Mahaney [14]. Their #NFA algorithm runs in time $O\left(\left(\frac{n\ell}{\varepsilon}\right)^{17}\right)$,[1] where n is the number of states and ℓ is the string length. More recently, Meel, Chakraborty, and Mathur claim an improved running algorithm which runs in time $\widetilde{O}(\frac{n^4\ell^{11}}{\varepsilon^4})$ [26, Theorem 3]. These algorithms first normalize the NFA into a particular layered structure. Applying similar methods on the $s-t$ reliability problem can simplify the analysis, but would greatly slow down the algorithm. In contrast, our method works directly on the DAG. This makes our estimation and sampling subroutines interlock in an intricate way. To analyze the algorithm, we have to carefully separate out various sources of randomness. This leads to a considerably more sophisticated analysis, with a reward of a much better (albeit still high) running time.

Independently and simultaneously, Amarilli, van Bremen, and Meel [2] also found an FPRAS for $s-t$ reliability in DAGs. Their method is to reduce the problem to #NFA via a sequence of reductions, and then invoke the algorithm in [5]. Indeed, as Marcelo Arenas subsequently pointed out to us, counting the number of subgraphs of a DAG in which s can reach t belongs to a complexity class **SpanL** [1], where #NFA is **SpanL**-complete under polynomial-time parsimonious reductions. In particular, every problem in **SpanL** admits an FPRAS because #NFA admits one [5], which implies that $s-t$ reliability in DAGs admits an FPRAS if $q_e = 1/2$ for all edges. The method of [2] reduces a reliability instance of n vertices and m edges, where $q_e = 1/2$ for all edges, to estimating length m accepting strings of an NFA with $O(m^2)$ states.[2] As a consequence, their algorithm (even using the faster algorithm for #NFA [26]) has a running time of $O\left(m^{19}\varepsilon^{-4}\right)$. When $q_e \neq 1/2$, their reduction needs to expand the instance further to reduce to the $q_e = 1/2$ case, slowing down the algorithm even more. In contrast, our algorithm deals with all possible probabilities $0 \leq q_e < 1$ in a unified way. In any case, an algorithm via reductions is much slower than the direct algorithm in Theorem 1.

As both all-terminal reliability and unreliability in undirected graphs have FPRASes [21, 16], one may wonder if FPRAS exists for $s-t$ *unreliability* in DAGs. Here $s-t$ unreliability is the probability that s cannot reach t in the random subgraph. In contrast to Theorem 1, we show that this problem is #**BIS**-hard, where #**BIS** is the problem of counting independent sets in bipartite graphs, whose approximation complexity is still open. This is a central problem in the complexity of approximate counting [13], and is conjectured to have no FPRAS.

▶ **Theorem 2.** *There is no FPRAS to estimate* $s-t$ unreliability *in DAGs unless there is an FPRAS for* #**BIS**. *This is still true even if all edges fail with the same probability.*

Theorem 2 is proved in Section 5. The hardness of $s-t$ unreliability does not contradict Theorem 1. This is because a good relative approximation of x does not necessarily provide a good approximation of $1-x$, especially when x is close to 1.

The complexity of estimating $s-t$ reliability in general directed or undirected graphs remains open. We hope that our work sheds some new light on these decades old problems. Another open problem is to reduce the running time of Theorem 1, as currently the exponent of the polynomial is still high.

[1] The running time of the algorithm in [5] is not explicitly given. This bound is obtained by going through their proof.

[2] In fact, [2] first reduces the reliability instance to an nOBDD (non-deterministic ordered binary decision diagram) of size $O(m)$, which can be further reduced to an NFA of size $O(m^2)$. As they are working with a more general context, no explicit reduction is given for the $s-t$ reliability problem in DAGs. We provide a direct (and essentially the same) reduction in the full version of this paper.

1.1 Algorithm overview

Here we give an overview of our algorithm. For simplicity, we assume that $q_e = 1/2$ for all edges. The general case of $0 \le q_e < 1$ can be solved with very small tweaks.

Let $s = v_1 \prec \cdots \prec v_n = t$ be a topological ordering of the DAG G. (Note that we can ignore vertices before s and after t.) Let R_u be the $u - t$ reliability so that our goal is to estimate R_s. Note that R_{v_i} depends only on the subgraph induced by the vertex set $\{v_i, v_{i+1}, \ldots, v_n\}$. We denote this subgraph by $G_{v_i} = (V_{v_i}, E_{v_i})$. As we assumed $q_e = 1/2$, estimating R_{v_i} is equivalent to estimating the number of (spanning) subgraphs of G_{v_i} in which v_i can reach t. Denote the latter quantity by Z_{v_i} so that $R_{v_i} = Z_{v_i}/2^{|E_{v_i}|}$. For each vertex v_i, our algorithm maintains an estimator and a multi-set of random samples:

- $\widetilde{Z}_{v_i}$:[3] an estimator that approximates Z_{v_i} with high probability;
- S_{v_i}: a multi-set of random subgraphs, where each $H \in S_{v_i}$ is an approximate sample from π_{v_i} and π_{v_i} is the uniform distribution over all spanning subgraphs of G_{v_i} in which v_i can reach t.

Our algorithm computes $\widetilde{Z}_{v_i}$ and S_{v_i} for i from n to 1 by dynamic programming. The base case $v_n = t$ is trivial. In the induction step, suppose the vertex v_i has d out-neighbors $u_1, u_2, \ldots, u_d$. Note that each u_j for $j \in [d]$ comes after v_i in the topological ordering. Let us further assume $v_i \prec u_1 \prec, \ldots, \prec u_d$. For any subgraph H of G_{v_i}, if v_i can reach t in H, then there exists a neighbor u_j such that v_i can reach u_j and u_j can reach t in H. We can write Z_{v_i} as the size of the union $\Omega := \cup_{j=1}^{d} \Omega^{(j)}$, where $\Omega^{(j)}$ contains all subgraph of G_{v_i} where v_i can reach t through the neighbor u_j. Note that it is straightforward to estimate the size of $\Omega^{(j)}$ given $\widetilde{Z}_{u_j}$, and to generate uniform random subgraphs from $\Omega^{(j)}$ using samples in S_{u_j}. Given the size and samples from $\Omega^{(j)}$, a classical algorithm by Karp and Luby [23, 25] can be applied to efficiently estimate the size of the union of sets, namely to compute $\widetilde{Z}_{v_i}$.

The more complicated task is to generate the samples of S_{v_i}. We use a sampling to counting self-reduction á la Jerrum-Valiant-Vazirani [20]. To generate a sample H, we go through each edge e in G_{v_i}, deciding if e is added into H according to its conditional marginal probability. The first edge to consider is (v_i, u_1). Its marginal probability depends on how many subgraphs in Ω contain it. This quantity is the same as the number of subgraphs in which Λ can reach t, where Λ is a new vertex after contracting v_i and u_1. To estimate this number, denoted by Z_Λ, we use the Karp-Luby algorithm again. Note that the Karp-Luby algorithm requires estimates and samples from all out-neighbours of Λ, which have been computed already as these vertices are larger in the topological ordering than v_i. Having estimated Z_Λ, we estimate the marginal probability of (v_i, u_1) and decide if it is included in H. The process then continues to consider the next edge. In each step, we contract all vertices that can be reached from v_i into Λ, and keep estimating new Z_Λ using the Karp-Luby algorithm to compute the conditional marginal probabilities, until all edges are considered to generate H.

A naive implementation of the process above is to generate fresh samples every time S_u is used, which would lead to an exponential number of samples required. To maintain efficiency, the key property of our algorithm is to *reuse* random samples. For any vertex u, the algorithm generates the multi-set of samples S_u only once. Whenever the algorithm needs to use random samples for u, it always picks one sample from the same set S_u. Hence, one sample may be used multiple times during the whole algorithm. Reusing samples

[3] Our algorithm actually directly maintains an estimate $\widetilde{R}_{v_i}$ to the reliability R_{v_i}. In this overview, we use $\widetilde{Z}_{v_i}$ instead for simplicity.

introduces very complicated correlation among all $(\widetilde{Z}_u, S_u)$'s, which is a challenge to proving the correctness of the algorithm. Essentially, our analysis shows that as long as the estimates ($\widetilde{Z}_u$'s) and the samples are accurate enough, the overall error can be controlled. Accurate estimates of Z_u's allow us to bound the total variation (TV) distance between our samples and perfect samples. In turn, the small TV distance implies that there is a coupling between them, which helps us bound the errors of the estimates. This way, we circumvent the effect of correlation on the analysis and achieve the desired overall error bound.

For the overall running time, there are two tasks for each vertex, namely the estimation step (based on Karp-Luby) and the sample generation step. As we also need to perform estimation steps as subroutines when generating samples, the running time is dominated by the time for the sampling step. Let ℓ be the number of samples required per vertex, so that the total number of samples generated is $n\ell$. Roughly speaking, because we can only use the union bound due to various correlation, and because errors accumulate throughout dynamic programming, we set the error to be $\delta := n^{-1}\min\{m^{-1}, \varepsilon\}$ for the estimation step. Each estimation has two stages, first getting a constant approximation and then using the crude estimation to tune the parameters and obtain a $1 \pm \delta$ approximation. This succeeds with constant probability using $O(n\delta^{-2})$ samples. The estimator itself requires $O(m)$ time to compute, and thus the total running time for each estimation step with constant success probability is $\widetilde{O}(mn\delta^{-2})$. However, as samples are reused, we need to apply a union bound to control the error over all possible values of the samples, which are exponentially many. This requires us to amplify the success probability of the estimation step to $\exp(-\Omega(m))$, which means we need to repeat the algorithm $O(m)$ times and take the median. Each estimation step thus takes $\widetilde{O}(m^2n\delta^{-2})$ time and $O(mn\delta^{-2})$ samples. Instead of maintaining $O(mn\delta^{-2})$ samples for every vertex, the aforementioned two-stage estimation allows us to spread the cost and maintain $\ell := \frac{O(mn\delta^{-2})}{n} = O(n^2 m \max\{m^2, \varepsilon^{-2}\})$ samples per vertex, which we show suffice with high probability. As we may do up to $O(m)$ estimation steps during each sampling step, the overall running time is then bounded by $\widetilde{O}(n\ell \cdot m \cdot m^2 n\delta^{-2}) = \widetilde{O}\big(n^6 m^4 \max\{m^4, \varepsilon^{-4}\}\big)$.

2 Preliminaries

2.1 Problem definitions

Let $G = (V, E)$ be a directed acyclic graph (DAG). Each directed edge (or arc) $e = (u, v)$ is associated with a failure probability $0 \le q_e < 1$. (Any edge with $q_e = 1$ can be simply removed.) We also assume graph G is simple because parallel edges with failure probabilities $q_{e_1}, q_{e_2}, \ldots, q_{e_k}$ can be replace with one edge with failure probability $q_e = \prod_{i=1}^{m} q_{e_i}$. Given two vertices $s, t \in V$, the $s - t$ reliability problem asks the probability that s can reach t if each edge $e \in E$ fails (namely gets removed) independently with probability q_e. Formally, let $\boldsymbol{q} = (q_e)_{e \in E}$. The $s - t$ reliability problem is to compute

$$R_{G,\boldsymbol{q}}(s, t) := \Pr_{\mathcal{G}}[\,\text{there is a path from } s \text{ to } t \text{ in } \mathcal{G}\,], \tag{1}$$

where $\mathcal{G} = (V, \mathcal{E})$ is a random subgraph of $G = (V, E)$ such that each $e \in E$ is added independently to $\mathcal{E}$ with probability $1 - q_e$.

Closely connected to estimating $s - t$ reliability is a sampling problem, which we call the $s - t$ *subgraph sampling* problem. Here the goal is to sample a random (spanning) subgraph G' conditional on that there is at least one path from s to t in G'. Formally, let $\Omega_{G,s,t}$ be

the set of all subgraphs $H = (V, E_H)$ of G such that $E_H \subseteq E$ and s can reach t in H. The algorithm needs to draw samples from the distribution $\pi_{G,s,t,\boldsymbol{q}}$ whose support is $\Omega_{G,s,t}$ and for any $H = (V, E_H) \in \Omega_{G,s,t}$,

$$\pi_{G,s,t,\boldsymbol{q}}(H) = \frac{1}{R_{G,\boldsymbol{q}}(s,t)} \cdot \prod_{e \in E_H} (1 - q_e) \prod_{f \in E \setminus E_H} q_f. \tag{2}$$

2.2 More notations

Fix a DAG $G = (V, E)$. For any two vertices u and v, we use $u \rightsquigarrow_G v$ to denote that u can reach v in the graph G and use $u \not\rightsquigarrow_G v$ to denote that u cannot reach v in the graph G. It always holds that $u \rightsquigarrow_G u$. Fix two vertices s and t, where s is the source and t is the sink. The failure probabilities $\mathbf{q}$, s, and t will be the same throughout the paper, and thus we omit them from the subscripts. For any vertex $u \in V$, we use $G_u = G[V_u]$ to denote the subgraph of G induced by the vertex set

$$V_u := \{w \in V \mid u \rightsquigarrow_G w \wedge w \rightsquigarrow_G t\}. \tag{3}$$

Without loss of generality, we assume $G_s = G$. This means that all vertices except s have at least one in-neighbour, and thus $m \geq n - 1$. If $G_s \neq G$, then all vertices and edges in $G - G_s$ have no effect on $s - t$ reliability and we can simply ignore them. For the sampling problem, we can first solve it on the graph G_s and then independently add each edge e in $G - G_s$ with probability $1 - q_e$.

Our algorithm actually solves the $u - t$ reliability and $u - t$ subgraph sampling problems in G_u for all $u \in V$. Let $G_u = (V_u, E_u)$. For any subgraph $H = (V_u, E_H)$ of G_u, define the weight function

$$w_u(H) := \begin{cases} \prod_{e \in E_H} (1 - q_e) \prod_{f \in E_u \setminus E_H} q_f & \text{if } u \rightsquigarrow_H t; \\ 0 & \text{if } u \not\rightsquigarrow_H t. \end{cases} \tag{4}$$

Define the distribution π_u by

$$\pi_u(H) := \frac{w_u(H)}{R_u},$$

where the partition function (the normalizing factor)

$$R_u := \sum_{H\text{: subgraph of } G_u} w_u(H)$$

is exactly the $u - t$ reliability in the graph G_u. Finally, let

$$\Omega_u := \{H = (V_u, E_H) \mid E_H \subseteq E_u \wedge u \rightsquigarrow_H t\} \tag{5}$$

be the support of π_u. Also note that R_s and π_s are the probability $R_{G,\boldsymbol{q}}(s,t)$ and the distribution $\pi_{G,s,t,\boldsymbol{q}}$ defined in (1) and (2), respectively. The set Ω_s is the set $\Omega_{G,s,t}$ in Section 2.1.

2.3 The total variation distance and coupling

Let μ and ν be two discrete distributions over Ω. The *total variation distance* between μ and ν is defined by

$$d_{\mathrm{TV}}(\mu, \nu) := \frac{1}{2} \sum_{x \in \Omega} |\mu(x) - \nu(x)|.$$

If $X \sim \mu$ and $Y \sim \nu$ are two random variables, we also abuse the notation and write $d_{\mathrm{TV}}(X, Y) := d_{\mathrm{TV}}(\mu, \nu)$.

A *coupling* between μ and ν is a joint distribution (X, Y) such that $X \sim \mu$ and $Y \sim \nu$. The following coupling inequality is well-known.

▶ **Lemma 3.** *For any coupling $\mathcal{C}$ between two random variables $X \sim \mu$ and $Y \sim \nu$, it holds that*

$$\Pr_{\mathcal{C}}[X \neq Y] \geq d_{TV}(\mu, \nu).$$

Moreover, there exists an optimal coupling that achieves equality.

3 The algorithm

In this section we give our algorithm. We also give intuitions behind various design choices, and give some basic properties of the algorithm along the way. We give a sketch of the analysis in Section 4 and the full analysis is in the full version of this paper.

3.1 The framework of the algorithm

As $G = G_s$ is a DAG, there is a topological ordering of all vertices. There may exist many topological orderings. We pick an arbitrary one, say, $v_1, \ldots, v_n$. It must hold that $v_1 = s$ and $v_n = t$. The topological ordering guarantees that if (u, v) is an edge, u must come before v in the ordering, denoted $u \prec v$.

On a high level, our algorithm is to inductively compute an estimator $\widetilde{R}_u$ of R_u, from $u = v_n$ to $u = v_1$. In addition to $\widetilde{R}_u$, we also maintain a multi-set S_u of samples from π_u over Ω_u. For any vertex $u \in V$, let $\Gamma_{\mathrm{out}}(u) := \{w \mid (u, w) \in E\}$ denote the set of out-neighbours of u. Let

$$\ell := (60n + 150m)(400n + 500\left\lceil 10^4 n^2 \max\{m^2, \varepsilon^{-2}\}\right\rceil) = O((n+m)n^2 \max\{m^2, \epsilon^{-2}\}) \tag{6}$$

be the size of S_v for all $v \in V_u$, where n is the number of vertices in G and m is the number of edges in G. The choice of this parameter is explained in the last paragraph of Section 1.1. Our algorithm is outlined in Algorithm 1. Note that G_t is an isolated vertex. For consistency, we let S_t contain ℓ copies of $\emptyset$.

The base case of $v_n = t$ is trivial. The subroutine $\mathsf{Sample}(\cdot)$ uses $(\widetilde{R}_{v_i}, S_{v_i})$ for all $i > k$ and $\widetilde{R}_{v_k}$ to generate samples in S_{v_k}. The subroutine $\mathsf{ApproxCount}(V, E, u, (\widetilde{R}_w, S_w)_{\Gamma_{\mathrm{out}}(u)})$ takes a graph $G = (V, E)$, a vertex u, and $(\widetilde{R}_w, S_w)$ for all $w \in \Gamma_{\mathrm{out}}(u)$ as the input, and it outputs an approximation of the $u - t$ reliability in the graph G. We describe Sample in Section 3.2 and (a slightly more general version of) $\mathsf{ApproxCount}$ in Section 3.3.

3.2 Generate samples

Let $u = v_k$ where $k < n$. Recall that $G_u = (V_u, E_u)$ is the graph defined in (3). The sampling algorithm aims to output a random spanning subgraph $H = (V_u, \mathcal{E})$ from the distribution π_u. The algorithm is based on the sampling-to-counting reduction in [20]. It scans each edge e in E_u and decides whether to put e into the set $\mathcal{E}$ or not. The algorithm maintains two edge sets:

- $E_1 \subseteq E_u$: the set of edges that have been scanned by the algorithm;
- $\mathcal{E} \subseteq E_1$: the current set of edges sampled by the algorithm.

Algorithm 1 An FPRAS for $s-t$ reliabilities in DAGs.

Input: a DAG $G=(V,E)$, a vector $\boldsymbol{q}=(q_e)_{e\in E}$, the source s, the sink t, and an error bound $0<\varepsilon<1$, where $G=G_s$ and $V=\{v_1,v_2,\ldots,v_n\}$ is topologically ordered with $v_1=s$ and $v_n=t$

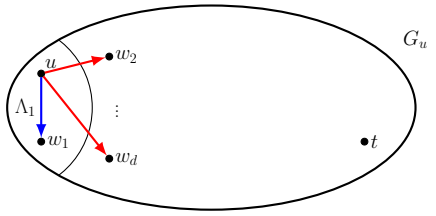
Output: an estimator $\widetilde{R}_s$ of R_s

let $\widetilde{R}_t=1$ and S_t be a multi set of ℓ $\emptyset$'s;
for k *from* $n-1$ *to* 1 **do**
  $\widetilde{R}_{v_k} \leftarrow \mathsf{ApproxCount}\Big(V_{v_k}, E_{v_k}, v_k, (\widetilde{R}_w, S_w)_{w\in\Gamma_{out}(v_k)}\Big)$;
  $S_{v_k} \leftarrow \emptyset$;
  for j *from* 1 *to* ℓ **do**
    $S_{v_k} \leftarrow S_{v_k} \cup \mathsf{Sample}\Big(v_k, (\widetilde{R}_w, S_w)_{w\in\{v_{k+1},v_{k+2},\ldots,v_n\}}, \widetilde{R}_{v_k}\Big)$;
return $\widetilde{R}_s$.

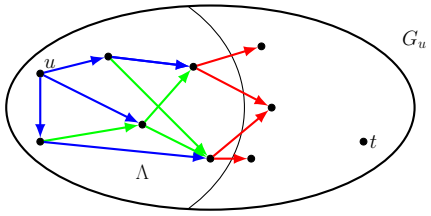
Also, let $E_2 := E_u \setminus E_1$ be the set of edges that have not been scanned yet by the algorithm. Given any $\mathcal{E}$, we can uniquely define the following subset of vertices

$$\Lambda = \Lambda_{\mathcal{E}} := \mathsf{rch}(u, V_u, \mathcal{E}) = \{w \in V_u \mid u \text{ can reach } w \text{ through edges in } \mathcal{E}\}. \tag{7}$$

In other words, let $G'=(V_u,\mathcal{E})$ and Λ is the set of vertices that u can reach in G'. Note that $u\in\Lambda$ for any $\mathcal{E}$. We will keep updating Λ as $\mathcal{E}$ expands. When calculating the marginal probability of the next edge, the path to t can start from any vertex in Λ. Thus we need to estimate the reliability from Λ to t. Instead of having a single source, as called in Algorithm 1, we use a slightly more general version of ApproxCount, described in Section 3.3, to allow a set Λ of sources. This subroutine ApproxCount takes input $(V,E,\Lambda,(\widetilde{R}_w,S_w)_{w\in\partial\Lambda})$ and approximates the $\Lambda-t$ reliability in (V,E), which is the probability that there exists at least one vertex in Λ being able to reach t if each edge $e\in E$ fails independently with probability q_e. An equivalent way of seeing it is to contract all vertices in Λ into a single vertex u first, and then calculate the $u-t$ reliability in the resulting graph. Sample is described in Algorithm 2, and some illustration is given in Figure 1.



(a) At the start, we consider the first edge (u,w_1). To compute its marginal, we estimate two reliability, where the source is either $\Lambda_1=\{u,w_1\}$ (shown in picture) or just u, respectively.



(b) As Algorithm 2 progresses, there are chosen edges $\mathcal{E}$ (blue), not chosen edges $E_1\setminus\mathcal{E}$ (green), and the boundary edges (red). The set Λ contains vertices reachable from u using only $\mathcal{E}$.

Figure 1 An illustration of sampling from π_u.

▶ Remark 4 (Crash of Sample). The subroutine Sample (Algorithm 2) may crash in following cases: (1) in Algorithm 2, $\partial\Lambda=\emptyset$; (2) in Algorithm 2, $q_e c_0+(1-q_e)c_1=0$; (3) in Algorithm 2, $\frac{w_u(H)}{4p_0 p}>1$; (4) in Algorithm 2, $F=0$. If it crashes, we stop Algorithm 1 immediately and output $\widetilde{R}_s=0$.

Algorithm 2 $\mathsf{Sample}\Big(u, (\widetilde{R}_w, S_w)_{w\in\{v_{k+1},v_{k+2},\ldots,v_n\}}, \widetilde{R}_{v_k}\Big)$.

Input: a vertex $u = v_k$, all $(\widetilde{R}_w, S_w)$ for $w \in \{v_{k+1}, v_{k+2}, \ldots, v_n\}$, and $\widetilde{R}_{v_k} = \widetilde{R}_u$
Output: a random subgraph $H = (V_u, \mathcal{E})$

$T \leftarrow \lceil 1000 \log \frac{n}{\varepsilon} \rceil$ and $F \leftarrow 0$;
$p_0 \leftarrow \widetilde{R}_u$;
repeat
  let $p \leftarrow 1$;
  let $E_1 \leftarrow \emptyset$, $E_2 \leftarrow E_u \setminus E_1$ and $\Lambda = \{u\}$;
  while $t \notin \Lambda$ **do**
    let $\partial\Lambda \leftarrow \{w \notin \Lambda \mid \exists w' \in \Lambda \text{ s.t. } (w', w) \in E_2\}$; let $w^* \in \partial\Lambda$ be the smallest vertex in the topological ordering; pick an arbitrary edge $e = (w', w^*) \in E_2$ such that $w' \in \Lambda$;
    let $\Lambda_1 \leftarrow \mathsf{rch}(u, V_u, \mathcal{E} \cup \{e\})$;
    $E_1 \leftarrow E_1 \cup \{e\}$ and $E_2 \leftarrow E_2 \setminus \{e\}$;
    $\partial\Lambda_1 \leftarrow \{w \notin \Lambda_1 \mid \exists w' \in \Lambda_1 \text{ s.t. } (w', w) \in E_2\}$ and $\partial\Lambda \leftarrow \{w \notin \Lambda \mid \exists w' \in \Lambda \text{ s.t. } (w', w) \in E_2\}$;
    $c_0 \leftarrow \mathsf{ApproxCount}(V_u, E_2, \Lambda, (\widetilde{R}_w, S_w)_{w\in\partial\Lambda})$;
    $c_1 \leftarrow \mathsf{ApproxCount}(V_u, E_2, \Lambda_1, (\widetilde{R}_w, S_w)_{w\in\partial\Lambda_1})$;
    let $c \leftarrow 1$ with probability $\frac{(1-q_e)c_1}{q_e c_0 + (1-q_e)c_1}$; otherwise $c \leftarrow 0$;
    if $c = 1$, **then** let $\mathcal{E} \leftarrow \mathcal{E} \cup \{e\}$, $\Lambda \leftarrow \Lambda_1$, $p \leftarrow p\frac{(1-q_e)c_1}{q_e c_0 + (1-q_e)c_1}$;
    if $c = 0$, **then** let $p \leftarrow p\Big(1 - \frac{(1-q_e)c_1}{q_e c_0 + (1-q_e)c_1}\Big)$;
  for *all edges* $e \in E_2$ **do**
    let $c \leftarrow 1$ with probability $1 - q_e$; otherwise $c \leftarrow 0$;
    if $c = 1$, **then** let $\mathcal{E} \leftarrow \mathcal{E} \cup \{e\}$ and $p \leftarrow p(1 - q_e)$;
    if $c = 0$, **then** let $p \leftarrow pq_e$;
  let $F \leftarrow 1$ with probability $\frac{w_u(H)}{4pp_0}$, where $H = (V_u, \mathcal{E})$;
  $T \leftarrow T - 1$;
until $T < 0$ *or* $F = 1$;
if $F = 1$ then **return** $H = (V_u, \mathcal{E})$; **else return** $\perp$;

The algorithm needs c_0 and c_1 in order to compute the marginal probability of e in Algorithm 2. The quantity c_0 is an estimate to the reliability conditional on e not selected and all choices made so far (namely $E_H \cap E_1 = \mathcal{E}$). Similarly, c_1 is an estimate to the reliability conditional on e selected and $E_H \cap E_1 = \mathcal{E}$. Thus, if $\mathsf{ApproxCount}$ returns exact values of c_0 and c_1, then

$$\Pr_{H=(V_u,E_H)\sim\pi_u}\left[e \in \mathcal{E}_H \mid E_H \cap E_1 = \mathcal{E}\right] = \frac{(1-q_e)c_1}{q_e c_0 + (1-q_e)c_1}.$$

However, $\mathsf{ApproxCount}$ can only approximate the reliabilities c_0 and c_1. To handle the error from $\mathsf{ApproxCount}$, our algorithm maintains a number p, which is the probability of selecting the edges in $\mathcal{E}$ and not selecting those in $E_1 \setminus \mathcal{E}$. By the time we reach Algorithm 2, p becomes the probability that H is generated by the algorithm. Then the algorithm uses a filter (with filter probability $\frac{w_u(H)}{4p_0 p}$) to correct the distribution of H. Conditional on passing the filter, H is a perfect sample from π_u. The detailed analysis of the error is given in the full version of this paper.

Before we go to the ApproxCount algorithm, we state one important property of Algorithm 2.

▶ **Lemma 5.** *In Algorithm 2, the following property holds: at the beginning of every while-loop, for any $w \in \partial\Lambda$, $E_1 \cap E_w = \emptyset$, where E_w is the edge set of the graph $G_w = (V_w, E_w)$ defined in* (3)*.*

The above lemma holds because we always pick the smallest vertex in the topological ordering at the beginning of the while-loop. The formal proof is in the full version of this paper.

▶ **Corollary 6.** *In Algorithm 2, in every while-loop, $\Lambda_1 = \Lambda \cup \{w^*\}$.*

Proof. Clearly $\Lambda \cup \{w^*\} \subseteq \Lambda_1$. Suppose there exists $w_0 \neq w^*$ such that $w_0 \in \Lambda_1 \setminus \Lambda$. Then $w_0 \in V_u$ can be reached from w^* through edges in $\mathcal{E}$. The vertex w_0 must be in G_{w^*}, which implies $\mathcal{E} \cap E_{w^*} \neq \emptyset$, and thus $E_1 \cap E_{w^*} \neq \emptyset$. A contradiction to Lemma 5. ◀

3.3 Approximate counting

Our ApproxCount subroutine is used in both Algorithm 1 and Algorithm 2. To suit Algorithm 2, ApproxCount takes input $(V, E, \Lambda, (\widetilde{R}_w, S_w)_{w\in\partial\Lambda})$ and approximates the $\Lambda - t$ reliability $R_\Lambda := \Pr_{\mathcal{G}}[\Lambda \rightsquigarrow_{\mathcal{G}} t]$, where $\mathcal{G}$ is a random spanning subgraph of G obtained by removing each edge e independently with probability q_e, and $\Lambda \rightsquigarrow_{\mathcal{G}} t$ denotes the event that $\exists w \in \Lambda$ s.t. $w \rightsquigarrow_{\mathcal{G}} t$. When called by Algorithm 1, Λ is a single vertex, and when called by Algorithm 2, Λ is the set defined in (7). Moreover, the input satisfies:

- $G = (V, E)$ is a DAG containing the sink t and each edge has a failure probability q_e (for simplicity, we do not write t and all q_e explicitly in the input as they do not change throughout Algorithm 1 and Algorithm 2);
- $\Lambda \subseteq V$ is a subset of vertices that act as sources and $\partial\Lambda := \{w \in V \setminus \Lambda \mid \exists w' \in \Lambda \text{ s.t. } (w', w) \in E\}$;
- for any $w \in \partial\Lambda$, $\widetilde{R}_w$ is an approximation of the $w - t$ reliability in G_w and S_w is a set of ℓ approximate random samples from the distribution π_w, where G_w is defined in (3).

All points above hold when Algorithm 3 is evoked by Algorithm 1 or Algorithm 2. The first two points are easy to verify and the last one is verified in the full version of this paper.

The algorithm first rules out the following two trivial cases:

- if $t \in \Lambda$, the algorithm returns 1;
- if Λ cannot reach t in graph G, the algorithm returns 0.[4]

As we are dealing with the more general set-to-vertex reliability, we need some more definitions. Define

$$\Omega_\Lambda := \{H = (V, E_H) \mid E_H \subseteq E \wedge \Lambda \rightsquigarrow_H t\}. \tag{8}$$

For any subgraph $H = (V, E_H)$ of $G = (V, E)$, define the weight function

$$w_\Lambda(H) := \begin{cases} \prod_{e\in E_H}(1 - q_e)\prod_{f\in E\setminus E_H} q_f & \text{if } \Lambda \rightsquigarrow_H t; \\ 0 & \text{if } \Lambda \not\rightsquigarrow_H t. \end{cases} \tag{9}$$

Define the distribution π_Λ, whose support is Ω_Λ, by

$$\pi_\Lambda(H) := \frac{w_\Lambda(H)}{R_\Lambda}, \quad \text{where } R_\Lambda := \sum_{H\in\Omega_\Lambda} w_\Lambda(H). \tag{10}$$

[4] Since all $q_e < 1$, $R_\Lambda > 0$ if and only if $\Lambda \rightsquigarrow_G t$.

Let $\partial\Lambda$ be listed as $\{u_1, \ldots, u_d\}$ for some $d \in [n]$. Note that $d \geq 1$ because $R_\Lambda > 0$ and $t \notin \Lambda$. To estimate R_Λ, we first write Ω_Λ in (8) as a union of d sets. For each $1 \leq i \leq d$, define

$$\Omega_\Lambda^{(i)} := \{H = (V, E_H) \mid (E_H \subseteq E) \wedge (\exists u \in \Lambda, \text{ s.t. } (u, u_i) \in E) \wedge (u_i \rightsquigarrow_H t)\}.$$

▶ **Lemma 7.** *If $t \notin \Lambda$, $\Omega_\Lambda = \cup_{i=1}^d \Omega_\Lambda^{(i)}$.*

Proof. We first show $\cup_{i=1}^d \Omega_\Lambda^{(i)} \subseteq \Omega_\Lambda$. Fix any $H \in \cup_{i=1}^d \Omega_\Lambda^{(i)}$, say $H \in \Omega_\Lambda^{(i^*)}$ ($i^* \in [d]$ may not be unique, in which case we pick an arbitrary one). Then Λ can reach t in H, because we can first move from Λ to u_{i^*} and then move from u_{i^*} to t. This implies $H \in \Omega_\Lambda$. We next show $\Omega_\Lambda \subseteq \cup_{i=1}^d \Omega_\Lambda^{(i)}$. Fix any $H \in \Omega_\Lambda$. There is a path from Λ to t in H. Say the path is $w_1, w_2, \ldots, w_p = t$. Then $w_1 \in \Lambda$ (hence $w_1 \neq t$) and $w_2 = u_{i^*}$ for some $i^* \in [d]$. Hence, H contains the edge (w_1, u_{i^*}) and $u_{i^*} \rightsquigarrow_H t$. This implies $H \in \cup_{i=1}^d \Omega_\Lambda^{(i)}$. ◀

Similar to (10), we define $\pi^{(i)}$,[5] whose support is $\Omega_\Lambda^{(i)}$, by

$$\pi_\Lambda^{(i)}(H) := \frac{w_\Lambda(H)}{R_\Lambda^{(i)}}, \quad \text{where } R_\Lambda^{(i)} := \sum_{H \in \Omega_\Lambda^{(i)}} w_\Lambda(H). \tag{11}$$

In order to perform the Karp-Luby style estimation, we need to be able to do the following three things:

1. compute the value $R_\Lambda^{(i)}$ for each $i \in [d]$;
2. draw samples from $\pi_\Lambda^{(i)}$ for each $i \in [d]$;
3. given any $i \in [d]$ and $H \in \Omega_\Lambda$, determine whether $H \in \Omega_\Lambda^{(i)}$.

Suppose we can do them for now.[6] Consider the following estimator Z_Λ:

1. draw an index $i \in [d]$ such that i is drawn with probability proportional to $R_\Lambda^{(i)}$;
2. draw an sample H from $\pi_\Lambda^{(i)}$;
3. let $Z_\Lambda \in \{0, 1\}$ indicate whether i is the smallest index $j \in [d]$ satisfying $H \in \Omega_\Lambda^{(j)}$.

It is straightforward to see that

$$\begin{aligned}
\mathbb{E}[Z_\Lambda] &= \sum_{i=1}^d \frac{R_\Lambda^{(i)}}{\sum_{j=1}^d R_\Lambda^{(j)}} \sum_{H \in \Omega_\Lambda^{(i)}} \pi_\Lambda^{(i)}(H) \cdot \mathbf{1}\left[H \in \Omega_\Lambda^{(i)} \wedge \left(\forall j < i, H \notin \Omega_\Lambda^{(j)}\right)\right] \\
&= \frac{\sum_{i=1}^d \sum_{H \in \Omega_\Lambda^{(i)}} w_\Lambda(H) \cdot \mathbf{1}\left[H \in \Omega_\Lambda^{(i)} \wedge \left(\forall j < i, H \notin \Omega_\Lambda^{(j)}\right)\right]}{\sum_{j=1}^d R_\Lambda^{(j)}} \\
\text{(by Lemma 7)} \quad &= \frac{R_\Lambda}{\sum_{j=1}^d R_\Lambda^{(j)}} \geq \frac{1}{d} \geq \frac{1}{n},
\end{aligned} \tag{12}$$

where the first inequality holds because each H belongs to at most d different sets. Since Z_Λ is a 0/1 random variable, $\mathrm{Var}(Z_\Lambda) \leq 1$. Hence, we can first estimate the expectation of Z_Λ by repeating the process above and taking the average, and then use $\mathbb{E}[Z_\Lambda] \sum_{j=1}^d R_\Lambda^{(j)}$ as the estimator $\widetilde{R}_\Lambda$ for R_Λ. However, in the input of ApproxCount, we only have estimates $\widetilde{R}_{u_i}$ and a limited set of samples S_{u_i} for each $u_i \in \partial\Lambda$. Our algorithm will need to handle these imperfections.

[5] One may notice that if $\Omega_\Lambda^{(i)} = \emptyset$, then $\pi_\Lambda^{(i)}$ is not well-defined. In the full version of this paper, we prove that $\Omega_\Lambda^{(i)} = \emptyset$ never happens.

[6] We will do (1) and (2) approximately rather than exactly. This will incur some error that will be controlled later.

The third step of implementing the estimator Z_Λ is straightforward by a BFS. For the first step, $R_\Lambda^{(i)}$ can be easily computed given R_{u_i}, and we will use the estimates $\widetilde{R}_{u_i}$ instead. For the second step, define

$$\delta_\Lambda(u_i) := \{(w, u_i) \in E \mid w \in \Lambda\}.$$

To sample from $\pi_\Lambda^{(i)}$, we shall sample at least one edge in $\delta_\Lambda(u_i)$, sample a subgraph H from π_{u_i}, and add all other edges independently. These are summarized by the next lemma.

▶ **Lemma 8.** *For any $i \in [d]$, it holds that $R_\Lambda^{(i)} = \left(1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}\right) R_{u_i}$ and a random sample $H' = (V, E_{H'}) \sim \pi_\Lambda^{(i)}$ can be generated by the following procedure:*

- *sample $H = (V_{u_i}, E_H) \sim \pi_{u_i}$;*
- *let $E_{H'} = E_H \cup D$, where $D \subseteq \delta_\Lambda(u_i)$ is a random subset with probability proportional to*

$$\mathbf{1}[D \neq \emptyset] \cdot \prod_{e \in \delta_\Lambda(u_i) \cap D} (1 - q_e) \prod_{f \in \delta_\Lambda(u_i) \setminus D} q_f; \tag{13}$$

- *add each $e \in E \setminus (E_{u_i} \cup \delta_\Lambda(u_i))$ into $E_{H'}$ independently with probability $1 - q_e$.*

All three steps above handle mutually exclusive edge sets and thus are mutually independent.

Proof. If each edge e in G is removed independently with probability q_e, we have a random spanning subgraph $\mathcal{G} = (V, \mathcal{E})$. By the definition of $R_\Lambda^{(i)}$,

$$\begin{aligned} R_\Lambda^{(i)} &= \Pr\left[\exists u \in \Lambda, \text{ s.t. } (u, u_i) \in \mathcal{E} \wedge u_i \rightsquigarrow_{\mathcal{G}} t\right] \\ &= \Pr\left[\exists u \in \Lambda, \text{ s.t. } (u, u_i) \in \mathcal{E}\right] \cdot \Pr\left[u_i \rightsquigarrow_{\mathcal{G}} t \mid \exists u \in \Lambda, \text{ s.t. } (u, u_i) \in \mathcal{E}\right]. \end{aligned}$$

It is easy to see $\Pr[\exists u \in \Lambda, \text{ s.t. } (u, u_i) \in \mathcal{E}] = 1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}$. For the second conditional probability, note that the event $u_i \rightsquigarrow_{\mathcal{G}} t$ depends only on the randomness of edges in graph G_{u_i}. In other words, for any edges $e \in E \setminus E_{u_i}$, whether or not e is removed has no effect on the $u_i - t$ reachability. Due to acyclicity, all edges in $\delta_\Lambda(u_i)$ are not in the graph G_{u_i}. We have

$$R_\Lambda^{(i)} = \left(1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}\right) R_{u_i}.$$

By definition (11), $\pi_\Lambda^{(i)}$ is the distribution of $\mathcal{G} = (V, \mathcal{E})$ conditional on $\exists u \in \Lambda, \text{ s.t. } (u, u_i) \in \mathcal{E}$ and $u_i \rightsquigarrow_{\mathcal{G}} t$. For any graph $H' = (V, E_{H'})$ satisfying $\exists u \in \Lambda, \text{ s.t. } (u, u_i) \in E_{H'}$ and $u_i \rightsquigarrow_{H'} t$, we have

$$\begin{aligned} \pi_\Lambda^{(i)}(H') &= \Pr\left[\mathcal{G} = H' \mid \exists u \in \Lambda, \text{ s.t. } (u, u_i) \in \mathcal{E} \wedge u_i \rightsquigarrow_{\mathcal{G}} t\right] \\ &= \frac{\Pr[\mathcal{G} = H']}{R_\Lambda^{(i)}} = \frac{\Pr[\mathcal{G} = H']}{(1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}) R_{u_i}} \\ &= \prod_{e \in E_{H'} : e \in E \setminus E_{u_i}} (1 - q_e) \prod_{f \notin E_{H'} : f \in E \setminus E_{u_i}} q_f \cdot \frac{w_{u_i}(H'[V_{u_i}])}{(1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}) R_{u_i}} \\ &= \pi_{u_i}(H'[V_{u_i}]) \cdot \frac{\prod_{e \in \delta_\Lambda(u_i) \cap E_{H'}} (1 - q_e) \prod_{f \in \delta_\Lambda(u_i) \setminus E_{H'}} q_f}{1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}} \\ &\quad \cdot \prod_{\substack{e \in E_{H'} : \\ e \in E \setminus (E_{u_i} \cup \delta_\Lambda(u_i))}} (1 - q_e) \prod_{\substack{f \notin E_{H'} : \\ f \in E \setminus (E_{u_i} \cup \delta_\Lambda(u_i))}} q_f. \end{aligned}$$

The probability above exactly matches the procedure in the lemma. ◀

The first sampling step in Lemma 8 can be done by directly using the samples from S_{u_i}. We still need to show that the second step in Lemma 8 can be done efficiently. The proof of Lemma 9 is in the full version of this paper.

▶ **Lemma 9.** *There is an algorithm such that given a set $S = \{1, 2, \dots, n\}$ and n numbers $0 \le q_1, q_2, \dots, q_n < 1$, it return a random non-empty subset $D \subseteq S$ with probability proportional to $\mathbf{1}[D \neq \emptyset] \prod_{i \in D}(1 - q_i) \prod_{j \in S \setminus D} q_j$ in time $O(n)$.*

Now, we are almost ready to describe ApproxCount (Algorithm 3). For any u_i, we have an approximate value $\widetilde{R}_{u_i}$ of R_{u_i} and we also have a set S_{u_i} of ℓ approximate samples from the distribution π_{u_i}. By Lemma 8 and Lemma 9, we can efficiently approximate $R^{(i)}_\Lambda$ and generate approximate samples from $\pi^{(i)}_\Lambda$. Hence, we can simulate the process described below Lemma 7 to estimate R_Λ.

However, to save the number of samples, there is a further complication. Our algorithm estimates the expectation of $\mathbb{E}[Z_\Lambda]$ in two rounds and then takes the median of estimators. Recall (6). We further divide ℓ by introducing the following parameters:

$$\begin{aligned} &\ell = B\ell_0, \quad B := 60n + 150m, \quad \ell_0 := \ell_1 + 500\ell_2, \\ &\ell_1 := 400n, \quad \ell_2 := \lceil 10^4 n^2 \max\{m^2, \epsilon^{-2}\} \rceil. \end{aligned} \tag{14}$$

Then we do the following.

- For any $u_i \in \partial\Lambda$, we divide all ℓ samples in S_{u_i} into B blocks, each containing ℓ_0 samples. Denote the B blocks by $S^{(1)}_{u_i}, S^{(2)}_{u_i}, \dots, S^{(B)}_{u_i}$. Each block here is used for one estimatior.
- For each $i \in [d]$ and $j \in [B]$, we further partition $S^{(j)}_{u_i}$ into two multi-sets $S^{(j,1)}_{u_i}$ and $S^{(j,2)}_{u_i}$, where $S^{(j,1)}_{u_i}$ has ℓ_1 samples and $S^{(j,2)}_{u_i}$ has $500\ell_2$ samples, used for the two rounds, respectively.
- For each $j \in [B]$, we do the following two round estimation:
  1. use samples in $(S^{(j,1)}_{u_i})_{i \in [d]}$ to obtain a *constant-error* estimation $\widehat{Z}^{(j)}_\Lambda$ of $\mathbb{E}[Z_\Lambda]$;
  2. use $\widehat{Z}^{(j)}_\Lambda$ and samples in $(S^{(j,2)}_{u_i})_{i \in [d]}$ to obtain a more accurate *estimation* $\widetilde{Z}^{(j)}_\Lambda$ of $\mathbb{E}[Z_\Lambda]$;
  3. let $Q^{(j)}_\Lambda \leftarrow \widetilde{Z}^{(j)}_\Lambda \sum_{i=1}^{d} \widetilde{R}^{(i)}_\Lambda$, where $\widetilde{R}^{(i)}_\Lambda := \big(1 - \prod_{u \in \delta_\Lambda(u_i)} q_{(u,u_i)}\big)\widetilde{R}_{u_i}$ for each $i \in [d]$.
- Return the median number $\widetilde{R}_\Lambda := \text{median}\left\{Q^{(1)}_\Lambda, Q^{(2)}_\Lambda, \dots, Q^{(B)}_\Lambda\right\}$.

A detailed description of ApproxCount is given in Algorithm 3. It uses a subroutine Estimate, which generates the Karp-Luby style estimator and is described in Algorithm 4.

Each time Algorithm 3 finishes, its input (V, E, Λ) and output $\widetilde{R}_\Lambda$ are stored in the memory. If Algorithm 3 is ever evoked again with the same (V, E, Λ), we simply return $\widetilde{R}_\Lambda$ from the memory.

Algorithm 3 first obtains the constant-error estimation $\widehat{Z}^{(j)}_\Lambda$ in Algorithm 3. Next, it puts $\widehat{Z}^{(j)}_\Lambda$ into the parameters and run the subroutine Estimate again to get a more accurate estimation $\widetilde{Z}^{(j)}_\Lambda$. The benefit of this two-round estimation is that we can save the number of samples maintained for each vertex. It costs only a small number of samples to get the crude estiamtion, but the crude estimation carries information of the ratio $\frac{\sum_{t \in [d]} R^{(t)}_\Lambda}{R_\Lambda}$, which allows us to fine tune the number of samples required per vertex for the good estimation. To be more specific, in the second call of the subroutine Estimate, the number of overall samples, namely the parameter T which depends on $\widehat{Z}^{(j)}_\Lambda$, can still be as large as $\Omega(\ell_2 n)$ in the worst case, and yet each $S^{(j,2)}_{u_i}$ has only $O(\ell_2)$ samples in the block. In the analysis, we will show that this many samples per vertex suffice with high probability and Algorithm 4 of Algorithm 4 (the failure case) is executed with low probability. The reason is that, roughly

Algorithm 3 $\mathsf{ApproxCount}\Big(V, E, \Lambda, (\widetilde{R}_w, S_w)_{w\in\partial\Lambda}\Big)$.

Input: a graph $G = (V, E)$, a subset $\Lambda \subseteq V$, all $(\widetilde{R}_w, S_w)$ for $w \in \partial\Lambda$, where $\partial\Lambda = \{w \in V \setminus \Lambda \mid \exists w' \in \Lambda \text{ s.t. } (w', w) \in E\}$;
Output: an estimator $\widetilde{R}_\Lambda$ of R_Λ
if $t \in \Lambda$, **then return** 0; **if** Λ cannot reach t in G, **then return** 1;
for $u_i \in \partial\Lambda$ **do**
  $\widetilde{R}^{(i)}_\Lambda \leftarrow \big(1 - \prod_{u\in\delta_\Lambda(u_i)} q_{(u,u_i)}\big)\widetilde{R}_{u_i}$;
  partition S_{u_i} (arbitrarily) into B multi-sets, denoted by $S^{(j)}_{u_i}$ for $j \in [B]$, where $B = 60n + 150m$ and each $S^{(j)}_{u_i}$ has $\ell_0 = \ell_1 + 500\ell_2$ samples;
  for each $j \in [B]$, partition $S^{(j)}_{u_i}$ further into two multi-sets $S^{(j,1)}_{u_i}$ and $S^{(j,2)}_{u_i}$, where $|S^{(j,1)}_{u_i}| = \ell_1$ and $|S^{(j,2)}_{u_i}| = 500\ell_2$;
for j *from* 1 *to* B **do**
  $\widehat{Z}^{(j)}_\Lambda \leftarrow \mathsf{Estimate}\Big((S^{(j,1)}_{u_i})_{i\in[d]}, \ell_1, \ell_1\Big)$;
  $\widetilde{Z}^{(j)}_\Lambda \leftarrow \mathsf{Estimate}\Big((S^{(j,2)}_{u_i})_{i\in[d]}, 500\ell_2, 25\ell_2 \cdot \min\{2/\widehat{Z}^{(j)}_\Lambda, 4n\}\Big)$;
  $Q^{(j)}_\Lambda \leftarrow \widetilde{Z}^{(j)}_\Lambda \sum_{i=1}^{d} \widetilde{R}^{(i)}_\Lambda$;
return $\widetilde{R}_\Lambda := \text{median}\Big\{Q^{(1)}_\Lambda, Q^{(2)}_\Lambda, \ldots, Q^{(B)}_\Lambda\Big\}$;

speaking, large T means large overlap among $\Omega^{(t)}_\Lambda$'s, and the chance of hitting each vertex is roughly the same, resulting in the number of samples required per vertex close to the average. Conversely, small T means little overlap, and some vertex or vertices may be sampled much more often than other vertices, but in this case the overall number of samples required, namely T, is small anyways. To summarize, with this two-round procedure, $O(\ell)$ overall samples per vertex are enough to obtain an estimation with the desired accuracy and high probability.

4 Sketch of analysis

In this section, we give a sketch of the analysis of our algorithm. The complete analysis is in the full version of this paper. Roughly speaking, what we need to show is that in the induction step, accurate samples (in terms of the TV distance) imply accurate estimates, and accurate estimates imply accurate samples.

First consider $\mathsf{Sample}\Big(v_k, (\widetilde{R}_w, S_w)_{w\in\{v_{k+1},v_{k+2},\ldots,v_n\}}, \widetilde{R}_{v_k}\Big)$ as being called by Algorithm 1. Let $u := v_k$, and the subroutine runs on the graph $G_u = (V_u, E_u)$. We show that in $\mathsf{Sample}(\cdot)$, if every value returned by the $\mathsf{ApproxCount}(\cdot)$ subroutine is accurate, then $\mathsf{Sample}(\cdot)$ also returns accurate samples. Formally, we assume access to an oracle $\mathcal{P}$ satisfying:

- given $u \in V_u$, $\mathcal{P}$ returns p_0 such that $1 - \frac{1}{10m} \le \frac{p_0}{R(V_u,E_u,\{u\})} \le 1 + \frac{1}{10m}$;
- given any $E_2 \subseteq E_u$ and $\Lambda, \Lambda_1 \subseteq V$ in Algorithm 2 and Algorithm 2 of Algorithm 2, $\mathcal{P}$ returns $c_0(V_u, E_2, \Lambda)$ and $c_1(V_u, E_2, \Lambda_1)$ such that $1 - \frac{1}{10m} \le \frac{c_0(V_u,E_2,\Lambda)}{R(V_u,E_2,\Lambda)} \le 1 + \frac{1}{10m}$, and $1 - \frac{1}{10m} \le \frac{c_1(V_u,E_2,\Lambda_1)}{R(V_u,E_2,\Lambda_1)} \le 1 + \frac{1}{10m}$.

Here, we use the convention $\frac{0}{0} = 1$ and $\frac{x}{0} = \infty$ for $x > 0$. For any V, E and $U \subseteq V_u$, $R(V, E, U)$ is the U-t reliability in the graph (V, E). The numbers p_0, c_0 and c_1 returned by $\mathcal{P}$ can be random variables, but we assume that the inequalities above are always satisfied.

Algorithm 4 Estimate$\left((S^{es}_{u_i})_{i\in[d]}, \ell_{es}, T\right)$.

Input: a set of samples $S^{es}_{u_i}$ for each $i \in [d]$, where $|S^{es}_{u_i}| = \ell_{es}$, a threshold T
Output: an estimator Z_{es} of $\mathbb{E}[Z_\Lambda]$

for each $i \in [d]$, let $c_i = 0$;
for k *from* 1 *to* T **do**
  draw an index $i \in [d]$ such that i is drawn with probability proportional to $\widetilde{R}^{(i)}_\Lambda$;
  $c_i \leftarrow c_i + 1$;
  if $c_i > \ell_{es}$ **then return** 0;
  let $H = (V_{u_i}, E_H)$ be the c_i-th sample from $S^{(j)}_{u_i}$;
  do the following transformation on H to get $H' = (V, E_{H'})$;
  - let $E_{H'} \leftarrow E_H$;
  - draw $D \subseteq \delta_\Lambda(u_i)$ with probability proportional to (13), and let $E_{H'} \leftarrow E_{H'} \cup D$;
  - for each $e \in E \setminus (E_{u_i} \cup \delta_\Lambda(u_i))$, add e into $E_{H'}$ independently with probability $1 - q_e$;

  let $Z^{(k)}_{es} \in \{0, 1\}$ indicate whether i is the smallest index $t \in [d]$ satisfying $H' \in \Omega^{(t)}_\Lambda$;
return $Z_{es} := \frac{1}{T}\sum_{k=1}^{T} Z^{(k)}_{es}$;

Consider the following modified sampling algorithm, in which we replace Algorithm 2, Algorithm 2 and Algorithm 2 of Algorithm 2 by calling the oracle $\mathcal{P}$. This modified algorithm has some nice properties, summarized in the next lemma.

▶ **Lemma 10.** *Given any $u = v_k \in V$, the with probability at least $1 - (\varepsilon/n)^{200}$, the modified sampling algorithm does not crash and returns a perfect independent sample from the distribution π_u. The running time is $\widetilde{O}(N(|E_u| + |V_u|))$, where N is the time cost for one oracle call and $\widetilde{O}$ hides polylog(n/ε) factors.*

In the full analysis, we need to handle the real sampling algorithm, the analysis of which also relies on the analysis of ApproxCount. ApproxCount behaves like $\mathcal{P}$ but only with high probability. To analyze the error bounds, we also need to identify several random sources and handle errors from different sources separately.

Next consider ApproxCount$(V, E, \Lambda, (\widetilde{R}_w, S_w)_{w\in\partial\Lambda})$, where $G = (V, E)$ is a DAG and $t \notin \Lambda$. Recall that for any $w \in V$, the graph $G_w = G[V_w]$, where V_w contains all vertices v satisfying $w \rightsquigarrow_G v$ and $v \rightsquigarrow_G t$. Let R_w be the $w - t$ reliability in G_w. Recall that ℓ_2 and B are parameters in ApproxCount, Algorithm 3. The next lemma shows that if in the input, all $\widetilde{R}_w$ are accurate estimators of R_w and all S_w are accurate samples, then ApproxCount$(\cdot)$ outputs an accurate estimator to R_Λ. Let S^{ideal}_w be a multi-set of ℓ *independent* and *prefect* samples from π_w.

▶ **Lemma 11.** *Suppose the following conditions are satisfied*
- *for any $w \in \partial\Lambda$, $1 - \varepsilon_0 \le \frac{\widetilde{R}_w}{R_w} \le 1 + \varepsilon_0$ for some $\varepsilon_0 < 1/2$;*
- *$d_{TV}\left((S_w)_{w\in\partial\Lambda}, (S^{\text{ideal}}_w)_{w\in\partial\Lambda}\right) \le \delta_0$.*

Then with probability at least $1 - \delta_0 - 2^{-B/30}$, it holds that

$$1 - \varepsilon_0 - \frac{2}{\sqrt{\ell_2}} \le \frac{\widetilde{R}_\Lambda}{R_\Lambda} \le 1 + \varepsilon_0 + \frac{2}{\sqrt{\ell_2}}. \tag{15}$$

The running time of ApproxCount *is $O(n\ell(|V| + |E|))$.*

As mentioned before, due to reusing samples, there is correlation among $\widetilde{R}_w$ and S_w for different w's. However, the conditions of Lemma 11 do not rely on correlation, which is key to the correctness of the algorithm.

We note that the failure probability in Lemma 11 is exponentially small (we plug the bound in (16) as δ_0). This is necessary because we eventually need to apply a union bound over the exponential possibilities of spanning subgraphs.

Theorem 1 is proved by combining Lemma 10 and Lemma 11. We use an induction from $v_n = t$ to $v_1 = s$ to show that the following events occur with high probability:

- for any $j \geq i$, let $S_{v_j}^{\text{ideal}}$ be a multi-set of ℓ independent perfect samples from π_{v_j}, it holds that

$$d_{\text{TV}}\left((S_{v_j})_{j\geq i}, (S_{v_j}^{\text{ideal}})_{j\geq i}\right) \leq 2^{-4m}(2^{n-i}-1); \tag{16}$$

- the estimator $\widetilde{R}_{v_i}$ approximates the $v_i - t$ reliability R_{v_i}:

$$1 - \frac{n-i}{50n\max\{m,\varepsilon^{-1}\}} \leq \frac{\widetilde{R}_{v_i}}{R_{v_i}} \leq 1 + \frac{n-i}{50n\max\{m,\varepsilon^{-1}\}}. \tag{17}$$

The base case of $i = n$ is trivial. In the induction step, by using the I.H., we can show that the condition in Lemma 11 is satisfied and thus $\mathsf{ApproxCount}(V, E, \Lambda, (\widetilde{R}_w, S_w)_{w\in\partial\Lambda})$ returns an accurate estimator of R_Λ. Hence, the subroutine $\mathsf{ApproxCount}(\cdot)$ behaves similarly like the oracle $\mathcal{P}$, which, by Lemma 10, implies that the $\mathsf{Sample}(\cdot)$ algorithm also generates accurate samples.

Here, we briefly explain why we set the parameter $\ell_2 = O(n^2\max\{m^2,\varepsilon^{-2}\})$, which controls the number of samples maintained (as $\ell = \Theta(B\ell_2)$, recall (14)) and thus the overall running-time of the algorithm. We want to guarantee that $\widetilde{R}_\Lambda$ returned by $\mathsf{ApproxCount}(\cdot)$ achieves the same accuracy as that returned by $\mathcal{P}$. Note that the relative error in (17) serves as ε_0 in (15). Therefore combining (15) and (17), we need

$$\frac{n-i}{50n\max\{m,\varepsilon^{-1}\}} + \frac{2}{\sqrt{\ell_2}} \leq \frac{1}{50\max\{m,\varepsilon^{-1}\}} + \frac{2}{\sqrt{\ell_2}} \leq \frac{1}{10m}. \tag{18}$$

To inductively prove (17), we also need

$$\frac{n-(i+1)}{50n\max\{m,\varepsilon^{-1}\}} + \frac{2}{\sqrt{\ell_2}} \leq \frac{n-i}{50n\max\{m,\varepsilon^{-1}\}}. \tag{19}$$

The condition in (18) forces us to assume a strong induction hypothesis such that for each v_i, $\widetilde{R}_{v_i}$ has $1 \pm O(\frac{1}{m})$ approximation error. And the condition in (19) is the bottleneck for setting parameter ℓ_2.

In the full analysis, we use a more complicated induction hypothesis in the induction proof. Moreover, we need to define certain bad and good events to carefully analyze where errors come from and how they accumulate in every step.

The approximation guarantee in Theorem 1 follows directly from (17). Note that this guarantee is always at least a $(1 \pm 1/m)$-approximation and is stronger than a $(1 \pm \varepsilon)$-approximation when $\varepsilon > 1/m$. For the running time, recall that the number of samples per vertex is $\ell = O\big(n^2 m\max\{m^2,\varepsilon^{-2}\}\big)$. The running time of $\mathsf{ApproxCount}$ (Algorithm 3) is at most

$$T_{\mathsf{count}} = O(mn\ell) = O\big(n^3m^2\max\{m^2,\varepsilon^{-2}\}\big).$$

The running time of Sample (Algorithm 2) is at most

$$T_{\mathsf{sample}} = \widetilde{O}((n+m)T_{\mathsf{count}}) = \widetilde{O}(mT_{\mathsf{count}}) = \widetilde{O}\big(n^3m^3\max\{m^2,\varepsilon^{-2}\}\big).$$

Hence, the running time of Algorithm 1 is

$$T = O(n(T_{\mathsf{count}} + \ell T_{\mathsf{sample}})) = O(n\ell T_{\mathsf{sample}}) = \widetilde{O}\big(n^6m^4\max\{m^4,\varepsilon^{-4}\}\big).$$

5 #BIS-hardness for $s-t$ unreliability

In this section we show Theorem 2. We first reduce #**BIS** to $s-t$ unreliability where each vertex (other than s and t) fails with $1/2$ probability independently. Note that in this version of the problem no edge would fail. Given a DAG $D=(V\cup\{s,t\},A)$, this is equivalent to counting the number of subsets $S\subseteq V$ such that in the induced subgraph $D[S\cup\{s,t\}]$, s cannot reach t. We call S a $s\not\rightsquigarrow t$ set.

Given a bipartite graph $G=(V,E)$, let its two partitions be L and R. We add two special vertices s and t, and connect, with directed edges, s to all vertices in L and all vertices in R to t. Lastly, for any edge $\{u,v\}\in E$, where $u\in L$ and $v\in R$, we replace it with a directed edge (u,v). Call the new directed graph D_G. Clearly it is a DAG.

For any independent set I in G, we claim that in $D_G[I\cup\{s,t\}]$, s cannot reach t. This is because for any $e\in E$, there is at least one vertex unoccupied. Thus s cannot reach t using the directed version of e, and this holds for any $e\in E$.

In the other direction, let S be a $s\not\rightsquigarrow t$ subset of V. This means that for any edge $\{u,v\}\in E$, either $u\notin S$ or $v\notin S$, as otherwise $s\to u\to v\to t$. This means that S is an independent set of G.

Thus, there is a one-to-one correspondence between independent sets of G and $s\not\rightsquigarrow t$ subsets of V. Namely, $s-t$ unreliability where vertices (other than s and t) fail with $1/2$ probability is #**BIS**-hard.

Next, we reduce $s-t$ unreliability from the vertex version. For this, we can replace each vertex v (other than s and t) by two vertices v,v' and a directed edge $v\to v'$. All incoming edges of v still goes into v, and all outgoing edges of v goes out from v'. Assign to the new edges the failure probabilities of their corresponding vertices, and assign failure probability 0 to all original edges. Clearly the unreliability is the same with these changes. To make failure probabilities uniform, we can replace edges with failure probability 0 by k parallel edges. Effectively, the connection fails only if all the parallel edges fail at the same time. If the failure probability of each edge is q, the probability of all parallel edges failing is q^k. As this probability approaches 0 exponentially fast, it is easy to set a polynomially bounded k so that the new unreliability is a sufficiently good approximation of the original.

As a side note, the last reduction also works for reliability. Thus Theorem 1 also works for $s-t$ reliability in DAGs where vertices rather than edges fail independently.

A Note on Approximating Weighted Nash Social Welfare with Additive Valuations

Yuda Feng

Shi Li
Department of Computer Science and Technology, Nanjing University, Jiangsu, China

Abstract

We give the first $O(1)$-approximation for the weighted Nash Social Welfare problem with additive valuations. The approximation ratio we obtain is $e^{1/e} + \epsilon \approx 1.445 + \epsilon$, which matches the best known approximation ratio for the unweighted case [3].

Both our algorithm and analysis are simple. We solve a natural configuration LP for the problem, and obtain the allocation of items to agents using a randomized version of the Shmoys-Tardos rounding algorithm developed for unrelated machine scheduling problems [30]. In the analysis, we show that the approximation ratio of the algorithm is at most the worst gap between the Nash social welfare of the optimum allocation and that of an EF1 allocation, for an unweighted Nash Social Welfare instance with identical additive valuations. This was shown to be at most $e^{1/e} \approx 1.445$ by Barman et al. [3], leading to our approximation ratio.

1 Introduction

In the weighted (or asymmetric) Nash Social Welfare problem with additive valuations, we are given a set $\mathcal{A}$ of n agents, and a set $\mathcal{G}$ of m indivisible items. Every agent $i \in \mathcal{A}$ has a weight $w_i \geq 0$ such that $\sum_{i \in \mathcal{A}} w_i = 1$. There is a value $v_{ij} \in \mathbb{R}_{\geq 0}$ for every $i \in \mathcal{A}$ and $j \in \mathcal{G}$. The goal of the problem is to find an allocation $\sigma : \mathcal{G} \to \mathcal{A}$ of items to agents so as to maximize the following weighted Nash social welfare of σ:

$$\prod_{i \in \mathcal{A}} \left(\sum_{j \in \sigma^{-1}(i)} v_{ij} \right)^{w_i}.$$

In the case where all w_i's are equal to $\frac{1}{n}$, we call the problem the unweighted (or symmetric) Nash Social Welfare problem.

Allocating resources in a fair and efficient manner among multiple agents is a fundamental problem in computer science, game theory, and economics, with applications across diverse domains [19, 33, 4, 28, 25, 2, 29, 5]. The weighted Nash social welfare function is a notable

objective that balances efficiency and fairness. The unweighted (or symmetric) objective was independently proposed by different communities [26, 20, 32], and later the study has been extended to the weighted case [16, 18]. Since then it has been used in a wide range of applications, including bargaining theory [21, 7, 31], water allocation [17, 10], and climate agreements [34].

The unweighted Nash Social Welfare problem with additive valuations is proved to be NP-hard by Nguyen et al. [27], and APX-hard by Lee [22]. Later the hardness of approximation was improved to $\sqrt{8/7} \approx 1.069$ by Garg et al. [12], via a reduction from Max-E3-Lin-2.

On the positive side, Cole and Gkatzelis [9] gave a $(2e^{1/e} + \epsilon \approx 2.889 + \epsilon)$-approximation using a market equilibrium with some spending restrictions. The ratio was improved by Cole et al. [8] to 2 using a tight analysis, and by Anari et al. [1] to e via a connection of the problem to real stable polynomials. Both papers formulated some convex program (CP) relaxations for the problem. In particular, [8] showed that the optimum solution to their CP corresponds to the spending-restricted market equilibrium defined in [9]. The state-of-the-art result for the problem is a combinatorial $(e^{1/e} + \epsilon \approx 1.45 + \epsilon)$-approximation algorithm due to Barman et al.[3]. They showed that when all the valuations of agents are identical, any allocation that is envy-free up to one item (EF1) is $e^{1/e}$-approximate. Their approximation result then follows from a connection between the non-identical and identical valuation settings they established.

All the results discussed above are for the unweighted case. For the weighted case with agent weights $w \in [0,1]^{\mathcal{A}}, |w|_1 = 1$, Brown et al. [6] presented a $5 \cdot \exp(2 \cdot D_{\mathrm{KL}}\left(w||\frac{\vec{1}}{n}\right)) = 5 \cdot \exp(2\log n + 2\sum_{i\in\mathcal{A}} w_i \log w_i)$ approximation algorithm, where D_{KL} denotes the KL divergence of two distributions. This is the first work that studies the weighted version for the additive valuation case. Prior to this work, there is an $O(nw_{\max}) = O(n \max_{i\in\mathcal{A}} w_i)$-approximation for the more general submodular valuation case [13], which we discuss soon. Brown et al. [6] showed that the two CPs from [8] and [1] are equivalent, and their result is based on the CP from [8], generalized to the weighted setting.

The additive valuation setting is a special case of the submodular valuation setting, which is another important setting studied in the literature. In this setting, instead of a v_{ij} value for every ij pair, we are given a monotone submodular function $v_i : 2^{\mathcal{G}} \to \mathbb{R}_{\geq 0}$ for every agent $i \in \mathcal{A}$. Our goal is to find an allocation $\sigma : \mathcal{G} \to \mathcal{A}$ so as to maximize $\prod_{i\in\mathcal{A}} \left(v_i(\sigma^{-1}(i))\right)^{w_i}$. A bulk of the previous work has focused on the unweighted case; that is, $w_i = \frac{1}{n}$ for all $i \in \mathcal{A}$. For this case, Garg et al. [15] proved a hardness of $e/(e-1) \approx 1.5819$ using a reduction from Max-3-Coloring; this is better than the 1.069 hardness for the additive valuation case.

On the positive side, Li and Vondrak [24] extended the techniques of Anari et al. [1], to obtain an $e^3/(e-1)^2$-approximation algorithm for the unweighted Nash Social Welfare problem for a large family of submodular valuations, including coverage functions and linear combinations of matroid rank functions. Later, Garg et al. [14] considered a family of submodular functions called Rado functions, and gave an $O(1)$-approximation for this family using the matching theory and convex program techniques. Li and Vondrak [23] developped the first $O(1)$-approximation for general submodular functions, with an approximation ratio of 380. Recently, Garg et al. [13] presented an elegant 4-approximation local search algorithm for the problem, which is the current best approximation result for the problem. All the results discussed above are for the unweighted case. For the weighted case, Garg et al. [13] gave an $O(nw_{\max})$-approximation, where $n_{\max} = \max_{i\in\mathcal{A}} w_i$. Whether the weighted Nash Social Welfare problem with submodular valuations admits a constant approximation is a big open problem.

Recently, the problem has been studied in an even more general setting, namely, the subadditive valuation setting. Dobzinski et al. [11] gives an $O(1)$-approximation for the unweighted Nash Social Welfare problem in this setting under the demand oracle model.

1.1 Our Result and Techniques

In this note, we give the first $O(1)$-approximation algorithm for the weighted Nash Social Welfare problem with additive valuations:

▶ **Theorem 1.** *For any $\epsilon > 0$, there is a randomized $(e^{1/e} + \epsilon \approx 1.445 + \epsilon)$-approximation algorithm for the weighted Nash Social Welfare problem with additive valuations, with running time polynomial in the size of the input and $\frac{1}{\epsilon}$.*

Our approximation ratio of $e^{1/e} + \epsilon$ matches the best ratio for the unweighted case due to Barman et al. [3]. In contrast, the ratio given by Brown et al. [6] is $5 \cdot \exp(2 \cdot D_{\mathrm{KL}}(w||\frac{\vec{1}}{n}))$, which could be polynomial in n.

Our algorithm is based on a natural configuration LP for the problem, which has not been studied before to the best of our knowledge. The configuration LP contains a $y_{i,S}$ variable for every agent i and subset S of items, indicating if the set of items i gets is S or not. We show that the configuration LP can be solved in polynomial time to any precision, despite having exponential number of variables. Once we obtain the LP solution, we define x_{ij} for every $i \in \mathcal{A}$ and $j \in \mathcal{G}$ to be the fraction of j assigned to i.

We use a randomized version of the Shmoys-Tardos rounding algorithm [30] developed for unrelated machine scheduling problems, to round x into an integral solution. For every agent i, we break the fractional items assigned to i into groups from the most valuable to the least, each containing 1 fractional item. The rounding algorithm maintains marginal probabilities, and the requirement that i gets exactly one item from each group (except for the last one, from which i gets at most one item). In the analysis for each agent i, we construct an instance of the unweighted Nash Social Welfare problem with *identical* additive valuations, that involves many copies of the agent i, along with two alloations $\mathcal{S}$ and $\mathcal{S}'$ to the instance. $\mathcal{S}$ corresponds to the LP solution, and $\mathcal{S}'$ corresponds to the randomized solution given by the rounding algorithm. Thanks to the condition that every group contains one item, the solution $\mathcal{S}'$ is envy-free up to one item (EF1). Using the result of [3] about EF1 allocations, we show that the Nash social welfare of $\mathcal{S}'$ is at least $e^{-1/e}$ times that of $\mathcal{S}$, which eventually leads to our $(e^{1/e} + \epsilon)$-approximation.

We believe the configuration LP could be used in many other settings. We leave as an immediate open problem whether it can give an $O(1)$-approximation for the weighted Nash Social Welfare problem with submodular valuations.

2 $(e^{1/e} + \epsilon)$-Approximation Using Configuration LP

We describe the configuration LP in Section 2.1 and the rounding algorithm in Section 2.2. The analysis is given in Section 2.3.

2.1 The Configuration LP

For convenience, for any value function $v : \mathcal{G} \to \mathbb{R}_{\geq 0}$, we define $v(S) := \sum_{j \in S} v_j$ for every $S \subseteq \mathcal{G}$ to be the total value of items in S according to the value funciton v. In the integer program correspondent to the configuration LP, for every $i \in \mathcal{A}$ and $S \subseteq \mathcal{G}$, we have a variable $y_{i,S} \in \{0, 1\}$ indicating if the set of items assigned to i is S or not. We relax the integer constraint to obtain the following configuration LP:

$$\max \sum_{i\in\mathcal{A},S\subseteq\mathcal{G}} w_i \cdot y_{i,S} \cdot \ln v_i(S) \qquad \text{s.t.} \tag{Conf-LP}$$

$$\sum_{i\in\mathcal{A},S\ni j} y_{i,S} \le 1 \qquad \forall j \in \mathcal{G} \tag{1}$$

$$\sum_{S\subseteq\mathcal{G}} y_{i,S} = 1 \qquad \forall i \in \mathcal{A} \tag{2}$$

$$y_{i,S} \ge 0 \qquad \forall i \in \mathcal{A}, S \subseteq \mathcal{G} \tag{3}$$

It is convenient for us to consider the natural logarithm of the Nash social welfare function as the objective, which is $\sum_{i\in\mathcal{A}} w_i \cdot \ln v_i(\sigma^{-1}(i))$. This leads to the objective in (Conf-LP). (1) requires that every item j is assigned to at most one agent, and (2) requires that every agent i is assigned one set of items.

The configuration LP has exponential number of variables, but it can be solved within an additive error of $\ln(1+\epsilon)$ for any $\epsilon > 0$, in time polynomial in the size of the instance and $\frac{1}{\epsilon}$. We defer the details to Appendix A. Notice that we are considering the logarithm of Nash social welfare, and the typical $(1+\epsilon)$-multiplicative factor becomes an additive error of $\ln(1+\epsilon)$.

2.2 The Rounding Algorithm

From now on, we assume we have obtained a vector y from solving the LP, described using a list of non-zero coordinates; the value of y to (Conf-LP) is at least the optimum value minus $\ln(1+\epsilon)$. We can assume (1) holds with equalities: $\sum_{i\in\mathcal{A},S\ni j} y_{i,S} = 1$ for every $j \in \mathcal{G}$. Then we let $x_{ij} = \sum_{S\ni j} y_{i,S}$ for every $i \in \mathcal{A}$ and $j \in \mathcal{G}$. So $\sum_{i\in\mathcal{A}} x_{ij} = 1$ for every $j \in \mathcal{G}$.

In this paragraph, we fix an agent i and break the fractional items assigned to i into a set G_i of groups, each containing 1 fractional item. They are created in non-increasing order of values, as in the Shmoys-Tardos algorithm for unrelated machine scheduling problems. That is, the first group contains the 1 fractional most valuable items assigned to i, the second group contains the 1 fractional most valuable items assigned to i after removing the first group, and so on. Formally, we sort the items in $\mathcal{G}$ in non-increasing order of v_{ij} values, breaking ties arbitrarily. Let $p_i = \lceil \sum_{j\in\mathcal{G}} x_{ij} \rceil$. Then we can find vectors $g^1, g^2, \cdots, g^{p_i} \in [0,1]^{\mathcal{G}}$ satisfying the following properties:

- **(P1)** For every $t \in [1, p_i-1]$, we have $|g^t|_1 = 1$; for $t = p_i$, we have $|g^t|_1 = \sum_{j\in\mathcal{G}} x_{ij} - (p_i-1) \in (0,1]$.
- **(P2)** $\sum_{t=1}^{p_i} g^t_j = x_{ij}$ for every $j \in \mathcal{G}$.
- **(P3)** For every $1 \le t < t' \le p_i$, and two items j, j' such that j appears before j' in the ordering, it can not happen that $g^t_{j'} > 0$ and $g^{t'}_j > 0$.

It is easy to see that $g^1, g^2, \cdots, g^{p_i}$ are uniquely decided by the three conditions. We say each g^t is a group. Let $G_i = \{g^1, g^2, \cdots, g^{p_i}\}$ be the set of all groups constructed for this agent i.

Now we take all agents i into consideration and let $G = \uplus_{i\in\mathcal{A}} G_i$ be the set of all groups constructed.[1] The representations of groups give a fractional matching between the groups G and items $\mathcal{G}$: an item j is matched to a group $g \in [0,1]^{\mathcal{G}}$ with a fraction of g_j. Then each item is matched to an extent of 1, and every group g is matched to an extent of $|g|_1$. So

[1] It is possible that two groups from different sets G_i and $G_{i'}$ have the same vector representation. So we treat G as a multiset and we assume we know which set G_i each group $g \in G$ belongs to.

a group is matched to an extent of 1 if it is not the last group for an agent, and at most 1 otherwise. Therefore, we can efficiently output a randomized (partial-)matching between the groups G and items $\mathcal{G}$ so that the marginal probabilities are maintained:
($\star$) For every group $g \in G$ and item $j \in \mathcal{G}$, we have $\Pr[j \text{ is matched to } g] = g_j$.

($\star$) implies that an item $j \in \mathcal{G}$ is matched with probability 1. If a group g has $|g|_1 = 1$, then it is matched with probability 1.

The matching naturally gives us an allocation of items to agents: If an item $j \in \mathcal{G}$ is matched to some group $g \in G_i$, then we assign j to i. By ($\star$) we know that the probability that j is assigned to i is precisely x_{ij}. Let S_i be the set of items assigned to i in the algorithm; notice that it is random. This finishes the description of the randomized rounding algorithm.

2.3 The Analysis

To analyze our rounding algorithm, we first formally define an EF1 allocation.

▶ **Definition 2.** *Given an instance of the unweighted Nash Social Welfare problem with agents $\mathcal{A}$, items $\mathcal{G}$, and identical additive valuation $v : \mathcal{G} \to \mathbb{R}_{\geq 0}$ for all agents, an allocation $\sigma : \mathcal{G} \to \mathcal{A}$ is said to be envy-free up to one item (EF1), if for every two distinct agents i, i' with $\sigma^{-1}(i') \neq \emptyset$, there exists some $j \in \sigma^{-1}(i')$, such that $v(\sigma^{-1}(i') \setminus j) \leq v(\sigma^{-1}(i))$.*

We use the following result from [3]:

▶ **Theorem 3** ([3])**.** *For the unweighted Nash Social Welfare problem with identical additive valuations, any EF1-allocation is an $e^{1/e}$-approximate solution.*

With the theorem, we prove the following key lemma:

▶ **Lemma 4.** *For every $i \in \mathcal{A}$, we have*

$$\mathbb{E}\left[\ln v_i(S_i)\right] \geq \sum_{S \subseteq \mathcal{G}} y_{i,S} \cdot \ln v_i(S) \; - \; \frac{1}{e}.$$

Proof. Throughout the proof, we fix the agent i. Let $\Delta > 0$ be an integer, so that every $y_{i,S}$ is an integer multiply of $1/\Delta$, and the probability that $S_i = S$ for any S is also an integer multiply of $1/\Delta$.[2] We consider an instance of the unweighted Nash Social Welfare problem with identical additive valuations. In the instance, there are Δ copies of the agent i, and Δx_{ij} copies of every item $j \in \mathcal{G}$; so all the agents are identical. The $y = (y_{i,S})_{S \subseteq \mathcal{G}}$ vector gives us an allocation $\mathcal{S}$ to the instance: For every $S \subseteq \mathcal{G}$, there are exactly $\Delta y_{i,S}$ agents who get a copy of S. Notice that this is a valid solution, as $\sum_S y_{i,S} = 1$ and $\sum_{S \ni j} y_{i,S} = x_{ij}$ for every item j.

The Nash Social Welfare of the allocation $\mathcal{S}$ is

$$\left(\prod_{S \subseteq \mathcal{G}} v_i(S)^{\Delta y_{i,S}}\right)^{1/\Delta} = \prod_{S \subseteq \mathcal{G}} v_i(S)^{y_{i,S}}.$$

The distribution for S_i also corresponds to an allocation $\mathcal{S}'$ of items to agents: For every $S \subseteq \mathcal{G}$, there are $\Delta \cdot \Pr[S_i = S]$ agents who get a copy of S. Again, this is a valid solution as $\sum_S \Pr[S_i = S] = 1$ and $\sum_{S \ni j} \Pr[S_i = S] = \mathbb{E}[S_i \ni j] = x_{ij}$.

[2] We can assume all $y_{i,S}$ values are rational numbers. Under this condition, it is easy to guarantee that the probabilities are rational numbers.

The Nash Social Welfare of the allocation $\mathcal{S}'$ is

$$\left(\prod_{S\subseteq\mathcal{G}} v_i(S)^{\Delta \Pr[S_i=S]}\right)^{1/\Delta} = \prod_{S\subseteq\mathcal{G}} v_i(S)^{\Pr[S_i=S]}.$$

A crucial property for the solution $\mathcal{S}'$ is that it is EF1. Indeed, if $\Pr[S_i = S] > 0$ for some S, then S contains exactly one item from each group in G_i except for the last one, from which S contains at most one item. Also, the items in the groups G_i are sorted by (P3). So if there are two sets S and S' in the support of the distribution for S_i, and we remove the most valuable item from S', then S beats S' item by item.

Therefore, by Theorem 3, we know that the Nash Social Welfare of $\mathcal{S}'$ is at least $e^{-1/e}$ times that of the optimum allocation for the instance, which is at least that of $\mathcal{S}$. That is,

$$\prod_{S\subseteq\mathcal{G}} v_i(S)^{\Pr[S_i=S]} \geq e^{-1/e} \cdot \prod_{S\subseteq\mathcal{G}} v_i(S)^{y_{i,S}}.$$

Taking logarithm on both sides gives the lemma. ◀

Applying the lemma for every $i \in \mathcal{A}$ and using linearity of expectation, we have

$$\mathbb{E}\left[\sum_{i\in\mathcal{A}} w_i \cdot \ln v_i(S_i)\right] \geq \sum_{i\in S, S\subseteq\mathcal{G}} w_i \cdot y_{i,S} \cdot \ln v_i(S) - \frac{1}{e}.$$

We used that $\sum_{i\in\mathcal{A}} w_i = 1$.

By the convexity of exponential function, we have

$$\mathbb{E}\left[\prod_{i\in\mathcal{A}} v_i(S_i)^{w_i}\right] \geq e^{-1/e} \cdot \exp\left(\sum_{i\in S, S\subseteq\mathcal{G}} w_i \cdot y_{i,S} \cdot \ln v_i(S_i)\right) \geq e^{-1/e} \cdot \frac{\text{opt}}{1+\epsilon},$$

where opt is the Nash Social Welfare of the optimum allocation, and the second inequality used that the value of our solution y to (Conf-LP) is at least its optimum value minus $\ln(1+\epsilon)$. By scaling ϵ down by an absolute constant at the beginning, we can make the right side to be at least $\frac{\text{opt}}{e^{1/e}+\epsilon}$. This finishes the proof of Theorem 1.

Finally, we briefly discuss how to derandomize the rounding algorithm. We round the solution to the configuration LP in iterations, maintaining a fractional assignment $\bar{x}$ of items to agents; $\bar{x} = x$ initially. Let Δ be a large enough integer so that every $y_{i,S}$ is an integer multiply of $1/\Delta$. Focus on a fixed agent $i \in \mathcal{A}$ and consider the Nash Social Welfare instance containing Δ copies of i, and $\Delta\bar{x}_{ij}$ copies of each item $j \in \mathcal{G}$. Group the items as follows: the Δ most valuable items belong to the first group, the next Δ most valuable items belong to the second group, and so on. We define Φ_i to be the logarithm of the Nash Social Welfare of the worst allocation satisfying the following condition: every agent gets at most one item from each group. Fortunately, the worst allocation can be defined naturally: the first agent takes the most valuable item from each group, and the second agent takes the second most valuable item from each group, and so on. Thus Φ_i can be computed efficiently. We define $\Phi = \sum_i w_i\Phi_i$ to be the overall potential function. In the randomized version of the algorithm, one can define the rotation operation over the fractional matching between groups G and items $\mathcal{G}$. In expectation the operation does not decrease Φ. To derandomize the algorithm, we can perform the operation deterministically so that Φ does not decrease. The potential value Φ at the end of the algorithm is at least that at the beginning, which is at least the value of the configuration LP minus $1/e$. On the other hand, the logarithm of the Nash Social Welfare of the integral solution is exactly the final Φ. Therefore, the Nash Social Welfare is at least $e^{-1/e}$ times the exponential of the value of the configuration LP.

A Solving Configuration LP within an Additive Error of $\ln(1+\epsilon)$

Let $\epsilon > 0$ be upper bounded by a sufficiently small constant (we allow ϵ to be a sub-constant). By only allowing every agent to get one item, we can obtain an m-approximation for the our Nash Social Welfare instance. Then, by making $O\left(\frac{\log m}{\epsilon}\right)$ guesses, we can assume we are given a number o such that the value of (Conf-LP) is in $(o, o+\epsilon/3]$.

We consider the dual of (Conf-LP), with the objective replaced by a constraint.

$$\sum_{j\in\mathcal{G}} \alpha_j + \sum_{i\in\mathcal{A}} \beta_i \le o \tag{4}$$

$$\sum_{j\in S} \alpha_j + \beta_i \ge w_i \cdot \ln v_i(S) \qquad \forall i \in \mathcal{A}, S \subseteq \mathcal{G} \tag{5}$$

$$\alpha_j \ge 0 \qquad \forall j \in \mathcal{G} \tag{6}$$

Since (Conf-LP) has value strictly larger than o, the dual LP (4-6) is infeasible. We design an approximate separation oracle for the LP. Given some $\alpha \in \mathbb{R}^{\mathcal{G}}_{\ge 0}$ and $\beta \in \mathbb{R}^{\mathcal{A}}$ that does not satisfy (5), we can find some $i \in \mathcal{A}$ and $S \subseteq \mathcal{G}$ such that

$$\sum_{j\in S} \alpha_j + \beta_i < w_i \ln\big((1+\epsilon/2)v_i(S)\big).$$

The running time of the oracle is polynomial in the input size and $\frac{1}{\epsilon}$. This can be achieved using the standard dynamic programming technique: For a fixed $i \in \mathcal{A}$, to find the S, we guess the item $j^* \in S$ with the largest v_{ij^*}, coarsen the v_{ij} values based on the guess, and run a dynamic programming to find the S.

So, using the ellipsoid method with the approximate separation oracle, we can find polynomially many half spaces of the form $\sum_{j\in S} \alpha_j + \beta_i \ge w_i \ln\big((1+\epsilon/2)v_i(S)\big)$, whose intersection is empty. Then, we consider the Nash Social Welfare instance where all v_{ij} values are scaled up by $1+\epsilon/2$, and (Conf-LP) to the instance. By solving the LP restricted to the variables $y_{i,S}$ correspondent to the half spaces (that is, we let all other variables be 0), we obtain a solution y whose value is at least o w.r.t the scaled instance. So, the value of the solution y to (Conf-LP) w.r.t the original instance is at least $o - \sum_{i\in\mathcal{A}, S\subseteq\mathcal{G}} y_{i,S} w_i \ln(1+\epsilon/2) = o - \sum_i w_i \ln(1+\epsilon/2) = o - \ln(1+\epsilon/2)$.

As the value of (Conf-LP) is at most $o+\epsilon/3$, we solved the LP up to an additive error of $\epsilon/3 + \ln(1+\epsilon/2)$. For a small enough ϵ, this is at most $\ln(1+\epsilon)$.

Minimizing Tardy Processing Time on a Single Machine in Near-Linear Time

Maastricht University, The Netherlands

Abstract

In this work we revisit the elementary scheduling problem $1||\sum p_jU_j$. The goal is to select, among n jobs with processing times and due dates, a subset of jobs with maximum total processing time that can be scheduled in sequence without violating their due dates. This problem is NP-hard, but a classical algorithm by Lawler and Moore from the 60s solves this problem in pseudo-polynomial time $O(nP)$, where P is the total processing time of all jobs. With the aim to develop best-possible pseudo-polynomial-time algorithms, a recent wave of results has improved Lawler and Moore's algorithm for $1||\sum p_jU_j$: First to time $\widetilde{O}(P^{7/4})$ [Bringmann, Fischer, Hermelin, Shabtay, Wellnitz; ICALP'20], then to time $\widetilde{O}(P^{5/3})$ [Klein, Polak, Rohwedder; SODA'23], and finally to time $\widetilde{O}(P^{7/5})$ [Schieber, Sitaraman; WADS'23]. It remained an exciting open question whether these works can be improved further.

In this work we develop an algorithm in near-linear time $\widetilde{O}(P)$ for the $1||\sum p_jU_j$ problem. This running time not only significantly improves upon the previous results, but also matches conditional lower bounds based on the Strong Exponential Time Hypothesis or the Set Cover Hypothesis and is therefore likely *optimal* (up to subpolynomial factors). Our new algorithm also extends to the case of m machines in time $\widetilde{O}(P^m)$. In contrast to the previous improvements, we take a different, more direct approach inspired by the recent reductions from Modular Subset Sum to dynamic string problems. We thereby arrive at a satisfyingly *simple* algorithm.

1 Introduction

Consider the following natural optimization problem: A worker is offered n *jobs*, where each job j requires a *processing time* of p_j days and must be completed before some *due date* d_j. Which jobs should the worker take on in order to maximize their pay, assuming that the worker is paid a fixed amount per day of work? In standard scheduling notation [22], this task is somewhat cryptically called the "$1||\sum p_jU_j$" problem (see Section 2 for a formal definition). The $1||\sum p_jU_j$ problem constitutes an important scheduling task that is arguably among the *simplest* nontrivial scheduling objectives, and has received considerable attention in the literature, especially in recent years.

The $1||\sum p_jU_j$ problem naturally generalizes the famous Subset Sum problem,[1] and is therefore NP-hard. However, it does admit pseudo-polynomial-time algorithms – in 1969, Lawler and Moore [31] pioneered the first such algorithm in time $O(nP)$, where $P = \sum_j p_j$ is the total processing time of all jobs. This result is the baseline in a line of research that, more than 50 years after the initial effort, is finally brought to a close in this paper.

State of the Art. Lawler and Moore originally designed their algorithm for a weighted generalization of the $1||\sum p_jU_j$ problem, and for this generalization the running time $O(nP)$ was proven to be conditionally tight.[2] Even for the $1||\sum p_jU_j$ problem the Lawler-Moore algorithm remained unchallenged for a long time. Only a few years ago, Bringmann, Fischer, Hermelin, Shabtay and Wellnitz [12] managed to solve $1||\sum p_jU_j$ in time[3] $\widetilde{O}(P^{7/4})$, showcasing that improvements over Lawler-Moore are indeed possible in certain parameter regimes (specifically, when $P \ll n^{4/3}$). Their strategy is to design a tight reduction to an intermediate problem called *Skewed Convolution*[4], and to develop an $\widetilde{O}(N^{7/4})$-time algorithm for this intermediate problem.

Their work was later improved in two orthogonal ways. On the one hand, Klein, Polak and Rohwedder [28] improved the running time of Skewed Convolution to $\widetilde{O}(N^{5/3})$. On the other hand, Schieber and Sitaraman [36] improved the algorithmic reduction and established that, if Skewed Convolution is in time $\widetilde{O}(N^\alpha)$, then $1||\sum p_jU_j$ is in time $\widetilde{O}(P^{2-1/\alpha})$. The state-of-the-art algorithm for $1||\sum p_jU_j$ is obtained by combining these two works, resulting in time $\widetilde{O}(P^{7/5})$.

In contrast, fine-grained lower bounds for the Subset Sum problem rule out $1||\sum p_jU_j$ algorithms in time $O(P^{1-\epsilon} \cdot n^{O(1)})$, for any $\epsilon > 0$, conditioned on either the influential Strong Exponential Time Hypothesis [1] or the Set Cover Hypothesis [17]. This leaves a substantial gap between the best known upper bound $\widetilde{O}(P^{7/5})$ and the conceivable optimum $\widetilde{O}(P)$. Closing this gap is the starting point of our paper:

Can the $1||\sum p_jU_j$ *problem be solved in near-linear time* $\widetilde{O}(P)$*?*

In light of the recent algorithmic developments [12, 28, 36], a reasonable strategy appears to aim for even faster algorithms for the Skewed Convolution problem – unfortunately, this approach soon faces a barrier. Namely, improving the running time of Skewed Convolution beyond $O(N^{3/2})$ would entail a similarly fast algorithm for $(\max, \min)$-Convolution, which, while not ruled out under one of the big hypotheses, would be a surprising break-through in fine-grained complexity theory. This leaves us in an uncertain situation. Even if Skewed Convolution could be improved to time $\widetilde{O}(N^{3/2})$, this would mean that the $1||\sum p_jU_j$ problem is in time $\widetilde{O}(P^{4/3})$ [36]. Are further improvements impossible?

Our Results. In this paper we bypass this barrier and develop a new algorithm for $1||\sum p_jU_j$ that avoids the reduction to Skewed Convolution altogether. We thereby successfully resolve our driving question:

---

[1] Indeed, Subset Sum is the special case of $1||\sum p_jU_j$ where all jobs share the same deadline d. In other words, Subset Sum is the $1|d_j = d|\sum p_jU_j$ problem.

[2] In the so-called $1||\sum w_jU_j$ problem each job j is rewarded by a specified pay w_j (instead of p_j). For this generalization the running time $O(nP)$ was proven to be conditionally optimal [18, 30], in the sense that an algorithm in time $O((n+P)^{2-\epsilon})$, for any $\epsilon > 0$, contradicts the well-established $(\min, +)$-Convolution hypothesis. See also the discussion in [12].

[3] We write $\widetilde{O}(T) = T(\log T)^{O(1)}$ to suppress polylogarithmic factors.

[4] Given length-N integer vectors A, B, the Skewed Convolution problem is to compute the length-$(2N-1)$ vector C defined by $C[k] = \min_{i+j=k} \max\{A[i], B[j] - i\}$.

▶ **Theorem 1.** *The* $1||\sum p_jU_j$ *problem can be solved in randomized time* $O(P \log P)$ *and in deterministic time* $O(P \log^{1+o(1)} P)$.

We stress that by the aforementioned lower bounds [1, 17] our new algorithm is *optimal*, up to lower-order factors, conditioned on the Strong Exponential Time Hypothesis or the Set Cover Hypothesis.

As an additional feature, and similar to all previous algorithms, our algorithm not only computes the optimal value of the given instance, but in fact reports for each value $0 \leq x \leq P$ whether there is a feasible schedule with processing time (i.e., pay) x. Moreover, we can compute an optimal schedule (represented as an ordered subset of jobs) in the same running time.

Another benefit of our work is that we managed to distill an astonishingly *simple* algorithm. In fact, our algorithm is basically identical to the original Lawler-Moore algorithm, except that we replace certain naive computations by an appropriate efficient data structure on *strings*, and employ a careful new analysis. This approach is inspired by the recent progress on the Modular Subset Sum problem [5, 4, 14, 34] (see Section 3 for more details). We find it surprising that these conceptually simple ideas lead to near-optimal running times for $1||\sum p_jU_j$.

In particular, in contrast to previous improvements for $1||\sum p_jU_j$ [12, 28, 36], our algorithm is purely combinatorial and does not require the use of the Fast Fourier Transform. Given this simple nature of our algorithm, we are confident that actual implementations of the algorithm would perform well.

Multiple Machines. The "$P_m||\sum p_jU_j$" problem is the straightforward generalization of the $1||\sum p_jU_j$ problem to m workers (or machines) that can partition the jobs arbitrarily among themselves. The goal, as before, is to maximize the total workload across all workers while respecting all due dates. We assume for simplicity that m is a constant.[5]

The Lawler-Moore algorithm generalizes in a straightforward manner to time $O(nP^m)$. For the algorithms based on Skewed Convolution, it seems significantly harder to derive multiple-machine generalizations. Luckily, with some appropriate changes our new algorithm also generalizes to multiple machines:

▶ **Theorem 2.** *The* $P_m||\sum p_jU_j$ *problem can be solved in randomized time* $O(P^m \log P)$ *and in deterministic time* $O(P^m \log^{1+o(1)} P)$.

In particular, Theorem 2 outperforms the Lawler-Moore algorithm by a near-linear factor $\widetilde{\Omega}(n)$. In contrast to the single-machine setting, however, we emphasize that this algorithm is not necessarily optimal. A conditional lower bound for this problem would, most likely, be derived from an analogous lower bound for the multiple-target Subset Sum problem [3]. This appears to be a challenging question which is not resolved yet.

Alternative Parameters. So far we have only mentioned the parameters n and $P = \sum_j p_j$, which have been the main focus in previous work. But there are many other parameters worth considering. Natural candidates include the number of distinct deadlines ($D_\#$), the sum of all distinct deadlines (D), the largest processing time ($p_{\max} = \max_j p_j$) and the largest deadline ($d_{\max} = \max_j d_j$).

[5] When viewing m as an input, it is easy to trace that our algorithms depend only polynomially on m.

There has been research on developing nontrivial $1||\sum p_jU_j$ algorithms (for a single machine) with respect to these parameters, such as an $\widetilde{O}(\min\{P\cdot D_{\#}, P+D\})$-time algorithm due to [12], and an $\widetilde{O}(n+p_{\max}^3)$-time algorithm due to [28]. We remark that the former is subsumed by our new results. The latter algorithm is incomparable to our result (specifically, our algorithm in time $\widetilde{O}(P)=\widetilde{O}(np_{\max})$ performs better if and only if $p_{\max}\gg n^{1/2}$). Both of these results [12, 28] generalize to m machines as well, leading to similar comparisons with our work.

It remains an interesting open question whether our $\widetilde{O}(P)$-time algorithm can be further improved with respect to the parameters $d_{\max}$ and $p_{\max}$. In principle it seems reasonable that time $\widetilde{O}(n+d_{\max})$ can be achieved, as the analogous question for Subset Sum is resolved [8, 26]. We leave this as an open question. An even more exciting question is whether we could possibly achieve time $\widetilde{O}(n+p_{\max})$. However, such an algorithm would entail a break-through for Subset Sum with small items, which currently seems out of reach.

Further Related Work. This work is part of a bigger effort of the fine-grained complexity community to design best-possible pseudo-polynomial time algorithms for a host of optimization problems. This line of research encompasses, besides the aforementioned scheduling problems [12, 23, 28, 36], various variants of Subset Sum [29, 8, 1, 5, 6, 13, 33, 4, 14, 34, 19], Knapsack [38, 18, 30, 7, 20, 33, 11, 16, 10, 9, 25], Integer Programming [20, 24] and many others [15, 19].

2 Preliminaries

Throughout, we write $[n]=\{0,\dots,n-1\}$ and use the interval notation $[i\,..\,j]=\{i,\dots,j\}$, and similarly $[i\,..\,j)$, $(i\,..\,j]$, $(i\,..\,j)$. For two sets of integers S,T and an integer t we employ the sumset notation $S+t=\{s+t : s\in S\}$ and $S+T=\{s+t : s\in S, t\in T\}$.

Scheduling Problems. We begin with a formal definition of the $1||\sum p_jU_j$ problem. The input consists of n *jobs*, where each job $j\in[n]$ has a *processing time* $p_j\in\mathbb{N}_{>0}$ and *due dates* $d_j\in\mathbb{N}_{>0}$. A schedule is a permutation $\sigma:[n]\to[n]$. The *completion time* C_j of a job j in the schedule σ is $C_j=\sum_{i:\sigma(i)\le\sigma(j)}p_j$ (i.e., the total processing time of all jobs preceding j, including j itself). We say that j is *early* if $C_j\le d_j$ and *tardy* otherwise, and let $U_j\in\{0,1\}$ be the indicator variable indicating whether j is tardy. In this notation, our objective is to find a schedule minimizing $\sum_j p_jU_j$ (i.e., the total processing time of all tardy jobs). This explains the description $1||\sum p_jU_j$ in three-field notation.[6] For convenience we have defined the problem in such a way that $p_j>0$, and as a consequence we can always bound $n\le P$.[7]

For the m-machine problem $P_m||\sum p_jU_j$ a schedule is analogously defined as a function $\sigma:[n]\to[n]\times[m]$, where the first coordinate determines the order of the jobs as before, and the second coordinate determines the machine which is supposed to execute the job. The completion time C_j is the total processing time of all jobs preceding j *on j's machine* (including j itself), and the objective of the problem remains unchanged. For simplicity, we assume throughout the paper that m is a constant (it can easily be verified that we only omit $m^{O(1)}$-factors this way).

[6] The 1 in the first field denotes a single machine, the empty second field symbolizes no additional constraints, and the third field gives the objective to minimize $\sum_j p_jU_j$.

[7] If jobs with processing time $p_j=0$ were permitted, all of our algorithms would additionally require $O(n)$ time preprocessing.

Earliest-Due-Date-First Schedules. A key observation about $1||\sum p_jU_j$ dating back to Lawler and Moore [31] is that, without loss of generality, the early jobs are scheduled in increasing order of their due dates. This observation is leveraged as follows: We reorder the jobs such that $d_0 \leq \cdots \leq d_{n-1}$ (we will stick to this ordering for the rest of the paper). Thus, the $1||\sum p_jU_j$ problem is effectively to compute a subset of jobs $J \subseteq [n]$ that maximizes $\sum_{j\in J} p_j$ and is *feasible* in the sense that all jobs in J are early (i.e., $C_j = \sum_{i\in J:i\leq j} p_i \leq d_j$ for all $j \in J$).

Machine Model. We work in the standard Word RAM model with word size $\Theta(\log n + \log P)$ (such that each job can be stored in a constant number of cells). Moreover, all randomized algorithms mentioned throughout are Las Vegas (i.e., zero-error) algorithms running in their claimed time bounds with high probability $1 - 1/n^{\Omega(1)}$.

3 Near-Optimal Algorithm for a Single Machine

In this section, we give the details of our near-optimal algorithm for $1||\sum p_jU_j$. We start with a brief summary of the Lawler-Moore algorithm.

Lawler and Moore's Baseline. The Lawler-Moore algorithm [31] is the natural dynamic programming solution for the $1||\sum p_jU_j$ problem. We present it here by recursively defining the following sets $S_0, \ldots, S_n \subseteq [0\,..\,P]$:

$$\begin{aligned} S_0 &= \{0\}, \\ S'_{j+1} &= S_j + \{0, p_j\} \quad (j \in [n]), \\ S_{j+1} &= S'_{j+1} \cap [0, d_j] \quad (j \in [n]). \end{aligned}$$

(The construction of S_{j+1} is divided into two steps as this will be convenient later on.) Each set S_{j+1} can naively be computed from S_j in time $O(P)$, and thus all sets $S_0, \ldots, S_n$ can be naively computed in time $O(nP)$. We can ultimately read off the optimal value as $\max S_n$, based on the following observation:

▶ **Observation 3** (Lawler and Moore [31]). *There is a feasible schedule of total processing time t if and only if $t \in S_n$.*

More generally, S_{j+1} is the set of processing times of feasible schedules involving the jobs $0, \ldots, j$. To see this, consider any feasible schedule of the jobs $0, \ldots, j-1$ (whose processing time is in S_j). We can either leave out the next job j or append to the schedule. Thereby, the set of processing times becomes $S'_{j+1} = S_j + \{0, p_j\} = \{s, s + p_j : s \in S'_{j+1}\}$. However, this appended schedule is not necessarily feasible as it might not comply with the due date d_j. Hence, all processing times greater than d_j are deleted again in the construction of S_j.

Our Approach. Perhaps surprisingly, our algorithm essentially follows the same approach, i.e., our goal remains to compute the sets $S_0, \ldots, S_n$. However, we will demonstrate that the naive $O(P)$-time computation of each step can be significantly sped up. Our algorithm relies on two ingredients – an algorithmic and a structural one.

Ingredient 1: An Efficient Data Structure. As the sets S'_j and S_j are constructed in a highly structured way, can we compute them faster than time $O(P)$? Specifically, is there a way to (i) compute each set S'_{j+1} in time proportional to the number of *insertions* $|S'_{j+1} \setminus S_j|$, and to (ii) compute S_{j+1} in time proportional to the number of *deletions* $|S'_{j+1} \setminus S_{j+1}|$?

Question (i) is closely related to the Subset Sum problem, and has been successfully resolved in [5] leading to near-optimal algorithms for *Modular* Subset Sum. Their solution based on linear sketching is quite involved [5], but two independent papers [4, 14] provided a significantly simpler proof by replacing linear sketching with a reduction to a dynamic string problem; see also [34][8]. Regarding (ii), it turns out that we can adapt this reduction to the dynamic string problem to efficiently accommodate our deletions. The following lemma summarizes the resulting data structure; we defer its proof to Section 3.1.

▶ **Lemma 4** (Sum-Cap Data Structure). *There is a randomized data structure that maintains a set $S \subseteq [u]$ and supports the following operations:*

- `init`(S)*:* *Initializes the data structure to the given set $S \subseteq [u]$.*
  Runs in time $O(|S| \cdot \log u + \log^2 u)$.
- `query`(s)*:* *Given $s \in [u]$, tests whether $s \in S$.*
  Runs in time $O(\log u)$.
- `sum`(p)*:* *Given $p \in [u]$, updates $S \leftarrow S + \{0, p\}$.*
  Runs in time $O(|(S+p) \setminus S| \cdot \log u)$ (where S is as before the operation).
- `cap`(d)*:* *Given $d \in [u]$, updates $S \leftarrow S \cap [d]$.*
  Runs in time $O(\log u)$.

If at any point during the execution an element $s \notin [u]$ is attempted to be inserted, the data structure becomes invalid. Moreover, the data structure can be made deterministic at the cost of worsening all operations by a factor $\log^{o(1)} u$.

Ingredient 2: A Structural Insight. What have we gained by computing the sets S_j and S'_j with the data structure from Lemma 4? Due to the particularly efficient `cap` operation, the computation of the sets S_j is essentially for free. Computing the sets S'_j using the `sum` operation, however, amounts to time

$$\widetilde{O}\left(\sum_{j\in[n]} |S'_{j+1} \setminus S_j|\right).$$

A priori, it is not clear whether this is helpful. In case of only *inserting* elements, this sum could be conveniently bounded by P (as is the case for Modular Subset Sum). Unfortunately, we additionally have to deal with *deletions*. Specifically, it is possible that some element s is inserted in S'_1, deleted in S_1, inserted again in S'_2, and so on. All in all, s could be inserted up to n times, and so the only immediate upper bound for the sum is nP (which recovers the Lawler-Moore running time).

Our crucial structural insight is that, while the same element can indeed be inserted and deleted multiple times, the *total number of insertions* is nevertheless bounded. More precisely, we show that the overall number of insertions is at most $O(P)$:

[8] In [34], Potepa proposes an improved deterministic data structure with applications to the Modular Subset Sum problem. A priori, it looks like their improvement might similarly apply to our setting. Unfortunately, the data structure is only efficient if we have the freedom to arbitrarily reorder the items, which is prohibitive for us as we have to stick to the order $d_0 \leq \cdots \leq d_{n-1}$.

▶ **Lemma 5** (Bounded Insertions). *It holds that* $\sum_{j\in[n]} |S'_{j+1} \setminus S_j| \leq 2P+1$.

Proof. We split the sum into two parts:

$$\sum_{j\in[n]} \big|(S'_{j+1} \setminus S_j)\big| = \sum_{j\in[n]} \big|(S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]\big| + \sum_{j\in[n]} \big|(S'_{j+1} \setminus S_j) \cap (d_j\,..\,P]\big|.$$

Intuitively, the first sum counts the number of elements that are irreversibly inserted into $S_{j+1}, \dots, S_n$ in the j-th step. The second sum counts the number of elements that are inserted into S'_{j+1} and immediately deleted in S_{j+1}.

For the first sum, consider the following observation: For any $x \in [0\,..\,P]$, if $x \leq d_j$ and $x \in S'_{j+1} \setminus S_j$, then $x \in S_{j+1}, \dots, S_n$ (since $d_j \leq d_{j+1}, \dots, d_{n-1}$). It follows that

$$\big|\{j \in [n] : x \in (S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]\}\big| \leq 1$$

for all $x \in [0\,..\,P]$. Thus,

$$\sum_{j\in[n]} \big|(S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]\big| = \sum_{x\in[0\,..\,P]} \big|\{j \in [n] : x \in (S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]\}\big| \leq P+1.$$

Second, we bound $|(S'_{j+1} \setminus S_j) \cap (d_j\,..\,P]| \leq |S'_{j+1} \cap (d_j\,..\,P]|$. Note that $S_j \subseteq [0\,..\,d_{j-1}]$ and therefore $S'_{j+1} = S_j + \{0, p_j\} \subseteq [0\,..\,d_{j-1} + p_j]$. Consequently,

$$\big|S'_j \cap (d_j\,..\,P]\big| \leq \big|[0\,..\,d_{j-1} + p_j] \cap (d_j\,..\,P]\big| \leq d_{j-1} + p_j - d_j \leq p_j,$$

where the final inequality follows from the assumption that $d_{j-1} \leq d_j$. Hence, the number of overall deletions is

$$\sum_{j\in[n]} \big|(S'_{j+1} \setminus S_j) \cap (d_j\,..\,P]\big| \leq \sum_{j\in[n]} p_j = P.$$

Combining both parts concludes the proof. ◀

The proof for Lemma 4 is provided in Section 3.1. Using Lemma 5 and 4, we are in the position to show our main result.

▶ **Theorem 1.** *The* $1||\sum p_j U_j$ *problem can be solved in randomized time* $O(P \log P)$ *and in deterministic time* $O(P \log^{1+o(1)} P)$.

Proof. In summary, our algorithm works as follows. We compute $S_0, \dots, S_n \subseteq [0\,..\,P]$ using the data structure from Lemma 4 (with $u = P+1$). Specifically, after initializing S with $\texttt{init}(S_0)$, we repeatedly construct the sets S'_j and S_j using the operations $\texttt{sum}(p_j)$ and $\texttt{cap}(d_j)$ for all $j \leftarrow 0, \dots, n-1$. The largest element in the final set $S = S_n$ is the maximal total processing of a feasible schedule of all jobs $0, \dots, n-1$. Finding and returning it is the last step of our algorithm, by repeatedly using the $\texttt{query}(i)$ operation and returning the largest index i for which the query returns yes. The correctness of our algorithm follows from Observation 3.

The running time is composed of the following parts: The initialization runs in time $O(\log^2 P)$, the repeated use of `sum` and `cap` takes time $O(\sum_{j\in[n]}(|S'_{j+1} \setminus S_j| \cdot \log P + \log P))$ and the optimal value is found in time $O(P)$. Using $n \leq P$ and Lemma 5, it holds that

$$O\left(\sum_{j\in[n]} (|S'_{j+1} \setminus S_j| \cdot \log P + \log P)\right) \leq O(P \log P).$$

In total, we have a randomized running time of $O(P \log P)$. Applying the same arguments yields the deterministic running time of $O(P \log^{1+o(1)} P)$. ◀

We stress that the algorithm described in this section only computes the optimal *value*. In Section 3.2, we explain how our algorithm can be easily extended to obtain the optimal *schedule* as well.

3.1 Cap-Sum Data Structure via Dynamic Strings

In this section, we provide the missing proof of Lemma 4 by a reduction to the *dynamic strings* data structure problem. This is the fundamental problem of maintaining a collection of strings that can be concatenated, split, updated, and tested for equality – see [37, 35, 32, 2, 21]. We summarize the state of the art in the following lemma; the fastest randomized (and in fact, optimal) data structure is due to Gawrychowski, Karczmarz, Kociumaka, Lacki and Sankowski [21], and for the fastest deterministic one see [27, Section 8].

Here we use standard string notation for a string x, where $x[i]$ denotes the letter at index i, and $x[i\,..\,j], x[i\,..\,j)$ denote the appropriate substrings.

▶ **Lemma 6** (Dynamic String Data Structure [21, 27]). *There is a data structure that maintains a dynamic collection X of non-empty strings and support the following operations:*

- `make_string`(x)*: Given any string $x \in \Sigma^+$, inserts x into X.*
- `concat`(x_1, x_2)*: Given $x_1, x_2 \in X$, inserts the concatenation x_1x_2 into X.*
- `split`(x, i)*: Given $x \in X$ and $i \in [0\,..\,|x|)$, inserts $x[0\,..\,i]$ and $x(i\,..\,|x|)$ into X.*
- `LCP`(x_1, x_2)*: Given $x_1, x_2 \in X$, returns the length ℓ of their longest common prefix, i.e., returns $\max\{0 \le \ell \le \min\{|x_1|, |x_2|\} : x_1[0\,..\,\ell) = x_2[0\,..\,\ell)\}$.*
- `query`(x, i)*: Given $x \in X$ and $i \in [|x|]$, returns $x[i]$.*

Let n be the maximum of the total length of all strings and the number of executed operations. Then all operations run in randomized time $O(\log n)$ or in deterministic time $O(\log^{1+o(1)} n)$, except for `make_string` *which takes time $O(|x| + \log n)$ and $O(|x| \cdot \log^{o(1)} n)$, respectively.*

For the sake of convenience, we include two more dynamic string operations that are derived from the previous lemma in a black-box fashion. As both are standard operations [21], we only provide their implementations for completeness.

- `update`(x, i, σ): Given $x \in X$, an index $i \in [|x|]$ and $\sigma \in \Sigma$, inserts the string obtained from x by changing the i-th character to σ into the data structure. To implement this, we split the string x twice to separate the letter $x[i]$ from the rest of the string. Specifically, we obtain the substring $x[0\,..\,i]$ using `split`(x, i) and further divide it to get the substring $x[0\,..\,i)$ by `split`$(x[0\,..\,i), i-1)$. Next, the `make_string`(σ) operation creates the string σ. Lastly, we use `concat`$(x[0\,..\,i), \texttt{concat}(\sigma, x(i\,..\,|x|)))$ to reinsert σ between the two substrings.
- `LCE`(x_1, x_2, i_1, i_2): Given $x_1, x_2 \in X$ and $i_1 \in [|x_1|], i_2 \in [|x_2|]$, returns the longest common extension $\max\{0 \le \ell \le \min\{|x_1| - i_1, |x_2| - i_2\} : x_1[i_1\,..\,i_1 + \ell) = x_2[i_2\,..\,i_2 + \ell)\}$. To implement this, using the two operations `split`$(x_1, i-1)$ and `split`$(x_2, j-1)$ we first separate the substrings $x_1[i\,..\,|x_1|)$ and $x_2[j\,..\,|x_2|)$. Observe that the length of the longest common extension of the original strings is exactly the length of the longest common prefix of $x_1[i\,..\,|x_1|)$ and $x_2[j\,..\,|x_2|)$ returned by the operation `LCP`$(x_1[i\,..\,|x_1|), x_2[j\,..\,|x_2|))$.

Both `update` and `LCE` require a constant number of original operations that run in randomized time $O(\log n)$, or deterministic time $O(\log^{1+o(1)} n)$.

Now, we are in the position to provide the proof of Lemma 4. Recall that this proof is in parts borrowed from [4, 14].

Proof of Lemma 4. We maintain the set $S \subseteq [u]$ as an indicator string $x_S \in \{0,1\}^u$ such that $i \in S$ if and only if $x_S[i] = 1$.

- $\texttt{init}(S)$: Using repeated squaring, we construct the string 0^u by inserting $w = 0$ and concatenating w with itself $\log u$ times. Note that 0^u will remain in the data structure and can be used by other operations. We compute x_S by updating 0^u using $\texttt{update}(x_S, S[i], 1)$ for all indices $i \in S$. Since the repeated squaring takes time $O(\log^2 u)$ and updating the elements takes time $O(|S| \cdot \log u)$, the `init` operation runs in time $O(\log^2 u + |S| \cdot \log u)$.
- $\texttt{query}(i)$: As the original data structure already provides a query operation, we use $\texttt{query}(x_S, i)$ that returns $x_S[i]$ in time $O(\log u)$.
- $\texttt{sum}(p)$: We implement `sum` in three steps. First, we will compute the string x_{S+p} that represents the set $S + p$. Observe that x_{S+p} is obtained by shifting x_S by p positions to the right. Thus, we extend x_S using $\texttt{concat}(0^p, x_S)$ where the string 0^p is split off the precomputed string 0^u using $\texttt{split}(0^u, p)$. Then we trim it down to length u with $\texttt{split}(0^p x_S, u)$.

  Second, note that the desired string $x_{S\cup(S+p)}$ is the result of the bit-wise OR of x_S and x_{S+p}. We compute the set $D = \{i \in [u] : x_S[i] \neq x_{S+p}[i]\}$ that contains all indices at which x_S and x_{S+p} differ from each other. To this end, starting with $i \leftarrow 0$, we will repeat the following process as long as $i < u$: Compute $\ell \leftarrow \texttt{LCE}(x_S, x_{S+p}, i, i)$ to determine the next index ℓ at which both strings differ, insert $D \leftarrow D \cup \{i + \ell\}$ and update $i \leftarrow i + \ell + 1$.

  As the third and last step, we compute $x_{S\cup(S+p)}$ by updating x_S using $\texttt{update}(x_S, i, 1)$ for all indices $i \in D$.

  Creating the shifted string x_{S+p} takes time $O(\log u)$. Both the construction of set D and computing the string $x_{S\cup(S+p)}$ require $|(S+p) \setminus S| + |S \setminus (S+p)|$ many operations that each run in time $O(\log u)$. Since $|S + p| = |S|$, we have

  $$|(S+p) \setminus S| = |S+p| - |(S+p) \cap S| = |S| - |(S+p) \cap S| = |S \setminus (S+p)|$$

  and therefore $|(S+p) \setminus S| + |S \setminus (S+p)| = 2 \cdot |(S+p) \setminus S|$. In summary, the `sum` operation takes time $O(|(S+p) \setminus S| \cdot \log u)$.
- $\texttt{cap}(d)$: In order to set $x_S[i] = 0$ for all $i \in (d\,..\,u)$, we separate the substring $x_S[0\,..\,d]$ with $\texttt{split}(x_S, d)$ and split the substring 0^{u-d+1} off the precomputed string 0^u using $\texttt{split}(0^u, u - d + 1)$. Then x_S is assembled using $\texttt{concat}(x_S[0\,..\,d], 0^{u-d+1})$. All three operations take time $O(\log u)$.

Following Lemma 6, the deterministic running times can be obtained by worsening all operations by a factor $\log^{o(1)} u$. ◀

3.2 Obtaining an Optimal Schedule

In the previous sections we have argued that the optimal value OPT (i.e., the maximum total processing of a feasible schedule) can be computed in near-linear time $\widetilde{O}(P)$. In this section we explain how the actual optimal schedule can be computed by a deterministic post-processing routine in time $O(n)$.

The idea is, as is standard for dynamic programming algorithms, to trace through the sets $S_0, \ldots, S_n$ in reverse order. Making this traversal efficient, we slightly modify our algorithm to additionally compute an array $A[0\,..\,P]$ such that $A[s] = \min\{j \in [n] : s \in S_{j+1}\}$. Intuitively, $A[s]$ stores the smallest job j such that there exists a feasible schedule with total processing time s that contains j. Updating A appropriately whenever an element is inserted into S'_{j+1} allows us to easily maintain the array without worsening the asymptotic running time. Then, in order to compute an optimal schedule, we apply the following

algorithm: We initialize $J \leftarrow \emptyset$ and $s \leftarrow \mathrm{OPT}$. We repeatedly retrieve the next job $j \leftarrow A[s]$ and update $J \leftarrow J \cup \{j\}$ and $s \leftarrow s - p_j$, until $s = 0$. In each step, we identify a job j that is contained in the optimal schedule, and thus J is an optimal schedule once the process has terminated. In fact, the same idea can be used to retrieve a feasible schedule for *any* given processing time $s \in S_n$.

4 Generalization to Multiple Machines

In this section, we show that our algorithm for $1||\sum p_j U_j$ can be extended to $P_m||\sum p_j U_j$. Since it follows the same approach as the single machine algorithm, we will keep this section short and concise. For more details refer to Section 3.

Let $e_0, \dots, e_{m-1}$ denote the standard unit vectors of $\mathbb{Z}^m$, then we recursively define the sets $S_0, \dots, S_n \subseteq [0, P]^m$ as follows:

$$\begin{aligned} S_0 &= \{0\}, \\ S'_{j+1} &= S_j + \{0, p_j \cdot e_0, \dots, p_j \cdot e_{m-1}\} && (j \in [n]), \\ S_{j+1} &= S'_{j+1} \cap [0, d_j]^m && (j \in [n]). \end{aligned}$$

As before, the optimal value is the maximum entry in S_n:

▶ **Observation 7** (Lawler and Moore [31]). *There is a feasible schedule of total processing time t if and only if there is some $s \in S_n$ with $s_0 + \dots + s_{m-1} = t$.*

The crucial difference to before is that here all $s \in S_j$ are vectors where their i-th entry corresponds to the i-th machine. Because each job is either scheduled on exactly one machine or not at all, we consider all scheduling possibilities of job j with $S_j + \{0, p_j \cdot e_0, \dots, p_j \cdot e_{m-1}\}$. As our goal is again to bound the total number of insertions, see the following lemma:

▶ **Lemma 8** (Generalized Bounded Insertions). *It holds that*

$$\sum_{j \in [n]} \left| S'_{j+1} \setminus S_j \right| \leq (m+1) \cdot (P+1)^m.$$

Proof. In the following, we consider two parts of the sum separately:

$$\sum_{j \in [n]} \left| (S'_{j+1} \setminus S_j) \right| = \sum_{j \in [n]} \left| (S'_{j+1} \setminus S_j) \cap [0\,..\,d_{j+1}]^m \right| + \sum_{j \in [n]} \left| (S'_{j+1} \setminus S_j) \setminus [0\,..\,d_{j+1}]^m \right|.$$

In other words, in analogy to Lemma 5, we first count the number of elements that are irrevocably inserted into $S_{j+1}, \dots, S_n$ in the j-th step. Second, we count the number of elements that are inserted into S'_{j+1} and instantly deleted in S_{j+1}.

We bound the first sum with the following observation. For any $x \in [0\,..\,P]^m$, it holds that if $x \in (S'_{j+1} \setminus S_j)$ and $x \in [0\,..\,d_j]$, then $x \in S_{j+1}, \dots, S_n$. This follows directly from the assumption that $d_j \leq d_{j+1}, \dots, d_{n-1}$. Therefore, it holds that

$$\left| \{ j \in [n] : x \in (S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]^m \} \right| \leq 1,$$

for all $x \in [0\,..\,P]^m$, and thus

$$\sum_{j \in [n]} \left| (S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]^m \right| = \sum_{x \in [0\,..\,P]^m} \left| \{ j \in [n] : x \in (S'_{j+1} \setminus S_j) \cap [0\,..\,d_j]^m \} \right| \leq (P+1)^m.$$

For the second sum, we bound $|(S'_{j+1} \setminus S_j) \setminus [0\,..\,d_j]^m| \leq |S'_{j+1} \setminus [0\,..\,d_j]^m|$. Using that $S_j \subseteq [0\,..\,d_{j-1}]^m$, we have that

$$\begin{aligned} S'_{j+1} &= S_j + \{0, p_j \cdot e_0, \dots, p_j \cdot e_{m-1}\} \\ &\subseteq [0\,..\,d_{j-1}]^m + \{0, p_j \cdot e_0, \dots, p_j \cdot e_{m-1}\} =: V_{j+1}. \end{aligned}$$

As each job j is scheduled on exactly one machine, we observe that V_{j+1} is the set of vectors where all entries are in $[0\,..\,d_{j-1}]$, except for possibly one entry that is in $[0\,..\,d_{j-1} + p_j]$. Hence, $V_{j+1} \setminus [0\,..\,d_j]^m$ is the set of vectors where all entries are in $[0\,..\,d_{j-1}]$, except for exactly one entry that is in $(d_j\,..\,d_{j-1} + p_j]$. Next, we bound the size of $V_{j+1} \setminus [0\,..\,d_j]^m$: There are m options for the index of the special entry, there are $d_{j-1} + p_j - d_j$ options for the value of the special entry, and finally there are $(P+1)^{m-1}$ options for the other $m-1$ entries. Thus,

$$\begin{aligned} \left|S'_{j+1} \setminus [0\,..\,d_j]^m\right| &\leq \left|V_{j+1} \setminus [0\,..\,d_j]^m\right| \\ &\leq m \cdot (P+1)^{m-1} \cdot (d_{j-1} + p_j - d_j) \\ &\leq m \cdot (P+1)^{m-1} \cdot p_j, \end{aligned}$$

where the final inequality follows from the assumption that $d_{j-1} \leq d_j$. Consequently, the second sum is bounded by

$$\sum_{j \in [n]} \left|S'_{j+1} \setminus [0\,..\,d_j]^m\right| \leq m \cdot (P+1)^{m-1} \cdot \sum_{j \in [n]} p_j \leq m \cdot (P+1)^m.$$

Combining the bounds for both sums yields the overall bound. ◀

Analogous to Section 3, we use the generalized sum-cap data structure to efficiently maintain the generalized sets $S_0, \dots, S_n$.

▶ **Lemma 9** (Generalized Sum-Cap Data Structure). *There is a randomized data structure maintaining a set $S \subseteq [u]^m$ that supports the following operations:*

- `init`(S): *Initializes the data structure to the given set $S \subseteq [u]^m$.*
  Runs in time $O(\log^2 u + |S| \cdot \log u)$.
- `query`(s): *Given $s \in [u]^m$, tests whether $s \in S$.*
  Runs in time $O(\log u)$.
- `sum`(T): *Given $T \subseteq [u]^m$, updates $S \leftarrow S + T$.*
  Runs in time $O(|T| \cdot |(S+T) \setminus S| \cdot \log u)$ (where S is as before the operation).
- `cap`(d): *Given $d \in [u]$, updates $S \leftarrow S \cap [d]^m$.*
  Runs in time $O(u^{m-1} \cdot \log u)$.

If at any point during the execution an element $s \notin [u]^m$ is attempted to be inserted, the data structure becomes invalid. Moreover, the data structure can be made deterministic at the cost of worsening all operations by a factor $\log^{o(1)} u$.

Proof. Let $U = u^m$. Let $\phi : [u]^m \to [U]$ be the bijection defined by $\phi(s) = \sum_{i \in [m]} s_i u^i$. We extend the definition to sets $S \subseteq [u]^m$ via $\phi(S) = \{\phi(s) : s \in S\}$. We maintain the set $S \subseteq [u]^m$ as the indicator string of $\phi(S)$, namely $x_{\phi(S)} \in \{0,1\}^U$, such that $i \in S$ if and only if $x_{\phi(S)}[i] = 1$. In other words, we store for each $s \in [u]^m$, listed in lexicographical order, whether $s \in S$.

- `init`(S): The string 0^U is constructed using repeated squaring by inserting $x = 0$ and concatenating x with itself $m \log u$ times. It will remain in the data structure available to other operations. Repeatedly using `update`$(\cdot, \phi(s), 1)$ for all entries $s \in S$, we update the string 0^U to obtain $x_{\phi(S)}$. As repeated squaring takes time $O(\log^2 u)$ and updating the elements takes time $O(|S| \cdot \log u)$, the `init` operation runs in time $O(\log^2 u + |S| \cdot \log u)$.

- $\texttt{query}(s)$: Using $\texttt{query}(x_{\phi(S)}, s)$ from the string data structure allows us to return $x_{\phi(S)}[s]$ in time $O(\log u)$.
- $\texttt{sum}(T)$: We can assume without loss of generality that $0 \in T$ (as otherwise we can simply shift T and $x_{\phi(S)}$ appropriately such that the smallest element in T becomes 0). Fix an arbitrary nonzero element $p \in T$. Analogously to Lemma 4, we first show how to compute the set $(S+p) \setminus S$ in output-sensitive time. The string $x_{\phi(S+p)}$ representing the set $S+p$ can be computed using the two following facts. If $x, y, x+y \in [u]^m$, then it holds that $\phi(x+y) = \phi(x) + \phi(y)$. Further, if $p \in [u]^m$ and $S, S+p \subseteq [u]^m$, then $\phi(S+p) = \phi(S) + \phi(p)$. Therefore, $x_{\phi(S+p)}$ is $x_{\phi(S)}$ up to a shift of $\phi(p)$, and can be obtained by $\texttt{split}(\texttt{concat}(0^{\phi(p)}, x_{\phi(S)}), U)$.

  Similarly to Lemma 4, repeatedly using $\texttt{LCE}$ queries allows us to first compute the set $\{i \subseteq [U] : x_{\phi(S)}[i] \neq x_{\phi(S+p)}[i]\}$ and then read off the symmetric difference of S and $S+p$, denoted by $D_p = (S \setminus (S+p)) \cup ((S+p) \setminus S)$. We repeat the same for all other nonzero elements $p \in T$. Let $D = \bigcup_{p \in T \setminus \{0\}} D_p$, then we have $D \supseteq (S+T) \setminus S$. Thus, we can update the indicator string $x_{\phi(S)}$ by calling $\texttt{update}(\cdot, \phi(s), 1)$ for all $s \in D$.

  In order to bound the running time, we bound the size of the sets D_p and D. Using that $|S \setminus (S+p)| = |(S+p) \setminus S|$, we have that $|D_p| \leq 2|(S+p) \setminus S| \leq 2|(S+T) \setminus S|$, and therefore $|D| \leq 2|T| \cdot |(S+T) \setminus S|$. In total, we used $O(|D|)$ data structure operations, leading to a running time of $O(|T| \cdot |(S+T) \setminus S| \cdot \log u)$.
- $\texttt{cap}(d)$: We delete all vectors $s \in S$ with at least one entry that is larger than d as follows. We enumerate all $(m-1)$-tuples $(s_1, \ldots, s_{m-1}) \in [u]^{m-1}$. Recall that the vectors are stored in lexicographical order. Thus, the set of vectors $(s_0, s_1, \ldots, s_{m-1})$ where s_0 ranges over $[u]$ and $s_1, \ldots, s_{m-1}$ are fixed, is represented by a length-u substring of $x_{\phi(S)}$. Specifically, the substring $x_{\phi(S)}[\phi(0, s_1, \ldots, s_{m-1}) .. \phi(u-1, s_1, \ldots, s_{m-1})]$. We distinguish two cases: If $\max_{i=1}^{m-1} s_i > d$, then the entire substring is replaced with 0^u. Otherwise, we retain its length-$(d+1)$ prefix and replace its suffix is by 0^{u-d+1}. It takes $O(u^{m-1})$ $\texttt{concat}$ and $\texttt{split}$ operations to perform these modifications, running in total time $O(u^{m-1} \cdot \log u)$.

Again, following Lemma 6 the deterministic running time of the operations differs by replacing $\log u$ with $\log^{1+o(1)} u$. ◀

Based on Lemma 8 and 9, we show the following generalization of our main result.

▶ **Theorem 2.** *The $P_m || \sum p_j U_j$ problem can be solved in randomized time $O(P^m \log P)$ and in deterministic time $O(P^m \log^{1+o(1)} P)$.*

Proof. Analogous to Theorem 1, we use the algorithm: We initialize the data structure from Lemma 8 (used with $u = P+1$) with $\texttt{init}(S_0)$. For all $j \leftarrow 0, \ldots, n-1$, we repeatedly use the operations $\texttt{sum}(\{0, p_j \cdot e_0, \ldots, p_j \cdot e_{m-1}\})$ and $\texttt{cap}(d_j)$ to compute the sets S'_{j+1} and S_{j+1}. We return the optimal value contained in S_n as described in Theorem 1. Our algorithm is correct due to Observation 7. Finally, using Lemmas 8 and 9 and the assumption $n \leq P$, we can bound the dominant term of the running time by

$$O\left(\sum_{j \in [n]} (m \cdot |S'_{j+1} \setminus S_j| \cdot \log P + P^{m-1} \log P)\right) = O(P^m \log P).$$

(Recall that m is constant.) Thus, we obtain a randomized running time of $O(P^m \log P)$, and similarly a deterministic running time of $O(P^m \log^{1+o(1)} P)$. ◀

Abstract

In this paper, we investigate the question of whether the electrical flow routing is a good oblivious routing scheme on an m-edge graph $G = (V, E)$ that is a Φ-expander, i.e. where $|\partial S| \geq \Phi \cdot \mathrm{vol}(S)$ for every $S \subseteq V, \mathrm{vol}(S) \leq \mathrm{vol}(V)/2$. Beyond its simplicity and structural importance, this question is well-motivated by the current state-of-the-art of fast algorithms for ℓ_∞ oblivious routings that reduce to the expander-case which is in turn solved by electrical flow routing.

Our main result proves that the electrical routing is an $O(\Phi^{-1} \log m)$-competitive oblivious routing in the ℓ_1- and ℓ_∞-norms. We further observe that the oblivious routing is $O(\log^2 m)$-competitive in the ℓ_2-norm and, in fact, $O(\log m)$-competitive if ℓ_2-localization is $O(\log m)$ which is widely believed.

Using these three upper bounds, we can smoothly interpolate to obtain upper bounds for every $p \in [2, \infty]$ and q given by $1/p + 1/q = 1$. Assuming ℓ_2-localization in $O(\log m)$, we obtain that in ℓ_p and ℓ_q, the electrical oblivious routing is $O(\Phi^{-(1-2/p)} \log m)$ competitive. Using the currently known result for ℓ_2-localization, this ratio deteriorates by at most a sublogarithmic factor for every $p, q \neq 2$.

We complement our upper bounds with lower bounds that show that the electrical routing for any such p and q is $\Omega(\Phi^{-(1-2/p)} \log m)$-competitive. This renders our results in ℓ_1 and ℓ_∞ unconditionally tight up to constants, and the result in any ℓ_p- and ℓ_q-norm to be tight in case of ℓ_2-localization in $O(\log m)$.

1 Introduction

In this paper, we study flow-routing problems on connected, undirected (multi-)graphs $G = (V, E)$. A broad and well-studied class of single-commodity flow problems arises by seeking a flow $\boldsymbol{f} \in \mathbb{R}^E$ that routes given demands $\boldsymbol{\chi} \in \mathbb{R}^V$, while minimizing a ℓ_p-norm of

the flow. Denoting the graph edge-vertex incidence matrix by $\boldsymbol{B} \in \mathbb{R}^{V \times E}$, we can write these optimization problems as

$$\min_{\boldsymbol{B}\boldsymbol{f}=\boldsymbol{\chi}} \|\boldsymbol{f}\|_p. \tag{1}$$

The case $p = \infty$ is known as undirected maximum flow, while $p = 2$ is called electrical flow and $p = 1$ is called transshipment. Here we focus for simplicity on the unweighted setting, but all results in this paper and in related work can in fact be extended to work in weighted graphs.

We can generalize these flow problems to the multi-commodity case by allowing a collection of demands $\{\boldsymbol{\chi}_i\}$ to be routed simultaneously by a collection of flows $\{\boldsymbol{f}_i\}$, while minimizing a single objective on all of them.

$$\min_{\boldsymbol{B}\boldsymbol{f}_i=\boldsymbol{\chi}_i,\forall i} \|\sum_i |\boldsymbol{f}_i|\|_p. \tag{2}$$

For any p, solutions with $(1 + 1/\operatorname{poly}(|E|))$-multiplicative error to these problems can be computed in polynomial time and for the single-commodity setting even in almost-linear time [18, 7]. For the special cases of $p = 1, 2, \infty$, optimal solutions can be computed in polynomial time via linear/convex programming.

However, in many settings, we may want to sacrifice optimality of our routing solutions for simplicity of the routing algorithm. A particularly simple and popular approach is *oblivious routing*, where a collection of routing paths are chosen in advance between every pair of nodes, without knowing the demands that will be eventually routed. Historically, oblivious routings were first studied on specific networks, specifically the hypercube [37, 38]. A deeply influential technique in this area is the work of Rackë [27]. An *oblivious routing* is linear operator $\boldsymbol{A} \in \mathbb{R}^{E \times V}$ that maps any valid[1] demand vector $\boldsymbol{\chi} \in \mathbb{R}^V$ to a flow $\boldsymbol{f} = \boldsymbol{A}\boldsymbol{\chi}$ that routes $\boldsymbol{\chi}$. This extends to routing multiple demands in the multi-commodity setting, $\{\boldsymbol{f}_i = \boldsymbol{A}\boldsymbol{\chi}_i\}$.

Conceptually, a highly attractive feature is that multiple demand vectors can be routed simultaneously without knowing the other demands, and a single demand can be broken down into multiple terms, e.g. source-sink demand pairs, and routings of each pair can be again computed separately. These features make oblivious routings ideal for online routing problems – which was the original motivation for their construction [27].

As mentioned above, using oblivious routing comes at the sacrifice of optimality. To get a quantitative measure of the loss a routing scheme $\boldsymbol{A}$ might incur in the ℓ_p metric, we define the *competitive ratio* of $\boldsymbol{A}$, denoted by $\rho_p(\boldsymbol{A})$, to be the maximal ratio between the objective value achieved by an oblivious routing $\boldsymbol{A}$ and the optimal solution achieved by *any* (multi-commodity) demand.

In a ground-breaking sequence of papers [27, 3, 9], Räcke, Azar, Cohen, Fiat, Kaplan, and Englert showed that for all ℓ_p-norms, oblivious routings with competitive ratio $\tilde{O}(1)$ exist[2]. In fact, for the well-studied setting of $p = \infty$, [28] gave an optimal construction with $O(\log m)$ competitive ratio in polynomial time, matching a $\Omega(\log m)$ lower bound [4, 25].

Fast Algorithms and Applications for ℓ_∞ Oblivious Routing

ℓ_∞ oblivious routings are a fundamental tool in obtaining fast approximate maximum flow algorithms in undirected graphs. Building on the techniques in [35, 24], [16, 33] give algorithms that show that $O(\operatorname{poly}(\alpha/\varepsilon))$ applications of a α-competitive ℓ_∞ oblivious routing

[1] A demand $\boldsymbol{\chi}$ can be routed on a connected graph iff $\sum_v \chi(v) = 0$.
[2] We use $\tilde{O}(\cdot)$ to hide polylogarithmic factors in the graph size m.

yield $(1+\varepsilon)$-approximate maximum flow on undirected graphs by using gradient descent. They then developed almost-linear time algorithms for $m^{o(1)}$-competitive ℓ_∞ oblivious routing. As a result, they obtained approximate undirected maximum flow in time $m^{1+o(1)}\,\mathrm{poly}(1/\varepsilon)$ – one of the major recent breakthroughs in modern graph algorithms.

Later, [29] gave a reduction from computing $\tilde{O}(1)$-competitive ℓ_∞ oblivious routings to approximate maximum flows resulting in a $m^{1+o(1)}$ time algorithm. [26] then showed that combining these approaches recursively yields a $\tilde{O}(m)$ algorithm to compute $\tilde{O}(1)$-competitive ℓ_∞ oblivious routings and a $\tilde{O}(m\,\mathrm{poly}(1/\varepsilon))$ algorithm for $(1+\varepsilon)$-approximate undirected maximum flow [26]. Recently, [12] presented an alternative, simple $\tilde{O}(m)$ algorithm to obtain (and maintain) ℓ_∞ oblivious routings with subpolynomial competitive factor.

While recently the first *exact* maximum flow algorithm with runtime $m^{1+o(1)}$ was given in [7], ℓ_∞ oblivious routings and approximate undirected maximum flow remain important tools with many algorithms crucially relying on them as subroutines to obtain runtime $\tilde{O}(m)$.

We point out that above, for simplicity, we did not properly distinguish between ℓ_∞ oblivious routings which are only constructed in [16], and their weaker counterparts *congestion approximators* which are used in all other constructions. A congestion approximator is a linear operator $\boldsymbol{C}$ that maps each demand $\boldsymbol{\chi}$ to vector $\boldsymbol{c} = \boldsymbol{C}\boldsymbol{\chi}$ such that $\|\boldsymbol{c}\|_\infty$ approximates the objective value of (2). Note, that $\boldsymbol{c}$ is not necessarily a flow.

ℓ_∞ Oblivious Routing on Expanders and in General Graphs

Valiant's trick [38], a popular scheme that routes demands from each source to a set of randomly chosen intermediate nodes before routing them to the destination, establishes the existence of $O(\Phi^{-1}\log n)$-competitive ℓ_∞-oblivious routings in expanders. However, implementing Valiant's trick algorithmically requires computing multi-commodity flows, which are expensive to compute.

To the best of our knowledge, the only fast algorithm that computes an ℓ_∞ oblivious routing on general graphs is given in [16]. In their approach, they first reduce the problem to finding an ℓ_∞ oblivious routing on a Φ-expander with unit-weights (in this case $\Phi = m^{-o(1)}$). They then exploit a simple but striking statement, previously demonstrated by Kelner and Maymounkov [15]: the electrical flow routing, henceforth denoted by $\boldsymbol{A}_{\mathcal{E}}$, on a Φ-expander is a $O(\Phi^{-2}\log m)$-competitive ℓ_∞-routing. It was later observed by Schild-Rao-Srivastava [32] that on unweighted graphs, the statement can be derived from Cheeger's Inequality ([5, 1]). Further, the electrical flow routing can be applied efficiently after $\tilde{O}(m)$ preprocessing, due to the breakthrough result by Spielman and Teng [35] and subsequent work [17, 8, 20, 14][3]. [16] then demonstrates that by assembling and combining these routings on expanders, one obtains an ℓ_∞ oblivious routing of the entire graph that can be evaluated efficiently.

As far as we know, no other fast algorithm is currently known to compute ℓ_∞ oblivious routing, and all fast algorithms that compute congestion approximators again reduce to expanders on which cuts can be approximated by stars. Therefore, to the best of our knowledge, every almost-linear time approach to constructing ℓ_∞ oblivious routing reduces to expanders, and on expanders the only known fast algorithm for obtaining an ℓ_∞ oblivious routing is to use the electrical flow routing.

[3] Technically, only a high-accuracy solution is obtained which suffices for our application.

Oblivious Routing for any ℓ_p

Analogous to the reduction of solving approximate undirected maximum flow via few applications of ℓ_∞ oblivious routing, Sherman later showed in [34], that any ℓ_p-norm minimizing flow on undirected graphs can be computed to an $(1+\varepsilon)$-approximation by applying ℓ_p oblivious routings with α competitive ratio $\tilde{O}(\text{poly}(\alpha/\varepsilon))$ times via gradient descent.

While we are not aware of any article studying fast algorithms for the general ℓ_p-norm, the ℓ_1-norm has received considerable attention and $\tilde{O}(m)$ time algorithms were given with competitive ratio $\tilde{O}(1)$ [23, 39, 30], and adapted to fully-dynamic graphs in [6].

Oblivious Routing for ℓ_1 on Expanders

Further, at least in the unit-capacity setting, the result by Kelner and Maymounkov [15] extends seamlessly to the ℓ_1-norm, i.e. the electric flow routing $\boldsymbol{A}_\mathcal{E}$ has competitive ratio $O(\Phi^{-2}\log m)$. This follows since the electrical flow routing is given by $\boldsymbol{A}_\mathcal{E} = \boldsymbol{B}^\top \boldsymbol{L}^+$, where $\boldsymbol{B}$ is the vertex-edge incidence matrix and $\boldsymbol{L} = \boldsymbol{B}\boldsymbol{B}^\top$ is the Laplacian matrix of the graph and then bounding the ℓ_∞ competitive ratio of the oblivious routing for multicommodity flow problems is equivalent to bounding the quantity $\||\boldsymbol{A}_\mathcal{E}\boldsymbol{B}|\|_{\infty\to\infty}$, where $|\cdot|$ denotes the entrywise absolute value, while the ℓ_1 competitive ratio equals $\||\boldsymbol{A}_\mathcal{E}\boldsymbol{B}|\|_{1\to 1}$. The matrix $\Pi = \boldsymbol{A}_\mathcal{E}\boldsymbol{B} = \boldsymbol{B}^\top\boldsymbol{L}^+\boldsymbol{B}$ is a frequently-studied orthogonal projection matrix and it is a symmetric matrix, since $\boldsymbol{B}^\top\boldsymbol{L}^+\boldsymbol{B} = \boldsymbol{B}^\top\boldsymbol{A}_\mathcal{E}^\top = (\boldsymbol{A}_\mathcal{E}\boldsymbol{B})^\top = (\boldsymbol{B}^\top\boldsymbol{L}^+\boldsymbol{B})^\top$ where we use that $\boldsymbol{L}^+$ is symmetric. But it is further well-known that $\|\boldsymbol{X}\|_{\infty\to\infty} = \|\boldsymbol{X}^\top\|_{1\to 1}$ and thus we have that $\||\Pi|\|_{\infty\to\infty} = \||\Pi|\|_{1\to 1}$, i.e. the competitive ratios achieved by $\boldsymbol{A}_\mathcal{E}$ in ℓ_1- and ℓ_∞-norm are equal.

Beyond Oblivious Routing

The quantity $\||\Pi|\|_{\infty\to 1}$ is important in several other contexts: It captures the so-called *localization* of electrical flow on the graph [32]. Localization measures the ℓ_1-length of the electrical flow corresponding to a demand placed at two endpoints of an edge, averaged over all edges. The bound $\rho_1(\boldsymbol{A}_\mathcal{E}) = O(\Phi^{-2}\log m)$ implies a stronger statement in expanders: For every such edge-demand, the ℓ_1-length is bounded by $O(\Phi^{-2}\log m)$. It is known that in general graphs, localization is bounded by $O(\log^2 m)$ – but it is open whether $O(\log m)$ holds (a lower bound of $\Omega(\log m)$ is known) although it is widely believed. From [15], we see that any graph with expansion $1/o(\sqrt{\log m})$ achieves localization $o(\log^2 m)$.

Localization has been used in a number of contexts, including sampling random spanning trees in almost-linear time [31], computing spectral subspace sparsification [22] of Laplacian matrices, and building oblivious routings using $\tilde{O}(\sqrt{m})$ electrical flows [11].

An interesting message of our paper is that electrical flow on expanders simultaneously is an excellent ℓ_1 and ℓ_∞ oblivious routing, i.e. it uses flow paths are are both short and low congestion. A broad theory of expanders that simultaneously allow for short and low-congestion paths has recently been developed in [10, 13], allowing for other possible trade-offs between length and congestion than those obtained by conventional expanders.

1.1 Main Contributions

In this article, we study a simple but important question:

> *Given* ***any*** $p \in [1,\infty]$*, what is the competitive ratio* $\rho_p(\boldsymbol{A}_\mathcal{E})$ *of the electrical flow routing* $\boldsymbol{A}_\mathcal{E}$ *on a* Φ*-expander?*

We first settle this question for the important cases when $p \in \{1, \infty\}$ by proving the following theorem that proves an upper bound that is tight up to constant factors.

▶ **Theorem 1.1.** *For a Φ-expander multigraph $G = (V, E)$ with edge-vertex incidence matrix $\boldsymbol{B}$ and Laplacian $\boldsymbol{L}$, the electrical routing $\boldsymbol{A}_{\mathcal{E}} = \boldsymbol{B}^\top \boldsymbol{L}^+$ has competitive ratios ρ_∞ and ρ_1 for multi-commodity ℓ_∞ and ℓ_1 routing both bounded by*

$$\rho_\infty(\boldsymbol{A}_{\mathcal{E}}), \rho_1(\boldsymbol{A}_{\mathcal{E}}) \leq 3 \cdot \frac{\log(2m)}{\Phi}$$

The Riesz-Thorin theorem then gives us a way to smoothly interpolate between the upper bounds of any two ℓ_{p_1}- and ℓ_{p_2}-norm competitive ratios to obtain an upper bound on the ℓ_p-norm competitive ratio $\rho_p(\boldsymbol{A}_{\mathcal{E}})$ for any $p_1 < p < p_2$. Using a smooth interpolation between our results for ℓ_1- and ℓ_∞-norm, we thus obtain the following more general result.

▶ **Theorem 1.2.** *For a Φ-expander multigraph $G = (V, E)$, and any $p \in [1, \infty]$, we have that the competitive ratio of $\boldsymbol{A}_{\mathcal{E}}$ is*

$$\rho_p(\boldsymbol{A}_{\mathcal{E}}) \leq 3 \cdot \frac{\log(2m)}{\Phi}.$$

It was proven in [32], that $\Pi = \boldsymbol{B}^\top \boldsymbol{L}^+ \boldsymbol{B}$ satisfies $\||\Pi|\|_{2\to 2} \leq O(\log^2 n)$ (where $|\cdot|$ indicates entry-wise absolute value). We refer to this quantity $\||\Pi|\|_{2\to 2}$ as *ℓ_2-localization*. It is widely believed that $\||\Pi|\|_{2\to 2} \leq O(\log m)$. Implicit in earlier works, albeit perhaps not widely observed, is that $\rho_2(\boldsymbol{A}_{\mathcal{E}}) = \||\Pi|\|_{2\to 2}$ (see Lemma 4.1), i.e. the competitive ratio of multi-commodity ℓ_2 routing is exactly characterized by ℓ_2-localization. By interpolating with this norm bound and our bounds on $\rho_1(\boldsymbol{A}_{\mathcal{E}})$ and $\rho_\infty(\boldsymbol{A}_{\mathcal{E}})$, we obtain potentially much stonger bounds on the competitive ratio $\rho_p(\boldsymbol{A}_{\mathcal{E}})$.

▶ **Corollary 1.3** (implied by Riesz-Thorin)**.** *For a Φ-expander multigraph $G = (V, E)$, and any $p \in [2, \infty]$ and q given by $1/p + 1/q = 1$, we have that the competitive ratios of $\boldsymbol{A}_{\mathcal{E}}$ for the ℓ_p and ℓ_q norms are*

$$\rho_p(\boldsymbol{A}_{\mathcal{E}}), \rho_q(\boldsymbol{A}_{\mathcal{E}}) \leq \||\Pi|\|_{2\to 2}^{2/p} \left(3 \cdot \frac{\log(2m)}{\Phi}\right)^{1-2/p}.$$

We complement our upper bounds with strong, unconditional lower bounds. Remarkably, if $\||\Pi|\|_{2\to 2} \leq O(\log m)$, as widely believed, then our bounds are tight up to constants. Even with the currently known fact $\||\Pi|\|_{2\to 2} \leq O(\log^2 n)$, our lower bounds still prove a sublogarithmic gap in every constant $p \neq 2$ and q and optimal Φ dependency.

▶ **Theorem 1.4.** *For an infinite number of positive integers n and any $\Phi \in [1/\sqrt[3]{n}, 1]$, for any $p \in [2, \infty]$ and q given by $1/p + 1/q = 1$, we have that*

$$\rho_p(\boldsymbol{A}_{\mathcal{E}}), \rho_q(\boldsymbol{A}_{\mathcal{E}}) \geq \Omega\left(\frac{\log m}{\Phi^{1-2/p}}\right).$$

1.2 Oblivious Electric Routing in Weighted Graphs

We can extend Theorem 1.1 to weighted graphs in the following way: Consider a graph $G = (V, E)$ with positive integer edge capacities $\boldsymbol{c} \in \mathbb{R}^E$ and positive integer edge lengths $\boldsymbol{s} \in \mathbb{R}^E$. Letting $\boldsymbol{C}, \boldsymbol{S} \in \mathbb{R}^{E\times E}$ denote diagonal matrices with $\boldsymbol{c}$ and $\boldsymbol{s}$ on the diagonal respectively, we are interested in the optimal weighted ℓ_∞- and ℓ_1-routings for given demands $D = \{\boldsymbol{\chi}_1, \ldots, \boldsymbol{\chi}_k\}$

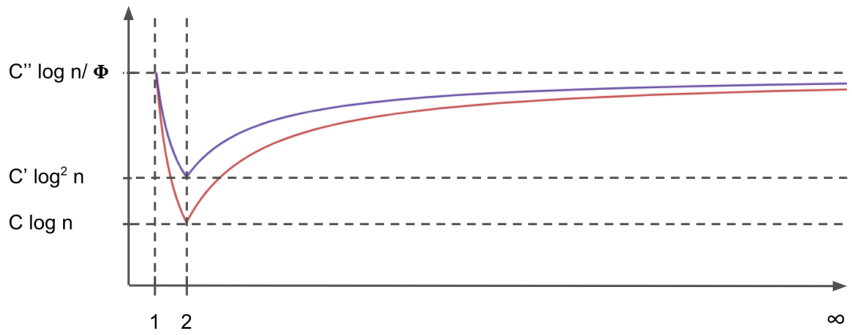

Figure 1 An illustration of the result given in Corollary 1.3 of the different competitive ratios achieved with respect to each ℓ_p-norm, where n and Φ are fixed and $\Phi \ll 1/\log m$. The red curve shows the optimal ratios, achieved if localization is in $O(\log m)$, which is also obtained up to constant factors by our lower bound in Theorem 1.4. The lilac curve shows the current trade-off where we use the known result that localization is in $O(\log^2 n)$. For $\Phi \gg 1/\log m$ the upper bound of Theorem 1.2 achieves values between the two curves.

$$\mathrm{opt}_\infty(D) = \min_{\boldsymbol{B}\boldsymbol{f}_i=\boldsymbol{\chi}_i,\forall i} \|\boldsymbol{C}^{-1}\sum_i |\boldsymbol{f}_i|\|_\infty \text{ and } \mathrm{opt}_1(D) = \min_{\boldsymbol{B}\boldsymbol{f}_i=\boldsymbol{\chi}_i,\forall i} \|\boldsymbol{S}\sum_i |\boldsymbol{f}_i|\|_1 \tag{3}$$

Now consider defining an electrical routing by choosing resistances $\boldsymbol{R} = \boldsymbol{S}\boldsymbol{C}^{-1}$ and defining the electrical routing $\boldsymbol{A}_\mathcal{E} = \boldsymbol{R}^{-1}\boldsymbol{B}^\top(\boldsymbol{B}\boldsymbol{R}^{-1}\boldsymbol{B}^\top)^+$. Let $\hat{G}$ denote the multigraph with edge e replaced by $\boldsymbol{c}(e)$ unit-weight paths of length $\boldsymbol{s}(e)$. Now, one can easily show that the electrical routing in G according to $\boldsymbol{A}_\mathcal{E}$ is equal to the unit-weight electrical routing in $\hat{G}$, when mapping flows on a capacitated edge to a collection of flows on multi-edge paths.

▶ **Corollary 1.5** ((Informal) Electrical Oblivious ℓ_∞- and ℓ_1-Routing on Weighted Expanders)**.** *For (multi-)graph $G = (V, E)$ with edge-vertex incidence matrix $\boldsymbol{B}$ and positive integer edge weights and lengths given as diagonal matrices $\boldsymbol{C}, \boldsymbol{S} \in \mathbb{R}^{E\times E}$, the electrical routing $\boldsymbol{A}_\mathcal{E} = \boldsymbol{R}^{-1}\boldsymbol{B}^\top(\boldsymbol{B}\boldsymbol{R}^{-1}\boldsymbol{B}^\top)^+$, where $\boldsymbol{R} = \boldsymbol{S}\boldsymbol{C}^{-1}$, has competitive ratios ρ_∞ and ρ_1 for multicommodity ℓ_∞ and ℓ_1 routing both bounded by*

$$\rho_\infty(\boldsymbol{A}_\mathcal{E}), \rho_1(\boldsymbol{A}_\mathcal{E}) \le 3 \cdot \frac{\ln(2|E_{\hat{G}}|)}{\Phi(\hat{G})}$$

where $\hat{G}$ denotes the multigraph with edge e replaced by a path of length $\boldsymbol{S}(e,e)$ with $\boldsymbol{C}(e,e)$ unit-weight multi-edges across each hop of the path.

▶ Remark 1.6. When we take all edge lengths $\boldsymbol{S}(e,e)$ to be 1, the expansion of $\hat{G}$ equals the usual definition of expansion in graph G with edge weight equal to capacity.

1.3 New Implications for Localization

From the connection to localization outlined earlier, we also immediately conclude that localization of graphs with $1/o(\log m)$ expansion improve over the general localization bound of $O(\log^2 m)$.

▶ **Corollary 1.7** ((Informal) Localization of Electrical Flow)**.** *For a multigraph $G = (V, E)$, the average over multi-edges of the ℓ_1-norm the electrical flow routing 1 unit of flow across the multi-edge is bounded by $O\left(\min\{\Phi^{-1}\log m, \log^2 n\}\right)$, and hence graphs with expansion $\Phi = 1/o(\log m)$ have localization $o(\log^2 m)$.*

1.4 Roadmap

We next give a Preliminary section to set up the necessary notation for the article. We then prove Theorem 3 in Section 3. We use this result together with the Riesz-Thorin theorem to obtain Theorem 1.2 and Corollary 1.3 in Section 4. Finally, in Section 5, we give our lower bounds as stated in Theorem 1.4.

2 Preliminaries

General Definitions

For any $n \in \mathbb{N}^*$, we let $[n]$ denote the set $\{1, 2, \ldots, n\}$. We let $\mathbf{1}$ denote the all ones vector and $\mathbf{1}_S$ denote the vector that has ones in the positions indexed by the elements of the set S and zeros otherwise. For any $\boldsymbol{A} \in \mathbb{R}^{m \times n}$, we let $|\boldsymbol{A}|$ denote the matrix where the absolute value operator has been applied entrywise.

Graphs

Although our results in the contribution section are for unweighted graphs, we also prove stronger statements in the article that also work on weighted graphs. Therefore, we define various notions with respect to weighted graphs.

Given an input graph $G = (V, E, w)$ with positive weights which we all assume to be at least 1, we define $n = |V|$ and $m = |E|$. We assume an arbitrary underlying direction assigned to each edge of G. We define the edge-vertex incidence matrix $\boldsymbol{B} \in \mathbb{R}^{V \times E}$ of G as

$$\boldsymbol{B}(w, e) = \begin{cases} -1, & \text{if } e = (w, v) \\ 1, & \text{if } e = (v, w) \\ 0, & \text{otherwise} \end{cases}.$$

We define the Laplacian $\boldsymbol{L} = \boldsymbol{B}\boldsymbol{W}\boldsymbol{B}^\top$ where $\boldsymbol{W}$ is the diagonal matrix given by the weights w and denote by $\boldsymbol{L}^+$ the pseudo-inverse of the Laplacian. We call $\Pi = \boldsymbol{B}^\top \boldsymbol{L}^+ \boldsymbol{B}$ the *unweighted* projection matrix of G.

Expanders

We say G is a Φ-expander if $|\partial S| \geq \Phi \cdot \mathrm{vol}(S)$ for every $S \subseteq V, \mathrm{vol}(S) \leq \mathrm{vol}(V)/2$, where we define $|\partial S|$ to be the weight of all edges with exactly one endpoint in S, and $\mathrm{vol}(S)$ to be the sum of weighted degrees of vertices in S.

Flows and Congestion

We say $\boldsymbol{\chi} \in \mathbb{R}^V$ is a demand vector if $\mathbf{1}^\top \boldsymbol{\chi} = 0$. We let $\boldsymbol{\chi}_{(a,b)} \in \mathbb{R}^V$ for every $(a, b) \in E$ to be the unitary demand on the edge (a, b), that is $\boldsymbol{\chi}_{(a,b)} = \mathbf{1}_a - \mathbf{1}_b$. We say a vector $\boldsymbol{f} \in \mathbb{R}^E$ is a flow that routes demand $\boldsymbol{\chi}$ if $\boldsymbol{B}\boldsymbol{f} = \boldsymbol{\chi}$. Given an arbitrary norm $\|\cdot\|$ on $\mathbb{R}^E$, we define the congestion of a multi-set of flows $\{\boldsymbol{f}_1, \ldots, \boldsymbol{f}_k\}$ to be:

$$\mathrm{cong}\left(\{\boldsymbol{f}_1, \ldots, \boldsymbol{f}_k\}\right) = \left\| \boldsymbol{W}^{-1} \sum_{i=1}^{k} |\boldsymbol{f}_i| \right\|.$$

Oblivious Routings

We define an oblivious routing on G to be a linear operator $\boldsymbol{A} \in \mathbb{R}^{E \times V}$ such that $\boldsymbol{B}\boldsymbol{A}\boldsymbol{\chi} = \boldsymbol{\chi}$ for all demand vectors $\boldsymbol{\chi} \in \mathbb{R}^V$, i.e. to be a flow that routes the demand $\boldsymbol{\chi}$.

Given a multiset of demands $D = \{\boldsymbol{\chi}_1, \ldots, \boldsymbol{\chi}_k\}$, we define the optimal congestion achievable by

$$\mathrm{opt}(D) = \min_{\{\boldsymbol{f}_i\}_{i\in[k]} \text{ multiset} \,:\, \boldsymbol{B}\boldsymbol{f}_i = \boldsymbol{\chi}_i, \forall i} \mathrm{cong}(\{\boldsymbol{f}_i\}_{i\in[k]}).$$

This allows us to define the competitive ratio of an oblivious routing, which we define

$$\rho(\boldsymbol{A}) = \max_{\{\boldsymbol{\chi}_i\}_{i\in[k]} \text{ multiset} \,:\, \boldsymbol{\chi}_i \perp \mathbf{1}, \forall i} \frac{\mathrm{cong}\left(\{\boldsymbol{A}\boldsymbol{\chi}_i\}_{i\in[k]}\right)}{\mathrm{opt}\left(\{\boldsymbol{\chi}_i\}_{i\in[k]}\right)}.$$

Note that whenever we use the subscript "p" for the competitive ratio ρ, we mean that the norm used in defining the congestion in that special case is the ℓ_p-norm.

Electrical Flows and Voltages

In this article, we define the electric flow routing operator $\boldsymbol{A}_{\mathcal{E}} = \boldsymbol{W}\boldsymbol{B}^\top\boldsymbol{L}^+$. Right-applying the operator $\boldsymbol{A}$ to any demand $\boldsymbol{\chi}$ yields the electric flow $\boldsymbol{f} = \boldsymbol{A}\boldsymbol{\chi}$ that routes the demand $\boldsymbol{\chi}$. We define the electrical energy associated with the flow vector $\boldsymbol{f}$ by $\mathcal{E}(\boldsymbol{f}) = \boldsymbol{f}^\top\boldsymbol{W}^{-1}\boldsymbol{f}$.

We define the electric voltage vector $\boldsymbol{v} \in \mathbb{R}^V$ with respect to a demand $\boldsymbol{\chi}$ by $\boldsymbol{v} = \boldsymbol{L}^+\boldsymbol{\chi}$. We define the electrical energy associated with the voltage vector $\boldsymbol{v}$ as $\mathcal{E}(\boldsymbol{v}) = \boldsymbol{v}^\top\boldsymbol{L}\boldsymbol{v}$. Note in particular that the energy of voltages induced by a certain demand coincides with the energy of the respective flow.

We introduce the notion of *"fractional" volume* at given a threshold $t \in \mathbb{R}$ with respect to a given voltage vector $\boldsymbol{v} \in \mathbb{R}^V$. We first define the fractional volume per edge and then for the whole graph. For an edge $(a, b) \in E$:

$$\mathrm{vol}_{\geq t}(a,b) = \begin{cases} 2 \cdot w(a,b), & \text{if } \boldsymbol{v}(a) > t \\ 2 \cdot w(a,b) \cdot \frac{\boldsymbol{v}(b) - t}{\boldsymbol{v}(b) - \boldsymbol{v}(a)}, & \text{if } \boldsymbol{v}(b) \leq t \\ 0, & \text{otherwise} \end{cases}.$$

For the whole graph G:

$$\mathrm{vol}_{\geq}(t) = \sum_{(a,b)\in E} \mathrm{vol}_{\geq t}(a,b),$$

$$\mathrm{vol}^+_{\geq}(t) = \mathrm{vol}_{\geq}(t) + 1.$$

Note that in our notation we omit specifying which voltage vector the "fractional" volume function is tied to, as it will be clearly specified upon usage during the proofs.

We define $S_t = \{a \in V \mid v(a) \geq t\}$ as the set of vertices whose voltages are greater or equal to the arbitrary threshold $t \in \mathbb{R}$ and the cut determined by the voltage threshold $t \in \mathbb{R}$ to be $C_t = (S_t, V \setminus S_t)$. For convenience, we let the weight of the cut C_t be $\delta(t) = |\partial C_t| = \sum_{e\in C_t} w(e)$.

3 An Upper Bound on the Competitive Ratio of Electrical Flow Routing for ℓ_∞

In this section, we prove our main technical result, Theorem 1.1, by establishing a tight upper bound on the competitive ratio when the congestion is defined in terms of ℓ_∞ which then by the symmetry of Π immediately gives the same competitive ratio in ℓ_1.

However, while Theorem 1.1 only claims a result for unweighted (multi-)graphs, we show in this section that $\boldsymbol{A}_{\mathcal{E}}$ even has good competitive ratio in weighted graphs with respect to ℓ_∞. However, in the weighted setting, we cannot use the bound for ℓ_∞ to derive a bound on ℓ_1, as the matrix-norms that exactly characterize the competitive ratio are not equal in general. Nonetheless, the "multi-graph" trick from Corollary 1.5 can be used to transform the weighted setting into an unweighted instance and derive bounds.

Intuition for our Proof

Kelner and Maymounkov showed that in order to bound the congestion of the electrical routing, it suffices, via a duality (or transposition) argument, to bound the worst case ℓ_1-norm of the flow induced by routing 1 unit of flow electrically across any edge. We adopt the same approach, but give a more precise analysis.

Suppose $e = (x, y)$ is the edge such that routing one unit of flow between the endpoints causes the highest overall congestion. We let $\boldsymbol{v}$ be the associated voltage vector that induces the electrical flow routing one unit from x to y. The overall congestion then equals $\sum_{(a,b)\in E} w(a,b)|\boldsymbol{v}(a) - \boldsymbol{v}(b)|$. We can express this by integrating with respect to voltage along a voltage threshold cut with respect to $\boldsymbol{v}$, where the function being integrated at point t is exactly $Y_t = \sum_{(a,b)\in C_t} w(a,b)$, where C_t is the cut at voltage threshold t. This ensures that after integrating Y_t over the entire voltage range, each edge (a, b) contributes exactly $w(a,b)|\boldsymbol{v}(a) - \boldsymbol{v}(b)|$, as desired. Our proof proceeds by leveraging that the flow crossing the cut C_t at threshold t is exactly $\sum_{(a,b)\in C_t} w(a,b)|\boldsymbol{v}(a) - \boldsymbol{v}(b)|$.

