(\pi) \cap ((\pi' \times (V \setminus \pi')) \cup ((V \setminus \pi') \times \pi'))| \leq 2.$$

When $\phi > 1$, we will split our analysis into the two cases:

- **Case 1.** There exists paths $\pi'_1, \pi'_2 \in \Pi'$ and nodes $v_1, v_2, v_3 \in \pi$ such that $v_1, v_3 \in \pi'_1$ and $v_2 \in \pi'_2$ and $v_1 <_\pi v_2 <_\pi v_3$. In this case, we can assume without any loss of generality that $\pi[v_1, v_3] \cap \pi'_1 = \{v_1, v_3\}$ (e.g., by choosing v_1, v_3 so that this equality holds). Let x be the node immediately following v_1 in π, and let y be the node immediately preceding v_3 in π. Recall that s is the first node of π and t is the last node of π. It will be useful for the analysis to split π into three subpaths:

  $$\pi = \pi[s, v_1] \circ \pi[x, y] \circ \pi[v_3, t],$$

  where $\circ$ denotes the concatenation operation. Let

  $$\phi_1 := |\{\pi' \in \Pi' \mid \pi[x, y] \cap \pi' \neq \emptyset\}| \text{ and } \phi_2 := |\{\pi' \in \Pi' \mid (\pi[s, v_1] \circ \pi[v_3, t]) \cap \pi' \neq \emptyset\}|.$$

  We claim that $\phi_1 < \phi$, $\phi_2 < \phi$, and $\phi_1 + \phi_2 = \phi$. We will use these facts to establish a recurrence relation for f. By our assumption that $\pi[v_1, v_3] \cap \pi'_1 = \{v_1, v_3\}$, it follows that $\pi[x, y] \cap \pi'_1 = \emptyset$, and so $\phi_1 < \phi$. Likewise, by the No Repeats Property of Proposition 18,

  $$(\pi[s, v_1] \circ \pi[v_3, t]) \cap \pi'_2 = \emptyset,$$

  so $\phi_2 < \phi$. Finally, observe that more generally, if there exists a path $\pi' \in \Pi'$ such that $\pi' \cap \pi[x, y] \neq \emptyset$ and $\pi' \cap (\pi[s, v_1] \circ \pi[v_3, t]) \neq \emptyset$, then the No Repeats Property of Proposition 18 is violated. We conclude that $\phi_1 + \phi_2 = \phi$.
  Now $|E_3|$ can be upper bounded by the following inequality:

  $$|E_3| \leq |E_3 \cap E(\pi[x, y])| + |E_3 \cap E(\pi[s, v_1] \circ \pi[v_3, t])| + 2.$$

  Then using the observations about ϕ_1, ϕ_2, and ϕ in the previous paragraph, we obtain the following recurrence for f:

  $$f(\phi) \leq f(\phi_1) + f(\phi_2) + 2 = f(i) + f(\phi - i) + 2,$$

  where $0 < i < \phi$.
- **Case 2.** There exists a path $\pi' \in \Pi'$ and $v_1, v_2 \in \pi$ such that $\pi \cap \pi' = \pi[v_1, v_2] \cap V'$. Let x be the node immediately preceding v_1 in π, and let y be the node immediately following v_2 in π. Again, we split π into three subpaths:

  $$\pi[s, t] = \pi[s, x] \circ \pi[v_1, v_2] \circ \pi[y, t].$$

  Let

  $$\phi_1 := |\{\pi' \in \Pi' \mid \pi[v_1, v_2] \cap \pi' \neq \emptyset\}| \text{ and } \phi_2 := |\{\pi' \in \Pi' \mid (\pi[s, x] \circ \pi[y, t]) \cap \pi' \neq \emptyset\}|.$$

By our assumption in Case 2, it follows that $\phi_1 = 1$ and $\phi_2 = \phi - 1$. Since $|E_3|$ can be upper bounded by the inequality

$$|E_3| \leq |E_3 \cap E(\pi[v_1, v_2])| + |E_3 \cap E(\pi[s, x] \circ \pi[y, t])| + 2,$$

we immediately obtain the recurrence

$$f(\phi) \leq f(\phi_1) + f(\phi_2) + 2 \leq f(1) + f(\phi - 1) + 2.$$

Taking our results from Case 1 and Case 2 together, we obtain the recurrence relation

$$f(\phi) \leq \begin{cases} \max\{f(i) + f(\phi - i) + 2,\ f(1) + f(\phi - 1) + 2\} & \phi > 1 \text{ and } 1 < i < \phi \\ 2 & \phi = 1 \end{cases}$$

Applying this recurrence $\leq \phi$ times, we find that

$$f(\phi) \leq \phi \cdot f(1) + 2\phi \leq 4\phi.$$

Finally, since $k \leq |\Pi'| \leq n^{1/2}$ and we defined f so that $f(k)$ equals the largest possible value of $|E_3|$, we conclude that

$$|E_3| \leq f(k) \leq f(n^{1/2}) = O(n^{1/2}).$$

Since the edges in $E_3 \subseteq E \setminus E'$ are labeled independently at random, we may apply a Chernoff bound as in Proposition 21 to argue that $\chi(E_3) = O(n^{1/4} \log^{1/2} n)$ with high probability. ◀

We have shown that with high probability, the discrepancy of our edge labeling is $O(n^{1/4} \log^{1/2} n)$ for E_1, E_2, and E_3, so we conclude that the total discrepancy of π is $O(n^{1/4} \log^{1/2} n)$. A straightforward extension of this argument implies identical bounds for hereditary discrepancy. We defer this proof to the full version of our paper [9].

4 Conclusion and Open Problems

This paper reported new bounds on the hereditary discrepancy of set systems of unique shortest paths in graphs. An open problem is to improve our edge discrepancy upper bound in directed graphs. Standard techniques in discrepancy theory imply an upper bound of $\min\{O(m^{1/4}), \widetilde{O}(D^{1/2})\}$ for this problem, leaving a gap with our $\Omega(n^{1/4}/\sqrt{\log n})$ lower bound when $m = \omega(n)$. Unfortunately, we were not able to extend our low-discrepancy edge and vertex coloring arguments for undirected graphs to the directed setting, due to the pathological example in Figure 4.

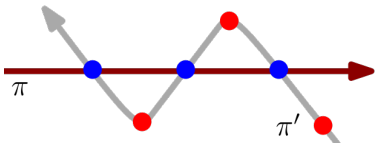

Figure 4 An example in directed graphs that demonstrates how coloring unique shortest paths with alternating colors can fail to imply low discrepancy.

Abstract

We construct n-node graphs on which any $O(n)$-size spanner has additive error at least $+\Omega(n^{3/17})$, improving on the previous best lower bound of $\Omega(n^{1/7})$ [Bodwin-Hoppenworth FOCS '22]. Our construction completes the first two steps of a particular three-step research program, introduced in prior work and overviewed here, aimed at producing tight bounds for the problem by aligning aspects of the upper and lower bound constructions. More specifically, we develop techniques that enable the use of *inner graphs* in the lower bound framework whose technical properties are provably tight with the corresponding assumptions made in the upper bounds. As an additional application of our techniques, we improve the corresponding lower bound for $O(n)$-size additive emulators to $+\Omega(n^{1/14})$.

1 Introduction

Suppose that we want to compute shortest paths or distances in an enormous graph G. When G is too big to store in memory, a popular strategy is to instead use a *spanner* of G, which is a much sparser subgraph H with approximately the same shortest path metric as G. This can substantially improve storage or runtime costs, in exchange for a small error in the distance information. Perhaps the most well-applied case is when the spanner is asymptotically as sparse as possible; that is, $|E(H)| = O(n)$ for an n-node input graph G (note that $\Omega(n)$ edges are needed just to preserve connectivity).

There are several ways to measure the quality of approximation of a spanner. The two most popular are as follows:

Table 1 The progression of upper and lower bounds on the additive error associated to n-node spanners on $O(n)$ edges; current state of the art bounds are highlighted in red. See also [10, 11, 6, 3, 2] for work on additive spanners of superlinear size.

	Upper Bound		Lower Bound	
$O(n)$-size Spanners			$\Omega(\log n)$	[23]
	$\widetilde{O}(n^{9/16})$	[20]	$\Omega(n^{1/22})$	[1]
	$\widetilde{O}(n^{1/2})$	[9]	$\Omega(n^{1/11})$	[16, 18]
	$O(n^{3/7+\varepsilon})$	[8]	$\Omega(n^{2/21})$	[19]
	$O(n^{\frac{15-\sqrt{54}}{19}<0.403})$	[21]	$\Omega(n^{1/7})$	[7]
			$\Omega(n^{3/17})$	this paper

▶ **Definition 1** (Multiplicative and Additive Spanners). *Given a graph G, a subgraph*[1] *$H \subseteq G$ is a* multiplicative $\cdot k$ spanner *if for all nodes s, t we have $dist_H(s,t) \leq dist_G(s,t) \cdot k$. It is an* additive $+k$ spanner *if we have $dist_H(s,t) \leq dist_G(s,t) + k$.*

The parameter k is called the (additive or multiplicative) *stretch* of the spanner. A famous paper of Althöfer, Das, Dobkin, Joseph, and Soares [4] settled the optimal *multiplicative* stretch for $O(n)$-size spanners:[2]

▶ **Theorem 2** ([4]). *Every n-node graph has a spanner H of size $|E(H)| = O(n)$ and multiplicative stretch $O(\log n)$. This stretch cannot generally be improved to $o(\log n)$.*

The goal of this paper is to make progress on the corresponding question for *additive* error. This question has been intensively studied; see Table 1 for the progression of results. Our contributions are on the lower bounds side:

▶ **Theorem 3** (Main Result). *There exists an infinite family of n-vertex undirected graphs for which any additive spanner on $O(n)$ edges has additive stretch $\Omega(n^{3/17})$.*

Our techniques also lead to progress on related questions for $O(n)$-size emulators, which we discuss further in Section 1.2. Before we explain this, we contextualize Theorem 3 by explaining in more depth the sense in which it moves the upper and lower bounds closer together.

1.1 Our Contribution and Next Steps for the Area

There are well-established frameworks in place for proving upper and lower bounds for $O(n)$-size spanners, and the current sentiment among experts is that these two frameworks *could* eventually produce near-matching (likely within n^{ε} factors) upper and lower bounds. Both frameworks can be broken down into three corresponding steps, and over the last few years, a research program has emerged in which the long-term goal is to find optimal bounds for the problem by making each of these three steps align.[3] That is, we can investigate what "should" happen in each step if a hypothetical optimal version of the upper bound framework were run on the graph from a hypothetical optimal version of the lower bound framework. This thought experiment leads to a list of three concrete features that should be realized in an ideal lower bound, which we overview at a high level in Table 2.

[1] Throughout the paper, for brevity, we write "subgraph" to specifically mean a subgraph over the same vertex set as the original graph.
[2] Although we generally treat input graphs G as undirected and unweighted in this paper, this particular theorem also extends to the setting where G is weighted.
[3] This program was made somewhat explicit in [7] (c.f. Section 2.4), but was implicit in work before that.

However, it is easier to write down this wishlist for the lower bound than it is to actually achieve the listed features in a construction; we discuss the various technical barriers in Section 2. The contribution of the current paper is to achieve the first two steps of alignment (i.e., the first two items in Table 2) simultaneously, which both have to do with optimizing properties of the so-called *inner graph* in the lower bound construction. That said, the ideal structure of an inner graph has been known since [8], and well before that Coppersmith and Elkin [12] found graph constructions achieving this ideal structure ("subset distance preserver lower bound graphs"). Our main technical contributions are not in designing new inner graphs, but rather, in improving the *outer graph* in a way that allows these previously known optimal inner graphs to be used within the framework for the first time.

This paper makes no real progress on the third and final point of alignment, which contends with optimizing certain quantitative properties of the shortest paths in the outer graph. Here there is still significant misalignment between the upper and lower bounds, which is responsible for essentially all of the remaining numeric gap between the current upper and lower bounds for $O(n)$-size spanners. Improving this third point, either on the upper bounds side or the lower bounds side, is the clear next step for the area and it may first require advances in our understanding of distance preservers [12]; see [7] for discussion.

1.2 Additional Results

The technical improvements to the construction that enable our improved spanner lower bounds also imply improvements for two nearby objects, which we overview next. First, an *emulator* is similar to a spanner, but not required to be a subgraph:

▶ **Definition 4** (Additive Emulators). *Given a graph G, a graph H on the same vertex set as G is an* additive $+k$ emulator *if for all nodes s, t we have*

$$dist_G(s,t) \leq dist_H(s,t) \leq dist_G(s,t) + k.$$

An emulator H is allowed to be weighted, even when the input graph G is unweighted. Emulators generalize spanners, and hence the upper and lower bounds known for $O(n)$-size emulators are a bit lower than the corresponding bounds for spanners. See Table 3 for the progression of results on the additive error that can be obtained for $O(n)$-size emulators.

A similar lower bound framework is used to achieve lower bounds for emulators, and hence our new technical machinery improves the current lower bounds for emulators as well:

▶ **Theorem 5.** *There exists an infinite family of n-vertex undirected graphs for which any additive emulator on $O(n)$ edges has additive stretch $\Omega(n^{1/14})$.*

Our numeric improvement in the lower bound for emulators is more modest than our improvement for spanners; at a high level, this is because our main improvement is to enable stronger inner graphs in the lower bound framework, but the role of the inner graph is generally less important in emulator lower bounds.

We next provide a more fine-grained overview of our lower bound framework, and we describe our technical improvements that lead to our new results in more detail.

2 Technical Overview

In this section we will give an overview of the different technical components in our lower bound graph construction. We start by reviewing the obstacle product framework in Section 2.1 and recalling some ideas from prior work in Section 2.2. Finally we will discuss the new components in our construction in Section 2.3.

Table 2 A point-by-point comparison of the frameworks used to prove upper and lower bounds. Our main technical contributions are to satisfy the first point of alignment by enabling the use of inner graphs with $\Theta(r^{4/3})$ nodes (where $+\Omega(r)$ is the desired lower bound on spanner error), and to satisfy the second point of alignment by enabling the use of subset distance preserver lower bounds for our inner graphs. Neither of these properties were fully achieved in prior work.

Step in Upper Bounds	Step in Lower Bounds	What should ideally happen when we run the upper bound framework on a lower bound graph?
Cover the input graph by clusters C of radius r each. These clusters are classified as either *small* or *large*, depending on whether their number of nodes is smaller or larger than $r^{4/3}$.	Start with an *outer graph*, and systematically replace each node with a disjoint copy of an *inner graph*.	The upper bound should select the inner graphs as its clusters. All inner graphs should have $\Theta(r^{4/3})$ nodes, since the worst case for the upper bound is when all clusters are near the large/small threshold.
Small clusters C have a node separator of size $\leq |C|^{1/4}$. Construct a *subset distance preserver* on each small cluster, preserving all shortest paths between separator nodes, at cost $O(\|C\|)$ [12].	The inner graphs should be selected as the union of many long unique shortest paths among nodes that form a separator for the graph, and also any two of these shortest paths may intersect on at most one node.	The inner graph should be a lower bound graph against subset distance preservers with $\Theta(\|C\|^{1/4})$ source nodes (with a large implicit constant), so that the approach of constructing a subset distance preserver is too expensive to be used in an attack against the lower bound.
Large clusters C are handled by adding some additional shortest paths in the spanner to connect far-away clusters to each other. Using the *path-buying framework* [6], we can limit the total number and length of the shortest paths we need to add.	The outer graph is selected to be the union of as many long unique shortest paths as possible, and any two of these shortest paths may intersect on at most one edge. That is, the outer graph is a slightly modified distance preserver lower bound graph.	The shortest paths added for large clusters should coincide with the shortest paths in the original outer graph (before inner graph replacement). The path-buying bounds on the number and length of these shortest paths should coincide with the number and length of these shortest paths in the outer graph.

Table 3 The progression of upper and lower bounds on the additive error associated to n-node emulators on $O(n)$ edges; current state of the art bounds are highlighted in red. See also [13].

2.1 The obstacle product framework

Similar to all previous works including [1, 16, 19, 7] on proving stretch lower bounds for linear-sized additive spanners, our construction falls under the *obstacle product* framework introduced in [1]. Any construction under this framework consists of an *outer graph* $G_O = (V_O, E_O)$ and an *inner graph* $G_I = (V_I, E_I)$ where every vertex in the outer graph is replaced by a copy of the inner graph. The desired outer graph should contain a set pairs $P_O \subseteq V_O \times V_O$ often called the *critical pairs* such that the following holds:

1. For each pair $(s, t) \in P_O$, the shortest path from s to t is *unique*. These unique shortest paths connecting between pairs in P_O are often called the *critical paths*.
2. The critical paths have roughly the same length $\Theta(k)$.
3. The critical paths are pairwise edge disjoint.

When we replace each vertex in the outer graph with a copy of the inner graph G_I, we make sure that the critical paths remain the unique shortest paths between their endpoints and pairwise edge-disjoint by attaching each incoming edge and outgoing edge to distinct vertices of the inner graph. Finally, we subdivide the edges originally in G_O into paths of length $\Theta(k)$. Now in the resulting graph denoted as $G_{obs} = (V_{obs}, E_{obs})$ with critical pairs P_{obs}, each critical path between the endpoints in P_{obs} uniquely corresponds to a critical path in G_O and it takes the form of traveling alternatingly between subdivided edges in G_O and paths in G_I. In particular, each critical path travels through $\Theta(k)$ subdivided paths of length $\Theta(k)$, and $\Theta(k)$ inner graph copies.

Now let us see how to show that any sparse spanner on G_{obs} must suffer additive distortion $+\Omega(k)$. The goal is to argue that if lots of edges are missing in the spanner $H \subseteq G_{obs}$ compared to G_{obs}, then there exists some pair $(s, t) \in P_{obs}$ whose shortest path π in H falls into one of the following two cases:

1. If π traverses the same sequence of inner graph copies as the critical path in G_{obs}, then it must use at least one *extra* edge in each inner graph copy compared to the critical path in the original graph due to missing edges. Since the critical path passes through $\Theta(k)$ inner graph copies, the path π must suffer a $+\Omega(k)$ distortion in total.
2. If π traverses a different sequence of inner graph copies, then it must traverse a different set of subdivided paths corresponding to the edges in G_O. Since the critical paths in G_O are the unique shortest paths between its endpoints, π must traverse at least one more subdivided path of length $\Theta(k)$ and thus suffer a $+\Omega(k)$ distortion.

Furthermore, note that the reason behind doing inner graph replacement is that without the inner graphs, subdividing each edge of the outer graph would significantly sparsify the graph so that even a trivial spanner including all the edges would have linear size. Adding the inner graphs helps balance the overall density of the graph so that any linear-sized spanner needs to be nontrivial. Thus, ideally we would want the inner graphs to be dense.

2.2 The outer graph: distance preservers and the alternation product

In this subsection, we review the two key components for the outer graph construction: the distance preserver lower bound graph given in [12] and the alternation product first used in [14].

2.2.1 Distance preserver lower bound graph

Given a graph $G = (V, E)$ and a set of pairs $P \subseteq V \times V$, a distance preserver H is a sparse subgraph of G that preserves the distances for every pair in P *exactly*. Previously, Coppersmith and Elkin [12] obtained a lower bound instance for distance preservers by

constructing a large set of vertex pairs with pairwise *edge-disjoint* unique shortest paths that are as long as possible; the union of the edges of these paths is the lower bound instance. Following the intuition outlined in Section 2.1, it is natural to consider using the distance preserver lower bound construction of [12] as the outer graph. From now on, we will abbreviate the term "distance preserver lower bound graph" to "DP LB graph" and the term "Coppersmith-Elkin construction" to "CE construction" for convenience.

Indeed, all prior work uses some version of the CE construction of DP LB graph as the outer graph, and so do we. The CE construction is a geometric construction where the vertex set corresponds to a d-dimensional integer grid $[n]^d$ and edges are added corresponding to a d-dimensional convex set $B_d(r)$ defined to be the vertices of the convex hull of integer points contained in a ball of radius $r > 0$. More specifically, the vertices corresponding to the points $\vec{x}, \vec{y}$ are connected by an edge if $\vec{y} - \vec{x} \in B_d(r)$. Then the critical paths are defined to be the paths corresponding to the straight lines starting from a "start zone" passing through the grid, i.e. the paths that repeatedly take the edge corresponding to the same vector in $B_d(r)$. By convexity of the set $B_d(r)$, one can show that these critical paths are edge-disjoint and they are the unique shortest paths between their endpoints.

Prior to the work of [7], works including [16, 19] all considered a *layered* version of the DP LB graph as the outer graph. Namely the graph contains $\ell + 1$ layers where each layer corresponds to a d-dimensional integer grid $[n]^d$ and edges are added between adjacent layers corresponding to the convex set $B_d(r)$ similarly as defined in [12]. Then the critical paths are defined to be the paths that start in the first layer and end in the last layer that repeatedly take the edge corresponding to the same vector in $B_d(r)$. This layering simplifies the stretch analysis for additive spanner lower bounds because it is easy to argue that all the critical paths have length exactly ℓ and the shortest path should not take any backward edges as it will then need to traverse more layers. However, the layered version resulted in worse bounds compared to the original unlayered version but it was unclear at the time how to analyze an unlayered outer graph. Most recently, Bodwin and Hoppenworth [7] developed a new analysis framework and successfully analyzed an obstacle product graph with a modified version of the unlayered DP LB graph as the outer graph. As a result, they improved the lower bound to $\Omega(n^{1/7})$ from $\Omega(n^{1/10.5})$ where the former remains the current best known lower bound before this work. We use the unlayered outer graph construction in [7] as an ingredient in our construction.

2.2.2 The alternation product

Another important idea that goes in to the outer graph construction is the alternation product first used in [14]. Subsequent works including [1, 16, 19] all use the alternation product in the outer graph construction. Consider two copies G_1, G_2 of the same 2-dimensional layered DP LB graph with $\ell + 1$ layers and convex set $B_2(r)$. Namely, each layer corresponds to the $[n]^2$ grid and the edges correspond to the 2-dimensional convex set $B_2(r)$ of radius r. The original implementation of the alternation product graph G_{alt} used in [14, 1, 16] of G_1 and G_2 is a graph on $2\ell + 1$ layers with each layer corresponding to the 4-dimensional grid $[n]^4$. Each vertex in G_{alt} corresponds the pair (v_1, v_2) where $v_1 \in G_1, v_2 \in G_2$ and the edges are added alternatingly between adjacent layers according to G_1 and G_2, respectively. Specifically, between layer i and $i+1$ for i odd, we connect the vertex $(\vec{x}, \vec{y})$ for $\vec{x}, \vec{y} \in [n]^2$ to $(\vec{x} + \vec{w}, \vec{y})$ for $\vec{w} \in B_2(r)$; for i even, we connect the vertex $(\vec{x}, \vec{y})$ to $(\vec{x}, \vec{y} + \vec{w})$ for $\vec{w} \in B_2(r)$. In other words, G_{alt} keeps track of G_1 using the first two coordinates and G_2 using the last two coordinates. Then a critical path π in G_{alt} corresponds to a pair of critical paths π_1 in G_1 and π_2 in G_2 by taking alternating steps from π_1 and π_2. So the main advantage of the alternation product for us is that it gives an extra product structure over the set of critical paths that we want in our construction.

Unlike in our construction, prior works including [14, 1, 16, 19] apply the alternation product in order to obtain a different relative count between the number of vertices and the number of critical pairs rather than to obtain the extra product structure. However, these changes in parameters are in fact unfavorable to the construction for linear-sized spanner lower bounds. To see this, notice that one can equivalently think of G_{alt} as 4-dimensional CE construction graph using the smaller convex set $\{(\vec{w}_1, \vec{w}_2) \mid \vec{w}_1, \vec{w}_2 \in B_2(r)\}$ instead of $B_4(r)$, which means that G_{alt} has fewer critical pairs (see Section 2.3 for a more detailed discussion). In fact, in [16], Huang and Pettie gave an $\Omega(n^{1/11})$ lower bound construction without the alternation product that improved on their own construction that uses the alternation product which gave a bound of $\Omega(n^{1/13})$ in the same paper. Later in [19], Lu, Vassilevska Wiliams, Wein and Xu improved on the alternation product that reduces the loss in the number of critical pairs compared to the CE construction, thereby obtaining an $\Omega(n^{1/10.5})$ lower bound that improved on the previous best bound of $\Omega(n^{1/11})$. Most recently, Vassilevska Wiliams, Xu and Xu implicitly constructed an alternation product graph in their $O(m)$-shortcut lower bound construction in [22] that asymptotically matches the number critical pairs in the CE construction. Unfortunately, their construction is under a different setting so we cannot directly apply their technique to our construction as a blackbox. However, by isolating a main observation implied in their work, we were able to integrate such an alternation product into our construction (see Section 2.3).

2.3 Our construction: optimal unlayered alternation product and optimal inner graph structure

Our main technical contribution is a linear-sized additive spanner lower bound construction that carefully combines the following ideas:

1. An unlayered DP LB graph as the outer graph, as in [7].
2. An optimal alternation product implicit in [22].
3. An optimal subset DP LB graph as the inner graphs, as motivated in Table 2.

We start with comparing our construction with the previously known lower bound constructions in Table 4.

Table 4 All known lower bound constructions.

Bodwin, Hoppenworth [7]	$\Omega(n^{1/7})$	Unlayered DP LB	DP LB
This work	$\Omega(n^{3/17})$	Unlayered DP LB + Optimal Alt Product	Subset DP LB

In the following, we will discuss the main components of our construction.

2.3.1 Outer Graph: Unlayered DP LB graph with optimal alternation product

As mentioned in Section 2.2, we would like to be able to apply the implicit alternation product in [22] to unlayered DP LB graphs. By isolating the main idea that one can use the set $\{(x, y, x^2 + y^2) \mid x, y \in [r]\}$ as the convex set in the alternation product graph, we are able to apply the implicit alternation product in [22] on unlayered DP LB graphs successfully after certain modifications (See Section 4.1 for more details). In the following, we give a more detailed discussion of the informal intuition behind why the alternation product we use is more desirable than the alternation product used in prior works including [1, 16, 19].

Recall that in Section 2.2, one may view an alternation product graph as a CE construction with a different convex set that determines the set of edges of the graph. In addition, a vector from the convex set and a vertex in the "start zone" determines a critical path, so we get more critical pairs if we use a larger convex set. More precisely, we want to use a convex set that is "large" with respect to the total number of integer points contained in the convex hull of the set. We recall from [5] that $|B_d(r)| = \Theta(r^{d \cdot \frac{d-1}{d+1}})$. Let us compare the convex sets used in the various alternation product graphs against $B_d(r)$ in the same number of dimension that is scaled to contain the same number of points in its convex hull asymptotically in Table 5. Then we can see from Table 5 that all prior constructions use a convex set that contains less points than the respective $B_d(r)$ while the convex set we use in this work matches the quality of $B_3(r)$, which is optimal in 3-dimensions (see [5] for more details). That is, the construction that we use is as good as the CE construction in 3-dimensions.

Table 5 Comparison between known constructions of the alternation product and the CE construction. The top row in each pair is the corresponding CE construction in the same number of dimensions and scaled to contain the same number of points in its convex hull. The bottom row in each pair indicates the alternation product construction used in the work cited.

Citation	Convex Set Used	Convex Set Size	Convex Hull Size
4-dim [12]	$B_4(r)$	$\Theta(r^{12/5})$	$\Theta(r^4)$
[1, 16]	$\{(\vec{x}, \vec{y}) \mid \vec{x}, \vec{y} \in B_2(r)\}$	$\Theta(r^{4/3})$	$\Theta(r^4)$
3-dim [12]	$B_3(r)$	$\Theta(r^{3/2})$	$\Theta(r^3)$
[19]	$\{(x_1, x_2 + y_1, y_2) \mid \vec{x}, \vec{y} \in B_2(r)\}$	$\Theta(r^{4/3})$	$\Theta(r^3)$
3-dim [12]	$B_3(r^{4/3})$	$\Theta(r^2)$	$\Theta(r^4)$
This work (based on [22])	$\{(x, y, x^2 + y^2) \mid x, y \in [r]\}$	$\Theta(r^2)$	$\Theta(r^4)$

One may wonder why we do not simply use the CE construction as our outer graph. The reason is that the alternation product has extra structure that is crucial for allowing us to use our desired inner graph. The CE construction lacks these properties. We elaborate on this below.

2.3.2 Inner graph: Optimal subset DP LB graph

For our inner graphs, we use the CE construction of subset DP LB graphs in the regime where the pairs $S \times S$ has size $|S| = \Theta(n^{1/4})$ where n denotes the number of vertices in the graph. In fact, this construction is tight in the sense that it has $\Omega(n)$ edges while on the other hand it is known that there exists subset distance preservers of size $O(n)$ for every set of sources S of size $O(n^{1/4})$. So not only are we using an inner graph structure that aligns with the upper bound algorithm as illustrated in Table 2, we are in fact using a tight construction of the desired structure.

The main reason why we are able to use subset DP LB graphs as inner graphs in our construction is that we have an alternation product graph as our outer graph. We discuss below why an alternation product is necessary for using subset DP LB graphs as inner graphs. In the inner graph replacement step under the obstacle product framework, we need to attach the incoming edges and outgoing edges adjacent to a vertex v to vertices in the corresponding inner graph copy so that each critical path passing through v in the outer graph will pass through a unique critical path in the inner graph copy as well. Since the subset DP LB graph has critical pairs of the form $S \times S$ for some subset S of the vertex set, it is required that the critical paths passing through v in the outer graph also be equipped with a product structure. In DP LB graphs, we have no such product structure over the critical paths. However, notice that applying an alternation product would exactly give us a product structure over the critical paths as desired.

3 Preliminaries

We use the following notations:

- We use $\texttt{Conv}(\cdot)$ to denote the convex hull of a set.
- We use $\langle \cdot, \cdot \rangle$ to denote the standard Euclidean inner product, $\| \cdot \|$ the Euclidean norm, and $\texttt{proj}_{\vec{w}}(\cdot)$ the Euclidean scalar projection onto $\vec{w}$.
- We use $[x]$, where x is a positive integer, to denote the set $\{1, \ldots, x\}$.

4 Outer Graph G_O

The goal of this section will be to construct the outer graph G_O of our additive spanner and emulator lower bound constructions. The key properties of G_O are summarized in Theorem 6.

▶ **Theorem 6** (Properties of Outer Graph). *For any $a, r > 0 \in \mathbb{Z}$, there exists a graph $G_O(a, r) = (V_O, E_O)$ with a set Π_O of critical paths in G_O that has the following properties:*

1. *The number of nodes, edges, and critical paths in G_O is:*

$$|V_O| = \Theta(a^3 r),$$
$$|E_O| = \Theta(a^3 r^2),$$
$$|\Pi_O| = \Theta(a^2 r^4).$$

2. *Every critical path $\pi \in \Pi_O$ is a unique shortest path in G_O of length at least $|\pi| \geq \frac{a}{4r}$.*
3. *Every pair of distinct critical paths $\pi_1, \pi_2 \in \Pi_O$ intersect on at most two nodes.*
4. *Every edge $e \in E_O$ lies on some critical path in Π_O.*

The rest of the section is devoted to constructing the graph $G_O(a, r)$ and paths Π_O that satisfy Theorem 6.

4.1 Convex Set of Vectors

Before specifying the construction of the graph G_O, we begin by specifying our construction of a set of vectors $W \subseteq \mathbb{R}^3$ that is crucial to the construction of G_O. Set W will be parameterized by a positive integer r, i.e., $W = W(r)$. The vectors in W will satisfy a certain strict convexity property that we will use to ensure the unique shortest paths property of paths Π_O in G_O.

▶ **Definition 7** ($W(r)$). *Given a positive integer r, let*

$$W_1(r) := \{(x, 0, x^2) \mid x \in \{r/2, \ldots, r\}\} \quad \text{and} \quad W_2(r) := \{(0, y, y^2) \mid y \in \{r/2, \ldots, r\}\}.$$

We define $W(r)$ to be the sumset

$$W(r) := W_1(r) + W_2(r) = \{(x, y, x^2 + y^2) \mid x, y \in \{r/2, \ldots, r\}\}.$$

We now verify that sets of vectors $W_1(r), W_2(r), W(r)$ have the necessary convexity property to ensure that graph G_O has unique shortest paths (Property 2 of Theorem 6). The convexity property of W stated in Lemma 8 is roughly similar to the notion of "strong convexity" in [7], but is in fact stronger.

▶ **Lemma 8** (Convexity property). *Let W_1, W_2, W be the sets defined in Definition 7 for some positive integer r. Let W' be the set*

$$W' = W \cup (-W) \cup (W_1 - W_2) \cup (W_2 - W_1).$$

Then each vector $\vec{w} \in W$ is an extreme point of the convex hull $\texttt{Conv}(W')$ of W'.

We omit the proof as it simply follows from checking that every vector in W' is an extreme point of $\texttt{Conv}(W')$.

4.2 Construction of G_O

Let $a, r > 0 \in \mathbb{Z}$ be the input parameters for our construction of outer graph $G_O = (V_O, E_O)$. Let $W_1 = W_1(r)$, $W_2 = W_2(r)$, and $W = W(r)$ be the sets of vectors constructed in Definition 7 and parameterized by our choice of r.

Vertex Set V_O

- Our vertex set V_O will correspond to two copies of integer points arranged in a grid in $\mathbb{R}^3$. These two copies will be denoted as V_O^L and V_O^R. For a point $p \in \mathbb{R}^3$, we will use p_L to denote the copy of point p in V_O^L, and p_R to denote the copy of point p in V_O^R. Likewise, for a set of points $P \subseteq \mathbb{R}^3$, we will use P_L to denote the copy of set P in V_O^L, and P_R to denote the copy of set P in V_O^R. Then we define V_O^L and V_O^R as:

  $$V_O^L = ([a] \times [a] \times [ar])_L, \qquad \text{and} \qquad V_O^R = ([a] \times [a] \times [ar])_R.$$

  When denoting a node v_L or v_R in V_O, we will drop the subscript and simply denote this node as v when its membership in V_O^L and V_O^R is clear from the context or otherwise irrelevant.

Edge Set E_O

- The edges E_O in G_O will pass between V_O^L and V_O^R, so that $E_O \subseteq V_O^L \times V_O^R$.
- Just as the nodes in V_O are integer points in $\mathbb{R}^3$, we will identify the edges in E_O with integer vectors in $\mathbb{R}^3$. Specifically, for each edge (x_L, y_R) in E_O, we identify $x_L \to y_R$ with the vector $y - x \in \mathbb{R}^3$. Note that $y - x$ corresponds to the orientation $x_L \to y_R$ of edge (x_L, y_R); we would use vector $x - y \in \mathbb{R}^3$ to denote $y_R \to x_L$.
- For each node $v_L \in V_O^L$ and each vector $\vec{w} \in W_1$, if $(v + \vec{w})_R \in V_O^R$, then add edge $(v_L, (v + \vec{w})_R)$ to E_O. Likewise, for each node $v_R \in V_O^R$ and each vector $\vec{w} \in W_2$, if $(v + \vec{w})_L \in V_O^L$, then add edge $(v_R, (v + \vec{w})_L)$ to E_O.

Critical Paths Π_O

- Let $S \subseteq \mathbb{R}^3$ denote the set of points $S = [a] \times [a] \times [r^2/8]$.
- Let s be a point in S. Additionally, let $\vec{w}_1$ be a vector in W_1, and let $\vec{w}_2$ be a vector in W_2, where $\vec{w}_1 + \vec{w}_2 \in W$.[4] If $s + \vec{w}_1 \notin S$, then we define a corresponding path in G_O starting from $s_L \in S_L$ as

$$s_L \to (s + \vec{w}_1)_R \to (s + \vec{w}_1 + \vec{w}_2)_L \to (s + 2\vec{w}_1 + \vec{w}_2)_R \to (s + 2\vec{w}_1 + 2\vec{w}_2)_L \to \cdots \to (s + i \cdot \vec{w}_1 + i \cdot \vec{w}_2)_L,$$

  where i is the largest integer i such that node $(s + i \cdot \vec{w}_1 + i \cdot \vec{w}_2)_L \in V_O^L$. Let $t = (s + i \cdot \vec{w}_1 + i \cdot \vec{w}_2)_L$ be the endpoint of this path, and add this $s \rightsquigarrow t$ path to our set of critical paths Π_O.
- Note that every critical path $\pi \in \Pi_O$ constructed this way is uniquely specified by a start node $s_L \in S_L$ and vectors $\vec{w}_1 \in W_1$ and $\vec{w}_2 \in W_2$.
- For every critical path $\pi \in \Pi_O$ where $|\pi| < \frac{a}{4r}$, remove π from Π_O.

As a final step in our construction of G_O, we remove all edges in G_O that do not lie on some critical path $\pi \in \Pi_O$.

4.3 Properties of G_O

We will now verify that G_O and Π_O satisfy the properties specified in Theorem 6 via the following claims. We omit the proofs as most of them follow from definition and Lemma 8.

▷ Claim 9. Every critical path $\pi \in \Pi_O$ is the unique shortest path between its endpoints in G_O. Moreover, $|\pi| \geq \frac{a}{4r}$.

▷ Claim 10. Every pair of distinct critical paths $\pi_1, \pi_2 \in \Pi_O$ can intersect on either a single vertex or a single edge.

▷ Claim 11. Every edge in G_O is used by at most $r/2$ critical paths $\pi \in \Pi_O$.

▷ Claim 12. The number of nodes, edges, and critical paths in $G_O(a, r)$ is:

$$|V_O| = \Theta(a^3 r),$$
$$|E_O| = \Theta(a^3 r^2),$$
$$|\Pi_O| = \Theta(a^2 r^4).$$

Proof of Theorem 6. Note that graph G_O and critical paths Π_O satisfy Properties 1, 2, and 3 of Theorem 6 by Claim 9, Claim 10, and Claim 12. Moreover, Property 4 of Theorem 6 follows immediately from the final step in our construction of G_O. This completes the proof of Theorem 6. ◀

5 Spanner Lower Bound Construction

In this section we present our lower bound construction for additive spanners. This construction will have a similar structure to the obstacle product graph G constructed for our emulator lower bound, but with several complications. We now describe these modifications to the obstacle product argument:

[4] Note that $\vec{w}_1 + \vec{w}_2 \in W$ for all $\vec{w}_1 \in W_1$ and $\vec{w}_2 \in W_2$, since $W = W_1 + W_2$. However, in Section 5.1, we will modify W so that W is a strict subset of $W_1 + W_2$, which will make this requirement relevant.

- **Convex Sets W_1, W_2, and W.** In Section 5.1, we modify the convex sets of vectors W_1, W_2, and W_3 that we defined in Section 4. The purpose of this modification is technical, but it has to do with the projection argument we employ in our analysis. Our new convex sets of vectors $W_1(r,c), W_2(r,c), W(r,c)$ will now be parameterized by an additional integer $c > 0$. These new sets of vectors will roughly resemble the outer graph vectors in Lemma 8 of [7] and will play a similar role in our analysis of G.
- **Inner Graph G_I.** We choose our inner graphs to be the sourcewise distance preserver lower bound graphs constructed in [12]. Lemma 19 specifies the exact properties of these new inner graphs G_I that we require in our analysis. See Subsections 1.1 and 2.2 for an overview of why we make this design choice.

5.1 Modifying Convex Sets W_1, W_2, and W in G_O

In this section, we modify the definitions of the convex sets of vectors W_1, W_2, and W used to construct outer graph G_O. Let $r, c > 0 \in \mathbb{Z}$ be the input parameters to our convex sets of vectors W_1, W_2, and W.

We define I_i be the interval

$$I_i := \left[\frac{r}{2} + \frac{(2i-2)\cdot r}{4c}, \quad \frac{r}{2} + \frac{(2i-2)\cdot r}{4c} + \frac{r}{16c^3}\right],$$

for $i \in [1, c]$. The following claim is immediate from the definition of intervals I_i.

▷ Claim 13. Intervals $\{I_i\}_{i\in[1,c]}$ satisfy the following properties:
- $I_i \subseteq [r/2, r]$,
- $|I_i| = \frac{r}{16c^3}$
- if $x, y \in I_i$, then $|x - y| \leq \frac{r}{16c^3}$, and
- if $x \in I_i$ and $y \in I_j$, where $i \neq j$, then $|x - y| \geq r/(2c)$.

We will use intervals $\{I_i\}_{i\in[1,c]}$ to construct our sets of vectors $W_1(r,c)$ and $W_2(r,c)$.

▶ **Definition 14** ($W_1(r,c)$ and $W_2(r,c)$). *Let r, c be positive integers. We define $W_1(r,c)$ and $W_2(r,c)$ as*

$$W_1(r,c) := \left\{(x, 0, x^2) \mid x \in I_i, i \in [1,c]\right\} \quad \text{and} \quad W_2(r,c) := \left\{(0, y, y^2) \mid y \in I_i, i \in [1,c]\right\}.$$

Now we partition the vectors in $W_1(r,c)$ into c sets $\mathcal{S}_1^1, \ldots, \mathcal{S}_c^1$ we call *stripes*. We define the ith stripe $\mathcal{S}_i^1$ of $W_1(r,c)$ as $\{(x, 0, x^2) \mid x \in I_i\}$. Likewise, we define the ith stripe $\mathcal{S}_i^2$ of $W_2(r,c)$ as $\{(0, y, y^2) \mid y \in I_i\}$. The key properties of our stripes are summarized in Claim 15, which follows immediately from Claim 13.

▷ Claim 15. Stripes $\{\mathcal{S}_i^1\}_{i\in[1,c]}$ satisfy the following properties:
- $\mathcal{S}_i^1 \subseteq [r/2, r]$,
- $|\mathcal{S}_i^1| = \frac{r}{16c^3}$,
- if $(x, 0, x^2), (y, 0, y^2) \in \mathcal{S}_i^1$, then $|x - y| \leq \frac{r}{16c^3}$, and
- if $(x, 0, x^2) \in \mathcal{S}_i^1$ and $(y, 0, y^2) \in \mathcal{S}_j^1$, where $i \neq j$, then $|x - y| \geq \frac{r}{2c}$.

Moreover, stripes $\{\mathcal{S}_i^2\}_{i\in[1,c]}$ satisfy analogous properties.

Roughly, Claim 15 states that vectors in the same stripe in $W_1(r,c)$ or $W_2(r,c)$ are "close" to each other in some sense, and vectors in different stripes in $W_1(r,c)$ and $W_2(r,c)$ are "far" from each other in some sense. This notion of partitioning a set of vectors into stripes satisfying these properties was introduced in the spanner lower bound construction of [7]. We are now ready to define our set of vectors $W(r,c)$.

▶ **Definition 16** ($W(r,c)$). *Let r, c be positive integers. Unlike in Definition 7, we will define $W(r,c)$ to be a subset of the sumset $W_1(r,c) + W_2(r,c)$. In particular, for $\vec{w}_1 \in W_1(r,c)$ and $\vec{w}_2 \in W_2(r,c)$, we only add $\vec{w}_1 + \vec{w}_2$ to $W(r,c)$ if $\vec{w}_1$ and $\vec{w}_2$ share the same stripe index $i \in [1,c]$. Formally,*

$$W(r,c) := \left\{(x, y, x^2 + y^2) \mid x, y \in I_i, i \in [1,c]\right\} \subset W_1(r,c) + W_2(r,c).$$

The following claim is immediate from the definitions of $W_1(r,c)$, $W_2(r,c)$ and $W(r,c)$.

▷ Claim 17. Sets $W_1(r,c)$, $W_2(r,c)$ and $W(r,c)$ satisfy the following properties:
- $|W_1(r,c)| = |W_2(r,c)| = \Theta\left(\frac{r}{c^2}\right)$,
- $|W(r,c)| = \Theta\left(\frac{r^2}{c^5}\right)$,
- $W_1(r,c) \subset W_1(r)$, $W_2(r,c) \subset W_2(r)$, and $W(r,c) \subset W(r)$, so $W(r,c)$ satisfies the convexity property stated in Lemma 8.

We modify the construction of outer graph G_O in Section 4 by replacing sets $W_1(r), W_2(r)$, and $W(r)$ defined in Section 4.1 with the new sets $W_1(r,c), W_2(r,c)$, and $W(r,c)$. Note that our new choice of sets $W_1(r,c)$ and $W_2(r,c)$ changes the the set of vectors E_O in G_O, while our new choice of set $W(r,c)$ changes the set of critical paths Π_O (see Footnote 4).

By inserting convex sets $W_1(r,c), W_2(r,c)$, and $W(r,c)$ into G_O in place of the sets $W_1(r), W_2(r)$, and $W(r)$, we obtain the following theorem about our modified outer graph $G_O = G_O(a,r,c)$.

▶ **Theorem 18** (Properties of Modified Outer Graph). *For any $a, r, c > 0 \in \mathbb{Z}$, there exists a graph $G_O(a,r,c) = (V_O, E_O)$ with a set of critical paths Π_O that has the following properties:*
1. *The number of nodes, edges, and critical paths in G_O is:*

$$|V_O| = \Theta(a^3 r), \quad |E_O| = \Theta\left(\frac{a^3 r^2}{c^2}\right), \quad |\Pi_O| = \Theta\left(\frac{a^2 r^4}{c^5}\right).$$

2. *Every critical path $\pi \in \Pi_O$ is a unique shortest path in G_O of length at least $|\pi| \geq \frac{a}{4r}$.*
3. *Every pair of distinct critical paths π_1 and π_2 intersect on at most two nodes.*
4. *Every edge $e \in E_O$ lies on some critical path in Π_O.*

Just like in the original construction of G_O in Section 4, every critical path $\pi \in \Pi_O$ corresponds to a unique vector $\vec{w} \in W(r,c)$. Specifically, by the definition of $W_1(r,c), W_2(r,c)$, and $W(r,c)$, path π is constructed using vectors $\vec{w}_1 \in W_1(r,c)$ and $\vec{w}_2 \in W_2(r,c)$, where
- $\vec{w} = \vec{w}_1 + \vec{w}_2$, and
- $\vec{w}_1 \in \mathcal{S}_i^1$ and $\vec{w}_2 \in \mathcal{S}_i^2$, for some $i \in [1,c]$.

Critically, $\vec{w}_1$ and $\vec{w}_2$ both lie in the ith stripe $\mathcal{S}_i^1$ and $\mathcal{S}_i^2$, respectively.

5.2 Inner Graph G_I

In this subsection, we formally state the properties of the family of graphs we choose for our inner graphs G_I when constructing the obstacle product graph G. We will choose our inner graphs to be the sourcewise distance preserver lower bound graphs constructed in [12]. Lemma 19 formally captures the exact properties of this family of graphs that we need for spanner lower bound argument. We will defer our proof of Lemma 19 to the appendix, as it largely follows from the proof of Theorem 5.10 in [12].

▶ **Lemma 19** (cf. Theorem 5.10 of [12]). *For any $a, c > 0 \in \mathbb{Z}$, there exists a graph $G_I(a,c) = (V_I, E_I)$ with a set $S_I \subseteq V_I$ of sources, a set $T_I \subseteq V_I$ of sinks, and a set $P_I \subseteq S_I \times T_I$ of critical pairs that has the following properties:*

1. *The number of nodes, edges, sources, sinks, and critical pairs in G_I is:*

$$|V_I| = \Theta(a^2),$$
$$|E_I| = \Theta(a^2 c),$$
$$|S_I| = \Theta(a^{1/2} c^{11/4}),$$
$$|T_I| = \Theta(a^{1/2} c^{11/4}),$$
$$|P_I| = \Theta(a c^{5/2}).$$

2. *Every path $\pi_{s,t}$, where $(s,t) \in P_I$, contains $\Theta(a/c^{3/2})$ edges that do not lie on any other path $\pi_{s',t'}$, where $(s',t') \in P_I$.*
3. *For every source $s \in S_I$ and sink $t \in T_I$, the distance between s and t in G_I satisfies the following:*

$$dist_{G_I}(s,t) = \Theta(ac^{1/2}).$$

4. *The set of sources S_I can be partitioned into $b = \Theta(c^3)$ sets $S_I^1, \ldots, S_I^b$, where $|S_I^i| = \Theta(a^{1/2}c^{-1/4})$ for all $i \in [b]$. Let $T_I^i = \{t \in T_I \mid (S_I^i \times \{t\}) \cap P_I \neq \emptyset\}$ be the set of all sinks that belong to a critical pair with a source in S_I^i. Then for all $i \in [b]$ the following properties hold:*
   - *$|T_I^i| = \Theta(a^{1/2}c^{-1/4})$ for all $i \in [b]$,*
   - *$S_I^i \times T_I^i \subseteq P_I$, and*
   - *for all $(s,t) \in P_I$ such that $s \in S_I^i$ and $t \in T_I^i$,*

$$dist_{G_I}(s,t) \leq dist_{G_I}(S_I^i, T_I^i),$$

   where $dist_{G_I}(S_I^i, T_I^i)$ denotes the minimum distance between S_I^i and T_I^i in G_I.

5.3 Construction of Obstacle Product Graph G

Let $a, r, c > 0 \in \mathbb{Z}$ be the input parameters of an instance of outer graph $G_O = G_O(a, r, c)$. Let $W_1 = W_1(r, c)$, $W_2 = W_2(r, c)$, and $W = W(r, c)$ be the sets of vectors constructed in Section 5.1. Additionally, let $a', c' > 0 \in \mathbb{Z}$ be the input parameters of an instance of inner graph $G_I = G_I(a', c')$. We will specify the precise values of a, r, c, a', and c' later, as needed. Roughly, our choices of parameters a, r, and a' will grow with the size of our final graph G, while parameters c and c' will be (sufficiently large) integer constants.

We will construct our final graph G by performing the obstacle product. The obstacle product is performed in two steps: the edge subdivision step and the inner graph replacement. In the inner graph replacement step, we will need to carefully define two functions, $\phi_1 : W_1 \mapsto S_I \times T_I$ and $\phi_2 : W_2 \mapsto S_I \times T_I$ between vectors in W_1 and W_2 and pairs of nodes in $S_I \times T_I$ in inner graph G_I.

Edge Subdivision

We subdivide each edge in G_O into a path of length ψ. Denote the resulting graph as G'_O. For any edge $e = (u, v) \in E_O$, let P_e denote the resulting $u \rightsquigarrow v$ path of length ψ. We will take $\psi = \Theta\left(\frac{r^3}{c^{29/3}}\right)$.

Inner Graph Replacement

We now perform the inner graph replacement step of the obstacle product.

- For each node v in $V(G'_O)$ originally in G_O, replace v with a copy of G_I. We refer to this copy of G_I as G_I^v. Likewise, refer to the sources and sinks S_I and T_I in G_I^v as S_I^v and T_I^v.
- After applying the previous operation, the endpoints of the subdivided paths P_e in G'_O no longer exist in the graph. If $e = (u, v) \in E_O$, then P_e will have endpoints u and v. We will replace the endpoints u and v of P_e with nodes in G_I^u and G_I^v, respectively.
- In order to precisely define this replacement operation, it will be helpful to define two functions, $\phi_1 : W_1 \mapsto S_I \times T_I$ and $\phi_2 : W_2 \mapsto S_I \times T_I$. For ease of understanding, we will first assume the existence functions ϕ_1 and ϕ_2. We will specify our choices of ϕ_1 and ϕ_2 later.
- Let $e = (u, v) \in E_O$. If $v - u \in W_1$, then let $\phi_1(v - u) = (x, y) \in S_I \times T_I$. We will replace the endpoints u and v of P_e with nodes $y \in T_I^u$ in G_I^u and $x \in S_I^v$ in G_I^v, respectively. Otherwise, if $v - u \in W_2$, then let $\phi_2(v - u) = (x, y) \in S_I \times T_I$, and replace the endpoints u and v of P_e with nodes $y \in T_I^u$ in G_I^u and $x \in S_I^v$ in G_I^v, respectively. We repeat this operation for each $e \in E_O$ to obtain the obstacle product graph G.
- Note that after performing the previous operation, every subdivided path P_e, where $e = (u, v)$, will have a start node in T_I^u and an end node in S_I^v. We will use t_e to denote the start node of P_e in T_I^u and s_e to the end node of P_e in S_I^v.

This completes the construction of the obstacle product graph G (up to defining functions ϕ_1 and ϕ_2).

Defining functions ϕ_1 and ϕ_2

Let $\mathcal{S}_1^1, \ldots, \mathcal{S}_c^1$ be the stripes of W_1, and let $\mathcal{S}_1^2, \ldots, \mathcal{S}_c^2$ be the stripes of W_2. Let $S_I^1, \ldots, S_I^b$ and $T_I^1, \ldots, T_I^b$ be the partition of sources S_I and sinks T_I as described in Lemma 19, where $b = \Theta(c'^4)$. In order to construct our desired functions, we will require the following relations to hold:

- $b \geq c$,
- $|S_I^i| \geq |\mathcal{S}_i^j|$, for all $i \in [1, c]$ and $j \in \{1, 2\}$, and
- $|T_I^i| \geq |\mathcal{S}_i^j|$, for all $i \in [1, c]$ and $j \in \{1, 2\}$.

This can be achieved by setting

$$c' = \Theta(c^{1/3}) \quad \text{and} \quad a' = \Theta\left(\frac{r^2}{c^{35/6}}\right),$$

using the fact that $|\mathcal{S}_i^j| = \Theta(r/c^3)$, $|S_I^i| = \Theta(a'^{1/2}c'^{-1/4})$, and $|T_I^i| = \Theta(a'^{1/2}c'^{-1/4})$ by Claim 15 and Lemma 19.

We are now ready to define our functions ϕ_1 and ϕ_2. Let $\vec{w}_{i,j}^k$ denote the jth vector of $\mathcal{S}_i^k$, where $i \in [1, c]$, $j \in [1, |\mathcal{S}_i^k|]$, and $k \in \{1, 2\}$. Let s_j^i denote the jth node of S_I^i, where $i \in [1, c]$ and $j \in [1, |S_I^i|]$. Likewise, let t_j^i denote the jth node of T_I^i, where $i \in [1, c]$ and $j \in [1, |T_I^i|]$. We define ϕ_1 and ϕ_2 as follows:

$$\phi_1(\vec{w}_{i,j}^1) = (s_j^i, t_j^i) \qquad \text{and} \qquad \phi_2(\vec{w}_{i,j}^2) = (s_j^i, t_j^i) \qquad \text{for } i \in [1, c],\ j \in [1, |\mathcal{S}_j^1|].$$

The key properties of functions ϕ_1 and ϕ_2 are summarized in Claim 20.

▷ Claim 20. Functions ϕ_1 and ϕ_2 satisfy the following properties:

1. Our choice of ϕ_1 and ϕ_2 imply that for each node $u \in S_I \cup T_I$ in an inner graph copy G_I^v, there is at most one subdivided path P_e incident to u in G.
2. $\phi_k(\mathcal{S}_i^1) \subseteq S_I^i \times T_I^i$ for $k \in \{1, 2\}$ and $i \in [1, c]$, where $\phi_k(\mathcal{S}_i^1)$ denotes the image of $\mathcal{S}_i^1$ under ϕ_k.

Critical Paths Π

- Fix a critical path $\pi_O \in \Pi_O$ with associated vectors $\vec{w}_1 \in W_1$ and $\vec{w}_2 \in W_2$.
- By our construction of G_O, there exists $\vec{w} \in W$ such that $\vec{w} = \vec{w}_1 + \vec{w}_2$ (see Footnote 4). Then by the construction of W there exists some index $i \in [1, c]$ such that every edge $(u, v) \in \pi_O$ satisfies $v - u \in \{\vec{w}_1, \vec{w}_2\} \subseteq \mathcal{S}_i^1 \cup \mathcal{S}_i^2$. Let $\chi \in [1, c]$ denote this index.
- Let e_i denote the ith edge of π_O for $i \in [1, k]$. Note that by Property 2 of Claim 20, it follows that $s_{e_i} \in S_I^\chi$ and $t_{e_i} \in T_I^\chi$ for $i \in [1, k]$. Then by Property 5 of Lemma 19, $(s_{e_i}, t_{e_{i+1}}) \in P_I$. By Property 2 of Lemma 19, path $\pi_{s_{e_i}, t_{e_{i+1}}}$ is a unique shortest $s_{e_i} \rightsquigarrow t_{e_{i+1}}$ path in G_I.
- We now define a corresponding path π in G:

$$\pi = P_{e_1} \circ \pi_{s_{e_1}, t_{e_2}} \circ P_{e_2} \circ \cdots \circ P_{e_{k-1}} \circ \pi_{s_{e_{k-1}}, t_{e_k}} \circ P_{e_k},$$

  Note that if $e_i = (x, y)$ and $e_{i+1} = (y, z)$, then $\pi_{s_{e_i}, t_{e_{i+1}}}$ corresponds to the unique shortest path between $s_{e_i} \in S_I^\chi$ and $t_{e_i} \in T_I^\chi$ in inner graph copy G_I^y. We add path π to our set of critical paths Π.
- We repeat this process for all critical paths in Π_O to obtain our set of critical paths Π in G. Each critical path $\pi \in \Pi$ is uniquely constructed from a critical path $\pi_O \in \Pi_O$, so $|\Pi| = |\Pi_O|$. We will use $\phi : \Pi \mapsto \Pi_O$ to denote the bijection between Π and Π_O implicit in the construction.

As the final step in our construction of obstacle product graph G, we remove all edges in G that do not lie on some critical path $\pi \in \Pi$. Note that this will only remove edges in G that are inside copies of the inner graph G_I. Theorem 21 summarizes some of the key properties of obstacle product graph G. The proof of Theorem 21 follows from straightforward calculations and arguments similar to those in Section 5.2 in the full paper.

▶ **Theorem 21** (Properties of Obstacle Product Graph). *For any $a, r, c > 0 \in \mathbb{Z}$, there exists a graph $G(a, r, c) = (V, E)$ with a set of critical paths Π that has the following properties:*

1. *The number of nodes, edges, and critical paths in G is:*

$$|V| = \Theta(a^3 r^5 c^{-23/2}),$$
$$|E| = \Theta\left(c^{1/4} \cdot |V|\right),$$
$$|\Pi| = \Theta\left(\frac{a^2 r^4}{c^5}\right).$$

2. *Every path $\pi \in \Pi$ that passes through inner graph copy G_I^v contains $\Theta(a'/c'^{3/2})$ edges that do not lie on any other path $\pi' \in \Pi$, for all $v \in V_O$.*

For the full analysis of our spanner construction, please refer to the full version of the paper on ArXiv.

A Tight Monte-Carlo Algorithm for Steiner Tree Parameterized by Clique-Width

Narek Bojikian
Humboldt-Universität zu Berlin, Germany

Stefan Kratsch
Humboldt-Universität zu Berlin, Germany

Abstract

Given a graph $G = (V, E)$, a set $T \subseteq V$, and an integer $\bar{b}$, the Steiner Tree problem asks whether G has a connected subgraph H with at most $\bar{b}$ vertices that spans all of T. This work presents a $3^k \cdot n^{\mathcal{O}(1)}$ time one-sided Monte-Carlo algorithm for solving Steiner Tree when additionally a clique-expression of width k is provided. Known lower bounds for less expressive parameters imply that this dependence on the clique-width of G is optimal assuming the Strong Exponential-Time Hypothesis (SETH). Indeed our work establishes that the parameter dependence of Steiner Tree is the same for any graph parameter between cutwidth and clique-width, assuming SETH.

Our work contributes to the program of determining the exact parameterized complexity of fundamental hard problems relative to structural graph parameters such as treewidth, which was initiated by Lokshtanov et al. [SODA 2011 & TALG 2018] and which by now has seen a plethora of results. Since the cut-and-count framework of Cygan et al. [FOCS 2011 & TALG 2022], connectivity problems have played a key role in this program as they pose many challenges for developing tight upper and lower bounds. Recently, Hegerfeld and Kratsch [ESA 2023] gave the first application of the cut-and-count technique to problems parameterized by clique-width and obtained tight bounds for Connected Dominating Set and Connected Vertex Cover, leaving open the complexity of other benchmark connectivity problems such as Steiner Tree and Feedback Vertex Set.

Our algorithm for Steiner Tree does not follow the cut-and-count technique and instead works with the connectivity patterns of partial solutions. As a first technical contribution we identify a special family of so-called complete patterns that has strong (existential) representation properties, and using these at least one solution will be preserved. Furthermore, there is a family of 3^k basis patterns that (parity) represents the complete patterns, i.e., it has the same number of solutions modulo two. Our main technical contribution, a new technique called "isolating a representative," allows us to leverage both forms of representation (existential and parity). Both complete patterns and isolation of a representative will likely be applicable to other (connectivity) problems.

1 Introduction

This work presents a $3^k \cdot n^{\mathcal{O}(1)}$ time one-sided Monte-Carlo algorithm for Steiner Tree[cw], i.e., Steiner Tree parameterized by clique-width.[1] Under the Strong Exponential-Time Hypothesis (SETH)[2] this dependence on the clique-width is optimal, i.e., time $(3-\varepsilon)^k \cdot n^{\mathcal{O}(1)}$

[1] Given a graph $G = (V, E)$, a set $T \subseteq V$ of terminals, a number $\bar{b}$, and a k-clique-expression of G, with k being the parameter, is there a connected subgraph H of G with at most $\bar{b}$ vertices that spans all of T?

[2] SETH posits that for each $c < 2$ there is $q \in \mathbb{N}$ such that q-CNF SAT cannot be solved in time $\mathcal{O}(c^n)$.

is known to be impossible [15]. Our algorithm relies on a new technique, called *isolating a representative*, that allows it to employ both counting modulo two and reduction to a specific smaller family of representative partial solutions. Implicitly, it thus works with a reduced compatibility matrix of $GF(2)$-rank 3^k, rather than the full matrix of $GF(2)$-rank 4^k, which is key for obtaining the claimed tight running time.

Our work fits into the program of determining the exact complexity of parameterized problems (modulo SETH), especially relative to width parameters like treewidth, which was initiated by Lokshtanov et al. [35, 36]. Since their work, there has been a plethora of such tight bounds relative to treewidth, see, e.g., [7, 13, 12, 14, 40, 26, 37, 41, 18, 22, 32, 21], but also relative to other parameters such as cutwidth [45, 30, 37, 44, 24, 4], modular treewidth [34, 28], and clique-width [29, 13, 31, 34, 23, 27]. An important breakthrough was made by Cygan et al. [15, 17], who were the first to obtain tight complexity bounds for connectivity problems such as Steiner Tree, Connected Vertex Cover, and Feedback Vertex Set (all parameterized by treewidth). In particular, their novel cut-and-count paradigm led to the surprising result that many of these problems admit $\mathcal{O}^*(c^{tw})$ time (randomized) dynamic programming (DP) algorithms. Intuitively, this is done by counting cuts of relaxed solutions modulo two and relying on cancellation of disconnected solutions. Note that this makes such algorithms inherently probabilistic as they rely on the isolation lemma to reduce, with high probability, to the case that there is a unique solution of minimum weight. In this way, they are able to reduce decision to counting modulo two.

The exact complexity of Steiner Tree[cw] is a natural and important question: Steiner Tree is central among connectivity problems, which have been key benchmarks in the exact complexity program. Clique-width is a well-studied graph parameter that, in particular, also allows to capture structure present in dense graphs (unlike treewidth and cutwidth etc.). So far, there are only two results regarding exact complexity (modulo SETH) of connectivity problems relative to clique-width: Hegerfeld and Kratsch [27] showed tight bounds of $6^k \cdot n^{\mathcal{O}(1)}$ for Connected Vertex Cover[cw] and $5^k \cdot n^{\mathcal{O}(1)}$ for Connected Dominating Set[cw], with both algorithms relying on cut-and-count. They explicitly leave open the exact complexities of Steiner Tree[cw], Connected Odd Cycle Transversal[cw], and Feedback Vertex Set[cw] as not being within range of their techniques. For the latter, the algorithm for Feedback Vertex Set[tw] [17] counts edges outside the tentative feedback vertex set to ensure that no cycles remain, but this seems infeasible relative to clique-width (cf. [1, 2]). For the former two, it is mentioned that their approach via cut-and-count would give time $4^k \cdot n^{\mathcal{O}(1)}$ for Steiner Tree[cw] and time $14^k \cdot n^{\mathcal{O}(1)}$ for Connected Odd Cycle Transversal[cw]. However, matching lower bounds were not in sight, as current lower bound methods rely on sufficiently large triangular submatrices inside certain compatibility matrices that correspond to the problem, which were lacking. Indeed, it is this gap between upper and lower bound that our technique allows us to close.

Our result and techniques. Formally, our result for Steiner Tree[cw] reads as follows.

▶ **Theorem 1.** *There is a one-sided error Monte Carlo algorithm (no false positives) that, given a graph $G = (V, E)$, a set of terminals $T \subseteq V$, a number $\bar{b}$, and a k-clique-expression of G, takes time $3^k \cdot n^{\mathcal{O}(1)}$ and determines, with high probability, whether a connected subgraph H of G of exactly $\bar{b}$ vertices exists that spans all of T.*

Since the clique-width of any graph G is at most its pathwidth plus two (folklore), i.e., $\mathrm{cw}(G) \leq \mathrm{pw}(G)+2$, the lower bound for Steiner Tree[pw] [15] rules out time $(3-\varepsilon)^k \cdot n^{\mathcal{O}(1)}$ for Steiner Tree[cw]. In fact, recent work of Bojikian et al. [4] shows that the same lower

Table 1 Tight complexity bounds (modulo SETH) for a selection of (connectivity) problems relative to cutwidth, treewidth, modular-treewidth, and clique-width. (Table adapted from [27].)

	cutwidth	treewidth	modular-tw	clique-width

bound already holds relative to cutwidth. Thus, for all parameters between cutwidth and clique-width we get the same tight dependence of $3^k \cdot n^{\mathcal{O}(1)}$ for solving Steiner Tree, which contrasts the growing dependence exhibited by most other problems (see Table 1).

Our algorithm does not apply cut-and-count, i.e., counting consistent cuts of relaxed partial solutions. Instead, it works with the connectivity patterns of partial solutions for the graphs that correspond to parts of the given k-clique-expression. Roughly, a connectivity pattern indicates how the connected components of a partial solution connect the different label classes, noting that several components may intersect the same label class. Of course, the full set of possible patterns is much too large to be of use for us. Instead, we identify a family of patterns, called *complete patterns*, that are representative for the class of all patterns in a strong and constructive sense: For each pattern p there is a set $R_p = \{q_1, \ldots, q_\ell\}$ of complete patterns that together completes into exactly the same set of solutions as p does. Moreover, we identify a subfamily of 3^k basis patterns such that for each complete pattern there is a set of basis patterns that completes into the same number *modulo two* of solutions; again, this necessitates randomization through the use of the isolation lemma to guarantee existence of a unique minimum weight solution.

Now, if we simply combine these two means of representation, namely existential and modulo two, we will not end up with a correct algorithm: Existential representation makes no guarantee about the number, and hence the parity, of representations, even if there is a unique global solution. This is where our technique of *isolating a representative* comes in: When a step in the DP creates a partial solution whose connectivity pattern p is not complete, then each representing complete pattern has its weight increased by a globally set random weight (with four weights per DP step sufficing for our algorithm). In this way, a unique minimum weight representation is isolated with high probability. Combined with the usual setup of isolating a unique solution of minimum weight (and fast convolution), this allows our algorithm to count modulo two the partial solutions relative to the 3^k basis patterns and arrive at the correct answer with high probability. Overall, we have two applications of the isolation lemma, once for isolating a solution and once for isolating a representation of the solution. This makes our algorithm inherently probabilistic, though with low error bounds, and it may fail (like preceding work) by returning a false negative when either isolation fails. Success chance (of this one-sided error algorithm) can be boosted in the usual way.

Our approach can be easily generalized to solve the vertex-weighted version of this problem, when weights are bounded polynomially by the size of the graph, in the obvious way with weights replacing cardinalities of partial solutions. This contrasts the status of the edge-weighted version of this problem, which can be easily seen to be para-NP-hard when

parameterized by clique-width: One can reduce any instance of the unweighted Steiner Tree problem to the edge-weighted version of this problem on a complete graph (of clique-width 2) by assigning weight one to existing edges, and some large weight to all other edges.

Related work. It has been observed that many results on exact parameterized complexity are closely related to properties of certain matrices that are related to the problem in question and the considered graph structure, and this was recently surveyed by Nederlof [39]: E.g., methods such as cut-and-count rely on low-rank factorizations of the corresponding matrices. Since cut-and-count works modulo two, i.e., over $GF(2)$, and since it can be verified that the relevant matrix for Steiner Tree[cw] has $GF(2)$-rank (at least) 4^k, this makes it unlikely that a pure cut-and-count approach could succeed in getting time $3^k \cdot n^{\mathcal{O}(1)}$. (Indeed, it was this fact combined with the intuition that current lower bound techniques would not stretch further than the $(3-\varepsilon)^k \cdot n^{\mathcal{O}(1)}$, known already relative to pathwidth, that motivated the present work.) This leaves open the possibility that the same time bound of $3^k \cdot n^{\mathcal{O}(1)}$ could be obtained by working over a different field and/or studying the support rank[3] of the matrix (cf. [39]). So far, there are few results that obtain tight complexity bounds that do not coincide with the rank of the corresponding matrices [30, 4].

Clique-width was introduced by Courcelle and Olariu [11] building on work of Courcelle et al. [9] and it is similar to the NLC-width of Wanke [46]. Courcelle et al. [10] showed that every graph problem expressible in MSO_1 logic (monadic second order logic of graphs with quantification over vertex sets but not edge sets) can be solved in linear time for graphs with a given k-clique-expression, i.e., in time $f(k) \cdot n$, though the function f depends on the formula capturing the problem and may be non-elementary (cf. [33]), so likely far from being tight. This tractability is not restricted to MSO_1-expressible problems but many other important problems are solvable in time $f(\mathrm{cw}) \cdot n^{\mathcal{O}(1)}$ or at least time $n^{f(\mathrm{cw})}$ (see, e.g., [19]). Nevertheless, some problems, like Disjoint Paths, are NP-complete on graphs of bounded clique-width, while being solvable in time $f(k) \cdot n^{\mathcal{O}(1)}$ with respect to treewidth (cf. [25]). The first single-exponential time algorithms for connectivity problems parameterized by clique-width were given by Bergougnoux and Kanté [1, 2], e.g., Steiner Tree, Connected Dominating Set, and Connected Vertex Cover each in time $2^{\mathcal{O}(\mathrm{cw})} \cdot n$, but building on the rank-based approach these bounds are likely not tight.

The main drawback of clique-width lies in the difficulty of finding good expressions, i.e., good bounds on the clique-width of given graphs, in reasonable time. Fellows et al. [20] showed that it is NP-complete to determine, on input of graph G and integer k, whether the clique-width of G is at most k. It is open, however, whether for each fixed value of k there is an efficient algorithm for recognizing graphs of clique-width at most k; such algorithms are known only for $k \leq 3$ [8]. In particular, there is neither an FPT-algorithm for Clique-Width[k] known, nor is it known to be W[1]-hard with respect to k. The arguably best way for using low clique-width is an exponential-ratio FPT-algorithm due to Seymour and Oum [43] (made faster by Oum [42]). That being said, better algorithms for computing clique-width are still possible, and there may be variants of clique-width that give similar complexity (used as parameters) but are easier to compute.