As we are sending one unit of flow from x to y, and all electrical flow goes one way across a voltage cut, this quantity is exactly 1. At each threshold t, this creates an "on average" relationship between voltage difference $|\boldsymbol{v}(a) - \boldsymbol{v}(b)|$ and weight $w(a, b)$ for edges being cut. This in turn allows us to establish a pointwise relationship at each threshold voltage t between the growth in congestion and the change in volume at t. Armed with this relationship, we can bound the accumulated congestion of the integrated cuts in terms of the accumulated volume, and this yields our result.

Contrast with the Kelner-Maymounkov Proof

It is instructive to consider why the Kelner-Maymounkov congestion bound loses an additional factor Φ compared to our bound. For concreteness, consider the graph given by a direct edge from x to y and an additional k disjoint paths of length k from x to y. It can be shown that in this example, the edge that governs the congestion bound in the strategy above is in fact the direct (x, y) edge.

Kelner-Maymounkov upper bound the true competitive ratio $\rho' = \sum_{(a,b)\in E} w(a,b)|\boldsymbol{v}(a) - \boldsymbol{v}(b)|$ by the quantity $\rho'' = \sum_{a\in V} \boldsymbol{d}(a)|\boldsymbol{v}(a) - c|$ for some constant c (see Equation (4.3) in [15]). On this concrete graph, ρ' can be explicitly evaluated and is $\Theta(k)$. As the graph has expansion $1/k$, we can think of this as a bound of $\Theta(1/\Phi)$. But, ρ'' is $\Theta(k^2)$ i.e. $\Theta(1/\Phi^2)$.

However, Kelner and Maymoukov's strategy makes it difficult to directly bound ρ' as they first measure changes in volume over a (discrete) sequence of threshold cuts, and then changes in voltage over the same sequence of cuts. Their discrete sequence of cuts skips entirely over some edges, i.e. there will be edges that are not crossing any of their cuts. This makes it difficult to establish an estimate for each edge of the pointwise relation between its contribution to volume growth versus voltage growth or congestion growth. Hence, they work with summed bounds on voltage and compare these with summed bounds on volume, which naturally yields bounds on ρ''. But, as we have seen, a bound on ρ'' must inherently be loose as there is a gap between ρ' and ρ''.

▶ **Theorem 3.1** (ℓ_∞ Competitive bound of electrical flows)**.** *For a weighted Φ-expander multigraph $G = (V, E, w)$, the following holds:*

$$\rho_\infty(\boldsymbol{A}_\mathcal{E}) \leq 3 \cdot \frac{\ln(\mathrm{vol}(V))}{\Phi}.$$

Proof. We first use that

$$\rho_\infty(\boldsymbol{A}_\mathcal{E}) = \max_{e \in E} \left\| \boldsymbol{W}\boldsymbol{B}^\top \boldsymbol{L}^+ \boldsymbol{\chi}_e \right\|_1. \tag{4}$$

as shown in [16] as part of the proof of Lemma 26 (by using primarily Lemmas 10 and 11). In order to prove the desired inequality, we then fix an $e \in E$ such that the quantity in (4) gets maximized, and let $\boldsymbol{v} = \boldsymbol{L}^+\boldsymbol{\chi}_e$ be the voltage induced by setting a unitary demand on this edge. Thus, we equivalently aim to bound:

$$\rho_\infty(\boldsymbol{A}_\mathcal{E}) = \left\| \boldsymbol{W}\boldsymbol{B}^\top \boldsymbol{L}^+ \boldsymbol{\chi}_e \right\|_1 = \left\| \boldsymbol{W}\boldsymbol{B}^\top \boldsymbol{v} \right\|_1 = \sum_{(a,b)\in E} w(a,b) \cdot |\boldsymbol{v}(a) - \boldsymbol{v}(b)|. \tag{5}$$

Observe now that shifting all the values of $\boldsymbol{v}$ by the same constant does not change the value expressed in (5), and therefore we can assume without loss of generality that the voltages are centered around 0, that is we can assume $\mathrm{vol}\left(\{i \in V \mid \boldsymbol{v}(i) \geq 0\}\right) \geq \mathrm{vol}(V)/2$ and $\mathrm{vol}\left(\{i \in V \mid \boldsymbol{v}(i) \leq 0\}\right) \geq \mathrm{vol}(V)/2$.

Note that, by convention, the electrical flow $\boldsymbol{f}_\mathcal{E} = \boldsymbol{A}_\mathcal{E}\boldsymbol{\chi}_e$ induces an orientation on the edges in the set E. Henceforth, we assume without loss of generality that orientations of edges in E align with the direction of the electrical flow $\boldsymbol{f}_\mathcal{E}$, that is $\boldsymbol{f}_\mathcal{E}(a,b) = w(a,b)\cdot(\boldsymbol{v}(b) - \boldsymbol{v}(a)) \geq 0$ for any $(a,b) \in E$.

In the following, we will employ the definitions introduced in Section 2. These concepts give rise to the notion of "fractional" volume, which will ultimately allow us to bound the quantity of Equation (5).

It can easily be proven that $\mathrm{vol}_\geq$ is continuous in $\mathbb{R}$ and differentiable at any threshold level $t \in \mathbb{R}$ for which there does not exist a node $a \in V$ such that $\boldsymbol{v}(a) = t$. Furthermore, if $t_{\min} = \min\{\boldsymbol{v}(a) \mid a \in V\}$ and $t_{\max} = \max\{\boldsymbol{v}(a) \mid a \in V\}$, then $\mathrm{vol}_\geq(t_{\min}) = \mathrm{vol}(G)$ and $\mathrm{vol}_\geq(t_{\max}) = 0$. We can even assume without loss of generality a more precise centering of the voltages around 0, namely that $\mathrm{vol}_\geq(0) = \mathrm{vol}(V)/2$.

A voltage threshold level $t \in \mathbb{R}$ can be seen as naturally determining a cut C_t in G. Note that the assumption about centering the voltages around 0 ensures that $\mathrm{vol}(S_t) \leq \mathrm{vol}(V)/2$ for any $t > 0$, so it holds that $\min\{\mathrm{vol}(S_t), \mathrm{vol}(V \setminus S_t)\} = \mathrm{vol}(S_t)$.

By taking the orientation of the edges into account, we can drop the absolute value operator and rewrite Equation (5) as:

$$\begin{aligned}
\sum_{(a,b)\in E} w(a,b) \cdot |\boldsymbol{v}(a) - \boldsymbol{v}(b)| &= \sum_{(a,b)\in E} w(a,b) \cdot (\boldsymbol{v}(b) - \boldsymbol{v}(a)) \\
&= \sum_{(a,b)\in E} w(a,b) \cdot \int_{t_{\min}}^{t_{\max}} \mathbb{1}_{\boldsymbol{v}(a) < t \leq \boldsymbol{v}(b)}\, dt \\
&= \int_{t_{\min}}^{t_{\max}} \sum_{(a,b)\in E} w(a,b) \cdot \mathbb{1}_{\boldsymbol{v}(a) < t \leq \boldsymbol{v}(b)}\, dt \\
&= \int_{t_{\min}}^{t_{\max}} \delta(t)\, dt \\
&= \int_{t_{\min}}^{0} \delta(t)\, dt + \int_{0}^{t_{\max}} \delta(t)\, dt.
\end{aligned} \tag{6}$$

We will bound the quantity in (6) by separately bounding each of the two terms in the last equality. Only the proof for the integral over the non-negative values of t will be presented, the one for the non-positive values proceeds in an analogous manner. Assume thus for the rest of the proof that $t \geq 0$ holds.

In order to obtain the bound on $\delta(t)$ for non-negative t, we will inspect the rate of change of the "fractional" volume with respect to the voltage threshold of the fixed voltage vector $\boldsymbol{v}$. Intuitively, we grow an electrical threshold ball, and directly relate the change in volume to the stretch accumulated at the current voltage threshold. In more precise terms, we compute a bound on the derivative of $\mathrm{vol}^{+}_{\geq}$ with respect to t on the domain of differentiability as follows:

$$\begin{aligned}
-\frac{d}{dt}\mathrm{vol}^{+}_{\geq}(t) &= -\frac{d}{dt}\mathrm{vol}_{\geq}(t) \\
&= -\frac{d}{dt}\left(\sum_{(a,b)\in E} \mathrm{vol}_{\geq t}(a,b)\right) \\
&= -\frac{d}{dt}\left(\sum_{(a,b)\in C_t} \mathrm{vol}_{\geq t}(a,b)\right) \\
&= \sum_{(a,b)\in C_t} -\frac{d}{dt}\mathrm{vol}_{\geq t}(a,b) \\
&= \sum_{(a,b)\in C_t} 2\frac{w(a,b)}{\boldsymbol{v}(b)-\boldsymbol{v}(a)}.
\end{aligned} \tag{7}$$

By the construction based on the voltage levels, all edges of the cut C_t have their head in the set S_t. Therefore, the flow carried by these edges has to be the unit flow, since this is the demand of $\boldsymbol{\chi}_e$:

$$1 = \sum_{(a,b)\in C_t} f_{\mathcal{E}}(a,b) = \sum_{(a,b)\in C_t} w(a,b)\cdot(\boldsymbol{v}(b)-\boldsymbol{v}(a)). \tag{8}$$

Hereafter, we show that the negative volume change must exceed the square of the cut size. Informally, the change in volume per edge is relatively large whenever the voltage gap across the edge is small (volume change scales as inversely proportional to the gap compared to the cut-value of the edge). But, a "typical" edge in the cut must have a fairly small voltage gap, as we otherwise route too much flow across the gap. Formally, since the voltage drops among the edges in the cut C_t are non-negative, we can use (8) and the definition of the conductance of G to further bound (7) using the Cauchy–Bunyakovsky–Schwarz inequality:

$$
\begin{aligned}
-\frac{d}{dt}\mathrm{vol}^{+}_{\geq}(t) &= 2\sum_{(a,b)\in C_t}\frac{w(a,b)}{\boldsymbol{v}(b)-\boldsymbol{v}(a)} \\
&= 2\left(\sum_{(a,b)\in C_t}\frac{w(a,b)}{\boldsymbol{v}(b)-\boldsymbol{v}(a)}\right)\cdot 1 \\
&= 2\left(\sum_{(a,b)\in C_t}\frac{w(a,b)}{\boldsymbol{v}(b)-\boldsymbol{v}(a)}\right)\left(\sum_{(a,b)\in C_t} w(a,b)\cdot(\boldsymbol{v}(b)-\boldsymbol{v}(a))\right) \\
&\geq 2\left(\sum_{(a,b)\in C_t}\sqrt{\frac{w(a,b)}{\boldsymbol{v}(b)-\boldsymbol{v}(a)}\cdot w(a,b)\cdot(\boldsymbol{v}(b)-\boldsymbol{v}(a))}\right)^2 \\
&\geq 2\left(\sum_{(a,b)\in C_t} w(a,b)\right)^2 \\
&= 2\cdot\delta(t)^2 \\
&\geq 2\cdot\delta(t)\cdot\Phi\cdot\mathrm{vol}(S_t).
\end{aligned}
\tag{9}
$$

Denote by $\mathrm{vol}_{\mathrm{int}}(t) = \mathrm{vol}(S_t) - \delta(t)$ twice the weight of the edges that have both endpoints in the set S_t. Recall that we assumed all of the edges to have weights at least 1, therefore it holds that $\delta(t) \geq 1$. The definition of "fractional" volume implies $\mathrm{vol}_{\geq}(t) \leq \mathrm{vol}_{\mathrm{int}} + 2\delta(t)$, which can be used to further bound (9):

$$
\begin{aligned}
-\frac{d}{dt}\mathrm{vol}^{+}_{\geq}(t) &\geq 2\cdot\delta(t)\cdot\Phi\cdot\mathrm{vol}(S_t) \\
&= 2\cdot\delta(t)\cdot\Phi\cdot(\mathrm{vol}_{\mathrm{int}}(t)+\delta(t)) \\
&= \delta(t)\cdot\frac{2\Phi}{3}\cdot(3\mathrm{vol}_{\mathrm{int}}(t)+3\delta(t)) \\
&\geq \delta(t)\cdot\frac{2\Phi}{3}\cdot(\mathrm{vol}_{\mathrm{int}}(t)+2\delta(t)+1) \\
&\geq \delta(t)\cdot\frac{2\Phi}{3}\cdot(\mathrm{vol}_{\geq}(t)+1) \\
&= \delta(t)\cdot\frac{2\Phi}{3}\cdot\mathrm{vol}^{+}_{\geq}(t).
\end{aligned}
$$

Observe that we can rewrite the inequality above to obtain a bound on $\delta(t)$:

$$
\delta(t) \leq -\frac{3}{2\Phi}\cdot\frac{1}{\mathrm{vol}^{+}_{\geq}(t)}\cdot\frac{d}{dt}\mathrm{vol}^{+}_{\geq}(t). \tag{10}
$$

We can now use equation (10) to bound the integral over the interval $[0, t_{\max}]$ in (6):

$$
\int_0^{t_{\max}}\delta(t)\,dt \leq \int_0^{t_{\max}} -\frac{3}{2\Phi}\cdot\frac{1}{\mathrm{vol}^{+}_{\geq}(t)}\cdot\frac{d}{dt}\mathrm{vol}^{+}_{\geq}(t)\,dt.
$$

The latter integral can easily be computed via the change of variable $u = \mathrm{vol}^{+}_{\geq}(t)$, yielding the integration bounds $\mathrm{vol}^{+}_{\geq}(t_{\max}) = \mathrm{vol}_{\geq}(t_{\max})+1 = 1$ and $\mathrm{vol}^{+}_{\geq}(0) = \mathrm{vol}_{\geq}(0)+1 = \mathrm{vol}(V)/2+1$:

$$\begin{aligned}\int_0^{t_{\max}} \delta(t)\,dt &\leq \int_0^{t_{\max}} -\frac{3}{2\Phi}\cdot\frac{1}{\mathrm{vol}^+_{\geq}(t)}\cdot\frac{d}{dt}\mathrm{vol}^+_{\geq}(t)\,dt \\ &= \int_{t_{\max}}^{0} \frac{3}{2\Phi}\cdot\frac{1}{\mathrm{vol}^+_{\geq}(t)}\cdot\frac{d}{dt}\mathrm{vol}^+_{\geq}(t)\,dt \\ &= \frac{3}{2\Phi}\int_1^{\mathrm{vol}(V)/2+1}\frac{1}{u}\,du.\end{aligned}$$

Since the graph has by assumption at least two nodes connected by an edge with weight at least 1, it follows that $\mathrm{vol}(V) \geq 2 \iff \mathrm{vol}(V) \geq \mathrm{vol}(V)/2 + 1$. Coupled with the fact that $u > 0$ for $u \in [1, \mathrm{vol}(V)]$, this gives us the final bound for the integral:

$$\begin{aligned}\int_0^{t_{\max}} \delta(t)\,dt &\leq \frac{3}{2\Phi}\int_1^{\mathrm{vol}(V)/2+1}\frac{1}{u}\,du \\ &\leq \frac{3}{2\Phi}\int_1^{\mathrm{vol}(V)}\frac{1}{u}\,du \\ &= \frac{3}{2\Phi}\cdot\ln(\mathrm{vol}(V)).\end{aligned}$$

As already mentioned, the same bound can be obtained for the other term in (6) in an analogous manner.

Combining the aforementioned result with the relations given by (5) and (6) gives the desired inequality:

$$\rho_\infty(\boldsymbol{A}_\mathcal{E}) = \int_{t_{\min}}^{0}\delta(t)\,dt + \int_0^{t_{\max}}\delta(t)\,dt \leq 2\cdot\frac{3\ln(\mathrm{vol}(V))}{2\Phi} = \frac{3\ln(\mathrm{vol}(V))}{\Phi}.$$ ◀

4 An Upper Bound on the Competitive Ratio of Electrical Flow Routing for ℓ_p (for any p)

In this section, we prove two generalizations of Theorem 3.1. Previously, we gave a bound on the competitive ratio when the congestion was defined in terms of the ℓ_∞-norm. This result can be extended to ℓ_p-norms for an arbitrary $p \in [1, \infty]$ by using Theorem 3.1, and instantiating a special case of the Riesz-Thorin theorem.

This establishes both the results in Theorem 1.2 and in Corollary 1.3. We stress that the results obtained in this section crucially exploit the symmetry of Π and therefore only hold for unweighted graphs.

A Toolbox for ℓ_p-Norms

We first use the following lemma. Its proof is fairly standard and follows the structure of the proof of Lemma 24 in [16]. We include a full proof in an extended version of this paper on arXiv.

▶ **Lemma 4.1** (Competitive ratio of ℓ_p-norms). *Let $G = (V, E)$ be a multigraph. For any $p \in [1, \infty]$ and oblivious routing $\boldsymbol{A}$, we have*

$$\rho_p(\boldsymbol{A}) = |||\boldsymbol{AB}|||_{p\to p}.$$

Our second tool is the Riesz-Thorin theorem. We explicitly state the two relevant special cases of the theorem that we require in the next section for the convenience of the reader.

▶ **Theorem 4.2** (Special cases of the Riesz-Thorin theorem, see [36, Theorem 1.3]). *Let $\boldsymbol{A} \in \mathbb{R}^{m\times n}$ be a matrix with non-negative entries. For any $p \in (1,\infty)$ it holds that:*

$$\|\boldsymbol{A}\|_{p\to p} \leq \|\boldsymbol{A}\|_{1\to 1}^{\frac{1}{p}} \cdot \|\boldsymbol{A}\|_{\infty\to\infty}^{1-\frac{1}{p}}.$$

Furthermore, for $p \in (2,\infty)$,

$$\|\boldsymbol{A}\|_{p\to p} \leq \|\boldsymbol{A}\|_{2\to 2}^{\frac{2}{p}} \cdot \|\boldsymbol{A}\|_{\infty\to\infty}^{1-\frac{2}{p}}.$$

Proof of Theorem 1.2

We have that the theorem already holds for ℓ_1 and ℓ_∞ since we have proven Theorem 1.1 in the previous section. Consider therefore any $p \in (1,\infty)$. Then, we have

$$\begin{aligned}
\rho_p(\boldsymbol{A}_{\mathcal{E}}) &\overset{\text{Lemma 4.1}}{=} \||\boldsymbol{A}_{\mathcal{E}}\boldsymbol{B}|\|_{p\to p} \\
&\overset{\text{Theorem 4.2}}{\leq} \||\boldsymbol{A}_{\mathcal{E}}\boldsymbol{B}|\|_{1\to 1}^{\frac{1}{p}} \cdot \||\boldsymbol{A}_{\mathcal{E}}\boldsymbol{B}|\|_{\infty\to\infty}^{1-\frac{1}{p}} \\
&\overset{\text{Lemma 4.1}}{=} (\rho_1(\boldsymbol{A}_{\mathcal{E}}))^{\frac{1}{p}} \cdot (\rho_\infty(\boldsymbol{A}_{\mathcal{E}}))^{1-\frac{1}{p}} \\
&\overset{\text{Theorem 1.1}}{\leq} \left(3\cdot\frac{\ln(2m)}{\Phi}\right)^{\frac{1}{p}} \cdot \left(3\cdot\frac{\ln(2m)}{\Phi}\right)^{1-\frac{1}{p}} \\
&= 3\cdot\frac{\ln(2m)}{\Phi}.
\end{aligned}$$

Proof of Corollary 1.3

Consider next any $p \in (1,\infty)$. Since we have again that for q given by $1/p + 1/q = 1$, we have $\|\boldsymbol{X}\|_{p\to p} = \|\boldsymbol{X}^\top\|_{q\to q}$, we can assume w.l.o.g. that $p \geq 2$. Similarly to [21], we obtain

$$\begin{aligned}
\rho_p(\boldsymbol{A}_{\mathcal{E}}) &\overset{\text{Lemma 4.1}}{=} \||\boldsymbol{A}_{\mathcal{E}}\boldsymbol{B}|\|_{p\to p} \\
&\overset{\text{Theorem 4.2}}{\leq} \||\boldsymbol{A}_{\mathcal{E}}\boldsymbol{B}|\|_{2\to 2}^{\frac{2}{p}} \cdot \||\boldsymbol{A}_{\mathcal{E}}\boldsymbol{B}|\|_{\infty\to\infty}^{1-\frac{2}{p}} \\
&\overset{\text{Lemma 4.1}}{=} (\rho_2(\boldsymbol{A}_{\mathcal{E}}))^{\frac{2}{p}} \cdot (\rho_\infty(\boldsymbol{A}_{\mathcal{E}}))^{1-\frac{2}{p}} \\
&\overset{\text{Lemma 4.1, Theorem 1.1}}{\leq} (\||\Pi|\|_{2\to 2})^{\frac{2}{p}} \cdot \left(3\cdot\frac{\ln(2m)}{\Phi}\right)^{1-\frac{2}{p}}.
\end{aligned}$$

5 A Lower Bound for Competitive Ratio of Electric Flow Routing

Finally, in this section, we provide a strong lower bound on the competitive ratio of the electrical routing scheme in any ℓ_p-norm.

▶ **Theorem 5.1** (Restatement of Theorem 1.4). *For an infinite number of positive integers n and any $\Phi \in [1/\sqrt[3]{n}, 1]$, for any $p \in [2,\infty]$ and q given by $1/p + 1/q = 1$, we have that*

$$\rho_p(\boldsymbol{A}_{\mathcal{E}}), \rho_q(\boldsymbol{A}_{\mathcal{E}}) \geq \Omega\left(\frac{\log m}{\Phi^{1-2/p}}\right).$$

In our proof, we use the following theorem given in [2]. We remind the reader that the *girth* of a graph G is the weight of the smallest weight cycle of G.

▶ **Theorem 5.2** ([2, Theorem 1.2]). *There are infinitely many positive integer Δ and n, for which an n-vertex unweighted graph $G_{\Delta,n} = (V,E)$ exists such that G is Φ_{const}-expander that is Δ-regular with $\Phi_{const} = \Theta(1)$ such that G has girth $\Omega(\log_\Delta n)$.*

In our proof, we use the existential result behind the statement to refine a proof technique previously used by Englert and Räcke [9] to give a lower bound on the competitive ratio of any ℓ_p oblivious routing scheme. Our refinement can also be used to strengthen their result by a $\Theta(\log \log n)$ factor.

In our proof, we crucially exploit the following facts about effective resistance. Recall that the effective resistance of a graph G for a pair $(s,t) \in V^2$ is the minimum energy required to route one unit of demand from s to t in G, or alternatively the difference in voltages of s and t induced by routing this unit of demand via an electrical flow which is given by $\chi_{(s,t)}\boldsymbol{L}^{+}\chi_{(s,t)}$. The facts below can be derived straightforwardly from Cheeger's Inequality, mixing of random walks, and characterization of effective resistance by commute times (see for example [19]).

▶ **Fact 5.3.** *For G being a constant-degree $\Omega(1)$-expander, we have that the effective resistance of any pair $(s,t) \in V$ is in $\Theta(1)$.*

▶ **Fact 5.4.** *Given two constant-degree graphs G and H over the same vertex set V. If the effective resistance for a pair $(s,t) \in V^2$ is in $\Theta(1)$ in both G and H, then the electrical flow routing one unit of demand from s to t on the union of graphs $G \cup H$ sends at least a constant fraction of the flow over G and a constant fraction of the flow over H.*

Let us now give a lower bound for any $p \geq 2$ and any parameter $\Phi \in [1/n, 1]$ such that $1/\Phi$ is integer. We start by considering the electrical routing $\boldsymbol{A}_{\mathcal{E}}$ for a large constant Δ and any n and $G_{\Delta,n}$ of the multi-commodity demand that is given by routing for each edge $e = (u,v)$ in $G_{\Delta,n}$ one unit of a commodity from u to v, i.e. we consider the demand $\boldsymbol{\chi} = \left\{\boldsymbol{\chi}_{(u,v)}\right\}_{e=(u,v)\in E(G_{\Delta,n})}$. Towards understanding the electrical routing, we prove the following simple claim.

▷ Claim 5.5. For any edge e in $G_{\Delta,n}$ where Δ is a large constant, we have that the electrical flow $\boldsymbol{f} = \boldsymbol{A}_{\mathcal{E}}\boldsymbol{\chi}_{(u,v)}$ routing the demand $\boldsymbol{\chi}_{(u,v)}$ has $\|\boldsymbol{f}\|_1 = \Omega(\log n)$.

Proof. The claim follows from showing that $\boldsymbol{f}(e)$ carries only $(1-\varepsilon)$ units of flow for some constant $\varepsilon > 0$. This is because it implies that a constant fraction of the flow is not routed via the edge e. But since each path between the endpoints of e that does not use the edge e is of length $\Omega(\log n)$ (by the girth bound in Theorem 5.2), we have that this ε-fraction adds $\Omega(\varepsilon \log n) = \Omega(\log n)$ units of flow to the network $G_{\Delta,n}$.

To prove the claim, it suffices to observe that the graph $G_{\Delta,n} \setminus \{e\}$ is a $\Omega(1)$-expander. But to this end, it suffices to observe that since the conductance of $G_{\Delta,n}$ does not depend on Δ by Fact 5.3, by choosing Δ sufficiently large (i.e. at least twice the inverse of the conductance), we have that each cut contains at least 2 edges and thus the conductance of $G_{\Delta,n} \setminus \{e\}$ is at least half of the conductance of $G_{\Delta,n}$, and thus still constant.

Using that the trivial graph consisting only of the edge e is a constant-degree $\Omega(1)$-expander, we thus have that the effective resistance of the pair (u,v) in both the graph $G_{\Delta,n} \setminus e$ and e is constant by Fact 5.3. Thus, by Fact 5.4, we have that a constant fraction of the demand $\boldsymbol{\chi}_{(u,v)}$ is not routed into e, as desired. ◁

Using that multi-commodity flows do not cancel, we thus have that each edge in $G_{\Delta,n}$ carries on average $\Omega(\log n)$ units of flow. We next transform the graph $G_{\Delta,n}$ to then obtain our final gadget on which we can prove the lower bound.

▶ **Definition 5.6.** *Let $G^{\Phi}_{\Delta,n}$ be the graph obtained from $G_{\Delta,n}$ by replacing each edge with $1/\Phi$ vertex-disjoint paths of length $1/\Phi$ between the endpoints of the vertices. Thus, $G^{\Phi}_{\Delta,n}$, for Δ being a constant, has $\Theta(n/\Phi^2)$ vertices.*

Next, we claim that the effective resistance of our demand pairs is the same up to a constant in $G_{\Delta,n}$ and $G^{\Phi}_{\Delta,n}$.

▷ Claim 5.7. For each edge $(u,v) \in E(G_{\Delta,n})$, the effective resistance of the pair (u,v) in the graph $G^{\Phi}_{\Delta,n}$ is $\Theta(1)$.

Proof. To show this result, we give an explicit mapping of the electrical flow routing $\boldsymbol{\chi_{(u,v)}}$ in $G_{\Delta,n}$ to routing the flow in $G^{\Phi}_{\Delta,n}$ whose energy is at most constant. Let $\boldsymbol{f}$ be this electrical flow routing on $G_{\Delta,n}$, then we map the flow on each edge e' in $G_{\Delta,n}$ uniformly through the $1/\Phi$ disjoint paths between the endpoints of e' in $G^{\Phi}_{\Delta,n}$. Since each path now routes only a Φ-fraction of the original flow on the edge e', we have that the energy used to route through each edge on the disjoint paths replacing e'_{middle} is $(\boldsymbol{f}(e')\Phi)^2 = \boldsymbol{f}(e')^2\Phi^2$. We thus have that the energy incurred by routing through the $1/\Phi$ disjoint paths each consisting of $1/\Phi$ edges is $1/\Phi^2 \cdot \boldsymbol{f}(e')^2\Phi^2 = \boldsymbol{f}(e')^2$. Thus, the effective resistance of (u,v) in $G^{\Phi}_{\Delta,n}$ is at most the resistance in $G_{\Delta,n}$ which implies it is in $O(1)$.

A lower bound of $\Omega(1)$ is observed by inversing this mapping to collect the amount of flow pushed through the disjoint paths replacing edge e' together and adding it to e' in $G_{\Delta,n}$. The proof is straightforward and therefore omitted. ◁

Before we can carry out the proof of our lower bound, it remains to show for our lower bound gadget which is the graph $G = G_{\Delta,n} \cup G^{\Phi}_{\Delta,n}$ that it is a $\Theta(\Phi)$-expander.

▷ Claim 5.8. G is $\Theta(\Phi)$-expander with $\Theta(n/\Phi^2)$ edges.

Proof. The number of edges is straightforward from our construction of G. To see that G is $O(\Phi)$-expander, observe that we can take the internal vertices of any path in $G^{\Phi}_{\Delta,n}$ replacing an edge in $G_{\Delta,n}$ which has volume $\Omega(1/\Phi)$ but only two edges leaving (the once to the endpoints of the replaced edges). To observe that it is an $\Omega(\Phi)$-expander, it suffices to show that each cut in S is maximized by assigning all internal vertices of each such path to one side of the cut. It is then not hard to show from $G_{\Delta,n}$ being a $\Omega(1)$-expander that the claim follows. ◁

Let us now give the proof of the main result. We take the graph under consideration to be $G = G_{\Delta,n} \cup G^{\Phi}_{\Delta,n}$. We take as demand, the vector $\boldsymbol{\chi}^{\Phi} = \frac{1}{\Phi} \cdot \boldsymbol{\chi} = \frac{1}{\Phi} \cdot \{\boldsymbol{\chi}_{(u,v)}\}_{e=(u,v)\in E(G_{\Delta,n})}$. Let $\boldsymbol{A_{\mathcal{E}}}$ denote the electrical flow routing on this graph G. Let us look at each edge $e = (u,v) \in E(G_{\Delta,n})$. From Fact 5.3, Claim 5.7 and Fact 5.4, we have that the flow $\boldsymbol{f}_e = \boldsymbol{A_{\mathcal{E}}} \cdot \frac{1}{\Phi}\boldsymbol{\chi}_{(u,v)}$ restricted to the edges in $E(G_{\Delta,n})$ routes in total at least $\log n/\varphi$ units of flow along all of these edges. By linearity of $\boldsymbol{A_{\mathcal{E}}}$ and the fact that flows do not cancel, we have that when routing $\boldsymbol{\chi}^{\Phi}$, an average edge in $E(G_{\Delta,n})$ carries $\Omega(\log n/\Phi)$ units of flow. Thus, the ℓ_p-norm of this flow is at least $\sqrt[p]{n \cdot (\log n/\Phi)^p} = n^{1/p} \cdot \log n \cdot \Phi$. But observe that we can route the flow with demand with congestion 1 in $G^{\Phi}_{\Delta,n}$ by routing for each demand $\boldsymbol{\chi}_{(u,v)}$ exactly 1 unit of flow through each of the disjoint paths corresponding to the edge $e' = (u,v)$ in $G^{\Phi}_{\Delta,n}$. The ℓ_p-norm of this flow is $\Theta((n/\Phi^2)^{1/p}) = \Theta(n^{1/p}\Phi^{-2/p})$ (using Claim 5.8). We thus have that $\rho_p(\boldsymbol{A_{\mathcal{E}}}) = \Omega(\log n \cdot \Phi^{p/(p-2)})$.

To obtain the result for $p < 2$, we use that for q given by $1/p + 1/q = 1$, we have $\|\boldsymbol{X}\|_{p\to p} = \|\boldsymbol{X}^{\top}\|_{q\to q}$, and for the electrical routing, $\boldsymbol{A_{\mathcal{E}}B} = (\boldsymbol{A_{\mathcal{E}}B})^{\top}$ since $\boldsymbol{L}^{+}$ is symmetric.

We note that in the construction above the number of vertices in the final graph G might be much larger than n. By considering all possible parameters for Φ in $[1/n, 1]$ (i.e. all such numbers were $1/\Phi$ is integer), we obtain a family of n'-vertex graphs with conductances in $[1, 1/\sqrt[3]{n'}]$, as claimed. Since every Φ-expander is also a Φ'-expander for every $\Phi' \leq \Phi$, we do further not need to restrict the domain of Φ' further than in range. We point out that by considering parameters Φ in our construction that are even smaller than $1/n$, one can get up to an arbitrarily small polynomial factor close to conductances as small as $1/\sqrt{n'}$.

Abstract

Treewidth serves as an important parameter that, when bounded, yields tractability for a wide class of problems. For example, graph problems expressible in Monadic Second Order (MSO) logic and Quantified SAT or, more generally, Quantified CSP, are fixed-parameter tractable parameterized by the treewidth of the input's (primal) graph plus the length of the MSO-formula [Courcelle, Information & Computation 1990] and the quantifier rank [Chen, ECAI 2004], respectively. The algorithms generated by these (meta-)results have running times whose dependence on treewidth is a tower of exponents. A conditional lower bound by Fichte, Hecher, and Pfandler [LICS 2020] shows that, for Quantified SAT, the height of this tower is equal to the number of quantifier alternations. These types of lower bounds, which show that at least *double-exponential* factors in the running time are *necessary*, exhibit the extraordinary level of computational hardness for such problems, and are rare in the current literature: there are only a handful of such lower bounds (for treewidth and vertex cover parameterizations) and all of them are for problems that are #NP-complete, Σ_2^p-complete, Π_2^p-complete, or complete for even higher levels of the polynomial hierarchy.

Our results demonstrate, for the first time, that it is not necessary to go higher up in the polynomial hierarchy to achieve double-exponential lower bounds: we derive double-exponential lower bounds in the treewidth (tw) and the vertex cover number (vc), for natural, important, and well-studied NP-*complete* graph problems. Specifically, we design a *technique* to obtain such lower bounds and show its *versatility* by applying it to three different problems: Metric Dimension, Strong Metric Dimension, and Geodetic Set. We prove that these problems do not admit $2^{2^{o(\mathsf{tw})}} \cdot n^{\mathcal{O}(1)}$-time algorithms, even on bounded diameter graphs, unless the ETH fails (here, n is the number of vertices in the graph). In fact, for Strong Metric Dimension, the double-exponential lower bound holds even for the vertex cover number. We further complement all our lower bounds with matching (and sometimes non-trivial) upper bounds.

For the conditional lower bounds, we design and use a novel, yet simple technique based on *Sperner families* of sets. We believe that the amenability of our technique will lead to obtaining such lower bounds for many other problems in NP.

1 Introduction

Many interesting computational problems turn out to be intractable. In these cases, identifying parameters under which the problems become tractable is desirable. In the area of parameterized complexity, treewidth is a cornerstone parameter since a large class of problems become tractable on graphs of bounded treewidth.

Courcelle's celebrated theorem [13] states that the class of graph problems expressible in Monadic Second-Order Logic (MSOL) of constant size is fixed-parameter tractable (FPT) when parameterized by the treewidth of the graph. That is, such problems admit algorithms whose running time is of the form $f(\mathtt{tw}) \cdot \mathsf{poly}(n)$, where $\mathtt{tw}$ is the treewidth of the input, n is the size of the input, and f is a function that depends only on $\mathtt{tw}$. Similarly, a result by Chen [12] shows that the Quantified SAT (Q-SAT) problem can also be solved in time $f(\mathtt{tw}) \cdot \mathsf{poly}(n)$, where $\mathtt{tw}$ is the treewidth of the primal graph of the input formula and f is a function that depends only on $\mathtt{tw}$ and the number of quantifier alternations in the input formula. Q-SAT is a generalization of SAT that allows universal and existential quantifications over the variables. Note that Q-SAT with k quantifier alternations is Π_k^p-complete or Σ_k^p-complete. Unfortunately, in both of the aforementioned results, the function f is a tower of exponents whose height depends roughly on the size of the MSOL and input formulas, respectively. For Q-SAT, the height of this tower equals the number of quantifier alternations in the Q-SAT instance [12].

Over the years, the focus shifted to making such FPT algorithms as efficient as possible. Thus, a natural question is to ask when this higher-exponential dependence on treewidth is necessary. There is a rich literature that provides (conditional) lower bounds on this dependency for many problems, and these bounds are commonly of the form $2^{o(\mathtt{tw})}$ or, in some unusual cases, $2^{o(\mathtt{tw}\log\mathtt{tw})}$ (e.g., [15, 50]) and even $2^{o(\mathsf{poly}(\mathtt{tw}))}$ (e.g., [14, 55]). Most notably, these lower bounds are far from the tower of exponents upper bounds given by the (meta-)results discussed above. In this work, we develop a simple technique that allows to prove double-exponential dependence on the treewidth $\mathtt{tw}$ and the vertex cover number $\mathtt{vc}$,

two of the most fundamental graph parameters. Notably, these are the first such results for problems in NP, and we believe that the amenability of our technique will lead to many more similar results for other problems in NP.

Indeed, after a preprint of this paper appeared on arxiv, our technique was also used to prove double-exponential dependence on vc for an NP-complete machine learning problem [11] and double-exponential dependence on the solution size and tw for NP-complete *identification problems* like Test Cover and Locating-Dominating Set [10].

Double-exponential lower bounds: treewidth and vertex cover parameterizations. Fichte, Hecher, and Pfander [25] recently proved that, assuming the Exponential Time Hypothesis[1] (ETH), Q-SAT with k quantifier alternations cannot be solved in time significantly better than a tower of exponents of height k in the treewidth. This exemplifies an interesting but expected trait of this problem: its complexity, in terms of the height of the exponential tower in tw, increases with each quantifier alternation. It strengthened the result that appeared in [48], where conditional double-exponential lower bounds for $\exists\forall$SAT and $\forall\exists$SAT were given. The results in [48] also yield a double-exponential lower bound in vc of the primal graph for both problems. Besides these results, there are only a handful of other problems known to require higher-exponential dependence in the treewidth of the input graph (or the primal graph of the input formula). Specifically, the Π_2^p-complete k-Choosability problem and the Σ_3^p-complete k-Choosability Deletion problem admit a double-exponential and a triple-exponential lower bound in treewidth [52], respectively. Recently, the Σ_p^2-complete problems Cycle HitPack and H-HitPack, for a fixed graph H, were shown to admit tight algorithms that are double-exponential in the treewidth [26]. Further, the Σ_p^2-complete problem Core Stability was shown to admit a tight double-exponential lower bound in the treewidth, even on graphs of bounded degree [32]. Lastly, the #NP-complete counting problem Projected Model Counting admits a double-exponential lower bound in tw [23, 24]. For other double-exponential lower bounds, see [1, 16, 27, 32, 37, 41, 43, 44, 47, 51, 56, 59].

All the double- (or higher) exponential lower bounds in treewidth mentioned so far are for problems that are #NP-complete, Σ_2^p-complete, Π_2^p-complete, or complete for even higher levels of the polynomial hierarchy. To quote [52]: *"Π_2^p-completeness of these problems already gives sufficient explanation why double- [...] exponential dependence on treewidth is needed. [...] the quantifier alternations in the problem definitions are the common underlying reasons for being in the higher levels of the polynomial hierarchy and for requiring unusually large dependence on treewidth."*

As mentioned above, we develop a technique that allows to demonstrate, for the first time, that it is not necessary to go to higher levels of the polynomial hierarchy to achieve double-exponential lower bounds in the treewidth or the vertex cover number of the graph.

We prove that three natural and well-studied NP-complete problems admit double-exponential lower bounds in tw or vc, under the ETH. These are the first problems in NP known to admit such lower bounds.[2]

[1] The Exponential Time Hypothesis roughly states that n-variable 3-SAT cannot be solved in time $2^{o(n)}$.

[2] While it may be possible to artificially engineer a graph problem or graph representation of a problem in NP that admits such lower bounds (although, to the best of our knowledge, this has not been done), we emphasize that this is not the case for these three natural and well-established graph problems in NP.

NP-complete metric-based graph problems. We study three *metric-based graph problems*. These problems are Metric Dimension [34, 58], Strong Metric Dimension [57], and Geodetic Set [33], and they arise from network design and network monitoring. Apart from serving as examples for double-exponential dependence on treewidth and the amenability of our technique, these problems are of interest in their own right, and possess a rich literature both in the algorithms and discrete mathematics communities (see, e.g., [2, 3, 4, 5, 7, 8, 17, 19, 20, 21, 31, 38, 45, 53] and the references below). Their non-local nature has posed interesting algorithmic challenges and our results, as we explain later, supplement the already vast literature on the structural parameterizations of these problems. Below we define the three above-mentioned problems formally, and particularly focus on Metric Dimension as it is the most popular and well-studied of the three.

Metric Dimension
Input: A graph G and a positive integer k.
Question: Does there exist $S \subseteq V(G)$ such that $|S| \leq k$ and, for any pair of vertices $u, v \in V(G)$, there exists a vertex $w \in S$ with $d(w, u) \neq d(w, v)$?

The Metric Dimension problem dates back to the 70s [34, 58]. As in geolocation problems, the aim is to distinguish the vertices of a graph via their distances to a solution set. Metric Dimension was first shown to be NP-complete in general graphs in Garey and Johnson's book [30, GT61], and this was later extended to many restricted graph classes [18, 22, 28], including graphs of diameter 2 [28] and graphs of pathwidth 24 [49]. In a seminal paper, Metric Dimension was proven to be W[2]-hard parameterized by the solution size k, even in subcubic bipartite graphs [35]. This drove the subsequent meticulous study of the problem under structural parameterizations.

In particular, the complexity of Metric Dimension parameterized by treewidth remained an intriguing open problem for a long time. Recently, it was shown that Metric Dimension is para-NP-hard parameterized by pathwidth (`pw`) [49] (an earlier result [6] showed that it is W[1]-hard for pathwidth). A subsequent paper showed that the problem is W[1]-hard parameterized by the combined parameter feedback vertex set number (`fvs`) plus pathwidth of the graph [29].

We conclude this part with the definitions of the remaining two problems, both of which are known to be NP-Complete [9, 54]. Geodetic Set is also W[1]-hard parameterized by the solution size, feedback vertex set number, and pathwidth, combined [39].

Strong Metric Dimension
Input: A graph G and a positive integer k.
Question: Does there exist $S \subseteq V(G)$ such that $|S| \leq k$ and, for any pair of vertices $u, v \in V(G)$, there exists a vertex $w \in S$ such that either u lies on some shortest path between v and w, or v lies on some shortest path between u and w?

Geodetic Set
Input: A graph G and a positive integer k.
Question: Does there exist $S \subseteq V(G)$ such that $|S| \leq k$ and, for any vertex $u \in V(G)$, there are two vertices $s_1, s_2 \in S$ such that a shortest path from s_1 to s_2 contains u?

Our technical contributions. As Metric Dimension and Geodetic Set are NP-complete on bounded diameter graphs *or* on bounded treewidth graphs, we study their parameterized complexity with $\mathtt{tw} + \mathtt{diam}$ as the parameter and prove the following results.

1. Metric Dimension and Geodetic Set do not admit algorithms running in time $2^{f(\mathtt{diam})^{o(\mathtt{tw})}} \cdot n^{\mathcal{O}(1)}$, for any computable function f, unless the ETH fails.
2. Strong Metric Dimension does not even admit an algorithm with a running time of $2^{2^{o(\mathtt{vc})}} \cdot n^{\mathcal{O}(1)}$, unless the ETH fails. This also implies the problem does not admit a kernelization algorithm that outputs an instance with $2^{o(\mathtt{vc})}$ *vertices*, unless the ETH fails.

The above lower bounds for $\mathtt{tw}+\mathtt{diam}$, in particular, imply that Metric Dimension and Geodetic Set on graphs of bounded diameter cannot admit $2^{2^{o(\mathtt{tw})}} \cdot n^{\mathcal{O}(1)}$-time algorithms, unless the ETH fails. The reduction for Metric Dimension (sketched in Section 2.3) also works for fvs and td, and the one for Geodetic Set (Section 3) also works for td.

We show that all our lower bounds are tight by providing algorithms (kernelization algorithms, respectively) with matching running times (guarantees, respectively).

1. Metric Dimension and Geodetic Set admit algorithms running in time $2^{\mathtt{diam}^{\mathcal{O}(\mathtt{tw})}} \cdot n^{\mathcal{O}(1)}$.
2. Strong Metric Dimension admits an algorithm running in time $2^{2^{\mathcal{O}(\mathtt{vc})}} \cdot n^{\mathcal{O}(1)}$ and a kernel with $2^{\mathcal{O}(\mathtt{vc})}$ vertices.

The (kernelization) algorithm for the vc parameterization is very simple, whereas the algorithms for the $\mathtt{tw}+\mathtt{diam}$ parameter are highly non-trivial and require showing interesting locality properties in the instance. Further, for our $\mathtt{tw}+\mathtt{diam}$ parameterized algorithms, the (double-exponential) dependency of treewidth in the running time is unusual (and rightly so, as exhibited by our lower bounds), as most natural graph problems in NP for which a dedicated algorithm (i.e., *not* relying on Courcelle's theorem) parameterized by treewidth is known, can be solved in time $2^{\mathcal{O}(\mathtt{tw})} \cdot n^{\mathcal{O}(1)}$, $2^{\mathcal{O}(\mathtt{tw}\cdot\log(\mathtt{tw}))} \cdot n^{\mathcal{O}(1)}$ or $2^{\mathcal{O}(\mathsf{poly}(\mathtt{tw}))} \cdot n^{\mathcal{O}(1)}$.

Finally, our reductions rely on a novel, yet simple technique based on *Sperner families* of sets that allows to encode particular SAT relations across large sets of variables and clauses into relatively small vertex-separators. As mentioned before, we believe that this technique is the key to obtaining such lower bound results for other problems in NP. In particular, as witnessed by our results, our technique has the additional features that it even allows to prove such lower bounds in very restricted cases, such as bounded diameter graphs, and is not specific to any one structural parameter, as it also works for, e.g., the feedback vertex set number and treedepth.

Due to space constraints, we cannot discuss all of our results in depth, and refer the reader to the full version for full proofs, formal details, and more related work. Nonetheless, we elaborate on our technique and present an overview of the results for Metric Dimension in the next section. Then, in Section 3, we present a formal proof for the lower bound for Geodetic Set. Finally, we conclude the paper in Section 4.

2 Technical Overview

In this section, we present an overview of our lower bound techniques. We first exhibit our technique to obtain the double-exponential lower bounds in its most general setting. Then, we continue with the problem-specific tools we developed that are required for the reductions.

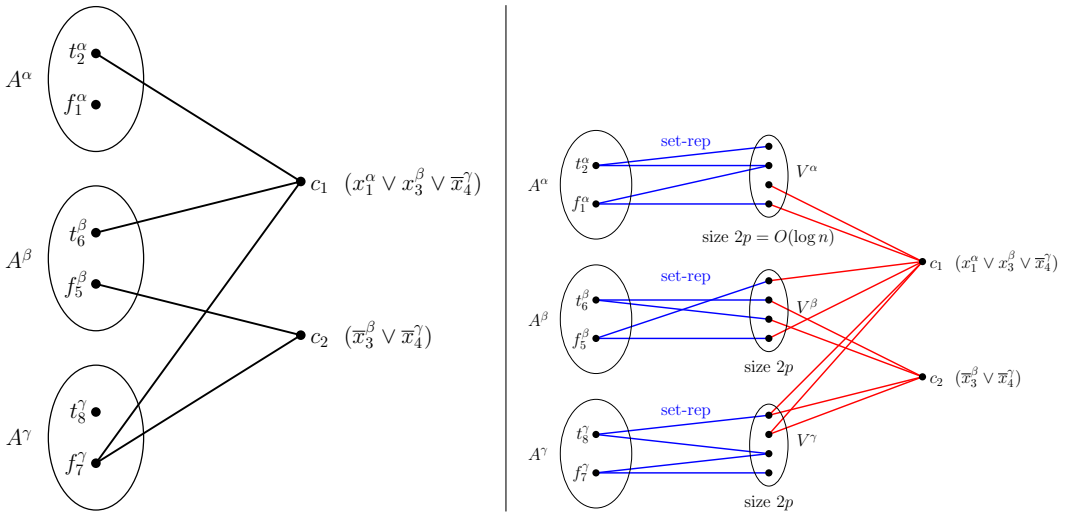

Figure 1 Graph representations of 3-Partitioned-3-SAT. (Left) incidence graph representation. (Right) representation with small separators using our technique. Note, for example, that x_1^α appears as a positive literal in the clause C_1. Thus, on the left, t_2^α is the only literal vertex in A^α incident to c_1, while on the right, t_2^α is the only literal vertex in A^α that does not share a common neighbor with c_1 in V^α. The edges from c_2 to each vertex in V^α are omitted for clarity.

2.1 General Technique for Double-Exponential Lower Bounds

The first integral part of our technique is to reduce from a variant of 3-SAT known as 3-Partitioned-3-SAT that was introduced in [46]. In this problem, the input is a formula ψ in 3-CNF form, together with a partition of the set of its variables into three disjoint sets X^α, X^β, X^γ, with $|X^\alpha| = |X^\beta| = |X^\gamma| = n$, and such that no clause contains more than one variable from each of X^α, X^β, and X^γ. The objective is to determine whether ψ is satisfiable. Unless the ETH fails, 3-Partitioned-3-SAT does not admit an algorithm running in time $2^{o(n)}$ [46, Theorem 3].

Typical reductions from satisfiability problems to graph problems usually entail representing the satisfiability problem by its incidence graph, in which each variable is represented by two vertices corresponding to its positive and negative literals. In this representation, a clause vertex is adjacent to a literal vertex if and only if it contains that literal in ψ (see Figure 1 (left) for an illustration). However, this naive approach does not lead to any structural parameters of the incidence graph being of bounded size. The *core idea* of our technique is to instead represent the relationships between clause and literal vertices via edges from these two sets of vertices to "small" separators (three separators in the case of 3-Partitioned-3-SAT) that encode these relationships.

Formally, this is achieved as follows. For a positive integer p, define $\mathcal{F}_p$ as the collection of subsets of $[2p]$ that contains exactly p integers. We critically use the fact that no set in $\mathcal{F}_p$ is contained in any other set in $\mathcal{F}_p$ (such a collection of sets are called a *Sperner family*). Let ℓ be a positive integer such that $\ell \leq \binom{2p}{p}$. We define $\mathsf{set\text{-}rep} : [\ell] \mapsto \mathcal{F}_p$ as a one-to-one function by arbitrarily assigning a set in $\mathcal{F}_p$ to an integer in $[\ell]$. By the asymptotic estimation of the central binomial coefficient, $\binom{2p}{p} \sim \frac{4^p}{\sqrt{\pi \cdot p}}$ [36]. To get the upper bound of p, we scale down the asymptotic function and have $\ell \leq \frac{4^p}{2^p} = 2^p$. Thus, $p = \mathcal{O}(\log \ell)$.

Let ψ be an instance of 3-Partitioned-3-SAT on $3n$ variables, and let p be the smallest integer such that $2n \leq \binom{2p}{p}$. In particular, $p = \mathcal{O}(\log n)$. Define $\mathsf{set\text{-}rep} : [2n] \mapsto \mathcal{F}_p$ as above. Rename the variables in X^α to x_i^α for all $i \in [n]$. For each variable x_i^α, add two vertices t_{2i}^α

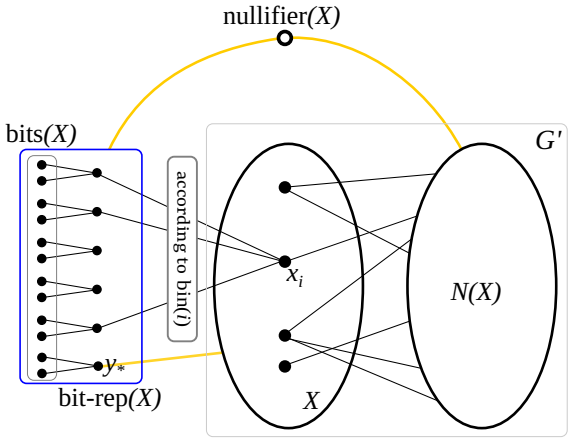

Figure 2 Set Identifying Gadget. The blue box represents bit-rep(X) and the yellow lines represent that nullifier(X) is adjacent to each vertex in bit-rep$(X) \cup N(X)$, and $y_\star$ is adjacent to each vertex in X. Also, G' is not necessarily restricted to the graph induced by the vertices in $X \cup N(X)$.

and f^{α}_{2i-1} corresponding to the positive and negative literals of x^{α}_i, respectively. Let $A^{\alpha} = \{t^{\alpha}_{2i}, f^{\alpha}_{2i-1} | \ i \in [n]\}$. Add a *validation portal* with $2p$ vertices, denoted by $V^{\alpha} = \{v^{\alpha}_1, \ldots, v^{\alpha}_{2p}\}$. For each $i \in [n]$, add the edge $t^{\alpha}_{2i}v^{\alpha}_{p'}$ for each $p' \in$ set-rep$(2i)$. Similarly, for each $i \in [n]$, add the edge $f^{\alpha}_{2i-1}v^{\alpha}_{p'}$ for each $p' \in$ set-rep$(2i-1)$. Repeat the above steps for β and γ.

Now, for each clause C_j ($j \in [m]$) in ψ, add a clause vertex c_j. Let $\delta \in \{\alpha, \beta, \gamma\}$. For all $i \in [n]$ and $j \in [m]$, if the variable x^{δ}_i appears as a positive (negative, respectively) literal in the clause C_j in ψ, then add the edge $c_j v^{\delta}_{p'}$ for each $p' \in [2p] \setminus$ set-rep$(2i)$ ($p' \in [2p] \setminus$ set-rep$(2i-1)$, respectively). For all $j \in [m]$, if no variable from X^{δ} appears in C_j in ψ, then make c_j adjacent to all the vertices in V^{δ}. See Figure 1 (right) for an illustration.

As a clause contains at most one variable from X^{δ} in ψ, c_j and t^{δ}_{2i} (f^{δ}_{2i-1}, respectively) do not share a common neighbor in V^{δ} if and only if the clause C_j contains x^{δ}_i as a positive (negative, respectively) literal in ψ. For the reductions, we use this representation of the relationship between clause and literal vertices. Since $p = \mathcal{O}(\log n)$, this ensures that $\mathtt{tw}(G) = \mathcal{O}(\log n)$, which we exploit along with the fact that, unless the ETH fails, 3-Partitioned-3-SAT does not admit an algorithm running in time $2^{o(n)}$.

2.2 Basic Tools for Lower Bounds

For brevity, we focus on Metric Dimension and explain our problem-specific tools in this context. We use two such simple tools: the *bit representation gadget* and the *set representation gadget*. The set representation gadget is the problem-specific implementation of the above technique, and it uses the bit representation gadget.

Before going further, we need to define some terms related to Metric Dimension. The set S defined in the problem statement of Metric Dimension is called a *resolving set* of G. A subset of vertices $S' \subseteq V(G)$ *resolves* a pair of vertices $u, v \in V(G)$ if there exists a vertex $w \in S'$ such that $d(w, u) \neq d(w, v)$. Lastly, a vertex $u \in V(G)$ is *distinguished* by a subset of vertices $S' \subseteq V(G)$ if, for any $v \in V(G) \setminus \{u\}$, there exists a vertex $w \in S'$ such that $d(w, u) \neq d(w, v)$.

Bit Representation Gadget to Identify Sets. Suppose we are given a graph G' and a subset $X \subseteq V(G')$ of its vertices. Further, suppose that we want to add a vertex set X^+ to G' to obtain a new graph G with the following properties. We want that each vertex in $X \cup X^+$ is

distinguished by vertices in X^+ that must be in any resolving set S of G, and that no vertex in X^+ can resolve any "critical pair" of vertices in G. Roughly, a pair of vertices is critical if it forces certain "types" of vertices to be in any resolving set S of G, and the selection of the specific vertices of those types depends on the solution to the problem being reduced from (which, in our case, is 3-PARTITIONED-3-SAT [46]). We refer to the graph induced by the vertices of X^+, along with the edges connecting X^+ to G', as the *Set Identifying Gadget* for the set X. Given a graph G' and a non-empty subset $X \subseteq V(G')$ of its vertices, to construct such a graph G, we add vertices and edges to G' as follows (see Figure 2):

- The vertex set X^+ that we are aiming to add is the union of a set $\mathsf{bit\text{-}rep}(X)$ and a special vertex denoted by $\mathsf{nullifier}(X)$.
- First, let $X = \{x_i \mid i \in [|X|]\}$, and set $q := \lceil \log(|X|+2) \rceil + 1$. We select this value for q to *(1)* uniquely represent each integer in $[|X|]$ by its bit-representation in binary (note that we start from 1 and not 0), *(2)* ensure that the only vertex whose bit-representation contains all 1's is $\mathsf{nullifier}(X)$, and *(3)* reserve one spot for an additional vertex $y_\star$.
- For every $i \in [q]$, add three vertices y_i^a, y_i, y_i^b, and add the path (y_i^a, y_i, y_i^b).
- Add 3 vertices $y_\star^a, y_\star, y_\star^b$ and the path $(y_\star^a, y_\star, y_\star^b)$. Add edges to make $\{y_i \mid i \in [q]\} \cup \{y_\star\}$ a clique. Make $y_\star$ adjacent to each vertex in X. Let $\mathsf{bit\text{-}rep}(X) = \{y_i, y_i^a, y_i^b \mid i \in [q]\} \cup \{y_\star, y_\star^a, y_\star^b\}$ and denote its subset by $\mathsf{bits}(X) = \{y_i^a, y_i^b \mid i \in [q]\} \cup \{y_\star^a, y_\star^b\}$.
- For every integer $j \in [|X|]$, let $\mathsf{bin}(j)$ denote the binary representation of j using q bits. Connect x_j with y_i if the i^{th} bit (going from left to right) in $\mathsf{bin}(j)$ is 1.
- Add a vertex, denoted by $\mathsf{nullifier}(X)$, and connect it to each vertex in $\{y_i \mid i \in [q]\} \cup \{y_\star\}$.
- For every vertex $u \in V(G) \setminus (X \cup X^+)$ such that u is adjacent to some vertex in X, add an edge between u and $\mathsf{nullifier}(X)$. We add this vertex to ensure that vertices in $\mathsf{bit\text{-}rep}(X)$ do not resolve critical pairs in $V(G)$.

Set Representation Gadget. We define $\mathsf{set\text{-}rep} : [\ell] \mapsto \mathcal{F}_p$ as in Section 2.1, and recall that $p = \mathcal{O}(\log \ell)$. Suppose we have a "large" collection of vertices, say $A = \{a_1, a_2, \ldots, a_\ell\}$, and a "large" collection of critical pairs $C = \{\langle c_1^\circ, c_1^\star\rangle, \langle c_2^\circ, c_2^\star\rangle, \ldots, \langle c_m^\circ, c_m^\star\rangle\}$. Moreover, we are given an injective function $\phi : [m] \mapsto [\ell]$. The objective is to design a gadget such that only $a_{\phi(q)} \in A$ can resolve a critical pair $\langle c_q^\circ, c_q^\star\rangle \in C$ for any $q \in [m]$, while keeping the treewidth of this part of the graph of order $\mathcal{O}(\log(|A|))$. With this in mind, we do the following.

- Add vertices and edges to identify the set A and to add critical pairs in C (for each critical pair in C, both vertices share the same bit-representation in the Set Identifying Gadget for C).
- Add a *validation portal*, a clique on $2p$ vertices, denoted by $V = \{v_1, v_2, \ldots, v_{2p}\}$, and vertices and edges to identify it.
- For every $i \in [\ell]$ and for every $p' \in \mathsf{set\text{-}rep}(i)$, add the edge $(a_i, v_{p'})$.
- For every critical pair $\langle c_q^\circ, c_q^\star\rangle$, make c_q° adjacent to every vertex in V, and add every edge of the form $(c_q^\star, v_{p'})$ for $p' \in [2p] \setminus \mathsf{set\text{-}rep}(\phi(q))$. Note that the vertices in V that are indexed using integers in $\mathsf{set\text{-}rep}(\phi(q))$ are *not* adjacent with $c_q^\star$.

See Figure 3 for an illustration. Now, consider a critical pair $\langle c_q^\circ, c_q^\star\rangle$ and suppose $i = \phi(q)$.

- By the construction, $N(a_i) \cap N(c_q^\circ) \neq \emptyset$, whereas $N(a_i) \cap N(c_q^\star) = \emptyset$. Hence, a_i resolves the critical pair $\langle c_q^\circ, c_q^\star\rangle$ as $d(a_i, c_q^\circ) = 2$ and $d(a_j, c_q^\star) > 2$.
- For any other vertex in A, say a_j, $\mathsf{set\text{-}rep}(j) \setminus \mathsf{set\text{-}rep}(i)$ is a non-empty set. So, there are paths from a_j to c_q° and a_j to $c_q^\star$ through vertices in V with indices in $\mathsf{set\text{-}rep}(j) \setminus \mathsf{set\text{-}rep}(i)$. This implies that $d(a_j, c_q^\circ) = d(a_j, c_q^\star) = 2$ and a_j cannot resolve the pair $\langle c_q^\circ, c_q^\star\rangle$.

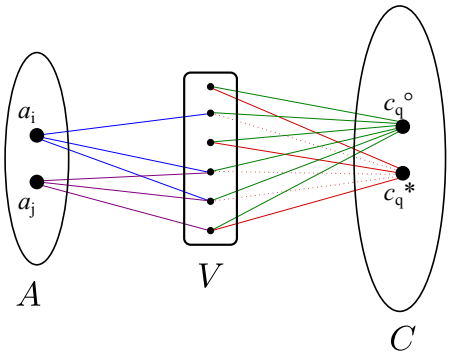

Figure 3 Set Representation Gadget. Let $\phi(q) = i$, i.e., only a_i in A can resolve the critical pair $\langle c_q^\circ, c_q^\star \rangle$. Let the vertices in V be indexed from top to bottom and let $\mathsf{set\text{-}rep}(i) = \{2, 4, 5\}$. By construction, the only vertices in V that $c_q^\star$ is *not* adjacent to are v_2, v_4, and v_5 (this is highlighted by red-dotted edges). Thus, $\mathrm{dist}(a_i, c_q^\circ) = 2$ and $\mathrm{dist}(a_i, c_q^\star) > 2$, and hence, a_i resolves $\langle c_q^\circ, c_q^\star \rangle$. For any other vertex in A, say a_j, $\mathsf{set\text{-}rep}(j) \setminus \mathsf{set\text{-}rep}(i)$ is non-empty, and thus, a_j cannot resolve $\langle c_q^\circ, c_q^\star \rangle$.

2.3 Sketch of the Lower Bound Proof for Metric Dimension

With these tools in hand, we present an overview of the reduction from 3-Partitioned-3-SAT used to prove Theorem 1, which we restate here for convenience.

▶ **Theorem 1.** *Unless the ETH fails,* Metric Dimension *does not admit an algorithm running in time* $2^{f(\mathtt{diam})^{o(\mathtt{tw})}} \cdot n^{\mathcal{O}(1)}$ *for any computable function* $f : \mathbb{N} \mapsto \mathbb{N}$.

The reduction in the proof of Theorem 1 takes as input an instance ψ of 3-Partitioned-3-SAT on $3n$ variables and returns (G, k) as an instance of Metric Dimension such that $\mathtt{tw}(G) = \mathcal{O}(\log(n))$ and $\mathtt{diam}(G) = \mathcal{O}(1)$. In the following, we mention a crude outline of the reduction, omitting some technical details.

2.3.1 Reduction

- We rename the variables in X^α to x_i^α for $i \in [n]$. For every variable x_i^α, we add a critical pair $\langle x_i^{\alpha,\circ}, x_i^{\alpha,\star} \rangle$ of vertices. We denote $X^\alpha = \{x_i^{\alpha,\circ}, x_i^{\alpha,\star} \mid i \in [n]\}$.
- For each variable x_i^α, we add the vertices t_{2i}^α and f_{2i-1}^α. Let $A^\alpha = \{t_{2i}^\alpha, f_{2i-1}^\alpha | \ i \in [n]\}$.
- For every $i \in [n]$, we add the edges $(x_i^{\alpha,\circ}, t_{2i}^\alpha)$ and $(x_i^{\alpha,\circ}, f_{2i-1}^\alpha)$ which will ensure that any resolving set contains at least one vertex in $\{t_{2i}^\alpha, f_{2i-1}^\alpha, x_i^{\alpha,\circ}, x_i^{\alpha,\star}\}$ for every $i \in [n]$.
- Let p be the smallest integer such that $2n \leq \binom{2p}{p}$. In particular, $p = \mathcal{O}(\log n)$. Define $\mathsf{set\text{-}rep} : [2n] \mapsto \mathcal{F}_p$ as in Section 2.1.
- We add a *validation portal*, a clique on $2p$ vertices, denoted by $V^\alpha = \{v_1^\alpha, v_2^\alpha, \ldots, v_{2p}^\alpha\}$.
- For each $i \in [n]$, we add the edge $(t_{2i}^\alpha, v_{p'}^\alpha)$ for every $p' \in \mathsf{set\text{-}rep}(2i)$. Similarly, for each $i \in [n]$, we add the edge $(f_{2i-1}^\alpha, v_{p'}^\alpha)$ for every $p' \in \mathsf{set\text{-}rep}(2i-1)$.

We repeat the above steps to construct $X^\beta, A^\beta, V^\beta$, $X^\gamma, A^\gamma, V^\gamma$.

- For every clause C_q in ψ, we introduce a pair $\langle c_q^\circ, c_q^\star \rangle$ of vertices. Let C be the collection of vertices in such pairs.
- We add edges across C and the portals as follows. Consider a clause C_q in ψ and the corresponding critical pair $\langle c_q^\circ, c_q^\star \rangle$ in C. Let $\delta \in \{\alpha, \beta, \gamma\}$. As ψ is an instance of 3-Partitioned-3-SAT, at most one variable in X^δ appears in C_q, say x_i^δ for some $i \in [n]$. We add all edges of the form $(v_{p'}^\delta, c_q^\circ)$ for every $p' \in [2p]$. If x_i^δ appears as a positive literal

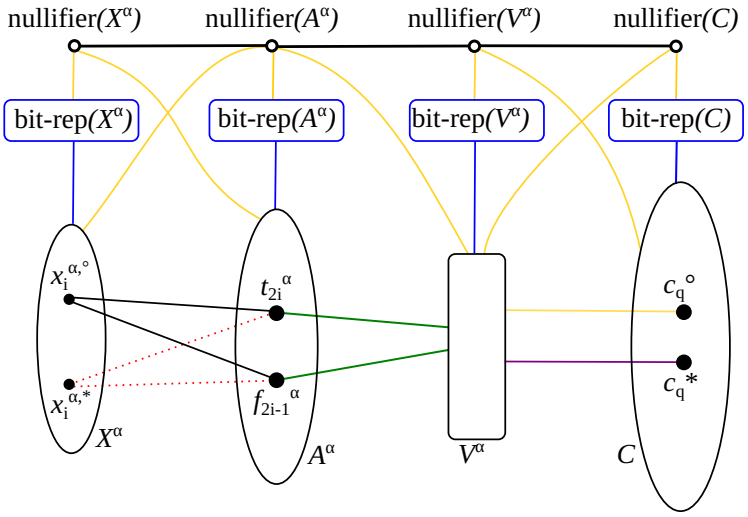

Figure 4 Reduction for proof of Theorem 1. Yellow lines represent that vertex is connected to every vertex in the set the edge goes to. Green edges denote adjacencies with respect to set-rep, e.g., t^{α}_{2i} is adjacent to $v_j \in V^{\alpha}$ if $j \in \textsf{set-rep}(2i)$. Purple lines also indicate adjacencies with respect to set-rep, but in a complementary way, i.e., if $x_i \in c_q$, then, for every $p' \in [2p] \setminus \textsf{set-rep}(2i)$, we have $(v^{\alpha}_{p'}, c^{\star}_q) \in E(G)$, and if $\overline{x}_i \in c_q$, then, for all $p' \in [2p] \setminus \textsf{set-rep}(2i-1)$, we have $(v^{\alpha}_{p'}, c^{\star}_q) \in E(G)$.

in C_q, then we add the edge $(v^{\delta}_{p'}, c^{\star}_q)$ for every $p' \in [2p] \setminus \textsf{set-rep}(2i)$ (which corresponds to t^{δ}_{2i}). If x^{δ}_i appears as a negative literal in C_q, then we add the edge $(v^{\delta}_{p'}, c^{\star}_q)$ for every $p' \in [2p] \setminus \textsf{set-rep}(2i-1)$ (which corresponds to f^{δ}_{2i-1}). Note that if x^{δ}_i appears as a positive (negative, respectively) literal in C_q, then the vertices in V^{δ} whose indices are in $\textsf{set-rep}(2i)$ ($\textsf{set-rep}(2i-1)$, respectively) are *not adjacent* to $c^{\star}_q$. If no variable in X^{δ} appears in C_q, then we make each vertex in V^{δ} adjacent to both c°_q and $c^{\star}_q$.

For all the sets mentioned above, we add vertices and edges to identify them as shown in Figure 4 (for each critical pair, both vertices share the same bit-representation in their Set Identifying Gadget). This concludes the construction of G. The reduction returns (G, k) as an instance of Metric Dimension for some appropriate value of k.

2.3.2 Correctness of the Reduction

We give an informal description of the proof of correctness of the reverse direction here. Fix $\delta \in \{\alpha, \beta, \gamma\}$. For all $i \in [n]$, the only vertices that can resolve the critical pair $\langle x^{\delta,\circ}_i, x^{\delta,\star}_i \rangle$ are the vertices in $\{x^{\delta,\circ}_i, x^{\delta,\star}_i\} \cup \{t^{\delta}_{2i}, f^{\delta}_{2i-1}\}$. This fact and the budget k ensure that any resolving set of G contains exactly one vertex from $\{t^{\delta}_{2i}, f^{\delta}_{2i-1}\} \cup \{x^{\delta,\circ}_i, x^{\delta,\star}_i\}$ for all $i \in [n]$. This naturally corresponds to an assignment of the variable x^{δ}_i if a vertex from $\{t^{\delta}_{2i}, f^{\delta}_{2i-1}\}$ is in the resolving set. However, if a vertex from $\{x^{\delta,\circ}_i, x^{\delta,\star}_i\}$ is in the resolving set, then we can see this as giving an arbitrary assignment to the variable x^{δ}_i. Suppose the clause C_q contains the variable x^{δ}_i as a positive literal. By the construction, every vertex in V^{δ} that is adjacent to t^{δ}_{2i} is *not* adjacent to $c^{\star}_q$. However, c°_q is adjacent to every vertex in V^{δ}. Hence, $d(t^{\delta}_{2i}, c^{\circ}_q) = 2$, whereas $d(t^{\delta}_{2i}, c^{\star}_q) > 2$. Thus, t^{δ}_{2i} resolves the critical pair $\langle c^{\circ}_q, c^{\star}_q \rangle$. Consider any other vertex in A^{δ}, say t^{δ}_{2j}. Since $\textsf{set-rep}(2i)$ is not a subset of $\textsf{set-rep}(2j)$ (as both have the same cardinality), there is at least one integer, say p', in $\textsf{set-rep}(2j) \setminus \textsf{set-rep}(2i)$. The vertex $v^{\delta}_{p'} \in V^{\delta}$ is adjacent to t^{δ}_{2j}, c°_q, and $c^{\star}_q$. Hence, t^{δ}_{2j} cannot resolve the critical pair $\langle c^{\circ}_q, c^{\star}_q \rangle$ as both these vertices are at distance 2 from it. Also, as ψ is an instance of

3-Partitioned-3-SAT, C_q contains at most one variable in X^δ, which is x_i^δ in this case. This also helps to encode the fact that at most one vertex from A^δ should be able to resolve the critical pair $\langle c_q^\circ, c_q^\star \rangle$. Since vertices in X^δ cannot resolve critical pairs $\langle c_q^\circ, c_q^\star \rangle$ in C, then finding a resolving set in G corresponds to finding a satisfying assignment for ψ.

2.3.3 Lower Bounds Obtained from the Reduction

Let $Z = \{V^\delta \cup X^+ \mid X \in \{X^\delta, A^\delta, V^\delta, C\}, \delta \in \{\alpha, \beta, \gamma\}\}$. Note that $|Z| = \mathcal{O}(\log(n))$ and $G - Z$ is a collection of P_3's and isolated vertices. Hence, $\mathtt{tw}(G)$, $\mathtt{fvs}(G)$, and $\mathtt{td}(G)$ are upper bounded by $\mathcal{O}(\log(n))$. Also, G has constant diameter. Thus, if there is an algorithm for Metric Dimension that runs in time $2^{f(\mathtt{diam})^{o(\mathtt{tw})}}$ (or $2^{f(\mathtt{diam})^{o(\mathtt{fvs})}}$ or $2^{f(\mathtt{diam})^{o(td)}}$), then there is an algorithm solving 3-Partitioned-3-SAT in time $2^{o(n)}$, contradicting the ETH.

2.4 High-Level Description of the Dynamic Programming Algorithm for Metric Dimension

The aim of this subsection is to give an informal description of how we prove the upper bound concerning the parameter $\mathtt{tw} + \mathtt{diam}$ for Metric Dimension. To this end, we give a dynamic programming algorithm on a tree decomposition for Metric Dimension. The algorithm is inspired by the one from [7] for chordal graphs, though there are some non-trivial differences. We will assume that a tree decomposition of the input graph G of width w is given to us. Note that one can compute a tree decomposition of width $w \leq 2\mathtt{tw}(G) + 1$ in time $2^{\mathcal{O}(\mathtt{tw}(G))}n$ [42], and it can be transformed into a *nice tree decomposition* of the same width with $\mathcal{O}(wn)$ bags in time $\mathcal{O}(w^2 n)$ [40]. We now give a high-level overview of the dynamic programming algorithm used to prove the following theorem.

▶ **Theorem 2.** *Metric Dimension admits an algorithm running in time* $2^{\mathtt{diam}^{\mathcal{O}(\mathtt{tw})}} \cdot n^{\mathcal{O}(1)}$.

In [7], as the diameter of the graph was unbounded, it was crucial to restrict the computations for each step of the dynamic programming to vertices "not too far" from the current bag. This was possible due to the metric properties of chordal graphs. In our case, as we consider the diameter of the graph as a parameter, we do not need such restrictions, which makes the proof a little bit simpler.

We now give an intuitive description of the dynamic programming scheme. At each step of the algorithm, we consider a bounded number of *solution types*, depending on the properties of the solution vertices with respect to the current bag. At a given dynamic programming step, we will assume that the current solution resolves all vertex pairs in G_i. Such a vertex pair may be resolved by a vertex from $G - G_i$, or by a vertex in G_i itself.

Any bag X_i of the tree decomposition whose node i lies on a path between two join nodes in T, forms a separator of G: there are no edges between the vertices of $G_i - X_i$ and $G - G_i$. For a vertex v not in X_i, we consider its distance-vector to the vertices of X_i; the distance-vectors induce an equivalence relation on the vertices of $G - X_i$, whose classes we call *X_i-classes*. Consider the two subgraphs G_i and $G - G_i$. Any two solution vertices x, y from $G - G_i$ that are in the same X_i-class, resolve the exact same pairs of vertices from G_i. Thus, for this purpose, it is irrelevant whether x or y will be in a resolving set, and it is sufficient to know that a vertex of their X_i-class will eventually be chosen. In this way, one can check whether a vertex pair from G_i is resolved by a solution vertex of $G - G_i$.

The same idea is used to "remember" the previously computed solution: it is sufficient to remember the X_i-classes of the vertices in the previously computed resolving set, rather than the vertices themselves.

It is slightly more delicate to make sure that vertex pairs in G_i are resolved in the case where such a pair is resolved by a vertex in G_i. Indeed, this must be ensured, in particular when processing a join node i, for vertex pairs belonging to bags in the two sub-trees corresponding to the children i_1, i_2 of i. Such pairs may be resolved by four types of solution vertices: from $G - G_i$, X_i, $G_{i_1} - X_i$, or $G_{i_2} - X_i$. To ensure this, the dynamic programming scheme makes sure that, at each step, for any possible pair C_1, C_2 of X_i-classes, all vertex pairs $\langle u, v\rangle$ consisting of a vertex u of G_i with class C_1 and a vertex v of $G - G_i$ with class C_2 are resolved. The crucial step here is that when a new vertex v is introduced (i.e., added to a bag X_i to form $X_{i'}$), depending on its X_i-class, it must be made sure that it is resolved from all other vertices depending on their X_i-classes, as described above. To ensure that v is distinguished from all other vertices of G_i, we keep track of vertex pairs of $G_i \times (G - G_i)$ that are already resolved by the partial solution, and enforce that, when processing bag $X_{i'}$, for every vertex x of G_i, the pair $\langle x, v\rangle$ is already resolved. As v belongs to the new bag $X_{i'}$, we know its distances to all resolving vertices (indeed, $X_{i'}$-classes of solution vertices can be computed from their X_i-classes), and thus, the information can be updated accurately.

For a bag X_i and a vertex v not in X_i, the number of possible distance vectors to the vertices of X_i is at most $\texttt{diam}(G)^{|X_i|}$. Thus, a solution for bag X_i will consist of: (i) the subset of vertices of X_i selected in the solution; (ii) a subset of the $\texttt{diam}(G)^{|X_i|}$ possible vectors to denote the X_i-classes from which the currently computed solution (for G_i) contains at least one vertex in the resolving set; (iii) a subset of the $\texttt{diam}(G)^{|X_i|}$ possible vectors denoting the X_i-classes from which the future solution needs at least one vertex of $G - G_i$ in the resolving set; (iv) a subset of the $\texttt{diam}(G)^{|X_i|} \times \texttt{diam}(G)^{|X_i|}$ possible pairs of vectors representing the X_i-classes of the pairs of vertices in $G_i \times (G - G_i)$ that are already resolved by the partial solution.

3 Geodetic Set: Lower Bound Regarding Diameter plus Treewidth

The aim of this section is to prove the following theorem.

▶ **Theorem 3.** *Unless the ETH fails,* Geodetic Set *does not admit an algorithm running in time* $2^{f(\texttt{diam})^{o(\texttt{tw})}} \cdot n^{\mathcal{O}(1)}$ *for any computable function* $f : \mathbb{N} \mapsto \mathbb{N}$.

Here, we present a different reduction from 3-Partitioned-3-SAT to Geodetic Set. The reduction takes as input an instance ψ of 3-Partitioned-3-SAT on $3n$ variables and returns (G, k) as an instance of Geodetic Set such that $\texttt{tw}(G) = \mathcal{O}(\log(n))$ and $\texttt{diam}(G) = \mathcal{O}(1)$. We rely on the tool of set representation from Section 2.2, that, for convenience, we reintroduce in the context of Geodetic Set in the next subsection.

3.1 Preliminary Tool: Set Representation

For a positive integer p, define $\mathcal{F}_p$ as the collection of subsets of $[2p]$ that contains exactly p integers. We critically use the fact that no set in $\mathcal{F}_p$ is contained in any other set in $\mathcal{F}_p$ (such a collection of sets is called a *Sperner family*). Let ℓ be a positive integer such that $\ell \leq \binom{2p}{p}$. We define $\mathsf{set\text{-}rep} : [\ell] \mapsto \mathcal{F}_p$ as a one-to-one function by arbitrarily assigning a set in $\mathcal{F}_p$ to an integer in $[\ell]$. By the asymptotic estimation of the central binomial coefficient, $\binom{2p}{p} \sim \frac{4^p}{\sqrt{\pi \cdot p}}$ [36]. To get the upper bound of p, we scale down the asymptotic function and have $\ell \leq \frac{4^p}{2^p} = 2^p$. Thus, $p = \mathcal{O}(\log \ell)$.

We will apply the existence of such a function in the context of Geodetic Set. Suppose we have a "large" collection of vertices, say $A = \{a_1, a_2, \ldots, a_\ell\}$, and a "large" collection of vertices $C = \{c_1, c_2, \ldots, c_m\}$. Moreover, we are given a function $\phi : [m] \mapsto [\ell]$. The basic

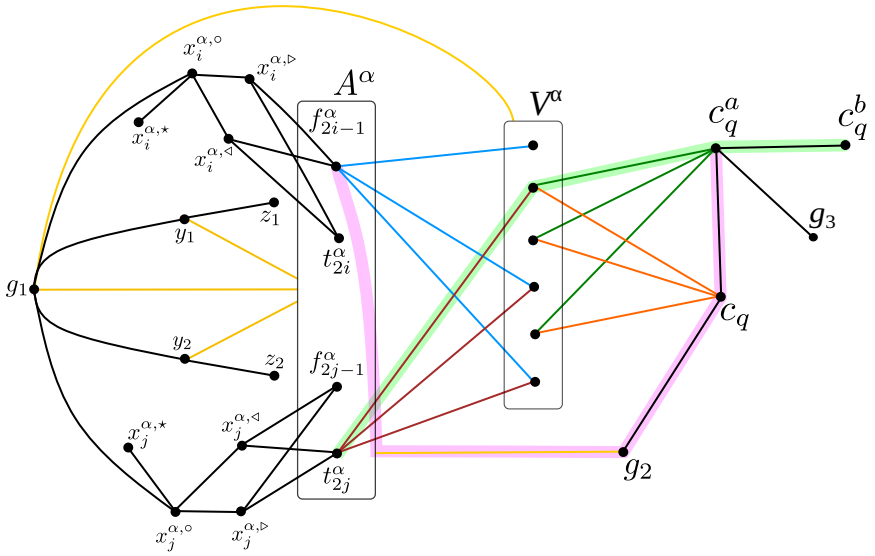

Figure 5 Overview of the reduction. We only draw A^α and V^α here, as A^β, A^γ, V^β, and V^γ are similar. The yellow lines joining g_1, g_2, y_1, and y_2 to sets indicate that the corresponding vertex is adjacent to all the vertices of the corresponding set. Suppose that f_{2i-1}^α and t_{2j}^α are in the geodetic set and $\overline{x}_i$ appears in the clause c_q. The thick green path is a shortest path between t_{2j}^α and c_q^b which does not cover c_q. The thick violet path plus the edge (c_q^a, c_q^b) is a shortest path between f_{2i-1}^α and c_q^b covering c_q.

idea is to design gadgets such that c_q is only covered by the shortest path from $a_{\phi(q)} \in A$ to c_q^b (c_q^b is forced to be chosen in the geodetic set) for any $q \in [m]$, while keeping the treewidth of this part of the graph of order $\mathcal{O}(\log(|A|))$. To do so, we create a "small" intermediate set V (of size $\mathcal{O}(\log(|A|))$) through which will go the shortest paths between vertices in A and C, and we connect a_i to the vertices of V corresponding to the bit-representation of $\mathsf{set\text{-}rep}(i)$, and c_q (with $i = \phi(q)$) to all the other vertices of V. In this way, the construction will ensure that c_q is covered by a shortest path between $a_{\phi(q)}$ and c_q^b, but is not covered by any other shortest path between a vertex of A and a vertex of C. We give the details in the following subsection.

3.2 Reduction

Consider an instance ψ of 3-Partitioned-3-SAT, with $X^\alpha, X^\beta, X^\gamma$ the partition of the variable set. From ψ, we construct the graph G as follows. We describe the construction of X^α, with the constructions for X^β and X^γ being analogous. See Figure 5 for an illustration. We rename the variables in X^α to x_i^α for $i \in [n]$.

- For every variable x_i^α, we add the vertices t_{2i}^α and f_{2i-1}^α. Formally, $A^\alpha = \{t_{2i}^\alpha, f_{2i-1}^\alpha \mid i \in [n]\}$, and hence, $|A^\alpha| = 2n$.
- For every variable x_i^α, we add four vertices: $x_i^{\alpha,\triangleleft}, x_i^{\alpha,\triangleright}, x_i^{\alpha,\circ}, x_i^{\alpha,\star}$. We make $x_i^{\alpha,\triangleleft}$ and $x_i^{\alpha,\triangleright}$ adjacent to both t_{2i}^α and f_{2i-1}^α. We make $x_i^{\alpha,\circ}$ adjacent to both $x_i^{\alpha,\triangleleft}$ and $x_i^{\alpha,\triangleright}$. We make $x_i^{\alpha,\star}$ adjacent to $x_i^{\alpha,\circ}$.
- We add the vertices y_1, y_2, z_1, z_2. We make y_1 and y_2 adjacent to every vertex of A^α. We make y_i adjacent to z_i for $i \in \{1, 2\}$. Note that y_1, y_2, z_1, z_2 are common to X^β and X^γ.
- We add the vertex g_1 and make it adjacent to y_1, y_2, and $x_i^{\alpha,\circ}$ for each $i \in [n]$. Note that g_1 is common to X^β and X^γ. We add edges between g_1 and every vertex of A^α.

- Let p be the smallest positive integer such that $2n \leq \binom{2p}{p}$. In particular, $p = \mathcal{O}(\log n)$. We add a *validation portal*, a clique on $2p$ vertices, denoted by $V^\alpha = \{v_1^\alpha, v_2^\alpha, \ldots, v_{2p}^\alpha\}$. For each $\delta \in \{\alpha, \beta, \gamma\}$, we add edges between g_1 and every vertex of V^δ.
- For every clause C_q in ψ, we introduce three vertices: c_q, c_q^a, c_q^b. We add the edges (c_q, c_q^a) and (c_q^a, c_q^b).
- Define $\mathsf{set\text{-}rep} : [2n] \mapsto \mathcal{F}_p$ as an arbitrary injective function, where $\mathcal{F}_p$ is the Sperner family (and p is as defined two items above). Add the edge $(t_{2i}^\alpha, v_{p'}^\alpha)$ for every $p' \in \mathsf{set\text{-}rep}(2i)$ and the edge $(f_{2i-1}^\alpha, v_{p'}^\alpha)$ for every $p' \in \mathsf{set\text{-}rep}(2i-1)$. If the variable x_i^α appears positively in the clause C_q, then we add the edges $(c_q, v_{p'}^\alpha)$ and $(c_q^a, v_{p'}^\alpha)$ for every $p' \in [2p] \setminus \mathsf{set\text{-}rep}(2i)$. If the variable x_i^α appears negatively in the clause C_q, then we add the edges $(c_q, v_{p'}^\alpha)$ and $(c_q^a, v_{p'}^\alpha)$ for every $p' \in [2p] \setminus \mathsf{set\text{-}rep}(2i-1)$.
- Add a vertex g_2 and make g_2 adjacent to every vertex of A^α and every vertex of $\{c_q : q \in [m]\}$. Note that g_2 is common to X^β and X^γ.
- Add a vertex g_3 and make it adjacent to every vertex of $\{c_q^a : q \in [m]\}$. Note that g_3 and the vertices of $\{c_q, c_q^a, c_q^b : q \in [m]\}$ are common to X^β and X^γ.

This concludes the construction of G. The reduction returns (G, k) as an instance of Geodetic Set where $k = 6n + m + 2$.

3.3 Correctness of the Reduction

Suppose, given an instance ψ of 3-Partitioned-3-SAT, that the reduction above returns (G, k) as an instance of Geodetic Set.

▶ **Lemma 4.** *If ψ is a satisfiable* 3-Partitioned-3-SAT *formula, then G admits a geodetic set of size k.*

Proof. Suppose that $\pi : X^\alpha \cup X^\beta \cup X^\gamma \mapsto \{\texttt{True}, \texttt{False}\}$ is a satisfying assignment for ψ. We construct a geodetic set S of size k for G using this assignment.

For every $\delta \in \{\alpha, \beta, \gamma\}$ and $i \in [n]$, if $\pi(x_i^\delta) = \texttt{True}$, then let $t_{2i}^\delta \in S$, and otherwise, $f_{2i-1}^\delta \in S$. We also put z_1, z_2, $x_i^{\delta,\star}$, and c_q^b into S for all $i \in [n]$, $\delta \in \{\alpha, \beta, \gamma\}$, and $q \in [m]$. Note that $|S| = k$.

Now, we show that S is indeed a geodetic set of G. First, y_1, y_2, z_1, z_2, g_1, and all the vertices of $A^\alpha, A^\beta, A^\gamma$ are covered by a shortest path between z_1 and z_2. Then, for each $\delta \in \{\alpha, \beta, \gamma\}$ and $i \in [n]$, $x_i^{\delta,\triangleleft}$, $x_i^{\delta,\triangleright}$, $x_i^{\delta,\circ}$, and $x_i^{\delta,\star}$ are covered by a shortest path between $S \cap \{t_{2i}^\delta, f_{2i-1}^\delta\}$ and $x_i^{\delta,\star}$. The vertex g_3 is covered by any shortest path between c_q^b and $c_{q'}^b$, where C_q and $C_{q'}$ are two clauses of ψ. Suppose that $\pi(x_i^\delta)$, for some $i \in [n]$ and $\delta \in \{\alpha, \beta, \gamma\}$, satisfies some clause C_q. By our construction, if x_i^δ appears positively (negatively, respectively) in C_q, then t_{2i}^δ (f_{2i-1}^δ, respectively) and c_q^b are at distance four since t_{2i}^δ (f_{2i-1}^δ, respectively) and c_q^a have no common neighbor in V^δ. Moreover, there is a shortest path from t_{2i}^δ (f_{2i-1}^δ, respectively) to c_q^b of length four, covering g_2, c_q, c_q^a, and c_q^b; there is also a shortest path from t_{2i}^δ (f_{2i-1}^δ, respectively) to c_q^b of length four, covering $v_j^\delta, v_h^\delta, c_q^a$, and c_q^b, where $v_j^\delta \in V^\delta$ is a vertex adjacent to t_{2i}^δ (f_{2i-1}^δ, respectively) and v_h^δ is any vertex of V^δ that is not adjacent to t_{2i}^δ (f_{2i-1}^δ, respectively). Thus, every vertex of V^δ for $\delta \in \{\alpha, \beta, \gamma\}$ is covered by a shortest path between two vertices of S. Since every clause of ψ is satisfied by π, it follows that every vertex of $\{c_q, c_q^a, c_q^b : q \in [m]\}$ is covered by a shortest path between two vertices of S. As a result, S is a geodetic set of G. ◀

▶ **Lemma 5.** *If G admits a geodetic set of size k, then ψ is a satisfiable* 3-Partitioned-3-SAT *formula.*

Proof. Suppose that G has a geodetic set S of size at most k. Since they all have degree 1, z_1, z_2, $x_i^{\delta,\star}$, and c_q^b for all $i \in [n]$, $\delta \in \{\alpha, \beta, \gamma\}$, and $q \in [m]$ must be in any geodetic set S of G.

▷ Claim 6. For each $i \in [n]$ and $\delta \in \{\alpha, \beta, \gamma\}$, exactly one of t_{2i}^δ and f_{2i-1}^δ must be in S.

Proof. Since S is a geodetic set, for each $i \in [n]$ and $\delta \in \{\alpha, \beta, \gamma\}$ $x_i^{\delta,\triangleleft}$ and $x_i^{\delta,\triangleright}$ must be covered by shortest paths between two vertices of S. If $t_{2i}^\delta \in S$ ($f_{2i-1}^\delta \in S$, respectively), $x_i^{\delta,\triangleleft}$ and $x_i^{\delta,\triangleright}$ are covered by shortest paths between $t_{2i}^\delta \in S$ ($f_{2i-1}^\delta \in S$, respectively) and $x_i^{\delta,\star}$. Suppose that, for some $i' \in [n]$ and $\delta' \in \{\alpha, \beta, \gamma\}$, neither of $t_{2i'}^{\delta'}$ and $f_{2i'-1}^{\delta'}$ is in S. Moreover, if neither of $x_{i'}^{\delta',\triangleleft}$ and $x_{i'}^{\delta',\triangleright}$ is in S, then, due to the edges incident with g_1, no vertices in S have a shortest path containing any of these two vertices. Similarly, if only one of $x_{i'}^{\delta',\triangleleft}$ and $x_{i'}^{\delta',\triangleright}$ is in S, then the other is not covered by S. Thus, if neither of $t_{2i'}^{\delta'}$ and $f_{2i'-1}^{\delta'}$ is in S, then both $x_{i'}^{\delta',\triangleleft}$ and $x_{i'}^{\delta',\triangleright}$ must be in S. Since $k - |\{z_1, z_2\} \cup \{x_i^{\delta,\star} : i \in [n], \delta \in \{\alpha, \beta, \gamma\}\} \cup \{c_q^b : q \in [m]\}| = 3n$, we conclude that exactly one of t_{2i}^δ and f_{2i-1}^δ must be in S for each $i \in [n]$ and $\delta \in \{\alpha, \beta, \gamma\}$. ◁

By Claim 6 and earlier arguments, we now have that $|S| = k$.

▷ Claim 7. For each $q \in [m]$, the vertex c_q is covered either by a shortest path between c_q^b and t_{2i}^δ, where the variable x_i^δ appears positively in the clause C_q, or by a shortest path between c_q^b and f_{2i-1}^δ, where the variable x_i^δ appears negatively in the clause C_q. Moreover, c_q is covered by no other type of shortest path between two vertices in S.

Proof. By the construction of G, if the variable x_i^δ appears positively in the clause C_q, then there is a shortest path from t_{2i}^δ to c_q^b of length four covering g_2, c_q, c_q^a, and c_q^b. If the variable x_i^δ appears negatively in the clause C_q, then there is a shortest path from f_{2i-1}^δ to c_q^b of length four covering g_2, c_q, c_q^a, and c_q^b.

Next, we show that c_q is not covered by any shortest path between any other two vertices of S. We can check that c_q is not covered by any of the shortest paths between z_1 and z_2, between z_j ($j \in \{1, 2\}$) and $x_i^{\delta,\star}$ ($i \in [n], \delta \in \{\alpha, \beta, \gamma\}$), and between z_j ($j \in \{1, 2\}$) and $S \cap \{t_{2i}^\delta, f_{2i-1}^\delta\}$ ($i \in [n], \delta \in \{\alpha, \beta, \gamma\}$). Note that any shortest path from z_j ($j \in \{1, 2\}$) to c_q^b ($q \in [m]$) is of length five, covering y_j, some vertex of A^δ ($\delta \in \{\alpha, \beta, \gamma\}$), some vertex of V^δ, c_q^a, and c_q^b.

We can check that c_q is not covered by any of the shortest paths between $x_i^{\delta,\star}$ and $x_{i'}^{\delta',\star}$ ($i, i' \in [n], \delta, \delta' \in \{\alpha, \beta, \gamma\}$), and between $x_i^{\delta,\star}$ and $S \cap \{t_{2i'}^{\delta'}, f_{2i'-1}^{\delta'}\}$ ($i, i' \in [n], \delta, \delta' \in \{\alpha, \beta, \gamma\}$). Note that any shortest path from $x_i^{\delta,\star}$ ($i \in [n], \delta \in \{\alpha, \beta, \gamma\}$) to c_q^b ($q \in [m]$) is of length five, covering $x_i^{\delta,\circ}$, g_1, some vertex of V^δ, c_q^a, and c_q^b.

Note that any shortest path between c_q^b and $c_{q'}^b$ ($q, q' \in [m]$) is of length four, covering c_q^a, g_3, and $c_{q'}^a$.

We can check that c_q is not covered by any shortest paths between $S \cap \{t_{2i}^\delta, f_{2i-1}^\delta\}$ and $S \cap \{t_{2i'}^{\delta'}, f_{2i'-1}^{\delta'}\}$ ($i, i' \in [n], \delta, \delta' \in \{\alpha, \beta, \gamma\}$).

If the variable x_i^δ does not appear positively in the clause C_q, then any shortest path between c_q^b and t_{2i}^δ is of length three (because c_q^a and t_{2i}^δ have a common neighbour in V^δ), covering some vertex of V^δ and c_q^a, but not c_q. Similarly, if x_i^δ does not appear negatively in C_q, then any shortest path between c_q^b and f_{2i-1}^δ is of length three and does not cover c_q.

By the case analysis above, the claim is true. ◁

By Claim 6, exactly one vertex of t_{2i}^δ and f_{2i-1}^δ belongs to S for each $i \in [n]$ and $\delta \in \{\alpha, \beta, \gamma\}$. We define an assignment π to the variables of ψ as follows. For each $i \in [n]$ and $\delta \in \{\alpha, \beta, \gamma\}$, if $t_{2i}^\delta \in S$, then $\pi(x_i^\delta) = \texttt{True}$. Otherwise, $\pi(x_i^\delta) = \texttt{False}$. Since S is a geodetic

set for G, every vertex c_q ($q \in [m]$) is covered by a shortest path between two vertices of S. By Claim 7, every vertex c_q ($q \in [m]$) is covered by a shortest path between $S \cap \{t^\delta_{2i}, f^\delta_{2i-1}\}$ and c^b_q, where the variable x^δ_i appears in the clause C_q. It follows that every clause C_q is satisfied by $\pi(x^\delta_i)$. As a result, ψ is a satisfiable 3-Partitioned-3-SAT formula. ◀

Proof of Theorem 3. First, it is not hard to check that the diameter of G is at most 5. Then, let $X = V^\alpha \cup V^\beta \cup V^\gamma \cup \{g_1, g_2, g_3, y_1, y_2\}$. We can check that every component of $G \setminus X$ has at most six vertices and $|X| = \mathcal{O}(\log n)$. Thus, the treewidth $\mathtt{tw}(G)$ – in fact, even the treedepth $\mathtt{td}(G)$ – of G is bounded by $\mathcal{O}(\log n)$. By the description of the reduction, it takes polynomial time to compute the reduced instance. Hence, if there is an algorithm for Geodetic Set that runs in time $2^{f(\mathtt{diam})^{o(\mathtt{tw})}}$ (or $2^{f(\mathtt{diam})^{o(\mathtt{td})}}$), then there is an algorithm running in time $2^{o(n)}$ for 3-Partitioned-3-SAT, which contradicts the ETH. ◀

4 Conclusion

We have shown (under the ETH) that three natural metric-based graph problems, Metric Dimension, Geodetic Set, and Strong Metric Dimension, exhibit tight (double-) exponential running times for the standard structural parameterizations by treewidth and vertex cover number. This includes tight double-exponential running times for treewidth plus diameter (Metric Dimension and Geodetic Set) and for vertex cover (Strong Metric Dimension).

Such tight double-exponential running times for FPT structural paramaterizations of graph problems had previously been observed only for counting problems and problems complete for classes above NP. Thus, surprisingly, our results show that some natural problems can be in NP and still exhibit such a behavior.

It would be interesting to see whether this phenomenon holds for other graph problems in NP, and for other structural parameterizations. Perhaps one can determine certain properties shared by these metric-based graph problems, that imply such running times, with the goal of generalizing our approach to a broader class of problems. In particular, concerning the general versatile technique that we designed to obtain the double-exponential lower bounds, it would be intriguing to see for which other problems in NP our technique works.

In fact, after this paper appeared online, our technique was successfully applied to an NP-complete problem in machine learning [11] (for vc) as well as NP-complete identification problems [10] (for tw).

Abstract

In the Directed Steiner Network problem, the input is a directed graph G, a set $T \subseteq V(G)$ of k terminals, and a demand graph D on T. The task is to find a subgraph $H \subseteq G$ with the minimum number of edges such that for every $(s,t) \in E(D)$, the solution H contains a directed $s \to t$ path. The goal of this paper is to investigate how the complexity of the problem depends on the demand pattern in *planar graphs*. Formally, if $\mathcal{D}$ is a class of directed graphs, then the $\mathcal{D}$-Steiner Network ($\mathcal{D}$-DSN) problem is the special case where the demand graph D is restricted to be from $\mathcal{D}$. We give a complete characterization of the behavior of every $\mathcal{D}$-DSN problem on planar graphs. We classify every class $\mathcal{D}$ closed under transitive equivalence and identification of vertices into three cases: assuming ETH, either the problem is

1. solvable in time $2^{O(k)} \cdot n^{O(1)}$, i.e., FPT parameterized by the number k of terminals, but not solvable in time $2^{o(k)} \cdot n^{O(1)}$,
2. solvable in time $f(k) \cdot n^{O(\sqrt{k})}$, but cannot be solved in time $f(k) \cdot n^{o(\sqrt{k})}$, or
3. solvable in time $f(k) \cdot n^{O(k)}$, but cannot be solved in time $f(k) \cdot n^{o(k)}$.

Our result is a far-reaching generalization and unification of earlier results on Directed Steiner Tree, Directed Steiner Network, and Strongly Connected Steiner Subgraph on planar graphs. As an important step of our lower bound proof, we discover a rare example of a genuinely planar problem (i.e., described by a planar graph and two sets of vertices) that cannot be solved in time $f(k) \cdot n^{o(k)}$: given two sets of terminals S and T with $|S| + |T| = k$, find a subgraph with minimum number of edges such that every vertex of T is reachable from every vertex of S.

1 Introduction

Finding Steiner trees and related network design problems were intensively studied in undirected graphs, directed graphs, and planar graphs, from the viewpoint of approximation and parameterized algorithms [1–3, 5–8, 11–14, 17–19, 22, 23, 25, 27, 29, 31–33]. The simplest problem of this type is Steiner Tree, where given an undirected graph G and set $T \subseteq V(G)$ of terminals, the task is to find a tree with smallest number of edges that contains every

terminal. This problem models a network-design scenario where the terminals need to be connected to each other with a network of minimum cost. Steiner Forest is the generalization where we do not require connection between every pair of terminals, but have to satisfy a given set of demands. Formally, the input of Steiner Forest is a graph G with pairs of vertices $(s_1, t_1), \ldots, (s_d, t_d)$, the task is to find a subgraph with the minimum number of edges that satisfies every request, that is, s_i and t_i are in the same component of the solution for every $i \in [d]$.

On directed graphs, Directed Steiner Tree (DST) is defined by specifying one of the terminals in T to be the root and the task is to find a subgraph with the smallest number of edges such that there is a path from the root to every terminal in the solution. This problem models a scenario where we need to construct a network where the root can broadcast to every other terminal. An equally natural network design problem on directed graphs is the Strongly Connected Steiner Subgraph (SCSS) problem, where given a directed graph G and a set $T \subseteq V(G)$ of terminals, the task is to find a subgraph with the smallest number of edges where T is in a single strongly connected component, or in other words, the solution contains a path from every terminal to every other terminal. The directed variant of Steiner Forest generalizes both of these problems: in Directed Steiner Network (DSN), the input is a digraph G with pairs of vertices $(s_1, t_1), \ldots, (s_d, t_d)$, and the task is to find a subgraph with the minimum number of edges that has an $s_i \to t_i$ path for every $i \in [d]$.

Planar graphs. A well-known phenomenon on planar graphs is that the running time of parameterized algorithms for typical NP-hard problems have exponential dependence on $O(\sqrt{k})$, where k is the parameter, and this dependence is best possible assuming the Exponential-Time Hypothesis (ETH) [8–10, 15, 20, 21, 24, 26–28, 30]. All three of DST, SCSS, and DSN remain NP-hard on planar graphs. However, they behave very differently from the viewpoint of parameterized complexity: the dependence of the running time on the number k of terminals is very different.

Our starting point

1. Planar DST can be solved in time $2^k \cdot n^{O(1)}$ [4], but cannot be solved in time $2^{o(k)} \cdot n^{O(1)}$ [27], assuming the ETH.
2. Planar SCSS can be solved in time $2^{O(k \log k)} \cdot n^{O(\sqrt{k})}$ [8], but has no algorithm with running time $f(k) \cdot n^{o(\sqrt{k})}$ for any function f, assuming the ETH [8].
3. Planar DSN can be solved in time $f(k) \cdot n^{O(k)}$ [12], but has no algorithm with running time $f(k) \cdot n^{o(k)}$ for any function f, assuming the ETH [8].

Using the terminology of parameterized complexity, Planar DST is *fixed-parameter tractable (FPT)* parameterized by the number k of terminals, but does not admit a *subexponential* FPT algorithm, assuming the ETH. For Planar SCSS and Planar DSN, it is already a highly nontrivial result to show that there is an algorithm that runs in polynomial time for fixed values of k; such an algorithm is called an *XP algorithm*. Furthermore, Planar SCSS admits a *subexponential* XP algorithm (i.e., the exponent of n is $o(k)$), while Planar DSN has no such algorithm, assuming the ETH.

As these results show, there has been significant interest in parameterized directed connectivity problems on planar graphs and in particular tight bounds were obtained for the three problems Planar DST, Planar SCSS, Planar DSN. But what can we say about other natural variants of connectivity requirements? For example, already with the simple extension that the input contains two sets of terminals T_1 and T_2, we can define three different natural connectivity requirements:

(1) The solution has to contain a directed path from any $t \in T_i$ to any $t' \in T_i$.
(2) The solution has to contain a directed path from any $t \in T_1$ to any $t' \in T_1 \cup T_2$.
(3) The solution has to contain a directed path from any $t \in T_1$ to any $t' \in T_2$.

Do these problems behave similarly to one of the three problems listed above? The goal of this paper is to answer such questions by putting the previous results into the context of a wider landscape of directed network design problems. We systematically explore other special cases of Planar DSN and determine their behavior on planar graphs. Our main result is showing that every special case defined in a formal setting behaves similarly to one of the three problems Planar DST, Planar SCSS, Planar DSN: assuming the ETH, the best possible running time is of the form $2^{O(k)} \cdot n^{O(1)}$, $f(k) \cdot n^{O(\sqrt{k})}$, or $f(k) \cdot n^{O(k)}$. Furthermore, we provide an exact combinatorial characterization of the problems belonging to the three classes. In particular, we can use these results to show that variants (1) and (2) behave similarly to Planar SCSS, while variant (3) behaves similarly to Planar DSN. Therefore, (3) is a rare (perhaps first) example of a planar problem with k terminals where the best possible running time is $n^{O(k)}$ and the input can be described in a purely planar way (by the two sets T_1 and T_2) that does not contain any extra information violating the planarity of the instance. This is in stark contrast with the general Planar DSN problem, where the lower bound showing the optimality of the $n^{O(k)}$ running time requires that the input contain an arbitary list of pairs of vertices, giving a highly nonplanar input.

Dichotomy for general graphs. We explore the different special cases of Directed Steiner Network on planar graphs in a framework similar to how Feldmann and Marx [14] treated the problem on general graphs. We can define various special cases of Directed Steiner Network by looking at what kind of graph the connection demands define on the terminals: it is an out-star for Directed Steiner Tree, a bidirected clique for Strongly Connected Steiner Subgraph, and a matching for Directed Steiner Network. More generally, for every class $\mathcal{D}$ of directed graphs, we investigate the problem where the pattern of demands has to belong to the class $\mathcal{D}$. Our goal is to understand how the graph-theoretic properties of the members of $\mathcal{D}$ influence the resulting special case of Directed Steiner Network.

Formally, for every class $\mathcal{D}$, Feldmann and Marx [14] defined the restriction of the problem in the following way.

$\mathcal{D}$-Steiner Network
Input: Digraph G, a set of k terminals $T \subseteq V(G)$, and a demand digraph $D \in \mathcal{D}$ with vertex set T.
Question: What is the minimum number of edges in a subgraph H of G where for each $(u, v) \in E(D)$ there is a $u \to v$ path in H?

One can define also the weighted version of the problem: the input contains weights on the edges and the goal is to minimize the total weight of the subgraph H. Typically, the weighted generalization does not make the problem harder (polynomially bounded integer weights can be easily simulated by subdivided edges, but the algorithmic results in this paper and earlier work allows integer weights in binary as well). Feldmann and Marx [14] characterized those classes $\mathcal{D}$ where $\mathcal{D}$-Steiner Network is fixed-parameter tractable (FPT) parameterized by the number of terminals, that is, can be solved in time $f(k) \cdot n^{O(1)}$. The characterization can be stated in a clean way in terms of five hard families of patterns if we observe the following closure properties of the problem. Observe first that only the transitive closure of D matters for the problem: if D_1 and D_2 have the same transitive closure, then having D_1 or D_2 in the

input results in exactly the same problem. Therefore, it makes sense to consider only classes $\mathcal{D}$ that are *closed under transitive equivalence,* that is, if D_1 and D_2 have the same transitive closure and $D_1 \in \mathcal{D}$, then $D_2 \in \mathcal{D}$ as well. Moreover, we may assume that $\mathcal{D}$ is *closed under identifying vertices:* that is, if $G \in \mathcal{D}$ and G' is obtained by merging two vertices $x, y \in V(G)$ to a single vertex whose in- and out-neighbors are the union of the in- and out-neighbors of x and y, respectively, then G' is also in $\mathcal{D}$. Feldmann and Marx [14, Lemma 5.2] showed that if $\mathcal{D}$-Steiner Network is FPT, then it is FPT also for the closure $\mathcal{D}'$ of $\mathcal{D}$ under identifying vertices, that is, adding further demand patterns obtained by identifying vertices does not make the problem any harder. Intuitively, if D' is obtained from $D \in \mathcal{D}$ by identifying x and y to w, then an instance with demand pattern D' can be simulated by an instance with demand pattern D if we replace w with the two terminals x and y connected by 0-weight edges in both direction (or something similar in case of unweighted graphs[1]).

These arguments show that it is sufficient to obtain a characterization for classes closed under transitive equivalence and identifying vertices. Under these assumptions, Feldmann and Marx [14] identified five graph classes that prevent the problem from being FPT. A *pure out-diamond* is a complete bipartite graph $K_{2,t}$ directed from the 2-element side to the t-element side. A *flawed out-diamond* has in addition a vertex v and edges going from v to the 2-element side. The pure in-diamond and flawed in-diamond are defined similarly by reversing edge orientations. Let us denote by $\mathcal{A}_1$, $\mathcal{A}_2$, ..., $\mathcal{A}_5$ the class of all pure out-diamonds, flawed out-diamonds, pure in-diamonds, flawed in-diamonds, and directed cycles, respectively.

▶ **Theorem 1** (Feldmann and Marx [14]). *Let $\mathcal{D}$ be a class of graphs closed under transitive equivalence and identifying vertices.*

1. ***FPT:*** *If $\mathcal{A}_i \not\subseteq \mathcal{D}$ for any $i \in [5]$, then $\mathcal{D}$-Steiner Network can be solved in time $2^{O(k)}n^{O(1)}$, where k is the number of terminals.*
2. ***Hard:*** *If $\mathcal{A}_i \subseteq \mathcal{D}$ for some $i \in [5]$, then $\mathcal{D}$-Steiner Network is W[1]-hard parameterized by the number k of terminals.*

The first part of Theorem 1 was proved by a combination of an algorithm that solves the problem in time $2^{O(kw \log w)} \cdot n^{O(w)}$ if there is an optimum solution with treewidth w and a combinatorial result showing that if $\mathcal{D}$ is not the superset of $\mathcal{A}_i$ for any $i \in [5]$, then there is a constant bound on the treewidth of optimum solutions. The second part follows from a W[1]-hardness result for each of the five classes $\mathcal{A}_i$.

Our result: trichotomy for planar graphs. Our main result classifies Planar $\mathcal{D}$-Steiner Network (the special case of the problem restricted to planar digraphs G) into three levels of complexity: $2^{O(k)} \cdot n^{O(1)}$, $f(k) \cdot n^{O(\sqrt{k})}$, or $f(k) \cdot n^{O(k)}$ time. In light of Theorem 1 and the earlier results on planar graphs, there are three natural questions that arise:

1. Are there cases that are FPT on planar graphs, but W[1]-hard on general graphs?
2. Are there subexponential FPT cases on planar graphs, that is, where the running time is $2^{o(k)} \cdot n^{O(1)}$?
3. Are there W[1]-hard cases where the optimal running time is neither $f(k) \cdot n^{O(\sqrt{k})}$ nor $f(k) \cdot n^{O(k)}$? If not, where is the boundary line between these two cases?

[1] As mentioned above, polynomially bounded integer weights can be simulated by subdivision of edges. If there are C edges of weight 0, then let us consider every original weight-1 edge to have weight $C+1$ (i.e., a path of length $C+1$) and every weight-0 to have weight 1. Then the original instance has a solution of weight at most x if and only if the new instance has a solution of weight at most $x(C+1)+C$.

We answer the first question negatively: the hard cases remain hard on planar graphs. The answer to the second question is also negative: we show that every (nontrivial) case of Planar $\mathcal{D}$-DSN is at least as hard as Directed Steiner Tree, hence a known lower bound [27] shows that there is no subexponential FPT algorithm, assuming the ETH.

The answer to the third question is positive, but arguably for the wrong reason. Consider the following artificial case. Let $\mathcal{D} = \{D_1, D_2, \dots\}$ be defined the following way: D_i consists of the disjoint union of an out-star of i edges and a directed matching of $\lceil \log_2 i \rceil$ edges. Using the results of Feldmann and Marx [14, Theorems 1.4 and 1.5], it can be shown that Planar $\mathcal{D}$-DSN is solvable in time $f(k)n^{O(\log k)}$, as the graph D_i can be interpreted as a "1-caterpillar with $\lceil \log_2 i \rceil$ extra edges" (see the definition in [14]) and hence there is an optimum solution of treewidth $O(\log k)$. On the other hand, a Planar DSN problem with $\lceil \log_2 i \rceil$ terminal pairs can be reduced to Planar $\mathcal{D}$-DSN with pattern D_i: we can effectively "ignore" the terminals in the out-star by putting these terminals on a directed cycle of 0-weight edges. Thus the lower bound ruling out $f(k)n^{o(k)}$ algorithms for Planar DSN [8] translates into a lower bound ruling out $f(k)n^{o(\log k)}$ algorithms for Planar $\mathcal{D}$-DSN, assuming the ETH. Therefore, the optimal exponent of n in the running time is $O(\log k)$. This is somewhat counterintuitive: as there is a simple reduction from Planar DSN to Planar $\mathcal{D}$-DSN, it feels that the latter problem should be harder. Formally, however, this is not the case: the reduction introduced a new, irrelevant, trivial part of the problem (the terminals on the cycle of 0-weight edges), which increased the parameter significantly.

One could argue that such trivial features of the instance should not influence the way we measure the complexity of the problem. Terminals that are in the same strongly connected component of 0-weight edges can be effectively treated as a single terminal. Therefore, instead of the parameter k being the number of terminals, one could consider the parameter to be the number of strongly connected components of the 0-weight edges that contain terminals, or in other words, the number of terminals after contracting every directed cycle of weight 0. With this parameterization, the reduction from Planar DSN increases the parameter only by 1 and shows that Planar $\mathcal{D}$-DSN has no $f(k)n^{o(k)}$ time algorithm, satisfying the expectation that the problem should be at least as hard as Planar DSN. Equivalently, we can consider the closure $\mathcal{D}'$ of $\mathcal{D}$ under identifying vertices: then $\mathcal{D}'$ contains every directed matching, hence the problem is clearly at least as hard as Planar SCSS. Assuming that the pattern class $\mathcal{D}$ is closed under identifying vertices is a clean way of formalizing the intention that we want to consider terminals in a strongly connected component of weight-0 edges as a single terminal that contributes only 1 to the parameter. In order to obtain meaningful classifications, we assume in the rest of the paper that the class of patterns has this closure property. This way, we avoid pathological examples similar to the one described above.

Under the assumption that $\mathcal{D}$ is closed under transitive equivalence and identifying vertices, we can answer the third question in the negative and map the boundary line between the $f(k)\cdot n^{O(\sqrt{k})}$ and the $f(k)\cdot n^{O(k)}$ cases. We define a finite number $\kappa \leq 300000$ of classes $\mathcal{C}_i$, $i \in [\kappa]$, and show that these are precisely the classes of patterns that prevent subexponential $f(k) \cdot n^{O(\sqrt{k})}$ time algorithms. Note that for every $i \in [\kappa]$, it is easy to show that arbitrary large strongly connected graphs can be obtained from $\mathcal{C}_i$ by identifying vertices. That is, if $\mathcal{D}$ is closed under transitive equivalence and identifying vertices, and $\mathcal{C}_i \subseteq \mathcal{D}$, then $\mathcal{A}_5 \subseteq \mathcal{C}_i \subseteq \mathcal{D}$, i.e., $\mathcal{D}$ contains every directed cycle. Thus we have three different cases depending on whether $\mathcal{D}$ contains (1) none of the $\mathcal{A}_i$'s, (2) some $\mathcal{A}_i$, but no $\mathcal{C}_i$, or (3) some $\mathcal{C}_i$.

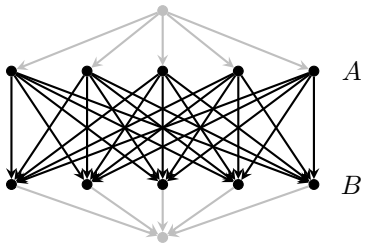

Figure 1 The 5-hard biclique patterns: each gray vertex may or may not be present.

Our main result

▶ **Theorem 2.** *Let $\mathcal{D}$ be a class of directed graphs closed under transitive equivalence and identifying vertices where the number of edges is not bounded.*

1. ***FPT:*** *If $\mathcal{A}_i \not\subseteq \mathcal{D}$ for any $i \in [5]$, then* Planar $\mathcal{D}$-Steiner Network
   - **(i)** *can be solved in time $2^{O(k)} \cdot n^{O(1)}$,*
   - **(ii)** *but has no $2^{o(k)} \cdot n^{O(1)}$ time algorithm assuming the ETH.*
2. ***Subexponential XP:*** *If $\mathcal{A}_i \subseteq \mathcal{D}$ for some $i \in [5]$, but $\mathcal{C}_i \not\subseteq \mathcal{D}$ for any $i \in [\kappa]$, then* Planar $\mathcal{D}$-Steiner Network
   - **(iii)** *can be solved in time $f(k) \cdot n^{O(\sqrt{k})}$,*
   - **(iv)** *but has no $f(k) \cdot n^{o(\sqrt{k})}$ time algorithm assuming the ETH.*
3. ***Hard XP:*** *If $\mathcal{C}_i \subseteq \mathcal{D}$ for some $i \in [\kappa]$, then* Planar $\mathcal{D}$-Steiner Network
   - **(v)** *can be solved in time $f(k) \cdot n^{O(k)}$,*
   - **(vi)** *but has no $f(k) \cdot n^{o(k)}$ time algorithm assuming the ETH.*

We remark that the algorithms work also for weighted graphs, while the lower bounds hold already for unweighted graphs.

Hard classes. Let us define now the graph classes $\mathcal{C}_i$ representing the hard-patterns. Given a digraph G and a set $X \subseteq V(G)$, an *X-source* is a vertex $s \in V(G) \setminus X$ such that $N^+(s) = X$. Similarly, an *X-sink* is a vertex $t \in V(G) \setminus X$ such that $N^-(t) = X$. The first 4 classes $\mathcal{C}_1$, $\ldots$, $\mathcal{C}_4$ are defined by extending a biclique.

▶ **Definition 3** (t-hard-biclique-pattern). *A* t-hard-biclique-pattern *is an (acyclic) digraph D constructed in the following way. We start with two disjoint sets A and B with $|A| = |B| = t$ and introduce every edge from A to B. Furthermore, we introduce into D any combination of the following items (see Figure 1):*

1. *an A-source;*
2. *a B-sink.*

In particular, there are $2 \cdot 2$ types of t-hard-biclique patterns: we let $\mathcal{C}_1, \ldots, \mathcal{C}_4$ be the 4 classes that each contain all the t-hard-biclique-patterns of a specific type for every t.

The following definition specifies the remaining classes.

▶ **Definition 4** (t-hard-matching-pattern). *A* t-hard-matching-pattern *is an (acyclic) digraph D constructed the following way. We start with disjoint vertex sets $W = \{w_1, \ldots, w_t\}$, $X = \{x_1, \ldots, x_t\}$, $Y = \{y_1, \ldots, y_t\}$ and $Z = \{z_1, \ldots, z_t\}$ and introduce the edges $w_i x_i$ and $y_i z_i$ for every $i \in [t]$. Furthermore, we introduce into D any combination of the following items:*

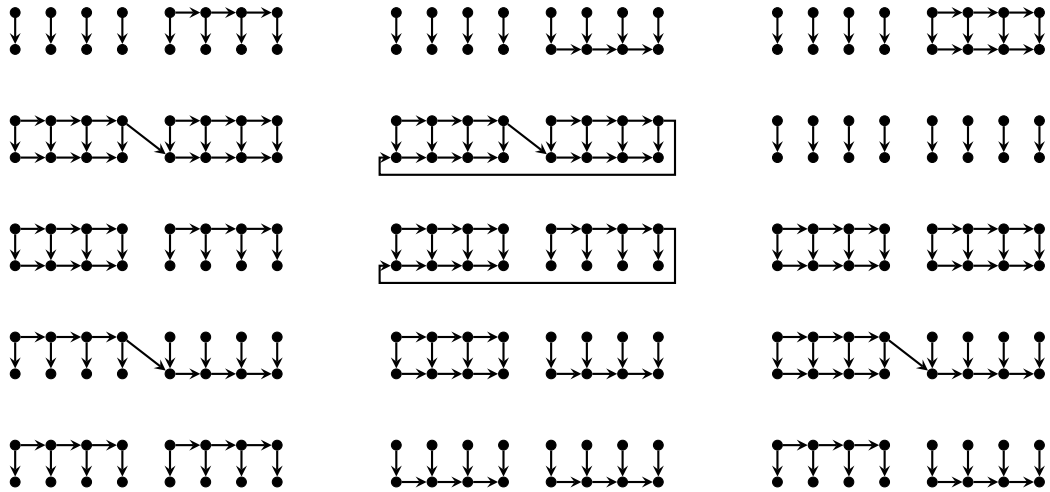

Figure 2 The 4-hard matching patterns (without source, sink, r_{WZ}, or r_{YX}).

1. *either the directed path* $w_1 \to w_2 \to \ldots \to w_t \to z_1 \to z_2 \to \ldots \to z_t$*, or any of the directed paths* $w_1 \to w_2 \to \ldots \to w_t$ *and* $z_1 \to z_2 \to \ldots \to z_t$*;*
2. *either the directed path* $y_1 \to y_2 \to \ldots \to y_t \to x_1 \to x_2 \to \ldots \to x_t$*, or any of the directed paths* $x_1 \to x_2 \to \ldots \to x_t$ *and* $y_1 \to y_2 \to \ldots \to y_t$*;*
3. *a vertex* s *such that for exactly one* $S \in \{W, X, Y, Z, W \cup Y, X \cup Z, X \cup Y, W \cup Z\}$*,* $N^+(s) \cap (W \cup X \cup Y \cup Z) = S$*;*
4. *a vertex* t *such that for exactly one* $S \in \{W, X, Y, Z, W \cup Y, X \cup Z, X \cup Y, W \cup Z\}$*,* $N^-(t) \cap (W \cup X \cup Y \cup Z) = S$*;*
5. *a vertex* r_{WZ} *such that* $N^-(r_{WZ}) \setminus \{s\} = W$ *and* $N^+(r_{WZ}) \setminus \{t\} = Z$*;*
6. *a vertex* r_{YX} *such that* $N^-(r_{YX}) \setminus \{s\} = Y$ *and* $N^+(r_{YX}) \setminus \{t\} = X$*;*
7. *arc* $s \to r_{WZ}$ *if* $N^+(s) \cap W = \emptyset$*, or arc* $s \to r_{YX}$ *if* $N^+(s) \cap Y = \emptyset$*, or both if* $N^+(s) \cap (W \cup Y) = \emptyset$*;*
8. *arc* $r_{WZ} \to t$ *if* $N^-(t) \cap Z = \emptyset$*, or arc* $r_{YX} \to t$ *if* $N^-(t) \cap X = \emptyset$*, or both if* $N^-(t) \cap (Z \cup X) = \emptyset$
9. *arc* $s \to t$ *if* s *cannot already reach* t*.*

In particular, there are less than $5 \cdot 5 \cdot 9 \cdot 9 \cdot 2 \cdot 2 \cdot 4 \cdot 4 \cdot 2$ *types of* t*-hard matching patterns: we let* $\mathcal{C}_5, \ldots, \mathcal{C}_\kappa$ *, where* $\kappa \leq 259200$*, be the classes that each contain all the* t*-hard-matching-patterns of a specific type for every* t*.*

Note that some of these classes are isomorphic. For example, adding the path $x_1 \to x_t$ or the path $z_1 \to z_t$ lead to isomorphic graphs. If we just consider the graph classes where we choose not to add a source, sink, vertex r_{WZ}, or vertex r_{YX}, then we have 15 non-isomorphic classes, as shown in Figure 2. One could think of t-hard-matching-patterns as (the transitive closure of) one of these graphs, potentially extended by appropriate sources, sinks, and r_{WZ}/r_{YX} vertices.

Finally, we define a t-hard pattern as any of the patterns defined above.

▶ **Definition 5** (t-hard-pattern). *A* t-hard-pattern *is either a* t*-hard-biclique-pattern or* t*-hard-matching-pattern, that is, a pattern that belongs to one of the* κ *classes* $\mathcal{C}_1, \ldots, \mathcal{C}_\kappa$ *defined in Definitions 3 and 4.*

1.1 Overview of our main result

Observe that Theorem 2 consists of six statements. Let us briefly discuss how these six statements are proved. Note that some of these statements follow from known results, while for others we need to do a substantial amount of new technical work. The proofs of statements (iii) and (vi) form the main technical part of the paper (see Figure 4).

The main problem studied in this paper, obtaining tight upper and lower bounds for different families of network design problems, is a genuine computer science question. Due to the nature of the question we are asking, our results are at the intersection of computational complexity, algorithms, and combinatorics (graph theory). The lower bounds are obtained using the standard method of computational complexity: by reductions from problems for which (conditional) lower bounds were already established. In particular, we are using the known lower bounds for Planar DSN and Planar SCSS on planar graphs [8]. However, the majority of the hardness proofs we present contain significant new ideas, new gadget constructions, and use new non-obvious global structures when connecting the gadgets.

The upper bounds are obtained using an algorithm of Feldmann and Marx [14] (see Theorem 7 below) solving the problem in time depending on the treewidth of an optimum solution. Therefore, in this paper the main technical effort is spent on the combinatorial question of bounding the treewidth of optimum solutions. Our proof uses planarity in a geometric way (arguing about faces, invoking Sperner's Lemma, etc.) and hence completely different from earlier proofs that relied only on bidimensionality of planar graphs [8]. The treewidth-based algorithm offers an abstraction that allows us to treat the upper bounds in a clean, modular manner. Thus we can focus our efforts on understanding the patterns that allow faster solutions, without having to develop details of algorithmic steps.

Furthermore, we have the purely combinatorial task of connecting the obstructions that prevent the treewidth upper bound and the hard structures. In the full version [16], we establish this connection with a heavy use of case analysis and Ramsey-theoretical arguments. The type and amount of combinatorial effort is very different from what was needed in earlier work on general graphs [14], where more elementary arguments were sufficient.

Statement (i): FPT algorithms

The FPT result (i) follows directly from Theorem 1 (here the surprising aspect is that, by statement (iv), there are no further FPT cases).

Statement (ii): no subexponential FPT algorithms

The lower bound (ii) follows by observing that every relevant class contains either all in-stars or all out-stars, hence the lower bound for Directed Steiner Tree [27] applies. To avoid triviality, we need to assume that the class contains graphs with arbitrarily large number of edges.

▶ **Lemma 6.** *Let $\mathcal{D}$ be a class of graphs closed under identifying vertices and transitive closure where the number of edges of the graphs is not bounded. Then one of the following holds:*

- *$\mathcal{D}$ contains every directed cycle,*
- *$\mathcal{D}$ contains every out-star, or*
- *$\mathcal{D}$ contains every in-star.*

In statement (ii) of Theorem 2, we assume that $\mathcal{A}_i \not\subseteq \mathcal{D}$, and $\mathcal{A}_5$ is the class of all directed cycles. Thus $\mathcal{D}$ contains either every out-star or every in-star.

Statement (iii): $f(k)n^{O(\sqrt{k})}$ algorithms

Our main technical result is proving statement (iii): the existence of an $f(k) \cdot n^{O(\sqrt{k})}$ time algorithm if $\mathcal{C}_i \not\subseteq \mathcal{D}$ for any $i \in [\kappa]$ (in the following subsection, we give a more detailed description of the proof). This algorithm is obtained by showing that the treewidth of the optimal solution is always $O(\sqrt{k})$ under these conditions. Then we can use the following result of Feldmann and Marx [14].

▶ **Theorem 7** (Theorem 1.5 of [14]). *If an instance (G, T, D) of* Directed Steiner Network *has an optimum solution H of treewidth w, then it can be solved in $2^{O(kw \log w)} \cdot n^{O(w)}$ time.*

Note that this is a slightly weaker form of the statement, with a simplified bound on the running time. With Theorem 7 at hand, our main goal is to prove that every optimum solution of Planar $\mathcal{D}$-DSN has treewidth $O(\sqrt{k})$ if $\mathcal{C}_i \not\subseteq \mathcal{D}$ for any $i \in [\kappa]$.

Towards proving this bound, we first translate the question to a problem on acyclic graphs: it is sufficient to show that if the solution is acyclic, then the total degree of the branch vertices (i.e., of degree > 2) is $O(k)$. More formally, for a vertex v of a digraph, let $d^*(v)$ denote the *branch degree* of v, defined as

$$d^*(v) = \max(d^+(v) + d^-(v) - 2, 0),$$

where $d^+(v)$ and $d^-(v)$ denotes the out- and in-degree of v, respectively. The total branch degree of a graph G is the sum of all branch degrees of the vertices of G.

We say that a feasible solution H of (G, T, D) is *edge-minimal* if for all edges $e \in E(H)$ the graph $H - e$ is not feasible. An edge e is *essential* for some demand edge $(t, t') \in E(D)$ if there is no $t \to t'$ path in $H - e$. Note that all edges of an edge-minimal graph H are essential for some demand edge of D. We say that a pattern class $\mathcal{D}$ is *c-acyclic-bounded* for some $c = O(1)$ if for any instance (G, T, D) of Planar $\mathcal{D}$-Steiner Network where G, D are acyclic, and any edge-minimal solution H, the total branch degree of H is at most $c|T|$.

The next theorem moves the problem to the domain of acyclic digraphs: what we need now is a linear bound on the total branch degree of acyclic solutions.

▶ **Theorem 8.** *If the pattern class $\mathcal{D}$ is c-acyclic-bounded for some $c = O(1)$, then for any instance of* Planar $\mathcal{D}$-Steiner Network *with $|T| = k$, the solution graph H has treewidth $O(\sqrt{k})$.*

Applying Theorem 7 implies that c-acyclic-bounded classes have the desired subexponential algorithm, but we still need to establish a link between non-c-acyclic-bounded classes and t-hard-patterns. First, we argue that if the total branch degree is too large, then a grid-like structure can be found in the solution. The grid-like structure appears in the solution to satisfy a set of edges in the demand graph D, and this set of demands forms a certain hard structure in the demand pattern that we call a t-tough-pair which we define informally here (see Definition 14 for a formal definition). We say that two edges e_1 and e_2 are *weakly independent* if there is no directed path from the head of one to the tail of the other. Edges e_1 and e_2 are *strongly independent* if, in addition to being weakly independent, there is no directed path containing the heads of both edges and there is no directed path containing the tails of both edges. An edge e is *minimal* in a digraph D if there is no path from the tail of e to the head of e avoiding e. Let $E_1 \cup E_2$ be a vertex-disjoint set of minimal edges with $|E_1| = |E_2| = t$. We say that (E_1, E_2) is a *t-tough-pair* if

- any two edges $e, e' \in E_1$ are weakly independent,
- any two edges $e, e' \in E_2$ are weakly independent, and
- any two edges $e_1 \in E_1$ and $e_2 \in E_2$ are strongly independent.

Observe that in particular the two matchings in a t-hard-matching-pattern form (vertical edges in Figure 2) a t-tough-pair. Similarly, taking two vertex-disjoint matchings of size t each in a $2t$-hard-biclique-pattern is also a t-tough-pair.

Our main structure theorem connects the total branch degree to the existence of these kind of hard structures.

▶ **Theorem 9** (Structure Theorem). *Let $\mathcal{D}$ be a class of graphs closed under identifying vertices and transitive equivalence. Then either $\mathcal{D}$ has a pattern with a t-tough-pair for each positive integer t, or it is c-acyclic-bounded for some constant c.*

Theorems 8 and Theorem 9 show that the existence of arbitrarily large t-tough-pairs is the canonical reason why the treewidth is not $O(\sqrt{k})$. The lower bounds ruling out $f(k) \cdot n^{o(k)}$ time algorithms essentially rely on the existence of t-tough-pairs. However, the existence of a t-tough-pair in a demand pattern $D \in \mathcal{D}$ is not sufficient for the lower bound: the t-tough-pair could be only a small part of the pattern D, and hence the lower bounds may not apply. We show, with heavy use of Ramsey's Theorem and other combinatorial arguments, that whenever a large t-tough-pair appears in a graph, then the graph can be "cleaned": we can identify vertices to obtain one of the t-hard-patterns. Therefore, if arbitrary large t-tough-pairs appear in the members of a class $\mathcal{D}$ closed under identifying vertices, then the class is a superset of one of the hard classes $\mathcal{C}_i$.

▶ **Theorem 10.** *Let $\mathcal{D}$ be a class of graphs closed under transitive equivalence and identifying vertices. The following two are equivalent:*

1. *For every t, there is a $D \in \mathcal{D}$ that has a t-tough pair.*
2. *$\mathcal{C}_i \subseteq \mathcal{D}$ for some $i \in [\kappa]$.*

We can conclude that if $\mathcal{D}$ is not the superset of $\mathcal{C}_i$ for any $i \in [\kappa]$, then the treewidth of the optimum solution is $O(\sqrt{k})$, implying that Planar $\mathcal{D}$-DSN can be solved in time $f(k) \cdot n^{O(\sqrt{k})}$.

Statement (iv): no $f(k)n^{o(\sqrt{k})}$ algorithms

If $\mathcal{D}$ contains $\mathcal{A}_5$ (directed cycles), then lower bounds ruling out $f(k) \cdot n^{o(\sqrt{k})}$ time algorithms follow from the known lower bound for Strongly Connected Steiner Subgraph [8]. When $\mathcal{D}$ contains one of $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3, \mathcal{A}_4$ (pure or flawed dimonds), the problem is known to be W[1]-hard on general graphs [14]. We reprove the hardness of diamonds, this time restricted to planar graphs, and observe that this W[1]-hardness proof actually rules out $f(k) \cdot n^{o(\sqrt{k})}$ time algorithms. Compared to the W[1]-hardness on general graphs, the proof for planar graphs is more involved. As it is very usual for planar problems, we establish these lower bounds by reducing from $k \times k$-Grid Tiling, which cannot be solved in time $f(k) \cdot n^{o(k)}$, assuming the ETH [9]. For statement (iv), we need to reduce from $\sqrt{k} \times \sqrt{k}$ Grid Tiling to a Planar $\mathcal{D}$-DSN with $O(k)$ terminals forming a pure/flawed in/out-diamond pattern, ruling out $f(k) \cdot n^{o(\sqrt{k})}$ algorithms for such patterns.

In all these reductions, we are reusing and extending the gadget constructions from earlier work [8]. However, the high-level structure of the reduction is substantially different and depends on the pattern class we are considering. In light of Theorem 7, we should first verify, as a sanity check, that the treewidth of the solution can be sufficiently large, that is, it can be $\Omega(\sqrt{k})$ in case of diamonds. Typically, one can expect that examples with sufficiently large treewidth shed some light on how the high-level structure of the hardness proof could look like. Figure 3 shows that treewidth can be indeed sufficiently large: a $\sqrt{k} \times \sqrt{k}$ grid can be obtained from two "interlocking combs."

Statement (v): $f(k)n^{O(k)}$ algorithms

The upper bound $f(k) \cdot n^{O(k)}$ (statement (v)) follows from the work of Eiben et al. [12], who showed that Planar DSN with k terminals can always be solved within this running time. Note that Feldman and Ruhl [13] presented a $n^{O(p)}$ time algorithm for DSN on general graphs where p is the number of demands. However, as the number of demands on k terminals can be $\Omega(k^2)$, their algorithm *does not* give an $f(k) \cdot n^{O(k)}$ algorithm where k is the number of terminals.

Statement (vi): no $f(k)n^{o(k)}$ algorithms

To prove statement (vi) ruling out $f(k) \cdot n^{o(k)}$ algorithms, we provide such a lower bound for each class $\mathcal{C}_i$ for $i \in [\kappa]$. Analogously to statement (iv), the proof is by reduction from $k \times k$ Grid Tiling to a Planar $\mathcal{D}$-DSN instance with a k-hard-matching-pattern or a k-hard-biclique-pattern, ruling out $f(k) \cdot n^{o(k)}$ algorithms. Again, let us verify that the treewidth can be sufficiently large: Figure 3 shows how a $k \times k$ grid can appear in the solution to an instance with k terminals.

For t-hard-matching-patterns, the simplest case is when we have two induced matchings of size t. Then a $t \times t$ grid can arise very easily in the solution if the terminals are on the boundary of a grid. The crucial point here is that the t-hard-matching-pattern was defined in a way that all the additional paths, sources etc. do not interfere with the grid, see the figure for an example. For the t-hard-biclique-pattern, there is a non-obvious and highly delicate way of constructing an instance with $2t$ terminals where a $t \times t$ grid appears. Combining these constructions gives the lower bound.

▶ **Theorem 11.** *Let $\mathcal{D}$ be a class of graphs closed under identifying vertices and transitive equivalence. If $\mathcal{C}_i \subseteq \mathcal{D}$ for some $i \in [\kappa]$, then* Planar $\mathcal{D}$-Steiner Network *has no $f(k) \cdot n^{o(k)}$ time algorithm assuming the ETH.*

Let us observe that if $\mathcal{D}$ consists of bicliques directed from one side to the other, then Planar $\mathcal{D}$-DSN corresponds to the following problem: given a planar digraph G with two sets $S, T \subseteq V(G)$ of terminals with $|S| + |T| = k$, find a subgraph with minimum number of edges such that there is a path from every vertex of S to every vertex of T. Our result shows that, assuming the ETH, this problem has no $f(k) \cdot n^{o(k)}$ time algorithm. This result is surprising, as the problem can be considered to be *genuinely planar* in the sense that the input is a planar graph with k terminals and a single bit of annotation at each terminal (and there is no extra information, such as terminal pairs, that can disregard the planarity of the instance). To our knowledge, this is the first example of a relatively natural planar problem where $f(k) \cdot n^{O(k)}$ is best possible and cannot be improved to $f(k) \cdot n^{O(\sqrt{k})}$.

1.2 Details of Statement (iii): the $f(k) \cdot n^{O(\sqrt{k})}$ algorithm

In this section, we give a more detailed overview of the technical steps of the proof of (iii) sketched above.

From treewidth to total branch degree. Theorem 8 translates the question about the treewidth of the solution in general graphs to a question about the total branch degree of the solution in acyclic graphs. Suppose that we have an edge-minimal solution H in a (not necessarily acyclic) graph G with k terminals. Let us contract the strongly connected

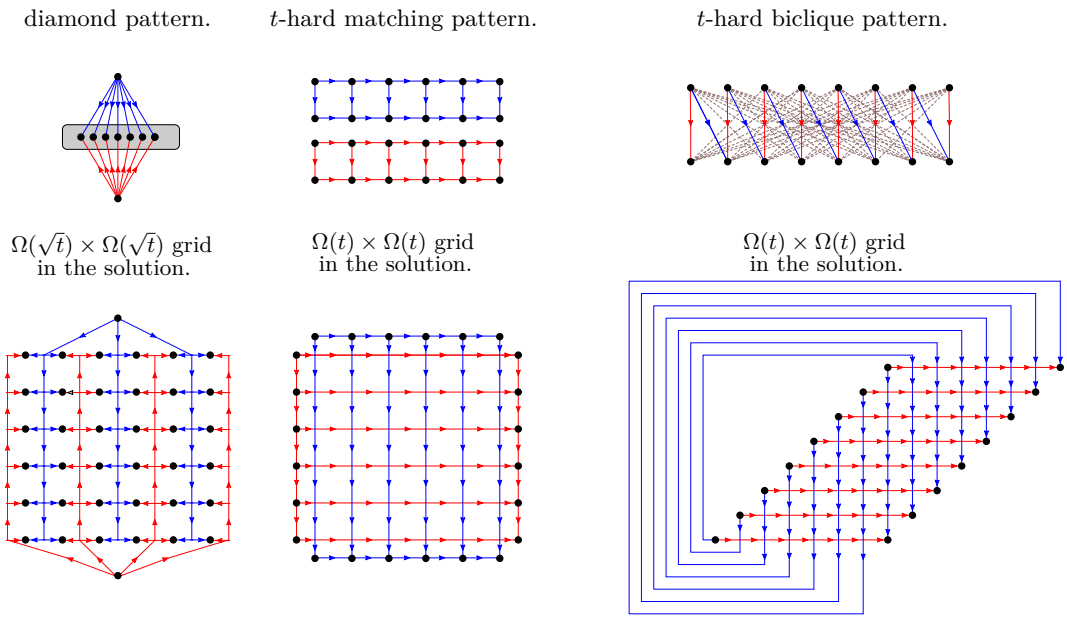

Figure 3 Pattern graphs (top row) and example minimal solution graphs with large grid patterns and large treewidth (bottom row). The red/blue edges show how (some of the) demands are connected in the solution.

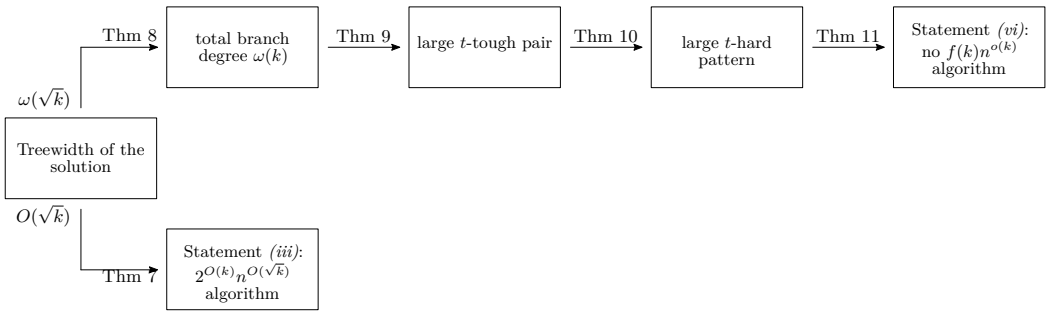

Figure 4 The structure of the proofs of statements (iii) and (vi).

components of H in both G and H to obtain G' and H', respectively. We can observe that H' is an acyclic graph that is the optimum solution to an instance in G' with at most k terminals. Our goal is to show that if H' has total branch degree d, then H has treewidth $O(\sqrt{d+k})$. Therefore, in the later steps of the proof, we bound the total branch degree of H' by $O(k)$, giving an $O(\sqrt{k})$ bound on the treewidth of H.

We say that a vertex of a strongly connected component of H is a *portal* if it is incident to an edge connecting it to some other component. For simplicity of discussion, let us assume here that every strongly connected component of H has at least 3 edges incident to the portals, that is, every vertex of H' has at least 3 incident edges. (If a component has less than 3 such edges and has no terminal, then it consists only of a single vertex and does not affect treewidth anyway; if it has terminals, then it can be taken into account with additional calculations.) By this assumption, the set P of portals has size at most $6d$, where d is the total branch degree of H'.

We want to bound the treewidth of H by showing that there is a set W of $O(d+k)$ vertices such that $H - W$ has treewidth at most 2. It is known that if removing a set W of vertices from a *planar* graph reduces treewidth to a constant, then the planar graph has treewidth $O(\sqrt{|W|})$. Thus the treewidth bound $O(\sqrt{d+k})$ follows from the existence of such a set W.

Let $H[V_i]$ be a strongly connected component of H that has p_i portals and contains k_i terminals. The key observation is that the only role of $H[V_i]$ in the solution is to fully connect the terminals and portals in $H[V_i]$. That is, we can assume that $H[V_i]$ is an optimum solution of a Strongly Connected Steiner Subgraph instance with $p_i + k_i$ terminals. Chitnis et al. [8] showed that we can remove a set W_i of $O(p_i + k_i)$ vertices from such an optimum solution to reduce its treewidth to 2. Therefore, taking the union of P and every W_i, we get a set W of size $O(d) + O(\sum(p_i + k_i)) = O(d + k)$ whose removal reduces treewidth to 2 (as removing P breaks the graph in a way that each component is a subset of some V_i, and the removal of W_i breaks $H[V_i]$ into components of treewidth at most 2).

Building a skeleton. Towards the proof of Theorem 9, our goal is to bound the total branch degree by $O(k)$ in an edge-minimal acyclic solution H. At some step of the proof, it will be important to assume that H is a triangulated planar graph (every face has exactly three vertices and edges), which is of course not true in general. Therefore, we introduce artificial undirected edges in the graph H to make it triangulated. As these edges do not play any role in the directed problem, it does not change the nature of the solution. Another simplification step is that we assume that there is no vertex $v \notin T$ with $d^-(v) = d^+(v) = 1$. Such a vertex has branch degree 0 and hence suppressing it (i.e., removing it and adding an edge from its in-neighbor to its out-neighbor) has no effect on the total branch degree and on the connectivity of the terminals.

We start by building a *skeleton* of the solution: a connected subgraph that contains every terminal. The skeleton is composed from *segments* of two types. A *long segment* is a directed path of H of length at least some constant L. A *short segment* is any path in the undirected sense of length at most L, possibly containing both undirected or directed edges of any orientation. Furthermore, we require that any two long segments in the skeleton are *distant,* that is, have distance at least L in the undirected sense.

A skeleton tree consisting of $O(k)$ segments and containing all the terminals can be built the following way. Initially, we start with an edgeless subgraph R containing only the k terminals. For simplicity of discussion, let us assume that the demand pattern is connected (in the undirected sense). Then there has to be a demand t_it_j such that t_i and t_j are in two different components C_i and C_j of R, respectively. This means that H has a directed path P connecting two different components of R. If P has length at most L, then we can introduce it as short segment to reduce the number of components of R. Otherwise, we can shorten P to P' such that every vertex of P' is at distance at least L from R and the two endpoints are at distance exactly L from two different components C and C' of R. Then we can reduce the number of components of R by introducing P' as a long segment and two short segments connecting the endpoints of P' to C and C'. By repeating these steps, we can reduce the number of components to 1 by introducing $O(k)$ segments in total.

Refining the faces. Our next goal is to further refine the skeleton such that every face of the skeleton has at most 35 segments on its boundary, and it is still true that the skeleton consists of $O(k)$ segments. We achieve this goal by iteratively dividing a face into two by introducing to the skeleton a new path consisting of at most 5 segments. We argue below that if the division is not very skewed in a certain sense, then the bound $O(k)$ on the number of segments can be achieved even after iterative applications of this step.

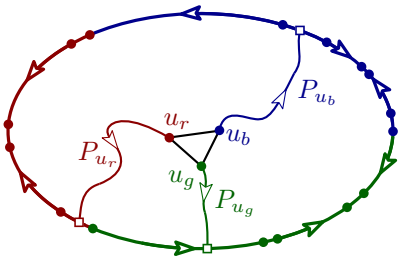

Figure 5 Finding a division that is not skewed.

Suppose that we have a face F where $x \geq 36$ segments appear on the boundary. Let P be a path between two segments of the boundary and assume that P consists of at most 5 segments. Introducing the path P into the skeleton creates two new faces F_1 and F_2 that see some number x_1 and x_2 segments on the boundary of F, plus the 5 new segments of P. We have $x_1 + x_2 \leq x + 2$: if the endpoints of P are internal vertices of segments, then we may have up to 2 segments that are now on the boundary of both F_1 and F_2.

For a face seeing $x \geq 13$ segments of the skeleton, let us define $x - 13 \geq 0$ to be the potential of the face. If we chose the path P such that $x_1, x_2 \geq 13$, then the potential of the two new faces F_1 and F_2 are defined. Moreover, the total potential of the two faces is at most

$$(x_1 + 5 - 13) + (x_2 + 5 - 13) \leq x - 14,$$

strictly less than the potential of F. This means that if we start with a face F that sees x segments of the skeleton, then repeated applications of this step can introduce only $O(x)$ new segments.

Finding a division that is not skewed. Next we show that if face F sees $x \geq 36$ segments of the skeleton, then we can find a division with $x_1, x_2 \geq 13$. Then as we have seen above, repeated applications of this step introduces $O(x)$ segments and divide F into faces that see at most 35 segments each.

Let us divide the boundary of F into three parts, red, green, and blue, each containing at least 12 segments (see Figure 5). As every vertex v inside the face F is essential for the solution, there is a directed path P_v from v to some vertex of the boundary; let us fix such a P_v for each v. This defines a color of v according to which of the three parts of the boundary contains the head of P_v. Then by Sperner's Lemma and fact that the graph is triangulated, there is a triangle u_r, u_g, u_b inside F where the three vertices have three different colors. From the assumptions that u_r, u_g, u_b are on three different parts, and each part has length at least 13, it follows that there are two vertices, say u_r and u_b, such that both subpaths of the boundary between the heads of P_{u_r} and P_{u_b} have at least 12 segments. Then putting together P_{u_r} and P_{u_b} creates a path P that divides the face F in the required way. This argument needs to be refined a bit further: as we said earlier, we want a skeleton where the long segments are distant, i.e., are at distance at least L from each other. But this can be easily achieved by appropriately shortening the long segments P_{u_r}, P_{u_b}, and then extending them by three short segments.

Many edges incident to a long path. We assume now that the skeleton has $O(k)$ faces, each seeing at most 35 segments. If we can show that the total branch degree (of the orginal solution H without the artificial edges) is a constant in each face, then we can bound by $O(k)$ the total branch degree of the solution. We can observe, using the acyclicity of the edges inside the face, that we need to bound only the number of edges incident on the boundary.

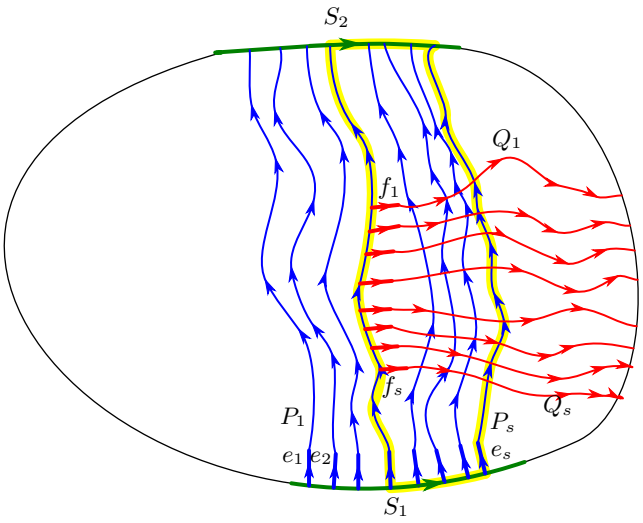

Figure 6 Finding a grid.

Let e be an edge inside the face incident to vertex v of the boundary. We say that e is *essential* for demand t_it_j if removing e breaks every path from t_i to t_j. Then we can define a path P_e the following way: let us take any path P from t_i to t_j, and let P_e be the subpath of P starting from e (which has to appear on P) to the first vertex on the boundary of F. Let us consider two edges e_1, e_2 starting from the same vertex v of the boundary. Let us observe that P_{e_1} and P_{e_2} cannot intersect: then we could bypass e.g. e_1 by starting on P_{e_2} and following it until intersection. By a similar argument, P_{e_1} and P_{e_2} cannot go to the same long segment: then one of P_{e_1} and P_{e_2} could be avoided by using the other path and part of the long segment. From these observations, it follows that the only way the boundary can have many edges incident to it is that if there are edges $e_1, \ldots, e_s$ incident to distinct vertices of a long segment S_1, with paths $P_1, \ldots, P_s$ going to distinct vertices of some other long segment S_2 (see Figure 6).

Finding a grid and a t-tough pair. Now comes the point where we use the assumption that long segments are distant. In particular, this means that the "middle path" $P_{e_{s/2}}$ is long. The internal vertices of this path have no terminals (as all the terminals are on the skeleton), hence it is not possible that $d^+(v) = d^-(v) = 1$ for any such internal vertex. Thus either there are many vertices on this path that have an edge leaving the path, or many vertices that have an edge entering the path. Assume without loss of generality the former, let $f_1, \ldots, f_s$ be these edges. Again, each edge is essential for some demand, hence the path satisfiying the demand has a subpath Q_i starting with f_i and going to the boundary. We can observe again that these paths have to be disjoint. Therefore, we can obtain a grid-like structure in the region surrounded by S_1, $P_{s/2}$, S_2, and P_s, see the region highlighted by yellow in Figure 6. (There are some other cases to consider, which we ignore here. For example, the paths Q_i may go to S_1 or S_2.) This region has $s/2 - 1$ "vertical" paths $P_{s/2}$, $\ldots$, P_{s-1}, intersected by the s "horizontal paths" $Q_1, \ldots, Q_s$.

We observe that if this grid has t horizontal and vertical paths, then we can use it to discover a t-tough pair. Each edge e_i is essential for some minimal demand; let E_1 be the set of these t demands. Similarly, we define E_2 based on choosing a minimal demand for which f_i is essential. Then we can carefully verify that (E_1, E_2) is a t-tough-pair: if there is an edge in the demand graph that is not allowed, then a careful analysis shows that there is a way of

bypassing some e_i or f_i in the grid, contradicting the fact that it is essential. This concludes the proof that if we have an upper bound on the size of the largest t-tough pair appearing in the graphs of class $\mathcal{D}$, then we can bound the treewidth of the solution by $O(\sqrt{k})$.

Cleaning. To prove Theorem 10, we need to show that if arbitrary large t-tough-pairs appear in the graphs of $\mathcal{D}$, then $\mathcal{C}_i \subseteq \mathcal{D}$ for some $i \in [\kappa]$. The proof is a long combinatorial argument to show that we can find t-tough-pairs that are canonical in some sense, and then we use the assumption that $\mathcal{D}$ is closed under identifying vertices to contract the vertices outside the t-tough-pair into a small constant number of well-behaved vertices.

Suppose that there is a t-tough-pair (E_1, E_2) in a digraph D. The minimality of the edges in E_1 and the fact that they do not appear in directed cycles (as they are weakly independent to themselves) imply that for any two edges $x_iy_i, x_jy_j \in E_1$, at least one of the following holds:

1. exactly the edges x_iy_j, x_jy_i appear between $\{x_i, y_i\}$ to $\{x_j, y_j\}$,
2. there is no edge from $\{x_i, y_i\}$ to $\{x_j, y_j\}$, or
3. there is no edge from $\{x_j, y_j\}$ to $\{x_i, y_i\}$.

Let us consider a complete graph on t vertices $w_1, \ldots, w_t$, and for every $i < j$, color the edge w_iw_j according to which of the three statements hold for the edges x_iy_i and x_jy_j (if more than one statement is true, we can choose arbitrarily). By Ramsey's Theorem, there is a large subset $E_1' \subseteq E_1$ where the same statement holds for any pair of edges. We can find a similar subset $E_2' \subseteq E_2$. We consider two main cases. The first case is when Statement 1 holds either in E_1' or E_2'. Then what we have is a matching x_iy_i of minimal edges that is part of a complete bipartite graph, that is, every x_i is adjacent to every y_j (but note that x_iy_j does not have to be a minimal edge). The second case is where we have Statement 2 or 3 in both E_1' and E_2'. Then we can reorder E_1 and E_2 to have a further ordering property: there is no edge from $\{x_i, y_i\}$ to $\{x_j, y_j\}$ for $j < i$. We handle the two cases separately. With further Ramsey arguments and case distinctions, we show that identifications can be used to find a t'-hard biclique pattern or a t'-hard matching pattern appearing in a graph in $\mathcal{D}$, where t' is some unbounded function of t. It follows that if arbitrarily large t-tough pairs appear in $\mathcal{D}$, then $\mathcal{D}$ is a superclass of some $\mathcal{C}_i$.

For full details and proofs, as well as a concluding discussion and open problems, please see the full version of this article [16].

2 Formal definition of a t-tough-pair

In this section we give the formal definition of a t-tough-pair. Further definitions, that are specific to the sections are defined in the beginning of the respective sections.

Given a digraph D and an edge $e = (u, v) \in E(D)$, we say that e is a *minimal* edge of D if D has no (u, v)-path of length strictly greater than 1 in D, where the length of the path is the number of edges in it. We say that a digraph D is *reachability-minimal* if each edge of D is minimal. For an edge $e = (u, v)$ in a directed graph D, v is called the *head* of e and u is called the *tail* of e. For any $E' \subseteq E(D)$, $\texttt{head}(E')$ (resp. $\texttt{tail}(E')$) denotes the set of heads (resp. tails) of the edges in E'. Next we define weak independence and strong independence that are crucial to define the t-tough-pair formally.

▶ **Definition 12** (Weakly independent edges). *Given a digraph D and edges $e_1 = (u_1, v_1), e_2 = (u_2, v_2) \in E(D)$, we say that the pair of edges (e_1, e_2) is weakly independent in D, if $u_1 \neq v_1 \neq u_2 \neq v_2$, and D has neither a (v_1, u_2)-path nor a (v_2, u_1)-path. A set of edges $E' \subseteq E(D)$ is weakly independent if every pair of distinct edges in E' are pairwise weakly independent and for each edge $(u_i, v_i) \in E'$, there is no (v_i, u_i)-path in D.*

Informally, a pair of edges is weakly independent, if the head of one edge cannot reach the tail of the other. Therefore, if a pair of edges is weakly independent, then they cannot lie on a directed path.

▶ **Definition 13** (Strongly independent edges). *Given a digraph D and edges $e_1 = (u_1, v_1), e_2 = (u_2, v_2) \in E(D)$, we say that the pair of edges (e_1, e_2) is strongly independent in D, if they are weakly independent in D, and additionally D has no (u_1, u_2)-path, no (u_2, u_1)-path, no (v_1, v_2)-path and no (v_2, v_1)-path.*

Informally, a pair of edges is strongly independent, if they are weakly independent, and the head of one cannot reach the head of the other, and the tail of one cannot reach the tail of the other. That is, the vertices of the heads (resp. vertices of tails) do not lie on any directed path.

▶ **Definition 14** (t-tough-pair). *Given a digraph D, $E_1, E_2 \subseteq E(D)$, we say that (E_1, E_2) is a tough-pair in D if:*

1. $|E_1| = |E_2|$,
2. *each edge of $E_1 \cup E_2$ is a minimal edge in D,*
3. *all edges in E_i are pairwise weakly independent in D, for both $i \in \{1, 2\}$, and*
4. *for each $e_1 \in E_1$ and $e_2 \in E_2$, (e_1, e_2) are strongly independent in D.*

Further, for a positive integer t, we say that (E_1, E_2) is a t-tough-pair if $|E_1| = |E_2| = t$.

Abstract

A book embedding of a graph is a drawing that maps vertices onto a line and edges to simple pairwise non-crossing curves drawn into "pages", which are half-planes bounded by that line. Two-page book embeddings, i.e., book embeddings into 2 pages, are of special importance as they are both NP-hard to compute and have specific applications. We obtain a $2^{\mathcal{O}(\sqrt{n})}$ algorithm for computing a book embedding of an n-vertex graph on two pages – a result which is asymptotically tight under the Exponential Time Hypothesis. As a key tool in our approach, we obtain a single-exponential fixed-parameter algorithm for the same problem when parameterized by the treewidth of the input graph. We conclude by establishing the fixed-parameter tractability of computing minimum-page book embeddings when parameterized by the feedback edge number, settling an open question arising from previous work on the problem.

1 Introduction

Book embeddings of graphs are drawings centered around a line, called the *spine*, and half-planes bounded by the spine, called *pages*. In particular, a k-page book embedding of a graph G is a drawing which maps vertices to distinct points on the spine and edges to simple curves on one of the k pages such that no two edges on the same page cross [6]. These embeddings have been the focus of extensive study to date [16, 20, 21, 22, 25, 38, 47], among others due to their classical applications in VLSI, bio-informatics, and parallel computing [11, 20, 31].

Every n-vertex graph is known to admit an $\lceil \frac{n}{2} \rceil$-page book embedding [6, 11, 30], but in many cases it is possible to obtain book embeddings with much fewer pages. Particular attention has been paid to two-page embeddings, which have specifically been used, e.g.,

to represent RNA pseudoknots [31, 42]. The class of graphs that can be embedded on two pages was studied by Di Giacomo and Liotta [27], Heath [32] as well as by other authors [1], and was shown to be a superclass of planar graphs with maximum degree at most 4 [5].

While two-page book embeddings are a special class of planar embeddings, they are not polynomial-time computable unless $\mathsf{P} = \mathsf{NP}$. Indeed, a graph admits a two-page book embedding if and only if it is *subhamiltonian* (*i.e.*, is a subgraph of a planar Hamiltonian graph) [6] and testing subhamiltonicity is an NP-hard problem [11]. On the other hand, the aforementioned problem of constructing a two-page book embedding (or determining that none exists) – which we hereinafter call Two-Page Book Embedding – becomes linear-time solvable if one is provided with a specific ordering of the n vertices of the input graph along the spine [31]. While Two-Page Book Embedding can be seen to admit a trivial brute-force $2^{\mathcal{O}(n \cdot \log n)}$ algorithm, it has also been shown to be solvable in $2^{\mathcal{O}(n)}$ time – in particular, one can branch to determine the allocation of edges into the two pages and then solve the problem via dynamic programming on SPQR trees [2, 33, 34].

Contribution. As our main contribution, we break the single-exponential barrier for Two-Page Book Embedding by providing an algorithm that solves the problem in $2^{\mathcal{O}(\sqrt{n})}$ time. Our algorithm is exact and deterministic, and avoids the single-exponential overhead of branching over edge allocations to pages by instead attacking the equivalent subhamiltonicity testing formulation of the problem. It is also asymptotically optimal under the Exponential Time Hypothesis [35]: there is a well-known quadratic reduction that excludes any $2^{o(\sqrt{n})}$ algorithm for Hamiltonian Cycle on cubic planar graphs [26], and a linear reduction from that problem (under the same restrictions) to subhamiltonicity testing [46] then excludes any $2^{o(\sqrt{n})}$ algorithm for our problem of interest.

The central component of our result is a non-trivial dynamic programming procedure that solves Two-Page Book Embedding in time $2^{\mathcal{O}(tw)} \cdot n$, where tw is the treewidth of the input graph. The desired subexponential algorithm then follows by the well-known fact that n-vertex planar graphs have treewidth at most $\mathcal{O}(\sqrt{n})$ [28, 39, 44]. But in addition to that, we believe our single-exponential treewidth-based algorithm to be of independent interest also in the context of parameterized algorithmics [13, 19].

Indeed, while Two-Page Book Embedding was already shown to be fixed-parameter tractable w.r.t. treewidth (i.e., to admit an algorithm running in time $f(tw) \cdot n$) by Bannister and Eppstein [3], that result crucially relied on Courcelle's Theorem [12]. More specifically, they showed that the required property can be encoded via a constant-size sentence in Monadic Second Order logic, which suffices for fixed-parameter tractability – but unfortunately not for a single-exponential algorithm, and a direct dynamic programming algorithm based on the characterization employed there seems to necessitate a parameter dependency that is more than single-exponential. Moreover, it is not at all obvious how one could employ convolution-based tools – which have successfully led to $2^{\mathcal{O}(tw)} \cdot n$ algorithms for, e.g., Hamiltonian Cycle [10, 14, 15] – for our problem of interest here.

Instead, we obtain our results by employing dynamic programming along a *sphere-cut decomposition* – a type of branch decomposition specifically designed for planar graphs of small treewidth [18]. However, unlike in previous applications of sphere-cut decompositions [36, 40], our algorithm requires the nooses delimiting the bags in the sphere-cut decomposition to admit a fixed drawing since our arguments rely on constructing a hypothetical solution (a subhamiltonian curve) that is "well-behaved" w.r.t. a fixed set of curves. While this would typically lead to extensive case analysis to compute the records of a parent noose from the records of the children, we introduce a generic framework that allows us to transfer records

from child to parent nooses via XOR operations. We believe that this technique may be of broader interest, specifically when working with problems which require one to enhance the embedding or drawing of an input graph.

In the final part of the article, we turn our attention to the parameterized complexity of computing book embeddings. While Two-Page Book Embedding is fixed-parameter tractable when parameterized by the treewidth of the input graph, the only graph parameter which has been shown to yield fixed-parameter algorithms for computing ℓ-page book embeddings for $\ell > 2$ is the *vertex cover number*[1] [7]. Whether this tractability result also holds for other structural graph parameters such as treewidth, *treedepth* [41] or the *feedback edge number* [45] has been stated as an open question in the field[2]. We conclude by providing a novel fixed-parameter algorithm for computing ℓ-page book embeddings (or determining that one does not exist) under the third parameterization mentioned above – the feedback edge number, i.e., the edge deletion distance to acyclicity. This result is complementary to the known vertex-cover based fixed-parameter algorithm, and can be seen as a necessary stepping stone towards eventually settling the complexity of computing ℓ-page book embeddings parameterized by treewidth. Moreover, since the obtained kernel is linear in the case of $\ell = 2$, the obtained kernel allows us to generalize our main algorithmic result to a run-time of $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ where k is the feedback edge number of the input graph.

2 Preliminaries

Basic Notions. We use basic terminology for graphs and multi-graphs [17], and assume familiarity with the basic notions of parameterized complexity and fixed-parameter tractability [13, 19]. The *feedback edge number* of G, denoted by $\mathsf{fen}(G)$, is the minimum size of any *feedback edge set* of G, *i.e.*, a set $F \subseteq E(G)$ such that $G - F = (V(G), E(G) \setminus F)$ is acyclic.

For a face f of a plane graph, we use $\sigma(f)$ to denote the cyclic sequence of the vertices obtained by traversing the closed curve representing the border of f in a clock-wise manner.

Book Embeddings and Subhamiltonicity. An ℓ-page book embedding of a multi-graph $G = (V, E)$ will be denoted by a pair $\langle \prec, \sigma \rangle$, where $\prec$ is a linear order of V, and $\sigma \colon E \to [\ell]$ is a function that maps each edge of E to one of ℓ pages $[\ell] = \{1, 2, \ldots, \ell\}$. In an ℓ-page book embedding $\langle \prec, \sigma \rangle$ it is required that for no pair of edges $uv, wx \in E$ with $\sigma(uv) = \sigma(wx)$ the vertices are ordered as $u \prec w \prec v \prec x$, i.e., each page must be crossing-free. The *page number* of a graph G is the minimum number ℓ such that G admits an ℓ-page book embedding. The general problem of computing the page number of an input graph is thus:

Book Thickness	
Instance:	A multi-graph G with n vertices and a positive integer ℓ.
Question:	Does G admit a ℓ-page book embedding?

It is known that a multi-graph admits a 2-page book embedding if and only if it is *subhamiltonian*, i.e., if it has a planar Hamiltonian supergraph on the same vertex set [6]; an illustration is provided in Figure 1. Hence, the problem of deciding whether a multi-graph has page number 2 can be equivalently stated as:

[1] The vertex cover number is the minimum size of a vertex cover, and represents a much stronger restriction on the structure of the input graphs than, e.g., treewidth.

[2] E.g., at **Advances in Parameterized Graph Algorithms** (Spain, May 2–7 2022) and also at Dagstuhl seminar 21293 **Parameterized Complexity in Graph Drawing** [23].

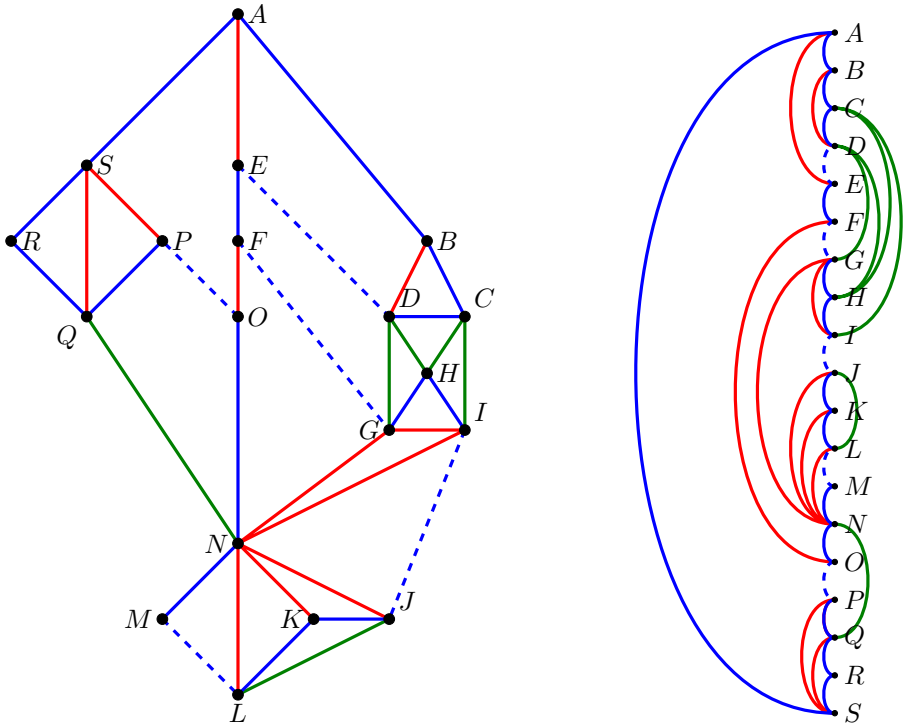

Figure 1 A drawing of a subhamiltonian graph G, made of the full-edges, which is completed by the dashed edges to one of its Hamiltonian supergraphs G_H (left) and the same graph drawn as a two-page book embedding (right). In both drawings the Hamiltonian cycle H is colored in blue and the edges belonging to page 1 and 2 are colored with green and red, respectively.

Subhamiltonicity (SUBHAM)	
Instance:	A multi-graph G with n vertices.
Question:	Is G subhamiltonian?

Since the transformation between 2-page book embeddings and Hamiltonian cycles of supergraphs is constructive in both directions, a constructive algorithm for SUBHAM (such as the one presented here) allows us to also output a 2-page book embedding for the graph.

Let G be subhamiltonian. For a Hamiltonian cycle H on $V(G)$ (where H is not necessarily a subgraph of G), we denote by G_H the graph obtained from G after adding the edges of H and say that H is a *witness* for G if G_H is planar. A drawing D of G *respects* H if D can be completed to a planar drawing of G_H by only adding the edges of H. We extend the notion of "witness" to include all the information defining the solution as follows: a tuple (D, D_H, G_H, H) is a *witness* for G if G_H is a planar supergraph of G containing the Hamiltonian cycle H, D_H is a planar drawing of G_H, and D is the restriction of D_H to G; note that D_H witnesses that D respects H.

SPQR-Trees. We assume familiarity with the SPQR-tree data structure for biconnected multi-graphs which decomposes a graph into (S)eries, (P)arallel, (R)igid and (Q) nodes (leaf nodes and root node), following the formalism used by Gutwenger et al. [29], see also [4, 8, 9]. For a node b in an SPQR-tree, we use $\textsc{Sk}(b)$ and $\textsc{Pe}(B)$ to denote the *skeleton* and *pertinent graph* of b, respectively. SPQR-trees can be computed in linear time, and an illustration of the data structure is provided in Figure 2.

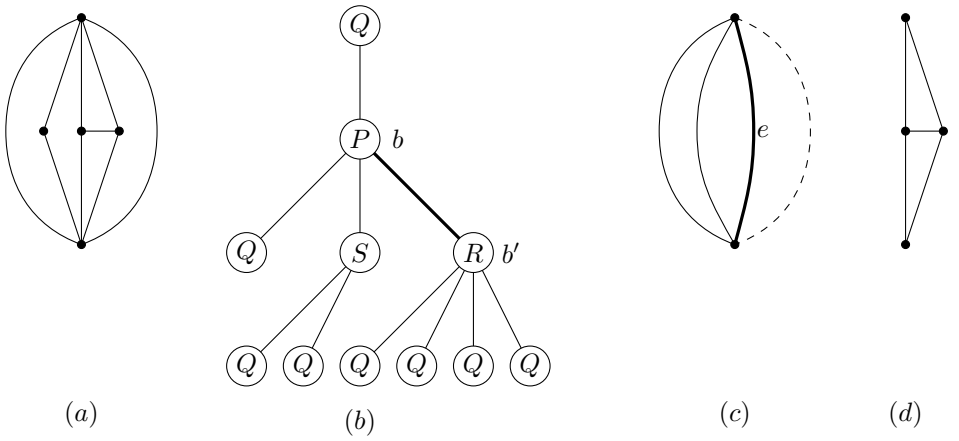

Figure 2 (a) shows a biconnected multi-graph G. (b) shows the SPQR-tree $\mathcal{B}$ of G. (c) shows the skeleton of b, $\textsc{Sk}(b)$, where the edge e that corresponds to the child (with pertinent node) b' is in bold and the dashed edge represents the reference edge. Finally, (d) shows $\textsc{Pe}(b')$.

Sphere-Cut Decompositions. A branch decomposition $\langle T, \lambda \rangle$ of a graph G consists of an unrooted ternary tree T (meaning that each node of T has degree one or three) and of a bijection $\lambda : \mathcal{L}(T) \leftrightarrow E(G)$ from the leaf set $\mathcal{L}(T)$ of T to the edge set $E(G)$ of G; to distinguish $E(T)$ from $E(G)$, we call the elements of the former *arcs* (as was also done in previous work [18]). For each arc a of T, let T_1 and T_2 be the two connected components of $T - a$, and, for $i = 1, 2$, let G_i be the subgraph of G that consists of the edges corresponding to the leaves of T_i, i.e., the edge set $\{\lambda(\mu) : \mu \in \mathcal{L}(T) \cap V(T_i)\}$. The middle set $mid(a) \subseteq V(G)$ is the intersection of the vertex sets of G_1 and G_2, i.e., $mid(a) := V(G_1) \cap V(G_2)$. The width $\beta(\langle T, \lambda \rangle)$ of $\langle T, \lambda \rangle$ is the maximum size of the middle sets over all arcs of T, i.e., $\beta(\langle T, \lambda \rangle) := max\{|mid(a)| : a \in E(T)\}$. An optimal branch decomposition of G is a branch decomposition with minimum width; this width is called the branchwidth $\beta(G)$ of G. We will need the following well-known relation between treewidth and branchwidth.

▶ **Lemma 1** ([43, Theorem 5.1]). *Let G be a graph. Then, $bw(G) - 1 \leq tw(G) \leq \frac{3}{2} bw(G) - 1$, where $bw(G)$ is the branchwidth and $tw(G)$ is the treewidth of G.*

Let D be a plane drawing of a connected planar graph G. A noose of D is a closed simple curve that (i) intersects D only at vertices and (ii) traverses each face at most once, i.e., its intersection with the region of each face forms a connected curve. The length of a noose is the number of vertices it intersects, and every noose O separates the plane into two regions δ_1 and δ_2. A *sphere-cut decomposition* $\langle T, \lambda, \Pi = \{ \pi_a \mid a \in E(T) \} \rangle$ of (G, D) is a branch decomposition$\langle T, \lambda \rangle$ of G together with a set Π of circular orders π_a of $mid(a)$ – one for each arc a of T – such that there exists a noose O_a whose closed discs δ_1 and δ_2 enclose the drawing of G_1 and of G_2, respectively. Observe that O_a intersect G exactly at $mid(a)$ and its length is $|mid(a)|$. Note that the fact that G is connected together with Conditions (i) and (ii) of the definition of a noose implies that the graphs G_1 and G_2 are both connected and that the set of nooses forms a laminar set family, that is, any two nooses are either disjoint or nested. A clockwise traversal of O_a in the drawing of G defines the cyclic ordering π_a of $mid(a)$. We always assume that the vertices of every middle set $mid(a)$ are enumerated according to π_a. A sphere-cut decomposition of a given planar graph with n vertices can be constructed in $\mathcal{O}(n^3)$ time [18].

We say that a biconnected planar multi-graph G equipped with an SPQR-tree $\mathcal{B}$ is *associated* with a set $\mathcal{T}$ of sphere-cut decompositions if $\mathcal{T}$ contains a sphere-cut decomposition of $\textsc{Sk}(b)$ for every R-node and every S-node b of $\mathcal{B}$.

▶ **Lemma 2.** *Let G be biconnected planar multi-graph with planar drawing D and SPQR-tree $\mathcal{B}$ of G together with the associated set $\mathcal{T}$ of sphere-cut decompositions. Then, D can be extended to a planar drawing D' of G together with all nooses in $\{ O_a \mid a \in E(T_b) \wedge \langle T_b, \lambda_b, \Pi_b \rangle \in \mathcal{T} \}$ as well as a noose N_b for every node b of $\mathcal{B}$ satisfying:*

- *N_b intersects with D only at s_b and t_b.*
- *N_b separates $P_E(b)$ from $G \setminus P_E(b)$ in D.*

Moreover, if any of the subcurves of the nooses O_a and the nooses N_b connect the same two vertices in the same face of D, then the two subcurves are identical in D'.

Non-Crossing Matchings. Let K_n be the complete graph on vertices $\{1, \ldots, n\}$ and let $<$ be a cyclic ordering of the elements in $\{1, \ldots, n\}$. A *non-crossing matching* is a matching M in the graph K_n such that for every two edges $\{a, b\}, \{c, d\} \in M$ it is not the case that $a < c < b < d$.

3 Solution Normal Form

Our first order of business is to show that we can assume that the solution (Hamiltonian cycle) to the SUBHAM problem interacts with the drawing in a restricted manner. In particular, we aim to show that every subhamiltonian graph G has a witness (D, D_H, G_H, H) in *normal form*, i.e., with the following property: it is possible to draw a curve in D_H between any two vertices occurring in a common face of D such that this curve only crosses the Hamiltonian cycle at most twice. Note that this property will allow us to bound the number of possible interactions of the Hamiltonian cycle with any subgraph corresponding to either a node in the SQPR-tree or an arc in a sphere-cut decomposition and is crucial to bound the number of types in our dynamic programming algorithm. The following lemma is the main technical lemma behind our normal form. An illustration of the main ideas behind the proof is provided in Figure 3.

▶ **Lemma 3.** *Let G be a subhamiltonian graph with witness (D, D_H, G_H, H), let f be a face of D and let c be a curve drawn inside f between two vertices $u, v \in V(f)$. Then, there is a witness $(D, D_{H'}, G_{H'}, H')$ for G such that:*

(1) *$D_{H'}$ and D_H differ only inside f.*
(2) *c crosses at most two curves corresponding to the edges of H'.*
(3) *c crosses each curve corresponding to an edge of H' at most once.*

We are now ready to define our normal form for the Hamiltonian cycle. Essentially, we show that if there is a Hamiltonian cycle, then there is one which crosses each subcurve that is either part of the border of a node in the SPQR-tree or that is a subcurve of some noose in a sphere-cut decomposition of an R-node or an S-node at most twice.

Let G be a biconnected subhamiltonian multi-graph with SPQR-tree $\mathcal{B}$ and the associated set $\mathcal{T}$ of sphere-cut decompositions $\langle T_b, \lambda_b, \Pi_b \rangle$ of $\textsc{Sk}(b)$ for every R-node and S-node b of $\mathcal{B}$. We say that a witness $W = (D, D_H, G_H, H)$ for G *respects* the sphere-cut decompositions in $\mathcal{T}$, if there is a planar drawing of all nooses in the sphere-cut decompositions of $\mathcal{T}$ into D such that every subcurve c in $\bigcup_{a \in E(T_b)} O_a$ crosses the curves corresponding to the edges of H at most twice in D_H. We say that the witness W for G *respects* $\mathcal{B}$ if it respects the sphere-cut decompositions in $\mathcal{T}$ and for every node b of $\mathcal{B}$ with reference edge (s_b, t_b), it holds that there is a noose N_b that can be drawn into D_H such that:

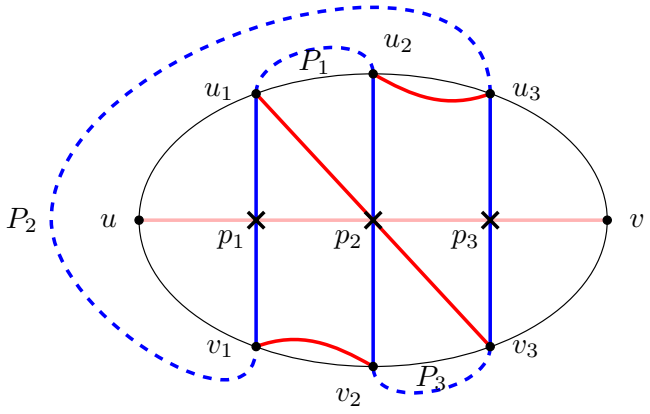

Figure 3 The cycle $H = (u_2, P_1, u_1, v_1, P_2, u_3, v_3, P_3, v_2, u_2)$ represents a Hamiltonian cycle that crosses the uv-curve at least three times (in p_1, p_2 and p_3). Thanks to Lemma 3, we obtain a Hamiltonian cycle $H' = (u_2, P_1, u_1, v_3, P_3, v_2, v_1, P_2, u_3, u_2)$ that differs from H only inside the face $f = (u, u_1, u_2, u_3, v, v_3, v_2, v_1)$ and crosses the uv-curve two fewer times than H does. Finally, note that the vertices u and v are part of either P_1, P_2, or P_3.

- N_b touches D only at s_b and t_b.
- N_b separates $\text{PE}(b)$ from $G \setminus \text{PE}(b)$ in D.
- Each of the two subcurves L_b and R_b obtained from N_b by splitting N_b at s_b and t_b crosses the curves corresponding to the edges of H at most twice.
- Moreover, if any of the subcurves of the nooses O_a and the nooses N_b connect the same two vertices in the same face of D, then the two subcurves are identical.

The following lemma allows us to assume our normal form and follows easily from a repeated application of Lemma 3.

▶ **Lemma 4.** *Let G be a biconnected subhamiltonian multi-graph with SPQR-tree $\mathcal{B}$ and the associated set $\mathcal{T}$ of sphere-cut decompositions. Then, there is a witness $W = (D, D_H, G_H, H)$ for G that respects $\mathcal{B}$.*

4 Setting Up the Framework

In this section we provide the foundations for our algorithm. That is, in Subsection 4.1, we show that it suffices to consider biconnected graphs allowing us to employ SPQR-trees. We then define the types for nodes in the SPQR-tree, which we compute in our dynamic programming algorithm on SPQR-trees, in Subsection 4.2. Finally, in Subsection 4.3 we introduce our general framework for simplifying dynamic programming algorithms on sphere-cut decompositions and introduce the types for nodes of a sphere-cut decomposition.

4.1 Reducing to the Biconnected Case

We begin by showing that any instance of SUBHAM can be easily reduced to solving the same problem on the biconnected components of the same instance. It is well-known that SUBHAM can be solved independently on each connected component of the input graph, the following theorem now also shows that the same holds for the biconnected components of the graph and allows us to employ SPQR-trees for our algorithm.

▶ **Theorem 5.** *Let G be a graph and let $C \subseteq V(G)$ such that $N(C) = \{n\}$, where $N(C) = \{ v \in V(G) \setminus C \mid \exists c \in C \ \{v, c\} \in E(G) \}$ is the set of neighbors of any vertex of C in $V(G) \setminus C$. Then G is subhamiltonian if and only if both $G^- = G - C$ and $G^C = G[C \cup \{n\}]$ are subhamiltonian.*

4.2 Defining the Types for Nodes in the SPQR-tree

Here, we define the types for nodes in the SPQR-tree that we will later compute using dynamic programming. In the following, we assume that G is a biconnected multi-graph with SPQR-tree $\mathcal{B}$ and the associated set $\mathcal{T}$ of sphere-cut decompositions. Let b be a node of $\mathcal{B}$ with pertinent graph $\textsc{Pe}(b)$ and reference edge $e = (s, t)$. A *type* of b is a triple (ψ, M, S) such that (please refer also to Figure 4 for an illustration of some types):

- ψ is a function from $\{L, R\}$ to subsets of $\{l, l', r, r'\}$ such that $\psi(L) \in \{\emptyset, \{l\}, \{l, l'\}\}$ and $\psi(R) \in \{\emptyset, \{r\}, \{r, r'\}\}$. We denote by $V(\psi)$ the set $\psi(L) \cup \psi(R)$. Informally, ψ captures how many times the Hamiltonian cycle enters and exits the graph $\textsc{Pe}(b)$ from the left (L) and from the right (R).
- $M \subseteq \{ \{u, v\} \mid u, v \in \{s, t\} \cup V(\psi) \wedge u \neq v \}$ and M is a non-crossing matching w.r.t. the circular ordering (s, r, r', t, l', l) that matches all vertices in $V(\psi)$ (i.e. $V(\psi) \subseteq V(M)$), where $V(M) = \bigcup_{e \in M} e$. Informally, M captures the maximal path segments of the Hamiltonian cycle inside $\textsc{Pe}(b) \cup V(\psi)$ with endpoints in $\{s, t\} \cup V(\psi)$.
- $S \subseteq \{s, t\} \setminus V(M)$. Informally, S captures whether s or t are contained as inner vertices on path segments corresponding to M.

We now provide the formal semantics of types; see Figure 4 for an illustration. Let $\mathcal{X}$ be the set of all types and $\textsc{Pe}^*(b)$ be the graph obtained from $\textsc{Pe}(b)$ after adding the dummy vertices l, l', r, and r' together with the edges sl, ll', $l't$, sr, rr', and $r't$. We say that b has type $X = (\psi, M, S)$ if there is a set $\mathcal{P}$ of vertex-disjoint paths or a single cycle in the complete graph with vertex set $V(\textsc{Pe}^*(b))$ such that:

- $\mathcal{P}$ consists of exactly one path P_e between u and v for every $e = \{u, v\} \in M$ or $\mathcal{P}$ is a cycle and $M = \emptyset$.
- $\{ \text{IN}(P) \mid P \in \mathcal{P} \}$ is a partition of $(V(\textsc{Pe}(b)) \setminus \{s, t\}) \cup S$, where $\text{IN}(P)$ denotes the set of inner vertices of P.
- there is a planar drawing $D(b, X)$ of $\textsc{Pe}^*(b) \cup \bigcup_{P \in \mathcal{P}} P$ with outer-face f such that $\sigma(f) = \{s, r, r', t, l', l\}$.

The way we define the types $X = (\psi, M, S)$ of a node b allows us to associate each witness $W = (D, D_H, G_H, H)$ with a type, denoted by $\Gamma_W(b)$, based on the restriction of the witness to the respective pertinent graph.

4.3 Framework for Sphere-cut Decomposition

Here, we introduce our framework to simplify the computation of records via bottom-up dynamic programming along a sphere-cut decomposition. Since the framework is independent of the type of records one aims to compute, we believe that the framework is widely applicable and therefore interesting in its own right. In particular, we introduce a simplified framework for computing the types of arcs (or, equivalently, nooses) in sphere-cut decompositions.

Indeed, the central ingredient of any dynamic programming algorithm on sphere-cut decompositions is a procedure that given an inner node with parent arc a_P and child arcs a_L and a_R computes the set of types for the noose O_{a_P} from the set of types for the nooses O_{a_L} and O_{a_R}. Unfortunately, there is no simple way to obtain O_{a_P} from O_{a_L} and O_{a_R} and this is why computing the set of types for O_{a_P} from the set of types for O_{a_L} and O_{a_R} usually involves a technical and cumbersome case distinction [18]. To circumvent this issue, we

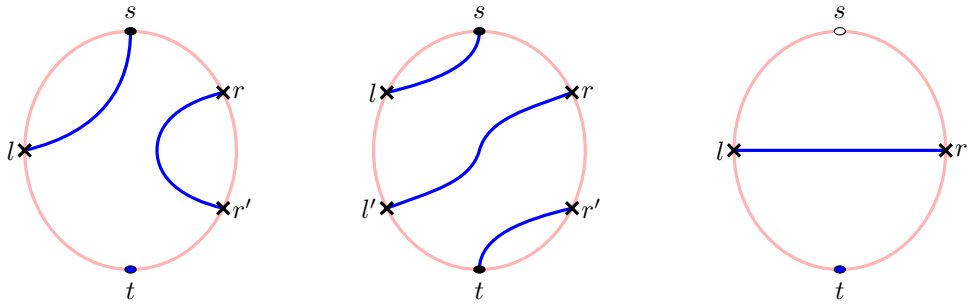

Figure 4 The figure shows three different types of a node in an SPQR-tree with reference edge (s,t), i.e., the types shown are (from left to right): $(\{\{L \to \{l\}\}, \{R \to \{r,r'\}\}, \{\{l,s\},\{r,r'\}\}, \{t\})$, $(\{\{L \to \{l,l'\}\}, \{R \to \{r,r'\}\}, \{\{l,s\},\{l',r\},\{t,r'\}\}, \emptyset)$, and $(\{\{L \to \{l\}\}, \{R \to \{r\}\}, \{\{l,r\}\}, \{t\})$. The subset of $\{l,l'\}$ and $\{r,r'\}$ that appears corresponds to $\psi(L)$ and $\psi(R)$ respectively. The blue edges correspond to the matching M and the blue vertices corresponds to S.

introduce a simple operation, i.e., the $\oplus$ (**XOR**) operation defined below, and show that the noose O_{a_p} can be obtained from the nooses O_{a_L} and O_{a_R} using merely a short sequence – one of length at most four – of $\oplus$ operations.

Central to our framework is the notion of *weak nooses*, which are defined below and can be seen as intermediate results in the above-mentioned sequence of simple operations from the child nooses to the parent noose; in particular, weak nooses are made up of subcurves of the nooses in the sphere-cut decomposition. Let G be a biconnected multi-graph and let $\mathcal{B}$ be an SPQR-tree of G. Let b be an R-node or S-node of $\mathcal{B}$ with pertinent graph $\textsc{Pe}(b)$. Let $\langle T_b, \lambda_b, \Pi_b\rangle$ be a sphere-cut decomposition of $\textsc{Sk}(b)$ and a be an arc of T_b with pertinent graph $\textsc{Pe}(b,a)$. Let $C(T_b)$ be the set of all subcurves of all nooses occurring in T_b, i.e., $C(T_b) = \bigcup_{a \in E(T_b)} O_a$ where O_a is seen as a set of subcurves. We say O is a *weak noose* if O is a noose consisting only of subcurves from $C(T_b)$. For each $O \subseteq C(T_b)$, let $V(O)$ be equal to the vertices of G touched by the noose O.

Having defined weak nooses, we will now define our simplified operation. Let $A \oplus B$ be an exclusive or for two sets A and B, i.e. $A \oplus B = (A \cup B) \setminus (A \cap B)$. We will apply the $\oplus$-operation to weak nooses, whose $\oplus$ is again a weak noose. The following lemma, whose setting is illustrated in Figure 5, is central to our framework as it shows that we can always obtain the noose for the parent arc a_P from the nooses of the child arcs a_L and a_R using a short sequence of $\oplus$-operations such that every intermediate result is a weak noose.

▶ **Lemma 6.** *Let a_P be a parent arc with two child arcs a_L and a_R in a sphere-cut decomposition $\langle T, \lambda, \Pi\rangle$ of a biconnected multi-graph G with the drawing D. There exists a sequence Q of at most 3 $\oplus$-operations such that:*

- *each step generates a weak noose O with $|O| \leq 1 + \max\{|mid(a_P)|, |mid(a_L)|, |mid(a_R)|\}$ as the $\oplus$-operation of two weak nooses O_1 and O_2, whose inside region contains all subcurves in $(O_1 \cap O_2)$,*
- *the last step generates the noose O_{a_P},*
- *Q contains O_{a_L} and O_{a_R} and at most two new weak nooses, each of them bounds the edge-less graph of size 3.*

We are now ready to define the types of weak nooses, which informally can be seen as a generalization of the types of nodes in an SPQR-tree introduced in Subsection 4.2. An illustration of the types is also provided in Figure 7. In the following we fix an arbitrary order π_G of the vertices in G. A type of a weak noose O is a triple (ψ, M, S) such that:

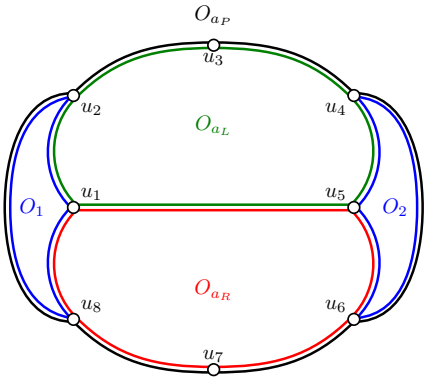

Figure 5 An illustration of the relationship of the parent noose O_{a_P} and the child nooses O_{a_L} and O_{a_R}. The illustration represents the case of Lemma 6 where $O' = O_{a_P} \oplus O_{a_L} \oplus O_{a_R}$ consists of two disjoint weak nooses (triangles) O_1 and O_2.

(1) ψ is a function that for each subcurve $c = (\{u, v\}, f)$ in O, i.e., the subcurve of O between u and v in face f, returns a sequence of at most two new nodes, (2) S is a subset of $V(O)$, and (3) $M \subseteq \{\, \{u, v\} \mid u, v \in V(\psi) \cup (V(O) \setminus S) \wedge u \neq v \,\}$, $V(\psi) \subseteq V(M)$, and M is a non-crossing matching w.r.t. the circular order $\pi^\circ(\psi)$ defined as follows. $\pi^\circ(\psi)$ is the circular order obtained from the circular order $\pi^\circ(O)$ of $V(O)$ after adding $\psi(c)$ between u and v, for every $c = (\{u, v\}, f) \in O$ assuming that $\pi_G(u) < \pi_G(v)$.

The semantics for the types as well as the definition of a type given a witness are now defined in a similar way as in the case of types for SPQR-tree nodes.

5 An FPT-algorithm for SUBHAM using Treewidth

In this section we show that SUBHAM admits a constructive single-exponential fixed-parameter algorithm parameterized by treewidth.

▶ **Theorem 7.** SUBHAM *can be solved in time* $2^{\mathcal{O}(\mathrm{tw})} \cdot n^{\mathcal{O}(1)}$*, where* tw *is the treewidth of the input graph.*

Since the treewidth of an n-vertex planar graph is upper-bounded by $\mathcal{O}(\sqrt{n})$ [28, 39, 44] and there are single-exponential constant-factor approximation algorithms for treewidth [37], Theorem 7 immediately implies the following corollary.

▶ **Corollary 8.** SUBHAM *can be solved in time* $2^{\mathcal{O}(\sqrt{n})}$.

The main component used towards proving Theorem 7 is the following lemma, from which Theorem 7 follows as an easy consequence .

▶ **Lemma 9.** *Let G be a biconnected multi-graph with n vertices and m edges and SPQR-tree $\mathcal{B}$. Then, we can decide in time $\mathcal{O}(315^\omega n + n^3)$ whether G is subhamiltonian, where ω is the maximum branchwidth of $S\kappa(b)$ over all R-nodes and S-nodes b of $\mathcal{B}$.*

The remainder of this section is therefore devoted to a proof of Lemma 9, which we show by providing a bottom-up dynamic programming algorithm along the SPQR-tree of the graph. That is, let G be a biconnected multi-graph, $\mathcal{B}$ be an SPQR-tree of G with associated set $\mathcal{T}$ of sphere-cut decompositions for every R-node and S-node of $\mathcal{B}$. Using a dynamic programming algorithm starting at the leaves of $\mathcal{B}$, we will compute a set $\mathcal{R}(b)$ of all types X satisfying the following two conditions:

(R1) If $X \in \mathcal{R}(b)$, then b has type X.
(R2) If there is a witness $W = (D, D_H, G_H, H)$ for G that *respects* $\mathcal{B}$ such that b has type $X = \Gamma_W(b)$, then $X \in \mathcal{R}(b)$.

Interestingly, we do not know whether it is possible to compute the set of all types X such that b has type X as one would usually expect to be able to do when looking at similar algorithms based on dynamic programming. That is, we do not know whether one can compute the set of types that also satisfies the reverse direction of **(R1)**. While we do not know, we suspect that this is not the case because b might have a type that can only be achieved by crossing some sub-curves of nooses inside of $\textsc{Pe}(b)$ more than twice. Indeed Lemma 3, which allows us to avoid more than two crossings per sub-curve, requires the property that the type of b can be extended to a Hamiltonian cycle of the whole graph, which is clearly not necessarily the case for every possible type of b.

5.1 Handling P-nodes

In this part, we show how to compute the set of types for any P-node in the given SPQR-tree by establishing the following lemma.

▶ **Lemma 10.** *Let b be a P-node of $\mathcal{B}$ such that $\mathcal{R}(c)$ has already been computed for every child c of b in $\mathcal{B}$. Then, we can compute $\mathcal{R}(b)$ in time $\mathcal{O}(\ell)$, where ℓ is the number of children of b in $\mathcal{B}$.*

In the following, let b be a P-node of $\mathcal{B}$ with reference edge (s,t) and let C with $|C| = \ell$ be the set of all children of b in $\mathcal{B}$. Informally, $\mathcal{R}(b)$ is the set of types X such that there is an ordering $\rho = (c_1, \ldots, c_\ell)$ of the children in C and an assignment $\tau : C \to \mathcal{X}$ of children to types with $\tau(c) \in \mathcal{R}(c)$ for every child $c \in C$ that "realizes" the type X for b. The main challenge is to compute $\mathcal{R}(b)$ efficiently, i.e., without having to enumerate all possible orderings ρ and assignments τ. Below, we make this intuition more precise before proceeding.

For a type $X = (\psi, M, S)$ of b and $A \in \{L, R\}$, we let $\#_A(X) = |\psi(A)|$. Moreover, for every $A \in \{s,t\}$, we set $\#_A(X)$ to be equal to 2 if $A \in S$, equal to 1 if $A \in V(M)$ and equal to 0 otherwise. Next, let $\rho = (X_1, \ldots, X_\ell)$ be a sequence of types, where $X_i = (\psi_i, M_i, S_i)$ for every i with $1 \leq i \leq \ell$. We say that ρ is *weakly compatible* if the following holds:
(C1) for every i with $1 \leq i < \ell$, $\#_R(X_i) = \#_L(X_{i+1})$, and
(C2) $\sum_{i=1}^{\ell} \#_s(X_i) \leq 2$ and $\sum_{i=1}^{\ell} \#_t(X_i) \leq 2$.

Note that **(C1)** corresponds to our assumption made in Lemma 4 that we can add the nooses N_b to any planar drawing D of G such that every face of D contains at most one subcurve of any N_b. This in particular means that if $\textsc{Pe}(c)$ is drawn immediately to the left of $\textsc{Pe}(c')$ for two children c and c' of b, then the subcurves R_c and $L_{c'}$ are identical. Please also refer to Figure 6 for an illustration of these subcurves.

Let ρ be weakly compatible. We define the following auxiliary graph $H(\rho)$. $H(\rho)$ has two vertices s and t and additionally for every i with $1 \leq i \leq \ell$ and every vertex $v \in V(\psi)$, $H(\rho)$ has a vertex v_i. For convenience, we also use s_i and t_i to refer to s and t, respectively. Moreover, $H(\rho)$ has the following edges:

- for every $1 \leq i \leq \ell$ if $M_i = \emptyset$ and $S_i = \{s_i, t_i\}$, $H(\rho)$ has a cycle on s_i and t_i,
- for every $1 \leq i \leq \ell$ if $M_i \neq \emptyset$ then for every $e = \{u, v\} \in M_i$, $H(\rho)$ has the edge $\{u_i v_i\}$,
- for every $1 \leq i < \ell$, $H(\rho)$ contains the edge $\{r_i, l_{i+1}\}$ if $r \in \psi_i(R)$ and $l \in \psi_{i+1}(L)$,
- for every $1 \leq i < \ell$, $H(\rho)$ contains the edge $\{r'_i, l'_{i+1}\}$ if $r' \in \psi_i(R)$ and $l' \in \psi_{i+1}(L)$.

We say that ρ is *compatible* if it is weakly compatible and furthermore either $H(\rho)$ is acyclic, or $H(\rho) - (\bigcup_{i=1}^{\ell} S_i)$ is a single (Hamiltonian) cycle.

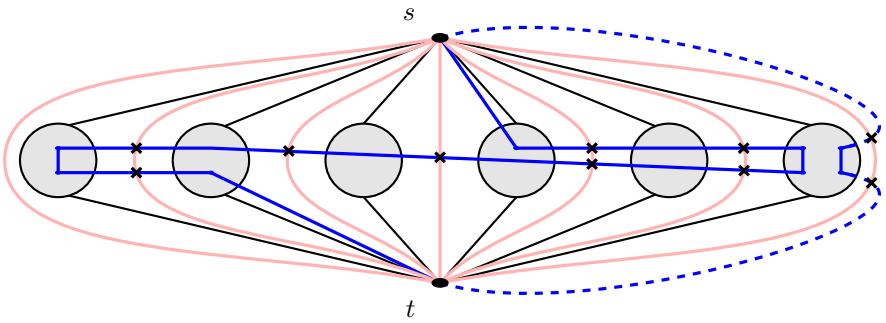

Figure 6 An illustration of how a Hamiltonian Cycle in normal form can interact with a drawing of $\text{PE}(b)$ for a P-node b. Here, the pertinent graphs $\text{PE}(c)$ for all children c of b (without the nodes s and t of the common reference edge (s,t)) are represented by gray ellipses. The Hamiltonian cycle is given in blue with dashed segments representing path segments outside of $\text{PE}(b)$. The red curves represent the subcurves of N_c for every child c of b. In this figure all but the types of the second and fourth pertinent graph are clean. Moreover, the type of the third and fifth pertinent graphs are 1-good and 2-good, respectively, and the types of all other pertinent graphs are bad.

In the following let $\rho = (X_1, \dots, X_\ell)$ be compatible. We now define the type X associated with ρ, which we denote by $X(\rho)$, as follows. If $H(\rho)$ is a single cycle and $\{s,t\} \subseteq \bigcup_{i=1}^{\ell} S_i$, then we set $X(\rho) = (\psi, \emptyset, \{s,t\})$, where $\psi(L) = \psi(R) = \emptyset$. Otherwise, let $\mathcal{P}(\rho)$ be the set of paths in $H(\rho)$, which can be shown to have their endpoints in $\{s,t,l_1,l'_1,r_\ell,r'_\ell\}$. Then, we set $X(\rho) = (\psi, M, S)$, where ψ, M, and S are defined as follows. M contains the set $\{u,v\}$ for every path in $\mathcal{P}(\rho)$ with endpoints u and v; for brevity, we denote l_1, l'_1, r_ℓ, r'_ℓ as l, l', r, r', respectively. Moreover, $\psi(L) = V(M) \cap \{l,l'\}$, $\psi(R) = V(M) \cap \{r,r'\}$, and S contains s (t) if $\sum_{i=1}^{\ell} \#_s(X_i) = 2$ ($\sum_{i=1}^{\ell} \#_t(X_i) = 2$).

We say that ρ is *realizable* if there is an ordering $\pi = (c_1, \dots, c_\ell)$ of the children in C and an assignment $\tau : C \to \mathcal{X}$ from children to types with $\tau(c) \in \mathcal{R}(c)$ for every $c \in C$ such that $\rho = \tau(\pi) = (\tau(c_1), \dots, \tau(c_\ell))$. The following lemma now allows us to focus on finding the set of all types X for which there is a compatible and realizable ρ such that $X = X(\rho)$.

▶ **Lemma 11.** *The set R containing every type $X \in \mathcal{X}$ such that there is a compatible and realizable ρ with $X = X(\rho)$ satisfies the properties* **(R1)** *and* **(R2)**.

We will now show that this can be achieved very efficiently because only a constant number, i.e., at most 8 types (and their ordering) need to be specified in order to infer the type of a sequence ρ. Let $X = (\psi, M, S) \in \mathcal{X}$ be a type. We say that X is *dirty* if $\#_s(X) + \#_t(X) > 0$ and otherwise we say that X is *clean*. We say that X is 0-*good*, 1-*good*, and 2-*good*, if X is clean and additionally $M = \emptyset$, $M = \{\{l,r\}\}$, and $M = \{\{l,r\},\{l',r'\}\}$, respectively. We say that X is *good* if it is x-good for some $x \in \{0,1,2\}$ and otherwise we say that X is *bad*. We denote by $\mathcal{X}_G$ and $\mathcal{X}_B$ the subset of $\mathcal{X}$ consisting only of the good respectively bad types. An illustration of these notions is provided in Figure 6.

▶ **Lemma 12.** *Let $\rho = (X_1, \dots, X_\ell)$ be compatible, then ρ contains at most 8 bad types.*

Next, we will show that any compatible sequence contains at most 8 bad types and that the type $X(\rho)$ is already determined by looking only at the sequence of bad types that occur in ρ. This will then allow us to simulate the enumeration of all possible sequences, by enumerating merely all sequences of at most 8 bad types.

We say that a sequence ρ' is an extension of ρ if ρ is a (not necessarily consecutive) sub-sequence of ρ'. We call a compatible sequence ρ (X,i)-*extendable* for some $X \in \mathcal{X}$ and

integer i, if there is a compatible extension ρ' of ρ such that ρ' is obtained by adding i elements of type X to ρ and $X(\rho) = X(\rho')$. We call ρ *X-extendable* if ρ is (X,i)-extendable for any integer i. We say that ρ' is an *(X,i)-extension* of ρ if ρ' is a compatible sequence obtained after adding i elements of type X to ρ and $X(\rho) = X(\rho')$.

▶ **Lemma 13.** *Let $\rho = (X_1, \ldots, X_\ell)$ with $X_i = (\psi_i, M_i, S_i)$ and $X \in \mathcal{X}_G$. Then, ρ is $(X,1)$-extendable if and only if ρ is X-extendable. Moreover, deciding whether ρ is $(X,1)$-extendable and if so computing an (X,i)-extension ρ' of ρ can be achieved in time $\mathcal{O}(\ell + i)$ for every integer i.*

▶ **Lemma 14.** *Let ρ be a compatible sequence and let ρ' be the sub-sequence of ρ consisting only of the bad types in ρ. Then, ρ' is compatible and $X(\rho) = X(\rho')$.*

At this point, we are ready to describe the algorithm we will use to compute $\mathcal{R}(b)$ (and argue its correctness). The algorithm first enumerates all possible compatible sequences ρ of at most 8 bad types, i.e., $\rho = (Y_1, \ldots, Y_r)$ with $r \leq 8$ and $Y_i \in \mathcal{X}_B$ for every i. Note that there are at most $(|\mathcal{X}_B| + 1)^8$ (and therefore constantly many) such sequences and those can be enumerated in constant time. Given one such sequence $\rho = (Y_1, \ldots, Y_r)$, the algorithm then tests whether the sequence can be realized given the types available for the children in C as follows. It first uses Lemma 13 to test whether ρ allows for adding a 0-good, 1-good or 2-good type in constant time. Let $A_\rho \subseteq \mathcal{X}_G$ be the set of all good types that can be added to ρ and let C_ρ be the subset of C containing all children c such that $A_\rho \cap \mathcal{R}(c) \neq \emptyset$.

Consider the following bipartite graph Q_ρ having one vertex y_i for every i with $1 \leq i \leq r$ representing the type Y_i on one side and one vertex v_c for every $c \in C$ representing the child c on the other side of the bipartition. Moreover, Q_ρ has an edge between y_i and v_c if $Y_i \in \mathcal{R}(c)$. We claim that ρ can be extended to a compatible and realizable sequence if and only if Q_ρ has a matching that saturates $\{y_1, \ldots, y_r\} \cup \{ v_c \mid c \in C \setminus C_\rho \}$. This problem can be solved using a simple reduction to the well-known maximum flow problem. The following lemma now establishes the correctness (i.e., the soundness and completeness) of the algorithm.

▶ **Lemma 15.** *Let $X \in \mathcal{X}$. Then, there is a compatible and realizable sequence ρ with $X = X(\rho)$ if and only if there is a compatible sequence $\rho = (Y_1, \ldots, Y_r)$ of bad types with $r \leq 8$ with $X = X(\rho)$ such that the bipartite graph H_ρ has a matching that saturates $\{y_1, \ldots, y_r\} \cup \{ v_c \mid c \in C \setminus C_\rho \}$.*

5.2 Handling R-nodes and S-nodes

Here, we will show how to compute a set of types satisfying **(R1)** and **(R2)** for every R-node and S-node of $\mathcal{B}$. To achieve this we will again use a dynamic programming algorithm albeit on a sphere-cut decomposition of $\textsc{Sk}(b)$ instead of on the SPQR-tree. The aim of this subsection is therefore to show the following lemma.

▶ **Lemma 16.** *Let b be an R-node or S-node of $\mathcal{B}$ such that $\mathcal{R}(c)$ has already been computed for every child c of b in $\mathcal{B}$. Then, we can compute $\mathcal{R}(b)$ in time $\mathcal{O}((84\sqrt{14})^\omega \omega \ell + \ell^3)$, where ω is the branchwidth of the graph $\textsc{Sk}(b)$ and ℓ is the number of children of b in $\mathcal{B}$.*

In the following, let b be an R-node or S-node of $\mathcal{B}$ with reference edge (s_b, t_b) and let $\langle T_b, \lambda_b, \Pi_b \rangle$ be a sphere-cut decomposition of $\textsc{Sk}(b)$ that is rooted in $r = \lambda_b^{-1}((s_b, t_b))$. For a weak noose $O \subseteq C(T_b)$, let $\mathcal{A}(O)$ be the set of all types of O satisfying the following two natural analogs of **(R1)** and **(R2)**, i.e.:

(RO1) if $X \in \mathcal{A}(O)$, then O has type X, and **(RO2)** if there is a witness (D, D_H, G_H, H) for G that *respects* $\mathcal{B}$ such that $\Gamma_W(b, O) = X$, where $\Gamma_W(b, O)$ is defined analogously to $\Gamma_W(b)$ for the graph $\textsc{Pe}(b, O)$, then $X \in \mathcal{A}(O)$.

Our aim is to compute $\mathcal{A}(O_{a^r})$ for the arc a^r incident to the root r of T_b. This is achieved by computing $\mathcal{A}(O_a)$ for every inner arc a of T_b via a bottom-up dynamic programming algorithm along T_b; after initially calculating $\mathcal{A}(O_a)$ from $\mathcal{R}(c)$ for every leaf-arc a corresponding to the child c of b. Employing our framework introduced in Subsection 4.3, we only have to show how to compute $\mathcal{A}(O_1 \oplus O_2)$ from $\mathcal{A}(O_1)$ and $\mathcal{A}(O_2)$ for any weak nooses O_1 and O_2.

Let O_1 and O_2 be two weak nooses having type $X_1 = (\psi_1, M_1, S_1)$ and type $X_2 = (\psi_2, M_2, S_2)$, respectively. We say that X_1 and X_2 are *compatible* if

(1) $O = O_1 \oplus O_2$ is a weak noose,
(2) the inside region of the noose O contains all subcurves in $(O_1 \cap O_2)$,
(3) $\forall c \in O_1 \cap O_2$, it holds $\psi_1(c) = \psi_2(c)$,
(4) for every $u \in V(O_1 \cap O_2) \setminus V(O_1 \oplus O_2)$, it holds that u is only in one of following sets: S_1, S_2 or $V(M_1) \cap V(M_2)$, and
(5) the multi-graph obtained from the union of M_1 and M_2 is acyclic, or is one cycle and $V(O) \subseteq S_1 \cup S_2 \cup (V(M_1) \cap V(M_2))$,
(6) if X_1 is the full type, then X_2 is the empty type and $V(O_2) \subseteq V(O_1)$, and vice versa.

We denote by $X_1 \circ X_2$ the *combined type* $X = (\psi, M, S)$ of $X_1 = (\psi_1, M_1, S_1)$ and $X_2 = (\psi_2, M_2, S_2)$ for the weak noose $O = O_1 \oplus O_2$ that is defined as follows and also illustrated in Figure 7. For each $c \in O$, if $c \in O_1$ then $\psi(c)$ is equal to $\psi_1(c)$, otherwise $\psi(c)$ is equal to $\psi_2(c)$ and the set S is equal to $(S_1 \cup S_2 \cup (V(M_1) \cap V(M_2))) \cap V(O)$, i.e., any vertex with degree two w.r.t. X must be in $V(O)$ and have degree two already w.r.t. X_1 or X_2, or it must be in both matchings M_1 and M_2. If either X_1 or X_2 is a full type, then by **(6)** we get that $M_1 = M_2 = M = \emptyset$ and $X_1 \circ X_2$ is the full type. If the multi-graph $M_1 \cup M_2$ is one cycle, then by **(5)** we get that $M = \emptyset$ and $X_1 \circ X_2$ is the full type. Otherwise, due to **(5)**, the multi-graph $M_1 \cup M_2$ is acyclic and corresponds to a set of paths. Therefore, the matching M is the set containing the two endpoints for every path in $M_1 \cup M_2$.

▶ **Observation 17.** *Let X_1 and X_2 be two types defined on the weak nooses O_1 and O_2, respectively. Then, we can check whether X_1 and X_2 are compatible and if so compute the type $X_1 \circ X_2$ in time $\mathcal{O}(|O_1| + |O_2|)$.*

To show the correctness of our approach it now remains to show that: (1) if there is a witness W for G that respects $\mathcal{B}$, then for every two weak nooses O_1 and O_2 it holds that $\Gamma_W(b, O_1)$ and $\Gamma_W(b, O_2)$ are compatible types and $\Gamma_W(b, O) = \Gamma_W(b, O_1) \circ \Gamma_W(b, O_2)$ and (2) if O_1 and O_2 have compatible types X_1 and X_2, then $O = O_1 \oplus O_1$ has type $X_1 \circ X_2$.

5.3 Putting Everything Together

Finally, we show how to compute the set of types for every leaf (Q-node) l of $\mathcal{B}$ in time $\mathcal{O}(1)$; informally, since $\textsc{Pe}(b)$ is just an edge (s, t), $\mathcal{R}(l)$ contains all types that do not allow the Hamiltonian cycle to cross from left to right without using either s or t. Together with Lemma 10 and 16, this then concludes the proof of Lemma 9.

6 An Algorithm Using the Feedback Edge Number

In this section, we establish the following theorem:

▶ **Theorem 18.** Book Thickness *is fixed-parameter tractable when parameterized by the feedback edge number of the input graph.*

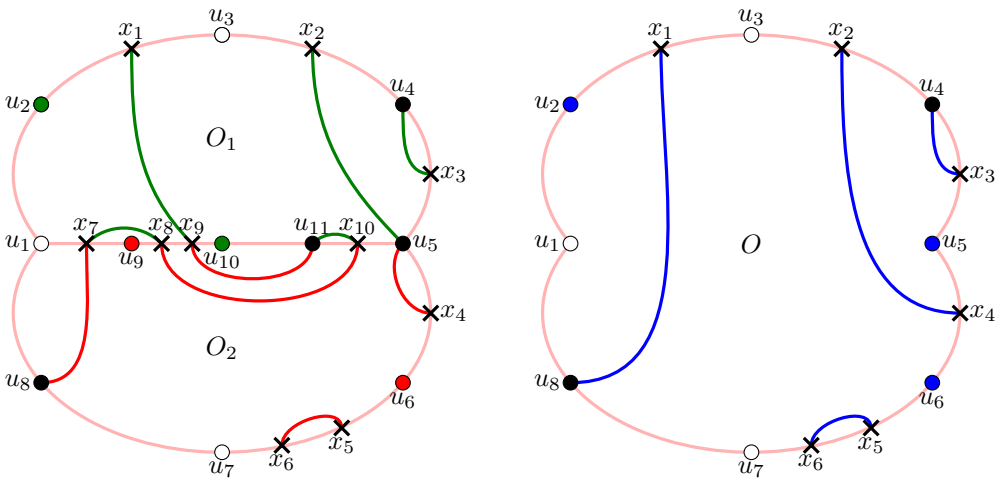

Figure 7 An illustration of combining two compatible types $X_1 = (\psi_1, M_1, S_1)$ and $X_2 = (\psi_2, M_2, S_2)$ for two weak nooses O_1 and O_2 into the combined type $X = (\psi, M, S) = X_1 \circ X_2$ for $O = O_1 \oplus O_2$. Vertices of the graph are represented as circles and vertices subdividing the nooses, i.e., vertices in $V(\psi_1) \cup V(\psi_2)$, are represented as crosses. Black vertices are the vertices that are within a matching, i.e., the vertices in $V(M_1) \cup V(M_2)$, green (red) vertices are the vertices in S_1 (S_2) and all other vertices of the graph are white.

The result is achieved by separately handling two cases: one where the targeted number of pages is greater than 2, or where it is precisely 2. Both cases are handled by a kernelization procedure, and in both cases it is easy to show that pendant vertices can be safely removed. At this point, the target graph consists of a tree plus k edges, whereas the only part that may remain large in this tree are paths of degree-2 vertices. In the former case, we obtain a non-trivial proof that allows us to reduce the maximum length of such a path to length that is bounded by an exponential function of the feedback edge number. In the latter case (which is equivalent to solving SUBHAM), the reduction step is easier and we in fact obtain a linear kernel for the problem:

▶ **Theorem 19.** SUBHAM *parameterized by the feedback edge number k admits a kernel with at most $12k - 8$ vertices and at most $14k - 9$ edges.*

Moreover, by combining Theorem 19 with the subexponential algorithm of Corollary 8, we can slightly strengthen our main result as follows.

▶ **Corollary 20.** SUBHAM *can be solved in time $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$, where k is the feedback edge number of the input graph.*

7 Concluding Remarks

While our main algorithmic result settles the complexity of computing 2-page book embeddings under the exponential time hypothesis, many questions remain when one aims at computing k-page book embeddings for a fixed k greater than 2. To the best of our knowledge, even the existence of a single-exponential algorithm for this problem is open.

In terms of the problem's parameterized complexity, it is natural to ask whether one can obtain a generalization of Theorem 7 for computing k-page book embeddings when $k > 2$. In fact, it is entirely open whether computing, e.g., 4-page book embeddings is even in XP

when parameterized by the treewidth. In this sense, our positive result for the feedback edge number can be seen as a natural step on the way towards finally settling the structural boundaries of tractability for computing page-optimal book embeddings.

Quantum Algorithms for Graph Coloring and Other Partitioning, Covering, and Packing Problems

Abstract

Let U be a universe on n elements, let k be a positive integer, and let $\mathcal{F}$ be a family of (implicitly defined) subsets of U. We consider the problems of partitioning U into k sets from $\mathcal{F}$, covering U with k sets from $\mathcal{F}$, and packing k non-intersecting sets from $\mathcal{F}$ into U. Classically, these problems can be solved via inclusion–exclusion in $2^n n^{O(1)}$ time [8]. Quantumly, there are faster algorithms for graph coloring with running time $O(1.9140^n)$ [26] and for Set Cover with a small number of sets with running time $O\left(1.7274^n |\mathcal{F}|^{O(1)}\right)$ [1]. In this paper, we give a quantum speedup for Set Partition, Set Cover, and Set Packing whenever there is a classical enumeration algorithm that lends itself to a quadratic quantum speedup, which, for any subinstance on a set $X \subseteq U$, enumerates at least one member of a k-partition, k-cover, or k-packing (if one exists) restricted to (or projected onto, in the case of k-cover) the set X in $c^{|X|}n^{O(1)}$ time with $c < 2$. Our bounded-error quantum algorithm runs in time $(2+c)^{n/2}n^{O(1)}$ for Set Partition, Set Cover, and Set Packing. It is obtained by combining three algorithms that have the best running time for some values of c. When $c \leq 1.147899$, our algorithm is slightly faster than $(2+c)^{n/2}n^{O(1)}$; when c approaches 1, it matches the $O\left(1.7274^n |\mathcal{F}|^{O(1)}\right)$ running time of [1] for Set Cover when $|\mathcal{F}|$ is subexponential in n.

For covering, packing, and partitioning into maximal independent sets, maximal cliques, maximal bicliques, maximal cluster graphs, maximal triangle-free graphs, maximal cographs, maximal claw-free graphs, maximal trivially-perfect graphs, maximal threshold graphs, maximal split graphs, maximal line graphs, and maximal induced forests, we obtain bounded-error quantum algorithms with running times ranging from $O(1.8554^n)$ to $O(1.9629^n)$. Packing and covering by maximal induced matchings can be done quantumly in $O(1.8934^n)$ time.

For Graph Coloring (covering with k maximal independent sets), we further improve the running time to $O(1.7956^n)$ by leveraging faster algorithms for coloring with a small number of colors to better balance our divide-and-conquer steps. For Domatic Number (packing k minimal dominating sets), we obtain a $O((2-\varepsilon)^n)$ running time for some $\varepsilon > 0$.

Several of our results should be of interest to proponents of classical computing:

- We present an inclusion-exclusion algorithm with running time $O^*\left(\sum_{i=0}^{\lfloor \alpha n \rfloor} \binom{n}{i}\right)$, which determines, for each $X \subseteq U$ of size at most αn, $0 \leq \alpha \leq 1$, whether $(X, \mathcal{F})$ has a k-cover, k-partition, or k-packing. This running time is best-possible, up to polynomial factors.
- We prove that for any linear-sized vertex subset $X \subseteq V$ of a graph $G = (V, E)$, the number of minimal dominating sets of G that are subsets of X is $O((2-\varepsilon)^{|X|})$ for some $\varepsilon > 0$.

1 Introduction

Graph Coloring is an example of a problem requiring to partition an n-element set U into k sets from a family $\mathcal{F}$. In this case U is the vertex set of a graph G and $\mathcal{F}$ is implicitly defined as the independent sets of G. We can also view Graph Coloring as a covering problem where the vertex set needs to be covered with k maximal independent sets.

In 2006, Björklund and Husfeldt [4] and Koivisto [25] independently solved Graph Coloring in $O^*(2^n)$ time via a new inclusion–exclusion approach, along with other partitioning and covering problems. The approach has been used for packing problems as well, and has been generalized to solve more generic subset convolution problems [5, 7, 8].

In this work, we give faster quantum algorithms for a range of partitioning, covering, and packing problems, including Graph Coloring and Domatic Number. To do this, we use the framework of Ambainis et al. [1] where a preprocessing step computes solutions to small subinstances and stores them in QRAM. These solutions are then accessed by a divide-and-conquer algorithm which enjoys a quadratic speedup in quantum models of computation via techniques such as Grover's search [22]. For the preprocessing step (Section 3), we adapt the afore-mentioned inclusion-exclusion approach [8] to compute the solutions to all subinstances induced by a small subset of U up to roughly $n/4$ elements. For the divide-and-conquer step (Section 4) one would ideally like to divide U into two halves; unfortunately, optimal partitions[1] may not allow for such a balanced split. However, we can restrict the divide-and-conquer step to divide U into two parts where in the larger part (equivalently, in both parts) the removal of one set of an optimal partition results in at most $n/2$ elements. Finding one set of the optimal partition is done via an algorithm that enumerates all relevant candidate sets; for Graph Coloring, it enumerates the maximal independent sets in the graph induced by the subset $X \subseteq U$ under consideration. Importantly, we need that this enumeration can be done in $O^*\left(c^{|X|}\right)$ time, for some $c < 2$ by a classical algorithm that has a quadratic quantum speedup, so that after two levels of divide-and-conquer, the overall quadratic quantum speedup outperforms the classical $O^*(2^n)$ running time.

Our algorithm differs from the previously fastest quantum algorithm for Graph Coloring by Shimizu and Mori [26] in both the preprocessing step and the divide-and-conquer step. Our preprocessing step is deterministic and its running time is optimal, matching the size of the output up to polynomial factors; the preprocessing step of [26] is a bounded-error quantum algorithm whose running time is a multiplicative factor of $3^{|X|/6}$ slower than ours for each small (up to size roughly $n/4$) subset $X \subseteq U$. For the divide-and-conquer step, our divide-then-enumerate strategy is described above; [26] employ an enumerate-then-divide strategy, where the enumeration is done on the set to be divided and the remainder is then divided into two sets of size at most half the original set. It turns out that blending the the divide-then-enumerate and the enumerate-then-divide strategy gives faster algorithms when $c \leq 1.147899$ (Section 5). For $c \leq 1.0872$ case, we also use a third level of divide-and-conquer, and when c approaches 1, our $O(1.7274^n)$ running time matches the running time for Set Cover with a subexponential number of sets of Ambainis et al. [1].

This gives improved algorithms for a range of partitioning, covering, and packing problems (Section 6). We further improve the running time for Graph Coloring (Section 7) to $O(1.7956^n)$ by leveraging faster algorithms for a small number of colors [26]. Our algorithm considers large subsets of vertices ($\geq 0.48n$) and checks whether they are 5-colorable, 6-colorable with

[1] For conciseness, we will mainly discuss partitions in the introduction. The treatment of covers and packings is similar.

no large 5-colorable subset, and in some cases 7-colorable via a new 7-Coloring algorithm that relies on the preprocessing step. The advantage of excluding such cases from further consideration is that we can make the divide-and-conquer steps more balanced.

For Domatic Number, at first glance it seems that our approach cannot be used. The issue is that when considering a vertex subset X, even though there is an algorithm that enumerates all minimal dominating sets of $G[X]$ in $O(1.7159^n)$ time [16], this is insufficient for our purposes: we need to enumerate minimal vertex subsets of X that dominate all of G, not just $G[X]$, in $O^*\left(c^{|X|}\right)$ time for some $c < 2$. In Section 8, we show that such an enumeration algorithm (with a quadratic quantum speedup) indeed exists provided that $|X| = \Omega(n)$. This then also gives a bounded-error quantum algorithm for Domatic Number running in $O((2-\varepsilon)^n)$ time.

2 Preliminaries

For a proposition P, the *Iverson bracket* $[P]$ is a function that returns 1 if P is true and 0 otherwise.

Asymptotic notation

The O^*-notation is similar to the usual O-notation but allows to hide polynomial factors in the input size. The $\tilde{O}$-notation hides polylogarithmic factors. We make heavy use of Stirling's approximation for factorials, which implies that $\binom{n}{k} = O^*\left(\left(\frac{n}{k}\right)^k \cdot \left(\frac{n}{n-k}\right)^{n-k}\right)$, and of the binomial theorem, $\sum_{k=0}^{n}\binom{n}{k}x^k y^{n-k} = (x+y)^n$.

Set Systems

An *implicit set system* [15] is a function Φ that takes as input a string $I \in \{0,1\}^*$ and outputs a set system $(U_I, \mathcal{F}_I)$, where U_I is a universe and $\mathcal{F}_I$ is a collection of subsets of U_I. The string I is referred to as an *instance* and we denote by $|U_I| = n$ the size of the universe and by $|I| = N$ the size of the instance. We assume that $N \geq n$. The implicit set system Φ is said to be *polynomial time computable* if (a) there exists a polynomial time algorithm that given I, produces U_I, and (b) there exists a polynomial time algorithm that given I, U_I and a subset S of U_I, determines whether $S \in \mathcal{F}_I$. Throughout this paper, we consider only polynomial time computable implicit set systems. We define a *subset polynomial time computable* implicit set system Φ to be a polynomial time computable set system, where (c) there exists a polynomial time algorithm that given I, U_I and a subset S of U_I, determines whether $S \subseteq S'$ for some $S' \in \mathcal{F}_I$. This is equivalent to determining whether $S \in \mathcal{F}\downarrow$, where the downward closure $\mathcal{F}\downarrow$ of $\mathcal{F}$ contains all sets in $\mathcal{F}$ and their subsets.

For any subset of elements $X \subseteq U$, an ordered tuple $(S_1, \ldots, S_k)$ of k sets from $\mathcal{F}$ is a *k-cover* for X if the union of these sets is X; it is a *k-packing* for X if the S_i's are contained in X and are pairwise non-intersecting; it is a *k-partition* for X if it is both a k-cover and a k-packing for X.

For a subset polynomial time computable implicit set system Φ, the input of the Φ-Set Cover problem is an instance I and an integer k, and the question is whether the set system $\Phi(I) = (U_I, \mathcal{F}_I)$ has a k-cover. This is equivalent to asking whether $(U_I, \mathcal{F}_I\downarrow)$ has a k-cover and therefore, we assume that $\mathcal{F}_I = \mathcal{F}_I\downarrow$ whenever discussing k-covers. For a polynomial time computable implicit set system Φ, the input of the Φ-Set Partition and Φ-Set Packing problem is an instance I and an integer k, and the question is whether the set system $\Phi(I) = (U_I, \mathcal{F}_I)$ has a k-partition or k-packing, respectively. We generally omit Φ and the subscript I when they are clear from context.

Graphs

In a graph $G = (V, E)$, the *open neighborhood* of a vertex v, denoted $N_G(v)$ is the set containing all vertices adjacent to v in G. The *closed neighborhood* of v in G also contains v itself, and is denoted $N_G[v] = \{v\} \cup N_G(v)$. Again, we may omit the subscript G. For a vertex subset $X \subseteq V$, the graph $G - X$ is obtained from G by removing the vertices in X and all their incident edges; the graph $G[X]$ induced on X is the graph $G - (V \setminus X)$.

Quantum Algorithms

It is known that most classical branching algorithms have a quadratic speedup on quantum machines. As [26], we also rely on the following results.

▶ **Theorem 1** ([22, 9]). *Let $A : \{1, 2, \ldots, N\} \to \{0, 1\}$ be a bounded-error quantum algorithm with running time T. Then, there is a bounded-error quantum algorithm computing $\bigvee_{x\in\{1,\ldots,N\}} A(x)$ with running time $\tilde{O}(\sqrt{N}T)$.*

▶ **Theorem 2** ([13]). *Let $A : \{1, 2, \ldots, N\} \to \{0, 1\}$ be a bounded-error quantum algorithm with running time T. Then, there is a bounded-error quantum algorithm computing $\min_{x\in\{1,\ldots,N\}} A(x)$ with running time $\tilde{O}(\sqrt{N}T)$.*

In our context, A is an algorithm exploring paths in superposition from the root to the leaves of the search tree of a classical branching algorithm. The amplitudes of this exploration depend on estimates of the sizes of the subtrees, either by relying on an analysis of the classical branching algorithm [18, 26] or by on-the-fly estimations [2]. We speak of a *simple* branching algorithm when the exploration of one root-to-leaf path is independent of the other paths; this excludes, for example, algorithms relying on clause learning, re-use of computation done in earlier branches, and branch-and-bound. For a simple branching algorithm with running time $O^*(c^n)$, one obtains a bounded-error quantum algorithm with running time $O^*(c^{n/2})$ in this way; we simply say that we apply Grover's search to the branching algorithm.

3 Preprocessing small subsets

For $\alpha \in [0, 1]$, a subset X of U is *α-small* if $|X| \leq \alpha n$. Denote by $s(n, \alpha) = \sum_{i=0}^{\lfloor \alpha n \rfloor} \binom{n}{i}$ the number of α-small subsets of U. In this section, we consider the problem of counting the number of k-covers, k-packings, and k-partitions for each α-small subset of U. When considering k-covers, we assume that $\mathcal{F}$ has been replaced by $\mathcal{F}\downarrow$. This is because when we would like to cover a subset of elements of X, we may use a set from $\mathcal{F}$ that also contains elements outside of X. Since Φ is subset polynomial time computable in the Φ-Set Cover problem, we may as well replace $\mathcal{F}$ by $\mathcal{F}\downarrow$; this makes the discussion of covering, partitioning, and packing problems more uniform. Our algorithms run in $O^*(s(n, \alpha))$ time, which is best possible, since the output is a list of $s(n, \alpha)$ integers.

This section heavily relies on previous $O^*(2^n)$ inclusion-exclusion approaches [7, 8] to compute the number of k-covers, k-packings, and k-partitions for U and these results are well-known when $\alpha = 1$. The work by [6] is also related, but their running times depends on the number of supersets of $\mathcal{F}$.

We start by defining the α-small zeta transform, which is central to this section.

▶ **Definition 3.** *Let f be a function from subsets of the universe U to an algebraic ring R. The* α-small zeta transform *of f, denoted $f\zeta_\alpha$ is*

$$f\zeta_\alpha(X) = \sum_{Y\subseteq X} f(Y)$$

for any α-small $X \subseteq U$.

The 1-small zeta transform is also called the *zeta transform* and the α-small zeta transform is precisely the restriction of the zeta transform to α-small sets. Throughout this paper we assume that arithmetic operations in the ring R take $O^*(1)$ time and each ring element is represented using $O^*(1)$ space.

▶ **Definition 4.** *Let f be a function from subsets of the universe U to an algebraic ring R. The* α-small Möbius transform *of f, denoted $f\mu_\alpha$ is*

$$f\mu_\alpha(X) = \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} f(Y)$$

for any α-small $X \subseteq U$.

It is well-known (see, e.g., [17]) that $f\zeta_\alpha\mu_\alpha = f\mu_\alpha\zeta_\alpha = f$ when $\alpha = 1$, and the same is true when $\alpha \neq 1$.

▶ **Lemma 5.** *The α-small zeta transform $f\zeta_\alpha$ and the α-small Möbius transform $f\mu_\alpha$ can be computed in $O^*(s(n, \alpha))$ time.*

Proof. We start with $f\zeta_\alpha$ and proceed as in Yates's method [27]. Consider an arbitrary ordering of the elements of $U = \{v_1, \ldots, v_n\}$. The algorithm considers each α-small $X \subseteq U$ by increasing order of cardinality.

Set $g_0(X) = f(X)$. Then, iterate over the elements of U in the ordering fixed above. When processing element v_i, set

$$g_i(X) = g_{i-1}(X) + [v_i \in X] \cdot g_{i-1}(X \setminus \{v_i\}).$$

Finally, set $f\zeta_\alpha(X) = g_n(X)$.

Correctness can be shown by induction on i by observing that

$$g_i(X) = \sum_{\{v_{i+1}, \ldots, v_n\} \cap X \subseteq Y \subseteq X} f(Y).$$

For each set X the computation takes $O^*(1)$ time, and the number of sets X to be considered is $s(n, \alpha)$.

To compute $f\mu_\alpha$, we use the fact that $\mu_\alpha = \sigma_\alpha\zeta_\alpha\sigma_\alpha$, where the α-small odd-negation transform is

$$f\sigma_\alpha(X) = (-1)^{|X|} f(X),$$

defined for any α-small $X \subseteq U$. Indeed,

$$\begin{aligned} f\sigma_\alpha\zeta_\alpha\sigma_\alpha(X) &= (-1)^{|X|} \cdot \sum_{Y \subseteq X} (-1)^{|Y|} \cdot f(Y) \\ &= \sum_{Y \subseteq X} (-1)^{|X|+|Y|} f(Y) \\ &= \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} f(Y) \end{aligned}$$

since $|X|+|Y|$ and $|X|-|Y| = |X \setminus Y|$ have the same parity. The result now follows, because, for a function g and a set X, $g\sigma_\alpha(X)$ can be computed in $O^*(1)$ time. ◀

We refer to these algorithms as the *fast α-small zeta transform* and the *fast α-small Möbius transform*.

By inclusion-exclusion, the number of k-covers for a subset $X \subseteq U$ is [7]

$$c_k(\mathcal{F}, X) = \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} a(Y)^k, \tag{1}$$

where $a(Y)$ is the number of subsets $Z \subseteq Y$ that belong to $\mathcal{F} = \mathcal{F}\downarrow$.

For the number of k-partitions, we use an indeterminate z in the ring R that allows us to keep track of the sum of the cardinalities of the sets in the cover. The number of k-partitions for a subset $X \subseteq U$ is given [7] by the coefficient of the monomial $z^{|X|}$ in the polynomial

$$d_k(\mathcal{F}, X) = \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} \left(\sum_{j=0}^{|Y|} a_j(Y) z^j \right)^k, \tag{2}$$

where $a_j(Y)$ is the number of size-j subsets $Z \subseteq Y$ that belong to $\mathcal{F}$.

For the number of k-packings of X, we compute the number of $(k+1)$-partitions where the first k members of the $(k+1)$-tuple belong to $\mathcal{F}$ and the last member is an arbitrary subset of X. Noting that $(1+z)^{|Y|} = \sum_{i=0}^{|Y|} \binom{|Y|}{i} z^i$, the number of k-packings for $X \subseteq U$ is [7] the coefficient of $z^{|X|}$ in

$$p_k(\mathcal{F}, X) = \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} (1+z)^{|Y|} \left(\sum_{j=0}^{|Y|} a_j(Y) z^j \right)^k. \tag{3}$$

The first algorithmic step is to compute the values for $a(Y)$ in (1) and the polynomials $\sum_{j=0}^{|Y|} a_j(Y) z^j$ in (2) and (3). Observe that $|Y| \leq |X| \leq \alpha n$. To compute the values $a(Y)$ for all α-small $Y \subseteq U$, observe that $a(Y) = \sum_{Z \subseteq Y} [Z \in \mathcal{F}]$ is the α-small zeta transform of the indicator function of $\mathcal{F}$. Since the implicit set system is polynomial time computable, the indicator function can be evaluated in polynomial time. Therefore, the fast α-small zeta transform allows us to compute all relevant values of $a(\cdot)$ in $O^*(s(n,\alpha))$ time. Similarly, the polynomial $\sum_{j=0}^{|Y|} a_j(Y) z^j$ equals $h\zeta_\alpha(Y)$ where $h(Z) = [Z \in \mathcal{F}] \cdot z^{|Z|}$ and can be computed in the same time bound by the fast α-small zeta transform.

The second algorithmic step is to to use the fast α-small Möbius transform and apply it to the functions that associate with each α-small $Y \subseteq U$ the values $a(Y)^k$; $\left(\sum_{j=0}^{|Y|} a_j(Y) z^j\right)^k$; and $(1+z)^{|Y|} \left(\sum_{j=0}^{|Y|} a_j(Y) z^j\right)^k$, respectively.

We conclude that $c_k(\mathcal{F}, X)$, $d_k(\mathcal{F}, X)$, and $p_k(\mathcal{F}, X)$ for each α-small $X \subseteq U$ can be computed in $O^*(s(n,\alpha))$ time.

▶ **Theorem 6.** *Given a polynomial time computable implicit set family $\Phi(I) = (U, \mathcal{F})$ with $|U| = n$, there is a $O^*(s(n,\alpha))$ time algorithm which determines, for all $k \leq \alpha n$ and all α-small $X \subseteq U$, whether $(X, \mathcal{F})$ has a k-cover (if we assume that $\mathcal{F}$ is closed under subsets), k-partition, or k-packing.*

4 Divide-and-conquer algorithm

Let $\Phi(I) = (U, \mathcal{F})$ be a polynomial time computable implicit set family for which we would like to determine whether there is a k-cover (assuming $\mathcal{F} = \mathcal{F}\downarrow$), k-partition, or k-packing.

We say that a simple branching algorithm *enumerates* a family $\mathcal{F}'$ of subsets of U if, at each leaf of its search tree it finds at most one member of $\mathcal{F}'$, and collectively the leaves find all members of $\mathcal{F}'$ (duplicates are allowed).

Our algorithm uses a divide-and-conquer strategy where the universe is twice partitioned into two.

▶ **Definition 7.** *For a family of subsets $\mathcal{F}$ of a universe U, and a subset $X \subseteq U$, the* restriction *of $\mathcal{F}$ to X is $r(\mathcal{F}, X) = \{S \subseteq X : S \in \mathcal{F}\}$.*

Observe that $(U, \mathcal{F})$ has a k-partition (resp., a k-packing or a k-cover) for $k \geq 2$ iff there is a set $L \subseteq U$ and a positive integer $k_l < k$ such that $(L, r(\mathcal{F}, L))$ has a k_l-partition (resp., a k_l-packing or a k_l-cover) and $(R, r(\mathcal{F}, R))$ has a k_r-partition (resp., a k_r-packing or a k_r-cover), where $R = U \setminus L$ and $k_r = k - k_l$. We say that a k-partition, k-packing, or k-cover $(S_1, \ldots, S_k)$ does not *straddle* X if for each $i \in \{1, \ldots, k\}$, either $S_i \subseteq X$ or $S_i \cap X = \emptyset$.

In this section we prove the following theorem.

▶ **Theorem 8.** *Suppose there is a simple (classical) branching algorithm A, which, given an instance I with $\Phi(I) = (U, \mathcal{F})$ and a subset $X \subseteq U$, enumerates a family $e(X, \mathcal{F}_X)$ of subsets of X from $\mathcal{F}_X$ such that*

- *if $(U, \mathcal{F})$ has a k-cover (resp., a k-partition or a k-packing) that does not straddle X, then $(U, \mathcal{F})$ has a k-cover (resp., a k-partition or a k-packing) $(S_1, \ldots, S_k)$ with $S_1 \in e(X, \mathcal{F}_X)$, and*
- *the algorithm runs in $O^*(c^{|X|})$ time for some $c \leq 2$.*

Then, there is a bounded-error quantum algorithm, which determines whether $(U, \mathcal{F})$ has a k-cover (resp., a k-partition or a k-packing) in $O^*\left(\binom{n}{n/4} + (2+c)^{n/2}\right)$ time, where $n = |U|$.

From now on, we focus on Set Cover; the discussion of Set Partition and Set Packing is analogous. The first step is to use the algorithm from Theorem 6 with $\alpha = \frac{1}{4}$ and store the result in QRAM.

Ideally, we would want to divide the universe U into equal sized sets L and R and compute a k-cover where each set of the cover is responsible for covering elements of either L or R. However, we cannot guarantee that such a k-cover exists. Instead, we can focus on partitions of U into L and R with $|L| \geq n/2$ where the removal of one member of the k-cover decreases the size of L to at most $n/2$.

▶ **Lemma 9.** *For any $x \in \{0, \ldots, n\}$, $(U, \mathcal{F})$ has a k-cover, $k \geq 2$, iff there is a partition of U into (L, R) with $|L| \geq x$ and integers $k_L, k_R \geq 1$ with $k = k_L + k_R$ such that $(L, r(\mathcal{F}, L))$ has a k_L-cover $(S_1, \ldots, S_{k_L})$ and $(R, r(\mathcal{F}, R))$ has a k_r-cover such that $|S_i| \geq |L| - x$ for every $i \in \{1, \ldots, k_L\}$.*

Proof. For the backward direction, assume that $(L, r(\mathcal{F}, L))$ has a k_l-cover and $(R, r(\mathcal{F}, R))$ has a k_r-cover. Then $(L \cup R, r(\mathcal{F}, L) \cup r(\mathcal{F}, R))$ has a k-cover where $k = k_l + k_r$. This k-cover is of the form $(S_1, S_2, \cdots, S_k)$, where $S_i \subseteq r(\mathcal{F}, L) \cup r(\mathcal{F}, R)$. To turn it into a k-cover for $(U, \mathcal{F})$, we replace each S_i by a set S'_i with $S_i \subseteq S'_i \in \mathcal{F}$, and we note that such a set S'_i exists in $\mathcal{F}$, since S_i is the restriction of some set in $\mathcal{F}$ to either L or R. Hence, $(U, \mathcal{F})$ has a k-cover.

For the forward direction, assume that $(U, \mathcal{F})$ has a k-cover $(S_1, S_2, \cdots, S_k)$ and assume, w.l.o.g., that $|S_1| \geq |S_2| \geq \cdots \geq |S_k|$. Let $L = \bigcup_{i=1}^{k_L} S_i$ and $R = U \setminus L$ where k_L is the smallest value such that $|L| > x$. Obviously, $(S_1, S_2, \cdots, S_{k_L})$ is a k_L-cover of $(L, r(\mathcal{F}, L))$ and $(S_{k+1} \cap R, S_{k+2} \cap R, \cdots, S_k \cap R)$ is a k_R-cover of $(R, r(\mathcal{F}, R))$ where $k_R = k - k_L$.

Focusing on S_{k_L}, the smallest set in the cover of L, we have that

$$\begin{aligned}
&\bigcup_{i=1}^{k_L} S_i \setminus S_{k_L} \subseteq \bigcup_{i=1}^{k_L-1} S_i \\
\implies &|\bigcup_{i=1}^{k_L} S_i| - |S_{k_L}| \leq |\bigcup_{i=1}^{k_L-1} S_i| \\
\implies &\quad |L| - |S_{k_L}| \leq x \\
\implies &\quad |S_i| \geq |S_{k_L}| \geq |L| - x \ \text{ for all } i \in \{1, \ldots, k_L\}.
\end{aligned}$$

Therefore, $(U, \mathcal{F})$ has a k-cover if and only if the conditions are satisfied. ◀

In particular, this means that removing any member S_i of the k_L-cover gives a $(k_L - 1)$-cover of $L \setminus S_i$ and $|L \setminus S_i| \leq x$.

We use Grover's search to divide the elements into two sets (L, R) where $|L| \geq n/2$ and k into $k_L + k_R$. Then, we solve each of these two instances independently, again using Grover's search on $(L, r(\mathcal{F}, L))$ (resp., on $(R, r(\mathcal{F}, R))$), dividing it into (LL, LR) where $|LL| \geq n/4$ and $k_{LL} + k_{LR} = k_L$ (similar for R). For $(LL, r(\mathcal{F}, LL))$ (and, similarly, on the corresponding instances for LR, RL, RR), we use Grover's search on the branching algorithm A to enumerate candidate sets $S_1 \in e(LL, r(\mathcal{F}, LL))$; if $|LL| - |S_1| > n/4$, then this branch is unsuccessful; otherwise, look up whether $LL \setminus S_1$ has a $(k_{LL} - 1)$-cover in QRAM.

The running time of this algorithm is

$$O^*\left(\binom{n}{n/4}\right)$$

for running the algorithm from Theorem 6; the steps using Grover's search take

$$O^*\left(\sqrt{\sum_{l=\lceil n/2 \rceil}^{n} \binom{n}{l} \sum_{l'=\lceil n/4 \rceil}^{l} \binom{l}{l'} c^{l'}}\right) = O^*\left((2+c)^{n/2}\right)$$

time to achieve constant success probability. This proves Theorem 8.

Discussion

When $c \geq \frac{16}{3^{3/2}} - 2 \approx 1.079201$, then the running time is $O^*\left((2+c)^{n/2}\right)$. When $c \leq \frac{16}{3^{3/2}} - 2$, then the running time is dominated by the term $\binom{n}{n/4} \approx 1.7548^n$. For $c \leq 1.147899$, the next section gives faster algorithms.

5 Divide-and-conquer algorithms for small c

In this section, we again assume that there is an enumeration algorithm A, as in Theorem 8, with running time $O^*\left(c^{|X|}\right)$. We present two divide-and-conquer algorithms which are faster for small values of c.

Throughout this section, we focus on Set Cover; the discussion of Set Partition and Set Packing is analogous.

▶ **Theorem 10.** *There is a bounded-error quantum algorithm, which determines whether $(U, \mathcal{F})$ has a k-cover (resp., a k-partition or a k-packing) in $O^*\left(\binom{n}{n/4} + (1+c)^{\frac{3}{4} \cdot n}\right)$ time, where $n = |U|$.*

The first step is to use the algorithm from Theorem 6 with $\alpha = \frac{1}{4}$ and store the result in QRAM. Our algorithm is similar to the algorithm in Theorem 8, but we use the branching algorithm A to remove a subset from L before dividing it into (LL, LR). Again, Lemma 9 is central to our algorithm.

We use Grover's Search to divide the elements into two sets (L, R) where $|L| \geq n/2$ and k into $k_L + k_R$. Then, we solve each of these two instances independently, again using Grover's search on $(R, r(\mathcal{F}, R))$, dividing it into (RL, RR) where $|RL| \geq n/4$ and $k_{RL} + k_{RR} = k_R$. For the instance $(L, r(\mathcal{F}, L))$, we use Grover's search on the branching algorithm A to enumerate candidate sets $S_1 \in e(L, r(\mathcal{F}, L))$; if $|L| - |S_1| > n/2$ then this branch is unsuccessful; otherwise, we use Grover's search on the subinstance $(L \setminus S_1, r(\mathcal{F}, L \setminus S_1))$, dividing it into (LL, LR) where $|LL| \geq n/4$ and $k_{LL} + k_{LR} = k_L - 1$.

We process $(LL, r(\mathcal{F}, LL))$ (and, similarly, the corresponding instances for LR, RL, RR) as we did in Theorem 8 – we use Grover's search on the branching algorithm A to enumerate candidate sets $S_1 \in e(LL, r(\mathcal{F}, LL))$; if $|LL| - |S_1| > n/4$, then this branch is unsuccessful; otherwise, look up whether $LL \setminus S_1$ has a $(k_{LL} - 1)$-cover in QRAM.

The running time of this algorithm is

$$O^*\left(\binom{n}{n/4}\right)$$

for the running the algorithm from Theorem 6; the steps using Grover's search take

$$O^*\left(\sqrt{\sum_{l=\lceil n/2\rceil}^{n}\binom{n}{l}c^l\sum_{l'=\lceil n/4\rceil}^{\lfloor n/2\rfloor}\binom{n/2}{l'}c^{l'}}\right) = O^*\left((1+c)^{\frac{3}{4}\cdot n}\right)$$

time to achieve constant success probability. This proves Theorem 10.

Discussion

When $c \geq \frac{2^{8/3}}{3} - 1 \approx 1.11653$, then the running time is $O^*\left((1+c)^{\frac{3}{4}\cdot n}\right)$. When $c \leq \frac{2^{8/3}}{3} - 1$, then the running time is dominated by the term $\binom{n}{n/4} \approx 1.7548^n$. When $c \leq 1.0872$, then the following algorithm is faster.

▶ **Theorem 11.** *If $c \leq 1.0872$, there is a bounded-error quantum algorithm, which determines whether $(U, \mathcal{F})$ has a k-cover (resp., a k-partition or a k-packing) in*

$$O^*\left(\left(\min_{0.1303\leq\alpha\leq 0.25}\left((1+c)^{3/4}c^{\alpha/2}\left(1-4\cdot\alpha\right)^{\frac{4\cdot\alpha-1}{8}}\left(4\cdot\alpha\right)^{-\frac{\alpha}{2}},\ \alpha^{-\alpha}\cdot(1-\alpha)^{\alpha-1}\right)\right)^n\right)$$

time.

The first step is to use the algorithm from Theorem 6 with some $0.1303 \leq \alpha < 0.25$ and store the result in QRAM. Our algorithm is identical to the one presented in Theorem 10 except that we cannot directly look up whether a subset $X \subseteq U$ has a k-cover in QRAM for $|X| \leq n/4$. Instead, we use the following approach.

▶ **Lemma 12.** *If $c \leq 1.0872$ and $0.1303 \leq \alpha < 0.25$, after running the algorithm from Theorem 6, there exists a bounded-error quantum algorithm that checks for a k-cover of a subset $X \subseteq U$ where $|X| \leq n/4$ in $O^*\left(\sqrt{\binom{n/4}{\alpha\cdot n}\cdot c^{\alpha\cdot n}}\right)$ time.*

Proof. We use Grover's search to divide the elements of X into two sets (XL, XR) where $|XL| \geq \alpha \cdot n$ and k into $k_{XL} + k_{XR}$. We use Grover's search on the branching algorithm A to enumerate candidate sets $S_1 \in e(XL, r(\mathcal{F}, XL))$; if $|XL| - |S_1| > \alpha \cdot n$, then this branch is unsuccessful; otherwise, look up whether $XL \setminus S_1$ has a $(k_{XL} - 1)$-cover and XR has a k_{XR}-cover in QRAM. The correctness of this approach follows from Lemma 9.

As the function $f(x) = \binom{n/4}{x} c^x$ is strictly decreasing for $x > \frac{c}{c+1} \cdot \frac{n}{4}$ and

$$\alpha \cdot n \geq 0.1303 \cdot n > \frac{1.0872 \,/\, 4}{1.0872 + 1} \cdot n \geq \frac{c}{c+1} \cdot \frac{n}{4},$$

the running time of this algorithm is

$$O^*\left(\sqrt{\sum_{i=\lceil \alpha \cdot n \rceil}^{\lfloor n/4 \rfloor} \binom{n/4}{i} c^i}\right) = O^*\left(\sqrt{\binom{n/4}{\alpha \cdot n} c^{\alpha \cdot n}}\right).$$

This proves the lemma. ◀

Our algorithm is the same as the one in Theorem 8, except when we check for a $(k_{LL} - 1)$-cover for $LL \setminus S_1$ (resp., on LR, RL, RR) we use Lemma 12 instead of a direct lookup in QRAM.

Running the algorithm from Theorem 6 takes

$$O^*\left(\binom{n}{\alpha \cdot n}\right) = O^*\left(\alpha^{-\alpha n} \cdot (1-\alpha)^{(\alpha-1)n}\right)$$

time. The steps using Grover's search take

$$O^*\left(\sqrt{\sum_{l=\lceil n/2 \rceil}^{n} \binom{n}{l} c^l \sum_{l'=\lceil n/4 \rceil}^{\lfloor n/2 \rfloor} \binom{n/2}{l'} c^{l'}} \sqrt{\binom{0.25 \cdot n}{\alpha \cdot n} c^{\alpha \cdot n}}\right)$$
$$= O^*\left(\left((1+c)^{3/4} c^{\alpha/2} \left(\frac{1}{1-4\cdot\alpha}\right)^{\frac{1-4\cdot\alpha}{8}} \left(\frac{1}{4\cdot\alpha}\right)^{\frac{\alpha}{2}}\right)^n\right) \text{ time.}$$

The running time of the first part increases with α while the running time of the second part decreases with α. We can therefore optimise the running time by balancing the value of α for a given c. To determine when this approach is faster than $O^*\left(\binom{n}{n/4}\right)$ we compute the value of c when α is balanced at 0.25:

$$(1+c)^{3/4} c^{1/8} = \frac{4}{3^{3/4}}$$
$$\implies \qquad c \approx 1.08724 \ .$$

Therefore, this algorithm outperforms the algorithms of Theorem 8 and Theorem 10 when $c \leq 1.08723$.

Combining Theorem 8, Theorem 10, and Theorem 11, we obtain the following corollary.

▶ **Corollary 13.** *There is a bounded-error quantum algorithm, which determines whether $(U, \mathcal{F})$ has a k-cover (resp., a k-partition or a k-packing) in $O^*\left((2+c)^{n/2}\right)$ time, where $n = |U|$.*

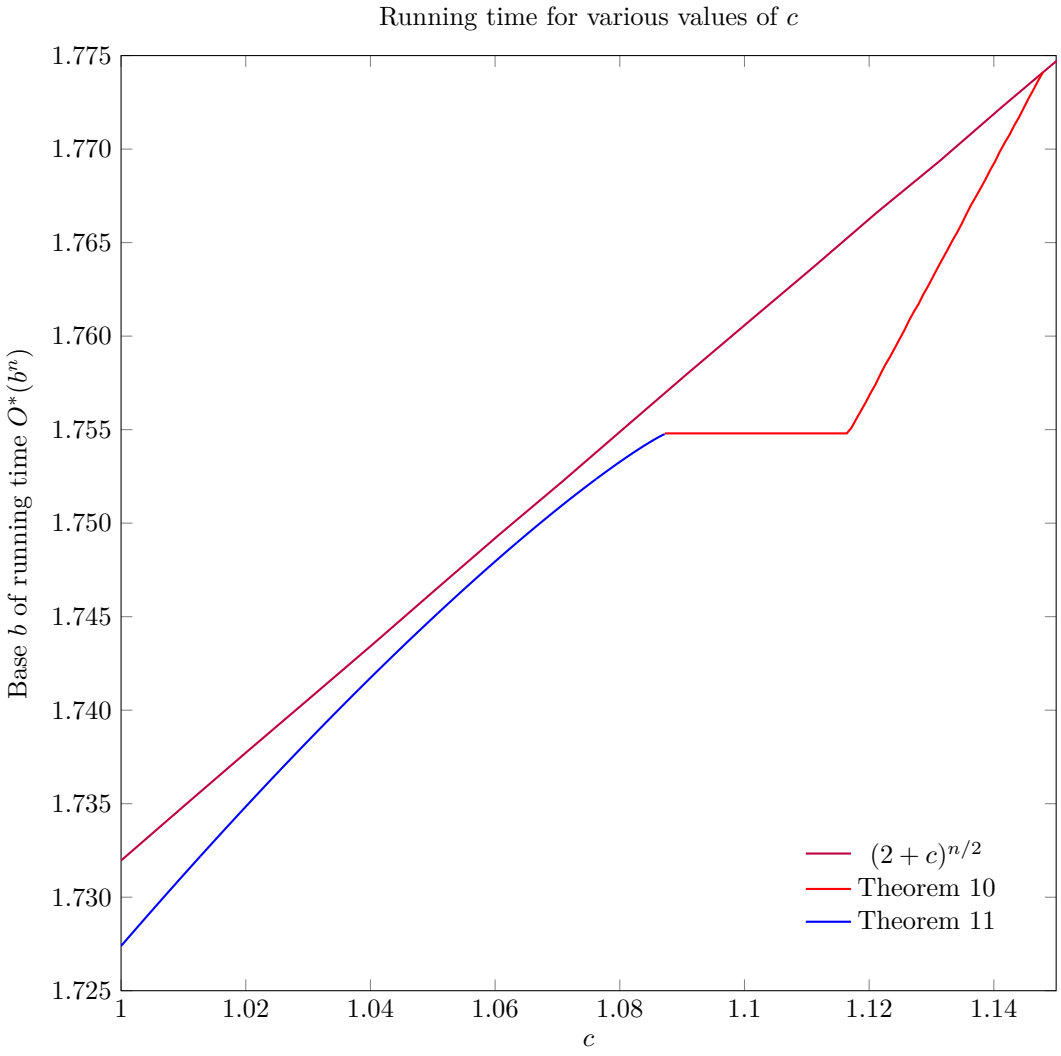

Figure 1 Visual presentation of running times of Theorem 10 and Theorem 11.

When $c \leq 1.147899$, then the running time provided by the best among Theorem 10 and Theorem 11 is slightly faster. At $c = 1$, the running time of Theorem 11 matches the running time of the Set Cover algorithm of [1] when $|\mathcal{F}|$ is subexponential in n.

When $c < -\frac{2}{3} + \sqrt[3]{\frac{47}{54} - \frac{\sqrt{93}}{18}} + \sqrt[3]{\frac{47}{54} + \frac{\sqrt{93}}{18}} \approx 1.147899$, then choosing the best algorithm among Theorem 10 and Theorem 11 gives an algorithm running in $O^*(b^n)$ time for some $b < \sqrt{c+2}$. This can be seen visually in Figure 1 and proved rigorously, e.g., by interleaving a stepwise function between the function $(c+2)^{n/2}$ and the function from Theorem 11 when $c \leq 1.08$:

$$\mathsf{steps}(c,n) = \begin{cases} 3^{n/2} & \text{if } c \leq 1.0123 \\ 1.735595^n & \text{if } 1.0123 \leq c \leq 1.0221 \\ \dots & \\ 1.7533^n & \text{if } 1.0742 \leq c \leq 1.08. \end{cases}$$

c	α	running time
1.0	0.236159	$O^*(1.7274^n)$
1.01	0.238036	$O^*(1.7312^n)$
1.02	0.239858	$O^*(1.7349^n)$
1.03	0.241622	$O^*(1.7384^n)$
1.04	0.243320	$O^*(1.7418^n)$
1.05	0.244946	$O^*(1.7450^n)$
1.06	0.246488	$O^*(1.7480^n)$
1.07	0.247928	$O^*(1.7508^n)$
1.08	0.249227	$O^*(1.7533^n)$

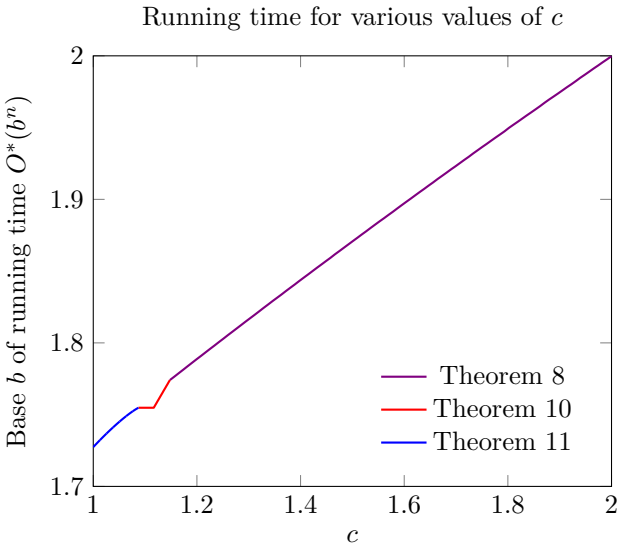

Figure 2 Running time for various values of c.

When $1.08 \leq c \leq 1.147899$, then Theorem 10 gives an algorithm with running time $O^*(d^n)$ for some $d < \sqrt{c+2}$. We list precise running times for certain values of c in Figure 2.

6 Applications

We can now use Corollary 13 in combination with simple branching algorithms enumerating various vertex sets in graphs, in particular algorithms enumerating maximal independent sets (equivalently, maximal cliques in the complement graph) in $O^*(3^{n/3})$ time [17] (we note that the algorithm of [24] is not a *simple* branching algorithm), maximal bicliques in $O^*(3^{n/3})$ time, maximal induced matchings in $O^*(10^{n/5})$ time [23], maximal induced forests in $O(1.8527^n)$ time [19], and minimal k-hitting sets in $O^*((2-1/k)^n)$ time [15]. The last result is used to enumerate maximal $\mathcal{H}$-free subgraphs, which have no induced subgraph isomorphic to any graph from the family $\mathcal{H}$ of graphs, all of which have at most k vertices. Some well-known $\mathcal{H}$-free graph classes are

- *cluster* graphs with $\mathcal{H} = \{P_3\}$, where P_k denotes the path on k vertices,
- *triangle-free* graphs with $\mathcal{H} = \{K_3\}$, where K_k denotes the complete graph on k vertices,
- *cographs* with $\mathcal{H} = \{P_4\}$ [12],
- *claw-free* graphs with $\mathcal{H} = \{K_{1,3}\}$, where $K_{k,\ell}$ denotes the complete bipartite graph with partite sets of size k and ℓ,
- *trivially-perfect* graphs with $\mathcal{H} = \{P_4, C_4\}$ [21], where C_k denotes the cycle on k vertices,
- *threshold* graphs with $\mathcal{H} = \{P_4, C_4, \overline{C_4}\}$ [11], where $\overline{G}$ denotes the complement of G,
- *split* graphs with $\mathcal{H} = \{C_4, \overline{C_4}, C_5\}$ [14], and
- *line* graphs, where $\mathcal{H}$ is a set of 9 graphs on at most 6 vertices each [3].

▶ **Theorem 14.** *There are bounded-error quantum algorithms, which, for a graph on n vertices and integer k, determine whether there is a k-packing, k-partitioning, or k-covering of G*

- *with maximal independent sets, maximal cliques, or maximal bicliques in $O(1.8554^n)$ time,*
- *with maximal cluster graphs or maximal triangle-free graphs in $O(1.9149^n)$ time,*

- *with maximal cographs, maximal claw-free graphs, maximal trivially-perfect graphs, or maximal threshold graphs in* $O(1.9365^n)$ *time,*
- *with maximal split graphs in* $O(1.9494^n)$ *time,*
- *with maximal line graphs in* $O(1.9579^n)$ *time, and*
- *with maximal induced forests in* $O(1.9629^n)$ *time.*

There are bounded-error quantum algorithms, which, for a graph on n *vertices and integer* k*, determine whether there is a* k*-packing or* k*-partitioning of* G

- *with maximal induced matchings in* $O(1.8934^n)$ *time*[2]*.*

In particular, this leads to a bounded-error quantum algorithm computing the chromatic number of an input graph in $O(1.8554^n)$ time; a graph can be covered with k maximal independent sets iff it has chromatic number at most k. In Section 7, we expedite this algorithm by exploiting fast algorithms for coloring a graph with a small number of colors and this will enable us to partition the vertex set in a more balanced way in the divide-and-conquer steps.

Even though there is a simple branching algorithm that enumerates all minimal dominating sets in $O(1.7159^n)$ time [16], this algorithm cannot be readily used for computing the domatic number using Theorem 8. This is because when we consider a subset X of the vertex set of $G = (V, E)$, we need to enumerate vertex subsets from X that are minimal dominating sets for G, and not $G[X]$. In Section 8, we prove that such minimal dominating sets can be enumerated in $O^*\left((2-\varepsilon)^{|X|}\right)$ time if $|X|$ is linear in $|V|$.

7 Faster Computation of the Chromatic Number

Assume the vertex set of input graph $G = (V, E)$ can be partitioned into independent sets $C = (I_1, I_2, \ldots, I_\chi)$ where χ is the chromatic number of G. Denote by n the number of vertices of G.

Using the algorithm from Theorem 8, we can compute the chromatic number of G in $O(1.8554^n)$ time. The family of subsets $\mathcal{F}$ corresponds to the independent sets of G and the family $e(X, r(\mathcal{F}, X))$ corresponds to the maximal independent sets of $G[X]$, which can be enumerated by a simple branching algorithm A in $O(3^{|X|/3})$ time [17]. We now prove a stronger result.

A proof of Lemma 17 along with a more detailed complexity analysis can be found in the full version of the paper [20].

▶ **Theorem 15.** *There is a bounded-error quantum algorithm, which for a graph on* n *vertices, computes the chromatic number in* $O(1.7956^n)$ *time.*

Assume, w.l.o.g., that $|I_1| \geq |I_2| \geq |I_3| \geq |I_4| \geq \cdots \geq |I_\chi|$.

In the first step, we use the algorithm from Theorem 6 with $\alpha = 0.27$ and store the result in QRAM. That is, for each α-small subset $X \subset V$, we find the chromatic number of X by finding the smallest k such that there exists a k-partition of X into independent sets. This takes $O^*(\binom{n}{0.27 \cdot n}) = O^*(1.79187^n)$ time.

We then consider a few different possibilities for the large sets in C and present an algorithm which finds a partition into a smallest number of independent sets for each of these cases. These possibilities cover all configurations of C so one result is guaranteed to find the chromatic number by detecting the partition C above, or an equivalent partition. The cases are as follows:

[2] Note that it is NP-hard to determine, for a graph $G = (V, E)$ and vertex subset $X \subseteq V$, whether there is a superset $Y \supseteq X$ that induces a 1-regular subgraph of G. This can be seen by a simple reduction from Independent Set.

1. G contains a vertex subset of size at least $0.48 \cdot n$ that is the union of at most five sets in C.
   We check for k-coloring for all $1 \leq k \leq n$ and take the minimum valid value of k as the chromatic number. To check for a certain k, we use Grover's search over all $Q \subset V$ where $|Q| \leq 0.52 \cdot n$ and check whether $G - Q$ is 5-colorable. If it is 5-colorable, we compute its chromatic number by checking its k'-colorability for $k' < 5$. We then solve the instance $(Q, r(\mathcal{F}, Q))$ to find a k_Q-coloring, where $k_Q = k - \chi(G - Q)$, using Grover's search to divide Q into (QL, QR) where $|QL| \geq 0.27 \cdot n$ and $k_{QL} + k_{QR} = k_Q$. For $(QL, r(\mathcal{F}, QL))$ (and similarly for QR) we use Grover's search on the branching algorithm A to enumerate candidate sets $S_1 \in e(QL, r(\mathcal{F}, QL))$; if $|QL| - |S_1| > 0.27 \cdot n$, then this branch is unsuccessful; otherwise, find $\chi(QL \setminus S_1)$ in QRAM.
   The running time of this case with quantum 5-coloring in $O^*(1.4695^n)$ [26] is $O^*(1.7831^n)$.
2. G contains a vertex subset of size at least $0.48 \cdot n$ that is the union of six sets in C, but does not contain a vertex subset of size at least $0.48 \cdot n$ that is the union of at most five sets in C.
   In this case we have

$$\begin{aligned} & |I_1| + |I_2| + \cdots + |I_5| < 0.48 \cdot n \\ \implies & 5 \cdot |I_6| \leq 5 \cdot |I_5| < 0.48 \cdot n \\ \implies & |I_1| + |I_2| + \cdots + |I_6| < 0.576 \cdot n, \end{aligned}$$

   which, along with the condition $0.48 \cdot n \leq |\bigcup_{i=1}^{6} I_i|$ gives

$$0.424 \cdot n < |V \setminus \bigcup_{i=1}^{6} I_i| \leq 0.52 \cdot n.$$

   For this case we check for k-coloring for all $1 \leq k \leq n$ and take the minimum valid value of k as the chromatic number. To check for a certain k, we use Grover's search over all $Q \subset V$ where $0.424 \cdot n < |Q| \leq 0.52 \cdot n$ and check whether $G - Q$ is 6-colorable. If so, we check whether the instance $(Q, r(\mathcal{F}, Q))$ is $(k-6)$-colorable in the same way as in item 1.
   The running time of this case with quantum 6-coloring in $O^*(1.5261^n)$ [26] is $O^*(1.7937^n)$.
3. G does not contain a vertex subset of size at least $0.48 \cdot n$ that is the union of at most six sets in C. That is $|\bigcup_{i=1}^{6} I_i| < 0.48 \cdot n$.
   Let $T = \bigcup_{i=1}^{q} I_i$ where q is the maximum index such that $|T| < \frac{n}{2}$. As $|\bigcup_{i=1}^{6} I_i| < 0.48 \cdot n$, we have $q \geq 6$. We consider two possibilities for the size of T and present an algorithm which finds a partition into a smallest number of independent sets for each case. As a valid coloring is computed in each case, the smallest partition gives the chromatic number if $|\bigcup_{i=1}^{6} I_i| < 0.48 \cdot n$.

   3.1. Consider the case where $|T| < \frac{6 \cdot n}{13}$:
   Let $L = \bigcup_{i=1}^{q+1} I_i$ and $R = \bigcup_{q+2}^{\chi} I_i$. We have

$$\begin{aligned} & |I_1| + |I_2| + \cdots + |I_q| < \frac{6 \cdot n}{13} \\ \implies & |I_1| + |I_2| + \cdots + |I_{q+1}| < \frac{7 \cdot n}{13} \\ \iff & |L| < \frac{7 \cdot n}{13} \end{aligned}$$

   and $0.5 \cdot n \leq |L|$ from the definition of q.

Assume L is not 7-colorable. There must be more than 7 independent sets in the construction of of L, which means

$$\begin{aligned} & q+1>7 \iff q \geq 7 \\ \implies & 7 \cdot |I_{q+1}| < \frac{6 \cdot n}{13} \\ \implies & |L| < \frac{48 \cdot n}{91} \end{aligned}$$

By contraposition, $|L| \geq \frac{48 \cdot n}{91}$ implies that L is 7-colorable.

▶ **Lemma 16.** *After running the algorithm presented in Theorem 6, there exists a bounded-error quantum algorithm to check the 7-colorability of a subset $X \subseteq U$ where $|X| \leq \frac{7}{3} \cdot \alpha \cdot n$ in $O^*(1.5622^{|X|})$ time.*

Proof. Assume that X is 7-colorable and there is a partition $D = (J_1, J_2, \ldots, J_7)$ of X into independent sets. Assume, w.l.o.g., that $|J_1| \geq |J_2| \geq \cdots \geq |J_7|$. Let $TL = J_1 \cup J_2 \cup J_3$ and $TR = J_4 \cup J_5 \cup J_6 \cup J_7$. We have

$$\begin{aligned} & \frac{|TL|}{3} \geq |J_3| \geq |J_4| \geq \frac{|TR|}{4} \\ \implies & |TL| + \frac{4}{3} \cdot |TL| \geq |X| \\ \iff & |TL| \geq \frac{3}{7} \cdot |X|. \end{aligned}$$

Consider $TR \setminus J_4$,

$$\begin{aligned} & |TR| \leq \frac{4}{7} \cdot |X| \text{ and } |J_4| \geq \frac{1}{4} \cdot |TR| \\ \implies & |TR \setminus J_4| \leq \frac{3}{7} \cdot |X| \leq \alpha \cdot n. \end{aligned}$$

So there exists a subset $S_1 \in e(TR, r(\mathcal{F}, TR))$ such that $|TR \setminus S_1| \leq \alpha \cdot n$.
We use Grover's search to divide X into two sets (XL, XR) where $|XL| \geq \frac{3 \cdot |X|}{7}$. We check XL for 3-colorability using a fast quantum algorithm. If it is 3-colorable, we use Grover's search on the branching algorithm A to enumerate candidate sets $S_1 \in e(XR, r(\mathcal{F}, XR))$; if $|XR| - |S_1| > \alpha \cdot n$, then this branch is unsuccessful; otherwise, check whether $\chi(XR \setminus S_1) \leq 3$ in QRAM. If X is 7-colorable and $(XL, XR) = (TL, TR)$, we indeed detect 7-colorability.
The running time of this algorithm with quantum 3-coloring in $O^*(1.1528^n)$ time [18] is $O^*(1.5622^{|X|})$. ◀

We check for k-coloring for all $1 \leq k \leq n$ and take the minimum valid value of k as the chromatic number. To check for a certain k, we use Grover's search to divide V into two sets (L, R) where $0.5 \cdot n \leq |L| < \frac{7 \cdot n}{13}$ and k into $k_L + k_R$. When $|L| < \frac{48 \cdot n}{91}$, we solve the subinstances $(L, r(\mathcal{F}, L))$ and $(R, r(\mathcal{F}, R))$ as in Theorem 8. When $|L| \geq \frac{48 \cdot n}{91}$, we solve the subinstance $(R, r(\mathcal{F}, R))$ as in Theorem 8 and run the algorithm in Lemma 16 on L; if L isn't 7-colorable, then this branch is unsuccessful; otherwise the subinstance $(L, r(\mathcal{F}, L))$ is k_L-colorable for $k_L \geq 7$. This algorithm finds the chromatic number of G when (L, R) are equal to the ones we constructed from C. The running time of this algorithm is $O^*(1.7956^n)$.

3.2. Otherwise, consider the case where $\frac{6 \cdot n}{13} \leq |T| < \frac{n}{2}$:
Let $L = T = \bigcup_{i=1}^{q} I_i$ and $R = \bigcup_{q+1}^{\chi} I_i$. We partition R into independent sets $C' = (I'_1, I'_2, \ldots, I'_{\chi'})$ where $I'_i = I_{q+i}$ for all $1 \leq i \leq \chi'$. By the definition of C, this is an optimal partition of R. As $q \geq 6$, we get $\frac{|L|}{6} \geq |I_q| \geq |I_{q+i}| = |I'_i|$ for all $1 \leq i \leq \chi'$.

▶ **Lemma 17.** *Assume we have a partition $D = (J_1, J_2, \ldots, J_m)$ of a set X where $t \geq |J_1| \geq |J_2| \geq \cdots \geq |J_m|$. Define $p = \left\lceil \frac{|X|}{t} \right\rceil$ and $r = \frac{|X|}{p}$. For any non-negative integer a, $1 \leq a \leq p-2$, there exists an integer k such that $a \cdot r \leq |\bigcup_{i=1}^{k} J_i| \leq (a+1) \cdot r$.*
Let $T_a = \bigcup_{i=1}^{q'} I'_i$ and $T_b = \bigcup_{i=1}^{q'+1} I'_i$ where q' is the maximum index such that $|T_a| < \frac{|R|}{2}$. Note that $\frac{|R|}{2} \leq |T_b|$. When we apply Lemma 17 with $X = R$, $D = C'$ and $t = \frac{|L|}{6}$, we get

$$\begin{aligned} \frac{|X|}{t} = \frac{6 \cdot |R|}{|L|} &\leq \frac{6 \cdot \frac{7 \cdot n}{13}}{\frac{6 \cdot n}{13}} = 7 \\ \text{and} \quad \frac{6 \cdot |R|}{|L|} &> \frac{6 \cdot \frac{n}{2}}{\frac{n}{2}} = 6 \\ \implies p = \left\lceil \frac{|X|}{t} \right\rceil &= 7. \end{aligned}$$

If we let $a = 3$, the lemma states that there exists a k such that $\frac{3 \cdot |R|}{7} \leq |\bigcup_{i=1}^{k} I'_i| \leq \frac{4 \cdot |R|}{7}$. As q' and $q'+1$ differ by 1, it is not possible that $|\bigcup_{i=1}^{q'} I'_i| < \frac{3 \cdot |R|}{7} \leq |\bigcup_{i=1}^{k} I'_i| \leq \frac{4 \cdot |R|}{7} < |\bigcup_{i=1}^{q'+1} I'_i|$. So, either $\frac{3 \cdot |R|}{7} \leq |T_a| < \frac{|R|}{2}$ or $\frac{|R|}{2} \leq |T_b| \leq \frac{4 \cdot |R|}{7}$. We let $TL = T_a$ or $TL = T_b$ such that $\frac{3 \cdot |R|}{7} \leq |TL| \leq \frac{4 \cdot |R|}{7}$ and $TR = R \setminus TL$. Note that in both cases, removing the independent set $I'_{q'+1}$ from either TL or TR would leave both subsets with a size $\leq \frac{|R|}{2}$. Therefore, there exists a subset $S_1 \in e(TL, r(\mathcal{F}, TL))$ (resp. for TR) such that $|TL \setminus S_1| \leq \frac{|R|}{2} \leq 0.27$ (and similarly for TR).

We check for k-coloring for all $1 \leq k \leq n$ and take the minimum valid value of k as the chromatic number. To check for a certain k, we use Grover's search to divide V into two sets (L, R) where $\frac{6 \cdot n}{13} \leq |L| < 0.5 \cdot n$ and k into $k_L + k_R$. We solve the subinstance $(L, r(\mathcal{F}, L))$ as in Theorem 8. We also solve the subinstance $(R, r(\mathcal{F}, R))$ as in Theorem 8, except that R is divided into (RL, RR) with $\frac{3 \cdot |R|}{7} \leq |RL| \leq \frac{4 \cdot |R|}{7}$ instead of $|RL| > 0.5 \cdot |R|$. This algorithm finds the chromatic number of G when (L, R) are equal to the ones we constructed from C and $(RL, RR) = (TL, TR)$. The running time of this algorithm is $O^*(1.7956^n)$.

We observe that the overall running time of the algorithm is

$$\begin{aligned} &O^*\left(\sqrt{\binom{n}{\frac{7}{13} \cdot n}\binom{\frac{7}{13} \cdot n}{\frac{4}{13} \cdot n} 3^{\frac{1}{3} \cdot \frac{4}{13} \cdot n}}\right) \\ &= O^*\left(\left(\frac{\sqrt{13}}{2^{7/13} \cdot 3^{23/78}}\right)^n\right) \\ &= O^*(1.7956^n) \end{aligned}$$

We reach this worst case when $\chi(G) = 13$ and $|I_1| = |I_2| = |I_3| = \cdots = |I_{13}|$. An example of such a graph is the disjoint union of $\frac{n}{13}$ complete graphs on 13 vertices. If the universe is partitioned into 2, one part must have at least 7 independent sets which is then partitioned into two parts where one part has at least 4 independent sets. Hence we cannot improve on the running time with a different twice-partitioning strategy.

We also note that the current best known quantum algorithms for checking 13-colorability, 7-colorability and 4-colorability [26] do not improve our running time. When iterating through $S_1 \in (X, r(\mathcal{F}, X))$, we only need to consider S_1 with $|S_1| \geq |X| - \alpha \cdot n$ so we can use an improved upper bound [10] when we only need to consider $|S_1| > |X| / 3$. However, this is only the case when $|X| > \frac{3}{2} \cdot \alpha \cdot n$; so it does not affect our overall running time as $|X| = \frac{4}{13} \cdot n$ in the worst case.

The pseudocode for the algorithm in this section can be found in [20].

8 Enumeration of Minimal Subset Dominating Sets

In this section, we prove that the number of minimal dominating sets of a graph that are subsets of some linear-sized subset of vertices X is at most $O^*\left((2-\varepsilon)^{|X|}\right)$. Moreover, they can be enumerated by a simple branching algorithm whose running time is within a polynomial factor of this bound.

▶ **Theorem 18.** *There is a simple branching algorithm, which, given any graph $G = (V, E)$ and any subset of vertices $X \subseteq V$ with $|X| \geq d \cdot |V|$ for some $d > 0$, enumerates all minimal dominating sets of G that are subsets of X in $O^*\left((2-\varepsilon_d)^{|X|}\right)$ time, for some $\varepsilon_d > 0$.*

The theorem will follow from a slightly more general theorem about minimal set covers of a set system. From a graph $G = (V, E)$ and a vertex subset $X \subseteq V$, we obtain a set system $(U, \mathcal{F})$ where $U = V$ and a set $S_x \in \mathcal{F}$ for each $x \in X$ that contains the closed neighborhood of vertex x in the graph G: $S_x = N_G[x]$. Then, there is a 1-to-1 correspondence between inclusion-wise minimal dominating sets in G that are subsets of X and inclusion-wise minimal set covers of $(U, \mathcal{F})$.

▶ **Theorem 19.** *There is a simple branching algorithm, which, given any set system $(U, \mathcal{F})$ with $|U| \leq r \cdot |\mathcal{F}|$ for some $r > 0$, enumerates all minimal set covers of $(U, \mathcal{F})$ in $O^*\left(2^{(1-\varepsilon_r)\cdot|\mathcal{F}|}\right)$ time, for some $\varepsilon_r > 0$.*

Fomin et al. [16] proved Theorem 18 for $X = V$ and Theorem 19 for $r = 1$. In particular, their algorithm enumerates all minimal dominating sets of a graph on n vertices in $O(1.7159^n)$ time.

Proof. Let $r > 0$. Let $\varepsilon = \frac{3(r+1)-\log(2^{3(r+1)}-1)}{3(r+1)^2}$. Consider the measure

$$\mu(U, \mathcal{F}) = (1 - (r+1)\varepsilon)|\mathcal{F}| + \varepsilon|U|$$

which associates a weight of $1 - (r+1)\varepsilon > 0$ to each set and a weight of $\varepsilon > 0$ to each element of a set system $(U, \mathcal{F})$. We will show that every set system $(U, \mathcal{F})$ has at most $2^{\mu(U,\mathcal{F})}$ minimal set covers by induction on $|\mathcal{F}|$. For a set system with $|U| \leq r \cdot |\mathcal{F}|$, this number is $2^{(1-(r+1)\varepsilon)|\mathcal{F}|+\varepsilon|U|} \leq 2^{(1-\varepsilon)\cdot|\mathcal{F}|}$. The proof can easily be turned into a simple branching algorithm enumerating all minimal set covers whose search tree is the induction tree of this proof.

The statement trivially holds when $|\mathcal{F}| = 0$ since such an instance has at most 1 minimal set cover. For the induction, we consider three cases.

1. $\mathcal{F}$ contains a set S with $|S| \geq 3(r+1)$. Any minimal set cover either contains S or not. Those that do not contain S are also minimal set covers of $(U, \mathcal{F} \setminus \{S\})$ and those that contain S are made up of S and a minimal set cover of $(U \setminus S, \mathcal{F} \setminus \{S\})$. For the induction, we would like that

$$\begin{aligned} & 2^{\mu(U,\mathcal{F}\setminus\{S\})} + 2^{\mu(U\setminus S,\mathcal{F}\setminus\{S\})} \leq 2^{\mu(U,\mathcal{F})} \\ \iff \quad & 2^{\mu(U,\mathcal{F})-(1-(r+1)\varepsilon)} + 2^{\mu(U,\mathcal{F})-(1-(r+1)\varepsilon)-|S|\cdot\varepsilon} \leq 2^{\mu(U,\mathcal{F})} \\ \iff \quad & 2^{-1+(r+1)\varepsilon} + 2^{-1+(r+1)\varepsilon-|S|\cdot\varepsilon} \leq 1 \\ \impliedby \quad & 2^{-1+(r+1)\varepsilon} + 2^{-1-2(r+1)\varepsilon} \leq 1, \end{aligned}$$

   and this inequality holds because $\varepsilon \leq \frac{1}{r+1} \log\left(\frac{1+\sqrt{5}}{2}\right)$.
2. There is an element $u \in U$ with frequency at most $3(r+1)$, i.e., u occurs in at most $3(r+1)$ sets of $\mathcal{F}$. Denote the sets that contain u by $\mathcal{S} = \{S \in \mathcal{F} : u \in S\}$. Since u needs to be covered, each set cover contains at least one set from $\mathcal{S}$. We use induction on all $2^{|\mathcal{S}|} - 1$ choices of including at least one set from $\mathcal{S}$ into the set covers and excluding the remaining sets from $\mathcal{S}$; each such choice leads to a set cover instance where we remove all sets in $\mathcal{S}$, and we remove all elements covered by the sets that are included in the set covers. Each such choice reduces the measure μ by more than $|\mathcal{S}| \cdot (1-(r+1)\varepsilon)$. Now, we would therefore like that

$$\begin{aligned} & (2^{|\mathcal{S}|}-1) \cdot 2^{\mu(U,\mathcal{F})-|\mathcal{S}|\cdot(1-(r+1)\varepsilon)} \leq 2^{\mu(U,\mathcal{F})} \\ \iff \quad & (2^{|\mathcal{S}|}-1) \cdot 2^{-|\mathcal{S}|\cdot(1-(r+1)\varepsilon)} \leq 1 \\ \iff \quad & 2^{-|\mathcal{S}|\cdot(1-(r+1)\varepsilon)} \leq (2^{|\mathcal{S}|}-1)^{-1} \\ \iff \quad & -|\mathcal{S}| \cdot (1-(r+1)\varepsilon) \leq -\log(2^{|\mathcal{S}|}-1) \\ \iff \quad & (r+1)\varepsilon - 1 \leq \frac{-\log(2^{|\mathcal{S}|}-1)}{|\mathcal{S}|} \\ \iff \quad & \varepsilon \leq \frac{|\mathcal{S}| - \log(2^{|\mathcal{S}|}-1)}{(r+1)|\mathcal{S}|} \end{aligned}$$

   Note that $\frac{|\mathcal{S}|-\log(2^{|\mathcal{S}|}-1)}{(r+1)|\mathcal{S}|}$ decreases when $|\mathcal{S}|$ increases, and for the maximum possible value of $|\mathcal{S}|$, which is $3(r+1)$, the inequality holds with equality for the value of ε given in the beginning of the proof.
3. It remains to consider the case where all sets have size less than $3(r+1)$ and all elements have frequency more than $3(r+1)$. Since the sum of set sizes equals the sum of element frequencies, we have that $|\mathcal{F}| \geq |U|$. Here, we use the result of Fomin et al. [16] who proved that the number of minimal set covers is at most $1.7159^{|\mathcal{F}|}$. For the induction, we would like that

$$\begin{aligned} & 1.7159^{|\mathcal{F}|} \leq 2^{\mu(U,\mathcal{F})} \\ \iff \quad & 2^{|\mathcal{F}|\log 1.7159} \leq 2^{(1-(r+1)\varepsilon)|\mathcal{F}|+\varepsilon|U|} \\ \impliedby \quad & 0.779|\mathcal{F}| \leq (1-(r+1)\varepsilon)|\mathcal{F}| \\ \iff \quad & \varepsilon \leq \frac{0.221}{r+1} \end{aligned}$$

   and this inequality holds for the value of ε given in the beginning of the proof.

This concludes the proof of the theorem. ◀

Theorem 8 now lets us conclude the following.

▶ **Corollary 20.** *There is a bounded-error quantum algorithm which computes the domatic number of any graph on n vertices in $O((2-\varepsilon)^n)$ time for some constant $\varepsilon > 0$.*

Abstract

What is the power of polynomial-time quantum computation with access to an NP oracle? In this work, we focus on two fundamental tasks from the study of Boolean satisfiability (SAT) problems: search-to-decision reductions, and approximate counting. We first show that, in strong contrast to the classical setting where a poly-time Turing machine requires $\Theta(n)$ queries to an NP oracle to compute a witness to a given SAT formula, quantumly $\Theta(\log n)$ queries suffice. We then show this is tight in the black-box model – any quantum algorithm with "NP-like" query access to a formula requires $\Omega(\log n)$ queries to extract a solution with constant probability.

Moving to approximate counting of SAT solutions, by exploiting a *quantum* link between search-to-decision reductions and approximate counting, we show that existing classical approximate counting algorithms are likely optimal. First, we give a lower bound in the "NP-like" black-box query setting: Approximate counting requires $\Omega(\log n)$ queries, even on a quantum computer. We then give a "white-box" lower bound (i.e. where the input formula is not hidden in the oracle) – if there exists a randomized poly-time classical or quantum algorithm for approximate counting making $o(\log n)$ NP queries, then $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ contains a P^{NP}-complete problem if the algorithm is classical and $\mathsf{FBQP}^{\mathsf{NP}[o(n)]}$ contains an $\mathsf{FP}^{\mathsf{NP}}$-complete problem if the algorithm is quantum.

1 Introduction

A fundamental direction of study in classical complexity theory is: What can P or BPP achieve with access to an NP oracle? Here, the study of relational-problems, i.e. where the output is not a single bit, but a string, has proven particularly fruitful. (Formally, this refers

to the classes FunctionP (FP) and FunctionBPP (FBPP); see Section 2.) A first direction here has been *search-to-decision* reductions. Namely, given a SAT formula φ and an NP oracle, it is well-known that $O(n)$ queries suffice to extract a solution to φ (assuming one exists). Moreover, this is likely classically optimal: an $o(n)$-query algorithm would violate the Exponential Time Hypothesis [17][1]. (Before ETH was posited, Krentel showed that if $O(\log n)$ queries suffice, then $\mathsf{P} = \mathsf{NP}$ [21].)

A second key direction has been *approximate counting* of the number of solutions of a Boolean formula, first studied by Stockmeyer [22]. Approximate counting has proven widely influential, even having applications in quantum advantage frameworks such as Aaronson and Arkhipov's Boson Sampling [2]. Stockmeyer showed [22] that an FBPP machine making $O(\log n \log\log n)$ NP queries suffices to approximate the number of solutions within a constant multiplicative factor, and that at least $\Omega(\log n)$ queries are required. This gap was closed by Chakraborty, Meel, and Vardi, who improved the upper bound to $O(\log n)$ queries [13]. Thus, the NP-query complexity of these two tasks is now well understood.

The quantum setting. The guiding question of this work is the next natural frontier: *Can* quantum *access to an NP oracle reduce the number of required queries?* For relation problems, this is a particularly intriguing question: Intuitively, a single classical NP query yields only 1 bit of information, suggesting that if an FP machine wishes to produce an n-bit output, then $\Theta(n)$ queries are necessary. (Indeed, as mentioned above, this is the case for search-to-decision reduction of SAT, assuming ETH.) *Quantum* access to an oracle, however, can sometimes bypass this obstacle, producing n bit outputs with just a *single* query. A notable instance of this is the Bernstein-Vazirani algorithm [11], which requires just a single query to an oracle encoding an affine function $f(x) = a \cdot x + b$ to output string $x \in \{0,1\}^n$. We thus ask: *Can a FunctionBQP (*FBQP*) machine make fewer queries to an* NP *oracle to extract a* SAT *solution or approximately count the number of solutions?*

Our results

In this work, we give tight resolutions to this question for both tasks.

Search-to-decision reductions. As mentioned earlier, classically, $\Theta(n)$ NP queries are necessary and sufficient for search-to-decision reduction for SAT, assuming ETH. Before proceeding to our main results, the lower bounds, we show that $O(\log n)$ queries suffice quantumly.

▶ **Theorem 1.** $\mathsf{FNP} \subseteq \mathsf{FBQP}^{\mathsf{NP}[\log]}$.

Here, FunctionNP (FNP) asks to produce a witness to an NP relation (Section 2), and NP[log] in the exponent denotes $O(\log n)$ NP queries. We remark that independently and prior to this work, Irani, Natarajan, Nirkhe, Rao and Yuen [18] showed that for SAT formulae with a *unique* satisfying assignment, a single NP query suffices to extract said solution (see Related Work).

[1] If there is an $\mathsf{FP}^{\mathsf{NP}[o(n)]}$ algorithm outputting a satisfying assignment then SAT can be decided in time $2^{o(n)}$ as follows: Enumerate through all possible strings y of $o(n)$ NP query answers, which takes $2^{o(n)}$ time. For each y, run the FP machine on y to obtain candidate solution x, and check if $\varphi(x) = 1$.

Is Theorem 1 tight? Unfortunately, since we are in the *white-box model* for search-to-decision reductions (i.e. the input formula φ is given as input to the FBQP machine, rather then hidden in the oracle), even a single-query lower bound would imply[2] NP $\not\subseteq$ BQP, and is thus likely out of reach. We hence move to the *black-box model* in order to prove a lower bound. For this, note that the standard quantum query model does not capture the power of "existential" or NP queries. Rather, we introduce the (straightforward quantum reformalization of) Stockmeyer's [22] existential query model:

▶ **Definition 2** (Existential query model). *An algorithm in the existential query model has access to the input string $x \in \{0,1\}^N$ via the following existential query gate:*

$$O_x^{\exists}\colon |z\rangle \mapsto (-1)^{\mathsf{overlap}(x,z)} |z\rangle \tag{1}$$

where $z \in \{0,1\}^N$ and $\mathsf{overlap}(x,z) = 1$ if there is an i such that $x_i = z_i = 1$ and 0 otherwise.

In this model, we show a matching lower bound for Theorem 1.

▶ **Theorem 3.** *Any quantum algorithm with existential query access to $x \in \{0,1\}^N$ that outputs a i with $x_i = 1$ with constant probability needs to make $\Omega(\log\log N) = \Omega(\log n)$ existential queries.*

Approximate counting. Recall that, classically, approximate counting requires $\Theta(\log n)$ NP queries. We next exploit the fact that the technique behind the proof of Theorem 1 (c.f. [18]) reveals a genuinely *quantum* link between search-to-decision reduction and approximate counting. This allows us to show the following tight black-box lower bound on *quantum* algorithms in the existential query model:

▶ **Corollary 4.** *Any quantum algorithm with existential query access to a string $x \in \{0,1\}^N$ which outputs an estimate c such that $2^{|x|-1} \leq c < 2^{|x|}$, where $|x|$ is the Hamming weight of x, requires at least $\Omega(\log\log N)$ queries to the oracle.*

Above, x denotes the truth table of the SAT formula, and so $N = 2^n$ for n the number of variables. Thus, for approximate counting, quantum algorithms do not outperform classical algorithms.

Finally, we prove a tight *white-box* lower bound for *both* classical or quantum algorithms which approximately count using $o(\log n)$ NP queries. As far as we are aware, no white-box lower bounds existed for either setting prior to this work.

▶ **Corollary 5.** *If there exists a* classical *randomized poly-time algorithm for approximate counting, making $o(\log n)$ NP queries, then $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ contains a P^{NP}-complete problem* [3]*. Similarly, if there is a poly-time* quantum *algorithm for approximate counting making $o(\log n)$ NP queries, then $\mathsf{FBQP}^{\mathsf{NP}[o(n)]}$ contains an $\mathsf{FP}^{\mathsf{NP}}$-complete problem.*

While the complexity theoretic implications above are not as standard as P = NP or the collapse of PH, they nevertheless would arguably be striking if true. This is because an $\mathsf{FP}^{\mathsf{NP}}$-complete problem is finding a satisfying assignment of *smallest lexicographical ordering* [21]. Thus, using $o(n)$ queries would seem to require resolving the lex-ordering in sublogarithmic time (in the search space size), whereas classical and quantum algorithms for the closely related task of binary search cannot achieve sublogarithmic time [5].

[2] If one could show that any FBQP machine requires at least 1 NP query for search-to-decision, then NP $\not\subseteq$ BQP. This is because if NP $\subseteq$ BQP, then FNP $\subseteq$ FBQP via the standard search-to-decision reduction for SAT.

[3] Note that this is not quite as strong as $\mathsf{P}^{\mathsf{NP}} \subseteq \mathsf{BPP}^{\mathsf{NP}[o(n)]}$ as overheads in the reduction to the P^{NP}-complete problem may erase the reduction in the number of queries.

Proof techniques

We now sketch our proof techniques, organized by topic.

Search-to-decision. Theorem 1 follows rather straightforwardly from prior results. We first note that, quantumly, the solution of a formula with a unique satisfying assignment can be found with a single NP query using the Bernstein Vazirani algorithm (c.f. [18]). Therefore, it remains to reduce an arbitrary formula to a uniquely satisfiable one. Valiant and Vazirani showed this can be done with probability $O\left(\frac{1}{n}\right)$ [23]. If, however, the approximate cardinality of the set of solutions is known, then this reduction succeeds with constant probability. Since approximately counting this cardinality can be done with $\log(n)$ NP queries [22, 13] classically, this gives a quantum algorithm for search-to-decision reduction using $O(\log n)$ queries and with *constant* success probability. The success probability can now be boosted to any constant by running the algorithm a constant number of times, checking the outputs and outputting one of the satisfying assignments.

Next, we discuss the first of our main results, the black-box lower bound (Theorem 3). Here the proof requires more work. Most quantum query lower bounds fall in one of two groups: polynomial methods and adversary methods [8, 10, 6]. Unfortunately, these methods are tailored to the standard query model, and it is not clear how to effectively utilize them in our *existential* query model. Another complicating factor for us is that search-to-decision is a *relational* problem, not a function problem. That is, for a given input formula φ there are *multiple* correct outputs: all solutions of φ.

To overcome this, we instead give a reduction from "(unstructured) search with existential queries" to "binary search with standard queries", so we may invoke Ambainis' binary search lower bound [5]. We show that an algorithm for search on strings of length $N = 2^n$ using q existential queries induces an algorithm for binary search on a space of size n with the same number of *standard* queries. The basic idea for this is as follows. If we can find a solution, then we can also sample a random solution by randomly permuting the solution space. Furthermore, a binary search instance, which is the task of finding the index of the first 1 in a monotonically increasing binary string $x \in \{0,1\}^n$, can be modified in the following way. We make a new exponentially longer string $y \in \{0,1\}^N$ where the first 2^{n-1} entries of y are set to x_1, the next 2^{n-2} to x_2 and so on. The index of a uniformly random 1 in y corresponds to the index of the least 1 in x with probability $> \frac{1}{2}$. Therefore, transforming x into y and running the random solution sampling algorithm on it solves binary search on x using q existential queries. We now note that because x is monotonically increasing, any existential query can be simulated by a standard query. The results of an existential query with string z will be the same as simply querying the largest index i where $z_i = 1$. As the last step of the proof, we invoke Ambainis result that binary search on a space of size n takes $\Omega(\log n)$ queries to complete the proof [5].

Approximate counting. Our black-box lower bound (Corollary 4) follows by combining the proof of Theorem 1 with Theorem 3. If there is an approximate counter making q existential queries, then an index with $x_i = 1$ can be found with constant success probability and $q + 1$ existential queries using the algorithm from Theorem 1. By Theorem 3 this is only possible if $q = \Omega(\log n)$.

Finally, we discuss our white-box lower bound (Corollary 5). We assume the existence of an approximate counter making $o(\log n)$ queries and show that we can, with $o(\log n)$ queries, find the lexicographically smallest solution of a formula φ, which is an $\mathsf{FP}^{\mathsf{NP}}$-complete problem [21]. The main idea is as follows. The algorithm from Theorem 1 samples approximately from

the uniform distribution on the set of solutions of φ. We run this algorithm on the AND of n^2 copies of φ, where we pick new sets of variables for each instance. This will give us n^2 solutions of φ picked almost uniformly at random. We find the least x_{min} and repeat the process on the formula $\varphi(x) \wedge (x \leq x_{min})$. After every round the number of solutions will be divided by at least n with high probability. Therefore, after $O(\log_n(|\operatorname{sol}(\varphi)|)) = O\left(\frac{n}{\log n}\right)$ rounds we will have found the lexicographically smallest solution of φ. As every round takes $o(\log n)$ queries, we have found the lexicographically smallest solution using $o(n)$ queries, completing the proof.

Related work

As previously mentioned, Irani, Natarajan, Nirkhe, Rao and Yuen already independently showed that the Bernstein-Vazirani algorithm can be used to find the solution of a *uniquely* satisfiable formula (our Lemma 17) [18]. They combine this with the Valiant-Vazirani theorem to do search-to-decision reduction for QCMA (and NP) with a single query and *inverse polynomial* success probability. However, they do not further study the case of a *constant* success probability as done here. They also show that there exists a quantum polynomial time algorithm that makes a single query to a PP oracle and generates a witness for a QMA problem up to polynomial precision. Additionally, they show that there is an oracle such that QMA search does not reduce to QMA decision relative to that oracle.

In their work [12], Buhrman and van Dam study the difference between classical and quantum access to an NP-oracle. They show that an EQP machine, that is, a quantum computer that is not allowed to err, can save on the number of queries compared to classical. Among other results they prove the inclusions $\mathsf{P}^{\|\,\mathsf{NP}[2k]} \subseteq \mathsf{EQP}^{\|\,\mathsf{NP}[k]}$ and $\mathsf{FP}^{\|NP} \subseteq \mathsf{FEQP}^{\mathsf{NP}(O(\log n))}$. Note that while $\mathsf{P}^{\|NP} = \mathsf{P}^{\mathsf{NP}(O(\log n))}$, a similar equality for FP would collapse the polynomial hierarchy.

Search-to-decision reduction has been studied in other settings. If only parallel (i.e. non-adaptive) queries to the NP oracle are allowed, then the standard $O(n)$-query search-to-decision reduction for NP does not work. Nevertheless, it has been shown that $O(n^2)$ parallel oracle queries suffice for classical randomized algorithms [9]. Kawachi, Rossman and Watanabe showed that this is optimal in a black-box model and give an algorithm with improved error tolerance [19]. In a later work they also consider more general black-box models and show that $O(n^2)$ parallel classical queries are still needed [20].

The class BQP with access to various resources has been studied before. Aaronson, Ingram and Kretschmer [4] study oracle separations between various complexity classes involving BQP as an oracle or BQP with access to an oracle. Among other results the authors prove that there is an oracle relative to which $\mathsf{BQP}^{\mathsf{NP}} \not\subseteq \mathsf{PH}^{\mathsf{BQP}}$ and an oracle relative to which $\mathsf{NP}^{\mathsf{BQP}} \not\subseteq \mathsf{BQP}^{\mathsf{PH}}$. Aaronson, Buhrman and Kretschmer [3] investigate BQP when given various types of advice. There it is shown, among other results, that $\mathsf{FBQP/qpoly} \neq \mathsf{FBQP/poly}$ (not relative to an oracle!).

Isolation algorithms, i.e., algorithms reducing the number of solutions of a Boolean formula to 1, have been studied by Dell, Kabanets, van Melkebeek and Watanabe [15]. They show that, unless $\mathsf{NP} \subseteq \mathsf{P/poly}$, no randomized polynomial time isolation algorithm with success probability better than $\frac{2}{3}$ can exist.

Discussion and open questions

Our paper characterizes the quantum NP-query complexity of search-to-decision reductions and approximate counting (and additionally gives a white-box lower bound for classical approximate counting algorithms). For this, some of our results utilized a quantum reformulation of Stockmeyer's classical existential query model. Can quantum query lower bound

methods like polynomial methods and adversary methods be adapted to apply directly to existential queries? An obstacle here is the fact that, for example, adversary methods often keep track of how a "progress measure" increases with each query made. Existential queries, however, seem to allow arbitrarily large jumps in such "progress measures".

Second, we prove that $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ and $\mathsf{FBQP}^{\mathsf{NP}[o(n)]}$ containing P^{NP}- and $\mathsf{FP}^{\mathsf{NP}}$-complete problems, respectively, are consequences to very efficient approximate counting. It would be interesting to see if there are further consequences to these conclusions or if our results can be strengthened. For example, can our results be strengthened to a contradiction of a common complexity theoretic hypothesis such as the (strong) Exponential Time Hypothesis? Third, what other tasks might a $\mathsf{BQP}^{\mathsf{NP}}$ or $\mathsf{FBQP}^{\mathsf{NP}}$ machine be good for? Finally, we close with a simple-to-state, concrete open question, which captures much of the difficulty of working with $\mathsf{BQP}^{\mathsf{NP}}$: Let φ be a SAT formula. Classically, it is easy to see that a solution to φ cannot be produced by an FBPP machine with a single NP query, for this would imply $\mathsf{BPP} = \mathsf{NP}$. This is because one can simply plug each possible answer, 0 or 1, from the NP machine into the FBPP machine, and check if the string x produced by the latter satisfies φ. Unfortunately, this approach completely breaks down for an FBQP machine making a single NP query, since the query may involve exponentially many inputs in superposition! Can one nevertheless show that $\mathsf{FNP} \subseteq \mathsf{FBQP}^{\mathsf{NP}[1]}$ implies $\mathsf{NP} \subseteq \mathsf{BQP}$?

Organization

In Section 2 we cover definitions and prior results used in this article. In Section 3, we will give the proof of Theorem 1, the upper bound on search-to-decision reduction for NP with quantum access to the oracle. Following that, in Section 4 we give the proofs of our results in the existential query model, Theorem 3 and Corollary 5. Finally, we prove Theorem 5 in Section 5.

2 Preliminaries

2.1 Notation

Throughout the paper we use n for the number of variables of the formulae and $N = 2^n$ for the size of their truth tables. We write $\mathrm{sol}(\varphi)$ for the set $\{x \in \{0,1\}^n : \varphi(x)\}$ of solutions of the Boolean formula φ. If $x \in \{0,1\}^*$ is a binary string we write $|x|$ for its Hamming weight.

2.2 Function classes

We briefly recall the definition the relevant function classes. Contrary to what the name suggests, function classes are actually classes of relations. We will require all relations R in these classes to be *p-bounded*.

▶ **Definition 6.** *A relation $R \subseteq \{0,1\}^* \times \{0,1\}^*$ is called p-bounded if there is some polynomial p such that, for each x, if $\exists y.R(x,y)$, then $\exists z$ such that $\mathrm{len}(z) \leq p(\mathrm{len}(x))$ and $R(x,z)$. Here $\mathrm{len}(x)$ is the length of the string x.*

▶ **Definition 7.** FP *is the class of polynomial time computable*[4] *p-bounded relations $R \subseteq \{0,1\}^* \times \{0,1\}^*$ such that there is a deterministic poly-time algorithm that on input x does the following:*

1. *If $\exists y$ such that $R(x,y)$ then the algorithm outputs one such y*
2. *If $\forall y.(x,y) \notin R$ then the algorithm outputs $\perp$.*

[4] With a poly-time computable relation we mean that there is a poly-time algorithm for evaluating $R(x,y)$ when given x and y as inputs.

▶ **Definition 8.** *The class* FNP *consists of all poly-time computable p-bounded relations* $R \subseteq \{0,1\}^* \times \{0,1\}^*$.

To see the similarities with the definition of FP we note that this condition implies the existence of a poly-time non-deterministic algorithm for computing R in the following sense. The algorithm takes as input a string z, and each branch of the (non-deterministic) computation outputs either a string z or $\perp$ and satisfies the following properties:

1. If $\exists y$ such that $R(x,y)$, then all branches either output $\perp$ or a string z such that $R(x,z)$ (not necessarily the same one). Furthermore, at least one branch does not output $\perp$.
2. If $\forall y\ (x,y) \notin R$, then all branches output $\perp$.

An FNP-complete problem is FunctionSAT. It is the relation $R(\varphi, x)$ where φ is a (binary encoding of) a Boolean formula and $(\varphi, x) \in R$ iff x is a satisfying assignment of φ. FunctionSAT is FNP-complete for the same reasons that SAT is NP-complete.

For the definition of FBQP we follow Aaronson [1].

▶ **Definition 9.** FBQP *is the class of p-bounded relations* $R \subseteq \{0,1\}^* \times \{0,1\}^*$ *for which are computable by a quantum algorithm in the following sense. There exists a poly-time quantum algorithm that takes as input* x *and* $0^{1/\epsilon}$ *and outputs a* y*. This is such that* $R(x,y)$ *with probability at least* $1-\epsilon$ *(assuming a* y *with* $R(x,y)$ *exists). If* $\forall y\ (x,y) \notin R$ *then it outputs* $\perp$ *with probability at least* $1-\epsilon$.

2.3 Witness isolation

We consider algorithms that reduce an arbitrary formula to a uniquely satisfying one.

▶ **Definition 10** (Isolation algorithm)**.** *An isolation algorithm with success probability* p *is a randomized algorithm that maps a Boolean formula* φ *on* n *variables to a formula* u *on the same variables such that the formula* $\varphi \wedge u$ *has a unique solution with probability at least* p.

A celebrated result by Valiant and Vazirani states that isolation algorithms exist.

▶ **Theorem 11** (Valiant Vazirani Theorem ([23]))**.** *There exists an isolation algorithm with success probability* $\frac{1}{O(n)}$.

The main idea of Valiant and Vazirani is to use cleverly chosen pairwise independent hash function to reduce the size of the solutions space.

▶ **Definition 12** (Pairwise independent hash functions ([7, Definition 8.14]))**.** *A collection* $\mathcal{H}_{n,k}$ *of functions from* $\{0,1\}^n$ *to* $\{0,1\}^k$ *is a collection of pairwise independent hash functions if for every* $x \neq x' \in \{0,1\}^n$ *and* $y, y' \in \{0,1\}^k$ *we have*

$$\Pr[h(x) = y \wedge h(x') = y'] = 2^{-2k} \tag{2}$$

where the probability is over h *being drawn uniformly at random from* $\mathcal{H}_{n,k}$.

The proof of Valiant and Vazirani's theorem follows from the following lemma which will also be of independent interest for us.

▶ **Lemma 13** ([7, Lemma 17.19])**.** *Let* $\mathcal{H}_{n,k}$ *be a collection of pairwise-independent hash functions from* $\{0,1\}^n$ *to* $\{0,1\}^k$ *and suppose that* $\mathrm{sol}(\varphi) \subseteq \{0,1\}^n$ *is such that* $2^{k-2} \leq |\mathrm{sol}(\varphi)| \leq 2^{k-1}$. *Then*

$$\Pr_{h \sim \mathcal{H}_{n,k}} \left[\left| \left\{ x \in \mathrm{sol}(\varphi) : h(x) = 0^k \right\} \right| = 1 \right] \geq \frac{1}{8}. \tag{3}$$

It follows that witness isolation can be performed with constant success probability if the approximate size of the set of solutions is known.

We will also consider witness isolation algorithms with the added requirement that all solutions of φ will be the unique solution of $\varphi \wedge u$ with approximately equal probability. We call such algorithms almost-uniform isolation algorithms.

▶ **Definition 14.** *An ϵ-almost-uniform isolation algorithm A_{iso} with success probability p takes as input a Boolean formula φ, and efficiently produces a Boolean formula u on the same variables such that:*

- *p-Completeness: if $\varphi \in \mathrm{SAT}$, then, with probability at least p, $\varphi(x) \wedge u(x)$ has a unique satisfying assignment. In this case we say that the isolation succeeds.*
- *ϵ-almost-uniformity: for all $x \in \mathrm{sol}(\varphi)$ we have:*

$$\Pr\left[\varphi(x) \wedge u(x) \middle| |\mathrm{sol}(\varphi(x) \wedge u(x))| = 1\right] \leq \frac{1+\epsilon}{|\mathrm{sol}(\varphi)|}.$$

Note that we do not require a lower bound on this probability.

2.4 Approximate counting

Stockmeyer was the first to realize that an NP oracle can be used for approximate counting. It was shown by Chakraborty, Meel and Vardi that a logarithmic number of NP queries suffice: [22, 13].

▶ **Theorem 15** (Approximate counting, [22, 13])**.** *Given a formula φ on n variables and parameters $\delta, \epsilon > 0$, there exists a randomized poly-time algorithm, making $O\left(\frac{\log n \log(1/\delta)}{\epsilon^2}\right)$ queries to an NP-oracle, that outputs a value c such that:*

$$\Pr\left(\frac{|\mathrm{sol}(\varphi)|}{1+\epsilon} \leq c \leq (1+\epsilon)|\mathrm{sol}(\varphi)|\right) \geq 1-\delta. \tag{4}$$

2.5 Query complexity

In query complexity one studies how often an algorithm needs to query an input string $x \in \{0,1\}^N$ in order to compute some function of x. In this paper we will consider three different types of oracles: standard oracles, succinct existential oracles and non-succinct existential oracles.

With the *standard oracle model* we will refer to the oracle model that is usually used in quantum query complexity. In this model, the queries give access to a string $x \in \{0,1\}^N$ using the following query gate:

$$O_x \colon |i\rangle \mapsto (-1)^{x_i} |i\rangle . \tag{5}$$

We will call an application of the oracle *classical* if it is applied to a computational basis state.

In this paper, the string x will usually be the truth table of a hidden formula φ (i.e. $x_i = 1 \iff \varphi(i)$). Then, querying the oracle on index i corresponds to computing $\varphi(i)$.

Standard queries do not satisfactorily capture the power of NP queries. For example, it only takes one NP query to determine if a formula is satisfiable (i.e. if its truth table is not all 0s), but it is well known that determining if there is an i with $x_i = 1$ takes $\Theta(\sqrt{N})$ standard queries ([16, 10]). Therefore, we will also consider other query models that better capture the power of NP queries.

The first of these query models we will call the *succinct existential query model*. Here, the oracle hides a formula φ. A query consists of a different poly-size formula ψ and the result to this query will be whether or not $\varphi \wedge \psi$ is satisfiable. Specifically, the oracle can be queried using the query gate

$$O_\varphi^{\mathsf{NP}} \colon |\psi\rangle \mapsto (-1)^{\mathsf{sat}(\varphi \wedge \psi)} |\psi\rangle \tag{6}$$

where $\mathsf{sat}(\varphi \wedge \psi)$ is 1 if $\varphi \wedge \psi$ is satisfiable and 0 otherwise. The succinct $\exists$-query model captures the power of an actual NP oracle well. It is strong enough to be used for the most common, if not all, well-known algorithms computing properties of Boolean formulae, such as finding the lexicographically-least solution of the hidden formula φ (a P^{NP}-complete problem) and approximately count the number of solutions of φ (e.g. with [13]).

We will also consider a non-succinct version of the existential query model, which we will also simply call the *existential query model*. Essentially this model is a reformulation of a model originally introduced by Stockmeyer [22] and used in e.g. [19]. We restated it in a manner closer to the standard query model. Existential queries ($\exists$-queries) are of the form

$$O_x^{\exists} \colon |z\rangle \mapsto (-1)^{\mathsf{overlap}(x,z)} |z\rangle \,, \tag{7}$$

where $\mathsf{overlap} \colon \{0,1\}^N \times \{0,1\}^N \to \{0,1\}$ is the function

$$\mathsf{overlap}(x,z) = \begin{cases} 1 & \text{if } \exists i, x_i = z_i = 1 \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

Again, the hidden string will usually be the truth table of a formula φ. At first glance, this query model may look rather useless. The query register has size exponential in n (the number of variables of φ). Therefore, even performing a single query will take exponential time. However, *if* one is only concerned with the number of queries, and not with other resources such as time and space, then non-succinct existential queries are more powerful than succinct ones. Instead of making a succinct $\exists$-query with formula ψ, an algorithm can make a non-succinct existential query with z the truth table of ψ. Furthermore, not all truth tables correspond to poly-size formulae. In this paper we will prove lower bounds on the number of existential queries an algorithm needs to make. The result will allow the algorithms unbounded time and space and hence these lower bounds will in particular hold for efficient algorithms making succinct $\exists$-queries.

We are interested in the number of these queries needed to find a solution of φ. In the existential query model this corresponds to solving the search problem on the truth table x of ϕ, that is, outputting an index i such that $x_i = 1$. It should be noted that, unlike in the case of standard queries, the existential query complexity of this function search problem is not necessarily the same as that of the decision search problem (i.e. determining if there is such an index). For example, an information theoretic argument shows that classically $\Theta(n)$ existential queries are needed for function search, but a single existential query with $z = 1^N$ solves decision search.[5]

We will also be interested in a slight variation of the search problem which we call the *index sampling* problem. Here the task is to sample according to the uniform distribution on the support of x. Formally, we define it as

[5] The string 1^N has overlap with any non-zero string. Hence it has overlap with the truth table of φ iff φ is satisfiable.

▶ **Definition 16** (Index sampling). *An algorithm solves the index sampling problem if it, for all $x \in \{0,1\}^N \setminus \{0^N\}$, outputs $s \in [N] \cup \{\perp\}$ such that:*

- *for all $i \in [N]$ with $x_i = 1$, $\Pr[s = i | s \neq \perp] = \frac{1}{|x|}$,*
- *there is a constant c such that $\Pr[s \neq \perp] \geq c$.*

3 Quantum algorithm for search-to-decision reduction

We are now ready to prove our results. For pedagogical reasons we start with the proof of the upper bound (Theorem 1) before proving our main results: the lower bounds in Theorem 3 and Theorem 5.

▶ **Theorem 1.** $\mathsf{FNP} \subseteq \mathsf{FBQP}^{\mathsf{NP}[\log]}$. *Furthermore, all queries made to the oracle are of the form $\varphi \wedge \chi$ where φ is the input formula and χ some other formula.*

Proof. We will show that there exists an $\mathsf{FBQP}^{\mathsf{NP}[\log]}$ algorithm that, when given a SAT instance φ, outputs a satisfying assignment $x \in \{0,1\}^n$ of φ if one exists, and outputs "no solution" otherwise. The algorithm succeeds with constant probability. This success probability can be boosted by running the algorithm a constant number of times, checking for each output if it is indeed a satisfying assignment and then outputting one that is. Hence, the success probability can be taken to be any arbitrary constant.

The existence of a satisfying assignment can be checked using a single query to the NP-oracle. Therefore, we will restrict our attention to the case where a satisfying assignment exists. We will proceed in two steps. First, we show how the satisfying assignment of a formula with *exactly* one satisfying assignment can be found with only a single query to the NP-oracle using the Bernstein Vazirani algorithm. Then we show how we can use $O(\log n)$ queries to reduce any formula to a uniquely satisfying one with constant probability.

▶ **Lemma 17** ("Bernstein-Vazirani (BV) trick" [18]). *Let φ be a formula with exactly one solution. There exists a* BQP *algorithm that makes a single query to an* NP*-oracle and finds this unique solution with probability 1.*

Proof of BV trick. Let the unique solution of φ be denoted by s and consider the formula

$$\psi_a \coloneqq \varphi(x) \wedge (x \cdot a = 1), \tag{9}$$

where $a \in \{0,1\}^n$ and $x \cdot a$ denotes the inner product of the two binary strings x and a modulo 2. (Note that ψ_a is of the form $\varphi \wedge \chi$.) We now have that ψ_a is satisfiable (i.e. there is a y such that $\varphi(y) \wedge y \cdot a = 1$) if and only if[6] $a \cdot s = 1$ because s is, by assumption, the only solution of φ. Now we run the Bernstein-Vazirani algorithm, where to evaluate $a \cdot s$ we ask the NP machine whether ψ_a is true. That is, we start with the state $|0^n\rangle$ and apply $H^{\otimes n}$ to get the uniform superposition on n qubits. The next step is to query the oracle on input ψ_a where a is in a uniform superposition:

$$\frac{1}{\sqrt{2^n}} \sum_{a \in \{0,1\}^n} |a\rangle \mapsto \frac{1}{\sqrt{2^n}} \sum_{a \in \{0,1\}^n} (-1)^{a \cdot s} |a\rangle . \tag{10}$$

Now another application of $H^{\otimes n}$ gives:

$$\frac{1}{2^n} \sum_{a,y \in \{0,1\}^n} (-1)^{a \cdot s + a \cdot y} |y\rangle = \frac{1}{2^n} \sum_{a,y \in \{0,1\}^n} (-1)^{a \cdot (s \oplus y)} |y\rangle = |s\rangle . \tag{11}$$

Hence measuring the final state in the computational basis gives the unique satisfying assignment s of φ. ◁

[6] Note this does not imply $a = s$.

To deal with an arbitrary number of solutions, we first use Theorem 15 and $O(\log n)$ queries to the NP oracle to find k such that $2^{k-2} \leq |\mathrm{sol}(\varphi)| < 2^{k-1}$. (All queries made by the approximate counting algorithm in [13] are of the form $\varphi \wedge \chi$.) Then, we invoke Lemma 13 to obtain $u(x) := h(x) = 0^k$ such that $\varphi \wedge u$ has a unique solution with probability $> \frac{1}{8}$. Applying the BV trick to $\varphi \wedge u$ then completes the proof. Furthermore, all queries made were of the claimed form. ◀

4 Lower bound for existential query complexity of search

We will prove that all quantum algorithms for the search problem need $\Omega(\log n)$ existential queries, even if we allow the algorithm to additionally make $\mathrm{poly}(n)$ classical standard queries. To do so, we will reduce binary search to this problem in order to use Ambainis' lower bound for binary search [5]. A binary search problem consists of a monotonic binary string $x = 00\ldots01\ldots1$ and the task is to find the index of the first 1.

▶ **Theorem 3** (Restated). *Any quantum algorithm with existential query access to $x \in \{0,1\}^N$ needs to make $\Omega(\log\log N) = \Omega(\log n)$ existential queries to find an i such that $x_i = 1$. This remains true even if the algorithm is allowed to make an additional $\mathrm{poly}(n)$ classical standard queries.*

The proof will follow from the following lemma.

▶ **Lemma 18.** *Consider the following statements:*

1. *There exists a quantum algorithm for search on strings of size $N = 2^n$ that makes q $\exists$-queries and $\mathrm{poly}(n)$ classical standard queries and succeeds with constant probability.*
2. *There exists a quantum algorithm for search on strings of size N using $q + O(\log\log n)$ $\exists$-queries and no additional standard queries which succeeds with constant probability.*
3. *There exists a quantum algorithm for index sampling on strings of size N using $q + O(\log\log n)$ $\exists$-queries and no additional standard queries which succeeds with constant probability.*
4. *There exists a quantum algorithm for binary search on strings of size n using $q+O(\log\log n)$ $\exists$-queries and no additional standard queries. The algorithm succeeds with constant probability.*
5. *There exists a quantum algorithm for binary search on strings of size n using $q+O(\log\log n)$ standard quantum queries and no $\exists$-queries. The algorithm succeeds with constant probability.*

Then, $1 \implies 2 \implies 3 \implies 4 \implies 5$.

It is worth noting that all success probabilities can be boosted to be bigger than any constant $c < 1$.

Proof. $1 \implies 2$: consider an algorithm for search using q $\exists$-queries and $\mathrm{poly}(n)$ classical standard queries. We will modify the algorithm to get rid of the standard queries. Our new modified algorithm will act exactly the same as the original algorithm, except it does not actually perform the classical standard queries. Instead, it assumes the answer to those queries is 0 and keeps track of the positions that should have been queried in a set A. At the end of the algorithm, it checks if its assumptions were correct using an $\exists$-query. That is, it performs an $\exists$-query with string z defined by $z_i = 1$ iff the i-th index should have been queried by a classical standard query at some point.

Now there are now two options. Either the result of this $\exists$-query is 0, in which case the assumptions that all indices queried by classical standard queries were 0 is correct, and hence the modified algorithm and the original algorithm coincide. Alternatively, the result of

the ∃-query is 1. Then at least one of the assumptions was wrong. But now the algorithm has determined that the set $A \subseteq [N]$ contains some $i \in A$ with $x_i = 1$. Furthermore, A contains at most $\mathrm{poly}(n)$ elements since only $\mathrm{poly}(n)$ classical queries were made. The search algorithm from Theorem 1 makes only (succinct) existential queries, so we can now use it to search, within A, for an i with $x_i = 1$.[7] Because we know that $|A| = \mathrm{poly}(n)$, approximately counting the number of solutions *within* A will take $O(\log\log|A|) = O(\log\log n)$ ∃-queries using the algorithm from [13].[8] Therefore, finding a solution within A given that there is one will take $O(\log\log n)$ existential queries.

2 $\implies$ 3: consider a permutation $\sigma \in S_N$ mapping $[N]$ to itself drawn uniformly at random. With slight abuse of notation we define $\sigma(x)$ by $\sigma(x)_i = x_{\sigma(i)}$. Our algorithm for index sampling will apply the algorithm for search to $\sigma(x)$, undo the permutation, check if it is indeed a solution and output the result if it is, and abort (i.e. output $\perp$) if it is not. The probability of aborting is exactly the failure probability of the search algorithm. In the following we condition on the sampling algorithm not aborting and assume $x \neq 0^N$ (this case can be checked with 1 ∃-query).

Denote by $\mathsf{search}(x)$ the output of the search algorithm on input x. Consider the probability $p(i) = \Pr[\sigma^{-1}(\mathsf{search}(\sigma(x))) = i] = \Pr[\mathsf{search}(\sigma(x)) = \sigma(i)]$. We will show that $p(i) = \frac{1}{|x|}$ if $x_i = 1$ and 0 otherwise. Note that there are two sources of randomness: the random choice of σ and potentially random behavior of the search algorithm. We can write:

$$p(i) = \sum_{y\in\{0,1\}^N} \sum_{k\in[N]} \Pr[\sigma(x) = y \wedge \sigma(i) = k \wedge \mathsf{search}(y) = k] \tag{12}$$

$$= \sum_{y,k} \Pr[\sigma(x) = y] \cdot \Pr[\sigma(i) = k | \sigma(x) = y] \cdot \Pr[\mathsf{search}(y) = k | \sigma(x) = y \wedge \sigma(i) = k]. \tag{13}$$

Because the algorithm for search does not depend on σ, we have that

$$p_y(k) \coloneqq \Pr[\mathsf{search}(y) = k | \sigma(x) = y \wedge \sigma(i) = k] = \Pr[\mathsf{search}(y) = k]. \tag{14}$$

The $p_y(k)$ are unknown, but because the algorithm solves the search problem we do know that $\Pr[\mathsf{search}(y) = k | y_k = 0] = 0$ and $\sum_{k:y_k=1} p_y(k) = 1$. Furthermore, we have

$$\Pr[\sigma(x) = y] = \begin{cases} 1/\binom{N}{|x|} & \text{if } |x| = |y| \\ 0 & \text{if } |x| \neq |y| \end{cases} \tag{15}$$

and

$$\Pr[\sigma(i) = k | \sigma(x) = y] = \begin{cases} \frac{1}{|x|} & \text{if } x_i = y_k = 1 \\ \frac{1}{N-|x|} & \text{if } x_i = y_k = 0 \\ 0 & \text{if } x_i \neq y_k. \end{cases} \tag{16}$$

We can now put everything together to get

$$p(i) = \sum_{y:|x|=|y|} \frac{1}{\binom{N}{|x|}} \sum_{k:y_k=1} \frac{1}{|x|} p_y(k) = \frac{1}{|x|} \tag{17}$$

[7] We can add $\wedge x \in A$ to all formulae to restrict the search to within A.

[8] Essentially, the algorithm from [13] uses binary search to find $k \in [n]$ such that $2^{k-1} < |\mathrm{sol}(\varphi)| < 2^k$. Because $|A| = O(\mathrm{poly}(n))$, it is already known that $|\mathrm{sol}(\varphi(x) \wedge x \in A)| \leq O(\mathrm{poly}(n)) = 2^{O(\log n)}$. Therefore, the binary search is sped up.

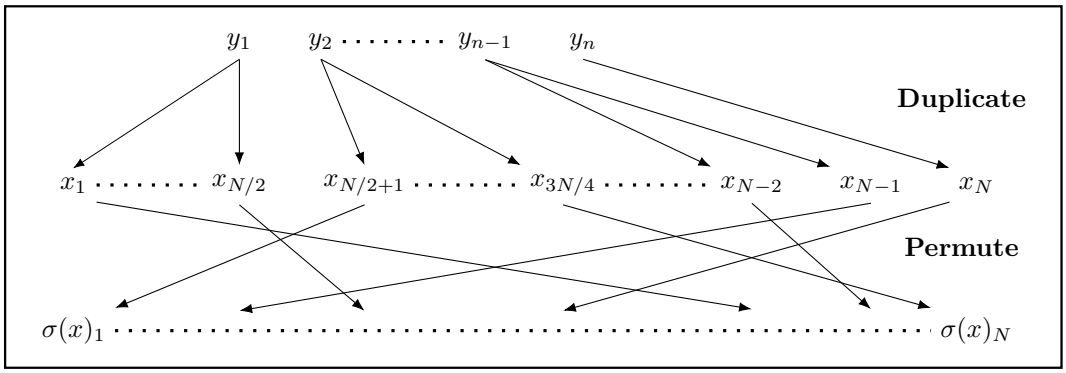

Figure 1 Modification of the binary-search oracle y in steps 2 $\implies$ 3 and 3 $\implies$ 4. Queries to $\sigma(x)$ are made by "going up the arrows".

if $x_i = 1$. On the other hand, if $x_i = 0$, we have that $p_y(k) = 0$ if $y_k = 0$ and that $\Pr[\sigma(i) = k|\sigma(x) = y] = 0$ if $y_k = 1$. Therefore, we have $p(i) = 0$ if $x_i = 0$.

3 $\implies$ 4: let $y \in \{0,1\}^n$ be a binary search instance. That is, $y = 00\ldots011\ldots1$ is monotonically increasing. For binary search, we want to find the smallest index i such that $y_i = 1$. We will now define another (exponentially longer) binary string $x \in \{0,1\}^N$ by $x_1 = x_2 = \cdots = x_{N/2} = y_1$, $x_{N/2+1} = \cdots = x_{3N/4} = y_2$ and so on, ending with $x_{N-2} = x_{N-1} = y_{\log N - 1}$ and $x_n = y_{\log N}$, i.e.

$$x = \underbrace{y_1 y_1 \ldots y_1}_{\frac{N}{2} \text{ times}} \underbrace{y_2 y_2 \ldots y_2}_{\frac{N}{4} \text{ times}} \cdots \underbrace{y_i y_i \ldots y_i}_{\frac{N}{2^i} \text{ times}} \cdots y_{\log N - 1} y_{\log N - 1} y_{\log N}. \tag{18}$$

If we sample an i with $x_i = 1$ uniformly at random, it will correspond to the smallest j with $y_j = 1$ with probability $> \frac{1}{2}$. This is because by construction each y_j appears more in x than all y_k for $k > j$ together. Furthermore, each query to y (standard or existential) can be simulated by a single query of the same kind to x (see Fig. 1). Therefore, statement 3. allows us to solve binary search with constant success probability and $q + O(\log\log n)$ $\exists$-queries.

4 $\implies$ 5: because the strings considered in a binary search problem are monotonically increasing we can simulate an $\exists$-query on such a string using only a single standard query. Instead of an $\exists$-query with z, we find the largest i such that $z_i = 1$ and use a standard query to query the i-th bit. The claimed implication follows. ◀

With this lemma in hand, Theorem 3 is easily proven.

Proof of Theorem 3. Suppose there exists an algorithm for search on $x \in \{0,1\}^N$ making $q = o(\log n)$ existential queries and poly(n) classical standard queries. Then, by Lemma 18 there is an algorithm for binary search on strings of length n making $q + O(\log\log n) = o(\log n)$ standard queries. This contradicts Ambainis' lower bound on binary search, which states that $\Omega(\log n)$ queries are required for binary search on size n strings [5]. Therefore, any search algorithm needs to make at least $q = \Omega \log n$ existential queries, even if it also makes poly(n) classical standard queries. ◀

Corollary 4 is an easy consequence of the previous theorem.

▶ **Corollary 4.** *Any quantum algorithm that is given existential query access to a string $x \in \{0,1\}^N$ and outputs an estimate c such that $2^{|x|-1} \leq c < 2^{|x|}$, where $|x|$ is the Hamming weight of x, needs to make at least $\Omega(\log\log N)$ queries to the oracle.*

Proof. We show that the existence of such an approximate counter making $o(\log\log N) = o(\log n)$ $\exists$-queries implies the existence of an algorithm for search making $o(\log n)$ $\exists$-queries. Using the approximate counter and Lemma 13 we can reduce x to be of Hamming weight 1 with constant probability and $o(\log n)$ $\exists$-queries. The index of the unique 1 can then be extracted using the BV trick (Lemma 17) and a single $\exists$-query. ◀

5 Conditional lower bound on number of NP queries for approximate counting

In order to prove Corollary 5 we will first concern ourselves with almost-uniform isolation algorithms. We will first prove the following theorem stating consequences of the existence of almost-uniform isolation algorithms making $o(\log n)$ NP queries. Thereafter, we will show that approximate counting with $o(\log n)$ NP queries implies almost-uniform isolation with $o(\log n)$ NP queries.