Organization. In Section 3 we introduce connectivity patterns and provide related notation. In Section 4 we show how to represent partial solutions through patterns. In Section 5 we show that one can represent arbitrary patterns using complete patterns only. In Section 6 we

[3] The smallest rank of any matrix with the same zero vs. non-zero pattern over any field, so this is only interesting for fields other than $GF(2)$.

show that one can count complete patterns by reducing them a smaller family of patterns. In Section 7 we show how to count these families efficiently, providing the main algorithm of this paper. Finally, we conclude with final thoughts in Section 8.

2 Preliminaries

In this work we deal with undirected graphs only. Given a natural number k, we denote by $[k] = \{1, 2, \dots k\}$ the set of natural numbers smaller than or equal to k, and $[k]_0 = [k] \cup \{0\}$. A *labeled graph* is a graph $G = (V, E)$ together with a *labeling function* $\text{lab}\colon V \to \mathbb{N}$. We usually omit the function lab and assume that it is given implicitly when defining a labeled graph G. We say that G is *k-labeled*, if it holds that $\text{lab}(v) \leq k$ for all $v \in V$. We define a *clique-expression* μ as a well-formed expression that consists only of the following operations on labeled graphs:

- *Create vertex* $i(v)$ for $i \in \mathbb{N}$. This operation constructs a graph containing a single vertex and assigns label i to this vertex.
- The *union* operation $G_1 \uplus G_2$. The constructed graph consists of the disjoint union of the labeled graphs G_1 and G_2.
- The *relabel* operation $\rho_{i\to j}(G)$ for $i, j \in \mathbb{N}$. This operations changes the labels of all vertices in G labeled i to the label j.
- The *join* operation $\eta_{i,j}(G)$ for $i, j \in \mathbb{N}, i \neq j$. The constructed graph results from G by adding all edges between the vertices labeled i and the vertices labeled j, i.e.

$$\eta_{i,j}(G) = (V, E \cup \{\{u, v\}\colon \text{lab}(u) = i \wedge \text{lab}(v) = j\}).$$

We denote the graph resulting from a clique-expression μ by G_μ, and the constructed labeling function by lab_μ. We associate with a clique-expression μ a syntax tree $\mathcal{T}_\mu$ (we omit the symbol μ when clear from the context) in the natural way, and associate with each node $x \in V(\mathcal{T})$ the corresponding operation. For $x \in V(\mathcal{T})$, the subtree rooted at x induces a subexpression μ_x. We define $G_x = G_{\mu_x}$, $V_x = V(G_x)$, $E_x = E(G_x)$ and $\text{lab}_x = \text{lab}_{\mu_x}$. Finally, we say that a clique-expression μ is a *k-expression* if G_x is a k-labeled graph for all $x \in V(\mathcal{T})$. We define the clique-width of a graph G (denoted by $\text{cw}(G)$) as the smallest value k such that there exists a k-expression μ with G_μ isomorphic to G. We can assume without loss of generality, that any given k-expression defining a graph $G = (V, E)$ uses at most $O(|V|)$ union operations, and at most $O(|V|k^2)$ unary operations [1, 11].

We define the Steiner Tree problem as follows: Given an undirected graph $G = (V, E)$, a terminal set $T \subseteq V$ and some value $\overline{b} \in \mathbb{N}$, asked is whether there exists a set of vertices $S \subseteq V$ of size at most $\overline{b}$, such that $T \subseteq S$ and $G[S]$ is connected. For $k \in \mathbb{N}$, and f some computable function, we denote by $\mathcal{O}^*(f(k))$ the running time $f(k)\,\text{poly}(n)$, where n is the size of the input.

Let $\mathbb{F}$ be a field, and let S be some set. For a vector $T \in \mathbb{F}^S$, and some value $x \in S$, we denote by $T[x]$ the element of T indexed by x. In general, we will only deal with binary vectors, i.e. $\mathbb{F} = \text{GF}(2)$. By $\overline{0}_S$ we denote the vector T with $T[x] = 0$ for all $x \in S$. We omit the subscript S when clear from the context. For two sets S, T, let $M \in \mathbb{F}^{S\times T}$ be some matrix, whose rows are indexed by S and columns by T. We denote by $M[s, t]$ the element of M indexed by s and t.

For some integer k, given sets $S_1, T_1, \dots, S_k, T_k$, let $M_i \in \mathbb{F}^{S_i\times T_i}$ for each $i \in [k]$. We define the Kronecker product of $M_1, \dots M_k$ as the matrix $M = M_1 \otimes \cdots \otimes M_k \in \mathbb{F}^{(S_1\times\cdots\times S_k)\times(T_1\times\cdots\times T_k)}$, where for $s_i \in S_i$ and $t_i \in T_i$ for all $i \in [k]$,

$$M[(s_1, \dots, s_k), (t_1, \dots, t_k)] = \prod_{i\in[k]} M_i[s_i, t_i].$$

It is well-known that $\text{rk}(M_1 \otimes \cdots \otimes M_k) = \text{rk}(M_1) \cdot \text{rk}(M_2) \cdot \cdots \cdot \text{rk}(M_k)$.

Given two sets S, T, we denote by $S \triangle T$ the symmetric difference of S and T. It holds by a simple counting argument that $|S \triangle T| \equiv_2 |S| + |T|$. Given a finite set U, the power-set of U (denoted by 2^U) is the set of all subsets of U. A partition is a family of pairwise disjoint subsets of U that span all its elements.

A *lattice* is a partial order $(\mathcal{L}, \preceq)$ over a set $\mathcal{L}$, such that any two elements have a greatest lower bound (called *meet*), and a least upper bound (called *join*). We call two lattices isomorphic, if the underlying orders are isomorphic.

Let $f : U \to V$ be a mapping between two sets U and V, and $x \notin U$ a new element. Let $i \in V$. We define the extension $f|_{x \mapsto i} : U \cup \{x\} \to V$ of f in the natural way. We also define the disjoint union of two mappings defined over two disjoint sets in the natural way.

Let U, V be two sets, and $f : U^k \to V$ a mapping. Given sets $S_1, \dots S_k \subseteq U$, we define

$$f(S_1, \dots S_k) = \{f(s_1, \dots s_k) \colon (s_1, \ \dots s_k) \in S_1 \times S_2 \times \dots S_k\}.$$

For a set $S \subseteq V$ we also define

$$f^{-1}(S) = \{(s_1, \ \dots s_k) \in S_1 \times S_2 \times \dots S_k \colon f(s_1, \dots s_k) \in S\}.$$

An exception to this notation, is when we explicitly mention that $f : U \to V$ is a weight function, and $V \subseteq \mathbb{Z}$. In this case, for some set $S \subseteq U$ we define $f(S) = \sum_{u \in S} f(u)$, where we compute the sum over $\mathbb{Z}$.

Given a logical expression ρ, we denote by $[\rho]$ the Iverson bracket of ρ. We refer the reader to the full version [5] for formal definitions of all mentioned notation.

3 Connectivity patterns

3.1 Definition and terminology

Along this work, let U be some totally ordered ground set. In this section we define the main structures we build this paper on, we call them patterns. A pattern, as we shall see, represents the state of a partial solution, and carries enough information to extend it to a solution over the whole graph.

▶ **Definition 2.** *Let* 0 *be an element not in* U*. A* pattern p *is a subset of the power-set of* $U \cup \{0\}$*, such that there exists exactly one set of* p *containing the element* 0*. With* $\mathcal{P}(U)$ *we denote the family of all patterns over* U*. We omit* U *when clear from the context. By* $Z_p \in p$ *we denote the only set of* p *containing the element* 0*, and we call it the* zero-set *of* p*.*

Given a pattern $p \in \mathcal{P}$*, we define* $\mathrm{label}(p) \subseteq U$ *as the set of all labels in* U *occurring in* p*, and with* $\mathrm{singleton}(p) \subseteq U$ *the set of all labels in* U *appearing as singletons in* p*, i.e.*

$$\mathrm{label}(p) = \bigcup_{S \in p} S \setminus \{0\}, \qquad \textit{and} \qquad \mathrm{singleton}(p) = \big\{u \colon \{u\} \in p \wedge u \neq 0\big\}.$$

▶ **Definition 3.** *We define a more concise way to write patterns, that we use quite often along this paper. For a pattern* $p = \{\{u_1^1, \dots, u_{r_1}^1\}, \dots, \{u_1^\ell, \dots, u_{r_\ell}^\ell\}\}$*, we write*

$$p = [u_1^1 u_2^1 \dots u_{r_1}^1, \dots, u_1^\ell \dots u_{r_\ell}^\ell],$$

where we use square brackets to enclose the pattern, we do not use any separator between the elements of the same set, and separate different sets with comas. We also sometimes omit the symbol 0 *when it appears as a singleton.*

When we use this notation, we assume that each element is represented by a single symbol. Hence, such patterns admit a unique interpretation. For example, both $[12]$ *and* $[0, 12]$ *denote the pattern* $\{\{0\}, \{1, 2\}\}$*, while the pattern* $\{\{0, 10\}\}$ *cannot be written in this concise way.*

Now we introduce pattern operations. These operations will allow us to extend families of patterns over the syntax tree of a clique-expression to build larger solutions recursively. We define these operations in a similar way to the operations on partitions defined in [3].

▶ **Definition 4.** *Let $p, q \in \mathcal{P}$. We define the following operations:*

Join: $r = p \sqcup q$. *Let* $\sim_I = \{(S,T) \colon S \in p \wedge T \in q \wedge S \cap T \neq \emptyset\}$ *be a relation over* $p \cup q$, *and* $\sim_I^T$ *be its reflexive, transitive and symmetric closure. Let* $\mathcal{R}$ *be the equivalence classes of* $\sim_I^T$, *then* $r = \{\bigcup_{S \in P} S \colon P \in \mathcal{R}\}$.

Relabel: $r = p_{i \to j}$, *for* $i, j \in U$, *where* r *results from* p *by replacing* i *with* j *in each set of* p.

Union: $r = p \oplus q$, *where* $r = (p \setminus \{Z_p\}) \cup (q \setminus \{Z_q\}) \cup \{Z_p \cup Z_q\}$.

▶ **Definition 5.** *For* $i, j \in U, i \neq j$, *we define the operation* $\square_{i,j} p$ *for* $p \in \mathcal{P}$ *as*

$$\square_{i,j} p = \begin{cases} p & : \{i,j\} \not\subseteq \text{label}(p), \\ p \sqcup [ij] & : \textit{otherwise.} \end{cases}$$

This combines all sets containing the labels i *or* j *into one set, if both labels appear in* p.

▶ **Definition 6.** *Let* $p, q \in \mathcal{P}$. *We say that* p *and* q *are* consistent *(denoted by* $p \sim q$*), if for* $r = p \sqcup q$ *it holds that* $r = \{Z_r\}$ *contains the zero-set only, i.e. the join operation merges all sets into one set only. We say that a pattern* p dominates *another pattern* q *(denoted by* $p \geq q$*), if it holds for all patterns* $r \in \mathcal{P}$ *that* $q \sim r$ *implies* $p \sim r$.

3.2 Characteristics of patterns

In the full version of this paper we introduce the notion of alternating walks between two patterns. Using this notion, we provide a new characterization of the join operation, upon which, we prove a multitude of properties of patterns. We use these properties to prove domination and consistency results on manipulated and derived patterns. In particular, this allows us to correctly reduce the states of a dynamic programming solution keeping the transitions correct. We present these properties here and refer the reader to the full version for a formal proof.

▶ **Lemma 7.** *Let* $p, q, r \in \mathcal{P}$ *be arbitrary patterns, and* $i, j \in U$ *two arbitrary labels, with* $i \neq j$. *Then all the following is true:*

1. *It holds that* $\square_{i,j} p \geq p$
2. *If* $\{i,j\} \subseteq \text{label}(p)$, *then* $p \sqcup [ij] \sim q$ *if and only if* $p \sim q \oplus [ij, i, j]$.
3. *If* $\text{singleton}(p) \setminus \text{label}(q) \neq \emptyset$, *then* $p \not\sim q$.
4. *For* $S \in p$, *and* $u \in S$, *let* $S' = S \setminus \{u\}$, *and* $p' = (p \setminus \{S\}) \cup \{S'\}$. *It holds that* $p \geq p'$.
5. *For* $S \in p$, $S' \subseteq S$, *and* $p' = p \cup \{S'\}$, *it holds that* $p \geq p'$.
6. *If* $p \sim q$ *holds, then it must hold that* $\text{label}(p) = \text{label}(q)$ *and* $\text{singleton}(p) = \text{singleton}(q)$.
7. *Let* q' *be the pattern that results from* q *by removing all labels in* $\text{label}(q) \setminus \text{label}(p)$ *from each set of* q. *Then* $p \sim q$ *if and only if* $p \sim q'$.

▶ **Definition 8.** *Given a pattern* $p \in \mathcal{P}$ *and two different labels* $i, j \in U$. *We define the operation* $p' = p_{j \curvearrowleft i}$ *over patterns, where* p' *results from* p *by removing the label* i *from all sets, and then adding* i *to each set that contains the label* j, *i.e.*

$$p_{j \curvearrowleft i} = \bigcup_{\substack{S \in p \\ j \notin S}} S \setminus \{i\} \cup \bigcup_{\substack{S \in p \\ j \in S}} S \cup \{i\}.$$

▶ **Lemma 9.** *For all $p, q, r \in \mathcal{P}$ the following two equivalences hold*
1. *It holds that $p \sqcup q \sim r$ if and only if $p \sim q \sqcup r$.*
2. *For $i, j \in U$ with $i \neq j$, it holds that $p_{i \to j} \sim q$ if and only if $p \sim q_{j \curvearrowleft i}$.*

▶ **Lemma 10.** *Given two patterns $p, q \in \mathcal{P}(U)$. Let U' be a new label set disjoint from U and ρ a one-to-one mapping from U to U'. Let q' be the pattern resulting from q by relabeling u to $\rho(u)$ for each $u \in U$. Then it holds for each pattern $r \in \mathcal{P}(U)$ that $p \oplus q \sim r$ if and only if $p \sim q' \sqcup r'$ for $r' \in \mathcal{P}(U \cup U')$ the pattern resulting from r by adding $\rho(u)$ to each set containing u for each $u \in U$.*

4 Partial solutions as patterns

From now on, let $(G, T, \bar{b})$ be the given instance of the Steiner Tree problem, for some graph $G = (V, E)$, a set of terminals $T \subseteq V$, and $\bar{b} \in \mathbb{N}$. Let $n = |V|$ and $m = |E|$. Let μ be a k-expression of G for some value $k \in \mathbb{N}$. We fix $U = [k]$. Let $\mathcal{T}$ be the corresponding syntax tree, and r its root. We also fix a value $W \in \mathbb{N}$, and a weight function $\mathbf{w} : V \to [W]$. Both will be chosen later. Let $v_0 \in T$ be an arbitrary but fixed terminal vertex. For a node $x \in V(\mathcal{T})$, we define $T_x = T \cap V_x$.

▶ **Definition 11.** *Let $x \in V(\mathcal{T})$. We call a set $S \subseteq V_x$ where $T_x \subseteq S$ a* partial solution. *Each partial solution defines a pattern $p = p_x(S)$ over G_x as follows: Let $C_1, \dots C_\ell$ be the connected components of $G_x[S]$. For $i \in [\ell]$, let $S_i = \mathrm{lab}_x(C_i)$ be the set of all labels appearing in C_i. If $v_0 \notin S$, we define $p = \{S_1, \dots, S_\ell\} \cup \{\{0\}\}$. Otherwise, assume that $v_0 \in C_\ell$ (otherwise swap C_ℓ and the component containing v_0). We define $p = \{S_1, \dots, S_{\ell-1}\} \cup \{S_\ell \cup \{0\}\}$. That means the zero-set is defined by the component containing v_0 if $v_0 \in S$, or as a singleton otherwise. We call $p_x(S)$ the pattern corresponding to S in G_x. We denote by $p(S)$ the pattern $p_r(S)$ corresponding to a partial solution S in the whole graph G.*

▶ **Lemma 12.** *Given a set $S \subseteq V$ such that $T \subseteq S$, it holds that S is a Steiner tree in G, if and only if $p(S)$ consists of one set only.*

We refer the reader to the full version for a formal proof. Now we define families of partial solutions that allow to build recursive formulas for a dynamic programming scheme over $\mathcal{T}$.

▶ **Definition 13.** *For $x \in V(\mathcal{T}), b \in [\bar{b}]_0, c \in [n \cdot W]_0$, we define the family $\mathcal{S}_x[b, c] \subseteq \mathcal{P}$ of patterns corresponding to partial solutions of cardinality b and weight c over G_x as*

$$\mathcal{S}_x[b, c] = \{p \in \mathcal{P} \colon \exists S \subseteq V_x, \text{ where } T_x \subseteq S \wedge p_x(S) = p \wedge |S| = b \wedge \mathbf{w}(S) = c\}.$$

From now on, we always assume that $x \in V(\mathcal{T}), b \in [\bar{b}]_0$, and $c \in [n \cdot W]_0$. We skip repeating this to avoid redundancy.

▶ **Lemma 14.** *The families $\mathcal{S}_x$ can be built recursively over the nodes of $\mathcal{T}$ in a bottom-up manner using the operations defined in Definition 4 and Definition 5.*

Proof. We sketch the recursive definitions of $\mathcal{S}_x$ for different types of nodes $x \in V(\mathcal{T})$, and refer to the full version for a complete proof of correctness.

For a create node $\mu_x = i(v)$ (a leaf of $\mathcal{T}$), let $c = \mathbf{w}(v)$. Let $p = [0, i]$ if $v \neq v_0$, and $p = [0i]$ otherwise. Then we set $\mathcal{S}_x[1, c] = \{p\}$. We set $\mathcal{S}_x[0, 0]$ to $\{[0]\}$, if $v \notin T$, and to $\emptyset$ otherwise. For all other values of b and c, we set $\mathcal{S}_x[b, c] = \emptyset$. We define $\mathcal{S}_x$ for the other cases as follows:

$$\begin{array}{lll} \text{Join node} & \mu_x = \eta_{i,j}(\mu_{x'}), & \text{then } \mathcal{S}_x[b,c] = \square_{i,j}\big(\mathcal{S}_{x'}[b,c]\big), \\ \text{Relabel node} & \mu_x = \rho_{i\to j}(\mu_{x'}), & \text{then } \mathcal{S}_x[b,c] = \big(\mathcal{S}_{x'}[b,c]\big)_{i\to j}, \\ \text{Union node} & \mu_x = \mu_{x_1} \uplus \mu_{x_2}, & \text{then } \mathcal{S}_x[b,c] = \bigcup_{\substack{b_1+b_2=b \\ c_1+c_2=c}} \big(\mathcal{S}_{x_1}[b_1,c_1] \oplus \mathcal{S}_{x_2}[b_2,c_2]\big). \end{array}$$

◀

▶ **Lemma 15.** *The graph G admits a Steiner tree of size $\overline{b}$ and weight $\overline{c}$, if and only if there exists a pattern $p \in \mathcal{S}_r\left[\overline{b},\overline{c}\right]$ with $p \sim [0]$.*

This lemma follows from Lemma 12 (see the full version for a proof). So far, we can solve the Steiner Tree problem by defining a dynamic programming over $\mathcal{T}$ that computes all families $\mathcal{S}_x\left[\overline{b},\overline{c}\right]$ for all values of $\overline{b}$ and $\overline{c}$. However, since there exist approximately 2^{2^k} different patterns over k labels, we seek to reduce the family of all patterns into a family of representing patterns in a sense that allow us to apply the dynamic programming scheme over the resulting families.

5 Pattern representation

Now we define a special family of patterns (called *complete patterns*), and show that we can represent any family of patterns by a family of complete patterns only.

5.1 Representation and complete patterns

▶ **Definition 16.** *Given two families $\mathcal{S},\mathcal{R} \subseteq \mathcal{P}$, we say that $\mathcal{R}$* represents *$\mathcal{S}$, if for each $q \in \mathcal{P}$ the following holds: there exists a pattern $p \in \mathcal{S}$ such that $p \sim q$ if and only if there exists a pattern $p' \in \mathcal{R}$ such that $p' \sim q$. Given a family $\mathcal{R} \subseteq \mathcal{P}$, and a pattern $p \in \mathcal{P}$, we say that $\mathcal{R}$ represents p if $\mathcal{R}$ represents $\{p\}$.*

Clearly, it holds that representation is an equivalence relation. In the full version, we define the notion of *representation-preserving* operations, and show that the operations defined in Definition 4 preserve representation. This allows to restrict a dynamic programming scheme to representing families, preserving the correctness of the transitions.

▶ **Definition 17.** *A pattern $p \in \mathcal{P}$ is* complete, *if* $\text{label}(p) = \text{singleton}(p)$, *i.e. a pattern p is complete, if each label of p appears as a singleton in p as well. We denote by $\mathcal{P}_C(U)$ the family of all complete patterns over U.*

▶ **Lemma 18.** *For all $p,q \in \mathcal{P}_C$ the following holds: $p \sim q$ implies that* $\text{label}(p) = \text{label}(q)$.

We refer to the full version for a proof.

▶ **Definition 19.** *Let $p \in \mathcal{P}$. For $i \in U$, we define the operations* $\text{fix}(p,i)$ *and* $\text{forget}(p,i)$ *as*

$$\text{fix}(p,i) = p \cup \big\{\{i\}\big\} \qquad \text{,and} \qquad \text{forget}(p,i) = \big\{S \setminus \{i\} \colon S \in p\big\},$$

if $i \in \text{label}(p) \setminus \text{singleton}(p)$. Otherwise, we define $\text{fix}(p,j) = \text{forget}(p,j) = p$. We say that $p' = \text{fix}(p,i)$ results from p by fixing *the label i, and $p'' = \text{forget}(p,i)$ results from p by* forgetting *the label i. Given a pattern $p \in \mathcal{P}$, we define* $\text{inc}(p) = \text{label}(p) \setminus \text{singleton}(p)$.

▶ **Definition 20.** *Given a pattern $p \in \mathcal{P}$. Let $\ell = |\text{inc}(p)|$, and $i_1, \ldots i_\ell$ be the elements of* $\text{inc}(p)$ *in an increasing order. Let $R_0 = \{p\}$, and $R_j = \text{forget}(R_{j-1}, i_j) \cup \text{fix}(R_{j-1}, i_j)$ for all $j \in [\ell]$. We define the family $R_p = R_\ell$ and call it a* complete representation *of p.*

The following lemmas show that R_p represents p, which proves that any set of patterns admits a representation of complete patterns only. We refer to the full version for proofs.

▶ **Lemma 21.** *Let $p \in \mathcal{P}$, and $i \in U$. It holds that $\{\mathrm{fix}(p,i), \mathrm{forget}(p,i)\}$ represents p.*

▶ **Lemma 22.** *It holds for all $p \in \mathcal{P}$ that $R_p \subseteq \mathcal{P}_C$, $|R_p| \leq 2^{|\operatorname{inc}(p)|}$, and R_p represents p.*

▶ **Corollary 23.** *Let $\mathcal{S} \subseteq \mathcal{P}$. Then the family $\mathcal{R} = \bigcup_{p\in\mathcal{S}} R_p \subseteq \mathcal{P}_C$ represents $\mathcal{S}$.*

▶ **Observation 24.** *It holds that the family of complete patterns is closed under both relabel operation $i \to j$ for all $i, j \in U$, and union operation $\oplus$. On the other hand, it holds for $i, j \in U, i \neq j$, $R \subseteq \mathcal{P}_C$, $R' = \square_{i,j} R$ and for each $p \in R'$ that $\operatorname{inc}(p) \in \{\emptyset, \{i,j\}\}$. If $\operatorname{inc}(p) = \{i,j\}$, then R_p contains at most four patterns, that result from p by fixing or forgetting either labels independently.*

5.2 Counting representations

▶ **Definition 25.** *Let $\mathrm{Op} : \mathcal{P}^k \to \mathcal{P}$ be a k-ary pattern operation. We define the operation $\overset{\triangle}{\mathrm{Op}} : \left(2^{\mathcal{P}}\right)^k \to 2^{\mathcal{P}}$ over subsets of $\mathcal{P}$ as $\overset{\triangle}{\mathrm{Op}}(S_1, \ldots, S_k) = \bigtriangleup_{\substack{(p_1,\ldots,p_k)\in \\ S_1\times\cdots\times S_k}} \{\mathrm{Op}(p_1, \ldots, s_k)\}$, for all $S_1, \ldots, S_k \subseteq \mathcal{P}$, and we call it the* exclusive *version of* Op. *We compare this operation to the notion $\mathrm{Op}(S_1, \ldots, S_k)$ given by the union over all resulting patterns from the operation. Given two sets of patterns $S_1, S_2 \subseteq \mathcal{P}$, we define $S_1 \overset{\triangle}{\sqcup} S_2, S_1 \overset{\triangle}{\oplus} S_2, S_{1_{i\overset{\triangle}{\to} j}}$ and $\overset{\triangle}{\square}_{i,j} S_1$ as the exclusive version of join, union, relabel and $\square_{i,j}$ of S_1 (and S_2) respectively.*

The following lemma can be proven by a simple counting argument. We refer to the full version for a formal proof.

▶ **Lemma 26.** *Let $\mathrm{Op} : \mathcal{P}^k \to \mathcal{P}$ be a k-ary pattern operation, and $S_1, \ldots S_k \subseteq \mathcal{P}$. It holds for $q \in \mathcal{P}$, that*

$$|\{p \in \overset{\triangle}{\mathrm{Op}}(S_1, \ldots S_k) \colon p \sim q\}| \equiv_2 |\{(p_1, \ldots p_k) \in S_1 \times \cdots \times S_k \colon \mathrm{Op}(p_1, \ldots p_k) \sim q\}|$$

As we have already mentioned, for $p \in \mathcal{P}_C$, and $p' = \square_{i,j} p$, it holds that either $R_{p'} = p'$, or $R_{p'}$ contains four patterns that result from p' by either forgetting or fixing both labels i and j independently. We can enumerate these patterns as follows:

▶ **Definition 27.** *We define a new operation called* actions $\mathrm{Ac} \colon \mathcal{P} \times [4] \to \mathcal{P}$ *as follows: Given $p \in \mathcal{P}$, if $p \in \mathcal{P}_C$, we define $\mathrm{Ac}(p, \ell) = p$, for all $\ell \in [4]$. For $\operatorname{inc}(p) = \{i\}$, we define*

- $\mathrm{Ac}(p, 1) = \mathrm{fix}(p, i)$,
- $\mathrm{Ac}(p, 2) = \mathrm{forget}(p, i)$.

We set $\mathrm{Ac}(p, 3)$ and $\mathrm{Ac}(p, 4)$ to undefined in this case. If $\operatorname{inc}(p) = \{i, j\}$ for $i < j$, we define

- $\mathrm{Ac}(p, 1) = \mathrm{fix}(\mathrm{fix}(p, i), j)$,
- $\mathrm{Ac}(p, 2) = \mathrm{forget}(\mathrm{fix}(p, i), j)$,
- $\mathrm{Ac}(p, 3) = \mathrm{fix}(\mathrm{forget}(p, i), j)$,
- $\mathrm{Ac}(p, 4) = \mathrm{forget}(\mathrm{forget}(p, i), j)$.

In all other cases we set $\mathrm{Ac}(p, \ell)$ to be undefined for all $\ell \in [4]$.

Using this enumeration, we can assign to each action at a create or a join node in the subtree of $\mathcal{T}_x$ a weight, which defines a different weight to each pattern in a complete pattern representation of the patterns in $\mathcal{S}_x \left[\overline{b}, \overline{c}\right]$.

▶ **Definition 28.** *For $x \in V(\mathcal{T})$ let $\pi : V(\mathcal{T}_x) \to [4]$ be some mapping, such that $\pi(x') \in [2]$ whenever x' is a create node, and $\pi(x') = 1$ whenever x' is a union node or a relabel node. We call π an* action sequence. *Let $D \in \mathbb{N}$ be some value that will be fixed later, and let $\mathbf{d} : V(\mathcal{T}) \times [4] \to [D]$ be a weight function. We define the weight of π as*

$$\mathbf{d}(\pi) = \sum_{\substack{x' \in V(\mathcal{T}_x),\\ x' \text{ is a join or create node}}} \mathbf{d}\big(x', \pi(x')\big).$$

Given a partial solution $S \subseteq V_x$ where $T_x \subseteq S$, the action sequence π defines a pattern p_S^π, that can be defined recursively over $\mathcal{T}_x$, where for a create node $i(v)$, let v be the vertex introduced at this node. If $v \notin S$, then we set $p_S^\pi = [0]$. Otherwise, we set $p_S^\pi = \mathrm{Ac}(p_x(\{v\}), \pi(x))$. For a relabel or union node, p_S^π results by applying the corresponding operation on the patterns resulting at the children of x in the natural way. For a join node $\mu_x = \eta_{i,j}(\mu_{x'})$, let $p' = \square_{i,j} p_S^{\pi'}$, where π' is the restriction of π to the nodes in $V(\mathcal{T}_{x'})$. We set $p_S^\pi = \mathrm{Ac}(p', \pi(x))$. We say that π is an action sequence generating the pattern p_S^π from S in G_x.

The proof of the following lemma follows by induction over $\mathcal{T}$ using transitivity of representation. We refer the reader to the full version for more details.

▶ **Lemma 29.** *Given a node $x \in V(\mathcal{T})$, and a partial solution $S \subseteq V_x$, where $T_x \subseteq S$. Let Π_x be the set of all action sequences at x. Let $P_x^S = \{p_S^\pi : \pi \in \Pi\}$. Then P_x^S represents $p_x(S)$.*

▶ **Definition 30.** *For $x \in V(\mathcal{T}), \overline{b} \in [n], \overline{c} \in [n \cdot W], \overline{d} \in [|V(\mathcal{T})| \cdot D]$, we define the families $\mathcal{D}_x\left[\overline{b}, \overline{c}, \overline{d}\right]$ as follows:*

- *Create node $i(v)$, let $c = \mathbf{w}(v)$. For $\ell \in [2]$, we set $\mathcal{D}_x\left[1, c, \mathbf{d}(x, \ell)\right] = \left\{\mathrm{Ac}\left(p_x(\{v\}), \ell\right)\right\}$, and set $\mathcal{D}_x\left[0, 0, \mathbf{d}(x, \ell)\right]$ to $\{[0]\}$ if $v \notin T$, or to $\emptyset$ otherwise. For all other values of $\overline{b}, \overline{c}$ and $\overline{d}$, we set $\mathcal{D}_x\left[\overline{b}, \overline{c}, \overline{d}\right] = \emptyset$.*
- *Relabel node $\mu_x = \rho_{i \to j}(\mu_{x'})$, then $\mathcal{D}_x\left[\overline{b}, \overline{c}, \overline{d}\right] = \left(\mathcal{D}_{x'}\left[\overline{b}, \overline{c}, \overline{d}\right]\right)_{i \overset{\triangle}{\to} j}$.*
- *Union node $\mu_x = \mu_{x_1} \uplus \mu_{x_2}$, then $\mathcal{D}_x\left[\overline{b}, \overline{c}, \overline{d}\right] = \triangle_{\substack{b_1+b_2=\overline{b}\\ c_1+c_2=\overline{c}\\ d_1+d_2=\overline{d}}} \left(\mathcal{D}_{x_1}\left[b_1, c_1, d_1\right] \overset{\triangle}{\oplus} \mathcal{D}_{x_2}\left[b_2, c_2, d_2\right]\right)$.*
- *Join node $\mu_x = \eta_{i,j}(\mu_{x'})$, we define the families $\mathcal{D}'_x\left[\overline{b}, \overline{c}, \overline{d}\right] = \overset{\triangle}{\square}_{i,j}\left(\mathcal{D}_{x'}\left[\overline{b}, \overline{c}, \overline{d}\right]\right)$. Now we set $\mathcal{D}_x\left[\overline{b}, \overline{c}, \overline{d}\right] = \triangle_{\ell \in [4]} \overset{\triangle}{\mathrm{Ac}}\left(\mathcal{D}'_x\left[\overline{b}, \overline{c}, \overline{d} - \mathbf{d}(x, \ell)\right], i\right)$.*

The following lemma shows that the families $\mathcal{D}_x$ correctly count action sequences. A formal proof of the lemma and the corollary following it can be found in the full version.

▶ **Lemma 31.** *For $x \in V(\mathcal{T})$, and all values $\overline{b}, \overline{c}$ and $\overline{d}$, it holds for $p \in \mathcal{P}_C$ that $p \in \mathcal{D}_x\left[\overline{b}, \overline{c}, \overline{d}\right]$ if and only if there exist odd many pairs (S, π) where $S \subseteq V_x$ with $T_x \subseteq S, |S| = \overline{b}, \mathbf{w}(S) = \overline{c}$ and π is an action sequence of weight $\overline{d}$ generating p from S in G_x.*

▶ **Corollary 32.** *If G does not admit a Steiner tree of size $\overline{b}$, then it holds for all values $\overline{c} \in [W \cdot n]$, $\overline{d} \in [D \cdot |V(\mathcal{T})|]$ that $[0] \notin \mathcal{D}_r\left[\overline{b}, \overline{c}, \overline{d}\right]$.*

5.3 Isolation Lemma

Now we fix $W = (2 + \sqrt{2})|V|$, and $D = 4(2 + \sqrt{2})|V(\mathcal{T})|$. We choose $\mathbf{w} \in [W]^V$ and $\mathbf{d} \in [D]^{V(\mathcal{T}) \times [4]}$ uniformly and independently at random. We use the isolation lemma to show that, if a Steiner tree of size $\overline{b}$ exists, then there exist two positive integers $\overline{c}$ and $\overline{d}$, such that, with high probability, there exists a unique solution S of size $\overline{b}$ and weight $\overline{c}$, and a unique action sequence of weight $\overline{d}$ that generates the pattern $[0]$ from S.

▶ **Definition 33.** *A function $\omega : U \to \mathbb{Z}$ isolates a set family $\mathcal{F} \subseteq 2^U$ if there exists a unique $S' \in \mathcal{F}$ with $\omega(S') = \min_{S \in \mathcal{F}} \omega(S)$.*

▶ **Lemma 34** ([38, 17])**.** *Let $\mathcal{F} \subseteq 2^U$ be a set family over a universe U with $|\mathcal{F}| > 0$, and let $N > |U|$ be an integer. For each $u \in U$, choose a weight $\omega(u) \in \{1, 2, \dots N\}$ uniformly and independently at random. Then it holds that $P[\omega \text{ isolates } \mathcal{F}] \geq 1 - |U|/N$.*

We use the following lemmas to show that, if a solution exists, then, with high probability, there exists a unique minimum weight representation of a minimum weight solution. We refer the reader to the full version for a formal proof.

▶ **Lemma 35.** *If a Steiner tree of size $\overline{b}$ exists, let $\overline{c}$ be the smallest weight of such a tree. Then there exists a unique Steiner tree of size $\overline{b}$ and weight $\overline{c}$ with probability at least $1 - \frac{1}{2+\sqrt{2}}$.*

▶ **Lemma 36.** *Let S be a Steiner tree in G, and π be a minimum weight action sequence generating $[0]$ from S in G. Then π is unique with probability at least $1 - \frac{1}{2+\sqrt{2}}$.*

▶ **Lemma 37.** *If G admits a Steiner tree of size $\overline{b}$, then with probability at least $1/2$ it holds that $[0] \in \mathcal{D}_r\left[\overline{b}, \overline{c}, \overline{d}\right]$ for some values of $\overline{c}$ and $\overline{d}$.*

6 Parity-representation

Now we define a new kind of representation, called the parity-representation. This allows to count complete patterns (modulo 2) that are consistent with a specific pattern.