▶ **Theorem 19.** *Let $\epsilon > 0$ and $p \in (0, 1]$ be constants such that there exists an ϵ-almost-uniform isolation algorithm A_{iso} with success probability p making $Q(n) = o(\log n)$ queries to an* NP*-oracle. Then,* $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ *contains a* P^{NP}*-complete problem if this algorithm is classical and* $\mathsf{FBQP}^{\mathsf{NP}[o(n)]}$ *contains an* $\mathsf{FP}^{\mathsf{NP}}$*-complete problem if it is quantum.*

Proof. We will give a $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ algorithm to isolate the lexicographically least solution of an input formula φ, as outputting the last bit of this solution is P^{NP}-complete [21]. The idea of the algorithm will be as follows. We work in rounds. In the first round we sample n^2 almost-uniformly random solutions of φ. We will not explicitly know what these solutions are, but we can find a formula to which they are the unique solution. Next, we sample n^2 solutions of φ among all solutions that are lexicographically smaller than the all previously found solutions. We keep going like this until only one solution remains, which will be the lexicographically least solution of φ. We show that with high probability, the number of solutions that are smaller than the least solution found yet decreases by at least a factor $\frac{1}{n}$ every round. Therefore, we will, with high probability, need at most $\log_n(|sol(\varphi)|) = \frac{\log(|sol(\varphi)|)}{\log n} \leq \frac{n}{\log n}$ rounds to isolate the lexicographically least solution of φ.

In the first round we apply A_{iso} to $\Psi_1(\vec{x}_1, \ldots, \vec{x}_{n^2}) \coloneqq \varphi(\vec{x}_1) \wedge \cdots \wedge \varphi(\vec{x}_{n^2})$. Here the $\vec{x}_i$ denote fresh sets of variables and we use the vector notation to emphasize that they are n-bit strings and not bits. The result of this application will be $u_1(\vec{x}_1, \ldots, \vec{x}_{n^2})$ such that $\Psi_1 \wedge u_1$ has a unique solution. This unique solution will be the concatenation of n^2 solutions of φ.

In round $r+1$ we will do the following. From the previous round we have already constructed

$$\Psi_r(\vec{x}_{r,1}, \ldots, \vec{x}_{r,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2})$$

with a unique solution. In this unique solution, $\vec{x}_{i,1}, \ldots, \vec{x}_{i,n^2}$ will be the solutions to φ picked in round i. We set

$$\begin{aligned}\chi_{r+1}(\vec{x}_{r+1,1}, \ldots, \vec{x}_{r+1,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2}) \coloneqq\ & \varphi(\vec{x}_{r+1,1}) \wedge \cdots \wedge \varphi(\vec{x}_{r+1,n^2}) \\ & \wedge \Psi_r(\vec{x}_{r,1}, \ldots, \vec{x}_{r,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2}) \\ & \wedge \vec{x}_{r+1,1} <_{lex} \vec{x}_{r,1} \wedge \cdots \wedge \vec{x}_{r+1,1} <_{lex} \vec{x}_{r,n^2} \\ & \wedge \vec{x}_{r+1,n^2} <_{lex} \vec{x}_{r,n^2} \wedge \cdots \wedge \vec{x}_{r+1,1} <_{lex} \vec{x}_{r,n^2}. \quad (19)\end{aligned}$$

In any satisfying assignment of χ_{r+1}, the first line of the RHS enforces that $\vec{x}_{r+1,1}, \ldots, \vec{x}_{r+1,n^2}$ are solutions of φ. The second line makes sure that $\vec{x}_{r,1}, \ldots, \vec{x}_{r,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2}$ are set to the unique solutions picked in previous rounds. The third and fourth lines make sure that the new solutions are lexicographically strictly smaller than any solution picked in a previous round.[9]

We now pick the new solutions of round $r+1$ by applying A_{iso} to χ_{r+1}. We call the round is successful if A_{iso} succeeds, i.e. if its output u_{r+1} is such that $\chi_{r+1} \wedge u_{r+1}$ has a unique solution. We can check if A_{iso} succeeded by spending 2 NP queries.[10] In case of a success $\Psi_{r+1} \coloneqq \chi_{r+1} \wedge u_{r+1}$ will have a unique solution, which is picked almost uniformly at random from all solutions of χ_{r+1} (by definition of A_{iso}). In this unique solution $\vec{x}_{r+1,1}, \ldots, \vec{x}_{r+1,n^2}$ will be the newly picked solutions. By construction they will be smaller than the solutions found in the previous rounds. The previously picked solutions $\vec{x}_{r,1}, \ldots, \vec{x}_{r,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2}$ will be the same as in previous rounds because the second line of Equation 19 has a unique solution. Finally, we check if there are still smaller solutions available by checking if

$$\varphi(y) \wedge \Psi_{r+1}(\vec{x}_{r+1,1}, \ldots, \vec{x}_{r+1,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2}) \wedge y <_{lex} \vec{x}_{r+1,1} \wedge \cdots \wedge y <_{lex} \vec{x}_{r+1,n^2} \quad (20)$$

is still satisfiable. If it is satisfiable we proceed to the next round and if it is not then, in the unique solution of Ψ_{r+1}, one of the $\vec{x}_{r+1,i}$ will be the minimal solution of φ. Therefore,

$$\varphi(y) \wedge \Psi_{r+1}(\vec{x}_{r+1,1}, \ldots, \vec{x}_{r+1,n^2}, \ldots, \vec{x}_{1,1}, \ldots, \vec{x}_{1,n^2}) \wedge y \leq_{lex} \vec{x}_{r+1,1} \wedge \cdots \wedge y \leq_{lex} \vec{x}_{r+1,n^2} \quad (21)$$

will have a unique solution where y is the lexicographically least assignment of φ (note the use of $\leq$ instead of $<$). Asking the oracle if this formula is still satisfiable with the last bit of y set to 1 will then tell us the last bit of the lexicographically least solution of φ. Alternatively, a BQP-machine can use the BV trick to obtain the *entire* lexicographically least solution with one query and solve the $\mathsf{FP}^{\mathsf{NP}}$-complete problem of outputting the lexicographically least solution of φ [21].

We will proceed by proving that this algorithm succeeds with probability at least $\frac{2}{3}$ and makes at most $o(n)$ NP queries using the following claims. The proofs of these claims can be found in Appendix A.1.

▷ Claim 20 (Number of successful rounds needed). For sufficiently large n, the probability that the algorithm described above has not terminated after $\frac{n}{\log n}$ *successful* rounds is less than $\frac{1}{6}$ (a successful round is a round in which a unique solution remains after the application of A_{iso}).

▷ Claim 21 (Probability of successful rounds). The probability that after $\frac{2n}{p \log n}$ rounds there have not been $\frac{n}{\log n}$ *successful* rounds is at most $\frac{1}{6}$ for sufficiently large n. Here, recall p is the success probability of A_{iso}.

From these claims it follows that with probability at least $\frac{2}{3}$, the algorithm will, after at most $\frac{2n}{p \log n}$ rounds, have terminated. In every round, $Q(\mathrm{poly}(n))$ queries are made because only a polynomial amount of terms are added to Ψ_r every round (recall that $Q(n)$ is the number of queries made by A_{iso}). Since $Q(n) = o(\log n)$ by assumption, we have $Q(n^c) = o(c \cdot \log n) = o(\log n)$. Hence the algorithm makes at most $\frac{2n}{p \log n} o(\log n) = o(n)$ queries. ◀

[9] Note that comparing only to the previous rounds solutions suffices.

[10] One query is used to check if the formula is satisfiable and the other is used to check if there are two or more distinct solutions.

Corollary 5 follows by showing that an algorithm for approximate counting induces an algorithm for almost-uniform isolation with the same number of NP queries.

▶ **Corollary 5.** *If there exists a classical randomized poly-time algorithm for approximate counting making $o(\log n)$ NP queries, then $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ contains a P^{NP}-complete problem. Similarly, if there is a poly-time quantum algorithm for approximate counting making $o(\log n)$ NP queries, then $\mathsf{BQP}^{\mathsf{NP}[o(n)]}$ contains an $\mathsf{FP}^{\mathsf{NP}}$-complete problem.*

The idea of the proof is that we can make a almost-uniform isolation algorithm by first approximately counting the number of solutions (using $o(\log n)$ NP queries by assumption) and then picking a suitable hash function. Using ideas from Dellanoy and Meel [14, Lemma 3] it can be shown that this procedure indeed gives an almost-uniform isolation algorithm. The full proof of the corollary can be found in Appendix A.2.

A Omitted proofs

A.1 Claims in proof of Theorem 19

▷ Claim 20 (Number of successful rounds needed). For sufficiently large n, the probability that the algorithm described above has not terminated after $\frac{n}{\log n}$ *successful* rounds is less than $\frac{1}{6}$ (a successful round is a round in which a unique solution remains after the application of A_{iso}).

Proof of Claim 20. Let $\vec{y}_1 < \cdots < \vec{y}_k$ denote all solutions to φ smaller than $\vec{y}_{min,r-1}$, the smallest solution found in round $r-1$. Define $g = \lceil \frac{k}{n} \rceil$. We now compute the probability that, in a single round r, $\vec{y}_{min,r}$ is larger than $\vec{y}_g$ as

$$\Pr[\vec{y}_{min,r} >_{lex} \vec{y}_g] = \Pr\left[\vec{x}_{r,1} >_{lex} \vec{y}_g \wedge \cdots \wedge \vec{x}_{r,n^2} >_{lex} \vec{y}_g\right] \tag{22}$$

$$= \Pr[(\vec{x}_{r,1}, \ldots, \vec{x}_{r,n^2}) \in \{\vec{y}_{g+1}, \ldots, \vec{y}_k\}^{n^2}] \tag{23}$$

$$\leq |\{\vec{y}_{g+1}, \ldots, \vec{y}_k\}^{n^2}| \cdot \frac{1+\epsilon}{|\{\vec{y}_1, \ldots, \vec{y}_k\}^{n^2}|} \tag{24}$$

$$= (k-g)^{n^2} \frac{1+\epsilon}{k^{n^2}} \tag{25}$$

$$\leq \left(k\left(1-\frac{1}{n}\right)\right)^{n^2} \frac{1+\epsilon}{k^{n^2}} \tag{26}$$

$$= (1+\epsilon)\left(1-\frac{1}{n}\right)^{n^2}, \tag{27}$$

where Equation 25 follows from a union bound and the definition of an ϵ-almost-uniform isolation algorithm Hence, by a union bound, the probability that in at least one of $\frac{n}{\log n}$ successful rounds $\vec{y}_{min,r} >_{lex} \vec{y}_{goal,r}$, i.e., the probability that in at least on of the rounds the search space is not cut down by at least a factor $\frac{1}{n}$ is

$$\Pr[\exists r \leq \frac{n}{\log n} \text{ s.t. } \vec{y}_{min,r} >_{lex} \vec{y}_{g,r}] \leq (1+\epsilon)\frac{n}{\log n}\left(1-\frac{1}{n}\right)^{n^2}, \tag{28}$$

of which the right-hand side goes to 0 as n goes to ∞. The claim follows. ◁

▷ Claim 21 (Probability of successful rounds). The probability that after $\frac{2n}{p \log n}$ rounds there have not been $\frac{n}{\log n}$ *successful* rounds is at most $\frac{1}{6}$ for sufficiently large n. Here, recall p is the success probability of A_{iso}.

Proof of claim 21. Each round succeeds with probability p. After $\frac{2n}{p \log n}$ rounds the expected number of successful rounds is $\frac{2n}{\log n}$. By a Chernoff bound we have:

$$\Pr[\#\text{successes} < \frac{n}{\log n}] \leq \exp\left(-\frac{n}{4p \log n}\right). \tag{29}$$

For sufficiently large n, the right-hand side will indeed be at most $\frac{1}{6}$. ◁

A.2 Full proof of Corollary 19

▶ **Corollary 5.** *If there exists a classical randomized poly-time algorithm for approximate counting making $o(\log n)$ NP queries, then $\mathsf{BPP}^{\mathsf{NP}[o(n)]}$ contains a P^{NP}-complete problem. Similarly, if there is a poly-time quantum algorithm for approximate counting making $o(\log n)$ NP queries, then $\mathsf{BQP}^{\mathsf{NP}[o(n)]}$ contains an $\mathsf{FP}^{\mathsf{NP}}$-complete problem.*

Proof of Corollary 5. The approximate counting algorithms can be used to make an almost-uniform isolation algorithm as follows. First, use the approximate counting algorithm to find k such that $2^{k-2} \leq |\operatorname{sol}(\varphi)| \leq 2^{k-1}$. Next, choose a random hash function h from a set of pairwise independent hash functions from $\{0,1\}^n$ to $\{0,1\}^k$. By Lemma 13, the formula $\varphi(x) \wedge h(x) = 0^k$ will then have a unique solution with probability at least $\frac{1}{8}$.[11] We claim that in this case the unique solution will be distributed almost-uniformly at random among all solutions of φ. Our proof of this claim is based on work by Dellanoy and Meel [14, Lemma 3].

[11] We only require almost-uniformity in the case that there is a unique solution.

Before we prove the claim let us first introduce some notation. Let the random variable N denote the number of solutions of $\varphi(x) \wedge h(x) = 0^k$ and let SC denote the event that the approximate counting was successful, i.e. $2^{k-2} \leq |\operatorname{sol}(\varphi)| \leq 2^{k-1}$. We assume that SC occurs with probability $1 - \delta$. For any fixed x, we are interested in

$$\Pr[h(x) = 0^k | N = 1] = \frac{\Pr[h(x) = 0^k \wedge N = 1]}{\Pr[N = 1]} \tag{30}$$

$$= \frac{\Pr[h(x) = 0^k \wedge N = 1]}{\sum_{y \in \operatorname{sol}(\varphi)} \Pr[h(y) = 0^k \wedge N = 1]} \tag{31}$$

$$= \frac{\Pr[N = 1 | h(x) = 0^k] \Pr[h(x) = 0^k]}{\sum_{y \in \operatorname{sol}(\varphi)} \Pr[N = 1 | h(y) = 0^k] \Pr[h(y) = 0^k]} \tag{32}$$

$$= \frac{\Pr[N = 1 | h(x) = 0^k]}{\sum_{y \in \operatorname{sol}(\varphi)} \Pr[N = 1 | h(y) = 0^k]} \tag{33}$$

and want to show that this probability is $\leq \frac{\epsilon}{|\operatorname{sol}(\varphi)|}$. Let $\chi(y)$ be 1 if $h(y) = 0^k$ and 0 otherwise. For any $x \in \operatorname{sol}(\varphi)$ we have:

$$\mathbb{E}\left[N \middle| h(x) = 0^k \wedge SC\right] = \mathbb{E}\left[\sum_{y \in \operatorname{sol}(\varphi)} \chi(y) \middle| h(x) = 0^k \wedge SC\right] \tag{34}$$

$$= \sum_{y \in \operatorname{sol}(\varphi)} \mathbb{E}\left[\chi(y) \middle| h(x) = 0^k \wedge SC\right] \tag{35}$$

$$= 1 + \frac{|\operatorname{sol}(\varphi)| - 1}{2^{-k}} \tag{36}$$

where we use that h is a 2-wise independent hash function. By Markov's inequality this means that for all $x \in \operatorname{sol}(\varphi)$

$$\Pr[N = 1 | h(x) = 0^k \wedge SC] = 1 - \Pr[N \geq 2 | h(x) = 0^k \wedge SC] \tag{37}$$

$$\geq 1 - \frac{\mathbb{E}[N | h(x) = 0 \wedge SC]}{2} \tag{38}$$

$$\geq \frac{1}{2} - \frac{|\operatorname{sol}(\varphi)| - 1}{2^{k+1}} \tag{39}$$

$$\geq \frac{1}{4}. \tag{40}$$

Combining with Equation 33 and using that $\Pr[N = 1 | h(y) = 0^k] \geq \Pr[N = 1 \wedge SC | h(y) = 0^k]$ and $\Pr[N = 1 | h(x) = 0^k] \leq 1$ gives

$$\Pr[h(x) = 0^k | N = 1] \leq \frac{1}{\sum_{y \in \operatorname{sol}(\varphi)} \Pr[N = 1 \wedge SC | h(y) = 0^k]} \tag{41}$$

$$\leq \frac{1}{\sum_{y \in \operatorname{sol}(\varphi)} \Pr[N = 1 | h(y) = 0^k \wedge SC] \Pr[SC]} \tag{42}$$

$$\leq \frac{4}{(1 - \delta)|\operatorname{sol}(\varphi)|}. \tag{43}$$

Note that this holds for *any* x. Hence the existence of an approximate counter gives us an almost-uniform isolation algorithm with $p = \frac{1-\delta}{8}$ and $\epsilon = \frac{3+\delta}{1-\delta}$. Furthermore, the approximate counter and isolation algorithm will make the same amount of NP queries (i.e. $o(\log n)$). ◀

Low-Memory Algorithms for Online Edge Coloring

Prantar Ghosh
Georgetown University, Washington, DC, USA

Manuel Stoeckl
Dartmouth College, Hanover, NH, USA

Abstract

For edge coloring, the online and the W-streaming models seem somewhat orthogonal: the former needs edges to be assigned colors immediately after insertion, typically without any space restrictions, while the latter limits memory to be sublinear in the input size but allows an edge's color to be announced any time after its insertion. We aim for the best of both worlds by designing small-space online algorithms for edge coloring.

Our online algorithms significantly improve upon the memory used by prior ones while achieving an $O(1)$-competitive ratio. We study the problem under both (adversarial) edge arrivals and vertex arrivals. Under vertex arrivals of any n-node graph with maximum vertex-degree Δ, our online $O(\Delta)$-coloring algorithm uses only semi-streaming space (i.e., $\tilde{O}(n)$ space, where the $\tilde{O}(.)$ notation hides polylog(n) factors). Under edge arrivals, we obtain an online $O(\Delta)$-coloring in $\tilde{O}(n\sqrt{\Delta})$ space. We also achieve a smooth color-space tradeoff: for any $t = O(\Delta)$, we get an $O(\Delta t(\log^2 \Delta))$-coloring in $\tilde{O}(n\sqrt{\Delta/t})$ space, improving upon the state of the art that used $\tilde{O}(n\Delta/t)$ space for the same number of colors.

The improvements stem from extensive use of random permutations that enable us to avoid previously used colors. Most of our algorithms can be derandomized and extended to multigraphs, where edge coloring is known to be considerably harder than for simple graphs.

1 Introduction

A proper edge-coloring of a graph or a multigraph colors its edges such that no two adjacent edges share the same color. The goal is to use as few colors as possible. Any graph with maximum vertex-degree Δ trivially requires Δ colors to be properly edge-colored. Vizing's celebrated theorem [46] asserts that $\Delta + 1$ colors suffice for any simple graph.[1] Constructive polynomial-time algorithms exist for $(\Delta + 1)$-edge-coloring in the classical offline setting [39], and these are likely to be optimal with respect to the number of colors: distinguishing between whether the edge-chromatic number (i.e., the minimum number of colors needed to edge-color a graph) of a simple graph is Δ or $\Delta + 1$ is NP-hard [33].

[1] For multigraphs, $3\Delta/2$ colors are necessary and sufficient. [44]

The edge-coloring problem finds applications in various practical scenarios, including switch routing [2], round-robin tournament scheduling [34], call scheduling [27], optical networks [42], and link scheduling in sensor networks [30]. In applications like switch routing, where the underlying graph evolves through edge insertions, the color assignments must be made instantly and irrevocably. This is modeled by the *online* edge coloring problem. Due to its restrictions, an online algorithm cannot obtain a $(\Delta+1)$-coloring [11]. Nevertheless, the simple greedy algorithm, which colors every edge with the first available color not assigned to any neighbor, obtains a $(2\Delta-1)$-coloring since each edge can have at most $2\Delta-2$ neighboring edges. Thus, the competitive ratio achieved is $2-o(1)$ (since the optimum is Δ or $\Delta+1$). Bar-Noy, Motwani, and Naor [11] showed that no online algorithm can outperform this greedy algorithm. However, they proved this only for graphs with max-degree $\Delta = O(\log n)$. They conjectured that for $\Delta = \omega(\log n)$, it is possible to get better bounds – specifically, a $(1+o(1))\Delta$-coloring. For this regime of Δ, several works [2, 10, 23, 18, 43, 35, 41] have studied online edge coloring with the goal of surpassing the greedy algorithm and, even further, of resolving the said conjecture. Additionally, other variants of the online problem have been investigated [29, 38, 28]. However, all prior works assume full storage of all graph edges and their colors in memory.

With the ubiquity of big data in the modern world, the assumption of storing entire graphs in memory becomes impractical. Even graphs like communication and internet routing networks that motivate the study of edge coloring often turn out to be large-scale networks. This challenge has given rise to big-graph processing models such as *graph streaming* which, like the online model, sequentially accesses the graph edges, but only retains a small summary. There is an immediate barrier for edge coloring in this setting: reporting all edge colors at the end of the stream would use space linear in the number of edges. To remedy this, a natural extension of the model, called the *W-streaming model*, allows reporting the output in streaming fashion. Here, an algorithm with limited working memory stores information about both the input graph and the output coloring and periodically streams or announces edge colors. Unlike the online model, here we don't need to assign a color to an incoming edge right away, and can defer it. However, due to space constraints, we are not able to remember all the previously announced colors. Note that this makes even the greedy $(2\Delta-1)$-coloring algorithm hard, if not impossible, to implement in this model.

In this work, we aim to get the best of both worlds of the online and the streaming models by designing *low-memory* online algorithms for edge coloring. This addresses the need for immediate color assignment in modern scenarios while optimizing space usage. We achieve an $O(1)$-competitive ratio, i.e., a color bound of $O(\Delta)$. Note that no prior work in the sublinear-space setting has achieved an $O(\Delta)$-coloring W-streaming algorithm, let alone an online algorithm. For adversarial edge-arrival streams, we get an online $O(\Delta)$-coloring in $\widetilde{O}(n\sqrt{\Delta})$ space[2], significantly reducing the space compared to prior online algorithms with only a constant factor increase in colors. We can smoothly trade off space with colors, obtaining an $\widetilde{O}(\Delta t)$-coloring in $\widetilde{O}(n\sqrt{\Delta/t})$ space. This improves upon the state of the art [21, 5] which used $\widetilde{O}(n\Delta/t)$ space for the same color bound. Furthermore, for natural and well-studied settings of vertex-arrival in general graphs and one-sided vertex arrival in bipartite graphs, we enhance the space usage to $\widetilde{O}(n)$, the prevalent *semi-streaming* memory regime for graph streaming problems. Most of our algorithms generalize to multigraphs and can be made deterministic.

[2] Throughout the paper, the $\widetilde{O}(.)$ notation hides polylog(n) and polylog(Δ) factors.

We remark that apart from being interesting online algorithms on their own, our results can be also viewed as strengthening W-streaming algorithms with the guarantee of online output-reporting. In particular, they contribute an important conceptual message: the state-of-the-art W-streaming space bound for $O(\Delta)$ edge coloring can be matched *without* the exclusive power of the W-streaming model (allowing delayed assignment of edge colors); we can report edge colors online.

1.1 Our Results and Contributions

We study edge-coloring in the online model with sublinear (i.e., $o(n\Delta)$) memory, under (adversarial) edge-arrivals as well as vertex-arrivals. These results are summarized in Table 1, and their corollaries for the W-streaming model in Table 2. The tables mention the state of the art, for comparison.

Table 1 Our results in the online model. Here, $t \leq \Delta$ is any positive integer. Algorithms marked with a $\star$ require oracle randomness for randomized algorithms and an advice string computable in exponential time for deterministic.

Arrival	Algorithm	Colors	Space	Graph	Reference
Edge	Randomized	$\left(\frac{e}{e-1}+o(1)\right)\Delta$	$\widetilde{O}(n\Delta)$	Simple	[35]
	Randomized	$O(\Delta)$	$\widetilde{O}(n\sqrt{\Delta})$	Simple	Theorem 1
	Deterministic	$(2\Delta-1)t$	$O(n\Delta/t)$	Multigraph	[5]
	Deterministic	$\widetilde{O}(\Delta t)$	$\widetilde{O}(n\sqrt{\Delta/t})\star$	Multigraph	Theorem 3 + Lemma 5
Vertex	Randomized	$(1.9+o(1))\Delta$	$\widetilde{O}(n\Delta)$	Simple	[43]

Deterministic	$\widetilde{O}(\Delta^2/s)$	$\widetilde{O}(n\sqrt{s})\star$	Multigraph	Corollary 4 + Lemma 5

Edge-arrival model

Here we design both online and W-streaming algorithms.

▶ **Theorem 1.** *Given any adversarial edge-arrival stream of a simple graph, there is a randomized algorithm for online $O(\Delta)$-edge-coloring using $\widetilde{O}(n\sqrt{\Delta})$ bits of space.*

Previously, there was no sublinear space online algorithm known for $O(\Delta)$-coloring. As observed in Table 1, all prior algorithms need $\Theta(n\Delta)$ space in the worst case to achieve a color bound of $O(\Delta)$.

Note that Theorem 1 immediately implies a randomized W-streaming algorithm with the same space and color bounds. Although immediate, we believe that it is important to note it as a corollary.

▶ **Corollary 2.** *Given an adversarially ordered edge stream of any simple graph, there is a randomized W-streaming algorithm for $O(\Delta)$-edge-coloring using $\widetilde{O}(n\sqrt{\Delta})$ bits of space.*

The above result improves upon the state of the art algorithms of [21, 5] which, as implied by Table 2, only obtain $\omega(\Delta)$-colorings for $o(n\Delta)$ space (the non-trivial memory regime in W-streaming). In fact, we improve upon them by a factor of $\Omega(\sqrt{\Delta})$ in space for $O(\Delta)$-coloring.

Further, we prove that we can make the above algorithms deterministic, and able to handle multigraphs, at the cost of only a polylogarithmic factor in the number of colors used. Once again, the online algorithm is also a W-streaming algorithm.

▶ **Theorem 3.** *Given an adversarially ordered edge-arrival stream of any multigraph, there is a deterministic algorithm for online $O(\Delta \log^2 \Delta)$-edge-coloring using $\widetilde{O}(n\sqrt{\Delta})$ bits of space.*

▶ **Corollary 4.** *Given an adversarially ordered edge stream of any multigraph, there is a deterministic W-streaming algorithm for $O(\Delta \log^2 \Delta)$-edge-coloring using $\widetilde{O}(n\sqrt{\Delta})$ bits of space.*

Furthermore, in each case, we can achieve a smooth tradeoff between the number of colors and the memory used. This is implied by a framework captured in the following lemma.

▶ **Lemma 5.** *Suppose that we are given an online $f(n, \Delta)$-space streaming algorithm $\mathcal{A}$ for $O(\Delta)$-coloring any n-node multigraph with max-degree Δ under adversarial edge arrivals. Then, for any $t \geq 1$, there is a online streaming algorithm $\mathcal{B}$ for $O(\Delta t)$-coloring the same kind of graphs under adversarial edge arrivals using $f(n/t, \Delta t) + \widetilde{O}(n)$ bits of space.*

For the online model, the above lemma combined with Theorem 3 immediately gives the tradeoff of $\widetilde{O}(\Delta t)$ colors and $\widetilde{O}(n\sqrt{\Delta/t})$ space for any $t = O(\Delta)$, as claimed in Table 1. In other words, combined with Corollary 4, it implies the W-streaming bounds of $\widetilde{O}(\Delta^2/s)$ colors and $O(n\sqrt{s})$ space for any $s = O(\Delta)$, as claimed in Table 2.[3] Note that our results match the tradeoff obtained by the state of the art for $t = \Theta(\Delta)$ and $s = O(1)$, and strictly improve upon them for $t = o(\Delta)$ and $s = \omega(1)$.

[3] We use the parameter t for online algorithms and s for W-streaming, where $t \cdot s = \Delta$, so that a reader can easily compare our bounds with the "ideal" bounds of $O(\Delta)$ colors and $\widetilde{O}(n)$ space in the respective models by smoothly growing t or s from 1 to Δ.

Vertex-arrival Model

We now turn to the weaker vertex-arrival model. The online edge-coloring problem has been widely studied in this setting as well (see Section 1.2 for a detailed discussion). Our online algorithms obtain significantly better space bounds than the edge-arrival setting.

▶ **Theorem 6.** *Given any adversarial vertex-arrival stream of a multigraph, there is a randomized online $O(\Delta)$-edge coloring algorithm using $\widetilde{O}(n)$ bits of space. It works even against an adaptive adversary and uses $\widetilde{O}(n\Delta)$ oracle random bits.*[4] *In particular, for one-sided bipartite vertex arrivals, there is an algorithm using 5Δ colors.*

Thus, at the cost of only a constant factor in the number of colors, we can improve the memory usage from $\widetilde{O}(n\Delta)$ to $\widetilde{O}(n)$ for vertex-arrival streams. Since this algorithm immediately implies a W-streaming algorithm with the same bounds, we see that for vertex-arrival streams, $O(\Delta)$-coloring can be achieved in semi-streaming space, the most popular space regime for graph streaming. Behnezhad et al. [12] mentioned that "a major open question is whether [the number of colors for W-streaming edge-coloring] can be improved to $O(\Delta)$ while also keeping the memory near-linear in n." Our results answer the question in the affirmative for the widely studied model of vertex-arrival streams.

Further, we show that the algorithm can be made deterministic using $\widetilde{O}(n)$ bits of *advice* instead of $\widetilde{O}(n\Delta)$ bits of oracle randomness. By picking a uniformly random advice string, the updated algorithm can alternatively be used as a robust algorithm (see Definition 12) with $1/\operatorname{poly}(n)$ error; the advice can also be computed in exponential time.

▶ **Theorem 7.** *Given any adversarial vertex-arrival stream of a multigraph, there is a deterministic online $O(\Delta)$-edge-coloring algorithm using $\widetilde{O}(n)$ bits of space, using $\widetilde{O}(n)$ bits of advice.*

An interesting special case of the vertex-arrival model is the one-sided vertex-arrival setting for bipartite graphs. Here, the vertices on one side of the bipartite graph are fixed, while the vertices on the other side arrive in a sequence along with their incident edges. A couple of works [23, 41] have studied online edge-coloring specifically in this model. We design low-memory online algorithms in this setting and use them as building blocks for our algorithms in the more general settings of vertex-arrival and edge-arrival. These algorithms may be of independent interest due to practical applications of the one-sided vertex-arrival model; moreover, the randomized algorithm here uses only 5Δ colors (as opposed to our other algorithms where the hidden constants in $O(\Delta)$ are rather large).

Finally, we present a lower bound on the space requirement of a deterministic online edge-coloring algorithm. To the best of our knowledge, this is the first non-trivial space lower bound proven for an online edge-coloring algorithm.

▶ **Theorem 8.** *For $\Delta \leq \varepsilon n$ for a sufficiently small constant ε, any deterministic online algorithm that edge-colors a graph using $(2 - o(1))\Delta$ colors requires $\Omega(n)$ space.*

[4] The use of oracle randomness here is not a big deal. In practice (where we assume cryptographic pseudo-random number generators exist), it is straightforward to generate the bits of the oracle random string on demand, ensuring that computationally bounded systems essentially cannot produce hard inputs for the algorithm. Also, against oblivious adversaries, one can easily modify the randomized vertex arrival algorithm to use only $\widetilde{O}(n)$ random bits, by choosing its random permutations from almost $O(\log n)$-wise independent families, but we skip this to keep the proof simple.

1.2 Related Work

Online model

Online edge-coloring has a rich literature [2, 5, 11, 10, 18, 19, 23, 28, 29, 37, 38, 41, 35, 43]. The seminal work of Bar-Noy, Motwani, and Naor [11] ruled out any online algorithm outperforming the $(2\Delta - 1)$-coloring greedy algorithm that assigns each edge the first available color not used by any adjacent edge. However, this lower bound applies only to graphs with $\Delta = O(\log n)$. They conjectured that for $\Delta = \omega(\log n)$, there exist online $(1 + o(1))\Delta$-coloring algorithms. Although this conjecture remains unresolved, there has been significant progress on it over the years. A number of works [2, 10, 18] considered the problem under *random-order* edge arrivals: Aggarwal et al. [2] showed that if $\Delta = \omega(n^2)$, then a tight $(1 + o(1))\Delta$-coloring is possible. For $\Delta = \omega(\log n)$ (the bound in the said conjecture), Bahmani et al. [10] obtained a 1.26Δ-coloring. Bhattacharya et al. [18] then achieved the best aspect of each result as they attained the tight color bound of $(1 + o(1))\Delta$ for the broad range of $\Delta = \omega(\log n)$, essentially resolving the conjecture for random-order arrivals.

More relevant to our work is the setting of *adversarial-order* edge arrivals. Cohen et al. [23] were the first to make progress on [11]'s conjecture in this regard, obtaining a $(1 + o(1))\Delta$-coloring for bipartite graphs under one-sided vertex arrivals (i.e., the nodes on one side are fixed, and the nodes on the other side arrive one by one with all incident edges). Their algorithm assumes a priori knowledge of the value of Δ. For unknown Δ, they rule out any online algorithm using fewer than $(e/(e-1))\Delta$ colors and also complement this result with a $(e/(e-1) + o(1))\Delta$-coloring algorithm. For bipartite *multigraphs* with one-sided vertex arrivals, Naor et al. [41] very recently proved that 1.533Δ colors suffice, while at least 1.207Δ colors are necessary even for $\Delta = 2$. Saberi and Wajc [43] showed that it is possible to beat the greedy algorithm for $\Delta = \omega(\log n)$ under vertex arrivals in general graphs: they designed a $(1.9 + o(1))\Delta$-coloring algorithm. Recently, Kulkarni et al. [35] made the first progress on the said conjecture for fully general adversarial edge arrivals: they obtained a $(e/(e-1) + o(1))\Delta$-coloring in this model. Note that the focus of all these works was on resolving [11]'s conjecture without any space limitations. Our focus is on designing low-memory online algorithms while staying within a constant competitive ratio. The only prior sublinear-space online edge-coloring algorithm we know was given by Ansari et al. [5]: a (deterministic) online $2\Delta t$-coloring in $O(n\Delta/t)$ space for any $t \leq \Delta$.

Several works [29, 26, 28] have addressed the variant where, given a fixed number of colors, the goal is to color as many edges as possible. Mikkelsen [37, 38] considered online edge coloring with limited advice for the future.

W-Streaming model

The W-streaming model [25] is a natural extension of the classical streaming model for studying problems where the output size is very large, possibly larger than our memory. While the W-streaming literature has considered several graph problems [25, 24, 36, 31], we are aware of only three past works [12, 21, 5] that have studied edge-coloring here. Behnezhad et al. [12] initiated the study of W-streaming edge coloring. They considered the problem for both adversarial-order and random-order streams: using $\widetilde{O}(n)$ bits of working memory, they gave an $O(\Delta^2)$-coloring in the former setting, and a $(2e\Delta)$-coloring in the latter setting. Charikar and Liu [21] improved these results: for adversarial-order streams, for any $s \in [\Omega(\log n), \Delta]$, they presented an $O(\Delta^2/s)$-coloring algorithm that uses $\widetilde{O}(ns)$ space; and for random-order streams, they gave a $(1 + o(1))\Delta$-coloring algorithm using $\widetilde{O}(n)$ space. Both of the said adversarial-order streaming algorithms are, however, randomized. Ansari

et al. [5] designed simple deterministic algorithms achieving the same bounds of $O(\Delta^2/s)$ colors and $\widetilde{O}(ns)$ space. Their algorithm can also be made online at the cost of a factor of 2 in the number of colors. Note that, parameterizing our results in Table 2 appropriately, our algorithms achieve $O(\Delta^2/s)$-colorings in $\widetilde{O}(n\sqrt{s})$ space, matching the state of the art for $s = O(1)$, and strictly improving upon it for $s = \omega(1)$.

The related problem of vertex coloring has a more mature literature in the streaming model [1, 3, 6, 7, 8, 9, 15, 16, 17, 20, 32]. However, due to fundamental differences between the classical streaming and W-streaming models and between the two problems, not many techniques seem to carry over.

Concurrent work

In an independent and parallel work, Behnezhad and Saneian [13] have designed a randomized $\widetilde{O}(n\sqrt{\Delta})$-space W-streaming algorithm for $O(\Delta)$-edge-coloring for edge-arrival streams in simple general graphs. This matches our Corollary 2. Their result generalizes to give, for any $s \in [\sqrt{\Delta}]$, an $O(\Delta^{1.5}/s)$ coloring algorithm in $\widetilde{O}(ns)$ space, while we achieve an $O(\Delta^2/s^2)$-coloring in the same space. They also get an $O(\Delta)$-edge-coloring algorithm for vertex-arrival streams using $\widetilde{O}(n)$ space, similar to our Theorem 6. Note that a crucial difference between the two papers is that most of our algorithms have the additional strong feature of being online, while it is not clear if their W-streaming edge-arrival algorithm can also be implemented in the online setting. Thus, conceptually, our results affirm that to obtain an $O(\Delta)$-coloring in sublinear space, the only advantage of W-streaming over online – enabling delay of color assignment – is not necessary.

In terms of techniques, while both works have some high level ideas in common (e.g., using random offsets/permutations to keep track of colors, or designing a one-sided vertex-arrival algorithm first and building on it to obtain the edge-arrival algorithm), the final algorithms and analyses in the two papers are fairly different.

Another independent work by Chechik, Mukhtar, and Zhang [22] obtains a randomized W-streaming algorithm that colors an edge-arrival stream on general multigraphs using $O(\Delta^{1.5}\log\Delta)$ colors in expectation[5], and $\widetilde{O}(n)$ space in expectation. Unlike us, they make no claims in the online model.

2 Notation and Definitions

Throughout the paper, logarithms are in base 2. The notation $[t]$ indicates the set of integers $\{1, \ldots, t\}$. The notation $\widetilde{O}(x)$ ignores $\mathrm{poly}(\log(n), \log(\Delta))$ factors in x. $A \sqcup B$ gives the disjoint union of A and B. $\mathbb{S}_t$ is the set of permutations over $[t]$, and for any permutation $\sigma \in \mathbb{S}_t$ and $X \subseteq [t]$, we denote $\sigma[X] := \{\sigma_i : i \in X\}$. For any set X, $\binom{X}{k}$ denotes the set of all k-sized subsets of X.

If not otherwise stated, n is the number of vertices in a graph G, V the set of vertices (or $A \sqcup B$ if the graph is bipartite), E the (multi-)set of edges, and Δ is the maximum degree of the graph (counting multiplicity, for multigraphs).

[5] While [22] does not claim this, one can prove their algorithm uses $O(\Delta^{1.5}\log\Delta)$ colors with $\geq 1 - 1/\mathrm{poly}(n)$ probability.

2.1 Models

We consider the following models for presenting edges (to be colored) to an algorithm. In all cases, the set of vertices for the graph is known in advance.

▶ **Definition 9** (Edge-Arrival Model). *With an* edge-arrival stream*, the algorithm is given a sequence of edges in the graph. Each edge is provided as an unordered pair $\{x, y\}$ of vertices in V. In this paper, online algorithms processing edge arrival streams will implement a method* Process$(\{x, y\})$ *which returns the color assigned to the edge. W-streaming algorithms may assign the color for an edge at any time, although all edges must be given a color at the end of the stream. We permit algorithms to output not just integers but also tuples of integers as "colors", since users of the algorithms can easily remap these colors to whatever space they wish.*

▶ **Definition 10** (Vertex-Arrival Model). *In a* vertex-arrival stream*, the algorithm is given a sequence of (vertex, edge-set) pairs (v, M_v), where the edge (multi-)set M_v contains all edges from v to vertices that have been seen earlier in the stream. Online algorithms should report colors for all edges in M_v when (v, M_v) is processed.*

A one-sided vertex-arrival stream *on a bipartite graph with partite sets A, B is a vertex arrival stream where the vertices in one partite set (B) are fixed, and then all the (vertex, edge-set) pairs for the other partite set (A) are given. This means that the stream consists of pairs (v, M_v), where each $v \in A$, and M_v contains all edges from v to vertices in B.*

▶ Remark 11 (Assumption of prior knowledge of Δ). We assume that the maximum degree Δ of G is known in advance. An edge-coloring algorithm for which Δ is not known in advance can be converted to one which is, although one way to do this conversion (by running a new 2Δ-coloring algorithm with a fresh set of colors whenever the maximum degree of graph formed by the input stream doubles) increases the total number of colors used by a constant factor, and uses $O(n \log \Delta)$ bits of space to keep track of the maximum degree. Since the algorithms in this paper already have large constant factors on number of colors used, it is not worth it to optimize the algorithms for the case where Δ is not known in advance.

▶ **Definition 12** (Robust Streaming). *An algorithm is said to be* robust *or* adversarially robust *if it works with $\geq 1 - \delta$ probability even when its input streams are adaptively generated. By "adaptively generated", we mean that the input is produced by an adaptive adversary that sees all outputs of the online (or W-streaming) algorithm, and repeatedly chooses the next element of the stream based on what the algorithm has output so far. See [14] for a more detailed explanation.*

2.2 Basic Definitions

▶ **Definition 13** ((ϵ, k)-wise independent permutation). *A random permutation σ is (ϵ, k)-wise independent if for all distinct $a_1, \ldots, a_k$ in $[n]$, the distribution of σ on $a_1, \ldots, a_k$ has total variation distance $\leq \epsilon$ from uniform. In other words,*

$$\frac{1}{2} \sum_{\text{distinct } b_1, \ldots, b_k \in [n]} \left| \Pr\left[\bigwedge_{i \in [k]} \{\sigma(a_i) = b_i\} \right] - \frac{1}{\prod_{i \in [k]} (n - i + 1)} \right| \leq \epsilon \,.$$

Per [4], while it is not known if there are nontrivial $(0, k)$-wise independent families of permutations for large k and n, one can always construct weighted distributions which have support of size $n^{O(k)}$ and provide $(0, k)$-wise independence. However, sampling from these may not be efficient.

We say a random permutation is almost k-wise independent *when it is (ϵ, k)-wise independent for sufficiently small ϵ.*

We, using a result by [40] on switching networks, give a short lemma describing an efficient construction of (ϵ, k)-wise independent permutations.

▶ **Lemma 14** (Random permutations through switching networks). *Let C be a power of 2, let s be a natural number $\leq C$, and let $\epsilon > 0$. For $r = O(s(\log C)^4 \log \frac{1}{\epsilon})$, there is a map f from $\{0,1\}^r$ to $\mathbb{S}_C$ so that, if U is a uniformly random string of r bits, then $\sigma = f(U)$ is an (ϵ, s) wise independent random permutation.*

Furthermore, for any $i \in [C]$ and $u \in \{0,1\}^r$, with $\sigma = f(u)$, we can evaluate $\sigma(i)$ and $\sigma^{-1}(i)$ in $O(s(\log C)^4 \log \frac{1}{\epsilon} \log C)$ time.

3 Technical Overview

In this section, we give a high-level overview of our algorithms and techniques. We see these techniques as a major contribution of the paper since many of them are used for the first time in the context of W-streaming and online edge coloring. The proofs of our results are given in the full version of this paper.

3.1 General Reductions

Reducing to bipartite case

We show that it is essentially enough to consider bipartite graphs. Suppose that we can partition a general graph into $O(\log n)$ bipartite graphs, each of which has max-degree roughly $\Delta/\log n$, where Δ is the max-degree of the original graph. Then, if we run our algorithm on these bipartite graphs with disjoint palettes, we use colors roughly proportional to Δ. It is known (see [21] or for a similar result, [43, Lemma 2.1]) that such a partition can be done in a randomized way, incurring a multiplicative overhead of just $1 + o(1)$ in the number of colors. In this work, we show that if we are willing to tolerate an $O(1)$ blowup in the number of colors, then this partition can be done deterministically. Since such a primitive is used in multiple edge-coloring algorithms, this deterministic version might be of independent interest. One advantage of this version is that it works against adaptive adversaries, unlike the randomized version which can be shown to be breakable by such an adversary.

We construct this partition using appropriate binary codes for the vertices: the codes are of length $O(\log n)$ and we have a bipartite graph corresponding to each bit, where the bipartition is given by whether the bit is 0 or 1. Now, we need to ensure that (a) every edge goes to "some" bipartition, and (b) the max-degree of a single bipartite graph is not much higher than $\Delta/\log n$. This can be done using codes with constant rate and relative distance, like the expander codes described by [45]. Now we can focus on getting $O(\Delta)$-colorings for bipartite graphs, which would give us asymptotically same number of colors for general graphs.

Note that for the vertex-arrival model, we can go one step farther and assume "one-sided" vertex arrival, i.e., vertices along with their incident edges arrive on only one side of the bipartite graph. This is because we can run two copies of the algorithm, one each for the vertices arriving on either side, with disjoint palettes. This incurs only a factor of 2 in the number of colors.

Space-color tradeoff for multigraphs

We show with Lemma 5 that if an algorithm can handle multigraphs, then we can smoothly tradeoff colors with space. This is one of our motivations behind extending our algorithms to multigraphs. Recall that we reduce the problem to just bipartite graphs. Now the idea for the tradeoff is simple: we arbitrarily group t nodes (for some parameter t) from the same partite set together as a single supernode. Since the vertices on the same partite set do not share any edges, there are no edges inside a supernode. Then, the resulting multigraph has no self-loops, but any pair of supernodes can have multiple edges between them. Observe that the max-degree can now increase to Δt, where Δ is the max-degree of the original graph. Thus, if we have an $S(n, \Delta)$-space $f(\Delta)$-coloring algorithm for multigraphs, then we can turn it into an $S(n/t, \Delta t)$-space $f(\Delta t)$-coloring algorithm. In particular, our $\widetilde{O}(n\sqrt{\Delta})$-space $\widetilde{O}(\Delta)$-coloring algorithm from Theorem 3 generalizes to an $\widetilde{O}(n\sqrt{\Delta/t})$-space $\widetilde{O}(\Delta t)$-coloring for any $1 \leq t \leq \Delta$. We generalize most of our algorithms to multigraphs and establish such a tradeoff.

3.2 Randomized Online Algorithms

Randomized online algorithm for vertex arrivals

Recall the simple greedy algorithm for online $(2\Delta - 1)$-coloring: we assign each incoming edge a color that is not already taken up by any of its adjacent edges. However, even in the one-sided vertex arrival model, to naively implement this algorithm, we need to remember the colors assigned to edges incident on *each* vertex on the "fixed" side, and hence, essentially colors assigned to all previous edges. This needs $O(n\Delta)$ space, and hence, the greedy algorithm doesn't seem to help in getting low-memory algorithms.

Algorithm 1 Randomized algorithm for 5Δ-coloring under one sided vertex arrivals.

Input: Stream of vertex arrivals of n-vertex graph $G = (A \sqcup B, E)$

Initialize:

Let $C = 5\Delta$.
for $v \in B$ **do**
    Let σ_v be a uniformly random permutation over $[C]$ ▷ *constructed on demand from random oracle bits*
    $h_v \leftarrow 1$. ▷ *counter for vertex v*

Process(vertex $x \in A$ with multiset M_x of edges)

Let $S_x \leftarrow \emptyset$ ▷ *set of colors M_x will have used so far*
for $e = \{x, y\}$ in M_x, in arbitrary order **do**
    ▷ *Increase counter for y to next value with color $\sigma_y[h_y]$ not already used, if possible*
    while $(h_y \leq C) \wedge (\sigma_y[h_y] \in S_x)$ **do**
        $h_y \leftarrow h_y + 1$ ▷ *increment counter for y*
    if $h_y > C$ **then** ▷ *counter exceeded 5Δ*
        abort
    Assign color $\sigma_y[h_y]$ to e ▷ *if this line is reached, current color must be unused; assign to e*
    $S_x \leftarrow S_x \cup \{\sigma_y[h_y]\}$ ▷ *add assigned color to set of used colors*
    $h_y \leftarrow h_y + 1$ ▷ *increment counter for y*

We observe, however, that for the vertex-arriving side, it is enough to remember only the colors assigned to edges on the "current" vertex so as to ensure no conflict among these edges. We shoot for a semi-streaming, i.e., $\widetilde{O}(n)$ space algorithm, and hence can afford to store the entire edge set of the current vertex with the assigned colors. To ensure that there is no color-conflict on the fixed side, we resort to random permutations. On each such vertex v, we have a random permutation σ_v of $[5\Delta]$ and a counter h_v. When an edge $\{a, b\}$ arrives with b on the fixed side, we look at the color at the h_bth index of σ_b. If that color is already taken by any edge incident on a (whose colors we explicitly store), then we increment the counter h_b. We continue this until we find an available color and increment the counter. The random permutations ensure (i) no color will be repeated on any fixed vertex (since a permutation takes distinct counter values to distinct colors) and (ii) with high probability, none of the counters can exceed 5Δ.[6] Intuitively, the slack in the number of colors ensure that for a single edge, an available color is reached within a constant counter increment in expectation. Hence, the Δ edges incident on a vertex can increase its counter to at most $O(\Delta)$ in expectation. Since we only store a counter for each vertex whose value can go up to $O(\Delta)$, the space usage is $\widetilde{O}(n)$. Thanks to the reductions discussed above, we can extend this to a semi-streaming[7] $O(\Delta)$-coloring for the general vertex arrival case, even for general graphs.

Randomized algorithm for online edge arrivals

When handling edge arrivals for simple graphs, our goal on receiving an edge $\{u, v\}$ is to assign a color that has not been used by any edge incident on u or on v. As precisely tracking the set of available colors for any given vertex requires $\Omega(\Delta)$ space, we will instead keep track of a subset of the available colors for a vertex, and choose colors for edges in a way that limits the amount of information we must store.

Algorithm 2 Storing free regions from a permutation.

$F \leftarrow$InitFreeTracker(C,s,Δ,σ)**:** ▷ *Assume C,s,Δ are powers of two, $C \geq \Delta$, $C \geq s$, and $\sigma \in S_C$*

$H \leftarrow [s]$ be a subset of $[s]$
$b \leftarrow 1$ be a counter with range from 1 to C/s

Interpreting F as subset of $[C]$
return $\sigma[H + (b-1)s]$

F**.RemoveAndUpdate**(c) ▷ *This will only be called with $c \in F$*
$H \leftarrow H \setminus \{\sigma^{-1}(c)\}$
if $|H| \leq s - s\Delta/C$ **then** ▷ *Switch to next block*
    $H \leftarrow [s]$
    $b \leftarrow b + 1$

Specifically, for each vertex v in the graph, we associate a uniform and independently chosen random permutation σ_v over the set $[C]$ of colors, where $C = O(\Delta)$ is the number of colors used. When edges incident on v arrive, we will choose colors by very roughly increasing

[6] This algorithm essentially discards colors that it skips over. We suspect one can obtain a semi-streaming $(2\Delta - 1)$-edge-coloring, or better, by retaining and promptly using the skipped colors in some fashion.
[7] Not counting random oracle bits. To implement without oracle randomness, choose each permutation independently from an almost $O(\log n)$-wise independent distribution over permutations.

order in σ_v. Specifically, we split σ_v up into a sequence of disjoint blocks $P_{v,1}, \ldots, P_{v,C/s}$ of size $s = O(\sqrt{\Delta \log n})$ each. At any given time, the algorithm have an integer b_v so that, all colors in blocks from $P_{v,1}$ up to P_{v,b_v-1} are assumed unsafe to use; none of the colors in $P_{v,b_v+1}, \ldots, P_{v,C/s}$ have been used; and the set F_v of colors in P_{v,b_v} that are still available is tracked exactly. Pseudocode for updating this state is given in Algorithm 2; it will ensure that $|F_v| \geq s(1 - \Delta/C)$. Whenever an edge $\{x, y\}$ arrives, the algorithm (Algorithm 3) will assign it a random color in $F_x \cap F_y$. We will prove that, since F_x and F_y have size close to s, and only a Δ/C fraction of (biased) random elements from P_{x,b_x} and P_{y,b_y} will have been used/excluded from F_x and F_y, the intersection of $F_x \cap F_y$ will have size $\Omega(s^2/C) = \Omega(\log n)$ with high probability. Thus, our algorithm will w.h.p. be able to pick a color for the edge $\{x, y\}$.

Algorithm 3 Randomized algorithm for $O(\Delta)$ edge coloring for simple graph edge arrival streams.

Input: Stream of vertex arrivals n-vertex graph $G = (V, E)$
Assume Δ is a power of two, and $\Delta = \Omega(\log(n/\delta))$
δ is the maximum failure probability over all input streams

Initialize:
Let $C = 128\Delta$ and $\epsilon = \frac{\delta}{16n^3}$
Let s be the least power of two which is $\geq 128\sqrt{\Delta \log(n/\delta)}$
for $v \in V$ **do**
    $\sigma_v \leftarrow$ permutation drawn from the (ϵ, s)-wise independent distribution over $\mathbb{S}_C$ from Lemma 14
    $F_v \leftarrow$ InitFreeTracker(C, s, Δ, σ_v)

Process(edge $\{x, y\}$) $\rightarrow$ **color**
if $F_x \cap F_y = \emptyset$ **then**
    abort
Let c be chosen uniformly at random from $F_x \cap F_y$.
F_x.RemoveAndUpdate(c)
F_y.RemoveAndUpdate(c)
return color c

Keeping track of the available colors for each vertex will use $\widetilde{O}(\sqrt{\Delta})$ space per vertex. We will choose the random permutations from an (ε, s)-wise independent distributions (see Definition 13). We show in a technical lemma that there is a particular such distribution whose permutations can be encoded using $\widetilde{O}(\sqrt{\Delta})$ space each, and for which sampling and permutation evaluation are efficient. In total over all vertices, we will use $\widetilde{O}(n\sqrt{\Delta})$ space for our algorithm.

3.3 Deterministic Online Algorithms

Derandomization of online vertex arrival

When a vertex a and its neighboring edges are processed, the randomized online vertex arrival algorithm is greedily finding an assignment for each edge incident on a to the next few available colors on the "fixed" vertex at the other endpoint. While this greedy selection works acceptably in the *average* case, it does not provide strong worst-case guarantees: with $\Omega(1/\operatorname{poly}(n))$ probability, *some* vertex adjacent to a will increase its counter by $\Omega(\log n)$,

thereby marking ("consuming") $\Omega(\log n)$ colors from its random permutation as unavailable. Consequently, there is small but nonzero risk that a vertex will use up too many colors from its random permutation and run out. In contrast, our deterministic algorithm for online edge coloring for one-sided vertex arrivals (Algorithm 4) is designed to ensure that, for any fixed vertex, the *amortized* number of colors consumed per edge incident on a fixed vertex is always bounded by a constant.

First, instead of greedily coloring the edges incident to a, we explicitly construct a matching in a bipartite graph between the set M_a of edges incident to a and the set of all colors, where each edge $\{a, b\}$ in M_a is linked to some of the colors that are known to be still available for vertex b. This avoids the problem of the greedy color selection, where there was always a small risk that for some vertex, all the next few colors in its random permutation were used; although it has the risk that the matching might not exist. Fortunately, as the number of color candidates per edge in M_a increases, the probability of there being no matching shrinks rapidly. If there are no repeated edges in M_a, and if each edge has t uniformly randomly chosen color candidates, the probability of there being no matching is $\exp(-\Omega(t|M_a|))$.

Second, instead of using random permutations, the deterministic algorithm uses a certain "good" array of permutations for which we are guaranteed that whenever we look for a matching, one will exist. This relies on an additional modification: instead of having each "fixed" vertex v keep track of a single counter h_v, we store a set of $\geq t = \Omega(\log n)$ colors known to still be available for vertex v, and periodically replace this set with a range of new colors from the permutation σ_v. The exact details of the encoding ensure that each fixed vertex has only $O(\operatorname{poly} n)$ possible states. Now, consider what happens when a vertex a (with incident edge set M_a) arrives, assuming for simplicity that M_a has no repeated edges. The number of possible configurations of states of vertices in $N(a)$ will be $\exp(|M_a| \log n)$. If each vertex had a random permutation, the probability of there being no matching would be $\exp(-\Omega(|M_a| \log n)$. By carefully adjusting parameters, we can ensure the product of these two is exponentially *small*. Then by a union bound we can show that the probability (over the random permutations) of *any* matching failing, for *any* set M_a and any associated vertex state, is at most $\frac{1}{2}$. In other words, for a good choice of permutations, our algorithm would *always* find a matching, in any state.

A notable problem is that storing each permutation would require $\widetilde{O}(\Delta)$ bits each.[8] To avoid this, we select the permutations from small, almost-k-wise independent families of permutations, instead. This works, but requires a more careful analysis to prove correct, and a large fraction of our proof is spent dealing with the interaction of this and support for multigraphs.

Derandomization of online edge arrival

We did not find a way to directly derandomize the randomized algorithm for online edge arrival. Instead, we created an algorithm (Algorithm 5) that manages to *partially* solve the edge coloring problem, only assigning a color to a $\geq 1/3$ fraction of the incoming edges, and leaving the rest uncolored. Now, say we run $O(\log \Delta)$ instances of this algorithm in parallel, each using a distinct palette of $O(\Delta)$ colors. When an edge arrives, we pass it to the first instance of the algorithm, and if it wasn't assigned a color, pass it to the second instance;

[8] One could recompute individual "good" permutations on demand, instead of storing all of the permutations, but this has the risk of the computation itself requiring $\widetilde{O}(n\Delta)$ bits of scratch space.

Algorithm 4 Deterministic $O(\Delta)$ edge coloring algorithm for one sided bipartite vertex arrivals.

Input: Stream of vertex arrivals for n-vertex graph $G = (A \sqcup B, E)$ of max degree Δ, where Δ is a power of 2

Initialize(δ):
Let $C = 2^{18}\Delta$.
Let $s = \lceil 2^{18} \log \frac{n\Delta}{\delta} \rceil$.
▷ *To get a deterministic algorithm, fix "good" values of these permutations*
▷ *When the permutations are chosen randomly, with probability* $\geq 1 - \delta$ *the algorithm will succeed on* all *inputs*
Let $(\sigma_v)_{v \in B}$ be permutations drawn from an $(\epsilon = C^{-s-1}, s)$-wise independent distribution over $\mathbb{S}_C$, using Lemma 14

for $v \in B$ **do**
  $b_v \leftarrow 1$.
  $Q_v \leftarrow [s]$.

Process(vertex x with multiset M_x of edges to B)
Let $d_{x,y}$ be the number of times edge $\{x, y\}$ is in M_x
for each $y \in B$ with $d_{x,y} > 0$ **do**
  if $d_{x,y} < \frac{1}{16}s$ **then**
    Let $F_y = (b_y - 1)s + Q_y$
  else
    Let $F_y = ((b_y - 1)s + Q_y) \sqcup \left[b_y s + 1, b_y s + \left\lceil \frac{64 d_{x,y}}{s} \right\rceil s\right]$
Construct bipartite graph H from M_x to $[C]$, edge $e \in M_x$ is linked to all $c \in \sigma_y[F_y]$.
Compute an M_x-saturating matching P of H.
for each $e \in M_x$ **do**
  Assign color $P(e)$ to e
  if $d_{x,y} < \frac{1}{16}s$ **then**
    Remove $\sigma_y^{-1}(P(e)) - (b_y - 1)s$ from Q_y
for each $y \in B$ with $d_{x,y} > 0$ **do**
  if $d_{x,y} < \frac{1}{16}s$ **then**
    if $|Q_y| \leq s - \frac{1}{2^{17}}s$ **then**
      $b_y \leftarrow b_y + 1$
      $Q_y \leftarrow [s]$
  else
    $Q_y \leftarrow [s]$
    $b_y \leftarrow b_y + \left\lceil \frac{64 d_{x,y}}{s} \right\rceil + 1$

and if that didn't assign a color, pass it to the third instance, and so on. All in all, only a $\leq 1/\operatorname{poly}(\Delta)$ fraction of the input stream will fail to be colored by this process, and there are few enough of these leftover edges that one can store them all and color them using $O(\Delta)$ colors. This approach uses $O(\Delta \log \Delta)$ colors in total.

The partial edge coloring algorithm itself uses an interesting trick. Let C be the number of colors allowed. Each vertex v has an associated permutation $\sigma_v \in S_C$, which is partitioned into a number of blocks $P_{v,1}, P_{v,2}, \ldots$ of $\widetilde{O}(\sqrt{\Delta})$ colors each. Whenever an edge $\{u, v\}$ arrives, it must be colored using a color in the set $P_{v,i} \cap P_{u,j}$, where i and j depend on the degrees of vertices v and u at the time. Parameters are set up so this set has size $\Omega(\log n)$, and the

Algorithm 5 (1/3)-partial $O(\Delta)$ edge coloring algorithm for graph edge arrival streams.

Input: Stream of edge arrivals in n-vertex graph $G = (V, E)$ of max degree Δ, where Δ is a power of two

Initialize(Δ,C,s):
▷ *C: number of colors used; s: block size parameter*
▷ *As with Algorithm 4, a "good" set of permutations will exist, if C/Δ is large*
$(\sigma_v)_{v\in V}$ are specific s-wise almost independent permutations
1: **for** $v \in V$ **do**
2: $F_v \leftarrow$ InitFreeTracker(C, s, Δ, σ_v). ▷ *Defined in: Algorithm 2*

Process(edge $\{x, y\}$) $\rightarrow$ **Option<color>** $\in \{\perp\} \cup [C]$
3: **if** $F_x \cap F_y \neq \emptyset$ **then**
4: Choose $c \in F_x \cap F_y$ arbitrarily
5: F_x.RemoveAndUpdate(c, $\{x, y\}$)
6: F_y.RemoveAndUpdate(c, $\{x, y\}$)
7: **return** color c
8: **else**
9: **return** $\perp$

algorithm knows which colors in $P_{v,i}$ and $P_{u,j}$ have been used so far. We prove that, if the algorithm could preview the future of the stream, it could always pick the "right" color in $P_{v,i} \cap P_{u,j}$, and thereby find a valid edge coloring. On the other hand, without being able to look at future edges, if one just greedily picks valid colors in $P_{v,i} \cap P_{u,j}$ that don't conflict with colors chosen earlier – assuming there are any – then the algorithm will color at least a 1/3 fraction of the edges.

Handling multigraphs in online edge arrival

Let us now turn to multigraphs. Note that the degree of a vertex takes into consideration the multiplicity of each incident edge. Both the randomized online edge arrival algorithm and what was described so far of the deterministic algorithm will fail when faced with input streams that repeat edges. But looking more closely, both can tolerate some amount of repeated edges – a given edge e could be repeated up to $\widetilde{O}(\sqrt{\Delta})$ times, as long as it doesn't arrive too frequently. Specifically, as long as, for a given endpoint x of e, the substream of edges incident on x does not contain e more than $\widetilde{O}(1)$ times in any interval of $\widetilde{O}(\sqrt{\Delta})$ edges. This is a consequence of the way the edge arrival algorithms rotate between blocks of colors for each vertex.

On the other hand, the edges that would break the sketch, which repeat many times within the last $\widetilde{O}(\sqrt{\Delta})$ edges incident on a given vertex, are easy to detect using $\widetilde{O}(n\sqrt{\Delta})$ space. All one must do is keep track of the edges which recently arrived at a vertex, and detect duplicates.

To handle the "bad" type of repeated edges, we maintain $O(\log \Delta)$ modified instances of an edge arrival algorithm. (In this paper, we use the basic deterministic online edge arrival algorithm, but the same argument would work for the randomized one.) The first instance processes all edges in the stream, filtering out the edges which it detects to have repeated at least once. The repeated edges are sent to the second instance, which filters out edges that it finds to have repeated twice, and sends those to the third instance. In general, the

ith instance will receive edges which have been seen $\Theta(2^i)$ times in the stream. (The exact condition is a bit more complicated.) The ith instance is also modified to handle edges with high repetition rates, assigning batches of colors to each edge type that it processes.

3.4 A Lower Bound

Space lower bound for online deterministic edge coloring

Our last notable result is a lower bound on the space needed for deterministic online edge coloring algorithms, which use $\beta\Delta$ colors, for a constant $\beta < 2$. It applies in the one sided bipartite vertex arrival setting, and thus automatically gives a lower bound for general vertex and edge arrivals. Let B be the "fixed" set of vertices, and A the "arriving" set of vertices. We prove the lower bound by reducing a deterministic, Δ-player, one way, communication game to (deterministic, one-sided, bipartite, vertex arrival) online edge coloring.

In this game, each player receives a set of edges to color, and must immediately output a coloring for the edges, before sending a message to the next player. Say that there are only $2^{o(n)}$ possible messages. Each message corresponds to a collection of inputs which the player could have received. One can show that each message "rules out" some of the colors for each vertex v in B, so that, if the protocol is correct, future players cannot mark edges going to v with one of the ruled out colors. Furthermore, there must be some message which has a large number of associated inputs, and which rules out $> \beta$ colors for each fixed vertex, on average. As this can happen for each of the Δ players, by the end of the protocol it is possible to have ruled out $> \beta\Delta$ colors per vertex, on average, which contradicts the assumption that the algorithm uses at most $\beta\Delta$ colors. Thus, there must be $2^{\Omega(n)}$ possible messages.

Abstract

We propose a unifying framework for smoothed analysis of combinatorial local optimization problems, and show how a diverse selection of problems within the complexity class PLS can be cast within this model. This abstraction allows us to identify key structural properties, and corresponding parameters, that determine the smoothed running time of local search dynamics. We formalize this via a black-box tool that provides concrete bounds on the expected maximum number of steps needed until local search reaches an exact local optimum. This bound is particularly strong, in the sense that it holds for any starting feasible solution, any choice of pivoting rule, and does not rely on the choice of specific noise distributions that are applied on the input, but it is parameterized by just a global upper bound ϕ on the probability density. The power of this tool can be demonstrated by instantiating it for various PLS-hard problems of interest to derive efficient smoothed running times (as a function of ϕ and the input size).

Most notably, we focus on the important local optimization problem of finding pure Nash equilibria in Congestion Games, that has not been studied before from a smoothed analysis perspective. Specifically, we propose novel smoothed analysis models for general and Network Congestion Games, under various representations, including explicit, step-function, and polynomial resource latencies. We study PLS-hard instances of these problems and show that their standard local search algorithms run in polynomial smoothed time.

Further applications of our framework to a wide range of additional combinatorial problems can be found in the full version of our paper.

1 Introduction

Local search heuristics are some of the most prominent, and widely used in practice, algorithms for solving computationally hard, combinatorial problems [1, 15]. Their appeal stems not only from their simplicity and theoretical elegance, but also from the fact that, for many applications, they seem to perform remarkably well both in terms of their running time and the quality of the solutions they produce.

Theoreticians have long tried to rigorously study the performance of local search, but also explain its prevalence in practice. Johnson, Papadimitriou, and Yannakakis [13] introduced the class PLS to capture the complexity of local optimization problems; since then, many important such problems have been shown to be PLS-complete, implying that they most likely cannot be solved (exactly) in polynomial time. This hardness applies not only to local search algorithms, but to arbitrary local optimization methods. For local search, in particular, PLS-hardness (under tight reductions) implies the provable existence of instances leading to exponentially slow convergence [26]. Examples include the Travelling Salesman problem under the k-Opt heuristic [14, 5] (TSP/k-Opt in the following), Local Maximum Cut on weighted graphs [23] (LocalMaxCut), and the problem of finding pure Nash equilibria in Congestion Games [10] (PNE-Congestion).

On the other hand, Orlin, Punnen, and Schulz [17] designed a local-search-based polynomial-time scheme for efficiently computing *approximately* locally-optimal solutions for general combinatorial optimization problems (with linear objectives). Although this result provides concrete justification for the practical tractability of local optimization, there are still many important aspects that call for further investigation. First, if one requires exponential accuracy, their FPTAS still cannot provide polynomial running times. Secondly, approximate solutions do not always make sense for all local optimization problems; there are problems in PLS that are inherently exact and they are not derived by simply considering the local version of some "master" global optimization problem. A notable example is PNE-Congestion [19]. Finally, we would like to be able to argue about the more general family of "vanilla" local search, and to ideally get positive results that do not depend on additional details and specific choices of pivoting rules. Addressing these points is a key objective of the present paper.

Smoothed analysis was introduced by Spielman and Teng [24] as a more realistic alternative to traditional worst-case analysis, where now the adversarially selected input is submitted to small random shocks of its numerical parameters, *before* being presented to the algorithm; the running time is then measured *in expectation* with respect to these perturbations. Under this model, Spielman and Teng were able to show that Simplex, the archetypical method for solving linear programs, is guaranteed to terminate in polynomial time (under a shadow pivoting rule) – as opposed to its exponential complexity under worst-case analysis. This remarkable result established smoothed analysis as a canonical framework for studying the performance of algorithms beyond the worst-case (see [20] for an overview of this field).

In particular, smoothed analysis has been applied successfully to important local search algorithms, providing thus a theoretical basis for the justification of their good performance in practice; these include, e.g., the k-Opt heuristic for TSP and the Flip heuristic for LocalMaxCut. (A more detailed exposition of related work on this front is deferred to the following sections of this paper, where each of our local optimization problems of interest is explicitly studied; see, namely, Section 4 and [12, Sec. 5].) A common characteristic of this prior work, though, is that running-time analysis is usually tailored specifically to the local optimization problem at hand. This naturally creates the need for technically

heavy derivations, from which it is generally not clear how to pin down the core properties of the underlying local-search structure that allow for the efficient smoothed complexity. Furthermore, as a result, it is often not easy to immediately generalize these results to capture interesting extensions, e.g., argue about the *asymmetric* version of TSP, or go from TSP/2-Opt to TSP/k-Opt. Finally, this lack of sufficient abstraction is one of the reasons that smoothed analysis has not been yet considered at all for prominent PLS-hard problems, including, e.g., PNE-Congestion. Dealing with this set of challenges is another driving force behind our paper.

Our Results and Outline

We start by proposing an abstract model for smoothed analysis of combinatorial local optimization (CLO) in Section 2. Our family of CLO problems includes problems in PLS that have an arbitrary combinatorial neighbourhood structure and linear objective functions; essentially, our model generalizes that of [17] beyond binary configurations. In Section 2.1, we add our smoothness layer that introduces probabilistic noise (independently) to the cost parameters of the CLO problem. No further assumptions are made on the distributions of the perturbed costs; their densities are only parameterized by a global upper bound of ϕ. This is a standard model (employed, e.g., in [3, 22, 8, 9]) that makes positive smoothed-analysis results even stronger, and extends the seminal model of Gaussian perturbations from [24].

Section 3 contains our key technical result for deriving upper bounds on the expected (under smoothness) number of local-search steps, until an *exact* local optimum is reached. Our black-box tool (Theorem 2) can be readily applied to an abstract CLO problem, once its underlying neighbourhood structure is appropriately captured; this is formalized through the notion of *separability* (see Definition 1), quantified by a collection of three parameters that are critical for the upper bound given by Theorem 2. We note here that our bounds are robust against the specific choice of a starting point for the local search dynamics, as well as the pivoting rule utilized at every step to transition to an improving neighbour. In other words, our main black-box tool establishes bounds for the entire *family* of local search heuristics of a local optimization problem. At a technical level, our proof works by lower-bounding the probability that *all* steps of the local-search sequence improve sufficiently the objective.

In Section 4 we demonstrate the applicability of our general framework by instantiating it for PNE-Congestion, a prominent PLS-complete problem which has not been studied before from a smoothed analysis perspective. First, we propose smoothed analysis formulations for various representations of interest for the problem, namely explicit, step-function, or polynomial resource latencies. Next, after formally establishing how PNE-Congestion is indeed a CLO problem in Section 4.1, we identify a natural parameterization of the problem that we call B-*restrained games* (Section 4.2), where B is an upper bound on the number of resources that can be changed during a single-player deviation (see Definition 5). Interestingly enough, the case of constant B is still rich enough to encode the full PLS-hardness of PNE-Congestion ([12, Appendix B]), while at the same time it can be shown (see the proof of Theorem 6) to be appropriately separable in order to immediately provide polynomial smoothed running time bounds via our black-box tool developed in Section 3. Similarly, in Section 4.3 we also study a special class of *network* congestion games, which we term (A, B)-*compact* (Definition 9); we establish polynomial smoothed complexity for various families of instances, including the one where A is polynomial and B is constant (Corollary 11), which we pair with a complementing PLS-hardness proof ([12, Appendix C]).

Finally, we apply our high-level framework to various other local optimization problems of interest, by first formally establishing that they can be viewed as CLO problems and then identifying the proper separability structures that can be plugged into our black-box tool to

provide good smoothed bounds for local search. This not only unifies, and greatly simplifies, prior existing positive results, but also allows us to extend or improve them. Notable examples include: rederiving and strengthening the polynomial smoothed time for local Max-Cut, for graphs with up to logarithmic degree, first given by Elsässer and Tscheuschner [7]; extending the polynomial smoothed time, of Englert, Röglin, and Vöcking [8], for the 2-Opt heuristic for the general (symmetric) Travelling Salesman problem (TSP), to k-Opt neighbourhoods and to *asymmetric* TSP (ATSP); and improving the quasipolynomial smoothed time for Network Coordination Games, by Boodaghians, Kulkarni, and Mehta [4], to polynomial for constant-degree graphs.

Due to space constraints, the study of all these additional applications of our framework is deferred to the full version of our paper [12].

2 Smoothed Combinatorial Local Optimization

In this section we formalize our model and fix the necessary notation.

We denote by $\mathbb{N}$ and $\mathbb{R}$, the natural and real numbers, respectively. We also denote $\mathbb{N}^* \coloneqq \mathbb{N} \setminus \{0\}$ and $[k] \coloneqq \{1, 2, \ldots, k\}$, $[\![k]\!] \coloneqq \{0\} \cup [k]$ for $k \in \mathbb{N}$. We will use boldface notation for vectors, $\boldsymbol{s} = (s_1, s_2, \ldots, s_n) \in \mathbb{R}^n$. For an index $i \in [n]$, we use $\boldsymbol{s}_{-i}$ to denote the $(n-1)$-dimensional vector that results from an n-dimensional vector $\boldsymbol{s}$ if we remove its i-component; in that way, we can express $\boldsymbol{s}$ as $(s_i, \boldsymbol{s}_{-i})$ in order to easily denote deviations in the i-th component. More generally, for a set of indices $I \subseteq [n]$, $\boldsymbol{s}_I$ denotes the $|I|$-dimensional vector that we get if we keep only the components of $\boldsymbol{s}$ whose indices are in I. For finite sets $I, \mathcal{I}$, we say that $\mathcal{I}$ is a *cover* of I if $I \subseteq \bigcup_{I' \in \mathcal{I}} I'$. All logarithms appearing in our paper are of base 2.

Combinatorial local optimization (CLO)

An instance of a *combinatorial local optimization (CLO)* problem is composed of:

- A set of feasible *configurations* $\boldsymbol{S} \subseteq [\![M]\!]^\nu \times \{0,1\}^{\bar{\nu}}$, where $M, \nu \in \mathbb{N}^*$, $\bar{\nu} \in \mathbb{N}$. A configuration $\boldsymbol{s}$ can be expressed as $\boldsymbol{s} = (\boldsymbol{s}^\bullet, \boldsymbol{s}^\circ)$, where $\boldsymbol{s}^\bullet = (s_1, \ldots, s_\nu) \in [\![M]\!]^\nu$ is called its *cost part* and $\boldsymbol{s}^\circ = (s_{\nu+1}, \ldots, s_{\nu+\bar{\nu}}) \in \{0,1\}^{\bar{\nu}}$ its *non-cost part*.
- A vector of *costs* $\boldsymbol{c} = (c_1, c_2, \ldots, c_\nu) \in [-1, 1]^\nu$. We call the c_i *cost coefficients*.[1]
- A *neighbourhood* function $N : \boldsymbol{S} \longrightarrow 2^{\boldsymbol{S}}$. For $\boldsymbol{s} \in \boldsymbol{S}$, any configuration $\boldsymbol{s}' \in N(\boldsymbol{s})$ will be called a *neighbour* of $\boldsymbol{s}$.

For the special case of $M = 1$ we will call our problem *binary*.

The *cost* of a configuration $\boldsymbol{s}$ (with respect to a fixed cost vector $\boldsymbol{c}$) is given by

$$C(\boldsymbol{s}) \coloneqq \boldsymbol{c} \cdot \boldsymbol{s}^\bullet = \sum_{i=1}^{\nu} c_i s_i.$$

[1] Note that the restriction of costs to the range of $[-1, 1]$ has been made to facilitate the translation to smoothed CLO problems below (see Section 2.1). In fact, due to the linearity of our objective, scaling $\boldsymbol{c}$ by any positive constant does not change the structure of the problem, and we will implicitly use this fact when formulating other problems as CLO problems.

A configuration $\boldsymbol{s}$ is said to be a *local optimum (minimum*[2]*)* if there are no neighbours with better costs; formally,

$$C(\boldsymbol{s}) \leq C(\boldsymbol{s}') \qquad \text{for all } \ \boldsymbol{s}' \in N(\boldsymbol{s}). \tag{1}$$

For every CLO problem we can define its *configuration* (or *neighbourhood*) *graph*, made up by all edges pointing from configurations to their neighbours. Formally, it is the directed graph $G = (V, E)$ with node set $V = \boldsymbol{S}$ and edges $E = \{(\boldsymbol{s}, \boldsymbol{s}') \mid \boldsymbol{s} \in \boldsymbol{S},\ \boldsymbol{s}' \in N(\boldsymbol{s})\}$. Observe that the configuration graph does not depend on the costs $\boldsymbol{c}$, but only on the combinatorial structure of the problem. Taking the cost vector $\boldsymbol{c}$ into consideration, we can now restrict the configuration graph edges to those that correspond to locally improving moves, i.e. take $E' = \{(\boldsymbol{s}, \boldsymbol{s}') \in E \mid C(\boldsymbol{s}') < C(\boldsymbol{s})\}$. The resulting acyclic subgraph $G' = (V, E')$ is called *transition graph*.

The transition graph provides an elegant and concise interpretation of local optimization: finding a local optimum of a combinatorial (local optimization) problem translates to finding a sink of its transition graph. This task is exactly the object of interest of our paper: we study (the running time of) algorithms that find local optima of such problems.

Complexity

If the configuration set and the neighbourhoods $N(\cdot)$ were given explicitly in the input of a local optimization algorithm, then finding a locally optimal solution would have been a computationally trivial task: we could afford (in polynomial time) to exhaustively go over all nodes of the transition graph, until we find a sink. Notice that the existence of a sink is guaranteed, by the fact that $\boldsymbol{S}$ is finite. However, most problems of interest (including all the problems that we study here) have exponential-size configuration graphs, with respect to the dimension $\nu + \bar{\nu}$ of the problem. Therefore, $\boldsymbol{S}$ and N are usually instead described *implicitly*, via some succinct representation (that is polynomial on ν, $\bar{\nu}$ and M). Then, the computational complexity of our algorithms is naturally measured as a function of the critical parameters ν, $\bar{\nu}$ and M (and the bit representation of the costs $\boldsymbol{c}$).

Polynomial local optimization (PLS)

In this paper we want to study problems contained in PLS, the "canonical" complexity class for local optimization problems, introduced by Johnson, Papadimitriou, and Yannakakis [13]. Therefore, without further mention, from now on we will assume that our CLO problems further satisfy the following properties:

- An *initial* configuration $\boldsymbol{s}_0 \in \boldsymbol{S}$ can be computed in polynomial time (on the size of the input).
- There exists a polynomial-time algorithm that, given as input any configuration $\boldsymbol{s}$, decides whether $\boldsymbol{s}$ is a local optimum and, if not, returns an improving neighbour $\boldsymbol{s}' \in N(\boldsymbol{s})$ with $C(\boldsymbol{s}') < C(\boldsymbol{s})$. Such an algorithm is called *pivoting rule*.

It is important to clarify that the polynomial time algorithms of the bullets above are formally *not* part of the description of the CLO problem, neither are they required to be specified in the input of a local optimization algorithm. The *existence* of these algorithms is

[2] Here we choose to write the local optimality condition with respect to minimization problems. All the theory developed in this paper applies immediately to local maximization problems as well: just flip the inequality in (1) or, equivalently, negate the cost vector $\boldsymbol{c}$.

merely a requirement for the *membership* of the problem in the class PLS (similarly to the existence of short certificates and an efficient verifier for membership in NP). As a result, PLS can be interpreted as the class of problems that correspond to looking for a sink in an (implicitly given, possibly exponentially large) directed acyclic graph[3], where at least one node can be found efficiently and, for any given node, at least one neighbour (if such exists) can be found efficiently [6, 11].

This interpretation naturally gives rise to the *standard local search* heuristic: start from an arbitrary initial configuration, and at every iteration perform an (arbitrary[4]) locally improving move until no such move exists anymore. For a fixed pivoting rule, this corresponds to traversing a single path of the transition graph. Due to the definition of PLS membership above, the running time of such a process is thus determined by the *number* of these local search iterations. In the worst case, this amounts to bounding the length of the *longest path* in the transition graph.

It is important to emphasize that, regardless of being a very natural heuristic, standard local search is definitely not the only method for finding local optima: as a matter of fact, we know that there exist local optimization problems that are efficiently solvable via more involved, "centralized" methods (e.g., by using linear programming), but for which standard local search would provably require exponential time (see, e.g., [2]): more precisely, there exist nodes in their transition graphs from which *all* paths have exponential length [23].

To assert the intractability of a problem, the common argumentation is via complexity theory techniques that prove the conditional inexistence of polynomial time algorithms. If a problem is PLS-hard, then unless PLS = P, there is no algorithm that solves it in polynomial time under traditional worst-case analysis. However, since we are studying the performance of local search heuristics, we are in fact interested in specifically *their* running time. Schäffer and Yannakakis [23] introduced the notion of a stronger reduction among problems in PLS, named *tight* PLS*-reduction*, which preserves key structural properties of the initial instance to the target-problem's instance. An important implication of an initial-problem P having a tight PLS-reduction to target-problem Q is the following: for any instance I of P, a path in the transition graph of the corresponding reduced instance J of Q induces a path of I of length no larger than its own. In particular, if for an instance I there exists a starting configuration from which all paths to solutions are exponentially long, this also applies to the reduced instance J. We show that all the problems we study have this property, either by referring to explicit bad instances for the problem at hand, or through (chains of) tight reductions, which we construct if they haven't been established before.

For a more thorough treatment of the complexity of local optimization and the class PLS, the interested reader is referred to the excellent monograph of Yannakakis [26].

2.1 Smoothed Combinatorial Local Search

Under traditional, worst-case algorithmic analysis, the running time of an algorithm for a CLO problem would be evaluated against an adversarially selected cost vector $\boldsymbol{c} = (c_1, \ldots, c_\nu)$. Instead, our goal here is to propose a systematic *smoothed analysis* [25, 21, 20] framework for local optimization. Therefore, for the remainder of this paper we assume that $\boldsymbol{c}$ is not fixed, but drawn randomly from a product distribution. More specifically, each cost coefficient c_i is drawn independently from a continuous probability distribution with density

[3] This is the transition graph mentioned earlier.

[4] Thus, standard local search is essentially a *family* of algorithms; different pivoting rules can give rise to different local search algorithms.

$f_i : [-1,1] \longrightarrow [0,\phi]$, where $\phi \geq \frac{1}{2}$. These distributions can be adversarially selected, but their realizations c_i are not; the running time is then computed *in expectation* with respect to the random cost vector $\boldsymbol{c}$. An efficient algorithm runs in time polynomial in the combinatorial-structure parameters ν, $\bar{\nu}$ and M of the problem, and in the smoothness parameter ϕ. We will sometimes refer to this model as *smoothed CLO*, if we want to give particular emphasis to the fact that we are performing a smoothed running time analysis (as opposed to worst-case analysis).

In that sense, smoothed analysis can be seen as interpolating between two extremes: an average-case analysis setting where all c_i's are drawn i.i.d. from a uniform distribution over $[-1,1]$, derived for $\phi = \frac{1}{2}$; and traditional worst-case analysis that can be derived in the limit, via $\phi \to \infty$, as distributions f_i approximate adversarial, single-point-mass instances.

In this paper we focus on smoothed analysis for standard local search, and so our quantity of interest will be the expected number of improving moves (for any set of adversarially given input distributions) until a local optimum is reached; that is, the expected length of the longest path in the transition graph. This allows us to also avoid some delicate representation issues that are typical of smoothed analysis, and which have to do with how the realizations c_i of *continuous* distributions (which therefore produce irrational numbers almost surely) can be handled as inputs to a Turing-machine-based computational model. For a careful discussion about this topic we point to the papers of Beier and Vöcking [3] or Röglin and Vöcking [22]. In a nutshell, for our purposes it is safe to think of the polynomial-time improving-local-move oracle (from the PLS definition) as having access to real-number arithmetic.

3 Smoothed Analysis of Local Search

In this section we present our first main result, which is a black-box tool for upper-bounding the number of improving moves of standard local search, under smoothed analysis. To achieve this, we first highlight an appropriate underlying structure of CLO problems and identify key parameters that characterize it (see Definition 1). Then, our bounds for standard local search are directly expressed as a function of these parameters (see Theorem 2). As we will demonstrate in Sections 4.2 and 4.3, and [12, Sec. 4.2], for various CLO problems of interest these parameters are well-behaved enough to result in polynomial smoothed running times.

We now introduce some terminology and notation that will be necessary for stating our main result in Theorem 2. Fix an instance of a CLO problem with cost coordinates $[\nu]$ and configurations $\boldsymbol{S}$ (see Section 2), and let $G = (\boldsymbol{S}, E)$ be its neighbourhood graph. A *covering* $(\mathcal{E}, \mathcal{I})$ of this instance consists of a cover $\mathcal{E}$ of the edges of its neighbourhood graph, and a cover $\mathcal{I}$ of its cost coordinates. That is, $\mathcal{E} \subseteq 2^E$ and $\mathcal{I} \subseteq 2^{[\nu]}$ such that $E = \bigcup_{E' \in \mathcal{E}} E'$ and $[\nu] = \bigcup_{I \in \mathcal{I}} I$. We call $\mathcal{E}$ the *transition cover* and $\mathcal{I}$ the *coordinate cover* and they contain *transition clusters* and *coordinate clusters* respectively. Recall that, under our previous discussion (see Section 2), $\mathcal{E}$ can be simply interpreted as covering all potential configuration transitions that can be made by standard local search, clustered appropriately in different groups $T \in \mathcal{E}$. For an arbitrary set of such transitions $T \subseteq E$, we also define its *core* to be the set of coordinates affected by any of the transitions:

$$\mathsf{core}(T) \coloneqq \{ i \in [\nu] \mid \boldsymbol{s}_i^\bullet \neq \boldsymbol{s}_i'^\bullet \text{ for some } (\boldsymbol{s}, \boldsymbol{s}') \in T \},$$

and its *diversity* with respect to a given set of coordinates $I \subseteq [\nu]$ to be the number of different configuration changes when projected to I:

$$\delta_I(T) \coloneqq |\mathsf{range}_I(T)|, \quad \text{where } \mathsf{range}_I(T) \coloneqq \{ \boldsymbol{s}_I^\bullet - \boldsymbol{s}_I'^\bullet \mid (\boldsymbol{s}, \boldsymbol{s}') \in T \}.$$

▶ **Definition 1** ((λ, β, μ)-separable instances)**.** *An instance of a CLO problem is called* (λ, β, μ)-separable *if it has a covering* $(\mathcal{E}, \mathcal{I})$ *with* $|\mathcal{E}| \leq \lambda$*, such that any transition cluster* $T \in \mathcal{E}$*:*

(a) *has a core that can be covered by using* β *many coordinate clusters from the cover* $\mathcal{I}$*; formally, there exists a* $\mathcal{I}_T \subseteq \mathcal{I}$ *with* $|\mathcal{I}_T| \leq \beta$ *such that* $\mathsf{core}(T) \subseteq \bigcup_{I \in \mathcal{I}_T} I$*, and*

(b) *has at most* μ *diversity with respect to all coordinate clusters; formally,* $\max_{I \in \mathcal{I}} \delta_I(T) \leq \mu$.

▶ **Theorem 2.** *On any* (λ, β, μ)*-separable smoothed combinatorial local optimization instance, standard local search terminates after at most*

$$3 \cdot \mu^\beta \lambda \cdot \nu^2 M \log(M+1) \cdot \phi$$

many steps (in expectation).

For the proof of Theorem 2 we will need the following technical lemmas. Their proofs can be found in [12, Appendix A]. We would like to highlight the fact that the structural quantities (λ, β, μ) appear as the expression $\mu^\beta \lambda$ in the statement of the theorem and are the deciding quantities for the running time complexity of the problem, as evidenced in the applications further below. As the choice of the covering is not unique (and often even allows for more than just one *natural* choice), this exact expression helps to explain the quantitative interaction between the properties of the covering.

▶ **Lemma 3.** *Let* $I \subseteq [\nu]$ *be a set of cost coordinates and* $\mathcal{J} \subseteq 2^{[\nu]}$ *be a cover of* I*, i.e.* $I \subseteq \bigcup_{J \in \mathcal{J}} J$*. Then, for any set of transitions* $T \subseteq E$*,*

$$\delta_I(T) \leq \prod_{J \in \mathcal{J}} \delta_J(T).$$

▶ **Lemma 4.** *Fix some* $\phi > 0$ *and let* $\boldsymbol{X} = (X_1, X_2, \ldots, X_m)$ *be a random real vector, where each component* X_i *is drawn independently from a continuous distribution with density* $f_i : \mathbb{R} \longrightarrow [0, \phi]$*. Then, for any nonzero vector* $\boldsymbol{\xi} \in \mathbb{R}^m$ *and any* $\varepsilon \geq 0$*,*

$$\mathrm{Prob}\left[0 \leq \boldsymbol{\xi} \cdot \boldsymbol{X} \leq \varepsilon\right] \leq \min\left(\frac{1}{\|\boldsymbol{\xi}\|_\infty}, \frac{\sqrt{2}}{\|\boldsymbol{\xi}\|_2}\right) \cdot \varepsilon\phi, \tag{2}$$

where $\|\cdot\|_2$ *and* $\|\cdot\|_\infty$ *denote the Euclidean and maximum norms, respectively. For the special*[5] *case where* $\boldsymbol{\xi}$ *is a (nonzero) integer vector we get*

$$\mathrm{Prob}\left[0 \leq \boldsymbol{\xi} \cdot \boldsymbol{X} \leq \varepsilon\right] \leq \varepsilon\phi. \tag{3}$$

Proof of Theorem 2. Fix a (λ, β, μ)-separable smoothed CLO instance, with neighbourhood graph $G = (\boldsymbol{S}, E)$, and let $(\mathcal{E}, \mathcal{I})$ be a covering satisfying the conditions of Definition 1.

We introduce the following notation:

$$\Delta(\boldsymbol{s}, \boldsymbol{s'}) \coloneqq \begin{cases} C(\boldsymbol{s}) - C(\boldsymbol{s'}), & \text{if this is positive,} \\ \infty, & \text{otherwise,} \end{cases}$$

[5] In this paper we will be actually making use of Lemma 4 only via its weaker bound (3), rather than the stronger form (2). This is sufficient for our purposes because, as it turns out, this has an asymptotically negligible effect on our bounds. However, we still choose to state (and prove) Lemma 4 in its full generality, since we expect it to be of potential independent interest for future extensions, especially if one considers more involved structures, or non-integral configurations.

for all $(\boldsymbol{s}, \boldsymbol{s'}) \in E$, and

$$\Delta \coloneqq \min_{(\boldsymbol{s},\boldsymbol{s'})\in E} \Delta(\boldsymbol{s}, \boldsymbol{s'}).$$

Notice that these are random variables, depending on the realizations of the cost vector $\boldsymbol{c}$.

Our first goal is to give a bound on the probability that there exists a local move that improves the cost only by (at most) $\varepsilon > 0$, as a function of this improvement bound ε. If this quantity is sufficiently small, then with high probability, standard local search will achieve improvements more than ε at *every* step, thus resulting in faster convergence. To upper bound this probability $\text{Prob}\left[\Delta \leq \varepsilon\right]$, we first use a union bound over the cover $\mathcal{E}$ of all transitions $(\boldsymbol{s}, \boldsymbol{s'}) \in E$ to get

$$\text{Prob}\left[\Delta \leq \varepsilon\right] = \text{Prob}\left[\bigcup_{(\boldsymbol{s},\boldsymbol{s'})\in E} \left[\Delta(\boldsymbol{s}, \boldsymbol{s'}) \leq \varepsilon\right]\right] \leq \sum_{T\in\mathcal{E}} \text{Prob}\left[\bigcup_{(\boldsymbol{s},\boldsymbol{s'})\in T} \left[\Delta(\boldsymbol{s}, \boldsymbol{s'}) \leq \varepsilon\right]\right]. \quad (4)$$

Next, for a fixed transition cluster $T \in \mathcal{E}$ we can express the inner union of events in (4) as

$$\begin{aligned}\bigcup_{(\boldsymbol{s},\boldsymbol{s'})\in T} \left[\Delta(\boldsymbol{s}, \boldsymbol{s'}) \leq \varepsilon\right] &= \bigcup_{(\boldsymbol{s},\boldsymbol{s'})\in T} \left[0 < \boldsymbol{c}_{\mathsf{core}(T)} \cdot \left(\boldsymbol{s}_{\mathsf{core}(T)} - \boldsymbol{s'}_{\mathsf{core}(T)}\right) \leq \varepsilon\right] \\ &= \bigcup_{\boldsymbol{x}\in\mathsf{range}_{\mathsf{core}(T)}(T)} \left[0 < \boldsymbol{c}_{\mathsf{core}(T)} \cdot \boldsymbol{x} \leq \varepsilon\right]. \quad (5)\end{aligned}$$

By the separability assumption of our CLO instance (see Definition 1), for any cluster $T \in \mathcal{E}$ there exists a subset $\mathcal{I}_T$ of $\mathcal{I}$ with $|\mathcal{I}_T| \leq \beta$ that covers $\mathsf{core}(T)$ such that, additionally, $\max_{J\in\mathcal{I}_T} \delta_J(T) \leq \max_{I\in\mathcal{I}} \delta_I(T) \leq \mu$. So, from Lemma 3 we can deduce that

$$\left|\mathsf{range}_{\mathsf{core}(T)}(T)\right| = \delta_{\mathsf{core}(T)}(T) \leq \prod_{J\in\mathcal{I}_T} \delta_J(T) \leq \mu^\beta.$$

Furthermore, observe that each $\boldsymbol{x} \in \mathsf{range}_{\mathsf{core}(T)}(T)$ is a nonzero integral vector. Thus, applying (3) of Lemma 4 we can derive that, for a fixed $\boldsymbol{x} \in \mathsf{range}_{\mathsf{core}(T)}(T)$, we have

$$\text{Prob}\left[0 < \boldsymbol{c}_{\mathsf{core}(T)} \cdot \boldsymbol{x} \leq \varepsilon\right] \leq \phi\varepsilon.$$

Therefore, using again a union bound, this time on event (5), we can see that

$$\text{Prob}\left[\bigcup_{(\boldsymbol{s},\boldsymbol{s'})\in T} \left[\Delta(\boldsymbol{s}, \boldsymbol{s'}) \leq \varepsilon\right]\right] \leq \sum_{\boldsymbol{x}\in\mathsf{range}_{\mathsf{core}(T)}(T)} \text{Prob}\left[0 < \boldsymbol{c}_{\mathsf{core}(T)} \cdot \boldsymbol{x} \leq \varepsilon\right] \leq \mu^\beta\phi\varepsilon.$$

Plugging this into (4), and using again the separability of our instance, we can finally bound our desired probability

$$\text{Prob}\left[\Delta \leq \varepsilon\right] \leq \lambda\mu^\beta\varepsilon\phi. \quad (6)$$

Now we continue with the second part of the proof, in which we utilize the probability bound in (6) to derive a concrete bound on the expected number of iterations of standard local search. Let $\mathcal{T}$ denote the random variable of that maximum length among all paths in the transition graph of our instance. Then, our goal is to bound $\mathbb{E}\left[\mathcal{T}\right]$.

Recall that the number of different possible cost-part configurations is trivially upper-bounded by $(M+1)^\nu$. Also, at every step of standard local search, the configuration cost is *strictly* decreasing. Thus $\mathcal{T} \leq (M+1)^\nu$ and, furthermore, since the range of configuration costs is within $[-M\nu, M\nu]$, and the minimum cost improvement of any iteration is Δ, we also know that $\mathcal{T} \leq \frac{2M\nu}{\Delta}$ holds. Using these, we get

$$\begin{aligned}
\mathbb{E}[\mathcal{T}] &= \sum_{t=1}^{(M+1)^\nu} \text{Prob}[\mathcal{T} \geq t] \\
&\leq \sum_{t=1}^{(M+1)^\nu} \text{Prob}\left[\Delta \leq \frac{2M\nu}{t}\right] \\
&\leq 2\lambda\mu^\beta\phi M\nu \sum_{t=1}^{(M+1)^\nu} \frac{1}{t}, && \text{due to (6)}, \\
&\leq 2\lambda\mu^\beta\phi M\nu \frac{3}{2}\log(M+1)^\nu, && \text{since } 1+\frac{1}{2}+\cdots+\frac{1}{n} \leq \frac{3}{2}\log n \ \ \forall n \geq 2, \\
&= 3\mu^\beta\lambda\phi\nu^2 M\log(M+1).
\end{aligned}$$

◀

4 Smoothed Analysis for Congestion Games

Congestion games are composed of finite nonempty sets of *players* $\mathcal{N} = [n]$ and *resources* $\mathcal{R}$. Each player $i \in \mathcal{N}$ has a *strategy set* $\Sigma_i \subseteq 2^{\mathcal{R}}$ and each resource $r \in \mathcal{R}$ has a *cost* (or *latency*) *function* $\kappa_r : [n] \longrightarrow \mathbb{R}_{\geq 0}$. Each (pure) *strategy profile* (or *outcome*) $\boldsymbol{\sigma} = (\sigma_1, \ldots, \sigma_n) \in \boldsymbol{\Sigma} \coloneqq \Sigma_1 \times \cdots \times \Sigma_n$ induces a *load* on each resource r, equal to the number of players that use it:

$$\ell_r(\boldsymbol{\sigma}) \coloneqq |\{i \in \mathcal{N} \mid r \in \sigma_i\}|.$$

Then, the *cost of player* i is the total cost she experiences from all resources that she is using:

$$C_i(\boldsymbol{\sigma}) \coloneqq \sum_{r \in \sigma_i} \kappa_r(\ell_r(\boldsymbol{\sigma})).$$

An (exact) pure *Nash equilibrium (PNE)* is an outcome $\boldsymbol{\sigma}^*$ from which no player can improve her cost by unilaterally deviating. Formally, for any player $i \in \mathcal{N}$ and any deviation $\sigma_i' \in \Sigma_i$:

$$C_i(\boldsymbol{\sigma}^*) \leq C_i(\sigma_i', \boldsymbol{\sigma}^*_{-i}).$$

Thus, if a strategy profile $\boldsymbol{\sigma}$ is *not* a PNE, there has to exist a player i and a deviation $\sigma_i' \in \Sigma_i$ that reduces her cost, i.e.

$$C_i(\sigma_i', \boldsymbol{\sigma}_{-i}) < C_i(\boldsymbol{\sigma}).$$

Such a strategy σ_i' is then called a *better-response* (of player i with respect to the profile $\boldsymbol{\sigma}$).

By the seminal work of Rosenthal [18] we know that function $\Phi : \boldsymbol{\Sigma} \longrightarrow \mathbb{R}_{\geq 0}$ defined by

$$\Phi(\boldsymbol{\sigma}) = \sum_{r \in \mathcal{R}} \sum_{\ell=1}^{\ell_r(\boldsymbol{\sigma})} \kappa_r(\ell) \tag{7}$$

and commonly referred to as *Rosenthal's potential*, has the property that

$$C_i(\sigma_i', \boldsymbol{\sigma}_{-i}) - C_i(\boldsymbol{\sigma}) = \Phi(\sigma_i', \boldsymbol{\sigma}_{-i}) - \Phi(\boldsymbol{\sigma}) \qquad \forall \boldsymbol{\sigma} \in \boldsymbol{\Sigma}\ \forall i \in \mathcal{N}\ \forall \sigma_i' \in \Sigma_i.$$

In other words, function Φ is an (exact) *potential* [16] of the corresponding congestion game. This implies that PNE of a congestion game correspond *exactly* to the set of *local* minimizers of its Rosenthal's potential (7), meaning that $\Phi(\boldsymbol{\sigma}^*) \leq \Phi(\sigma_i', \boldsymbol{\sigma}^*_{-i})$ for any player i and any deviation $\sigma_i' \in \Sigma_i$. This also immediately establishes the existence of PNE in *all* congestion games, since the potential function $\Phi(\boldsymbol{\sigma})$ can only take finitely many different values.

Depending on the type and representation of the cost functions, different classes of congestion games can arise. Below, we describe three prominent ones which we will focus on in this paper:

- *General.* The cost functions are given explicitly as a list of nonnegative values, one for each possible load on the resource; $(\kappa_r(1), \kappa_r(2), \ldots, \kappa_r(n))$. Notice how in this model we do not impose a monotonicity constraint; this is deliberate, to maintain full generality. If one wants to focus on nondecreasing cost functions (as is many times the case in the literature), then the step-function representation (see below) can easily be used instead.
- *Polynomials (of degree d).* The cost functions are polynomials of maximum degree $d \in \mathbb{N}$ with nonnegative coefficients. More specifically, the cost functions are given implicitly by the coefficients $\{\alpha_{r,j}\}_{r\in\mathcal{R}, j\in[\![d_r]\!]} \subseteq \mathbb{R}_{\geq 0}$, where $d_r \leq d$, via

$$\kappa_r(\ell) = \sum_{j=0}^{d_r} \alpha_{r,j}\ell^j \qquad \text{for all } \ \ell \in [n]. \tag{8}$$

- *Step functions (with d break-points).* The cost functions are nondecreasing, piecewise constant, given by pairs of break-points and value-increases. More specifically, for each resource $r \in \mathcal{R}$ there is a list of break-points $\mathcal{B}_r \subseteq [n]$ and associated jumps $\{\alpha_{r,j}\}_{j\in\mathcal{B}_r}$. We denote the number of break-points of a resource r by $d_r \coloneqq |\mathcal{B}_r|$, and we set $d \coloneqq \max_{r\in\mathcal{R}} d_r$. Then, the cost functions are given via

$$\kappa_r(\ell) = \sum_{j\in\mathcal{B}_r\cap[\ell]} \alpha_{r,j} \qquad \text{for all } \ \ell \in [n]. \tag{9}$$

To the best of our knowledge, no smoothed analysis model has been established so far for congestion games. In this paper, we propose and study the following perturbation semantics for the aforementioned classes:

- *General congestion games.* The costs $\kappa_r(\ell)$ are independently distributed according to densities $f_{r,\ell} : [0,1] \longrightarrow [0,\phi]$, for all $r \in \mathcal{R}$ and $\ell \in [n]$.
- *Polynomial games.* The coefficients $\alpha_{r,j}$ are independently distributed according to densities $f_{r,j} : [0,1] \longrightarrow [0,\phi]$, for all $r \in \mathcal{R}$ and $j \in [\![d_r]\!]$.
- *Step-function games.* The jump increases $\alpha_{r,j}$ are independently distributed according to densities $f_{r,j} : [0,1] \longrightarrow [0,\phi]$, for all $r \in \mathcal{R}$ and $j \in \mathcal{B}_r$. Notice, however, that the break-points $\mathcal{B}_r$ themselves are not subjected to any noise, and they are assumed to be fixed (and adversarially selected).

4.1 Nash Equilibria as Combinatorial Local Optimization Problems

We now show how PNE-Congestion, the problem of finding a pure Nash equilibrium in congestion games, can actually be interpreted as a combinatorial local optimization problem (with respect to our definitions in Section 2.1), for any of the cost models described above. For all models, their randomness semantics translate directly to the respective randomness of cost coefficients in the smoothed CLO problem.

- *General congestion games.* By (7) we know that PNE correspond exactly to local minimizers of the potential function $\Phi(\boldsymbol{\sigma}) = \sum_{r\in\mathcal{R}} \sum_{j=1}^{\ell_r(\boldsymbol{\sigma})} \kappa_r(j)$. Therefore, finding a PNE of a general congestion game can be viewed as a binary ($M = 1$) CLO problem, with cost dimension $\nu = |\mathcal{R}|\, n$ (the cost coordinates are given by $\mathcal{R} \times [n]$), where each strategy profile $\boldsymbol{\sigma}$ is mapped to a cost configuration $\boldsymbol{s}^\bullet = (s_{r,j})_{r\in\mathcal{R}, j\in[n]}$ given by the indicator functions:

$$s_{r,j} = \mathbb{1}\left[j \leq \ell_r(\boldsymbol{\sigma})\right]. \tag{10}$$

The CLO cost coefficients are given by $c_{r,j} = \kappa_r(j)$.

Furthermore, we want to establish a one-to-one correspondence between configurations $\boldsymbol{s}$ of the CLO problem and strategy profiles $\boldsymbol{\sigma}$ of our congestion games where, in particular, the neighbours of $\boldsymbol{s}$ are exactly the configurations corresponding to single-player deviations $\{(\sigma_i', \boldsymbol{\sigma}_{-i})\}_{i\in\mathcal{N}, \sigma_i'\in\Sigma_i}$. In that way, better-responses of the congestion game would correspond exactly to local improvements in the CLO formulation. However, this cannot be achieved by using just the cost part defined above by (10), since in that case, different strategy profiles may end up being mapped to the same cost part configuration (when they induce the same resource loads). To overcome this technical pitfall, we also maintain a non-cost part $\boldsymbol{s}^\circ$, which keeps track of the actual strategies of the players: this can be easily achieved, with only an additional polynomial size burden.[6]

Finally, notice that the neighbourhoods of the CLO problem we created can be explicitly listed and efficiently searched for a better (smaller cost) value: they have a maximum size of $n \cdot \max_{i\in\mathcal{N}} |\Sigma_i|$, which is polynomial in the description of the original congestion game.

- *Polynomial games.* Using (8), Rosenthal's potential (7) can now be written as

$$\Phi(\boldsymbol{\sigma}) = \sum_{r\in\mathcal{R}} \sum_{\ell=1}^{\ell_r(\boldsymbol{\sigma})} \sum_{j=0}^{d_r} \alpha_{r,j}\ell^j = \sum_{r\in\mathcal{R}} \sum_{j=0}^{d_r} \alpha_{r,j} \sum_{\ell=1}^{\ell_r(\boldsymbol{\sigma})} \ell^j = \sum_{r\in\mathcal{R}} \sum_{j=0}^{d_r} \alpha_{r,j}\mathfrak{S}_j(\ell_r(\boldsymbol{\sigma})),$$

where

$$\mathfrak{S}_j(\ell) \coloneqq \sum_{k=1}^{\ell} k^j \leq \ell^{j+1} \leq \ell^{d+1} \leq n^{d+1}$$

for any $\ell \in \mathbb{N}$. This induces a CLO problem with parameters

$$\nu = \sum_{r\in\mathcal{R}} (d_r + 1) \leq |\mathcal{R}|\,(d+1) \qquad \text{and} \qquad M = n^{d+1},$$

with each strategy profile $\boldsymbol{\sigma}$ corresponding to a cost configuration $\boldsymbol{s}^\bullet = (s_{r,j})_{r\in\mathcal{R}, j\in[\![d_r]\!]}$ given by:

$$s_{r,j} = \mathfrak{S}_j(\ell_r(\boldsymbol{\sigma})).$$

The costs coefficients are given by $c_{r,j} = \alpha_{r,j}$. Notice that again all neighbourhoods are efficiently searchable since they have a polynomial maximum size of $n \cdot \max_{i\in\mathcal{N}} |\Sigma_i|$.

- *Step-function games.* Using (9), Rosenthal's potential (7) can now be written as

$$\begin{aligned}\Phi(\boldsymbol{\sigma}) = \sum_{r\in\mathcal{R}} \sum_{\ell=1}^{\ell_r(\boldsymbol{\sigma})} \sum_{j\in\mathcal{B}_r\cap[\ell]} \alpha_{r,j} &= \sum_{r\in\mathcal{R}} \sum_{j\in\mathcal{B}_r\cap[\ell_r(\boldsymbol{\sigma})]} (\ell_r(\boldsymbol{\sigma}) - j + 1)\alpha_{r,j} \\ &= \sum_{r\in\mathcal{R}} \sum_{j\in\mathcal{B}_r} \max(0, \ell_r(\boldsymbol{\sigma}) - j + 1)\alpha_{r,j}.\end{aligned}$$

This induces a CLO problem with dimension

$$\nu = \sum_{r\in\mathcal{R}} |\mathcal{B}_r| = \sum_{r\in\mathcal{R}} d_r \leq |\mathcal{R}|\,d \qquad \text{and} \qquad M = n,$$

with each strategy profile $\boldsymbol{\sigma}$ corresponding to configuration $\boldsymbol{s}^\bullet = (s_{r,j})_{r\in\mathcal{R}, j\in[d_r]}$ given by

$$s_{r,j} = \max(0, \ell_r(\boldsymbol{\sigma}) - \mathcal{B}_r(j) + 1),$$

[6] E.g. we can choose $\bar{\nu} = |\mathcal{N}|$ and let $s_i^\circ \in [|\Sigma_i|]$ be the index of strategy σ_i deployed by player i in profile $\boldsymbol{\sigma}$. To simplify our exposition, in the remaining congestion game classes studied below, we will avoid explicitly discussing these non-cost parts; they are identical to the general congestion game model.

where we use $\mathcal{B}_r(j)$ to denote the j-th break-point[7] of resource r. The costs are given by $c_{r,j} = \alpha_{r,\mathcal{B}_r(j)}$. Again, it is straightforward to see that all neighbourhoods are efficiently searchable.

4.2 Restrained Congestion Games

Although congestion games are guaranteed to have (at least one) PNE, the computational problem of actually finding one is considered hard; as a matter of fact, the problem PNE-Congestion is one of the most prominent PLS-complete problems. Our goal in this section is to investigate whether this computational barrier can be bypassed, under the lens of the more optimistic complexity model of smoothed analysis.

To achieve this, we establish an upper bound (Theorem 6) on the expected number of better-responses that need to be performed until a PNE is found in a congestion game, as a function of a critical structural parameter of its action space that we identify (see Definition 5). Then, we can deduce that for congestion games in which this parameter is appropriately bounded, the smoothed running time becomes tractable (Corollary 7). At the same time, we show how such a restriction does not make the problem trivially tractable, by proving that PNE-Congestion remains PLS-complete even for this subclass of games (Theorem 8).

▶ **Definition 5** (Restrained Congestion Games). *A congestion game will be called* B-restrained, *where* $B \in \mathbb{N}$, *if the maximum number of resources changed by any single-player deviation is at most* B. *Formally,*

$$\max_{i \in \mathcal{N}} \max_{\sigma, \sigma' \in \Sigma_i} |\sigma \triangle \sigma'| \leq B,$$

where $\triangle$ *denotes the standard symmetric difference operator (recall that* σ, σ' *are subsets of resources).*

▶ **Theorem 6.** *Consider a* B*-restrained* n*-player congestion game, under any of the smoothed-analysis models described in Section 4 (namely general, polynomial, or step-function latencies), with maximum density parameter* ϕ. *Then, performing any better-response dynamics, starting from an arbitrary strategy profile, converge to an (exact) PNE of the congestion game in an expected number of iterations that is bounded by*

- $\mathcal{O}\left(n^{B+3}k^2m^2\phi\right)$ *for general games,*
- $\mathcal{O}\left(n^{B+d+2}\log(n)(d+1)^3k^2m^2\phi\right)$ *for polynomial games with degree at most* d, *and*
- $\mathcal{O}\left((d+1)^{B+2}n^2\log(n)k^2m^2\phi\right)$ *for step-function games with at most* d *break-points,*

where $m = |\mathcal{R}|$ *is the number of resources and* $k = \max_{i \in \mathcal{N}} |\Sigma_i|$ *is the maximum strategy set size.*

Proof. In Section 4.1 we already showed how congestion games can be interpreted as CLO problems. In particular, we established a one-to-one correspondence between better-responses of the players to local improvements of the CLO cost objective (which corresponds to the value of Rosenthal's potential). Using this interpretation, we can now make use of our main black-box tool from Section 3: bounding the expected number of local search steps will induce the same bound in the expected iterations of better-response dynamics in the original congestion game. Therefore, the gist of our proof is to construct coverings $(\mathcal{E}, \mathcal{I})$ so that the induced CLO problem can be shown to be (λ, β, μ)-separable (see Definition 1) for parameters with appropriately small magnitude.

[7] That is, if $\mathcal{B}_r = \{b_1, b_2, \ldots, b_{d_r}\} \subseteq [n]$, then $\mathcal{B}_r(j) = b_j$, for any $j \in [d_r]$.

We start by establishing some properties that will be shared across all three different cost models. Fix a congestion game and its corresponding CLO problem, as described in Section 4.1.[8] For convenience, we denote by $k_i \coloneqq |\Sigma_i|$ the size of the strategy set of a player i, and let $k \coloneqq \max_{i\in\mathcal{N}} k_i$. Also, in all of the models we have a similar index structure in the cost part; the cost-part is given by $(s_{r,j})_{r\in\mathcal{R},j\in J_r}$, where J_r depends on the cost function model ($J_r = [n]$ for general, $J_r = [\![d_r]\!]$ for polynomial, and $J_r = [d_r]$ for step-function costs).

The transition cover $\mathcal{E}$ is constructed from clusters that collect all edges in the neighbourhood graph (of the CLO problem) that correspond to a fixed deviation of a player, regardless of the configuration of the remaining players. Formally, we let

$$\mathcal{E} \coloneqq \{E(i,\sigma_i,\sigma_i') \mid i\in\mathcal{N},\ \sigma_i,\sigma_i'\in\Sigma_i\}, \quad \text{where}$$
$$E(i,\sigma_i,\sigma_i') \coloneqq \{(\boldsymbol{s}(\sigma_i,\boldsymbol{\sigma}_{-i}),\boldsymbol{s}(\sigma_i',\boldsymbol{\sigma}_{-i}))\in E \mid \boldsymbol{\sigma}_{-i}\in\boldsymbol{\Sigma}_{-i}\},$$

and $\boldsymbol{s}(\boldsymbol{\sigma})$ is used to denote the CLO configuration corresponding to strategy profile $\boldsymbol{\sigma}$ in the congestion game. Now we immediately get the bound

$$|\mathcal{E}| \le nk(k-1),$$

which will be used as the value for our separability parameter λ (see Definition 1).

Next, for the coordinate cover $\mathcal{I}$, we cluster the indices with respect to each resource, i.e. we choose

$$\mathcal{I} \coloneqq \{I_r \mid r\in\mathcal{R}\}, \quad \text{where} \quad I_r = \{(r,j) \mid j\in J_r\}.$$

In congestion games, a deviation $\sigma_i \to \sigma_i'$ only affects the resources $r \in \sigma_i \triangle \sigma_i'$. Their loads are changed to increase by 1 for $r \in \sigma_i' \setminus \sigma_i$ and decrease by 1 for $r \in \sigma_i \setminus \sigma_i'$; the load of all other resources does not change. Our choice of the cover $\mathcal{I}$, therefore, will allow us to settle β for all models due to the B-restrain assumption on the size of $\sigma_i \triangle \sigma_i'$. In more detail, recall that the cost parts of a configuration depend only on the loads of the resources, thus all components associated with resources $r \notin \sigma_i \triangle \sigma_i'$ (specifically, the components with coordinates I_r) remain unchanged during the transition, since the load of r does not change either. The fact that the size of those sets $\sigma_i \triangle \sigma_i'$ is universally bounded, by assumption, will let us use $\beta = B$ as a separability parameter (see Definition 1).

The remaining parameter μ depends on the structure of the configurations in the cost part. Again, we emphasize that for all cost models in Section 4.1, the sub-configuration $\boldsymbol{s}_{I_r}(\boldsymbol{\sigma})$, which comprises all components of $\boldsymbol{s}(\boldsymbol{\sigma})$ that correspond to a resource r, depends only on the load $\ell_r(\boldsymbol{\sigma})$ of resource r (under strategy profile $\boldsymbol{\sigma}$). We can therefore represent it as a function $\boldsymbol{h}_r : [\![n]\!] \to [\![M]\!]^{J_r}$, i.e., $\boldsymbol{s}_{I_r}(\boldsymbol{\sigma}) = \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma}))$. For ease of notation we write $\boldsymbol{s}_r = \boldsymbol{s}_{I_r}$ in the following.

To discuss $\mathsf{range}_{I_r}(E(i,\sigma_i,\sigma_i'))$, we need to consider the configuration changes given by

$$\boldsymbol{s}_r(\boldsymbol{\sigma}) - \boldsymbol{s}_r(\boldsymbol{\sigma}') = \begin{cases} \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma})) - \boldsymbol{h}_r(\ell_r(\sigma')) = \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma})) - \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma})+1), & r\in\sigma_i'\setminus\sigma_i, \\ \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma})) - \boldsymbol{h}_r(\ell_r(\sigma')) = \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma})) - \boldsymbol{h}_r(\ell_r(\boldsymbol{\sigma})-1), & r\in\sigma_i\setminus\sigma_i'. \end{cases}$$

The only variable in this expression is therefore the initial load $\ell_r(\boldsymbol{\sigma})$. In either case, there are n possible initial loads for each resource[9] and therefore also at most n difference-vectors within $\mathsf{range}_{I_r}(E(i,\sigma_i,\sigma_i'))$; thus $\mu \le n$. In the following, we will discuss the actual configuration difference structure for each model and whether we can improve μ over this basic bound.

[8] We will use standard notation for the various components and parameters of the game and the CLO problem, as introduced above in Section 4.

[9] Note that although there are $n+1$ different loads $0,\dots,n$, a load-increasing resource cannot already have load n and a decreasing one cannot have 0.

- *General.* The CLO representation follows a binary model with $M = 1$ and $\nu = mn$: each resource r corresponds to components $s_{r,j}$, $j = 1, \ldots, n$ (the indices from I_r), with a value of $s_{r,j} = 1$ for $j \leq \ell_r(\boldsymbol{\sigma})$ and $s_{r,j} = 0$ otherwise. The function $\boldsymbol{h}_r : [\![n]\!] \longrightarrow \{0,1\}^n$ is thus given by

$$(\boldsymbol{h}_r(\ell))_j = \mathbb{1}[j \leq \ell], \qquad \text{for all } \; j \in [n].$$

  In particular, the vectors $\boldsymbol{\delta} \in \mathsf{range}_{I_r}(E(i, \sigma_i, \sigma_i'))$ are a result of moving the rightmost entry with value 1 within the vector $\boldsymbol{s}_r$ to the next larger or smaller load in the configuration, i.e. they are given by: $\delta_{\ell_r(\boldsymbol{\sigma})+1} = -1$ for $r \in \sigma_i' \setminus \sigma_i$; $\delta_{\ell_r(\boldsymbol{\sigma})} = +1$ for $r \in \sigma_i \setminus \sigma_i'$; and zeroes elsewhere. Since there are n many such vectors for every resource r, we cannot improve over $\mu = n$.
  In this case, thus, Theorem 2 yields an expected running time of at most

$$3 \cdot n^B nk(k-1) \cdot (mn)^2 \cdot \phi = \mathcal{O}\left(n^{B+3} k^2 m^2 \phi\right).$$

- *Polynomial games.* For this model, each (cost-part) configuration component $s_{r,j}$ is given by accumulated monomials $\mathfrak{S}_j(\ell_r(\boldsymbol{\sigma}))$, for degrees $j = 0, 1, \ldots, d_r$. Thus, $\nu = m(d+1)$, and also $M = n^{d+1}$, in order to capture all possible values of these functions. Therefore we now get $\boldsymbol{h}_r : [\![n]\!] \longrightarrow [\![n^{d+1}]\!]^{d_r+1}$ with

$$\boldsymbol{h}_r(\ell) = (\mathfrak{S}_0(\ell), \ldots, \mathfrak{S}_{d_r}(\ell))$$

  for the configuration component of I_r. Again, we cannot do better than the basic bound, so we use $\mu = n$.
  Similarly to the previous case for general latency functions, using Theorem 2 we can bound the expected number of better-response iterations by

$$3 \cdot n^B nk(k-1) \cdot (m(d+1))^2 n^{d+1} \log(n^{d+1}) \cdot \phi = \mathcal{O}\left(n^{B+d+2} \log(n)(d+1)^3 k^2 m^2 \phi\right).$$

- *Step-function games.* The configuration mapping is now given by

$$s_{r,j} = \max\left(0, \ell_r(\boldsymbol{\sigma}) - \mathcal{B}_r(j) + 1\right)$$

  and $M = n, \nu = m \cdot d$. Therefore, the (cost-part) configuration components of a resource r are represented by the function $\boldsymbol{h}_r : [\![n]\!] \longrightarrow [\![n]\!]^{d_r}$ given by

$$\boldsymbol{h}_r(\ell) = (\max(0, \ell - \mathcal{B}_r(1) + 1), \ldots, \max(0, \ell - \mathcal{B}_r(d_r) + 1)).$$

  In this case, we can do even better than the basic $\mu = n$ bound. We investigate the structure of the differences with respect to each coordinate $j \in J_r$, for an increase in the load of a resource r, i.e. for $r \in \sigma_i' \setminus \sigma_i$ (the decreasing case follows analogously):

$$\begin{aligned}(\boldsymbol{h}_r(\ell) - \boldsymbol{h}_r(\ell+1))_j &= \max\left(0, \ell - \mathcal{B}_r(j) + 1\right) - \max\left(0, (\ell+1) - \mathcal{B}_r(j) + 1\right) \\ &= \begin{cases} 0 - 0 = 0, & \text{if } \; \ell < \mathcal{B}_r(j) - 1, \\ -\left((\ell+1) - \mathcal{B}_r(j) + 1 - 0\right) = -1, & \text{if } \; \ell = \mathcal{B}_r(j) - 1, \\ (\ell - \mathcal{B}_r(j) + 1) - ((\ell+1) - \mathcal{B}_r(j) + 1) = -1, & \text{if } \; \ell > \mathcal{B}_r(j) - 1. \end{cases}\end{aligned}$$

  Because the jump points $\mathcal{B}_r(j)$ are ordered increasingly with respect to j, the resulting vectors $\boldsymbol{h}_r(\ell) - \boldsymbol{h}_r(\ell+1)$ are of the form $(-1, \ldots, -1, 0, \ldots, 0)$, including the zero vector. Therefore, with respect to the coordinate cluster I_r, there are at most $d_r + 1$ possible distinct vectors for the (cost-part) configuration differences, and we choose $\mu = \max_r d_r + 1 = d + 1$. By Theorem 2 we can thus bound the expected number of iterations by

$$3 \cdot (d+1)^B nk(k-1) \cdot (m \cdot d)^2 n \log(n) \cdot \phi = \mathcal{O}\left((d+1)^{B+2} n^2 \log(n) k^2 m^2 \phi\right). \qquad \blacktriangleleft$$

An immediate corollary of Theorem 6 is that, when congestion games are sufficiently restrained, PNE can be found efficiently via better-response dynamics. In what follows, by a *constantly-* and *polylogarithmically*-restrained congestion game we mean a B-restrained game with $B \in \mathcal{O}(1)$ and $B \in \mathcal{O}(\log^c N)$ for some constant $c > 0$, respectively, where N is the size of the input.

▶ **Corollary 7.** *Better-response dynamics terminate in polynomial smoothed time for the class of constantly-restrained congestion games, and in quasipolynomial smoothed time for polylogarithmically-restrained games, under any cost model. Under the step-function cost model, in $\mathcal{O}(\log N)$-restrained congestion games with a constant number of steps d, better-response dynamics terminate in polynomial smoothed time.*

We now show that the class of constantly-restrained congestion games, for which Corollary 7 provides efficient smooth running time, constitutes a computationally meaningful restriction of arbitrary congestion games, since they can still encode the PLS-completeness of the original problem. The hardness is a straightforward adaptation of that in [19], and so the proof of Theorem 8 is deferred to [12, Appendix B] for completeness. It makes use of the fact that LocalMaxCut is PLS-complete even for constant-degree graphs.

▶ **Theorem 8.** *The problem of computing a PNE of a constantly-restrained congestion game is* PLS*-complete, for all the input models described in Section 4 (namely general, polynomial, or step-function cost representations).*

In addition to the conditional intractability that PLS-hardness implies for these families of congestion games, we show an unconditional lower bound on the worst-case running time of the standard local search algorithm of the problem. We do this by using the notion of a *tight* PLS*-reduction*, as discussed in Section 2. Since we reduce from the problem LocalMaxCut-d for $d \geq 5$ (defined in [12, Appendix B]), which admits a configuration starting from which the standard local search algorithm needs exponentially many iterations (see discussion after proof of [12, Theorem 5.10]), our tight PLS-reduction implies that standard local search of our families of congestion games – under *any* pivoting rule – takes exponential time in the worst case.

4.3 Network Congestion Games

An interesting, and very well studied, variation on the vanilla representation model for congestion games (which we presented at the start of Section 4 above) is that of *network* congestion games. In such games, the strategy sets Σ_i of the players are not given explicitly in the input, but implicitly via an underlying directed graph G whose edges constitute the resources of the game. More precisely, for each player i we are given an origin o_i and a destination d_i node of G. Then, Σ_i is defined (implicitly) as the set of all (simple) $o_i \to d_i$ paths in G. Importantly, this means that now players may have exponentially many strategies available to them.

A critical implication is that Σ_i cannot be searched *exhaustively* for better-responses. However, a better-response can still be found efficiently: keeping all other players fixed, a minimum-cost strategy of player i is a shortest path on graph G with edge costs equal to the cost $c_r(\ell_r(\boldsymbol{\sigma}_{-i}) + 1)$ of an edge/resource r when used by player i. This means that actually a polynomial-time *best*-response oracle does exist. This immediately places network congestion games in the complexity class PLS (since neighbourhoods can be searched efficiently for a local cost improvement; see our discussion in Section 2) and thus it constitutes a valid CLO

problem (via a similar interpretation as we did for general congestion games in Section 4.1). To emphasize this, we will refer to these "canonical" best-response dynamics of network congestion games as *shortest-path* dynamics.

Finding PNE of network congestion games remains a PLS-complete problem [2]. Given the prominence of these games, both in the theoretical and applied literature, in this section we want to identify conditions under which network congestion games inherit the desirable properties of their general counterparts that allow them to be tractable under smoothed analysis. More precisely, can our positive result from Theorem 6 be applied to network congestion games in a straightforward way? And which structural parameters are now relevant for the running time bound? At the same time, the network congestion game instances that allow for efficient smoothed solutions should still be interesting enough to remain PLS-hard under traditional worst-case analysis. We introduce the following family of network congestion games that are defined by two parameters.

▶ **Definition 9** (Compact Network Congestion Games). *For A, B positive integers, a network congestion game is called* (A, B)-compact *if (a) each player has at most A different best-response strategies, and (b) all such strategies are paths of length at most B. Formally, there exist strategy sets $\Sigma_i^* \subseteq \Sigma_i$, such that:*
(a) $|\Sigma_i^*| \leq A$ *for all* $i \in \mathcal{N}$ *and* $\operatorname{argmin}_{\sigma_i \in \Sigma_i} C_i(\sigma_i, \boldsymbol{\sigma}_{-i}) \subseteq \Sigma_i^*$ *for all* $i \in \mathcal{N}, \boldsymbol{\sigma}_{-i} \in \boldsymbol{\Sigma}_{-i}$, *and*
(b) $|\sigma_i| \leq B$ *for all* $i \in \mathcal{N}, \sigma_i \in \Sigma_i^*$.

Property (b) above will serve the purpose of imposing the restraint condition (see Definition 5) needed to deploy Theorem 6. Property (a) will help us constrain the exponentiality of the strategy space of network games, in order to be able to handle them using tools designed for general games. Intuitively, this property can be related to classical vehicle routing settings in which players can a priori exclude unreasonable detours or paths that involve a road with a construction site with large delay. Both properties are illuminated within the proof of our following positive result for network congestion games.

▶ **Theorem 10.** *Consider an (A, B)-compact n-player network congestion game, under any of the smoothed-analysis models described in Section 4 (namely general, polynomial, or step-function latencies), with maximum density parameter ϕ. Then, performing shortest-path dynamics, starting from an arbitrary strategy profile, converges to a PNE of the game in an expected number of iterations that is polynomial in ϕ, $(d+1)^B$, A, and the description of the game, where the parameter d depends on the cost function representation. In particular: for general latencies, $(d+1)$ can be replaced by n; for polynomial latencies, d is the maximum degree; and for step-functions, d is the maximum number of break-points.*

An immediate consequence of Theorem 10 is that (analogously to Corollary 7 for general congestion games) in (A, B)-compact network games with sufficiently small parameters A, B, a PNE can be found efficiently under smoothness.

▶ **Corollary 11.** *Let N be the size of the input, and A be a polynomial in N. Shortest-path dynamics on (A, B)-compact network congestion games under any cost model terminate in polynomial smoothed time when $B \in \mathcal{O}(1)$ and in quasipolynomial smoothed time when $B \in \mathcal{O}(\log^c N)$ for some constant $c > 0$. Under the step-function cost model, when A is a polynomial in N, $B \in \mathcal{O}(\log N)$, and the number of steps d is constant, shortest-path dynamics terminate in polynomial smoothed time.*

The following hardness result establishes that such games, even for $A, B \in \mathcal{O}(1)$, are PLS-hard. The proof is deferred to [12, Appendix C]. It is based on the reduction constructed by Ackermann, Röglin, and Vöcking [2], with special care taken in order to incorporate constant-length paths that can be established by making use of the fact that LocalMaxCut is PLS-complete even for constant degree graphs.

▶ **Theorem 12.** *The problem of computing a PNE of an (A, B)-compact network congestion game is* PLS*-complete, even for $A, B \in \mathcal{O}(1)$, for all the input models described in Section 4 (namely general, polynomial, or step-function latencies).*

Similarly to our PLS-hardness reduction of Theorem 8, the above theorem's PLS-reduction is tight, in the sense of [23] (see Section 2). The chain of tight PLS-reductions that leads to Network Congestion Games starts from LocalMaxCut with maximum degree 5, and includes Congestion Games. As we discuss after the proof of [12, Theorem 5.10], in such LocalMaxCut instances there is a starting configuration from which all improvement sequences of standard local search have exponential length in the worst case. Therefore, shortest-path dynamics on our family of network congestion games – under *any* pivoting rule – need exponentially many iterations in the worst case. In contrast, our Theorem 10 and Corollary 11 show that under smoothness, even for significantly wider instance families that include these problematic cases, shortest-path dynamics terminate after polynomially many steps in expectation.

A Characterization of Complexity in Public Goods Games

Matan Gilboa
University of Oxford, UK

Abstract

We complete the characterization of the computational complexity of equilibrium in public goods games on graphs. In this model, each vertex represents an agent deciding whether to produce a public good, with utility defined by a "best-response pattern" determining the best response to any number of productive neighbors. We prove that the equilibrium problem is NP-complete for every finite non-monotone best-response pattern. This answers the open problem of [Gilboa and Nisan, 2022], and completes the answer to a question raised by [Papadimitriou and Peng, 2021], for all finite best-response patterns.

Acknowledgements I would like to thank Noam Nisan for many useful conversations, and for suggesting the Copy Gadget in the proof of Theorem 3.2. I would like to thank Roy Gilboa for many useful conversations, and for adjusting the Copy Gadget in the proof of Theorem 3.2. I would like to thank Noam Nisan for communicating to me the alternative solution to the monotone case (see footnote 2), which was suggested by Sigal Oren. I would like to thank the anonymous ICALP reviewers for their helpful feedback.

1 Introduction

Public goods games describe scenarios where multiple agents face a decision of whether or not to produce some "good", such that producing this good benefits not only themselves, but also other (though not necessarily all) agents. Typically, we consider the good to be costly to produce, and therefore an agent might choose not to produce it, depending on the actions of the agents that affect her. This type of social scenarios can be found in various real-life examples, such as vaccination efforts (an individual pays some personal cost for being vaccinated but she and other people in her proximity gain from it) and research efforts (a research requires many resources, but the researcher benefits from the results along with other researchers in similar areas). As is common in the literature, to model this we use an undirected graph, where each node represents an agent and an edge between two nodes captures the fact that these nodes directly affect one another by their strategy. As in [4, 6, 7, 9, 10], in our model the utility of an agent is completely determined by the number of productive neighbors she has, as well as by her own action. We focus on a specific version of the game which has the following characteristics. Firstly, our strategy space is binary, i.e. an agent can only choose whether or not to produce the good, rather than choose a quantity (we call an agent who produces the good a *productive* agent); secondly, our game is *fully-homogeneous*, meaning that all agents share the same utility function and cost of

producing the good; and thirdly, our game is *strict*, which means that an agent has a single best response to any number of productive neighbors she might have (i.e. we do not allow indifference between the actions).

The game is formally defined by some fixed cost c of producing the good, and by some "social" function $X(s_i, n_i)$, which takes into account the boolean strategy of agent i and the number of productive neighbors she has (marked as s_i and n_i respectively), and outputs a number representing how much the agent gains. The utility u_i of agent i is then given by the social function $X(s_i, n_i)$, reduced by the cost c if the agent produces the good, i.e. $u_i(s_i, n_i) = X(s_i, n_i) - c \cdot s_i$. However, since any number of productive neighbors yields a unique best response (i.e. the game is *strict*), we can capture the essence of the utility function and the cost using what we call (as in [3]), a Best-Response Pattern $T : \mathbb{N} \to \{0, 1\}$. We think of the Best-Response Pattern as a boolean vector in which the k^{th} entry represents the best response to exactly k productive neighbors. We are interested in the problem of determining the existence of a non-trivial pure Nash equilibrium in these games, which is defined as follows.

Equilibrium decision problem in a public goods game. For a fixed Best-Response Pattern $T : \mathbb{N} \to \{0, 1\}$, and with an undirected graph $G = (V, E)$ given as input, determine whether there exists a pure non-trivial Nash equilibrium of the public goods game defined by T on G, i.e. an assignment $s : V \to \{0, 1\}$ that is not all 0, such that for every $1 \leq i \leq |V|$ we have that

$$s_i = T[\sum_{j \in N(i)} s_j],$$

where $N(i)$ is the set of neighbors of agent i.

The first Best-Response Pattern for which this problem was studied was the so-called Best-Shot pattern (where an agent's best response is to produce the good only if she has no productive neighbors, namely $T = [1, 0, 0, 0, ...]$), which was shown in [1] to have a pure Nash equilibrium in any graph. In [1], they also show algorithmic results for "convex" patterns, which are monotonically increasing (best response is 1 if you have at least k productive neighbors). The question of characterizing the complexity of this problem for all possible patterns was first raised in [7], where they manage to fully answer an equivalent problem on directed graphs: They show tractability for the All-1 pattern, the infinite alternating $[1, 0, 1, 0, ...]$ pattern, and all patterns beginning with 0, and NP-completeness for all other patterns. The open question on undirected graphs was then partially answered in [3], where an efficient algorithm is shown for the pattern $[1, 1, 0, 0, 0, ...]$, and NP-completeness is established for several classes of non-monotone patterns: Those beginning with 0 or 11, or have a prefix of the form $1, 0, 0, ..., 0, 1, 1$. There have been several studies concerning other versions of this problem as well. In [9], the general version of this problem (where the pattern is part of the input rather than being fixed) was shown to be NP-complete when removing the strictness assumption, (i.e. allowing indifference between actions, such that both 0 and 1 are best responses in certain cases) [1]. In [10], NP-completeness is shown for the general version of the problem in the heterogeneous public goods game, in which the utility function varies between agents. In [4], they show NP-completeness of the equilibrium problem when restricting the equilibrium to have at least k productive agents, or at least some specific subset of agents. In [6], the parameterized complexity of the equilibrium problem is studied, for a number of parameters of the graph on which the game is defined.

[1] The paper [11] had an earlier version [10] which presented a proof for this case as well, but an error in the proof was pointed out in [9], who then also provided an alternative proof.

In [3], two open problems are suggested regarding the two following patterns: $T_1 = [1, 1, 1, 0, 0, 0, ...]$, $T_2 = [1, 0, 1, 0, 0, 0, ...]$. T_1 has been recently solved in [5], where they show that all monotonically decreasing patterns can be viewed as potential games, and thus always have a pure Nash equilibrium[2].

There are various instances where non-monotonic patterns are of interest. For example, consider work that necessitates collaboration from n agents or a financial effort that is irrelevant if too few agents contribute but if too many do so it becomes redundant from an agent's perspective. Our main contribution is completing the characterization of the equilibrium decision problem for all finite patterns, by showing that for all non-monotone patterns the problem is NP-complete.

Theorem. For any Best-Response Pattern that is non-monotone and finite (i.e., has a finite number of entries with value 1), the equilibrium decision problem in a public goods game is NP-complete (under Turing reductions).

The first step along this way was to prove NP-completeness for the above pattern T_2 (which we call the 0-Or-2-Neighbors pattern), namely the second open problem by [3]. An alternative proof to this specific problem was obtained independently and concurrently in [5].

We note that we only focus on finite patterns, which we believe to be more applicable to real-life problems that can be modeled by this game. Nonetheless, we find the characterization of all infinite patterns to be of interest, and this topic remains open, though some initial results can be found in Corollary 3.9. Another interesting open problem is to obtain a similar characterization for the non-strict version of the game, where agents are allowed to be indifferent between the two possible actions.

The rest of this paper is organized as follows. In Section 2 we introduce the formal model and some relevant definitions. We then set out to show hardness of all remaining patterns, dividing them into classes. In Section 3 we present a solution for the open question from [3], showing hardness of the 0-Or-2-Neighbors Best Response Pattern, and expanding the result to a larger sub-class of patterns that begin with 1,0,1. In Section 4 we show hardness of all patterns beginning with 1,0,0 (where we also have a slightly more subtle division into sub-classes), and in Section 5 we show hardness of all patterns beginning with 1,0,1 that were not covered in Section 3, thus completing the characterization for all finite patterns. The outline of this paper is also depicted[3] in Figure 1.

2 Model and Definitions

A *Public Goods Game* (PGG) is defined on an undirected graph $G = (V, E)$, $V = \{v_1, ..., v_n\}$, where each node represents an agent. The strategy space, which is identical for all agents, is $S = \{0, 1\}$, where 1 represents producing the good and 0 represents not producing it. The utility of node v_i (which is assumed to be the same for all agents) is completely determined by the number of productive neighbors v_i has, as well as by v_i's own strategy. Moreover, our model is restricted to utility functions where an agent always has a single best response to the strategies of its neighbors, i.e. there is no indifference between actions in the game. Therefore, rather than defining a PGG with an explicit utility function and cost for producing

[2] Alternatively, known results about k-Dominating and k-Independent sets (Theorem 19 in [2]) can be used to prove this.

[3] Some patterns which start with 1,0 were solved in [3], though for simplicity we omit them from Figure 1.

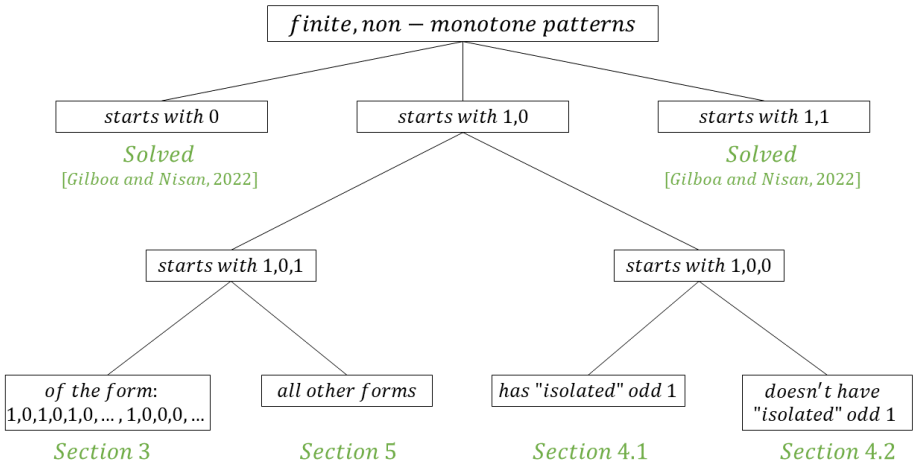

Figure 1 Outline of this paper.

the good, we can simply consider the best response of an agent for any number of productive agents in its neighborhood. Essentially, this can be modeled as a function $T : \mathbb{N} \to \{0, 1\}$, which, as in [3], we represent in the form of a *Best Response Pattern*:

▶ **Definition 2.1.** *A Best-Response Pattern (BRP) of a PGG, denoted by T, is an infinite boolean vector in which the k^{th} entry indicates the best response for each agent v_i given that exactly k neighbors of v_i (excluding v_i) produce the good:*

$$\forall k \geq 0 \;\; T[k] = \textit{best response to } k \textit{ productive neighbors.}$$

▶ **Definition 2.2.** *Given a Public Goods Game defined on a graph $G = (V, E)$ with respect to a BRP T, a strategy profile $s = (s_1, ..., s_n) \in S^n$ (where $s_i \in \{0, 1\}$ represents the strategy of node $v_i \in V$) is a pure Nash equilibrium (PNE) if all agents play the best response to the strategies of their neighbors:*

$$\forall 1 \leq i \leq n \;\; s_i = T[\sum_{j \in N(i)} s_j],$$

where $N(i) = \{j : \{v_i, v_j\} \in E\}$. In addition, if there exists $1 \leq i \leq n$ s.t. $s_i = 1$, then s is called a non-trivial pure Nash equilibrium (NTPNE).

We note that throughout the paper we also use the notation $v_i = 0$ and $v_i = 1$ to indicate the strategy of some node v_i, rather than use $s_i = 0$ and $s_i = 1$, respectively.

▶ **Definition 2.3.** *For a fixed BRP T, the non-trivial[4] pure Nash equilibrium decision problem corresponding to T, denoted by NTPNE(T), is defined as follows: The input is an undirected graph G. The output is 'True' if there exists an NTPNE in the PGG defined on G with respect to T, and 'False' otherwise.*

[4] In this paper, we only study BRPs where the best response for zero productive neighbors is 1, for which there never exists a trivial all-zero PNE (as these are the only BRPs left to solve). However, we sometimes reduce from patterns where this is not the case, and therefore include the non-triviality restriction in our problem definition, in order to correspond with the literature.

▶ **Definition 2.4.** *A BRP T is called monotonically increasing (resp. decreasing) if* $\forall k \in \mathbb{N}$, $T[k] \leq T[k+1]$ *(resp.* $T[k] \geq T[k+1]$*).*

▶ **Definition 2.5.** *A BRP T is called finite if it has a finite number of entries with value 1:*

$$\exists N \in \mathbb{N} \;\; s.t. \;\; \forall n > N \;\; T[n] = 0$$

As seen in Figure 1, the only patterns for which the equilibrium decision problem remains open are patterns that begin with 1,0. We divide those into the two following classes of patterns.

▶ **Definition 2.6.** *A BRP T is called semi-sharp if:*
1. $T[0] = 1$
2. $T[1] = T[2] = 0$

i.e. T begins with $1, 0, 0$.

▶ **Definition 2.7.** *A BRP T is called spiked if:*
1. $T[0] = T[2] = 1$
2. $T[1] = 0$

i.e. T begins with $1, 0, 1$.

We note that given any finite BRP T, the NTPNE(T) problem is in NP, since an assignment to the nodes can be easily verified as an NTPNE by iterating over the nodes and checking whether they all play their best response. Therefore, we only prove NP-hardness of the problems throughout the paper.

3 Hardness of the 0-Or-2-Neighbors Pattern

In this section we show that the equilibrium problem is NP-complete for the 0-Or-2-Neighbors pattern, and provide some intuition about the problem. This result answers an open question from [3]. We then expand this to show hardness of a slightly more general class of patterns. In the 0-Or-2-Neighbors BRP the best response is 1 only to zero or two productive neighbors, as we now define.

▶ **Definition 3.1.** *The 0-Or-2-Neighbors Best Response Pattern is defined as follows:*

$$\forall k \in \mathbb{N} \;\; T[k] = \begin{cases} 1 & \text{if } k = 0 \;\; or \;\; k = 2 \\ 0 & otherwise \end{cases}$$

i.e.

$$T = [1, 0, 1, 0, 0, 0, ...].$$

▶ **Theorem 3.2.** *Let T be the 0-Or-2 Neighbors BRP. Then NTPNE(T) is NP-complete.*

Before proving the theorem, we wish to provide basic intuition about the 0-Or-2-Neighbors BRP, by examining several simple graphs. Take for example a simple cycle. Since $T[2] = 1$ (i.e. best response for two productive neighbors is 1), we have that any simple cycle admits a pure Nash equilibrium[5], assigning 1 to all nodes (see Figure 2). However, looking at a simple path with n nodes, we see that the all-ones assignment is never a pure Nash equilibrium.

[5] In this pattern, any pure Nash equilibrium must also be non-trivial, since $T[0] = 1$.

The reason for this is that $T[1] = 0$ (i.e. best response for one productive neighbors is 0), and so the two nodes at both ends of the path, having only one productive neighbor, do not play best response. Nevertheless, any simple path does admit a pure Nash equilibrium. To see why, let us observe the three smallest paths, of length 2, 3 and 4. Notice that in a path of length two a PNE is given by the assignment 0,1; in a path of length three a PNE is given by the assignment 0,1,0; and in a path of length four a PNE is given by the assignment 1,0,0,1. We can use these assignment to achieve a PNE in any simple path: given a simple path of length n, if $n \equiv 0 \pmod 3$ we use the path of length three as our basis, adding 0,1,0 to it as many times as needed; if $n \equiv 1 \pmod 3$ we use the path of length four as our basis, adding 0,0,1 to it as many times as needed; and if $n \equiv 2 \pmod 3$ we use the path of length two as our basis, adding 0,0,1 to it as many times as needed (see example in Figure 3).

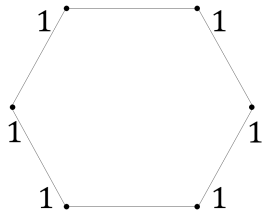

Figure 2 PNE in cycles.

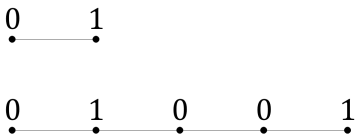

Figure 3 PNE in paths of lengths 2 and 5.

In contrast to the graphs discussed so far, there are graphs in which a pure Nash equilibrium doesn't exist for the 0-Or-2-Neighbors pattern. An example of this can be seen in a graph composed of four triangles, connected as a chain where each two neighboring triangles have a single overlapping vertex, as demonstrated in Figure 4. One may verify that no PNE exists in this graph. This specific structure will also be of use to us during our proof[6].

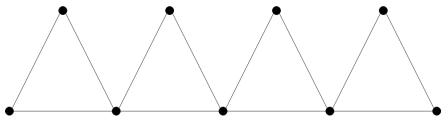

Figure 4 No PNE exists in this graph.

Having provided some intuition regarding the problem, we move on to prove Theorem 3.2. The reduction is from ONE-IN-THREE 3SAT, which is a well known NP-complete problem (see [8]). In ONE-IN-THREE 3SAT, the input is a CNF formula with 3 literals in each clause, and the goal is to determine whether there exists a boolean assignment to the variables such that in each clause exactly one of the literals is assigned True. We begin by introducing our Clause Gadget, which is a main component of the proof. Given a CNF formula, for each of its clauses we construct a 21-nodes Clause Gadget, in which three of the nodes, denoted l_1, l_2, l_3 (also referred to as the *literal nodes*) represent the three literals of the matching clause. The purpose of this gadget is to enforce the property that in any NTPNE, exactly one literal node in the gadget will be assigned 1, which easily translates to the key property of a satisfying assignment in the ONE-IN-THREE 3SAT problem. The three literal

[6] The Negation Gadget defined throughout the proof of Theorem 3.2 is constructed similarly to the graph described here.

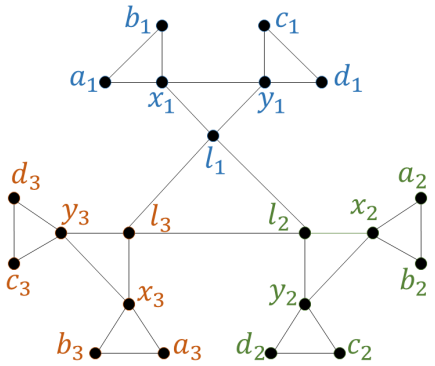

Figure 5 Clause Gadget.

nodes are connected to one another, forming a triangle. Additionally, for each $i \in \{1, 2, 3\}$, l_i is connected to two other nodes x_i, y_i, which are also connected to one another, forming another triangle. Lastly, x_i and y_i each form yet another triangle, along with nodes a_i, b_i and c_i, d_i respectively. We refer to $x_i, y_i, a_i, b_i, c_i, d_i$ as the *sub-gadget* of l_i. We note that out of the nodes of the Clause Gadget, only the literal nodes may be connected to other nodes outside of their gadget, a property on which we rely throughout the proof. The structure of the Clause Gadget is demonstrated in Figure 5, where each sub-gadget is colored differently.

The next four lemmas lead us to the conclusion that the gadget indeed has the desired property mentioned above.

▶ **Lemma 3.3.** *In any NTPNE in a graph G which includes a Clause Gadget cg, if a literal node l_i of cg is assigned 1 then so are its two neighbors from its respective sub-gadget, x_i, y_i. Furthermore, there exists an assignment to the sub-gadget of l_i such that all its nodes play best response.*

Proof. Divide into cases.

Case 1: If $x_i = y_i = 0$, then if $a_i \neq b_i$ (meaning only one of them is assigned 1) then x_i would have two productive neighbors and would not be playing its best response. However, if $a_i = b_i$ then a_i and b_i would not be playing their best response, and we reach a contradiction.

Case 2: If $x_i = 1, y_i = 0$ (the case where $x_i = 0, y_i = 1$ is, of course, symmetric) then x_i must have exactly one more productive neighbor (either a_i or b_i) in order to be playing best response. But then that node would not be playing best response, in contradiction.

Case 3: We are left with the option where $x_i = y_i = 1$, where it is easy to verify that all nodes of the sub-gadget of l_i are playing their best response if we set $a_i = b_i = c_i = d_i = 0$. ◀

▶ **Lemma 3.4.** *In any NTPNE in a graph G which includes a Clause Gadget cg, if one of the literal nodes l_i of cg is assigned 1 then the other two literal nodes of cg must be assigned 0.*

Proof. Since $l_i = 1$, from Lemma 3.3 we have that $x_i = y_i = 1$. Therefore, l_i has two productive neighbors and cannot have any more, and so we have that the other two literal nodes must play 0. ◀

▶ **Lemma 3.5.** *In any graph G which includes a Clause Gadget cg, if exactly one of the literal nodes of cg is assigned 1 then there exists an assignment to the other nodes of cg such that they all (excluding the literal nodes) play best response. In addition, in any such assignment, if the literal nodes have no productive neighbors outside cg, then they also play best response.*

Proof. W.l.o.g. assume that $l_1 = 1, l_2 = l_3 = 0$. Let us observe several details that must hold in such an assignment. Focusing first on the sub-gadget of l_1, according to Lemma 3.3 there exists an assignment the nodes of this sub-gadget such that they all play best response. Furthermore, Lemma 3.3 tells us that $x_1 = y_1 = 1$ (and so l_1 has two productive neighbors within cg). We move on to the sub-gadget of l_2. If $x_2 \neq y_2$ then l_2 would have 2 productive neighbors and would not be playing its best response. If $x_2 = y_2 = 1$ then there is no assignment to a_2, b_2 s.t. a_2, b_2, x_2 all play their best response. Therefore $x_2 = y_2 = 0$. We are left only with the option of setting $a_2 \neq b_2$ and $c_2 \neq d_2$ (for instance $a_2 = c_2 = 1, b_2 = d_2 = 0$). The sub-gadget of l_3 is symmetric to that of l_2. One may verify that in this assignment all nodes of cg excluding the literal nodes indeed play best response, and that if the literal nodes have no productive neighbors outside cg then they also play best response. ◀

▶ **Lemma 3.6.** *In any graph G which includes a Clause Gadget cg, if all three of the literal nodes of cg are assigned 0, and the literal nodes do not have any productive neighbors outside of cg, then the assignment is not a PNE.*

Proof. Assume by way of contradiction that there exists a PNE where $l_1 = l_2 = l_3 = 0$, and all three of them have no productive neighbors outside cg. It must be that the other two neighbors of l_1, x_1, y_1, are assigned with different values (otherwise l_1 is not playing its best response). W.l.o.g. assume $x_1 = 1, y_1 = 0$. Now, if the remaining neighbors of y_1 (c_1 and d_1) are both assigned with 0 or both assigned with 1, then they themselves would not be playing their best response. On the other hand, if we assign them with different values then y_1 would not be playing its best response, and so we have reached a contradiction. ◀

So far, we have seen that in any PNE which includes a Clause Gadget, it must be that exactly one of the literal nodes of that gadget is assigned with 1, as long as the literal nodes don't have productive neighbors outside of their Clause Gadget. As we introduce the external nodes that will be connected to the literal nodes, we will show that indeed they all must be assigned 0 in any PNE, and thus a literal node cannot have any productive neighbor outside of its Clause Gadget, which will finalize the property we were looking to achieve with the Clause Gadget.

Our next goal is to make sure the translation between solutions from one domain to the other is always valid. Specifically, we wish to ensure that in any PNE in our constructed graph, if any two literal nodes represent the same variable in the CNF formula then they will be assigned the same value, and if they represent a variable and its negation then they will be assigned opposite values. We begin with the latter, introducing our Negation Gadget. The goal of the Negation Gadget is to force opposite assignments to two chosen nodes, in any Nash equilibrium. The Negation Gadget is composed of 9 nodes: five 'bottom' nodes b_1, b_2, b_3, b_4, b_5, and four 'top' nodes t_1, t_2, t_3, t_4, and for each $i \leq 4$ we create the edges $\{b_i, b_{i+1}\}$, $\{t_i, b_i\}$ and $\{t_i, b_{i+1}\}$. It can intuitively be described as four triangles that are connected as a chain. Say we have two nodes u, v which we want to force to have opposite assignments, we simply connect them both to node t_2 of a Negation Gadget, as demonstrated in Figure 6.

▶ **Lemma 3.7.** *In any Nash equilibrium in a graph G which includes two nodes u, v connected through a Negation Gadget ng, u and v must have different assignments. Moreover, the node t_2 of ng, to which u and v are connected, must be assigned 0. In addition, if indeed $u \neq v$ and $t_2 = 0$, there exists an assignment to the the nodes of ng such that they all play best response.*

Proof. We first show that u and v must have different assignments, dividing into two cases.

Case 1: Assume by way of contradiction that $u = v = 0$. We divide into two sub-cases, where in the first one $t_2 = 0$; in this case, exactly one of the two remaining neighbors of t_2 must be assigned 1 in order for t_2 itself to be playing best response. If $b_2 = 0$ then $b_3 = 1$ and so, looking at t_1, b_1 (the remaining neighbors of b_2), we see that any assignment to them results either in b_2 not playing best response, or in t_1 not playing best response, in contradiction. If, however, $b_3 = 0$, then $b_2 = 1$, and so, symmetrically, looking at t_3, b_4 (the remaining neighbors of b_3) we see that any assignment to them results either in b_3 not playing best response, or in t_3 not playing best response, in contradiction. In the second sub-case, where $t_2 = 1$, we have that its two remaining neighbors must be assigned the same value in order for t_2 itself to be playing best response. If $b_2 = b_3 = 0$ then again there is no assignment to b_1, t_1 s.t. all of b_1, t_1, b_2 play best response, and if $b_2 = b_3 = 1$ then one may verify that there is no assignment to t_3, t_4, b_4, b_5 s.t. all of t_3, t_4, b_3, b_4, b_5 play best response, and so we reach a contradiction.

Case 2: Assume $u = v = 1$. Then we again divide into sub-cases according to t_2's assignment. If $t_2 = 0$, it must have at least one more productive neighbor in order to play best response. The assignments where $b_2 = b_3 = 1$ or $b_2 = 0, b_3 = 1$ are easily disqualified, seeing as there is no assignment to t_1, b_1 s.t. t_1, b_1, b_2 all play best response. If $b_2 = 1, b_3 = 0$ then it must hold that $t_3 = b_4$ in order for b_3 to play best response, but this would mean that t_3 is not playing best response, in contradiction. If $t_2 = 1$, then its two remaining neighbors b_2, b_3 must be set to 0 in order for it to play best response, and then there is no assignment to b_1, t_1 s.t. all of t_1, b_1, b_2 play best response, in contradiction.

And so it cannot be that $u = v$. We move on to show that t_2 must play 0. Assume by way of contradiction that $t_2 = 1$. Then, seeing as exactly one of u, v is productive, t_2 must have exactly one more productive neighbor in order to play best response. If $b_2 = 1, b_3 = 0$ we reach a contradiction as there is no assignment to t_1, b_1 s.t. t_1, b_1, b_2 all play best response. If $b_2 = 0, b_3 = 1$ we reach a contradiction as there is no assignment to t_3, t_4, b_4, b_5 s.t. all of t_3, t_4, b_3, b_4, b_5 play best response. Lastly, one may verify that in the assignment where $t_1 = b_4 = 1, b_1 = b_2 = b_3 = b_5 = t_2 = t_3 = t_4 = 0$ all nodes of the gadget play best response. ◀

Now, for each variable that appears in the CNF formula, we choose one instance of it and one instance of its negation[7] and connect the literal nodes representing these instances via a Negation Gadget, thus ensuring they are assigned opposite values in any PNE, according to Lemma 3.7. We note that this is not the only place where we use this gadget, as we will see shortly.

We move on to introduce our Copy Gadget, which we will use to force literal nodes which represent the same variable to have the same assignment in any PNE. The Copy Gadget is composed of two negation gadgets ng_1, ng_2, and two additional nodes x, y which have an edge between them. Say we have two nodes u, v which we want to force to have the same assignment in any PNE, then we simply connect u and x to ng_1, and we connect v and x to ng_2. The gadget is demonstrated in Figure 7.

▶ **Lemma 3.8.** *In any Nash equilibrium in a graph G which includes two nodes u, v connected through a Copy Gadget cpg, u, v must have the same assignment, and must have no productive neighbors from cpg. In addition, if $u = v$ then there exists an assignment to the nodes of cpg s.t. all of them play best response.*

[7] We will soon ensure that instances of the same variable would get the same assignment in any PNE, and thus it is sufficient to negate the assignments of only one instance of a variable and its negation.

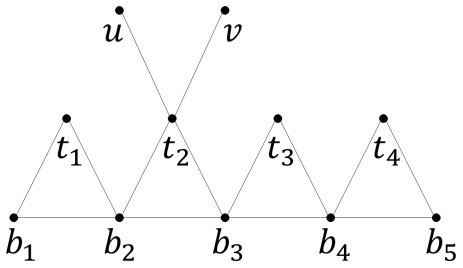

Figure 6 *Negation Gadget connecting u and v.*

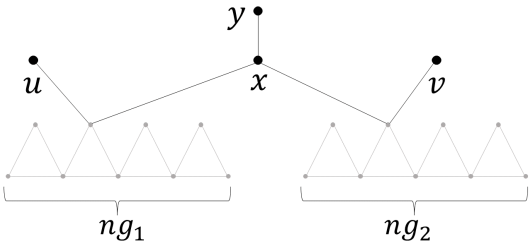

Figure 7 *Copy Gadget connecting u and v.*

Proof. We first show that u and v must have the same assignment. This follows directly from the fact that x is connected to both u and v via a Negation Gadget. Therefore, from Lemma 3.7 we have that $x \neq u$ and $x \neq v$, and so $u = v$. Lemma 3.7 also tells us that the Negation Gadget cannot add productive neighbors to the nodes that are connected to it in any PNE, and therefore u and v have no productive neighbors from *cpg*. Lastly, we show that there exists an assignment to the nodes of *cpg* s.t. they all play best response. From Lemma 3.7 x cannot have any productive neighbors from ng_1 or ng_2. Therefore, if $u = v = 0$ then we can assign $x = 1, y = 0$, and if $u = v = 1$ then we can assign $x = 0, y = 1$. In both cases, we assign ng_1 and ng_2 as suggested in the proof of Lemma 3.7. One may verify that in this assignment indeed all nodes of *cpg* play best response. ◀

Now, for each variable in the CNF formula, we connect all the literal nodes representing its different instances via a chain of copy gadgets, thus (transitively) ensuring they are all assigned the same value in any PNE, according to Lemma 3.8.

Given these lemmas and the graph we constructed, we can now prove Theorem 3.2.

Proof. (Theorem 3.2) Given a ONE-IN-THREE 3SAT instance, we construct a graph G as described previously[8]: For each clause we create a Clause Gadget, we connect all literal nodes representing the same variable through a chain of Copy Gadgets, and for each variable we choose one instance of it and one instance of its negation, and connect the literal nodes representing those instances with a Negation Gadget. If there exists a satisfying assignment to the 3SAT problem, we can set all literal nodes according to the assignment of their matching variable, and set all other nodes as described throughout Lemmas 3.5, 3.7 and 3.8, and according to those lemmas, we get a pure Nash equilibrium. On the opposite direction, if there exists a non-trivial pure Nash equilibrium, then by Lemmas 3.4 and 3.6 in each Clause Gadget exactly one literal node is assigned 1, and by Lemmas 3.7 and 3.8 we have that literal nodes have the same assignment if they represent the same variable, and opposite ones if they represent a variable and its negation. Thus we can translate the NTPNE into a satisfying ONE-IN-THREE 3SAT assignment, assigning 'True' to variables whose literal nodes are set to 1, and 'False' otherwise. ◀

[8] Note that we do not need to explicitly represent the conjunction between the clauses: It is given to us implicitly by the fact that each Clause Gadget must independently satisfy the 1-In-3 property in any Nash equilibrium.

We now wish to expand this result to two slightly more general classes of patterns. Firstly, we notice that the graph constructed throughout the proof of Theorem 3.2 is bounded[9] by a maximum degree of 6. Therefore, the proof is indifferent to entries of the pattern from index 7 onward, which means it holds for any pattern that agrees with the first 7 entries of the 0-Or-2-Neighbors pattern.

▶ **Corollary 3.9.** *Let T be a BRP such that:*

- $T[0] = T[2] = 1$
- $\forall k \in \{1, 3, 4, 5, 6\}\ \ T[k] = 0$

Then NTPNE(T) is NP-complete.

Secondly, according to Theorem 7 in [3], adding 1,0 at the beginning of a hard pattern that begins with 1 yields yet another hard pattern. Using this theorem recursively on the patterns of Corollary 3.9, we have that the equilibrium decision problem is hard for any pattern of the form:

$$T = [\underbrace{1, 0, 1, 0, 1, 0, ..., 1, 0}_{finite\ number\ of\ '1,0'}, 0, 0, 0, ?, ?, ...].$$

▶ **Corollary 3.10.** *Fix $m \geq 1$, and let T be a BRP such that:*

- $\forall 0 \leq k \leq m$
  1. $T[2k] = 1$
  2. $T[2k + 1] = 0$
- $T[2m + 2] = T[2m + 3] = T[2m + 4] = 0$

Then NTPNE(T) is NP-complete.

We will see later on that this result will also be of use during the proof of Theorem 5.1.

There is one very similar class of patterns on which the proofs throughout the paper rely. This is the class of all finite patterns that start with a finite number of 1,0, followed by 1,1, i.e. all patterns of the form:

$$T = [\underbrace{1, 0, 1, 0, 1, 0, ..., 1, 0}_{finite\ number\ of\ '1,0'}, 1, 1, ?, ?, ..., 0, 0, ...].$$

The complexity of those patterns was already discussed and solved in Section 5.4 of [3], but was not formalized and so we state it here in the following lemma.

▶ **Lemma 3.11.** *Fix $m \geq 2$, and let T be a BRP s.t.:*

- *T is finite*
- *$\forall k \in \mathbb{N}$ s.t. $2k \leq m$ $T[2k] = 1$*
- *$T[1] = 0$*
- *$\exists 1 \leq n$ where $2n + 1 \leq m + 1$, s.t. $T[2n + 1] = 1$*

Then NTPNE(T) is NP-complete under Turing reduction.

Proof. The proof follows directly from Theorems 6 and 7 from [3]. ◀

[9] A literal node is connected to 4 nodes within its clause gadget, and possibly 2 nodes from copy gadgets or 1 node from a negation gadget and 1 node from a copy gadget (assuming we connect the negation gadgets at the end of their respective Copy-Gadget-chains).

4 Hardness of Semi-Sharp Patterns

In this section we show hardness of semi-sharp Best-Response Patterns, beginning with a specific sub-class of those patterns in Section 4.1, and expanding to all other semi-sharp patterns in Section 4.2. We remind the reader that semi-sharp patterns are patterns that begin with 1,0,0.

4.1 Semi-Sharp Patterns with Isolated Odd 1

In this section we show that any finite, semi-sharp pattern such that there exists some "isolated" 1 (namely it has a zero right before and after it) at an odd index, presents a hard equilibrium decision problem. Those patterns can be summarized by the following form:

$$T = [1, 0, 0, ?, ?, ..., 0, \underbrace{1}_{odd\ index}, 0, ?, ?, ..., 0, 0, 0, ...]$$

▶ **Theorem 4.1.** *Let T be a BRP which satisfies the following conditions:*

- *T is finite*
- *T is semi-sharp*
- *$\exists m \geq 1$ s.t.:*
  1. *$T[2m] = T[2m+2] = 0$*
  2. *$T[2m+1] = 1$*

Then NTPNE(T) is NP-complete under Turing reduction.

Before we proceed to the proof, we introduce two gadgets and prove two lemmas regarding their functionality.

Force-1-Gadget. The first gadget is denoted the Force-1-Gadget, and it will appear in several parts of the graph we construct for the reduction. The goal of this gadget is to enable us to force any node to be assigned 1 in any Nash equilibrium in a PGG defined by T. This gadget is composed primarily of a triangle x, y, z, where the triangle's nodes have also several 'Antenna' nodes, which are connected only to their respective node from the triangle. Specifically, x will have $2m+1$ Antenna nodes, and y and z will each have $2m$ Antenna nodes. Say we have some node u, whose assignment we wish to force to be 1, then we simply connect u to one of the Antenna nodes of x, denoted a. The gadget is demonstrated in Figure 8.