▶ **Definition 38.** *We define the family of CS-patterns $\mathcal{P}_{CS}(U) \subseteq \mathcal{P}_C(U)$ as the family of complete patterns containing only a zero-set and singletons, i.e.*

$$\mathcal{P}_{CS}(U) = \Big\{\big\{X \cup \{0\}\big\} \cup \big\{\{u\} \colon u \in Y\big\} \colon X \subseteq Y \subseteq U\Big\}.$$

▶ **Observation 39.** *For each ground set U it holds that $|\mathcal{P}_{CS}(U)| = 3^{|U|}$.*

▶ **Observation 40.** *For $p, q \in \mathcal{P}_{CS}$ and all $i, j \in U$, it holds that $p_{i \to j}, p \oplus q \in \mathcal{P}_{CS}$.*

▶ **Definition 41.** *Given two sets of patterns $D, C \subseteq \mathcal{P}$, we say that C* parity-represents *D, if and only if for each $q \in \mathcal{P}_C$ it holds*

$$|\{p \in C \colon p \sim q\}| \equiv_2 |\{p \in D \colon p \sim q\}|.$$

For a set of patterns $C \subseteq \mathcal{P}$ and a single pattern $p \in \mathcal{P}$, we say that C parity-represents p if it holds that C parity-represents $\{p\}$.

▶ **Observation 42.** *Parity-representation is an equivalence relation.*

Now we show how to build a concrete parity-representation of an arbitrary complete pattern using CS-patterns only. We refer the reader to the full version for formal proofs.

▶ **Lemma 43.** *Given a pattern $p \in \mathcal{P}_C \setminus \mathcal{P}_{CS}$. Let $S \in p \setminus \{Z_p\}$ be an inclusion-wise minimal set, such that $|S| > 1$. Let $A = A_p^S$ be the family of patterns defined from p as follows $A_p^S = \big\{(p \setminus \{Z_p, S\}) \cup (Z_p \cup S') \colon S' \subset S\big\}$. Then A parity-represents of p.*

▶ **Lemma 44.** *Given a complete pattern $p \in \mathcal{P}_C$. Let $S_1, \dots S_r$ be the sets in p such that $S_i \neq Z_p$ and $|S_i| \geq 2$ for each $i \in [r]$. Let $A_0 = \{p\}$. For $i \in [r]$, we define $A_i = \triangle_{q \in A_{i-1}} A_q^{S_i}$. Let $A_p = A_r$. Then it holds that $A_p \subseteq \mathcal{P}_{CS}$, and that it parity-represents p.*

▶ **Corollary 45.** *For each family of complete patterns $D \subseteq \mathcal{P}_C$, there exists a family of CS-patterns $C \subseteq \mathcal{P}_{CS}$ that parity-represents D.*

Similar to pattern representation, in the full version of this paper we define the notion of *parity-representation-preserving* operations. We show that all defined operations (including actions and symmetric difference) preserve parity-representation. This allows to restrict a dynamic programming algorithm to a parity-representation of the underlying families.

Now we define families of partial solutions over $\mathcal{P}_{CS}$ that parity-represent the families $\mathcal{D}_x\left[\overline{b},\overline{c},\overline{d}\right]$. In the next section, we show that we can efficiently compute these families, and hence, solve the decision version of the Steiner Tree problem with high probability.

▶ **Definition 46.** *For $p \in \mathcal{P}_C$ let A_p be the set defined in Lemma 44. We define the operator $\mathrm{Ac}^* : \mathcal{P} \times 4 \to 2^{\mathcal{P}_{CS}}$ as $\mathrm{Ac}^*(p,\ell) = A_{\mathrm{Ac}(p,\ell)}$ if $\mathrm{Ac}(p,\ell) \in \mathcal{P}_C$ or as undefined otherwise. We denote the* exclusive *version of Ac^* by $\overset{\triangle}{\mathrm{Ac}}{}^*$.*

▶ **Definition 47.** *For $x \in V(\mathcal{T}), \overline{b} \in [n], \overline{c} \in [n \cdot W], \overline{d} \in [|V(\mathcal{T})| \cdot D]$, we define the families $\mathcal{C}_x\left[\overline{b},\overline{c},\overline{d}\right]$ as follows: For a create, relabel or union nodes x, we define the families $\mathcal{C}_x$ in an analogous way to $\mathcal{D}_x$, where we replace each $\mathcal{C}$ with $\mathcal{D}$ in the definition. For a join node $\mu_x = \eta_{i,j}(\mu_{x'})$, we define the families*

$$\mathcal{C}'_x\left[\overline{b},\overline{c},\overline{d}\right] = \overset{\triangle}{\square}_{i,j}\left(\mathcal{C}_{x'}\left[\overline{b},\overline{c},\overline{d}\right]\right) \quad \text{,and set} \quad \mathcal{C}_x\left[\overline{b},\overline{c},\overline{d}\right] = \bigtriangleup_{\ell\in[4]} \overset{\triangle}{\mathrm{Ac}}{}^*\left(\mathcal{C}'_x\left[\overline{b},\overline{c},\overline{d}-\mathbf{d}(x,\ell)\right],\ell\right).$$

In the full version, we show that $\mathcal{C}_x\left[\overline{b},\overline{c},\overline{d}\right]$ parity-represents $\mathcal{D}_x\left[\overline{b},\overline{c},\overline{d}\right]$ for all $x \in V(\mathcal{T})$ and all values $\overline{b},\overline{c},\overline{d}$. The following corollary follows

▶ **Corollary 48.** *It holds for all values $\overline{b},\overline{c},\overline{d}$ that $[0] \in \mathcal{C}_r\left[\overline{b},\overline{c},\overline{d}\right] \iff [0] \in \mathcal{D}_r\left[\overline{b},\overline{c},\overline{d}\right]$.*

7 Algorithm

In this section, we define the final dynamic programming table that computes $\mathcal{C}_x\left[\overline{b},\overline{c},\overline{d}\right]$ for $x \in V(\mathcal{T})$ and all values $\overline{b},\overline{c}$ and $\overline{d}$ in time $O^*(3^k)$.

▶ **Definition 49.** *For all $x \in V(\mathcal{T})$ and all values $\overline{b} \in [k]_0, \overline{c} \in [|V|\cdot W]_0$ and $\overline{d} \in [|V(\mathcal{T})|\cdot D]_0$, we define the vectors $T = T\left[x,\overline{b},\overline{c},\overline{d}\right] \in \{0,1\}^{\mathcal{P}_{CS}}$ as follows:*

- *Create node $i(v)$. Let $p = [0,i]$ if $v \neq v_0$, and $p = [0i]$ otherwise. First we initialize $T[x,\overline{b},\overline{c},\overline{d}] = \overline{0}$ for all values $\overline{b},\overline{c},\overline{d}$. Now we set $T[x,0,0,0][[0]] = [v \notin T]$, and for $\ell \in [2]$ we set $T[x,1,\mathbf{w}(v),\mathbf{d}(x,\ell)][\mathrm{Ac}(p,\ell)] = 1$.*
- *Relabel node $\mu_x = \rho_{i\to j}(\mu_{x'})$, we define $T\left[x,\overline{b},\overline{c},\overline{d}\right][p] = \sum_{\substack{q\in\mathcal{P}_{CS}\\ q_{i\to j}=p}} T\left[x',\overline{b},\overline{c},\overline{d}\right][q]$.*
- *Join node $\mu_x = \eta_{i,j}(\mu_{x'})$. For all values $\overline{b},\overline{c},\overline{d}$, we define $T'\left[x,\overline{b},\overline{c},\overline{d}\right] \in \{0,1\}^{\mathcal{P}}$ as*

$$T'\left[x,\overline{b},\overline{c},\overline{d}\right][p] = \sum_{\substack{q\in\mathcal{P}_{CS},\\ \square_{ij}q=p}} T\left[x',\overline{b},\overline{c},\overline{d}\right][q],$$

for all patterns $p \in \mathcal{P}$. Now for all $p \in \mathcal{P}_{CS}$ we set

$$T\left[x,\overline{b},\overline{c},\overline{d}\right][p] = \sum_{\ell\in[4]} \sum_{\substack{q\in\mathcal{P},\\ p\in\mathrm{Ac}^*(q,\ell)}} T'\left[x,\overline{b},\overline{c},\overline{d}-\mathbf{d}(x,\ell)\right][q].$$

- *Union node* $\mu_x = \mu_{x_1} \uplus \mu_{x_2}$. *For all* $p \in \mathcal{P}_{CS}$, *we define*

$$T\big[x, \overline{b}, \overline{c}, \overline{d}\big][p] = \sum_{\substack{b_1+b_2=\overline{b} \\ c_1+c_2=\overline{c} \\ d_1+d_2=\overline{d}}} \sum_{\substack{p_1,p_2 \in \mathcal{P}_{CS} \\ p_1 \oplus p_2 = p}} T[x_1, b_1, c_1, d_1][p_1] \cdot T[x_2, b_2, c_2, d_2][p_2].$$

The following lemmas show the correctness of the algorithm (proof in the full version).

▶ **Lemma 50.** *It holds that* $T\big[x, \overline{b}, \overline{c}, \overline{d}\big][p] = \big[p \in \mathcal{C}_x\big[\overline{b}, \overline{c}, \overline{d}\big]\big]$ *for all* $x, \overline{b}, \overline{c}, \overline{d}$, *and* $p \in \mathcal{P}_{CS}$.

▶ **Corollary 51.** *It holds for all* $\overline{b}, \overline{c}, \overline{d}$ *that* $T\left[r, \overline{b}, \overline{c}, \overline{d}\right][[0]] \equiv_2 1 \iff [0] \in \mathcal{D}_r\big[\overline{b}, \overline{c}, \overline{d}\big]$.

Although computing the tables $T\big[x, \overline{b}, \overline{c}, \overline{d}\big]$ for a union node x in the naive way yields a running time polynomial in $|\mathcal{P}_{CS}|^2$ which exceeds the bound we seek by far, we make use of a result by Hegerfeld and Kratsch [27] to compute convolutions over lattices more efficiently.

▶ **Definition 52.** *Given a lattice* $(\mathcal{L}, \preceq)$, *and two tables* $A, B : \mathcal{L} \to \mathbb{F}$ *for some field* $\mathbb{F}$, *we define the* join-product *(or* $\vee$*-product)* $A \otimes_{\mathcal{L}} B$ *as follows: for each* $x \in \mathcal{L}$ *we define*

$$A \otimes_{\mathcal{L}} B(x) = \sum_{\substack{y,z \in \mathcal{L} \\ y \vee z = x}} A(y) \cdot B(z).$$

To avoid unnecessary notation, we state a modified, more restrictive version of the mentioned result by Hegerfeld and Kratsch [27, Corollary A.10], and refer the reader to the full version for an exact statement and background definitions.

▶ **Corollary 53.** *Let* $(\mathcal{L}, \preceq)$ *be a finite lattice such that the join operation over* $\mathcal{L}$ *can be computed in polynomial time. Let* k *be a natural number. Given two tables* $A, B \colon \mathcal{L}^k \to \mathbb{Z}_2$, *the* $\vee$*-product* $A \otimes_{\mathcal{L}^k} B$ *can be computed in time* $\mathcal{O}^*(|\mathcal{L}|^k)$.

▶ **Definition 54.** *We define a new ordering* $\preceq_{CS}$ *over* $\mathcal{P}_{CS}$ *where* $p_1 \preceq_{CS} p_2$, *if for each* $i \in U$ *it holds that* $i \in Z_{p_1}$ *if* $i \in Z_{p_2}$ *and* $i \in \mathrm{label}(p_1)$ *if* $i \in \mathrm{label}(p_2)$.

▶ **Observation 55.** *The join operation over the lattice* $(\mathcal{P}_{CS}, \preceq_{CS})$ *is given by* $p \vee q = r$, *where* $Z_r = Z_p \cup Z_q$ *and* $\mathrm{label}(r) = \mathrm{label}(p) \cup \mathrm{label}(q)$. *This corresponds exactly to the union operation over CS-patterns* $r = p \oplus q$. *Hence, it holds for a union node that*

$$T\big[x, \overline{b}, \overline{c}, \overline{d}\big] = \sum_{\substack{b_1+b_2=\overline{b} \\ c_1+c_2=\overline{c} \\ d_1+d_2=\overline{d}}} T[x', b_1, c_1, d_1] \otimes_{\mathcal{P}_{CS}} T[x'', b_2, c_2, d_2].$$

In the full version, we show that the lattice $(\mathcal{P}_{CS}(U), \preceq_{CS})$ is isomorphic to the lattice $\mathcal{L}^k$, where $\mathcal{L} = (\{1, 2, 3\}, \leq)$ is defined in the natural way. Using Corollary 53, it follows that $T\big[x, \overline{b}, \overline{c}, \overline{d}\big]$ for a union node x can be computed in time $O^*(3^k)$. The following lemma states that this is indeed the case for all nodes x of $\mathcal{T}$. We refer the reader to the full version for formal proofs.

▶ **Lemma 56.** *The families* $T\big[x, \overline{b}, \overline{c}, \overline{d}\big]$ *for all* $x \in V(\mathcal{T})$ *and all values* $\overline{b}, \overline{c}, \overline{d}$ *can be computed in time* $\mathcal{O}^*(3^k)$.

Now we are ready to prove the main theorem of this work (Theorem 1).

Proof (Theorem 1). The algorithm first computes all families $T\left[x, b, \overline{c}, \overline{d}\right]$ for all $x \in V(\mathcal{T})$ and all values of $b, \overline{c}, \overline{d}$. The algorithm states that there exists a Steiner tree of size $\overline{b}$, if and only if there exist two values $\overline{c}, \overline{d}$ with $T\left[r, \overline{b}, \overline{c}, \overline{d}\right][[0]] = 1$.

By Lemma 56, we can compute all families $T\left[x, b, \overline{c}, \overline{d}\right]$ in time $\mathcal{O}^*(3^k)$. By Lemma 50, it holds for all values $\overline{b}, \overline{c}, \overline{d}$ that

$$T\left[r, \overline{b}, \overline{c}, \overline{d}\right][[0]] \equiv_2 1 \iff [0] \in \mathcal{D}_r\left[\overline{b}, \overline{c}, \overline{d}\right].$$

By Corollary 32 it holds that if no Steiner tree of size $\overline{b}$ exists, then the algorithm will always return false. On the other hand if a Steiner tree of size $\overline{b}$ exists, by choosing $W = (2+\sqrt{2})|V|$, and $D = 4(2+\sqrt{2})|V(\mathcal{T})|$, and by choosing both function $\mathbf{w} \in [W]^V$, and $\mathbf{d} \in [D]^{V(\mathcal{T})\times[4]}$ uniformly and independently at random, it holds by Lemma 37 that the algorithm will correctly decide the existence of such a tree with probability at least one half. ◀

8 Conclusion

We have presented a $3^k \cdot n^{\mathcal{O}(1)}$ time one-sided Monte-Carlo algorithm for Steiner Tree[cw]. Under the Strong Exponential-Time Hypothesis, lower bounds for Steiner Tree relative to less expressive parameters [15, 4] rule out time $(3-\varepsilon)^k \cdot n^{\mathcal{O}(1)}$, and show that this parameter dependence is optimal for all parameters between cutwidth and clique-width.

Rather than using cut-and-count, which is the go-to technique for connectivity problems, our algorithm works with connectivity patterns. Two technical contributions, make this work: The family of complete connectivity patterns has strong existential representation properties, so that each connectivity pattern has an explicit existential replacement by complete patterns. This avoids spending more time for getting the representative partial solutions (such as for Gaussian elimination in the rank-based approach [3]). The second technical contribution, the technique of *isolating a representative*, allows to combine this with working via a 3^k-sized family of basis patterns, that represents complete patterns modulo two. We expect that both techniques will be of use for settling the complexity of other (connectivity) problems.

Very recently, the present authors announced a tight bound of $12^k \cdot n^{\mathcal{O}(1)}$ (modulo SETH) for Connected Odd Cycle Transversal[cw] [6].

Abstract

Dynamic Time Warping (DTW) distance is the optimal cost of matching two strings when extending runs of letters is for free. Therefore, it is natural to measure the time complexity of DTW in terms of the number of runs n (rather than the string lengths N).

In this paper, we give an $\tilde{O}(n^2)$ time algorithm for computing the DTW distance. This matches (up to log factors) the known (conditional) lower bound, and should be compared with the previous fastest $O(n^3)$ time exact algorithm and the $\tilde{O}(n^2)$ time approximation algorithm. Our method also immediately implies an $\tilde{O}(nk)$ time algorithm when the distance is bounded by k. This should be compared with the previous fastest $O(n^2k)$ and $O(Nk)$ time exact algorithms and the $\tilde{O}(nk)$ time approximation algorithm.

1 Introduction

Dynamic Time Warping (DTW) [39] is one of the most popular methods for comparing time-series (see e.g. [2, 5, 8, 25, 27, 30, 33, 40, 43]). It is appealing in numerous applications such as bioinformatics, signature verification, and speech recognition, where two time-series can vary in speed but still be considered similar. For example, in speech recognition, DTW can detect similarities even if one person is talking faster than the other.

To define DTW, recall that a run-length encoding $S = s_1^{\ell_1} s_2^{\ell_2} \cdots s_n^{\ell_n}$ of a string S over an alphabet Σ is a concise (length n) representation of the (length $N = \sum_i \ell_i$) string S. Here $s_i^{\ell_i}$ denotes a letter $s_i \in \Sigma$ repeated ℓ_i times. For example, the string $S = aaaabbbaaaaa$ is encoded as $a^4b^3a^5$. A string $S' = s_1^{\ell'_1} s_2^{\ell'_2} \cdots s_n^{\ell'_n}$ is a *time-warp* of string $S = s_1^{\ell_1} s_2^{\ell_2} \cdots s_n^{\ell_n}$ if every $\ell'_i \geq \ell_i$.

▶ **Definition 1** (Dynamic Time Warping). *For a function $\delta : \Sigma^2 \to \mathbb{R}^+$, the Dynamic Time Warping distance of two strings S and T over alphabet Σ is defined as*

$$\mathsf{DTW}(S,T) = \min_{|S'|=|T'|} \sum_{i=1}^{|S'|} \delta(S'[i], T'[i]),$$

where S' and T' range over all time-warps of S and T respectively.

In 1968, Vintzyuk [39] gave an $O(MN)$ time dynamic programming algorithm for computing the DTW of two strings S and T of lengths N and M respectively. His algorithm is one of the earliest uses of dynamic programming and is taught today in basic algorithms courses and textbooks. Apart from logarithmic factor improvements [17], the $O(MN)$ quadratic time complexity remains the fastest known and a strongly subquadratic-time $O((MN)^{1-\varepsilon})$ algorithm is unlikely as it would refute the popular Strong Exponential Time Hypothesis (SETH) [3, 10].

The complexity of DTW in terms of N and M is thus well understood. Special cases of DTW are also well understood. These include DTW on binary strings [23, 38], approximation algorithms [4, 22, 42], the low distance regime [22], sparse inputs [20, 31, 32], and reductions to other similarity measures [22, 36, 37]. However, the complexity of DTW is not yet resolved in terms of n and m (the run-length encoding sizes of S and T respectively). Namely, in the (especially appealing) case where the strings contain long runs. The currently fastest algorithms are $O(Nm+Mn)$ [13,15,22] and $O(n^2m+m^2n)$ [15]. In particular, an $\tilde{O}(nm)$ time algorithm is only known to be possible if we are willing to settle for a $(1+\varepsilon)$-approximation [41]. It remained an open question whether it is possible to obtain an exact $\tilde{O}(nm)$ algorithm (which is optimal up to log factors). In this paper we answer this open question in the affirmative.

Prior work on DTW. The classical dynamic programming for DTW is as follows. Let $\mathsf{DTW}(i,j) = \mathsf{DTW}(S[1\dots i], T[1\dots j])$, then $\mathsf{DTW}(0,0) = 0$, $\mathsf{DTW}(i,0) = \mathsf{DTW}(0,j) = \infty$ for every $i > 0$ and $j > 0$, and otherwise:

$$\mathsf{DTW}(i,j) = \delta(S[i], T[j]) + \min \begin{cases} \mathsf{DTW}(i-1,j) \\ \mathsf{DTW}(i,j-1) \\ \mathsf{DTW}(i-1,j-1) \end{cases} \tag{1}$$

The above dynamic programming is equivalent to a single-source shortest path (SSSP) computation in the following grid graph. We denote $[n] = \{1, 2, \dots, n\}$.

▶ **Definition 2** (The Alignment Graph). *The alignment graph of S and T is a directed weighted graph G with vertices $V = [0\dots N] \times [0\dots M]$. Every vertex $(i,j) \in [N] \times [M]$ has three entering edges, all with weight $\delta(S[i], T[j])$: A vertical edge from $(i-1,j)$, a horizontal edge from $(i,j-1)$, and a diagonal edge from $(i-1,j-1)$.*

We denote the distance from vertex $(0,0)$ to (i,j) as $\mathsf{dist}(i,j)$.[1] Clearly, $\mathsf{DTW}(i,j) = \mathsf{dist}(i,j)$. Therefore, $\mathsf{DTW}(S,T) = \mathsf{dist}(N,M)$ and can be computed in $O(MN)$ time by an SSSP algorithm (that explicitly computes the distances from $(0,0)$ to all the $O(MN)$ vertices of the graph). The way to beat $O(MN)$ is to only compute distances to a subset of vertices.

[1] Abusing notation, we will later also use $\mathsf{dist}((x,y),(x',y'))$ to denote the distance from vertex (x,y) to vertex (x',y').

Namely, partition the alignment graph into *blocks* where each block is the subgraph corresponding to a single run in S and a single run in T. Then, proceed block-by-block and for each block compute its *output* (the last row and last column) given its *input* (the last row of the block above and the last column of the block to the left). Since blocks are highly regular (i.e., all edges inside a block have the same weight), it is not difficult to compute the output in time linear in the size of the output. Since the total size of all outputs (and all inputs) is $O(Nm + Mn)$, this leads to an overall $O(Nm + Mn)$ time algorithm [13, 15, 22].

In order to go below $O(Nm + Mn)$, in [15] it was observed that we do not really need to compute the entire output. It suffices to compute only the intersection of the output with a set of $O(mn)$ diagonals. Specifically, each block contributes one diagonal starting in its top-left corner, so there are overall $O(mn)$ diagonals and each diagonal intersects with $O(m + n)$ blocks. This leads to an $O(n^2m + m^2n)$ time algorithm. In [41] it was shown that if we are willing to settle for a $(1 + \varepsilon)$-approximation, then it suffices to compute only $\tilde{O}(1)$ output values per block.

Prior work on edit distance. There are many similarities between DTW and the edit distance problem: (1) like DTW, edit distance can be computed in $O(MN)$ time using the alignment graph [35, 39]. The only difference is in the edge-weights. (2) like DTW, edit distance has a lower bound prohibiting strongly subquadratic time algorithms conditioned on the SETH [3, 10, 22], and (3) like DTW, edit distance can be computed in $O(Nm + Mn)$ time by proceeding block-by-block and computing the outputs from the inputs. However, unlike DTW, it is known how to compute the edit distance of run-length encoded strings in $\tilde{O}(nm)$ time [6, 7, 11–13, 19, 26, 28, 29]. Specifically, Clifford et. al. [13] showed that the input and output of a block can be implicitly represented by a piecewise linear function, and, that the representation of the output can be computed in amortized $O(\mathsf{polylog}(mn))$ time from the representation of the input. This implies an $\tilde{O}(nm)$ time algorithm for edit distance.

In [41], Xi and Kuszmaul write about the prospects of obtaining an $\tilde{O}(nm)$ time algorithm for DTW: "*Such an algorithm would finally unify edit distance and DTW in the run-length-encoded setting*".

Our result and techniques. We present an $\tilde{O}(nm)$ time algorithm for DTW. This is optimal up to logarithmic factors under the SETH. Our algorithm is independent of the alphabet size $|\Sigma|$ and of the function δ. In fact, δ need not even satisfy the triangle inequality.

We follow the approach for edit distance by Clifford et. al. [13] of representing and manipulating inputs and outputs with a piecewise-linear function. However, the manipulation is more challenging for several reasons which were highlighted by Xi and Kuszmaul [41]: (1) unlike edit distance, DTW does not satisfy the triangle inequality. (2) we are interested in arbitrary cost functions δ for DTW, whereas the $\tilde{O}(nm)$ algorithm for edit distance [13] works only for Levenshtein distance (when $\delta(\cdot, \cdot) \in \{0, 1\}$). (3) in the standard setting (i.e. not the run-length encoded setting) edit distance actually reduces to DTW [22].

In Section 2, we show that the required manipulation of inputs and outputs naturally reduces to $O(nm)$ operations on a data structure that, given an array A of size $M + N$ initialized to all zeros, supports the following range operations:

▶ **Definition 3** (Range Operations).

- $\mathsf{Lookup}(i)$ - *return* $A[i]$.
- $\mathsf{AddConst}(i, j, c)$ - *for every* $k \in [i \dots j]$, *set* $A[k] \leftarrow A[k] + c$.
- $\mathsf{AddGradient}(i, j, g)$ - *for every* $k \in [i \dots j]$, *set* $A[k] \leftarrow A[k] + k \cdot g$.
- $\mathsf{LeftLinearWave}(i, j, \alpha)$ - *for every* $k \in [i \dots j]$, *set* $A[k] \leftarrow \min_{t \in [i \dots k]} \big(A[t] + (k - t)\alpha\big)$.
- $\mathsf{RightLinearWave}(i, j, \alpha)$ - *for every* $k \in [i \dots j]$, *set* $A[k] \leftarrow \min_{t \in [k \dots j]} \big(A[t] + (t - k)\alpha\big)$.

In Section 3, we show our main technical contribution:

▶ **Theorem 4.** *Performing s range operations of Definition 3 can be done in amortized $O(\mathsf{polylog}(s))$ time per operation.*

The proof of Theorem 4 can be roughly described as follows: We represent the array A by the line segments of the linear interpolation of A. This way, the range operations of Definition 3 translate to creating and deleting segments, changing their slopes, and shiftings segments up and down. For most operations, these changes apply to a single contiguous range of A and are therefore quite simple to implement in polylog time. The difficult operations are LeftLinearWave and RightLinearWave. These operations may need to replace each of $\Omega(n)$ different sets of consecutive segments with a single new segment. We refer to the process of replacing a set of consecutive segments with a single new segment as a *ray shooting* process. Shooting each of these rays separately would be too costly. More accurately, a ray shooting process that replaces many segments with a single one is not problematic since its cost can be charged to the decrease in the number of segments. The challenge is in shooting rays that replace a single segment with another one, as this does not decrease the number of segments.

Our main technical contribution is a lazy approach for handling the problematic ray shooting processes. We study the structural properties of ray shooting processes, and characterize long rays which we can afford to shoot explicitly, and short rays, which we cannot. The structure we identify allows us to divide the segments representing A into mega-segments, and keep track of a single pending short ray in each mega-segment such that executing the pending ray shooting process in each mega-segment would result in the correct representation of the array A. While we cannot afford to actually carry out all of these pending ray shooting processes, we can afford to perform the process locally, e.g., in order to support Lookup for a specific element of A, or to facilitate the other range operations.

One component of our lazy approach is a data structure (sometimes called *Segment tree beats* in programming competitions) for the following problem: Maintain an array A under lookup queries and two kinds of update: $\mathsf{AddConst}(i, j, c)$ - for every $k \in [i \dots j]$ set $A[k] \leftarrow A[k] + c$, and $\mathsf{Min}(i, j, c)$ - for every $k \in [i \dots j]$ set $A[k] \leftarrow \min\{A[k], c\}$. Though we are not aware of any official publication, it is known (see e.g. [1]) that this problem can be solved in amortized polylog time. We show a different and *worst-case* polylog time solution.[2]

Implications for low regime DTW. In Section 4, we show that our $\tilde{O}(n \cdot m)$ algorithm for computing $\mathsf{DTW}(S, T)$ immediately implies an $\tilde{O}(n \cdot k)$ time algorithm where $k = \mathsf{DTW}(S, T)$. This is useful when k is small. It is achieved using the standard trick of limiting the computation to blocks that are in the k-neighborhood of the alignment graph's main diagonal. It improves the $O(N \cdot k)$ algorithm of [22], the $\tilde{O}(n^2 \cdot k)$ algorithm of [15], and the $\tilde{O}(n \cdot k)$ time approximation algorithm of [41] (all obtained with the same k-neighborhood idea).

We note that for the closely related problem of low regime *edit distance*, using the same k-neighborhood idea, the algorithm of [13] runs in $\tilde{O}(n \cdot k)$ time (now k is the edit distance between S and T). However, unlike DTW, there is a vast literature on low regime edit distance (and the approximation algorithms inspired by it). Most notable are the celebrated $O(N + k^2)$ time algorithms of Myers [34] and Landau-Vishkin [24] for unweighted edit distance, and the very recent $O(N + k^5)$ time algorithm for weighted edit distance [14].

[2] We note that the solution in [1] also supports range-sum queries and for such a conditional lower bound (from the Online Matrix-Vector Multiplication (OMV) problem) is known [16]. The lower bound implies that *worst-case* operations unlikely to be possible in $O(n^{1/2-\varepsilon})$ time. We are able to circumvent this lower bound because we only support lookups, but not range-sum queries.

Implications for pattern matching DTW. The pattern matching version of DTW asks to compute, for every index $j \in [1 \dots |T|]$ the value $\min_{i \in [1 \dots j]}(\mathsf{DTW}(S, T[i \dots j]))$. In [18], an $O(NM)$ algorithm was presented for pattern matching DTW. Additionally, they provided an $O(nmk)$ algorithm for the low regime version of the problem, in which the goal is to report every index j such that $\min_{i \in [1 \dots j]}(\mathsf{DTW}(S, T[i \dots j])) \leq k$. The key ingredient of these algorithms (See [18, Lemma 2]) is a dynamic programming formula that is identical to Equation (1), except for the initialization. Since our $\tilde{O}(nm)$ algorithm for DTW is obtained by implementing the dynamic programming implicitly, by changing the initialization step, our algorithm implies an $\tilde{O}(nm)$ time algorithm for pattern matching DTW. This improves upon both the $O(NM)$ algorithm for DTW pattern matching and the $O(nmk)$ algorithm for the low regime DTW pattern matching (when k is super poly-logarithmic).

2 DTW via Range Operations

In this section we prove that Theorem 4 implies an $\tilde{O}(nm)$ algorithm for DTW. Namely, that DTW reduces to efficiently supporting the range operations of Definition 3.

Blocks in the alignment graph. Let $S[i_1 \dots i_2]$ and $T[j_1 \dots j_2]$ be the i'th run in S and the j'th run in T respectively. The block $B_{i,j}$ in the alignment graph is the set of vertices (a, b) with $a \in [i_1 \dots i_2]$ and $b \in [j_1 \dots j_2]$. All of the edges entering any vertex in block $B_{i,j}$ have the same weight $\delta(S[i_1], T[j_1])$, which we denote by $c_{B_{i,j}}$. We call the blocks $B_{i-1,j}$, $B_{i,j-1}$ and $B_{i-1,j-1}$ the *entering blocks* of $B_{i,j}$. The *input* of a block consists of all vertices belonging to the first row or first column of the block. The *output* of a block consists of all vertices belonging to the last row or last column of the block. The following structural lemma was also used implicitly in previous works (see formal proof in the full version).

▶ **Lemma 5.** *Let B be a block.*

- *If $(x, y), (x, y+1) \in B$ then there is a shortest path from $(0, 0)$ to $(x+1, y+1)$ that does not visit $(x, y+1)$.*
- *If $(x, y), (x+1, y) \in B$ then there is a shortest path from $(0, 0)$ to $(x+1, y+1)$ that does not visit $(x+1, y)$.*
- *If $(x, y), (x+1, y+1) \in B$ then there is a shortest path from $(0, 0)$ to $(x+1, y+1)$ that goes through (x, y).*

Frontiers in the alignment graph. Our algorithm for DTW processes all blocks in the alignment graph. At every step, the algorithm can process any block B as long as all its entering blocks have already been processed. When block B is processed, the algorithm computes $\mathsf{dist}(x, y)$ for every output vertex (x, y) of B. After processing block B, we say that the output vertices of B are *resolved*. At every step of the algorithm, the *frontier* is the set of resolved vertices with an outgoing edge to a block that was not yet processed. Observe that, at any given time in the execution of the algorithm, for every value $d \in [-N \dots M]$, the frontier includes exactly one vertex (x, y) such that $y - x = d$. At every step t of the algorithm, we will maintain an array $\mathsf{F}_t[-N \dots M]$ where $F_t[d] = \mathsf{dist}(x, y)$ such that vertex (x, y) belongs to the current frontier and $y - x = d$. In the full version of this paper ([9]), we prove the following lemma.

▶ **Lemma 6.** *F_{t+1} can be obtained by using $O(1)$ range operations (Definition 3) on F_t.*

In the rest of this section, we prove that Lemma 6 implies our main result:

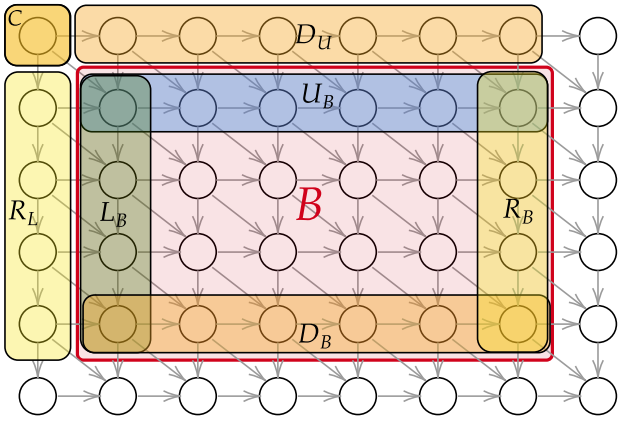

Figure 1 A block B, its inputs $L_B \cup U_B$ and its outputs $D_B \cup R_B$. The entering edges to L_B are from R_L, the corner of its diagonally adjacent block C, and the leftmost node of D_U. The entering edges to U_B are from D_U, the corner of C, and the topmost node of R_L.

▶ **Theorem 7.** *The Dynamic Time Warping distance of two run-length encoded strings S and T with n and m runs respectively can be computed in $\tilde{O}(nm)$ time.*

Proof. We initialize the data structure of Theorem 4 as an array of length $N + M + 1$. We treat the indices of A as if they are in $[-N \dots M]$[3]. Initially, the frontier consists of the vertices $(x, 0)$ with $x \in [0 \dots N]$ and $(0, y)$ with $y \in [M]$. We start by turning A into F_0. According to Equation (1), we need to set $A[0] = 0$ and $A[i] = \infty$ for $i \neq 0$. This can be done by applying $\mathsf{AddConst}(1, M, \infty)$ and $\mathsf{AddConst}(-N, -1, \infty)$.