Add-1-Gadget. our second gadget of this proof is denoted the Add-1-Gadget, and its goal is to enable us to assure the existence of (at least) a single productive neighbor to any node in a Nash equilibrium of a PGG defined by T. Say we have a node v, to which we wish to add a single productive neighbor, in any equilibrium. We construct the Add-1-Gadget as follows. We create $m+1$ nodes denoted $x_1, ..., x_{m+1}$, $m+1$ nodes denoted $y_1, ...y_{m+1}$, and an additional 'bridge' node, denoted b. We connect x_1 and y_1 to all of the other x_i and y_i nodes. For all $i, j \geq 2$ s.t. $i \neq j$, we create the edges $\{x_i, x_j\}, \{y_i, y_j\}, \{x_i, y_j\}$ (the x_i, y_i nodes almost form a clique, except that for each $i \geq 2$ we omit the edge $\{x_i, y_i\}$). Additionally, for all $i \geq 2$ the bridge node b is connected to x_i and to y_i. To b we attach a Force-1-Gadget, and we also connect b to v. The gadget is demonstrated in Figure 9.

The following lemmas formalize the functionality of the two gadgets, beginning with the Force-1-Gadget in Lemma 4.2.

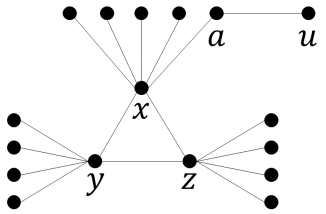

Figure 8 *Force-1-Gadget with $m = 2$, attached to u.*

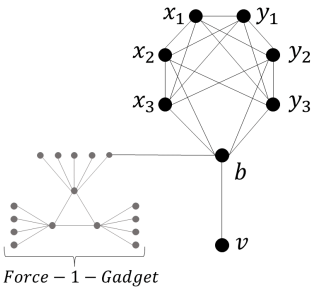

Figure 9 *Add-1-Gadget with $m = 2$, attached to v.*

▶ **Lemma 4.2.** *In any PNE in a graph G corresponding to the BRP T (from Theorem 4.1), where G has a node u that is connected to a Force-1-Gadget fg as described, u must be assigned 1, and its neighbor from fg, a, must be assigned 0.*[10] *Furthermore, if $u = 1$ there exists an assignment to the nodes of fg such that they each play their best response.*

Proof. First we show that u must be assigned 1. Assume by way of contradiction that $u = 0$. Divide into the following two cases. If $x = 1$, then all of its Antenna nodes must be assigned 0 (according to T). Additionally, y and z must also be assigned 0, as otherwise x wouldn't be playing best response, since T is semi-sharp. Therefore, the best response of all of the Antenna nodes of y and z is to play 1, which leaves y and z with $2m+1$ productive neighbors each, and so they are not playing best response, in contradiction. If $x = 0$, then all of its Antenna nodes must play 1. Therefore, x must have at least one other productive neighbor, as otherwise it would have $2m + 1$ productive neighbors and wouldn't be playing best response; w.l.o.g. assume $y = 1$. Then all of y's Antenna nodes must play 0. Therefore, z must play 0, as otherwise y wouldn't be playing best response. This means the best response for z's Antenna nodes is to play 1, which leaves z with $2m + 1$ productive neighbors, and so it isn't playing best response, in contradiction. We move on to showing that a must play 0. This follows directly from the fact that $u = 1$. Since a only has one other neighbor (x), regardless of its strategy the best response for a, according to T, would be playing 0. It is left to show that when $u = 1$ and $a = 0$, there exists an assignment to the nodes of fg s.t. they all play best response. One may verify that when we set $x = y = z = 0$ and set all the Antenna nodes in fg (except for a) to 1, then all nodes of fg play best response (specifically, x, y, z would each have exactly $2m$ productive neighbors, which, by definition of T, means they are playing best response). ◀

We move on to proving the following Lemma, which formalizes the functionality of the Add-1-Gadget.

▶ **Lemma 4.3.** *In any graph G corresponding to the BRP T (from Theorem 4.1), where G has a node v that is connected to an Add-1-Gadget ag as described, there always exists an assignment to the nodes of ag such that they all play best response, regardless of v's strategy. In addition, the bridge node b of ag must be assigned 1 in such an assignment.*

[10] The property that $a = 0$ allows us to use the Force-1-Gadget without risking potentially adding productive neighbors to the respective node.

Proof. The claim that b must play 1 follows directly from the fact that it has a Force-1-Gadget attached to it, i.e. from Lemma 4.2. Additionally, all the nodes of the Force-1-Gadget attached to b can be assigned as suggested in Lemma 4.2. It is left to show a possible assignment to the rest of the nodes of ag. We divide into cases. If $v = 0$, then we set $x_1 = 1$ and all other x_i, y_i nodes we set to 0. If $v = 1$, then we set $x_i = y_i = 1$ for all $1 \leq i \leq m + 1$. One may verify that given these assignments all nodes of ag play their best response. ◀

Given these two gadgets, we are almost ready to prove Theorem 4.1. We now introduce a useful definition, and then proceed to the proof of the theorem.

▶ **Definition 4.4.** *Let T and T' be two BRPs. We say that T' is shifted left by t from T if*

$$\forall k \geq 0 \;\; T'[k] = T[k + t].$$

Proof. (Theorem 4.1) Denote by T' the pattern which is shifted left by 1 from T, i.e.:

$$\forall k \geq 0 \;\; T'[k] = T[k + 1].$$

Notice that T' is non-monotonic, finite, and begins with 0, and therefore NTPNE(T') is NP-complete according to Theorem 4 in [3], which allows us to construct a Turing reduction from it. The technique of the reduction is very similar to those of the proofs of Theorems 5 and 6 in [3]. Given any graph $G = (V, E)$, where $V = v_1, ..., v_n$, we construct n graphs $G_1, ..., G_n$, where for each $1 \leq i \leq n$ the graph G_i is defined as follows. The graph G_i contains the original input graph G, and in addition, we connect a unique Add-1-Gadget to each of the original nodes, and a Force-1-Gadget only to node v_i. If there exists some non-trivial PNE in the PGG defined on G by T', let v_j be some node who plays 1. Then the same NTPNE is also an NTPNE in the PGG defined by T on G_j, when we assign the nodes of the additional gadget as suggested in Lemmas 4.2 and 4.3. To see why, notice that T' is shifted left by 1 from T, and the Add-1-Gadgets ensure that all nodes have exactly one additional productive neighbor than they had in G.

In the other direction, if there exists an NTPNE in a PGG defined by T on one of the graphs G_j, then by the same logic this is also a PNE in the game defined by T' on G (ignoring the assignments of the added nodes). Moreover, the Force-1-Gadget ensures this assignment is non-trivial even after removing the added nodes, since v_j must play 1 in this assignment. ◀

4.2 All Semi-Sharp Patterns

In this section we show that any finite, non-monotone, semi-sharp pattern presents a hard equilibrium problem.

▶ **Theorem 4.5.** *Let T_1 be a finite, non-monotone, semi-sharp BRP. Then NTPNE(T_1) is NP-complete under Turing reduction.*

Before proceeding to the proof, we wish to introduce the following definition and prove two lemmas related to it.

▶ **Definition 4.6.** *Let T and T' be two BRPs such that $\forall k \in \mathbb{N}$ it holds that $T[k] = T'[2k]$. Then we say that T' is a double-pattern of T, and T is the half-pattern of T'. Notice that a pattern has a unique half-pattern, whereas, since the definition does not restrict T' in the odd indices, any pattern has infinite double-patterns.*

The first lemma is very simple and intuitive, stating that the largest index with value 1 in a half pattern is strictly smaller than the largest index with value 1 in its original pattern. This is true since for any index i s.t. the value of the half pattern is 1 in that index, the original pattern has a value of 1 in index $2i$.

▶ **Lemma 4.7.** *Let T and T' be two finite BRPs such that T is the half-pattern of T'. Denote by i the largest index s.t. $T[i] = 1$ and denote by j the largest index s.t. $T'[j] = 1$. Then if $j > 0$ we have that $i < j$.*

Proof. The proof is trivially given by the definition of a half pattern, since $T'[2i] = T[i]$. ◀

The next lemma is less trivial, stating the relation between hardness of a pattern and its double-pattern.

▶ **Lemma 4.8.** *Let T be a BRP such that NTPNE(T) is NP-complete, and let T' be a double-pattern of T. Then NTPNE(T') is NP-complete.*

Proof. We use a specific case of the same reduction that was used to prove Theorem 4 in [3]. Given a graph $G_1 = (V_1, E_1)$ as input, where $V_1 = v_1^1, ..., v_n^1$, we create another replica of it $G_2 = (V_2, E_2)$, where $V_2 = v_1^2, ..., v_n^2$. For each node (from both graphs), we add edges connecting it to all replicas of its neighbors from the opposite graph. That is, the following group of edges is added to the graph:

$$E = \{\{v_i^1, v_j^2\} | \{v_i^1, v_j^1\} \in E_1\}.$$

A demonstration of the reduction can be seen in Figure 10.

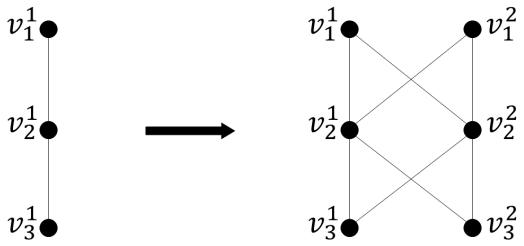

Figure 10 Example of the reduction of Lemma 4.8's proof.

Denote by P the PGG defined on G_1 by T, and by P' the PGG defined by T' on $G' = (V', E')$ where $V' = V_1 \cup V_2$, $E' = E \cup E_1 \cup E_2$. We show that there exists an NTPNE in P iff there exists one in P'. If there exists an NTPNE in P, we simply give the nodes of G_2 the same assignment as those of G_1. Since T' is a double pattern of T, any node $v' \in V'$ must play best response, having exactly twice as many supporting neighbors than it had (or its replica had) in P. In addition, this assignment is clearly non-trivial as the nodes of G_1 have the same (non-trivial) assignment they had in P.

In the opposite direction, if there exists an NTPNE in P', notice that for all $1 \leq i \leq n$ it must be that v_i^1 and v_i^2 have identical assignments, since they both share exactly the same neighbors, and thus have identical best responses. Therefore, any node $v' \in V$ must have an even number of productive neighbors, half of which are in V_1 and the other half in V_2 (as for each productive neighbor from V_1 there is a respective productive neighbor from V_2). We then simply ignore G_2, and leave the assignment of G_1 as it is, and each node shall now have exactly half as many productive neighbors as it had in the original assignment. Since T is a half pattern of T', we get a PNE in P. Furthermore, the symmetry between matching nodes from G_1 and G_2 ensures that at least one node from G_1 was originally assigned 1, and so the constructed PNE in P' is also non-trivial. ◀

Given Lemmas 4.7 and 4.8, we are now able to prove Theorem 4.5. The intuitive idea of the proof is that we halve the pattern T_1 (i.e. find its half-pattern) repeatedly, until eventually we reach some pattern for which we already know the equilibrium problem is hard, which, as we will see, must happen at some point. Then, by applying Lemma 4.8 recursively, we have that T_1 is hard.

Proof of Theorem 4.5. From Lemma 4.7 we have that if we halve a pattern beginning with 1 enough times, we will eventually reach the Best-Shot pattern: $T_{Best\text{-}Shot}[0] = 1$ and $\forall k \geq 1 \;\; T_{Best\text{-}Shot}[k] = 0$. Divide into two cases.

In the first case assume that $\forall k \in \mathbb{N}$ it holds that $T_1[2^k] = 0$. In this case, we know that no matter how many times we halve T_1 into patterns $T_2, T_3, ...$, the value in index 1 of all these half-patterns will always be 0, i.e. $T_i[1] = 0$ for all i. Assume that we halve T_1 repeatedly into patterns $T_2, T_3, ..., T_m$ (where T_i is the half pattern of T_{i-1}) such that T_m is the first time that we reach the Best-Shot pattern. Observe T_{m-1}. For any *even* index $k \neq 0$ it must hold that $T_{m-1}[k] = 0$, otherwise T_m would not be the Best-Shot pattern. Additionally, there must exist at least one *odd* index j s.t. $T_{m-1}[j] = 1$, since T_m is the *first* time we reach the Best-Shot pattern. For these two reasons, we have that T_{m-1} satisfies the conditions of Theorem 4.1 and therefore NTPNE(T_{m-1}) is NP-complete under Turing reduction. From Lemma 4.8 (used inductively), we have that $\forall 1 \leq i \leq m-2$ NTPNE(T_i) is also NP-complete under Turing reduction, and specifically NTPNE(T_1).

In the second case, assume that there exists some $k \in \mathbb{N}$ s.t. $T_1[2^k] = 1$. In that case, after at most k halvings, we reach some pattern for which the value of index 1 is 1. Assume that we halve T_1 repeatedly into patterns $T_2, T_3, ..., T_n$ (where T_i is the half pattern of T_{i-1}) such that T_n is the first time that we reach a pattern for which index 1 is 1, i.e. $\forall 1 \leq i \leq n-1 \;\; T_i[1] = 0$ and $T_n[1] = 1$. Notice that, additionally, by definition of a half-pattern for each i it holds that $T_i[0] = 1$ (since $T_1[0] = 1$). If T_n is non-monotone, then by Theorem 5 in [3] we have that NTPNE(T_n) is NP-complete under Turing reduction, and from Lemma 4.8 (used inductively), we have that $\forall 1 \leq i \leq n-1$ NTPNE(T_i) is also NP-complete under Turing reduction, and specifically NTPNE(T_1). Otherwise (i.e. T_n is monotone), denote by l the largest index s.t. $T_n[l] = 1$, and observe T_{n-1}. By definition of double-patterns, we have that:

$$\forall j \in \mathbb{N} \;\; T_{n-1}[2j] = \begin{cases} 1 & \text{if } j \leq l \\ 0 & \text{otherwise} \end{cases}$$

i.e. the value in the even indices up to $2l$ is 1, and afterwards 0. Since T_n is defined to be the first halving of T_1 s.t. its value in index 1 is 1, we have that $T_{n-1}[1] = 0$. However, since the definition of a double-pattern does not restrict its values in odd indices, there might be odd indices (strictly larger than 1) for which the value of T_{n-1} is 1. Divide into 3 sub-cases:

Sub-case 1: If there exists some $z \leq l$ s.t. $T_{n-1}[2z+1] = 1$, then by Lemma 3.11, we have that NTPNE(T_{n-1}) is NP-complete under Turing reduction.

Sub-case 2: Otherwise, if there exists some $z > l$ s.t. $T_{n-1}[2z+1] = 1$, then observe the pattern T'_{n-1}, which we define as the pattern shifted left by $2l$ from T_{n-1} i.e.:

$$\forall j \in \mathbb{N} \;\; T'_{n-1}[j] = T_{n-1}[j + 2l]$$

Notice that this pattern satisfies the conditions of Theorem 4.1, and therefore NTPNE(T'_{n-1}) is NP-complete under Turing reduction. Then, by applying Theorem 7 from [3] l times, we have that NTPNE(T_{n-1}) is also NP-complete under Turing reduction.

Sub-case 3: Otherwise (i.e. there is no odd index whatsoever in which the value of T_{n-1} is 1), then by Corollary 3.10 we have that NTPNE(T_{n-1}) is NP-complete under Turing reduction.

And so, in either case we have that NTPNE(T_{n-1}) is NP-complete under Turing reduction, and therefore from Lemma 4.8 (used inductively), we have that $\forall 1 \leq i \leq n-1$ NTPNE(T_i) is also NP-complete under Turing reduction, and specifically NTPNE(T_1). ◀

5 Hardness of All Spiked Patterns

There are several finite, spiked patterns that we have not yet proved hardness for, and we now have enough tools to close the remaining gaps. We remind the reader that spiked patterns are patterns that begin with 1,0,1. The following theorem formalizes the result of this section, and completes the characterization of all finite patterns.

▶ **Theorem 5.1.** *Let T be a finite, spiked BRP. Then NTPNE(T) is NP-complete under Turing reduction.*

The intuitive idea of the proof is as follows. If the pattern simply alternates between 1 and 0 a finite amount of times (and at least twice, since the pattern is spiked), followed by infinite 0's, i.e. the pattern is of the form

$$T = [\underbrace{1,0,1,0,1,0,...,1,0}_{finite\ number\ of\ '1{,}0'},0,0,0,...]$$

then the problem[11] is already shown to be hard by Corollary 3.10. Otherwise, we wish to look at the first "disturbance" where this pattern stops alternating from 1 to 0 regularly. Either the first "disturbance" is a 1 at an odd index, i.e. the pattern is of the form

$$T = [\underbrace{1,0,1,0,1,0,...,1,0}_{finite\ number\ of\ '1{,}0'},1,1,?,?,...]$$

or the first "disturbance" is a 0 at an even index, i.e. the pattern is of the form

$$T = [\underbrace{1,0,1,0,1,0,...,1,0}_{finite\ number\ of\ '1{,}0'},0,?,?,...,1,?,?,...]$$

(in the latter option, after the first "disturbance" there must be some other index with value 1, since otherwise the pattern fits the form of Corollary 3.10). The first option was solved in Lemma 3.11, and the second option can be solved using our previous results, as we shall now formalize in the proof.

Proof of Theorem 4.5. If T satisfies the conditions of Corollary 3.10 or Lemma 3.11 then NTPNE(T) is NP-complete under Turing reduction according to them. Otherwise, let k be the smallest integer such that $T[2k] = 0$. Denote by T' the pattern which is shifted left by $2k-2$ from T, i.e.:

$$\forall j \geq 0 \;\; T'[j] = T[j + 2k - 2]$$

[11] In fact, Corollary 3.10 gives a more general result, but we currently only need the special case where the pattern ends with infinite 0's.

Notice that from definition of k (being the first even index such that $T[2k] = 0$) we have that for all $j < k$ it holds that $T[2j] = 1$. Moreover, since T does not satisfy the conditions of Lemma 3.11 it must hold for all $j \leq k$ that $T[2j-1] = 0$, i.e. the value of T in the odd indices until $2k$ is 0 (since otherwise T would start with a finite number of 1,0, followed by two consecutive 1's, and would satisfy the conditions of Lemma 3.11). Thus, we have that

$$\forall j < 2k \;\; T[j] = \begin{cases} 1 \text{ if } j \text{ is even} \\ 0 \text{ if } j \text{ is odd} \end{cases} \tag{1}$$

In particular, we have that $T[2k-2] = 1,\ T[2k-1] = 0$, which implies that $T'[0] = 1,\ T'[1] = 0$; as $T[2k] = 0$ we have that $T'[2] = 0$, and thus we conclude that T' is semi-sharp. In addition, since T does not satisfy the conditions of Corollary 3.10, there must be some other index $x > 2k$ such that $T[x] = 1$, and therefore we have that T' is non-monotone. Therefore, by Theorems 4.1 and 4.5, we have that NTPNE(T') is NP-complete under Turing reduction. We now wish to use this in order to prove that NTPNE(T) is also hard.

From Equation 1, we can apply Theorem 7 of [3] $(k-1)$ times (we remind the reader that this theorem states that prefixing a hard pattern with $1, 0$ maintains its hardness), and we have that NTPNE(T) is NP-complete under Turing reduction. ◀

Linear Relaxed Locally Decodable and Correctable Codes Do Not Need Adaptivity and Two-Sided Error

Guy Goldberg
Weizmann Institute of Science, Rehovot, Israel

Abstract

Relaxed locally decodable codes (RLDCs) are error-correcting codes in which individual bits of the message can be recovered by querying only a few bits from a noisy codeword. For uncorrupted codewords, and for every bit, the decoder must decode the bit correctly with high probability. However, for a noisy codeword, a relaxed local decoder is allowed to output a "rejection" symbol, indicating that the decoding failed.

We study the power of adaptivity and two-sided error for RLDCs. Our main result is that if the underlying code is linear, *adaptivity and two-sided error do not give any power to relaxed local decoding.* We construct a reduction from adaptive, two-sided error relaxed local decoders to non-adaptive, one-sided error ones. That is, the reduction produces a relaxed local decoder that never errs or rejects if its input is a valid codeword and makes queries based on its internal randomness (and the requested index to decode), independently of the input.

The reduction essentially maintains the query complexity, requiring at most one additional query. For any input, the decoder's error probability increases at most two-fold. Furthermore, assuming the underlying code is in systematic form, where the original message is embedded as the first bits of its encoding, the reduction also conserves both the code itself and its rate and distance properties

We base the reduction on our new notion of *additive* promise problems. A promise problem is additive if the sum of any two YES-instances is a YES-instance and the sum of any NO-instance and a YES-instance is a NO-instance. This novel framework captures both linear RLDCs and property testing (of linear properties), despite their significant differences.

We prove that in general, algorithms for *any* additive promise problem do not gain power from adaptivity or two-sided error, and obtain the result for RLDCs as a special case. The result also holds for relaxed locally *correctable* codes (RLCCs), where a *codeword* bit should be recovered.

As an application, we improve the best known lower bound for linear adaptive RLDCs. Specifically, we prove that such codes require block length of $n \geq k^{1+\Omega(1/q^2)}$, where k denotes the message length and q denotes the number of queries.

1 Introduction

Suppose you receive a binary string (a "message"), and would like to know the value of the message at some index i. How many queries do you need to make? The answer is obviously 1, as you can query index i and get the value. But what if some of the message bits are corrupted, because they were, say, transmitted over a noisy channel? The bit at the needed index i might have been corrupted.

Error-correcting codes might help. Such codes allow encoding the message with extra redundancy as a codeword, and the original message can be recovered even if some bits of the codeword were corrupted. However, one needs to read the entire codeword to recover the original message. As our goal was to read only one bit from the message, this solution seems inefficient.

Locally decodable codes (LDCs), introduced by Katz and Trevisan [17], are aimed at solving this problem. These codes are equipped with a local decoding algorithm ("decoder") that recovers each message bit by querying a few bits from a codeword, instead of reading all of it. Two main measures of efficiency for LDCs are the query complexity of the decoder (which we want to be as small as possible) and the rate of the code (which we want to be high). A similar notion, originated in works on program checking by Blum and Kannan [5] and Lipton [21], is of locally *correctable* codes (LCCs). These are error-correcting codes that admit a local algorithm (now called "corrector") that not only recovers each message bit, but is also required to correct any bit from the *codeword*.

LDCs and LCCs have profoundly impacted theoretical computer science and found numerous applications. Despite the extensive research, current constructions require adding a large amount of redundancy. Motivated by this, Ben-Sasson et. al. [3] introduced Relaxed Locally Decodable Codes (RLDCs). For uncorrupted codewords, and for every bit, a relaxed local decoder still must correctly decode the bit with high probability. However, for a noisy codeword, it is now allowed to output a "rejection" symbol, indicating that the decoding failed. This relaxation allows constructing codes with a dramatically better tradeoff between query complexity and rate. Such codes have found various applications, notably in the construction of proof systems (e.g., [22]) and within the area of property testing (e.g., [11]).

More formally, a relaxed local decoder of radius $\rho > 0$ for a code C with soundness error $\epsilon_{\text{soundness}}$ and completeness error $\epsilon_{\text{completeness}}$ is a procedure that gets oracle access to $w \in \{0,1\}^n$, that is ρ-close[1] to some codeword $c = C(x)$ and an index i, and satisfies the following two requirements:

1. (completeness) If w is a valid codeword (that is, $w = c$) then for every i the relaxed local decoder outputs x_i with probability at least $1 - \epsilon_{\text{completeness}}$.
2. (relaxed local decoding) Otherwise, with probability at least $1 - \epsilon_{\text{soundness}}$, the relaxed local decoder outputs x_i or a "reject" symbol $\perp$, indicating the decoding failed.

We call n the *block length* of the code, and the length of x the *message length*.

Gur, Ramnarayan, and Rothblum [14] considered an analogous relaxation for local *correction*, where the corrector either recovers the desired codeword bit, or rejects in case it detects a corruption. They named such codes Relaxed Locally *Correctable* Codes, or RLCCs (see Definition 7).

In this work, we study the power of adaptivity and two-sided error of linear RLDCs and RLCCs. We say that a local algorithm is *adaptive* if it is allowed to choose its queries according to answers of previous queries, and that it is *non-adaptive* otherwise (i.e, if it

[1] Two strings are ρ-close to each other if the normalized Hamming distance between them is at most ρ.

determines its queries based only on its internal coin tosses). Though adaptive algorithms are syntactically stronger than non-adaptive ones, all known constructions of RLDCs and RLCCs are non-adaptive (e.g. [3, 15, 2, 7, 20, 8]). This raises the question of whether it is possible to cleverly utilize adaptivity in order to make improved constructions.

Adaptivity also plays a central role in the study of lower bounds. A common strategy for establishing these bounds is to first address the easier case of non-adaptive RLDCs. Then, the lower bound for adaptive RLDCs is derived by using a generic reduction from adaptive decoders to non-adaptive ones. Alas, known reductions cause an exponential blow-up in the query complexity (or a similar blow-up in the soundness error), resulting in worse lower bounds for adaptive RLDCs [13, 10].

A main question in the study of probabilistic algorithms concerns the strength of two-sided error algorithms vs. one-sided ones. We say that an algorithm has a one-sided error if it never errs on "YES" instances, and a two-sided error if it is allowed to err on "both sides". A major open problem in computational complexity is whether $\mathcal{BPP} = \mathcal{RP}$, which asks whether, in general, an algorithm allowed two-sided error possesses more computational power than one restricted to have a one-sided error. In the standard definition of RLDCs, the decoder can err with a small probability, even when its input is a valid codeword. That is, it is allowed to have two-sided error. In this work, we ask the equivalent $\mathcal{BPP} = \mathcal{RP}$ question for RLCCs: Are one-sided error relaxed local decoders weaker than two-sided error ones? Can we transform any two-sided error decoder, eliminate its errors on valid codewords, to become a one-sided error decoder?

1.1 Our results

Our main result is that for linear codes, two-sided error and adaptivity do not give any strength to RLDCs and RLCCs.

We show a reduction that starts with a relaxed local decoder (resp., corrector) that might query adaptively and err on valid codewords, and ends with a relaxed local decoder (resp., corrector) for the same code, that is non-adaptive and never errs or rejects on valid codewords. The reduction adds at most one additional query. The new soundness error is the sum of the completeness error and soundness error of the original algorithm. Hence the gap between completeness and soundness stays the same. In particular, the error probability, which is the probability to err on *any* specific input (i.e, $\max(\epsilon_{\text{completeness}}, \epsilon_{\text{soundness}})$) is at most doubled.

▶ **Theorem 1.** *Let C be a* linear *systematic*[2] *code.*

If C has a relaxed local decoder of radius ρ with completeness error $\epsilon_{completeness}$, soundness error $\epsilon_{soundness}$ and query complexity q, then it has a one-sided error, non-adaptive *decoder of radius ρ, with soundness error $\epsilon_{completeness} + \epsilon_{soundness}$ and query complexity $q + 1$.*

▶ **Theorem 2.** *Let C be a* linear *code.*

If C has a relaxed local corrector of radius ρ with completeness error $\epsilon_{completeness}$, soundness error $\epsilon_{soundness}$ and query complexity q, then it has a one-sided error, non-adaptive *corrector of radius ρ, with soundness error $\epsilon_{completeness} + \epsilon_{soundness}$ and query complexity $q + 1$.*

[2] A code is called *systematic* if the entire original message is embedded as the first bits of its encoding.

Improved lower bound

Building upon the work of Gur and Lachish [13], Goldreich [10] established lower bounds on the achievable rate by an RLDC with a constant query complexity q. Specifically, the lower bounds are $n \geq k^{1+\Omega(1/q^2)}$ for the non-adaptive case and $n \geq k^{1+\Omega(1/q^3)}$ for adaptive RLDCs. By utilizing Theorem 1, we can remove the adaptivity restriction from the tighter lower bound (for linear codes), leading to the following result:

▶ **Theorem 3.** *Let C be a linear RLDC with message length k, block length n, constant query complexity q and constant correction radius and error probability.*

Then $n \geq k^{1+\Omega(1/q^2)}$.

This represents an improvement over the current state-of-the-art lower bound by Dall'Agnol, Gur and Lachish [9], which is $n \geq k^{1+\Omega(\frac{1}{q^2 \log^2 q})}$ (although it holds for non-linear codes as well).

Linearity

Our reduction only works for linear codes. Nevertheless, linear codes are an important type of error-correcting codes and have been extensively studied. Virtually all known RLDCs and RLCCs (and their non-relaxed counterparts) constructions are of linear codes.[3]

Non-systematic codes

In Theorem 1, it is assumed that the code is in a systematic form. This is a technical detail, not an inherent limitation. Any RLDC can be transformed to be systematic by adding the message bits to the beginning of its encoding. This transformation results in, at most, a doubling of the block length of the code and a corresponding reduction in the decoding radius by the same factor. Consequently, if the code's rate and decoding radius were initially constant, they remain unchanged after this transformation. In addition, this transformation enables the elimination of the systematic requirement in Theorem 3.

It is worth noting that any linear code can be made systematic through a basis change without altering its block length. While such a transformation does not affect the set of valid codewords, it does alter the encoding function. For RLDCs, this implies that the code's decoder may no longer be valid after the transformation.

Known reductions

We note two well-known immediate reductions from adaptive to non-adaptive local algorithms. These reductions date back to [17], which stated them for non-relaxed LDCs, but they also apply to relaxed ones.

The first reduction is to replace each of the q adaptive queries with multiple non-adaptive ones. We replace the i-th query with 2^{i-1} queries, one for each possible result of the previous queries. This reduction yields an exponential blowup in the query complexity. The second reduction is to "guess" the result of the first $q-1$ queries, and query a set of indices based on that guess. This reduction exponentially decreases the algorithm's soundness.

[3] A remarkable exception is multiplicity codes, which are not linear. Fortunately, their codewords constitute a subgroup (the sum of two codewords is a codeword), so our framework still covers them. See Definition 4.

In light of the above, even a reduction with a polynomial blowup in the query complexity would have been an exciting result.

Our contribution

Ben-Sasson, Harsh and, Raskhodnikov [4] showed that for testing *linear* properties, adaptivity and two-sided error do not help. Our work is based on [4], and extends their reductions to the setting of RLDCs and RLCCs.

One technical difficulty in extending their work is that decoders and correctors get an index as an input, in addition to the noisy codeword. This difficulty turns out to be minor. The major difficulty is regarding the actual task at hand. First, testers work under the promise that the input either has the property, or is *far* from any element having it. In contrast, decoders and correctors work under the promise that the input is *close* to the code (or in it). Furthermore, the "output type" is different between those algorithms. On the one hand, a tester has a binary verdict - it accepts or rejects the input. On the other hand, the output of decoders and correctors is not binary - it is a symbol of the message, or a rejection symbol.

To overcome those differences, we introduce the abstract notion of *additive promise problem* (Definition 4). We show that testing linear properties and relaxed decoding/correction of linear codes satisfy this notion.

We then present a reduction that applies to *any* promise problem satisfying this notion. The reduction is a generalization of the one in [4]. The generalization is done by decoupling the logic of the reduction from the testing context. We prove the main results by combining the interpretation of relaxed decoding/correction as promise problems with the generic reduction. Arguably, the generalized reduction also provides a cleaner and more straightforward presentation of [4].

We consider the main contribution of this work to be conceptual. By formalizing the notion of additive promise problem, we demonstrate what is the minimal set of requirements necessary for the techniques of [4] to be applicable. We believe the new notion is natural and intuitive, and hope it will find more applications in the future.

1.2 Motivation

The primary motivation for this work is to enhance our understanding of RLDCs and RLCCs. Additionally, we outline specific motivations as follows.

Applications for lower bounds

Our results show that, for linear codes, any lower bound for non-adaptive, one-sided error RLDCs (resp., RLCCs) can be translated to a lower bound for adaptive, two-sided error RLDCs (resp., RLCCs). Applying this outcome to the work of [10] yields Theorem 3, which is the current best lower bound for linear, adaptive, two-sided error RLDCs. However, this bound is not known to be tight; specifically, the best RLCC construction with constant query complexity q, of Asadi and Shinkar [2], achieves block length $n = k^{1+O(1/q)}$. As our reduction is applicable to any RLCC, it holds potential for accommodating future improvements in lower bounds

In addition, in the case of linear codes, any lower bound applicable to RLDCs also serves as a lower bound for RLCCs, but the reverse is not true. This arises from the fact that every linear code can be represented systematically, with the initial bits of the codeword corresponding to the original message. Hence, for such codes, the corrector can be used as a

decoder, so RLCCs are stronger objects than RLDCs. Our reduction operates independently on each type, implying its potential application for improved lower bounds on RLCCs, which may surpass those for RLDCs.

We note that the work of [9] extends the result of [13] to adaptive, two-sided error RLDCs, for all codes, including non-linear ones. However, this extension does not rely on a generic reduction and is notably highly involved. In contrast, our reduction is arguably much simpler, offering an alternative, simpler proof for linear codes.

Constructions

Virtually all known constructions of RLDCs and RLCCs are non-adaptive, linear, and have one-sided error. Our results show that this should not be a surprise. It is impossible to use adaptivity or two-sided error to improve constructions of linear RLDCs / RLCCs.

Definitions

In some works (e.g, [6, 15, 2, 7]), the definition of RLDC requires it to have one-sided error (i.e., it is not an additional property that a decoder might have). Other works (e.g., [3, 9]) use the same definition we gave above. Our result settles this nuance in the definitions - both are equivalent (for linear codes).

1.3 Technical overview

We next give a high-level sketch of the reduction.

Promise problems

We prove Theorem 1 and Theorem 2 by proving a general result on a family of promise problems. First, a promise problem is a pair of disjoint sets, Y (the YES-instances) and N (the NO-instances). A randomized algorithm for a promise problem gets as input $x \in Y \cup N$ (we sometimes call $Y \cup N$ "the promise") and outputs YES or NO. If $x \in Y$ then the algorithm must output YES with high probability. Similarly, if $x \in N$ it must output NO with high probability.

The main new idea we introduce in this work is of *additive* promise problems.

▶ **Definition 4.** *A promise problem* $(Y, N) \subseteq \{0,1\}^n$ *is* additive *if it satisfies the following conditions:*

1. *(YES-instances are a linear subspace*[4]*) For every* $x, y \in Y$, $x + y \in Y$
2. *(NO-instances are a collection of cosets) For every* $x \in N, y \in Y$, $x + y \in N$

This definition can be generalized to any abelian group instead of $\{0,1\}^n$. For simplicity, in this work we focus on $\{0,1\}^n$.

Testing linear properties

As a demonstration for the new definition, we next show that property testing, when the tested property $\Pi \subseteq \{0,1\}^n$ is a linear subspace, is an additive promise problem. The YES-instances in this case are the elements of the tested property. That is, $Y = \Pi$. The NO-instances are the elements ϵ-far from every YES-instances. Namely,

[4] Strictly speaking, the requirement is that the YES-instances are a *subgroup*. For $\{0,1\}^n$ these requirements are equivalent.

$$N = \{x \in \{0,1\}^n \mid \forall y \in Y,\ \mathrm{dist}(x,y) > \epsilon\}$$

where $\mathrm{dist}(x,y)$ is the relative Hamming distance between x and y, (i.e., $\mathrm{dist}(x,y) = \frac{|\{x_i \neq y_i | i \in [n]\}|}{n}$).

The first item of Definition 4 follows from the assumptions that the property Π is linear. For the second item, let $x \in N, y \in Y$. We need to show that $x + y \in N$. I.e, that $x + y$ is ϵ-far from every $y' \in Y$. Indeed, for every $y' \in Y$ we have

$$\mathrm{dist}(x + y, y') = \mathrm{dist}(x, y' - y) > \epsilon.$$

The equality holds because in general, $\mathrm{dist}(a,b) = \mathrm{dist}(a + c, b + c)$ for every a, b, c. The inequality holds because, since y and y' are in the linear space Y then $y' - y \in Y$, and since $x \in N$ it is ϵ-far from every element in Y.

In Section 3, we show how to interpret relaxed decoding and correction of linear codes as promise problems. This step might result in performing one additional query. We use similar arguments as in the proof above to show that the resulting promise problems are additive.

The reduction

Next, we construct a reduction from adaptive, two-sided error local algorithms to non-adaptive, one-sided error ones that works for *any* additive promise problem.

▶ **Theorem 5.** *Let $(Y, N) \subseteq \{0,1\}^n$ be an additive promise problem. If (Y, N) has an adaptive algorithm A with completeness error ϵ_Y, soundness error ϵ_N and query complexity q, it has a non-adaptive, one-sided error algorithm A' with soundness error $\epsilon_Y + \epsilon_N$ and query complexity q.*

By applying Theorem 5 to relaxed decoding we prove Theorem 1, and by applying it to relaxed correction we prove Theorem 2.

The reduction works in two steps. The first step ensures that the algorithm never errs on YES-instances. We start with an adaptive, two-sided error arbitrary algorithm, and transform it to have one-sided error (and it remains adaptive). This step does not increase the query complexity. If the original algorithm errs on YES-instances with probability at most ϵ_Y and on NO-instances with probability at most ϵ_N, then the transformed algorithm errs on NO-instances with probability at most $\epsilon_Y + \epsilon_N$.

The second step handles adaptivity. We start with an adaptive, one-sided error algorithm, and transform it to a non-adaptive algorithm (that still has one-sided error). This step maintains the query complexity and the soundness error.

We next describe the two reductions.

Two-sided to one-sided error

Every randomized algorithm A can be described as a distribution over a set of deterministic decision trees. Each leaf of each decision tree is labeled with YES or NO, which is the output of the algorithm when that tree is chosen. The first step of the reduction is to *relabel* the leaves of all trees, in the following way: If there is an input $x \in Y$ that "leads" to this leaf, then it is relabeled to YES. This step is necessary to get a one-sided error algorithm. However, this transformation may not maintain the algorithm's soundness. In Section 4.1, we explain the issue in detail.

The solution is to modify the algorithm. Instead of using the (relabeled) decision trees of A with the given input x, choose a random YES-instance y, and use the tree as if the input was $x + y$. Since (Y, N) is an additive promise problem, if $x \in Y$ then $x + y \in Y$ for any (randomly chosen) y, and the original algorithm's completeness can be used. Similarly, if $x \in N$ then $x + y \in N$ for any y, and the soundness of the original algorithm can be used. In Lemma 16, we prove that with this modification the transformation maintains the sum of soundness and completeness error.

Adaptivity

Consider an adaptive, one-sided error algorithm A. Without loss of generality, the only freedom A has is in choosing its queries. Once it queried an input x, it must output YES if there exists a YES-instance consistent with the queries. Otherwise, when no YES-instance is consistent, then x cannot be a YES-instance and w.l.o.g A outputs NO.

The new non-adaptive algorithm A' works as follows: On input x, choose a random YES-instance y. Query x on all indices A would have queried y, and output YES if the partial view of x is consistent with some YES-instance (which might be different than y).

The new algorithm is non-adaptive since now it determines its queries independently of its input. Its query complexity is maintained, and it has one-sided error (as it always outputs YES for YES-instances). In Lemma 20, we show that its soundness error is also maintained. This is done by relating the probability A' outputs YES on some specific x to the *average* probability A outputs YES for a random element of the set $x + Y$.

1.4 Related work

Error correcting codes date back to the seminal works of Shannon [23] and Hamming [16]. LDCs, LCCs and their relaxed counterparts have attracted significant attention in recent years. See the works of Yekhanin [26] and Kopparty and Saraf [19] and references within for comprehensive surveys of LDCs, LCCs and their applications.

RLDCs and RLCCs constructions

The constructions of RLDCs and RLCCs can be separated into two regimes of parameters: constant query complexity, and constant rate. In the constant rate regime, the state-of-the-art code is the construction of Cohen and Yankovitz [8]. This construction is of a linear RLCC with rate arbitrarily close to 1, and query complexity $q = (\log n)^{2+o(1)}$. This construction builds upon the result of Kumar and Mon [20], which shows a similar code but with query complexity $q = (\log n)^{O(1)}$.

In the constant query regime, the original work of [3] achieves RLDC with constant query complexity $O(q)$ and block length $n = O(k^{1+1/\sqrt{q}})$. The work of [15] introduced the notion of RLCCs, and constructed such a code with constant query complexity, but with worse block length. Chiesa, Gur, and Shinkar [6] constructed an improved RLCC, matching the block length of [3].

The current state-of-the-art construction is of Asadi and Shinkar [2], which builds upon [15] and [6]. Their construction is of RLCC and RLDC with constant query complexity $O(q)$ and block length $n = O(k^{1+1/q})$. This is the first construction of RLDC, in the constant query complexity regime, with better block length than of [3].

We remark that all the above constructions are linear, non-adaptive, and have one-sided error.

Lower bounds

In recent decades, extensive research has been conducted on lower bounds for (non-relaxed) LDCs in various regimes [17, 18, 24, 25, 1]. Gur and Lachish [13] presented the first lower bound for relaxed LDCs. Such lower bounds are arguably harder to obtain, as RLDCs are weaker objects than LDCs. Specifically, they showed that any non-adaptive RLDC requires a block length of $n \geq k^{1+\Omega(\frac{1}{q^2 \log^2 q})}$. For the adaptive case, they established a lower bound of $n \geq k^{1+\Omega(\frac{1}{2^{2q} \log^2 q})}$, by using the known reduction mentioned above, that causes an exponential blowup in the query complexity.

The result of [13] was extended to additional settings, such as proofs of proximity, property testing and to adaptive settings by Dall'Agnol, Gur and Lachish [9]. Their result extends the lower bound of $n \geq k^{1+\Omega(\frac{1}{q^2 \log^2 q})}$ to *adaptive* RLDCs.

Goldreich [10] surveyed and simplified the work of [13], without employing the new techniques of [9]). He established an improved bound of $n \geq k^{1+\Omega(1/q^2)}$ for the non-adaptive case, and a bound of $n \geq k^{1+\Omega(1/q^3)}$ for the adaptive case (which is weaker than the one presented in [9]).

Locally testable codes and RLDCs

Our work follows the theme of extending ideas from the area of *LTCs* (locally testable codes [12]) to RLDCs. Refer to the full paper for an analysis comparing RLDCs and LTCs, including details about their similarities, distinctions, and relevance to this study.

1.5 Open problems

We conclude this section with a few questions we leave for future research.

Non-linear codes

Our result holds only for linear codes. A natural open problem is to extend the result to non-linear codes, or to show that for non-linear codes, adaptivity and / or two-sided error *do* give more power. Our reduction heavily relies on linearity, so we believe other techniques than the ones used in this paper will be needed.

Adaptivity of LDCs and LCCs

The power of adaptivity for (non-relaxed) LDCs and LCCs is an interesting open problem. As we discuss in Section 3, our framework of additive problems does not seem to cover them. This leaves the question open, even for linear codes. To the best of our knowledge, there are currently no known reductions from adaptive to non-adaptive LDCs, besides the ones described above. Even a reduction that polynomially increases the query complexity, or slightly increases the code's block length, would be an interesting result.

A main open problem is to separate the power of LDCs and that of relaxed LDCs. Constructing an adaptive (linear) LDC might aid in this effort, showing that LDCs and relaxed LDC differ regarding adaptivity.

Efficient reduction

The reduction we propose could potentially incur an exponential cost in terms of time complexity. Addressing the challenge of making the reduction efficient, (i.e., ensuring that the transformed algorithm runs in polynomial time), remains an open problem. See Remark 19 for details.

2 Definitions and preliminaries

Refer to the full paper for basic notations used herein.

2.1 Error correcting codes

Throughout, an error correcting code C with *message length* k and *block length* n is a function $C : \{0,1\}^k \to \{0,1\}^n$. For simplicity, we consider only binary alphabet in this work. We identify a code with its image, i.e, $C \subseteq \{0,1\}^n$.

A code C is *linear* if it is a linear function (or, equivalently, if C as a set is closed under addition).

▶ **Definition 6.** *Let $C : \{0,1\}^k \to \{0,1\}^n$ be an error correcting code. A relaxed* decoder *of radius $\rho > 0$ for C is a randomized procedure A, that gets as inputs oracle access to $x \in \{0,1\}^n$, and explicit input $i \in [k]$, outputs an element of $\{0,1,\perp\}$, and satisfies the following two requirements:*

1. *(completeness) If $x = C(y)$ for some $y \in \{0,1\}^k$ then $A^x(i) = y_i$ with probability at least $1 - \epsilon_{completeness}$.*
2. *(relaxed local decoding) If there exists $y \in \{0,1\}^k$ such that $dist(x, C(y)) < \rho$, then $A^x(i) \in \{y_i, \perp\}$ with probability at least $1 - \epsilon_{soundness}$.*

The probabilities are over the internal randomness of A.

▶ **Definition 7.** *Let $C \subseteq \{0,1\}^n$ be an error correcting code. A relaxed* corrector *of radius $\rho > 0$ for C is a randomized procedure A, that gets as inputs oracle access to $x \in \{0,1\}^n$, and explicit input $i \in [n]$, outputs an element of $\{0,1,\perp\}$, and satisfies the following two requirements:*

1. *(completeness) If $x \in C$ then $A^x(i) = x_i$ with probability at least $1 - \epsilon_{completeness}$.*
2. *(relaxed local correction) If there exists $c \in C$ such that $dist(x, c) < \rho$, then $A^x(i) \in \{c_i, \perp\}$ with probability at least $1 - \epsilon_{soundness}$.*

The probabilities are over the internal randomness of A.

In both definitions we call $\epsilon_{\text{completeness}}$ the *completeness error*, and $\epsilon_{\text{soundness}}$ the *soundness error*.

In what follows we use the term *local algorithm* to refer to an algorithm which is a relaxed local decoder or a relaxed local corrector. A local algorithm has *one-sided error* if its completeness error is 0 (i.e., if it never errs on valid codewords). We say that a local algorithm has *query complexity* $q = q(n)$ if, on input i, and with oracle access to any $x \in \{0,1\}^n$, the corrector makes at most $q(n)$ queries. We say that a local algorithm is *non-adaptive* if it determines all its queries based on its explicit input (namely, the index to decode / correct) and internal coin tosses, independently of the specific x to which it is given oracle access. Otherwise, we say that it is *adaptive*.

For an RLDC, we view its decoder A of a code as a set of k decoders $A_1, \ldots, A_k$, where $A_i(x) = A^x(i)$. We call A_i the *decoders* of C. Similarly, we view the corrector of a RLCC as a set of n correctors, $A_1, \ldots, A_n$, and call them the *correctors* of C. The benefit of this view is that each A_i is now an algorithm that gets a single (implicit) input $x \in \{0,1\}^n$.

2.2 Promise problems

▶ **Definition 8.** *A* Promise Problem *is couple $(Y, N) \subseteq \{0,1\}^n$ such that $Y \cap N = \emptyset$. We call Y the* YES-instances *of the problem, and N the* NO-instances *of the problem.*

▶ **Definition 9.** *An* algorithm for a promise problem $(Y, N) \subseteq \{0,1\}^n$ *with* completeness error $\epsilon_Y > 0$ *and* soundness error $\epsilon_N > 0$ *is a randomized procedure that gets oracle access to an input* $x \in \{0,1\}^n$*, outputs YES or NO, and satisfies the following conditions:*

1. *(completeness) If* $x \in Y$ *then it outputs YES with probability at least* $1 - \epsilon_Y$*.*
2. *(soundness) If* $x \in N$ *then its outputs NO with probability at least* $1 - \epsilon_N$*.*

We define query complexity and adaptivity of promise problem algorithms as they are defined in Definition 7. We say that a promise problem algorithm has *one-sided* error if its completeness error is 0 (i.e., if it never errs on YES-instances).

The main new definition of this work is of additive promise problems. See Definition 4.

3 Relaxed decoding and correction as additive promise problems

In this section, we show how to interpret relaxed decoding and relaxed correction of linear codes as promise problems. We do that in Section 3.1. We then show, in Section 3.2, that the resulting promise problems are additive.

3.1 Interpretation as promise problems

We start by showing how to interpret relaxed correction as a promise problem. There are three possible values for the output of a relaxed local corrector: $0, 1$ or $\perp$.[5] In contrast, an algorithm for a promise problem has only two possible outputs: YES and NO. We must specify how to translate a correction problem (with multiple possible output values) into a yes/no question. The following observation enables us to do that.

▷ Claim 10. If a code has a corrector A, then it has a corrector A' such that for every $x \in \{0,1\}^n$, the output of A' for index i is x_i or $\perp$. A' has the same completeness and soundness errors as A, and it might make one additional query.

Proof. The new corrector A'_i works according to the following rule:

$$A'_i(x) = \begin{cases} A_i(x), & \text{if } A_i(x) \in \{x_i, \perp\} \\ \perp, & \text{otherwise.} \end{cases}$$

From the construction, the output of $A'_i(x)$ is x_i or $\perp$ for every input x (and never $1 - x_i$). A' makes at most one additional query compared to A in order to retrieve the value x_i.

We next show that A'_i satisfies the required completeness and soundness (Definition 7). For completeness, if $x \in C$ then $A_i(x) = x_i$ with probability $1 - \epsilon_{\text{completeness}}$, and hence $A'_i(x) = x_i$ with the same probability.

For soundness, assume there exists $c \in C$ such that $\text{dist}(x, c) < \rho$. We need to show $A'_i(x) \in \{c_i, \perp\}$ with high probability. Consider the case $c_i = x_i$. From the soundness of A_i, $A_i(x) \in \{x_i, \perp\}$ with probability at least $1 - \epsilon_{\text{soundness}}$, and hence $A'_i(x) \in \{x_i, \perp\} = \{c_i, \perp\}$ with the same probability.

Otherwise, $c_i \neq x_i$. With probability at least $1 - \epsilon_{\text{soundness}}$, the output of A_i is c_i or $\perp$. From the construction, whenever the output of A_i is c_i or $\perp$, the output of A'_i is $\perp$. Hence, with the same probability, $A'_i(x) = \perp \in \{c_i, \perp\}$. ◁

By using Claim 10, we can replace item 2 of Definition 7, and assume the corrector always outputs x_i or $\perp$:

[5] For a larger alphabet, the number of possible outputs of a corrector is the size of the alphabet +1.

▶ **Definition 11** (alternative definition of RLCCs). *A relaxed corrector of radius $\rho > 0$ for C is a randomized procedure A, that gets as inputs oracle access to $x \in \{0,1\}^n$, and explicit input $i \in [n]$, outputs x_i or $\perp$, and satisfies the following:*

1. *(completeness) If $x \in C$ then $A^x(i) = x_i$ with probability at least $1 - \epsilon_{completeness}$.*
2. *(soundness) If there exists $c \in C$ such that $dist(x, c) < \rho$ and $x_i \neq c_i$, then $A_i(x) = \perp$ with probability at least $1 - \epsilon_{soundness}$.*

Definition 11 allows us to treat a corrector as having a "binary" output; On input x, the output of A_i is either $x_i \in \{0,1\}$ (signifying "accept") or $\perp$ (signifying "reject"). We can now phrase relaxed correction as a promise problem, as follows[6]:

▶ **Definition 12.** *Let $C \subset \{0,1\}^n$ be an error correcting code, let $\rho > 0$ and let $i \in [n]$. The* promise problem of relaxed correction *of C at index i with correction radius ρ is defined by:*

1. *(YES-instances are the codewords)*
   $Y = C$
2. *(NO-instances are the inputs a corrector rejects)*
   $N = \{x \in \{0,1\}^n \mid \exists c \in C \text{ with } dist(x, c) < \rho \text{ and } x_i \neq c_i\}$.

The promise problem of relaxed correction is equivalent to relaxed correction of codes (of Definition 11) in the following sense:

▷ Claim 13. A corrector for index i of the code C can be translated to an algorithm for the promise problem of relaxed correction of C at index i (Definition 12) by identifying the outputs $0, 1$ as "YES" and the output $\perp$ as "NO". The parameters $\epsilon_{\text{completeness}}, \epsilon_{\text{soundness}}, \rho$ remain the same.

Relaxed decoding

From the hypothesis for RLDCs, the code at hand is in systematic form. That is, we assume that the first k bits of each codeword are the message encoded in it. Hence, a decoder is simply a corrector that needs to "correct" only the first k bits of the input. The observation above (Claim 10) holds for relaxed local decoders as well. Hence, we can assume w.l.o.g that the output of the decoder, for input x and index $i \in [k]$, is either x_i or $\perp$. This allows us to handle RLDCs in a manner similar to RLCCs. For further details, please refer to the full paper."

3.2 Additive promise problems

In this section, we show that the promise problems formulated above for relaxed decoding and relaxed correction, have the special property of being *additive* (Definition 4).

▷ Claim 14. The relaxed correction and relaxed decoding promise problems for linear codes is additive.

We prove the claim for relaxed correction. The proof for relaxed decoding is the same, with the restriction that $i \in [k]$ (instead of in $[n]$).

[6] Another possible formulation is $Y = \{(x, b) \mid x \in C \text{ and } b = x_i\}$ and $N = \{(x, b) \mid \exists c \in C \text{ with } \text{dist}(x, c) < \rho \text{ and } c_i \neq b\}$. This formulation preserves better the decoding "flavor" of the problem. We use the formulation of Definition 11, as it emphasizes the similarity to testing, with $\perp$ corresponding to "reject" and any other output corresponding to "accept".

Proof. Let C be a *linear* error correcting code, let $\rho > 0$ and let $i \in [n]$. Let Y, N be as in Definition 12.

From the linearity assumption $Y = C$ is a linear subspace of $\{0,1\}^n$, and the first item of Definition 4 holds.

To show the second item, let $x \in N, y \in Y$. We need to show that $x + y \in N$. Since $x \in N$, there exists a codeword $c \in C$ such that $\text{dist}(x, c) < \rho$ and $x_i \neq c_i$. Define $c' = c + y$. c' is a codeword in C, since it is a sum of two codewords, and C is a linear code. We get $\text{dist}(x + y, c') = \text{dist}(x + y, c + y) = \text{dist}(x, c) < \rho$, and $(x + y)_i = x_i + y_i \neq c_i + y_i = c'_i$. Hence $x + y \in N$. ◁

Non-relaxed LDCs

We remark that *non-relaxed* decoding / correction (for a specific index) does not seem to fit into our new framework. Refer to the full paper for an in-depth discussion on this topic.

4 The reduction

In this section, we prove our main results, Theorem 1 and Theorem 2.

We prove these theorems by constructing the following, more general reduction:

▶ **Theorem 15** (Restatement of Theorem 5). *Let $(Y, N) \subseteq \{0,1\}^n$ be an additive promise problem. If (Y, N) has an adaptive algorithm A with completeness error ϵ_Y, soundness error ϵ_N and query complexity q, it has a* one-sided error, non-adaptive algorithm *A' with soundness error $\epsilon_Y + \epsilon_N$ and query complexity q.*

Theorem 1 and Theorem 2 are direct corollary of Theorem 15 applied to the relaxed decoding and correcting promise problem.

The proof of Theorem 15 has two steps. The first is a reduction from two-sided error to one-sided error algorithms. We show this reduction in Section 4.1. The second step is a reduction from one-sided, adaptive algorithms to one-sided, non-adaptive algorithms. We show this reduction in Section 4.2.

4.1 From two-sided to one-sided error

In this section, we show a reduction from two-sided error algorithms to one-sided error ones for additive promise problems. The reduction does not change the query complexity of the algorithm, and maintains the sum of the completeness and soundness errors.

▶ **Lemma 16.** *Let $(Y, N) \subseteq \{0,1\}^n$ be an additive promise problem. If (Y, N) has an (adaptive) algorithm A with completeness error ϵ_Y, soundness error ϵ_N and query complexity q, it has an (adaptive) one-sided error algorithm A' with soundness error $\epsilon_Y + \epsilon_N$ and query complexity q.*

Randomized algorithms as distributions over decision trees

Consider some randomized algorithm A for a promise problem. A can be described as a distribution D_A over a set of deterministic decision trees $\Upsilon_A = \{\Gamma_1, \Gamma_2, \ldots\}$. We denote by $\Gamma \sim D_A$ a tree chosen randomly from Υ_A according to the distribution D_A. Each leaf ℓ of each tree corresponds to a set of indices $I = (i_1, \ldots, i_t) \in [n]^t$ that are queried along the path leading to ℓ, and the corresponding values $\sigma = (\sigma_1, \ldots, \sigma_t) \in \{0,1\}^t$ at these indices. We identify each leaf with the corresponding indices and values and write $\ell = (I, \sigma)$.

For an input x, we denote by $\Gamma(x)$ the *leaf* of Γ at the end of the path corresponding to querying x. That is, $\Gamma(x) = \ell$ if $x|_I = \sigma$, where $\ell = (I, \sigma)$, and $x|_I$ is the restriction of x to indices I. Each leaf is labeled with YES or NO.

We can now describe the operation of A on input x as follows: It chooses a $\Gamma \sim D_A$ and outputs the label of $\Gamma(x)$.

Relabeling decision trees

To convert an algorithm A to have one-sided error, we first go over all of $\Gamma \in \Upsilon_A$ and relabel them, so each Γ will have one-sided error. The relabeling works as follows: For every leaf ℓ of Γ, if there exists a YES-instance y such that $\Gamma(y) = \ell$, relabel ℓ with YES. We denote the relabeled tree by Γ_c and call it the *one-sided error relabeling* of Γ.

This step is necessary to get a one-sided error algorithm; as long as there exists $y \in Y$ and Γ such that the label of $\Gamma(y)$ is NO, there is some probability that A outputs NO for a YES-instance. The issue, however, is that this transformation may not maintain the algorithm's soundness. There might be NO-instances that the new algorithm (wrongly) accepts with a high probability.

The soundness issue with relabeling

Pretend the transformed algorithm A' worked as follows. For an input x, choose a random decision tree $\Gamma \sim D_A$, relabel the tree to get Γ_c, and output the label of $\Gamma_c(x)$ (instead of using $\Gamma(x)$ as the original algorithm did). This new algorithm has one-sided error. In fact, we can transform *any* algorithm this way to have one-sided error, so we should not expect it to maintain soundness.

To see that the soundness is not necessarily maintained, consider some leaf ℓ of a tree Γ that was relabeled from NO to YES. Let $x \in \{0,1\}^n$ such that $\Gamma(x) = \ell$. If $x \in Y$, the relabeling was beneficial. Before the relabeling, the algorithm returned a wrong output for x (whenever it used the tree Γ), and now it returns the correct output. However, what if x is a NO-instance? In this case, after the relabeling we return the *wrong* output for x each time Γ is used. The tree Γ is sampled according to the distribution D_A, which is arbitrary. If D_A gives much weight to Γ (say, it is chosen with probability $\frac{1}{2}$), then the new algorithm returns the wrong output for x with high probability.[7] This implies that A' does not have the required soundness property, as it should hold for *every* NO-instance.

The actual reduction

The solution is to modify the algorithm in the following way. Instead of deterministically returning the label of $\Gamma_c(x)$ (after Γ was chosen at random), the transformed algorithm outputs the label of $\Gamma_c(x + y)$ for a random $y \in Y$. We give a formal description of the transformation in Algorithm 1. Now, even if $\Gamma_c(x)$ was relabeled to YES, we output its label with a small probability. In the proof of Lemma 16, we show that the soundness error of the transformed algorithm is at most $\epsilon_Y + \epsilon_N$.[8]

[7] Even if there is no one heavy tree, relabels of many leaves in different trees might have the same effect if their total weight is high.

[8] Recall that ϵ_N is error probability of the original algorithm for NO-instances, and ϵ_Y is its error probability for YES-instances.

Algorithm 1 One-sided error local algorithm, A'.

Input: Oracle access to $x \in \{0,1\}^n$.
Output: YES or NO.

1. Choose $\Gamma \sim D_A$.
2. Choose $y \in Y$ uniformly at random.
3. Output the label of $\Gamma_c(x+y)$.

Query complexity

The relabeling does not change the query complexity (i.e., depth) of the decision trees. Hence, the query complexity of A' is the same as that of A.

One-sided error

Let $x \in Y$. We argue that A' always outputs YES for x. From the definition of A', its output for x is the label of $\Gamma_c(x+y)$ for some $y \in Y$. Since (Y,N) is an additive problem and $x \in Y$, we get that $x+y \in Y$. From the relabeling scheme for Γ_c, the label of $\Gamma_c(y')$ is YES for every $y' \in Y$, and in particular for $y' = x+y$. Hence, the output of A' for x is YES.

Before arguing about the soundness of the transformed algorithm, we need the following preparations.

Probability of hitting a specific leaf

We stated above that for an input x, the modified algorithm uses the label of a specific leaf ℓ with a small probability. We next calculate this probability (conditioning on first choosing the tree Γ_c of ℓ). There are $|Y|$ possible options for y. The leaf ℓ is used if the chosen y satisfies $\Gamma_c(x+y) = \ell$. Hence, we choose the label of ℓ with probability $\frac{|(x+Y)\cap\Gamma^{-1}(\ell)|}{|Y|}$, where $x+Y = \{x+y \mid y \in Y\} \subseteq \{0,1\}^n$, and $\Gamma^{-1}(\ell) = \{z \mid \Gamma(z) = \ell\} \subseteq \{0,1\}^n$. We argue that this probability is either 0 (when there is no $y \in Y$ such that $\Gamma(x+y) = \ell$ so $(x+Y)\cap\Gamma^{-1}(\ell)$ is empty), or is equal to a quantity not depending on x.

▶ **Lemma 17.** *Let $Y \subseteq \{0,1\}^n$ be a subspace of $\{0,1\}^n$, and fix a decision tree Γ and a leaf $\ell = (I,\sigma)$. Define $U = \{u \in Y \mid u|_I = 0\}$. Then for every $x \in \{0,1\}^n$, if there exists $y \in Y$ such that $\Gamma(x+y) = \ell$, then $|(x+Y)\cap\Gamma^{-1}(\ell)| = |U|$.*

Proof. First, notice that U is not empty since the all-zeros string is in Y (as Y is a linear subspace). Furthermore, U is a subspace of Y, since if $u,u' \in U$ then $(u+u')|_I = u|_I + u'|_I = 0$ and $u+u' \in U$. We argue that $(x+Y)\cap\Gamma^{-1}(\ell)$ is a coset of U, hence having the same size as U. Namely, we claim:

$$(x+Y)\cap\Gamma^{-1}(\ell) = x+y+U$$

where y is an element of Y such that $\Gamma(x+y) = \ell$.

We begin by proving the inclusion $(x+Y)\cap\Gamma^{-1}(\ell) \subseteq x+y+U$. Let $x+y' \in (x+Y)\cap\Gamma^{-1}(\ell)$. That is, $(x+y')|_I = \sigma$. Define $u = y'-y$. Since $(x+y)|_I = (x+y')|_I = \sigma$, we have $u|_I = ((x+y')-(x+y))|_I = 0$ and $u \in U$. Therefore $x+y' = x+y+u \in x+y+U$.

To prove that $(x+Y)\cap\Gamma^{-1}(\ell) \supseteq x+y+U$, let $u \in U$. Since $y \in Y$ and $u \in U \subseteq Y$, and Y is closed under addition, we have $y+u \in Y$ and $x+y+u \in x+Y$. Next, $(x+y+u)|_I = (x+y)_I + u|_I = (x+y)_I = \sigma$ and hence $x+y+u \in \Gamma^{-1}(\ell)$. ◀

We are now ready to prove Lemma 16.

Proof of Lemma 16. We proved above that the reduction maintains the query complexity of the algorithm, and that the transformed algorithm has one-sided error. We are left with establishing an upper bound for its soundness error.

Let $x \in N$. We need to show that A' outputs NO for x with probability at least $1-\epsilon_{\mathrm{Y}}-\epsilon_{\mathrm{N}}$. That is, we need to prove $\Pr[A'(x) = \text{ YES }] < \epsilon_{\mathrm{Y}} + \epsilon_{\mathrm{N}}$.

The probability for (wrongly) outputting YES for x may increase due to the transformation. Nevertheless, it does not increase too much. We argue the transformation does not decrease the gap between the expected probability of returning YES for a random element of Y and the expected probability of outputting YES for a random element of $x + Y$. That is, we claim:

▷ Claim 18. For every $x \in N$:

$$\begin{aligned}\mathop{\mathbb{E}}_{y\in Y}[\Pr[A(y) = \mathrm{YES}]] - \mathop{\mathbb{E}}_{y\in Y}[\Pr[A(x+y) = \mathrm{YES}]] \\ \leq \quad \mathop{\mathbb{E}}_{y\in Y}[\Pr[A'(y) = \mathrm{YES}]] - \mathop{\mathbb{E}}_{y\in Y}[\Pr[A'(x+y) = \mathrm{YES}]]\end{aligned}$$

where the probabilities are over the internal randomness of A and A'.

Proof of Claim 18. To prove this claim, it is enough to show that relabeling one leaf ℓ of one decision tree does not decrease the gap. Then we obtain the claim by relabeling one leaf at a time, to get A' from A.

Assume ℓ was relabeled from NO to YES. Let $G := Y \cap \Gamma^{-1}(\ell)$ be the strings $y \in Y$ such that $\Gamma(y) = \ell$ (these are the "Good" strings, which are now labeled YES and are in Y). The set G is not empty since we relabel ℓ only if there exists $y \in Y$ such that $\Gamma(y) = \ell$, i.e. $y \in G$. Let $B := (x + Y) \cap \Gamma^{-1}(\ell)$ be the strings $x + y \in x + Y$ such that $\Gamma(x + y) = \ell$ (these are the "Bad" strings, which are now labeled YES but in $x + Y \subseteq N$).

Every string in $G \cup B$ was rejected before the relabeling but is now accepted. The algorithm's behavior on the other elements in Y and $x+Y$ is unaltered. Hence, $\mathop{\mathbb{E}}_{y\in Y}[\Pr[A(y) = \mathrm{YES}]]$ increases by $D(\Gamma) \cdot \frac{|G|}{|Y|}$ when ℓ is relabeled (recall that $D(\Gamma)$ is the probability the algorithm chooses Γ). Similarly, $\mathop{\mathbb{E}}_{y\in Y}[\Pr[A(x + y) = \mathrm{YES}]]$ increases by $D(\Gamma) \cdot \frac{|B|}{|Y|}$. It suffices to show that $|G| \geq |B|$. Intuitively, this means any "harm" done to x by the relabeling (an element of B that increases the probability to wrongly output YES) is "compensated" by the relabeling (by an element of G improving the algorithm's completeness).

If B is empty, we are done. Otherwise, due to Lemma 17, $|B| = |U|$ and $|G| = |U|$, and we conclude that $|G| = |B|$. ◁

From the claim, the soundness error for x gets worse by an amount bounded by the completeness improvement. Since the completeness error reduces from ϵ_{Y} to 0, the soundness error for x increases by at most ϵ_{Y}.

More formally, from Claim 18, the prefect completeness of A' and the completeness error of A:

$$\begin{aligned}&\mathop{\mathbb{E}}_{y\in Y}[\Pr[A'(x+y) = \mathrm{YES}]] \\ &\quad\leq \quad \mathop{\mathbb{E}}_{y\in Y}[\Pr[A'(y) = \mathrm{YES}]] - \mathop{\mathbb{E}}_{y\in Y}[\Pr[A(y) = \mathrm{YES}]] + \mathop{\mathbb{E}}_{y\in Y}[\Pr[A(x+y) = \mathrm{YES}]] \qquad (1) \\ &\quad\leq \quad 1 - (1-\epsilon_{\mathrm{Y}}) + \mathop{\mathbb{E}}_{y\in Y}[\Pr[A(x+y) = \mathrm{YES}]] = \mathop{\mathbb{E}}_{y\in Y}[\Pr[A(x+y) = \mathrm{YES}]] + \epsilon_{\mathrm{Y}}.\end{aligned}$$

Now, $x + y \in N$ for every $y \in Y$, since $x \in N$ and (Y, N) is additive. Hence, applying the soundness of A to *every* $x + y$, we have $\mathop{\mathbb{E}}_{y \in Y}[\Pr[A(x + y) = \text{ YES }]] < \epsilon_{\mathrm{N}}$.

In addition, from the definition of A', $\Pr[A'(x + y) = \text{YES}] = \Pr[A'(x) = \text{YES}]$ for every $y \in Y$. Hence, from equation 1 we get that $\Pr[A'(x) = \text{YES}] < \epsilon_{\mathrm{Y}} + \epsilon_{\mathrm{N}}$. ◀

▶ Remark 19. As described, the reduction might be expansive in the terms of time complexity. Sampling a YES instance uniformly at random and relabeling the trees can be computationally intensive tasks.

On the positive side, sampling a YES instance can be implemented in polynomial time. The set of YES instances Y forms a subspace, allowing for efficient sampling by taking a random linear combination of elements in a basis of Y. In the context of codes, this is equivalent to encoding a random message using a generating matrix of the code, where the columns of the matrix constitute a basis for the code.

Unfortunately, the relabeling process, even for a single leaf, appears to be computationally hard. Brute-force relabeling involves iterating over a potentially exponentially large set of candidates (all elements of $\{0,1\}^n$ consistent with the leaf) and checking their membership in Y. Checking membership in Y can be preformed efficiently by considering the dual space of Y. However, we do not see a way to eliminate the iteration over an exponential set of candidates, and leave this question for further research.

4.2 From adaptive to non-adaptive algorithms

In this section, we show a reduction from one-sided error adaptive to (one-sided error) non-adaptive algorithms for additive promise problems. The reduction maintains the algorithm's query complexity and its soundness error.

▶ **Lemma 20.** *Let $(Y, N) \subseteq \{0,1\}^n$ be an additive promise problem. If (Y, N) has an* one-sided error, adaptive algorithm *A with soundness error ϵ_N and query complexity q, it has an one-sided error* non-adaptive algorithm *A' with soundness error ϵ_N and query complexity q.*

Proof. Let $D = D_A$ be a distribution over decision trees $\Upsilon = \Upsilon_A$ corresponding to A.

We first observe that we can assume w.l.o.g that the label of each leaf $\ell = (I, \sigma)$ is YES if and only if $\exists y \in Y$ such that $y|_I = \sigma$. Since A never errs on YES-instances, if there exists $y \in Y$ such that $y|_I = \sigma$, then ℓ must be labeled YES. On the other hand, we can assume that if no such $y \in Y$ exists, then ℓ is labeled NO. Otherwise, ℓ can be relabeled from YES to NO while only improving the algorithm's soundness and maintaining its one-sided error.

Description of A'

The new non-adaptive algorithm works as follows. On input x, choose a random $y \in Y$. Query x on all indices A would have queried y, and output YES if the partial view of x is consistent with some $y' \in Y$. We give a formal description of the new algorithm in Algorithm 2.

Analysis

The algorithm A' is non-adaptive, as its queries depend only on its internal randomness (the choice of Γ and y). It has the same query complexity as A, since it uses the same decision trees. The algorithm has one-sided error since if $x \in Y$, we can take $y' = x$ at the last step of the algorithm, and $x|_I = y'|_I$ for every I.

Algorithm 2 Non-adaptive local algorithm, A'.

Input: Oracle access to $x \in \{0,1\}^n$.
Output: YES or NO.

1. Choose $\Gamma \sim D$.
2. Choose $y \in Y$ uniformly at random.
3. Let $\ell = (I, \sigma) = \Gamma(y)$.
4. Query x on the indices I.
5. Output "YES" if $\exists y' \in Y$ such that $x|_I = y'|_I$, and "NO" otherwise.

We are left with proving that the transformation does not decrease the soundness error. Towards this end, we relate the acceptance probability of A' to the *average* acceptance probability of A.

▷ Claim 21. For every $x \in \{0,1\}^n$:

$$\Pr[A'(x) = \text{YES}] = \mathop{\mathbb{E}}_{y \in Y}[\Pr[A(x+y) = \text{YES}]]$$

where the probabilities are over the internal randomness of A and A'.

This claim shows that soundness is maintained. If $x \in N$, then since (Y, N) is additive, $x + y \in N$ for every $y \in Y$. Hence, by using the soundness of A for *every* $x + y$, we get that

$$\Pr[A'(x) = \text{YES}] = \mathop{\mathbb{E}}_{y \in Y}[\Pr[A(x+y) = \text{YES}]] < \epsilon_{\text{N}}$$ ◀

Proof of Claim 21. We begin by calculating $\mathop{\mathbb{E}}_{y \in Y}[\Pr[A(x+y) = \text{YES}]]$. Identifying the output YES with 1, we can take expectation instead of probability. We denote by $\Gamma(Y)$ the set of leaves in Γ labeled YES[9] , and get:

$$\begin{aligned}\mathop{\mathbb{E}}_{y \in Y}[\Pr[A(x+y) = \text{YES}]] &= \mathop{\mathbb{E}}_{y \in Y} \mathop{\mathbb{E}}_{\Gamma \sim D}[A(x+y)] = \mathop{\mathbb{E}}_{\Gamma \sim D} \mathop{\mathbb{E}}_{y \in Y}[A(x+y)] \\ &= \mathop{\mathbb{E}}_{\Gamma \sim D}\left[\frac{1}{|Y|} \cdot \sum_{\ell \in \Gamma(Y)} |(x+Y) \cap \Gamma^{-1}(\ell)|\right] \end{aligned} \tag{2}$$

where in the last equality, we take into account all $y \in Y$ by iterating over each leaf $\ell \in \Gamma(Y)$ (for other leaves the algorithm's output is 0) and counting the number of y values for which $\Gamma(x+y) = \ell$ (i.e., that lead the algorithm to output the label of ℓ).

On the other hand, for any $I \subseteq \{0,1\}^n$ and $x \in \{0,1\}^n$ define:

$$H_I(x) = \begin{cases} 1, & \text{if } \exists y \in Y \text{ such that } x|_I = y|_I \\ 0, & \text{otherwise.} \end{cases}$$

With this notation, the last step of A' can be described as "output $H_I(x)$".

[9] This definition is equivalent to $\Gamma(Y) = \{\Gamma(y) \mid y \in Y\}$ since, as discussed above, a leaf ℓ is labeled YES if and only if there exists $y \in Y$ such that $\Gamma(y) = \ell$.

We get:

$$\Pr[A'(x) = \text{YES}] = \mathbb{E}[A'(x)] = \mathop{\mathbb{E}}_{\Gamma\sim D} \mathop{\mathbb{E}}_{\substack{y\in Y \\ (I,\sigma)\leftarrow\Gamma(y)}} [H_I(x)]$$

$$= \mathop{\mathbb{E}}_{\Gamma\sim D}\left[\frac{1}{|Y|}\cdot \sum_{\ell=(I,\sigma)\in\Gamma(Y)} |Y\cap\Gamma^{-1}(\ell)|\cdot H_I(x)\right] \tag{3}$$

Here it is sufficient to iterate over the leaves in $\Gamma(Y)$: the algorithm A never errs on YES instances, so if ℓ is labeled NO, there cannot be $y \in Y$ such that $\Gamma(y) = \ell$.

From equations 2 and 3 it is enough to show that for every $\ell = (I, \sigma) \in \Gamma(Y)$:

$$|(x + Y) \cap \Gamma^{-1}(\ell)| = |Y \cap \Gamma^{-1}(\ell)| \cdot H_I(x)$$

Since (I, σ) is labeled YES, and as discussed above, there exists $y' \in Y$ such that $y'|_I = \sigma$ and $Y \cap \Gamma^{-1}(\ell)$ is not empty.

Consider the case $H_I(x) = 0$. We claim $(x + Y) \cap \Gamma^{-1}(\ell)$ is empty and hence the equality holds. Assume towards contradiction that this set is not empty. Then there exists $(x + y) \in (x + Y)$ such that $(x + y)|_I = \sigma$. Hence $(x + y)|_I = y'|_I$ and $x|_I = (y' - y)|_I$, which implies $H_I(x) = 1$ (since $y' - y \in Y$).

Next, consider the case $H_I(x) = 1$. We argue that $(x + Y) \cap \Gamma^{-1}(\ell)$ is not empty. $H_I(x) = 1$ implies there exists $y \in Y$ such that $x|_I = y|_I$, and $(x - y)|_I = 0$. Now $(x-y+y')|_I = (x-y)|_I + y'|_I = \sigma$, and hence $x-y+y' \in (x+Y)\cap\Gamma^{-1}(\ell)$ (as $-y+y' \in Y$). Since $(x + Y) \cap \Gamma^{-1}(\ell)$ is not empty, from Lemma 17 we get that $|(x + Y) \cap \Gamma^{-1}(\ell)| = |U|$. The set $Y \cap \Gamma^{-1}(\ell)$ is also not empty, and again from Lemma 17 $|Y \cap \Gamma^{-1}(\ell)| = |U|$. We conclude that $|(x + Y) \cap \Gamma^{-1}(\ell)| = |Y \cap \Gamma^{-1}(\ell)|$. ◁

▶ Remark 22. As in the previous reduction, the adaptive to non-adaptive reduction might be expansive in the terms of time complexity. Similar to before, sampling a YES instance uniformly at random might appear computationally intensive, although it can be implemented in polynomial time without much difficulty.

Unfortunately, determining whether there exists a YES instance consistent with a partial view of the input (step 5 in Algorithm 2) is computationally hard. We currently do not see a feasible way to perform this task efficiently, for reasons similar to those outlined in Remark 19. We leave addressing the efficiency of this reduction as an open problem.

Sharp Noisy Binary Search with Monotonic Probabilities

Abstract

We revisit the noisy binary search model of [10], in which we have n coins with unknown probabilities p_i that we can flip. The coins are sorted by increasing p_i, and we would like to find where the probability crosses (to within ε) of a target value τ. This generalized the fixed-noise model of [2], in which $p_i = \frac{1}{2} \pm \varepsilon$, to a setting where coins near the target may be indistinguishable from it. It was shown in [10] that $\Theta(\frac{1}{\varepsilon^2} \log n)$ samples are necessary and sufficient for this task.

We produce a *practical* algorithm by solving two theoretical challenges: high-probability behavior and sharp constants. We give an algorithm that succeeds with probability $1 - \delta$ from

$$\frac{1}{C_{\tau,\varepsilon}} \cdot \left(\log_2 n + O(\log^{2/3} n \log^{1/3} \frac{1}{\delta} + \log \frac{1}{\delta}) \right)$$

samples, where $C_{\tau,\varepsilon}$ is the optimal such constant achievable. For $\delta > n^{-o(1)}$ this is within $1 + o(1)$ of optimal, and for $\delta \ll 1$ it is the first bound within constant factors of optimal.

1 Introduction

Binary search is one of the most fundamental algorithms in computer science, finding an index $i^* \in [n]$ from $\log_2 n$ queries asking if a given index i is larger than i^*. But what if the queries are noisy?

One model for noisy binary search has each query be incorrect independently with exactly the same probability $\frac{1}{2} - \varepsilon$. In this model, which we call FixedNoiseNBS, a line of work [2, 1, 5, 9] has found a sharp bound for the required expected sample complexity, with tight constants. However, in many applications of noisy binary search the error probability is not fixed, but varies with i: comparing i to i^* is much harder when i is close to i^*.

As one example, consider the problem of estimating the sample complexity of an algorithm such as for distribution testing or noisy binary search itself. Proofs in this space are often sloppy with constant factors, so the proven bound is not reflective of the true performance. If so, we would like to empirically estimate the sample complexity i at which the success

Table 1 Comparison of our result to prior algorithms for MonotonicNBS in the regime of $\varepsilon \ll \min(\tau, 1-\tau)$ and $\delta = 1/n^{o(1)}$, ignoring lower order terms. The analysis in [10] is not careful with constants, so we also include our best estimate of the actual constant after tuning constant factors in the algorithms.

Algorithm	Proven query complexity	Actual constant
Binary Search w/ Repetition	$2\frac{\tau(1-\tau)}{\varepsilon^2}\log n \cdot \log\frac{\log_2 n}{\delta}$	
[10] Multiplicative Weights	$4000\frac{\max(\tau,1-\tau)}{\varepsilon^2}\log n \cdot \log\frac{1}{\delta}$	≈ 31
[10] Backtracking	$476909\frac{\max(\tau,1-\tau)}{\varepsilon^2}\log n \cdot \log\frac{1}{\delta}$	≈ 2000
BayesianScreeningSearch	$2\frac{\tau(1-\tau)}{\varepsilon^2}\log n$	

probability p_i is above a given threshold τ (say, 90%). (In some cases we even know the worst-case distribution [6] so the empirical estimate is of the worst-case performance, not just the distributional performance.) We can run the algorithm at a given sample complexity i and check correctness, getting Success with probability p_i. The success probability is monotonic in i, and we would like to estimate the i^* where p_i crosses τ. Finding i^* exactly may be very hard – the success probability at 10000 and 10001 samples are likely to be almost identical – so we would settle for *some* index with $p_i \approx \tau$.

For a non-computer science example, calculating the LD50 for a substance (the dose needed to kill half of the members of a specific population) is a noisy binary search problem with error probability that skyrockets close to the true answer.

Such considerations led to the noisy binary search model of Karp and Kleinberg [10], which we call MonotonicNBS: we have n coins whose unknown probabilities $p_i \in [0,1]$ are sorted in nondecreasing order. We can flip coin i to see heads with probability p_i. The goal is to find any coin i with nonempty $[p_i, p_{i+1}] \cap (\tau-\varepsilon, \tau+\varepsilon)$ (See Figure 1 for a graphical representation). This model subsumes FixedNoiseNBS (where $p_i = \frac{1}{2}-\varepsilon$ for $i \le i^*$ and $\frac{1}{2}+\varepsilon$ otherwise) and of course regular binary search (where $p_i \in \{0,1\}$). Throughout this paper we will suppose that τ is a constant bounded away from $\{0,1\}$, n grows to ∞, and ε and the desired failure probability δ may be constant or may approach 0 as $n \to \infty$.

The naive solution to MonotonicNBS is binary search with repetition: we do regular binary search, but repeat each query enough times to have $\frac{\delta}{\log n}$ failure probability if $p_i \notin [\tau-\varepsilon, \tau+\varepsilon]$. This gives sample complexity $O(\frac{1}{\varepsilon^2}\log n \log\frac{\log n}{\delta})$. In [10] it was shown that this extra $\log\log n$ term is unnecessary, giving two algorithms that each have sample complexity

$$O(\frac{1}{\varepsilon^2}\log n \log\frac{1}{\delta}).$$

In this paper, we show how to improve this bound. We show upper and lower bounds that achieve the tight constant on $\log n$, and reduce the $\log\frac{1}{\delta}$ dependence from multiplicative to additive. Table 1 compares our result to existing methods for MonotonicNBS.

On Studying Constants. When analyzing sublinear algorithms, and trying to remove $\log\log n$ factors in query complexity, constant factors really matter. The proofs in [10] are not careful with constants, but the algorithms themselves inherently lose constants. Our best estimate is that one algorithm "improves" upon naive repetition by a factor of $\frac{\log\log_2 n}{31}$, and the other by $\frac{\log\log_2 n}{2000}$ (where log is the natural log). Neither is an improvement for any n that will ever be practical – the better algorithm is only an improvement for $n > 2^{e^{31}} \approx 10^{10^{11}}$. By studying constants, we are forced to design an algorithm that (as we shall see) gives improvements for practical values of n. We give further discussion of the value of studying constants in Section 2.2.

Connection to Communication. Noisy binary search is intimately connected to the asymmetric binary channel, i.e., the binary channel that can choose between sending 1 with probability $\tau - \varepsilon$ or with probability $\tau + \varepsilon$. If each $p_i \in \{\tau \pm \varepsilon\}$, then noisy binary search needs to reveal the $\log_2 n$-bit i^* through such a channel; queries below i^* are 1 with probability $\tau - \varepsilon$ and those above i^* are 1 with probability $\tau + \varepsilon$. The natural target sample complexity is therefore $\frac{1}{C_{\tau,\varepsilon}} \log_2 n$, where $C_{\tau,\varepsilon}$ is the *information capacity* of the asymmetric binary channel:

$$C_{\tau,\varepsilon} := \max_q H((1-q)(\tau-\varepsilon) + q(\tau+\varepsilon)) - (1-q)H(\tau-\varepsilon) - qH(\tau+\varepsilon) \tag{1}$$

where $H(p)$ is the binary entropy function. For $\tau = \frac{1}{2}$, the maximum is at $q = \frac{1}{2}$ and this is just $C_{\frac{1}{2},\varepsilon} = 1 - H(\frac{1}{2} - \varepsilon)$, the capacity of the binary *symmetric* channel with error probability $\frac{1}{2} - \varepsilon$. For $\tau \neq \frac{1}{2}$, the information obtained from $\tau - \varepsilon$ and $\tau + \varepsilon$ probability coins is not the same, so the capacity is achieved by getting $\tau + \varepsilon$ coins with some probability q different from 1/2; it satisfies $C_{\tau,\varepsilon} \approx \frac{\varepsilon^2}{2\tau(1-\tau)\log 2}$ for fixed τ as $\varepsilon \to 0$.

Our results. Our main result is the following:

▶ **Theorem 1** (Upper bound). *Let $0 < \tau < 1$ be a constant. Consider any parameters $0 < \varepsilon, \delta < 1/2$ with $0 < \varepsilon < \min(\tau, 1-\tau)/2$. On any* MonotonicNBS$(\tau, \varepsilon)$ *input, the algorithm* BayesianScreeningSearch *uses at most*

$$\frac{1}{C_{\tau,\varepsilon}}(\log_2 n + O(\log^{2/3} n \log^{1/3} \frac{1}{\delta} + \log \frac{1}{\delta}))$$

queries and succeeds with probability $1 - \delta$.

Unlike [2, 1, 5, 15, 9], our results apply to MonotonicNBS, not just FixedNoiseNBS, so they do not restrict the value of p_i and handle $\tau \neq \frac{1}{2}$. Unlike [10], we achieve good constant factors, high-probability results, and a better scaling with the target τ. In particular, [10] scales multiplicatively rather than additively with $O(\log \frac{1}{\delta})$; and it uses a reduction that incurs a constant-factor *loss* for targets $\tau \neq \frac{1}{2}$, while Theorem 1 scales with $\Theta(\tau(1-\tau))$ so *improves* for $\tau \neq \frac{1}{2}$.

Using Shannon's strong converse theorem, we show that the dependence on n is tight: for $\varepsilon \gg n^{-1/4}$, any algorithm must sometimes use $(1 - o(1))\frac{1}{C_{\tau,\varepsilon}} \log_2 n$ queries; in fact, it must use this many queries with nearly $1 - \delta$ probability.

▶ **Theorem 2** (Strong converse). *Any* MonotonicNBS(τ, ε) *algorithm that succeeds with $1 - \delta$ probability on inputs with all $p_i \in \{\tau \pm \varepsilon\}$ must have at least a $1 - \delta - O(\frac{1}{\gamma^2 n \varepsilon^4})$ chance of using at least*

$$(1-\gamma)\frac{1}{C_{\tau,\varepsilon}} \log_2 n$$

queries, for any $\gamma > 0$.

For $\tau = \frac{1}{2}$, this is also a lower bound for FixedNoiseNBS. Thus Theorem 2 gives a new *worst-case* lower bound for FixedNoiseNBS, which is a $\frac{1}{1-\delta}$ factor larger than the lower bound for *expected* query complexity achieved in prior work [2, 1, 5, 9].

For $\tau \neq \frac{1}{2}$, our results are the first ones connecting noisy binary search to $C_{\tau,\varepsilon}$, the information capacity of the binary asymmetric channel.

Our results: expected queries. For constant δ, one can get a better bound for the expected number of queries in a simple way: only run the algorithm with probability $1-(1-\frac{1}{\log n})\delta$, and otherwise output the wrong answer from zero queries. This saves essentially a $1-\delta$ factor in queries, which for constant δ is nontrivial:

▶ **Corollary 3** (Upper bound: expected queries)**.** *Under the same conditions as Theorem 1 and for any* MonotonicNBS(τ,ε) *input, algorithm* SillyBayesianScreeningSearch *uses*

$$\frac{1-\delta}{C_{\tau,\varepsilon}}(\log_2 n + O(\log^{2/3} n \log^{1/3} \frac{\log n}{\delta} + \log\frac{1}{\delta}))$$

queries in expectation and succeeds with probability $1-\delta$*.*

This $1-\delta$ savings is essentially the best possible. Our strong converse (Theorem 2) already implies this, if $\varepsilon \gg n^{-1/4}$; but using Fano's inequality, the optimality is true in general:

▶ **Theorem 4** (Weak converse)**.** *Any* MonotonicNBS(τ,ε) *algorithm that succeeds with* $1-\delta$ *probability on inputs with all* $p_i \in \{\tau \pm \varepsilon\}$ *must use*

$$(1-\delta)\frac{\log_2(n-2)-1}{C_{\tau,\varepsilon}}$$

queries in expectation.

Theorem 4 was essentially shown in [2], which proved the $\tau=\frac{1}{2}$ case (by giving hardness for FixedNoiseNBS).

Our results: experiments. In Section A we compare our approach to naive repetition and the [10] algorithms. We find, for $n \geq 10^3$ and $\varepsilon = .1$, that our approach outperforms naive repetition, which outperforms both [10] algorithms. For $n = 10^9$, our approach uses $2.3\times$ fewer samples than naive repetition.

1.1 Algorithm Overview

We now describe our noisy binary search algorithm in the case of $\tau=\frac{1}{2}$ and $\delta > 1/n^{o(1)}$.

Bayesian start. The natural choice for a "hard" instance is when $p_i \in \{\tau \pm \varepsilon\}$ (though we will see that having multiple right answers is also hard in a different way), so the algorithm must find the transition location i^*, and information theoretic arguments show $\frac{1}{C_{\tau,\varepsilon}}\log_2 n$ queries are necessary. To avoid losing a constant factor in sample complexity, the algorithm essentially must spend most of its time running the Bayesian algorithm. This algorithm starts with a uniform prior over which interval crosses τ, makes the maximally informative query, updates its posterior, and repeats. When $\tau=\frac{1}{2}$, the maximally informative query is the median under the posterior, and the Bayesian update is to multiply intervals on one side of the query by $1+2\varepsilon$ and the other side by $1-2\varepsilon$. This algorithm, BayesLearn, is given in Algorithm 1; the algorithm for general τ is given in Section 4.

As a technical side note, the discrete nature of the problem introduces a bit of subtlety. Note that MonotonicNBS flips coins i but returns an *interval* between coins that should be good:

▶ **Definition 5.** *We say that an interval* $[i,i+1]$ *is* (τ,ε)-good *if* $[p_i,p_{i+1}]\cap(\tau-\varepsilon,\tau+\varepsilon)$ *is nonempty.*

Precisely, our version of the Bayesian algorithm is as follows: we start with a uniform prior over intervals. The median of our posterior can be viewed as a fractional coin, and we flip the nearest actual coin but update our posterior as if we flipped the fractional coin. So, for example, suppose the median is 4.7 ($.7 * w(5) + \sum_{i=1}^{4} w(i) = .5$). We flip coin 5, and if it comes out 0, that suggests the true threshold is probably above 5. We then scale up our posterior on all intervals above 5 by $1 + 2\varepsilon$; scale down intervals below 4 by $1 - 2\varepsilon$; and scale the weight on interval $[4, 5]$ by $.3(1 + 2\varepsilon) + .7(1 - 2\varepsilon)$. This new posterior is still a distribution that sums to 1.

Algorithm 1 Bayesian learner in $\tau = \frac{1}{2}$ case. Flips M coins and returns M intervals.

Input A set of n queryable coins, update size ε, number of steps M.
Output A list of M intervals queried.

procedure BayesLearn(coins, ε, M)
  $n \leftarrow |\text{coins}|$
  $w_1 \leftarrow \text{uniform}([n-1])$ ▷ Prior distribution over intervals
  $L \leftarrow \{\}$
  for $i \in [M]$ **do**
    $j_i \leftarrow$ median interval of w_i
    $x_i \leftarrow$ either j_i or $j_i + 1$, whichever is closer to the median
    append j_i to L
    $y_i \leftarrow$ flip coin x_i ▷ 1 with probability p_{x_i}
    $$w_{i+1}(x) \leftarrow \begin{cases} w_i(x) \cdot (1 - 2\varepsilon(-1)^{y_i}) & \text{if } x < j_i \\ w_i(x) \cdot (1 + 2\varepsilon(-1)^{y_i}) & \text{if } x > j_i \\ \text{remainder so } w_{i+1} \text{ sums to 1} & \text{if } x = j_i \end{cases}$$
  return L

Using the result. After running the Bayesian algorithm for most of our query budget, we need to output an answer. The question becomes: how can we take the transcript of the Bayesian algorithm and extract a useful worst-case frequentist guarantee? We need the algorithm to work for *all* monotonic p, which can have values very different than $\tau \pm \varepsilon$.

In the prior work achieving tight constants for FixedNoiseNBS [2, 5], because the p_i are guaranteed to be $\frac{1}{2} \pm \varepsilon$, the analysis can show that the weight of the single "good" interval grows in expectation at each step. By a Hoeffding bound, after the desired number of iterations the "good" interval has more weight than every other interval combined, so it can be easily selected. But that property is not true for the more general p_i of MonotonicNBS: if many p_i are $\frac{1}{2} \pm 0.6\varepsilon$, the Bayesian algorithm will wander somewhat too slowly through these samples without growing any single interval by the desired amount.

However, in such cases the Bayesian algorithm is spending a lot of time among good intervals. This holds in general. Our key lemma shows that, if we run BayesLearn for $1 + O(\gamma)$ times the information theoretic bound $\frac{1}{C_{\tau,\varepsilon}} \log_2 n$, a γ fraction of the intervals it visits are (τ, ε)-good:

▶ **Lemma 6** (Bayesian performance). *Consider any $0 < \varepsilon, \tau, \delta, \gamma < 1$ with $\gamma \leq \frac{1}{7}$, $\varepsilon < \min(\tau, 1 - \tau)/2$, and let L be the list of intervals returned by BayesLearn, when run for*

$$\frac{1 + O(\gamma)}{C_{\tau,\varepsilon}} \cdot \left(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta}) \right)$$

iterations on an MonotonicNBS instance. With probability $1 - \delta$, at least a γ fraction of the intervals in L are (τ, ε)-good.

2 Proofs of Statements

By considering the γ-quantiles of the returned list, we reduce n to $\frac{1}{\gamma}$. We can now run a less efficient noisy binary search algorithm on this small subproblem. There are some complications, as the solution to the new noisy binary search could correspond to a larger interval than two adjacent coins. To deal with this, we run BayesLearn with $\varepsilon' = (1-o(1))\varepsilon$, which lets us test our candidate answers.

Technical comparison of techniques. How we leverage the bayesian learner is the main technical difference between our upper bound and that of prior work [10, 2, 5]. As described above, the situation is rather simpler for FixedNoiseNBS. For MonotonicNBS, [10] instead used conservative updates in their multiplicative weights algorithm: rather than the true Bayesian update $1 \pm 2\varepsilon$, it multiplies by about $1 \pm \frac{3}{5}\varepsilon$. This necessarily loses a constant factor, but ensures that either the median interval queried or the last interval queried is good. This property is not true for the true Bayesian algorithm with sharp constant.

2.1 Related Work

The FixedNoiseNBS version of noisy binary search, where $\tau = \frac{1}{2}$ and $p_i \in \{\frac{1}{2} \pm \varepsilon\}$, was posed by Burnashev and Zigangirov [2], who showed how to achieve

$$\frac{1}{C_{\frac{1}{2},\varepsilon}}\left(\log_2 n + \log_2 \frac{1}{\delta} + \log_2 \frac{1+2\varepsilon}{1-2\varepsilon}\right)$$

expected queries (in Russian; see [15] for an English proof). Essentially the same [2] algorithm for FixedNoiseNBS was rediscovered in [1]. Some bugs with the [1] proof were discovered and fixed in [5], as well as an analysis of a variant of the algorithm for *worst-case* sample complexity

$$\frac{1}{C_{\frac{1}{2},\varepsilon}}\left(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}}) + O(\log \frac{1}{\delta})\right).$$

For $1 \ll \log \frac{1}{\delta} \ll \log n$, Gu and Xu [9] showed black-box improvements for other δ. If δ is constant, they output $\perp$ with probability $\delta - \frac{1}{\log n}$, and otherwise run the [5] algorithm with $\delta' = \frac{1}{\log n}$. On the other hand, for $\delta = n^{-\Omega(1)}$, repeatedly running [5] with $\delta' = \frac{1}{\log n}$ and checking the result gives improvements:

$$(1+o(1))\left(\frac{1-\delta}{C_{\frac{1}{2},\varepsilon}}\log_2 n + \frac{\log \frac{1}{\delta}}{\varepsilon \log \frac{1+2\varepsilon}{1-2\varepsilon}}\right)$$

For $\varepsilon \ll 1$, this is a factor 2 improvement on the constant factor on $\log \frac{1}{\delta}$. Moreover, [9] shows that this bound is sharp in both n and δ.

Our version of noisy binary search, MonotonicNBS, was first posed by Karp and Kleinberg [10]. They gave two algorithms, based on recursive backtracking and multiplicative weights respectively, that take $O(\frac{1}{\varepsilon^2}\log n)$ queries for constant δ, which they showed is within constant factors of optimal for constant τ, δ. Unfortunately, the constant factors make both algorithms worse than the naive repetition algorithm for any reasonable n (see Table 1 and Section A).

Other models. There are many different variations for noisy binary search (see [12] for a survey of older work on the subject). Emamjomeh-Zadeh, Kempe, and Singhal [7] solve an extension of FixedNoiseNBS from the line to graphs. This result was improved and simplied by Dereniowski, Tiegel, Uznański and Wolleb-Graf [4], which was in later improved and simplified by Dereniowski, Łukasiewicz, and Uznański [5]. Nowak developed a different generalization of FixedNoiseNBS to general hypothesis classes [11]. Waeber, Frazier, and Henderson [14] investigates a continuous variant of FixedNoiseNBS, where the target is a point in the real interval $[0, 1]$, and show that the Bayesian algorithm converges geometrically (the ideal convergence up to constant factors).

To our knowledge, [10] is the only previous work that handles a setting like MonotonicNBS where the "true" coin may be indistinguishable from nearby coins, and the goal is just to find a sufficiently good answer.

Applications. Noisy binary search is also used as a subroutine in other algorithms. For instance in [13] it is used for group testing, and in Crume [3] as a replacement for git-bisect under unreliable tests. Both implementations were based on the multiplicative weights algorithm of Karp and Kleinberg [10].

2.2 Why constants?

There is a tendency in theoretical computer science to regard constant factors as unimportant. But theorists care about constants in many situations, such as approximation ratios or rates of codes, and we believe that the query complexity of sublinear algorithms is another situation where they should be considered.

In general, the arguments for ignoring constants in time complexity hold with much less force for query complexity. The constant for time complexity is highly dependent on the machine architecture, which changes over time (e.g., the relative cost of addition and multiplication). Moreover, these hardware improvements mitigate the cost of poor constants. But the number of queries is a mathematical value, and the cost of queries (which may be, e.g., blood tests or running a giant test suite) does not clearly decrease with time.

The question should be: does theoretical study of constant factors lead to algorithmic insights necessary for more practical algorithms? Our paper shows that it does. By considering constants, we are forced to find a more efficient way of translating the Bayesian algorithm into one with frequentist guarantees (via Lemma 6). The constants lost in the previous attempt at this (in [10]) mean that it is worse than the naive method until $n > 10^{10^{11}}$.

It should not be surprising that a simple method that loses an $O(\log \log n)$ factor can beat an algorithm that loses "only" constants, for all practical values of n. The study of leading constants is a lens by which we found a new algorithm that actually outperforms the naive method for reasonable values of n (namely $n > 1000$).

3 Detailed Proof Sketch for Upper Bound

3.1 Key Lemma on Bayesian Learner

For this proof overview, we focus on the case of $\delta > n^{-o(1)}$ and target $\tau = \frac{1}{2}$, where BayesLearn queries the median of the posterior at each stage, and

$$C_{\tau,\varepsilon} = 1 - H(\frac{1}{2} + \varepsilon) = (\frac{1}{2} + \varepsilon)\log_2(1 + 2\varepsilon) + (\frac{1}{2} - \varepsilon)\log_2(1 - 2\varepsilon) \approx \frac{2\varepsilon^2}{\log 2}.$$

We give an overview of the proof of our key lemma in this case:

▶ **Lemma 6** (Bayesian performance). *Consider any $0 < \varepsilon, \tau, \delta, \gamma < 1$ with $\gamma \le \frac{1}{7}$, $\varepsilon < \min(\tau, 1-\tau)/2$, and let L be the list of intervals returned by* BayesLearn*, when run for*

$$\frac{1+O(\gamma)}{C_{\tau,\varepsilon}} \cdot \left(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta}) \right)$$

iterations on an MonotonicNBS *instance. With probability $1-\delta$, at least a γ fraction of the intervals in L are (τ,ε)-good.*

Let a be the "best answer", an interval that straddles the bias $\frac{1}{2}$. The algorithm keeps track of a distribution w on $[n-1]$; at each step i, it queries the median of the current distribution w_i, then multiplies the density on one side by $1+2\varepsilon$ and the other by $1-2\varepsilon$ to form w_{i+1}. We analyze the algorithm by looking at $\log_2 w(a)$.

At each step, the interval j we choose is either good (a valid answer) or bad (invalid). If it is *bad*, suppose the sampled coin x has probability $p_x \ge \frac{1}{2} + \varepsilon$. Then x is above a, so $w(a)$ multiplies by $1+2\varepsilon$ with probability p_x, and $1-2\varepsilon$ with probability $1-p_x$. Hence:

$$\mathbb{E}[\log_2 w_{i+1}(a) - \log_2 w_i(a)] = p_x \log_2(1+2\varepsilon) + (1-p_x)\log_2(1-2\varepsilon) \ge C_{\tau,\varepsilon}.$$

The case of $p_x \le \frac{1}{2} - \varepsilon$ is symmetric, giving the same bound. So every bad interval we select increases $\log_2 w(a)$ by $C_{\tau,\varepsilon}$ in expectation.

On the other hand, if the interval we select is *good*, $\log_2 w(a)$ may decrease in expectation. For example, if we query coin a and $\sum_{i=1}^{a-1} w(i) = \frac{1}{2}$, we could have

$$\mathbb{E}[\log_2 w_{i+1}(a) - \log_2 w_i(a)] = \frac{1}{2}\log_2(1-2\varepsilon) + \frac{1}{2}\log_2(1+2\varepsilon) \approx -\frac{2\varepsilon^2}{\log 2} \approx -C_{\tau,\varepsilon}$$

It turns out this is essentially the worst case, and in general the expected decrease in $\log_2 w(a)$ is no more than $5C_{\tau,\varepsilon}$ for any $\varepsilon < \frac{1}{2}\min(\tau, 1-\tau)$. As a result, the potential function

$$\log_2 w_i(a) - \gamma C_{\tau,\varepsilon} \cdot (\#\text{ intervals chosen}) + 6C_{\tau,\varepsilon} \cdot (\#\text{ good intervals chosen})$$

increases by at least $(1-\gamma)C_{\tau,\varepsilon}$ in expectation in each step i, regardless of where the median is in that step. This potential function starts at $-\log_2(n-1)$, so after $M = (1+2\gamma)\frac{1}{C_{\tau,\varepsilon}}\log_2 n$ steps it is at least $\Theta(\gamma)\log_2 n$ in expectation. An Azuma-Hoeffding bound shows that the value concentrates about this expectation, and in particular will be positive with $1-\delta$ probability. If so, since $\log_2 w_i(a) \le 0$ always, we have

$$6 \cdot (\#\text{ good intervals chosen}) - \gamma(\#\text{ intervals chosen}) \ge 0,$$

and hence a $\frac{\gamma}{6}$ fraction of chosen intervals are good.

This proves the key lemma: after $(1+O(\gamma))\frac{1}{C_{\tau,\varepsilon}}\log n$ steps of BayesLearn, a γ fraction of coins flipped are good with decent probability.

Targets $\tau \ne \frac{1}{2}$. When $\tau \ne \frac{1}{2}$, the maximum-information query is no longer the median coin, but a slightly different quantile $\frac{1}{2} \pm O(\frac{\varepsilon}{\tau(1-\tau)})$, and the Bayesian updates use more complicated factors. This choice is still capacity-achieving on bad intervals, i.e., the expected "information gain" is $\mathbb{E}[\log_2 w_i(a) - \log_2 w_{i+1}(a)] \ge C_{\tau,\varepsilon}$, and on good intervals the expected information loss is still at most $5C_{\tau,\varepsilon}$, so the proof structure works unchanged.

3.2 Rest of Upper Bound

Recall that in this overview we assume $\log \frac{1}{\delta} \ll \log n$. By Lemma 6, if we take all $\{\gamma, 2\gamma, \dots, \lfloor \frac{1}{\gamma} \rfloor \gamma\}$ quantiles of the list returned by BayesLearn, run with parameter $\varepsilon' = \varepsilon(1-\alpha)$ (where α is introduced so we can later test the bias of each coin), we get a size-$\frac{1}{\gamma}$ list containing at least one ε'-good interval. This ε' has $C_{\tau,\varepsilon'} = (1 - O(\alpha))C_{\tau,\varepsilon}$. For any γ, we can just flip all of these coins $O(\frac{1}{\alpha^2\varepsilon^2} \log \frac{1}{\gamma\delta})$ times to find an ε-good one. This would give sample complexity

$$\underbrace{(1+O(\gamma))(1+O(\alpha))\frac{1}{C_{\tau,\varepsilon}}\left(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}})\right)}_{\text{BayesLearn, Lemma 6}} + \underbrace{O(\frac{1}{\gamma} \cdot \frac{1}{\alpha^2\varepsilon^2} \log \frac{1}{\gamma\delta})}_{\text{Testing quantiles}} \tag{2}$$

which, by setting γ and α to $(\frac{\log \frac{1}{\delta}}{\log n})^{1/4}$, gives sample complexity

$$(1 + O(\frac{\log \frac{1}{\delta}}{\log n})^{1/4})\frac{1}{C_{\tau,\varepsilon}} \log_2 n.$$

This is the desired sharp bound, within $(1 + o(1))$ of optimal. One can do slightly better: the second stage is itself a noisy binary search question on $O(1/\gamma)$ coins, so by applying the algorithm recursively with $\gamma' = O(1)$ we can solve it on the size-$O(1/\gamma)$ list in $O(\frac{1}{(1-\alpha)C_{\tau,\varepsilon}} \log \frac{1}{\gamma\delta} + \frac{1}{\alpha^2\varepsilon^2} \log \frac{1}{\gamma\delta})$ queries. As we recurse on a much smaller list, the samples used are all lower order and we do not need to recurse more than once. However, the answer to the recursive call might not be a valid answer to the original problem. Regardless, one of the endpoints of the return call must be a valid answer, which we can test for. By optimizing the parameters, this improves the sample complexity to

$$(1 + O(\frac{\log \frac{1}{\delta}}{\log n})^{1/3})\frac{1}{C_{\tau,\varepsilon}} \log_2 n,$$

giving Theorem 1.

4 Proof of Lemma 6

4.1 Definitions

Let $\{l, \dots, r\}$ be the set of good intervals. Let a be the maximum $i \in [n-1]$ such that $p_i \le \tau$. We also define the following functions:

$$C_{\tau,\varepsilon} = \max_q H((1-q)(\tau-\varepsilon) + q(\tau+\varepsilon)) - (1-q)H(\tau-\varepsilon) - qH(\tau+\varepsilon) \tag{3}$$

$$W(x) = \sum_{i \in [x]} w(i) \tag{4}$$

$$\Phi(w, L) = \log_2 w(a) + 6C_{\tau,\varepsilon}(|\{x \in L | x \in [l, r]\}| - \gamma|L|) \tag{5}$$

$$q = \arg\max_x H((1-x)(\tau-\varepsilon) + x(\tau+\varepsilon)) - (1-x)H(\tau-\varepsilon) - xH(\tau+\varepsilon) \tag{6}$$

$C_{\tau,\varepsilon}$ is the capacity of a (τ, ε)-BAC. We let q satisfy the equation which expresses the shared information between a sent and received message through a (τ, ε)-BAC. (See 12, 13 for explicit formulas for $C_{\tau,\varepsilon}, q$) If our prior were true – so the coins really were $\tau \pm \varepsilon$ – we would like to flip a $\tau + \varepsilon$ coin with probability q. This is achieved by selecting the q-quantile of our posterior, which is above the true threshold with probability q. If $\tau = \frac{1}{2}$, $q = \frac{1}{2}$ and we query the median; in general, we query the $q = \frac{1}{2} \pm O(\frac{\varepsilon}{\tau(1-\tau)})$ quantile.

Φ is a potential function that we will be analyzing. We also define:

$$d_{0,0} = \frac{1-\tau-\varepsilon}{1-\tau-(2q-1)\varepsilon}, d_{0,1} = \frac{1-\tau+\varepsilon}{1-\tau-(2q-1)\varepsilon}, d_{1,0} = \frac{\tau+\varepsilon}{\tau+(2q-1)\varepsilon}, d_{1,1} = \frac{\tau-\varepsilon}{\tau+(2q-1)\varepsilon} \tag{7}$$

for brevity. In terms of BayesLearn we can think of $d_{x,y}$ as "the multiplicative effect of a flip resulting in x ($1 =$ Heads, $0 =$ Tails) on the density of an interval on side y ($1 =$ Right, $0 =$ Left) of the flipped coin." When $\tau = \frac{1}{2}$, $d_{x,y} = 1 - 2\varepsilon(-1)^{x \oplus y}$.

Algorithm 2 Acts as a Bayesian learner for M iterations, returns a list of all the chosen intervals. Expressions for the $d_{x,y}$ values are given in (7).

procedure getIntervalFromQuantile(w, q)
  $i \leftarrow \min i \in [n]$ s.t. $W(i) \geq q$
procedure roundIntervalToCoin(i, w, q)
  return i **if** $\frac{q-W(i-1)}{w(i)} \leq q$ **else** $i+1$
procedure BayesLearn($\{c_i\}_{i=1}^n, n, \tau, \varepsilon, M$)
  $w_1 \leftarrow$ uniform($[n-1]$)
  Define q as in (13) ▷ The quantile we choose
  $L \leftarrow \{\}$
  for $i \in [M]$ **do**
    $j_i \leftarrow$ getIntervalFromQuantile(w_i, q) ▷ The chosen interval
    $x_i \leftarrow$ roundIntervalToCoin(j_i, w_i, q) ▷ The index of the coin we are going to flip
    append j_i to L
    $y_i \leftarrow$ flip(c_{x_i})
    $$w_{i+1} \leftarrow \begin{cases} w_i(x) d_{y_i,0} & \text{if } x \in \{1, \ldots, j_i - 1\} \\ d_{y_i,0}(q - W_i(j_i - 1)) + d_{y_i,1}(W_i(j_i) - q) & \text{if } x = j_i \\ w(x) d_{y_i,1} & \text{if } x \in \{j_i + 1, \ldots, n-1\} \end{cases}$$
  return L

▶ **Lemma 7.** *In BayesLearn,* $\mathbb{E}[\Phi_{t+1} - \Phi_t | y_t, y_{t-1}, \ldots, y_1] \geq (1 - O(\gamma)) C_{\tau,\varepsilon}$.

Proof. Φ is given by the sum of equations (8) and (9).

$$6C_{\tau,\varepsilon}(|\{j \in L | j \in [l, r]\}| - \gamma |L|) \tag{8}$$

$$\log_2 w(a) \tag{9}$$

Recall that in the tth round, j_t is the interval chosen, and x_t is index of the coin flipped. Let p be the probability c_{x_t} lands heads.

Bad queries. Suppose $j_t \notin [l, r]$. If $j_t > r$, then $p \geq \tau + \varepsilon$ and the expected change in (9) is

$$p \log_2 d_{1,0} + (1-p) \log_2 d_{0,0}$$

The first log is positive and the second log is negative, so this expression is minimized at $p = \tau + \varepsilon$, at which point some computation (Lemma 9) shows that it equals $C_{\tau,\varepsilon}$. Similarly, if $x_t < l$ then $p \leq \tau - \varepsilon$ and the expected change is

$$p \log_2 d_{1,1} + (1-p) \log_2 d_{0,1}$$

which is also at least $C_{\tau,\varepsilon}$ by Lemma 9. As $j_t \notin [l, r]$, the change in (8) is $-\gamma \cdot 6C_{\tau,\varepsilon}$. Therefore in this case the expected change in Φ is at least $(1 - 6\gamma)C_{\tau,\varepsilon}$.

Good queries. Suppose $j_t \in [l, r]$. The change in (8) is now $6C_{\tau,\varepsilon}(1-\gamma)$. But how much can (9) decrease in expectation? Suppose that $j_t \neq a$. Then the expected change is either

$$p \log_2 d_{1,0} + (1-p) \log_2 d_{0,0}$$

with $p \geq \tau$, or

$$p \log_2 d_{1,1} + (1-p) \log_2 d_{0,1}$$

with $p \leq \tau$.

As $d_{1,0} = \frac{\tau+\varepsilon}{\tau+(2q-1)\varepsilon} \geq \frac{1-\tau-\varepsilon}{1-\tau-(2q-1)\varepsilon} = d_{0,0}$ and $d_{1,1} = \frac{\tau-\varepsilon}{\tau+(2q-1)\varepsilon} \leq \frac{1-\tau+\varepsilon}{1-\tau-(2q-1)\varepsilon} = d_{0,1}$, both of these expressions are minimized when $p = \tau$. So the expected change in (9) is lower bounded by:

$$\min\left(\tau \log_2 d_{1,0} + (1-\tau)\log_2 d_{0,0}, \tau \log_2 d_{1,1} + (1-\tau)\log_2 d_{0,1}\right). \tag{10}$$

We note that

$$\begin{aligned}
\tau \log_2 d_{1,0} + (1-\tau)\log_2 d_{0,0} &= (\tau+\varepsilon)\log_2 d_{1,0} + (1-\tau-\varepsilon)\log_2 d_{0,0} - \varepsilon \log_2 d_{1,0} + \varepsilon \log_2 d_{0,0} \\
&= C_{\tau,\varepsilon} - \varepsilon \log_2 d_{1,0} + \varepsilon \log_2 d_{0,0} \\
&\geq C_{\tau,\varepsilon} - 3\varepsilon\left(\frac{\varepsilon}{\tau} + \frac{\varepsilon}{1-\tau}\right) \qquad \text{(Lemma 13)} \\
&= C_{\tau,\varepsilon} - \frac{3\varepsilon^2}{\tau(1-\tau)} \\
&\geq C_{\tau,\varepsilon} - (6\log 2) C_{\tau,\varepsilon} \qquad \text{(Lemma 10)} \\
&\geq -5C_{\tau,\varepsilon}
\end{aligned}$$

a symmetric argument for lower bounding $\tau \log_2 d_{1,1} + (1-\tau)\log_2 d_{0,1}$ holds. Therefore, the change in (9) is lower bounded by $-5C_{\tau,\varepsilon}$.

Now suppose that $j_t = a$. Then for some $k \in [0,1]$ the expected change in (9) is:

$$p \log_2(d_{1,0}k + d_{1,1}(1-k)) + (1-p)\log_2(d_{0,0}k + d_{0,1}(1-k))$$

If $k \leq q$ then we flip a so $p \leq \tau$. $d_{0,0}k + d_{0,1}(1-k) \geq d_{0,0}q + d_{0,1}(1-q) = 1$. Also $d_{1,0}k + d_{1,1}(1-k) \leq d_{1,0}q + d_{1,1}(1-q) = 1$. Therefore, this expression is minimized when $p = \tau$. By symmetry, when $k > q$ this expression is also minimized when $p = \tau$.

So the expected change in (9) is lower bounded by

$$\tau \log_2(d_{1,0}k + d_{1,1}(1-k)) + (1-\tau)\log_2(d_{0,0}k + d_{0,1}(1-k))$$

for some $k \in [0,1]$. Taking the derivative with respect to k, we get

$$\tau \frac{d_{1,0} - d_{1,1}}{d_{1,1} + (d_{1,0} - d_{1,1})k} + (1-\tau)\frac{d_{0,0} - d_{0,1}}{d_{0,1} + (d_{0,0} - d_{0,1})k}$$

As $d_{1,1} < d_{1,0}$ and $d_{0,1} > d_{0,0}$, $\tau \frac{d_{1,0}-d_{1,1}}{d_{1,1}+(d_{1,0}-d_{1,1})k} > 0 > (1-\tau)\frac{d_{0,0}-d_{0,1}}{d_{0,1}+(d_{0,0}-d_{0,1})k}$. We note that as k increases, $\tau \frac{d_{1,0}-d_{1,1}}{d_{1,1}+(d_{1,0}-d_{1,1})k}$ decreases in magnitude, while $(1-\tau)\frac{d_{0,0}-d_{0,1}}{d_{0,1}+(d_{0,0}-d_{0,1})k}$ increases in magnitude. Therefore, the minimum value of the above expression is achieved when $k = 0$ or $k = 1$.

So the expected change in (9) is lower bounded by

$$\min(\tau \log_2 d_{1,0} + (1-\tau)\log_2 d_{0,0}, \tau \log_2 d_{1,1} + (1-\tau)\log_2 d_{0,1})$$

which is the same expression which we lower bounded for the $j_t \neq a$ case. Combining these two cases, when we are querying a good interval, the expected change is lower bounded by $6C_{\tau,\varepsilon}(1-\gamma) - 5C_{\tau,\varepsilon} = (1-6\gamma)C_{\tau,\varepsilon}$. Therefore $\mathbb{E}[\Phi_{t+1} - \Phi_t | y_t, y_{t-1}, \ldots, y_1] \geq (1 - O(\gamma))C_{\tau,\varepsilon}$. ◀

Now that we have the gain in our potential function, we can apply a stochastic domination argument with Freedman's inequality in order to get Lemma 6 (Appendix C).

5 Algorithm and Analysis

Algorithm 3 Noisy Binary Search. It recurses at most once.

Input n queryable coins $\{c_i\}_{i=1}^n$, update size ε, target τ, failure probability δ
Output An interval which is (τ, ε)-good

procedure ReductionToGamma($\{c_i\}_{i=1}^n, n, \tau, \varepsilon, \delta, \gamma$)
  $L \leftarrow$ BayesLearn($\{c_i\}_{i=1}^n, n, \tau, \varepsilon, \frac{1+O(\gamma)}{C_{\tau,\varepsilon}}(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta}))$)
  $R \leftarrow \{\}$
  for $i \in [\lfloor \frac{|L|}{\lceil \gamma |L| \rceil} \rfloor]$ **do**
    append $L_{\lceil \gamma |L| \rceil i}$ to R
  return Sorted(removeDuplicates(R))
procedure BayesianScreeningSearch($\{c_i\}_{i=1}^n, n, \tau, \varepsilon, \delta, \gamma = \frac{1}{7\log_2(n)}$)
  $\varepsilon' = \varepsilon \cdot \max(1 - \sqrt[3]{\log_n(1/\delta)}, \frac{2}{3})$
  $R \leftarrow$ ReductionToGamma($\{c_i\}_{i=1}^n, n, \tau, \varepsilon', \delta/3, \frac{1}{3\log_2(n)}$)
  if $|R| > 7$ **then**
    $R \leftarrow [1] + R + [n]$ ▷ Pad R with the extremes of the initial problem.
    $i \leftarrow$ BayesianScreeningSearch($\{c_{R_i}\}_{i=1}^{|R|}, |R|, \tau, \varepsilon', \delta/3, \frac{1}{7}$)
    $\hat{p}_{R_i+1} \leftarrow$ estimate p_{R_i+1} up to $\pm \frac{\varepsilon - \varepsilon'}{2}$ error with $\delta/3$ f.p.
    if $\hat{p}_{R_i+1} > \tau - \varepsilon + \frac{\varepsilon - \varepsilon'}{2}$ **then**
      return R_i
    else
      return $R_{i+1} - 1$
  else
    for $x \in R$ **do**
      $\hat{p}_{x+1} \leftarrow$ estimate p_{x+1} up to $\pm \frac{\varepsilon - \varepsilon'}{2}$ error with $\delta/18$ f.p.
      if $\hat{p}_{x+1} > \tau - \varepsilon + \frac{\varepsilon - \varepsilon'}{2}$ **then**
        return x

▶ **Theorem 1** (Upper bound). *Let $0 < \tau < 1$ be a constant. Consider any parameters $0 < \varepsilon, \delta < 1/2$ with $0 < \varepsilon < \min(\tau, 1-\tau)/2$. On any MonotonicNBS$(\tau, \varepsilon)$ input, the algorithm BayesianScreeningSearch uses at most*

$$\frac{1}{C_{\tau,\varepsilon}}(\log_2 n + O(\log^{2/3} n \log^{1/3} \frac{1}{\delta} + \log \frac{1}{\delta}))$$

queries and succeeds with probability $1 - \delta$.

Proof.

Correctness. Suppose that we run BayesianScreeningSearch on a MonotonicNBS instance with parameters $\{c_i\}_{i=1}^n, n, \tau, \varepsilon, \delta$. Also assume that all probabilistic stages succeed, meaning that ReductionToGamma, BayesianScreeningSearch, and our coin bias estimation all succeed. By a union bound, this occurs with probability $\geq 1 - \delta$.

As we pick every $\gamma|L|$th coin from L and L contains at least $\lceil \gamma |L| \rceil$ ε'-good intervals, R contains at least one ε'-good interval. Suppose that $|R| \leq 7$ and that R_i is the first ε'-good interval in R.

Then for all $j \in \{1, \dots, i-1\}$, either R_j is an ε-good interval or it is not. If it is, then we have nothing to worry about outputting it. If it is not, then $p_{R_j+1} \leq \tau - \varepsilon$ (as if $p_{R_j+1} \geq \tau + \varepsilon$ then R_i is not ε-good), so $\hat{p}_{R_j+1} \leq \tau - \varepsilon + \frac{\varepsilon - \varepsilon'}{2}$. So we do not output any not ε-good interval before R_i. Once we reach R_i, $p_{R_i+1} > \tau - \varepsilon'$, so $\hat{p}_{R_i+1} > \tau - \varepsilon' - \frac{\varepsilon - \varepsilon'}{2} = \tau - \varepsilon + \frac{\varepsilon - \varepsilon'}{2}$ and we output R_i.

Now suppose that $|R| > 7$. As we recursively run BayesianScreeningSearch with $\gamma = 1/7$, we note that for the R in the recursive call R', $|R'| = \lfloor \frac{|L|}{\lceil \gamma |L| \rceil} \rfloor \leq \lfloor \frac{1}{\gamma} \rfloor = 7$, so $|R'| \leq 7$. By our work above, this means that the recursive call returns i such that $[p_{R_i}, p_{R_{i+1}}] \cap (\tau - \varepsilon', \tau + \varepsilon') \neq \emptyset$.

Either R_i or $R_{i+1} - 1$ is ε'-good, as if $p_{R_i+1} \leq \tau - \varepsilon'$ and $p_{R_{i+1}-1} \geq \tau + \varepsilon'$ then R must not contain any good intervals. The same logic as for the $|R| \leq 7$ case holds, and we have shown correctness.

Number of samples. Suppose that we run BayesianScreeningSearch with $\gamma = 1/7$. The ReductionToGamma call takes

$$\frac{1 + O(\gamma)}{C_{\tau,\varepsilon'}} \left(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta}) \right) = \frac{1}{C_{\tau,\varepsilon}} O(\log n + \log \frac{1}{\delta})$$

samples. As we have $\gamma = 1/7$, $|R| \leq 7$ and we go through the second branch. Then the bias estimation takes $O(\frac{\tau(1-\tau)\log \frac{1}{\delta}}{(\varepsilon - (1 - \sqrt[3]{\log_n \frac{1}{\delta}})\varepsilon)^2}) = O(\frac{\tau(1-\tau)\log \frac{1}{\delta}}{(\varepsilon \sqrt[3]{\log_n \frac{1}{\delta}})^2}) = O(\frac{\log^{2/3} n \log^{1/3} \frac{1}{\delta}}{C_{\tau,\varepsilon}})$ samples, for overall $\frac{1}{C_{\tau,\varepsilon}} O(\log n + \log \frac{1}{\delta})$ samples.

Now consider the case $\gamma = \frac{1}{7 \log_2 n}$, and suppose that $1 - \sqrt[3]{\log_n(1/\delta)} \geq 2/3$. When $\gamma = O(1/\log(n)), \varepsilon' = \varepsilon * (1 - \sqrt[3]{\log_n(1/\delta)})$, we have $\frac{1+O(\gamma)}{C_{\tau,\varepsilon'}} = \frac{1+O(\frac{1}{\log n})}{C_{\tau,\varepsilon'}} = \frac{1}{C_{\tau,\varepsilon'}} = \frac{1}{(1 - O(\sqrt[3]{\log_n(1/\delta)}) C_{\tau,\varepsilon}}$, by Lemma 12. So ReductionToGamma takes

$$\frac{1}{(1 - O(\sqrt[3]{\log_n(1/\delta)}) C_{\tau,\varepsilon}} \cdot \left(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta} \right)$$
$$= \frac{1}{C_{\tau,\varepsilon}} \cdot \left(\log_2 n + O(\log^{2/3} n \log^{1/3} \frac{1}{\delta} + \log \frac{1}{\delta}) \right)$$

samples.

If $|R| \leq 7$ we take the second branch and take $O(\frac{\log^{2/3} n \log^{1/3} \frac{1}{\delta}}{C_{\tau,\varepsilon}})$ more samples, which meets our bound. If $|R| > 7$ we take the first branch and recurse with $\gamma = 1/7$ and $n' = O(\log n)$, for $\frac{1}{C_{\tau,\varepsilon}} O(\log \log n + \log \frac{1}{\delta})$ samples.

As established previously, the bias estimation takes $O(\frac{\log^{2/3} n \log^{1/3} \frac{1}{\delta}}{C_{\tau,\varepsilon}})$ samples. Overall the algorithm takes

$$\frac{1}{C_{\tau,\varepsilon}} (\log_2 n + O(\log^{2/3} n \log^{1/3} \frac{1}{\delta} + \log \frac{1}{\delta}))$$

samples. In the case $1 - \sqrt[3]{\log_n(1/\delta)} < 2/3$, the $\frac{O(\log \frac{1}{\delta})}{C_{\tau,\varepsilon}}$ term dominates the rest, and the bound holds. ◀

Corollary 3 then follows by elementary analysis.

6 Lower Bounds

We achieve our lower bounds by a communication complexity reduction.

▶ **Lemma 8.** *Given any algorithm $\mathcal{A}$ which solves NBS for parameters (τ, ε) with sample budget m and failure probability δ, there exists a protocol that communicates over a discrete memoryless channel with capacity $C_{\tau,\varepsilon}$ with rate $R = \frac{\log_2(n-1)}{m}$ with failure probability δ.*

Now we can use lower bounds from information theory. By applying Shannon's Strong Converse Theorem, we get Theorem 2, and by applying Fano's inequality we get Theorem 4. See Appendix C for proofs.

7 Future Work

One interesting topic of research is *instance-dependent* noisy binary search. If an instance is much nicer than the worst case, say every coin has bias $\frac{1}{2} \pm \alpha$ for $\alpha \gg \varepsilon$, we would hope to get a $O(\frac{\log n}{\alpha^2})$ dependence, which BayesianScreeningSearch does not get. One could use an adaptive coin bias estimator to get some adaptivity, but the constants gotten from this will likely not be good.

Another open problem is attenuating the lower order terms in the upper bound for NBS. For realistic n, lower order terms such as $\sqrt{\log n}$, or even $\log \log n$ are not negligible compared to $\log n$, and influences the practical application of BayesianScreeningSearch, as seen in the experimental results where we spent 28% of our samples on the "lower order" recursive calls.

One conjectural algorithm for noisy binary search would be: run BayesLearn for $(1 + O(\gamma))OPT$ steps, then output the median of the last γOPT intervals chosen. This interpolates between the overall median (which loses a constant factor) and the final interval (which has a large probability of failure), and avoids the inefficiency of recursive calls.

A Figures and Experiments

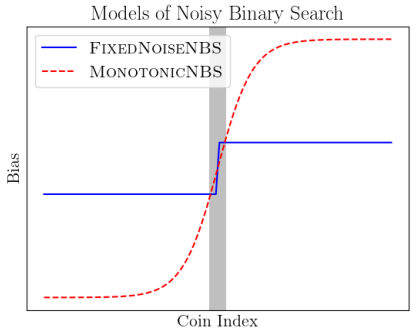

Figure 1 In FixedNoiseNBS, every coin is ε-far from the true i^* that must be found. We consider MonotonicNBS, where many coins may be close to the threshold and the goal is to find some good coin (the gray shaded region).

Applying NBS. To demonstrate the practicality of BayesianScreeningSearch we compare it to standard binary search with repetition (NaiveNBS) and the two algorithms of [10] (KKBacktracking and KKMultiplicativeWeights).

To fairly compare between these algorithms, we can't just use the descriptions given in [10], as the constants used in analysis are not optimized. We leverage BayesianScreeningSearch to address this. We tweak the listed algorithms so they take a sample budget as input which they allocate among all their stages. To estimate how large a budget is needed for algorithm $\mathcal{A}$ to perform well on distribution $\mathcal{D}$, we run BayesianScreeningSearch where when the ith coin is flipped we run $\mathcal{A}$ on some input drawn from $\mathcal{D}$, and return 1 if $\mathcal{A}$ succeeds and 0 if $\mathcal{A}$ fails. By setting $\tau = .8, .9$ and $\varepsilon = .05$, we get upper and lower bounds for how many samples is needed to get $\delta = .15$ failure probability.

Experiments. We compare results on 4 different problem distributions: Standard, Biased, Lopsided, and Wide.

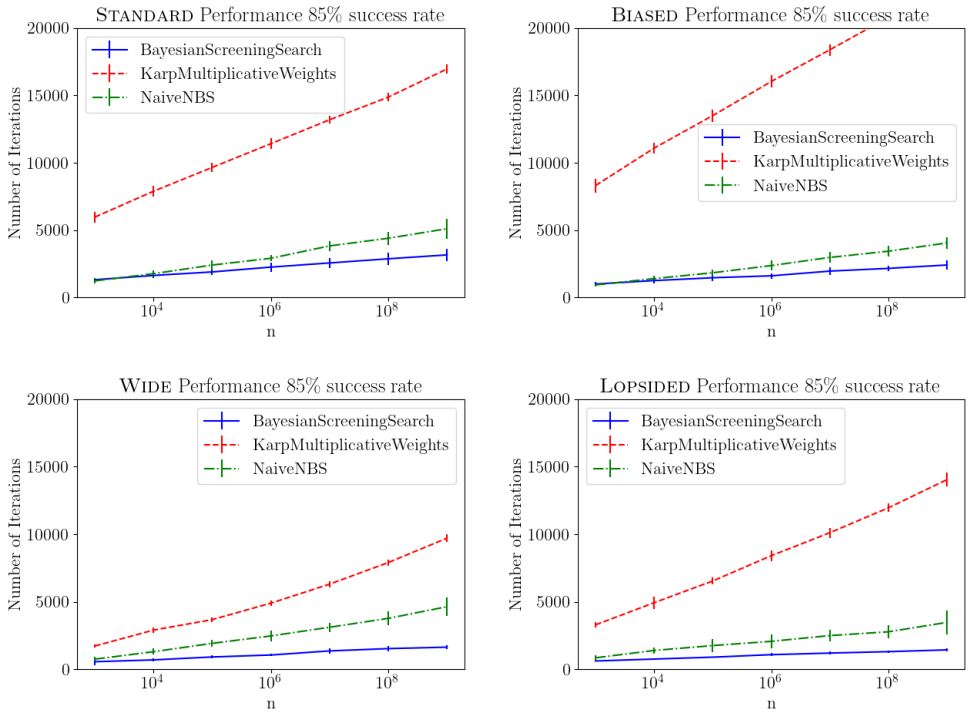

Figure 2 Performance of various MONOTONICNBS algorithms for listed distributions.

- STANDARD. $p_i \in \{\tau - \varepsilon, \tau + \varepsilon\}$, $\tau = \frac{1}{2}, \varepsilon = .1$, the transition interval chosen uniformly at random..
- BIASED. $p_i \in \{\tau - \varepsilon, \tau + \varepsilon\}, \tau = \frac{3}{4}, \varepsilon = .1$, the transition interval chosen uniformly at random.
- LOPSIDED. $p_i \in \{\tau - .6\varepsilon, \tau + \varepsilon\}$, $\tau = \frac{1}{2}, \varepsilon = .1$, the transition interval chosen uniformly at random..
- WIDE. we choose an interval (uniformly at random) of size $10 \log n$ that linearly interpolates between $\tau - \varepsilon$ and $\tau + \varepsilon$, and set the rest to be $p_i \in \{\tau - \varepsilon, \tau + \varepsilon\}, \tau = \frac{1}{2}, \varepsilon = .1$.

Results. We remark that KKBACKTRACKING performed markedly worse than the other algorithms, and so is not included in the figures. For reference, for STANDARD, $N = 1000$ KKBACKTRACKING required $m > 2.9 \times 10^6$ samples, while the other algorithms need $m < 6000$ samples (see Figure 2).

We find that KKMULTIPLICATIVEWEIGHTS is outperformed by NAIVENBS on all of these distributions. In contrast, BAYESIANSCREENINGSEARCH outperforms NAIVENBS for $n > 10^3$.

When $\tau \neq \frac{1}{2}$ the difference between BAYESIANSCREENINGSEARCH, NAIVENBS and the [10] algorithms increases. This is in line with our theory, as the first two perform better when τ is further from $\frac{1}{2}$, while the [10] algorithms reduce to the case $\tau = \frac{1}{2}$, losing a constant factor.

More details on the experiments are in the full version.

B Computations

This section gives the statements of some approximations used in the body of the paper. The proofs are in the full version.

We give explicit formulas for some functions used in this paper

$$z = 2^{\frac{H(\tau-\varepsilon)-H(\tau+\varepsilon)}{2\varepsilon}} \tag{11}$$

$$C_{\tau,\varepsilon} = \log_2(z+1) + \frac{\tau-\epsilon}{2\epsilon}H(\tau+\epsilon) - \frac{\tau+\epsilon}{2\epsilon}H(\tau-\epsilon) \tag{12}$$

$$q = \frac{(1-\tau+\varepsilon) - \frac{1}{1+z}}{2\varepsilon} \tag{13}$$

▶ **Lemma 9.**

$$C_{\tau,\varepsilon} = (\tau+\epsilon)\log_2(\frac{\tau+\epsilon}{\tau+(2q-1)\varepsilon}) + (1-\tau-\epsilon)\log_2(\frac{1-\tau-\epsilon}{1-\tau-(2q-1)\varepsilon})$$

and

$$C_{\tau,\varepsilon} = (\tau-\epsilon)\log_2(\frac{\tau-\epsilon}{\tau+(2q-1)\varepsilon}) + (1-\tau+\epsilon)\log_2(\frac{1-\tau+\epsilon}{1-\tau-(2q-1)\varepsilon})$$

▶ **Lemma 10.** *For* $\varepsilon \le \frac{1}{2}\min(\tau, 1-\tau)$,

$$\frac{1}{2\log 2}\frac{\varepsilon^2}{\tau(1-\tau)} \le C_{\tau,\varepsilon} \le \frac{1}{\log 2}\frac{\varepsilon^2}{\tau(1-\tau)}.$$

▶ **Lemma 11.** *For* $0 < \varepsilon \le \frac{1}{2}\min(\tau, 1-\tau)$,

$$|q - \frac{1}{2}| \le \frac{2\varepsilon}{\tau(1-\tau)}.$$

▶ **Lemma 12.**

$$C_{\tau,(1-o(1))\varepsilon} \ge (1-o(1))C_{\tau,\varepsilon}$$

▶ **Lemma 13.** *For* $\varepsilon < \frac{1}{2}\min(\tau, 1-\tau)$,

- $\log_2 d_{0,0} \ge -3\frac{\varepsilon}{1-\tau}$
- $\log_2 \frac{1}{d_{0,1}} \ge -3\frac{\varepsilon}{1-\tau}$
- $\log_2 \frac{1}{d_{1,0}} \ge -3\frac{\varepsilon}{\tau}$
- $\log_2 d_{1,1} \ge -3\frac{\varepsilon}{\tau}$

C Omitted Proofs

▶ **Lemma 6** (Bayesian performance). *Consider any* $0 < \varepsilon, \tau, \delta, \gamma < 1$ *with* $\gamma \le \frac{1}{7}$, $\varepsilon < \min(\tau, 1-\tau)/2$, *and let* L *be the list of intervals returned by* BayesLearn, *when run for*

$$\frac{1+O(\gamma)}{C_{\tau,\varepsilon}} \cdot \left(\log_2 n + O(\sqrt{\log n \log\frac{1}{\delta}} + \log\frac{1}{\delta})\right)$$

iterations on an MonotonicNBS *instance. With probability* $1-\delta$, *at least a* γ *fraction of the intervals in* L *are* (τ,ε)*-good.*

Proof of Lemma 6. In this proof we omit some of the routine calculations, see the full version for the complete proof.

Recall that Φ is given by the sum of equations (8) and (9).

$$6C_{\tau,\varepsilon}(|\{j \in L | j \in [l,r]\}| - \gamma|L|) \tag{8}$$

$$\log_2 w(a) \tag{9}$$

Reduction to $\Phi > 0$. First note that $\Phi_1 = -\log_2(n-1)$, as initially L is empty so (8) is 0, and we initialize w as uniform so $w(a) = \frac{1}{n-1}$. Next note that if (8) > 0, then

$$\begin{aligned} 6C_{\tau,\varepsilon}(|\{x \in L | x \in [l,r]\}| - \gamma|L|) &> 0 \\ |\{x \in L | x \in [l,r]\}| &> \gamma|L| \end{aligned}$$

So there are strictly more than $\gamma|L|$ good intervals in L. Next note that (9) is ≤ 0 always, so $\Phi > 0 \implies (8) > 0$. So it suffices to show that with δ failure probability $\Phi_{t+1} > 0$, where $t = \frac{1+O(\gamma)}{C_{\tau,\varepsilon}}(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta}))$

Establishing a submartingale. By a stochastic domination argument, we can consider the worst case where all coins sampled have bias in $[\tau - \varepsilon, \tau + \varepsilon]$. Suppose that we are flipping a coin that has bias $p \leq \tau - \varepsilon$. The potential function consists of two parts, one of which does not depend on the flip, and the other which does. We see that a tails increases the potential function, while a heads decreases it. So $p = \tau - \varepsilon$ is the worst case. The argument for when $p \geq \tau + \varepsilon$ is symmetric. We do not need to worry about how this affects future states as Lemma 7 conditions on the prior flips.

Let σ_i^2 be the variance of the difference random variables $\Phi_{i+1} - \Phi_i$, then we note that σ_i^2 is a Bernoulli random variable with parameter $p \in [\tau - \varepsilon, \tau + \varepsilon]$, that is scaled by at most a $\max(\log_2 d_{1,0} - \log_2 d_{0,0}, \log_2 d_{0,1} - \log_2 d_{1,1}) \lesssim \frac{\varepsilon}{\tau(1-\tau)}$ factor, therefore

$$\sigma_i^2 \lesssim p(1-p)\left(\frac{\varepsilon}{\tau(1-\tau)}\right)^2 \lesssim \tau(1-\tau)\left(\frac{\varepsilon}{\tau(1-\tau)}\right)^2 = \frac{\varepsilon^2}{\tau(1-\tau)} \lesssim C_{\tau,\varepsilon}$$

Where we use the fact that $\varepsilon \leq \frac{\min(\tau, 1-\tau)}{2}$. Therefore $\sigma_i^2 \lesssim C_{\tau,\varepsilon}$.

Freedman's inequality. For brevity let $g = (1 - O(\gamma))C_{\tau,\varepsilon}$, the lower bound given in Lemma 7.

$$\begin{aligned} \Pr[\Phi_{t+1} \leq 0] &= \Pr[\Phi_{t+1} - \Phi_1 \leq -\Phi_1] \\ &\leq \exp\left(-\frac{2(-gt - \Phi_1)^2}{\sum_{i=1}^t \sigma_i^2 + O(\frac{\varepsilon}{\tau(1-\tau)})(gt + \Phi_1)}\right) \quad \text{Freedman's when } gt \geq -\Phi_1 \\ &\leq \exp(-\frac{O(1)}{tC_{\tau,\varepsilon}} \cdot (g^2t^2 + 2gt\Phi_1 + \Phi_1^2)) \end{aligned}$$

Bounding this expression by δ, we get

$$g^2t^2 + (2g\Phi_1 - \log_{O(1)}(1/\delta)C_{\tau,\varepsilon})t + \Phi_1^2 \geq 0 \tag{14}$$

(14) is a quadratic with respect to t, and has a positive leading coefficient. Applying the quadratic formula, if we set

$$t \geq \frac{-\Phi_1}{g} + \frac{C_{\tau,\varepsilon}\log_{O(1)}(1/\delta)}{2g^2} + \frac{\sqrt{(\log_{O(1)}(1/\delta)C_{\tau,\varepsilon})^2 - 4g\Phi_1\log_{O(1)}(1/\delta)C_{\tau,\varepsilon}}}{2g^2} \tag{15}$$

then (14) holds. As $\Phi_1 = -\log_2(n-1), g = (1 - O(\gamma))C_{\tau,\varepsilon}$ we get that (15) is

$$\frac{1}{1-O(\gamma)} \cdot \frac{1}{C_{\tau,\varepsilon}}(\log_2 n + O(\sqrt{\log n \log \frac{1}{\delta}} + \log \frac{1}{\delta}))$$

As $\frac{1}{1-O(\gamma)}$ is $1 + O(\gamma)$, our lemma holds. ◀

Algorithm 4 Noisy Binary Search that gets the optimal expected queries.

1: **procedure** SillyBayesianScreeningSearch($\{c_i\}_{i=1}^n, n, \tau, \varepsilon, \delta$)

2: **return** $\begin{cases} \textsc{Random}([n-1]) & \text{w.p. } \delta - \delta/\log_2 n \\ \textsc{BayesianScreeningSearch}(\{c_i\}_{i=1}^n, n, \tau, \varepsilon, \frac{\delta}{\log(n)}) & \text{otherwise} \end{cases}$

Proof of Corollary 3. The failure probability of SillyBayesianScreeningSearch is $\leq \delta - \delta/\log_2 n + (1-\delta+\delta/\log_2 n)\delta/\log_2 n = \delta - \delta^2/\log_2 n + \delta^2/\log_2^2 n \leq \delta$. We use 0 samples with probability $\delta - \delta/\log_2 n$, and the expression in Theorem 1 with $\delta' = \delta/\log_2 n$, with probability $1 - \delta + \delta/\log_2 n$. ◀

Proof of Lemma 8. Omitted, see the full version. ◀

▶ **Lemma 14** (Shannon's Strong Converse Theorem). *Over any discrete memoryless channel, for $R > C$*

$$P_e \geq 1 - \frac{K_1}{n(R-C)^2} - \exp(-K_2 n(R-C))$$

where P_e is the probability of error, K_1, K_2 are positive constants which depend on the channel, n is the input alphabet size, R is the rate of information, and C is the channel capacity [8].

Proof of Theorem 2. Let $\alpha = \frac{1}{1+\frac{K}{C_{\tau,\varepsilon}\sqrt{\beta(n-1)}}}$, for constant K to be determined later. Suppose that $\mathcal{A}$ uses at most $\alpha\frac{\log_2(n-1)}{C_{\tau,\varepsilon}}$ samples with probability at least $\delta + \beta$. Let $\mathcal{A}'$ be the algorithm that runs $\mathcal{A}$, but outputs a random answer if $\mathcal{A}$ uses more than $\alpha\frac{\log_2(n-1)}{C_{\tau,\varepsilon}}$ samples. $\mathcal{A}'$ fails only whenever $\mathcal{A}$ fails or uses more than $\alpha\frac{\log_2(n-1)}{C_{\tau,\varepsilon}}$ samples, so by a union bound $\mathcal{A}'$ has a failure probability of at most $1-\beta$. By Lemma 8 we can construct a protocol over a discrete memoryless channel with capacity $C_{\tau,\varepsilon}$ that communicates at rate $R = \frac{\log_2(n-1)}{\alpha\frac{\log_2(n-1)}{C_{\tau,\varepsilon}}} = \frac{C_{\tau,\varepsilon}}{\alpha} = \frac{C}{\alpha}$ with a failure probability of at most $1-\beta$.

By Lemma 14 we have that

$$\begin{aligned} 1-\beta &\geq 1 - \frac{K_1}{(n-1)(R-C)^2} - \exp(-K_2(n-1)(R-C)) \\ &= 1 - \frac{K_1}{(n-1)((1/\alpha-1)C)^2} - \exp(-(n-1)K_2((1/\alpha-1)C)) \\ &= 1 - \frac{K_1\beta}{K} - \exp(-\sqrt{\frac{n-1}{\beta}}K_2K) \\ &\geq 1 - \frac{\beta}{2} && \text{sufficiently large } K \text{ and } n \end{aligned}$$

which is a contradiction. Therefore with probability at least $1-\delta-\beta$ $\mathcal{A}$ uses $\frac{1}{1+\frac{K}{\sqrt{\beta(n-1)}(C_{\tau,\varepsilon})}}\frac{1}{C_{\tau,\varepsilon}}\log_2 n$ samples. ◀

Proof of Theorem 4. Omitted, see the full version. ◀

Solution Discovery via Reconfiguration for Problems in P

Abstract

In the recently introduced framework of solution discovery via reconfiguration [Fellows et al., ECAI 2023], we are given an initial configuration of k tokens on a graph and the question is whether we can transform this configuration into a feasible solution (for some problem) via a bounded number b of small modification steps. In this work, we study solution discovery variants of polynomial-time solvable problems, namely Spanning Tree Discovery, Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery in the unrestricted token addition/removal model, the token jumping model, and the token sliding model. In the unrestricted token addition/removal model, we show that all four discovery variants remain in P. For the token jumping model we also prove containment in P, except for Vertex/Edge Cut Discovery, for which we prove NP-completeness. Finally, in the token sliding model, almost all considered problems become NP-complete, the exception being Spanning Tree Discovery, which remains polynomial-time solvable. We then study the parameterized complexity of the NP-complete problems and provide a full classification of tractability with respect to the parameters solution size (number of tokens) k and transformation budget (number of steps) b. Along the way, we observe strong connections between the solution discovery variants of our base problems and their (weighted) rainbow variants as well as their red-blue variants with cardinality constraints.

1 Introduction

In classical optimization problems, we are given a problem instance and the task is to compute an optimal solution. However, in many applications and real-world scenarios we are already provided with a current solution, albeit non-optimal or infeasible for a given instance. Depending on the application, it might be desirable to find an optimal or feasible solution via a bounded number of small modification steps starting from the current solution.

Very prominent examples for such "systems" are typically settings where humans are involved in the system and big changes to the running system are not easily implementable or even accepted. When optimizing public transport lines, shift plans, or when assigning workers to tasks it is clearly desirable to aim for an optimal solution that is as similar as possible to the current state of the system. Fellows et al. [13] recently introduced the *solution discovery via reconfiguration* framework addressing the computational aspects of such problems. In their model, an optimizer is given a problem instance together with a current (possibly) infeasible solution. The aim is to decide whether a feasible solution to the given problem can be constructed by applying only a bounded number of changes to the current state. We extend this line of work and focus on core polynomial-time solvable problems on graphs, namely Spanning Tree, Shortest Path, Matching, and Vertex/Edge Cut. More precisely, for any of the four aforementioned problems, say Π, we consider instances consisting of a graph G, a budget b, and a starting configuration of k tokens, which is not necessarily a feasible solution for Π (and where tokens either occupy vertices or edges of G). The goal is to decide whether one can transform the starting configuration of tokens into a feasible solution for Π by applying at most b "local changes".

The solution discovery framework is inspired by approaches transforming one solution to another such as *local search*, *reoptimization*, and *combinatorial reconfiguration*. *Local search* is an algorithmic paradigm that is based on iterative improvement of solutions in a previously defined neighborhood. In contrast to our setting, *local search* typically improves the current solution in each step, while we allow arbitrary configurations between the starting and ending configurations (our only restriction is that each vertex/edge can be occupied by at most one token). In *reoptimization* the aim is also to compute optimal solutions starting from optimal solutions of "neighboring" instances (distance between instances being usually defined as the number of vertex/edge addition/deletion required to make the two graphs isomorphic). Closely related is the field of *sensitivity analysis*, a very classical area studying how sensitive an optimal solution is (how it reacts) to small changes in the input. In *combinatorial reconfiguration* we are also given a starting solution, but additionally a *target solution*, and very often constraints on the intermediate steps, e. g., that every intermediate step maintains a valid solution. In our setting the target and intermediate steps are not explicitly specified, but we aim for any final configuration satisfying some desired properties.

As an illustrating example application, consider the scenario in which a city experiences severe weather conditions, leading to a rapid increase in river water levels. The city relies on the protection of a dam, but there is a foreseeable risk that the dam may eventually fail. We assume that the dam breaks (continuously) from point A to point B, where the (shortest) distance between A and B in our graph-view of the world is exactly k vertices (including A and B). In anticipation of such emergencies, the city has also placed (at least) k sandbags in fixed locations across the city so that one can move them as fast as possible to avoid greater damage (we here make the simplifying assumption that each unit of the broken dam can be fixed by a single sandbag). When the dam breaks we can easily compute a shortest path between A and B, which also allows us to compute the minimum number of

sandbags required to stop the flowing water. However, computing such a shortest path is not enough in this situation. Instead, we additionally need to account for sandbags having to move to the appropriate locations as quickly as possible. This corresponds exactly to the problem of finding a shortest path (between two fixed vertices) that is quickly reachable from a predefined set of positions (vertices) in the graph. In other words, this motivates the study of discovery variants of the Shortest Path problem.

An alternative perspective at solution discovery problems is as follows. Consider a vertex (resp. edge) selection problem Π on graphs. Assume that each element (vertex or edge) in the solution of size k must be *supported* by one of k support points, which are located at k different elements of the input graph, and which can each support exactly one element of the solution. The cost of supporting an element is measured by the distance to the chosen support point. The problem of deciding whether there exists a solution that can be supported with cost b corresponds to a discovery variant of problem Π.

Before we proceed and state our results we quickly recall the solution discovery framework of Fellows et al. [13] (see preliminaries for formal definitions). Consider an instance of a vertex (resp. edge) selection problem Π on graphs, where some vertices (resp. edges) of the input graph are occupied by (distinct and indistinguishable) tokens. A token may be moved (in a specific way depending on the concrete model) for a cost of 1. In the *unrestricted token addition/removal* model[1], an existing token may be removed, or a new token may be placed on an unoccupied vertex (resp. edge) for a cost of 1. In the *token jumping* model, a token may be moved from one vertex (resp. edge) to an arbitrary unoccupied vertex (resp. edge) for a cost of 1. In the *token sliding* model, a token may be moved to a neighboring unoccupied vertex (resp. edge) for a cost of 1. The goal is to move the tokens such that they form a valid solution for problem Π within the given budget. We remark that these notions of token moves have also been studied in the realm of combinatorial reconfiguration [21, 24].

Fellows et al. [13] considered the solution discovery variants of (computationally hard) fundamental graph problems, namely Vertex Cover, Independent Set, Dominating Set and Vertex Coloring. The complexity of solution discovery for Vertex Coloring in the color flipping model was studied in [16] under the name k-Fix and in the color swapping model in [10] under the name k-Swap. Since these problems, which we call *base problems*, are NP-complete, it is not surprising that their solution discovery variants are also NP-complete in all of the aforementioned models. In this work, we continue the examination of the solution discovery framework and focus on the discovery variants of polynomial-time solvable base problems, namely Spanning Tree Discovery, Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery. When a base problem is polynomial-time solvable, one may, given an instance with a partial or infeasible solution, efficiently compute an optimal solution from scratch. However, as previously illustrated, there are situations in which a solution that is close to a currently established configuration is more desirable. As we show in this work, the constraints put on these problems in the solution discovery framework, namely a limited number of changes, can drastically alter their complexities.

We observe strong connections between the solution discovery variants of our base problems and their *weighted rainbow variants* as well as their *red-blue variants with cardinality constraints*. An instance of a weighted rainbow vertex (resp. edge) selection problem consists

[1] We call the model "unrestricted" to differentiate it from the addition/removal model usually considered in reconfiguration problems as the latter imposes a lower or upper bound on the number of tokens in the graph at all times.

of a weighted vertex (resp. edge) colored graph, and the solution of such an instance may not contain two vertices (resp. edges) of the same color, while "collecting" a certain amount of weight. We show that if (the parameterized version of) the weighted rainbow variant of problem Π admits a fixed-parameter tractable (FPT-) algorithm, then this algorithm can be used to design a fixed-parameter tractable algorithm for the solution discovery variant of Π in the token sliding model. Similarly, solving the solution discovery variant of a problem in the token jumping model boils down to solving the red-blue variant of that same problem. An instance of a red-blue vertex (resp. edge) selection problem consists of a graph where every vertex (resp. edge) is either colored red or blue and two integer parameters k and b. The goal is to find a solution of size k that contains at most b blue vertices (resp. edges).

1.1 Our results

We provide a full classification of tractability vs. intractability with respect to the classical as well as the parameterized complexity of the aforementioned solution discovery problems in all three token models (Table 1). Moreover, we prove some results for rainbow problems as well as red-blue problems, which we believe to be of independent interest. Our main results can be summarized as follows:

- Spanning Tree Discovery, Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery are polynomial-time solvable in the unrestricted token addition/removal model.
- Spanning Tree Discovery, Shortest Path Discovery and Matching Discovery are polynomial-time solvable, while Vertex/Edge Cut Discovery is NP-complete in the token jumping model.
- Spanning Tree Discovery is polynomial-time solvable, while Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery are NP-complete in the token sliding model.

We then consider the parameterized complexity of the NP-complete discovery problems and establish the following connection with their rainbow variants.

- Meta theorem: For an optimization problem Π, if the weighted Rainbow-Π problem (parameterized by solution size k) admits an FPT algorithm, then Π-Discovery (parameterized by solution size k) admits an FPT algorithm in the token sliding model.

FPT algorithms for the Weighted Rainbow Shortest Path problem [1], Weighted Rainbow Matching problem [19], and the Weighted Rainbow Vertex/Edge Cut problem (which we provide in this paper) immediately imply FPT algorithms for the discovery variants parameterized by k (in the token sliding model). We demonstrate the power of our meta theorem by using it to show that Vertex/Edge Cut Discovery is FPT with respect to parameter k in the sliding model. For Shortest Path Discovery and Matching Discovery, we then give more intuitive and direct FPT algorithms, which also achieve better running times. We conclude by studying the parameterized complexity of all hard problems (not covered by the meta-theorem) when parameterized by either k or b, obtaining the following results.

- Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery are FPT when parameterized by solution size k in the token sliding model. Furthermore, Vertex/Edge Cut Discovery is FPT when parameterized by k in the token jumping model.

Table 1 Overview of our results.

	Spanning Tree	Shortest Path	Matching	Vertex/Edge Cut
Discovery Add/Rem.	in P	in P	in P	in P
Discovery Jumping	in P	in P	in P	NP-c., FPT[k], W[1]-hard[b]
Discovery Sliding	in P	NP-complete, FPT[k], FPT[b]	NP-c., FPT[k], W[1]-hard[b]	NP-c., FPT[k], W[1]-hard[b]
Rainbow	in P [6]	NP-complete	NP-complete on paths [25]	NP-complete [3], NP-c. on planar
Red-Blue	in P	in P	in P	NP-c., FPT[k], W[1]-hard[b]

- Shortest Path Discovery is FPT, while Matching Discovery and Vertex/Edge Cut Discovery are W[1]-hard when parameterized by the budget b in the token sliding model. Furthermore, Vertex/Edge Cut Discovery is W[1]-hard when parameterized by the budget b in the token jumping model.

1.2 Related work

The solution discovery framework is closely related to the combinatorial reconfiguration framework, introduced by Ito et al. [21] and studied widely since then. In the reconfiguration variant of a problem we are given an initial solution S and a target solution T and the question is whether S can be transformed into T by a sequence of reconfiguration steps (e. g., token additions/removals, token jumps, or token slides) such that each intermediate configuration also constitutes a solution.

The Minimum Spanning Tree Reconfiguration problem by edge exchanges, i.e., token jumps, was first studied by Ito et al. [21]. They showed that the problem is in P by extending the exchange property of matroids to the reconfiguration of weighted matroid bases. Shortest Path Reconfiguration was introduced by Kamiński et al. [23] and shown to be PSPACE-complete by Bonsma [4]. Reconfiguration of perfect matchings was studied by Ito et al. [22]. The Vertex Cut Reconfiguration and Minimum Vertex Cut Reconfiguration problems were studied by Gomes et al. [18, 17]. For further related work on reconfiguration problems we refer the reader to the surveys of van den Heuvel [20], Nishimura [28], and Bousquet et al. [5].

Rainbow spanning trees have been investigated by Broersma and Li [6]. They characterize graphs in which there exists a rainbow spanning tree via matroid intersection. The question to decide whether a graph contains a rainbow path has been studied in the classical and influential work of Alon et al. [1] that introduced the color coding technique. In the related Rainbow s-t-Connectivity problem the question is to decide whether there exists a rainbow path between s and t, that is, a path on which no color repeats [31]. To the best of our knowledge the Rainbow Shortest Path problem has not been studied in the literature. We refer the reader to [7] for more background. The Rainbow Matching problem is NP-complete, even when restricted to properly edge-colored paths [25]. The Rainbow s-t-Cut problem is known to be NP-complete [3] on general graphs. We show that this problem remains NP-complete even if we restrict it to the class of planar graphs.

We furthermore consider red-blue variants of our base problems. Graphs are now vertex (resp. edge) colored with colors red and blue. We are given two integers k and b and the question is whether there exists a solution of size k using at most b blue vertices (resp. edges). To the best of our knowledge these problem variants have not been studied in the literature, however, variants where we have a cardinality constraint on both colors are related, but seem to be more difficult to solve. For example in the Color Constrained Matching problem [29] we are given a 2-edge-colored graph (colors red and blue) and two parameters k and w and we search for a matching of size k with at most w blue and at most w red edges. This problem is known to be at least as hard as the Exact Matching problem [29] (via a logarithmic-space reduction), which was introduced in [30]. Here, where we are given a red-blue edge-colored graph and a parameter b and the question is whether there exists a perfect matching with exactly b blue edges. The complexity of Exact Matching has been open for more than 40 years [26].

2 Preliminaries

We denote the set of non-negative integers by $\mathbb{N}$ and the set of non-negative reals by $\mathbb{R}_+$. For $k \in \mathbb{N}$ we define $[k] = \{1, 2, \ldots, k\}$ with the convention $[0] = \varnothing$.

Graphs. We consider finite and loopless graphs. An undirected simple graph G consists of its vertex set $V(G)$ and edge set $E(G)$, where $E(G)$ is a subset of all two element sets of $V(G)$. Similarly, the edge set $E(G)$ of a directed simple graph is a subset of pairs of its vertices. In a multigraph we allow $E(G)$ to be a multiset. We assume our graphs to be undirected and simple if not stated otherwise. We denote an edge connecting vertices u and v by uv. Observe that $uv = vu$ for every undirected edge $uv \in E(G)$. A sequence $v_1, \ldots, v_q$ of pairwise distinct vertices is a path of length $q-1$ if $v_i v_{i+1} \in E(G)$ for all $1 \leq i < q$. We write P_q for the path of length q. The distance $\mathrm{dist}_G(u, v)$ (or simply $\mathrm{dist}(u, v)$ if G is clear) between two vertices $u, v \in V(G)$ is the length of a shortest path starting in u and ending in v in G. A graph is d-degenerate if it can be reduced to the empty graph by iterative removal of vertices of degree at most d. For example, forests are 1-degenerate. A graph is bipartite if its vertices can be partitioned into two parts A, B such that no edge has both its endpoints in the same part. Equivalently, a graph is bipartite if it does not contain cycles of odd length. For a vertex subset $S \subseteq V(G)$, we denote by $G[S]$ the subgraph of G induced by S, i.e., the graph with vertex set S and edge set $\{uv \in E(G) \mid u, v \in S\}$. Likewise, for an edge subset $M \subseteq E(G)$, we denote by $G[M]$ the graph with edge set M and vertex set $\{u, v \mid uv \in M\}$.

An edge coloring $\varphi : E(G) \to \mathcal{C}$ is a function mapping each edge $e \in E(G)$ to a color $\varphi(e) \in \mathcal{C}$. Similarly, a vertex coloring assigns colors to vertices. An edge-weight function is a function $w : E(G) \to \mathbb{R}_+$, and similarly a vertex-weight function assigns weights to vertices. We denote colored weighted graphs by tuples (G, w, φ). The weight of a set of vertices/edges is the sum of the weights of its elements.

Solution discovery. Let G be a graph. A *configuration* of G is either a subset of its vertices or a subset of its edges. We formalize the notions of token moves. In the *unrestricted token addition/removal* model[2], a configuration C' can be obtained (in one step) from C, written $C \vdash C'$, if $C' = C \cup \{x\}$ for an element $x \notin C$, or if $C' = C \setminus \{x\}$ for an element

[2] Recall that this definition differs from the definition in [13].

$x \in C$. In the *token jumping* model, a configuration C' can be obtained (in one step) from C if $C' = (C \setminus \{y\}) \cup \{x\}$ for elements $y \in C$ and $x \notin C$. In the *token sliding* model, a configuration C' can be obtained (in one step) from C if $C' = (C \setminus \{y\}) \cup \{x\}$ for elements $y \in C$ and $x \notin C$ if x and y are neighbors in G, that is, if $x, y \in V(G)$, then $xy \in E(G)$; and if $x, y \in E(G)$, then $x \cap y \neq \varnothing$. If C' can be obtained from C (in any model), we write $C \vdash C'$. A *discovery sequence* of length ℓ in G is a sequence of configurations $C_0C_1 \dots C_\ell$ of G such that $C_i \vdash C_{i+1}$ for all $0 \leq i < \ell$.

Let Π be a vertex (resp. edge) selection problem, i.e., a problem defined on graphs such that a solution consists of a subset of vertices (resp. edges) satisfying certain requirements. The Π-Discovery problem is defined as follows. We are given a graph G, a subset $S \subseteq V(G)$ (resp. $S \subseteq E(G)$) of size k (which at this point is not necessarily a solution for Π), and a budget b (as a non-negative integer). The goal is to decide whether there exists a discovery sequence $C_0C_1 \dots C_\ell$ in G for some $\ell \leq b$ such that $S = C_0$ and C_ℓ is a solution for Π.

Note that for discovery problems in the token sliding model we can always assume that $b \leq kn$, where n is the number of vertices in the input graph. This follows from the fact that each token will have to traverse a path of length at most n to reach its target position. For discovery problems in the token jumping model we can always assume $b \leq k$, as it is sufficient to move every token at most once. Similarly, for the unrestricted token addition/removal model we can always assume that $b \leq n$ for vertex selection problems and $b \leq m$ for edge selection problems, where m is the number of edges in the input graph. As k is trivially upper-bounded by n for vertex selection problems (resp. m for edge selection problems), all solution discovery variants we consider are in NP and thus proving NP-hardness suffices to prove NP-completeness.

Parameterized complexity. A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, where Σ is a fixed finite alphabet. For an instance $(x, \kappa) \in \Sigma^* \times \mathbb{N}$, κ is called the *parameter*. The problem L is called *fixed-parameter tractable*, FPT for short, if there exists an algorithm that on input (x, κ) decides in time $f(\kappa) \cdot |(x, \kappa)|^c$ whether $(x, \kappa) \in L$, for a computable function f and constant c.

The *W-hierarchy* is a collection of parameterized complexity classes $\mathsf{FPT} \subseteq \mathsf{W[1]} \subseteq \mathsf{W[2]} \subseteq \dots$. It is standard to assume that the inclusion $\mathsf{FPT} \subseteq \mathsf{W[1]}$ is strict. Therefore, showing intractability in the parameterized setting is usually accomplished by establishing an FPT-reduction from a W-hard problem.

Let $L, L' \subseteq \Sigma^* \times \mathbb{N}$ be parameterized problems. A *parameterized reduction* from L to L' is an algorithm that, given an instance (x, κ) of L, outputs an instance (x', κ') of L' such that $(x, \kappa) \in L \Leftrightarrow (x', \kappa') \in L'$, $\kappa' \leq g(\kappa)$ for some computable function g, and the running time of the algorithm is bounded by $f(\kappa) \cdot |(x, \kappa)|^c$ for some computable function f and constant c. We refer to the textbooks [9, 12, 14] for extensive background on parameterized complexity.

3 Spanning trees

A *spanning tree* in a connected graph G is a subset of edges $E' \subseteq E(G)$, where $|E'| = |V(G)| - 1$ and $G[E']$ is a tree containing all vertices of G. In the Spanning Tree problem we are given a graph G and the goal is to compute a spanning tree in G.

3.1 Rainbow minimum spanning trees

We reduce the problem of discovering spanning trees in the sliding model to the problem of finding (weighted) rainbow spanning trees. A spanning tree $T \subseteq E(G)$ in a weighted edge-colored multigraph (G, w, φ) is a *rainbow spanning tree* if every edge in T has a distinct color, i.e., $\forall e, e' \in T$ we have $\varphi(e) = \varphi(e')$ if and only if $e = e'$. In the Rainbow Minimum Spanning Tree (Rainbow MST) problem, we are given (G, w, φ) and the goal is to compute a rainbow spanning tree of minimum total weight in G, or report that no such rainbow spanning tree exists. The Rainbow Spanning Tree (Rainbow ST) problem can be defined similarly, i. e., by dropping the weights or assuming that all weights are uniform.

Rainbow spanning trees and their existence have been discussed by Broersma and Li [6]. In our reduction we will construct an instance of Rainbow Minimum Spanning Tree that trivially guarantees the existence of at least one rainbow spanning tree. We show that we can find a Rainbow MST efficiently, even in multigraphs. The proof of the theorem uses arguments similar to those presented in [6] and builds on matroid intersection.

▶ **Theorem 1.** *The* Rainbow Minimum Spanning Tree *problem in weighted edge-colored multigraphs can be solved in polynomial time.*

3.2 Spanning tree discovery

In the Spanning Tree Discovery (STD) problem in the token sliding model, we are given a graph G, an edge subset $S \subseteq E(G)$ with $|S| = |V(G)| - 1$ as a starting configuration, and a non-negative integer b. The goal is to decide whether there is a spanning tree of G that can be discovered (starting from S) using at most b token slides.

▶ **Theorem 2.** *The* Spanning Tree Discovery *problem in the token sliding model can be solved in polynomial time.*

In the full version of the paper we show that the weighted discovery problem, i.e., where we seek a spanning tree of minimum weight, can also be solved in polynomial time.

4 Shortest paths

A *shortest path* between two vertices of a graph G, say s and t, is a path connecting s and t of minimum length. In the Shortest Path problem we are given a graph G and $s, t \in V(G)$ and the goal is to compute a shortest path between s and t in G.

4.1 Rainbow shortest paths

In the Rainbow Shortest Path (Rainbow SP) problem we are given a vertex-colored graph (G, φ) and two vertices $s, t \in V(G)$. A shortest path P from s to t in G is a *rainbow shortest path* if every vertex in P has a distinct color, i. e., $\forall v, v' \in V(P)$, we have $\varphi(v) = \varphi(v')$ if and only if $v = v'$. The Rainbow Shortest Path problem asks for a rainbow shortest path P from s to t in G (one can similarly define the edge-colored variant of the problem).

Rainbow paths have been studied in the literature before, specifically in relation to the rainbow vertex-connection or edge-connection number of a graph. We refer the reader to [7] for more details. In the following theorem, we show that the extra rainbow requirement makes the problem a lot harder than the base problem, even on very restricted families of graphs. To do so, we describe a reduction from the NP-complete [15] Hamiltonian Path problem to the Rainbow Shortest Path problem.

▶ **Theorem 3.** *The* Rainbow Shortest Path *problem is* NP*-complete on the class of* 2*-degenerate bipartite graphs.*

Proof. The fact that the problem is in NP is immediate. We show NP-hardness by a reduction from the Hamiltonian Path problem, which is known to be NP-complete [15]. Given an instance G of Hamiltonian Path, where G is a graph with n vertices denoted by $V(G) = \{v_1, \ldots, v_n\}$, we construct an instance (H, φ, s, t) of Rainbow Shortest Path as follows. See Figure 1 for an illustration.

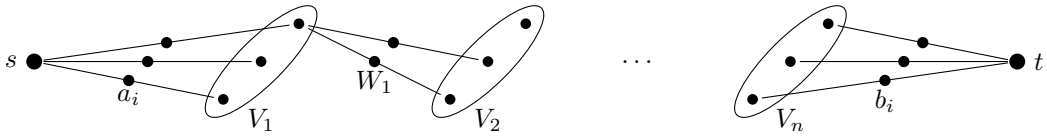

Figure 1 An illustration of the hardness reduction for the Rainbow Shortest Path problem.

First, H consists of two vertices s and t. For every pair $i, j \leq n$ we add a new vertex $v_{i,j}$ in H. We define $V_i = \{v_{i,j} \mid j \leq n\}$. Then, for every $i < n$ and $e \in E(G)$ we add a new vertex $w_{i,e}$ and define $W_i = \{w_{i,e} \mid e \in E(G)\}$. Finally, for every $i \leq n$ we add new vertices a_i and b_i. We define $A = \{a_i \mid i \leq n\}$ and $B = \{b_i \mid i \leq n\}$. We connect the vertices as follows. For every $i \leq n$, we insert the edges $\{s, a_i\}, \{a_i, v_{1,i}\}, \{v_{n,i}, b_i\}$, and $\{b_i, t\}$. Finally, for every $i < n$ and $e = \{v_j, v_\ell\}$ we insert the edges $\{v_{i,j}, w_{i,e}\}$ and $\{w_{i,e}, v_{i+1,\ell}\}$. We assign all vertices in A the same color, all vertices in B the same new color, all vertices $\{v_{i,j} \mid i \leq n\}$ the same new color (this set represents all copies of a vertex $v \in V(G)$), all vertices in W_i the same new color, all vertices in B the same new color, and s and t receive two fresh new colors. This finishes the construction of the instance (H, φ, s, t).

Observe that H is indeed bipartite and 2-degenerate; all vertices of the form $w_{i,j}$ are of degree two. Their removal results in a forest, which is 1-degenerate. Bipartiteness follows from the fact that there are no edges in $G[S]$, $G[T]$, $G[V_i]$, nor $G[W_i]$.

We show that G contains a Hamiltonian path if and only if (H, φ, s, t) is a yes-instance of Rainbow Shortest Path. Observe that every shortest s-t-path in H consists of s, exactly one of the vertices $a_i \in A$, exactly one vertex from every V_i and one from every W_i, exactly one of the vertices $b_i \in B$ and t. Hence, there is no path of length less than $2n + 2$ and every such path of length $2n + 2$ is exactly of this form.

Now assume that G contains a Hamiltonian path $v_{i_1} v_{i_2} \ldots v_{i_n}$. We pick the following vertices in H. We pick a_{i_1} and b_{i_n}, the vertices v_{j,i_j}, and, for every $j < n$, we pick the vertices $w_{j,e}$ where $e = \{v_{i_j}, v_{i_{j+1}}\}$. It is not hard to see that these vertices indeed form a rainbow shortest path from s to t in H.

Conversely, assume that (H, φ, s, t) is a yes-instance of Rainbow Shortest Path. By the above observations, every shortest path must be of the same form (picking vertices from the same sets). As every rainbow shortest path cannot contain two copies of the same vertex from $V(G)$ the claim follows, finishing the proof. ◀

4.2 Shortest path discovery

In the Shortest Path Discovery (SPD) problem in the token sliding model we are given a graph G, two vertices $s, t \in V(G)$, a starting configuration $S \subseteq V(G)$ with $|S| = k$, which is equal to the number of vertices on a shortest path between s and t (including s and t), and a non-negative integer b. The goal is to decide whether we can discover a shortest path between s and t (starting from S) using at most b token slides. We denote an instance of

Shortest Path Discovery by a tuple (G, s, t, S, b). We show that the Shortest Path Discovery problem is NP-complete even when restricted to 2-degenerate bipartite graphs by a minor modification of the reduction from the Hamiltonian Path problem to the Rainbow Shortest Path problem.

▶ **Theorem 4.** *The Shortest Path Discovery problem in the token sliding model is NP-complete on the class of 2-degenerate bipartite graphs.*

In fact, since Hamiltonian Path remains NP-complete on cubic planar graphs, it turns out that the class of all graphs arising in the reduction of Theorem 4 is not only 2-degenerate but also has bounded expansion.

It remains an interesting open problem to determine whether Shortest Path Discovery is polynomial-time solvable on classes of graphs excluding a topological minor, or even on planar graphs. Next, we show that the problem is fixed-parameter tractable with respect to the parameter k as well as the parameter b.

▶ **Theorem 5.** *The Shortest Path Discovery problem in the token sliding model is fixed-parameter tractable with respect to parameter k.*

Proof. Let (G, s, t, S, b) be an instance of SPD. For every $v \in V(G)$ we compute its distance to s and delete v if the distance is larger than k. We enumerate the tokens in S as $s_0, s_1, \ldots, s_{k-1}$ such that token s_i shall slide to a vertex at distance i from s. There are $k!$ such enumerations. Now we orient and assign weights to the edges of G to obtain a weighted directed graph H. If uv is an edge such that $\text{dist}_G(s, u) = i$ and $\text{dist}_G(s, v) = i + 1$, then we orient the edge as (u, v) and assign it weight $\text{dist}_G(s_{i+1}, v)$, that is, the cost of moving token s_{i+1} to vertex v. We delete all edges that did not receive a weight, that is, all edges that connect vertices at the same distance from s.

Since H contains only edges between vertices of distance i to distance $i + 1$ from s, an s-t-path in H corresponds to a shortest s-t-path in G. Furthermore, by definition of the weights, a shortest s-t-path P (with respect to the weights) corresponds exactly to the discovery of a shortest path in G where token s_i slides to the vertex of P which is at distance i from s. We can therefore simply compute a shortest s-t-path in H and verify whether its weight is at most $b - \text{dist}_G(s, s_0)$. Since H is a DAG we can compute such a path in time $\mathcal{O}(n + m)$ and, consequently, the full algorithm runs in time $\mathcal{O}(k!(n + m))$. ◀

▶ **Theorem 6.** *The Shortest Path Discovery problem in the token sliding model is fixed-parameter tractable with respect to parameter b.*

Proof. Let (G, s, t, S, b) be an instance of SPD. Let us call the vertices at distance i from s the vertices at level i. If we can discover a solution with budget b, then it must be the case that all but at most b tokens of S are already in their correct positions. In particular, there can be at most b many levels that do not contain a token from S and at most b many levels containing two or more tokens (and each level can contain at most $b + 1$ many tokens). We call levels not containing exactly one token *very bad* levels. Now, for a level i containing exactly one token on vertex v (not a very bad level), we say that i is a *bad* level whenever one of the following is true:

- $i - 1 \geq 0$, level $i - 1$ contains exactly one token on vertex u, and $uv \notin E(G)$; or
- $i + 1 \leq \text{dist}(s, t) + 1$, level $i + 1$ contains exactly one token on vertex w, and $vw \notin E(G)$.

Note that we can have at most b very bad levels and at most $3b$ bad levels (every 3 bad levels require at least one unit of the budget); otherwise we can reject the instance. Each bad or very bad level contains at most $b+1$ tokens and at most b tokens do not belong to a level between s and t. Hence, the total number of tokens that potentially have to move is so far $5b(b+1) = 5b^2 + 5b$ (located on at most $5b$ levels).

We call a level that is neither bad nor very bad a *good* level. Note that we can group the good levels into at most $5b+1$ groups of consecutive levels. Moreover, the tokens of each group form a path. We denote those paths by $P_1, \ldots, P_q$, for $q \leq 5b+1$. Consider some P_i with at least $2b+1$ many vertices, say $P_i = v_1 \ldots v_\ell$ for $\ell \geq 2b+1$. Let v_x be a vertex of P_i such that $\ell + 1 \leq x \leq \ell - (b+1)$. In other words, there are at least b vertices preceding and at least b vertices succeeding v_x in P_i. In what follows we assume, without loss of generality, that the token on v_x does not move whenever v_x belongs to the final shortest path between s and t. This is a safe assumption because if any other token must pass via v_x to reach its destination we simply swap the roles of both tokens. In other words, getting a token on v_x does not consume any units of the budget. We claim that in a shortest discovery sequence of at most b token slides the token on vertex v_x does not move. This follows from the fact that otherwise it must be the case that either all tokens on v_y, $1 \leq y < x$, or all tokens on v_z, $\ell \geq z > x$, must move. However, as there are at least b tokens to move in either case this contradicts the fact that our discovery sequence slides no more than b tokens. To prove that either every token before or after v_x must move in a shortest discovery sequence we aim towards a contradiction. Assume that the token at level x moves but there are two levels $y < x$ and $z > x$ such that the tokens on level y and z do not move. Since the subpath between levels y and z is already a path connecting v_y and v_z (going through v_x), the movement of the token at level x can be ignored, contradicting our assumption of a shortest discovery sequence. Since at most b tokens can move, and by symmetry, we conclude that at most $2b$ many tokens on the two boundaries of P_i can move. We call the tokens on good levels that are not at distance at most b from some boundary of a P_i *fixed* tokens. Note that the number of tokens that are not fixed is at most $10b^2 + 2b$.

Putting it all together, we conclude that the set of tokens that can potentially move has size at most $15b^2 + 7b$. We can now proceed just as in the proof of Theorem 5 to obtain the required algorithm for parameter b; we can now guess the subset of tokens that move as well as the level each moving token will occupy. ◀

5 Matchings

A *matching* in a graph G is a set of edges $M \subseteq E(G)$ such that each vertex $v \in V(G)$ appears in at most one edge in M. In the Matching problem we are given a graph G and an integer k and the goal is to compute a matching of size k in G.

5.1 Rainbow matchings

We show NP-hardness of the Matching Discovery problem via a reduction from the Rainbow Matching problem. Let (G, φ) be an edge-colored graph. A matching $M \subseteq E(G)$ is said to be a *rainbow matching* if all edges in M have pairwise distinct colors. Formally, the Rainbow Matching problem is defined as follows. Given an edge-colored graph (G, φ) and an integer k, decide whether there exists a rainbow matching of size k in G.

▶ **Theorem 7** ([25]). *The Rainbow Matching problem is NP-complete, even when restricted to properly edge-colored paths.*

5.2 Matching discovery

In the Matching Discovery problem in the token sliding model we are given a graph G, a starting configuration $S \subseteq E(G)$ of size k, and a non-negative integer b. The goal is to decide whether we can discover a k-sized matching M (starting from S) using at most b token slides. Recall that a token on some edge e can only slide (in one step) to some edge e' such that e and e' are adjacent, i.e., share a vertex. We denote an instance of Matching Discovery by a tuple (G, S, b). We first show that the Matching Discovery problem is NP-complete even on restricted graph classes.

▶ **Theorem 8.** *The Matching Discovery problem in the token sliding model is NP-hard on 2-degenerate bipartite graphs.*

Furthermore, we show intractability of the problem when parameterized by the budget. This result is established by a parameterized reduction from the W[1]-hard Multicolored Clique problem and is the technically most demanding contribution of the paper.

▶ **Theorem 9.** *The Matching Discovery problem in the token sliding model is W[1]-hard when parameterized by b, even on the class of 3-degenerate graphs.*

On the positive side, we next show that the Matching Discovery problem is fixed-parameter tractable with respect to parameter $k + b$. Then we show that for any instance of the problem one can bound b by a (quadratic) function of k, which implies fixed-parameter tractability of the problem parameterized by k alone. We start with some relevant definitions.

Let $d(t, w)$ denote the minimum number of slides token t has to slide in order to become incident to vertex w. For an integer $i \in \{1, \ldots, b\}$ and a token $t \in S$, let $Y_t^i = \{w \in V(G) \mid d(t, w) = i - 1\}$ and $Z_t^i = \{w \in V(G) \mid d(t, w) = i\}$. Let G_t^i denote the graph $G[Y_t^i \cup Z_t^i] - E(G[Z_t^i])$.

▶ **Theorem 10.** *The Matching Discovery problem in the token sliding model parameterized by both the number of tokens k and the budget b is fixed-parameter tractable.*

Proof Sketch. Let (G, S, b) be an instance of the Matching Discovery problem, where $|S| = k$. The algorithm proceeds as follows. We first guess a set $S' \subseteq S$ of tokens that will slide form their original positions. If such a guess leaves any overloaded vertices, i.e., vertices incident to more than one token, we ignore the guess and proceed to the next one. Note that this *guessing* procedure requires $\mathcal{O}(2^k)$ time in the worst case. Next, for each $r \in \{0, 1, \ldots, b\}$ and for a fixed S', we guess a partition of r over the tokens in S'. In other words, we try all possible ways of distributing the budget r over the tokens in S'.

Now, for a fixed subset S', a fixed r, and a fixed distribution D of r over the tokens of S', let r_i be the budget allocated to a token $t_i \in S'$ under D. The algorithm computes the sets $Y_{t_i}^{r_i}$ and $Z_{t_i}^{r_i}$ for each $t_i \in S'$. The next step is to produce a set of candidate target edges for each t_i, which we denote by T_i. To do so, we run a maximum matching algorithm in the graph $G_{t_i}^{r_i} - (S \setminus S')$. Roughly speaking, we show that it is enough to retain $\mathcal{O}(k^2)$ edges of the matching in $G_{t_i}^{r_i} - (S \setminus S')$; which also implies a bound on the size of T_i. Once the candidate sets have been constructed, the algorithm exhaustively checks whether it can reach a valid matching in the graph G where each token $t_i \in S'$ moves to some edge in T_i. The algorithm declares a no-instance if no valid matching is found during the exhaustive search; otherwise we have a yes-instance. ◀

Finally, using the notion of augmenting paths, we show that the algorithm of Theorem 10 is also a fixed-parameter tractable algorithm for parameter k alone by proving that k upper bounds the parameter b.

▶ **Lemma 11.** *In any yes-instance (G, S, b) of the* Matching Discovery *problem in the sliding model, b can be upper bounded by $2(k^2 + k)$, where $k = |S|$.*

Combining Theorem 10 with Lemma 11 we get the following result.

▶ **Corollary 12.** *The* Matching Discovery *problem in the token sliding model is fixed-parameter tractable with respect to parameter k.*

6 Vertex/edge cuts

Let G be a graph and s and t vertices of G. A *vertex s-t-cut* is a set of vertices $C \subseteq V(G)$ such that every s-t-path contains a vertex of C. Likewise, an *edge s-t-cut* is a set of edges $C \subseteq E(G)$ such that every s-t-path contains an edge of C. In the Vertex Cut (resp. Edge Cut) problem we are given a graph G, vertices s, t and an integer k and the goal is to compute a vertex s-t-cut (resp. edge s-t-cut) of size k.

6.1 Rainbow vertex/edge cut

Given an edge-colored graph (G, φ) with vertices $s, t \in V(G)$, the Rainbow Vertex Cut problem asks whether there exists a vertex s-t-cut $C \subseteq V(G)$ such that all vertices in C have pairwise different colors. Such a cut is called a rainbow vertex s-t-cut. Likewise, the Rainbow Edge Cut problem asks whether there exists an edge s-t-cut $C \subseteq E(G)$ such that all edges in C have pairwise different colors. The Rainbow Edge Cut problem is known to be NP-complete [3, Theorem 5.5]. We start by showing that the problem remains NP-complete on planar graphs.

▶ **Theorem 13.** *The Rainbow Edge Cut problem is NP-complete on planar graphs.*

Proof. Containment in NP is clear as Rainbow Edge Cut on general graphs is in NP. Hence we focus on the hardness proof. We present a reduction from Rainbow Matching on paths. Let (P, κ) be an instance of Rainbow Matching where P is a path on n vertices denoted by $v_1, \dots v_n$ and the edges are colored with colors from a color set $\mathcal{C}$.

We construct an instance $(G, \psi : E(G) \to \mathcal{C}')$ of Rainbow s-t-Cut as follows. The new color set is $\mathcal{C}' = \mathcal{C} \cup \{\mathsf{black}\} \cup \{c_i \mid i \leq n-2\}$, that is, $\mathcal{C}'$ uses the colors from $\mathcal{C}$ as well as $n-2$ fresh colors and the color black.

Let us describe the construction of G in detail; see Figure 2 for an illustration. In the first step, G consists of κ disjoint copies of P, which we call $P_1, \dots, P_\kappa$. Let the vertices of P_j be called $v_{j,1} \dots v_{j,n}$. Additionally, we add two fresh vertices s and t. For every $j < \kappa$, insert a set L_j of $n-1$ fresh vertices, and call them $u_{j,1}, \dots, u_{j,n-1}$. Hence, $V(G) = \bigcup_{j \leq \kappa} V(P_j) \cup \bigcup_{j < \kappa} V(L_j) \cup \{s, t\}$.

Now we connect s and t with a black edge, which enforces that this black edge must be part of every (rainbow) s-t-cut. Hence, any other black edge may not be part of any rainbow s-t-cut of G. We connect s and t to the vertices in P_j and L_j as follows. For every $j \leq \kappa$ we insert the edges $\{s, v_{j,1}\}$ and $\{v_{j,n}, t\}$, which are colored black. Likewise, for every $j < \kappa$ we insert the edges $\{s, u_{j,1}\}$ and $\{u_{j,n-1}, t\}$, which are also colored black. Finally, for every $j < \kappa$ and $i \leq n-2$, we insert the edge $\{v_{j,i}, u_{j,i}\}$ which is colored black and the edges $\{u_{j,i}, v_{j,i+1}\}$ and $\{u_{j,i}, v_{j+1,i+2}\}$, which are colored c_i. This finishes the construction.

We claim that P has a rainbow matching of size κ if and only if G admits a rainbow s-t-cut. Assume that P has a rainbow matching $M = \{e_1, \dots, e_\kappa\}$ of size κ. Without loss of generality, we assume that the edges in M are ordered with respect to the v_i, i.e., if

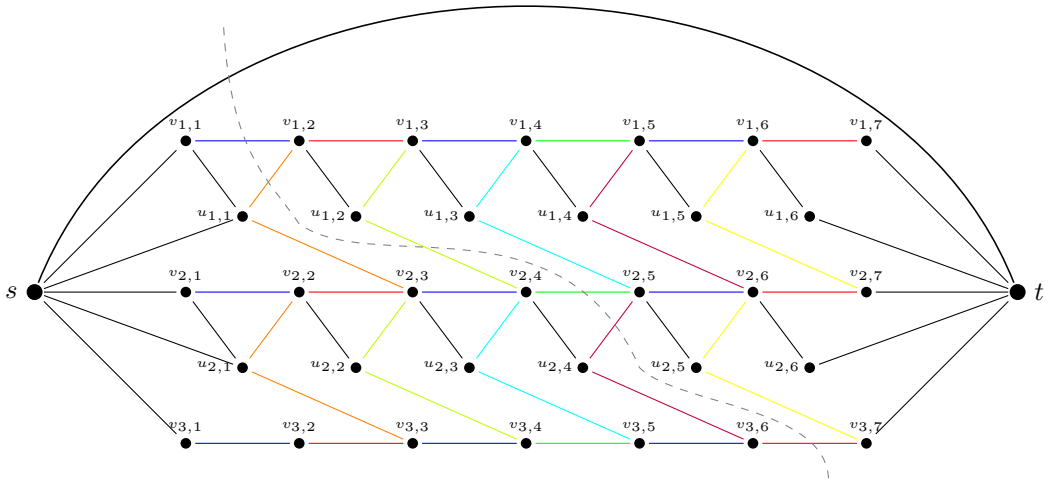

Figure 2 Illustration of the hardness reduction for Rainbow s-t-Cut on planar graphs.

$e_i = \{v_{\ell_i}, v_{\ell_{i+1}}\}$ and $i < j$, then $\ell_i < \ell_j$. We claim that the set C that consists of the black edge $\{s,t\}$, the copy of e_i in P_i, and the obvious edges connecting the P_i and L_j is a rainbow s-t-cut of G. To be precise, we have

$$C = \{s,t\} \cup \{\{v_{i,\ell_i}, v_{i,\ell_i+1}\}, \{u_{i,\ell_i}, v_{i,\ell_i+1}\} \mid i \leq \kappa\} \cup \bigcup_{i \leq \kappa} \{\{u_{i,j}, v_{i,j+2}\} \mid \ell_i < j \leq \ell_{i+1} - 2\}.$$

Observe that C is a cut by construction (see Figure 2), and that no two edges in C have the same color, as M is a rainbow matching, and for every $j < \kappa$ and $i \leq n-2$ at most one of the edges $\{v_{j,i}, u_{j_i}\}$ and $\{u_{j_i}, v_{j+1,i+2}\}$ is contained in C.

Now assume that G admits a rainbow s-t-cut. As s and t are directly connected, every rainbow s-t-cut C for G must contain $\{s,t\}$. Furthermore, by construction C contains exactly one edge from every P_j, say the edge $\{v_{j,\ell_i}, v_{j,\ell_{i+1}}\}$, as no other black edge is part of C. We claim that $M = \{\{v_{\ell_i}, v_{\ell_{i+1}}\} \mid \{v_{j,\ell_i}, v_{j,\ell_{i+1}}\} \in C \text{ for some } j \leq \kappa\}$ is a rainbow matching of P. Obviously, M is rainbow, as C is rainbow. To show that M is indeed a matching, observe that for all $\ell_i \neq \ell_j$ we have $|\ell_i - \ell_j| \geq 2$, that is, M does not contain two (copies of) consecutive edges of P. To see this, assume for the sake of contradiction that there are $i \neq j$ such that $|\ell_i - \ell_j| \leq 1$. Let $j_1 < j_2$ be such that $\{v_{j_1,\ell_i}, v_{j_1,\ell_{i+1}}\}$ and $\{v_{j_2,\ell_j}, v_{j_2,\ell_{j+1}}\}$ are contained in C. By construction, C must also contain $\{u_{j_1,\ell_i}, v_{j_1,\ell_{i+1}}\}$ and can hence not contain $\{u_{j_1,\ell_i}, v_{j_1+1,\ell_i+2}\}$, as they share the same color. This however implies that $\{v_{j_2,\ell_j}, v_{j_2,\ell_{i+1}}\}$ cannot be contained in C, a contradiction. This finishes the proof. ◀

We reuse the ideas of the proof of Theorem 13 combined with standard tricks for edge/vertex cuts, e.g., subdivision of edges, to obtain the following corollary.

▶ **Corollary 14.** *The Rainbow Vertex Cut problem is NP-complete on planar graphs.*

The following theorem is one of two main ingredients required for establishing the fixed-parameter tractability of the discovery variants of cut problems parameterized by k, the other being the aforementioned meta-theorem, which is formally stated in Section 7. In what follows, we consider weighted variants of the rainbow problems, where in addition to finding a rainbow cut of size k it is also required that it has weight at most b.

▶ **Theorem 15.** *The* Weighted Rainbow Vertex/Edge Cut *problem is fixed-parameter tractable when parameterized by k.*

Proof Sketch. We present an FPT algorithm for the Weighted Rainbow Vertex Cut problem. The tractability of Weighted Rainbow Edge Cut follows by considering the vertex cut version in the line graph of the input graph.

We use the *treewidth reduction theorem* [27, Theorem 2.15], which essentially states that for every colored and weighted graph G and integer k we can efficiently compute a graph H of low treewidth that preserves all minimal vertex s-t-cuts of size at most k. Hence, it is sufficient to find a minimum weight rainbow vertex s-t-cut of size at most k in H.

To do so, we apply the optimization version of Courcelle's Theorem as presented in [2, 8]. In our case we conclude a running time of $f(k) \cdot n^2$ where f is some computable function and $n = |V(H)| \leq |V(G)|$. ◀

6.2 Vertex/edge cut discovery

In the Vertex Cut Discovery problem in the token sliding model we are given a graph G, vertices $s, t \in V(G)$, a starting configuration $S \subseteq V(G)$ of size k and a non-negative integer b. The goal is to decide whether we can discover a vertex cut separating s and t in G (starting from S) using at most b token slides. Similarly, in the Edge Cut Discovery problem, we are given a graph G, vertices $s, t \in V(G)$, a starting configuration $S \subseteq E(G)$ of size k and a non-negative integer b. The goal is again to decide whether we can discover an edge cut separating s and t in G (starting from S) using at most b token slides. We denote an instance of Vertex Cut Discovery resp. Edge Cut Discovery by a tuple (G, s, t, S, b). We always use k to denote the size of S.

We prove that Vertex Cut Discovery in the token sliding model is NP-hard, fixed-parameter tractable with respect to parameter k and W[1]-hard with respect to parameter b. We show that these observations translate to Edge Cut Discovery as well. We start by proving hardness via a reduction from the Clique problem, which is NP-hard and its parameterized variant is W[1]-hard with respect to the solution size [11].

▶ **Theorem 16.** *The Vertex Cut Discovery problem in the sliding model is NP-hard and W[1]-hard with respect to parameter b on 2-degenerate bipartite graphs.*

Proof Sketch. We show NP-hardness by a reduction from the Clique problem. The reduction is both a polynomial time reduction as well as a parameterized reduction, showing both claimed results. Let (G, κ) be an instance of the Clique problem.

We construct the following graph H (see Figure 3 for an illustration). We add two vertices s and t in H where s has κ pendent vertices, which we collect in a set named Z. For every vertex $u \in V(G)$, we add a vertex x_u in H, which we connect with s, and for every $e \in E(G)$ we add a vertex y_e in H, which we connect with t. Let X denote the set of the x_u and Y denote the set of the y_e. For every vertex $u \in V(G)$ and for each edge $e \in E(G)$ incident with u, connect x_u and y_e via a 1-subdivided edge (that is, a path with one interval vertex). Furthermore, we add $\binom{\kappa}{2}$ disjoint paths $P_1, \ldots, P_{\binom{\kappa}{2}}$, each with a single internal vertex, connecting s and t. We denote the internal vertex of P_i by p_i. This completes the construction of H. We define the initial configuration S as $Z \cup Y$ and $b = 2\kappa + 2\binom{\kappa}{2}$. ◀

▶ **Corollary 17.** *The Edge Cut Discovery problem in the token sliding model is NP-hard and W[1]-hard with respect to parameter b on 2-degenerate bipartite graphs.*

Finally, combining Theorem 15 and Theorem 19 (Section 7), we get the following result:

▶ **Theorem 18.** *The Vertex/Edge Cut Discovery problem in the token sliding model is fixed-parameter tractable with respect to parameter k.*

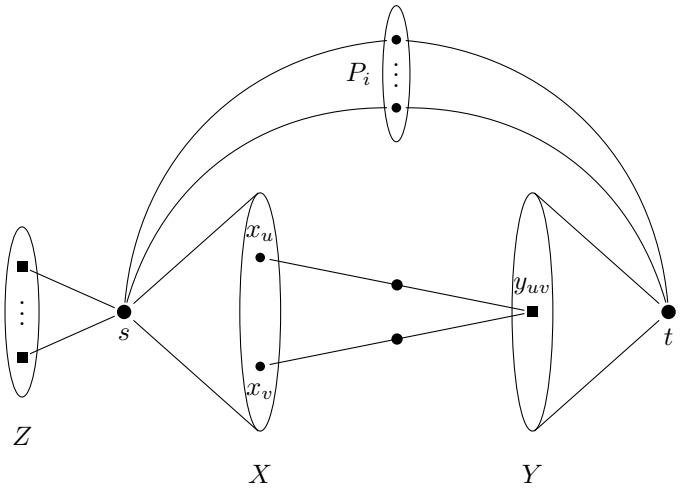

Figure 3 An illustration of the hardness reduction for the Vertex Cut Discovery problem.

7 Tractability via rainbow problems

In this section, we establish an algorithmic meta-theorem showing tractability of discovery problems in the token sliding model (when parameterized by k) via the tractability of (weighted) rainbow variants of optimization problems. We utilize the color-coding technique introduced by Alon et al. [1] along with FPT algorithms for the rainbow problems to design FPT algorithms for the discovery problems parameterized by k.

Let Π be an optimization problem and (G, k) be an instance of Π. In the Rainbow-Π problem we assume that G is either a vertex-colored graph or an edge-colored graph. The parameter k refers to the solution size to be optimized. We consider problems that seek to optimize the selection of edges or vertices, but not both. For instance, the rainbow variants for shortest paths and vertex cuts are vertex selection problems whereas for spanning trees, matchings and edge cuts we have edge selection problems. For a vertex (or edge) selection problem, the Weighted Rainbow-Π problem refers to the weighted variant where the input graph G additionally has weights on the edges (or vertices) and we seek a solution of weight at most b (amongst all solutions satisfying the cardinality constraint k).

▶ **Theorem 19.** *For an optimization problem Π, if the Weighted Rainbow-Π problem parameterized by k admits an FPT algorithm, then the Π-Discovery problem in the token sliding model parameterized by k admits an FPT algorithm.*

Proof Sketch. Without loss of generality, assume that the problem Π is an edge selection problem. Let $(G, S \subseteq E(G), b)$ be an instance of the Π-Discovery problem. Let $\mathcal{C}$ be a palette of k colors, and $\pi : \mathcal{C} \to S$ be a bijection. We color the edges $E(G) \setminus S$ uniformly at random using $\mathcal{C}$, yielding an edge coloring $\varphi : E(G) \to \mathcal{C}$. Now we define a weight function $w : E(G) \to \mathbb{R}_+$ such that for each $e \in E(G)$ we have $w(e) = \text{dist}(e, \pi(\varphi(e)))$. Intuitively, the weight function denotes the cost of moving a token from the initial configuration to an edge with the same color. Observe that the weights of the edges in the initial configuration are zero and they are colored using piece-wise distinct colors. Now we have an edge-colored graph (G, φ). We claim that if (G, φ, k, b) is a yes-instance of the Weighted Rainbow-Π problem, then (G, S, b) is a yes-instance of the Π-Discovery problem in the token sliding model. Intuitively speaking, the color-coding step allows us to transforms the discovery problem into a weighted rainbow problem.

The rest of the proof consists of showing that if (G, S, b) is a yes-instance of the Π-Discovery problem, then the probability that (G, φ, k, b) is a yes-instance of the Weighted Rainbow-Π problem is at least e^{-k}. We then derandomize the algorithm using the technique introduced by Alon et al. [1]. Instead of a random coloring φ, we construct an $(m-k, k)$-perfect hash family $\mathcal{F}$ such that for every $X \subseteq E(G) \setminus S$ with $|X| = k$, there is a function $f \in F$ such that every element of X is mapped to a different element in $\mathcal{C}$ (color palette as a k-sized set). The family $\mathcal{F}$ can be constructed deterministically in time $O(2^{O(k)} \log m)$ [1]. ◀

8 The jumping and addition/removal models

We now turn to the *token jumping* and *unrestricted token addition/removal* models. Recall that in these models we are no longer restricted to sliding tokens along edges.

8.1 Token jumping

We first define the *red-blue* variant of a vertex (resp. edge) selection problem and show that it is always at least as hard as the solution discovery variant in the token jumping model.

Let Π be an arbitrary vertex (resp. edge) selection problem. An instance of the Red-Blue-Π problem consists of a graph G whose vertices (resp. edges) are either colored red or blue, as well as two non-negative integers k and b. If Π is the decision variant of a minimization/maximization problem, the goal is to decide whether there exists a solution $X \subseteq V(G)$ (resp. $X \subseteq E(G)$) of Π of size k such that the number of blue elements in X is at most b. We denote an instance of Red-Blue-Π by (G, k, b).

▶ **Corollary 20.** *Let Π be an arbitrary vertex (resp. edge) selection problem. Then the following results hold in the token jumping model:*

1. *If Red-Blue-Π is in P, then so is Π-Discovery.*
2. *If Red-Blue-Π is in FPT with respect to k or b, then so is Π-Discovery.*
3. *If Π-Discovery is NP-hard, then so is Red-Blue-Π.*
4. *If Π-Discovery is W[1]-hard with respect to k or b, then so is Red-Blue-Π.*

We remark that the other direction does not trivially hold, i. e., we can in general not consider an instance of Red-Blue-Π as an instance of Π-Discovery, as the number of red vertices/edges might exceed the bound k on the solution size. Nevertheless, we show that Red-Blue Spanning Tree, Red-Blue Shortest Path and Red-Blue Matching are in P, implying that their discovery variants in the token jumping model are in P as well, whereas Vertex/Edge Cut Discovery is NP-hard in the token jumping model, implying that Red-Blue Vertex/Edge Cut Discovery is NP-hard as well.

▶ **Proposition 21.** *Red-Blue Spanning Tree, Red-Blue Shortest Path, and Red-Blue Matching can be solved in polynomial time. Hence, Spanning Tree Discovery, Shortest Path Discovery, and Matching Discovery in the token jumping model can be solved in polynomial time.*

▶ **Proposition 22.** *The Vertex/Edge Cut Discovery problem in the token jumping model is NP-complete. Hence, the Red-Blue Vertex/Edge Cut problem is NP-complete.*

▶ **Theorem 23.** *The Weighted Red-Blue Vertex/Edge Cut problem is fixed-parameter tractable when parameterized by k.*

8.2 Unrestricted token addition/removal

Obviously, every spanning tree of a connected graph G has size $|V(G)| - 1$ by definition. Hence, the Spanning Tree Discovery problem in the unrestricted token addition/removal model can easily be reduced to the token jumping model by halving the budget b (rounded down). To see this, note that any solution to the Spanning Tree Discovery problem in the unrestricted token addition/removal model adds and removes the same number of tokens. Furthermore, the order in which we add or remove tokens from the initial configuration S does not matter. Thus, we assume that the first modification step to S is a token removal, followed by a token addition, followed by removals/additions in alternating order. This can easily be simulated by jumps.

Similarly, the length of a shortest s-t-path in a graph G is a fixed number for fixed s and t. Hence, the same argument as above boils the Shortest Path Discovery problem in the unrestricted token addition/removal model down to the Shortest Path Discovery problem in the token jumping model. When it comes to Matching Discovery and Vertex/Edge Cut Discovery, the unrestricted token addition/removal model allows for two natural variations on the problems. On one hand, and in tune with the rest of the paper, if we impose solutions of size exactly $|S|$ then it is not hard to see that the addition/removal model becomes again equivalent to the jumping model.

▶ **Corollary 24.** *The Spanning Tree Discovery, Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery problems in the unrestricted token addition/removal model can be solved in polynomial time.*

Alternatively, if we drop the constraints on solution size and allow solutions of any size then the problems become considerably different. In particular, the Matching Discovery problem becomes equivalent to asking for a smallest subset of S whose removal (from S) results in a matching. Similarly, the Vertex/Edge Cut Discovery problem becomes equivalent to the problem of computing a smallest subset of vertices whose addition to S results in a cut between s and t. We show that, even in the relaxed setting, both problems remain polynomial-time solvable.

▶ **Proposition 25.** *The (Relaxed) Matching Discovery problem in the unrestricted token addition/removal model can be solved in polynomial time.*

▶ **Proposition 26.** *The (Relaxed) Vertex/Edge Cut Discovery problem can be solved in the unrestricted token addition/removal model in polynomial time.*

Conclusion and future work

We contribute to the new framework of solution discovery via reconfiguration with complexity theoretic and algorithmic results for solution discovery variants of *polynomial-time solvable* problems. While we can employ the efficient machinery of Weighted Matroid Intersection for the Spanning Tree Discovery problem, all other problems under consideration are shown to be NP-complete, namely, Shortest Path Discovery, Matching Discovery, and Vertex/Edge Cut Discovery. For the latter problems, we provide a full classification of tractability with respect to the parameters solution size k and transformation budget b.

We expect further research on this new model capturing the dynamics of real-world situations as well as constraints on the adaptability of solutions. It seems particularly interesting to investigate directed and/or weighted versions of the studied problems. Notice that all base problems that we studied remain polynomial-time solvable in the presence of

edge weights and for cost functions summing the total weight of the solution (spanning tree, path, matching, cut). Interestingly, our result on the Spanning Tree Discovery problem can be generalized to the weighted setting with a clever adaptation of the reduction. For other problems the hardness results clearly hold, but we leave the existence of FPT algorithms for future work. Another challenge is the design of efficient algorithms that can compute approximate solutions with respect to the solution size/value or with respect to the allowed transformation budget. We note, without proof, that the hardness reduction for the Vertex Cut Discovery problem (Theorem 16) can be adjusted to give a $n^{1-\varepsilon}$-inapproximability of the optimal transformation budget.

Abstract

A homomorphism from a graph G to a graph H is an edge-preserving mapping from $V(G)$ to $V(H)$. In the graph homomorphism problem, denoted by $\textsc{Hom}(H)$, the graph H is fixed and we need to determine if there exists a homomorphism from an instance graph G to H. We study the complexity of the problem parameterized by the *cutwidth* of G, i.e., we assume that G is given along with a linear ordering $v_1, \ldots, v_n$ of $V(G)$ such that, for each $i \in \{1, \ldots, n-1\}$, the number of edges with one endpoint in $\{v_1, \ldots, v_i\}$ and the other in $\{v_{i+1}, \ldots, v_n\}$ is at most k.

We aim, for each H, for algorithms for $\textsc{Hom}(H)$ running in time $c_H^k n^{\mathcal{O}(1)}$ and matching lower bounds that exclude $c_H^{k \cdot o(1)} n^{\mathcal{O}(1)}$ or $c_H^{k(1-\Omega(1))} n^{\mathcal{O}(1)}$ time algorithms under the (Strong) Exponential Time Hypothesis. In the paper we introduce a new parameter that we call $\mathrm{mimsup}(H)$. Our main contribution is strong evidence of a close connection between c_H and $\mathrm{mimsup}(H)$:

- an information-theoretic argument that the number of states needed in a natural dynamic programming algorithm is at most $\mathrm{mimsup}(H)^k$,
- lower bounds that show that for almost all graphs H indeed we have $c_H \geq \mathrm{mimsup}(H)$, assuming the (Strong) Exponential-Time Hypothesis, and
- an algorithm with running time $\exp(\mathcal{O}(\mathrm{mimsup}(H) \cdot k \log k)) n^{\mathcal{O}(1)}$.

In the last result we do not need to assume that H is a fixed graph. Thus, as a consequence, we obtain that the problem of deciding whether G admits a homomorphism to H is fixed-parameter tractable, when parameterized by cutwidth of G and $\mathrm{mimsup}(H)$.

The parameter $\mathrm{mimsup}(H)$ can be thought of as the p-th root of the maximum induced matching number in the graph obtained by multiplying p copies of H via a certain graph product, where p tends to infinity. It can also be defined as an *asymptotic rank parameter* of the adjacency matrix of H. Such parameters play a central role in, among others, algebraic complexity theory and additive combinatorics. Our results tightly link the parameterized complexity of a problem to such an asymptotic matrix parameter for the first time.

1 Introduction

The study of the fine-grained complexity of NP-hard problems parameterized by width parameters has recently received an explosive amount of attention. In this study one aims to determine, for a given computational problem, a function f such that (1) the problem can be solved in $f(k)n^{\mathcal{O}(1)}$ time on given instances formed by an n-vertex graph along with an appropriate decomposition with width k, and (2) any improvement to $f(k)^{o(1)}n^{\mathcal{O}(1)}$ or even $f(k)^{1-\Omega(1)}n^{\mathcal{O}(1)}$ time would violate a standard hypothesis, typically being respectively the Exponential Time Hypothesis (ETH) and the Strong Exponential Time Hypothesis (SETH). Characterizing this complexity tightly often gives a deep insight in the combinatorial structure of the problem at hand, in particular about the relation that indicates when two "subsolutions" (for some definition of "subsolutions") combine into a global solution. An example where such insights had major consequences is Hamiltonian Cycle and the Traveling Salesperson Problem [4, 17, 50].

In contrast to the study of such fine-grained complexity, on the other side of the spectrum, a celebrated *meta-theorem* by Courcelle [13] shows that every graph property definable in the *monadic second-order logic* can be decided in time $f(k) \cdot n$ on n-vertex graphs given with a tree decomposition of width k. While this is extremely general, it is not precise at all in the sense that the functions $f(k)$ given by Courcelle's theorem are typically doubly-exponential or more, while more tailored algorithms with single-exponential functions exist. This begs the question: Could there be such a meta-theorem that gives a more fine-grained upper bound akin to the ones sought after above? Unfortunately, such a fine-grained meta-theorem still seems out of reach, and many recent works apply some highly non-trivial problem-specific insights to actually get the combination of tight algorithms and lower bounds [4, 5, 15, 16, 37, 38, 43, 46, 57, 60].

An intermediate step towards more general results such as Courcelle's theorem is to consider general problems that capture many natural well-studied problems as special cases. Such a step was already taken for certain locally checkable vertex subset problems, which capture natural problems including Independent Set and Dominating Set [25]. A particularly rich and elegant family of such problems can be defined via *graph homomorphisms*. A homomorphism from G to H is a mapping $\varphi : V(G) \to V(H)$ such that for every $uv \in E(G)$ we have $\varphi(u)\varphi(v) \in E(H)$. If H is the complete graph on k vertices, such mappings φ are exactly proper k-colorings, and this is why these mappings are often referred to as a *H-colorings* of G. For a fixed graph H, by Hom(H) we denote the computational problem in which one needs to determine whether there is a homomorphism to H from an input graph G. The complexity dichotomy for Hom(H) was provided by Hell and Nešetřil [34]: Hom(H) is polynomial-time solvable if H is bipartite, and NP-hard otherwise. So the cases relevant to our work are when H is non-bipartite.

There has been impressive work on the complexity of Hom(H) in various settings [7, 9, 11, 12, 14, 19, 20, 29, 58]. From the fine-grained perspective, a lot of attention was put in the parameterization by treewidth of the instance graph [21, 23, 26, 53, 54]. In particular,

for Hom(H) and some of its close relatives we exactly understand the fastest possible (up to the SETH) running time of algorithms parameterized by treewidth. Perhaps even more interestingly, the techniques developed in this line of research led to a deep understanding of combinatorial properties of Hom(H) and its variants, and the results obtained on the way can be used far beyond the bounded-treewidth case.

Typically, the lower bounds for (a variant of) Hom(H) are shown by a reduction from (a variant of) q-Coloring, where the choice of q depends on H. In particular, Marx, Lokshtanov, and Saurabh [44] showed that for any $q \geq 3$, the q-Coloring problem on every instance G cannot be solved in time $(q-\varepsilon)^{\mathrm{tw}(G)} \cdot |V(G)|^{\mathcal{O}(1)}$ for any $\varepsilon > 0$, unless the SETH fails (here $\mathrm{tw}(G)$ is the treewidth of G). Similar lower bounds for q-Coloring are also known for other parameters, like *cliquewidth* [40], *feedback vertex set number* [44], *vertex cover number* [35], or *component-order-connectivity* [23]. A common element in all these results is that the constant in the base of the exponential factor in the complexity bound is an increasing function of the number q of colors.

However, it appears that this is not the case for all natural width parameters. For a linear ordering $v_1, v_2, \ldots, v_n$ of vertices of a graph G, its *width* is the maximum number of edges between the sets $\{v_1, \ldots, v_i\}$ and $\{v_{i+1}, \ldots, v_n\}$, over all $i \in \{1, \ldots, n-1\}$. The *cutwidth* of G, denoted by $\mathrm{ctw}(G)$, is the minimum width of a linear ordering of $V(G)$.

In stark contrast to the results listed above, Jansen and Nederlof [36] showed that for every q, the q-Coloring problem on instances G given with a linear ordering of width k can be solved in randomized[1] time $2^k \cdot |V(G)|^{\mathcal{O}(1)}$. In particular, the base of the exponential factor does not depend on q.

This phenomenon appears to be very fragile, e.g., it no longer occurs for the *counting* variant of q-Coloring [32]. In the context of the discussion above, it is very natural to ask about the situation for Hom(H), i.e., whether the natural dynamic programming approach that works in time $|V(H)|^k \cdot |V(G)|^{\mathcal{O}(1)}$ can be improved. In particular, whether there exists an absolute constant c_H, such that for every graph H, the Hom(H) problem on n-vertex instances of cutwidth k can be solved in time $c_H^k \cdot n^{\mathcal{O}(1)}$. This question was answered in the negative by Piecyk and Rzążewski [56], who showed that the base c_H of the exponential factor in the complexity bound (seen as a function of H) grows to infinity even if we restrict ourselves to cycles. More specifically, they show that c_H is lower-bounded by the number of edges in a maximum *induced matching*[2] in H, multiplied by 2.

Note that a maximum induced matching of a clique has only one edge, so this lower bound matches the running time of the randomized algorithm for q-Coloring [36].

However, Piecyk and Rzążewski [56] failed to provide an algorithm matching this lower bound, even functionally, i.e., an algorithm with running time $f(p,k) \cdot n^{\mathcal{O}(1)}$, where f is any function of the size p of a maximum matching in H and the cutwidth k of the instance. Thus, while the size of a maximum induced matching in H certainly plays some important role in the complexity of Hom(H) parameterized by the cutwidth, it is far from clear whether it indeed determines the base of the exponential factor. The discussion above leads to the following.

▶ **Open Problem 1.** *Describe, for any fixed non-bipartite graph H, a constant c_H such that:*

1. *There is an algorithm that, for all $k, n \in \mathbb{N}$, given an n-vertex graph G with linear ordering of width k, solves Hom(H) in time $c_H^k \cdot n^{\mathcal{O}(1)}$, and*
2. *Assuming the SETH, for any $\varepsilon > 0$, there is no algorithm that, for all $k, n \in \mathbb{N}$, given an n-vertex graph G with linear ordering of width k, solves Hom(H) in time $(c_H - \varepsilon)^k \cdot n^{\mathcal{O}(1)}$.*

[1] A slightly slower deterministic algorithm was also given.

[2] An *induced matching* of a graph is a set M of edges such that the graph induced by the endpoints of M is a matching.

Recall that when H is bipartite, $\textsc{Hom}(H)$ is already known to be solvable in polynomial time. Therefore, we restrict ourselves to non-bipartite graphs.

Moreover, for each graph H we have $c_H \leq |V(H)|$, as a straightforward dynamic programming algorithm works in time $|V(H)|^k \cdot n^{\mathcal{O}(1)}$.

Our contribution. We make significant progress towards Open Problem 1. In particular, for each non-bipartite graph H we define a constant c_H which we conjecture to have the desired properties. We prove, for almost all graphs, that $\textsc{Hom}(H)$ in n-vertex instances given with a linear ordering of width k cannot be solved in time $(c_H - \varepsilon)^k \cdot n^{\mathcal{O}(1)}$ for any $\varepsilon > 0$, assuming the SETH. Moreover, we give a dynamic programming approach of which we show the table sizes can be compressed to $c_H^k \cdot n^{\mathcal{O}(1)}$ (see the paragraph on *representative sets* below for more details). This can be interpreted as an upper bound, for each $i \in \{1, \ldots, n-1\}$ on the amount of *information* of the graph $G[\{v_1, \ldots, v_i\}]$ needed to decide $\textsc{Hom}(H)$ based on *only* $G - G[\{v_1, \ldots, v_i\}]$. Unfortunately, this is an existential result and we do not yet know how to efficiently perform this compression. We give partial progress towards such a computation, yielding an algorithm with running time $\exp(2c_H k \log k) n^{\mathcal{O}(1)}$.

For a 0/1-matrix A, we define $\operatorname{mim}(A)$ as the largest r for which A has an $r \times r$ permutation submatrix.[3] The aforementioned work [56] shows that c_H needs to be at least $\operatorname{mim}(A_H)$, if A_H is the adjacency matrix of H. However, one of our main insights is that, as the cutwidth k increases, the accurate parameter for measuring the aforementioned amount of needed information on $G[\{v_1, \ldots, v_i\}]$ is actually $\operatorname{mim}(A_H^{\otimes k})$, where $A_H^{\otimes k}$ denotes the result of taking the Kronecker product of k copies of A_H. Specifically, we introduce a new asymptotic rank parameter, called *mimsup*, defined by

$$\operatorname{mimsup}(A) = \limsup_{k \to \infty} \operatorname{mim}(A^{\otimes k})^{1/k}.$$

For a graph H, we define $\operatorname{mimsup}(H)$ to be $\operatorname{mimsup}(A_H)$, where A_H is the adjacency matrix of H. We remark that $\operatorname{mimsup}(H)$ can be also defined in a purely graph-theoretic way, in terms of the size of a maximum matching in a certain graph product. See Section 2 for more thorough definitions and details. We prove the results above for c_H equal to $\operatorname{mimsup}(H)$ (modulo some standard preprocessing of H).

The parameter becomes especially clean and elegant if H is a *projective core*; such graphs play a prominent role in the study of graph homomorphisms [29, 42, 54]. Their definition is somewhat complicated, we refer the interested reader to the full version of the paper (in Appendix). Let us just mention that this class captures *almost all graphs* [33, 45]. Formally, let p_n denote the probability that an n-vertex graph, chosen uniformly at random, is a non-bipartite projective core. Then p_n tends to 1 as n tends to infinity. Furthermore, up to some conjectures from algebraic graph theory from the early 2000s [41, 42], every graph H that cannot be simplified by the above-mentioned preprocessing is actually a projective core. We refer the interested reader to [54] for more information.

Going back to our setting, if H is a non-bipartite projective core, then we simply have $c_H = \operatorname{mimsup}(H)$. The first evidence that c_H is indeed the "right" choice of the parameter is the following lower bound[4].

[3] It is easily seen that $\operatorname{mim}(A)$ equals the maximum size of an induced matching in the bipartite graph that has A as biadjacency matrix. If A is symmetric, it is the adjacency matrix of a graph H and $\operatorname{mim}(A)$ equals twice the maximum size of an induced matching in H.

[4] Full proofs of statements marked with (♠) can be found in the full version of the paper [31]

▶ **Theorem 1** (♠).
1. *There exists $\delta > 0$, such that for every non-bipartite projective core H, there is no algorithm solving every instance G of $\textsc{Hom}(H)$ in time* $\operatorname{mimsup}(H)^{\delta \cdot \operatorname{ctw}(G)} \cdot n^{\mathcal{O}(1)}$*, unless the ETH fails.*
2. *Let H be a connected non-bipartite projective core. There is no algorithm solving every instance G of $\textsc{Hom}(H)$ in time* $(\operatorname{mimsup}(H) - \varepsilon)^{\operatorname{ctw}(G)} \cdot |V(G)|^{\mathcal{O}(1)}$ *for any $\varepsilon > 0$, unless the SETH fails.*

We next elaborate on the mentioned dynamic programming approach along with the table size compression via which we aim to match these lower bounds.

Representative Sets. A crucial technique in our arguments is that of *representative sets*. This is a method that allows us to considerably speed up dynamic programming algorithms by sparsifying the associated tables. Specifically, dynamic programming algorithms generally define a space of possible partial solutions $\mathcal{S}$, and a dynamic programming table stores a subset $\mathcal{A}$ of partial solutions that are valid in the given instance. A binary *compatibility matrix* M with rows and columns indexed by $\mathcal{S}$ indicates whether two partial solutions combine into a global solution. Generally speaking, a *representative set* of a set $\mathcal{A} \subseteq \mathcal{S}$ is a subset $\mathcal{A}'$ such that for each $j \in \mathcal{S}$ we have that there exists $i \in \mathcal{A}$ with $M[i,j] = 1$ if and only if there exists $i' \in \mathcal{A}'$ with $M[i',j] = 1$; see Section 3.1 for details more specific to the setting of our paper.

The power of representative sets lies in that (i) by definition, in any dynamic programming algorithm we can replace the set $\mathcal{A}$ with the smaller set $\mathcal{A}'$ without missing solutions, and (ii) for many matrices M, surprisingly small representative sets are guaranteed to exist. This underlies, for example, fast algorithms for the k-Path problem [48] or connectivity problems parameterized by treewidth [4,27]. However, a serious bottleneck in these algorithm is the *computation* of such representative sets: It withholds us, for example, for getting faster algorithms for connectivity problems such as Traveling Salesperson (both parameterized by treewidth [4,17] and the classic parameterization by the number of cities [50, Theorem 3]), and polynomial kernelization algorithms for Odd Cycle Transversal [39].

This already led some researchers to design faster algorithms for finding representative sets in special settings. A natural setting that comes up, for example for connectivity problems parameterized by treewidth, is to find representative sets for sets of partial solutions with a certain *product structure*. In [28], the authors show that representative sets for such families can be found faster than known for general families.

In this paper, the computation of representative sets is also a major bottleneck; in fact, modulo the standard conjectures discussed above, it is the only issue that withholds us from solving Open Problem 1 completely. Specifically, we show:

▶ **Theorem 2** (Informal statement of Theorem 6). *In the context of the natural dynamic programming algorithm for $\textsc{Hom}(H)$ parameterized by cutwidth k, there exist representative sets of size at most* $\operatorname{mimsup}(H)^k$.

Thus, by the definition of representative sets, any algorithm that computes these representative sets fast enough would imply a $\operatorname{mimsup}(H)^{\operatorname{ctw}(G)} n^{\mathcal{O}(1)}$ time algorithm for $\textsc{Hom}(H)$ and thus solve Open Problem 1. We view this as strong evidence that our lower bounds cannot be improved. Indeed, state-of-the-art hardness reduction techniques (like [44]) for problems parameterized by width parameters encode assignments to decision variables as states of dynamic programming tables and gradually check constraints on global consistency of these assignments throughout the graph. Our proof of existence of small representative

Figure 1 Illustration of a maximum induced matching (or equivalently, induced permutation submatrix) of size $\mathrm{mim}(A_H^{\otimes 2})$ shown in red, where $A_H = \left(\begin{smallmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{smallmatrix}\right)$ and $H = K_3$. More generally, the proof from [36] for determining the chromatic number of a graph shows that whenever H is a complete graph, $\mathrm{mim}(A_H^{\otimes k}) = 2^k$ and thus $\mathrm{mimsup}(H) = 2$.

sets means the number of assignments that need to be considered in order to find a global solution is also small, which means that this kind of approach to design lower bounds hits a natural barrier at our lower bound.

Coping Algorithmically with the Mimsup Parameter. Matrix or graph parameters that are defined in terms of large powers are sometimes called *asymptotic rank parameters*, and they are notoriously hard to compute. For example, the value of the asymptotic rank of the matrix multiplication tensor [8] (also known as ω) or the Shannon capacity of the cycle on 7 vertices [30] remain elusive. Unfortunately, $\mathrm{mimsup}(H)$ seems no exception. Similarly to the Shannon capacity [1, Question 6], it is even not clear whether its computation is decidable. For $\mathrm{mimsup}(H)$, even for simple graphs such as $H = K_q$, determining its value is non-trivial as well. As an illustration we depict the maximum induced matching in the second Kronecker power of the adjacency matrix of K_3 in Figure 1. One of the main insights of the $2^{\mathrm{ctw}(G)}n^{\mathcal{O}(1)}$ time algorithm for the chromatic number from [36] shows that $\mathrm{mimsup}(K_q)$ in fact equals 2.

Even when the existence of small representative sets is guaranteed because $\mathrm{mimsup}(H)$ is small, it is still challenging to find them quickly. Since mimsup is about products of graphs, one may expect that this product structure can be used algorithmically. Indeed, product structure has been exploited to compute representative sets in previous work [28], but there the family that needs to be represented has some (Cartesian) product structure. In our setting, this is not guaranteed and it is much less obvious how to proceed.

Nevertheless we show that, with some loss in precision (and hence, running time), we can work with graphs with small mimsup, by approximating it with another (easier to compute) value that we call the maximum *half induced matching* number $\mathrm{him}(H)$. For a matrix A, we define $\mathrm{him}(A)$ as the largest r for which A has an $r \times r$ triangular submatrix with ones on its diagonal.[5] For a graph H, we define $\mathrm{him}(H)$ to be $\mathrm{him}(A_H)$, where A_H is the adjacency matrix of H. We show that $\mathrm{him}(A_H)$ approximates $\mathrm{mimsup}(A_H)$ in the following sense:

▶ **Theorem 3.** *For every non-bipartite graph H with adjacency matrix A_H and $k \in \mathbb{N}$,*

$$\mathrm{him}(A_H) \leq \mathrm{mimsup}(A_H) = \limsup_{k\to\infty} \mathrm{mim}(A_H^{\otimes k})^{1/k} \quad \text{and} \quad \mathrm{mim}(A_H^{\otimes k}) \leq k^{(\mathrm{him}(A_H)+1)k}.$$

[5] A submatrix of a matrix A is any matrix that can be obtained from A by removing and reordering any of its rows and columns.

The parameter $\mathrm{him}(A_H)$ is easily computable in time $2^{\mathcal{O}(|V(H)|)}$. While the lower bound on $\mathrm{mimsup}(A_H^{\otimes k})$ is relatively easy, the upper bound uses an argument similar to the "neighborhood chasing" argument for the upper bounds on multi-colored Ramsey numbers [22]. This argument can in fact be made algorithmic in the sense that it can be used to compute representative sets for $\textsc{Hom}(H)$ of size at most $\mathcal{O}(k^{\mathrm{him}(H)k})$ in time $\mathcal{O}(k^{2\mathrm{him}(H)k})$. Combining this result with the dynamic programming algorithm for $\textsc{Hom}(H)$ for graphs of small cutwidth yields the following.

▶ **Theorem 4.** *For any graphs G and H, where G is given with a linear ordering of width k, in time $\mathcal{O}(k^{2k\cdot\mathrm{mimsup}(H)} \cdot |V(H)|^4|V(G)|)$ one can decide whether G admits a homomorphism to H.*

Let us compare the running time in Theorem 4 with the naive approach; recall that its complexity is $|V(H)|^k \cdot |V(G)|^{\mathcal{O}(1)}$. If we treat H as a constant and k as a parameter, then the latter one is faster. However, we emphasize here that in Theorem 4 we do not assume that H is a constant, so these two algorithms are incomparable. In particular, Theorem 4 shows that the homomorphism problem, where the input consists of both G and H, is *fixed-parameter-tractable* when parameterized by the cutwidth of G and $\mathrm{mimsup}(H)$.

It should be noted that a similar notion of half-induced matching of a compatibility matrix was already introduced in previous work in the context of representative sets of the AntiFactor problem [47] parameterized by treewidth and list size. However, in that setting, the authors were only able to provide a lower bound for their problem, and they did not manage to make the connection with half-induced matchings algorithmic. Additionally, their compatibility matrix has a very specific structure: it is indexed with integers and the value of an entry only depends on the sum of the values associated with the row and column.

Comparison of Mimsup With Other Rank Parameters. One of our main conceptual contributions is the introduction of the mimsup parameter in the context of parameterized algorithms. It is actually the first asymptotic rank parameter shown to be relevant in this context. Our mimsup parameter is very similar to the *asymptotic induced matching number* studied by Arunachalam et al. [2] which was introduced for k-partite, k-uniform hypergraphs (and so, in the graph setting, only for bipartite graphs). Various asymptotic variants of rank parameters have been studied for tensors. For example, this has been done for rank parameters such as subrank, tensor rank and slice rank. However, for matrices (2-tensors) these are equal to the "standard" rank for matrices and so have no interesting asymptotic aspects.

That being said, it is only natural to compare the mimsup parameter with different related rank parameters from the literature. We will discuss this now, and provide proofs that formally support this discussion in the Appendix. The approach from [36] naturally extends to solve $\textsc{Hom}(H)$ quickly for all graphs H where the so-called *support-rank* [18, 49] of the adjacency matrix of H is small. The following sequence of inequalities holds for every matrix A:

$$\mathrm{mim}(A) \leq \mathrm{him}(A) \leq \mathrm{mimsup}(A) \leq \text{support-rank}(A) \leq \mathrm{rank}(A).$$

We believe all of the inequalities can be strict. When A is the $(r \times r)$-matrix with ones on and above the diagonal and zeros below the diagonal, then $\mathrm{mim}(A) = 1 < r = \mathrm{him}(A)$ for $r \geq 2$. This means that mim is not functionally equivalent to him nor mimsup. We use random matrices to show that him and mimsup may take very different values (see Theorem 13 for a formal statement). In the Appendix we find a connection of support-rank to a parameter called *graph dimension* (or *Prague dimension*) [51, 52]. We also show there

that him is not functionally equivalent to support-rank. This shows that our algorithm from Theorem 4 can be significantly faster than the discussed natural generalization of [36]. We leave it as an interesting open problem if mimsup is functionally equivalent to him or support-rank.

The aforementioned (well studied) Shannon capacity has a definition that is very similar to the mimsup parameter: It is defined in terms of the maximum size of an independent set (also called the independence number) in an appropriate graph product, and the size of a maximum induced matching of a graph equals the independence number of the square of its line graph. Unfortunately, because the definitions of mimsup and Shannon capacity use different graph products, the relation between the two is somewhat loose; see Appendix for details. Nevertheless, based on their similarity, one may expect that Shannon capacity shares some of its peculiarities with mimsup, such as an unpredictable behaviour of the value in graph powers [1].

2 Preliminaries

For an integer n, by $[n]$ we denote the set $\{1, 2, \ldots, n\}$ and for integers a, b we write $[a, b] = \{a, a+1, \ldots, b\}$. For a set X, by 2^X we denote the family of all subsets of X. For $i, s \in \mathbb{N}$, the multinomial coefficient

$$\binom{is}{s, \ldots, s} = \frac{(is)!}{s!, \ldots, s!} = i^{(1+o(1))is}$$

is the number of partitions of $[as]$ into a parts of size s.

For a graph G and $V' \subseteq V(G)$ (resp. $E' \subseteq E(G)$), by $G[V']$ (resp. $G[E']$) we denote the subgraph of G induced by V' (resp. E'). We say two graph parameters p and q are functionally equivalent if there are functions $f, g : \mathbb{R} \to \mathbb{R}$ such that $p(G) \leq f(q(G))$ and $q(G) \leq g(p(G))$ for all graphs G.

Homomorphisms. For graphs G and H, a *homomorphism* from G to H is a mapping $\varphi : V(G) \to V(H)$ such that for every $uv \in E(G)$ we have $\varphi(u)\varphi(v) \in E(H)$. If φ is a homomorphism from G to H, we denote it by writing $\varphi : G \to H$. If G admits a homomorphism to H, we denote is shortly by $G \to H$.

In the Hom problem we are given a pair (G, H) of graphs, and we ask whether $G \to H$. In the Hom(H) the graph H is considered to be fixed and we ask whether a graph G given as an input admits a homomorpshism to H.

We will always assume that H is a connected graph. Indeed, each component of G must map to a single component of H, so the problem can be solved component-wise.

Cutwidth. Let G be a graph and consider a linear ordering $\sigma = (v_1, \ldots, v_n)$ of its vertices. For $i \in [n-1]$, the *i-th cut* is the partition of $V(G)$ into sets $\{v_1, \ldots, v_i\}$ and $\{v_{i+1}, \ldots, v_n\}$. The *width* of such a cut is the number of edges with one endvertex in $\{v_1, \ldots, v_i\}$ and the other in $\{v_{i+1}, \ldots, v_n\}$. The *width* of σ is the maximum width of a cut of σ. Finally, the *cutwidth* of G, denoted by $\mathrm{ctw}(G)$, is the minimum width of a linear ordering of the vertices of G.

Associated bipartite graphs. In order to define the main parameters of our paper, we will use a notion of *associated bipartite graphs*. For a graph G, the graph G^* is defined as follows.

$$V(G^*) = \{u', u'' \mid u \in V(G)\},$$
$$E(G^*) = \{u'w'', u''w' \mid uw \in E(G)\}.$$

Induced matchings and half-induced matchings. A set $M \subseteq E$ of edges of a graph $H = (V, E)$ forms an *induced matching* if the edges in M are vertex disjoint and no edge in E is incident with two edges from M. We may also view this as two sequences of distinct vertices $v_1, \ldots, v_m$ and $u_1, \ldots, u_m$ where $v_i u_j \in E$ if and only if $i = j$. For a bipartite graph H, by $\mathrm{mim}(H)$ we denote the size of a maximum induced matching in H. For non-bipartite H, we define $\mathrm{mim}(H) := \mathrm{mim}(H^*)$.

A *half-induced matching* of a graph H consists of two sequences $v_1, \ldots, v_m$ and $u_1, \ldots, u_m$ of distinct vertices where $v_i u_i \in E$ for $i \in [m]$ and $u_i v_j \notin E$ if $1 \leq i < j \leq m$. For a bipartite graph H, we denote the size of the largest half-induced matching in H by $\mathrm{him}(H)$. We extend the definition to graphs H that are non-bipartite via $\mathrm{him}(H) = \mathrm{him}(H^*)$. This notion has been studied under the name *constrained matching* (a subset with a unique matching, see e.g. [10, 55, 59]), but we decided to use the name which appeared more recently in a similar setting to ours [47], since the word "constrained matching" has also been used for various other purposes in the algorithmic community.

Mim and him for matrices. Let $A \in \{0,1\}^{n \times n}$ be a matrix. Given a sequence $r \in [n]^a$ of distinct row indices and $c \in [n]^b$ of distinct columns indices, for some integers $a, b \in [n]$, we write $A[r, c]$ for the $a \times b$ matrix with entries $A[r, c]_{i,j} = A_{r_i, c_j}$ for $i \in [a]$ and $j \in [b]$. We refer to any matrix which arises in such a manner as a *submatrix after permutation* of A.

We write $\mathrm{mim}(A)$ for the maximum r for which A has the $r \times r$ identity matrix as submatrix after permutation (equivalently, the largest permutation submatrix). We write $\mathrm{him}(A)$ for the largest r for which A has an $r \times r$ triangular matrix with 1's on the diagonal as submatrix after permutation. We will also refer to such a submatrix as *half induced matching*. (A matrix is called *triangular* if either all entries below the diagonal, or all entries above the diagonal are 0.)

For bipartite graphs $H = (U, V, E)$, the *bi-adjacency matrix* B is indexed by rows from U and columns from V where $B[u, v] = 1$ if $uv \in E$ and $B[u, v] = 0$ otherwise. For a bipartite graph H, there is a one-to-one correspondence between induced matchings of H of size m and $m \times m$ permutation submatrices of the bi-adjancency matrix of H. In particular, for a bi-adjacency matrix B of H, $\mathrm{mim}(B) = \mathrm{mim}(H)$. Similarly, $\mathrm{him}(B) = \mathrm{him}(H)$.

For a non-bipartite graph G, if A_G is its adjacency matrix, then A_G is also the bi-adjacency matrix of G^*. This means that for non-bipartite H with adjacency matrix A_H, $\mathrm{mim}(H) = \mathrm{mim}(A_H)$ and $\mathrm{him}(H) = \mathrm{him}(A_H)$.

Mimsup. For a matrix A, we define

$$\mathrm{mimsup}(A) = \limsup_{k \to \infty} \mathrm{mim}(A^{\otimes k})^{1/k}.$$

Here $\otimes$ denotes the Kronecker product of the matrix. Given an $n \times m$ matrix $A = (a_{i,j})_{i \in [n], j \in [m]}$ and a matrix B, the Kronecker product is given by

$$A \otimes B = \begin{pmatrix} a_{1,1}B & a_{1,2}B & \ldots & a_{1,m}B \\ a_{2,1}B & a_{2,2}B & \ldots & a_{2,m}B \\ & \ldots & & \\ a_{n,1}B & a_{n,2}B & \ldots & a_{n,m}B \end{pmatrix}.$$

Since $\operatorname{mim}(A \otimes B) \geq \operatorname{mim}(A)\operatorname{mim}(B)$, Fekete's lemma [24] applies to show that (♠)

$$\limsup_{k\to\infty} \operatorname{mim}(A^{\otimes k})^{1/k} = \lim_{k\to\infty} \operatorname{mim}(A^{\otimes k})^{1/k} = \sup_{k\in\mathbb{N}} \operatorname{mim}(A^{\otimes k})^{1/k}.$$

For a non-bipartite graph H, with adjacency matrix A, we set

$$\operatorname{mimsup}(H) = \operatorname{mimsup}(A).$$

When H is bipartite with bi-adjancency matrix[6] B, $\operatorname{mimsup}(H) = \operatorname{mimsup}(B)$. The parameters can also be defined in purely graph theoretical terms, as we now explain.

For a bipartite graph H with bipartition classes X, Y, and for $k \in \mathbb{N}$, we define $H^{\otimes k}$ to be the graph on vertex set $X^k \cup Y^k$ where there is an edge $(x_1, \ldots, x_k)(y_1, \ldots, y_k)$ in $H^{\otimes k}$ if and only if $x_i y_i \in E(H)$ for every $i \in [k]$. With this definition of graph product $\otimes$, we define

$$\operatorname{mimsup}(H) = \begin{cases} \limsup_{k\to\infty} \operatorname{mim}(H^{\otimes k})^{1/k} & \text{if } H \text{ is bipartite,} \\ \operatorname{mimsup}(H^*) & \text{otherwise.} \end{cases}$$

The following property of mimsup is straightforward.

▶ **Observation 5.** *If H is an induced subgraph of G, then* $\operatorname{mimsup}(H) \leq \operatorname{mimsup}(G)$.

For bipartite graphs, mimsup coincides with the parameter asymptotic induced matching number studied by [2]. Although asymptotic rank parameters (e.g. asymptotic subrank, asymptotic tensor rank and asymptotic slice rank) have been widely studied for tensors, the "non-asymptotic" parameters are usually equal to the matrix rank for matrices, which has no interesting asymptotic behaviour since $\operatorname{rank}(A^{\otimes n}) = \operatorname{rank}(A)^n$. In particular, the *subrank* in some sense looks for the largest "identity subtensor", similar to our mim, but since it allows row operations to be applied (instead of merely permutations), this notion is the same as the usual rank for matrices and the same holds for the asymptotic subrank.

3 Solving Hom with representative sets

In this section we discuss how we can use representative sets to create fast algorithms for Hom. We start by giving a definition of a representative set in our setting. Intuitively we want a representative set $\mathcal{A}'$ of $\mathcal{A}$ to carry all the important information from $\mathcal{A}$, while being smaller in size. In practice, being able to find small representative sets corresponds to having to compute less entries in a dynamic programming algorithm. So this gives the following natural extremal problem: how small of a representative set are we always guaranteed to find, that is, *what is the largest size of a set which has no smaller representative set?* After giving the definition, we explain why mimsup exactly determines the answer to this question in our setting.

Finally, we give a general framework for solving Hom instances; it consists of an algorithm that takes as input some reduction algorithm R that produces small representative sets and uses it to solve Hom on input graphs G and H. In Section 4 we give examples of such reduction algorithms.

[6] Note that mimsup is invariant under row and column permutations. This means that the choice of bi-adjacency matrix does not affect the mimsup and thus mimsup on bipartite graphs is well-defined.

3.1 Definition of Representative Set

Given a 0/1 matrix M, with rows indexed by a set $\mathcal{R}$ and $\mathcal{A} \subseteq \mathcal{R}$, we are interested in knowing whether for a column c, there is a row $r \in \mathcal{A}$ with $M[r,c] = 1$. In our case,

- each row represents a coloring of the left-hand side of the cut;
- all the colorings that can be extended to the left-hand side of the (input) graph are contained in $\mathcal{A}$;
- each column represents a coloring of the right-hand side of the cut;
- $M[r,c] = 1$ if and only if the colorings represented by row r and column c are compatible.

This makes the following definition very natural. We say that a subset $\mathcal{A}' \subseteq \mathcal{A}$ *M-represents* $\mathcal{A}$, if for any column j we have that if there is a row index $i \in \mathcal{A}$ such that $M[i,j] = 1$, then there is also $i' \in \mathcal{A}'$ such that $M[i',j] = 1$. Intuitively, this means that we do not "lose any solutions" by restricting to $\mathcal{A}'$.

We will also refer to $\mathcal{A}'$ as an *M-representative set* of $\mathcal{A}$. We may omit M if it is clear from context.

We remark that representing is transitive: if $\mathcal{A}''$ represents $\mathcal{A}'$ and $\mathcal{A}'$ represents $\mathcal{A}$, then $\mathcal{A}''$ represents $\mathcal{A}$.

Suppose we aim to solve Hom for input graphs G and H, where H is non-bipartite. We will be interested in representative sets with respect to $M = A_H^{\otimes k}$ for integers k, where A_H is the adjacency matrix of H. We assume that G is given with a linear order $v_1, \ldots, v_n$ of width at most w. For an integer $i \in [n]$, then $G[\{v_1, \ldots, v_i\}]$ is the "left-hand side of the graph" with respect to the ith cut and

$$X_i := \{v \in \{v_1, \ldots, v_i\} \mid \exists v' \in \{v_{i+1}, \ldots, v_n\}, vv' \in E(G)\}.$$

is "the left-hand side of the i-th cut." Suppose there are k edges crossing the ith cut: $\{a_1, b_1\}, \ldots, \{a_k, b_k\} \in E(G)$ with $a_1, \ldots, a_k \in \{v_1, \ldots, v_i\}$ and $b_1, \ldots, b_k \in \{v_{i+1}, \ldots, v_n\}$. Let $L_i = (a_1, \ldots, a_k)$ and $R_i = (b_1, \ldots, b_k)$. Note that $\{a_1, \ldots, a_k\} = X_i$ but some elements may be repeated. A row r (seen as "index") of the matrix $M = A_H^{\otimes k}$ is a k-tuple $(r_1, \ldots, r_k) \in V(H)^k$, which corresponds to a coloring $X_i \to V(H)$ if $r_j = r_{j'}$ whenever $a_j = a_{j'}$. If similarly $c \in V(H)^k$ represents a coloring of the "right-hand side of the cut", then $M[r,c] = 1$ if and only if $r_j c_j \in E(H)$ for all $j \in [k]$, i.e. the colorings are compatible. So indeed we capture the properties informally claimed above.

Since in our setting M will be the adjacency matrix of some graph H, we may refer to H-representative sets rather than A_H-representative sets.

3.2 Connection to Mimsup

When applied to the adjacency matrix A_H of a non-bipartite graph H, the following result shows that $\text{mimsup}(H)^k$ approximates how large a set $\mathcal{A} \subseteq V(H)^k$ without smaller $A_H^{\otimes k}$-representative set can be. This easily follows from the definitions but is still an important conceptual contribution.

▶ **Theorem 6.** *Let $M \in \{0,1\}^{h \times h}$ be a matrix with rows indexed by $\mathcal{R}$.*

- *For each integer $k \in \mathbb{N}$, for any $\mathcal{A} \subseteq \mathcal{R}^k$, there is a subset $\mathcal{A}' \subseteq \mathcal{A}$ of size $\text{mimsup}(M)^k$ that $M^{\otimes k}$-represents $\mathcal{A}$.*
- *Conversely, for each $\varepsilon > 0$, for each sufficiently large k, there is a $\mathcal{A} \subseteq \mathcal{R}^k$, for which no $\mathcal{A}' \subseteq \mathcal{A}$ of size at most $(\text{mimsup}(M) - \varepsilon)^k$ can $M^{\otimes k}$-represent $\mathcal{A}$.*

Proof. Let $\mathcal{A}' \subseteq \mathcal{A}$ be of minimal size among the subsets that M-represent $\mathcal{A}$. Then no proper subset of it M-represents $\mathcal{A}$. This means that for each $a \in \mathcal{A}'$ it cannot be removed from $\mathcal{A}'$ to get a set that M-represents $\mathcal{A}$. Thus, for each $a \in \mathcal{A}'$ there is some $\mu(a) \in V(H)^k$

such that $M[a, \mu(a)] = 1$, but for every $a' \in \mathcal{A}' \setminus \{a\}$ we have that $M[a', \mu(a)] = 0$. This gives a permutation $(|\mathcal{A}'| \times |\mathcal{A}'|)$-submatrix of M. This shows that $|\mathcal{A}'| \leq \mathrm{mim}(M^{\otimes k})$. By definition of mimsup, $\mathrm{mim}(M^{\otimes k}) \leq \mathrm{mimsup}(M)^k$.

Conversely, by definition of limit, for each $\varepsilon > 0$ there is a k_0 such that $\mathrm{mim}(M^{\otimes k}) \geq (\mathrm{mimsup}(M) - \varepsilon)^k$ for all $k \geq k_0$. Let $k \geq k_0$. Let $\mathcal{A} \subseteq \mathcal{R}$ be the rows of a largest induced permutation submatrix of $M^{\otimes k}$. Then $|\mathcal{A}| = \mathrm{mim}(M^{\otimes k}) \geq (\mathrm{mimsup}(M) - \varepsilon)^k$ and none of the strict subsets of $\mathcal{A}$ can $M^{\otimes k}$-represent it. ◀

3.3 Exploiting Representative Sets in Dynamic Programming

The main idea behind the use of representative sets in an algorithmic setting is as follows. We solve the problem with a standard dynamic programming approach, where the cells are indexed by the elements of the set $\mathcal{A}$. A representative set then forms a small subset of these indices, which still carries enough information to solve the problem. By regularly applying the reduction algorithm, we can effectively run our dynamic programming algorithm on only a small subset of the cells in the table. We formalize this in the following theorem. Let us emphasize that H is not assumed to be fixed here but rather given as an input.

▶ **Theorem 7.** *Let H be a non-bipartite graph on h vertices. Let R be a reduction algorithm that, given an integer $k \geq 2$ and a subset $\mathcal{A} \subseteq V(H)^k$, outputs a set $\mathcal{A}'$ of size $\mathsf{size}(H, k)$ that $A_H^{\otimes k}$-represents $\mathcal{A}$, running in time $\mathsf{time}(|\mathcal{A}|, H, k)$. Then there exists an algorithm that, given a linear ordering of an n-vertex graph G of width w, decides whether $G \to H$ in time*

$$\mathcal{O}\Big(\big(\mathsf{size}(H, w) \cdot h + \mathsf{time}\left(\mathsf{size}(H, w) \cdot h, H, w\right)\big)n\Big).$$

Proof. Let $v_1, \ldots, v_n$ be a linear ordering of G of width k. For $i \in [n]$, by E_i we denote the set of edges that cross the i-th cut, i.e., those with one endpoint in $\{v_1, \ldots, v_i\}$ and the other in $\{v_{i+1}, \ldots, v_n\}$. For $i \in [n]$, let X_i be the set that contains all vertices from $\{v_1, \ldots, v_i\}$ incident to an edge from E_i, i.e.,

$$X_i := \{v \in \{v_1, \ldots, v_i\} \mid \exists v' \in \{v_{i+1}, \ldots, v_n\}, vv' \in E(G)\}.$$

Note that we have $|X_i| \leq |E_i| \leq w$ and $X_1 = \{v_1\}$ (since G is connected). For a mapping $c : X_i \to V(H)$, we define the table entry $T_i[c]$ as true if there exists a homomorphism $\varphi : G[\{v_1, \ldots, v_i\}] \to V(H)$, such that for all $v \in X_i$ we have $\varphi(v) = c(v)$. (In other words, the keys are given by the H-colorings of X_i and the table entry is true if there is an extension of the coloring of X_i to the left-hand side of the graph.)

This table can be easily computed in time $h^{w+1} \cdot n^{\mathcal{O}(1)}$ by the following naive dynamic programming procedure. We initiate every entry $T_i[c]$ to be false and every entry $T_1[c]$ to be true. Then, for every $i \in [2, n]$, every mapping $c' : X_{i-1} \to V(H)$, such that $T_{i-1}[c']$ is true, and every $u \in V(H)$, we check whether $c : X_{i-1} \cup \{v_i\} \to V(H)$ defined as

$$c(v) = \begin{cases} u & \text{if } v = v_i, \\ c'(v) & v \in X_{i-1}. \end{cases} \tag{1}$$

is a homomorphism from $G[X_{i-1} \cup \{v_i\}]$ to H. If so, we set $T_i[c|_{X_i}]$ to true.

We first outline why this correctly computes the table entries (that is, that at the end $T_i[c]$ is true if and only if c extends to a coloring of $G[\{v_1, \ldots, v_i\}]$) and then explain how to improve on this naive algorithm. We prove the claim by induction on i. For $i = 1$, the coloring only assigns a color to v_1 and does not need to be extended (and is automatically proper). Now suppose that the claim has been shown for $i = 1, \ldots j$ and let $\alpha : X_{j+1} \to V(H)$

be a coloring. If this extends to a coloring ϕ of $G[\{v_1, \ldots, v_{j+1}\}]$, then $T_j[c']$ is true for $c' = \phi|_{X_j}$ (by the induction hypothesis) and we could obtain α as the restriction from c from (1) with $u = \phi(v_{j+1})$ and $i = j + 1$. So $T_{j+1}[\alpha]$ is true. Vice versa, if $T_{j+1}[\alpha]$ has been set to true, then there is a $c' : X_j \to V(H)$ and $u \in V(H)$ such that c (again defined as in (1)) is a homomorphism $G[X_j \cup \{v_{j+1}\}] \to H$ which restricts to α on X_{j+1}. By the induction hypothesis, there exists a proper coloring ϕ' that extends c' to $G[\{v_1, \ldots, v_j\}]$ and we extend this to a coloring ϕ of $G[\{v_1, \ldots, v_{j+1}\}]$ by setting $\phi(v_{j+1}) = u$. Then ϕ still restricts to α and all of the edge constraints have been verified by c and/or ϕ'. In particular, $G \to H$ if and only if $T_n[\emptyset]$ is true, where $\emptyset$ denotes the empty mapping ($X_n = \emptyset$).

We will speed up this naive version of the dynamic program by computing a representative table T' as follows. We first set $T'_1 = T_1$. For $i = 1, 2, \ldots, n-1$ we proceed as follows. Let $k = |E_i| \leq w$ and $M = A_H^{\otimes k}$. Let $\{a_1, b_1\}, \ldots, \{a_k, b_k\} \in E_i$ be an enumeration of the edges, with $a_j \in \{v_1, \ldots, v_i\}$ for all $j \in [k]$. For each $c : X_i \to V(H)$ such that $T'_i[c]$ is set to true, we put the k-tuple $(c(a_1), \ldots, c(a_k))$ in $\mathcal{A}_i$. When $k \geq 2$, we apply the reduction algorithm R to $\mathcal{A}_i$, resulting in a set $\mathcal{A}'_i$ of size at most $\mathsf{size}(H, k)$ that $A_H^{\otimes k}$-represents $\mathcal{A}_i$. When $k = 1$, we set $\mathcal{A}'_i = \mathcal{A}_i$. We then compute the next table entries similarly as in the previous approach. Each element of $\mathcal{A}'_i$ corresponds to a coloring $c' : X_i \to V(H)$. For $u \in V(H)$, we check whether $c : X_i \cup \{v_{i+1}\} \to V(H)$ with $c(v_{i+1}) = u$ and $c|_{X_i} = c'$ is a homomorphism from $G[X_i \cup \{v_{i+1}\}]$ to H. If so, we set $T'_{i+1}[c|_{X_{i+1}}]$ to true. We repeat this for all pairs (c', u).

The procedure above is repeated for $i = 1, \ldots, n-1$, after which we return $T'_n[\emptyset]$.

When $|\mathcal{A}'_i| \leq \mathsf{size}(H, k)$, we find that $|\mathcal{A}_{i+1}| \leq \mathsf{size}(H, k)h$ (for $k = |E_i| \leq w$ and $\mathsf{size}(H, k) = h$ for $k = 1$). We may assume size is a non-decreasing function on each coordinate. So the total running time is as claimed:

$$\mathcal{O}\Big(\big(\mathsf{size}(H, w) \cdot h + \mathsf{time}\left(\mathsf{size}(H, w) \cdot h, H, w\right)\big)n\Big).$$

The fact that the dynamic programming steps preserve representation follows from transitivity of representation, but let us spell out the details.

Let Y_{i+1} be the set of endpoints on the right-hand side of the $(i+1)$th cut and enumerate the edges in E_{i+1} as $\{x_1, y_1\}, \ldots, \{x_k, y_k\}$, with $x_j \in X_{i+1}$ and $y_j \in Y_{i+1}$. We will show that for every $i \in [n-1]$, if $\mathcal{A}'_i$ represents the set $\mathrm{True}_i := \{(c(x_1), \ldots, c(x_k)) \mid T_i[c] = \mathrm{True}\}$, then $\mathcal{A}_{i+1}$ represents the set True_{i+1}. The same then holds for $\mathcal{A}'_{i+1}$ since the reduction algorithm is assumed to work correctly.

We started with setting $T'_1 = T_1$, so $\mathcal{A}'_1$ indeed represents True_1.

Let us first unravel the definitions to see what we need to show. Let $i \in [n-1]$ and suppose that $c : G[X_{i+1}] \to H$ extends to a homomorphism $\phi : G[\{v_1, \ldots, v_{i+1}\}] \to H$ (i.e. $T_i[c] = \mathrm{True}$). For the definition of represents, we will then assume there is a homomorphism $d : G[Y_{i+1}] \to H$ for which $c \cup d$ respects all edges from the $(i+1)$th cut (those in E_{i+1}), i.e. this corresponds to a "one-entry in the compatibility matrix". What needs to be shown is that this "one-entry" can also be generated via a coloring coming from $\mathcal{A}_{i+1}$, that is, there is $\alpha : G[X_{i+1}] \to H$, such that $(\alpha(x_1), \ldots, \alpha(x_k)) \in \mathcal{A}_{i+1}$ and $(\alpha \cup d)|_{G[E_{i+1}]}$ is a homomorphism.

By assumption, $\phi \cup d$ respects all the edges with at least one endpoint in $\{v_1, \ldots, v_{i+1}\}$, and in particular those with one endpoint in $\{v_1, \ldots, v_i\}$. Since $\mathcal{A}'_i$ is a representative set of True_i, there must be $c' : G[X_i] \to H$ such that $(c'(x'_1), \ldots, c'(x'_{k'})) \in \mathcal{A}'_i$, for $\{x'_1, \ldots, x'_{k'}\} = X_i$, and where $c' \cup \phi|_{\{v_{i+1}\}} \cup d$ respects all the edges with at least one endpoint in $\{v_1, \ldots, v_i\}$. We set $\alpha = (c' \cup \phi|_{\{v_{i+1}\}})|_{X_{i+1}}$. Then $(\alpha(x_1), \ldots, \alpha(x_k)) \in \mathcal{A}_{i+1}$, by definition of how we obtain $\mathcal{A}_{i+1}$ from $\mathcal{A}'_i$. Moreover, $\alpha \cup d$ is a homomorphism $G[E_{i+1}] \to H$, as desired. ◀

4 Computing representative sets via half-induced matchings

In this section we present one of our main technical contributions, i.e., an algorithm to compute H-representative sets whose size is bounded in terms of $\mathrm{him}(H)$. Actually, our approach is rather general since it finds representative sets non-trivially fast for any large Kronecker power of a matrix with small him parameter.

We will show how to find a representative set that has one fewer element, by finding some element that can be safely removed. We then use this intermediate result to find our final reduction algorithm, which will result in the following lemma.

▶ **Lemma 8.** *Let $\ell \geq 1$ and $k \geq 2$ be integers. Let $A \in \{0,1\}^{h \times h}$ be a matrix with $\mathrm{him}(A) < \ell$, and let $\mathcal{A} \subseteq [h]^k$. Then we can compute $\mathcal{A}' \subseteq \mathcal{A}$ that $A^{\otimes k}$-represents $\mathcal{A}$ with $|\mathcal{A}'| \leq k^{k\ell}$ in time $\mathcal{O}(|\mathcal{A}|^2 h^2 k^2)$.*

We will combine the reduction algorithm from Lemma 8 with Theorem 7 to find the following result.

▶ **Theorem 9.** *The Hom problem on an instance (G, H), where G is given with a linear ordering of width k, can be solved in time $\mathcal{O}(k^{2k\cdot(\mathrm{him}(H)+1)} \cdot |V(H)|^4 |V(G)|)$.*

We emphasize that the algorithm does not need to know the value of $\mathrm{him}(H)$.

Proof. Let $h = |V(H)|$ and let A_H be the adjacency matrix of H. Recall that $\mathrm{him}(A_H) = \mathrm{him}(H)$ is always an integer. By Lemma 8 we have a reduction algorithm R that returns a representative set of size $\mathsf{size}(H,k) \leq k^{k\cdot(\mathrm{him}(H)+1)}$ in time $\mathsf{time}(|\mathcal{A}|, H, k) = \mathcal{O}(|\mathcal{A}|^2 h^2 k^2)$. Then

$$\mathsf{time}(\mathsf{size}(H,k)\cdot h, H, k) = \mathcal{O}\left(k^2 \cdot k^{2k\cdot(\mathrm{him}(H)+1)} \cdot h^4\right).$$

By Theorem 7 we find an algorithm that decides $\textsc{Hom}(H)$ in time

$$\mathcal{O}\left((\mathsf{size}(H,k)\cdot h + \mathsf{time}(\mathsf{size}(H,k)\cdot h, H, k))|V(G)|\right) = \mathcal{O}(k^{2k\cdot(\mathrm{him}(H)+1)} h^4 \cdot |V(G)|).$$

This completes the proof. ◀

Since $\mathrm{him}(H) \leq \mathrm{mimsup}(H)$ (see Lemma 11), we obtain Theorem 4 as a corollary from Theorem 9. Lemma 8 and Lemma 11 also imply Theorem 3.

In order to prove the lemma, we will perform a recursive algorithm for which we want to no longer treat all the coordinates symmetrically. We therefore define

$$g_k(\ell_1, \ldots, \ell_k) = \binom{\sum_i \ell_i}{\ell_1, \ldots, \ell_k}.$$

When $\ell_1 = \cdots = \ell_k = \ell$, we have $g_k(\ell, \ldots, \ell) = \binom{k\ell}{\ell,\ldots,\ell} \leq k^{k\ell}$ (= the number of partitions of $k\ell$ into k parts, which no longer need to have the same size). The lemma will follow easily from the following more complicated statement.

▶ **Lemma 10.** *Let $k \geq 2, \ell_1, \ldots, \ell_k \geq 1$ be integers. Let $A \in \{0,1\}^{h\times h}$ be a matrix and let $\mathcal{A} \subseteq [h]^k$ with $|\mathcal{A}| \geq g_k(\ell_1, \ldots, \ell_k)$. Suppose that for every $i \in [k]$, for the set of rows $\mathcal{R}_i = \{r_i \mid r \in \mathcal{A}\}$, we have $\mathrm{him}(A[\mathcal{R}_i, \cdot]) < \ell_i$. Then there exists $v \in \mathcal{A}$ such that $\mathcal{A} \setminus \{v\}$ $A^{\otimes k}$-represents $\mathcal{A}$. Moreover, v can be found in time $\mathcal{O}(\sum_{i=1}^k \ell_i \cdot |\mathcal{A}| hk)$.*

Proof. Note that $|\mathcal{A}| \geq g_k(\ell_1, \dots, \ell_k) \geq 1$ for $\ell_1, \dots, \ell_k, k \geq 1$ so $\mathcal{A}$ is non-empty.

For $i \in [k]$ and $u \in [h]$, let

$$\mathcal{A}^i_u = \{v = (v_1, \dots, v_k) \in \mathcal{A} \mid A[v_i, u] = 0\}$$

be the set of rows which cannot "represent" u in the ith coordinate. We choose $v \in \mathcal{A}$ (arbitrarily). We then iterate over $u \in [h]$ and $i \in [k]$ to find if there is (u, i) for which

- $A[v_i, u] = 1$, and
- $|\mathcal{A}^i_u| \geq g_k(\ell_1, \dots, \ell_i - 1, \dots, \ell_k)$.

This step can be performed in time $\mathcal{O}(|\mathcal{A}|hk)$.

If we cannot find such (u, i) pair for v, then we return v as the row to be removed from $\mathcal{A}$ (and the algorithm terminates).

Otherwise, we did find (u, i). If $\ell_i = 1$, then since $\mathrm{him}(A[\mathcal{R}_i, \cdot]) < \ell_i$, we know $A[\mathcal{R}_i, \cdot]$ has all zero-entries and so $A[v_i, u] = 1$ would not have been possible. This means that $\ell_i \geq 2$. We apply the same process after updating $\ell_i \leftarrow \ell_i - 1$ and $\mathcal{A} \leftarrow \mathcal{A}^i_u$. Note that $v \notin \mathcal{A}^i_u$ and $\ell_i - 1 \geq 1$. We will show that

- when v is returned, indeed $\mathcal{A} \setminus \{v\}$ $A^{\otimes k}$-represents $\mathcal{A}$, and
- when we recursively apply the algorithm, the conditions of the lemma are again satisfied, for which it remains to show that $\mathrm{him}(A[\mathcal{R}'_i, \cdot]) < \ell_i - 1$ for $\mathcal{R}'_i = \{r_i \mid r \in \mathcal{A}^i_u\}$.

Since we reduce $\sum_{i=1}^k \ell_i$ by one in each recursive call, the algorithm will terminate. Moreover, the number of recursive calls is at most $\sum_{i=1}^k \ell_i$. This shows that assuming the claims above, the time complexity is as stated.

Correctness. We first show the first claim: if the algorithm outputs v, indeed it can be removed. Note that if for some subset $\mathcal{A}' \subseteq \mathcal{A}$, it is the case that $\mathcal{A}' \setminus \{v\}$ represents $\mathcal{A}'$, then

$$\mathcal{A}' \setminus \{v\} \cup (\mathcal{A} \setminus \mathcal{A}') = \mathcal{A} \setminus \{v\}$$

will also represent $\mathcal{A}$. This means we only have to check the claims in the "base case". Suppose towards a contradiction that we wrongly outputted $v \in \mathcal{A}$, so

- there exists $u \in [h]^k$ such that $A^{\otimes k}[v, u] = 1$ yet $A^{\otimes k}[v', u] = 0$ for all $v' \in \mathcal{A} \setminus \{v\}$ (since we "wrongly" outputted v, there needs to be a reason why we could not remove it),
- for this u, for all $i \in [k]$, $|\mathcal{A}^i_{u_i}| < g_k(\ell_1, \dots, \ell_i - 1, \dots, \ell_k)$ (else the algorithm would have "recursed" instead of outputting v).

The fact that $A^{\otimes k}[v', u] = 0$ in the first condition, means that each $v' \in \mathcal{A} \setminus \{v\}$ is an element of $\mathcal{A}^i_{u_i}$ for some $i \in [k]$. In particular,

$$|\mathcal{A} \setminus \{v\}| \leq \sum_{i=1}^k |\mathcal{A}^i_{u_i}| \leq \sum_{i=1}^k g_k(\ell_1, \dots, \ell_i - 1, \dots, \ell_k) - k = g_k(\ell_1, \dots, \ell_k) - k,$$

which contradicts the assumptions of the lemma since $k \geq 2$.

We now prove the second claim: the conditions of the lemma are satisfied when we "recurse". By assumption, $\ell_i \geq 1$ for all i and the new $\mathcal{A}$ is sufficiently large. Moreover, him can also decrease when taking submatrices, so indeed we only need to show that $\mathrm{him}(A[\mathcal{R}'_i, \cdot]) < \ell_i - 1$ for $\mathcal{R}'_i = \{r_i \mid r \in \mathcal{A}^i_{u_i}\}$. If there is a half-induced matching of size $\ell_i - 1$, induced on rows $w_1, \dots, w_{\ell_i - 1} \in \mathcal{R}'_i$ and columns $z_1, \dots, z_{\ell_i - 1}$, then there is a half-induced matching of size ℓ_i in $A[\mathcal{R}_i, \cdot]$ by considering rows $w_1, \dots, w_{\ell_i - 1}, v_i \in \mathcal{R}_i$ and columns $z_1, \dots, z_{\ell - 1}, u$. But by assumption this does not exist, so indeed $\mathrm{him}(A[\mathcal{R}'_i, \cdot]) < \ell_i - 1$. ◀

Proof of Lemma 8. Suppose that $|\mathcal{A}| \geq g_k(\ell, \ldots, \ell)$. For $i \in [k]$, set $\mathcal{R}_i = \{r_i \mid r \in \mathcal{A}\}$. Then $\operatorname{him}(A[\mathcal{R}_i, \cdot]) < \ell$ for each i. By Lemma 10 we can find a row v in $\mathcal{A}$ such that $\mathcal{A} \setminus \{v\}$ $A^{\otimes k}$-represents $\mathcal{A}$ in time $\mathcal{O}(\ell k \cdot |\mathcal{A}|hk) = \mathcal{O}(|\mathcal{A}|h^2k^2)$, where we use that $\ell \leq h$.

We repeat this at most $|\mathcal{A}| - g_k(\ell, \ldots, \ell)$ times until we find the desired representative set in time $\mathcal{O}(|\mathcal{A}|^2h^2k^2)$. ◀

5 Comparing him and mimsup

In this section, we discuss the relation between the considered parameters.

▶ **Lemma 11.** *Let A be a matrix. Then* $\operatorname{mimsup}(A) \geq \operatorname{him}(A) \geq \operatorname{mim}(A)$.

Proof. The second inequality follows directly since each induced matching is a half-induced matching. We prove the first inequality.

Let $R = \{a_1, \ldots, a_i\}$ and $C = \{b_1, \ldots, b_i\}$ be the rows and columns respectively of a maximum half-induced matching in A. We may assume that these are ordered such that $A[a_j, b_j] = 1$ for all $j \in [i]$ and $A[a_k, b_j] = 0$ for all $k < j$. For integers $s \geq 1$, we consider the submatrix of $A^{\otimes is}$ induced on the rows consisting of "balanced" sequences, and similarly for the columns

$$\{(r_1, \ldots, r_{is}) \in R^{is} \mid |\{\ell : r_\ell = a_j\}| = s, \text{ for every } j \in [i]\},$$
$$\{(c_1, \ldots, c_{is}) \in C^{is} \mid |\{\ell : c_\ell = b_j\}| = s, \text{ for every } j \in [i]\}.$$

We claim this forms an induced matching of size $\binom{is}{s,\ldots,s}$. By Stirling approximation, $\binom{is}{s,\ldots,s} = i^{(1+o(1))is}$ and so the claim implies that $\operatorname{mimsup}(A) \geq i = \operatorname{him}(A)$. Since the size is clear from the definition, it only remains to check that it indeed forms an induced matching. To show this, we explain why the row of

$$r = (a_1, \ldots, a_1, a_2, \ldots, a_2, \ldots, a_i, \ldots, a_i)$$

has a single one entry in column

$$c = (b_1, \ldots, b_1, b_2, \ldots, b_2, \ldots, b_i, \ldots, b_i).$$

The other cases follow by symmetry. It is clear that $A^{\otimes is}[r, c] = 1$. Any column c' with $A^{\otimes is}[r, c'] = 1$ must have $A[a_1, c'_j] = 1$ for all $j \in [s]$. But $A[a_1, b_j] = 0$ when $j > 1$, so this implies that $\{j : c'_j = b_1\} = [s]$. Similarly, we require $A[a_2, c'_j] = 1$ for all $j \in [s+1, 2s]$, but c' has already "used" all its b_1's and so $\{j \mid c'_j = b_2\}$ needs to be $[s+1, 2s]$. Continuing inductively, we find that $\{j \mid c'_j = b_k\} = [(k-1)s + 1, ks]$ for all $k \in [i]$, that is, $c' = c$. ◀

We are now ready to prove previously claimed bounds.

▶ **Theorem 3.** *For every non-bipartite graph H with adjacency matrix A_H and $k \in \mathbb{N}$,*

$$\operatorname{him}(A_H) \leq \operatorname{mimsup}(A_H) = \limsup_{k\to\infty} \operatorname{mim}(A_H^{\otimes k})^{1/k} \quad \text{and} \quad \operatorname{mim}(A_H^{\otimes k}) \leq k^{(\operatorname{him}(A_H)+1)k}.$$

Proof. Lemma 11 shows the first inequality. The proof of Lemma 10 implies that for any matrix A, $\operatorname{mim}(A^{\otimes k}) \leq k^{\operatorname{him}(A)k}$, since no smaller representative set can be found when the rows induce an induced matching (with some set of columns). ◀

The following observation implies that sequences such as $\operatorname{mim}(A^{\otimes 2^k})^{1/2^k}$ are non-decreasing.

▶ **Lemma 12 (♠).** *Given two matrices A and B,* $\operatorname{mim}(A \otimes B) \geq \operatorname{mim}(A)\operatorname{mim}(B)$. *In particular,* $\operatorname{mimsup}(A^{\otimes k}) = \operatorname{mimsup}(A)^k$.

The results above also imply that

$$\operatorname{mimsup}(A) = \limsup_{k\to\infty} \operatorname{him}(A^{\otimes k})^{1/k}.$$

At first glance, it may be natural to conjecture that in fact $\operatorname{mimsup}(A) = \operatorname{him}(A)$ for all matrices A. This is however not true, as the following result shows.

▶ **Theorem 13 (♠).** *For all sufficiently large integers h, there is a symmetric $(2h \times 2h)$ matrix A with* $\operatorname{him}(A) \leq 10\log_2 h$ *and* $\operatorname{mimsup}(A) \geq \sqrt{h}$.

6 Conclusion

An obvious open problem is to fully resolve Open Problem 1. As discussed, to achieve this goal we only lack a fast algorithm that computes representative sets for partial solutions to $\textsc{Hom}(H)$. A far more ambitious (and probably currently out of reach) goal is to provide a (more) fine-grained version of the Courcelle's theorem for deciding any graph property definable in the monadic second-order logic. While being homomorphic to a given graph H is of course only a very special sort of such a property, we find our progress on Open Problem 1 encouraging in this respect and hope that eventually similar connections between the complexity of more general computational problems and asymptotic rank parameters can be made as well. In particular, we believe that mimsup (or a similar parameter that tracks the asymptotic behavior under appropriate products) is likely to determine the limit of dynamic programming approaches in other settings as well, especially those determined by various graph width parameters.

Another suggested direction of research is purely combinatorial/algebraic: we expect that mimsup is an interesting parameter for further study in its own right. We suggest following questions. (i) What type of values can $\operatorname{mimsup}(H)$ take given a matrix H? Can it take non-integer values? Similar questions have recently been investigated for asymptotic tensor parameters, see e.g. [3,6]. (ii) What is the value of mimsup for a $n \times n$ random matrix, where each entry of the matrix gets sampled independently to be 1 with probability p and to be 0 with probability $1-p$? (iii) We showed that him and the support rank are not functionally equivalent. Is mimsup functionally equivalent to either him or the support rank?

Isomorphism for Tournaments of Small Twin Width

Martin Grohe
RWTH Aachen University, Germany

Daniel Neuen
University of Regensburg, Germany

Abstract

We prove that isomorphism of tournaments of twin width at most k can be decided in time $k^{O(\log k)}n^{O(1)}$. This implies that the isomorphism problem for classes of tournaments of bounded or moderately growing twin width is in polynomial time. By comparison, there are classes of undirected graphs of bounded twin width that are isomorphism complete, that is, the isomorphism problem for the classes is as hard as the general graph isomorphism problem. Twin width is a graph parameter that has been introduced only recently (Bonnet et al., FOCS 2020), but has received a lot of attention in structural graph theory since then. On directed graphs, it is functionally smaller than clique width. We prove that on tournaments (but not on general directed graphs) it is also functionally smaller than directed tree width (and thus, the same also holds for cut width and directed path width). Hence, our result implies that tournament isomorphism testing is also fixed-parameter tractable when parameterized by any of these parameters.

Our isomorphism algorithm heavily employs group-theoretic techniques. This seems to be necessary: as a second main result, we show that the combinatorial Weisfeiler-Leman algorithm does not decide isomorphism of tournaments of twin width at most 35 if its dimension is $o(n)$. (Throughout this abstract, n is the order of the input graphs.)

Acknowledgements We thank the anonymous reviewers of an earlier version of this paper for helpful feedback which, in particular, resulted an improved bound in Theorem 1.2.

1 Introduction

The tournament isomorphism problem (TI) was recognized as a particularly interesting special case of the graph isomorphism problem (GI) early-on. Already in 1983, Babai and Luks [3] proved that TI is solvable in time $n^{O(\log n)}$; it took 33 more years for Babai [2] to prove that the general GI is in quasi-polynomial time. An important fact that makes TI more accessible than GI is that tournaments always have solvable automorphism groups. This is a consequence of the observation that the automorphism groups of tournaments have odd order and the famous Feit-Thompson Theorem [18] stating that all groups of odd order are solvable. However, even Babai's powerful new machinery did not help us to

improve the upper bound for TI, as one might have hoped. But TI is not only special from a group-theoretic perspective. Another remarkable result, due to Schweitzer [42], states that TI reduces to the problem of deciding whether a tournament has a nontrivial automorphism; the so-called *rigidity problem*. It is an open question whether the same holds for general graphs.

While there is an extensive literature on GI restricted to classes of graphs (see [25] for a recent survey), remarkably little is known for restrictions of TI. Ponomarenko [40] proved that TI is in polynomial time for tournaments whose automorphism group contains a regular cyclic subgroup, and recently Arvind, Ponomarenko, and Ryabov [1] proved that TI is in polynomial time for edge-colored tournaments where at least one edge color induces a (strongly) connected spanning subgraph of bounded degree (even fixed-parameter tractable when parameterized by the out-degree). While both of these results are very interesting from a technical perspective, they consider classes of tournaments that would hardly be called natural from a graph-theoretic point of view. Natural graph parameters that have played a central role in the structural theory of tournaments developed by Chudnovsky, Seymour and others [13, 14, 15, 16, 19] are *cut width* and *path width*. The more recent theory of structural sparsity [20, 21, 36, 37] highlights *clique width* and *twin width*. Here twin width is the key parameter. Not only is it functionally smaller than the other parameters, which means that if cut width, path width, or clique width is bounded, then twin width is bounded as well, it is also known [23] that a class of tournaments has bounded twin width if and only if it has a property known as *monadic dependence (NIP)*. Dependence is a key property studied in classical model theory. A class of graphs is monadically dependent if and only if all set systems definable in this class by a first-order transduction have bounded VC dimension. This property seems to characterize precisely the graph classes that are regarded as structurally sparse. Since twin width of graphs and binary relational structures has been introduced in [11], it received a lot of attention in algorithmic structural graph theory [5, 6, 7, 8, 9, 10, 21, 22, 23, 29, 44]. (We defer the somewhat unwieldy definition of twin width to Section 2.3.) Our main result states that tournament isomorphism is fixed-parameter tractable when parameterized by twin width.

▶ **Theorem 1.1.** *The isomorphism problem for tournaments of twin width at most k can be solved in time $k^{O(\log k)} \cdot n^{O(1)}$.*

Interestingly, isomorphism testing for undirected graphs of bounded twin width is as hard as the general GI. This follows easily from the fact that an $\Omega(\log n)$-subdivision of every graph with n vertices has bounded twin width [5]. Once more, this demonstrates the special role of the tournament isomorphism problem, though here the reason is not group-theoretic, but purely combinatorial.

Note that the dependence on the twin width k of the algorithm in Theorem 1.1 is subexponential, so our result implies that TI is in polynomial time even for tournaments of twin width $2^{O(\sqrt{\log n})}$. Since twin width is functionally smaller than clique width, our result implies that TI is also fixed-parameter tractable when parameterized by clique width. Additionally, we prove that the twin width of a tournament is functionally smaller than its *directed tree width*, a graph parameter originally introduced in [31]. Since the directed tree width of every directed graph is smaller than its cut width or directed path width, the same also holds for these two parameters. Hence, TI is fixed-parameter tractable also when parameterized by directed tree width, directed path width or cut width. To the best of our knowledge, this was not known for any of these parameters. The fact that twin width is functionally smaller than directed tree width, directed path width and cut width on tournaments is interesting in its own right, because this result does not extend to general directed graphs (for any of the three parameters).

Our proof of Theorem 1.1 heavily relies on group-theoretic techniques. In a nutshell, we show that bounded twin width allows us to cover a tournament by a sequence of directed graphs that have a property resembling bounded degree sufficiently closely to apply a group-theoretic machinery going back to Luks [33] and developed to great depth since then (see, e.g., [2, 3, 27, 35, 38]). Specifically, we generalize arguments that have been introduced by Arvind et al. [1] for TI on edge-colored tournaments where at least one edge color induces a spanning subgraph of bounded out-degree.

Yet one may wonder if this heavy machinery is even needed to prove our theorem, in particular in view of the fact that on many natural graph classes, including, for example, undirected graphs of bounded clique width [26], the purely combinatorial Weisfeiler-Leman algorithm is sufficient to decide isomorphism (see, e.g., [24, 32]). We prove that this is not the case for tournaments of bounded twin width.

▶ **Theorem 1.2.** *For every $k \geq 2$ there are non-isomorphic tournaments T_k and T'_k of order $|V(T_k)| = |V(T'_k)| = O(k)$ and twin width at most 35 that are not distinguished by the k-dimensional Weisfeiler-Leman algorithm.*

We remark that it was known before that the Weisfeiler-Leman algorithm fails to decide tournament isomorphism. Indeed, Dawar and Kopczynski (unpublished) proved that for every $k \geq 2$ there are non-isomorphic tournaments U_k and U'_k of order $|V(U_k)| = |V(U'_k)| = O(k)$ that are not distinguished by the k-dimensional Weisfeiler-Leman algorithm. Theorem 1.2 strengthens this result by constructing tournaments where additionally the twin width is bounded by a fixed constant.

The paper is organized as follows. After introducing the necessary preliminaries in Section 2, Theorem 1.1 is proved in Sections 3 and 4. First, we give our main combinatorial arguments in Section 3. After that, the mainly group-theoretic isomorphism algorithm of Theorem 1.1 is presented in Section 4. Theorem 1.2 is proved in Section 5. Finally, in Section 6 we compare twin width to other width measures for directed graphs. All omitted proofs can be found in the full version.

2 Preliminaries

2.1 Graphs

Graphs in this paper are usually directed. We often emphasize this by calling them "digraphs". However, when we make general statements about graphs, this refers to directed graphs and includes undirected graphs a special case (directed graphs with a symmetric edge relation). We denote the vertex set of a graph G by $V(G)$ and the edge relation by $E(G)$. The vertex set $V(G)$ is always finite and non-empty. The edge relation is always anti-reflexive, that is, graphs are loop-free, and there are no parallel edges. For a digraph G and a vertex $v \in V(G)$, we denote the set of out-neighbors and in-neighbors of v by $N_+(v)$ and $N_-(v)$, respectively. Also, the *out-degree* and *in-degree* of v are denoted by $\deg_+(v) := |N_+(v)|$ and $\deg_-(v) := |N_-(v)|$, respectively. Furthermore, $E_+(v)$ and $E_-(v)$ denote the set of outgoing and incoming edges into v, respectively. For $X \subseteq V(G)$, we write $G[X]$ to denote the subgraph of G induced on X. For two sets $X, Y \subseteq V(G)$ we write $E_G(X,Y) := \{(v,w) \in E(G) \mid v \in X, w \in Y\}$ to denote the set of directed edges from X to Y.

Let G be an undirected graph. A directed graph $\vec{G}$ is an *orientation* of G if, for every undirected edge $\{v,w\} \in E(G)$, exactly one of (v,w) and (w,v) is an edge of $\vec{G}$, and there are no other edges present in $\vec{G}$. A *tournament* is an orientation of a complete graph.

A tournament T is *regular* if $\deg_+(v) = \deg_+(w)$ for all $v, w \in V(T)$. In this case, $\deg_+(v) = \deg_-(v) = \frac{|V(G)|-1}{2}$ for all $v \in V(T)$. This implies that every regular tournament has an odd number of vertices.

Let G_1, G_2 be two graphs. An *isomorphism* from G_1 to G_2 is a bijection $\varphi\colon V(G_1) \to V(G_2)$ such that $(v,w) \in E(G_1)$ if and only if $(\varphi(v), \varphi(w)) \in E(G_2)$ for all $v, w \in V(G_1)$. We write $\varphi\colon G_1) \cong G_2$ to denote that φ is an isomorphism from G_1 to G_2. Also, $\mathrm{Iso}(G_1, G_2)$ denotes the set of all isomorphisms from G_1 to G_2. The graphs G_1 and G_2 are *isomorphic* if $\mathrm{Iso}(G_1, G_2) \neq \emptyset$. The *automorphism group* of G_1 is $\mathrm{Aut}(G_1) \coloneqq \mathrm{Iso}(G_1, G_1)$.

An *arc coloring* of a digraph G is a mapping $\lambda\colon (E(G) \cup \{(v,v) \mid v \in V(G)\}) \to C$ for some set C of "colors". An *arc-colored graph* is a triple $G = (V, E, \lambda)$, where (V, E) is a graph an λ an arc coloring of (V, E). Isomorphisms between arc-colored graphs are required to preserve the coloring.

2.2 Partitions and Colorings

Let S be a finite set. A *partition* of S is a set $\mathcal{P} \subseteq 2^S$ whose elements we refer to as *parts*, such that any two parts are mutually disjoint, and the union of all parts is S. A partition $\mathcal{P}$ *refines* another partition $\mathcal{Q}$, denoted by $\mathcal{P} \preceq \mathcal{Q}$, if for all $P \in \mathcal{P}$ there is some $Q \in \mathcal{Q}$ such that $P \subseteq Q$. We say a partition $\mathcal{P}$ is *trivial* if $|\mathcal{P}| = 1$, which means that the only part is S, and it is *discrete* if $|P| = 1$ for all $P \in \mathcal{P}$.

Every mapping $\chi\colon S \to C$, for some set C, induces a partition $\mathcal{P}_\chi$ of S into the sets $\chi^{-1}(c)$ for all c in the range of χ. In this context, we think of χ as a "coloring" of S, the elements $c \in C$ as "colors", and the parts $\chi^{-1}(c)$ of the partition as "color classes". If $\chi'\colon S \to C'$ is another coloring, then we say that χ *refines* χ', denoted by $\chi \preceq \chi'$, if $\mathcal{P}_\chi \preceq \mathcal{P}_{\chi'}$. The colorings are *equivalent* (we write $\chi \equiv \chi'$) if $\chi \preceq \chi'$ and $\chi \preceq \chi'$, i.e., $\mathcal{P}_\chi = \mathcal{P}_{\chi'}$.

2.3 Twin Width

Twin width [11] is defined for binary relational structures, which in this paper are mostly directed graphs. We need one distinguished binary relation symbol E_{red} that plays a special role in the definition of twin width. Following [11], we refer to elements of E_{red} as *red edges*. For every structure A, we assume the relation $E_{\mathsf{red}}(A)$ to be symmetric and anti-reflexive, that is, the edge relation of an undirected graph, and we refer to the maximum degree of this graph as the *red degree* of A. If $E_{\mathsf{red}}(A)$ is not explicitly defined, we assume $E_{\mathsf{red}}(A) = \emptyset$ (and the red degree of A is 0).

Let $A = (V(A), R_1(A), \ldots, R_k(A))$ be a binary relational structure, where $V(A)$ is a non-empty finite vertex set and $R_i(A) \subseteq (V(A))^2$ are binary relations on $V(A)$ (possibly, $R_i = E_{\mathsf{red}}$ for some $i \in [k]$). We call a pair (X, Y) of disjoint subsets of $V(A)$ *homogeneous* if for all $x, x' \in X$, and all $y, y' \in Y$ it holds that

- **(i)** $(x,y) \in R_i(A) \Leftrightarrow (x',y') \in R_i(A)$ and $(y,x) \in R_i(A) \Leftrightarrow (y',x') \in R_i(A)$ for all $i \in [k]$, and
- **(ii)** $(x,y) \notin E_{\mathsf{red}}(A)$ and $(y,x) \notin E_{\mathsf{red}}(A)$.

For a partition $\mathcal{P}$ of $V(A)$, we define $A/\mathcal{P}$ to be the structure with vertex set $V(A/\mathcal{P}) \coloneqq \mathcal{P}$ and relations

$$R_i(A/\mathcal{P}) \coloneqq \left\{(X,Y) \in \mathcal{P}^2 \;\middle|\; (X,Y) \text{ is homogeneous and } X \times Y \subseteq R_i(A)\right\}$$

for all $R_i \neq E_{\mathsf{red}}$, and

$$E_{\mathsf{red}}(A/\mathcal{P}) \coloneqq \left\{(X,Y) \in \mathcal{P}^2 \;\middle|\; (X,Y) \text{ is not homogeneous and } X \neq Y\right\}.$$

A *contraction sequence for* A is a sequence of partitions $\mathcal{P}_1, \dots, \mathcal{P}_n$ of $V(A)$ such that $\mathcal{P}_1 = \{\{v\} \mid v \in V(A)\}$ is the discrete partition, $\mathcal{P}_n = \{V(A)\}$ is the trivial partition, and for every $i \in [n-1]$ the partition $\mathcal{P}_{i+1}$ is obtained from $\mathcal{P}_i$ by merging two parts, i.e., there are distinct $P, P' \in \mathcal{P}_i$ such that $\mathcal{P}_{i+1} = \{P \cup P'\} \cup (\mathcal{P}_i \setminus \{P, P'\})$. The *width* of a contraction sequence $\mathcal{P}_1, \dots, \mathcal{P}_n$ of A is the minimum k such that for every $i \in [n]$ the structure $A/\mathcal{P}_i$ has red degree at most k. The *twin width* of A, denoted by $\operatorname{tww}(A)$, is the minimum $k \geq 0$ such that A has a contraction sequence of width k.

Note that red edges are introduced as we contract parts of the partitions. However, the structure A we start with may already have red edges, which then have direct impact on its twin width. In particular, the twin width of a graph G may be smaller than the twin width of the structure G^{red} obtained from G by coloring all edges red. This fact is used later.

We also remark that for our isomorphism algorithms, we never have to compute a contraction sequence of minimum width or the twin width.

We state two simple lemmas on basic properties of twin width.

▶ **Lemma 2.1** ([11]). *Let A be a binary relational structure and $X \subseteq V(A)$. Then* $\operatorname{tww}(A[X]) \leq \operatorname{tww}(A)$.

▶ **Lemma 2.2.** *Let A be a structure over the vocabulary τ. Then there is a linear order $<$ on $V(A)$ such that* $\operatorname{tww}(A, <) = \operatorname{tww}(A)$.

2.4 Weisfeiler-Leman

In this section, we describe the k-dimensional Weisfeiler-Leman algorithm (k-WL). The algorithm has been originally introduced in its 2-dimensional form by Weisfeiler and Leman [46] (see also [45]). The k-dimensional version, coloring k-tuples, was introduced later by Babai and Mathon (see [12]).

Fix $k \geq 2$, and let G be a graph. For $i \geq 0$, we describe the coloring $\chi^{k,G}_{(i)}$ of $(V(G))^k$ computed in the i-th iteration of k-WL. For $i = 0$, each tuple is colored with the isomorphism type of the underlying ordered induced subgraph. So if H is another graph and $\bar{v} = (v_1, \dots, v_k) \in (V(G))^k$, $\bar{w} = (w_1, \dots, w_k) \in (V(H))^k$, then $\chi^{k,G}_{(0)}(\bar{v}) = \chi^{k,H}_{(0)}(\bar{w})$ if and only if, for all $i, j \in [k]$, it holds that $v_i = v_j \Leftrightarrow w_i = w_j$ and $(v_i, v_j) \in E(G) \Leftrightarrow (w_i, w_j) \in E(H)$. If G and H are arc-colored, then the colors are also taken into account.

Now let $i \geq 0$. For $\bar{v} = (v_1, \dots, v_k)$ we define

$$\chi^{k,G}_{(i+1)}(\bar{v}) \coloneqq \left(\chi^{k,G}_{(i)}(\bar{v}), \mathcal{M}_i(\bar{v})\right)$$

where

$$\mathcal{M}_i(\bar{v}) \coloneqq \left\{\!\!\left\{ \left(\chi^{k,G}_{(i)}(\bar{v}[w/1]), \dots, \chi^{k,G}_{(i)}(\bar{v}[w/k])\right) \;\middle|\; w \in V(G) \right\}\!\!\right\}$$

and $\bar{v}[w/i] \coloneqq (v_1, \dots, v_{i-1}, w, v_{i+1}, \dots, v_k)$ is the tuple obtained from $\bar{v}$ by replacing the i-th entry by w (and $\{\!\{\dots\}\!\}$ denotes a multiset).

Clearly, $\chi^{k,G}_{(i+1)} \preceq \chi^{k,G}_{(i)}$ for all $i \geq 0$. So there is a unique minimal $i_\infty \geq 0$ such that $\chi^{k,G}_{(i_\infty+1)} \equiv \chi^{k,G}_{(i_\infty)}$ and we write $\chi^{k,G} \coloneqq \chi^{k,G}_{(i_\infty)}$ to denote the corresponding coloring.

The k-dimensional Weisfeiler-Leman algorithm takes as input a (possibly colored) graph G and outputs (a coloring that is equivalent to) $\chi^{k,G}$. This can be done in time $O(k^2 n^{k+1} \log n)$ [30].

Let H be a second graph. The k-dimensional Weisfeiler-Leman algorithm *distinguishes* G and H if there is a color $c \in C$ such that

$$\left|\left\{\bar{v} \in (V(G))^k \;\middle|\; \chi^{k,G}(\bar{v}) = c\right\}\right| \neq \left|\left\{\bar{w} \in (V(H))^k \;\middle|\; \chi^{k,H}(\bar{w}) = c\right\}\right|.$$

We write $G \simeq_k H$ to denote that k-WL does not distinguish between G and H.

A graph G is *k-WL-homogeneous* if for all $v, w \in V(G)$ it holds that $\chi^{k,G}(v, \dots, v) = \chi^{k,G}(w, \dots, w)$.

2.5 Group Theory

For a general background on group theory we refer to [41], whereas background on permutation groups can be found in [17]. Also, basics facts on algorithms for permutation groups are given in [43].

Basics for Permutation Groups. A *permutation group* acting on a set Ω is a subgroup $\Gamma \leq \mathrm{Sym}(\Omega)$ of the symmetric group. The size of the permutation domain Ω is called the *degree* of Γ. If $\Omega = [n] \coloneqq \{1, \dots, n\}$, then we also write S_n instead of $\mathrm{Sym}(\Omega)$. For $A \subseteq \Omega$ and $\gamma \in \Gamma$ let $\gamma(A) \coloneqq \{\gamma(\alpha) \mid \alpha \in A\}$. The set A is Γ-*invariant* if $\gamma(A) = A$ for all $\gamma \in \Gamma$.

Let $\theta \colon \Omega \to \Omega'$ be a bijection. We write $\Gamma\theta \coloneqq \{\gamma\theta \mid \gamma \in \Gamma\}$ for the set of bijections from Ω to Ω' obtained from concatenating a permutation from Γ and θ. Note that $(\gamma\theta)(\alpha) = \theta(\gamma(\alpha))$ for all $\alpha \in \Omega$.

A set $S \subseteq \Gamma$ is a *generating set* for Γ if for every $\gamma \in \Gamma$ there are $\delta_1, \dots, \delta_k \in S$ such that $\gamma = \delta_1 \dots \delta_k$. In order to perform computational tasks for permutation groups efficiently the groups are represented by generating sets of small size (i.e., polynomial in the size of the permutation domain). Indeed, most algorithms are based on so-called strong generating sets, which can be chosen of size quadratic in the size of the permutation domain of the group and can be computed in polynomial time given an arbitrary generating set (see, e.g., [43]).

Group-Theoretic Methods for Isomorphism Testing. In this work, we shall be interested in a particular subclass of permutation groups. Let Γ be a group and let $\gamma, \delta \in \Gamma$. The *commutator* of γ and δ is $[\gamma, \delta] \coloneqq \gamma^{-1}\delta^{-1}\gamma\delta$. The *commutator subgroup* $[\Gamma, \Gamma]$ of Γ is the unique subgroup of Γ generated by all commutators $[\gamma, \delta]$ for $\gamma, \delta \in \Gamma$. Note that $[\Gamma, \Gamma]$ is a normal subgroup of Γ. The *derived series of* Γ is the sequence of subgroups $\Gamma^{(0)} \trianglerighteq \Gamma^{(1)} \trianglerighteq \Gamma^{(2)} \trianglerighteq \dots$ where $\Gamma^{(0)} \coloneqq \Gamma$ and $\Gamma^{(i+1)} \coloneqq [\Gamma^{(i)}, \Gamma^{(i)}]$ for all $i \geq 0$. A group Γ is *solvable* if there is some $i \geq 0$ such that $\Gamma^{(i)}$ is the trivial group (i.e., it only contains the identity element). The next theorem follows from the Feit-Thompson Theorem stating that every group of odd order is solvable.

▶ **Theorem 2.3.** *Let T be a tournament. Then* $\mathrm{Aut}(T)$ *is solvable.*

Next, we state several basic group-theoretic algorithms for isomorphism testing.

▶ **Theorem 2.4** ([3, Theorem 4.1])**.** *There is an algorithm that, given two tournaments T_1 and T_2, computes* $\mathrm{Iso}(T_1, T_2)$ *in time $n^{O(\log n)}$.*

Note that $\mathrm{Iso}(T_1, T_2)$ may be of size exponential in the number of vertices of T_1 and T_2. However, if T_1 and T_2 are isomorphic (i.e., $\mathrm{Iso}(T_1, T_2) \neq \emptyset$), we have $\mathrm{Iso}(T_1, T_2) = \mathrm{Aut}(T_1)\varphi$ where $\varphi \in \mathrm{Iso}(T_1, T_2)$ is an arbitrary isomorphism from T_1 to T_2. Hence, the set $\mathrm{Iso}(T_1, T_2)$ can be represented by a generating set for $\mathrm{Aut}(T_1)$ of size polynomial in $|V(T_1)|$ and a single element $\varphi \in \mathrm{Iso}(T_1, T_2)$. Let us stress at this point that all isomorphism sets computed by the various algorithms discussed in this work are represented in this way.

Let G_1 and G_2 be two (colored) directed graphs. Also let $\Gamma \leq \mathrm{Sym}(V(G_1))$ be a permutation group and let $\theta \colon V(G_1) \to V(G_2)$ be a bijection. We define

$$\mathrm{Iso}_{\Gamma\theta}(G_1, G_2) \coloneqq \mathrm{Iso}(G_1, G_2) \cap \Gamma\theta = \{\varphi \in \Gamma\theta \mid \varphi \colon G_1 \cong G_2\}$$

and $\mathrm{Aut}_\Gamma(G_1) \coloneqq \mathrm{Iso}_\Gamma(G_1, G_1)$. Note that $\mathrm{Aut}_\Gamma(G_1) \leq \Gamma$ and, if $\mathrm{Iso}_{\Gamma\theta}(G_1, G_2) \neq \emptyset$, then $\mathrm{Iso}_{\Gamma\theta}(G_1, G_2) = \mathrm{Aut}_\Gamma(G_1)\varphi$ where $\varphi \in \mathrm{Iso}(G_1, G_2)$ is an arbitrary isomorphism from G_1 to G_2.

▶ **Theorem 2.5** ([3, Corollary 3.6]). *Let $G_1 = (V_1, E_1, \lambda_1)$ and $G_1 = (V_2, E_2, \lambda_2)$ be two arc-colored directed graphs. Also let $\Gamma \leq \mathrm{Sym}(V_1)$ be a solvable group and $\theta\colon V_1 \to V_2$ a bijection. Then $\mathrm{Iso}_{\Gamma\theta}(G_1, G_2)$ can be computed in polynomial time.*

3 Small Degree Partition Sequences

In the following, we design an isomorphism test for tournaments of twin width k which runs in time $k^{O(\log k)}n^{O(1)}$. On a high level, the algorithm essentially proceeds in three phases. First, we use well-established group-theoretic methods going back to [3, 33] to reduce to the case where both input tournaments are 2-WL-homogeneous (without increasing the twin width). In the second step, we identify a substructure of an input tournament T (that is 2-WL-homogeneous) that has some kind of bounded-degree property. More concretely, we apply the 2-dimensional Weisfeiler-Leman algorithm and compute a sequence of colors $c_1, \dots, c_\ell$ in the image of the 2-WL coloring $\chi^{2,T}$ so that the subgraph induced by all edges with a color from $c_1, \dots, c_\ell$ has a certain type of bounded-degree property. After that, we rely on the computed bounded-degree structure to determine isomorphisms based on the group-theoretic graph isomorphism machinery. Similar tools have also been used in [1] to solve isomorphism of k-spanning tournaments. However, as we shall see below, the bounded-degree property guaranteed by the second step is weaker than the notion of k-spanning tournaments, which requires us to further extend the methods from [1].

In this section, we implement the second phase and prove the key combinatorial lemma (Lemma 3.6) underlying our isomorphism algorithm. Our arguments rely on the notion of *mixed neighbors* for a pair of vertices. For a pair $v, w \in V(T)$ of vertices we let

$$M(v, w) \coloneqq \Big(N_-(v) \cap N_+(w)\Big) \cup \Big(N_+(v) \cap N_-(w)\Big). \tag{1}$$

We call the elements of $M(v, w)$ the *mixed neighbors* of (v, w), and we call $\mathrm{md}(v, w) \coloneqq |M(v, w)|$ the *mixed degree* of (v, w). The following simple observation links the mixed degree to twin width.

▶ **Observation 3.1.** *There is an edge $(v, w) \in E(T)$ such that $\mathrm{md}(v, w) \leq \mathrm{tww}(T)$.*

Proof. Let $k \coloneqq \mathrm{tww}(T)$ and let $\mathcal{P}_1, \dots, \mathcal{P}_n$ be a contraction sequence of T of width k. Let $\{v, w\}$ be the unique 2-element part in $\mathcal{P}_2$. Then $\mathrm{md}(v, w) = \mathrm{md}(w, v) \leq k$, and either $(v, w) \in E(T)$ or $(w, v) \in E(T)$. ◀

In the following, let G_T be the directed graph with vertex set $V(G_T) \coloneqq V(T)$ and edge set $E(G_T) \coloneqq \{(v, w) \in E(T) \mid \mathrm{md}(v, w) \leq \mathrm{tww}(T)\}$. The next lemma implies that G_T has maximum out-degree at most $2 \cdot \mathrm{tww}(T) + 1$.

▶ **Lemma 3.2.** *Suppose $k \geq 1$. Let T be a tournament and let $v \in V(T)$. Also let*

$$W \coloneqq \{w \in N_+(v) \mid \mathrm{md}(v, w) \leq k\}.$$

Then $|W| \leq 2k + 1$.

Proof. Let $\ell := |W|$. The induced subtournament $T[W]$ has a vertex w of in-degree at least $(\ell-1)/2$. Since $\mathrm{md}(v,w) \leq k$ and $(v,w') \in E(T)$ for all $w' \in W$, we have

$$|\{w' \in W \mid (w',w) \in E(T)\}| \leq k.$$

Thus $\frac{\ell-1}{2} \leq k$, which implies that $|W| = \ell \leq 2k+1$. ◀

So G_T is a subgraph of T of maximum out-degree $d := 2 \cdot \mathrm{tww}(T) + 1$. We remark that similar arguments also show that G_T has maximum in-degree at most d (technically, this property is not required by our algorithm, but it is helpful for the following explanations). Now, first suppose that G_T is strongly connected. Then the edges of G_T define a (strongly) connected spanning subgraph of maximum degree $2d$ (in-degree plus out-degree). In this situation, we can directly use the algorithm from [1] to test isomorphism in time $d^{O(\log d)} n^{O(1)}$.

So suppose G_T is not strongly connected. If T is 2-WL-homogeneous, then G_T is also not weakly connected (i.e., the undirected version of G_T is not connected). In this case, the basic idea is to identify further edges to be added to decrease the number of connected components while keeping some kind of bounded-degree property.

In the following, let $\mathcal{Q}$ be a partition of $V(T)$ that is non-trivial, that is, has at least two parts. The reader is encouraged to think of $\mathcal{Q}$ as the partition into the (weakly) connected components of G_T, but the following results hold for any non-trivial partition $\mathcal{Q}$. We call an edge $(v,v') \in E(T)$ *cross-cluster with respect to* $\mathcal{Q}$ if it connects distinct $Q, Q' \in \mathcal{Q}$. For a cross-cluster edge (v,v') with $Q \ni v, Q' \ni v'$, we let

$$\mathcal{M}_{\mathcal{Q}}(v,v') := \left\{Q'' \in \mathcal{Q} \setminus \{Q,Q'\} \;\middle|\; Q'' \cap M(v,v') \neq \emptyset\right\}$$

and $\mathrm{md}_{\mathcal{Q}}(v,v') := |\mathcal{M}_{\mathcal{Q}}(v,v')|$.

The next two lemmas generalize Observation 3.1 and Lemma 3.2.

▶ **Lemma 3.3.** *Let T be a tournament and suppose $\mathcal{Q}$ is a non-trivial partition of $V(T)$. Then there is a cross-cluster edge $(v,w) \in E(T)$ such that $\mathrm{md}_{\mathcal{Q}}(v,w) \leq \mathrm{tww}(T)$.*

Proof. Let $k := \mathrm{tww}(T)$ and let $\mathcal{P}_1, \ldots, \mathcal{P}_n$ be a contraction sequence of T of width k. Note that $\mathcal{P}_1$ refines $\mathcal{Q}$ and $\mathcal{P}_n$ does not refine $\mathcal{Q}$, because $\mathcal{Q}$ is nontrivial. Let $i \geq 1$ be minimal such that $\mathcal{P}_{i+1}$ does not refine $\mathcal{Q}$.

Let $P, P' \in \mathcal{P}_i$ denote the parts merged in the step from $\mathcal{P}_i$ to $\mathcal{P}_{i+1}$. Since $\mathcal{P}_i$ refines $\mathcal{Q}$, there are $Q, Q' \in \mathcal{Q}$ such that $P \subseteq Q$ and $P' \subseteq Q'$. Moreover, $Q \neq Q'$, because $\mathcal{P}_{i+1}$ does not refine $\mathcal{Q}$. We pick arbitrary elements $v \in P$ and $w \in P'$ such that $(v,w) \in E(T)$ (if $(w,v) \in E(T)$, we swap the roles of P and P'). Then (v,w) is a cross-cluster edge with respect to $\mathcal{Q}$.

Let $P_1, \ldots, P_{k'}$ be a list of all $P'' \in \mathcal{P}_{i+1} \setminus \{P \cup P'\}$ such that the pair $(P \cup P', P'')$ is not homogeneous. Then $k' \leq k$ by the definition of twin width. Since $\mathcal{P}_i \setminus \{P,P'\} = \mathcal{P}_{i+1} \setminus \{P \cup P'\}$ and $\mathcal{P}_i$ refines $\mathcal{Q}$, there are $Q_1, \ldots, Q_{k'} \in \mathcal{Q}$ such that $P_i \subseteq Q_i$ for all $i \in [k']$.

Now let $Q'' \in \mathcal{Q} \setminus \{Q, Q', Q_1, \ldots, Q_{k'}\}$. Suppose for contradiction that $Q'' \cap M(v,w) \neq \emptyset$, and pick an element $w' \in Q'' \cap M(v,w)$. Then there is a $P'' \in \mathcal{P}_i \setminus \{P, P', P_1, \ldots, P_{k'}\} = \mathcal{P}_{i+1} \setminus \{P \cup P', P_1, \ldots, P_{k'}\}$ such that $w' \in P''$. But then the pair $(P \cup P', P'')$ is not homogeneous, which is a contradiction. So $Q'' \cap M(v,w) = \emptyset$. This implies that $\mathcal{M}_{\mathcal{Q}}(v,w) \subseteq \{Q_1, \ldots, Q_{k'}\}$. In particular, $\mathrm{md}_{\mathcal{Q}}(v,w) \leq k' \leq k$. ◀

▶ **Lemma 3.4.** *Suppose $k \geq 1$. Let T be a tournament and let $\mathcal{Q}$ be a non-trivial partition of $V(T)$. Also let $Q \in \mathcal{Q}$ and $v \in Q$. Let*

$$\mathcal{W} := \{Q' \in \mathcal{Q} \setminus \{Q\} \mid \exists w \in Q' \colon (v,w) \in E(T) \wedge \mathrm{md}_{\mathcal{Q}}(v,w) \leq k\}.$$

Then $|\mathcal{W}| \leq 2k+1$.

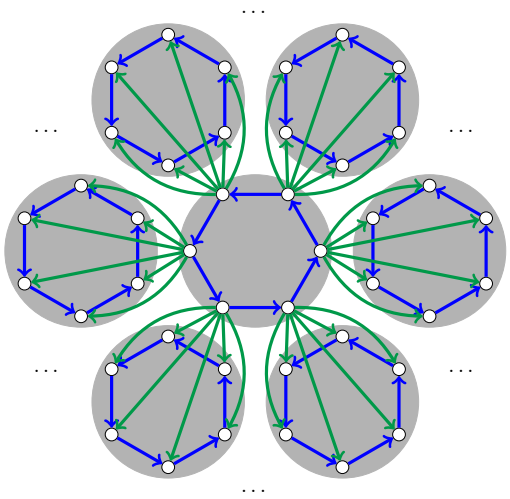

Figure 1 The figure shows part of a tournament T. The colors c_1 and c_2 are shown in blue and green, respectively. Also, the parts of the partition $\mathcal{Q}_1$ are highlighted in gray. Note that only green edges, which are outgoing from the middle part, are shown.

The proof is very similar to the proof of Lemma 3.2.

Proof. Let $\ell := |\mathcal{W}|$ and suppose $\mathcal{W} = \{Q_1, \dots, Q_\ell\}$. For every $i \in [\ell]$ pick an element $w_i \in Q_i$ such that $(v, w_i) \in E(T)$ and $\mathrm{md}_{\mathcal{Q}}(v, w_i) \leq k$. We define $W := \{w_1, \dots, w_\ell\}$. Then there is some $w \in W$ such that

$$|\{w' \in W \mid (w', w) \in E(T)\}| \geq \frac{\ell - 1}{2},$$

because the induced subtournament $T[W]$ has a vertex of in-degree at least $(\ell - 1)/2$.

Since $\mathrm{md}_{\mathcal{Q}}(v, w) \leq k$ and $(v, w') \in E(T)$ for all $w' \in W$, it follows that

$$|\{w' \in W \mid (w', w) \in E(T)\}| \leq k.$$

Thus $\frac{\ell-1}{2} \leq k$, which implies that $|\mathcal{W}| = \ell \leq 2k + 1$. ◀

Now, suppose we color all edges (v, w) of T with $\mathrm{md}(v, w) \leq \mathrm{tww}(T)$ using the color $c_1 = \mathsf{blue}$ (see Figure 1). Let $\mathcal{Q}_1$ be the partition into the (weakly) connected components of the graph induced by the blue edges and suppose that $\mathcal{Q}_1$ is non-trivial. We can compute isomorphisms between the different parts of $\mathcal{Q}_1$ using the algorithm from [1]. Next, let us color all cross-cluster edges $(v, w) \in E(T)$ with $\mathrm{md}_{\mathcal{Q}}(v, w) \leq \mathrm{tww}(T)$ using the color $c_2 = \mathsf{green}$. Then every vertex has outgoing green edges to at most $2\,\mathrm{tww}(T) + 1$ other parts of $\mathcal{Q}_1$ (see Lemma 3.4). However, since a vertex may have an unbounded number of green neighbors in a single part, the out-degree of the graph induced by the green edges may be unbounded. So it is not possible to use the algorithm from [1] as a black-box on the components induced by blue and green edges. Luckily, the methods used in [1] can be extended to work even in this more general setting (see Section 4). So if the graph induced by the blue and green edges is connected, then we are again done. Otherwise, we let $\mathcal{Q}_2$ denote the partition into (weakly) connected components of the graph induced by the blue and green edges. Now, we can continue in the same fashion identifying colors $c_3, c_4, \dots$ and corresponding partitions $\mathcal{Q}_3, \mathcal{Q}_4, \dots$ until the graph induced by all edges of colors $c_1, \dots, c_\ell$ is eventually connected.

Below, we provide a lemma that computes the corresponding sequence of partitions and edge colors using 2-WL. To state the lemma in its cleanest form, we restrict our attention to tournaments that are 2-WL-homogeneous. Recall that a tournament T is 2-WL-homogeneous if for all $v, w \in V(T)$ is holds that $\chi^{2,T}(v,v) = \chi^{2,T}(w,w)$.

We also require another piece of notation. For a directed graph G and a set of colors $C \subseteq \{\chi^{2,G}(v,w) \mid (v,w) \in E(G)\}$ we write $G[C]$ for the directed graph with vertex set $V(G[C]) \coloneqq V(G)$ and edge set

$$E(G[C]) \coloneqq \{(v,w) \in E(G) \mid \chi^{2,G} \in C\}.$$

To prove Lemma 3.6 we need the following lemma about the connected components of the graphs $G[C]$.

▶ **Lemma 3.5.** *Let G be a 2-WL-homogeneous graph, and let C a set of colors in the range of $\chi^{2,G}$. Then the weakly connected components of $G[C]$ equal the strongly connected components of $G[C]$.*

▶ **Lemma 3.6.** *Let T be a 2-WL-homogeneous tournament of twin width $\mathrm{tww}(T) \leq k$. Then there is a sequence of partitions $\{\{v\} \mid v \in V(T)\} = \mathcal{Q}_0, \dots, \mathcal{Q}_\ell = \{V(T)\}$ of $V(T)$ where $\mathcal{Q}_{i-1}$ refines $\mathcal{Q}_i$ for all i, and a sequence of colors $c_1, \dots, c_\ell$ in the range of $\chi^{2,T}$ such that*

(1) *$\mathcal{Q}_i$ is the partition into the strongly connected components of $T[\{c_1, \dots, c_i\}]$ for every $i \in [\ell]$, and*

(2) *for every $i \in [\ell]$ and every $v \in V(T)$ it holds that*

$$\left|\left\{Q \in \mathcal{Q}_{i-1} \;\middle|\; \exists w \in Q \colon \chi^{2,T}(v,w) = c_i\right\}\right| \leq 2k+1.$$

Moreover, there is a polynomial-time algorithm that, given a tournament T and an integer $k \geq 1$, computes the desired sequences $\mathcal{Q}_0, \dots, \mathcal{Q}_\ell$ and $c_1, \dots, c_\ell$ or concludes that $\mathrm{tww}(T) > k$.

Proof. We set $\mathcal{Q}_0 = \{\{v\} \mid v \in V(T)\}$ and inductively define a sequence of partitions and colors as follows. Let $i \geq 0$ and suppose we already defined partitions $\mathcal{Q}_0 \prec \cdots \prec \mathcal{Q}_i$ and colors $c_1, \dots, c_i$. If $\mathcal{Q}_i = \{V(T)\}$, we set $\ell \coloneqq i$ and complete both sequences. Otherwise, there is a cross-cluster edge (v_{i+1}, w_{i+1}) with respect to $\mathcal{Q}_i$ such that $\mathrm{md}_{\mathcal{Q}_i}(v_{i+1}, w_{i+1}) \leq k$ by Lemma 3.3. We set $c_{i+1} \coloneqq \chi^{2,T}(v_{i+1}, w_{i+1})$ and define $\mathcal{Q}_{i+1}$ to be the set of weakly connected components of $T[c_1, \dots, c_{i+1}]$. By Lemma 3.5, these are also the strongly connected components.

First observe that $\mathcal{Q}_i \prec \mathcal{Q}_{i+1}$ since (v_{i+1}, w_{i+1}) is a cross-cluster edge with respect to $\mathcal{Q}_i$, and v_{i+1}, w_{i+1} are contained in the same part of $\mathcal{Q}_{i+1}$ by Lemma 3.5. Also, Property 1 is satisfied by definition. For Property 2 note that every edge $(v,w) \in E(T)$ such that $\chi^{2,G}(v,w) = c_{i+1}$ is a cross-cluster edge with respect to $\mathcal{Q}_i$. So Property 2 follows directly from Lemma 3.4.

Finally, it is clear from the description above that $\mathcal{Q}_0 \prec \cdots \prec \mathcal{Q}_\ell$ and $c_1, \dots, c_\ell$ can be computed in polynomial time, or we conclude that $\mathrm{tww}(T) > k$. ◀

4 The Isomorphism Algorithm

Based on the structural insights summarized in Lemma 3.6, we now design an isomorphism test for tournaments of small twin width.

The strategy of our algorithm is the following. We are given two tournaments T_1 and T_2, and we want to compute $\mathrm{Iso}(T_1, T_2)$. First, we reduce to the case where both T_1 and T_2 are 2-WL-homogeneous.

Towards this end, we start by applying 2-WL and, for $j = 1, 2$, compute the coloring χ^{2,T_j}. If 2-WL distinguishes the two tournaments, we can immediately conclude that they are non-isomorphic and return $\mathrm{Iso}(T_1, T_2) = \emptyset$.

So suppose that 2-WL does not distinguish the tournaments. Then T_1 is 2-WL-homogeneous if and only if T_2 is 2-WL-homogeneous.

If the T_j are not 2-WL-homogeneous, we rely on the following standard argument. Let $c_1, \dots, c_p$ be the vertex colors. For $i \in [p]$ and $j = 1, 2$, let $P_{j,i}$ be the set of all $v \in V(T_j)$ such that $\chi^{2,T_j}(v, v) = c_i$. We recursively compute the sets $\Lambda_i := \mathrm{Iso}(T_1[P_{1,i}], T_2[P_{2,i}])$ for all $i \in [p]$. Note that this is possible since $\mathrm{tww}(T_1[P_{1,i}]) \leq \mathrm{tww}(T_1)$ and $\mathrm{tww}(T_2[P_{2,i}]) \leq \mathrm{tww}(T_2)$ for all $i \in [p]$ by Lemma 2.1. If there is some $i \in [p]$ such that $\Lambda_i = \emptyset$, then T_1 and T_2 are non-isomorphic, and we return $\mathrm{Iso}(T_1, T_2) = \emptyset$. Otherwise, the set Λ_i is a coset of $\Gamma_i := \mathrm{Aut}(T_1[P_{1,i}])$ for all $i \in [p]$, i.e., $\Lambda_i = \Gamma_i\theta_i$ for some bijection $\theta_i \colon P_{1,i} \to P_{2,i}$. As the automorphism group of a tournament, Γ_i is solvable (see Theorem 2.3). Moreover, since the color classes $P_{1,i}$ are invariant under automorphisms of T_1, the automorphism group $\Gamma := \mathrm{Aut}(T_1)$ is a subgroup of the direct product $\prod_i \Gamma_i$, which is also a solvable group. Also, $\mathrm{Iso}(T_1, T_2) \subseteq \Gamma\theta$ where $\theta \colon V(T_1) \to V(T_2)$ is the unique bijection defined via $\theta(v) := \theta_i(v)$ for all $v \in V(T_1)$, where $i \in [p]$ is the unique index such that $v \in P_{1,i}$. So $\mathrm{Iso}(T_1, T_2) = \mathrm{Iso}_{\Gamma\theta}(T_1, T_2)$ can be computed in polynomial time using Theorem 2.5.

So we may assume that T_1 and T_2 are 2-WL-homogeneous. In this case, we apply Lemma 3.6 and obtain colors $c_1, \dots, c_\ell$ and, for $j = 1, 2$, a partition sequence $\{\{v\} \mid v \in V(T_j)\} = \mathcal{Q}_{j,0}, \dots, \mathcal{Q}_{j,\ell} = \{V(T_j)\}$ where $\mathcal{Q}_{j,i-1}$ refines $\mathcal{Q}_{j,i}$ for all $i \in [\ell]$.

Now, we iteratively compute for $i = 0, \dots, \ell$ the sets $\mathrm{Iso}(T_j[Q], T_{j'}[Q'])$ for all $j, j' \in \{1, 2\}$ and all $Q \in \mathcal{Q}_{j,i}$ and $Q' \in \mathcal{Q}_{j',i}$. For $i = 0$ this is trivial since all parts have size 1. So suppose $i > 0$ and consider some elements $j, j' \in \{1, 2\}$ and $Q \in \mathcal{Q}_{j,i}$, $Q' \in \mathcal{Q}_{j',i}$. For simplicity, let us assume that $j = 1$ and $j' = 2$. Our goal is to compute $\mathrm{Iso}(T_1[Q], T_2[Q'])$. To do so, we exploit that we already computed all isomorphisms between all pairs of subgraphs of $T_1[Q]$ and $T_2[Q']$ induced by sets $R \in \mathcal{Q}_{1,i-1} \cup \mathcal{Q}_{2,i-1}$ and for which $R \subseteq Q$ or $R \subseteq Q'$. The next lemma describes the key subroutine of the main algorithm which achieves this goal. Note that, on the last level ℓ, we compute the set $\mathrm{Iso}(T_1, T_2)$ since $\mathcal{Q}_{j,\ell} = \{V(T_j)\}$ for both $j \in \{1, 2\}$.

To state the lemma, we need additional terminology. Let $T = (V, E, \lambda)$ be an arc-colored tournament. A partition $\mathcal{Q}$ of V is *λ-definable* if there is a set of colors $C \subseteq \{\lambda(v, w) \mid v = w \vee (v, w) \in E\}$ such that

$$v \sim_{\mathcal{Q}} w \quad \iff \quad \lambda(v, w) \in C$$

for all $v, w \in V$ such that $v = w$ or $(v, w) \in E$. We also say that *$\mathcal{Q}$ is λ-defined by C*. If $\mathcal{Q}$ is λ-defined by C then we can partition the colors in the range of λ into the colors in C, which we call *intra-cluster* colors, and the remaining colors, which we call *cross-cluster* colors. Note that if a color c is intra-cluster, then for all $(v, w) \in E$ with $\lambda(v, w) = c$ it holds that $v, w \in Q$ for some $Q \in \mathcal{Q}$, and if c is cross-cluster, then for all $(v, w) \in E$ with $\lambda(v, w) = c$ it holds that (v, w) is a cross-cluster edge, that is, $v \in Q$ and $w \in Q'$ for distinct $Q, Q' \in \mathcal{Q}$.

▶ **Lemma 4.1.** *There is an algorithm that, given*

(A) *an integer $d \geq 1$;*
(B) *two arc-colored tournaments $T_1 = (V_1, E_1, \lambda_1)$ and $T_2 = (V_2, E_2, \lambda_2)$;*
(C) *a set of colors C and for $j = 1, 2$ a partition $\mathcal{Q}_j$ of V_j that is λ_j-defined by C;*
(D) *a color c^* that is cross-cluster with respect to $\mathcal{Q}_j$ for $j = 1, 2$ and*

- *for every $v \in V_j$ it holds that*

$$\left|\left\{Q \in \mathcal{Q}_j \;\middle|\; \exists w \in Q \colon (v, w) \in E_j \wedge \lambda_j(v, w) = c^*\right\}\right| \leq d;$$

- *for*

$$F_j \coloneqq \left\{(Q,Q') \in \mathcal{Q}_j^2 \;\middle|\; Q \neq Q', \exists w \in Q, w' \in Q' \colon (w,w') \in E_j \wedge \lambda_j(w,w') = c^*\right\}$$

the directed graph $G_j = (\mathcal{Q}_j, F_j)$ *is strongly connected;*

(E) $\mathrm{Iso}\left(T_j[Q], T_{j'}[Q']\right)$ *for every* $j, j' \in \{1,2\}$ *and every* $Q \in \mathcal{Q}_j$, $Q' \in \mathcal{Q}_{j'}$,

computes $\mathrm{Iso}(T_1, T_2)$ *in time* $d^{O(\log d)} \cdot n^{O(1)}$.

The proof builds on the algorithmic ideas presented in [1]. Since it is quite lengthy and technical, we only present a rough idea of the proof; the details can be found in the full version.

Proof Idea. The algorithm fixes an arbitrary vertex $r_1 \in V_1$ and for every $r_2 \in V_2$ computes the set $\mathrm{Iso}((T_1, r_1), (T_2, r_2))$ of all isomorphisms $\varphi \in \mathrm{Iso}(T_1, T_2)$ such that $\varphi(r_1) = r_2$. Observe that $\mathrm{Iso}(T_1, T_2)$ is the union over all these sets.

The central idea is to iteratively compute larger and larger sets $W_{1,i} \subseteq V_1$ and $W_{2,i} \subseteq V_2$ such that

(I.1) there is some $\mathcal{W}_{j,i} \subseteq \mathcal{Q}_j$ such that $W_{j,i} = \bigcup_{Q \in \mathcal{W}_{j,i}} Q$, and

(I.2) $\varphi(W_{1,i}) = W_{2,i}$ for every $\varphi \in \mathrm{Iso}((T_1, r_1), (T_2, r_2))$

and compute the set $\mathrm{Iso}((T_1[W_{1,i}], r_1), (T_2[W_{2,i}], r_2))$. Initially, we set $W_{1,0} \coloneqq R_1$ and $W_{2,0} \coloneqq R_2$ where R_1 and R_2 are the unique parts of $\mathcal{Q}_1$ and $\mathcal{Q}_2$ containing r_1 and r_2, respectively. Note that the set $\mathrm{Iso}((T_1[W_{1,0}], r_1), (T_2[W_{2,0}], r_2))$ can easily be computed from Item E.

Now suppose we already computed $\mathrm{Iso}((T_1[W_{1,i}], r_1), (T_2[W_{2,i}], r_2))$ for some $W_{1,i} \subseteq V_1$ and $W_{2,i} \subseteq V_2$ satisfying (I.1) and (I.2). Consider a vertex $u \in W_{1,i}$ that has an outgoing edge of color c^* to a vertex outside of $W_{1,i}$. Note that, if $W_{1,i} \neq V_1$, such a vertex exists by the second part of Item D. We call such a vertex a *boundary vertex*. Let $U_{1,i}$ denote the set of boundary vertices. For a boundary vertex $u \in U_{1,i}$ let $\mathcal{L}^u_{1,i+1}$ denote the set of all parts $Q \in \mathcal{Q}_1$ that are outside of $W_{1,i}$ and contain a vertex $v \in Q$ such that $(u,v) \in E_1$ and $\lambda_1(u,v) = c^*$. Also, we define $L^u_{1,i+1} \coloneqq \bigcup_{Q \in \mathcal{L}^u_{1,i+1}} Q$. A visualization is given in Figure 2. Note that $|\mathcal{L}^u_{1,i+1}| \leq d$ by the first part of Item D.

For every boundary vertex $u \in U_{1,i}$ we construct an isomorphism-invariant tournament $\widetilde{T}^u_{1,i+1}$ with vertex set $\mathcal{L}^u_{1,i+1}$. Roughly speaking, for two distinct $Q, Q' \in \mathcal{L}^u_{1,i+1}$, in order to decide whether to add (Q,Q') or (Q',Q) to the edge set of $\widetilde{T}^u_{1,i+1}$, we take a majority vote on the edges between Q and Q' in T_1 (if there is a tie, we need to invoke further rules; see the full version for details).

Since $|\mathcal{L}^u_{1,i+1}| \leq d$, the automorphism group of $\widetilde{T}^u_{1,i+1}$ can be computed in time $d^{O(\log d)}$ by Theorem 2.4. Also, for each $Q \in \mathcal{L}^u_{1,i+1}$, the automorphism group of $T[Q]$ is given as part of the input (see Item E). By taking a wreath product, we obtain a solvable permutation group $\Gamma \leq \mathrm{Sym}(L^u_{1,i+1})$ such that $\mathrm{Aut}(T_1[L^u_{1,i+1}]) \leq \Gamma$. Using Theorem 2.5, this allows us to compute $\mathrm{Aut}(T_1[L^u_{1,i+1}])$ and, more generally, compute the isomorphism sets between the corresponding subgraphs for different boundary vertices $u, u' \in V_1 \cup V_2$.

Now, we extend $W_{1,i}$ by all sets $L^u_{1,i+1}$, $u \in U_{1,i}$, to obtain the next layer $W_{1,i+1}$ (actually, for technical reasons, the final proof proceeds in a slightly different manner); the set $W_{2,i+1}$ is defined analogously. To compute the desired isomorphism set, we proceed as follows. For simplicity, first suppose that all sets $L^u_{1,i+1}$, $u \in U_{1,i}$, are pairwise disjoint. Then, we can again take a wreath product to obtain a solvable permutation group $\Delta \leq \mathrm{Sym}(W_{1,i+1} \setminus W_{1,i})$ such that $\mathrm{Aut}(T_1[W_{1,i+1}], r_1) \leq \mathrm{Aut}(T_1[W_{1,i}], r_1) \times \Delta$. Using Theorem 2.5, this allows us to compute $\mathrm{Aut}(T_1[W_{1,i+1}], r_1)$. Similarly, we can also compute the set $\mathrm{Iso}((T_1[W_{1,i+1}], r_1), (T_2[W_{2,i+1}], r_2))$.

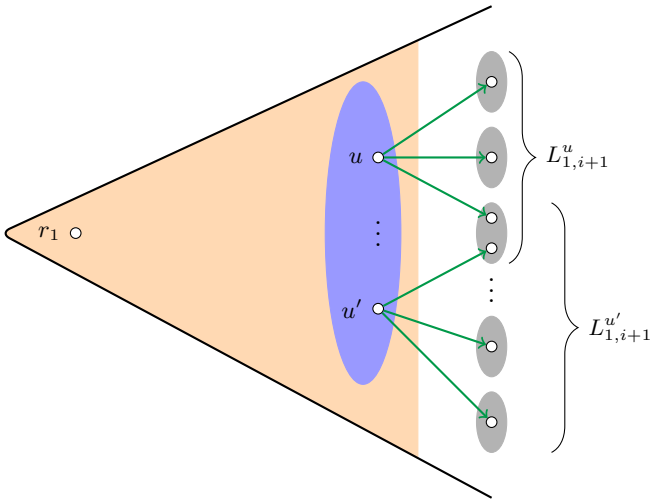

Figure 2 The figure shows the sets $W_{1,i}$ (orange), $U_{1,i}$ (blue) and $L^u_{1,i+1}$ computed in the proof sketch of Lemme 4.1. The color c^* is shown in green and gray regions depict parts of the partition $\mathcal{Q}_1$.

To cover the case that not all sets $L^u_{1,i+1}$, $u \in U_{1,i}$, are pairwise disjoint, we use the following trick. For each vertex $v \in W_{1,i+1} \setminus W_{1,i}$ let $\mu(v)$ denote the number of boundary vertices $u \in U_{1,i}$ such that $v \in L^u_{1,i+1}$. We replace each $v \in W_{1,i+1} \setminus W_{1,i}$ with $\mu(v)$ copies of the vertex; each copy is associated with one of the corresponding boundary vertices. Now, we can proceed as in the previous case to compute the set of isomorphisms. Afterwards, we rely on group-theoretic algorithms from [35] to "merge" the different copies of the same vertex again to finally obtain the group $\mathrm{Iso}((T_1[W_{1,i+1}], r_1), (T_2[W_{2,i+1}], r_2))$.

Note that the second part of Item D guarantees that we can continue this process until eventually $W_{1,i} = V_1$ and $W_{2,i} = V_2$, at which point we have computed the desired set $\mathrm{Iso}((T_1, r_1), (T_2, r_2))$. ◀

Building on the subroutine from Lemma 4.1, we can now design an isomorphism test for tournaments of bounded twin width following the outline given above.

▶ **Theorem 4.2.** *There is an algorithm that, given two tournaments T_1 and T_2 and an integer $k \geq 1$, either concludes that $\mathrm{tww}(T_1) > k$ or computes $\mathrm{Iso}(T_1, T_2)$ in time $k^{O(\log k)} \cdot n^{O(1)}$.*

5 The WL-Dimension of Tournaments of Bounded Twin Width

In this section, we prove Theorem 1.2. To prove that the WL algorithm on its own is unable to determine isomorphisms between tournaments of bounded twin width, we adapt a construction of Cai, Fürer and Immerman [12]. Towards this end, we first describe a construction of directed graphs with large WL dimension, and then argue how to translate those graphs into tournaments while preserving their WL dimension.

In the following, let G be a connected, 3-regular (undirected) graph. Let G^{red} denote the structure obtained from G be replacing every edge with a red edge and let $t := \mathrm{tww}(G^{\mathsf{red}})$.

Let us remark at this point that the Cai-Fürer-Immerman construction [12] replaces each vertex in G with a certain gadget, and those gadgets are connected along the edges of G. In order to bound the twin width of the resulting graph, we start with a graph G for which the

twin width of G^{red} is bounded.[1] This is because the connections between gadgets are not homogeneous, so when contracting all gadgets in a contraction sequence, we obtain precisely the graph G^{red} which allows to "complete" the contraction sequence using that G^{red} has bounded twin width.

Now, let us formally describe the construction of tournaments with large WL dimension. By Lemma 2.2 there is some linear order $<$ on $V(G)$ such that $\mathrm{tww}(G^{\mathsf{red}}, <) = t$. Also, let $\vec{G}$ be an arbitrary orientation of G.

Recall that for every $v \in V(G)$ we denote by $E_+(v)$ the set of outgoing edges and $E_-(v)$ the set of incoming edges in $\vec{G}$. Also, we write $E(v)$ to denote the set of incident (undirected) edges in G. For $a \in \mathbb{Z}_3$ we define

$$M_a(v) \coloneqq \left\{ f \colon E(v) \to \mathbb{Z}_3 \;\middle|\; \sum_{(v,w)\in E_+(v)} f(\{v,w\}) - \sum_{(w,v)\in E_-(v)} f(\{v,w\}) = a \pmod 3 \right\}$$

We also define $F_a(v)$ to contain all pairs $(f,g) \in (M_a(v))^2$ such that, for the minimal element $w \in N_G(v)$ (with respect to $<$) such that $f(vw) \neq g(vw)$, it holds that

$$f(vw) + 1 = g(vw) \pmod 3.$$

Observe that, for every distinct $f, g \in M_a(v)$, either $(f,g) \in F_a(v)$ or $(g,f) \in F_a(v)$.

Let $\alpha \colon V(G) \to \mathbb{Z}_3$ be a function. We define the graph $\mathsf{CFI}_3(\vec{G}, <, \alpha)$ with vertex set

$$V(\mathsf{CFI}_3(\vec{G}, <, \alpha)) \coloneqq \bigcup_{v \in V(G)} \{v\} \times M_{\alpha(v)}(v)$$

and edge set

$$\begin{aligned} E(\mathsf{CFI}_3(\vec{G}, <, \alpha)) \coloneqq \; & \left\{ \{(v,f)(w,g)\} \;\middle|\; vw \in E(G) \wedge f(vw) = g(vw) \right\} \\ & \cup \left\{ ((v,f)(v,g)) \;\middle|\; (f,g) \in F_{\alpha(v)}(v) \right\}. \end{aligned}$$

Observe that $\mathsf{CFI}_3(\vec{G}, <, \alpha)$ is a *mixed graph*, i.e., it contains both directed and undirected edges. Also, we color the vertices of $\mathsf{CFI}_3(\vec{G}, <, \alpha)$ using the coloring $\lambda \colon V(\mathsf{CFI}_3(\vec{G}, <, \alpha)) \to C$ defined via $\lambda(v,f) \coloneqq v$ for all $(v,f) \in V(\mathsf{CFI}_3(\vec{G}, \alpha))$, i.e., each set $M_{\alpha(v)}(v)$ forms a color class under λ.

Now fix an arbitrary vertex $u_0 \in V(G)$. For every $i \in \mathbb{Z}_3$ we define the mapping $\alpha_i \colon V(G) \to \mathbb{Z}_3$ via $\alpha_i(u_0) \coloneqq i$ and $\alpha_i(w) \coloneqq 0$ for all $w \in V(G) \setminus \{u_0\}$.

▶ **Lemma 5.1.** $\mathsf{CFI}_3(\vec{G}, <, \alpha_0) \ncong \mathsf{CFI}_3(\vec{G}, <, \alpha_1)$.

Now, we analyse the WL algorithm on the graphs $\mathsf{CFI}_3(\vec{G}, <, \alpha)$ for different functions $\alpha \colon V(G) \to \mathbb{Z}_3$. We write $\mathrm{tw}(G)$ to denote the tree width of G.

▶ **Lemma 5.2.** *Let k be an integer such that $\mathrm{tw}(G) \geq k+1$. Also let $\alpha, \beta \colon V(G) \to \mathbb{Z}_3$ be two functions. Then $\mathsf{CFI}_3(\vec{G}, <, \alpha) \simeq_k \mathsf{CFI}_3(\vec{G}, <, \beta)$.*

Together, Lemmas 5.1 and 5.2 provide pairs of non-isomorphic graphs that are not distinguished by k-WL assuming $\mathrm{tw}(G) > k$. Next, we argue how to turn these graphs into tournaments.