The algorithm runs in nm iterations. At the beginning of iteration t, we have $A = \mathsf{F}_t$. The algorithm picks any block B whose entering blocks have already been processed, and applies $O(1)$ range operations (due to Lemma 6) on A in order to obtain $A = \mathsf{F}_{t+1}$. After the last iteration, it is guaranteed that the block $B_{n,m}$ has been processed. Therefore, $\mathsf{F}_{nm}[M - N] = \mathsf{DTW}(S, T)$. Every iteration requires $O(1)$ range operations each in $O(\mathsf{polylog}(nm))$ time, so overall the algorithm performs $O(nm)$ operations in total $\tilde{O}(nm)$ time. ◀

3 Implementing the Range Operations

In this section, we prove Theorem 4. We view the array A as a piecewise linear function. We associate with A a set $\mathcal{P} = \{p_1 = (x_1, y_1), p_2 = (x_2, y_2), \dots\}$ of points satisfying $A[x_i] = y_i$. The set $\mathcal{P}$ is uniquely defined by A as the endpoints of the maximal linear segments of the linear interpolation of A. Note that the first point of $\mathcal{P}$ is always $(1, A[1])$ and the last point is $(n, A[n])$.[4] Let $\ell_i(x) = \alpha_i x + \beta_i$ be the line segment between p_i and p_{i+1}. Our representation will maintain the α_i's and β_i's. With this representation we can retrieve $A[x]$ for any $x \in [1, n]$ from α_i and β_i where x_i is predecessor of x in the sequence $(x_1, x_2, \dots)$. Upon initialization, A is represented as one linear segment, with $\alpha_1 = 0$, and $\beta_1 = 0$.

We will use the following simple data structure.[5]

[3] When a gradient update $\mathsf{AddGradient}(i, j, c)$ affects a value $A[k]$, we would like $A[k]$ to be increased by $k \cdot c$ with $k \in [-N \dots M]$ being the 'simulated' index rather then the actual index $k + N + 1$. This can be achieved by applying an additional operation $\mathsf{AddConst}(i, j, (-N - 1) \cdot c)$.

[4] Here we use n to denote the size of the array A.

[5] The data structure can be implemented using a balanced search tree with a delta-representation (where

▶ **Lemma 8** (Interval-add Data Structure). *There is a data structure supporting the following operations in $O(\log n)$ time per operation on a set of n points with distinct first coordinates.*

- Lookup(x) - *return the second coordinate of the point with first coordinate x, if exists.*
- Insert(x, y) - *insert the point (x, y).*
- Remove(x) - *remove the point with first coordinate x, if exists.*
- AddToRange(i, j, c) - *for every point (x,y) with $x \in [i \dots j]$ set $y \leftarrow y + c$.*
- nextGT(x, y) - *return the point $p' = (x', y')$ with smallest $x' > x$ among points with $y' > y$.*
- prevLT(x, y) - *return the point $p' = (x', y')$ with largest $x' < x$ among points with $y' < y$.*

3.1 A Warmup Algorithm

We first present a naive and inefficient implementation of a range operations data structure. We maintain the sequence $\mathcal{P}$ in a predecessor/successor data structure over the sequence $(x_1, x_2, \dots)$. With a slight abuse of notation we shall also use $\mathcal{P}$ to refer to this data structure. We maintain the α_i's and β_i's using two Interval-add data structures D_α and D_β, respectively. The parameters α_i, β_i of the linear segment ℓ_i starting at x_i are represented by points (x_i, α_i) in D_α and (x_i, β_i) in D_β. In what follows, whenever we say we add a point $p = (x, y)$ to $\mathcal{P}$ we mean that (x, y) is inserted into the predecessor/successor data structure $\mathcal{P}$, and that points with first coordinate x are inserted into D_α and D_β, with their second coordinates appropriately set to reflect the parameters α, β of the segment ending at p and the segment starting at p. This process requires $O(1)$ operations on $\mathcal{P}, D_\alpha$ and D_β.

The effect of AddConst(i, j, c) (see Figure 2) is to break the segment containing i into at most three linear segments (a prefix ending at $i-1$, a segment $[i-1, i]$, and a suffix starting at i), and similarly for the segment containing j. Thus, to apply AddConst(i, j, c), we first replace the segments containing i and j with these $O(1)$ new segments by inserting or updating the endpoints of the segments in $\mathcal{P}, D_\alpha$, and D_β. We then invoke AddToRange(i, j, c) on D_β to shift all segments between i and j by c. Next, we set the parameters for the segment $[i-1, i]$ and for the segment $[j, j+1]$ by $O(1)$ additional calls to AddToRange on D_α and D_β. Finally, we check if any of the new segments we inserted has the same slope as its adjacent segments and, if so, we merge them into a single segment by removing their common point from $\mathcal{P}, D_\alpha$ and D_β. This guarantees that the set $\mathcal{P}$ we maintain is indeed the set $\mathcal{P}$ defined by A. Supporting AddGradient(i, j, g) is similar. The only difference is that we invoke AddToRange(i, j, g) on D_α instead of on D_β because the slopes of the segments are shifted rather than their values.

The challenge is thus in supporting LeftLinearWave(i, j, α). We first describe its effect and then describe how it is implemented. We assume without loss of generality that i and j are both endpoints of segments (otherwise we break the segments containing them into $O(1)$ segments as above). Let $p_a = (i, A[i])$ and $p_{b+1} = (j, A[j])$ be the points corresponding to i and j. Thus, the segments contained within $[i \dots j]$ are $\ell_a, \ell_{a+1} \dots \ell_b$.

If $\alpha_a \le \alpha$ then the segment ℓ_a is not affected by the linear wave. This is because for every $k \in [x_a \dots x_{a+1}]$, the linear wave assigns

$$\begin{aligned} A[k] &\leftarrow \min_{x_a \le t \le k} (A[t] + (k-t)\alpha) = \min_{x_a \le t \le k} (A[k] - (k-t)\alpha_a + (k-t)\alpha) \\ &= \min_{x_a \le t \le k} (A[k] + (k-t)(\alpha - \alpha_a)) = A[k]. \end{aligned}$$

the value of a node is represented by the sum of values of its ancestors), and having every node also store the minimal and maximal values in its subtree. See e.g. [21].

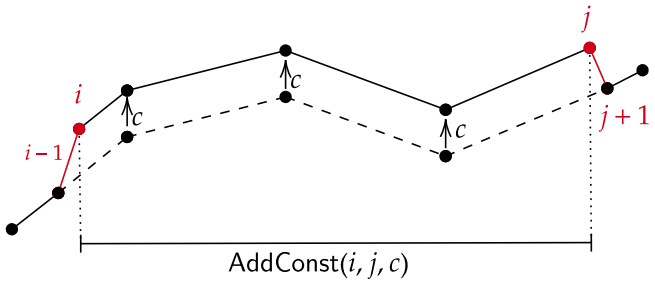

Figure 2 An illustration of applying the AddConst(i, j, c) operation. The dashed line represents the segments before the operation. After the operation, new points are created with x coordinates $i-1, i, j$ and $j+1$ and the segments in $[i \dots j]$ are shifted by c.

Let $z \in [a \dots b]$ be the minimum index such that $\alpha_z > \alpha$. By the same reasoning, none of the segments $\ell_a, \ell_{a+1}, \dots, \ell_{z-1}$ are affected by the linear wave. Let $r_z(x)$ be the (positive) ray with slope[6] α starting at p_z. Since $\alpha_z > \alpha$, the ray r_z is below the linear segment ℓ_z. Hence, the segment ℓ_z starting at p_z is affected by the linear wave; its slope changes from α_z to α, and it extends beyond x_{z+1} as long as $A[x] \geq r_z(x)$. We describe this effect of LeftLinearWave by a *ray shooting* process from p_z (See Figure 3). This process identifies the new endpoint p' of ℓ_z, and removes all the existing segments between p_z and p', as follows.

Let $z' \in [z+1..b+1]$ be the minimum index with $y_{z'} < r_z(x_{z'})$, i.e. the first point in $\mathcal{P}$ that lies strictly below the ray r_z. Let $p^* = (x^*, y^*)$ be the intersection point of the ray r_z with $\ell_{z'-1}$ (if z' does not exist, then $p^* = p_b$). The new endpoint of ℓ_z is the point $p' = (x', y') = (\lfloor x^* \rfloor, r_z(\lfloor x^* \rfloor))$, and it replaces all the points p_w for $w \in (z \dots z')$. If x^* is not an integer (or if z' does not exist) then a new segment is formed between p' and $p'' = (x'+1, A[x'+1])$.

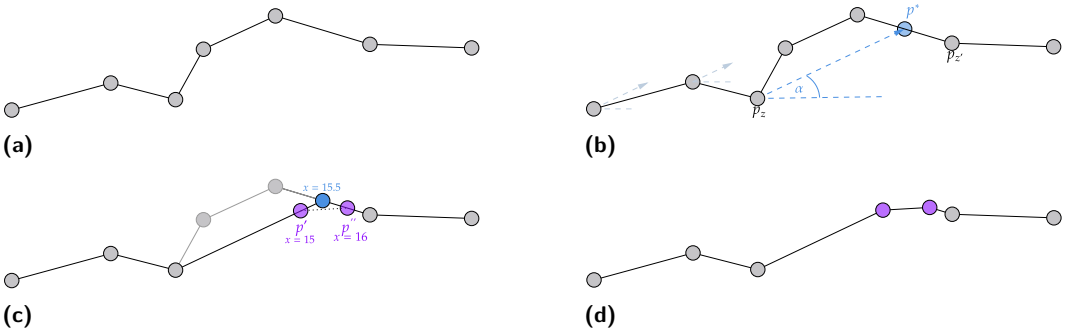

Figure 3 The effect of LeftLinearWave(i, j, α). The segments before p_z are not affected. The segments between p_z and $p_{z'}$ are affected. Namely, a ray r_z with slope α (in dashed blue) is shot from p_z and intersects at point $p^* = (x^*, y^*)$. The new endpoint of ℓ_z becomes p' and all the segments between p_z and p' are removed. Since $x^* = 15.5$ is not an integer, a new segment is formed between p' (with x coordinate 15) and p'' (with x coordinate 16).

The effect of LeftLinearWave(i, j, α) on the remaining part of A, namely on $A[x_{z'} \dots j]$ is analyzed in the same way as above, this time starting from $p_{z'}$ instead of from p_a. In particular, the prefix of segments with slopes less than α is not affected, and a ray with slope

[6] Note that in Figure 3 and in all subsequent figures we indicate the slope α of the ray r_z by drawing an angle α between the ray and the positive direction of the x-axis. However, formally α is the slope of the ray, not the indicated angle.

α is shot from the next p_w with $\alpha_w > \alpha$, and so on. In the the full version of this paper ([9]) we formally prove that the above characterization indeed represents the new values of $A[i \dots j]$.

We now describe a naive, non-efficient implementation of LeftLinearWave(i, j, α) according to the description above. Recall that i and j are assumed to be endpoints p_a and p_{b+1} of segments. We begin by finding the first p_z with $x_z \in [i \dots j]$ and $\alpha_z > \alpha$ by querying D_α.nextGT(i, α). A ray shooting process is then performed from p_z (if p_z exists) as follows: Recall that $r_z(x)$ denotes the positive ray with slope α shot from p_z. We scan the successor points of p_z one by one in order, and for every point p_w we check whether the ray $r_z(x_w) \leq y_w$. If so, p_w is removed by removing x_w from $\mathcal{P}$, D_β and D_α. Otherwise, we compute $p^* = (x^*, y^*)$, the intersection point of r_z and ℓ_{w-1}, and from it the points $p' = (x', y') = (\lfloor x^* \rfloor, r_z(\lfloor x^* \rfloor)$ and, if x^* is not an integer, also $p'' = (\lceil x^* \rceil, \ell_{w-1}(\lceil x^* \rceil))$. Then, we insert the new points p' and p'' just before p_w, as discussed above for AddConst. The scanning then continues with another nextGT query from p_w, and so on. If, at the end of the process, the last point p_b is removed since it is above some r_z, we insert a new point $(x_b, r_z(x_b))$.

Time Complexity. We now analyze the time complexity of this naive implementation. Each AddConst and AddGradient operation requires $O(1)$ operations on the Interval-add data structures, and therefore takes $O(\text{polylog}|\mathcal{P}|)$ time per operation, with $|\mathcal{P}|$ being the cardinality of $\mathcal{P}$ when the operation is applied.

Regarding LeftLinearWave operations, one might hope that the cost of each ray shooting process can be charged to the removal of points from $\mathcal{P}$ during the process. However, each ray shooting process might also add up to two new points, which might result in the size of $\mathcal{P}$ increasing. Indeed, a LeftLinearWave operation may give rise to many such ray shooting processes, and hence may significantly increase the size of $\mathcal{P}$ and take too much time. This is the main technical challenge we need to address.

The idea is to distinguish between *long* ray shootings for which we can globally charge the new insertions, and *short* ray shootings for which we cannot. We handle the long rays as in the naive solution and devise a separate lazy mechanism that delays the application of all the short rays stemming from a single LeftLinearWave operation using a constant number of updates to a separate data structure that keeps track of the delayed rays.

Symmetry of RightLinearWave. The discussion so far was focused on the LeftLinearWave operation. We note that the analysis of RightLinearWave is symmetric. In particular, the execution of RightLinearWave(i, j, α) can be described as a sequence of ray shootings with *negative* rays. The first point from which a ray is shot is p_z with largest $z \in [a \dots b]$ such that $\alpha_{z-1} < -\alpha$ (p_z is found using D_α.prevLT). Note that the condition for starting a ray shooting process for RightLinearWave is on α_{z-1} rather than α_z since the slope of the segment to the left of p_z is α_{z-1}. To simplify the presentation, we will keep describing only LeftLinearWave, and will comment at the very end about the minor adjustments required to also handle the symmetric RightLinearWave.

3.2 Active and Passive Points, Long and Short Rays

On our way to formally define long rays and short rays we first observe that ray shootings only occur at points where slopes increase. We call such points *active* points.

▶ **Definition 9** (Active and Passive points). *A point p_z in $\mathcal{P}$ is called* active *if $z \in \{1, |\mathcal{P}|\}$ or $\alpha_z > \alpha_{z-1}$. A point that is not active, is called* passive. *We denote the sets of active points by $\mathcal{P}_{\text{active}}$.*

▶ **Lemma 10.** *Ray shootings stemming from* LeftLinearWave(i, j, α) *occur either at point* $p_a = (i, A[i])$ *or at active points. Ray shootings stemming from* RightLinearWave(i, j, α) *occur either at point* $p_b = (j, A[j])$ *or at active points.*

Proof. We focus on LeftLinearWave. The proof for RightLinearWave is symmetric. Assume to the contrary that a ray shooting process starts at a passive point $p_z \neq p_a$. If p_z is the first point where a ray shooting starts, then z is the minimal index in $[a \dots b]$ with $\alpha_z > \alpha$. But since p_z is passive, we have $\alpha < \alpha_z \leq \alpha_{z-1}$, contradicting the minimality of z (note that $p_z \neq p_a$ so $z - 1 \in [a \dots b]$).

Otherwise, let p_q be the last point before p_z from which a ray shooting process occurred. Let $p_{q'}$ be the first point below the ray shot from p_q. Since p_z is the next point from which a ray is shot, z is the first point in $[q' \dots b]$ with $\alpha_z \geq \alpha$. Since p_z is passive, we have $\alpha < \alpha_z \leq \alpha_{z-1}$. If $z \neq q'$, we have $z - 1 \in [q' \dots b]$, a contradiction to the minimality of z. Otherwise, $p_z = p_{q'}$ is the first point below the ray with slope α shot from p_q. It follows that p_{z-1} is above the ray, and $\alpha_{z-1} > \alpha$. It must be the case that $p_{q'}$ is above the ray, a contradiction. ◀

Let $\mathcal{P}_{\mathsf{active}} = (q_1, q_2, \dots)$ be the restriction of the sequence $\mathcal{P}$ to the active points. We can think of the active points as defining a piecewise linear function whose segments are a coarsening of the segments of A. We refer to these segments as *mega-segments*. Let γ_z denote the slope of the mega-segment whose endpoints are q_z and q_{z+1}. The following lemma asserts that the segments of A are never below their corresponding mega-segments, and that the slope of a segment starting at an active point is never smaller than the slope of the mega-segment starting at the same point.

▶ **Lemma 11.** *Let* $q_z = p_w$ *and* $q_{z+1} = p_{w'}$ *be two consecutive active points. For every* $k \in [w \dots w']$*, the passive point* p_k *is not below the mega-segment connecting* q_z *and* q_{z+1}*. Furthermore,* $\alpha_w \geq \gamma_z$*.*

Proof. (See Figure 4) Clearly, p_w and $p_{w'}$ are on the mega-segment, and in particular not below it. Assume by contradiction that there is a point below the mega-segment, and let $k' \in (w \dots w')$ be the smallest index of such a point. Since $p_{k'-1}$ is not below the mega-segment and $p_{k'}$ is below the mega-segment, we must have $\alpha_{k'-1} < \gamma_z$. Moreover, since the points p_k with $k \in [k' \dots w')$ are passive, the slopes are non-increasing and therefore every $\alpha_k \leq \gamma_z$. This means that all these points and in particular $p_{w'}$ are below the mega-segment. In contradiction to $p_{w'}$ lying on the mega-segment. Furthermore, since p_{w+1} is not below the mega-segment, we have $\alpha_w \geq \gamma_z$. ◀

We next show that if a ray shooting process starts at an active point q_z with $\gamma_z < \alpha$ then the process ends before q_{z+1}, and the only affected points are the passive points between q_z and q_{z+1}. On the other hand, if $\gamma_z \geq \alpha$ then as a result of the process q_{z+1} ceases to be an active point, so $|\mathcal{P}_{\mathsf{active}}|$ decreases.

▶ **Lemma 12.** *Consider a ray shooting process starting from point* $p_w = q_z \in \mathcal{P}_{\mathsf{active}}$ *during the application of* LeftLinearWave(i, j, α)*. Let* $q_{z+1} = p_{w'}$*.*

1. *No new active points* $p = (x, y)$ *with* $x \neq j$ *are created in this process.*
2. *If* $\gamma_z < \alpha$ *then the points that are deleted by this process are the (passive) points* p_k *with* $k \in [w + 1 \dots r]$ *for some* $w < r < w'$*. No other points between* p_w *and* $p_{w'}$ *are deleted by* LeftLinearWave(i, j, α)*.*
3. *If* $\gamma_z \geq \alpha$ *then* q_{z+1} *is either deleted or becomes passive.*

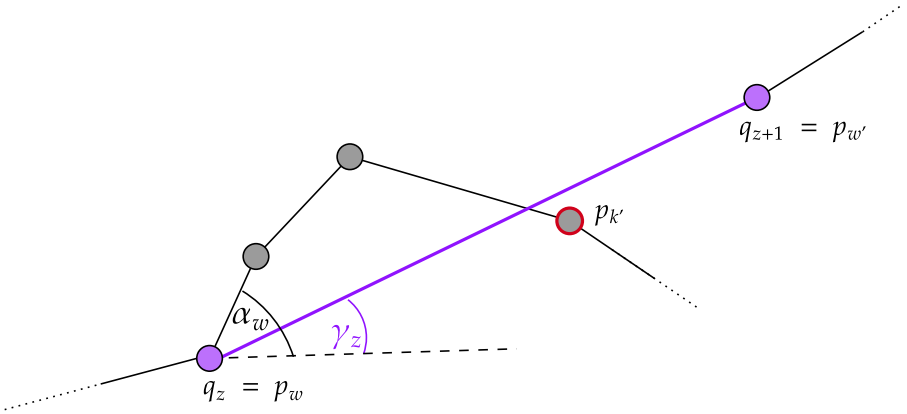

Figure 4 The impossible configuration in Lemma 11. The points q_z and q_{z+1} are represented by the purple points and the mega-segment connecting them is represented by a thick purple line. The first point $p_{k'}$ below the segment is marked with red stroke. Since the points strictly within the mega-segment are passive, the points following $p_{k'}$ within the mega-segment (and in particular q_{z+1}) must remain below the mega-segment.

Proof. Let ℓ be the ray starting from $p_w = q_z$. Assume the process terminates by finding the first point $p^* = (x^*, y^*)$ below ℓ (the only process that does not end this way is the one that ends by reaching $(j, A[j])$). The ray shooting process adds at most two new points p' and p'' with decreasing slopes, so no new active points are created by the process. The slope of p' is decreasing because the segment entering p' is (a sub-segment of) ℓ and the segment leaving p' is to a point below ℓ. The slope of p'' is decreasing because the line segment entering p'' is a line from p' (a point on ℓ) and the line segment leaving p'' is to the suffix of a line segment below ℓ.

Consider the case $\gamma_z < \alpha$. Then q_{z+1} is below the ray with slope α starting at q_z. Hence the ray shooting process terminates at a point after p_{w+1} and before q_{z+1}. Since no active points are created, the next ray will be shot from q_{z+1} or later, so no other points between q_z and q_{z+1} are deleted by $\mathsf{LeftLinearWave}(i, j, \alpha)$.

Now consider the case $\gamma_z > \alpha$. Then the mega-segment between q_z and q_{z+1} is above the ray with slope α shot from q_z. By Lemma 11, all the (passive) points between q_z and q_{z+1} are also above this ray. Hence q_{z+1} is deleted by the ray shooting process.

Finally, consider the case $\gamma_z = \alpha$. Then the mega-segment between q_z and q_{z+1} coincides with the ray with slope α shot from q_z. By Lemma 11, all the (passive) points between q_z and q_{z+1} will be deleted by the ray shooting process. Let w' be such that $q_{z+1} = p_{w'}$. If $\alpha_{w'} \geq \alpha$ then q_{z+1} will be deleted by the process. Otherwise, $\alpha_{w'} < \alpha$, so the ray shooting process terminates at q_{z+1}. Since all the passive points between q_z and q_{z+1} were deleted, q_z and q_{z+1} become consecutive in $\mathcal{P}$, and the slope of the corresponding segment is $\gamma_z = \alpha$. But the slope of the segment starting at q_{z+1} is $\alpha_{w'} < \alpha$, so q_{z+1} becomes passive. ◀

We call rays with $\gamma_z > \alpha$ *long* rays, and those with $\gamma_z \leq \alpha$ *short* rays. Since long rays decrease the size of $\mathcal{P}_{\mathsf{active}}$ we can handle them explicitly as in the warmup, charging the deletion of passive points during the process to their creation, and charging the insertion of the at most two passive points at the end of the process to the decrease in $|\mathcal{P}_{\mathsf{active}}|$. The short rays, which do not decrease $|\mathcal{P}_{\mathsf{active}}|$, will be handled lazily. Namely, instead of explicitly shooting a short ray in the mega-segment starting at an active point q_z, we only store the slope of the ray and postpone its execution until it is required (e.g., by a Lookup operation). Note that subsequent short rays shot in this mega-segment may further change the stored slope, and subsequent long rays may also affect it. We explain this in detail next.

3.3 The Data Structure

In this section, we provide a technical overview of the construction of the range operation data structure of Definition 3. The complete implementation details and proofs appear in the full version of this paper ([9]). Since our data structure is lazy, the sequence of points it maintains will be different than the sequence $\mathcal{P}$ that would have been maintained had we used the warmup algorithm from Section 3.1. We will therefore use $\tilde{\mathcal{P}}$ to denote the set of points actually maintained by the data structure. The points $\tilde{\mathcal{P}}$ define linear segments $\tilde{\ell}_i(x)$ in the usual way. For $x \in [1, n]$ we denote by $\tilde{A}[x]$ the value $\tilde{\ell}_i(x)$, where $\tilde{\ell}_i$ is the segment containing x. We stress that our algorithm does not maintain $\mathcal{P}$. However, for the sake of description and analysis only we shall keep referring to the original $\mathcal{P}$, and array A. The definition of active and passive points, of the slopes γ of mega-segments, and of short and long rays are now with respect to the slopes of the $\tilde{\ell}_i$'s.[7] However, we shall maintain that the set of active points with respect to $\mathcal{P}$ and $\mathcal{P}_{\mathsf{active}}$ is the same:

▶ **Invariant 1.** $\tilde{\mathcal{P}}_{\mathsf{active}} = \mathcal{P}_{\mathsf{active}}$.

Following Section 3.1, we maintain $\tilde{\mathcal{P}}$ in a predecessor/successor data structure, as well as the Interval-add data structures D_α and D_β representing the parameters of the linear segments $\tilde{\ell}_i(x)$ defined by the points of $\tilde{\mathcal{P}}$. By implementing AddConst, AddGradient and long ray shootings similarly to Section 3.1 (the exact details will be spelled out below), we shall maintain the invariant that this part of the data structure correctly represents the values of active points.[8]

We maintain the set of active points $\tilde{\mathcal{P}}_{\mathsf{active}} = (q_1, q_2, \ldots)$ using a predecessor/successor structure on their x-coordinates. For each $q_z \in \tilde{\mathcal{P}}_{\mathsf{active}}$, we maintain the slope γ_z of the mega-segment starting at q_z in an Interval-add data structure D_γ. In addition, we maintain a pending short ray r_z with slope ρ_z passing through q_z (see Figure 5) by maintaining ρ_z in a data structure D_ρ. This data structure, which we call the Add-min data structure is summarized below and proved in the full version of this paper.

▶ **Lemma 13** (Add-min Data Structure). *There exists a data structure supporting the following operations in $O(\mathsf{polylog} n)$ time on a set of points S.*

1. Insert(x, y) - *insert the point (x, y) to S.*
2. Remove(x) - *remove the point $p = (x, y)$ from S, if such a point exists.*
3. Lookup(x) - *return y such that $p = (x, y)$ is in S, or report that there is no such point.*
4. AddToRange(i, j, c) - *for every $p = (x, y) \in S$ with $x \in [i \ldots j]$ set $y \leftarrow y + c$.*
5. Min(i, j, c) - *for every $p = (x, y) \in S$ with $x \in [i \ldots j]$ set $y \leftarrow \min(y, c)$.*

Note that storing ρ_z suffices to compute $r_z(x)$ since the active point q_z that determines the free coefficient of r_z is correctly represented by D_α and D_β. We shall show that storing a single pending ray suffices to represent all the pending changes in a mega-segment. This property will rely on maintaining the following invariant.

▶ **Invariant 2.** *For every active point q_z we have $\rho_z > \gamma_z$. (Recall that γ_z is the slope of the mega-segment connecting q_z and q_{z+1}.)*

---

[7] It would have been more accurate to use $\tilde{\alpha}, \tilde{\beta}$, and $\tilde{\gamma}$, but this would be too cumbersome, so we stick to using α, β, γ.

[8] See Invariant 3 and the note following it.

The idea is that with this representation, for any x, the value of $A[x]$ is given by the minimum of the value $\tilde{A}[x] = \ell_w(x)$ of the segment of $\tilde{\mathcal{P}}$ containing x, and the value $r_z(x)$ of the pending short ray for the mega-segment containing x. This is captured by the following main invariant maintained by the data structure.

▶ **Invariant 3.** *Let $x \in [1, n]$, and let p_w and q_z be the predecessor of x in $\tilde{\mathcal{P}}$ and in $\tilde{\mathcal{P}}_{\mathsf{active}}$, respectively. It holds that $A[x] = \min(\tilde{\ell}_w(x), r_z(x))$. Furthermore, if $p = (x, A[x])$ is an active point in $\mathcal{P}$, then $A[x] = \tilde{A}[x]$.*

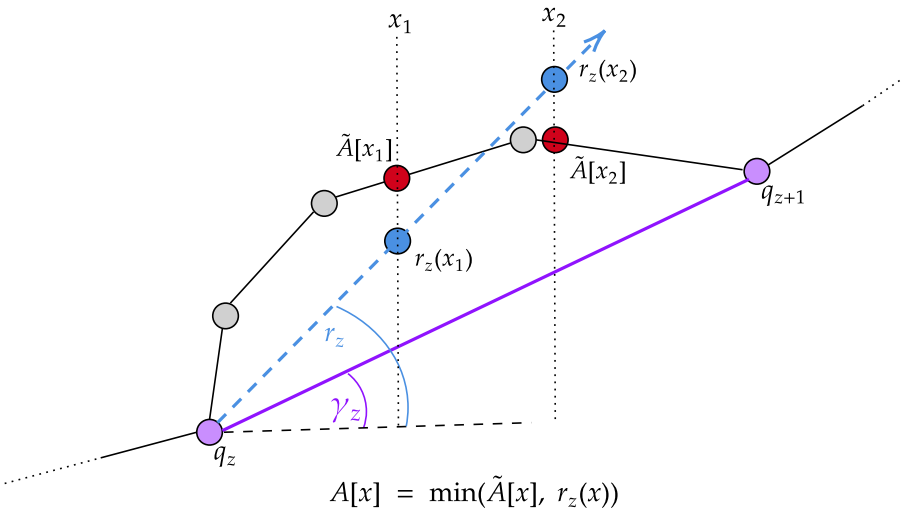

Figure 5 An illustration of the data stored for a mega-segment between two consecutive active points q_z and q_{z+1} (purple points). The slope γ_z is the slope of the mega-segment. The slope $\rho_z > \gamma_z$ stored in q_z represents a pending ray r_z (dashed blue) that should be shot from q_z. The value of $A[x]$ is the minimum between $r_z(x)$ (a blue point) and $\tilde{A}[x]$ (a red point), the value of the piece-wise linear function defined by $\tilde{\mathcal{P}}$ (in grey).

Note that the first part of Invariant 3, together with Invariant 1 implies the second part of Invariant 3. This is because the predecessor of x for an active point $p = (x, A[x])$ in $\mathcal{P}_{\mathsf{active}}$ is itself. Since $\mathcal{P}_{\mathsf{active}} = \tilde{\mathcal{P}}_{\mathsf{active}}$ we have that $p \in \tilde{\mathcal{P}}_{\mathsf{active}}$ is the predecessor of x in $\tilde{\mathcal{P}}_{\mathsf{active}}$ as well. By definition r_z goes through $p = q_z$, so $r_z(x) = \tilde{A}[x]$, and $\tilde{A}[x] = \tilde{\ell}_w(x)$ by definition. Hence, when proving that the invariants are maintained, we will not need to explicitly establish the second statement in Invariant 3.

Initially, $\tilde{\mathcal{P}} = \mathcal{P} = \{(1, 0), (|A|, 0)\}$, and $\rho_1 = \rho_2 = \infty$ (We interpret a line with a slope of ∞ as $y = \infty$). Indeed, $A[x] = \min(\tilde{A}[x], r_1(x)) = \min(0, \infty) = 0$ and Invariant 3 is satisfied. It remains to specify the implementation of the various operations supported by the data structure, to prove that the invariants are maintained, and to analyze the running times.

The flush Operation. We first describe a service operation $\mathsf{flush}(q_z)$ which explicitly shoots the pending short ray in the mega-segment starting at the active point q_z. It will be useful to invoke flush before serving Lookup operations, but also when serving the other operations in order to guarantee that the lazy implementation properly follows the explicit implementation in the warmup. This is particularly important in operations which may create $O(1)$ new active points and thus change the partition into mega-segments, but is also useful to streamline the proof of correctness. Recall that the reason we avoided shooting local rays in the first place was that there could be many of them, and we could not afford to pay for the possible

creation of $O(1)$ new passive points at the end of each of them. We can afford, however, to perform $O(1)$ flush operations before each Lookup, AddConst or AddGradient operation, because the cost of adding the $O(1)$ new points can be charged to the operation itself.

A flush of $q_z = p_w \in \mathcal{P}_{\text{active}}$ is performed as follows. Starting from p_{w+1}, we scan the points in $\tilde{\mathcal{P}}$. When scanning $p = (x, y)$, we compare y and r_z. If $r_z(x) \leq y$, we remove p from $\tilde{\mathcal{P}}$. Otherwise, the scan halts. Let p_{end} be the point on which the scan halts. If no point was deleted throughout the scan, we set $\rho_z = \infty$ and terminate. Otherwise, let p_{del} be the last point deleted by the scan. We compute the intersection $p^* = (x^*, y^*)$ of r_z and the line $\tilde{\ell}$ between p_{del} and p_{end}. Finally, we insert $p' = (\lfloor x^* \rfloor, r_z(\lfloor x^* \rfloor))$ and $p'' = (\lceil x^* \rceil, \tilde{\ell}(\lceil x^* \rceil))$ to $\tilde{\mathcal{P}}$ (as in the warmup algorithm of Section 3.1), update D_α and D_β with the new parameters of the segments ending and starting at p' or at p'', and set $\rho_z = \infty$.

▶ **Lemma 14.** *Applying* flush *to an active point* $q_z \in \mathcal{P}_{\text{active}}$ *preserves Invariants 1–3. Furthermore, it guarantees that the restriction of* $\mathcal{P}$ *and* $\tilde{\mathcal{P}}$ *to the (passive) points between* q_z *and* q_{z+1} *is identical, and that for every* $x \in [x_z \dots x_{z+1}]$, $A[x] = \tilde{A}[x]$.

Proof. Invariant 2 is maintained because the flush operation sets ρ_z to ∞. Since $\rho_z > \gamma_z$, it is guaranteed by Lemma 12 that the scan of flush ends at q_{z+1} or before q_{z+1}. It follows that Invariant 1 is maintained because $\mathcal{P}_{\text{active}}$ does not change and flush only deletes passive points of $\tilde{\mathcal{P}}$. We proceed to prove that Invariant 3 is maintained. Note that ρ_z is set to ∞ by the end of flush, and that q_z remains the predecessor active point of every $x \in [x_z \dots x_{z+1}]$, so we need to show $A[x] = \tilde{A}[x]$. Let $x \in [x_z \dots x_{z+1}]$. If $x \leq x^*$, then before flush was applied, we had $\tilde{A}[x] \geq r_z(x)$, and therefore by Invariant 3 $A[x] = \min(\tilde{A}[x], r_z(x)) = r_z(x)$. Since flush sets the value of $\tilde{A}[x]$ to be $r_z(x)$ for $x < x^*$, Invariant 3 still holds. If $x > x^*$, the value of $\tilde{A}[x]$ is not changed by flush. Since the line $\tilde{\ell}$ between p_{del} and p_{end} starts not below the r_z and ends below r_z, its slope is smaller than ρ_z. Since the points between p_{end} and q_z (excluding q_z) are passive, the slopes of the corresponding segments are also lower than ρ_z and therefore $(x, \tilde{A}[x])$ is below r_z for every $x \in (x' \dots x_{z+1}]$. Due to Invariant 3 before the application of flush, we have $A[x] = \min(\tilde{A}[x], r_z(x)) = \tilde{A}[x]$. Therefore, assigning $\rho_z \leftarrow \infty$ and not changing $\tilde{A}[x]$ satisfies Invariant 3. ◀

4 Bounded DTW

In this section, we study the k-bounded version of DTW. In this version, every $\delta(a, b) \geq 1$, and we wish to compute $\mathsf{DTW}_k(S, T) = \min(\mathsf{DTW}(S, T), k + 1)$ for a given integer k. In this section, we prove the following theorem:

▶ **Theorem 15.** *The Dynamic Time Warping distance of two run-length encoded strings* S *and* T *with* n *and* m *runs respectively can be computed in* $\tilde{O}(nk)$ *time if* $\mathsf{DTW}(S, T) \leq k$.

The key structural insight for Theorem 15 is that there is a set of $O(nk)$ blocks containing all the vertices (x, y) with $\mathsf{dist}(x, y) \leq k$. Therefore, it is sufficient to process only those blocks instead of the entire grid. Informally, the set of $O(nk)$ blocks is a band of width $\Theta(k)$ around the main diagonal of blocks. This property holds since a path to a vertex outside the band requires $\Omega(k)$ orthogonal steps between blocks. Note that since every $\delta(a, b) \geq 1$, at least one of any two orthogonally adjacent blocks is a non-zero block, and the part of the path that goes through this block must incur a cost of at least 1. Formally:

▷ Claim 16. Let (x, y) be a vertex in the alignment graph. Let $B_{i,j}$ be the block containing (x, y). If $|j - i| > 2k$, then $\mathsf{dist}(x, y) > k$.

Proof. We assume without loss of generality that $j - i > 2k$. Let p be a path from $(0,0)$ to (x,y). Let $P = B_{i_1,j_1}, B_{i_2,j_2} \dots B_{i_{|P|},j_{|P|}}$ be the sequence of blocks visited by p (where $B_{i_1,j_1} = B_{0,0}$ and $B_{i_{|P|},j_{|P|}} = B_{i,j}$). Note that for every $a \in [1 \dots |P| - 1]$ we have $(i_{a+1}, j_{a+1}) \in \{(i_a + 1, j_a), (i_a, j_a + 1), (i_a + 1, j_a + 1)\}$. Since $j_{|P|} - i_{|P|} > 2k$, and $i_1 - j_1 = 0$, there must be at least $2k + 1$ values of $a \in [1 \dots |P| - 1]$ such that $(i_{a+1}, j_{a+1}) = (i_a, j_a + 1)$.

Consider a value of a with this property. Since the j_a'th run and the $(j_a + 1)$'th run in T are adjacent, they must consist of different symbols. It follows that either $c_{B_{i_a,j_a}} \geq 1$ or $c_{B_{i_a,j_a+1}} \geq 1$. Let $B' \in \{B_{i_a,j_a}, B_{i_a,j_a+1}\}$ be the block with non-zero weight. The fragment of p that goes through B' incurs a weight of at least 1. Note that every block may be associated with at most 2 different values of a - once when p enters the block and once when it leaves the block. Therefore, $2k + 1$ different values of a indicate that the cost of p is at least $k + 1$. ◁

We denote the set of blocks $B_{i,j}$ such that $|j - i| \leq 2k$ as the *band*. It follows directly from Claim 16 that if $\mathsf{dist}(x,y) \leq k$ for some vertex (x,y) then there is a shortest path from $(0,0)$ to (x,y) that uses only the vertices of the band. Therefore, we can set the weight of every block outside of the band to ∞. Then, instead of processing all the blocks, we only process the blocks of the band. Any block not in the band is considered vacuously processed. Before processing a block with an input that is not in the band, we initialize the values in the frontier corresponding to this input to ∞. This is implemented by an $\mathsf{AddConst}(i, j, \infty)$ for the appropriate interval $[i, j]$. Note that with this assignment, the inputs have the same values as if the algorithm would have processed all the blocks. Finally, the algorithm reports $\mathsf{DTW}_k(S,T) = \min(\mathsf{dist}(N,M), k+1)$.

Abstract

A class of graphs admits an adjacency labeling scheme of size $b(n)$, if the vertices in each of its n-vertex graphs can be assigned binary strings (called labels) of length $b(n)$ so that the adjacency of two vertices can be determined solely from their labels.

We give bounds on the size of adjacency labels for every family of monotone (i.e., subgraph-closed) classes with a "well-behaved" growth function between $2^{\Omega(n \log n)}$ and $2^{O(n^{2-\delta})}$ for any $\delta > 0$. Specifically, we show that for any function $f : \mathbb{N} \to \mathbb{R}$ satisfying $\log n \leqslant f(n) \leqslant n^{1-\delta}$ for any fixed $\delta > 0$, and some sub-multiplicativity condition, there are monotone graph classes with growth $2^{O(nf(n))}$ that do not admit adjacency labels of size at most $f(n) \log n$. On the other hand, any such class does admit adjacency labels of size $O(f(n) \log n)$. Surprisingly this bound is a $\Theta(\log n)$ factor away from the information-theoretic bound of $\Omega(f(n))$. Our bounds are tight upto constant factors, and the special case when $f = \log$ implies that the recently-refuted Implicit Graph Conjecture [Hatami and Hatami, FOCS 2022] also fails within monotone classes.

We further show that the Implicit Graph Conjecture holds for all monotone *small* classes. In other words, any monotone class with growth rate at most $n!\, c^n$ for some constant $c > 0$, admits adjacency labels of information-theoretic order optimal size. In fact, we show a more general result that is of independent interest: any monotone small class of graphs has bounded degeneracy. We conjecture that the Implicit Graph Conjecture holds for all hereditary small classes.

1 Introduction

A *class* of graphs is a set of graphs which is closed under isomorphism. For a class of graphs $\mathcal{X}$ we denote by $\mathcal{X}_n$ the set of graphs in $\mathcal{X}$ with vertex set $[n]$. The function $n \mapsto |\mathcal{X}_n|$ is called the *speed* of $\mathcal{X}$. A *coding* of graphs is a representation of graphs by words in the binary alphabet $\{0,1\}$. One of the main considerations with graph representations is their succinctness; clearly, any representation of n-vertex graphs in a class $\mathcal{X}$ would require at least $\lceil \log |\mathcal{X}_n| \rceil$ bits for some graphs in $\mathcal{X}_n$.

Another consideration is whether the representation is global or local. Standard graph representations, such as adjacency matrix or adjacency lists, are examples of *global* representations, where a graph is stored in a single data structure that needs to be accessed in order to query some information about the graph, e.g., adjacency between a pair of vertices. By contrast, in *local* graph representations, the encoding of a graph is distributed over its vertices in such a way that the queries can be answered by looking only into the local information associated with the vertices involved in the query. In this work we are concerned with local graph representations for adjacency queries, i.e., queries that given two vertices answer whether they are adjacent or not.

Let $\mathcal{X}$ be a class of graphs and $b : \mathbb{N} \to \mathbb{N}$ be a function. A *$b(n)$-bit adjacency labeling scheme* (or simply *$b(n)$-bit labeling scheme*) for $\mathcal{X}$ is a pair (encoder, decoder) of algorithms where for any n-vertex graph $G \in \mathcal{X}_n$ the encoder assigns binary strings, called *labels*, of length $b(n)$ to the vertices of G such that the adjacency between any pair of vertices can be inferred by the decoder only from their labels. We note that the decoder depends on the class $\mathcal{X}$, but not on the graph G. The function $b(\cdot)$ is the *size* of the labeling scheme. Adjacency labeling schemes were introduced by Kannan, Naor, and Rudich [24, 25], and independently by Muller [28] in the late 1980s and have been actively studied since then. Adjacency labeling schemes are closely related to induced universal graphs, which we will refer to simply as universal graphs. For a function $u : \mathbb{N} \to \mathbb{N}$, a *universal graph sequence* or simply *universal graph* of size $u(n)$ is a sequence of graphs $(U_n)_{n\in\mathbb{N}}$ such that for every $n \in \mathbb{N}$ the graph U_n has at most $u(n)$ vertices and every n-vertex graph in $\mathcal{X}$ is an induced subgraph of U_n. It was observed in [25] that for a class of graphs the existence of a $b(n)$-bit labeling scheme is equivalent to the existence of a universal graph of size $2^{b(n)}$.

The binary word, obtained by concatenating labels of the vertices of a graph $G \in \mathcal{X}_n$ assigned by an adjacency labeling scheme, uniquely determines graph G. Thus, a $b(n)$-bit labeling scheme cannot represent more than $2^{nb(n)}$ graphs on n vertices, and therefore, if $\mathcal{X}$ admits a $b(n)$-bit labeling scheme, then $|\mathcal{X}_n| \leqslant 2^{nb(n)}$. This implies a lower bound of $\frac{\log |\mathcal{X}_n|}{n}$ on the size $b(n)$ of any adjacency labeling scheme for $\mathcal{X}$. A natural and important question is: which classes admit an adjacency labeling scheme of a size that matches this information-theoretic lower bound?

We say that a graph class $\mathcal{X}$ admits an *implicit representation*, if it admits an information-theoretic *order optimal* adjacency labeling scheme, i.e., if $\mathcal{X}$ has a $b(n)$-bit labeling scheme, where $b(n) = O(\log |\mathcal{X}_n|/n)$. Equivalently, $\mathcal{X}$ admits an implicit representation if $\mathcal{X}$ has a universal graph of size $\exp(O(\log |\mathcal{X}_n|/n))$. For example, the class $\mathcal{A}$ of all graphs admits an implicit representation, because

$$|\mathcal{A}_n| = 2^{\binom{n}{2}} = 2^{\Theta(n^2)} \text{ and } b(n) = O\left(\frac{\log |\mathcal{A}_n|}{n}\right) = O(n),$$

and one can easily design an $O(n)$-bit labeling scheme for $\mathcal{A}$, e.g., by assigning to each vertex of a graph an $(n + \lceil \log n \rceil)$-bit label consisting of the row in an adjacency matrix of the graph corresponding to the vertex and the index of that row; in fact, as we discuss below, the class of all graphs admits an asymptotically optimal $(1 + o(1))n/2$-bit labeling scheme [3].

However, not every class admits an implicit representation. The following example is due to Muller [28] (see also [32]). Let $\mathcal{Y}$ be the class of graphs in which the number of edges does not exceed the number of vertices. It is easy to estimate that $|\mathcal{Y}_n| = 2^{O(n \log n)}$. To show that this class does not admit an implicit representation, consider an arbitrary n-vertex graph G. Obviously, G does not necessarily belong to $\mathcal{Y}$, but after adding $n^2 - n$ isolated vertices to G, we obtain a graph H on $N = n^2$ vertices that belongs to $\mathcal{Y}$. Now, if an $O(\log n)$-bit labeling scheme for $\mathcal{Y}$ existed, then the $O(\log N)$-bit adjacency labels for H could be used as $O(\log n)$-bit adjacency labels for G. Since, G was chosen arbitrarily, this is in contradiction with the lower bound of $\frac{\log |\mathcal{A}_n|}{n} = \Omega(n)$ on the size of any labeling scheme for the class $\mathcal{A}$ of all graphs.

The crucial property used in the above example is that by adding isolated vertices to a graph not in $\mathcal{Y}$, one can obtain a graph in $\mathcal{Y}$. Using more familiar terminology, one would say that class $\mathcal{Y}$ is not *hereditary*, i.e., it is not closed under vertex removal or, equivalently, under taking induced subgraphs. Many natural graph classes (e.g., forests, planar graphs, bipartite graphs, geometric intersection graphs) are hereditary. It turns out that finding a hereditary graph class that does not admit an implicit representation is a non-trivial question. The first instance of this question was asked by Kannan, Naor, and Rudich [24] for *factorial classes* (i.e., graph classes $\mathcal{X}$ with the speed $|\mathcal{X}_n| = 2^{O(n \log n)}$), which was later stated by Spinrad [32] in the form of a conjecture, that became known as the *Implicit Graph Conjecture*.

(*IGC*): Any hereditary graph class of at most factorial speed admits an $O(\log n)$-bit labeling scheme.

This question remained open for over 30 years until a recent breakthrough by Hatami and Hatami [23]. They showed that, for any $\delta > 0$, there exists a hereditary factorial class that does not admit a labeling scheme of size $n^{1/2-\delta}$, which is very far from the information-theoretic lower bound of $\Omega(\log n)$. This result leaves wide open the question of characterizing factorial hereditary graph classes that admit an implicit representation (see e.g. [22] for more discussion).

Factorial hereditary classes form an important family, as many classes of theoretical or practical interest are factorial (e.g., forests, planar graphs, disk graphs, graphs of bounded twin-width). However, as was noted by Spinrad [32], there is nothing that prevents one from considering implicit representability of other hereditary graph classes. Spinrad [32] raised this as the *Generalized Implicit Graph Question*, which we restate using the terminology of our paper as follows.

▶ **Question 1** ([32]). *Which hereditary graph classes admit implicit representations?*

The answer to this question is known for classes with $|\mathcal{X}_n| = 2^{\Omega(n^2)}$, and for *subfactorial* graph classes, i.e., classes $\mathcal{X}$ with $|\mathcal{X}_n| = 2^{o(n \log n)}$. Indeed, for the latter classes, it is known that they have at most exponential speed, i.e., $|\mathcal{X}_n| = 2^{O(n)}$ [2, 31], and also admit $O(1)$-bit labeling schemes [30]. For the former classes, the $O(n)$-bit labeling scheme mentioned above for the class $\mathcal{A}$ of all graphs is an order optimal labeling scheme. In fact, in this regime, *information-theoretic asymptotically optimal* (up to the second-order term) labeling schemes are available. For the class of all graphs, such results (in the language of universal graphs) were available since 1965 [27, 6, 3]. For proper hereditary graph classes $\mathcal{X}$ with the speed $2^{\Omega(n^2)}$, by the Alekseev–Bollobás–Thomason theorem [1, 9], their speed is $|\mathcal{X}_n| = 2^{(1-1/k(\mathcal{X}))n^2/2+o(n^2)}$, where $k(\mathcal{X})$ is an integer greater than 1. Recently, Bonamy, Esperet, Groenland, and Scott showed [10] that all such classes have asymptotically optimal adjacency labeling schemes of size $(1 - 1/k(\mathcal{X}))n/2 + o(n)$.

For the classes in the intermediate range, i.e., the classes with the speed between $2^{\Omega(n \log n)}$ and $2^{o(n^2)}$ the picture is much less understood (see Figure 1). Most known information is concentrated on the lower extreme of the range, i.e., around factorial speed, which was promoted by the Implicit Graph Conjecture. Factorial graph classes from certain families are known to admit implicit representations: proper minor-closed graph classes [20], graph classes of bounded degeneracy (equivalently, of bounded arboricity) [24], clique-width [15, 32] (see also [7]), and twin-width [13] all admit implicit representations. The only lower bound witnessing (non-constructively) factorial classes[1] that do not admit an implicit representation is the above-mentioned result by Hatami and Hatami [23]. A notable family of hereditary graph classes where Question 1 remains open is the *small* graph classes, i.e., classes $\mathcal{X}$ with $|\mathcal{X}_n| \leqslant n! \, c^n$ for some constant c. These classes encompass only the bottom part of the factorial layer and include proper minor-closed classes [8, 29], and more generally, classes of bounded twin-width [13]. However, it is still unknown if all such classes admit an implicit representation (see [12] for more details on implicit representation of small classes). Alon showed [4] that every hereditary graph class $\mathcal{X}$ with $|\mathcal{X}_n| = 2^{o(n^2)}$ admits an $n^{1-\delta}$-bit labeling scheme for some $\delta > 0$.

1.1 Our contribution

In this paper, we study Question 1 for *monotone* graph classes, i.e., graph classes that are closed under taking subgraphs. Monotone graph classes form a subfamily of hereditary graph classes. Many interesting and natural classes are monotone, for example classes of bounded chromatic number/index, bounded clique number, bounded genus, triangle free, and so on. Together with some previous results mentioned in the introduction, the contribution of this paper is to give a near complete resolution of Question 1 for monotone classes.

The *degeneracy* of a graph G is the minimum d such that every subgraph of G has a vertex of degree at most d. We say that a class of graphs $\mathcal{X}$ has bounded degeneracy, if there exists a constant d such that the degeneracy of every graph $G \in \mathcal{X}$ is at most d; otherwise, we say that $\mathcal{X}$ has unbounded degeneracy. Our first main result shows that degeneracy is bounded for monotone small classes.

▶ **Theorem 2.** *Let $\mathcal{X}$ be a monotone small class. Then, $\mathcal{X}$ has bounded degeneracy.*

Theorem 2 has wider reaching implications than just labeling schemes, and is of independent interest. In the context of Question 1, we obtain the following result from Theorem 2 and a classical labeling scheme for classes of bounded degeneracy [24] (see also Lemma 14).

▶ **Theorem 3.** *Any monotone small class admits an implicit representation.*

This answers Question 1 from [12] for monotone graph classes.

We now turn to monotone classes that are not small. Our next result shows that any monotone class with non-decreasing speed admits a labeling scheme of size at most $O(\log n)$ away from the information-theoretic lower bound.

▶ **Proposition 4.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a non-decreasing function. Then, any monotone class of graphs $\mathcal{X}$ with speed $|\mathcal{X}_n| = 2^{O(nf(n))}$ admits an adjacency labeling scheme of size $O(f(n) \log n)$.*

[1] This lower bound is sufficiently large to rule out the existence of implicit representations even for hereditary classes of size $2^{\Theta(n^{3/2-\delta})}$, for any fixed $0 < \delta < 1/2$.

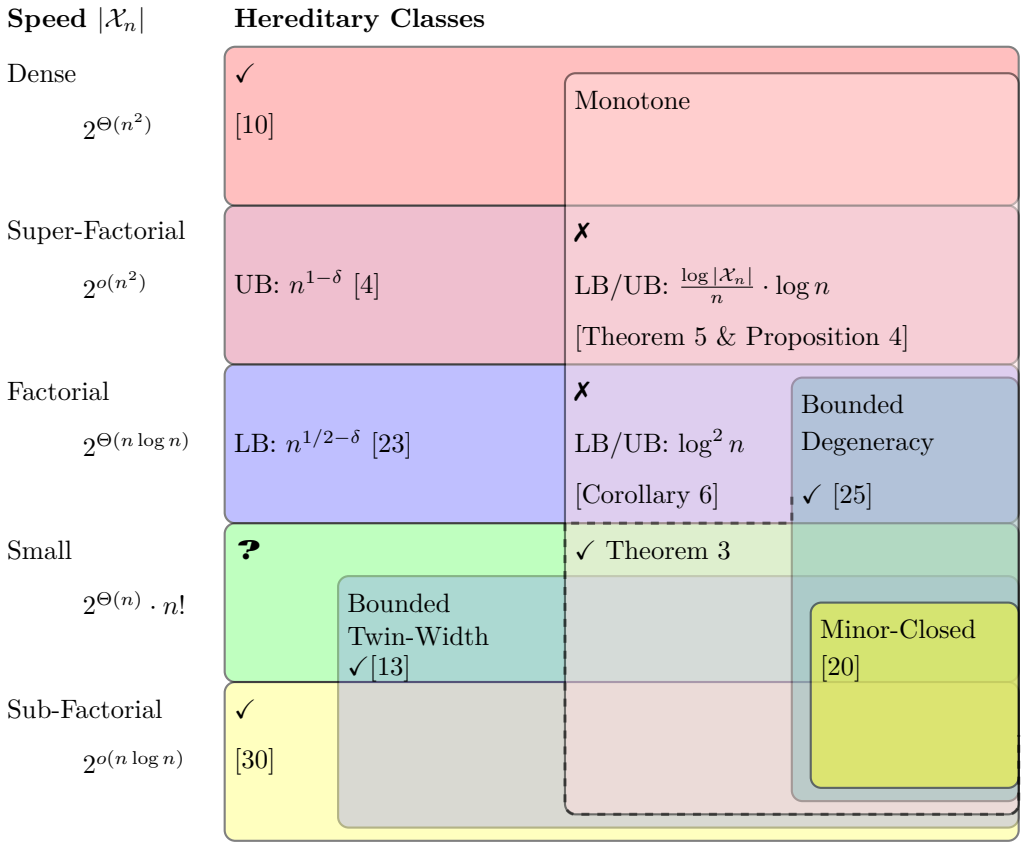

Figure 1 A ✓ indicates that all classes of the given type have an implicit representation, a ✗ shows that they do not, and a **?** signals that the question is open. A ✓ is inherited by every sub-region, a ✗ is inherited to the left of the marked region, and a **?** only holds in that region. The upper and lower bounds (UB and LB respectively) are stated up to constants which may depend on the class. The dashed extension of the *bounded degeneracy* region illustrates its containment of monotone small classes (Theorem 3).

This upper bound is an easy consequence of an estimation of the number of edges in graphs from monotone classes combined with a standard labeling scheme for k-degenerate graphs [24]. Our second main result shows that this upper bound is attained by some monotone classes. Before stating the result formally we must briefly introduce a family of non-decreasing functions we call "decent". Roughly speaking, on some domain $[s, \infty)$, decent functions are sub-multiplicative, i.e., $f(xy) \leqslant f(x)f(y)$, and moderate-growing, that is $\log x \leqslant f(x) \leqslant x^{1-\delta}$ for some constant $\delta \in (0, 1)$, see Definition 16 for the formal definition of decent functions.

▶ **Theorem 5.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a decent function. Then, there exists a monotone graph class $\mathcal{X}$ with speed $|\mathcal{X}_n| = 2^{O(nf(n))}$ that does not admit a universal graph of size at most $2^{f(n)\log n}$. Equivalently, $\mathcal{X}$ admits no adjacency labeling scheme of size at most $f(n)\log n$.*

Theorem 5 gives the existence of monotone classes requiring labels whose size is a $\log n$-factor above the information-theoretic lower bound. In particular, this shows that Proposition 4 is tight. A special case of Theorem 5 (when $f(x) = \log x$) implies that the Implicit Graph Conjecture does not hold even for monotone graph classes. Combining this observation with Proposition 4 gives the following result.

▶ **Corollary 6.** *For any constant $c > 0$, there are factorial monotone classes that do not admit a $(c \log^2 n)$-bit labeling scheme, while any factorial monotone class admits an $O(\log^2 n)$-bit labeling scheme.*

This result (more generally Theorem 5 and Proposition 4) gives the first example of tight bounds for families of graph classes that do not admit information-theoretic order optimal adjacency labeling schemes. Chandoo [14] observed that the proof of the refutation of the IGC by Hatami and Hatami [23] implies that the family of factorial classes cannot be "described" by a countable set of factorial classes. Using the same ideas, we establish the following result from our proof for monotone classes.

▶ **Theorem 7.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be any decent function, and $\mathbb{X}$ be any countable set of graph classes, each with speed at most $2^{nf(n)\log n}$. Then, there exists a monotone graph class $\mathcal{X}$ of speed $2^{O(nf(n))}$ such that there does not exist a $\mathcal{D} \in \mathbb{X}$ with $\mathcal{X} \subseteq \mathcal{D}$.*

This shows that monotone classes are complex in the sense that they cannot be covered by a countably infinite family of classes growing slightly faster, even if these classes are not restricted to being hereditary (thus, also to being monotone).

1.2 Proof outline and techniques

Monotone small classes have bounded degeneracy and implicit representations

We establish Theorem 2 in the contrapositive: if a monotone class $\mathcal{X}$ has unbounded degeneracy, then it is not small. To prove this we establish the following two intermediate steps:

1. We first show that every graph of minimum degree d admits an induced subgraph with minimum degree at least d that has a spanning tree of *maximum* degree at most d.
2. Next, we show that if $\mathcal{G} = \mathrm{Mon}(\{G\})$, where G is any graph with minimum degree $d \geqslant 1000$, then there exists a $k \in \mathbb{N}$ such that $|\mathcal{G}_k| \geqslant k! \cdot 2^{kd/3}$.

   To achieve this, we start from an induced graph H of G satisfying the previous item, with $k = |V(H)|$ and $m = |E(H)|$. Graph H can be shown to have at least $2^{4m/5}$ pairwise non-isomorphic spanning subgraphs, due to its large minimum degree. Let us denote by $\mathcal{F}$ this set of subgraphs. Crucially each member of $\mathcal{F}$ has at most $2^{m/10}$ automorphisms, due to the spanning tree of bounded maximum degree. We conclude since $|\mathcal{G}_k| \geqslant \sum_{F \in \mathcal{F}} \frac{k!}{\mathrm{aut}(F)}$.

Finally, to show the contrapositive of Theorem 2, we consider an arbitrary monotone class $\mathcal{X}$ of unbounded degeneracy and assume that for some constant c we have $|\mathcal{X}_n| \leqslant n!\, c^n$ for every $n \in \mathbb{N}$. Since $\mathcal{X}$ has unbounded degeneracy, it contains a graph G with arbitrarily large minimum degree d. If we take d suitably large, then applying Step 2 to such a graph yields a contradiction with the assumption of smallness of $\mathcal{X}$.

Having established Theorem 2, any small monotone class $\mathcal{X}$ has bounded degeneracy. Thus, Theorem 3 follows by applying a classical $O(\log n)$-bit labeling scheme for classes of bounded degeneracy [25], see Lemma 14 for a description of this scheme.

Monotone classes that do not admit implicit representations

Recall that, roughly speaking[2], a function $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ is decent if $\log x \leqslant f(x) \leqslant x^{1-\delta}$ for some constant $\delta \in (0, 1)$, and f is sub-multiplicative, i.e., $f(xy) \leqslant f(x) \cdot f(y)$, for all x, y in the domain. Our approach is inspired by the refutation of the IGC by Hatami and Hatami [23]. Namely, for any decent function f, we expose so many *monotone* classes of speed $2^{nf(n)}$ that there are not enough universal graphs of size $2^{f(n)\log n}$ to capture all of them. The approach involves several key ingredients:

1. Estimation of the number of sets of graphs of fixed cardinality representable by universal graphs. A set of graphs $\mathcal{M}$ is *representable* by a universal graph U, if every graph in $\mathcal{M}$ is an induced subgraph of U. A direct estimation shows that the number of sets of cardinality $k_n := \lceil 2^{\sqrt{nf(n)}} \rceil$ of n-vertex graphs that are representable by a u_n-vertex universal graph, with $u_n := 2^{f(n)\log n}$, is at most
$$2^{u_n^2} \cdot u_n^{nk_n} = 2^{2^{2f(n)\log n} + k_n \cdot nf(n)\log n}. \tag{1}$$
2. Notion of *f-good graphs*. We will construct our monotone classes of speed $2^{nf(n)}$ by taking the monotone closure of an appropriately chosen set of graphs. The monotonicity and the speed of target classes impose a natural restriction on the number of edges in graphs that can be used in such constructions. To explain, let $\mathcal{X}$ be a monotone class with $|\mathcal{X}_n| \leqslant 2^{nf(n)}$. Since $\mathcal{X}$ is closed under taking subgraphs, if $\mathcal{X}$ contains an n-vertex graph with m edges, then $\mathcal{X}$ contains at least 2^m labeled n-vertex graphs. This, together with the speed assumption, imply that for any $G \in \mathcal{X}$ and k, every subgraph of G on k vertices contains at most $kf(k)$ edges.

   This restriction, however, is not strong enough for our purposes. Indeed, while each graph with the above property contributes to the monotone closure an appropriate number of subgraphs at every *level* (i.e., on every number of vertices), we build our desired classes by taking the monotone closure of *infinitely* many of such graphs, and this can result in some levels having too many graphs. To overcome this difficulty, we introduce the notion of *f-good* graphs, which are n-vertex graphs in which the number of edges in every k-vertex subgraph is at most $kf(k)$ if $k > \sqrt{n}$, and at most $\frac{kf(k)}{\log k}$ if $2 \leqslant k \leqslant \sqrt{n}$. The latter condition ensures that if we take the monotone closure of a set of f-good graphs, then all sufficiently small subgraphs of any graph in this class belong to a *fixed* monotone class of speed $2^{nf(n)}$. Namely, the class of all n-vertex graphs in which very k-vertex subgraph has at most $\frac{kf(k)}{\log k}$ edges for every $2 \leqslant k \leqslant n$.
3. Construction of monotone classes of speed $2^{nf(n)}$ from sets of f-good graphs. We show that for any sequence $(\mathcal{M}_n)_{n\in\mathbb{N}}$, where $\mathcal{M}_n$ is a set of f-good n-vertex graphs of cardinality k_n, the monotone closure $\mathrm{Mon}(\cup_{n\in\mathbb{N}}\mathcal{M}_n)$ has speed at most $2^{nf(n)}$.
4. Lower bound on the number of sets of cardinality k_n of f-good n-vertex graphs. We show that for any $\gamma > 1$, there exists some $c := c(\gamma, \delta) > 0$ such that for every $n \in \mathbb{N}$ there are at least $2^{(\gamma\delta/2 - o(1)) \cdot nf(n)\log n}$ many unlabeled cf-good n-vertex graphs. Thus, the number of sets of cardinality k_n of cf-good n-vertex graphs is at least
$$2^{k_n \cdot (\gamma\delta/2 - o(1)) \cdot nf(n)\log n}. \tag{2}$$

[2] The formal definition of decent (Definition 16) is more general and depends on three parameters δ, C, s. For this proof sketch it suffices to work with the simplified (informal) definition above which only has one parameter δ.

By setting $\gamma = 4/\delta$ and recalling that $k_n = \lceil 2^{\sqrt{nf(n)}} \rceil$, we show that Equation (2) is larger than Equation (1). Therefore, there exists a monotone class $\mathrm{Mon}(\cup_{n\in\mathbb{N}}\mathcal{M}_n)$ of speed $2^{nf(n)}$ that is not representable by a universal graph of size $2^{f(n)\log n}$.

Many f-good graphs

A core step in the above approach is to show that for any $\gamma > 1$, there exists some $c := c(\gamma, \delta) > 0$ such that the number of n-vertex cf-good graphs grows as $2^{(\gamma\delta/2-o(1))\cdot nf(n)\log n}$. To do so, we show that a random graph $G_n \sim G(n, \gamma f(n)/n)$ is cf-good with high probability (*w.h.p.*). It is in this step that we really need to use the sub-multiplicativity property of decent functions, as we need to relate the magnitude of f at two different parts of its domain.

In particular, to show that w.h.p. G_n is cf-good, we apply a first moment bound to show there are no "large" k-vertex subgraphs of G_n with more than $ckf(k)$ edges, and "small" ones with more than $ckf(k)/\log k$ edges. Observe that the number of edges ξ in a given k-vertex subgraph has expectation $\binom{k}{2}\frac{\gamma f(n)}{n}$. Thus, for "large" subgraphs, the probability that ξ is constant factor larger than $ckf(k)$ decays with exponent $\propto -f(k)\cdot\ln\frac{nf(k)}{kf(n)}$ by the Chernoff bound. From this we see that unless $f(k)/f(n) > k/n$, then the bound fails. Sub-multiplicativity helps us here as it allows us to say $f(n) = f(k\cdot(n/k)) \leqslant f(k)\cdot f(n/k)$, moderate-growth then bounds the term $f(n/k)$. A similar issue occurs for "small" subgraphs.

From the explanation above it may seem that needing such tight control over the ratio of $f(k)$ to $f(n)$ for all $k \leqslant n$ is an artifact of our proof, however some "smoothness" condition on the function is necessary. To see this, consider a function $f : \mathbb{N} \to \mathbb{R}_{\geqslant 0}$ such that $f(n) = \log n$, if n is odd, and $f(n) = \sqrt{n}$, if n is even. Then, for any $c > 0$, and large enough even n, $G(n, f(n)/n)$ will not be cf-good as the restriction on the subgraphs with odd number of vertices is far too stringent. Sub-multiplicativity was the most natural and broad condition we could find to combat this issue, and we show in Lemma 17 that many common functions growing at a suitable rate satisfy this.

It would be interesting to see if sub-multiplicativity can be replaced with something more general. We also used sub-multiplicativity in Step 3 above (which corresponds to Lemma 22) to bound the speed of $\mathrm{Mon}(\cup_{n\in\mathbb{N}}\mathcal{M}_n)$, however it is possible that some less stringent property can be used there.

A matching upper bound on the size of adjacency labels

We show that for any non-decreasing function $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$, any monotone class with speed $2^{O(nf(n))}$ admits an $O(f(n)\log n)$-bit labeling scheme. This follows from an easy observation that any such class is $O(f(n))$-degenerate, followed by the same standard $O(k\log n)$-bit labeling scheme for k-degenerate graphs used to prove Theorem 3. One consequence of this upper bound is that our result on the "f-goodness" of a random graph (Theorem 18) is tight: for any $p \in \omega(f(n)/n)$ and $c \geqslant 0$, a random graph $G_n \sim G(n,p)$ is not cf-good w.h.p.

1.3 Discussion

A natural question arising from our work is to characterize monotone classes that admit an implicit representation. Motivated by the Implicit Graph Conjecture, of particular interest is the case of factorial classes.

▶ **Question 8.** *Which* monotone *factorial graph classes admit an* $O(\log n)$*-bit labeling scheme?*

An analogous question is completely understood for constant-size *adjacency sketches* (a probabilistic version of adjacency labeling schemes) that were studied in [18, 21, 22]. The importance of constant-size adjacency sketches is that they can be derandomized to $O(\log n)$-bit adjacency labels [21, 22]. Thus, if a class admits constant-size adjacency sketches, then it admits an $O(\log n)$-bit labeling scheme. Though, the converse is not always true. Esperet, Harms, and Kupavskii showed [16] that a monotone class admits constant-size adjacency sketches if and only if it has bounded degeneracy. This result may suggest that bounded degeneracy also characterizes monotone classes that admit $O(\log n)$-bit labeling schemes. This, however, is not the case, as the class of subgraphs of hypercubes is monotone, has unbounded degeneracy, and admits an $O(\log n)$-bit labeling scheme [17].

Recall that Question 1 (first raised in [32]), asks which hereditary graph classes admit implicit representations. A prominent instance of Question 1 is whether every hereditary small class admits an implicit representation. It was shown in [12] that for any $\kappa > 0$ there is a monotone small class which does not admit a $(\kappa \log n)$-bit labeling scheme; in particular, some monotone small classes admit no *information-theoretic asymptotically optimal* labeling scheme. One of our main results (Theorem 3) shows that every monotone class admits an *information-theoretic order optimal* labeling scheme, i.e., an implicit representation. We conjecture that the same holds for all hereditary small classes.

▶ **Conjecture 9** (Small Implicit Graph Conjecture). *Any hereditary small class admits an implicit representation.*

Conjecture 9 is also known to hold for classes of bounded twin-width [13].

We conclude this discussion with a more technical (yet natural) question of whether the conditions (moderate-growth and sub-multiplicativity) of "decent" can be relaxed. Due to the discussion under the heading "Many f-good graphs" in Section 1.2, the moderate-growth condition is essentially necessary, and if one is to follow our method, some notion of global "smoothness" is required to prove Theorem 18. However, it is not so clear to what extent the sub-multiplicativity condition is necessary to achieve the required "smoothness".

1.4 Organization

The rest of the paper is organized as follows. In Section 2, we cover some common notation and definitions. In Section 3, we prove our first main result, namely, that any monotone small class has bounded degeneracy, and therefore admits an implicit representation. Sections 4 and 5 are devoted to our second main result, namely, tight bounds on the size of adjacency labeling schemes for monotone classes. In Section 4.1 we introduce two key concepts used in the proofs. Firstly, we give the notion of *f-good* graphs, which are the building blocks for the monotone classes used to prove the lower bounds. Secondly, we formally define *decent* functions which describe the speeds of these monotone graph classes, before concluding Section 4.1 with some natural examples of decent functions. In Section 4.2, we prove a result about random graphs which is the main technical ingredient of our lower bounds. In Section 5, we establish the lower and upper bounds on labeling schemes for monotone classes, along with the result on the complexity of monotone graph classes.

2 Standard definitions and notation

We let $[n]$ denote the set $\{1, \dots, n\}$ of natural numbers, and use $\ln^c x$ as a shorthand for $(\ln x)^c$. We take $\mathbb{R}_{\geqslant 0}$ to denote the set of non-negative real numbers. We use $X \sim \mathcal{D}$ to denote that the random variable X has distribution $\mathcal{D}$. We say that a sequence of events (A_n) holds *with high probability (w.h.p.)* if $\mathbb{P}[A_n] \to 1$ as $n \to \infty$.

We consider finite undirected graphs, without loops or multiple edges. Given a graph G, we write $V(G)$ for its vertex set, and $E(G)$ for its edge set. A graph H is a *subgraph* of G if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. Thus, H can be obtained from G by vertex and edge deletions. The graph H is an *induced subgraph* of G if $V(H) \subseteq V(G)$, and $E(H)$ consists exactly of the edges in $E(G)$ with both endpoints in $V(H)$. In that case, H can be obtained from G by vertex deletions only. In the usual way, for a set of vertices $U \subseteq V(G)$, we denote by $G[U]$ the induced subgraph of G with the set of vertices U. We denote by $e(G)$ the number of edges in G

When we refer to an n-vertex graph G as *labeled*, we mean that the vertex set of G is $[n]$, and we distinguish two different labeled graphs even if they are isomorphic. In contrast, if we refer to G as *unlabeled* graph, its vertices are indistinguishable and two isomorphic graphs correspond to the same unlabeled graph.

A graph class is *hereditary* if it is closed under taking induced subgraphs, and it is *monotone* if it closed under taking subgraphs. For a set $\mathcal{X}$ of graphs we let $\mathrm{Her}(\mathcal{X})$ denote the hereditary closure of $\mathcal{X}$, i.e., the inclusion-wise minimal hereditary class that contains $\mathcal{X}$; and $\mathrm{Mon}(\mathcal{X})$ denote the monotone closure of $\mathcal{X}$, i.e., the minimal monotone class that contains $\mathcal{X}$.