[1] We remark that, since G has maximum degree 3, the twin width of G^{red} is actually bounded in the twin width of G. However, we feel it is more convenient to directly bound the twin width of G^{red}.

We define the tournament $T = T(\vec{G}, <, \alpha)$ with vertex set

$$V(T) \coloneqq V(\mathsf{CFI}_3(\vec{G}, <, \alpha)) = \bigcup_{v \in V(G)} \{v\} \times M_{\alpha(v)}(v)$$

and edge set

$$\begin{aligned} E(T) \coloneqq & \left\{((v,f)(v,g)) \;\middle|\; (f,g) \in F_{\alpha(v)}(v)\right\} \\ & \cup \left\{((v,f)(w,g)) \;\middle|\; v < w \wedge \{(v,f)(w,g)\} \notin E(\mathsf{CFI}_3(\vec{G}, <, \alpha))\right\} \\ & \cup \left\{((w,g)(v,f)) \;\middle|\; v < w \wedge \{(v,f)(w,g)\} \in E(\mathsf{CFI}_3(\vec{G}, <, \alpha))\right\}. \end{aligned}$$

It can be shown that the relevant properties are preserved by this translation.

▶ **Lemma 5.3.** *Let $\alpha, \beta \colon V(G) \to \mathbb{Z}_3$ be two functions. Then $T(\vec{G}, <, \alpha) \cong T(\vec{G}, <, \beta)$ if and only if $\mathsf{CFI}_3(\vec{G}, <, \alpha) \cong \mathsf{CFI}_3(\vec{G}, <, \beta)$.*

▶ **Lemma 5.4.** *Let $k \geq 2$ be an integer such that $\mathrm{tw}(G) \geq k+1$. Also let $\alpha, \beta \colon V(G) \to \mathbb{Z}_3$ be two functions. Then $T(\vec{G}, <, \alpha) \simeq_k T(\vec{G}, <, \beta)$.*

To prove Theorem 1.2, we also need to bound the twin width of the resulting graph. Recall that $t \coloneqq \mathrm{tww}(G^{\mathsf{red}})$ where G^{red} denotes the version of G where every edge is red.

▶ **Lemma 5.5.** *For every function $\alpha \colon V(G) \to \mathbb{Z}_3$ it holds that $\mathrm{tww}(T(\vec{G}, <, \alpha)) \leq \max(35, t)$.*

Proof. Throughout the proof, we define $M(v) \coloneqq M_{\alpha(v)}(v)$ for every $v \in V(G)$. Since G is 3-regular, we have that $|M(v)| = 9$ for every $v \in V(G)$. So $|V(T(\vec{G}, <, \alpha))| = 9 \cdot |V(G)|$. Also note that $(M(v), M(w))$ is homogeneous for all distinct $v, w \in V(G)$ such that $\{v, w\} \notin E(G)$.

We construct a partial contraction sequence as follows. Let $n \coloneqq |V(G)|$. We define $\mathcal{P}_1, \ldots, \mathcal{P}_{8n+1}$ arbitrarily such that $\mathcal{P}_{8n+1} = \{M(v) \mid v \in V(G)\}$. Since G is 3-regular and $|M(v)| = 9$ for every $v \in V(G)$, we conclude that $(T(\vec{G}, <, \alpha))/\mathcal{P}_i$ has red degree at most $4 \cdot 9 - 1 = 35$ for every $i \in [8n+1]$. Now observe that

$$\mathrm{tww}((T(\vec{G}, <, \alpha))/\mathcal{P}_{8n+1}) \leq \mathrm{tww}(G^{\mathsf{red}}, <) = t.$$

It follows that $\mathrm{tww}(T(\vec{G}, <, \alpha)) \leq \max(35, t)$ as desired. ◀

With Lemma 5.5 in hand, we apply the construction $T(\vec{G}, <, \alpha)$ to a 3-regular base graph G which has tree width linear in the number of vertices, but the twin width of G^{red} is bounded. The existence of such graphs has already been observed in [5]. More precisely, the following theorem follows from combining the arguments from [5, Lemma 5.1] and the results from [4, 34].

▶ **Theorem 5.6.** *There is a family of 3-regular graphs $(G_n)_{n \geq 1}$ such that $|V(G_n)| = O(n)$, $\mathrm{tww}(G_n^{\mathsf{red}}) \leq 6$ (where G_n^{red} denotes the version of G_n where all edges are turned into red edges), and $\mathrm{tw}(G_n) \geq n$ for every $n \geq 1$.*

Now, we are ready to give a proof for Theorem 1.2.

▶ **Theorem 5.7.** *For every $k \geq 2$ there are non-isomorphic tournaments T_k and T_k' such that*
(1) *$|V(T_k)| = |V(T_k')| = O(k)$,*
(2) *$\mathrm{tww}(T_k) \leq 35$ and $\mathrm{tww}(T_k') \leq 35$, and*
(3) *$T_k \simeq_k T_k'$.*

Proof. Let $k \geq 2$. Let G_{k+1} be the 3-regular graph obtained from Theorem 5.6. Note that $\mathrm{tw}(G_{k+1}) \geq k+1$.

We also fix an arbitrary orientation $\vec{G}_{k+1}$ of G_{k+1} and let G^{red}_{k+1} denote the version of G_{k+1} where every edge is replaced by a red edge. We have $t := \mathrm{tww}(G^{\mathsf{red}}_{k+1}) \leq 6$ by Theorem 5.6. By Lemma 2.2 there is some linear order $<$ on $V(G_{k+1})$ such that $\mathrm{tww}(G^{\mathsf{red}}_{k+1}, <) \leq t \leq 6$.

Now fix an arbitrary $u_0 \in V(G_{k+1})$. For $p \in \mathbb{Z}_3$ we define the mapping $\alpha_p \colon V(G_{k+1}) \to \mathbb{Z}_3$ via $\alpha_p(u_0) = p$ and $\alpha_p(w) = 0$ for all $w \in V(G_{k+1}) \setminus \{u_0\}$. We define $T_k := T(\vec{G}_{k+1}, <, \alpha_0)$ and $T'_k := T(\vec{G}_{k+1}, <, \alpha_1)$. We have $|V(T_k)| = |V(T'_k)| = 9 \cdot |V(G_{k+1})| = O(k)$. Also, $\mathrm{tww}(T_k) \leq 35$ and $\mathrm{tww}(T'_k) \leq 35$ by Lemma 5.5. Finally, $T_k \ncong T'_k$ by Lemmas 5.1 and 5.3, and $T_k \simeq_k T'_k$ by Lemma 5.4. ◀

6 Twin Width is Smaller Than Other Widths

In this section, we compare twin width with other natural width parameters of tournaments. If f, g are mappings from (directed) graphs to the natural numbers, we say that f is *functionally smaller* than g on a class $\mathcal{C}$ of graphs if for every k there is a k' such that for all graphs $G \in \mathcal{C}$, if $g(G) \leq k$ then $f(G) \leq k'$. We write $f \preceq_{\mathcal{C}} g$ to denote that f is functionally smaller than g on $\mathcal{C}$. We omit the subscript $_{\mathcal{C}}$ if $\mathcal{C}$ is the class of all digraphs.

Natural width measures for directed graphs are *cut width*, *directed path width*, *directed tree width*, and *clique width*. On the class of tournaments twin width turns out to be functionally smaller than all of these. For clique width, it has already been shown in [11] that twin width is functionally smaller than clique width on undirected graphs; the proof easily extends to arbitrary binary relational structures and hence to tournaments.

We start by giving definitions for the other width measures. Let G be a digraph. For a linear order $\leq$ on $V(G)$ and a vertex $v \in V(G)$, we let $S_{\leq}(v) := \{w \in V(G) \mid w \leq v\}$ be the set of all vertices smaller than or equal to v in $\leq$. Let $s_{\leq}(v) := |E_G(S_{\leq}(v), V(G) \setminus S_{\leq}(v))|$ be the number of edges from $S_{\leq}(v)$ to its complements. The *width* of $\leq$ is $\max_{v \in V(G)} s_{\leq}(v)$, and the *cut width* $\mathrm{ctw}(G)$ is the minimum over the width of all linear orders of $V(G)$.

A *directed path decomposition* of a digraph G is a mapping $\beta \colon [p] \to 2^{V(G)}$, for some $p \in \mathbb{N}$, such that for every vertex $v \in V(G)$ there are $\ell, r \in [p]$ such that $v \in \beta(t) \iff \ell \leq t \leq r$, and for all edges $(v, w) \in E(G)$ there are $\ell, r \in [p]$ with $\ell \leq r$ such that $v \in \beta(r)$ and $w \in \beta(\ell)$. The sets $\beta(t)$, $t \in [p]$, are the *bags* of the decomposition. The *width* of the decomposition is $\max_{t \in [p]} |\beta(t)| - 1$, and the *directed path width* $\mathrm{dpw}(G)$ is the minimum width of a directed path decomposition of G.

A digraph R is a *rooted directed tree* if there is a vertex $r_0 \in V(R)$ such that for every $t \in V(R)$ there is a unique directed walk from r_0 to t. Note that every rooted directed tree can be obtained from an undirected tree by selecting a root r_0 and directing all edges away from the root. For $t \in V(R)$ we denote by R_t the unique induced subgraph of R rooted at t.

Let G be a digraph. A *directed tree decomposition* of G is a triple (R, β, γ) where R is a rooted directed tree, $\beta \colon V(R) \to 2^{V(G)}$ and $\gamma \colon E(R) \to 2^{V(G)}$ such that

(D.1) $\{\beta(t) \mid t \in V(R)\}$ is a partition of $V(G)$, and

(D.2) for every $(s, t) \in E(R)$ the set $\gamma(s, t)$ is a hitting set for all directed walks that start and end in $\beta(R_t) := \bigcup_{t' \in V(R_t)} \beta(t')$ and contain a vertex outside of $\beta(R_t)$.

For $t \in V(R)$ we define $\Gamma(t) := \beta(t) \cup \bigcup_{(s,s') \in E(t)} \gamma(s, s')$ where $E(t)$ denotes the set of edges incident to t. The *width* of (R, β, γ) is defined as

$$\mathrm{width}(R, \beta, \gamma) := \max_{t \in V(R)} |\Gamma(t)| - 1.$$

The *directed tree width* $\mathrm{dtw}(G)$ is the minimum width of a directed tree decomposition of G.

Let us first recall the following well-known inequalities.

▶ **Proposition 6.1.** *For all digraphs G, it holds that* $\mathrm{dtw}(G) \leq \mathrm{dpw}(G) \leq \mathrm{ctw}(G)$.

The proposition implies that dtw $\precsim$ dpw $\precsim$ ctw. It can be shown that tww $\not\precsim$ ctw and hence tww $\not\precsim$ dpw and tww $\not\precsim$ dtw on the class of all digraphs. In contrast, it turns out that on the class of tournaments, twin width is functionally smaller than directed tree width. Actually, this even holds for the larger class of semi-complete graphs. A digraph G is *semi-complete* if for all distinct $v, w \in V(G)$ at least one of the pairs $(v, w), (w, v)$ is an edge. Note that every tournament is semi-complete.

▶ **Theorem 6.2** ([28, Proposition 5])**.** *Let G be a semi-complete graph. Then*

$$\mathrm{dpw}(G) \leq 4(\mathrm{dtw}(G) + 2)^2 + 7(\mathrm{dtw}(G) + 2) - 1.$$

▶ **Theorem 6.3.** *Let G be a semi-complete graph. Then* $\mathrm{tww}(G) \leq \mathrm{dpw}(G)$.

In combination, we get that $\mathrm{tww}(G) \leq 4(\mathrm{dtw}(G) + 2)^2 + 7(\mathrm{dtw}(G) + 2) - 1$ for every semi-complete graph G. In particular

$$\text{tww} \precsim_{\mathcal{S}} \text{dtw}, \tag{2}$$

where $\mathcal{S}$ denotes the class of all semi-complete digraphs. This inequality is strict even on tournaments, that is, dtw $\not\precsim_{\mathcal{T}}$ tww where $\mathcal{T}$ denotes the class of all tournaments.

7 Conclusion

We prove that the isomorphism problem for classes of tournaments of bounded (or slowly growing) twin width is in polynomial time. Many algorithmic problems that can be solved efficiently on (classes of) tournaments can also be solved efficiently on (corresponding classes of) semi-complete graphs, that is, directed graphs where for every pair (v, w) of vertices at least one of the pairs $(v, w), (w, v)$ is an edge (see, e.g., [39]). Contrary to this, we remark that isomorphism of semi-complete graphs of bounded twin width is GI-complete: we can reduce isomorphism of oriented graphs to isomorphism of semi-complete graphs by replacing each non-edge by a bidirectional edge. This reduction preserves twin with.

Classes of tournaments of bounded twin width are precisely the classes that are considered to be structurally sparse. Formally, these are the classes that are monadically dependent, which means that all set systems definable over the tournaments in such a class have bounded VC dimension. The most natural set systems definable within a tournament are those consisting of the in-neighbors of the vertices and of the out-neighbors of the vertices. Bounded twin width implies that the VC dimension of these two set systems is bounded, but the converse does not hold. It is easy to see that the VC dimensions of the in-neighbors and out-neighbors systems as well as the set system consisting of the mixed neighbors of all edges are within a linear factor of one another. As a natural next step, we may ask if isomorphism of tournaments where the VC-dimension of these systems is bounded is in polynomial time.

From Trees to Polynomials and Back Again: New Capacity Bounds with Applications to TSP

Leonid Gurvits

Institute for Advanced Study, Princeton, NJ, USA

Jonathan Leake
University of Waterloo, Canada

Abstract

We give simply exponential lower bounds on the probabilities of a given strongly Rayleigh distribution, depending only on its expectation. This resolves a weak version of a problem left open by Karlin-Klein-Oveis Gharan in their recent breakthrough work on metric TSP, and this resolution leads to a minor improvement of their approximation factor for metric TSP. Our results also allow for a more streamlined analysis of the algorithm.

To achieve these new bounds, we build upon the work of Gurvits-Leake on the use of the productization technique for bounding the capacity of a real stable polynomial. This technique allows one to reduce certain inequalities for real stable polynomials to products of affine linear forms, which have an underlying matrix structure. In this paper, we push this technique further by characterizing the worst-case polynomials via bipartitioned forests. This rigid combinatorial structure yields a clean induction argument, which implies our stronger bounds.

In general, we believe the results of this paper will lead to further improvement and simplification of the analysis of various combinatorial and probabilistic bounds and algorithms.

1 Introduction

The theory of real stable and log-concave polynomials has seen numerous applications in combinatorics and theoretical computer science (TCS). This includes bounds and approximation algorithms for various combinatorial quantities [18, 11, 7, 28, 5, 8, 2, 15], proofs of long-standing log-concavity and sampling conjectures related to matroids [1, 3, 4, 14], proofs

of the Kadison-Singer conjecture and generalizations [26, 6, 13], an improved approximation factor for the traveling salesperson problem (TSP) [27, 24, 25], and many more. The power of these polynomial classes comes from two features: (1) their *robustness*, shown in the fact that many natural operations preserve these log-concavity properties, and (2) their *convex analytic properties*, which can be used to prove bounds and other analytic statements. The typical way these polynomials are utilized is by encoding combinatorial objects as real stable and log-concave polynomials, which essentially allows these operations and convexity properties to automatically transfer to the combinatorial objects. This idea, while simple, has led to important breakthroughs in combinatorics, TCS, and beyond.

For example, [18] utilized real stable polynomials to give a new proof of the Van der Waerden conjecture on the permanent of a doubly stochastic matrix (originally due to [16, 17]). This proof led to a vast generalization of Van der Waerden bound, including an improved Schrijver's bound for regular bipartite graphs [18], an analogous bound for mixed discriminants [19], and an analogous bound for mixed volumes that led to the development of strongly log-concave polynomials [21, 20]. One reason the original bound was historically so difficult to prove is a lack of a usable inductive structure coming from the matrices themselves. One of the key insights of the new proof was to use the simple inductive structure of real stable polynomials given by partial derivatives. By encoding the matrices as polynomials, the correct induction becomes straightforward, and the bound follows from a simple calculus argument.

More recently, the approximation factor improvement for the metric traveling salesperson problem (TSP) crucially utilized real stable polynomials [24, 25]. The idea is to encode certain discrete probability distributions related to spanning trees as real stable polynomials. The coefficients of these polynomials give probabilities of certain graph-theoretic events (e.g., the number of edges in a given spanning tree incident on a particular vertex), and analytic properties of real stable polynomials allow one to lower bound these probabilities. This in turn implies bounds on the expected cost of the output of a randomized algorithm for metric TSP.

In this paper, we improve upon the polynomial capacity bounds of [22], and our applications touch on the two problems discussed above. Specifically, we give:

1. robust coefficient lower bounds for all (not necessarily homogeneous) real stable polynomials,
2. simply exponential lower bounds on probabilities of strongly Rayleigh distributions (solving a weak version of an open problem of [24]), and
3. a further improvement to the approximation factor for metric TSP (predicted by [22]).

Interestingly, our approach goes in the opposite direction to that discussed above. Our technical results answer questions regarding real stable polynomials, but to prove these results we use various graph and matrix structures inherent to the polynomials. In [22], this was seen in the "productization" technique: bounds on real stable polynomials were achieved by showing that the worst-case bounds come from polynomials associated to certain matrices. In this paper, we push this idea further by showing that these worst-case matrices are bipartite adjacency matrices of forests. This very rigid structure enables a clean induction argument, which implies stronger polynomial capacity bounds. These new bounds lead to the applications discussed above, with the strongest bounds implying the metric TSP improvement.

2 Main Results

We first state here our main technical results; see Section 3 for any undefined notation.

Our first main result is a non-homogeneous version of Theorem 2.1 of [22] which implies robust coefficient lower bounds for all real stable polynomials as a direct corollary. Crucially, these bounds do not depend on the total degree of the polynomial. This was one of the main barriers to applying the results of [22] to metric TSP.

▶ **Theorem 1** (Main non-homogeneous capacity bound). *Let $p \in \mathbb{R}_{\geq 0}[x_1, \ldots, x_n]$ be a real stable polynomial in n variables, and fix any $\boldsymbol{\kappa} \in \mathbb{Z}^n$ with non-negative entries. If $p(\mathbf{1}) = 1$ and $\|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1 < 1$, then*

$$\inf_{x_1,\ldots,x_n>0} \frac{p(\boldsymbol{x})}{x_1^{\kappa_1} \cdots x_n^{\kappa_n}} \geq (1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)^n .$$

This bound is tight for any fixed $\boldsymbol{\kappa}$ with strictly positive entries.

▶ **Corollary 2** (Main non-homogeneous coefficient bound). *Let $p \in \mathbb{R}_{\geq 0}[x_1, \ldots, x_n]$ be a real stable polynomial in n variables, and fix any $\boldsymbol{\kappa} \in \mathbb{Z}^n$ with non-negative entries. If $p(\mathbf{1}) = 1$ and $\|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1 < 1$, then*

$$p_{\boldsymbol{\kappa}} \geq \left(\prod_{i=1}^{n} \frac{\kappa_i^{\kappa_i} e^{-\kappa_i}}{\kappa_i!} \right) (1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)^n,$$

where $p_{\boldsymbol{\kappa}}$ is the coefficient of $\boldsymbol{x}^{\boldsymbol{\kappa}}$ in p. The dependence on $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ is tight for any fixed $\boldsymbol{\kappa}$ with strictly positive entries.

The above results[1] are robust (i.e., resilient to ℓ^1 perturbations) versions of the results utilized to bound various combinatorial and probabilistic quantities, as discussed above. That said, they are still not quite strong enough to imply an improvement to the metric TSP approximation factor. To obtain this improvement, we resolve a weak version of an open problem from [24], which we discuss below. Stronger versions of Theorem 1 and Corollary 2 which imply this result can be found in Section 5.

2.1 Application: Minimum Permanent

Before discussing the application to TSP, we first describe a different application of our bounds as a sort of prelude. It is at this point well-known that the permanent of any $n \times n$ doubly stochastic matrix is at least $\frac{n!}{n^n}$, and that $\frac{1}{n}\mathbf{1} \cdot \mathbf{1}^\top$ is the unique minimizer of the permanent over all doubly stochastic matrices. On the other hand, a similar tight lower bound with explicit minimizer is not known for sets of matrices with different row and column sums. The following then slightly extends what is known in the doubly stochastic case. See Section 6 for further details.

Given $\boldsymbol{c} \in \mathbb{R}^n_{\geq 0}$, let $\mathrm{Mat}_n(\boldsymbol{c})$ denote the set of $n \times n$ matrices with non-negative entries, row sums equal to $\mathbf{1}$, and columns sums equal to $\boldsymbol{c}$.

▶ **Theorem 3.** *For all $n \geq 1$, there exists $\epsilon_n > 0$ such that if $\|\boldsymbol{c} - \mathbf{1}\|_1 < \epsilon_n$ then $\frac{1}{n}\mathbf{1} \cdot \boldsymbol{c}^\top$ is the unique minimizer of the permanent over $\mathrm{Mat}_n(\boldsymbol{c})$. Specifically, this holds if $\frac{c_1 c_2 \cdots c_n}{L(\boldsymbol{c})} < \frac{(n-2)^{n-2} n^{n-1}}{(n-1)^{2n-3}}$, where $L(\boldsymbol{c})$ is any lower bound on the capacity.*

[1] Note that these bounds already appear in the arXiv version of [22], but not in the STOC version.

The proof utilizes Theorem 1 or results of [22] to guarantee all minimizers of the permanent lie in the relative interior of $\mathrm{Mat}_n(\boldsymbol{c})$. The symmetry and multilinearity of the permanent then imply the minimizer must be the rank-one matrix of $\mathrm{Mat}_n(\boldsymbol{c})$ described above. See Section Section 6 for the explicit value of ϵ_n and the details of the proof. It should be noted that in proving uniqueness, we were able to avoid usage of the conditions for equality in the Alexandrov-Fenchel inequalities.

On the other hand, when $\boldsymbol{c}$ is far from $\mathbf{1}$, the above result can be far from correct. Recall from [22] that $\mathrm{per}(M) > 0$ for all $M \in \mathrm{Mat}_n(\boldsymbol{c})$ if and only if $\|\boldsymbol{c} - \mathbf{1}\|_1 < 2$.

▶ **Proposition 4.** *For all n large enough, there exists $\boldsymbol{c}$ such that $\|\boldsymbol{c} - \mathbf{1}\|_1 < 2$ and a sparse matrix $M \in \mathrm{Mat}_n(\boldsymbol{c})$ (with linearly many non-zero entries) which has smaller permanent than that of $\frac{1}{n}\mathbf{1} \cdot \boldsymbol{c}^\top$.*

These two results suggest the complexity of the minimizer of the permanent, given the column sums $\boldsymbol{c}$. The coefficient bound given above in Corollary 2 is then a lower bound which generalizes that of the permanent to coefficients of real stable polynomials. (Consider the coefficient $p_{\mathbf{1}}$ of $p(\boldsymbol{x}) = \prod_{i=1}^n \sum_{j=1}^n m_{ij} x_j$.) Thus Corollary 2 can be seen as a sort of "smoothing" of the complexities that can occur for minima of the permanent and its generalizations.

Further, Theorem 3 can generalized to a permanent-like function on rectangular matrices using Theorem 1, and even beyond that to the mixed discriminant. (For the mixed discriminant, the row sum condition becomes a trace condition, and the column sum condition becomes an eigenvalue condition.) On the other hand, we can generalize the statement of Theorem 3 to coefficients of real stable polynomials in general, but we do not yet know how to prove it.

2.2 Application: Metric TSP

We first recall an important probabilistic bound from [24] used in the analysis of their metric TSP approximation algorithm (which is a slight modification of the max entropy algorithm from [27] first studied by [9]). In what follows, we let $A_S := \sum_{i \in S} A_i$ and $\kappa_S := \sum_{i \in S} \kappa_i$. See Section 3 for any undefined notation.

▶ **Theorem 5** (Prop. 5.1 of [24])**.** *Let μ be a strongly Rayleigh distribution on $[m]$, let $A_1, \ldots, A_n$ be random variables counting the number of elements contained in disjoint subsets of $[m]$, and fix $\boldsymbol{\kappa} \in \mathbb{Z}^n$ with non-negative entries. Suppose for all $S \subseteq [n]$ we have*

$$\mathbb{P}_\mu\left[A_S \geq \kappa_S\right] \geq \epsilon \qquad \text{and} \qquad \mathbb{P}_\mu\left[A_S \leq \kappa_S\right] \geq \epsilon.$$

Then we have

$$\mathbb{P}_\mu\left[A_1 = \kappa_1, \ldots, A_n = \kappa_n\right] \geq f(\epsilon) \cdot \mathbb{P}_\mu\left[A_{[n]} = \kappa_{[n]}\right],$$

where $f(\epsilon) \geq \epsilon^{2^n} \prod_{i=2}^n \frac{1}{\max\{\kappa_i, \kappa_{[i-1]}\}+1}$.

In [24], the authors note two things about this bound. First, they note that to apply the bound it is sufficient to have

$$\left|\mathbb{E}_\mu\left[A_S\right] - \kappa_S\right| < 1 \qquad \forall S \subseteq [n], \tag{1}$$

since this implies a lower bound on $\mathbb{P}_\mu\left[A_S = \kappa_S\right]$ for all $S \subseteq [n]$ for strongly Rayleigh distributions. Second, they note that the bound on $f(\epsilon)$ is doubly exponential in n, but they expect the true dependency to only be simply exponential. They leave it as an open problem to determine a tight lower bound on $f(\epsilon)$.

In this paper, we further improve the metric TSP approximation factor by resolving a weak version of this open problem: we give a simply exponential lower bound which depends tightly on ϵ, under the stronger condition of (1). Concretely, we prove the following.

▶ **Theorem 6** (Improved probability lower bound). *Let μ be a strongly Rayleigh distribution on $[m]$, let $A_1, \ldots, A_n$ be random variables counting the number of elements contained in disjoint subsets of $[m]$, and fix $\boldsymbol{\kappa} \in \mathbb{Z}^n$ with non-negative entries. Suppose for all $S \subseteq [n]$ we have*

$$\left|\mathbb{E}_\mu [A_S] - \kappa_S\right| \leq 1 - \epsilon.$$

Then we have

$$\mathbb{P}_\mu [A_1 = \kappa_1, \ldots, A_n = \kappa_n] \geq \epsilon^n \prod_{\kappa_i > 0} \frac{1}{e\sqrt{\kappa_i}}.$$

The dependence on ϵ is tight for any fixed $\boldsymbol{\kappa}$ with strictly positive entries.

In fact, we prove stronger versions of this result which more directly depend on the specific values of $(\mathbb{E}_\mu [A_S] - \kappa_S)$ for all $S \subseteq [n]$; see Theorem 9 and Corollary 10. These results are analogous to our main coefficient bound Corollary 2 because the coefficients and the gradient of probability generating polynomials can be interpreted as the probabilities and the expectation of the associated distribution. That said, our stronger probabilistic results require a more delicate analysis of the expectations (gradient) beyond what is required for Corollary 2. In particular, note that the conditions on the expectations in Theorem 6 are more general than a bound on the ℓ^1 norm of $(\mathbb{E}_\mu [A_i] - \kappa_i)_{i=1}^n$. See Section 4 for further details.

Using Theorem 6, we improve the metric TSP approximation factor for the algorithm given in [24].

▶ **Theorem 7.** *There exists a randomized algorithm for metric TSP with approximation factor $\frac{3}{2} - \epsilon$ for some $\epsilon > 10^{-34}$.*

This is about a 100 times improvement over the result of [23]. Thus our improvement in terms of the approximation factor itself may be smaller than anticipated, given that we were able to improve the probability bound in Theorem 6 from doubly exponential to simply exponential. The reason for this is that while Theorem 5 was useful in [24] to quickly determine which events occurred with constant probability (and indeed provided a single unifying explanation for why one should expect many of their probabilistic bounds to hold), it gave such small guarantees that [24] resorted to ad hoc arguments instead to give their final probabilistic bounds.

We show that Theorem 6 alone can be used to give bounds that are comparable to the ad hod methods of [24] (and, in several important cases, much better) whenever the bounds came purely from information on the expectations as in (1). Thus, we believe our main contribution to work on metric TSP is a version of Theorem 5 that is "reasonable" to use, allowing one to show a similar approximation factor but with a more streamlined proof.

Unfortunately, not all of the bounds in [24] follow from expectation information, and two of them become bottlenecks for improving the approximation factor after applying Theorem 6 to the other statements. Thus, to demonstrate Theorem 7 we need to sharpen these bounds using other techniques. For one of these lemmas we show that the existing proof in [24] was far from tight, and in the other we refine their proof. In particular, using Theorem 6, we show we can reduce this second lemma to a special case that is possible to analyze more carefully. See Section 4 for further details.

3 Technical Overview

In this section we discuss the proof strategy of our main capacity and coefficient bounds, Theorem 1 and Corollary 2, and their stronger forms.

Notation

Given a vector $\boldsymbol{z} \in \mathbb{R}^E$ and a subset S of E, let $\boldsymbol{z}^S := \prod_{e \in S} z_e$. Let $\mu : \{0,1\}^E \to \mathbb{R}$ be a probability distribution over subsets of E. The generating polynomial $g_\mu \in \mathbb{R}_{\geq 0}[\{z_e\}_{e \in E}]$ of μ is defined as

$$g_\mu(z) := \sum_{S \subseteq E} \mu(S) \cdot \boldsymbol{z}^S.$$

The distribution μ is **strongly Rayleigh** if g_μ is real stable, where a polynomial $p \in \mathbb{R}[z_1, \ldots, z_n]$ is **real stable** if $p(\boldsymbol{z}) \neq 0$ whenever $\Im(z_i) > 0$ for all $i \in [n]$ (i.e., when all inputs are in the complex upper half-plane). See [12] for much more on strongly Rayleigh measures. Further, given a polynomial $p \in \mathbb{R}_{\geq 0}[x_1, \ldots, x_n]$ and $\boldsymbol{\kappa} \in \mathbb{Z}^n_{\geq 0}$, the **capacity** of p is defined as

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) := \inf_{\boldsymbol{x} > 0} \frac{p(\boldsymbol{x})}{\boldsymbol{x}^{\boldsymbol{\kappa}}}.$$

Finally, we let $p_{\boldsymbol{\kappa}}$ denote the coefficient of $\boldsymbol{x}^{\boldsymbol{\kappa}}$ in p.

Conceptual strategy

We first give an overarching view of the strategy used to prove our main results, as well as the key similarities and differences compared to that of [22]. The general idea for proving our bounds is to find a simple and sparse underlying structure for the worst-case inputs. The space of all real stable polynomials can be complicated, but we show that the worst-case polynomials for our bounds are far simpler: they are "sparse" products of affine linear forms. More concretely, we reduce the space of input polynomials (and the corresponding combinatorial structures) as follows:

$$\begin{array}{ccccc} \text{real stable polynomials} & \Longrightarrow & \text{products of linears} & \Longrightarrow & \text{sparse products of linears} \\ \text{matroids} & \Longrightarrow & \text{matrices} & \Longrightarrow & \text{forests} \end{array}$$

The first reduction step uses the idea of productization which was the key idea from [22]. This allows for one to utilize the matrix structure inherent to products of affine linear forms.

The second reduction step is then new to this paper. We first show that we may restrict to the extreme points of the set of matrices corresponding to products of affine linear forms, and then we show that these extreme matrices are supported on the edges of forests. This implies a significant decrease in density of the matrices: general graphs can have quadratically many edges, whereas forests can only have linearly many. This allows for an intricate but clean induction on the leaf vertices of these forests, which yields the strongest bounds of this paper. Additionally, it is this step that allows for bounds which do not depend on the total degree of the polynomial, and this was a crucial barrier to applying the bounds of [22] to metric TSP.

3.1 Conceptual Strategy, in More Detail

We now go through the steps of the conceptual strategy described above in more detail. Let us first restate our main capacity and coefficient bounds.

▶ **Theorem 8** (= Theorem 1 and Corollary 2)**.** *Let $p \in \mathbb{R}_{\geq 0}[x_1, \ldots, x_n]$ be a real stable polynomial in n variables, and fix any $\boldsymbol{\kappa} \in \mathbb{Z}^n$ with non-negative entries. If $p(\mathbf{1}) = 1$ and $\|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1 < 1$, then*

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq (1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)^n$$

and

$$p_{\boldsymbol{\kappa}} \geq \left(\prod_{i=1}^{n} \frac{\kappa_i^{\kappa_i} e^{-\kappa_i}}{\kappa_i!} \right) (1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)^n ,$$

*where $\mathrm{Cap}_{\boldsymbol{\kappa}}(p) := \inf_{\boldsymbol{x} > 0} \frac{p(\boldsymbol{x})}{\boldsymbol{x}^{\boldsymbol{\kappa}}}$ is the **capacity** of p and $p_{\boldsymbol{\kappa}}$ is the coefficient of $\boldsymbol{x}^{\boldsymbol{\kappa}}$ in p. The dependence on $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ in these bounds is tight for any fixed $\boldsymbol{\kappa}$ with strictly positive entries.*

Analogous bounds required for the metric TSP application then follow from interpreting desired quantities as the coefficients and gradient of certain real stable polynomials. Specifically, the strongly Rayleigh probabilities we wish to lower bound are the coefficients of the corresponding real stable generating polynomial, and the expectations of the associated random variables are given by the gradient of that polynomial. We leave further details to Section 4.

We now discuss the proof of Theorem 8. First note that the coefficient bound follows from the capacity bound. This immediately follows from Corollary 3.6 of [20], which implies

$$p_{\boldsymbol{\kappa}} \geq \left(\prod_{i=1}^{n} \frac{\kappa_i^{\kappa_i} e^{-\kappa_i}}{\kappa_i!} \right) \mathrm{Cap}_{\boldsymbol{\kappa}}(p). \tag{2}$$

Thus what remains to be proven is the capacity bound

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq (1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)^n ,$$

which is precisely the bound of Theorem 1, as well as its tightness, which follows from considering a particular example of p (see Lemma 28).

The remainder of the proof then has four main steps. We also note here that these proof steps actually imply stronger bounds than Theorem 1, see Corollary 27 for the formal statement. These stronger bounds are required for the metric TSP application.

Step 1: Reduce to products of affine linear forms via productization

We first generalize the productization technique of [22] to non-homogeneous real stable polynomials. The upshot of this technique is that it implies it is sufficient to prove Theorem 1 for products of affine linear forms with non-negative coefficients (see Corollary 18). Such polynomials correspond to $d \times (n+1)$ $\mathbb{R}_{\geq 0}$-valued matrices with row sums $\mathbf{1}$ and column sums $\boldsymbol{\alpha}$ equal the entries of the gradient of the polynomial, via

$$\phi : A \mapsto \prod_{i=1}^{d} \left(a_{i,n+1} + \sum_{j=1}^{n} a_{i,j} x_j \right) .$$

This gives far more structure to work with, beyond that of real stable polynomials in general. This part is a straightforward generalization of the analogous result of [22].

Step 2: Reduce to extreme points

The set of $\mathbb{R}_{\geq 0}$-valued matrices with row sums $\mathbf{1}$ and column sums $\boldsymbol{\alpha}$ forms a convex polytope $P^d_{\boldsymbol{\alpha}}$, and thus the polynomials we now must consider correspond to the points of this polytope via the map ϕ defined above. Inspired by a result of Barvinok (see Lemma 19), we next show that the function

$$A \mapsto \mathrm{Cap}_{\boldsymbol{\kappa}}(\phi(A))$$

is log-concave on the above described polytope. Since we want to minimize the capacity, this implies we may further restrict to the polynomials associated to the extreme points of the polytope.

Step 3: Extreme points correspond to bipartitioned forests

Any $\mathbb{R}_{\geq 0}$-valued matrix A can be interpreted as the weighted bipartite adjacency matrix of a bipartite graph, where the left vertices correspond to the rows of A and the right vertices correspond to the columns of A. A matrix $A \in P^d_{\boldsymbol{\alpha}}$ being extreme implies the associated bipartite graph has no cycles. This implies the associated bipartite graph is a forest (see Lemma 20). The sparsity properties of such matrices implies a simple structure for the associated polynomials, which is particularly amenable to an intricate but clean induction.[2]

Step 4: Induction on leaf vertices of the bipartitioned forests

Leaf vertices in the forest corresponding to a given matrix $A \in P^d_{\boldsymbol{\alpha}}$ indicate rows or columns of the matrix A which have exactly one non-zero entry. If a row of A has exactly one non-zero entry, the induction proceeds in a straightforward fashion, by simply removing the corresponding row of A and recalculating the column sums (see the $d \geq n+1$ case of the proof of Theorem 25).

If a column of A (say column i) has exactly one non-zero entry, then the induction is more complicated. We prove lemmas showing how much the capacity can change after applying the partial derivative ∂_{x_i} (when $\kappa_i \geq \alpha_i$, see Lemma 24) or setting x_i to 0 (when $\kappa_i < \alpha_i$, see Lemma 23). Since column i has only one entry, applying ∂_{x_i} corresponds to removing column i and the row of A which contains the non-zero entry, and setting x_i to 0 corresponds to removing column i. After renormalizing the row sums and recalculating the column sums, the proof again proceeds by induction. (See the proof of Theorem 25 to see the above arguments presented formally.) Example 29 and Example 30 show that the distinction between the $\kappa_i \geq \alpha_i$ and $\kappa_i < \alpha_i$ cases is not an artifact of the proof.

Some comments on tightness of the bounds

The main coefficient bound of Corollary 2 is proven via two different bounds, as discussed at the beginning of this section. That is, one first bounds the coefficient in terms of the capacity (2) via Corollary 3.6 of [20], and then one bounds the capacity via the steps outlined above. Thus while the capacity bound (Theorem 1) is tight for $\boldsymbol{\kappa} > \mathbf{0}$, the coefficient bound

[2] Note that it is already mentioned in [22] that the supports of the extreme points correspond to forests, but the application of this observation in [22] is somewhat "naive" and kind of brute-force: it was mainly used to describe an (inefficient) algorithm to compute the capacity lower bound for products of linear forms, which is not related to main lower bound in this paper. Additionally, its use in [22] is quite conceptually far from how it could actually be used to improve the TSP approximation factor.

(Corollary 2) may not be. We note that the coefficient bound is likely close to tight in the case that $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ is close to 1, but it seems this tightness deteriorates as $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ gets close to 0. That said, the dependence on $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ in Theorem 1 and Corollary 2 is tight for $\boldsymbol{\kappa} > \mathbf{0}$ by Lemma 28, though there is still potential for improvement in the more refined capacity bounds; see Section 5.5.

That said, tight coefficient lower bounds in the univariate case can be achieved by directly applying a bound of Hoeffding, and these lower bounds resemble the coefficient lower bound of Corollary 2. Thus one can view Corollary 2 as a step towards a multivariate generalization of Hoeffding's theorem. It is an interesting question whether or not the techniques used here can be extended to a full multivariate generalization of Hoeffding's theorem.

3.2 Example: The Univariate Case

In this section, we demonstrate the proof of Theorem 1 in the univariate case. This will serve as a sort of proof of concept for the more general proof.

Here we consider real stable non-homogeneous polynomials $p \in \mathbb{R}_{\geq 0}[x_1]$ such that $p(1) = 1$ and $\nabla p(1) = \alpha_1$, and we define $\epsilon := 1 - |\alpha_1 - \kappa_1| > 0$. By Step 1 above, we may assume that p is of the form

$$p(x_1) = \prod_{i=1}^{d}(a_{i,1}x_1 + a_{1,2}),$$

where A is an $\mathbb{R}_{\geq 0}$-valued $d \times 2$ matrix with row sums 1 and column sums $(\alpha_1, d - \alpha_1)$. By Steps 2-3, we may further assume A is the weighted bipartite adjacency matrix of a forest. If every row of A contains exactly one non-zero entry then $p(x_1) = x_1^{k_1}$, and the result is trivial in this case. Otherwise, $d - 1$ rows of M have exactly one non-zero entry (see Lemma 21). Thus for some $k \leq d - 1$ we have

$$p(x_1) = x_1^k(ax_1 + b),$$

where $a + b = 1$ and $a + k = \alpha_1$. Since $\kappa_1 \in \mathbb{Z}_{\geq 0}$ and

$$\epsilon = 1 - |\alpha_1 - \kappa_1| = 1 - |a + k - \kappa_1|,$$

we have that k is equal to either κ_1 or $\kappa_1 - 1$. If $k = \kappa_1$, then

$$\mathrm{Cap}_{\kappa_1}(p) = \inf_{x_1 > 0} \frac{x_1^k(ax_1 + b)}{x_1^k} = b \qquad \text{and} \qquad \epsilon = 1 - |a + k - \kappa_1| = 1 - a = b.$$

If $k = \kappa_1 - 1$, then

$$\mathrm{Cap}_{\kappa_1}(p) = \inf_{x_1 > 0} \frac{x_1^k(ax_1 + b)}{x_1^{k+1}} = a \qquad \text{and} \qquad \epsilon = 1 - |a + k - \kappa_1| = 1 - (1 - a) = a.$$

Therefore in both cases we have

$$\mathrm{Cap}_{\kappa_1}(p) = \epsilon = (1 - |\alpha_1 - \kappa_1|),$$

which proves Theorem 1 in the univariate case and demonstrates the tight dependence on $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ in this case.

4 Proof of Application: Metric TSP

The following is the strongest probability lower bound, which we will use for the metric TSP application. In what follows, we let $A_S := \sum_{i \in S} A_i$ and $\kappa_S := \sum_{i \in S} \kappa_i$. Note that if

$$\left|\mathbb{E}_\mu [A_S] - \kappa_S\right| \leq 1 - \epsilon,$$

then Theorem 6 immediately follows from Theorem 9, Lemma 28, and a standard computation.

▶ **Theorem 9** (Strongest form of the probability bound). *Let μ be a strongly Rayleigh distribution on $[m]$, let $A_1, \ldots, A_n$ be random variables counting the number of elements contained in some associated disjoint subsets of $[m]$, and fix $\boldsymbol{\kappa} \in \mathbb{Z}^n_{\geq 0}$. Suppose for all $S \subseteq [n]$ we have $|\mathbb{E}_\mu [A_S] - \kappa_S| < 1$. Define $\boldsymbol{\epsilon}, \boldsymbol{\delta} \in \mathbb{R}^n_{>0}$ via*

$$\delta_k := 1 + \min_{S \in \binom{[n]}{k}} \left(\mathbb{E}_\mu [A_S] - \kappa_S\right) \qquad \text{and} \qquad \epsilon_k := 1 - \max_{S \in \binom{[n]}{k}} \left(\mathbb{E}_\mu [A_S] - \kappa_S\right).$$

Then we have

$$\mathbb{P}_\mu [A_1 = \kappa_1, \ldots, A_n = \kappa_n] \geq \prod_{i=1}^n \frac{\kappa_i^{\kappa_i} e^{-\kappa_i}}{\kappa_i!} \cdot \min_{0 \leq \ell \leq n} \prod_{k=1}^{\ell} \epsilon_k \prod_{k=1}^{n-\ell} \delta_k.$$

Proof. Let q be the probability generating polynomial of μ, and let p be the polynomial obtained by setting the variables of q associated to A_i to x_i for all $i \in [n]$, and setting all other variables to equal 1. Since μ is strongly Rayleigh, p is real stable. Further, $p(\mathbf{1}) = 1$, $\nabla p(\mathbf{1}) = (\mathbb{E}_\mu [A_i])_{i=1}^n$, and $\mathbb{P}_\mu [A_1 = \kappa_1, \ldots, A_n = \kappa_n]$ is the $\boldsymbol{x}^{\boldsymbol{\kappa}}$ coefficient of p. Thus Gurvits' capacity inequality (2) and Corollary 27 imply the desired result. ◀

We also give a slightly weaker bound which is a bit easier to use in practice. Note that Theorem 6 also follows from Corollary 10.

▶ **Corollary 10.** *Let μ be a strongly Rayleigh distribution on $[m]$, let $A_1, \ldots, A_n$ be random variables counting the number of elements contained in some associated disjoint subsets of $[m]$, and fix $\boldsymbol{\kappa} \in \mathbb{Z}^n_{\geq 0}$. Suppose for all $S \subseteq [n]$ we have $|\mathbb{E}_\mu [A_S] - \kappa_S| < 1$. Define $\boldsymbol{\epsilon} \in \mathbb{R}^n_{>0}$ via*

$$\epsilon_k := 1 - \max_{\substack{S \subseteq [n] \\ |S| \leq k}} \left|\mathbb{E}_\mu [A_S] - \kappa_S\right|$$

Then we have

$$\mathbb{P}_\mu [A_1 = \kappa_1, \ldots, A_n = \kappa_n] \geq \prod_{i=1}^n \frac{\kappa_i^{\kappa_i} e^{-\kappa_i}}{\kappa_i!} \cdot \prod_{k=1}^n \epsilon_k.$$

Proof. Follows from Theorem 9; see the proof of Corollary 26 for more details. ◀

The remainder of this section is devoted to demonstrating how one can use the above results to improve the approximation factor for metric TSP.

4.1 A Simple Application

We recall some definitions from [24]. There, we have a graph $G = (V, E)$ and a strongly Rayleigh (SR) distribution $\mu : 2^E \to \mathbb{R}_{\geq 0}$ supported on spanning trees of G. We let $x_e = \mathbb{P}_{T\sim\mu}[e \in T]$ and for a set of edges F let $x(F) = \sum_{e\in F} x_e$. Furthermore we let $\delta(S) = \{e = \{u, v\} \mid |e \cap S| = 1\}$. The guarantee on x is that $x \in P_{\text{Sub}}$,[3] where

$$P_{\text{Sub}} := \begin{cases} x(\delta(S)) \geq 2 & \forall\, S \subsetneq V \\ x(\delta(v)) = 2 & \forall v \in V \\ x_{\{u,v\}} \geq 0 & \forall\, u, v \in V \end{cases} \tag{3}$$

In the algorithm they analyze, one first samples a spanning tree T from μ and then add the minimum cost matching on the odd vertices of T. Their work involves analyzing the expected cost of this matching over the randomness of the sampled tree T. Unsurprisingly, the *parity* of vertices is therefore very important, as it determines which vertices are involved in the matching.

In this section, to give some sense of the utility of Theorem 9, we show an application in a simplified setting. Namely, we show that for any two vertices u, v, except in the special case that $x_{\{u,v\}} \approx \frac{1}{2}$, we have $\mathbb{P}_{T\sim\mu}[|\delta(u) \cap T| = |\delta(v) \cap T| = 2] \geq \Omega(1)$, i.e. for any two vertices that do not share an edge of value $\frac{1}{2}$ there is a constant probability that they have even parity simultaneously. This is helpful because (under some conditions on the point $x \in P_{\text{Sub}}$) the event that u, v are even simultaneously indicates one can strictly decrease the cost of the matching proportional to the cost of the edge e.

We now prove $\mathbb{P}_{T\sim\mu}[|\delta(u) \cap T| = |\delta(v) \cap T| = 2] \geq \Omega(1)$ whenever $x_{\{u,v\}} \not\approx \frac{1}{2}$. To do this, we split into two cases: when $x_{\{u,v\}} \geq \frac{1}{2} + \epsilon$ and when $x_{\{u,v\}} \leq \frac{1}{2} - \epsilon$.

▶ **Lemma 11.** *Let u, v be two vertices such that $x_{\{u,v\}} \geq \frac{1}{2} + \epsilon$ for some $\epsilon > 0$. Then,*

$$\mathbb{P}_{T\sim\mu}[|\delta(u) \cap T| = |\delta(v) \cap T| = 2] \geq \frac{\epsilon}{2e^3}.$$

Proof. Let $e = (u, v)$. For $T \sim \mu$, let $A_1 = \mathbb{I}[e \in T]$, $A_2 = |(\delta(u) \setminus \{e\}) \cap T|$, $A_3 = |(\delta(v) \setminus \{e\}) \cap T|$. We are now interested in the event $A_i = \kappa_i, \forall i$ for the vector $\kappa = (1, 1, 1)$ as this implies $|\delta(u) \cap T| = |\delta(v) \cap T| = 2$. We have $\mathbb{E}[A_1] = x_e$, $\mathbb{E}[A_2] = \mathbb{E}[A_3] = 2 - x_e$. Therefore, to apply Theorem 9 we can set:

$$\delta_1 = x_e, \delta_2 = 1, \delta_3 = 2 - x_e, \qquad \epsilon_1 = x_e, \epsilon_2 = 2x_e - 1, \epsilon_3 = x_e$$

In this case the worst case is using all of the ϵ terms in the bound, giving $e^{-3}x_e^2(2x_e - 1) \geq \frac{\epsilon}{2e^3}$ as desired. ◀

▶ **Lemma 12.** *Let u, v be two vertices such that $x_{\{u,v\}} \leq \frac{1}{2} - \epsilon$ for some $\epsilon > 0$. Then,*

$$\mathbb{P}_{T\sim\mu}[|\delta(u) \cap T| = |\delta(v) \cap T| = 2] \geq \frac{2\epsilon}{e^4}.$$

Proof. As above, $e = (u, v)$, and for $T \sim \mu$, let $A_1 = \mathbb{I}[e \in T]$, $A_2 = |(\delta(u) \setminus \{e\}) \cap T|$, $A_3 = |(\delta(v) \setminus \{e\}) \cap T|$. We are now interested in the event $A_i = \kappa_i, \forall i$ for the vector $\kappa = (0, 2, 2)$ as this implies $|\delta(u) \cap T| = |\delta(v) \cap T| = 2$. We have $\mathbb{E}[A_1] = x_e$, $\mathbb{E}[A_2] = \mathbb{E}[A_3] = 2 - x_e$. Therefore, to apply Theorem 9 we can set:

$$\delta_1 = 1 - x_e, \delta_2 = 1 - 2x_e, \delta_3 = 1 - x_e, \qquad \epsilon_1 = 1 - x_e, \epsilon_2 = 1, \epsilon_3 = 1 + x_e$$

In this case the worst case is using all of the δ terms in the bound, giving $4e^{-4}(1 - x_e)^2(1 - 2x_e) \geq \frac{2\epsilon}{e^4}$. ◀

[3] Technically, a spanning tree plus an edge is sampled, as otherwise one cannot exactly have $x \in P_{\text{Sub}}$, but we ignore that here.

We leave further background about TSP and the proofs of our improved probabilistic statements to the full version of the paper, as understanding their importance requires some knowledge of the (highly technical) proof in [24]. However, in the next section we summarize the new probabilistic bounds we get and their consequences.

4.2 Summary of Probabilistic Bounds and New Approximation Factor

The current bound on the performance of the max entropy algorithm is $\frac{3}{2} - 4.11 \cdot 10^{-36}$. This is primarily governed by a constant p that is determined by the minimum probability over a number of events. In [24], p was equal to $2 \cdot 10^{-10}$, and these events are described by the following statements in [24]:

1. Corollary 5.9, which gives a bound of $1.5 \cdot 10^{-9}$. We do not modify this bound, although we note that Lemma 5.7 can be slightly improved which would lead to a small improvement here.
2. Lemma 5.21, which gives a bound of $0.005\epsilon_{1/2}^2 = 2 \cdot 10^{-10}$. We improve this to $0.039\epsilon_{1/2}^2 = 1.56 \cdot 10^{-9}$.
3. Lemma 5.22, which gives a bound of $0.006\epsilon_{1/2}^2 = 2.4 \cdot 10^{-10}$. We improve this to $0.038\epsilon_{1/2}^2 = 1.52 \cdot 10^{-9}$.
4. Lemma 5.23, which gives a bound of $0.005 \cdot \epsilon_{1/2} = 2 \cdot 10^{-10}$. We observe here that arguments already in [24] can be used to give $0.0498\epsilon_{1/2}^2 \geq 1.9 \cdot 10^{-9}$.
5. Lemma 5.24, which gives a bound of $0.02\epsilon_{1/2}^2 = 8 \cdot 10^{-10}$. We improve this to $0.0485\epsilon_{1/2}^2 \geq 1.9 \cdot 10^{-9}$.
6. Lemma 5.27, which gives a bound of 0.01. This lemma actually uses that the threshold p is *small*, and therefore this bound decreases slightly upon raising p. However, as it is quite far from being the bottleneck in these bounds, we omit the proof that the probability remains above $1.5 \cdot 10^{-9}$.

Therefore, we may increase p to the minimum of all these probabilities, $1.5 \cdot 10^{-9}$. Using statements from [24, 23], the following then holds:

▶ **Lemma 13.** *Let p be a lower bound on the probabilities guaranteed by (1) - (6) for $\epsilon_{1/2} \leq 0.0002$, and suppose $p \leq 10^{-4}$. Then given $x \in P_{\text{Sub}}$, the max entropy algorithm returns a solution of expected cost at most $(\frac{3}{2} - 9.7p^2 \cdot 10^{-17}) \cdot c(x)$.*

As we improve the bounds on p to $1.5 \cdot 10^{-9}$, an immediate corollary is the following:

▶ **Corollary 14.** *The max entropy algorithm is a $\frac{3}{2} - 2.18 \cdot 10^{-34}$ approximation algorithm for metric TSP.*

Using [25] this guarantee can be made deterministic, as we do not require any modifications to the algorithm.

In the full version of the paper, we also observe a lower bound on Lemma 5.21 for strongly Rayleigh distributions of $\Omega(\epsilon_{1/2}^2)$. The fact that $\epsilon_{1/2} \leq 0.0002$ is used in many places in [24] and thus decreasing it may require more effort. Thus without modifying other parts of the argument, it may not be possible to improve the bound below $1.5 \cdot 10^{-31}$.

In the rest of the paper we prove our main capacity bound.

5 Proofs of the Main Capacity Bounds

In this section we prove the strongest forms of the main capacity bounds, which give Theorem 1 and Corollary 2 as corollaries. See the full version of the paper for any missing proofs. For this section, we utilize the following notation.

▶ **Definition 15.** *For $n, d \in \mathbb{N}$ and $\boldsymbol{\alpha} \in \mathbb{R}^n_{\geq 0}$, we define the following:*

1. $\mathrm{NHMat}^d_n(\boldsymbol{\alpha})$ *is the set of all $\mathbb{R}_{\geq 0}$-valued $d \times (n+1)$ matrices with row sums all equal to 1 and column sums equal to $\alpha_1, \ldots, \alpha_n, d - \|\boldsymbol{\alpha}\|_1$.*
2. $\mathrm{NHProd}^d_n(\boldsymbol{\alpha})$ *is the set of all polynomials of the form*

$$p(x) = \prod_{i=1}^{d} \left(a_{i,n+1} + \sum_{j=1}^{n} a_{i,j} x_j \right),$$

where $A \in \mathrm{NHMat}^d_n(\boldsymbol{\alpha})$. In this case, we call p the polynomial associated to A. *Note that $p(\mathbf{1}) = 1$ and $\nabla p(\mathbf{1}) = \boldsymbol{\alpha}$ for all such polynomials.*
3. $\mathrm{NHStab}^d_n(\boldsymbol{\alpha})$ *is the set of all real stable polynomials in $\mathbb{R}_{\geq 0}[x_1, \ldots, x_n]$ of degree at most d for which $p(\mathbf{1}) = 1$ and $\nabla p(\mathbf{1}) = \boldsymbol{\alpha}$. (Recall that a polynomial is stable if it is never zero when all inputs are in the open complex upper half-plane.)*

We also define the following for $n \in \mathbb{N}$, $\boldsymbol{\alpha} \in \mathbb{R}^n_{\geq 0}$, and $\boldsymbol{\kappa} \in \mathbb{Z}^n_{\geq 0}$:

$$L^{\mathrm{NHProd}}_n(\boldsymbol{\alpha}; \boldsymbol{\kappa}) := \min_{d \in \mathbb{N}} \min_{p \in \mathrm{NHProd}^d_n(\boldsymbol{\alpha})} \mathrm{Cap}_{\boldsymbol{\kappa}}(p).$$

We now follow the steps of the proof given in Section 3.

5.1 Productization for Non-homogeneous Stable Polynomials

We first show how we can reduce the problem of bounding the capacity to products of affine linear forms. We recall the main productization result from [22], which gives the non-homogeneous productization result as an immediate corollary.

▶ **Theorem 16** (Thm. 6.2, [22])**.** *Fix $n, d \in \mathbb{N}$, $\boldsymbol{u}, \boldsymbol{\alpha} \in \mathbb{R}^n_{\geq 0}$, and $p \in \mathbb{R}_{\geq 0}[x_1, \ldots, x_n]$ of homogeneous degree d, such that $p(\mathbf{1}) = 1$ and $\nabla p(\mathbf{1}) = \boldsymbol{\alpha}$. There exists an $\mathbb{R}_{\geq 0}$-valued $d \times n$ matrix A such that the rows sums of A are all equal to $\mathbf{1}$, the column sums of A are given by $\boldsymbol{\alpha}$, and $p(\boldsymbol{u}) = \prod_{i=1}^{d} (A\boldsymbol{u})_i$.*

▶ **Corollary 17.** *Fix $n, d \in \mathbb{N}$, $\boldsymbol{u}, \boldsymbol{\alpha} \in \mathbb{R}^n_{\geq 0}$, and $p \in \mathrm{NHStab}^d_n(\boldsymbol{\alpha})$. There exists $f \in \mathrm{NHProd}^d_n(\boldsymbol{\alpha})$ such that $p(\boldsymbol{u}) = f(\boldsymbol{u})$.*

Proof. Let $q(\boldsymbol{x}) = x_{n+1}^d \cdot p\left(\frac{x_1}{x_{n+1}}, \ldots, \frac{x_n}{x_{n+1}}\right)$ be the homogenization of p, and define $\boldsymbol{\beta} := \nabla q(\mathbf{1})$. So $q \in \mathbb{R}_{\geq 0}[x_1, \ldots, x_{n+1}]$ of homogeneous degree d such that $q(\mathbf{1}) = 1$ and $\nabla q(\mathbf{1}) = \boldsymbol{\beta} = (\alpha_1, \ldots, \alpha_n, d - \|\boldsymbol{\alpha}\|_1)$. Define $u_{n+1} := 1$, apply Theorem 16 to q and $\boldsymbol{u}$, and dehomogenize to obtain the desired result. ◀

We now use this result to reduce the problem of bounding the capacity to products of affine linear forms.

▶ **Corollary 18.** *For $p \in \mathrm{NHStab}^d_n(\boldsymbol{\alpha})$, we have*

$$\mathrm{Cap}_{\kappa}(p) \geq L^{\mathrm{NHProd}}_n(\boldsymbol{\alpha}; \boldsymbol{\kappa}).$$

Proof. For any $\boldsymbol{x} \in \mathbb{R}^n_{\geq 0}$, let $f \in \mathrm{NHProd}^d_n(\boldsymbol{\alpha})$ be such that $p(\boldsymbol{x}) = f(\boldsymbol{x})$ according to Corollary 17. With this, we have

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) = \inf_{\boldsymbol{x} > 0} \frac{p(\boldsymbol{x})}{\boldsymbol{x}^{\boldsymbol{\kappa}}} \geq \inf_{\boldsymbol{x} > 0} \min_{d \in \mathbb{N}} \min_{f \in \mathrm{NHProd}^d_n(\boldsymbol{\alpha})} \frac{f(\boldsymbol{x})}{\boldsymbol{x}^{\boldsymbol{\kappa}}} = L^{\mathrm{NHProd}}_n(\boldsymbol{\alpha}; \boldsymbol{\kappa}).$$ ◀

5.2 The Extreme Points of $\mathbf{NHMat}_{\boldsymbol{n}}^{\boldsymbol{d}}(\boldsymbol{\alpha})$

The next result implies we can reduce to the extreme points of $\mathrm{NHMat}_n^d(\boldsymbol{\alpha})$ to lower bound $L_n^{\mathrm{NHProd}}(\boldsymbol{\alpha};\boldsymbol{\kappa})$.

▶ **Lemma 19** (See Thm. 3.1 of [10]). *Given $\boldsymbol{\kappa} \in \mathbb{Z}_{\geq 0}^n$ and $\boldsymbol{\alpha} \in \mathbb{R}_{\geq 0}^n$, let $\phi : \mathrm{NHMat}_n^d(\boldsymbol{\alpha}) \to \mathbb{R}_{\geq 0}$ be the function which maps M to $\mathrm{Cap}_{\boldsymbol{\kappa}}(p)$ where p is the polynomial associated to M. Then ϕ is log-concave on $\mathrm{NHMat}_n^d(\boldsymbol{\alpha})$.*

We next describe the extreme points of $\mathrm{NHMat}_n^d(\boldsymbol{\alpha})$ via bipartitioned forests.

▶ **Lemma 20.** *Any extreme point of $\mathrm{NHMat}_n^d(\boldsymbol{\alpha})$ has support given by a bipartite forest on d left vertices and $n+1$ right vertices.*

Proof. Let M be an extreme point of $\mathrm{NHMat}_n^d(\boldsymbol{\alpha})$, and suppose its bipartite support graph G does not give a forest. Then G must contain an even simple cycle. Group the edges of this cycle into two groups such that the odd edges make up one group, and the even edges make up the other (with any starting point). Add $\epsilon > 0$ to all matrix entries corresponding to even edges and subtract ϵ to all matrix entries corresponding to odd edges, to construct $M_+ \in \mathrm{NHMat}_n^d(\boldsymbol{\alpha})$. Do the same thing, but reverse the signs, to construct $M_- \in \mathrm{NHMat}_n^d(\boldsymbol{\alpha})$. Thus $M = \frac{M_+ + M_-}{2}$, contradicting the fact that M is an extreme point. ◀

In what follows, we will also need the following basic graph theoretic result.

▶ **Lemma 21.** *Let G be a bipartite forest on m left vertices and n right vertices such that G has no vertices of degree 0. Then G has at least $m - n + 1$ left leaves.*

5.3 Capacity Bounds via Induction

Here we complete the proof of Theorem 1. We first give a simple lemma, which bears some resemblance to the probabilistic union bound.

▶ **Lemma 22.** *Given $\boldsymbol{c} \in \mathbb{R}_{\geq 0}^d$ such that $c_i < 1$ for all $i \in [d]$, we have $1 - \sum_{i=1}^d c_i \leq \prod_{i=1}^d (1 - c_i)$.*

The next lemma handles the case from Step 4 in Section 3 of setting some variable equal to 0. To see how these next two lemmas actually are actually used, see Theorem 25 below.

▶ **Lemma 23.** *For $n \geq 1$, let $p \in \mathrm{NHProd}_n^d(\boldsymbol{\alpha})$ be the polynomial associated to a $d \times (n+1)$ matrix M, and suppose $\boldsymbol{\kappa} \in \mathbb{Z}_{\geq 0}^n$ such that $\kappa_n = 0$ and $\alpha_n - \kappa_n \leq 1 - \epsilon$ for some $\epsilon > 0$. Then there exists $q \in \mathrm{NHProd}_{n-1}^d(\boldsymbol{\beta})$ such that*

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq \epsilon \cdot \mathrm{Cap}_{\boldsymbol{\gamma}}(q),$$

where $\boldsymbol{\gamma} = (\kappa_1, \ldots, \kappa_{n-1}) \in \mathbb{Z}_{\geq 0}^{n-1}$ and $\boldsymbol{\beta} \in \mathbb{R}_{\geq 0}^{n-1}$ is such that for all $S \subseteq [n-1]$ we have

$$\sum_{j \in S} (\alpha_j - \kappa_j) \leq \sum_{j \in S} (\beta_j - \gamma_j) \leq (\alpha_n - \kappa_n) + \sum_{j \in S} (\alpha_j - \kappa_j).$$

The next lemma handles the case from Step 4 in Section 3 of taking the partial derivative with respect to some variable.

▶ **Lemma 24.** *For $n \geq 1$, let $p \in \mathrm{NHProd}_n^d(\boldsymbol{\alpha})$ be the polynomial associated to a $d \times (n+1)$ matrix M such that column n has exactly one non-zero entry, and suppose $\boldsymbol{\kappa} \in \mathbb{Z}_{\geq 0}^n$ is such that $\kappa_n = 1$ and $\kappa_n - \alpha_n \leq 1 - \epsilon$ for some $\epsilon > 0$. Then there exists $q \in \mathrm{NHProd}_{n-1}^{d-1}(\boldsymbol{\beta})$ such that*

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq \epsilon \cdot \mathrm{Cap}_{\boldsymbol{\gamma}}(q),$$

where $\boldsymbol{\gamma} = (\kappa_1, \ldots, \kappa_{n-1}) \in \mathbb{Z}_{\geq 0}^{n-1}$ and $\boldsymbol{\beta} \in \mathbb{R}_{\geq 0}^{n-1}$ is such that for all $S \subseteq [n-1]$ we have

$$\sum_{j \in S} (\kappa_j - \alpha_j) \leq \sum_{j \in S} (\gamma_j - \beta_j) \leq (\kappa_n - \alpha_n) + \sum_{j \in S} (\kappa_j - \alpha_j).$$

We now combine the lemmas above to prove our strongest capacity lower bound for polynomials in $\mathrm{NHProd}_n^d(\boldsymbol{\alpha})$.

▶ **Theorem 25.** *Fix any $\boldsymbol{\kappa} \in \mathbb{Z}_{\geq 0}^n$, $\boldsymbol{\alpha} \in \mathbb{R}_{\geq 0}^n$, and $\boldsymbol{\epsilon}, \boldsymbol{\delta} \in \mathbb{R}_{>0}^n$ such that*

$$\max_{S \in \binom{[n]}{k}} \sum_{j \in S} (\alpha_j - \kappa_j) \leq 1 - \epsilon_k \qquad \text{and} \qquad \max_{S \in \binom{[n]}{k}} \sum_{j \in S} (\kappa_j - \alpha_j) \leq 1 - \delta_k$$

for all $k \in [n]$. Then

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq \min_{0 \leq \ell \leq n} \prod_{k=1}^{\ell} \epsilon_k \prod_{k=1}^{n-\ell} \delta_k$$

for every $p \in \mathrm{NHProd}_n^d(\boldsymbol{\alpha})$.

The next result gives the bound which we will use in Section 4 to prove Theorem 6, the simply exponential improvement to the probability bound used for the metric TSP application.

▶ **Corollary 26.** *Fix any $\boldsymbol{\kappa} \in \mathbb{Z}_{\geq 0}^n$ and $\boldsymbol{\alpha} \in \mathbb{R}_{\geq 0}^n$ such that $\boldsymbol{\epsilon} \in \mathbb{R}_{>0}^n$ can be defined via*

$$\epsilon_k := 1 - \max_{\substack{S \subseteq [n] \\ |S| \leq k}} \left| \sum_{j \in S} (\kappa_j - \alpha_j) \right|$$

for all $k \in [n]$. Then $\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq \prod_{k=1}^n \epsilon_k$ for every $p \in \mathrm{NHProd}_n^d(\boldsymbol{\alpha})$.

By Corollary 18, the above results hold for all $p \in \mathrm{NHStab}_n^d(\boldsymbol{\alpha})$, and we state this formally now.

▶ **Corollary 27.** *Theorem 25 and Corollary 26 hold for all $p \in \mathrm{NHStab}_n^d(\boldsymbol{\alpha})$.*

5.4 Proving Theorem 1 and Theorem 2

We now complete the proof of Theorem 1, and thus also of Corollary 2. Fix $p \in \mathrm{NHStab}_n^d(\boldsymbol{\alpha})$. Thus

$$1 - \max_{\substack{S \subseteq [n] \\ |S| \leq k}} \left| \sum_{j \in S} (\kappa_j - \alpha_j) \right| \geq 1 - \|\boldsymbol{\kappa} - \boldsymbol{\alpha}\|_1$$

and Corollary 27 (via Corollary 26) imply

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) \geq (1 - \|\boldsymbol{\kappa} - \boldsymbol{\alpha}\|_1)^n,$$

which completes the proof. The tightness claim follows from Lemma 28.

5.5 Examples and Tightness

The δ parameters in Theorem 25 are tight, and this is shown in Example 29. However, the ϵ parameters are not, as shown in Example 30. Example 29 also demonstrates tightness of the dependence on the error parameter for some of our results, and we state this formally now.

▶ **Lemma 28.** *The dependence on* $(1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)$ *in Theorem 1 and Corollary 2 and the dependence on* ϵ *in Theorem 6 are all tight for any fixed* $\boldsymbol{\kappa} > \mathbf{0}$.

Proof. Define $\alpha_1 := \kappa_1 - (1-\epsilon) > 0$ and $\alpha_i := \kappa_i \geq 1$ for all $i \geq 2$. Let p be the polynomial described by Example 29, given explicitly by

$$p(\boldsymbol{x}) = \left(\prod_{i=1}^{n} x_i^{\kappa_i - 1}\right) \cdot \left(\prod_{i=1}^{n-1} (\epsilon x_i + (1-\epsilon)x_{i+1})\right) \cdot (\epsilon x_n + (1-\epsilon)).$$

Then $\boldsymbol{\kappa}$ is a vertex of of the Newton polytope of p. Thus

$$p_{\boldsymbol{\kappa}} = \mathrm{Cap}_{\boldsymbol{\kappa}}(p) = \prod_{k=1}^{n} \left(1 - \sum_{j=1}^{k} (\kappa_j - \alpha_j)\right) = \epsilon^n = (1 - \|\boldsymbol{\kappa} - \nabla p(\mathbf{1})\|_1)^n.$$

To see that p can be the probability generating polynomial for some random variables associated to a strongly Rayleigh distribution (as in Theorem 6), note that the polarization of p is real stable and gives the probability generating polynomial for such a strongly Rayleigh distribution. ◀

▶ **Example 29.** Fix any $\boldsymbol{\kappa} \in \mathbb{Z}^n_{\geq 0}$ and $\boldsymbol{\alpha} \in \mathbb{R}^n_{\geq 0}$ such that $\kappa_j - \alpha_j \geq 0$ for all $j \in [n]$ and $\|\boldsymbol{\kappa} - \boldsymbol{\alpha}\|_1 < 1$. Thus $\kappa_j \geq 1$ for all $j \in [n]$. For $d = \|\boldsymbol{\kappa}\|_1$, consider the matrix $M = \left[\begin{smallmatrix} A \\ B \end{smallmatrix}\right]$, where A is the $(\|\boldsymbol{\kappa}\| - n) \times (n+1)$ matrix given by

$$A = \begin{bmatrix} \mathbf{1}_{\kappa_1 - 1} \boldsymbol{e}_1^\top \\ \mathbf{1}_{\kappa_2 - 1} \boldsymbol{e}_2^\top \\ \vdots \\ \mathbf{1}_{\kappa_n - 1} \boldsymbol{e}_n^\top \end{bmatrix},$$

and B is the $n \times (n+1)$ matrix for which

$$b_{kk} = 1 - \sum_{j=1}^{k} (\kappa_j - \alpha_j), \qquad b_{k,k+1} = \sum_{j=1}^{k} (\kappa_j - \alpha_j),$$

for all $k \in [n]$ and $b_{ij} = 0$ otherwise. Note that every row sum of A is equal to 1, and the row sums of B are given by

$$\sum_{j=1}^{n} b_{kj} = 1 - \sum_{j=1}^{k} (\kappa_j - \alpha_j) + \sum_{j=1}^{k} (\kappa_j - \alpha_j) = 1$$

for all $k \in [n]$. The column sums of M are then given by

$$\sum_{i=1}^{d} m_{ik} = (\kappa_k - 1) + 1 - \sum_{j=1}^{k} (\kappa_j - \alpha_j) + \sum_{j=1}^{k-1} (\kappa_j - \alpha_j) = \kappa_k - (\kappa_k - \alpha_k) = \alpha_k$$

for all $k \in [n]$. Thus $M \in \mathrm{NHMat}_n^d(\boldsymbol{\alpha})$. Let p be the polynomial associated to M, and let q be the polynomial associated to B. We then have $\mathrm{Cap}_{\boldsymbol{\kappa}}(p) = \mathrm{Cap}_{\mathbf{1}}(q)$. Note that $\mathbf{1}$ is a vertex of the Newton polytope of q, and thus

$$\mathrm{Cap}_{\boldsymbol{\kappa}}(p) = \mathrm{Cap}_{\mathbf{1}}(q) = \prod_{k=1}^{n} b_{kk} = \prod_{k=1}^{n} \left(1 - \sum_{j=1}^{k} (\kappa_j - \alpha_j)\right).$$

By possibly permuting the variables to put $\kappa_j - \alpha_j$ in non-increasing order, this is precisely the lower bound guaranteed by Theorem 25.

▶ **Example 30.** Consider the case that $\boldsymbol{\kappa} = \mathbf{0}$ and $\|\boldsymbol{\alpha}\|_1 < 1$. Given any d, let M be any extreme point of $\mathrm{NHMat}_n^d(\boldsymbol{\alpha})$. Then the column sum of column $n+1$ of M is equal to $d - \sum_{j=1}^{n} \alpha_j > d - 1$. Since every row sum equals 1, all entries of column $n+1$ of M are strictly positive. Since M is an extreme point, this further implies that each column of M has at most 1 positive entry except column $n+1$. Letting p be the polynomial associated to M, there exists a partition $S_1 \sqcup \cdots \sqcup S_k = [n]$ such that

$$p(\boldsymbol{x}) = \prod_{i=1}^{k} \left(\left(\sum_{j \in S_i} \alpha_j x_j \right) + \left(1 - \sum_{j \in S_i} \alpha_j \right) \right).$$

Thus by Lemma 22,

$$\mathrm{Cap}_{\mathbf{0}}(p) = p_{\mathbf{0}} = \prod_{i=1}^{k} \left(1 - \sum_{j \in S_i} \alpha_j \right) \geq 1 - \sum_{j=1}^{n} \alpha_j.$$

By Lemma 19, this gives a lower bound on the capacity of every $p \in \mathrm{NHProd}_n^d(\boldsymbol{\alpha})$. However, this lower bound is strictly better than the one guaranteed by Theorem 25.

As a note, this can be partially remedied by removing all $\kappa_j = 0$ columns at the same time (i.e., adjusting Lemma 23 to remove many columns at once). However, it is currently unclear how to inductively do this correctly.

6 Uniqueness of Permanent Minimizers

In this section, let $\mathrm{Mat}_n(\boldsymbol{c})$ be the set of $n \times n$ matrices with non-negative entries and rows sums $\mathbf{1}$ and column sums $\boldsymbol{c} > 0$, let $p_M(\boldsymbol{x}) := \prod_{i=1}^{n} \sum_{j=1}^{n} m_{ij} x_j$ be the real stable polynomial associated to a given $M \in \mathrm{Mat}_n(\boldsymbol{c})$, and let $L(\boldsymbol{c})$ be any lower bound on $\mathrm{Cap}_{\mathbf{1}}(p_M)$ over all $M \in \mathrm{Mat}_n(\boldsymbol{c})$ (e.g., as given by Theorem 1 above or the results of [22]).

We now prove Theorem 3 via Theorem 32 below. We note that the argument in the proof of Theorem 32 given below can be made into a general statement about minimizers of quadratic forms. And further, the same argument given here applies to mixed discriminants, as mentioned in Section 2.

▶ **Lemma 31.** *If* $\frac{(n-2)^{n-2} n^{n-1}}{(n-1)^{2n-3}} > \frac{c_1 c_2 \cdots c_n}{L(\boldsymbol{c})}$, *then all minimizers of the permanent over over* $\mathrm{Mat}_n(\boldsymbol{c})$ *have all strictly positive entries.*

Proof. Note that the rank-one matrix $\frac{1}{n} \mathbf{1} \cdot \boldsymbol{c}^{\top}$ has all strictly positive entries and permanent equal to $\frac{n!}{n^n} \prod_{i=1}^{n} c_i$. Thus, to obtain a contradiction, let us assume that there exists $M \in \mathrm{Mat}_n(\boldsymbol{c})$ with at least one zero entry such that $\mathrm{per}(M) \leq \frac{n!}{n^n} \prod_{i=1}^{n} c_i$. By the main result of [18], we have

$$\frac{n!}{n^n} \prod_{i=1}^{n} c_i \geq \mathrm{per}(M) \geq \left(\frac{n-2}{n-1} \right)^{n-2} \frac{(n-1)!}{(n-1)^{n-1}} \cdot L(\boldsymbol{c}),$$

which after rearranging implies

$$\frac{(n-2)^{n-2}n^{n-1}}{(n-1)^{2n-3}} > \left(\frac{n-2}{n-1}\right)^{n-2} \frac{n^{n-1}}{(n-1)^{n-1}},$$

which is a contradiction. ◀

▶ **Theorem 32.** *If* $\frac{(n-2)^{n-2}n^{n-1}}{(n-1)^{2n-3}} > \frac{c_1 c_2 \cdots c_n}{L(\boldsymbol{c})}$, *then the rank-one matrix* $\frac{1}{n}\mathbf{1} \cdot \boldsymbol{c}^\top$ *is the unique minimizer of the permanent over* $\mathrm{Mat}_n(\boldsymbol{c})$.

Proof. Let M be a minimizer of the permanent over $\mathrm{Mat}_n(\boldsymbol{c})$. Thus every entry of M is positive by Lemma 31. We will show that every pair of rows of M must be equal, which immediately implies $M = \frac{1}{n}\mathbf{1} \cdot \boldsymbol{c}^\top$.

Let $P \subset \mathbb{R}^{2\times n}$ be the convex polytope given by the first two rows of all matrices in $\mathrm{Mat}_n(\boldsymbol{c})$ with rows 3 through n equal to those of M. Thus by positivity, $(\boldsymbol{m}_1, \boldsymbol{m}_2)$ is in the relative interior of P where $\boldsymbol{m}_i$ is the i^{th} row of M. Let $f(\boldsymbol{u}, \boldsymbol{v})$ be defined as the permanent of the matrix M with the first two rows replaced by $(\boldsymbol{u}, \boldsymbol{v})$. Since M minimizes the permanent and $(\boldsymbol{m}_1, \boldsymbol{m}_2)$ is contained in the relative interior of P, the necessary conditions on the minimum given by Lagrange multipliers implies

$$\nabla f(\boldsymbol{m}_1, \boldsymbol{m}_2) = \big(\mathrm{per}(M_{(i,j)})\big)_{i\in[2],j\in[n]} = (a_i + b_j)_{i\in[2],j\in[n]}$$

for some a_i, b_j, where $M_{(i,j)}$ is the matrix M with row i and column j deleted. That is, the gradient of f points in a direction orthogonal to P at $(\boldsymbol{m}_1, \boldsymbol{m}_2)$.

By row symmetry of the permanent, we also have that $\nabla f(\boldsymbol{m}_2, \boldsymbol{m}_1) = (a'_i + b_j)_{i\in[2],j\in[n]}$, where $a'_1 = a_2$ and $a'_2 = a_1$. By row multilinearity of the permanent, we thus have

$$\nabla f(t \cdot \boldsymbol{m}_1 + (1-t) \cdot \boldsymbol{m}_2, (1-t) \cdot \boldsymbol{m}_1 + t \cdot \boldsymbol{m}_2) = (t \cdot a_i + (1-t) \cdot a'_i + b_j)_{i\in[2],j\in[n]}$$

for all $t \in \mathbb{R}$. If $\boldsymbol{m}_1 \neq \boldsymbol{m}_2$ then the gradient of f is orthogonal to P at all points on a line in P through M, and thus the permanent is minimized at all these points. At least one such point (on the boundary of P) has a zero entry, which contradicts Lemma 31. Therefore it must be that $\boldsymbol{m}_1 = \boldsymbol{m}_2$. Applying this argument to every pair of rows of M implies the desired result. ◀

We now give the example which proves Proposition 4.

▶ **Example 33.** Fix $t > 0$ and $n \in \mathbb{N}$, and define $\epsilon := \frac{1}{n^{1+t}}$. Further define $\boldsymbol{\alpha} \in \mathbb{R}^n_{>0}$ and $\boldsymbol{c} \in \mathbb{R}^{n+1}_{>0}$ via

$$\boldsymbol{\alpha} := \big(1-\epsilon, 1-\epsilon, \ldots, 1-\epsilon\big) \in \mathbb{R}^n_{>0} \quad \text{and} \quad \boldsymbol{c} := \Big(1+\alpha_1, \alpha_2, \alpha_3, \ldots, \alpha_n, \sum_{j=1}^{n}(1-\alpha_j)\Big) \in \mathbb{R}^{n+1}_{>0}.$$

Note that $\|\boldsymbol{c} - \mathbf{1}\|_1 = 1 + (n-2)\epsilon + 1 - n\epsilon = 2(1-\epsilon) < 2$. We first have

$$\mathrm{per}\left(\frac{1}{n+1}\mathbf{1} \cdot \boldsymbol{c}^\top\right) = \frac{(n+1)!}{(n+1)^{n+1}}(2-\epsilon)(1-\epsilon)^{n-1}n\epsilon = \frac{n!}{n^{(1+t)n}} \cdot \frac{2-n^{-1-t}}{1-n^{-1-t}} \cdot \frac{(n^{1+t}-1)^n}{n^t(n+1)^n}.$$

Now consider the $(n+1) \times (n+1)$ matrix with diagonal entries

$$1, \quad \sum_{j=1}^{1}(1-\alpha_j), \quad \sum_{j=1}^{2}(1-\alpha_j), \quad \cdots, \quad \sum_{j=1}^{n}(1-\alpha_j),$$

subdiagonal entries to obtain row sums $\mathbf{1}$ and column sums $\boldsymbol{c}$, and zero entries elsewhere. Note that $M \in \mathrm{Mat}_{n+1}(\boldsymbol{c})$. The matrix M is upper-triangular, and thus we have

$$\mathrm{per}(M) = \prod_{k=1}^{n} \sum_{j=1}^{k} (1 - \alpha_j) = \prod_{k=1}^{n} (k\epsilon) = n! \cdot \epsilon^n = \frac{n!}{n^{(1+t)n}}.$$

We then further have

$$\frac{2 - n^{-1-t}}{1 - n^{-1-t}} \cdot \frac{(n^{1+t} - 1)^n}{n^t (n+1)^n} \approx 2n^{(n-1)t} \cdot \frac{(n - n^{-t})^n}{(n+1)^n} \geq 2n^{(n-1)t} \cdot \frac{(n-1)^n}{(n+1)^n} > 1,$$

which implies $\mathrm{per}(M) < \mathrm{per}\left(\frac{1}{n+1}\mathbf{1} \cdot \boldsymbol{c}^\top\right)$ for large enough n.

Distributed Fast Crash-Tolerant Consensus with Nearly-Linear Quantum Communication

Mohammad T. HajiAghayi

Abstract

Fault-tolerant *Consensus* is about reaching agreement on some of the input values in a limited time by non-faulty autonomous processes, despite of failures of processes or communication medium. This problem is particularly challenging and costly against an adaptive adversary with full information. Bar-Joseph and Ben-Or (PODC'98) were the first who proved an absolute lower bound $\Omega(\sqrt{n/\log n})$ on expected time complexity of Consensus in any classical (i.e., randomized or deterministic) message-passing network with n processes succeeding with probability 1 against such a strong adaptive adversary crashing processes.

Seminal work of Ben-Or and Hassidim (STOC'05) broke the $\Omega(\sqrt{n/\log n})$ barrier for consensus in the classical (deterministic and randomized) networks by enhancing the model with quantum channels. In such networks, quantum communication between every pair of processes participating in the protocol is also allowed. They showed an (expected) constant-time quantum algorithm for a linear number of crashes $t < n/3$.

In this paper, we improve upon that seminal work by reducing the number of quantum and communication bits to an arbitrarily small polynomial, and even more, to a polylogarithmic number – though, the latter in the cost of a slightly larger polylogarithmic time (still exponentially smaller than the time lower bound $\Omega(\sqrt{n/\log n})$ for the classical computation models).

1 Introduction

Consensus is about making a common decision among the processes' initial input values in a limited time by every non-faulty process, despite the faulty behaviour of some of the players. Since its introduction by Pease, Shostak and Lamport [31] (JACM'80), who ruled out trivial solutions (such as always deciding on the same bit), fault-tolerant Consensus has constantly

been among foundation problems in distributed computing. This problem has been studied in synchronous/asynchronous and deterministic/randomized computation models and under various fault-tolerant or adversarial models: Fail-Stop (crashes) and Byzantine, Static and Adaptive, Computationally Bounded and Unbounded Adversaries - just to name a few (see Section 2.1 for related work).

While the landscape of Consensus problem under the classic model of computation is well-developed, much less is known if we allow for quantum computation. The seminal work of Ben-Or and Hassidim [9] (albeit a short 5-pager in STOC'05) broke the $\Omega(\sqrt{n/\log n})$ rounds time barrier for classic computing by employing quantum computing to further use the power of randomization in distributed computing. They showed an (expected) constant-time quantum algorithm for a linear number of crashes $t < n/3$, however, the algorithm is inefficient in terms of communication bits and, even more importantly, in terms of the number of quantum bits (qubits), as it uses $\Omega(n)$ of them per process. Since then no algorithm has managed to reduce the quantum resources needed to solve Consensus. Because generating, maintaining and sending quantum bits is extremely costly (today's quantum devices use less than 500 qubits), thus the main question of our paper emerges naturally:

Could the number of qubits be substantially reduced without harming the time complexity?

1.1 Distributed setting

We consider a quantum synchronous message-passing model (c.f., [6]), consisting of n synchronous processes (also called players), each with common clock (a clock tick is called a round or a step) and unique id from the known set $\mathcal{P} = [n] = \{1, \ldots, n\}$.

Between any pair of processes we assume the existence of a quantum channel being able to transmit reliable[1] messages caring quantum bits, qubits. For the sake of completeness, we also augment the model by classic point-to-point channels between any pair of processes. In each round, a process can send (personalized) quantum and classic messages to any selected subset of other processes. After *multicasting messages*, in the same round a process *receives messages* that were just sent to it by other processes, and performs *local computation*, which involves both quantum and classic bits.[2]

Processes are prone to *crash failures*, also called *fail-stops*. A crashed process permanently stops any activity, including sending and receiving messages.

We model crashes as incurred by a full-information *adversary* (the same as in [7, 9]) that knows the algorithm, the exact pure quantum state (see Section 3) and the classic state of the system at any point of an execution, and has an unbounded computational power. The adversary decides which processes to fail and when. The adversary is also *adaptive* – it can make a decision on-line based on its current full-knowledge of the system. However, the adversary does not know the future computation, which means that it does not know future random bits drawn by processes.

As for the quantum part, the adversary can apply no quantum operation to the system, but it is aware of all quantum and classic changes of state that the network undergoes. If a process is crashed by the adversary, we assume that its quantum bits are not destroyed (in particular, entangled qubits in other processes do not collapse but maintain their entanglement), however they cannot be used in further computation.

[1] Messages are not lost nor corrupted while in transit.
[2] Local computation also decides what messages to send in the next round and to whom.

Failures are *not clean* – when a process crashes when attempting to multicast a message, then some of the recipients may receive the message and some may not; this aspect is controlled by the adversary. A *t-adversary* is additionally restricted by the the number of crashed processes being *smaller than* t; if $t = n$ then the n-adversary is also called an unbounded adversary (note that even in such case, at least one process must survive for Consensus to make sense). Throughout the paper, we will be calling the adversary described above "adaptive", for short.

Consensus problem. each process p has its own initial value $input_p$ and has to output a (common) decision value, so that the following conditions hold: *validity* – decision must be on an input value of some process; *agreement* – no two processes decide on different values; and *termination* – each process eventually decides on some value, unless it is faulty. All those three requirements must hold with probability 1. We focus on *binary Consensus*, in which initial values are in $\{0, 1\}$.

Correctness and complexity – in terms of time (the number of rounds needed for all processes to terminate) and the number of quantum bits (qubits) and communication bits – are analyzed and maximized (worst-case) against an adaptive adversary.

We say that a random event occurs *with high probability* (*whp* for short), if its probability could be made $1 - O(n^{-c})$ for any sufficiently large positive constant c by linear scaling of parameters.

2 Our Results

In this work, we focus on improving quantum bits' and communication complexities (without harming time complexity) of quantum algorithms solving Consensus problem with probability 1 against an adaptive full-information adversary capable of causing processes' crashes. We observe that the maximum, per process, number of communication bits in Consensus problem is $\Omega(n)$, therefore one can only hope to improve amortized communication complexity (per process), see the full version of the paper.[3]

Our first main result is a quantum algorithm that solves Consensus in expected constant number of rounds and amortized number of qubits and classical communication bits per process being an arbitrarily low polynomial. This directly improves, by a polynomial factor, on the result of Ben-Or and Hassidim [9], which required $\Theta(n)$ qubits and communication bits, amortized per process. The detailed description of the algorithm and the proof of its correctness is presented in Section 4.

▶ **Theorem 1.** *For any $\epsilon > 0$, there is an algorithm solving consensus against an adaptive $n/3$-adversary in expected $O(1)$ rounds while using $O(n^\epsilon)$ qubits and communication bits (amortized) per process, w.h.p.*

To achieve this result, we give improved protocols for several existing tools that have been historically used in consensus algorithms. Combining all our advancements together provides a tighter approach to the general problem of consensus.

Our first technique is a new quantum implementation of a weak global coin.

▶ **Definition 2** ([9]). *Let $\mathcal{C}$ be a protocol for n players (with no input), where each player i outputs a (classical) bit $v_i \in \{0, 1\}$. We say that the protocol $\mathcal{C}$ is a t-resilient weak global coin protocol (or computes a weak global coin, for short) with fairness $\rho > 0$, if for any adaptive t-adversary and any value $b \in \{0, 1\}$, with probability at least ρ, $v_i = b$ for all good players i.*

[3] All omitted proofs and materials can be found in the full version of the paper, under the link given in "Related Version" on page 1.

We show a $\frac{1}{3}$-resilient weak global coin that works in constant, $O\left(\frac{1}{\epsilon}\right)$, time, uses an arbitrarily small polynomial number of bits $O(n^\epsilon)$, amortized per process (for any chosen constant $\epsilon > 0$), and results in all non-faulty processes returning the same value with a non-zero constant probability, c.f., Theorem 12. The main idea behind our improvement is to couple a quantum protocol for selecting a leader in the system, proposed in [9], with generalized sparse patterns of fault-tolerant communication induced on random graphs, which in a classical version (i.e., non-quantum) was firstly used in [23].

Our second technical result is a deterministic algorithm for counting, which returns, in constant time, a count of the number of input 1 (or 0, resp.) among the processes. Specifically, our algorithm solves the following problem.

▶ **Definition 3** (Fuzzy Counting [23]). *A Fuzzy Counting is a distributed problem in which every active process is required a number between the initial and the final number of active processes. The notion of "being active" usually depends on the goal of the counting, e.g., all non-faulty processes, non-faulty processes with initial value* 1*, etc.*

The authors of [23] provided an algorithm to this problem that works in $O(\log^3 n)$ rounds and uses $O(\log^7 n)$ communication bits per process. By employing random graphs of asymptotically larger degree than those in [23], we generalize this result by showing a solution that works in constant time. As consequence of this improvement a tradeoff between the number of rounds and the communication complexity arises. Our protocol is faster than the one in [23], but on the other hand it uses a polynomial, yet of an arbitrarily small degree, number of communication bits, amortized per process. On the way to achieve this result, we also propose a new solution to Gossip – a distributed problem in which every non-faulty process, despite the presences of the adversary, have to collect inputs of every other non-faulty processes.[4] The novelty in this approach is that our solution, by exploiting similar properties of random graphs to the approach used for generating a weak global coin, we can solve Gossip in constant time $O\left(\frac{1}{\epsilon}\right)$ while using only $O(n^\epsilon)$ bits per processes, for any constant $1 > \epsilon > 0$. The formal statement of the Gossip algorithm is provided in Theorem 13 and the analysis of our implementation of a weak global coin can be found in the Section 5 and the analysis of our implementation of Fuzzy Counting in Section 6.

Although constant-time algorithms cannot low (sub-polynomial) amortized communication complexity, we show that our main algorithm could be re-instantiated in such a way that it uses only a *polylogarithmic* number of qubits and classical communication bits to solve consensus in just a *polylogarithmically* larger number of rounds (see Section 4, and technical counterpart Theorem 7 for more details).

▶ **Theorem 4.** *There is an algorithm solving consensus against an unbounded adaptive adversary in polylogarithmic number of rounds, in expectation, while using a polylogarithmic number of qubits and communication bits (amortized) per process, whp.*

We believe that the newly developed techniques could be also applied to other types of failures, after failure-specific modifications. For example, although message omission failures require linear amortized communication per process (c.f., [22]), one could still use a small polynomial or even a polylogarithmic number of qubits (together with a linear number of classic communication bits) per process, if qubits are handled according to our techniques while some additional classic communication bits are introduced to handle message omissions. We leave details to follow-up work.

[4] The main difference between Gossip and Fuzzy Counting is that the latter allows for aggregating information, i.e. counting the number of 1's in the system vs collecting a set of identifiers of these active processes that start with 1.

2.1 Previous and Related Work

Consensus in the classic (non-quantum) model. Bar-Joseph and Ben-Or [7] (see also their extended version [8]) proved a lower bound $O(\sqrt{\frac{n}{\log n}})$ on expected time complexity of consensus against an adaptive adversary. They also complemented it by time-optimal randomized algorithm. Their algorithm uses expected $O(\frac{n^{3/2}}{\log n})$ number of communications bits, amortized per process, which has been recently improved by Hajiaghayi et al [23] to $O(\sqrt{n})$ (while maintaining the almost-optimal round complexity $O(\sqrt{n}\log n)$).

Fisher and Lynch [19] proved a lower bound $f+1$ on *deterministic* consensus with f crashes (that actually occurred, i.e., $f < t$), thus separating deterministic solutions from randomized. Regarding communication complexity, Amdur, Weber and Hadzilacos [3] showed that the amortized number of messages per process is at least constant, even in some failure-free execution. Dwork, Halpern and Waarts [18] found a solution with $O(\log n)$ messages per process, but requiring an exponential time, and later Galil, Mayer and Yung [20] developed a message-optimal algorithm working in super-linear $O(n^{1+\varepsilon})$ time, for any $0 < \varepsilon < 1$ and any $f < n$. They also improved the communication further to a constant number of communication bits per process, but the resulting algorithm was exponential in the number of rounds. Chlebus and Kowalski [11] showed that consensus can be solved in $O(f+1)$ time and with $O(\log^2 f)$ messages if only the number $n-f$ of non-faulty processors satisfies $n - f = \Omega(n)$. It was later improved in [12] to $O(f+1)$ time and $O(\text{polylog } n)$ number of communication bits. All the abovementioned communication complexities are amortized per process.

Quantum consensus. To the best of our knowledge, almost all previous papers on quantum consensus concentrated on assuring feasibility of the problem against strong Byzantine adversaries, c.f., [14, 24, 26], or on optimizing time complexity, including the work of Ben-Or and Hassidim [9] achieving constant time against an adaptive adversary.

In recent years, the primary application of (classical) consensus has been in the synchronization of distributed blockchains. A blockchain algorithm based on asymmetric quantum encryption was proposed in [34]. Blockchain algorithms often use leader election as an important subroutine. Quantum algorithms for leader election in anonymous networks, a problem intrinsically unsolved in the classical setting, has been considered in [32, 29]. [36] implemented the first algorithm for the anonymous leader election problem on a quantum computer. A more thorough study of challenges arising from practical implementations of quantum distributed networks is a pending, but unresolved issue [17]. The dynamics of quantum consensus and gossip over a contiguous space was studied in [28].

Sparse quantum communication has been considered by Chlebus, Kowalski and Strojnowski in [13], in the context of solving some version of consensus, but their protocols work correctly only with some probability smaller than 1 and for a specific number of failures corresponding to the probability of success. Another difference is that they used quantum operations to encode the classical inputs in quantum registers and used it to directly solve consensus. In this paper, we show another, more-efficient approach, in which we first create a quantum, weak global coin and later employ this tool to the state-of-the-art framework of solving consensus based on the common coin. Other distributed computing problems, not necessarily fault-prone, were also analyzed in quantum models, c.f., [10, 33, 35]. Finally, the readers interested in more broad treatment of quantum consensus are referenced to a recent survey [27].

More efficient classic randomized solutions against *weak adversaries*. Whenever weaker oblivious adversaries are considered, randomness itself proved to be enough in reducing time complexity to a constant. Chor, Merritt and Shmoys [15] developed constant-time algorithms for consensus against an *oblivious adversary* – that is, the adversary who knows the algorithm but has to decide which process fails and when before the execution starts. Their solution, however, requires a linear number of communication bits per process. Gilbert and Kowalski [21] gave a randomized consensus algorithm that achieves optimal communication complexity of $O(1)$ amortized communication bits per process while terminating in $O(\log n)$ time w.h.p., as long as the number of crashes $f < n/2$.

Classic consensus in more demanding models. Dolev and Reischuk [16] and Hadzilacos and Halpern [22] proved the $\Omega(f+1)$ lower bound on the amortized message complexity per process of deterministic consensus for *omission or (authenticated) Byzantine failures*. However, under some limitation on the adversary and requiring termination only whp, the sublinear expected communication complexity $O(\sqrt{n}\ \text{polylog}\ n)$ per process can be achieved even in case of Byzantine failures, as proved by King and Saia [25]. Such limitations are apparently necessary to achieve subquadratic time complexity for Byzantine failures, c.f., Abraham et al. [1]. *Asynchrony* also implies large communication – Aspnes [4] proved a lower bound $\Omega(n/\log^2 n)$ on communication complexity per process. The complexity bounds in this setting have been later improved, see e.g., [5, 2].

3 Technical Preliminaries

Quantum model of computation. We provide a short review of those parts of the quantum model of computing that are relevant to our results. The reader can find a comprehensive introduction to quantum computing in e.g. [30]. We use only the pure state of qubits. A pure state of a single qubit is a vector in a 2-dimensional Hilbert space $\mathcal{H}$. A pure quantum state of d qubits, denoted $|x\rangle$, is a vector of 2^d-dimensional Hilbert space $\mathcal{H}^{\otimes d} = \mathcal{H} \otimes \ldots \otimes \mathcal{H}$. In our paper, we use only the standard computational basis of the Hilbert space, which consists of vectors $\{|b_1 \ldots b_d\rangle : b_1 \ldots, b_d \in \{0,1\}^d\}$, to describe the system. Therefore, any state $|x\rangle$ can be expressed as $|x\rangle = \sum_{i=0}^{2^d-1} \alpha_i |i\rangle$, with the condition that $\sum_i |\alpha_i|^2 = 1$, since quantum states can be only normalized vectors.

Transitions, or equivalently – changes of states of a quantum system, are given by unitary transformations on the Hilbert space of d qubits. These unitary transformations are called *quantum gates*. These operations are exhaustive in the sense that any quantum computation can be expressed as a unitary operator on some Hilbert space. There are small-size sets of quantum gates working on two-dimensional space that are universal – any unitary transformation on a 2^d-dimensional quantum space can be approximated by a finite collection of these universal gates. In our applications, any quantum algorithm computation run by a process requires a polynomial (in n) number of universal gates.

Finally, an important part of quantum computation is also a quantum measurement. Measurements are performed with respect to a basis of the Hilbert space – in our case, this is always the computational basis. A complete measurement in the computational basis executed on a state $|x\rangle = \sum_{i=0}^{2^d-1} \alpha_i |i\rangle$ leaves the state in one of the basis vectors, $|i\rangle$, for $i \in \{0,1\}^d$, with probability α_i^2. The outcome of the measurement is a classic register of d bits, informing to which vector the state has been transformed. It is also possible to measure only some qubits of the system, which is called a partial measurement. If A describes the subset of qubits that we want to measure and B is the remaining part of the system, then the partial

measurement is defined by the set of projectors $\{\Pi_i = |i\rangle_A \langle i|_A \otimes I_B \mid \text{for } i \in \{0,1\}^d\}$.[5] In the former, a subscript refers to the part of the system on which the object exists, I denotes the identity function, while $\langle i|$ is a functional of the dual space to the original Hilbert space (its matrix representation is the conjugate transpose of the matrix representation of $|i\rangle$). If before the measurement the system was in a state $|x\rangle_{AB}$ then, after the measurement, it is in one of the states $\{\Pi_i |x\rangle_{AB} \mid \text{for } i \in \{0,1\}^d\}$, where state $\Pi_i |x\rangle_{AB}$ is achieved with probability $\langle x|_{AB} \Pi_i |x\rangle_{AB}$.[6] We would like to note that, similarly to all other quantum operations, measurements are local in our model. The result of a measurement is visible only to the process that performed this measurement; however, any quantum operation in some process may affect quantum bits stored in some other process.

Graph notations. Let $G = (V, E)$ denote an undirected graph. Let $W \subseteq V$ be a set of nodes of G. We say that an edge (v, w) of G is *internal for* W if v and w are both in W. We say that an edge (v, w) of G *connects the sets* W_1 *and* W_2, or *is between* W_1 *and* W_2, for any disjoint subsets W_1 and W_2 of V, if one of its ends is in W_1 and the other in W_2. The *subgraph of* G *induced by* W, denoted $G|_W$, is the subgraph of G containing the nodes in W and all the edges internal for W in G. A node adjacent to a node v is a *neighbor of* v and the set of all the neighbors of a node v is the *neighborhood of* v. $N^i_G(W)$ denotes the set of all the nodes in V that are of distance at most i from some node in W in graph G. In particular, the (direct) neighborhood of v is denoted $N_G(v) = N^1_G(v)$.

The following combinatorial properties are of utter importance in the analysis of our algorithms. Graph G is said to be ℓ-*expanding*, or to be an ℓ-*expander*, if any two subsets of ℓ nodes each are connected by an edge. Graph G is said to be (ℓ, α, β)-*edge-dense* if, for any set $X \subseteq V$ of *at least* ℓ nodes, there are at least $\alpha|X|$ edges internal for X, and for any set $Y \subseteq V$ of *at most* ℓ nodes, there are at most $\beta|Y|$ edges internal for Y. Graph G is said to be $(\ell, \varepsilon, \delta)$-*compact* if, for any set $B \subseteq V$ of at least ℓ nodes, there is a subset $C \subseteq B$ of at least $\varepsilon\ell$ nodes such that each node's degree in $G|_C$ is at least δ. We call any such set C a *survival set for* B.

4 Consensus Algorithm

The very high-level description of our consensus algorithm CheapQuantumConsensus is as follows. Each process starts by setting its preferred value (the value which it would like to decide for now) to the input bit. Then, the processes repeatedly use the counting procedure FastCounting, specified in Section 6, to compute the number of preferred 0's and 1's stored by processes that have not crashed yet, see line 3. Due to the definition of Fuzzy Counting, the outcomes of FastCounting can be slightly different across processes, but by no more than the number of crashes. Depending on the outcome, each process may change its preferred value to the dominating one (among the received preferred values), decide if the domination is substantial, or run the quantum common coin procedure, if the number of preferred 0's and 1's are very close to each other – see lines 14-17 in the pseudocode of CheapQuantumConsensus in Figure 1; all lines involving communication are underlined. Repeating the entire process (i.e., counting) for a constant number of rounds and then calculating the weak global coin and updating the decision either deterministically or based on the global coin, guarantees to produce one preferred value in all correct processes with probability 1, provided strong enough protocol for computing the global coin.

[5] We follow the standard notation in quantum computing and skip writing normalizing factors.
[6] $\Pi_i |x\rangle_{AB}$ and $\langle x|_{AB} \Pi_i |x\rangle_{AB}$ are simply linear operations on matrices and vectors.

In general, this type of framework is well-known for solving consensus and was proposed first by Bar-Joseph and Ben-Or [8] in the context of classical randomized computation against an adaptive adversary. However, for classical randomized computation the limitation of this approach is in the fact that any weak global coin obtained so far can tolerate at most $O(\sqrt{n})$ crashes to guarantee constant fairness of the coin. In contrast, by employing quantum communication we propose a new quantum protocol that computes a weak global coin with constant fairness even when a linear number of processes crash.

Besides this improvement, we also propose two new techniques for sparse classical and quantum communication, employed in lines 3 and 18 of the pseudocode in Figure 1: fast and communication-efficient counting and, as mentioned before, fast and quantum-communication-efficient weak global coin, respectively. Both these techniques use parameters x, d, α, which, roughly speaking, correspond to the density of random communication graphs used in these algorithms. The detailed performance formulas of these algorithms, with respect to those parameters, are stated in Theorems 12 and 14.

In the heart of these two techniques lies a crucial observation: consensus (as well as common coin and counting) could be achieved quickly even if many processes do not directly exchange messages, but use some carefully selected sparse set of communication links instead. This way, instead of creating qubits for each pair of processes, we could do it only per some pairs corresponding to some communication links to be used. This set of links, modeled as an evolving communication graph, needs to be maintained adaptively and locally by processes throughout the execution – otherwise, an adaptive adversary would learn it and design crashes to separate processes and prevent consensus.

Algorithm's description. Each process p stores its current choice in b_p (which is initialized to p's input). The value b_p at the end of the algorithm indicates p's decision. Now, processes use $O(1)$ (in expectation) *phases* to update their values b_p such that eventually every process keeps the same decision. To do so, in a round r every process p calculates the number of processes whose current choice is 1 and the number of processes whose current choice is 0, denoted O_p^r and Z_p^r respectively. Based on these numbers, process p: either sets b_p to 1, if the number O_p^r is large enough; or it sets b_p to 0 if the number Z_p^r is large; or it replaces b_p with a random bit if the numbers of zeros and ones are close to each other. If for generating the random bit, in line 18, processes use a quantum implementation of a weak global coin (implemented with CheapQuantumCoin algorithm, specified in Section 5), they will all have the same value b_p with constant probability unless more than third of alive processes crash. Assuming the presence of the adaptive adversary, this could not be achieved quickly if using classical communication only. Once it happens with the help of the quantum weak global coin, the conditional statements in lines 14-17, run in the next iteration of the "while" loop, guarantee that once the majority of processes have the same value b_p, the system converges to this value in at most 2 phases. Since the probability of this event is constant (guaranteed by the quantum weak global coin combined), the expected number of phases before the consensus algorithm terminates is constant. That reasoning holds, assuming that at most 1/3 fraction of processes crashed (we will generalize it to any $t \leq n$ at the end of this section).

As mentioned earlier, the major improvement in the above protocol comes from using novel techniques for counting and weak global coin. For the former, we use the FastCounting algorithm (Theorem 14), which, with the choice of parameters given in line 3, works in $O\Big(\big(\frac{1}{\epsilon}\big)^4\Big)$ rounds and uses $O\big(n^{1+3\epsilon}\log^2 n\big)$ (classic) communication bits in total. Similarly, the CheapQuantumCoin algorithm (Theorem 12), executed in line 18, terminates in $O\Big(\big(\frac{1}{\epsilon}\big)^3\Big)$ rounds and uses $O\Big(n^{1+2\epsilon}\log^2 n\Big)$ both quantum and classical bits; we need to divide the communication formulas by n to obtain the complexity amortized per process.

Algorithm 1 CheapQuantumConsensus for process p.

input: $\mathcal{P}$, p, $input_p$

1 $b_p \leftarrow input_p$; $r \leftarrow 1$; `decided` $\leftarrow FALSE$;
2 **while** $TRUE$ **do**
3 participate in FastCounting$(\mathcal{P}, p, b_p)$ (run with parameters $x = n^\epsilon, d = \log n, \alpha = n^\epsilon$) that counts the processes who have $b_p = 1$ and the processes who have $b_p = 0$; let O_p^r, Z_p^r be the numbers of ones and zeros (resp.) returned by FastCounting;
4 $N_p^r \leftarrow Z_p^r + O_p^r$;
5 **if** $(N_p^r < \sqrt{n/\log n})$ **then**
6 1) send b_p to all processes; 2) receive all messages sent to p in round $r+1$;
7 3) implement a deterministic protocol for $\sqrt{n/\log n}$ rounds;
8 **end**
9 **if** *decided* $= TRUE$ **then**
10 `diff` $\leftarrow N_p^{r-3}$ - N_p^r;
11 **if** *(diff* $\leq N_p^{r-2}/10$*)* **then** STOP;
12 **else** `decided` $\leftarrow FALSE$;
13 **end**
14 **if** $O_p^r > (7N_p^r - 1)/10$ **then** $b_p \leftarrow 1$, `decided` $\leftarrow TRUE$;
15 **else if** $O_p^r > (6N_p^r - 1)/10$ **then** $b_p \leftarrow 1$;
16 **else if** $O_p^r < (4N_p^r - 1)/10$ **then** $b_p \leftarrow 0$, `decided` $\leftarrow TRUE$;
17 **else if** $O_p^r < (5N_p^r - 1)/10$ **then** $b_p \leftarrow 0$;
18 **else** set b_p to the output of CheapQuantumCoin$(\mathcal{P}, p)$ executed with parameters $d = \log n$, $\alpha = n^\epsilon$;
19 $r \leftarrow r + 1$;
20 **end**
21 **return** b_p ; `/* p outputs final decision */`

Algorithm's analysis. To analyze the CheapQuantumConsensus algorithm we first recall a combinations of lemmas from [8].

▶ **Lemma 5** (Lemmas 4.1, 4.2, 4.3 in [8]). *If all processes have the same value at the beginning of an iteration of the main while loop, then the algorithm returns the decision after at most two iterations.*

▶ **Theorem 6.** *For any $\epsilon > 0$, the CheapQuantumConsensus algorithm solves Consensus against $n/3$-adversary in $O\left(\left(\frac{1}{\epsilon}\right)^4\right)$ rounds in expectation while using $O(n^{3\epsilon})$ qubits and communication bits per process (amortized), whp.*

Proof. First, we argue for correctness. Compared to the protocol of Bar-Joseph and Ben-Or [8], which works for an arbitrary number of failures $t \leq n$, we changed the method of deriving random coin, c.f., line 18. Observe that even if CheapQuantumCoin fails to meet conditions of t-resilient coin flip, it always outputs some bit in every non-faulty process. Thus, regardless of the number of crashes the output could be an output of local coin flips with a non-zero probability. Since Bar-Josephs's and Ben-Or's algorithm works with probability 1 (see Theorem 3 in [8]), thus CheapQuantumConsensus also achieves correctness with probability 1.

Next, we estimate the expected number of phases (i.e. the number of iterations of the main while loop). We consider only *good* phases, i.e. phases in which the adversary crashed at most $\frac{1}{10}$ fraction of processes that were correct at the beginning of this iteration. Note, that there can be at most $\frac{1}{3}/\frac{1}{10} < 4$ "bad" phases. Let x be the number of non-faulty processes at the beginning of some good phase. We consider the following cases:
Case *a)* There exists a process that in this iteration executes line 15 or line 14. In this case, all other processes have to execute line 14, 15 or line 18, since the number of ones counted in different processes may differ by $\frac{x}{10}$ at most. All processes that in this iteration execute CheapQuantumCoin will set b_p to 1 with probability $\frac{1}{4}$ at least. What follows, in the next iteration all processes will start with b_p set to 1, and by Lemma 5 the algorithms will decide within two next phases.
Case *b)* There exists a process that in this phase executes line 16 or line 17. Similarly to the previous case, we observe that all other processes have to execute line 17 or line 18, since, again, the number of ones counted in different processes may differ by $\frac{x}{10}$ at most. Therefore the same arguments apply but know the final decision will be 0.
Case *c)* None of processes executes one of lines 14, 15, 16, or 17. Thus, all processes participated in CheapQuantumCoin in line 18. By Theorem 12, with probability at least $\frac{1}{4}$, all processes will set value b_p to the same value. Thus, again by applying Lemma 5, we get that the algorithms will decide within the two next phases.

We showed that if a good phase happens, then the algorithm terminates within 2 next iterations with probability at least $\frac{1}{4}$. Since there can be at most 4 bad iterations, thus we can calculate the expected number of iterations as follows: $\mathbb{E}(\#\text{iterations}) = \sum_{i=4}^{\infty} i \left(\frac{1}{4}\right)^i = O(1)$.

Executing a single phase takes $O\left(\left(\frac{1}{\epsilon}\right)^4\right)$ rounds, which is the round complexity of the FastCounting algorithm and an upper bound of the time complexity of the CheapQuantumCoin algorithm, therefore the algorithm terminates in $O\left(\left(\frac{1}{\epsilon}\right)^4\right)$ rounds in expectation. Similarly, by taking the upper bounds on the communication complexity of the algorithms FastCounting and CheapQuantumCoin we get that the expected number of amortized communication bits used by the algorithm is $O(n^{3\epsilon})$. ◀

Handling arbitrary number of crashes. Consider $O(\log n)$ repetitions of the main loop (phases) of the CheapQuantumConsensus algorithm. If during these phases, the processes with value $b_p = 1$ become a large majority (at least $\frac{6}{10}$ fraction of alive processes), then, as discussed before, every process will decide within the next two rounds. The same holds if processes with value $b_p = 0$ start to overpopulate by a ratio of $\frac{6}{10}$ all non-faulty processes. On the other hand, if the cardinalities of the two groups with different values b_p are close to each other, then the processes execute the CheapQuantumCoin algorithm. It outputs a random bit (the same in every participating process), under the assumption that at least a $\frac{2}{3}$ fraction of processes that started this phase as non-faulty have not crashed during this phase. However, in these $O(\log n)$ phases there must be at least one phase in which the property of a $\frac{2}{3}$ fraction of processes survive holds. In what follows, we argue that if the adversary can crash arbitrarily many processes, but smaller than n, then the expected number of phases should still be $O(\log n)$. Now, to obtain the algorithm stated in Theorem 4, we make two more adjustments to the original CheapQuantumConsensus algorithm. In lines 3 and 18, processes execute the algorithms FastCounting and CheapQuantumCoin, respectively, with parameters x, d, α set as follows: $x = 2, d = \log n, \alpha = \log n$. This corresponds to the use of a sparse graph for communication (of degree roughly $O(\log n)$). In consequence, the time complexity of the FastCounting algorithm increases to $O(\log^4 n)$, but the communication complexity decreases to $O(\log^8 n)$ amortized per process. The details of the implementation

of the FastCounting algorithm are presented in Section 6, and performance follows from putting the aforementioned parameters to the formulas in Theorem 14. Similarly, the time complexity of the CheapQuantumCoin algorithm increases to $O(\log^3 n)$, but the communication complexity (both quantum and classical) decreases to $O(\log^7 n)$ amortized per process. Formally:

▶ **Theorem 7.** *The modified version of the CheapQuantumConsensus algorithm solves Consensus against any adversary in $O(\log^5 n)$ rounds in expectation while using $O(\log^8 n)$ qubits and communication bits per process (amortized), whp.*

Proof. For correctness, we argue exactly the same as in the proof of the previous Theorem. We also define good and bad phases, with only this difference that now the number of bad phases is at most $O(\log n)$ since the adversary has the full power of crashing an arbitrary number of processes. This being said we get that, by the very same reasoning, the expected number of phases is

$$\mathbb{E}(ITE) = \sum_{i=\log n}^{\infty} i \left(\frac{1}{4}\right)^i = \Theta(\log n) \ .$$

By examining the time and bits complexity of the algorithms FastCounting and CheapQuantumCoin (c.f. Theorems 14, 12) with parameters $x = 2, d = \log n, \alpha = \log n$, we get a single phase lasts $O(\log^4 n)$ rounds and contributes $O(n \log^7 n)$ bits to the total communication complexity. The latter, after dividing by n, gives the sought complexity amortized per process. Thus, the theorem follows. ◀

5 Qubit-and-Communication Efficient Quantum Common Coin

In this section, we design a new t-resilient weak global coin, for $t < n$, with the help of quantum communication and computation.

On a high level, our protocol CheapQuantumCoin chooses a leader process uniformly at random and all other processes agree on the random bit proposed by the leader. Quantum phenomena are used to hide the random choices of the leader and its output from the adaptive adversary when processes communicate with each other. The idea was first proposed in [9], yet there are key differences between that work and our algorithm. Instead of all-to-all communication, which required large number of qubits, we use a sequence of random graphs of node degrees $d, d\alpha^1, \ldots, d\alpha^k$, respectively, where $d, \alpha \in \Omega(\log n)$ and $k = \lceil \log n / \log \alpha \rceil$ are some integer parameters. The vertices of these graphs correspond to processes and edges correspond to communication links – each process communicates with neighbors in one of the graphs at a time. If the graph is chosen properly (i.e., so that there is no situation in which too many processes use denser graphs), it reduces the communication complexity but simultaneously imposes a new challenge. Mainly, the communication procedure has to now assure the delivery of quantum bits between every two non-faulty processes regardless of the pattern of crashes. For instance, if only one random graph of degree d was used then the adversary could easily isolate any vertex using only $O(d)$ crashes (i.e., by crashing all its neighbors). Hence, strictly speaking, assuring such delivery is not possible while using a sparse communication graph as relays, but we show that a certain majority could still come up with a common coin value based only on their exchanges with neighbors in the communication graphs; they could later propagate their common value to other processes by adaptively controlling their (increasing) set of neighbors, taken from subsequent communication graphs of increasing density. A thorough analysis shows that in this way it is possible to achieve the same quantum properties that are guaranteed by Ben-Or's and Hassidim's global coin [9], and at the same time reducing the quantum communication by a polynomial factor.

Algorithm's description. We now describe the CheapQuantumCoin algorithm. Its pseudocode is presented in Figure 2. It takes as input: a process name p and two integers, d and α. The two latter parameters are used to determine communication patterns between non-faulty processes, and their choice determines the complexity of the algorithm.

As mentioned before, processes use the quantum equivalent of a procedure in which processes draw random names from the range $[1, \ldots, n^3]$ and decide on a random bit proposed by the process with the largest name.[7] We view the quantum part of the algorithm as a quantum circuit on the joint space of all qubits ever used by different processes. Due to the distributed nature of the system, not all quantum operations are allowed by the quantum circuit. That is, (i) any process can perform arbitrary unitary gates on its part of the system, (ii) unitary gates on qubits of different processes might be performed but must be preceded by quantum communication that sends qubits involved in the operation to a single process. The communication can be either direct or via relays. We use the following unitary gates to simulate the classical algorithm of the leader election in the quantum distributed setting: `Hadamard` gate, `CNOT` and `Pairwise_CNOT` gates, and `F_CNOT` and `Controlled_Swap` gates. (Although they are all standard quantum gates, a thorough description of these gates can be found in the full version.)

Let us now explain how all the gates listed above work together. As mentioned in the description of the Hadamard gate, after line 2 ends, the main registers of the system are in the state of being a uniform superposition of all vectors of the computational basis. Starting from this point, the composition of all gates applied to different registers along the execution can be viewed as a single unitary gate on the entire system, consisting of the qubits that any process ever created. Note that the unitary transformation might be different depending on the failure in communication, i.e., a failure in the delivery of some block of qubits between two processes may result in abandoning gates involving these qubits, but for a moment let us assume that the links are reliable. Since the unitary transformation is linear, it is enough to consider how it affects the vectors of the computational basis. However, all the gates described above behave on the computational basis as their classical equivalents. More precisely, let $|x\rangle$ be a vector from the computational basis spanning the whole circuit. Let p be the process whose main register has the largest[8] value in the state $|x\rangle$. From the point of view of this register, the following happens in the algorithm. In each round, p creates an entangled state on $6 \log n + 2$ qubits (see point (2)) that has the same qubits on its new block of $3 \log n + 1$ qubits as it has on the main register. Then, it propagates the new block to its neighbors (lines 9- 12). The neighbors compare the content of received qubits and exchange them with their main register if their content is smaller (gates `F_CNOT` and `Controlled_Swap` in lines 16- 17). This operation is then repeated $(k+2)^2(\gamma_\alpha + 1)$ times on the set of links defined by some random evolving graphs, see the later paragraph about adaptive communication pattern. In the end, the processes who, either directly or via relays, received the content of the largest main register, have the same value in their main register. Therefore, the result of the measurement in line 27 must be the same in all these processes.

Assume now that we are able to achieve bidirectional quantum communication between any pair of processes of an τ fraction of the entire system, regardless of the (dynamic) actions of the adversary, for some constant $0 \leq \tau \leq 1$. From the above, the algorithm transforms any vector whose largest main register is one of the registers of the τ fraction of the processes to a

[7] Note that the latter procedure cannot be used against an adaptive adversary, as it could crash such a leader.

[8] The probability of a tie is polynomially small.

vector such that the processes from the τ fraction have the same values in the main registers. The initial state of the system is a uniform superposition which is a linear combination of all vectors from the computational basis. From this perspective, the normalized sum of coefficients of these vectors of the superposition that have the property that the largest register is one of the registers of the τ fraction is $\tau - o(1)$.[9] Thus, we get that the probability of measuring the same values in the processes of the τ fraction is at least $\tau - o(1)$ and we can claim the following lemma.

▶ **Lemma 8.** *Let A be a set of correct processes such that any pair of them was connected by quantum communication either directly or by relays. Then the probability that all processes from A output the same bit from the algorithm* CheapQuantumConsensus *is at least* $\frac{|A|}{n} - o(1)$.

Adaptive communication pattern. As explained, we not only need that communication should be efficient in terms of the number of qubits and classical bits, but also it should be such that any two correct processes of a large fraction of the entire system are connected by a short path of the correct process so that quantum registers can be relayed. Let d, α be two integer parameters. We define $k = \left\lceil \frac{\log(n/d)}{\log \alpha} \right\rceil$, $\gamma_\alpha = \frac{\log n}{\log \alpha}$, and $\delta_\alpha = \frac{2}{3}\alpha$. Initially, each process p draws independently $k+1$ sets $\mathcal{N}_p(d), \mathcal{N}_p(d\alpha^1), \ldots, \mathcal{N}_p(d\alpha^k)$, where a set $\mathcal{N}_p(d\alpha^i)$, for $0 \leq i \leq k$, includes each process from $\mathcal{P}$ with probability $\frac{d\alpha^i}{n}$.

Communication is structured into $(k+2)^2$ *epochs*, see line 4. Each epoch consists of $2(\gamma_\alpha + 1)$ communication rounds, also called *testing* rounds. They are scheduled in $\gamma_\alpha + 1$ iterations within the loop "for" in line 7, each iteration containing two communication rounds (underlined in the pseudocode): sending/receiving inquiries in line 9 and sending/receiving responses in line 12. In the testing rounds of the first epoch, a process p sends inquiries to processes in set $\mathcal{N}_p(d)$. The inquired processes respond by sending in the next round (line 12) their current classical state and specially prepared, in line 6, quantum register. However, if in a result of crashes p starts receiving less than δ_α responses per round, it switches its communication neighborhood from $\mathcal{N}_p(d)$ to the next, larger set, $\mathcal{N}_p(d \cdot \alpha)$. A similar adaptation to a crash pattern is continued in the remaining epochs.

Process p stores the cardinally of the set being inquired in an epoch in the variable $\texttt{degree}_p$ (initialized to d in line 2). For the purpose of testing rounds, p copies the value $\texttt{degree}_p$ to a variable $\texttt{adaptive\_degree}_p$ (line 6). In every testing round, p adapts its variable $\texttt{adaptive\_degree}_p$ to the largest value $x \leq \texttt{adaptive\_degree}_p$ such that it received at least δ_a responses from processes that have their variable `adaptive_degree` at least x (loop "while" in line 19). If p had to decrease the value $\texttt{adaptive\_degree}_p$ in testing rounds of an epoch, it then *increases* the main variable $\texttt{degree}_p$ by the factor α before the next epoch, see line 24. The latter operation formally encodes the intuition that the process p expected to have δ_α non-faulty neighbors with their values of `degree` at least as big as its own, but due to crashes it did not happen; Therefore, p increases the number of inquired processes, by adopting the next, larger neighborhood set $\mathcal{N}_p(\cdot)$, randomly selected, in order to increase the chance of communication with the majority of non-faulty processes in the next epoch. On the other hand, the adaptive procedure of reducing `adaptive_degree` in testing rounds of a single epoch helps neighbors of p to estimate correctly the size of the

[9] The $o(1)$ part contributes to the normalized sum of these vectors that correspond to having more than one largest register.

Algorithm 2 CheapQuantumCoin for process p.

input: p, two parameters: d, α

For $0 \leq i \leq \left\lceil \frac{\log(n/d)}{\log \alpha} \right\rceil$: $\mathcal{N}_p(d\alpha^i) \leftarrow$ a set of processes such that each process is chosen independently with probability $\frac{d\alpha^i}{n}$;

$\texttt{degree}_p \leftarrow d$, $\gamma_\alpha \leftarrow \frac{\log n}{\log \alpha}$, $\delta_\alpha \leftarrow \frac{2}{3}\log n$;

  do

    send to each process in $\mathcal{N}_p(\texttt{degree}_p)$: an inquire bit 1 ;

    $\mathcal{I} \leftarrow$ the set of processes who sent an inquire bit to p ;

    $\forall_{q\in\mathcal{I}} : |B\rangle_q \leftarrow \texttt{Pairwise\_CNOT}\left(|LeaderCoin\rangle_p, |0\ldots0\rangle\right)$;

    send to each process $q \in \mathcal{I}$: a quantum message containing first $3\log n+1$ bits of $|B_q\rangle$, and a classical message containing $\texttt{adaptive\_degree}_p$;

    $\mathcal{R} \leftarrow$ the set of processes who responded to p's inquires ;

    foreach $q \in \mathcal{R}$ **do**

      $|CLeader\rangle_q |CCoin\rangle_q \leftarrow$ received quantum bits from q, $|S\rangle \leftarrow |0\rangle$;

      $\texttt{F\_CNOT}_{|Leader\rangle_p > |CLeader\rangle_q}\left(|Leader\rangle_p, |CLeader\rangle_q, |S\rangle\right)$;

      $\texttt{Controlled\_Swap}\left(|LeaderCoin\rangle_p, |CLeaderCCoin\rangle_q, |S\rangle\right)$;

    end

    while $|\{q \in \mathcal{R} : \textit{adaptive\_degree}_q \geq \textit{adaptive\_degree}_p\}| < \delta_\alpha$ *and* $\textit{adaptive\_degree}_p \geq d$; `/* adapting #neighbors during testing */`

    do

      $\texttt{adaptive\_degree}_p \leftarrow \frac{1}{\alpha}\texttt{adaptive\_degree}_p$;

    end

  end

  if $\textit{adaptive\_degree}_p < \textit{degree}_p$ **then**

    $\texttt{degree}_p \leftarrow \min\{\texttt{degree}_p \cdot \alpha, d\alpha^k\}$; `/* neighborhood for next epoch grows */`

end

$b_p \leftarrow$ be the last bit of the result of measuring $|Leader\rangle_p |Coin\rangle_p$ in the computational basis;

return b_p ; `/* p outputs random bit */`

neighborhood that process p is using in the current testing round, which might be much smaller than the value $\texttt{degree}_p$ from the beginning of the epoch. This, in turn, calibrate the value of $\texttt{adaptive\_degree}$ of the neighbors of p, and this calibration can propagate to other processes of distance up to γ_α from p in the next iterations of testing rounds.

Analysis. Let us define graphs $\mathcal{G}(d\alpha^i)$, for $0 \leq i \leq k$, as the union of random sets $\cup_{p\in\mathcal{P}}\mathcal{N}_p(d\alpha^i)$. The probability distribution of the graph $\mathcal{G}(d\alpha^i)$ is the same as the random graph $G(n, y)$ for $y = \frac{d\alpha^i}{n}$. Chlebus, Kowalski and Strojnowski [12] showed in their Theorem 2, applied for $k = \frac{64n}{d\alpha^{i-1}}$, that the graph $\mathcal{G}(d\alpha^i)$ has the following properties, whp:

- **(i)** it is $(\frac{n}{d\alpha^{i-1}})$-expanding, which follows from $(\frac{n}{d\alpha^{i-1}}, \frac{2}{3}\frac{n}{d\alpha^{i-2}}, \frac{4}{3}\frac{n}{d\alpha^{i-2}})$-edge-expanding property,
- **(ii)** it is $(\frac{n}{d\alpha^{i-1}}, \frac{1}{3}\alpha, \frac{2}{3}\alpha)$-edge-dense,
- **(iii)** it is $(16\frac{n}{d\alpha^{i-1}}, 3/4, \frac{2}{3}\alpha)$-compact,
- **(iv)** the degree of each node is at most $\frac{21}{20}d\alpha^i$.

Since the variable $\texttt{degree}_p$ takes values in the set $\{d, d\alpha^1, \ldots, d\alpha^k\}$, the pigeonhole principle assures that eventually p will participate in an epoch in which $\texttt{degree}_p$ has not been increased. In the most severe scenario, p will use the set $\mathcal{N}_p(d\alpha^k)$, which consists of all other processes – because it contains each process, as a neighbor of p, with probability 1. The $(\gamma_\alpha, \delta_\alpha)$-dense-neighborhood property of random graphs composed from neighborhoods $\mathcal{N}(\texttt{degree}_p)$ implies that p will then contact a majority of other non-faulty processes via at most $\gamma_\alpha + 1$ intermediate processes (during testing rounds). Formally, the following holds:

▶ **Lemma 9.** *If a process p does not change its variable $\texttt{degree}_p$ at the end of an epoch i, then at the beginning of epoch i there exists a $(\gamma_\alpha, \delta_\alpha)$-dense-neighborhood of p in the graph $\mathcal{G}(\texttt{degree}_p)$ consisting of non-faulty processes with variable $\texttt{degree}$ being at least $\texttt{degree}_p$ in the epoch i, whp.*

On the other hand, $(16n/d\alpha^{i-1}, 3/4, 2\alpha/3)$-compactness of the (random) graph composed of processes that have the variable $\texttt{degree}$ at least $d\alpha^i$, guarantees that the total number of processes that use sets $\mathcal{N}(d\alpha^i)$ during the epoch i is at most $\frac{n}{\alpha^{i-2}}$, which amortizes communication complexity.

▶ **Lemma 10.** *For any integer i, such that $0 \leq i \leq k$, at the beginning of each epoch there is at most $\frac{16n}{d\alpha^{i-2}}$ processes with the variable $\texttt{degree}$ greater than $d\alpha^i$, whp.*

In the above proof of Lemma 10, we use the fact that a suitable set C of processes that have been correct throughout the whole epoch exists. We may choose this set and argue about it after the epoch, as the communication pattern in the algorithm is deterministic. Hence, in any round of the epoch, processes in C have at least as many non-faulty neighbors in the communication graph as they have neighbors from set C. We use this number of neighbors in C as a *lower bound* to argue about the behavior of variables $\texttt{degree}$; therefore, our arguments do not depend on the behavior of processes outside of C and whether/when some of them fail during the epoch.

▶ **Lemma 11.** *Any two non-faulty processes p and q were connected by a quantum path of communication during the run of the algorithm.*

The above lemmas yield the following result.

▶ **Theorem 12.** *For two integer parameters $d, \alpha \in \Omega(\log n)$, the algorithm* QuantumCoinFlip *generates a weak global coin, provided that at most $\frac{1}{3}$-fraction of initially non-faulty processes have crashed. It terminates in $O\left(\left(\frac{\log n}{\log \alpha}\right)^3\right)$ rounds and with high probability uses $O\left(\left(\frac{\log n}{\log \alpha}\right)^4 d\alpha^2 \log n\right)$ both quantum and classical communication bits (amortized) per process.*

Proof of Theorem 12. Let $\mathcal{H} \subseteq \mathcal{P}$ be the set of initially non-faulty processes. Assume that at least $\frac{2}{3}|\mathcal{H}|$ of them remains non-faulty during the execution of the algorithm. By Lemma 11, any pair of processes from $\mathcal{H}$ is connected by quantum communication, therefore applying Lemma 8 to this set, give that there is at least $\frac{2}{3} - o(1)$ (which is greater than $\frac{1}{2}$ for sufficiently large n) probability that all non-faulty processes return the same output bit. Since 0 and 1 are equally likely, thus the probabilistic guarantee on the weak global coin follows.

The number of rounds is deterministic and upper bounded by $O(k^2 \cdot \gamma_\alpha) = O\left(\left(\frac{\log(n/d)}{\log \alpha}\right)^2 \frac{\log n}{\log \alpha}\right) = O\left(\left(\frac{\log n}{\log \alpha}\right)^3\right)$. To bound the communication complexity, assume that each graph $\mathcal{G}(d\alpha^i)$, for $0 \leq i \leq k$, satisfies the desired expanding properties listed in the description of the algorithm. This, by the union bound argument, holds whp. By Lemma 10

at the beginning of each epoch there are at most $\frac{16n}{d\alpha^{i-2}}$ processes that inquire more than $d\alpha^i$ other processes in testing rounds of this epoch, for each $0 \leq i \leq k$. Since each message uses at most $O(\log n)$ bits and qubits, thus a single testing round in an epoch adds at most $\sum_{i=0}^{k} \frac{16n}{d\alpha^{i-2}} \cdot d\alpha^i \leq 16kd\alpha^2 \cdot n \log n$ qubits and bits to communication complexity. Since there is exactly $O\left(\left(\frac{\log n}{\log \alpha}\right)^3\right)$ testing rounds, thus the $O\left(\left(\frac{\log n}{\log \alpha}\right)^4 d\alpha^2 \cdot n \log n\right)$ upper bound on the total communication complexity of the algorithm follows. Dividing the latter by n we receive amortized formula per process. ◀

6 Constant-Time Communication-Efficient Fuzzy Counting

Although generating a weak global coin in a constant number of rounds against an adaptive adversary requires quantum communication (due to the lower bound by Ben-Or and Bar-Joseph [7]), the CheapQuantumCoin algorithm, even without quantum communication, achieves few other goals. As discussed in the previous section, its random communication pattern guarantees, whp, that any additional classical message, also called a rumor, of a non-faulty process can be conveyed to any other non-faulty process if added to every classical message sent/received in line 12. Even more, assume that there is a set of x messages/rumors $M = \{m_1, \ldots, m_x\}$, distributed as inputs among some subset of processes (one message from M per process). If processes always convey all the known rumors from set M when using classical communication (avoiding repetition), then they solve a Gossip problem, whp, i.e., every rumor m_i given to a non-faulty process, for $1 \leq i \leq x$, is known at the end of the protocol to every other non-faulty process. Observe that processes resign from the quantum content of communication for this purpose, and instead of $\log n$ bits (or qubits) per message, they use $|M|$ bits, where $|M|$ denotes the number of bits needed to encode all rumors from M. Finally, if processes work in a model where the names of other processes are commonly known, they can withdraw from using random communication. Instead, they can use a deterministic family of graphs $\mathcal{G}(d\alpha^i)$, for the same choice of parameters d and α. The proof of existence of such graphs, using the probabilistic argument, was described in [12] (Theorem 2). In such case, the set $\mathcal{N}_p(d\alpha^i)$ is the neighborhood of process p in the deterministic graph $\mathcal{G}(d\alpha^i)$. (Processes compute the same copies of graphs $\mathcal{G}$ locally in the beginning of the algorithm.) The above augmentation of the algorithm, together with the proof of Theorem 12, from which we take the upper bound on the number of messages send and the upper bound on the number of rounds, gives:

▶ **Theorem 13.** *For integer parameters $d, \alpha \in \Omega(\log n)$, there is a deterministic algorithm that solves the gossip problem in $O\left(\left(\frac{\log n}{\log \alpha}\right)^3\right)$ rounds using $O\left(\left(\frac{\log n}{\log \alpha}\right)^4 d\alpha^2 \cdot (|M| + \log n)\right)$ communication bits per process (amortized), where $|M|$ is the number of bits needed to encode all rumors in M.*

Generalized Fuzzy Counting. In this part, we refine the state-of-art method of solving the Fuzzy Counting problem (c.f. Definition 3), even deterministically, and propose a new recursive algorithm with any branching factor x, called FastCounting. We prove the following:

▶ **Theorem 14.** *For any $2 \leq x \leq n$ and $\delta, \alpha \in \Omega(n)$, the FastCounting deterministic algorithm solves the Fuzzy Counting problem in $O\left(\frac{\log n}{\log x}\left(\frac{\log n}{\log \alpha}\right)^3\right)$ rounds, using $O\left(\frac{\log n}{\log x}\left(\frac{\log n}{\log \alpha}\right)^4 d\alpha^2 \cdot x \log n\right)$ communication bits (amortized) per process.*

Obviously, the constant-time is achieved in Theorem 14 when $x, \alpha = n^{\epsilon}$, for a constant $\epsilon \in (0,1)$. In this case, the number of rounds is $O\left(\left(\frac{1}{\epsilon}\right)^4\right)$, while the communication complexity is $O(n^{3\epsilon}\log^2 n)$ (amortized) per process. In our approach, we generalize the method of Hajiaghayi et al. [23] to denser communication graphs of certain properties, which allows us to achieve constant running time. The constant running time is the key feature of the algorithm, since it is used in the implementation of (expected) constant-round quantum consensus protocol CheapQuantumConsensus. The main difference between ours and the state-of-art approach is a different Gossip protocol used in the divide-and-conquer method.

The FastCounting algorithm is recurrent. It takes as an input the following values: $\mathcal{P}$ is the set of processes on which the algorithm is executed; p is the name of a process which executes the algorithm; $a_p \in \{0,1\}$ denotes if p is active ($a_p = 1$) or not; and parameters x, d, α, where x is the branching factor and d, α steer the density of the communication graph in the execution. Knowing the set $\mathcal{P}$ of n processes, FastCounting splits the set into x disjoint groups of processes, each of size between $\lfloor \frac{n}{x} \rfloor$ and $\lceil \frac{n}{x} \rceil$. Name these groups $\mathcal{P}_1, \ldots, \mathcal{P}_x$. The groups are known to each participating process. The algorithm then makes x parallel recursive calls on each of these groups. As a result, a process p from a group $\mathcal{P}_i$, for $1 \leq i \leq x$, gets the number of the active processes in its group $\mathcal{P}_i$. In the merging step, all processes execute Gossip algorithm, proposed in Theorem 13, with parameters d, α, where the input rumors are the numbers calculated in the recursive calls. To keep the communication small, when processes learn new rumors they always store at most one rumor corresponding to each of the x groups. This way, the number of bits needed to encode all rumors is $O(x \log n)$. Let $r_1, \ldots, r_\ell$ be the rumors learned by process p from the execution of the Gossip algorithm. The final output of p is the sum $\sum_{i=1}^{\ell} r_i$. The pseudocode of the algorithm can be found in the full version.

7 Future Work

We believe that the outcome of our work effectively establishes the foundation for the efficient integration of classical fault-tolerant distributed and quantum computing. We show that in the basic model of failures, crash failures, a fundamental problem of reaching consensus fast is feasible with only polylog n qubit communication. An immediate open question arises whether such performance improvement is possible in the case of more severe failures, such as omissions, authenticated Byzantine, or even full Byzantine. Another interesting idea is to approach the communication bound from the lower bound side. We believe that investigating even conditional lower bounds on the minimal quantum communication needed to solve various distributed problems, foremost the Consensus problem, could lead to many breakthroughs in both distributed and quantum realms.

Abstract

In the classical prophet inequality setting, a gambler is given a sequence of n random variables $X_1, \ldots, X_n$, taken from known distributions, observes their values in adversarial order and selects one of them, immediately after it is being observed, aiming to select a value that is as high as possible. The classical *prophet inequality* shows a strategy that guarantees a value at least half of the value of an omniscience prophet that always picks the maximum, and this ratio is optimal.

Here, we generalize the prophet inequality, allowing the gambler some additional information about the future that is otherwise privy only to the prophet. Specifically, at any point in the process, the gambler is allowed to query an oracle $\mathcal{O}$. The oracle responds with a single bit answer: YES if the current realization is greater than the remaining realizations, and NO otherwise. We show that the oracle model with m oracle calls is equivalent to the Top-1-of-$(m+1)$ model when the objective is maximizing the probability of selecting the maximum. This equivalence fails to hold when the objective is maximizing the competitive ratio, but we still show that any algorithm for the oracle model implies an equivalent competitive ratio for the Top-1-of-$(m+1)$ model.

We resolve the oracle model for any m, giving tight lower and upper bound on the best possible competitive ratio compared to an almighty adversary. As a consequence, we provide new results as well as improvements on known results for the Top-1-of-m model.

1 Introduction

The field of optimal stopping theory concerns optimization settings where one makes decisions in a sequential manner, given imperfect information about the future, in a bid to maximize a reward or minimize a cost. A canonical setting in this area is the *prophet inequality* [18, 19]. In these settings, a gambler is presented with rewards $X_1, \ldots, X_n$, one after the other, drawn independently from known distributions. Upon seeing a reward X_i, the gambler must immediately make an irrevocable decision to either accept X_i, in which case the process ends, or to reject X_i and continue, losing the option to select X_i in the future. The goal of the gambler is to maximize the selected reward comparing against a *prophet* who knows all realizations in advance and selects the maximum realized reward. Throughout, we assume, without loss of generality, that $X_1, \ldots, X_n$ are continuous random variables.

The performance of the gambler can be measured in terms of several objectives. A common metric used in the literature is the *competitive ratio*, which is also known as the *Ratio of Expectations (RoE)* (see Definition 1.1). Another common distinction is between the case in which the given distributions are different and the case in which they are identical. For the former, Krengel et al. [18, 19] showed an optimal strategy that is $1/2$-competitive. In this setting, the optimal competitive ratio can be achieved by simple, single-threshold algorithms [21, 17]. For IID and non-IID random variables, Hill and Kertz [15] initially gave a $(1 - 1/e)$-competitive algorithm. This was improved to ≈ 0.738 [1] and later ≈ 0.745 [7], which is tight, due to a matching upper bound [15, 16].

Another relevant metric, introduced by Gilbert and Mosteller [12] for IID random variables, is that of maximizing the *Probability of selecting the Maximum realization* ($\mathbb{P}_{\max}$) - see Definition 1.2. For this objective and IID random variables, Gilbert and Mosteller [12] gave an algorithm that achieves a probability of ≈ 0.58, which is the best possible. Later, Esfandiari, Hajiaghayi, Lucier and Mitzenmacher [9] studied the same objective for general random variables, obtaining a tight probability equal to $1/e$ when the random variables arrive in adversarial order and 0.517 when the random variables arrive in random order. The latter case was recently improved to the tight ≈ 0.58 by Nuti [20], showing that the IID setting is not easier than the non-IID setting with random order. In this paper, we introduce a new model as a means to study variations of both the IID and the general settings, for both the RoE and $\mathbb{P}_{\max}$ objectives.

A setting that is related to ours is the Top-1-of-m model, formally introduced by Assaf and Samuel-Cahn [3] for IID random variables, although it had been studied initially by Gilbert and Mosteller [12]. In this setting, the algorithm is allowed to select $m \geq 1$ values, but the value it gets judged by is the maximum selected value. Gilbert and Mosteller [12] gave numerical approximations of the $\mathbb{P}_{\max}$ objective for $2 \leq m \leq 10$, using a simple, single-threshold algorithm. Later, Assaf and Samuel-Cahn [3] studied the RoE objective for general distributions and gave an elegant and simple $(1 - 1/m+1)$-competitive algorithm. This was improved [2] by bounding the competitive ratio of the optimal algorithm by a recursive differential equation. They gave numerical approximations for $2 \leq m \leq 5$, but studying the asymptotic nature of the constants for large m turned out to be difficult. Ezra et al. [11] later revisited the problem and gave a new algorithm for large m that is $1 - \mathcal{O}\big(e^{-m/6}\big)$-competitive for the same problem. This improves the error term from [2] from linear in m to exponential in m. Harb [14] recently improved this into a $1 - e^{-mW_0\left(\frac{m\sqrt{m!}}{m}\right)}$-competitive algorithm, where W_0 is the Lambert-W function[1], and improved the lower bound for $m = 2$ separately. However, the asymptotic nature of this function is difficult to analyze.

Model

We introduce a new model that generalizes the standard prophet inequality setting, and analyze it as a means to obtain new results and improvements in the Top-1-of-m model. Our model allows the algorithm some information about the future that is otherwise privy only to the prophet. Specifically, at any point in the process, upon seeing a reward X_i, the algorithm is allowed to query an oracle $\mathcal{O}$. The oracle $\mathcal{O}$ responds with a single bit answer: YES if the current realization is larger than the remaining realizations, i.e., $X_i > \max_{j=i+1}^{n} X_j$ and NO otherwise. In other words, the oracle $\mathcal{O}$ informs the algorithm it should select X_i, or reject it, because there is a reward coming up that is at least as good. Clearly, with no

[1] The Lambert-W function is $W_0(x)$ defined as the solution y to the equation $ye^y = x$.

queries available, one recovers the classical prophet inequality setting, whereas with $n-1$ queries, the strategy of using a query on every X_i, for $i = 1, \ldots, n-1$, leads to the algorithm selecting the highest realization always. Thus, this model interpolates nicely between the two extremes of full or no information about the future.

In this paper, we consider the following different settings.

▶ **Definition 1.1** (Competitive Ratio). *The competitive ratio or* Ratio of Expectations *is denoted by* RoE*. Specifically, for an instance $\mathcal{I}$ of a prophet inequality setting, we denote by* RoE$(x, \mathcal{I})$ *the competitive ratio of an optimal algorithm for $\mathcal{I}$. An algorithm ALG is* α-competitive*, for $\alpha \in [0,1]$, if $\mathbb{E}[ALG] \geq \alpha \cdot \mathbb{E}[\max_i X_i]$, and α is called the* competitive ratio*.*

▶ **Definition 1.2** (Probability of Selecting the Maximum). *The* Probability of selecting the Maximum *realization is denoted by $\mathbb{P}_{\max}$. An algorithm ALG achieves a $\mathbb{P}_{\max}$ of α if it returns a value v such that $\mathbb{P}[v = Z] \geq \alpha$, where $Z = \max\{X_1, \ldots, X_n\}$. In some works (for example [12]), the notation PbM has also been used.*

▶ **Definition 1.3** (IID Setting). *We use the term* IID *to refer to the setting where $X_1, \ldots, X_n$ are independent and identically distributed random variables. We use* non-IID *to refer to the more general setting where $X_1, \ldots, X_n$ are independent, but not necessarily identical.*

▶ **Definition 1.4** ($\textsc{Proph}_m$). *We use $\textsc{Proph}_m$ to refer to the* Top-1-of-m *model, in which the algorithm can choose up to m values, and its payoff is the maximum of the chosen values. We use $\mathcal{O}_m$ refers to our oracle model where the algorithm has access to m oracle calls, and can only select one value.*

Note that the model $\textsc{Proph}_{m+1}$ is comparable to $\mathcal{O}_m$, since in the former the algorithm can choose $m+1$ values, where as the later can ask the oracle m times and then choose an item. To help distinguish between the different settings, we denote each model as $\mathcal{M}(x, y, z)$, where

- x is either $\textsc{Proph}_m$ or $\mathcal{O}_m$ with $m \in \mathbb{N}$,
- y is either IID or non-IID, and
- z is either $\mathbb{P}_{\max}$ or RoE.

Our Contributions

In this paper, we study the oracle model for independent random variables following identical or general distributions with the $\mathbb{P}_{\max}$ and RoE objectives and make the following contributions:

(I) We establish an *equivalence* between the oracle model and the Top-1-of-m model for the $\mathbb{P}_{\max}$ objective.

(II) We show that this equivalence fails to hold for the RoE objective. However, we show that guarantees for RoE in the oracle model translate to guarantees in the Top-1-of-m model, thus further motivating our study of the oracle model.

(III) We resolve the oracle model $\mathcal{M}(\mathcal{O}_m, \text{non-IID}, \text{RoE})$ by presenting a single-threshold algorithm. Our algorithm achieves a competitive ratio of $1 - e^{-\xi_m} = 1 - \mathcal{O}e^{-m/e}$ for general m, where ξ_m is the unique *positive* solution[2] to the equation $1 - e^{-\xi_m} =$

[2] In Section 3, we prove that there is indeed a unique positive solution.

$\frac{\Gamma(m+1,\xi_m)}{m!}$[3]. Furthermore, we show that this lower bound is optimal by showing a construction that yields an equal upper bound. Since we showed that lower bound guarantees for $\mathcal{M}(\mathcal{O}_m, \textsf{non-IID}, \textsf{RoE})$ also hold for the $\mathcal{M}(\textsc{Proph}_{m+1}, \textsf{non-IID}, \textsf{RoE})$ setting, this strictly improves the current state of the art bounds of [14], even though the guarantees are obtained in the weaker oracle model.

(IV) We give a single-threshold algorithm for the $\mathcal{M}(\mathcal{O}_m, \textsf{IID}, \mathbb{P}_{\max})$ model that achieves a $1 - \mathcal{O}(m^{-m/5})$ probability of selecting the maximum, as well as providing an upper bound that is asymptotically (almost) tight. To the best of our knowledge, this is the first result for the $\mathbb{P}_{\max}$ objective and general m in the well studied Top-1-of-m model. Our algorithm achieves a probability of ≈ 0.797 even with $m = 1$ calls to the oracle, a significant improvement on the ≈ 0.58 achieved without oracle calls [12].

As discussed earlier, the main motivation behind our oracle model comes from our first two results which relate it to the Top-1-of-m model.

Equivalence of Models for $\mathbb{P}_{\max}$

▶ **Theorem 1.5.** *The $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$ model is equivalent to the $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$ model, where $y =$ IID or non-IID. In other words, for every prophet inequality instance, the probability achieved by the best-possible algorithm in the $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$ model is the same as the one achieved by the best-possible algorithm in the $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$ model.*

In Section 2 and Theorem 1.5, we establish the equivalence between the $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$ and $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$ models, for $y =$ IID or non-IID. In other words, the best algorithms in these models achieve the same probability of selecting the maximum.

This result might not seem that surprising due to the apparent similarity of the two models. However, thinking about the Top-1-of-m setting from the viewpoint of oracle calls allows for a different perspective that we exploit in our analysis. Furthermore, such intuition can sometimes be wrong, as our next result shows.

Difference of Models for RoE

▶ **Theorem 1.6.** *For every $m \geq 1$, and for* all *input instances $\mathcal{J}$ (of IID or non-IID variables), we have $\textsf{RoE}(\mathcal{O}_m, \mathcal{J}) \leq \textsf{RoE}(\textsc{Proph}_{m+1}, \mathcal{J})$, Furthermore, for every $m \geq 1$, there* exists *an input instance $\mathcal{I}$ with $m + 2$ non-IID random variables, such that $\textsf{RoE}(\mathcal{O}_m, \mathcal{I}) \leq (1 - 1/2^{m+1})\textsf{RoE}(\textsc{Proph}_2, \mathcal{I})$.*

Perhaps more surprisingly, our oracle model and the Top-1-of-m model stop being equivalent when one considers the RoE objective, with the oracle model being strictly weaker.

In Section 2, we show Theorem 1.6, which gives a prophet inequality instance, and an algorithm $\mathcal{A}$ for $\mathcal{M}(\textsc{Proph}_{m+1}, \textsf{non-IID}, \textsf{RoE})$, such that no algorithm for $\mathcal{M}(\mathcal{O}_m, \textsf{non-IID}, \textsf{RoE})$ can achieve the same competitive ratio as that of $\mathcal{A}$. Furthermore, we show that any algorithm for $\mathcal{M}(\mathcal{O}_m, y, \textsf{RoE})$ can be modified to an algorithm for $\mathcal{M}(\textsc{Proph}_{m+1}, y, \textsf{RoE})$ that achieves an equal or greater competitive ratio.

Bounding the Performance of the Oracle Model

▶ **Theorem 1.7.** *For every $m \geq 1$, let $\alpha_m = 1 - e^{-\xi_m}$, where ξ_m is the unique positive solution to the equation $1 - e^{-\xi_m} = \frac{\Gamma(m+1,\xi_m)}{m!}$. For any finite sequence $\mathbf{X}$ of non-IID variables, one can compute a value τ, such that the single-threshold algorithm (with initial threshold τ) has competitive ratio $\geq \alpha_m$.*

---

Figure 1.1 The value of $1-e^{-\xi_m}$, for $m=1,\ldots,15$.

After establishing the relationship between our oracle model and the Top-1-of-m model, we turn our attention to upper and lower bounds for the oracle model. First, for the non-IID setting and the RoE objective, we present a simple, single-threshold algorithm achieving a competitive ratio that approaches 1 exponentially fast with respect to m. Even though our algorithm is for the oracle model, for which weaker guarantees are expected due to Theorem 1.6, it improves upon the best-known guarantee for the Top-1-of-m setting, due to Harb [14]. Our algorithm relies on two techniques; sharding and Poissonization, introduced by [14] for the analysis of threshold-based algorithms for prophet inequalities. As an added benefit, the algorithm's analysis is easy to understand.

Specifically, in Section 3, Theorem 1.7, we show that there is a constant ξ_m, such that for the oracle model $\mathcal{M}(\mathcal{O}_m, \text{non-IID}, \text{RoE})$, there exists an algorithm with competitive ratio at least $1-e^{-\xi_m}$. As $m\to+\infty$, this behaves as $1-e^{-m/e+o(m)}$. The competitive ratio plot for $m=1,\ldots 15$ is shown in Figure 1.1.

Matching Upper Bound

▶ **Theorem 1.8.** *For any $m\geq 1$ and $\delta>0$, there exists an input instance $\mathcal{I}$ such that for any algorithm, we have $\text{RoE}(\mathcal{A})\leq 1-e^{-\xi_m}+\delta$.*

In addition, we provide a construction for every m that gives a matching upper bound to the competitive ratio, thus resolving the problem for the case of general distributions and the RoE objective. The construction we have is perhaps of independent interest in the design of counterexamples for other settings, as it combines and generalizes standard counterexamples of prophet inequalities.

In Section 3 and Theorem 1.8, we show that for any $\delta>0$, there exists an instance of $\mathcal{M}(\mathcal{O}_m, \text{non-IID}, z)$, where $z=\text{RoE}$ or $\mathbb{P}_{\max}$, in which no single-threshold algorithm can achieve a $\left(1-e^{-\xi_m}+\delta\right)$-competitive ratio or select the maximum realization with probability at least $\left(1-e^{-\xi_m}+\delta\right)$.

Intuitively, the above follows since an algorithm for the oracle model performs poorly when, every time it uses an oracle call and gets a YES answer, the next value it sees that is at least the queried value is roughly equal, and thus the oracle call was used without any real gain. The idea behind the worst-case for this setting is to have what is essentially a Poisson random variable with rate ξ_m, providing the algorithm with several non-zero values, each roughly the same. By carefully selecting ξ_m in order to equate the probability of having no non-zero values and the probability of having more than m non-zero values, we are forcing the algorithm to use a query for every non-zero realization, thus rendering the oracle calls as useless as possible.

Model	Lower Bound		Upper Bound	
	Prev. Best	Current Best	Prev.	Current Best
RoE, General Setting	$1-\mathcal{O}\left(e^{-m/6}\right)$ [11]	$1-e^{-m/e+o(m)}$	-	$1-e^{-m/e+o(m)}$ single-threshold
$\mathbb{P}_{\max}$, IID Setting	≈ 0.58 [12]	≈ 0.797 $(m=1)$ $1-\mathcal{O}\left(m^{-m/5}\right)$	-	$1-\mathcal{O}\left(m^{-m}\right)$

Figure 1.2 State of the art.

The IID Setting

▶ **Theorem 1.9** (see [13] for proof). *For sufficiently large m, n, there exists an algorithm for the $\mathcal{M}(\mathcal{O}_m, \mathit{IID}, \mathbb{P}_{\max})$ model that selects the maximum realization with probability at least $1-\mathcal{O}\left(m^{-m/5}\right)$.*

Next, we turn our attention to the IID setting with m oracles calls and the $\mathbb{P}_{\max}$ objective. We present a simple, single-threshold algorithm that selects the maximum realization with probability that approaches 1 in a super-exponential fashion. As a warm-up, we first present the analysis for $m=1$ before generalizing it to all m.

Specifically, in Section 4, Theorem 1.9, we show that for $\mathcal{M}(\mathcal{O}_m, \mathsf{IID}, \mathbb{P}_{\max})$, one can select the maximum realization with probability at least $1-\mathcal{O}\left(m^{-m/5}\right)$.

▶ **Theorem 1.10** (see [13] for proof). *There exists an instance of $\mathcal{M}(\mathcal{O}_m, \mathit{IID}, \mathbb{P}_{\max})$ for which no algorithm can select the maximum realization with probability greater than $1-\mathcal{O}(m^{-m})$.*

We also present, in Section 4, Theorem 1.10, an upper bound on the probability of success that is asymptotically tight, up to small multiplicative constants in the exponent. Because of Theorem 1.5, both upper and lower bounds on the probability of success carry over in the Top-1-of-m settings as well. Figure 1.2 contains a summary of our results for the oracle model in the different settings.

1.1 Additional related work

We have already mentioned the works of Gilbert and Mosteller [12], Esfandiari, Hajiaghayi, Lucier and Mitzenmacher [9] and Nuti [20] for the $\mathbb{P}_{\max}$ objective. Related work includes the study of order-aware algorithms by Ezra, Feldman et al. [10], algorithms with fairness guarantees by Correa et al. [6] and algorithms with a-priori information of some of the values by Correa et al. [4]. In addition to these, Esfandiari et al. [9] study a related but distinct variant to ours. They relax the objective to allow the return of one out of the top k realizations, and show exponential upper and lower bounds. Their model, however, is incomparable to ours.

Organization

In Section 2 we relate our model to Top-1-of-m model of Assaf and Samuel-Cahn [3] and prove the reductions. In Section 3 we present our tight algorithm for the non-IID setting. Section 4 contains our algorithms and upper bounds for the IID setting. Due to space constraints, some of the proofs as well as background information on concentration inequalities that we use for our results can be found in the full version [13].

2 Reductions

To motivate our oracle model, we start by establishing an equivalence between $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$ and $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$, for both the $y = \mathsf{IID}$ and $y = \mathsf{non\text{-}IID}$ case (see Theorem 1.5 below). We also show that, perhaps surprisingly, this equivalence does not hold for the RoE objective; lower bound guarantees for $\mathcal{M}(\mathcal{O}_m, y, \mathsf{RoE})$ translate to guarantees for $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathsf{RoE})$ (Theorem 1.6), but not the converse. Later, we use this result to improve the best-known lower bound guarantees on $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathsf{RoE})$.

2.1 The $\mathbb{P}_{\max}$ objective

▶ **Lemma 2.1.** *Fix an instance of the prophet problem. Let $\mathcal{A}$ be an algorithm for this instance in $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$, where $y = \mathsf{IID}$ or $\mathsf{non\text{-}IID}$. Then, there exists an algorithm $\mathcal{B}$ for tor this instance in $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$, with black-box access to $\mathcal{A}$, such that $\mathbb{P}_{\max}(\mathcal{B}) \geq \mathbb{P}_{\max}(\mathcal{A})$.*

Proof. The idea is for $\mathcal{B}$ to simulate $\mathcal{A}$'s behavior by selecting each realization that $\mathcal{A}$ decides to query. Initially, $\mathcal{B}$ starts with an empty set S of selected values. Whenever $\mathcal{B}$ is presented with a realization X_i, it feeds it to $\mathcal{A}$. If $\mathcal{A}$ decides to select X_i or expend a query for X_i, regardless of the outcome of the query, $\mathcal{B}$ always selects X_i into S, otherwise $\mathcal{B}$ decides not to select X_i. By induction, S contains exactly all the realizations that were queried by $\mathcal{A}$ as well as at most one more realization that might have been selected by $\mathcal{A}$ if it run out of queries. Therefore, $|S| \leq m + 1$.

Observe that $\mathcal{A}$ succeeds if and only if it selects the maximum, and it only selects a realization X_i if (i) it chose to expend a query on X_i, or (ii) when it observed X_i it run out of queries. In both cases, by the description of $\mathcal{B}$, we know that $X_i \in S$, and thus the probability that $\mathcal{B}$ succeeds is at least $\mathbb{P}_{\max}(\mathcal{A})$. ◀

▶ **Lemma 2.2** (see [13] for proof)**.** *Fix an input instance of the prophet problem. Fix an algorithm $\mathcal{B}$ for $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$, where $y = \mathsf{IID}$ or $\mathsf{non\text{-}IID}$. Then, there exists an algorithm $\mathcal{A}$ for $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$, with black-box access to $\mathcal{B}$, such that such that $\mathbb{P}_{\max}(\mathcal{A}) \geq \mathbb{P}_{\max}(\mathcal{B})$.*

Combining the above two lemmas, we get the following result.

▶ **Theorem 1.5.** *The $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$ model is equivalent to the $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$ model, where $y = \mathsf{IID}$ or $\mathsf{non\text{-}IID}$. In other words, for every prophet inequality instance, the probability achieved by the best-possible algorithm in the $\mathcal{M}(\mathcal{O}_m, y, \mathbb{P}_{\max})$ model is the same as the one achieved by the best-possible algorithm in the $\mathcal{M}(\textsc{Proph}_{m+1}, y, \mathbb{P}_{\max})$ model.*

2.2 For the RoE objective $\mathcal{O}_m \leq \textsc{Proph}_{m+1}$

We demonstrate that the $\textsc{Proph}_m$ model strictly surpasses the $\mathcal{O}_m$ for $\mathsf{non\text{-}IID}$ random variables.

▶ **Definition 2.3.** *For two integers $i \leq j$, let $[\![i : j]\!] = \{i, i+1, \ldots, j\}$.*

▶ **Lemma 2.4.** *For $m = 1$, there exists an input instance $\mathcal{I}$ with 3 $\mathsf{non\text{-}IID}$ random variables, such that $\mathsf{RoE}(\mathcal{O}_1, \mathcal{I}) \leq \frac{3}{4}\mathsf{RoE}(\textsc{Proph}_2, \mathcal{I})$.*

Proof. For a fixed $\varepsilon > 0$, consider the input instance $\mathcal{I}$ of three independent random variables X_1, X_2, X_3, where

$$X_1 = 1 \text{ w.p. } 1, \qquad X_2 = \begin{cases} 1+\varepsilon & \text{w.p. } \frac{1}{2}-\varepsilon \\ 0 & \text{otherwise} \end{cases}, \qquad \text{and} \qquad X_3 = \begin{cases} \frac{1}{\varepsilon} & \text{w.p. } \varepsilon \\ 0 & \text{otherwise} \end{cases}.$$

We have that

$$\mathbb{E}\Big[\max\{X_1, X_2, X_3\}\Big] = \frac{1}{\varepsilon}\varepsilon + (1+\varepsilon)(1-\varepsilon)\left(\frac{1}{2}-\varepsilon\right) + 1(1-\varepsilon)\left(\frac{1}{2}+\varepsilon\right) = 2 - O(\varepsilon).$$

For small ε, an algorithm $\mathcal{B}$ that is optimal for the $\textsc{Proph}_2$ model in this instance is to select X_1, ignore X_2 and then select X_3 if it is non-zero. This yields

$$\mathbb{E}[\mathcal{B}] = 1(1-\varepsilon) + 1/\varepsilon \cdot \varepsilon = 2 - \varepsilon.$$

However, the optimal $\mathcal{A}$ for the oracle model queries $\mathcal{O}$ at X_1. With probability $(1-\varepsilon)(1/2+\varepsilon)$, it stops and select X_1, getting a value of 1. Otherwise, it continues, with no oracle calls left. It ignores X_2 and select X_3. Thus,

$$\mathbb{E}[\mathcal{A}] = 1\left(\frac{1}{2}+\varepsilon\right)(1-\varepsilon) + \frac{1}{\varepsilon}\varepsilon = \frac{3}{2} + \frac{\varepsilon}{2} - \varepsilon^2.$$

The competitive ratios of $\mathcal{A}$ is $\mathsf{RoE}(\mathcal{O}_1, \mathcal{I}) = \dfrac{\frac{3}{2}+\frac{\varepsilon}{2}-\varepsilon^2}{2-O(\varepsilon)} = \dfrac{3}{4} + O(\varepsilon) \to \dfrac{3}{4}$, as $\varepsilon \to 0$, whereas the competitive ratio of $\mathcal{B}$, as $\varepsilon \to 0$, is

$$\mathsf{RoE}(\textsc{Proph}_2, \mathcal{I}) = \frac{2-\varepsilon}{2+O(\varepsilon)} = 1 - O(\varepsilon) \to 1. \qquad \blacktriangleleft$$

The above example, appropriately generalized for $m > 1$ by having random variables

$$X_1 = 1 \quad \text{w.p. } 1, \quad X_i = \begin{cases} 1+(i-1)\varepsilon & \text{w.p. } \frac{1}{2}-\varepsilon \\ 0 & \text{w.p. } \frac{1}{2}+\varepsilon \end{cases}, \quad \text{for } i = 2, \ldots, m+1, \text{ and}$$

$$X_{m+2} = \begin{cases} \frac{1}{\varepsilon} & \text{w.p. } \varepsilon \\ 0 & \text{w.p. } 1-\varepsilon \end{cases},$$

shows that the gap between $\mathsf{RoE}(\mathcal{O}_m, \mathcal{I}))$ and $\mathsf{RoE}(\textsc{Proph}_{m+1}, \mathcal{I}))$ is at most $1 - 1/2^{m+1}$ for general m. The analysis of this example for general m is similar to the $m = 1$ case. We do not present it here as, even though this example is very simple, this gap is not the tightest possible. For a tighter gap between the competitive ratio of the two models, see the example in the proof of Theorem 1.8.

▶ **Lemma 2.5.** *For any input instance $\mathcal{I}$, we have $\mathsf{RoE}(\textsc{Proph}_{m+1}, \mathcal{I}) \geq \mathsf{RoE}(\mathcal{O}_m, \mathcal{I})$, for IID or non-IID variables.*

Proof. Let $\mathcal{A}$ be the algorithm in $\mathcal{M}(\mathcal{O}_m, \mathsf{RoE}, \mathcal{I})$ realizing the maximum RoE for $\mathcal{I}$. We construct an algorithm $\mathcal{B} \in \mathcal{M}(\mathcal{O}_m, \mathsf{RoE}, \mathcal{I})$.

The algorithm $\mathcal{B}$ simulates $\mathcal{A}$'s behavior by selecting each realization that $\mathcal{A}$ decides to query. Initially, $\mathcal{B}$ starts with an empty set S. Whenever $\mathcal{B}$ is presented with a realization X_i, it feeds it to $\mathcal{A}$. If $\mathcal{A}$ decides to return X_i, or performs an oracle query for X_i, the algorithm $\mathcal{B}$ adds X_i to S.