3 Monotone small classes admit an implicit representation

In this section we show that any monotone small class admits an implicit representation. To do so, we first establish (Theorem 2) that any small monotone classes has bounded degeneracy. This result has a broader scope than just implicit representations, and is of independent interest. For example, it generalizes the fact that monotone classes of bounded twin-width have bounded degeneracy [13, $(iv) \Rightarrow (iii)$ in Theorem 2.12]. The labeling scheme for monotone small classes then follows from a classical labeling scheme for graphs of bounded degeneracy, see Lemma 14.

We proceed with some notation and known auxiliary facts that we will employ in the proof. Recall that for a class of graphs $\mathcal{X}$, we denote by $\mathcal{X}_n$ the set of graphs in $\mathcal{X}$ with vertex set $[n]$. We will denote by $\mathcal{X}_n^u$ the set of *unlabeled* n-vertex graphs in $\mathcal{X}$, i.e., the set of isomorphism classes in $\mathcal{X}_n$. Observe that for an unlabeled n-vertex graph G there are exactly $\frac{n!}{\mathrm{aut}(G)}$ labeled graphs isomorphic to G, where $\mathrm{aut}(G)$ is the order of the automorphism group of G. Thus we have

$$|\mathcal{X}_n| = \sum_{G \in \mathcal{X}_n^u} \frac{n!}{\mathrm{aut}(G)}.$$

Let F be a spanning subgraph of a fixed labeled graph G. Thus, we recall, F is defined by a subset of $E(G)$. We denote by $\#\mathrm{Sub}(F \to G)$ the number of subgraphs of G isomorphic to F, and by $\#\mathrm{Emb}(F \to G)$ the number of embeddings of F into G, i.e., the number of permutations from $\mathfrak{S}_n$ that map F to an isomorphic copy of F in G. Thus,

$$\#\mathrm{Emb}(F \to G) = \#\mathrm{Sub}(F \to G) \cdot \mathrm{aut}(F).$$

We will use the following well known facts (see e.g. [26]).

▶ **Lemma 10.** *Let F be a spanning subgraph of a graph G. Then*

$$\mathrm{aut}(G) \leqslant \#\mathrm{Emb}(F \to G) = \#\mathrm{Sub}(F \to G) \cdot \mathrm{aut}(F).$$

▶ **Lemma 11.** *Let G be a connected graph of maximum degree Δ. Then*

$$\mathrm{aut}(G) \leqslant n \cdot \Delta! \cdot (\Delta - 1)^{n-\Delta-1} \leqslant n\Delta^{n-1}.$$

We start with the following deceptively simple lemma.

▶ **Lemma 12.** *Let G be a graph of minimum degree d. Then G has an induced subgraph H of minimum degree at least d with a spanning tree of* maximum degree *at most d.*

Proof. Let T be an inclusion-wise maximal tree among subgraphs of G with maximum degree at most d. Let H be $G[V(T)]$. Note that any vertex v of H that has degree less than d in T, has no neighbors among $V(G) \setminus V(H)$ in G, as otherwise T could have been extended by adding any neighbor of v from $V(G) \setminus V(H)$, which would contradict the maximality of T. Thus all neighbors of v are in $V(H)$, which implies that the minimum degree of H is at least d. ◀

We show next that if a graph has large minimum degree and a spanning tree of bounded maximum degree, then it contains many pairwise non-isomorphic spanning connected subgraphs with a small number of automorphisms.

▶ **Lemma 13.** *Let G be an n-vertex m-edge connected graph of minimum degree $d \geqslant 1000$, with a spanning tree of maximum degree at most d. Then, G contains at least $2^{4m/5}$ pairwise non-isomorphic spanning connected subgraphs F with* $\mathrm{aut}(F) \leqslant 2^{m/10}$. *Consequently,* $\mathrm{Mon}(\{G\})$ *contains at least $n! \cdot 2^{nd/3}$ graphs on vertex set $[n]$.*

Proof. Fix a spanning tree T of G of maximum degree at most d. Denote by $\mathcal{F}$ the family of all subgraphs of G containing T. Then,

$$|\mathcal{F}| = 2^{m-n+1} \geqslant 2^{m-\frac{2m}{d}} \geqslant 2^{9m/10},$$

where we used the fact that $n \leqslant 2m/d$ by the assumption on the minimum degree of G, and the assumption $d \geqslant 1000$.

For a fixed graph $F \in \mathcal{F}$, we will now estimate the number $N_{\mathcal{F}}(F)$ of graphs in $\mathcal{F}$ that are isomorphic to F. This number is at most the number $\#\mathrm{Emb}(T \to G) = \#\mathrm{Sub}(T \to G) \cdot \mathrm{aut}(T)$ of embeddings of T into G. The number $\#\mathrm{Sub}(T \to G)$ of subgraphs of G isomorphic to T is at most

$$\binom{m}{n-1} \leqslant \binom{m}{2m/d} \leqslant \left(\frac{ed}{2}\right)^{2m/d} \leqslant 2^{m/20},$$

where the last inequality holds for every $d \geqslant 1000$. Recalling that the maximum degree of T is at most d and using Lemma 11, we conclude that $\mathrm{aut}(T) \leqslant nd^{n-1} \leqslant 2^{2n \log d}$. Consequently,

$$N_{\mathcal{F}}(F) \leqslant \#\mathrm{Emb}(T \to G) \leqslant 2^{m/20} \cdot 2^{2n \log d} \leqslant 2^{m/20 + 2(2m/d)\log d} \leqslant 2^{m/10}, \tag{3}$$

where again we used $n \leqslant 2m/d$ and $d \geqslant 1000$. Note that the bound in (3) holds for any $F \in \mathcal{F}$. Thus, the number of pairwise non-isomorphic graphs in $\mathcal{F}$ is at least

$$\frac{|\mathcal{F}|}{\max_{F \in \mathcal{F}} N_{\mathcal{F}}(F)} \geqslant 2^{9m/10} \cdot 2^{-m/10} = 2^{4m/5}.$$

Furthermore, for any $F \in \mathcal{F}$, we have

$$\mathrm{aut}(F) \leqslant \#\mathrm{Sub}(T \to F) \cdot \mathrm{aut}(T) \leqslant \#\mathrm{Sub}(T \to G) \cdot \mathrm{aut}(T) = \#\mathrm{Emb}(T \to G) \leqslant 2^{m/10},$$

where we used Lemma 10, the fact that $\#\mathrm{Sub}(T \to F) \leqslant \#\mathrm{Sub}(T \to G)$, and (3).

Finally, the number of graphs with vertex set $[n]$ isomorphic to a subgraph of G is at least

$$\sum_{F \in \mathcal{F}} \frac{n!}{\mathrm{aut}(F)} \geqslant 2^{4m/5} \cdot \frac{n!}{2^{m/10}} = n! \cdot 2^{7m/10} \geqslant n! \cdot 2^{dn/3},$$

where in the last inequality we used $m \geqslant dn/2$. ◀

We can now prove the main result of this section.

▶ **Theorem 2.** *Let $\mathcal{X}$ be a monotone small class. Then, $\mathcal{X}$ has bounded degeneracy.*

Proof. To prove the theorem we will show the contrapositive, i.e., if a class $\mathcal{X}$ has unbounded degeneracy, then it is not small. Suppose towards a contradiction that $\mathcal{X}$ has unbounded degeneracy, but there exists a constant c, such that $|\mathcal{X}_n| \leqslant n! \cdot c^n$ holds for every $n \in \mathbb{N}$.

Since $\mathcal{X}$ has unbounded degeneracy and is closed under taking subgraphs, for any positive d, the class $\mathcal{X}$ contains a connected graph with minimum degree at least d. Fix any $d > \max\{1000, 3\log c\}$, and let $G \in \mathcal{X}$ be a connected graph of minimum degree at least d. Let $\mathcal{G} = \mathrm{Mon}(\{G\})$. By Lemmas 12 and 13, for some $n \in \mathbb{N}$ we have

$$|\mathcal{G}_n| \geqslant n! \cdot 2^{nd/3} > n! \cdot 2^{n \log c} = n! \cdot c^n,$$

where the first strict inequality holds due to $d > 3\log c$. Since $\mathcal{G} \subseteq \mathcal{X}$, this is in contradiction with the assumed upper bound on the number of labeled graphs in $\mathcal{X}$. Thus $\mathcal{X}$ is not small. ◀

The previous result is of independent interest, and provides some structural insight on monotone small classes. To show that some property generally holds on small monotone classes, one can now use their degeneracy. We give the first such application of Theorem 2.

▶ **Theorem 3.** *Any monotone small class admits an implicit representation.*

The relevance of Theorem 2 to labeling schemes should be clear from the following folklore bound [25], which we recall for completeness.

▶ **Lemma 14.** *The class of k-degenerate graphs has a $(k+1) \cdot \lceil \log n \rceil$-bit adjacency labeling scheme.*

Proof. For any k-degenerate graph G on n-vertices, we first order vertices so that each vertex has at most k neighbors appearing after it in the ordering. This can be done greedily since each subgraph has a vertex of degree at most k. One can then assign each vertex a label consisting of its place in the order, followed by the places of the at most k neighbor vertices following it in the ordering. ◀

Theorem 3 follows directly from Lemma 14 and Theorem 2.

4 Ingredients for the proof of the lower bound

This section contains many of the components needed to construct the classes used in the proof of the lower bound (Theorem 5). In Section 4.1 we introduce several notions related to subgraph density, which are then applied to random graphs in Section 4.2.

4.1 Good graphs and decent functions

Our first definition describes graphs which do not have overly dense subgraphs.

▶ **Definition 15** (f-good)**.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a function. An n-vertex graph G is* f-good *if the number of edges in any subgraph on k vertices is bounded from above by*

$$\begin{cases} \frac{k \cdot f(k)}{\log k} & \text{if } 2 \leqslant k \leqslant \sqrt{n} \\ k \cdot f(k) & \text{if } \sqrt{n} < k \leqslant n \end{cases}.$$

We observe that f-goodness is a monotone property, i.e., if a graph G is f-good, then so is any of its subgraphs. Indeed, moving the threshold (between the first and the second, more relaxed, upper bound) from $\sqrt{n}$ down to a smaller value may only help in satisfying these bounds.

The next definition gives a class of functions used to describe speeds of monotone classes, where, for such a function $f(n)$, we will consider classes of growth $2^{nf(n)}$.

▶ **Definition 16** (*(δ, C, s)-decent*). *For constants $\delta \in (0,1)$, $C \geqslant 1$ and $s \geqslant 2$, we say that a non-decreasing function $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ is* (δ, C, s)-decent *if the following properties hold*
(Moderate-growth): *$\log x \leqslant f(x) \leqslant C \cdot x^{1-\delta}$ holds for every $x \in [s, \infty)$,*
(Sub-multiplicativity): *$f(xy) \leqslant C \cdot f(x) \cdot f(y)$ holds for any $x, y \in [s, \infty)$.*

We say that a function f is *decent* if there exist some constants $\delta \in (0,1)$, $C \geqslant 1$, and $s \geqslant 2$ such that f is (δ, C, s)-decent. For any constant $\kappa \geqslant 1$, the function $f(x) = \kappa \log x$ is decent; this captures factorial growth. We now give some other natural examples of decent functions, due to space constraints a proof can be found in the full version [11].

▶ **Lemma 17.** *For any fixed $\alpha > 0, \beta \geqslant 1, \gamma \geqslant 1$ and $d \in (0,1)$, the following are decent:*
(i) $f(x) = \alpha x^d$,
(ii) $f(x) = \exp\left(\alpha \cdot \ln^d x\right)$,
(iii) $f(x) = \exp\left(\beta \cdot \ln^\gamma(\log x)\right)$,
(iv) $f(x) = \beta \cdot g(x)$, *where $g(x)$ is decent,*
(v) $f(x) = g(x) \cdot h(x)$, *where $g(x), h(x)$ are decent and $g(x) \cdot h(x)$ is moderately-growing.*

4.2 Growth of the number of edges in subgraphs of random graphs

The aim of this Section is to show that there are many graphs which are suitable for building the classes we need to prove Theorem 5. We will achieve this using random graphs, where $G(n,p)$ denotes the distribution on n-vertex graphs where each edge is included independently with probability p, see (for example) [19]. Our main result shows that random graphs are suitable with high probably.

▶ **Theorem 18.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be (δ, C, s)-decent for some constants $\delta \in (0,1)$, $C \geqslant 1$, and $s \geqslant 2$. Then, for any fixed $\gamma > 1$, there exists $c := c(\delta, C, s, \gamma) > 0$ such that, for large n,*

$$\mathbb{P}\left[\, G(n, \gamma f(n)/n) \text{ is not } (cf)\text{-good} \,\right] \leqslant n^{-2}.$$

To prove this we will utilize the following version of the Chernoff bound (see [5, Theorem A.1.15]), where $\mathrm{Bin}(N,p)$ denotes the binomial distribution with parameters N and p.

▶ **Lemma 19** (Chernoff bound). *Let $\xi \sim \mathrm{Bin}(N,p)$, $\mu = Np$, and $a, t > 0$. Then,*

$$\mathbb{P}(\xi > (1+a)\mu) \leqslant \left(\frac{e^a}{(1+a)^{1+a}}\right)^\mu \leqslant \exp\left(-(1+a)\mu \cdot \ln\frac{1+a}{e}\right).$$

Proof of Theorem 18. Let $p := p(n) = \gamma f(n)/n$, and let c_1, c_2 be sufficiently large constants (depending on γ) fixed later. Let $\mathcal{E}_{1,k}$ (respectively $\mathcal{E}_{2,k}$) be the event that there are no subgraphs of size k with more than $c_1 k f(k)/\log k$ edges (respectively $c_2 k f(k)$ edges). Observe that if $c = \max\{c_1, c_2, \binom{s}{2}\}$, then

$$\{G(n,p) \text{ is not } (cf)\text{-good}\} \subseteq \left(\bigcup_{k=s}^{\lfloor\sqrt{n}\rfloor} \neg\mathcal{E}_{1,k}\right) \cup \left(\bigcup_{k=\lfloor\sqrt{n}\rfloor+1}^{n} \neg\mathcal{E}_{2,k}\right). \tag{4}$$

Let k denote the number of vertices in a subgraph, and thus $\xi \sim \mathrm{Bin}\left(\binom{k}{2}, p\right)$ denotes the number of edges in a given k-vertex subgraph. The expectation of ξ is

$$\mu := \binom{k}{2}p = \frac{\gamma}{2} \cdot \frac{k(k-1)f(n)}{n}.$$

On the other hand, the number of ways to select a k-vertex subgraph is

$$\binom{n}{k} \leqslant \left(\frac{en}{k}\right)^k = \exp\left(k \ln \frac{n}{k} + k\right) \leqslant \exp\left(2k \ln n\right). \tag{5}$$

Our strategy will be to bound the probability of the events on the right-hand side of (4) using the union and Chernoff bounds.

We begin by considering events of the form $\mathcal{E}_{2,k}$ and thus can assume that $\lfloor\sqrt{n}\rfloor+1 \leqslant k \leqslant n$. Observe that since f is sub-multiplicative, non-decreasing, and moderately-growing, we have

$$\frac{f(k)}{f(n)} = \frac{f(k)}{f\left(\frac{n}{k} \cdot k\right)} \geqslant \frac{f(k)}{C \cdot f(\frac{n}{k}) \cdot f(k)} \geqslant \frac{f(k)}{C \cdot f(\frac{sn}{k}) \cdot f(k)} \geqslant \frac{f(k)}{C^2 \cdot (\frac{sn}{k})^{1-\delta} \cdot f(k)} \geqslant \frac{k}{C^2 s \cdot n}. \tag{6}$$

If we now fix

$$c_2 = C^2 s \cdot e^2 \cdot \gamma > 6, \tag{7}$$

then by (6) we have

$$\frac{2c_2 n f(k)}{e\gamma(k-1)f(n)} = \frac{2C^2 se \cdot nf(k)}{(k-1)f(n)} \geqslant \frac{2ek}{k-1} > e. \tag{8}$$

So, applying Chernoff bound (Lemma 19) with $1 + a = \frac{c_2 kf(k)}{\mu} = \frac{2c_2 nf(k)}{\gamma(k-1)f(n)}$ gives

$$\begin{aligned}
\mathbb{P}(\xi > c_2 kf(k)) &\leqslant \exp\left(-(1+a)\mu \cdot \ln \frac{1+a}{e}\right) \\
&= \exp\left(-c_2 kf(k) \cdot \ln \frac{2c_2 nf(k)}{e\gamma(k-1)f(n)}\right) \\
&\overset{(8)}{\leqslant} \exp\left(-c_2 kf(k)\right) \\
&\overset{(7)}{\leqslant} \exp\left(-6kf(k)\right).
\end{aligned} \tag{9}$$

Thus, by (5), (9), the union bound, and as $f(k) \geqslant \log k > \ln k$, we have

$$\begin{aligned}
\mathbb{P}\left(\bigcup_{k=\lfloor\sqrt{n}\rfloor+1}^{n} \neg\mathcal{E}_{2,k}\right) &\leqslant \sum_{k=\lfloor\sqrt{n}\rfloor+1}^{n} \exp\left(2k \ln n\right) \cdot \exp\left(-6kf(k)\right) \leqslant \sum_{k=\lfloor\sqrt{n}\rfloor+1}^{n} k^{-k} \\
&\leqslant \exp(-\sqrt{n}).
\end{aligned} \tag{10}$$

We now treat events of the form $\mathcal{E}_{1,k}$, and thus we can assume that $s \leqslant k \leqslant \lfloor\sqrt{n}\rfloor$. Observe that for any fixed constant $d > 0$ and sufficiently large n we have $\frac{n^{2/3}}{k(\log k)^d} \geqslant s$ as $k \leqslant \sqrt{n}$. Thus, by sub-multiplicativity, and moderate-growth we have

$$\begin{aligned}
f\left(\frac{n^{2/3}}{(\log k)^d}\right) &= f\left(\frac{n^{2/3}}{k(\log k)^d} \cdot k\right) \\
&\leqslant C \cdot f\left(\frac{n^{2/3}}{k(\log k)^d}\right) \cdot f\left(k\right) \\
&\leqslant C^2 \cdot \left(\frac{n^{2/3}}{k(\log k)^d}\right)^{1-\delta} \cdot f(k) \\
&\leqslant C^2 \cdot \frac{n^{2/3}}{k(\log k)^d} \cdot f(k).
\end{aligned}$$

Similarly, by sub-multiplicativity and moderate-growth, we have

$$\begin{aligned} f(n) &= f\left(\frac{n^{2/3}}{(\log k)^d}\cdot n^{1/3}(\log k)^d\right) \\ &\leqslant C\cdot f\left(\frac{n^{2/3}}{(\log k)^d}\right)\cdot f\left(n^{1/3}(\log k)^d\right) \\ &\leqslant C^2\cdot f\left(\frac{n^{2/3}}{(\log k)^d}\right)\cdot n^{(1-\delta)/3}(\log k)^{(1-\delta)\cdot d}. \end{aligned}$$

If we set $d = 1/\delta > 0$ then the two bounds above give

$$\frac{f(k)}{f(n)} \geqslant \frac{f\left(\frac{n^{2/3}}{(\log k)^d}\right)\cdot\frac{k(\log k)^d}{C^2 n^{2/3}}}{C^2\cdot f\left(\frac{n^{2/3}}{(\log k)^d}\right)\cdot n^{(1-\delta)/3}(\log k)^{(1-\delta)\cdot d}} = \frac{k(\log k)^{\delta d}}{C^4 n^{1-\delta/3}} = \frac{k\log k}{C^4 n}\cdot n^{\delta/3}. \tag{11}$$

Foreseeing the need for the constant 15 later on, we now set

$$c_1 = e\cdot 15\cdot C^4\gamma/\delta. \tag{12}$$

We now set $1+a := \frac{c_1 k f(k)}{\mu\cdot\log k}$, which by (11) satisfies

$$1+a = \frac{c_1 k f(k)}{\mu\cdot\log k} = \frac{2c_1 n f(k)}{\gamma(k-1)f(n)\log k} \geqslant \frac{2c_1 k}{\gamma(k-1)C^4}\cdot n^{\delta/3} > e\cdot n^{\delta/3}. \tag{13}$$

As before, Chernoff bound (Lemma 19) with this $1+a$ gives

$$\mathbb{P}\left(\xi > \frac{c_1 k f(k)}{\log k}\right) \leqslant \exp\left(-\frac{c_1 k f(k)}{\log k}\cdot\ln\frac{1+a}{e}\right) \overset{(13)}{\leqslant} \exp\left(-\frac{c_1 k f(k)}{\log k}\cdot\frac{\delta}{3}\ln n\right). \tag{14}$$

Recall that the bound $f(k)\geqslant\log k$ holds by moderate-growth. Applying this to (14) yields

$$\mathbb{P}\left(\xi > \frac{c_1 k f(k)}{\log k}\right) \leqslant \exp\left(-c_1 k\cdot\frac{\delta}{3}\ln n\right) \overset{(12)}{\leqslant} \exp\left(-5k\ln n\right). \tag{15}$$

Thus, by (5), (15), and the union bound,

$$\mathbb{P}\left(\bigcup_{k=s}^{\lfloor\sqrt{n}\rfloor}\neg\mathcal{E}_{1,k}\right) \leqslant \sum_{k=s}^{\lfloor\sqrt{n}\rfloor}\exp\left(2k\ln n\right)\cdot\exp\left(-5k\ln n\right) \leqslant \sqrt{n}\cdot n^{-3s} \leqslant n^{-5}. \tag{16}$$

The result follows by taking $c = \max\{c_1, c_2, \binom{s}{2}\}$, (4), and the union bound over (10) and (16). ◀

We now use Theorem 18 to prove Lemma 21, which bounds the number of cf-good graphs from below. To prove Lemma 21, it is convenient to switch to an alternative model of random graphs with a fixed number of edges. We let $G(n,m)$ to denote the uniform distribution on n-vertex graphs with m edges. The following lemma allows us to transfer results from one graph model to another.

▶ **Lemma 20.** *Let $\mathcal{P}$ be any graph property (i.e., graph class) and $0\leqslant p\leqslant 1$ satisfy $p\binom{n}{2}\to\infty$ and $\binom{n}{2}-p\binom{n}{2}\to\infty$ and $m = \left\lceil p\binom{n}{2}\right\rceil$. Then, for $G_n\sim G(n,m)$ and $G'_n\sim G(n,p)$, we have*

$$\mathbb{P}\left[G_n\in\mathcal{P}\right] \leqslant 10\sqrt{m}\cdot\mathbb{P}\left[G'_n\in\mathcal{P}\right].$$

Lemma 20 follows by a very minor adaption of [19, Lemma 3.2], the only difference is a ceiling in the number of edges, which makes no difference in the proof.

▶ **Lemma 21.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be (δ, C, s)-decent for some constants $\delta \in (0,1)$, $C \geqslant 1$, and $s \geqslant 2$. Then, for any fixed $\gamma > 1$, there exists some $c := c(\gamma, \delta, C, s) > 0$ such that for every $n \in \mathbb{N}$ there are at least $2^{(\gamma\delta/2 - o(1)) \cdot nf(n)\log n}$ many unlabeled (cf)-good n-vertex graphs.*

Proof. Let $m := \left\lceil \frac{\gamma(n-1)f(n)}{2} \right\rceil$ and $G_n \sim G\big(n, m\big)$. Observe that by Theorem 18 and Lemma 20, there exists some fixed $c > 0$ such that for sufficiently large n

$$\mathbb{P}\left[\, G_n \text{ is } (cf)\text{-good} \,\right] \geqslant 1 - 10\sqrt{\left\lceil \tfrac{\gamma(n-1)f(n)}{2} \right\rceil} \cdot n^{-2} = 1 - o(1). \tag{17}$$

The number of labeled graphs in the support of $G\big(n, m\big)$ is

$$\binom{\binom{n}{2}}{m} = \binom{\binom{n}{2}}{\left\lceil \frac{\gamma(n-1)f(n)}{2} \right\rceil} \geqslant \left(\frac{n}{\gamma f(n)} \right)^{\frac{\gamma(n-1)f(n)}{2}} = 2^{\frac{\gamma}{2} \cdot (n-1)f(n) \cdot (\log n - \log(\gamma f(n)))}.$$

By (17), a $1 - o(1)$ fraction of these labeled graphs are (cf)-good. Furthermore, there are at most $n! \leqslant n^n$ labelings of a given unlabeled graph. Thus, the number of unlabeled n-vertex (cf)-good graphs is bounded from below by

$$\begin{aligned}(1 - o(1)) \cdot \frac{1}{n^n} \cdot 2^{\frac{\gamma}{2} \cdot (n-1)f(n) \cdot (\log n - \log(\gamma f(n)))} &= 2^{\frac{\gamma}{2} \cdot nf(n) \cdot (\log n - \log(f(n)) - O(1))} \\ &\geqslant 2^{\frac{\gamma}{2} \cdot nf(n) \cdot (\log n - (1-\delta)\log(n) - O(1))} \\ &= 2^{(\delta\gamma/2 - o(1)) \cdot nf(n)\log n},\end{aligned}$$

as claimed, since $\log n \leqslant f(n) \leqslant Cn^{1-\delta}$ by moderate-growth. ◀

5 Tight bounds on labeling schemes for monotone classes

We begin in Section 5.1 with a lemma which is useful for bounding the speed when constructing monotone classes with no implicit representation. This is then used to prove our lower bound in Section 5.2. Finally, in Section 5.3 we give a matching upper bound on labeling schemes for monotone classes, this follows from [25] and included mainly for completeness.

5.1 Construction of monotone classes

We begin with a lemma showing that, for a decent function f, we can create monotone classes from the union of many f-good graphs and still maintain control over the speed. The proof follows the broad idea of [23, Claim 3.1].

▶ **Lemma 22.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be (δ, C, s)-decent for some constants $\delta \in (0,1)$, $C \geqslant 1$, and $s \geqslant 2$. Let $c > 0$ be a constant, and, for every $n \in \mathbb{N}$, let M_n be any set of (cf)-good unlabeled n-vertex graphs satisfying $|M_n| \leqslant \left\lceil 2^{\sqrt{nf(n)}} \right\rceil$. Then the speed of $\mathcal{X} := \mathrm{Mon}(\cup_{n\in\mathbb{N}} M_n)$ is $2^{O(nf(n))}$.*

Proof. Let $\mathcal{Y} := \mathrm{Her}(\cup_{n\in\mathbb{N}} M_n)$. Note that $\mathcal{X} = \mathrm{Mon}(\mathcal{Y})$. We first estimate the speed of $\mathcal{Y}$. For an n-vertex graph $G \in \mathcal{Y}$, let N be the smallest integer such that G is an induced subgraph of a graph $H \in M_N$. We split the proof over two cases: (i): $N \geqslant n^2$, and (ii): $N < n^2$.

Case (i): Since H is a (cf)-good N-vertex graph and G is its n-vertex induced subgraph, where $n \leqslant \sqrt{N}$, it follows from Definition 15 that G must have at most $g(n) := cnf(n)/\log n$ many edges. The number of such graphs is at most

$$\binom{\binom{n}{2}}{g(n)} \leqslant \left(\frac{n^2 e}{g(n)}\right)^{g(n)} = 2^{g(n)\cdot\log\frac{n^2 e}{g(n)}} = 2^{c\frac{nf(n)}{\log n}\cdot\log\frac{n^2 e}{g(n)}} = 2^{O(nf(n))},$$

and so $\mathcal{Y}$ contains $2^{O(nf(n))}$ many n-vertex labeled graphs each of which is an induced subgraph of a graph in M_N for some N with $n \leqslant \sqrt{N}$.

Case (ii): For this case, we simply use the fact that any $H \in M_N$ has at most N^n many n-vertex induced subgraphs. Thus, the number of n-vertex labeled graphs in $\mathcal{Y}$ each of which is an induced subgraph of a graph in M_N for some N with $N < n^2$ is bounded from above by

$$\begin{aligned} n! \cdot \sum_{N=n}^{n^2} N^n \cdot |M_N| &\leqslant n! \cdot \sum_{N=n}^{n^2} N^n \cdot \left\lceil 2^{\sqrt{Nf(N)}} \right\rceil \\ &\leqslant n! \cdot n^2 \cdot (n^2)^n \cdot \left\lceil 2^{\sqrt{n^2 f(n^2)}} \right\rceil \\ &\leqslant 2^{O(n\log n)} \cdot \left\lceil 2^{\sqrt{C}nf(n)} \right\rceil \\ &= 2^{O(nf(n))}, \end{aligned}$$

where in the last inequality we used sub-multiplicativity of f, and in the final equality we used the fact that $f(x) \geqslant \log x$.

Thus, $|\mathcal{Y}_n| = 2^{O(nf(n))}$. Now, since every n-vertex labeled graph in $\mathcal{X}$ is a subgraph of an n-vertex labeled graph in $\mathcal{Y}$, and, due to (cf)-goodness, every graph in $\mathcal{Y}_n$ has at most $2^{cnf(n)}$ n-vertex subgraphs, we conclude that $|\mathcal{X}_n| \leqslant |\mathcal{Y}_n| \cdot 2^{cnf(n)} = 2^{O(nf(n))}$. ◀

5.2 Lower bound

We can now show the main result of the paper, which we recall for convenience.

▶ **Theorem 5.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a decent function. Then, there exists a monotone graph class $\mathcal{X}$ with speed $|\mathcal{X}_n| = 2^{O(nf(n))}$ that does not admit a universal graph of size at most $2^{f(n)\log n}$. Equivalently, $\mathcal{X}$ admits no adjacency labeling scheme of size at most $f(n)\log n$.*

Proof. By assumption $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ is (δ, C, s)-decent for some constants $\delta \in (0,1)$, $C \geqslant 1$, and $s \geqslant 2$. We will construct a monotone class (via the probabilistic method) with the speed $2^{O(nf(n))}$ that does not admit a universal graph of size $u_n := 2^{f(n)\log n}$. Fix $\gamma := 4/\delta > 1$ and let $c := c(\gamma, \delta, C, s) > 0$ be the satisfying constant from Theorem 18 corresponding to this choice of γ. Let $k_n := \left\lceil 2^{\sqrt{nf(n)}} \right\rceil$.

The number of distinct u_n-vertex graphs is at most $2^{u_n^2}$ and the number of n-vertex induced subgraphs of a fixed u_n-vertex graph is at most $\binom{u_n}{n}$. Hence the number of collections of k_n graphs on n vertices that are induced subgraphs of a u_n-vertex (universal) graph is at most

$$2^{u_n^2} \cdot \binom{\binom{u_n}{n}}{k_n} \leqslant 2^{u_n^2} \cdot u_n^{k_n \cdot n}. \tag{18}$$

On the other hand, from Lemma 21, the number of different collections of n-vertex (cf)-good graphs of cardinality k_n is at least

$$\binom{2^{(\gamma\delta/2-o(1))\cdot nf(n)\log n}}{k_n} \geqslant \left(\frac{2^{(\gamma\delta/2-o(1))\cdot nf(n)\log n}}{k_n}\right)^{k_n} = 2^{k_n\cdot(\gamma\delta/2-o(1))\cdot nf(n)\log n}, \tag{19}$$

as $\log k_n = O(\sqrt{nf(n)}) = o(nf(n)\log n)$. By taking logarithms, we can see that for sufficiently large n the upper bound (18) is smaller than the lower bound (19). In particular, taking the logarithm of (18) gives

$$\begin{aligned}\log\left(2^{u_n^2}\cdot u_n^{k_n\cdot n}\right) &= u_n^2 + k_n\cdot n\log u_n\\ &= 2^{2f(n)\log n} + k_n\cdot nf(n)\log n\\ &= (1+o(1))\cdot k_n\cdot nf(n)\log n,\end{aligned}$$

as $k_n := \left\lceil 2^{\sqrt{nf(n)}}\right\rceil = \omega(2^{2f(n)\log n})$. However, since $\gamma = 4/\delta$, the logarithm of (19) is

$$\begin{aligned}\log\left(2^{k_n\cdot(\gamma\delta/2-o(1))\cdot nf(n)\log n}\right) &= k_n\cdot(\gamma\delta/2-o(1))\cdot nf(n)\log n\\ &= (2-o(1))\cdot k_n\cdot nf(n)\log n.\end{aligned}$$

Thus, for any sufficiently large n, there exists a collection M_n of k_n (cf)-good n-vertex graphs that are not representable by any universal graph of size at most $u_n = 2^{f(n)\log n}$. Consequently, by Lemma 22, the speed of $\mathcal{X} := \mathrm{Mon}(\cup_n M_n)$ is $|\mathcal{X}_n| = 2^{O(nf(n))}$ and $\mathcal{X}$ does not admit a universal graph of size at most $2^{f(n)\log n}$. ◀

5.3 Upper bound

In this section we prove the following upper bound on labeling schemes for monotone classes.

▶ **Proposition 4.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a non-decreasing function. Then, any monotone class of graphs $\mathcal{X}$ with speed $|\mathcal{X}_n| = 2^{O(nf(n))}$ admits an adjacency labeling scheme of size $O(f(n)\log n)$.*

Proof. Let $\mathcal{X}$ be a monotone class with at most $2^{Cnf(n)}$ labeled n-vertex graphs for every n. If an n-vertex graph $G \in \mathcal{X}$ has m edges, then $\mathcal{X}$ contains at least 2^m labeled n-vertex graphs, as every subgraph of G also belongs to $\mathcal{X}$ due to monotonicity.

This implies that every n-vertex graph G in $\mathcal{X}$ contains at most $Cnf(n)$ edges, and hence, has a vertex of degree at most $2Cf(n)$. Due to monotonicity of f, the same is true for every subgraph of G. Indeed, if H is a k-vertex subgraph of G, then, since H belongs to $\mathcal{X}$, the number of edges in H is at most $Ckf(k) \leqslant Ckf(n)$, and therefore H has a vertex of degree at most $2Cf(n)$. Thus, every n-vertex graph in $\mathcal{X}$ is $2Cf(n)$-degenerate, and Lemma 14 implies that $\mathcal{X}$ admits a $(2Cf(n)+1)\cdot\lceil\log n\rceil$-bit labeling scheme. ◀

5.4 Complexity of monotone classes

The following result shows that monotone classes are complex in the sense that they cannot be "described" by even a countable number of classes of a slightly larger speed. The proof of this theorem follows the exact same idea as [14, Lemma 2.4], also see [12, Theorem 1.2] for the proof of a similar theorem in the context of small classes.

▶ **Theorem 7.** *Let $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be any decent function, and $\mathbb{X}$ be any countable set of graph classes, each with speed at most $2^{nf(n)\log n}$. Then, there exists a monotone graph class $\mathcal{X}$ of speed $2^{O(nf(n))}$ such that there does not exist a $\mathcal{D} \in \mathbb{X}$ with $\mathcal{X} \subseteq \mathcal{D}$.*

Proof. Let $\mathcal{X}$ be a monotone class with at most $2^{Cnf(n)}$ labeled n-vertex graphs for every n. If an n-vertex graph $G \in \mathcal{X}$ has m edges, then $\mathcal{X}$ contains at least 2^m labeled n-vertex graphs, as every subgraph of G also belongs to $\mathcal{X}$ due to monotonicity.

This implies that every n-vertex graph G in $\mathcal{X}$ contains at most $Cnf(n)$ edges, and hence, has a vertex of degree at most $2Cf(n)$. Due to monotonicity of f, the same is true for every subgraph of G. Indeed, if H is a k-vertex subgraph of G, then, since H belongs to $\mathcal{X}$, the number of edges in H is at most $Ckf(k) \leqslant Ckf(n)$, and therefore H has a vertex of degree at most $2Cf(n)$. Thus, every n-vertex graph in $\mathcal{X}$ is $2Cf(n)$-degenerate, and Lemma 14 implies that $\mathcal{X}$ admits a $(2Cf(n)+1) \cdot \lceil \log n \rceil$-bit labeling scheme. ◀

Abstract

We provide polynomial-time reductions between three search problems from three distinct areas: the P-matrix linear complementarity problem (P-LCP), finding the sink of a unique sink orientation (USO), and a variant of the α-Ham Sandwich problem. For all three settings, we show that "two choices are enough", meaning that the general non-binary version of the problem can be reduced in polynomial time to the binary version. This specifically means that generalized P-LCPs are equivalent to P-LCPs, and grid USOs are equivalent to cube USOs. These results are obtained by showing that both the P-LCP and our α-Ham Sandwich variant are equivalent to a new problem we introduce, P-Lin-Bellman. This problem can be seen as a new tool for formulating problems as P-LCPs.

1 Introduction

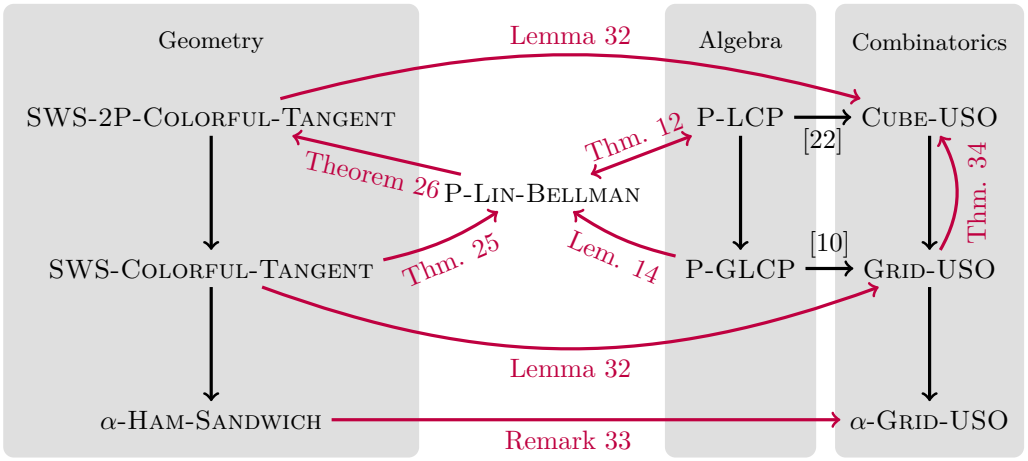

Figure 1 Red: Reductions we show in this paper. Black: Existing reductions and trivial inclusions.

In this paper we study three search problems from three distinct areas: the problem of solving a P-matrix linear complementarity problem (P-LCP), an algebraic problem, the problem of finding the sink of a unique sink orientation (USO), a combinatorial problem, and a variant of the α-Ham Sandwich problem, a geometric problem. Our results are a suite of reductions between these problems, which are shown in Figure 1.

There are two main themes for these reductions.

- **Two choices are enough.** For all three settings, the problems can be restricted to variants in which all choices are binary. In all three cases we show that the general non-binary problem can be reduced in polynomial time to the binary version.
- **A new tool for working with P-LCPs.** We introduce the P-Lin-Bellman problem, which serves as a crucial intermediate problem for our reductions with P-LCPs, and provides a new tool for showing equivalence to the P-LCP problem.

We now describe each of the three problems and our results.

P-Matrix LCPs. In the *Linear Complementarity Problem* (LCP), we are given an $n \times n$ matrix M and an n-dimensional vector q, and we are asked to find two n-dimensional vectors w, z such that $w = Mz + q$, both w and z are non-negative, and w and z satisfy the *complementarity* condition of $w^T z = 0$. In general, there is no guarantee that an LCP has a solution. However, if M is promised to be a P-matrix, that is, all its principal minors are positive, then the LCP problem always has a unique solution for every possible q [19], and we call this the P-LCP problem.

The P-LCP problem is important because many optimization problems reduce to it, for example, *Linear Programming* [12, 16] and *Strictly Convex Quadratic Programming* [5, 20], and solving a *Simple Stochastic Game (SSG)* [11, 23]. However, the complexity status of the P-LCP remains a major open question. The P-LCP problem is not known to be polynomial-time solvable, but NP-hardness (in the sense that an oracle for it could be used to solve SAT in polynomial time) would imply NP = co-NP [18].

The P-LCP problem naturally encodes problems that have *two choices*. This property arises from the complementarity condition, where for each index i, one must choose either $w_i = 0$ or $z_i = 0$. Thus the problem can be seen as making one of two choices for each of the

n possible dimensions of w and z. For example, this means that the direct encoding of a Simple Stochastic Game as a P-LCP [16] only works for *binary* games, in which each vertex has exactly two outgoing edges, and for each vertex the choice between the two outgoing edges is encoded by choosing between w_i and z_i.

To directly encode a non-binary SSG one must instead turn to *generalized* LCPs, which allow for more than two choices in the complementarity condition [23]. Generalized LCPs, which were defined by Habetler and Szanc [15], also have a P-matrix version, which we will refer to as P-GLCP.

Two choices are enough for P-LCPs. Our first main result is to show that P-GLCP and P-LCP are polynomial-time equivalent problems. Every P-LCP is a P-GLCP by definition, so our contribution is to give a polynomial-time reduction from P-GLCP to P-LCP, meaning that any problem that can be formulated as a P-GLCP can also be efficiently recast as a P-LCP. Such a result was already claimed in 1995, but later a counterexample to a crucial step in the proof was found by the same author [6, 7].

To show this result we draw inspiration from the world of infinite games. SSGs are a special case of *stochastic discounted games* (SDGs), which are known to be reducible in polynomial-time to the P-LCP problem [16, 17]. This reduction first writes down a system of *Bellman equations* for the game, which are a system of linear equations using min and max operations. These equations are then formulated as a P-LCP using the complementarity condition to encode the min and max operations.

We introduce a generalization of the Bellman equations for SDGs, which we call P-Lin-Bellman. We show that the existing reduction from SDGs to P-LCP continues to work for P-Lin-Bellman, and we show that we can polynomial-time reduce P-LCP to P-Lin-Bellman. Thus, we obtain a Bellman-equation type problem that is equivalent to P-LCP.

Then we use P-Lin-Bellman as a tool to reduce P-GLCP to P-LCP. Specifically we show that a P-GLCP can be reduced to P-Lin-Bellman. Here our use of P-Lin-Bellman as an intermediary shows its usefulness: while it is not at all clear how one can reduce P-GLCP to P-LCP directly, when both problems are formulated as P-Lin-Bellman instances, their equivalence essentially boils down to the fact that $\max(a, b, c) = \max(a, \max(b, c))$.

Unique Sink Orientations. A Unique Sink Orientation (USO) is an orientation of the n-dimensional hypercube such that every subcube contains a unique sink. An example of an USO can be found in Figure 2. The goal is to find the unique sink of the entire hypercube. USOs were introduced by Stickney and Watson [22] as a combinatorial abstraction of the candidate solutions of the P-LCP and have been studied ever since Szabó and Welzl formally defined them in 2001 [24].

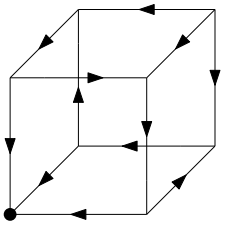

Figure 2 A 3-dimensional USO. The marked vertex denotes its unique global sink.

USOs have received much attention because many problems are known to reduce to them. This includes linear programming and more generally convex quadratic programming, simple stochastic games, and finding the smallest enclosing ball of given points.

As with P-LCPs, USOs naturally capture problems in which there are two choices. Each dimension of the cube allows us to pick between one of two faces, and thus each vertex of the cube is the result of making n binary choices. To remove this restriction, prior work has studied unique sink orientations of products of complete graphs [10], which the literature somewhat confusingly calls *grid USOs*. For example, as with P-LCP, the direct reduction from SSGs to USOs only works for binary games, while a direct reduction from non-binary games yields a grid USO.

Two choices are enough for USOs. Our second main result is to show that grid USOs and cube USOs are polynomial-time equivalent problems. Every cube USO is a grid USO by definition, so our contribution is to provide a polynomial-time reduction from grid USOs to cube USOs. Despite many researchers suspecting that grid USOs are a strict generalization of cube USOs, our result shows that at least in the promise setting, the two problems are computationally equivalent. For the reduction we embed a k-regular grid into a (also k-regular) k-cube. The main challenge to overcome is that the k-cube contains many more vertices and significantly more edges. These edges need to be oriented in such a way to be consistent with the orientation of the grid, and this orientation also needs to be computable locally, i.e., without looking at the whole orientation of the grid.

It should be noted that while P-LCP is known to reduce to cube USOs, and P-GLCP is known to reduce to grid USOs, neither of our "two choices is enough" results imply each other. This is because there is no known reduction from an USO-type problem to an LCP-type problem.

Equivalence between P-LCP and Colorful Tangent Problems. The Ham Sandwich theorem is a classical theorem in computational geometry: given d sets of points in $\mathbb{R}^d$, we can find a hyperplane that simultaneously *bisects* all of the sets. Steiger and Zhao [21] have shown that in a restricted input setting we can not only bisect, but cut off arbitrary fractions of each point set. This is the so-called α-Ham Sandwich theorem: if the point sets are *well-separated*, then for each vector α there exists a unique choice of one point per set, such that the hyperplane spanned by these points has exactly α_i of the points from set i above. The α-Ham Sandwich problem asks to determine this unique choice of one point per set.

In this paper, we consider a restricted variant of the α-Ham Sandwich problem. Firstly, we slightly strengthen the assumption of well-separation to *strong* well-separation. Secondly we restrict the input vector α such that each entry takes either be the minimum or maximum possible value. This means that for every point set, either all points of the set must lie above, or all below the desired α-cut. Thus, the α-cuts we search for are tangents to all the point sets. Combining the assumption of strong well-separation and the solutions being tangents, we call this problem SWS-Colorful-Tangent. We also consider the binary variant of the problem, which we call SWS-2P-Colorful-Tangent, where we restrict the size of each point set to 2; finding an α-cut then corresponds to a series of binary choices, one per set.

Here our contribution is to show that SWS-Colorful-Tangent is polynomial-time equivalent to the P-LCP problem. Our new intermediate problem P-Lin-Bellman plays a crucial role in this result: we give a polynomial-time reduction from SWS-Colorful-Tangent to P-Lin-Bellman, and a polynomial-time reduction from P-Lin-Bellman to SWS-2P-Colorful-Tangent. This also shows that two choices are enough for this problem as well.

For these reductions, we consider the point-hyperplane dual of the colorful tangent problems. In the dual, every input point becomes a hyperplane, and the solution we search for is a point lying on one hyperplane of each color, and lying either above or below all

other hyperplanes. This can be encoded in the min and max operations of the P-Lin-Bellman problem. This demonstrates the usefulness of P-Lin-Bellman as an intermediate problem, since it has allowed us to show what is – to the best of our knowledge – the first polynomial-time equivalence between P-LCP and another problem.

Related Work. All problems we consider in this paper are promise search problems which lie in the complexity class PromiseUEOPL [2, 3], which is the promise setting analogue of the class UEOPL (short for Unique End of Potential Line) [9]. The latter has recently attracted the attention of many researchers trying to further the understanding of the hierarchy of total search problem classes, with a breakthrough result separating UEOPL from EOPL [14]. There is only one known natural[1] complete problem for UEOPL, called One Permutation Discrete Contraction (OPDC). OPDC also admits a natural binary variant, and it has already been shown implicitly that the binary variant is polynomial-time equivalent to the general variant [9]. Our reductions may help in finding another natural UEOPL-complete problem, even though our results for now only hold in the promise setting.

2 A New Intermediate Problem: P-Lin-Bellman

Our new P-Lin-Bellman problem is motivated by discounted games. A stochastic discounted game (SDG) is defined by a set of states S, which are partitioned into S_{Max} and S_{Min}, a set of actions A, a transition function $p : S \times A \times S \to \mathbb{R}$, a reward function $r : S \times A \to \mathbb{R}$, and a discount factor λ. The value of a SDG is known to be the solution to the following system of *Bellman equations*. For each state s we have an equation

$$x_s = \begin{cases} \max_{a \in A} \left(r(s,a) + \lambda \cdot \sum_{s' \in S} p(s,a,s') \cdot x_{s'} \right) & \text{if } s \in S_{\text{Max}}, \\ \min_{a \in A} \left(r(s,a) + \lambda \cdot \sum_{s' \in S} p(s,a,s') \cdot x_{s'} \right) & \text{if } s \in S_{\text{Min}}. \end{cases}$$

Prior work has shown that, if the game is binary, meaning that $|A| = 2$, then these Bellman equations can be formulated as a P-LCP [17, 16].

For our purposes, we are interested in the format of these equations. Note that each equation is a max or min over affine functions of the other variables. We capture this idea in the following generalized definition.

▶ **Definition 1.** *A Lin-Bellman system $G = (L, R, q, S)$ is defined by two matrices $L, R \in \mathbb{R}^{n \times n}$, a vector $q \in \mathbb{R}^n$, and a set $S \subseteq \{1, 2, \ldots, n\}$. These inputs define the following system of equations over a vector of variables $x \in \mathbb{R}^n$:*

$$x_i = \begin{cases} \max(\sum_{1 \le j \le n} L_{ij} x_j + q_i, \ \sum_{1 \le j \le n} R_{ij} x_j) & \text{if } i \in S, \\ \min(\sum_{1 \le j \le n} L_{ij} x_j + q_i, \ \sum_{1 \le j \le n} R_{ij} x_j) & \text{if } i \notin S. \end{cases} \tag{1}$$

Observe that this definition captures systems of equations in which a min or max operation is taken over two affine expressions in the other variables. Note that here we have included the additive q term only in the first of the two expressions (the second is thus linear), whereas the SDG equations have additive terms in all of the affine expressions. This is because, for our reductions, we do not need the second additive term. Otherwise, this definition captures the style of Bellman equations that are used in SDGs and other infinite games.

[1] By natural we mean a problem that is not a variant of the Unique End of Potential Line problem which naturally characterizes the class.

We say that $x \in \mathbb{R}^n$ is a solution of a Lin-Bellman system G if Equation (1) is satisfied for all i. In general, however, such an x may not exist or may not be unique. To get a problem that is equivalent to P-LCP, we need a restriction that ensures that the problem always has a unique solution, like the P-matrix restriction on the LCP problem.

To make sure that a unique solution exists, we introduce a promise to yield the promise problem P-Lin-Bellman. As the promise we guarantee the same property that is implied by the promise of the P-LCP: For every $q' \in \mathbb{R}^n$, the given Lin-Bellman system shall have a unique solution. We use the following restriction.

▶ **Definition 2.** *P-Lin-Bellman*
Input: *A Lin-Bellman system $G = (L, R, q, S)$.*
Promise: *The Lin-Bellman system (L, R, q', S) has a unique solution for every $q' \in \mathbb{R}^n$.*
Output: *A solution $x \in \mathbb{R}^n$ of G.*

This promise insists that the linear equations not only have a unique solution for the given vector q, but that they also have a unique solution no matter what vector q is given. This is analogous to a property from SDGs: an SDG has a unique solution no matter the rewards for the actions, and this corresponds to the additive q vector in the problem above.

Similarly to the LCP, where unique solutions for any right-hand side q imply that the matrix M is a P-matrix (and vice versa), this promise of P-Lin-Bellman implies something about the involved matrices. However, for P-Lin-Bellman we do not have a full characterization of the systems $(L, R, \cdot, S)$ that fulfill the promise. We only have the following rather weak necessary condition (proven in the full version of the paper), which is however useful for several of our reductions.

▶ **Lemma 3.** *In any P-Lin-Bellman instance, $R - I$ is invertible.*

Since P-Lin-Bellman is so similar to the P-LCP, we will prove the equivalence of P-LCP and P-Lin-Bellman first, in the next section.

3 Linear Complementarity Problems

We begin by giving the definitions of the (binary) linear complementarity problems.

▶ **Definition 4.** *$LCP(M, q)$*
Input: *An $n \times n$ matrix M and a vector $q \in \mathbb{R}^n$.*
Output: *Two vectors $w, z \in \mathbb{R}^n$ such that*
- *$w = Mz + q$,*
- *$w, z \geq 0$, and*
- *$w^T \cdot z = 0$.*

We are particularly interested in the case where the input matrix M is a P-matrix.

▶ **Definition 5.** *An $n \times n$ matrix M is a P-matrix if every principal minor of M is positive.*

One particularly interesting feature of the P-matrix Linear Complementarity Problem is that it always has a unique solution.

▶ **Theorem 6** ([5])**.** *M is a P-matrix if and only if $LCP(M, q)$ has a unique solution for every $q \in \mathbb{R}^n$.*

There are two problems associated with P-matrix LCPs. The first problem is a total search problem in which we must either solve the LCP, or show that the input matrix M is not a P-matrix by producing a non-positive principal minor of M. The second problem is a promise problem, where the promise is that the input is a P-matrix.

▶ **Definition 7.** *P-LCP*(M, q)
Input: *An* $n \times n$ *matrix* M *and a vector* $q \in \mathbb{R}^n$.
Promise: M *is a P-matrix.*
Output: *Two vectors* $w, z \in \mathbb{R}^n$ *that are solutions of LCP*(M, q).

In the next two sections, we will show that P-Lin-Bellman and P-LCP are equivalent under polynomial-time many-one reductions.

3.1 P-LCP to P-Lin-Bellman

Let $M \in \mathbb{R}^{n \times n}$ and $q \in \mathbb{R}^n$ be an instance of P-LCP. We will build a P-Lin-Bellman instance $G(M, q)$ in the following way. For each i in the range $1 \leq i \leq n$, we set

$$x_i = \min((Mx + x)_i + q_i, 2x_i). \tag{2}$$

In other words, we set $L = M + I$, $R = 2I$, and $S = \emptyset$. We first show that every solution of $G(M, q)$ corresponds to a solution of the LCP. We do not need to use any properties of the P-matrix in this part of the proof.

▶ **Lemma 8.** *A vector* $z \in \mathbb{R}^n$ *is a solution of the Lin-Bellman system* $G(M, q)$ *if and only if* z *and* $w = Mz + q$ *are a solution of LCP*(M, q).

Proof. If z solves Equation (2) then we have $\min(Mz + z + q, 2z) - z = 0$, and hence that $\min(Mz + q, z) = 0$. This implies that both z and w are non-negative:

$$z \geq \min(Mz + q, z) = 0,$$
$$w = Mz + q \geq \min(Mz + q, z) = 0.$$

Moreover, since $\min(Mz + q, z) = 0$, the complementarity condition also holds. Hence w and z are a solution of the LCP.

In the other direction, if w and z are solutions of the LCP, then we argue that z must be a solution of $G(M, q)$. This is because any solution of the LCP satisfies $\min(Mz + q, z) = 0$ due to the complementarity condition, and so we must have that z solves Equation (2). ◀

Next we show that the promise of P-Lin-Bellman is also satisfied.

▶ **Lemma 9.** *If* M *is a P-matrix, then* $G(M, q)$ *satisfies the promise of P-Lin-Bellman.*

Proof. We must show that the Lin-Bellman system $G(M, q')$ has a unique solution for every q'. This follows from Lemma 8, which shows that $G(M, q')$ has a unique solution if and only if the LCP defined by M and q' has a unique solution, which follows from the fact that M is a P-matrix. ◀

3.2 P-Lin-Bellman to P-LCP

For this direction, we follow and generalize the approach used by Jurdziński and Savani [17]. Suppose that we have a P-Lin-Bellman instance defined by $G = (L, R, q, S)$.

The reduction is based on the idea of simulating the operation $x = \max(a, b)$ by introducing two non-negative slack variables w and z:

$$x - w = a, \qquad x - z = b, \qquad w, z \geq 0, \qquad w \cdot z = 0.$$

Since w and z are both non-negative, any solution to the system of equations above must satisfy $x \geq \max(a, b)$. Moreover, since the complementarity condition insists that either $w = 0$ or $z = 0$, we have that $x = \max(a, b)$.

An operation $x = \min(a, b)$ can likewise be simulated by

$$x + w = a, \qquad x + z = b, \qquad w, z \geq 0, \qquad w \cdot z = 0.$$

We use this technique to rewrite the system of equations given in (1) in the following way. For each i in $1 \leq i \leq n$ we have the following.

$$x_i + w_i = \sum_{1 \leq j \leq n} L_{ij} \cdot x_j + q_i, \qquad \text{if } i \notin S \tag{3}$$

$$x_i - w_i = \sum_{1 \leq j \leq n} L_{ij} \cdot x_j + q_i, \qquad \text{if } i \in S \tag{4}$$

$$x_i + z_i = \sum_{1 \leq j \leq n} R_{ij} \cdot x_j, \qquad \text{if } i \notin S \tag{5}$$

$$x_i - z_i = \sum_{1 \leq j \leq n} R_{ij} \cdot x_j, \qquad \text{if } i \in S \tag{6}$$

$$w_i, z_i \geq 0 \tag{7}$$

$$w_i \cdot z_i = 0. \tag{8}$$

We have already argued that this will correctly simulate the max and min operations in Equation (1), and so we have the following lemma.

▶ **Lemma 10.** *$x \in \mathbb{R}^n$ is a solution of G if and only if x is a solution of the system defined by Equations* (3)–(8)*.*

We shall now reformulate Equations (3)–(8) as an LCP. To achieve this we first introduce some helpful notation: For every $n \times n$ matrix A, we define $\widehat{A}$ in the following way. For each $i, j \in \{1, 2, \ldots, n\}$ we let

$$\widehat{A}_{ij} := \begin{cases} A_{ij} & \text{if } i \in S, \\ -A_{ij} & \text{if } i \notin S. \end{cases}$$

Equations (3)–(6) can be rewritten as the following matrix equations:

$$\widehat{I}x = w + \widehat{L}x + \widehat{I}q,$$
$$\widehat{I}x = z + \widehat{R}x,$$

Eliminating x yields $(\widehat{I} - \widehat{L})(\widehat{I} - \widehat{R})^{-1}z = w + \widehat{I}q$, which is equivalent to $w = Mz + q'$ for $M = (\widehat{I} - \widehat{L})(\widehat{I} - \widehat{R})^{-1}$, $q' = -\widehat{I}q$.

We rely here on the fact that by Lemma 3, $R - I$ and thus also $(\widehat{I} - \widehat{R})$ is invertible. We have so far shown the following lemma.

▶ **Lemma 11.** *A vector $x \in \mathbb{R}^n$ is a solution of G if and only if there are vectors w, z such that w, z are a solution of $LCP(M, q)$ and x, w, and z are a solution of Equations* (3)–(8)*.*

To show that M is a P matrix, we must show that $\mathrm{LCP}(M, q'')$ has a unique solution for every $q'' \in \mathbb{R}^n$. By Lemma 11, this holds if and only if $G(L, R, q'', S)$ has a unique solution for every q'', which holds due to the P-Lin-Bellman promise. Our reduction is thus correct, and we have established our first main result:

▶ **Theorem 12.** *P-Lin-Bellman and P-LCP are equivalent under polynomial-time many-one reductions.*

3.3 P-matrix Generalized LCP to P-LCP

Generalized LCPs were originally introduced by Cottle and Dantzig [4]. A generalized LCP instance is defined by a vertical block matrix M, and a vertical block vector q where

$$M = \begin{bmatrix} M_1 \\ M_2 \\ \vdots \\ M_n \end{bmatrix} \qquad q = \begin{pmatrix} q_1 \\ q_2 \\ \vdots \\ q_n \end{pmatrix}$$

Each matrix M_i has dimensionality $b_i \times n$, while each vector q_i has b_i dimensions. Thus, if $N = \sum_i b_i$, we have that $M \in \mathbb{R}^{N \times n}$ and $q \in \mathbb{R}^N$. Given a vertical block vector x with n blocks, we use x_i^j to refer to the jth element of the ith block of x.

Given such an M and q, the *generalized linear complementarity problem* (GLCP) is to find vectors $w \in \mathbb{R}^N$ and $z \in \mathbb{R}^n$ such that

- $w = Mz + q$,
- $w \geq 0$,
- $z \geq 0$, and
- $z_i \cdot \prod_{j=1}^{b_i} w_i^j = 0$ for all i.

Given a tuple $p = (p_1, p_2, \ldots, p_n)$ such that each p_i lies in the range $1 \leq i \leq b_i$, the representative submatrix of M defined by p is given by $M(p) \in \mathbb{R}^{n \times n}$ and is constructed by selecting row p_i from each block-matrix M_i. We then say that M is a P-matrix if all of its representative submatrices are P-matrices.

We define the P-matrix GLCP (P-GLCP) as a promise problem, analogously to the P-LCP: The input is a GLCP instance (M, q) with the promise that M is a P-matrix. This promise again guarantees unique solutions:

▶ **Theorem 13** (Habetler, Szanc [15]). *A vertical block matrix M is a P-matrix if and only if the GLCP instance (M, q') has a unique solution for every $q' \in \mathbb{R}^N$.*

We are now ready to show our reduction of P-GLCP to P-Lin-Bellman.

▶ **Lemma 14.** *There is a poly-time many-one reduction from P-GLCP to P-Lin-Bellman.*

Proof. We can turn a P-matrix GLCP instance into a P-Lin-Bellman instance in much the same way as we did for P-LCPs in Section 3.1. For each i in the range $1 \leq i \leq n$ we set

$$z_i = \min\Big(\min\big\{(Mz+q)_i^j + z_i \ : 1 \leq j \leq b_i\big\}, 2z_i\Big). \tag{9}$$

We claim that any solution of the system of equations defined above yields a solution of the GLCP. In any solution to the system we have

$$\min\Big(\min\big\{(Mz+q)_i^j \ : 1 \leq j \leq b_i\big\}, z_i\Big) = 0.$$

So if we set $w_i^j = (Mz+q)_i^j$ then we have the following non-negativities

$$w_i^j = (Mz+q)_i^j \geq \min\Big(\min\big\{(Mz+q)_i^j \ : 1 \leq j \leq b_i\big\}, z_i\Big) = 0.$$
$$z_i \geq \min\Big(\min\big\{(Mz+q)_i^j \ : 1 \leq j \leq b_i\big\}, z_i\Big) = 0.$$

We can also see that the complementarity condition is satisfied, since either $z_i = 0$ or $w_i^j = 0$ for some j.

To write this as a Lin-Bellman system, we must carefully write Equation (9) using two-input min operations. We will introduce a variable x_i^j for each i in the range $1 \leq i \leq n$ and each j in the range $1 \leq j \leq b_i$. We use $\mathbf{x}^1$ to denote the vector $(x_1^1, x_2^1, \ldots, x_n^1)$. For each i, and each j in the range $1 \leq j < b_i$ we use the following.

$$x_i^j = \min\Big((M\mathbf{x}^1 + q)_i^j + x_i^1,\ x_i^{j+1}\Big) \tag{10}$$

We also use the following when $j = b_i$.

$$x_i^{b_i} = \min\Big((M\mathbf{x}^1 + q)_i^{b_i} + x_i^1,\ 2x_i^1\Big) \tag{11}$$

Let $G = (L, R, q, S)$ denote the resulting Lin-Bellman system. It is now easy to see that on the one hand, for every solution $\mathbf{x}$ of G the vectors $z := \mathbf{x}^1$ and w with $w_i^j = (Mz + q)_i^j$ form a solution of the input P-matrix GLCP. On the other hand, from any solution to the GLCP we can extract the vector $\mathbf{x}^1 := z$. Given this vector $\mathbf{x}^1$ there is only one way to extend this to an assignment for all x_i^j that is a solution to G. We thus get a one-to-one correspondence between solutions to G and solutions to the GLCP. Since the GLCP defined by M is promised to have a unique solution for every q', this thus implies that the Lin-Bellman system $G' = (L, R, q', S)$ also has a unique solution for every q'. Thus, this is indeed a P-Lin-Bellman instance. ◀

Combining this with the previously proven Theorem 12, we get the following corollary:

▶ **Corollary 15.** *P-GLCP and P-LCP are polynomial-time equivalent.*

4 Colorful Tangents and P-Lin-Bellman

Let us start by introducing the definitions and prior results on the α-Ham Sandwich theorem.

▶ **Definition 16.** *A family of point sets $P_1 = \{p_{1,1}, \ldots, p_{1,s_1}\}, P_2, \ldots, P_d \subset \mathbb{R}^d$ is said to be* well-separated *if for any non-empty index set $I \subset [d]$, there exists a hyperplane h such that h separates the points in $\bigcup_{i\in I} P_i$ from those in $\bigcup_{i\in[d]\setminus I} P_i$.*

In the setting of well-separated point sets, the classical Ham Sandwich theorem can be strengthened to the more modern α-Ham Sandwich theorem due to Steiger and Zhao [21], for which we need the definition of an $(\alpha_1, \ldots, \alpha_d)$-cut:

▶ **Definition 17.** *Given positive integers $\alpha_i \leq |P_i|$ for all $i \in [d]$, an $(\alpha_1, \ldots, \alpha_d)$-cut is a hyperplane h such that $h \cap P_i \neq \emptyset$ and $|h^+ \cap P_i| = \alpha_i$ for all $i \in [d]$.*

In this definition and in the rest of this section, h^+ and h^- denote the two closed halfspaces bounded by a hyperplane h. When h is a colorful hyperplane (i.e., a hyperplane containing a colorful point set, which is a set $\{p_1, \ldots, p_d\}$ with $p_i \in P_i$), its positive side is determined by the orientation of the points $p_i \in P_i$ spanning it.

▶ **Theorem 18** (α-Ham Sandwich theorem [21])**.** *Given d point sets $P_1, \ldots, P_d \subset \mathbb{R}^d$ that are well-separated and in weak general position*[2]*, for every $(\alpha_1, \ldots, \alpha_d)$ where $1 \leq \alpha_i \leq |P_i|$, there exists a unique $(\alpha_1, \ldots, \alpha_d)$-cut.*

[2] Weak general position is a weaker version of general position. We will not go further into this since we will always ensure classical general position when invoking this theorem.

The α-Ham Sandwich theorem guarantees us existence and uniqueness of an $(\alpha_1, \ldots, \alpha_d)$-cut, and it is thus not too surprising that the problem of finding such a cut is contained in UEOPL [3].

In this section, we wish to show equivalence of this problem to P-Lin-Bellman, however, we only manage this with some slight changes. Firstly, we wish to drop the assumption of weak general position, since it is not easily guaranteed when reducing from P-Lin-Bellman. Because of this we need to weaken the definition of $(\alpha_1, \ldots, \alpha_d)$-cuts accordingly:

▶ **Definition 19.** *Given a well-separated family of point sets $P_1, \ldots, P_d \subset \mathbb{R}^d$ and $(\alpha_1, \ldots, \alpha_d)$ such that $1 \leq \alpha_i \leq |P_i|$, a hyperplane h is an $(\alpha_1, \ldots, \alpha_d)$-cut if for all $i \in [d]$, $h \cap P_i \neq \emptyset$ and $|(h^+ \setminus h) \cap P_i| + 1 \leq \alpha_i \leq |h^+ \cap P_i|$.*

In other words, we allow a hyperplane to contain more than one point per color, and all the additional points may be "counted" for either side of the hyperplane. Note that even without any general position assumption, the affine hull of every colorful set of points must have dimension at least $d-1$, and thus span a unique hyperplane (see the full version of the paper). We further show in the full version that every colorful subset of points on the same hyperplane h must be oriented the same way, and thus h^+ is uniquely defined even without the weak general position assumption.

Note that the α-Ham Sandwich theorem (Theorem 18) generalizes directly to the setting where the assumption of weak general position is dropped and Definition 17 is replaced by Definition 19.

▶ **Theorem 20.** *Given a well-separated family of point sets $P_1, P_2, \ldots, P_d \subset \mathbb{R}^d$ and $(\alpha_1, \ldots, \alpha_d)$ for $1 \leq \alpha_i \leq |P_i|$, there exists a unique hyperplane h that is an $(\alpha_1, \ldots, \alpha_d)$-cut according to Definition 19.*

Proof. This simply follows from perturbing the points and applying Theorem 18. ◀

Secondly, we have to strengthen well-separation to *strong well-separation*. We illustrate well-separation and strong well-separation in Figure 3.

▶ **Definition 21.** *A family of point sets $P_1 = \{p_{1,1}, \ldots, p_{1,s_1}\}, P_2, \ldots, P_d \subset \mathbb{R}^d$ is said to be* strongly well-separated *if the point sets $P'_1, \ldots, P'_d$ obtained by projecting $P_1, \ldots, P_d$ to the hyperplane spanned by $p_{1,1}, \ldots, p_{d,1}$ are well-separated.*

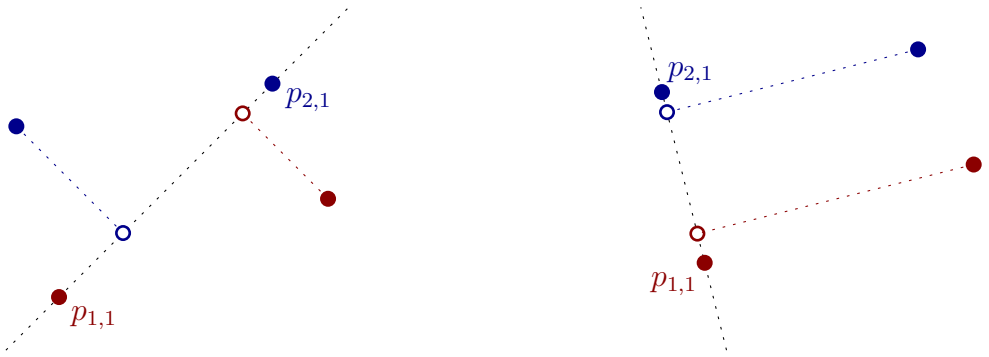

Figure 3 The point sets (dots) on the left are well-separated but not strongly well-separated, since their projections (circles) are not well-separated. The point sets on the right are strongly well-separated.

We are now ready to introduce the problem we wish to study.

▶ **Definition 22.** *SWS-Colorful-Tangent*$(P_1, \ldots, P_d, \alpha_1, \ldots, \alpha_d)$
Input: *d point sets $P_1, \ldots, P_d \subset \mathbb{R}^d$ and a vector $(\alpha_1, \ldots, \alpha_d)$, where $\alpha_i \in \{1, |P_i|\}$.*
Promise: *The point sets $P_1, \ldots, P_d$ are strongly well-separated.*
Output: *An $(\alpha_1, \ldots, \alpha_d)$-cut.*
We depart from the *Ham Sandwich* name for this problem since for $\alpha_i \in \{1, |P_i|\}$, the α-"cuts" are really just colorful tangent hyperplanes, as can be seen in Figure 4.

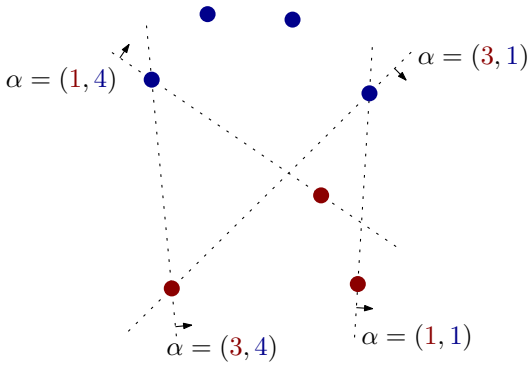

Figure 4 Two well-separated point sets and the solution α-cuts to all four possible α-vectors. Note that the positive side of a colorful line is considered to be the right side when orienting the line from the red point to the blue point.