Observe that the algorithm $\mathcal{A}$ stops as soon as an oracle query returns NO. Thus, the simulation $\mathcal{B}$ of $\mathcal{A}$, assumes the oracle always answers YES (i.e., a larger value is coming up in the future). (i.e., the simulation replaces a call to the oracle by a function that always returns YES), as this enables it (potentially) to save more values into the available slots, thus increasing its RoE.

The set S contains exactly all the realizations that were queried by $\mathcal{A}$, as well as at most one additional realization returned by $\mathcal{A}$. Therefore, $|S| \leq m+1$.

Every possible sequence of realizations $\mathcal{A}$ queried (or selected to return) are in S. Therefore, if $V_{\mathcal{A}}$ is the value returned by $\mathcal{A}$ and $V_{\mathcal{B}}$ is the value returned by $\mathcal{B}$, we have $V_{\mathcal{B}} \geq V_{\mathcal{A}}$, which readily implies that $\mathsf{RoE}(\mathcal{B}) \geq \mathsf{RoE}(\mathcal{A})$. ◀

▶ **Theorem 1.6.** *For every $m \geq 1$, and for* all *input instances $\mathcal{J}$ (of IID or non-IID variables), we have $\mathsf{RoE}(\mathcal{O}_m, \mathcal{J}) \leq \mathsf{RoE}(\textsc{Proph}_{m+1}, \mathcal{J})$, Furthermore, for every $m \geq 1$, there* exists *an input instance $\mathcal{I}$ with $m+2$ non-IID random variables, such that $\mathsf{RoE}(\mathcal{O}_m, \mathcal{I}) \leq (1 - 1/2^{m+1})\mathsf{RoE}(\textsc{Proph}_2, \mathcal{I})$.*

3 The non-IID settings

By Theorem 1.6, any guarantees we provide for the oracle model with the RoE objective can be directly translated to guarantees for the Top-1-of-m model, improving upon the previous work on this model [3, 2, 11, 14]. We provide a simple, single-threshold algorithm that resolves the RoE objective in the oracle model.

3.1 The exponent sequence

▶ **Definition 3.1** (Exponent Sequence). *For every $m \geq 1$, let ξ_m denote the unique positive solution to the following equation:*

$$1 - e^{-\xi_m} = \frac{\Gamma(m+1, \xi_m)}{m!},$$

where $\Gamma(m+1, x) = \int_{t=x}^{\infty} t^m e^{-t}\, dt$ denotes the upper incomplete gamma *function. We call the sequence $\{\xi_m\}_{m \in \mathbb{N}}$ the* exponent sequence.

We show below that the optimal competitive ratio of $\mathcal{M}(\mathcal{O}_m, \mathsf{non\text{-}IID}, \mathsf{RoE})$ is exactly $1 - e^{-\xi_m}$. It is known that, for $x \geq 0$ and an integer $m+1 > 0$, we have

$$\Gamma(m+1, x) = m!\, e^{-x} \sum_{k=0}^{m} \frac{x^k}{k!} \leq m! e^{-x} e^{x} \leq m!. \tag{3.1}$$

As such, the above equation on the value of ξ_m, becomes

$$1 - e^{-\xi_m} = e^{-\xi_m} \sum_{k=0}^{m} \frac{(\xi_m)^k}{k!} \qquad \Longleftrightarrow \qquad \sum_{k=m+1}^{\infty} \frac{(\xi_m)^k}{k!} = 1.$$

This readily implies that the exponent sequence is monotonically increasing, and $m/e^2 \leq \xi_m \leq m$.

▶ **Definition 3.2.** *Let $\mathsf{q}_{k+1}(x) = \frac{\Gamma(k+1,x)}{k!} = e^{-x} \sum_{j=0}^{k} \frac{x^j}{j!}$. This implies $\mathsf{q}_{m+1}(\xi_m) = 1 - e^{-\xi_m}$.*

▶ **Lemma 3.3.** *$\mathsf{q}'_{m+1}(x) = -e^{-x} \frac{x^m}{m!}$.*

Proof. As $(e^{-x})' = -e^{-x}$, we have $\mathsf{q}'_{m+1}(x) = -e^{-x} + \sum_{j=1}^{m}\left(e^{-x}\frac{x^{j-1}}{(j-1)!} - e^{-x}\frac{x^j}{j!}\right) = -e^{-x} + e^{-x} - e^{-x}\frac{x^m}{m!} = -e^{-x}\frac{x^m}{m!}$. ◀

▶ **Lemma 3.4** (see [13] for proof). *For all $m \geq 1$, we have $(m!)^{1/m} < \xi_m < ((m+1)!)^{1/m+1}$.*

▶ Remark 3.5. Setting $\nu(x) = \nu(m,x) = \frac{\Gamma(m+1,x)}{m!}$, and arguing as in Lemma 3.4, we have $\nu'(x) < 0$, which readily implies that $\nu(x)$ is monotonically decreasing.

Stirling's formula applied to Lemma 3.4 readily implies the following.

▶ **Lemma 3.6.** *We have* $\lim_{m\to\infty}\frac{\xi_m}{m} = \frac{1}{e}$.

▶ **Lemma 3.7** (see [13] for proof). *For all $k, m \geq 0$ integers, we have*

$$f(k,m) = \sum_{j=1}^{k}\frac{\xi_m^j}{j!} - \sum_{j=m+1}^{m+k}\frac{\xi_m^j}{j!} \geq 0.$$

3.2 Background: Sharding, poissonization, and stochastic dominance

For a sequence of random variables $\mathbf{X} = X_1, \ldots, X_n$, let $|\alpha \leq \mathbf{X} \leq \beta| = |\{i \mid \alpha \leq X_i \leq \beta\}|$ denote the number of realizations in this sequence falling in the interval $[\alpha, \beta]$.

3.2.1 Sharding

For the lower bound, we use poissonization and sharding [14]. Given random variables $X_1, \ldots, X_n$ with cdfs $F_1, \ldots, F_n$, instead of sampling X_i from F_i, we instead replace it with a sequence of K independent random variables $\mathbf{H}_i = Y_{i,1}, \ldots, Y_{i,K}$, such that $\max_j Y_{i,j}$ has the same distribution as X_i. Specifically, the cdf of $Y_{i,j}$, for all j, is $F_i^{1/K}$. Thus, the distribution of $\max\{Y_{i,1}, \ldots, Y_{i,K}\}$ is the same as X_i. This creates a new sequence of Kn samples $\mathbf{S} = \mathbf{H}_1 \cdot \mathbf{H}_2 \cdot \cdots \cdot \mathbf{H}_n$, where $\cdot$ is the concatenation operator. Observe that for any $\alpha \geq 0$ and integer t, we have

$$\mathbb{P}[|\mathbf{X} \geq \alpha| > t] < \mathbb{P}[|\mathbf{S} \geq \alpha| > t].$$

Intuitively, this implies that, for threshold algorithms, an instance consisting of $\mathbf{S}$ instead of $\mathbf{X}$ can only generate worse results. We emphasize that this sharding technique is done only for analysis purposes.

3.2.2 Poissonization

▶ **Definition 3.8** (Poisson Distribution). *A random variable X has Poisson distribution with rate λ, denoted by $X \sim \mathrm{Pois}(\lambda)$, if $\mathbb{P}[X = i] = \lambda^k e^{-\lambda}/k!$. Conveniently, $\mathbb{E}[X] = \mathbb{V}[X] = \lambda$.*

The purpose of the sharding is to be able to bound quantities of the form $\mathbb{P}[|\beta \leq \mathbf{S} \leq \tau| = t]$. As K grows, the underlying random variable $|\beta \leq \mathbf{S} \leq \tau|$ has a binomial distribution that converges to a Poisson distribution.

▶ **Observation 3.9.** *For $c \in (0,1]$, we have, using L'Hôpital's rule, that* $\lim_{x\to\infty} x(1-c^{1/x}) = \lim_{x\to\infty}\frac{1-\exp(\log(c)/x)}{1/x} = \lim_{x\to\infty}\frac{\log(c)\exp(\log(c)/x)/x^2}{-1/x^2} = -\log c$, *where* $\log = \log_e$.

Let τ be a threshold such that $\sum_{i=1}^{n}\sum_{j=1}^{K}\mathbb{P}[Y_{i,j}\geq\tau]=c$ for some constant c to be determined shortly. We can rewrite this into the following.

$$\sum_{i=1}^{n}K\Big(1-\mathbb{P}[X_i\leq\tau]^{1/K}\Big)=c. \tag{3.2}$$

The limit of Eq. (3.2), as $K\to+\infty$, is $\sum_{i=1}^{n}-\log\mathbb{P}[X_i\leq\tau]=c$, by Observation 3.9. Equivalently, for $Z=\max\{X_1,\ldots,X_n\}$, we have

$$e^{-c}=\exp\Big(\sum_{i=1}^{n}\log\mathbb{P}[X_i\leq\tau]\Big)=\prod_{i=1}^{n}\mathbb{P}[X_i\leq\tau]=\mathbb{P}[X_1,\ldots,X_n\leq\tau]=\mathbb{P}[Z\leq\tau].$$

In particular, the distribution of the number of indices j, such that $Y_{i,j}\geq\tau$ can be well approximated with a Poisson distribution. Specifically, let $V_{i,j}=1\iff Y_{i,j}\geq\tau$, and consider the sum $V_i=\sum_{j=1}^{K}V_{i,j}$. The variable $V_i\sim\mathrm{bin}(K,\psi_i)$, where $\psi_i=1-\mathbb{P}[X_i\leq\tau]^{1/K}$.

Let $\lambda_i=\psi_iK$, and consider the random variable $U_i\sim\mathrm{Pois}(\lambda_i)$ (i.e., U_i has a Poisson distribution with rate λ_i). Intuitively, V_i and U_i have similar distributions. Formally, Le Cam theorem implies that for any set $T\subseteq\{0,1,\ldots,K\}$, we have $|\mathbb{P}[V_i\in T]-\mathbb{P}[U_i\in T]|\leq 2K\psi_i^2=2\lambda_i^2/K\leq 2c^2/K$, by Eq. (3.2). The later quantity goes to zero as K increases.

Thus, we get a variable U_i with a Poisson distribution for each shard sequence $\mathbf{H}_i$, with rate λ_i, where U_i models the number of times we encounter in $\mathbf{H}_i$ values larger than τ. Thus, $U_\tau=\sum_i U_i$ models the total number of times in the splintered sequence $\mathbf{S}$ that values encountered are larger than τ. The variable U_τ has a Poisson distribution with rate $\lambda_\tau=\sum_{i=1}^{n}\lambda_i$.

3.2.3 The distribution in a range

Repeating the same process with a bigger threshold $\beta>\tau$, would yield a similar Poisson random variable U_β with a *lower* rate λ_β. The quantity $\Delta=U_\tau-U_\beta$ is the number of values in $\mathbf{S}$ in the range $[\tau,\beta]$. Furthermore, Δ has a Poisson distribution with rate $\lambda_\tau-\lambda_\beta$. Specifically, $\mathbb{P}[|\beta\leq\mathbf{S}\leq\tau|=t]=\mathbb{P}[\Delta=t]$.

The key to our analysis is that the variables Δ and U_β are independent (in the limit as K increases).

3.2.4 Stochastic dominance

A standard observation is that for a non-negative random variable X, we have that $\mathbb{E}[X]=\int_{x=0}^{\infty}\mathbb{P}[X\geq x]\,\mathrm{d}x$. Thus, for $Z=\max\{X_1,\ldots,X_n\}$, and for an algorithm $\mathcal{A}$, if one can guarantee that there is $c\in[0,1]$, such that for all $\nu\geq 0$, $\mathbb{P}[\mathcal{A}\geq\nu]\geq c\,\mathbb{P}[Z\geq\nu]$, then

$$\mathbb{E}[\mathcal{A}]=\int_0^\infty\mathbb{P}[\mathcal{A}\geq x]\,\mathrm{d}x\geq c\int_0^\infty\mathbb{P}[Z\geq x]\,\mathrm{d}x\geq c\,\mathbb{E}[Z]\,,$$

and thus c is a lower bound on the competitive ratio of $\mathcal{A}$. This argument is used in several results on prophet inequalities and is often referred to as *majorizing* $\mathcal{A}$ with Z.

3.3 An optimal single-threshold algorithm

Here, we describe a single-threshold algorithm that achieves the optimal competitive ratio in the oracle model.

▶ **Definition 3.10** (Single-Threshold Algorithm). *A single threshold algorithm for $\mathcal{O}_m$ sets a threshold τ, and starts observing the sequence. Whenever it encounters a realization $> \tau$, the algorithm stops and queries the oracle whether all the values remaining in the suffix of the sequence are of value $\leq \tau$. If the oracle returns YES, the algorithm accepts the current value and stops. Otherwise, it raises its threshold to $\tau = X_i$ and continues. If the oracle runs out of oracle calls, it selects the first value encountered after the last oracle call that is bigger than τ (which exists, since all oracle calls returned NO).*

While technically, the querying threshold of the algorithm might change during its execution, we call the algorithm a single-threshold algorithm since it uses a single-threshold to decide whether to query the oracle or not, and this threshold *does not change with i*, unlike for example the optimal DP for the IID prophet inequality or the prophet secretary model. Our oracle model is quite different than most other prophet inequality models in the sense that the algorithm has some knowledge of the (true) future. Of course, any algorithm that knows that the maximum of $X_{i+1}, \ldots, X_n$ is larger than X_i would be wasting queries if it expended them on some $X_j < X_i$ for $j > i$, and thus the spirit of it being a single-threshold algorithm to decide whether to query the oracle or not remains.

▶ **Theorem 1.7.** *For every $m \geq 1$, let $\alpha_m = 1 - e^{-\xi_m}$, where ξ_m is the unique positive solution to the equation $1 - e^{-\xi_m} = \frac{\Gamma(m+1,\xi_m)}{m!}$. For any finite sequence $\mathbf{X}$ of non-IID variables, one can compute a value τ, such that the single-threshold algorithm (with initial threshold τ) has competitive ratio $\geq \alpha_m$.*

Proof. Let $\mathbf{X} = X_1, \ldots, X_n$, and $Z = \max_i X_i$. The threshold τ is the $e^{-\xi_m}$ quantile of the maximum, i.e. $\mathbb{P}[Z \leq \tau] = e^{-\xi_m}$. We use $\mathcal{A}(\mathbf{X})$ to denote the result of running the algorithm on $\mathbf{X}$.

As suggested in Section 3.2.1 (for the analysis), we imagine running the algorithm on the splintered sequence $\mathbf{S}$. Somewhat counterintuitively, imagine first generating $\mathbf{S}$, and computing $X_i = \max_j Y_{i,j}$, see Section 3.2.1. Thus, $\max \mathbf{S} = \max \mathbf{X}$. For the sequence $\mathbf{S}$, let $\mathbf{S}_{\geq\tau}$ denote the subsequence of elements of $\mathbf{S}$ that their values are above τ. Observe that $\mathbf{X}_{\geq\tau}$ is a subsequence of $\mathbf{S}_{\geq\tau}$. Thus, we analyze the algorithm performance on $\mathbf{S}$.

Let $\beta \in [0, \tau]$. The probability the algorithm selects a value above β is equal to the probability it selects any value. Thus,

$$\mathbb{P}[\mathcal{A}(\mathbf{X}) \geq \beta] = \mathbb{P}[\mathcal{A} \geq \tau] = \mathbb{P}[Z \geq \tau] = 1 - e^{-\xi_m} \geq \left(1 - e^{-\xi_m}\right) \mathbb{P}[Z \geq \beta]. \tag{3.3}$$

For $\beta \in [\tau, +\infty)$, let $\mathbb{P}[Z \leq \beta] = e^{-q} > e^{-\xi_m}$, implying $\mathbb{P}[Z \geq \beta] = 1 - e^{-q}$. By sharding and Poissonization, the number of shards in the range $[\tau, \beta]$ (resp. $\geq \beta$) is a Poisson random variable Δ (resp. U_β) with rate $\xi_m - q$ (resp. q), see Section 3.2.3. Critically, U_β and Δ are independent. Consider the event of there being at most m values in the range $[\tau, \beta]$, and there being at least one value in $[\beta, +\infty)$. The value $\mathcal{A}(\mathbf{X}) \geq \beta$ in that case. Hence, by the independence of Δ and U_β, we have

$$\frac{\mathbb{P}[\mathcal{A}(\mathbf{X}) \geq \beta]}{\mathbb{P}[Z \geq \beta]} \geq \frac{\mathbb{P}[(U_\beta \geq 1) \cap (0 \leq \Delta \leq m)]}{\mathbb{P}[Z \geq \beta]} = \frac{\mathbb{P}[U_\beta \geq 1]}{\mathbb{P}[Z \geq \beta]} \mathbb{P}[0 \leq \Delta \leq m] = \mathbb{P}[0 \leq \Delta \leq m].$$

Now, we have

$$\mathbb{P}[0 \leq \Delta \leq m] = \sum_{i=0}^{m} e^{-(\xi_m - q)} \frac{(\xi_m - q)^i}{i!} = \frac{\Gamma(m+1, \xi_m - q)}{m!} \geq \frac{\Gamma(m+1, \xi_m)}{m!} = 1 - e^{-\xi_m}.$$

by Eq. (3.1), Remark 3.5 and Definition 3.1.

The above implies that, for any $\beta \geq 0$, we have $\mathbb{P}[\mathcal{A}(\mathbf{X}) \geq \beta] \geq (1 - e^{-\xi_m}) \mathbb{P}[Z \geq \beta]$, Namely, $\mathsf{RoE}(\mathcal{A}) \geq 1 - e^{-\xi_m}$. ◀

3.4 A matching upper bound for single-threshold algorithms

To this end, we present an input sequence for which no algorithm can do better for the oracle that answers if $X_i > \max_{j=i+1}^{n} X_j$. Our upper bound is with respect to the strongest possible form of adversary, the almighty adversary, who knows from the beginning all possible realizations as well as the outcome of any random coins tossed by the algorithm.

Input instance

The input instance $\mathcal{I}$ consists of $n+2$ random variables, for sufficiently large n. Each of these random variables can have only two values – either zero or some positive value. Specifically, for $\varepsilon > 0$ sufficiently small, let

$$X_1 = 1, \quad X_i = \begin{cases} 1 + \varepsilon(i-1) & \text{w.p. } \frac{\xi_m}{n} \\ 0 & \text{otherwise} \end{cases}, \quad \text{for} \quad i \in [\![2 : n+1]\!], \quad \text{and}$$

$$X_{n+2} = \begin{cases} \frac{1}{\varepsilon} & \text{w.p. } \varepsilon \\ 0 & \text{otherwise} \end{cases}.$$

By Lemma 3.6, we have $\xi_m \approx m/e$ and as such, the expected number of non-zero entries in this sequence is (roughly) $m/e + 1$.

▶ **Lemma 3.11.** *For $Z = \max_i X_i$, we have $\mathbb{E}[Z] = 2$ as $\varepsilon \to 0$.*

Proof. Let $Z' = \max_{i \in [\![n+1]\!]} X_i$. Observe that $Z' = 1$. As such, for $Z = \max(Z', X_{n+2})$, we have $\mathbb{E}[Z] = \mathbb{E}[\max_i X_i] = (1/\varepsilon)\varepsilon + (1-\varepsilon)\,\mathbb{E}[Z'] \xrightarrow[\varepsilon \to 0]{} 2$. ◀

Next, we will need the following result on the approximation of a binomial distribution by a Poisson distribution, known as Le Cam's theorem ([5, 8]).

▶ **Theorem 3.12** (Le Cam's theorem). *Let $X_1, \ldots, X_n$ be independent Bernoulli random variables, with $p_i = \mathbb{P}[X_i = 1]$, for $i \in [\![n]\!]$. Let $S = \sum_i X_i$ and $\lambda = \sum_i p_i$. Then S has a Poisson binomial distribution with expectation λ. Furthermore, let $Y \sim \operatorname{Pois} \lambda$. Then we have*

$$\sum_{i=0}^{n} |\mathbb{P}[S = i] - \mathbb{P}[Y = i]| = \sum_{i=0}^{n} \left| \mathbb{P}[S = i] - e^{-\lambda} \frac{\lambda^i}{i!} \right| \leq 2 \sum_{i=1}^{n} p_i^2.$$

▶ **Observation 3.13.** *Let $\widehat{X}_i$ be an indicator variable for the event that $X_i = 1$. For sufficiently large n, $\nabla = \sum_{i=2}^{n+1} \widehat{X}_i$ has a binomial distribution that can be well approximated by a Poisson distribution (Theorem 3.12) with rate ξ_m. That is, $\lim_{n \to \infty} \mathbb{P}[\nabla = k] = e^{-\xi_m} \dfrac{(\xi_m)^k}{k!}$.*

Observe that $\lim_{n \to \infty} \mathbb{P}[\nabla \leq k] = \sum_{i=0}^{k} e^{-\xi_m} \frac{(\xi_m)^i}{i!} = \mathsf{q}_{k+1}(\xi_m)$. In the analysis to follow, we assume $n \to \infty$.

▶ **Theorem 1.8.** *For any $m \geq 1$ and $\delta > 0$, there exists an input instance $\mathcal{I}$ such that for any algorithm, we have $\mathsf{RoE}(\mathcal{A}) \leq 1 - e^{-\xi_m} + \delta$.*

Proof. First, we discuss the strategy that the adversary adopts: the adversary first observes all values. Suppose k nonzero values show up from $X_2, ..., X_n$ at indices $U = \{i_1, ..., i_k\}$, and all other $n-k$ values from $X_2, \ldots, X_{n+1}$ at indices $B = \{\hat{i}_1, \ldots, \hat{i}_{n-k}\}$ are zero. One can easily see that it is optimal for the adversary to provide the random variables in the order $X_{\sigma(1)}, \ldots, X_{\sigma(n+2)}$ where σ is defined as $\sigma(1) = 1$, $\sigma(j) = i_j, j = 2, \ldots, k+1$, $\sigma(j) = \hat{i}_j$ and finally $\sigma(n+2) = n+2$. In other words, the adversary stacks all the k non zero values from $X_2, \ldots, X_{n+1}$ starting from index 2 to index $k+1$.

Now we consider an algorithm for this setting. The algorithm is aware of the adversary's strategy and thus knows that it will observe $X_{\sigma(1)} = X_1$, then a stream of k ones (where k is unknown), then $n-k$ zeros, and finally $X_{\sigma(n+2)} = X_{n+2}$. The algorithm has a simple decision to make in the beginning; it either queries at X_1 and if the answer is NO it continues to $X_{\sigma(2)}, \dots X_{\sigma(n+1)}$ with $m-1$ oracle calls, or it can just proceed to $X_{\sigma(2)}, \dots X_{\sigma(n+1)}$ with m oracle calls. Thus, the only difference in the two cases is that in the former, it has only $m-1$ oracle calls for $X_{\sigma(2)}, \dots, X_{\sigma(n+1)}$ but it gets an expected reward of 1 if $X_{\sigma(2)} = \dots = X_{\sigma(n+2)} = 0$, and in the later case, it has m oracle calls for $X_{\sigma(2)}, \dots, X_{\sigma(n+1)}$, but it gets 0 reward if $X_{\sigma(2)} = \dots = X_{\sigma(n+2)} = 0$.

Let k be the number of non-zeros in $X_2, \dots, X_{n+1}$ (i.e., $X_{\sigma(k+1)}$ is the last 1). When the algorithm observes the stream of approximate ones from $X_{\sigma(2)}, ..., X_{\sigma(n+1)}$, it needs to decide indices $S \subseteq [\![2 : n+1]\!], |S| \leq m$ where it will expend the oracle call. Clearly, it is suboptimal to use the oracle at a 0 value, since regardless, the algorithm will receive a value of 0 in the end if it fails. Consider what happens if the algorithm decides to query at index $i \in [\![2 : n+1]\!]$ with $X_{\sigma(i)} = 1$. If $X_{\sigma(i+1)} = \dots X_{\sigma(n+1)} = 0$, then the algorithm gets on expectation $1/\varepsilon \cdot \varepsilon + (1-\varepsilon) \cdot 1 \xrightarrow[\varepsilon \to 0]{} 2$ reward on expectation. However, if $X_{\sigma(i+1)} > 0$, then the oracle will return NO because $X_{\sigma(i)} \not> \max(X_{\sigma(i+1)}, \dots, X_{\sigma(n+2)})$. On the other hand, if the algorithm does not query at index $k+1$ (i.e., $(k+1) \notin S$), then the algorithm gets on expectation $\mathbb{E}\big[X_{\sigma(n+2)}\big] = \mathbb{E}[X_{n+2}] = 1/\varepsilon \cdot \varepsilon = 1$.

Hence, the crucial observation is that an algorithm starting at $X_{\sigma(2)}$ that uses its query calls at indices $S \subseteq [\![2 : n+1]\!]$ gets on expectation 2 if and only if $(k+1) \in S$, and 1 otherwise. Thus, for algorithm $\mathcal{A}_1$ that skips $X_{\sigma(1)}$ and uses its oracles at indices $S, |S| = m$, it satisfies

$$\begin{aligned}
\mathbb{E}[\mathcal{A}_1] &= 2 \cdot \sum_{i \geq 0, (i+1) \in S} e^{-\xi_m} \frac{\xi_m^i}{i!} + 1 \cdot \sum_{i \geq 0, (i+1) \notin S} e^{-\xi_m} \frac{\xi_m^i}{i!} \\
&= \sum_{i \geq 0} e^{-\xi_m} \frac{\xi_m^i}{i!} + \sum_{i \geq 0, (i+1) \in S} e^{-\xi_m} \frac{\xi_m^i}{i!} \\
&= 1 + \sum_{(i+1) \in S} e^{-\xi_m} \frac{\xi_m^i}{i!}
\end{aligned}$$

On the other hand, for algorithm $\mathcal{A}_2$ that uses its oracle at $X_{\sigma(1)}$ and uses its remaining oracles at indices $S' \in [\![2 : n+1]\!], |S'| = m-1$, it gets an extra benefit of getting a reward with expected value 2 (as $\varepsilon \to 0$) if $X_{\sigma(2)} = \dots = X_{\sigma(n+1)} = 0$. Hence, it satisfies

$$\begin{aligned}
\mathbb{E}[\mathcal{A}_2] &= \left(e^{-\xi_m} \cdot 2\right) + \left(2 \cdot \sum_{i \geq 0, (i+1) \in S'} e^{-\xi_m} \frac{\xi_m^i}{i!}\right) + \left(1 \cdot \sum_{i \geq 1, (i+1) \notin S'} e^{-\xi_m} \frac{\xi_m^i}{i!}\right) \\
&= \left(\sum_{i \geq 0} e^{-\xi_m} \frac{\xi_m^i}{i!}\right) + e^{-\xi_m} + \sum_{(i+1) \in S'} e^{-\xi_m} \frac{\xi_m^i}{i!} \\
&= 1 + e^{-\xi_m} + \sum_{(i+1) \in S'} e^{-\xi_m} \frac{\xi_m^i}{i!}.
\end{aligned}$$

First, we show that the expression $\sum_{(i+1) \in S} e^{-\xi_m} \frac{\xi_m^i}{i!}$ subject to $S \subseteq [\![2 : n+1]\!], |S| = m$ is maximized for $S^* = [\![2 : m+1]\!]$. Note that it is easy to verify that for a Poisson distribution with rate λ, its probability mass function $e^{-\lambda}\lambda^i/i!$ is increasing for $i < \lambda$, and decreasing

after $i > \lambda$. Hence, the optimal $S^* = [\![k : k+m-1]\!]$ for some $k \geq 2$ that "covers" the rate ξ_m (this is the region with the most mass for a Poisson distribution). The optimal choice of k is $k = 2$ because

$$\sum_{i=1}^{m} e^{-\xi_m} \frac{\xi_m^i}{i!} - \sum_{i=k-1}^{k+m-2} e^{-\xi_m} \frac{\xi_m^i}{i!} = \sum_{i=1}^{k-2} e^{-\xi_m} \frac{\xi_m^i}{i!} - \sum_{i=m+1}^{m+k-2} e^{-\xi_m} \frac{\xi_m^i}{i!} \geq 0,$$

where the last inequality holds by Lemma 3.7. Similarly, $k = 2$ is optimal for when $|S| = m-1$. Hence, we get the inequalities

$$\mathbb{E}[\mathcal{A}_1] \leq 1 + \sum_{i=1}^{m} e^{-\xi_m} \frac{\xi_m^i}{i!} = 1 + \mathsf{q}_{m+1}(\xi_m) - e^{-\xi_m},$$

$$\mathbb{E}[\mathcal{A}_2] \leq 1 + e^{-\xi_m} + \sum_{i=1}^{m-1} e^{-\xi_m} \frac{\xi_m^i}{i!} = 1 + \mathsf{q}_m(\xi_m).$$

Thus, we have

$$\max(\mathbb{E}[\mathcal{A}_1], \mathbb{E}[\mathcal{A}_2]) \leq 1 - e^{-\xi_m} + \mathsf{q}_m(\xi_m) + e^{-\xi_m} \max\left\{1, \frac{\xi_m^m}{m!}\right\}$$

But recall from Lemma 3.4 that $\xi_m^m \geq m!$, thus

$$\begin{aligned}\max(\mathbb{E}[\mathcal{A}_1], \mathbb{E}[\mathcal{A}_2]) &\leq 1 - e^{-\xi_m} + \mathsf{q}_m(\xi_m) + e^{-\xi_m} \cdot \frac{\xi_m^m}{m!} \\ &= 1 - e^{-\xi_m} + \mathsf{q}_{m+1}(\xi_m) \\ &= 2\big(1 - e^{-\xi_m}\big).\end{aligned}$$

Therefore, the competitive ratio of every algorithm is

$$\mathsf{RoE} \leq \frac{2\big(1 - e^{-\xi_m}\big)}{2} = 1 - e^{-\xi_m}.$$ ◀

4 The IID settings

Motivated by the early work of [12] for the Top-1-of-m model, in this section we study the IID setting and the $\mathbb{P}_{\max}$ objective. As a warm-up, we take a look at the IID setting with the $\mathbb{P}_{\max}$ objective and the case of $m = 1$, providing a simple, single-threshold algorithm.

4.1 A single-threshold algorithm for $m = 1$

Our single-threshold algorithm $\mathcal{A}_p$ for $\mathcal{M}(\mathcal{O}_1, \mathsf{IID}, \mathbb{P}_{\max})$ selects a threshold τ equal to the pth quantile of the given distribution $\mathcal{D}$, for some $p \in [0, 1]$. In other words, τ is set such that $p = \mathbb{P}[X_i \geq \tau]$. The first time the algorithm observes a realization above τ, it queries the oracle to see whether the realization should be selected or not. If it continues, it simply accepts the first value encountered above the observed realization on which it queried $\mathcal{O}$.

▶ **Lemma 4.1.** *There exists $p \in [0, 1]$ such that $\mathcal{A}_p$ selects the maximum realization with probability at least 0.797 in the $\mathcal{M}(\mathcal{O}_1, \mathsf{IID}, \mathbb{P}_{\max})$ model for large n.*

Proof. Let Y be the total number of realizations above τ, and $i_1 < i_2 < \cdots < i_Y$ be the indices of the random variables above τ, i.e. $X_{i_t} > \tau$, for $t = 1, \ldots, Y$. Furthermore, let r_t be the rank of X_{i_t} in $\mathcal{X} = \{X_{i_1}, \ldots, X_{i_Y}\}$, i.e. the number k such that X_{i_t} is the kth largest number in $\mathcal{X}$, and Z be the maximum realization of $X_1, \ldots, X_n$.

X_{i_1} is the first realization we observe above τ. Notice that if $r_1 = 1$ or $r_1 = 2$ then the algorithm always selects the maximum realization Z. In other words, given that $Y = 1$ or $Y = 2$, the algorithm selects Z with probability 1. Consider the case $Y > 2$. Again, if $r_1 \leq 2$, the algorithm selects Z with probability 1. Otherwise, if $r_1 > 2$, the algorithm returns Z if and only if for all realizations above τ that appear after X_{i_1} and are also larger than X_{i_1}, the first to encounter is Z. In other words, for the algorithm to succeed in this case, it must be that among the $r_1 - 1$ values of rank smaller than r_1, the first one in the arrival order is the element of rank 1. Since the random variables are IID, the probability of this event is exactly $1/r_1-1$.

Let j be the first index such that $X_{i_j} > X_{i_1}$, and $\alpha(Y) = \mathbb{P}[\mathcal{A} \text{ selects } Z \mid Y]$. Conditioned on $Y \geq 3$, the probability that the algorithm selects Z is

$$\begin{aligned}
\alpha(Y \mid Y \geq 3) &= \mathbb{P}[r_1 = 1] + \mathbb{P}[r_1 = 2] + \sum_{t=3}^{Y} \mathbb{P}[r_1 = t]\,\mathbb{P}[r_j = 1 \mid r_1 = t] \\
&= \frac{2}{Y} + \sum_{t=3}^{Y} \frac{\mathbb{P}[r_z = 1 \mid r_1 = t]}{Y} = \frac{1}{Y}\left(2 + \sum_{t=3}^{Y} \mathbb{P}[r_z = 1 \mid r_1 = t]\right) \\
&= \frac{1}{Y}\left(2 + \sum_{t=3}^{Y} \frac{1}{t-1}\right) = \frac{1}{Y}\left(1 + \sum_{t=1}^{Y-1} \frac{1}{t}\right) \\
&= \frac{1}{Y}(1 + H_{Y-1}),
\end{aligned}$$

where H_n denotes the nth harmonic number. Recall also that $\alpha(Y \mid Y = 1) = \alpha(Y \mid Y = 2) = 1$.

Next, we estimate $\mathbb{P}[Y = i]$, by approximating Y with a Poisson distribution via Le Cam's theorem. Let $\delta_i = \left|\binom{n}{i}p^i(1-p)^{n-i} - e^{-np}\frac{(np)^i}{i!}\right|$. The idea is to set p such that $np = q$, where $q \geq 1$ is a fixed constant. We know that $\mathbb{P}[Y = i] = \binom{n}{i}p^i(1-p)^{n-i}$, and thus, by Theorem 3.12, we have

$$\sum_{i=0}^{\infty}\delta_i = \sum_{i=0}^{\infty}\left|\mathbb{P}[Y = i] - e^{-np}\frac{(np)^i}{i!}\right| = \sum_{i=0}^{\infty}\left|\mathbb{P}[Y = i] - e^{-q}\frac{(q)^i}{i!}\right| \leq \frac{2qp}{\max\{1,q\}} \leq 2p = \frac{2q}{n}.$$

Overall, the probability that $\mathcal{A}$ selects Z is

$$\begin{aligned}
\alpha(Y) &= \sum_{i=0}^{n}\mathbb{P}[Y = i]\cdot\alpha(Y \mid Y = i) \\
&= \mathbb{P}[Y = 1] + \sum_{i=2}^{n}\mathbb{P}[Y = i]\cdot\alpha(Y \mid Y = i) \\
&\geq np(1-p)^{(n-1)} + \sum_{i=2}^{n}\left(e^{-q}\frac{q^i}{i!} - \delta_i\right)\cdot\alpha(Y \mid Y = i),
\end{aligned}$$

where the last inequality follows by the definition of δ_i. Thus,

$$\begin{aligned}
\alpha(Y) &= q(1-q/n)^{(n-1)} + \sum_{i=2}^{n} e^{-q}\frac{q^i}{i!}\cdot\alpha(Y \mid Y = i) - \sum_{i=2}^{n}\delta_i\cdot\alpha(Y \mid Y = i) \\
&\geq q(1-q/n)^{(n-1)} + \sum_{i=2}^{n} e^{-q}\frac{q^i}{i!}\frac{1 + H_{i-1}}{i} - \sum_{i=2}^{n}\delta_i \\
&\geq q(1-q/n)^{(n-1)} + e^{-q}\sum_{i=2}^{n}\frac{q^i(1 + H_{i-1})}{i!\cdot i} - \frac{2q}{n}. \qquad (4.1)
\end{aligned}$$

◀

It is easy to see that simply setting $q = 2$, which corresponds to $p = 2/n$ and τ being the $2/n$th quantile of $\mathcal{D}$, yields $\alpha(Y) > 0.5801$ for all $n \geq 20$. Thus, our simple single-threshold algorithm, augmented with a single oracle call, beats, even for small n, the optimal algorithm for the IID prophet inequality which uses different thresholds per distribution and achieves a probability of success approximately 0.5801 [12].

Since the worst-case probability of ≈ 0.5801 by [12] is achieved for $n \to \infty$, one might be interested in the asymptotic behavior of the probability of our algorithm, $\alpha(Y)$, for large n. It is not too difficult to see after some calculations that, as $n \to \infty$, Eq. (4.1) is maximized for $q \approx 2.435$, yielding $\alpha(Y) \approx 0.798$.

4.2 A single-threshold algorithm for general m

As we saw in the previous section, even for a simple, single-threshold algorithm, the analysis of the winning probability gets tedious quickly. In this section, we generalize our single-threshold algorithm to the case of general m, and use the fact that the maximum of a uniformly random permutation of n values changes $\mathcal{O}(\log n)$ times with high probability to obtain a guarantee on the winning probability that is super-exponential with respect to m.

As before, our algorithm selects a threshold τ such that $p = \mathbb{P}[X \geq \tau]$ and every time the algorithm observes a realization above τ, it uses an oracle query and asks $\mathcal{O}$ if the realization should be selected or not. If not, then it updates the threshold to the new higher value. If the algorithm runs out of oracle calls, then it selects the first element above the current threshold τ that is encounters, if any. In other words, the algorithm uses the oracle calls greedily for all realizations above τ.

▶ **Theorem 1.9** (see [13] for proof). *For sufficiently large m, n, there exists an algorithm for the $\mathcal{M}(\mathcal{O}_m, \mathit{IID}, \mathbb{P}_{\max})$ model that selects the maximum realization with probability at least $1 - \mathcal{O}\big(m^{-m/5}\big)$.*

4.3 An (almost) tight upper bound

Given that we have a simple, single-threshold algorithm for the $\mathcal{M}(\mathcal{O}_m, \mathsf{IID}, \mathbb{P}_{\max})$ setting, a reasonable question to ask is how far it is from being optimal. As we show in this section, the algorithm is asymptotically almost optimal.

▶ **Theorem 1.10** (see [13] for proof). *There exists an instance of $\mathcal{M}(\mathcal{O}_m, \mathit{IID}, \mathbb{P}_{\max})$ for which no algorithm can select the maximum realization with probability greater than $1 - \mathcal{O}(m^{-m})$.*

5 Conclusion

In this work, we improved on the known results for the Top-1-of-m model, for both the RoE and $\mathbb{P}_{\max}$ objectives, via the lens of a simple prophet inequality augmented with oracle calls. All our results hold with respect to the strongest possible adversary, the almighty adversary. A weaker, offline, adversary is forced to select the order of distributions upfront, given only access to the same information as the algorithm. For such an adversary, one can do very slightly better than Theorem 1.8 – see the full version [13] for more details.

Our oracle choice was motivated by our efforts to reformulate the Top-1-of-m model in order to improve upon the current known bounds. We mention a few other oracle models that are interesting and could potentially be useful in analyzing other prophet inequality settings: (i) the oracle can predict a *range* for the maximum value, but formalizing this in a more general setting turns out to be difficult without assuming something about the

support of each random variable, (*ii*) the algorithm can ask the oracle if there is a value that is greater than $c \cdot X_i$, for some constant c. This latter oracle is more powerful, as it doesn't exhibit the same limitations that our oracle model has in the example of Theorem 1.8. We leave exploring more complex oracle models for future work.

Finally, there are subtle differences between an oracle that answers queries of the form $X_i > \max\{X_{i+1}, \ldots, X_n\}$ and one that answers queries of the form $X_i \geq \max\{X_{i+1}, \ldots, X_n\}$; in particular, the $>$ oracle is weaker than the $\geq$ oracle. We refer the reader to the full version [13] for a discussion on this topic.

Abstract

The log-rank conjecture, a longstanding problem in communication complexity, has persistently eluded resolution for decades. Consequently, some recent efforts have focused on potential approaches for establishing the conjecture in the special case of XOR functions, where the communication matrix is lifted from a boolean function, and the rank of the matrix equals the Fourier sparsity of the function, which is the number of its nonzero Fourier coefficients.

In this note, we refute two conjectures. The first has origins in Montanaro and Osborne (arXiv'09) and is considered in Tsang, Wong, Xie, and Zhang (FOCS'13), and the second is due to Mande and Sanyal (FSTTCS'20). These conjectures were proposed in order to improve the best-known bound of Lovett (STOC'14) regarding the log-rank conjecture in the special case of XOR functions. Both conjectures speculate that the set of nonzero Fourier coefficients of the boolean function has some strong additive structure. We refute these conjectures by constructing two specific boolean functions tailored to each.

1 Introduction

The study of communication complexity seeks to determine the inherent amount of communication between multiple parties required to complete a computational task. Arguably, the most outstanding conjecture in the field is the *log-rank conjecture* of Lovász and Saks [4]. They suggest that the (deterministic) communication complexity of a two-party boolean function is upper bounded by the matrix rank over $\mathbb{R}$. More precisely,

▶ **Conjecture 1** (Log-rank conjecture [4]). *Let $f : X \times Y \to \{-1, 1\}$ be an arbitrary two-party boolean function. Then,*

$$\mathrm{CC}(f) \leq \mathrm{polylog}(\mathrm{rank}(f)),$$

where $\mathrm{CC}(f)$ is the communication complexity of f and $\mathrm{rank}(f)$ is the rank over $\mathbb{R}$ of the corresponding boolean matrix.

It is well-known that $\log(\mathrm{rank}(f)) \leq \mathrm{CC}(f)$ [7], so a positive resolution to Conjecture 1 would imply that the communication complexity of two-party boolean functions is determined by rank, up to polynomial factors.

To date, the best known bound is still exponentially far from that in Conjecture 1. Concretely, Lovett [5] showed that $\mathrm{CC}(f) \leq O(\sqrt{\mathrm{rank}(f)} \log \mathrm{rank}(f))$. Very recently, Sudakov and Tomon posted a preprint improving the bound to $O(\sqrt{\mathrm{rank}(f)})$ [13]. In hopes of gaining further insight, many researchers have considered the special case of *XOR functions*, where $f_\oplus(x, y) \coloneqq f(x + y)$ for a boolean function $f : \mathbb{F}_2^n \to \{-1, 1\}$ [8, 15, 14, 12, 2, 6].

The XOR setting has several convenient properties. For example, the eigenvalues of $f_\oplus$ correspond to the Fourier coefficients of f. Thus, $\mathrm{rank}(f_\oplus) = |\mathrm{supp}(\widehat{f})|$, the number of nonzero coefficients in f's Fourier expansion (also known as the *Fourier sparsity*). Additionally, Hatami, Hosseini, and Lovett [2] proved a polynomial equivalence between $\mathrm{CC}(f_\oplus)$ and the *parity decision tree* complexity of f, denoted $\mathrm{PDT}(f)$. Parity decision trees are defined similarly to standard decision trees, with the extra power that each node can query an arbitrary parity of input bits. These facts together imply that the log-rank conjecture for XOR functions can be restated as follows:

▶ **Conjecture 2** (XOR log-rank conjecture). *Let $f : \mathbb{F}_2^n \to \{-1, 1\}$. Then,*

$$\mathrm{PDT}(f) \leq \mathrm{polylog}(|\mathrm{supp}(\widehat{f})|).$$

The best known bound, due to [14, 12], is $\mathrm{PDT}(f) \leq O(\sqrt{|\mathrm{supp}(\widehat{f})|})$, a mere log-factor improvement on the general case bound by Lovett [5], and matched by the recent bound of Sudakov and Tomon [13].

1.1 Folding

Folding is a fundamental concept in the analysis of the additive structure of a function's Fourier support. Let

$$\mathcal{S} = \mathrm{supp}(\widehat{f}) = \{\gamma \in \mathbb{F}_2^n : \widehat{f}(\gamma) \neq 0\} \quad \text{and} \quad \mathcal{S} + \gamma = \{s + \gamma : s \in \mathcal{S}\}.$$

If $(s_1, s_2), (s_3, s_4) \in \binom{\mathcal{S}}{2}$ satisfy $s_1 + s_2 = s_3 + s_4 = \gamma$, we say the pairs (s_1, s_2) and (s_3, s_4) *fold* in the direction γ.

Analyzing folding directions is useful in constructing efficient PDTs in the context of Conjecture 2. In particular, when a function f is restricted according to the result of some parity query γ, all pairs of elements in $\mathcal{S}$ that fold in the direction γ collapse to a single term in the restricted function $f|_\gamma$'s Fourier support. Iterating this process until the restricted function is constant yields a PDT whose depth depends on the number of iterations performed and, thus, on the size of the folding directions queried. Indeed, this is the general strategy used to prove the aforementioned closest result to Conjecture 2 [14, 12].

1.2 Refuting a greedy approach

An approach dating back to [8] seeks to prove Conjecture 2 through the existence of a single large folding direction. They conjectured that there always exists γ_1, γ_2 such that $|(\mathcal{S}+\gamma_1)\cap(\mathcal{S}+\gamma_2)| \geq |\mathcal{S}|/K$ for some constant $K > 1$. This yields the following $O(\log|\mathcal{S}|)$-rounds greedy approach: query $\gamma_1+\gamma_2$ and consider the function restricted to the query response. This restriction decreases the Fourier sparsity by a constant factor, so the function must become constant in $O(\log|\mathcal{S}|)$ rounds. This implies the strong upper bound of

$$\mathrm{PDT}(f) \leq O\left(\log|\mathcal{S}|\right).$$

However, O'Donnell, Wright, Zhao, Sun, and Tan [10] constructed a function with communication complexity $\Omega(\log(|\mathcal{S}|)^{\log_3(6)})$; hence one can not take K to be a constant. Yet to prove the log-rank conjecture, it suffices to take $K = O(\mathrm{polylog}(|\mathcal{S}|))$, and this choice of K remained plausible up to date. Such an approach is mentioned in both [14] and [6], and a similar approach was used to verify the log-rank conjecture for many cases of functions lifted with AND (rather than XOR) gadgets [3]. We strongly refute this conjecture.

▶ **Theorem 3** (Informal version of Theorem 8). *For infinitely many n, there is a function $f:\mathbb{F}_2^n \to \{-1,1\}$ such that for $\mathcal{S} = \mathrm{supp}(\widehat{f})$, it holds*

$$|(\mathcal{S}+\gamma_1)\cap(\mathcal{S}+\gamma_2)| \leq O\left(|\mathcal{S}|^{5/6}\right)$$

for all distinct $\gamma_1, \gamma_2 \in \mathbb{F}_2^n$.

▶ Remark 4. Observe that this theorem implies the greedy method cannot obtain a bound better than $\mathrm{PDT}(f) = \widetilde{O}(|\mathcal{S}|^{1/6})$. In fact, a more careful analysis can rule out bounds better than $\mathrm{PDT}(f) = \widetilde{O}(|\mathcal{S}|^{1/5})$ (see Remark 15).

The functions used in Theorem 3 are a variant of the addressing function using disjoint (affine) subspaces. While we believe the specific construction is novel, the concept of using functions defined with disjoint subspaces has previously appeared in the literature in this context. Most notably, Chattopadhyay, Garg, and Sherif used XOR functions based on this idea in the pursuit of stronger counterexamples to a more general version of the log-rank conjecture [1].

1.3 Refuting a randomized approach

Rather than simply looking for a large folding direction, a recent work of Mande and Sanyal [6] attempts to address Conjecture 2 through a deeper understanding of the additive structure of the spectrum of boolean functions. They proposed the following conjecture on the number of nontrivial folding directions, and showed it would yield a polynomial improvement to the state-of-the-art upper bound for the XOR log-rank conjecture via a randomized approach.

▶ **Conjecture 5** ([6]). *There are constants $\alpha, \beta \in (0,1)$ such that for every boolean function $f:\mathbb{F}_2^n \to \{-1,1\}$, for $\mathcal{S} = \mathrm{supp}(\widehat{f})$, it holds*

$$\Pr_{\gamma_1,\gamma_2\in\mathcal{S}}\left[|(\mathcal{S}+\gamma_1)\cap(\mathcal{S}+\gamma_2)| > |\mathcal{S}|^{\beta}\right] \geq \alpha.$$

In fact, Mande and Sanyal conjectured that one can take $\beta = \frac{1}{2} - o(1)$. The conjecture might seem plausible given the numerous results on the additive structure of the spectrum of boolean functions. However, we strongly refute it, as well:

▶ **Theorem 6** (Informal version of Theorem 16). *For infinitely many n, there is a function $f : \mathbb{F}_2^n \to \{-1, 1\}$ such that for $\mathcal{S} = \mathrm{supp}(\widehat{f})$, it holds*

$$\Pr_{\gamma_1,\gamma_2 \in \mathcal{S}}[|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)| > k] = O(1/k) \qquad \forall k \geq 1.$$

Overview

Some preliminary material is reviewed in Section 2. We prove more precise versions of Theorem 3 in Section 3 and Theorem 6 in Section 4. Section 5 contains some final thoughts.

2 Preliminaries

Communication complexity

Let $f : X \times Y \to \{-1, 1\}$ be an arbitrary function. Additionally, assume two parties are given an element $x \in X$ and $y \in Y$, respectively, which the other party cannot see. The (deterministic) *communication complexity of* f, denoted $\mathrm{CC}(f)$, is the minimum number of bits over all assignments (x, y) needed to be exchanged in order to evaluate f, where the parties may decide on a strategy prior to receiving their inputs.

One can view such a function as an $X \times Y$ matrix, where the (x, y) entry takes the value $f(x, y)$. Thus, it is natural to consider the relationship between linear algebraic measures, such as matrix rank, and communication complexity, as in Conjecture 1. For a more thorough treatment of communication complexity, see the excellent book [11].

Decision trees

Decision trees are simple models of computation. The (deterministic) decision tree *depth* of a function $f : \mathbb{F}_2^n \to \{-1, 1\}$ is the maximum over all inputs $x \in \mathbb{F}_2^n$ of the fewest number of input bits one must query to correctly evaluate $f(x)$.

Parity decision trees (PDTs) extend the power of "traditional" decision trees by allowing queries to return the sum modulo two of an arbitrary subset of the bits. They are particularly relevant in the study of communication complexity, since for functions of the form $f_{\oplus}(x, y) = f(x + y)$ for $f : \mathbb{F}_2^n \to \{-1, 1\}$, the parity decision tree depth and communication complexity are equivalent (up to polynomial factors) [2].

Boolean analysis

Every function $f : \mathbb{F}_2^n \to \mathbb{R}$ has a unique *Fourier expansion*

$$f = \sum_{\alpha \in \mathbb{F}_2^n} \widehat{f}(\alpha)\chi_\alpha,$$

where

$$\chi_\alpha(x) = (-1)^{\langle x,\alpha \rangle} \quad \text{and} \quad \widehat{f}(\alpha) = \langle f, \chi_\alpha \rangle = \mathbb{E}_{x \in \mathbb{F}_2^n}[f(x)\chi_\alpha(x)].$$

The set $\mathrm{supp}(\widehat{f}) = \{\alpha \in \mathbb{F}_2^n : \widehat{f}(\alpha) \neq 0\}$ is the *Fourier support*, occasionally denoted $\mathcal{S}$. Its size $|\mathrm{supp}(\widehat{f})|$ is the *Fourier sparsity*. In light of Conjecture 2, we are primarily interested in the relationship between a function's Fourier sparsity and parity decision tree depth.

In general, a vast array of information about a function can be learned from its Fourier expansion, and we direct readers to the standard text [9] for additional background. For our purposes, we will only require the following simple fact. Let $V^\perp = \{w : \langle w, v \rangle = 0 \text{ for all } v \in V\}$ be the orthogonal complement of a subspace V.

▶ **Proposition 7** (See e.g., [9, Proposition 3.12]). *If $A = V + v \subseteq \mathbb{F}_2^n$ is an affine subspace of codimension k, then*

$$\mathbb{1}_A = \sum_{\alpha \in V^\perp} 2^{-k} \chi_\alpha(v) \chi_\alpha.$$

3 One excellent folding direction

A large folding direction implies the existence of a parity query whose answer substantially simplifies the resulting restricted function. This suggests the following greedy approach to resolve the XOR log-rank conjecture: if we can always find distinct γ_1, γ_2 such that $|(\mathcal{S} + \gamma_1) \cap (S + \gamma_2)| \geq \Omega(|\mathcal{S}| \,/\, \mathrm{polylog}(|\mathcal{S}|))$, then querying $\gamma_1 + \gamma_2$ and recursing on the appropriate restriction of f will force f to be constant in $\mathrm{polylog}(|\mathcal{S}|)$ rounds.

We refute this strategy by proving a precise version of Theorem 3.

▶ **Theorem 8.** *For $n = 2^k + 7k$ with $k \in \mathbb{N}^{\geq 3}$, there is a function $f : \mathbb{F}_2^n \to \{-1, 1\}$ such that for $\mathcal{S} = \mathrm{supp}(\widehat{f})$, it holds $|\mathcal{S}| \geq 2^{6k}$, and yet $|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)| \leq 2^{5k+4}$ for all distinct $\gamma_1, \gamma_2 \in \mathbb{F}_2^n$.*

To build intuition for our construction, we first consider the standard addressing function.

▶ **Example 9** (Addressing). Define $f : \mathbb{F}_2^{k+2^k} \to \{-1, 1\}$ by

$$f(x, y) = (-1)^{y_x} = \sum_{z \in \mathbb{F}_2^k} \mathbb{1}_z(x) \cdot (-1)^{y_z},$$

where $x \in \mathbb{F}_2^k$ and $y \in \mathbb{F}_2^{2^k}$ (and slightly abusing notation by indexing y with vectors).

A greedy approach is sufficient for a PDT to evaluate this function. Simply query each address bit, then the corresponding addressed bit. Each query eliminates half of the remaining possible address values, so the PDT has depth $k + 1$, while the function's sparsity is exponential in k. To modify the function to prevent this approach, we encode the address using subspaces to obfuscate it while maintaining Fourier sparsity.

▶ **Example 10** (Subspace addressing). Let $A_1, \ldots, A_{2^k} \subset \mathbb{F}_2^{7k}$ be disjoint affine subspaces of dimension $2k$. Define $f : \mathbb{F}_2^{7k+2^k} \to \{-1, 1\}$ by

$$f(x, y) = \begin{cases} (-1)^{y_i} & x \in A_i \\ 1 & x \notin A_1 \cup \cdots \cup A_{2^k} \end{cases},$$

where $x \in \mathbb{F}_2^{7k}$ and $y \in \mathbb{F}_2^{2^k}$.

We choose A_i's randomly and show that the resulting function f has the suitable properties we need with high probability.

▶ **Lemma 11.** *Suppose the random function f is constructed by picking random affine subspaces $A_1, \cdots, A_{2^k} \subset \mathbb{F}_2^{7k}$ as follows: for each $i \in [2^k]$, choose vectors $a_i, v_i^1, \cdots, v_i^{2k} \in \mathbb{F}_2^{7k}$ uniformly and independently, and let $V_i = \langle v_i^1, \cdots, v_i^{2k} \rangle$ and $A_i = V_i + a_i$. Then with probability $1 - 2^{-k+2}$, all of the following hold:*

(a) *$\forall i$, $\dim(V_i) = 2k$.*
(b) *$\forall i \neq j$, $A_i \cap A_j = \emptyset$.*
(c) *$\forall i \neq j$, $V_i \cap V_j = \{0\}$.*
(d) *For all nonzero $v \in \mathbb{F}_2^{7k}$, $|\{i : v \in V_i^\perp\}| \leq 7$.*

Proof. For brevity, let $m = 7k$.

(a) Fix $i \in [2^k]$. The probability that vectors $v_i^1, \cdots, v_i^{2k}$ are linearly independent is at least

$$\frac{2^m-1}{2^m} \cdot \frac{2^m-2}{2^m} \cdot \frac{2^m-2^2}{2^m} \cdot \cdots \cdot \frac{2^m-2^{2k-1}}{2^m} \geq (1-2^{2k-m})^m \geq 1 - m2^{2k-m}.$$

Hence the probability that there is $i \in [2^k]$ for which $v_i^1, \cdots, v_i^{2k}$ are not linearly independent is at most $m2^{3k-m} = 7k2^{-4k} \leq 2^{-k}$.

(b) Fix $i \neq j$. The probability that $A_i \cap A_j \neq \emptyset$ is at most $2^{2k}2^{2k-m} = 2^{4k-m}$. Hence, the probability that there are $i \neq j$ with $A_i \cap A_j \neq \emptyset$ is at most $2^{2k}2^{4k-m} = 2^{-k}$.

(c) Fix $i \neq j$. The probability that $V_i \cap V_j \neq \{0\}$ is at most $(2^{2k}-1)2^{2k-m} \leq 2^{4k-m}$. Hence, the probability that there are $i \neq j$ with $V_i \cap V_j \neq \emptyset$ is at most $2^{2k}2^{4k-m} = 2^{-k}$.

(d) The probability that a fixed nonzero vector $v \in \mathbb{F}_2^{7k}$ is orthogonal to at least t subspaces among $V_1, \cdots, V_{2^k}$ is at most $\binom{2^k}{t}2^{-2tk} \leq 2^{-tk}$. Taking $t = 8$ and union bounding over all $2^{7k}-1$ options for v shows that the probability that there is v for which $|\{i : v \in V_i^\perp\}| \geq 8$ is at most 2^{-k}.

By the union bound, the probability that any of items (a) to (d) are not satisfied is at most $4 \cdot 2^{-k} = 2^{-k+2}$. ◀

We will assume from now on that f is chosen randomly so that Lemma 11 holds, and set $\mathcal{S} = \mathrm{supp}(\widehat{f})$. It remains to prove there is no large folding direction. First, we give a lower bound on the size of Fourier support of f.

▷ Claim 12. $|\mathcal{S}| \geq 2^{6k}$.

Proof. We can express f as

$$\begin{aligned} f(x,y) &= \mathbb{1}_{(A_1 \cup \cdots \cup A_{2^k})^c}(x) + \sum_{i=1}^{2^k} \mathbb{1}_{A_i}(x) \cdot (-1)^{y_i} \\ &= 1 - \sum_{i=1}^{2^k} \mathbb{1}_{A_i}(x) + \sum_{i=1}^{2^k} \mathbb{1}_{A_i}(x) \cdot (-1)^{y_i} \\ &= 1 + \sum_{i=1}^{2^k} \mathbb{1}_{A_i}(x) \cdot ((-1)^{y_i} - 1). \end{aligned}$$

By Proposition 7, the Fourier support of the function $\mathbb{1}_{A_i}(x)$ is $V_i^\perp \subset \mathbb{F}_2^{7k}$, and of $\mathbb{1}_{A_i}(x) \cdot (-1)^{y_i}$ is $V_i^\perp + e_i$, where e_i is the i-th basis vector in the standard basis for $\mathbb{F}_2^{2^k}$ embedded in the space $\mathbb{F}_2^{7k} \times \mathbb{F}_2^{2^k}$. Since the affine subspaces $V_i^\perp + e_i$ are disjoint and also $\left(V_i^\perp + e_i\right) \cap \left(V_i^\perp\right) = \emptyset$ the coefficients of characters in $V_i^\perp + e_i$ will not be canceled. Hence, we get that

$$\bigcup_{i=1}^{2^k} \left(V_i^\perp + e_i\right) \subset \mathcal{S}$$

and so $|\mathcal{S}| \geq 2^k \cdot 2^{7k-2k} = 2^{6k}$. ◁

We also need the following claim.

▷ Claim 13. Suppose $W_1, W_2 \subset \mathbb{F}_2^n$ are two linear subspaces such that $W_1 \cap W_2 = \{0\}$. Then for all $x \in \mathbb{F}_2^n$,

$$|W_1^\perp \cap (W_2^\perp + x)| = 2^{n - \dim W_1 - \dim W_2}.$$

Proof. Suppose $\dim(W_1) = d_1$ and $\dim(W_2) = d_2$. Without loss of generality, assume that $W_1 = \mathbb{F}_2^{d_1} \times 0^{d_2} \times 0^{n-d_1-d_2}$ and $W_2 = 0^{d_1} \times \mathbb{F}_2^{d_2} \times 0^{n-d_1-d_2}$. Note that $W_1^\perp = 0^{d_1} \times \mathbb{F}_2^{d_2} \times \mathbb{F}_2^{n-d_1-d_2}$ and $W_2^\perp = \mathbb{F}_2^{d_1} \times 0^{d_2} \times \mathbb{F}_2^{n-d_1-d_2}$. Pick an arbitrary $x = (x_1, x_2, x_3) \in \mathbb{F}_2^{d_1} \times \mathbb{F}_2^{d_2} \times \mathbb{F}_2^{n-d_1-d_2}$. Then $W_2^\perp + (x_1, x_2, x_3) = \mathbb{F}_2^{d_1} \times \{x_2\} \times \mathbb{F}_2^{n-d_1-d_2}$ and $W_1^\perp \cap (W_2^\perp + x) = 0^{d_1} \times \{x_2\} \times \mathbb{F}_2^{n-d_1-d_2}$ has the claimed size. ◁

Finally, Theorem 8 follows from claim below.

▷ Claim 14. For all distinct $\gamma_1, \gamma_2 \in \mathbb{F}_2^{7k+2^k}$, we have

$$|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)| \leq 2^{5k+4}.$$

Proof. First, note that it suffices to prove the claim for all distinct $\gamma_1, \gamma_2 \in \mathcal{S}$, since if $s_1 + \gamma_1 = s_2 + \gamma_2$ for $s_1, s_2 \in \mathcal{S}$, it must be that $\gamma_1 + \gamma_2 = s_1 + s_2 \in \mathcal{S} + \mathcal{S}$. Pick an arbitrary non-zero $\gamma = \gamma_1 + \gamma_2$ for $\gamma_1, \gamma_2 \in \mathcal{S}$. Remember that

$$|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)| = |\mathcal{S} \cap (\mathcal{S} + \gamma)| \quad \text{and} \quad \mathcal{S} \subseteq \left(\bigcup_{i=1}^{2^k} V_i^\perp \right) \cup \left(\bigcup_{i=1}^{2^k} (V_i^\perp + e_i) \right).$$

Hence $\mathcal{S} \cap (\mathcal{S} + \gamma) \subseteq A \cup B \cup C$, where

$$A = \bigcup_{i,j} \left(V_i^\perp \cap (V_j^\perp + \gamma) \right)$$
$$B = \bigcup_{i,j} \left(V_i^\perp \cap (V_j^\perp + e_j + \gamma) \right)$$
$$C = \bigcup_{i,j} \left((V_i^\perp + e_i) \cap (V_j^\perp + e_j + \gamma) \right).$$

Let $|\cdot|$ denote the Hamming weight of a vector. Decompose $\gamma = (\gamma_x, \gamma_y)$ where $\gamma_x \in \mathbb{F}_2^{7k}$ and $\gamma_y \in \mathbb{F}_2^{2^k}$. Observe that $|\gamma_y| \leq 2$, since (as noted above) we may assume $\gamma \in \mathcal{S} + \mathcal{S}$ without loss of generality.

Case 1: $|\gamma_y| = 0$.

Note that in this case $B = \emptyset$ and $C = \bigcup_i \left((V_i^\perp + e_i) \cap (V_i^\perp + e_i + \gamma_x) \right)$. Overall, we get

$$\begin{aligned}
|\mathcal{S} \cap (\mathcal{S} + \gamma_x)| &\leq \left| \bigcup_{i,j} \left(V_i^\perp \cap (V_j^\perp + \gamma_x) \right) \right| + \left| \bigcup_i \left((V_i^\perp + e_i) \cap (V_i^\perp + e_i + \gamma_x) \right) \right| \\
&= \left| \bigcup_{i,j} \left(V_i^\perp \cap (V_j^\perp + \gamma_x) \right) \right| + \left| \bigcup_i \left(V_i^\perp \cap (V_i^\perp + \gamma_x) \right) \right| \\
&\leq \sum_{i \neq j} |V_i^\perp \cap (V_j^\perp + \gamma_x)| + 2 \sum_i |V_i^\perp \cap (V_i^\perp + \gamma_x)| \\
&\leq \sum_{i \neq j} |V_i^\perp \cap (V_j^\perp + \gamma_x)| + 2 \cdot 2^{5k} \cdot |\{i : \gamma_x \in V_i^\perp\}|.
\end{aligned}$$

To bound the first term, note that $V_i \cap V_j = \{0\}$ for all $i \neq j$ (by item (c) of Lemma 11). Using Claim 13 we have that $|V_i^\perp \cap (V_j^\perp + \gamma_x)| = 2^{7k - \dim(V_i) - \dim(V_j)} = 2^{7k-2k-2k} = 2^{3k}$. To bound the second term, by item (d) of Lemma 11, we have that $|\{i : \gamma_x \in V_i^\perp\}| \leq 7$. Overall, we get that

$$|\mathcal{S} \cap (\mathcal{S} + \gamma)| \leq 2^{2k} \cdot 2^{3k} + 7 \cdot 2^{5k+1} \leq 2^{5k+4}.$$

Case 2: $|\gamma_y| = 1$. Suppose $\gamma_y = e_i$ for some i.

In this case, $A = C = \emptyset$ and $B = V_i^\perp \cap (V_i^\perp + e_i + \gamma_y)$. Hence,

$$|\mathcal{S} \cap (\mathcal{S} + \gamma)| \leq |V_i^\perp \cap (V_i^\perp + e_i + \gamma_y)| \leq |V_i^\perp| = 2^{5k},$$

Case 3: $|\gamma_y| = 2$. This is similar to Case 2. ◀

▶ Remark 15. We have chosen parameters for simplicity of exhibition; however, by choosing the original disjoint affine subspaces from $\mathbb{F}_2^{(6+\varepsilon)k}$ rather than $\mathbb{F}_2^{7k}$, a similar analysis rules out any bounds stronger than $\mathrm{PDT}(f) = \widetilde{O}(|\mathcal{S}|^{1/5})$ resulting from this greedy method.

4 Many good folding directions

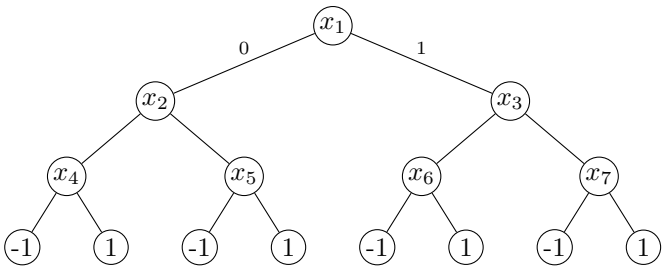
Rather than hoping for one large folding direction, [6] sought many nontrivial ones. In this section, we refute their conjecture (Conjecture 5) with the following quantified version of Theorem 6.

▶ **Theorem 16.** *For $n = 2^d - 1$ with $d \in \mathbb{N}$, there is a function $f : \mathbb{F}_2^n \to \{-1, 1\}$ such that for $\mathcal{S} = \mathrm{supp}(\widehat{f})$, it holds*

$$\Pr_{\gamma_1, \gamma_2 \in \mathcal{S}} \left[|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)| \geq 2^{k+2} \right] \leq 2^{-k} + 2^{1-d} \qquad \forall k \geq 1.$$

In our construction, $|\mathcal{S}| = \mathrm{poly}(n)$, which is the primary regime of interest. For larger $\mathcal{S}$, say of size $|\mathcal{S}| = \exp(n^c)$ for some constant $c > 0$, the log-rank conjecture is trivially true, since $n < \mathrm{polylog}(|\mathcal{S}|)$.

Let T be a full binary decision tree of depth d. There are $n = 2^d - 1$ internal nodes indexed by $[2^d - 1]$, where we query (distinct) x_i at node i. Each of the largest depth internal nodes v is adjacent to two leaves: -1 and 1, corresponding to $v = 0$ and $v = 1$, respectively. Let $f : \mathbb{F}_2^n \to \{-1, 1\}$ be the resulting function. For example, the following decision tree corresponds to f for $n = 7$.



As we will soon show, the Fourier support of f corresponds to (subsets of) paths down the tree, where $|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)|$ is determined by the lowest common ancestor of the paths of γ_1 and γ_2. Since it is overwhelmingly likely the two paths will quickly diverge, we find $|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)|$ is typically small.

Suppose the leaves are indexed by $[2^d]$. Then f can be written as

$$\sum_{i \in [2^d]} \mathrm{sign}(L_i) \cdot \mathbb{1}_{L_i}, \tag{1}$$

where $\mathbb{1}_{L_i}$ denotes the indicator function of the inputs that result in leaf i, and $\mathrm{sign}(L_i) \in \{-1, 1\}$ is the output at leaf i. Let P_i be the ordered set of coordinates that are queried to reach the leaf i. Then for input $x = (x_1, \ldots, x_n) \in \mathbb{F}_2^n$, we can write

$$\mathbb{1}_{L_i}(x) = \prod_{t \in P_i} \left(\frac{1 + (-1)^{a_t + x_t}}{2} \right) = \frac{1}{2^d} \left(\sum_{P \subseteq P_i} (-1)^{\sum_{j \in P} a_j} \cdot (-1)^{\sum_{j \in P} x_j} \right),$$

where $a_t \in \mathbb{F}_2$ is the output of node t on the path P_i.

To find the Fourier support $\mathcal{S} = \mathrm{supp}(\widehat{f})$, it remains to determine which terms "survive" cancellation in Equation (1). Let $\mathcal{N}(i)$ be the index of the internal node adjacent to leaf i. Observe that when $\mathcal{N}(i) = \mathcal{N}(j)$ for $i \neq j$ (so $\mathrm{sign}(L_i) = -\mathrm{sign}(L_j)$),

$$\begin{aligned} 2^d(\mathrm{sign}(L_i) \cdot \mathbb{1}_{L_i}(x) + \mathrm{sign}(L_j) \cdot \mathbb{1}_{L_j}(x)) &= \mathrm{sign}(L_i) \sum_{P \subseteq P_i} (-1)^{\sum_{t \in P} a_t} \cdot (-1)^{\sum_{t \in P} x_t} \\ &\quad - \mathrm{sign}(L_i) \sum_{P \subseteq P_j} (-1)^{\sum_{t \in P} a_t} \cdot (-1)^{\sum_{t \in P} x_t} \\ &= 2 \cdot \mathrm{sign}(L_i) \cdot \sum_{P \subseteq P_i \,:\, \mathcal{N}(i) \in P} (-1)^{\sum_{t \in P} a_t} \cdot (-1)^{\sum_{t \in P} x_t}, \end{aligned}$$

since $x_{\mathcal{N}(i)}$ is the only x value that P_i and P_j disagree on. That is, each term in f's expansion must contain $\mathcal{N}(i)$ for some i. Moreover, once these cancellations are made, $\mathbb{1}_{L_i}$ does not interact with $\mathbb{1}_{L_j}$ for $\mathcal{N}(i) \neq \mathcal{N}(j)$, since no term can contain both $\mathcal{N}(i)$ and $\mathcal{N}(j)$. In summary,

$$\mathcal{S} = \bigcup_{i \in [2^d]} \{s : s \subseteq P_i \text{ and } \mathcal{N}(i) \in s\}.$$

Let $\gamma_1, \gamma_2 \in \mathcal{S}$. By our observation on the structure of $\mathcal{S}$, they have the form $\gamma_1 = \alpha_1 \dot\cup \{\mathcal{N}(i)\}$ and $\gamma_2 = \alpha_2 \dot\cup \{\mathcal{N}(j)\}$ for some $i, j \in [2^d]$. We are interested in the number of pairs $(\beta_1, \beta_2) \in \mathcal{S} \times \mathcal{S}$ such that $\gamma_1 + \gamma_2 = \beta_1 + \beta_2$. It will suffice to focus on the setting $\mathcal{N}(i) \neq \mathcal{N}(j)$ since this occurs with overwhelming probability. In this case, the quantity $|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)|$ depends only on the depth of the lowest common ancestor of P_i and P_j.

▷ Claim 17. If $|(\mathcal{S} + \gamma_1) \cap (\mathcal{S} + \gamma_2)| \geq 2^{k+2}$, then the lowest common ancestor of P_i and P_j is at depth at least k.

Proof. We will show the contrapositive. Suppose the lowest common ancestor a of P_i and P_j is at depth $\ell < k$, and suppose $\beta_1, \beta_2 \in \mathcal{S}$ satisfy $\beta_1 + \gamma_1 = \beta_2 + \gamma_2$. Without loss of generality, assume $\mathcal{N}(i) \in \beta_1$ and $\mathcal{N}(j) \in \beta_2$. Then β_1 and β_2 must be a subset of the elements in the paths P_i and P_j, respectively.

First, consider each element $E \in P_i \cap P_j$, which is all those above (and including) a. If $E \in \gamma_1 + \gamma_2$, then $E \in \beta_1 + \beta_2$ only if E is in precisely one of β_1, β_2. Likewise, if $E \notin \gamma_1 + \gamma_2$, then $E \notin \beta_1 + \beta_2$ only if E is in neither or both of β_1, β_2. In either case, we have two options for each E.

Now consider each element $E \in P_i$ below a. By assumption, $E \notin P_j$. Thus, if $E \in \gamma_1 + \gamma_2$, it must be that $E \in \gamma_1$ and $E \notin \gamma_2$. For $\beta_1 + \beta_2$ to contain E, we must likewise have $E \in \beta_1$ and $E \notin \beta_2$. Similarly, if $E \notin \gamma_1 + \gamma_2$, it cannot be in γ_1 or γ_2. Thus, it is not in β_1 or β_2 either. An identical argument for $E \in P_j$ shows that we only have one way to account for elements in the paths P_i or P_j below a.

Doubling to compensate for the cases where $\mathcal{N}(j) \in \beta_1$ and $\mathcal{N}(i) \in \beta_2$, we find the number of options for $(\beta_1, \beta_2) \in \mathcal{S} \times \mathcal{S}$ such that $\beta_1 + \gamma_1 = \beta_2 + \gamma_2$ is at most $2^{\ell+2} < 2^{k+2}$. ◁

Theorem 16 follows quickly from the claim. The probability that P_i and P_j have a common ancestor at depth at least k is at most 2^{-k}, so

$$\begin{aligned}
&\Pr_{\gamma_1,\gamma_2\in\mathcal{S}}\left[|(\mathcal{S}+\gamma_1)\cap(\mathcal{S}+\gamma_2)|\geq 2^{k+2}\right]\\
&\leq \Pr_{\gamma_1,\gamma_2\in\mathcal{S}}\left[|(\mathcal{S}+\gamma_1)\cap(\mathcal{S}+\gamma_2)|\geq 2^{k+2}\,\middle|\,\mathcal{N}(\gamma_1)\neq\mathcal{N}(\gamma_2)\right]+2^{1-d}\\
&\leq 2^{-k}+2^{1-d},
\end{aligned}$$

where we overload notation by letting $\mathcal{N}(\gamma)=\mathcal{N}(i)\in\gamma$.

5 Conclusion

While the provided functions rule out specific approaches, it is worth noting that neither are a counterexample to the log-rank conjecture. The subspace addressing function (Section 3) has a simple PDT: first individually query all $7k$ address bits, then query the bit to the corresponding subspace. Since the Fourier sparsity is at least 2^{6k}, this is certainly affordable. While this example refutes a general greedy approach, such an approach works for the decision tree function (Section 4). Each query of the root variable eliminates half the paths (and thus reduces the sparsity by two), so iterating this process quickly makes the function constant.

Abstract

This paper focuses on kernelization algorithms for the fundamental Knapsack problem. A kernelization algorithm (or kernel) is a polynomial-time reduction from a problem onto itself, where the output size is bounded by a function of some problem-specific parameter. Such algorithms provide a theoretical model for data reduction and preprocessing and are central in the area of parameterized complexity. In this way, a kernel for Knapsack for some parameter k reduces any instance of Knapsack to an equivalent instance of size at most $f(k)$ in polynomial time, for some computable function f. When $f(k) = k^{O(1)}$ then we call such a reduction a polynomial kernel.

Our study focuses on two natural parameters for Knapsack: The number $w_\#$ of different item weights, and the number $p_\#$ of different item profits. Our main technical contribution is a proof showing that Knapsack does not admit a polynomial kernel for any of these two parameters under standard complexity-theoretic assumptions. Our proof discovers an elaborate application of the standard kernelization lower bound framework, and develops along the way novel ideas that should be useful for other problems as well. We complement our lower bounds by showing that Knapsack admits a polynomial kernel for the combined parameter $w_\# \cdot p_\#$.

1 Introduction

This paper proves a new complexity-theoretic barrier for the classic Knapsack problem. Namely, we prove that Knapsack has no polynomial kernels when parameterized by either the number $w_\#$ of different weights, or the number $p_\#$ of different profits. Our results hold under the standard complexity-theoretic assumption NP $\not\subseteq$ coNP/poly. We also show that when both $w_\#$ and $p_\#$ are taken as a combined parameter, Knapsack does admit a polynomial kernel. Below we give a brief review of recent algorithmic progress for the

Knapsack problem, as well as a quick survey through kernelization and parameterized complexity. We then describe how our results fit into the current state of the art, and give an overview of the main techniques used for obtaining our new hardness result for Knapsack.

The Knapsack problem. Knapsack (also known as 0/1 Knapsack) is one the most fundamental and well studied problems in combinatorial optimization and theoretical computer science. In its most basic form, it is defined as follows:

Knapsack
Input: A set $\mathcal{X} = \{x_1, \ldots, x_n\}$ of n items, a weight function $w : \mathcal{X} \to \mathbb{N}$, a profit function $p : \mathcal{X} \to \mathbb{N}$, and two integers W and P.
Question: Is there a subset $\mathcal{S} \subseteq \mathcal{X}$ with total weight $w(\mathcal{S}) = \sum_{x \in \mathcal{S}} w(x) \leq W$ and total profit $p(\mathcal{S}) = \sum_{x \in \mathcal{S}} p(x) \geq P$?

Knapsack enjoys a key status in algorithmic design due to numerous reasons. First, it has many natural applications, in various practical areas such as resource allocation and scheduling. Second, it has immense educational value: Karp's NP-hardness proof (from his seminal paper [35]) is the first example of a reduction to a problem involving numbers, while the $O(Wn)$-time (or $O(Pn)$-time) algorithm by Bellman [4] from 1957 is one of the first dynamic programming algorithms, and it is still taught in most undergraduate algorithms courses to this day. And third, Knapsack has deep connections to other areas of computation: For example, one of the earliest cryptosystems by Merkle and Hellman [41] was based on Knapsack, and this was later extended to a host of other *Knapsack-type* cryptosystems [7, 14, 30, 42].

Knapsack is also important since it is both a generalization and a special case of a few other classic problems. For instance, it is a special case of the fundamental scheduling problem of minimizing the weighted number of tardy jobs on a single machine, the so-called $1||\sum w_j U_j$ problem [43, p. 19]. The variant of Knapsack where $W = P$ and $w(x) = p(x)$ for each item $x \in \mathcal{X}$ is precisely the Subset Sum problem:

Subset Sum
Input: A set $\mathcal{A} = \{a_1, \ldots, a_n\}$ of n non-negative integers and a target integer B.
Question: Is there a subset $\mathcal{A}^* \subseteq \mathcal{A}$ with $\sum_{a \in \mathcal{A}^*} a = B$?

Entire books [37, 40] are dedicated to algorithmics for Knapsack. Quite surprisingly, major algorithmic advances are still being discovered in recent years. These typically involve improvements on Bellman's classic $O(\min\{W, P\} \cdot n)$-time algorithm in cases where the maximum weight $w_{\max} = \max_x w(x)$ or the maximum profit $p_{\max} = \max_x p(x)$ (or both) are relatively small. Furthermore, they may result in faster approximation schemes. Currently, the fastest known approximation scheme runs – after a series of improvements in recent years [9, 12, 32] – in $\widetilde{O}(n + (1/\varepsilon)^{2.2})$ time [19]. Pisinger [44] was the first to present such an improvement with his $O(w_{\max} \cdot p_{\max} \cdot n)$-time algorithm. Later followed a series of papers with further improvements [2, 3, 36], culminating in an $\widetilde{O}(\min\{w_{\max}^3, p_{\max}^3\} + n)$-time[1] algorithm by Polak et al. [45], and an $\widetilde{O}(\min\{w_{\max}^{2/3} \cdot p_{\max},\ w_{\max} \cdot p_{\max}^{2/3}\} \cdot n)$-time algorithm by Bringmann and Cassis [10]. Very recently, Chen et al. [13] gave an $O(n + w_{\max}^{2.4})$-time algorithm. Subsequently, Bringmann [8] as well as Jin [33] announced $\widetilde{O}(n + w_{\max}^2)$-time algorithms (and also $\widetilde{O}(n + p_{\max}^2)$-time algorithms) for Knapsack. Cygan et al. [17]

[1] We use $\widetilde{O}(\cdot)$ to suppress polylogarithmic factors.

and independently Künnemann et al. [38] showed that there are no $O((W+n)^{2-\varepsilon})$-time algorithms for Knapsack, for any $\varepsilon > 0$, unless $(\min, +)$-convolutions can be solved in truly subquadratic time. An easy modification of their argument shows also that there are also no $O((P+n)^{2-\varepsilon})$-time algorithms under the same hypothesis. However, interestingly enough, these two lower bounds do not hold simultaneously together as shown by Bringmann and Cassis [9], who showed that Knapsack can be solved in $O((W+P)^{1.5}+n)$ time.

Parameters $w_\#$ and $p_\#$. As discussed above, the time complexity of Knapsack with respect to $w_{\max}$ and $p_{\max}$ is well understood. Thus, it makes sense to consider other natural parameters. Let $w_\# = |\{w(x_i) : i \in \{1,\dots,n\}\}|$ denote the number of *different* weights in a given Knapsack instance, and let $p_\# = |\{p(x_i) : i \in \{1,\dots,n\}|$ denote the number of different profits. These parameters can be expected to be small in several natural applications (for example, the first step of many approximation schemes is to round the profits of the items such that only $f(\varepsilon)$ many different profits remain; see, e.g., the approximation scheme by Deng et al. [19]) and have been initially studied for Subset Sum (i.e., when $w(x_i) = p(x_i)$ for all items x_i) by Fellows et al. [23] in the context of the more general *small number of numbers* paradigm. Clearly, $w_\# \leq w_{\max}$ and $p_\# \leq p_{\max}$, and so designing algorithms which are efficient in terms of $w_\#$ or $p_\#$ is more challenging than for $w_{\max}$ and $p_{\max}$. In particular, since Knapsack is NP-hard and $w_\#, p_\# \leq n$, we cannot expect algorithms with running times of the form $(w_\# \cdot n)^{O(1)}$, $(p_\# \cdot n)^{O(1)}$, or even $(w_\# \cdot p_\# \cdot n)^{O(1)}$.

Since polynomial-time algorithms with respect to $w_\#$ and $p_\#$ are unlikely to exist, it is natural to consider these two parameters in the context of parameterized complexity [16]. In this context, it is not difficult to show that Knapsack can be formulated as an Integer Linear Program (ILP) with either $O(w_\#)$ or $O(p_\#)$ variables [22]. Using one of several solvers for ILP with few variables, such as Lenstra's famous algorithm [39, 34], gives us algorithms with running times of $2^{\widetilde{O}(w_\#)} \cdot |I|$ and $2^{\widetilde{O}(p_\#)} \cdot |I|$ for Knapsack, where $|I|$ is the total encoding length of the input (see Hermelin et al. [29] for algorithms with similar running times for the more general $1||\sum w_j U_j$ problem). Such algorithms are known as *fixed-parameter algorithms* (FPT) in the terminology of parameterized complexity.

Note that both of these algorithms cannot be significantly improved assuming the Exponential Time Hypothesis (ETH). Indeed, it is known that assuming ETH, there are no $2^{o(n)}$-time algorithms for Subset Sum [11, 31]. As both $w_\#$ and $p_\#$ are bounded by n, and Subset Sum is a special case of Knapsack, this implies that, most likely, there are no $2^{o(w_\#)} \cdot n$-time or $2^{o(p_\#)} \cdot n$-time algorithms for Knapsack. Using the Strong Exponential Time Hypothesis (SETH) instead of ETH, Abboud et al. [1] showed a stronger lower bound for Subset Sum, excluding $B^{1-\varepsilon} \cdot 2^{o(n)}$-time algorithms for any $\varepsilon > 0$ (which excludes $(W+P)^{1-\varepsilon} \cdot 2^{o(w_\#+p_\#)}$-time algorithms for Knapsack). Once fixed-parameter algorithms for a particular problem – in this case, Knapsack – have been devised, the next step is to understand the kernelization complexity of the problem at hand.

Kernelization. One of the most fundamental and important techniques in parameterized complexity is kernelization [24]:

▶ **Definition 1.** *A* kernelization *algorithm (or* kernel*) for a parameterized problem* Π *is an algorithm that receives as input an instance* I *of* Π *with parameter* k *and outputs in polynomial time an instance* J *of* Π *with parameter* ℓ *such that*

- (I,k) *is a "yes"-instance for* Π *if and only if* (J,ℓ) *is a "yes"-instance for* Π*, and*
- $|J| + \ell \leq f(k)$ *for some computable function* f*.*

The expression $f(k)$ *is referred to as the* size *of the kernel.*

Thus, a kernel is a self-reduction from a problem onto itself that produces an equivalent instance with size bounded by the input parameter. In this way, kernelization may be thought of as preprocessing that aims to simplify or "kernelize" a problem instance by reducing its size while preserving some solution. Following this line of thought, problems that admit kernels of small sizes may be thought of as problems that allow efficient and effective preprocessing. For this reason, research into kernelization algorithms has seen a significant surge in recent years, and has become one of the central topics in parameterized complexity (see e.g. the monograph by Fomin et al. [24] and the numerous references within).

In the context of Knapsack, a kernelization algorithm for say parameter $w_\#$ transforms any Knapsack instance in polynomial time into an equivalent instance where the total encoding length of item weights and profits are bounded by $f(w_\#)$, for some function f. Observe that the $2^{\widetilde{O}(w_\#)} \cdot n$-time algorithm for Knapsack implies a kernel of size $2^{\widetilde{O}(w_\#)}$ [22]: Indeed, let $|I|$ denote the total encoding length of item weights and profits in a given Knapsack instance I with n items and observe that $n \leq |I|$. The kernelization algorithm can first check whether $|I| = 2^{\widetilde{O}(w_\#)}$. If this is the case, then the instance already has size bounded by $2^{\widetilde{O}(w_\#)}$, and otherwise it is solvable in polynomial time by the $2^{\widetilde{O}(w_\#)} \cdot n = 2^{\widetilde{O}(w_\#)} \cdot |I|$-time algorithm. A similar argument shows that Knapsack has a kernel of size $2^{\widetilde{O}(p_\#)}$.

The obvious question to ask is whether we can obtain smaller kernels with respect to either $w_\#$ or $p_\#$. Here, the gold standard in parameterized complexity are *polynomial kernels*, kernels with size $f(k) = k^{O(1)}$. By now we know of countless fixed-parameter tractable (NP-hard) problems that also admit polynomial kernels [24]; yet, at the same time, for many other problems polynomial kernels were shown to be unlikely to exist. Thus, the central question this paper addresses is:

Does Knapsack admit a polynomial kernel with respect to either $w_\#$ or $p_\#$?

Note that there are results that give encouraging indications to the question above. Etscheid et al. [22] show that Subset Sum admits a polynomial kernel with respect to $a_\#$, the number of different numbers in the instance (i.e, $a_\# = |\{a_i : i \in \{1, \ldots, n\}\}|$). Can this result be generalized to hold also for the Knapsack problem?

1.1 Our results

Our main technical result of the paper is a negative answer to the question above. We use the by now standard framework for excluding polynomial kernels [5] based on the assumption NP $\not\subseteq$ coNP/poly (whose negation implies that the polynomial hierarchy collapses) to show the following:

▶ **Theorem 2.** *Assuming NP $\not\subseteq$ coNP/poly, there is no polynomial kernel for* Knapsack *parameterized by the number $w_\#$ of different weights, nor by the number $p_\#$ of different profits.*

The proof of the theorem above is obtained through a rather involved construction of what is known as a composition algorithm (see Definition 4). This algorithm composes several instances of a specialized variant of Subset Sum into a single Knapsack instance where either $w_\#$ or $p_\#$ is kept relatively small. We give an overview of this algorithm in Section 1.2.

Complementing the negative result of Theorem 2, we show that when both $w_\#$ and $p_\#$ are taken as a combined parameter, the polynomial kernel for Subset Sum [22] can be extended to a polynomial kernel for Knapsack.

▶ **Theorem 3.** Knapsack *parameterized by $w_\# \cdot p_\#$ admits a polynomial kernel.*

Thus, the lower bounds for $w_\#$ and $p_\#$ cannot be combined. This is somewhat reminiscent to the situation mentioned above, where Knapsack is unlikely to have algorithms with subquadratic running times in either $(W+n)$ or $(P+n)$ [17], but admits an algorithm with subquadratic running time in $(W+P+n)$ [9].

1.2 Technical overview

We prove Theorem 2 for the parameter $w_\#$; the statement for parameter $p_\#$ then follows by a reduction from Polak et al. [45, Chapter 4]. In broad terms, our proof follows the standard framework for showing kernelization lower bounds that has been developed over the years [5, 6, 18, 21]. In this framework, to exclude a polynomial kernel for a given problem Π_1 parameterized by some parameter k, one shows what is called an *OR-composition algorithm* (see Definition 4 for a formal definition) from some known NP-hard problem Π_2 to Π_1. This algorithm takes as input t instances of Π_2 of size n each, and converts these instances in polynomial time to an equivalent instance of Π_1 such that $k = (n \lg t)^{O(1)}$. Here, equivalence means that at least one of the t input instances is a "yes"-instance for Π_2 if and only if the output instance of the composition is a "yes"-instance for Π_1. Such a composition algorithm then directly implies that Π_2 has no polynomial kernel with respect to k under the assumption NP $\not\subseteq$ coNP/poly [5, 6].

We show an OR-composition algorithm from a restricted version of Subset Sum which we call Restricted Subset Sum. In this restricted version, any instance of size n is restricted to include only numbers from a known set $\widetilde{\mathcal{A}}_n$ of size $O(n^3)$. This allows us to bound the number of different numbers in any t instances of Restricted Subset Sum of the same size. Our composition algorithm then proceeds as follows: Given any t instances $\mathcal{A}_0, \ldots, \mathcal{A}_{t-1}$ of Restricted Subset Sum, the algorithm converts any integer $a \in \mathcal{A}_i$, $i \in \{0, \ldots, t-1\}$, to a Knapsack item x_a (which we refer to as an *encoding item*) with weight $w(x_a) = a$. We then assign a higher profit to items corresponding to Restricted Subset Sum instances of higher index, meaning that it is always less profitable to choose an item corresponding to some integer $a \in \mathcal{A}_i$ than choosing an item corresponding to some integer $a \in \mathcal{A}_{i_0}$ for $i_0 > i$. This allows us to encode any solution $\mathcal{A}_i^* \subseteq \mathcal{A}_i$ to the i'th Restricted Subset Sum instance by a solution $\mathcal{X}(\mathcal{A}_i^*)$ to our Knapsack instance which includes all items x_a for $a \in \mathcal{A}_i^*$, and all items x_a for $a \in \mathcal{A}_{i_0}$ for $i_0 > i$. Thus, if we knew index i in advance, our composition would be complete.

However, we do not have a priori knowledge of index i. To circumvent this, we use *index items* that encode the selection of $i \in \{0, \ldots, t-1\}$. These are $2 \lg t$ items that encode the selection of t binary values $i(0), \ldots, i(\lg t - 1)$ that correspond to the base-2 representation of i, i.e., $i = \sum_k i(k) \cdot 2^k$. This is somewhat akin to the *"colors and IDs"* technique for composition algorithms which was introduced by Dom et al. [20]. The goal of these index items is to ensure that choosing a solution $\mathcal{X}(\mathcal{A}_i^*)$, for any value of i, allows adding a subset of index items to the knapsack such that any such selection has the same weight and profit. However, just adding the $O(\lg t)$ index items is not sufficient: As the composed instance shall achieve the same profit for any solution $\mathcal{X}(\mathcal{A}_i^*)$, we need to compensate for this difference in profit between $\mathcal{X}(\mathcal{A}_i^*)$ and $\mathcal{A}_{t-1}$. The difference in profit between solution $\mathcal{X}(\mathcal{A}_i^*)$ which includes all items from instances $\mathcal{A}_{i_0}$ for $i_0 > i$, and solution $\mathcal{X}(\mathcal{A}_{t-1}^*)$ which includes only items corresponding to instance $\mathcal{A}_{t-1}$, is quadratic in i. Hence, we cannot compensate for this difference using only the $O(\lg t)$ index items.

We therefore introduce additional $O(\lg^2 t)$ items which we refer to as *quadratization items*. These encode the selection of binary pair values $i(k)i(\ell)$ in $i^2 = \sum_k \sum_\ell i(k)i(\ell) \cdot 2^{k+\ell}$, and allow us to encode the quadratic compensation mentioned above. Unfortunately, this introduces

additional technical difficulties, such as ensuring compatibility between the selection of the index and quadratization items. Meanwhile, we still need to maintain the compatibility between the encoding and index items as well. These difficulties are overcome using various applications of a basic algebraic lemma that we prove in Section 2. In the end, we obtain an instance with $w_\# = O(n^3 \cdot \lg^2 t)$ many different weights, which by previously known results (Theorem 5) implies that a polynomial kernel would imply NP $\not\subseteq$ coNP/poly. The full details of the entire composition are given in Section 3.

In Section 4, we derive a polynomial kernel by first modeling Knapsack by an ILP with $w_\# \cdot p_\#$ many variables, and then reducing the size of the numbers occurring in the ILP by a well-known result by Frank and Tardos [26].

Theorems whose proof is omitted (and can be found in the full version [28]) are marked by $\star$.

2 Preliminaries

We next quickly review the kernelization lower bounds framework, introduced by Bodlaender et al. [5] and further developed by [6, 18, 21], that will be used for proving Theorem 2. At the heart of the framework lies the notion of a composition.

▶ **Definition 4.** *A composition algorithm from a problem Π_1 to a parameterized problem Π_2 is an algorithm that receives as input t instances $I_0, \ldots, I_{t-1}$ of size n of Π_1, and computes in polynomial time an instance (J, k) of Π_2 such that*

- *J is a "yes"-instance of Π_2 if and only if I_i is a "yes"-instance of Π_1 for some $i \in \{0, \ldots, t-1\}$,*
- *and $k \leq (n + \lg t)^{O(1)}$.*

The main connection between composition algorithms and the exclusion of polynomial kernels is given in the theorem below, whose proof relies on a complexity-theoretic lemma by Fortnow and Santhanam [25].

▶ **Theorem 5** ([5, 6])**.** *Let Π_1 be an NP-hard problem, and Π_2 be a parameterized problem with a composition algorithm from Π_1 to Π_2. Then Π_2 does not admit a polynomial kernel, assuming NP $\not\subseteq$ coNP/poly.*

Note that NP $\not\subseteq$ coNP/poly is a widely believed assumption in complexity theory, and if it were false then the polynomial hierarchy would collapse to its third level [47].

As a final point, we will also make use of the following basic algebraic lemma throughout our proof. Below we provide a proof for the sake of completeness.

▶ **Lemma 6.** *Let $b > 1$ and k be positive integers. Then there exists a unique integer solution to the equation*

$$x_0 b^0 + x_1 b^1 + \cdots + x_{k-1} b^{k-1} = \sum_{i=0}^{k-1} b^i$$

constrained by $x_i \in \{0, 1, \ldots, b\}$ for each $i \in \{0, \ldots, k-1\}$. Namely, the solution is

$$x_0 = x_1 = \cdots = x_{k-1} = 1 \ .$$

Proof. We show the statement by induction on k. For $k = 1$, the statement is obvious. So fix $k > 1$. Note that $\sum_{i=0}^{k-1} b^i = b^{k-1} + \sum_{i=0}^{k-2} b^i = b^{k-1} + \frac{b^{k-1}}{b-1} < 2b^{k-1}$, so we have that $x_{k-1} \in \{0, 1\}$. Further, we have $\sum_{i=0}^{k-2} x_i b^i \leq \sum_{i=0}^{k-2} b \cdot b^i = \sum_{i=1}^{k-1} b^i < \sum_{i=0}^{k-1} b^i$, implying that $x_k > 0$. Thus, we have $x_{k-1} = 1$ and $x_i = 1$ for $i \in \{0, \ldots, k-2\}$ follows by induction. ◀

Further, for any function $f : S \to \mathbb{R}$, we define $f(S') := \sum_{s \in S'} f(s)$ for any $S' \subseteq S$.

3 No Polynomial Kernel for Parameter $w_{\#}$

In the following, we present the proof of Theorem 2 for parameter $w_{\#}$, the total number of different weights in a Knapsack instance. As mentioned above, in our proof we construct a composition from a restricted version of Subset Sum to Knapsack parameterized by $w_{\#}$. The proof is divided into four parts: In the first part, we introduce the Restricted Subset Sum problem, and prove that it is NP-hard. In the second part we begin to describe our composition by showing how to encode t instances $\mathcal{A}_0, \ldots, \mathcal{A}_{t-1}$ of Restricted Subset Sum into a single set $\mathcal{X}$ of *encoding items*. In the third part we describe the set $\mathcal{Y}$ of *quadratization items*, and the set $\mathcal{Z}$ of *index items*, which together form the instance selection gadget of the composition. The final part is devoted to finishing details, and to proving the correctness of the composition.

3.1 Restricted Subset Sum

We start with a restricted version of Subset Sum which allows us to bound the number of different numbers appearing in any set of t Subset Sum instances. Namely, in our restricted version of Subset Sum, any instance of size n contains numbers from a restricted set of $O(n^3)$ numbers. Apart from this, its useful properties are that the target value only depends on the number of input numbers, and that any solution must have the same cardinality. For this, we define the set of possible numbers which may be contained in a Restricted Subset Sum instance of size n as

$$\widetilde{\mathcal{A}}_n := \left\{(3n+1)^{j_1} + (3n+1)^{j_2} + (3n+1)^{j_3} \;:\; j_1, j_2, j_3 \in \{1, \ldots, 3n\}\right\} .$$

Note that $\widetilde{\mathcal{A}}_n$ contains $27n^3 = O(n^3)$ integers. Furthermore, we also define a global target for all instances of size n by $B_n := \sum_{j=1}^{3n}(3n+1)^j$.

Restricted Subset Sum
Input: A set $\mathcal{A} = \{a_1, \ldots, a_{3n}\}$ of $3n$ integers from $\widetilde{\mathcal{A}}_n$ with $\sum_{j=1}^{3n} a_j = 3B_n$.
Question: Is there a subset $\mathcal{A}^* \subseteq \mathcal{A}$ with $|\mathcal{A}^*| = n$ such that $\sum_{a \in \mathcal{A}^*} a = B_n$?

▶ **Lemma 7.** Restricted Subset Sum *is NP-complete.*

Proof. We present a reduction from a variant of Restricted Exact Cover by 3-Sets where each element appears in exactly three sets. Recall that in Restricted Exact Cover by 3-Sets, the input consists of a set $\mathcal{T}$ consisting of 3-element subsets of $\{1, \ldots, 3n\}$ such that each $j \in \{1, \ldots, 3n\}$ appears in exactly three sets from $\mathcal{T}$, and the question is whether there exists a subset $\mathcal{T}' \subseteq \mathcal{T}$ such that each element from $\{1, \ldots, 3n\}$ appears in exactly one set from $\mathcal{T}'$. This variant of Restricted Exact Cover by 3-Sets is well-known to be NP-hard [27].

Our reduction is almost identical to the original hardness reduction for Subset Sum by Karp [35], only that we reduce from Restricted Exact Cover by 3-Sets instead of the more general Exact Cover: Let $\mathcal{T}$ be an instance of Restricted Exact Cover by 3-Sets. For each 3-element set $T \in \mathcal{T}$, a number $a_T := \sum_{j \in T}(3n+1)^j$ is added to the Restricted Subset Sum instance. In this way, the constructed instance of Restricted Subset Sum is $\mathcal{A} := \{a_T : T \in \mathcal{T}\}$. Note that $a_T \in \widetilde{\mathcal{A}}_n$ for every $T \in \mathcal{T}$. Further, since each $j \in \{1, \ldots, 3n\}$ appears in exactly three sets from $\mathcal{T}$, we have $\sum_{T \in \mathcal{T}} a_T = 3\sum_{j=1}^{3n}(3n+1)^j = 3B_n$. Below we prove the correctness of this construction.

Suppose there is a solution $\mathcal{T}' \subseteq \mathcal{T}$ for the Restricted Exact Cover by 3-Sets instance. Then $|\mathcal{T}'| = n$ and we have $\sum_{T \in \mathcal{T}} a_T = \sum_{\ell=1}^{3n}(3n+1)^\ell = B_n$. Conversely, suppose there is a solution $\mathcal{A}^* \subseteq \mathcal{A}$ with $|\mathcal{A}^*| = n$ for the Restricted Subset Sum instance. Let

$\mathcal{T}^* := \{T : a_T \in \mathcal{A}^*\}$. Since each term $(3n+1)^j$ appears only $3 < 3n+1$ times, Lemma 6 implies that the only way for some numbers from $\mathcal{A}$ to add up to $B_n = \sum_{j=1}^{3n}(3n+1)^j$ is that each term $(3n+1)^j$ appears in exactly one $a_T \in \mathcal{A}^*$. In other words, for each $j \in \{1,\dots,3n\}$, there is exactly one $T \in \mathcal{T}^*$ with $j \in T$. ◀

3.2 Encoding Gadget

In the following, we show how to encode t instances of Restricted Subset Sum into a single Knapsack instance. Throughout the remainder of the section, we use $\mathcal{A}_0,\dots,\mathcal{A}_{t-1}$ to denote the t input instances of Restricted Subset Sum to our composition, where $|\mathcal{A}_i| = 3n$ for each $i \in \{0,\dots,t-1\}$. By copying instances, we may assume without loss of generality that t is a power of 2, i.e., $t = 2^s$ for some $s \in \mathbb{N}$. Furthermore, we let $\mathcal{A}_i = \{a_1^i,\dots,a_{3n}^i\}$ denote the i'th instance for each $i \in \{0,\dots,t-1\}$. By the definition of Restricted Subset Sum, we have $a_j^i \in \widetilde{\mathcal{A}}_n$ for each each $i \in \{0,\dots,t-1\}$ and $j \in \{1,\dots,3n\}$, and $\sum_j a_j^i = 3B_n$ for each $i \in \{0,\dots,t-1\}$.

Recall that Subset Sum can be seen as a special case of Knapsack where the profit of each item equals its weight. This yields an easy reduction from each single Restricted Subset Sum instance $\mathcal{A}_i$ to Knapsack. We apply this reduction with a slight modification: To capture the condition that each solution of Restricted Subset Sum shall contain exactly n numbers, we add a large number $X = 3tnB_n$ to each number in a Restricted Subset Sum instance, and set $B := B_n + n \cdot X$. We also increase the profit of each item corresponding to the i'th Restricted Subset Sum instance by adding $i \cdot 3B$ to its profit. More precisely, for each $i \in \{0,\dots,t-1\}$ and $j \in \{1,\dots,3n\}$, we construct an *encoding item* x_j^i with

- $w(x_j^i) = X + a_j^i$, and
- $p(x_j^i) = X + a_j^i + i \cdot 3B$.

Intuitvely, adding the constant X to the weights ensures that all encoding items have roughly the same size, so for any weight budget W^*, the set of maximum profit will always have size $\lfloor W^*/X \rfloor$ or $\lfloor W^*/X \rfloor - 1$. Adding the constant X to the profits of x_j^i ensures that for any two sets of encoding items with different cardinalities, the larger one will always have the larger profit. Further, adding $i \cdot 3B$ to the profits will ensure that it will be always more profitable to pick an item $x_{j_1}^{i_1}$ over item $x_{j_0}^{i_0}$ for any $i_1 > i_0$. We use $\mathcal{X} = \{x_j^i : i \in \{0,\dots,t-1\}, j \in \{1,\dots,3n\}\}$ to denote the set of all encoding items.

Let $\mathcal{X}_i$ denote the set of encoding items corresponding to instance $\mathcal{A}_i$ of Restricted Subset Sum, i.e., $\mathcal{X}_i = \{x_j^i : j \in \{1,\dots,3n\}\}$. Note that $w(\mathcal{X}_i) = 3B$ and $p(\mathcal{X}_i) = 3B + 9nB \cdot i$. Now suppose $\mathcal{A}_i$ has a solution $\mathcal{A}_i^* \subset \mathcal{A}_i$. We would like to encode this solution using the following set of encoding items

$$\mathcal{X}(\mathcal{A}_i^*) = \mathcal{X}_i^* \cup \mathcal{X}_{i+1} \cup \mathcal{X}_{i+2} \cup \dots \cup \mathcal{X}_{t-1},$$

where $\mathcal{X}_i^* := \{x_i^j : a_i^j \in \mathcal{A}_i^*\}$ is the set of items corresponding to $\mathcal{A}_i^*$. An easy calculation shows that if the elements of $\mathcal{A}_i^*$ sum up to B (i.e., $\mathcal{A}_i^*$ is indeed a solution), then $w(\mathcal{X}(\mathcal{A}_i^*)) = (3t - 3i - 2) \cdot B$ and $p(\mathcal{X}(\mathcal{A}_i^*)) = (3t - 3i - 2) \cdot B + (\binom{t}{2} - \binom{i+1}{2} + \frac{i}{3}) \cdot 9nB$. The next lemma shows that the converse is also true; namely, that if there is a subset of encoding items with the above weight and profit, then there must be a solution to the i'th Restricted Subset Sum instance.

▶ **Lemma 8** (⋆). *Let $i \in \{0,\dots,t-1\}$. There exists a subset $\mathcal{X}^* \subseteq \mathcal{X}$ of encoding items with total weight*

$$w(\mathcal{X}^*) \leq (3t - 3i - 2) \cdot B$$

and total profit

$$p(\mathcal{X}^*) \geq (3t - 3i - 2) \cdot B \; + \; \left(\binom{t}{2} - \binom{i+1}{2} + \frac{i}{3} \right) \cdot 9nB$$

for our Knapsack *instance if and only if there exist a solution* $\mathcal{A}_i^* \subseteq \mathcal{A}_i$ *to the* i*'th* Restricted Subset Sum *instance.*

Lemma 8 implies that if we knew which Restricted Subset Sum instance $\mathcal{A}_i$ has a solution, then we could easily set the weight and profit of our composed Knapsack instance to encode this solution. However, we do not have prior information about index i. Furthermore, observe that as the value of i increases, both the profit and weight of the required solution decrease. Since we do not know the value of i, it would be beneficial to balance all possible choices of i in terms of weight and profit.

Thus, the remaining construction focuses on ensuring that solutions to the Knapsack instance corresponding to different $\mathcal{A}_i$'s all have the same weight and profit. In particular, the construction guarantees that any choice of i can obtain a profit of $(3t-2) \cdot B + 9 \cdot \binom{t}{2} \cdot nB$, in addition to some large constant. Considering the profit guaranteed by solutions of Lemma 8, we need to compensate for the loss of the quadratic term

$$\left(\binom{i+1}{2} - \frac{i}{3} \right) \cdot 9nB \; . \tag{1}$$

We call the term above the *compensation term of* i. It will play an important role in the remainder of our construction.

3.3 Instance Selection Gadget

We next add additional items to our Knapsack instance that will serve as an instance selection gadget. This gadget selects an instance of Restricted Subset Sum for which presumably there is a solution. The gadget consists of two types of items: The *index items* which encode an index of an Restricted Subset Sum instance $i \in \{0, \ldots, t-1\}$, and *quadratization items* that help to encode the compensation term of i given in Equation 1.

Quadratization items. The main idea behind the quadratization items is as follows: Any integer $i \in \{0, \ldots, t-1\}$ can be written as the sum

$$i = \sum_{k=0}^{\lg t - 1} i(k) \cdot 2^k,$$

for some binary values $i(0), \ldots, i(\lg t - 1) \in \{0, 1\}$. Thus, using these same $\lg t$ binary values, we can write the compensation term of i as

$$\begin{aligned}
\left(\binom{i+1}{2} - \frac{i}{3} \right) \cdot 9nB \quad &= \quad \left(0.5 \cdot i^2 + \frac{1}{6} \cdot i \right) \cdot 9nB \\
&= \quad \left(0.5 \cdot \sum_{k=0}^{\lg t - 1} \sum_{\ell=0}^{\lg t - 1} i(k) \cdot i(\ell) \cdot 2^{k+\ell} + \frac{1}{6} \sum_{k=0}^{\lg t - 1} i(k) \cdot 2^k \right) \cdot 9nB \\
&= \quad \left(9 \cdot \sum_{\substack{i(k)=1, \\ i(\ell)=1, \\ k<\ell}} 2^{k+\ell} \; + \; 4.5 \cdot \sum_{i(k)=1} 2^{k+k} \; + \; 1.5 \cdot \sum_{i(k)=1} 2^k \right) \cdot nB \; .
\end{aligned}$$

(2)

Thus, we construct $3 \cdot \binom{\lg t}{2} + \lg t$ different quadratization items, each modeling the contribution of all possible values of $i(k)$ and $i(\ell)$, $k \leq \ell \in \{0, \ldots, \lg t - 1\}$, in the last equality of Equation 2 above.

Let $Y = t^2 \cdot 3nB$, and observe that Y is larger than the total profit of all encoding items. Furthermore, let $f : \{0, \ldots, \lg t - 1\}^2 \to \{0, \ldots, \lg^2 t - 1\}$ be any bijective function. For each pair of indices k and ℓ with $0 \leq k < \ell \leq \lg t - 1$, we add three quadratization items $y^{1,0}_{k,\ell}$, $y^{0,1}_{k,\ell}$, and $y^{1,1}_{k,\ell}$ with the following weight and profit:

- $w(y^{1,0}_{k,\ell}) = p(y^{1,0}_{k,\ell}) = 3^{f(k,\ell)} \cdot Y$.
- $w(y^{0,1}_{k,\ell}) = p(y^{0,1}_{k,\ell}) = 3^{f(\ell,k)} \cdot Y$.
- $w(y^{1,1}_{k,\ell}) = (3^{f(k,\ell)} + 3^{f(\ell,k)}) \cdot Y$ and $p(y^{1,1}_{k,\ell}) = (3^{f(k,\ell)} + 3^{f(\ell,k)}) \cdot Y + 2^{k+\ell} \cdot 9nB$.

Furthermore, for each $k \in \{0, \ldots, \lg t - 1\}$, we add a single quadratization item $y^{1,1}_{k,k}$ with:

- $w(y^{1,1}_{k,k}) = 3^{f(k,k)} \cdot Y$ and $p(y^{1,1}_{k,k}) = 3^{f(k,k)} \cdot Y + 2^{k+k} \cdot 4.5nB + 2^k \cdot 1.5nB$.

We use $\mathcal{Y} = \{y^{1,0}_{k,\ell}, y^{0,1}_{k,\ell}, y^{1,1}_{k,\ell} : 0 \leq k < \ell \leq \lg t - 1\} \cup \{y^{1,1}_{k,k} : 0 \leq k \leq \lg t - 1\}$ to denote the set of all quadratization items.

The role of the additional terms that depend on Y will become clearer when we introduce the index items. But for now, one can observe that the smaller terms used in the profits of $y^{1,1}_{k,\ell}$ and $y^{1,1}_{k,k}$ allow us to encode the compensation term of i. In particular, an easy calculation using Equation 2 gives us the following useful lemma:

▶ **Lemma 9.** *Let $i \in \{0, \ldots, t-1\}$, and let $i(0), \ldots, i(t-1) \in \{0, 1\}$ be binary values such that $i = \sum_k i(k) \cdot 2^k$. Moreover, let $\mathcal{Y}_i$ denote the set of quadratization items defined by*

$$\mathcal{Y}_i = \{y^{i(k),i(\ell)}_{k,\ell} : 0 \leq k \leq \ell \leq \lg t - 1\},$$

where $y^{i(k),i(\ell)}_{k,\ell}$ is the empty item (i.e., an item with weight and profit 0) if $i(k) = i(\ell) = 0$. Then

$$p(\mathcal{Y}_i) \quad = \quad w(\mathcal{Y}_i) + \left(\binom{i+1}{2} - \frac{i}{3}\right) \cdot 9nB \ .$$

Index items. The index items ensure that only quadratization items that correspond to subsets $\mathcal{Y}_i$ as in Lemma 9 above can be picked into any solution of our Knapsack instance. In particular, the index items will encode the selection of an index $i \in \{0, \ldots, \lg t - 1\}$ that will be compatible with the selection of a subset $\mathcal{Y}_i$ of quadratization items.

Let $Z = \lg^2 t Y^2 \cdot 3^{\lg^2 t}$, and observe that Z is larger than the profit of all encoding and quadratization items in total. For each $k \in \{0, \ldots, \lg t - 1\}$, we construct two *index items* z^0_k and z^1_k corresponding to selecting either $i(k) = 0$ or $i(k) = 1$ in the binary representation $i(0), \ldots, i(\lg t - 1)$ of i. The weight and profit of these two items are defined by:

- $w(z^0_k) = p(z^0_k) = 2^k \cdot Z + \sum_{\ell=0}^{\lg t - 1} 3^{f(k,\ell)} \cdot Y$.
- $w(z^1_k) = p(z^1_k) = 2^k \cdot Z + 2^k \cdot 3B$.

We use $\mathcal{Z} = \{z^0_k, z^1_k : 0 \leq k \leq \lg t - 1\}$ to denote the set of all index items.

Let $i \in \{0, \ldots, t-1\}$, and let $i(0), \ldots, i(t-1) \in \{0, 1\}$ be binary values such that $i = \sum_k i(k) \cdot 2^k$. Observe that the set of index items $\mathcal{Z}_i$ defined by

$$\mathcal{Z}_i = \{z^{i(k)}_k : 0 \leq k \leq \lg t - 1\}$$

naturally corresponds to index i. In the lemma below, we show that due to our selection of the large value Z, any set of items of sufficiently small weight and sufficiently large profit contains a subset of index items that corresponds precisely to some index $i \in \{0, \ldots, t-1\}$. We let w_Z denote the weight function $w_Z(x) = \lfloor w(x)/Z \rfloor$, and p_Z denote the profit function $p_Z(x) = \lfloor p(x)/Z \rfloor$.

▶ **Lemma 10** (⋆). *Let $\mathcal{S} \subseteq \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ be a set of items with $w_Z(\mathcal{S}) \leq t-1$ and $p_Z(\mathcal{S}) \geq t-1$. Then there exists some $i \in \{0, \ldots, t-1\}$ for which $\mathcal{S} \cap \mathcal{Z} = \mathcal{Z}_i$.*

Now let us address the terms that depend on Y in the profit and weight of the instance selection items. Define T to be the constant $T := \sum_{k=0}^{\lg^2 t-1} 3^k$. Now consider some set $\mathcal{Z}_i$ of index items corresponding to index $i \in \{0, \ldots, t-1\}$. Let w_Y denote the weight function $w_Y(x) = \lfloor (w(x) - Z \cdot w_Z(x))/Y \rfloor$, and similarly define the profit function p_Y as $p_Y(x) = \lfloor (p(x) - Z \cdot p_Z(x))/Y \rfloor$. Then one can observe that, by construction of the weights and profits above, we have that both $w_Y(\mathcal{Z}_i) + w_Y(\mathcal{Y}_i)$ and $p_Y(\mathcal{Z}_i) + p_Y(\mathcal{Y}_i)$ equal T. Moreover, any other set of items with w_Y-weight at most T has lesser profit. This ensures a compatible selection of the index items and the quadratization items, formally proven in the lemma below.

▶ **Lemma 11.** *Let $\mathcal{S} \subseteq \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ be a set of items with weight $w_Z(\mathcal{S}) \leq (t-1)$, $w_Y(\mathcal{S}) \leq T$, $p_Z(\mathcal{S}) \geq (t-1)$, $p_Y(\mathcal{S}) \geq T$, and there is no set $\mathcal{S}' \subseteq \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ with $w(\mathcal{S}') \leq w(\mathcal{S})$ and $p(\mathcal{S}') > p(\mathcal{S})$. Then $\mathcal{S} \cap \mathcal{Y} = \mathcal{Y}_i$ and $\mathcal{S} \cap \mathcal{Z} = \mathcal{Z}_i$ for some $i \in \{0, \ldots, t-1\}$.*

Proof. Let $\mathcal{Z}^* = \mathcal{S} \cap \mathcal{Z}$ and $\mathcal{Y}^* = \mathcal{S} \cap \mathcal{Y}$. As $w_Z(\mathcal{S}) \leq (t-1)$ and $p_Z(\mathcal{S}) \geq (t-1)$, by Lemma 10 we have that $\mathcal{Z}^* = \mathcal{Z}_i$ for some $i \in \{0, \ldots, t-1\}$. Thus, to complete the proof, we focus on showing that $\mathcal{Y}^* = \mathcal{Y}_i$. Let $i(0), \ldots, i(\lg t - 1) \in \{0, 1\}$ be such that $i = \sum_k i(k) \cdot 2^k$.

Observe that by the construction of the weights and profits of the index items, we have $w_Y(\mathcal{Z}_i) = p_Y(\mathcal{Z}_i) = \sum_{\alpha(k)=0} \sum_\ell 3^{f(k,\ell)}$. From this, one can see that both $w_Y(\mathcal{Z}_i) + w_Y(\mathcal{Y}^*)$ and $w_Y(\mathcal{Z}_i) + p_Y(\mathcal{Y}^*)$ equal

$$\Big(\sum_{\substack{i(k)=0,\\ 0\leq \ell \leq \lg t-1}} 3^{f(k,\ell)} \Big) + \Big(\sum_{y^{1,0}_{k,\ell} \in \mathcal{Y}_i} 3^{f(k,\ell)} + \sum_{y^{0,1}_{k,\ell} \in \mathcal{Y}_i} 3^{f(\ell,k)} + \sum_{y^{1,1}_{k,\ell} \in \mathcal{Y}_i} (3^{f(k,\ell)} + 3^{f(\ell,k)}) + \sum_{y^{1,1}_{k,\ell} \in \mathcal{Y}_i} 3^{f(k,k)} \Big) =$$
$$\Big(\sum_{\substack{i(k)=0,\\ 0\leq \ell \leq \lg t-1}} 3^{f(k,\ell)} \Big) + \Big(\sum_{\substack{i(k)=1,\\ i(\ell)=0,\\ k<\ell}} 3^{f(k,\ell)} + \sum_{\substack{i(k)=1,\\ i(\ell)=0,\\ k>\ell}} 3^{f(k,\ell)} + \sum_{\substack{i(k)=1,\\ i(\ell)=1,\\ k\neq\ell}} 3^{f(k,\ell)} + \sum_{i(k)=1} 3^{f(k,k)} \Big) \ .$$

Note that as $w_Y(\mathcal{Z}_i) + w_Y(\mathcal{Y}^*) = w_Y(\mathcal{S}) \leq T$, the sum above is bounded from above by T. Moreover, by Lemma 6, the only way this reaches the bound with equality is if we have

$$w_Y(\mathcal{Y}^*) = \sum_{\substack{i(k)=1,\\ i(\ell)=0,\\ k<\ell}} 3^{f(k,\ell)} + \sum_{\substack{i(k)=1,\\ i(\ell)=0,\\ k>\ell}} 3^{f(k,\ell)} + \sum_{\substack{i(k)=1,\\ i(\ell)=1,\\ k\neq\ell}} 3^{f(k,\ell)} + \sum_{i(k)=1} 3^{f(k,k)} = \sum_{\substack{i(k)=0,\\ 0\leq \ell \leq \lg t-1}} 3^{f(k,\ell)} \ ,$$

which then gives us

$$w_Y(\mathcal{Z}_i) + w_Y(\mathcal{Y}^*) = \sum_{\substack{i(k)=0,\\ 0\leq \ell \leq \lg t-1}} 3^{f(k,\ell)} + \sum_{\substack{i(k)=1,\\ 0\leq \ell \leq \lg t-1}} 3^{f(k,\ell)} = \sum_{k=0}^{\lg^2 t-1} 3^k = T \ .$$

(Here, the penultimate equality follows because $f(\cdot,\cdot)$ is bijective.)

Note that by construction and Lemma 6, the only sets of quadratization items $\mathcal{Y}^*$ with $w_Y(\mathcal{Y}^*) = p_Y(\mathcal{Y}^*) = \sum_{\alpha(k)=1} \sum_\ell 3^{f(k,\ell)}$ are either $\mathcal{Y}_i$, or any set of quadratization items obtained from $\mathcal{Y}_i$ by replacing some $y^{1,1}_{k,\ell} \in \mathcal{Y}_i$ with $y^{1,0}_{k,\ell}$ and $y^{0,1}_{k,\ell}$. If $\mathcal{S}$ contained $y^{1,0}_{k,\ell}$ and $y^{0,1}_{\ell,k}$ for some $0 \leq k < \ell \leq \lg t - 1$, then $\mathcal{S}' := (\mathcal{S} \setminus \{y^{1,0}_{k,\ell}, y^{0,1}_{k,\ell}\}) \cup \{y^{1,1}_{k,\ell}\}$ satisfies $w(\mathcal{S}') = w(\mathcal{S})$ and $p(\mathcal{S}') > p(\mathcal{S})$, a contradiction to the definition of $\mathcal{S}$. Thus, we conclude that $\mathcal{Y}^* = \mathcal{Y}_i$ and the lemma is proven. ◀

Table 1 The weights and profits of the items used in the proof of Theorem 2 for parameter $w_{\#}$. The three large constants used in the proof are $X = 3tn \cdot B_n$, $Y = t^2 \cdot 3nB$, and $Z = \lg^2 tY^2 \cdot 3^{\lg^2 t}$.

Item	Weight	Profit	Index Range
z_k^1	$2^k \cdot Z + 2^k \cdot 3B$	$2^k \cdot Z + 2^k \cdot 3B$	$0 \leq k \leq \lg t - 1$
z_k^0	$2^k \cdot Z + \sum_\ell 3^{f(k,\ell)} \cdot Y$	$2^k \cdot Z + \sum_\ell 3^{f(k,\ell)} \cdot Y$	$0 \leq k \leq \lg t - 1$
$y_{k,\ell}^{1,0}$	$3^{f(k,\ell)} \cdot Y$	$3^{f(k,\ell)} \cdot Y$	$0 \leq k < \ell \leq \lg t - 1$
$y_{k,\ell}^{0,1}$	$3^{f(\ell,k)} \cdot Y$	$3^{f(\ell,k)} \cdot Y$	$0 \leq k < \ell \leq \lg t - 1$
$y_{k,\ell}^{1,1}$	$(3^{f(k,\ell)} + 3^{f(\ell,k)}) \cdot Y$	$(3^{f(k,\ell)} + 3^{f(\ell,k)}) \cdot Y + 2^{k+\ell} \cdot 9nB$	$0 \leq k < \ell \leq \lg t - 1$
$y_{k,k}^{1,1}$	$3^{f(k,k)} \cdot Y$	$3^{f(k,k)} \cdot Y + 2^{k+k} \cdot 4.5nB + 2^k \cdot 1.5nB$	$0 \leq k \leq \lg t - 1$
x_j^i	$X + a_j^i$	$X + a_j^i + i \cdot 3B$	$0 \leq i \leq t-1$, $1 \leq j \leq 3n$

3.4 Correctness

Our entire Knapsack instance consists of all items $\mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$. An overview of the weight and profit of each item can be found in Table 1. We set the weight W of the Knapsack instance to

$$W := (t-1) \cdot Z \; + \; T \cdot Y \; + \; (3t-2) \cdot B$$

and the desired profit P to

$$\begin{aligned} P &:= W \; + \; \binom{t}{2} \cdot 9nB \\ &= (t-1) \cdot Z \; + \; T \cdot Y \; + \; (3t-2) \cdot B \; + \; \binom{t}{2} \cdot 9nB \; . \end{aligned}$$

In the next two lemmas below we prove the correctness of our constructed composition.

▶ **Lemma 12.** *If $\mathcal{A}_i$ is a "yes"-instance of* Restricted Subset Sum *for some $i \in \{0, \ldots, t-1\}$ then there exists a subset of items $\mathcal{S} \subseteq \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ with $w(\mathcal{S}) \leq W$ and $p(\mathcal{S}) \geq P$.*

Proof. Suppose $\mathcal{A}_i$ is a "yes"-instance of Restricted Subset Sum for some $i \in \{0, \ldots, t-1\}$, and let $i(0), \ldots, i(\lg t - 1) \in \{0,1\}$ be such that $i = \sum_k i(k) \cdot 2^k$. Then $w(\mathcal{X}(\mathcal{A}_i)) = (3t-3i-2) \cdot B$ as discussed in Section 3.2. Furthermore, $w(\mathcal{Y}_i) = w_Y(\mathcal{Y}_i) \cdot Y = (T - w_Y(\mathcal{Z}_i)) \cdot Y$ as is shown in the proof of Lemma 11. Finally, we have $w_Z(\mathcal{Z}_i) = (t-1) \cdot Z$, and

$$w(\mathcal{Z}_i) \; = \; w_Z(\mathcal{Z}_i) + w_Y(\mathcal{Z}_i) + \sum_{i(k)=1} 2^k \cdot 3B \; = \; (t-1) \cdot Z + w_Y(\mathcal{Z}_i) \cdot Y + i \cdot 3B \; .$$

So altogether we have

$$\begin{aligned} w(\mathcal{X}(\mathcal{A}_i) \cup \mathcal{Y}_i \cup \mathcal{Z}_i) \; &= \; (3t - 3i - 2) \cdot B \; + \; (T - w_Y(\mathcal{Z}_i)) \cdot Y \\ &\quad + (t-1) \cdot Z \; + \; w_Y(\mathcal{Z}_i) \cdot Y \; + \; i \cdot 3B \\ &= (t-1) \cdot Z \; + \; T \cdot Y \; + \; (3t-2) \cdot B \; = W \; . \end{aligned}$$

Let us next calculate the profit of $\mathcal{X}(\mathcal{A}_i) \cup \mathcal{Y}_i \cup \mathcal{Z}_i$. Recall that $p(\mathcal{X}(\mathcal{A}_i)) = w(\mathcal{X}(\mathcal{A}_i)) + (\binom{t}{2} - \binom{i+1}{2} + \frac{i}{3}) \cdot 9nB$ as discussed in Section 3.2. By Lemma 9 we have $p(\mathcal{Y}_i) = w(\mathcal{Y}_i) + (\binom{i+1}{2} - \frac{i}{3}) \cdot 9nB$, and by construction we have $p(\mathcal{Z}_i) = w(\mathcal{Z}_i)$. Thus, altogether we have

$$\begin{aligned} p(\mathcal{X}(\mathcal{A}_i) \cup \mathcal{Y}_i \cup \mathcal{Z}_i) &= w(\mathcal{X}(\mathcal{A}_i)) + (\binom{t}{2} - \binom{i+1}{2} + \frac{i}{3}) \cdot 9nB \\ &\quad + w(\mathcal{Y}_i) + (\binom{i+1}{2} - \frac{i}{3}) \cdot 9nB \ + \ w(\mathcal{Z}_i) \\ &= w(\mathcal{X}(\mathcal{A}_i) \cup \mathcal{Y}_i \cup \mathcal{Z}_i) + \binom{t}{2} \cdot 9nB = P \ . \end{aligned}$$

Thus the set of items $\mathcal{S} = \mathcal{X}(\mathcal{A}_i) \cup \mathcal{Y}_i \cup \mathcal{Z}_i$ is a solution for our Knapsack instance, and the lemma is proven. ◀

▶ **Lemma 13.** *If there exists a subset of items $\mathcal{S} \subseteq \mathcal{X} \cup \mathcal{Y} \cup \mathcal{Z}$ with $w(\mathcal{S}) \leq W$ and $p(\mathcal{S}) \geq P$ then there is some $i \in \{0, \ldots, t-1\}$ for which $\mathcal{A}_i$ is a "yes"-instance of* Restricted Subset Sum.

Proof. Let $\mathcal{S}$ be a solution with $w(\mathcal{S}) \leq W$ and $p(\mathcal{S}) \geq P$. Let $\mathcal{X}^* = \mathcal{S} \cap \mathcal{X}$, $\mathcal{Y}^* = \mathcal{S} \cap \mathcal{Y}$, and $\mathcal{Z}^* = \mathcal{S} \cap \mathcal{Z}$. Then as $w(\mathcal{S}) \leq W < t \cdot Z$ and $p(\mathcal{S}) \leq P < t \cdot Z$, we have by Lemma 10 that $\mathcal{Z}^* = \mathcal{Z}_i$ for some $i \in \{0, \ldots, t-1\}$. Assume, without loss of generality, that $\mathcal{S}$ is of maximal profit among all solutions with weight at most $w(\mathcal{S})$ (i.e., there is no set $\mathcal{S}'$ with $w(\mathcal{S}') \leq w(\mathcal{S})$ and $p(\mathcal{S}') > p(\mathcal{S})$. Then, by Lemma 11, we have $\mathcal{Y}^* = \mathcal{Y}_i$. As shown in the proof of Lemma 12, we have $w(\mathcal{Z}_i) + w(\mathcal{Y}_i) = (t-1) \cdot Z + T \cdot Y + i \cdot 3B$. Thus,

$$w(\mathcal{X}^*) \leq W - w(\mathcal{Z}_i) - w(\mathcal{Y}_i) = (3t - 3i - 2) \cdot B \ .$$

Moreover, by Lemma 9 we have $p(\mathcal{Y}_i) = w(\mathcal{Y}_i) + (\binom{i+1}{2} - \frac{i}{3}) \cdot 9nB$, and by construction we have $p(\mathcal{Z}_i) = w(\mathcal{Z}_i)$. Thus,

$$\begin{aligned} p(\mathcal{X}^*) &\geq P - p(\mathcal{Z}_i) - p(\mathcal{Y}_i) \\ &= P - w(\mathcal{Z}_i) - w(\mathcal{Y}_i) - \left(\binom{i+1}{2} - \frac{i}{3}\right) \cdot 9nB \\ &= P - (t-1) \cdot Z - T \cdot Y - i \cdot 3B - \left(\binom{i+1}{2} - \frac{i}{3}\right) \cdot 9nB \\ &= (3t - 3i - 2) \cdot B + \left(\binom{t}{2} - \binom{i+1}{2} + \frac{i}{3}\right) \cdot 9nB \ . \end{aligned}$$

It therefore follows by Lemma 8 that instance $\mathcal{A}_i$ is indeed a "yes"-instance of Restricted Subset Sum, and the lemma follows. ◀

Proof of Theorem 2. We presented above an algorithm that composes any t instances $\mathcal{A}_0, \ldots, \mathcal{A}_{t-1}$ of Restricted Subset Sum into a single instance of Knapsack in polynomial-time. By Lemmas 12 and 13, the constructed Knapsack instance is a "yes"-instance if and only if $\mathcal{A}_i$ is "yes"-instance of Restricted Subset Sum for some $i \in \{0, \ldots, t-1\}$. Observe that total number of different weights in our constructed Knapsack instance is

$$w_\# \leq |\widetilde{\mathcal{A}}_n| + |\mathcal{Y}| + |\mathcal{Z}| = O(n^3 + \lg^2 t) \ .$$

Thus our algorithm fulfills all requirements of a composition algorithm, as given in Definition 4. The proof for $w_\#$ then follows by a direct application of Theorem 5. The statement for $p_\#$ follows by applying the reduction from Polak et al. [45, Chapter 4] which reduces an instance with $w_\# = k$ different item weights to an instance with $p_\# = k$ different item profits. ◀

4 Polynomial Kernel for Parameter $w_\# \cdot p_\#$

In this section we present a polynomial kernel for Knapsack parameterized by $w_\# + p_\#$, thereby proving Theorem 3. Our kernel is a direct generalization of the polynomial kernel for Subset Sum parameterized by $a_\#$ of Etscheid et al. [22].

The presented kernel utilizes two classic results: First, we use the fact that integer programming is fixed-parameter tractable with respect to the number of variables (this was first shown by Lenstra [39], and the currently best known running time with respect to the number of variable is due to Reis and Rothvoss [46]):

▶ **Theorem 14** ([46]). Integer Linear Programming *with input size s (i.e., the number of bits needed to encode the instance) and n variables can be solved in $2^{O(n \lg \lg n)} \cdot s^{O(1)}$ time.*

Second, we use the following theorem by Frank and Tardos [26]:

▶ **Theorem 15** ([26]). *There is an algorithm that, given a vector $w \in \mathbb{Q}^r$ and a natural number N, computes in polynomial time a vector $\overline{w} \in \mathbb{Q}^r$ with $\|w\|_\infty \leq 2^{4r^3} \cdot N^{r^2+2r}$ and $\operatorname{sign}(w \cdot b) = \operatorname{sign}(\overline{w} \cdot b)$ for every $b \in \mathbb{Z}^r$ with $\|b\|_1 \leq N$.*

Proof of Theorem 3. Let $w_1, \ldots, w_{w_\#}$ be the different weights and $p_1, \ldots, p_{p_\#}$ be the different profits in a given Knapsack instance with n items. We denote by $n_{i,j}$ for $i \in \{1, \ldots, w_\#\}$ and $j \in \{1, \ldots, p_\#\}$ the number of items with weight w_i and profit p_j. First note that the following is an ILP formulation of Knapsack with $w_\# \cdot p_\#$ many variables $x_{i,j}$, one for each $i \in \{1, \ldots, w_\#\}$ and $j \in \{1, \ldots, p_\#\}$, and two inequalities:

$$\begin{aligned} \sum_{i=1}^{w_\#} \sum_{j=1}^{p_\#} x_{i,j} \cdot w_i &\leq W \\ \sum_{i=1}^{w_\#} \sum_{j=1}^{p_\#} x_{i,j} \cdot p_j &\geq P \\ x_{i,j} &\in \{0, 1, \ldots, n_{i,j}\}. \end{aligned} \tag{3}$$

By Theorem 14, if $w_\# \cdot p_\# \cdot \lg\lg(w_\# \cdot p_\#) \leq \lg n$ (recall that n denotes the total number of items of the Knapsack instance), then the instance can be solved in polynomial time using ILP (3). Thus, devising a polynomial kernel in this case is trivial. So assume that $w_\# \cdot p_\# \cdot \lg(w_\# \cdot p_\#) > \lg n$. To reduce the encoding length of ILP (3), we apply Theorem 15 to the first two inequalities of ILP (3) as follows: let w^* be a $w_\# \cdot p_\#$-dimensional vector whose $(p_\# \cdot (i-1) + j)$'th component equals w_i, for each $i \in \{1, \ldots, w_\#\}$ and $j \in \{1, \ldots, p_\#\}$. We apply Theorem 15 to the $(w_\# \cdot p_\# + 1)$-dimensional vector $w := (w^*, -W)$ and $N := n+1$, resulting in a vector $(\overline{w}^*, -\overline{W})$. Similarly, let p^* be a $w_\# \cdot p_\#$-dimensional vector whose $(p_\# \cdot (i-1) + j)$'th component equals p_j, for $i \in \{1, \ldots, w_\#\}$ and $j \in \{1, \ldots, p_\#\}$. We apply Theorem 15 to the vector $w := (-p^*, P)$ and $N := n+1$, resulting in a vector $(-\overline{p}^*, \overline{P})$. By Theorem 15, ILP (3) is equivalent to the following ILP (4):

$$\begin{aligned} \overline{w}^* \cdot x &\leq \overline{W} \\ \overline{p}^* \cdot x &\geq \overline{P} \\ x_{i,j} &\in \{0, 1, \ldots, n_{i,j}\} \end{aligned} \tag{4}$$

By Theorem 15, each number from ILP (4) has encoding length $O(r^3 + r^2 \lg n)$ for $r = w_\# \cdot p_\#$. Since $\lg n \leq r \cdot \lg r$, it follows that the size of ILP (4) is $O(r^4 \cdot \lg r)$. As Knapsack is NP-complete, and Integer Linear Programming is in NP (see e.g. [15]), we can reduce ILP (4) in polynomial time to an instance of Knapsack. The resulting Knapsack instance is equivalent to the original instance, and has size polynomial in $r = w_\# \cdot p_\#$. ◀

Using the reduction from Unbounded Knapsack (i.e., the variation of Knapsack where a solution is a multiset of items instead of a regular set) to Knapsack (essentially also used e.g. by Etscheid et al. [22, Theorem 12]), one can also make the reduction from ILP (4) to Knapsack explicit, resulting in a kernel of size $\widetilde{O}((w_{\#} \cdot p_{\#})^5)$; see the full version [28] for details.

Abstract

The k-Opt algorithm is a local search algorithm for the Traveling Salesman Problem. Starting with an initial tour, it iteratively replaces at most k edges in the tour with the same number of edges to obtain a better tour. Krentel (FOCS 1989) showed that the Traveling Salesman Problem with the k-Opt neighborhood is complete for the class PLS (polynomial time local search) and that the k-Opt algorithm can have exponential running time for any pivot rule. However, his proof requires $k \gg 1000$ and has a substantial gap. We show the two properties above for a much smaller value of k, addressing an open question by Monien, Dumrauf, and Tscheuschner (ICALP 2010). In particular, we prove the PLS-completeness for $k \geq 17$ and the exponential running time for $k \geq 5$.

1 Introduction

The well-known Traveling Salesman Problem (TSP) consists of finding a spanning cycle of an edge weighted complete graph, such that the total edge weight of the cycle is the smallest possible. A popular heuristic for this problem is a local search algorithm called k-Opt. Starting with an arbitrary tour, it iteratively replaces at most k edges in the tour with the same number of edges, as long as the resulting tour has smaller total edge weight. We define TSP/k-Opt to be the problem of finding a local optimum for a TSP instance with the k-Opt algorithm.

A fundamental question in the area of local search algorithms is to determine the number of iterations a given local search algorithm may need in the worst case. A local search algorithm with a specified pivot rule has the *is-exp* property if there exist problem instances and initial solutions for which the local search algorithm requires an exponential number of iterations. For example, it is well known that the Simplex algorithm for linear programming

has the is-exp property for many different pivot rules [12, 9, 1, 6]. For TSP, Chandra, Karloff, and Tovey [2] showed that TSP/k-Opt has the is-exp property. This even holds for Euclidean TSP with the 2-Opt neighborhood [5].

For the Simplex algorithm it is not known whether there exists a pivot rule that guarantees a polynomial number of iterations. This is one of the most important open problems in the area of linear programming. Contrary to this Krentel [13] proved in 1989 that for sufficiently large values of k, TSP/k-Opt exhibits the *all-exp* property, that is, the k-Opt algorithm requires an exponential number of iterations to find a local optimum, for all possible pivot rules and for infinitely many pairs of a TSP instance and an initial tour. Krentel estimated that his proof yields a value for k between 1,000 and 10,000. By using a straight forward way to implement some missing details in Krentel's proof it was recently shown that his proof yields the value 14,208 for k [8].

Following Krentel's paper there have been claims in other papers [10, 22] through private communication with Krentel that a careful analysis of the original proof can bring down the value to $k = 8$ and conceivably to $k = 6$. However, there has been no available written proof for these claims. In fact, up to date, the 1989 paper of Krentel [13] is the only paper on the topic. Consequently, Monien, Dumrauf, and Tscheuschner [16] posed an open question on the complexity of TSP/k-Opt for $k \ll 1000$.

In this paper, we show that TSP/k-Opt has the all-exp property for much smaller k:

▶ **Theorem 1.** *TSP/k-Opt has the all-exp property for $k \geq 5$.*

Our proof of Theorem 1 is based on a new reduction from the bounded degree Max-Cut problem to TSP (see Section 3) which involves the construction of so called *parity gadgets* (see Section 3.1). With a first such approach we are able to prove the all-exp property of TSP/k-Opt for $k \geq 13$ (see Section 4). To lower the value of k additional ideas are required. First, we exploit the structure of a recent construction of Michel and Scott [15] of a degree-four bounded Max-Cut instance with the all-exp property under the flip neighborhood. Second, we show how to use global properties of our overall reduction to relax some local conditions on our parity gadgets. Combining these two ideas we achieve the value $k \geq 9$ (see Section 5). To arrive at our final result for $k \geq 5$ we have to modify the construction of Michel and Scott [15]. Moreover, we have to combine our parity gadgets with so called *double gadgets* and use a labeling scheme to assign different gadgets at different places in the reduction. These results we present in Section 6.

The second main contribution of our paper is a proof of the following result:

▶ **Theorem 2.** *TSP/k-Opt is PLS-complete for $k \geq 17$.*

The complexity class PLS and the notion of PLS-completeness (for definitions see Section 2) were introduced in 1988 by Johnson, Papdimitriou, and Yannakakis [11] to capture the observation that for many NP-hard problems it is not only difficult to compute a global optimum but even computing a local optimum is also hard. Examples of such problems are the Maximum Satisfiability problem [14], Max-Cut [21], and Set Cover [3]. The PLS-completeness of a problem means that a polynomial time algorithm to find a local optimum for that problem would imply polynomial time algorithms for finding a local optimum for all problems in PLS.

The PLS-completeness of TSP/k-Opt was proved by Krentel [13] for $k \gg 1000$. However, his proof has a substantial gap as he assumes that edges of weight infinity cannot occur in a local optimum. We present in Section 7 the first rigorous proof for the PLS-completeness of TSP/k-Opt and at the same time drastically lower the value of k from Krentel's $k \gg 1000$ [13]

to $k \geq 17$. Our proof uses several of the ideas used in our proof for Theorem 1. But in this case we need to take more care on the order in which the parity gadgets are plugged together in our construction. In addition, we show in Lemma 14 how to assign specific weights to the non-edges in our construction to prove that no local optimum can contain such an edge. We achieve this by defining a weight assignment that exploits the special structure of the TSP instance resulting from our PLS-reduction. This is the first rigorous proof of such a result for the k-Opt algorithm and there seems not to be a generic way to prove it for arbitrary TSP instances (as for example those constructed by Krentel [13]).

2 Preliminaries

2.1 Local search problems and the class PLS

A *local search problem* P is an optimization problem that consists of a set of instances D_P, a finite set of (feasible) solutions $F_P(I)$ for each instance $I \in D_P$, an objective function f_P that assigns an integer value to each instance $I \in D_P$ and solution $s \in F_P(I)$, and a neighborhood $N_P(s, I) \subseteq F_P(I)$ for each solution $s \in F_P(I)$. The size of every solution $s \in F_P(I)$ is bounded by a polynomial in the size of I. The goal is to find a *locally optimal solution* for a given instance I; that is, a solution $s \in F_P(I)$, such that no solution $s' \in N_P(s, I)$ yields a better objective value than $f_P(s, I)$. Formally, this means, for all $s' \in N_P(s, I)$, $f_P(s, I) \leq f_P(s', I)$ if P is a minimization problem, and $f_P(s, I) \geq f_P(s', I)$ if P is a maximization problem.

A *standard local search algorithm* for an instance I proceeds as follows. It starts with some initial solution $s \in F_P(I)$. Then it iteratively visits a neighbor with better objective value, until it reaches a local optimum. If a solution has more than one better neighbor, the algorithm has to choose one by some prespecified rule, often referred as a *pivot rule*.

A local search problem P has the *all-exp* property, if there are infinitely many pairs of an instance I of D_P and an initial solution $s \in F_P(I)$, for which the standard local search algorithm always needs an exponential number of iterations for all possible pivot rules.

A local search problem P is in the class *PLS* [11], if there are three polynomial time algorithms A_P, B_P, C_P such that

- Given an instance $I \in D_P$, A_P returns a solution $s \in F_P(I)$;
- Given an instance $I \in D_P$ and a solution $s \in F_P(I)$, B_P computes the objective value $f_P(s, I)$ of s; and
- Given an instance $I \in D_P$ and a solution $s \in F_P(I)$, C_P returns a neighbor of s with strictly better objective value, if it exists, and "locally optimal", otherwise.

A *PLS-reduction* from a problem $P \in$ PLS to a problem $Q \in$ PLS is a pair of polynomial-time computable functions h and g that satisfy:

1. Given an instance $I \in D_P$, h computes an instance $h(I) \in D_Q$; and
2. Given an instance $I \in D_P$ and a solution $s_q \in F_Q(h(I))$, g returns a solution $s_p \in F_P(I)$ such that if s_q is a local optimum for $h(I)$, then s_p is a local optimum for I.

A problem $Q \in$ PLS is *PLS-complete* [11] if for every problem $P \in$ PLS, there exists a PLS reduction from P to Q.

2.2 TSP/k-Opt

A *spanning cycle*, a *Hamiltonian cycle*, or a *tour* of an undirected graph is a cycle that contains all vertices of the graph.

A TSP instance is a tuple (G, w), where G is a complete undirected graph (V, E), and $w : E \to \mathbb{R}_{\geq 0}$ is a function that assigns a nonnegative weight to each edge of G. The goal is to find a tour of G that minimizes the sum of edge weights in the tour. The definition of the class PLS requires that we have a polynomial time algorithm to find *some* solution. For complete graphs such an algorithm certainly exists. If the graph is not complete then because of the NP-completeness of the Hamiltonian cycle problem we do not know such an algorithm.

A *swap* is a tuple (E_1, E_2) of subsets $E_1, E_2 \subseteq E$, $|E_1| = |E_2|$. We say that it is a swap of $|E_1|$ edges. If $|E_1| \leq k$ for some k, then we call it a k-swap. Performing a swap (E_1, E_2) from a subgraph G' of G refers to the act of removing E_1 from G' and adding E_2 to G'. We also call it swapping E_1 for E_2 in G'. Given a tour τ, a swap (E_1, E_2) is *improving* for τ, if after swapping E_1 for E_2 in τ, we obtain a tour with lower total edge weight.

A *(k-)swap sequence* is a sequence $L = (S_1, \ldots, S_\ell)$, such that each S_i is a (k-)swap. For a tour τ, we denote by τ^L the subgraph obtained from τ by performing $S_1, \ldots, S_\ell$ in their order in L. L is *improving* for a tour τ if each S_i is an improving (k-)swap for $\tau^{(S_1,\ldots,S_{i-1})}$.

The local search problem TSP/k-Opt corresponds to TSP with the k-Opt neighborhood (that is, the neighbors of a tour τ are those that can be obtained from τ by an improving k-swap). The k-Opt algorithm is then the standard local search algorithm for this problem, and an execution of the algorithm corresponds to an improving k-swap sequence.

2.3 Max-Cut/Flip

A Max-Cut instance is a tuple (G, w), where G is an undirected graph (V, E) and $w : E \to \mathbb{R}$ is a function assigning weights to the edges of G. A *cut* (V_1, V_2) of G is a partition of the vertices of G into two disjoint sets V_1 and V_2. The *cut-set* of a cut (V_1, V_2) is the set of edges $xy \in E$ such that $x \in V_1$ and $y \in V_2$. The goal of Max-Cut is to find a cut that maximizes the *value* of the cut, that is the total weight of the edges in the cut-set.

Given a Max-Cut instance and an initial cut, the *flip* of a vertex is a move of that vertex from a set of the cut to the other. The flip of a vertex is *improving*, if it results in an increase in the value of the cut. For a cut σ, its *flip neighborhood* is the set of all cuts obtained from σ by an improving flip. The Max-Cut/Flip problem is the local search problem that corresponds to the Max-Cut problem with the flip neighborhood. We call its standard local search algorithm the *Flip algorithm*. A *flip sequence* is a sequence $(v_1, \ldots, v_\ell)$ of vertices of G. A flip sequence is *improving*, if flipping the vertices in the order in the sequence increases the value of the cut at every step. In other words, an improving flip sequence corresponds to an execution of the Flip algorithm.

Monien and Tscheuschner [17] showed the all-exp property for Max-Cut/Flip even for graphs with bounded degree.

▶ **Theorem 3** ([17, 15]). *Max-Cut/Flip has the all-exp property, even when restricted to instances where all vertices have degree at most four.*

Michel and Scott [15] recently presented an alternative proof for Theorem 3. Interestingly, their construction is highly structured and exhibits a unique property: With a suitable initial cut, there is exactly one (maximal) improving flip sequence, and this sequence has exponential length. We rely on this particular construction and especially the unique property to achieve the low value of k in Theorem 1.

Note that Theorem 3 is tight with respect to the maximum degree, since the Flip algorithm on graphs with maximum degree at most three always terminates after a polynomial number of iterations [20].

3 The main reduction

In this section, we describe the main reduction to TSP/k-Opt from Max-Cut/Flip.

Let (H, w) be a Max-Cut instance. In order to avoid confusion with the vertices and edges in the TSP instance later on, we use *H-vertices* and *H-edges* for the vertices and edges of H. We denote by n and m the number of H-vertices and H-edges, respectively.

We construct from H the corresponding TSP instance as follows. We start with a cycle of $3(n+m)$ edges. We assign $n+m$ edges of this cycle to each of the n H-vertices and the m H-edges, such that any two assigned edges have distance at least two on the cycle.

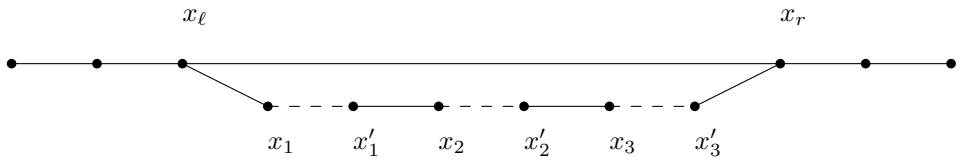

Figure 1 The first-set edge $x_\ell x_r$ and the second-set path $(x_\ell, x_1, x'_1, x_2, x'_2, x_3, x'_3, x_r)$ of an H-vertex x of degree three. The dashed edges are gateways. The other edges of the second-set path are doors.

Next, in the cycle consider an edge that is assigned to an H-vertex x. (Refer to Figure 1 for an illustration of the following concepts.) We label the two incident vertices of this edge x_ℓ and x_r, representing the left and the right vertex of the edge. Let $d(x)$ be the degree of x in H. We add a new path of length $2d(x)+1$ to connect x_ℓ and x_r. We call this new path the *second-set path* of x, while we call the original edge that was assigned to x the *first-set edge* of x. The idea is that the tour can connect x_ℓ and x_r either via the first-set edge or via the second-set path. This simulates whether the H-vertex x is in the first set or second set of the cut for the Max-Cut problem. Let $x_\ell, x_1, x'_1, \ldots, x_{d(x)}, x'_{d(x)}, x_r$ be the labels of the vertices along the second-set path. For $i \in \{1, \ldots, d(x)\}$, we call the edge $x_i x'_i$ a *gateway* of x. The other edges of the second-set path are called the *doors* of x. In other words, we have alternating doors and gateways along the path, with doors at both ends of the path.

For each H-edge xy, we call the edge in the cycle of length $3(n+m)$ assigned to xy the *xy-edge*. We remove a gateway of x, a gateway of y, and the xy-edge, and we connect the six incident vertices of the three removed edges by a *parity gadget*.

The purpose of this parity gadget is to simulate the contribution of the weight of edge xy to the objective of the Max-Cut problem, based on whether x and y are in the same set. We will formally define the parity gadget in Section 3.1.

Finally, for each H-vertex x, we assign an *XOR gadget* to the first-set edge of x and the door of x incident to x_r. The purpose of the XOR gadget is to make sure that we can simulate only one flip in H by a k-swap in the new graph. The formal definition of the XOR gadget and its assignment are discussed in Section 3.2.

Let G be the resulting graph after all the operations above (see Figure 2 for an example). Except for certain edges in the parity gadgets, which we will specify later, the other edges have weight zero, including the edges in the XOR gadgets, the initial cycle, and the doors. As a TSP instance requires a complete graph, we add the remaining edges with weight ∞ to obtain the final graph G_∞. However, if we start with a tour with a finite total weight, the k-Opt algorithm will never visit a tour that uses an edge with weight ∞. Hence, for the remaining of the reduction, we will argue based only on G.

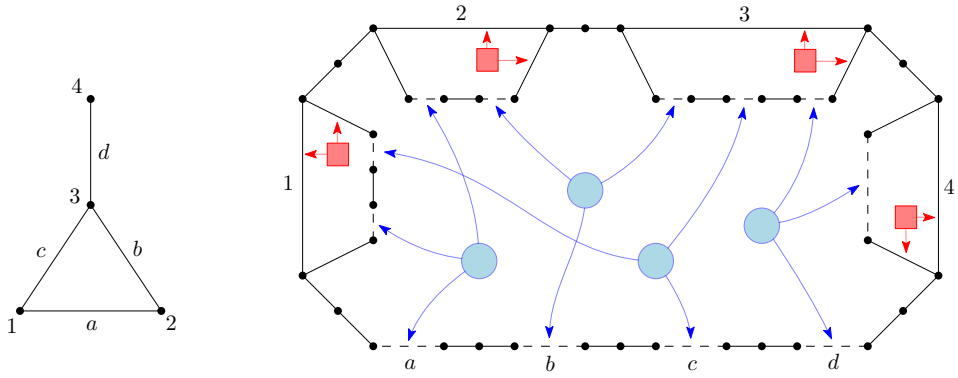

Figure 2 An example of our reduction from a Max-Cut instance (left figure) to a TSP instance (right figure). The parity gadgets are indicated by the blue circles attached to three edges each. The XOR gadgets are indicated by red boxes attached to two edges each.

3.1 Parity gadgets

In this section, we specify the parity gadgets, formally defined as follows.

▶ **Definition 4** (Parity Gadget). *A* parity gadget *is an edge weighted graph containing at least six distinct vertices labeled X, X', Y, Y', Z, Z' that satisfies the following two properties. First there exist at least the following four possibilities to cover the vertices of the parity gadget by vertex disjoint paths with endpoints in the set $\{X, X', Y, Y', Z, Z'\}$:*

(1) *A $\{Z, Z'\}$-path;*

(2) *An $\{X, X'\}$-path and a $\{Z, Z'\}$-path;*

(3) *A $\{Y, Y'\}$-path and a $\{Z, Z'\}$-path; or*

(4) *An $\{X, X'\}$-path, a $\{Y, Y'\}$-path and a $\{Z, Z'\}$-path.*

The four possibilities are called subtour *(1),* subtour *(2),* subtour *(3), and* subtour *(4) (see Figure 3 for an example). We require that in these four cases the cover is unique. A parity gadget may allow more than these four possibilities to cover the vertices by vertex disjoint paths with all endpoints in the set $\{X, X', Y, Y', Z, Z'\}$. Any such cover is called a* subtour *as long as Z and Z' are endpoints of some path(s) in this cover.*

We require in addition if X and X' are in the set of endpoints, then there must exist an $\{X, X'\}$-path in the cover. We require the same for the vertices Y and Y'.

Second, the edges of a parity gadget must allow a partition into three subsets, the same-set edges*, the* different-set edges*, and the remaining edges. The same-set edges have the same weight, which we call the* same-set weight*. Similarly, the different-set edges have the same* different-set weight*. The remaining edges have weight zero.*

We require that subtours (1) and (4) contain exactly one same-set edge and no different-set edge, and that subtours (2) and (3) contain exactly one different-set edge and no same-set edge. See Figure 3 for an example.

As explained before, a parity gadget is used to replace a gateway XX' of an H-vertex x, a gateway YY' of an H-vertex y, and the xy-edge ZZ'. The vertices X, X', Y, Y', Z, and Z' are part of the parity gadget, and the gadget is connected with the rest of G via exactly one incident edge to each of these vertices. We call these six incident edges the *external edges* of the gadget. We define the *internal edges* as the edges within the parity gadget. Further, we say that the gadget is *related* to the H-vertices x and y.

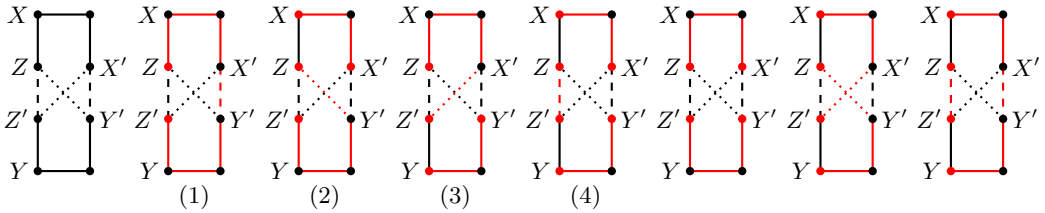

Figure 3 An example of a parity gadget (left figure). The next four figures show the four possibilities, subtour (1)–(4), to cover the vertices of the parity gadget by disjoint paths (red edges and red endpoints). The right three figures show additional subtours. The dashed edges are the same-set edges, the dotted edges are the different-set edges, and the solid edges are the remaining edges.

By construction, the removed edge ZZ' was originally part of a path of length five, say $(Z_1, Z_2, Z, Z', Z_3, Z_4)$. Since Z_2 and Z_3 have degree two in G, any tour of G has to contain Z_2Z and $Z'Z_3$. Therefore, the tour can only contain exactly one internal edge incident to Z and one incident to Z' (which may coincide). This is the reason why in the definition of a parity gadget the set $\{Z, Z'\}$ appears in all four cases.

A subtour containing an $\{X, X'\}$-path (i.e., subtour (2) or subtour (4)) represents that the corresponding H-vertex x is in the second set of the cut; otherwise, x is in the first set. When such a subtour occurs in the gadget, we say the gadget *uses* an $\{X, X'\}$-path. We have a similar representation and notation for the $\{Y, Y'\}$-path.

By definition of a parity gadget the total weight of the tour edges within a parity gadget is the same-set weight, when x and y are in the same set of the cut, and it is the different-set weight, when they are in different sets.

Next, a parity gadget is an (r_x, r_y)-*parity gadget*, if

- We need to remove exactly r_x internal edges and add exactly $r_x - 1$ internal edges to change from subtour (1) to subtour (2) or from subtour (3) to subtour (4);
- We need to remove exactly r_y internal edges and add exactly $r_y - 1$ internal edges to change from subtour (1) to subtour (3) or from subtour (2) to subtour (4);
- In order to change from subtour (1) to subtour (4) or between subtour (2) and subtour (3), we need to remove at least $\max\{r_x, r_y\}$ internal edges and add at least $\max\{r_x, r_y\} - 1$ internal edges.

We call the changes in the first two conditions above and their reverses the *standard subtour changes*.

By definition, a parity gadget may allow more than the four subtours (1)–(4) as possibilities to cover the vertices by disjoint paths with end vertices in the set $\{X, X', Y, Y', Z, Z'\}$. The parity gadget shown in Figure 3 allows for example to cover the vertices by a $\{Z, X'\}$-path and a $\{Z', Y'\}$-path. We say that a parity gadget is a *strict parity gadget*, or simply a *strict gadget*, if subtours (1)–(4) are the only possible subtours for the gadget in G, *after* we equip all gadgets (details are given in Section 3.3) used in the reduction. Thus the property of being strict may depend on the other gadgets used in the reduction.

3.2 XOR gadgets

The remaining gadgets used in the reduction are the XOR gadgets. We generalize these gadgets from the XOR gadget by [18]. See Figure 4(a)–(c) for an illustration for the definition below.

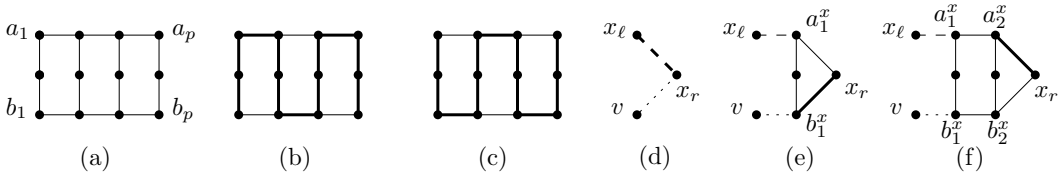

Figure 4 The XOR gadget of order four (a) and its two subtours ((b) and (c)). (d)–(f) are examples of assigning the XOR gadgets of order from zero to two to the H-vertex x, where dashed edges, dotted edges, and bold edges represent the left first-set edge, the door closest to x_r, and the right first-set edge, respectively.

▶ **Definition 5** (XOR Gadget). *Let p be a nonnegative integer. The* XOR gadget *of order p is a graph containing two paths $(a_1, \ldots, a_p)$ and $(b_1, \ldots, b_p)$, and for $i \in \{1, \ldots, p\}$, there is a path of length two with a_i and b_i as endpoints. A* subtour *of the XOR gadget is a spanning path with two endpoints in the set $\{a_1, a_p, b_1, b_p\}$. For convenience, when $p = 0$, both the XOR gadget of order zero and its only subtour are defined to be the empty graph.*

It is easy to see that an XOR gadget has two subtours, except when $p \leq 1$, in which case, it has only one subtour. Further, for $p \geq 2$, changing from one subtour to the other requires a swap of $p - 1$ edges.

We define the *assigning* of the XOR gadget of some order p to an H-vertex x as follows. (See Figure 4(d)–(f) for an illustration.) Recall that $x_\ell x_r$ is the first-set edge of x, and let vx_r be the incident door of x to x_r. We subdivide the two edges above into paths of length $p+1$, $(x_\ell, a_1^x, \ldots, a_p^x, x_r)$ and $(v, b_1^x, \ldots, b_p^x, x_r)$. Then for $i \in \{1, \ldots, p\}$, we connect a_i^x and b_i^x with a path of length two. Note that when $p = 0$, we do nothing. Further note that when we remove the edges incident to x_ℓ, x_r, and v in the construction above, we obtain the XOR gadget of order p as defined in Definition 5.

We call these incident edges to x_ℓ, x_r, and v the *external edges* of the XOR gadget, and we call the other edges in the construction the *internal edges* of the gadget. For convenience, we still refer to the external edge incident to v (i.e., vb_1^x for $p \geq 1$ and vx_r for $p = 0$) as a door of x. Additionally, we call it the *closest door to x_r*. We call the external edge incident to x_ℓ (i.e., $x_\ell a_1^x$ for $p \geq 1$ and $x_\ell x_r$ for $p = 0$) the *left first-set edge* of x. We define the *right first-set edge* of x as $x_r x_\ell$ if $p = 0$, $x_r a_p^x$ if p is positive and even, and $x_r b_p^x$ if p is odd. Lastly, we call the other external edge incident to x_r the *right second-set edge* of x.

We define an *incident edge* of a nonempty subtour of the XOR gadget to be an external edge incident to an endpoint of the subtour. The incident edge of an empty subtour (i.e., when $p = 0$) is defined to be simply an external edge of the XOR gadget.

Based on the definitions above, it is easy to verify the following.

▶ **Observation 6.** *For the XOR gadget assigned to an H-vertex x, one subtour of the gadget is incident to the left and right first-set edges of x, and another subtour of the gadget is incident to the closest door to x_r and the right second-set edge of x. The two subtours above are identical, if the order of the gadget is at most one. Otherwise, they are distinct.*

3.3 Equipping gadgets

Within our reduction we will use different parity gadgets at different places and XOR gadgets of different orders. The exact specification of which parity gadget we use at what place and the XOR gadget of which order is used for which H-vertex will be called the *equipping* of gadgets. We equip the gadgets through a labeling scheme. Specifically, for an H-vertex x

and an incident H-edge z, a labeling L assigns an integer label to the pair (x, z). We say the label is incident to x and to z. Additionally, L also assigns an integer label to each H-vertex. We also say this label is incident to x. We call a labeling L *valid*, if for every H-edge xy, there exists a $(L(x, xy), L(y, xy))$-parity gadget, and for every H-vertex x, $L(x) \geq 0$.

Then we equip the gadgets based on a valid labeling L as follows. For an H-edge xy, we equip the $(L(x, xy), L(y, xy))$-parity gadget to xy. Recall that $w(xy)$ is the weight of xy. If $w(xy) \geq 0$, the same-set weight of the gadget is $w(xy)$, and its different-set weight is zero. Otherwise, the same-set weight of the gadget is zero, and its different-set weight is $-w(xy)$. Finally, for an H-vertex x, we assign the XOR gadget of order $L(x)$ to x, and all edges involved in this assignment have weight zero. We call this a *gadget arrangement* corresponding to L. Note that this construction implies that edge weights in the TSP instance are nonnegative.

For each H-vertex x, we define the *label sum* of x to be the sum of the labels incident to x, i.e., $L(x) + \sum_{y:xy \in E(H)} L(x, xy)$. We say a labeling is an s-labeling, if each H-vertex has label sum s.

3.4 Initial tour

To complete the description of the TSP/k-Opt instance, we specify the initial tour of G. We obtain this tour from the initial cut of H as follows. The tour contains all incident edges of degree-two vertices. For an H-vertex x, if x is in the first set, we include the left and right first-set edges of x in the tour. Further, we use the subtour of the XOR gadget assigned to x, such that this subtour is incident to the left and right first-set edges of x. If x is in the second set, we include all the doors and the right second-set edge of x in the tour. Moreover, we use the subtour of the XOR gadget assigned to x, such that this subtour is incident to the right second-set edge of x and the closest door to x_r.

For an H-edge xy, in the corresponding gadget, we use the subtour (1) if x and y are in the first set, subtour (2) if x is in the second set and y in the first set, subtour (3) if x is in the first set and y in the second set, and subtour (4) if x and y are in the second set.

By the construction of G and the definition of the subtours, it can be verified that we obtain a tour of G.

3.5 Correspondence between flip sequences and swap sequences

Let us assume that we have a valid s-labeling L, and that the parity gadgets in the corresponding gadget arrangement are strict. Then we have the following correspondence (for a proof see [7]).

▶ **Lemma 7.** *Let I be a Max-Cut/Flip instance and σ be an initial cut for I. Suppose for some s, there is a valid s-labeling L for I such that all gadgets in the gadget arrangement in L are strict. Then we can reduce I to a TSP/k-Opt instance I', for $k = s + 1$, and obtain an initial tour τ from σ, such that there is a one-to-one correspondence between improving flip sequences for I and σ and improving k-swap sequences for I' and τ.*

4 All-exp property for $k \geq 13$

In this section, we prove the following statement.

▶ **Lemma 8.** *TSP/k-Opt has the all-exp property for $k \geq 13$.*

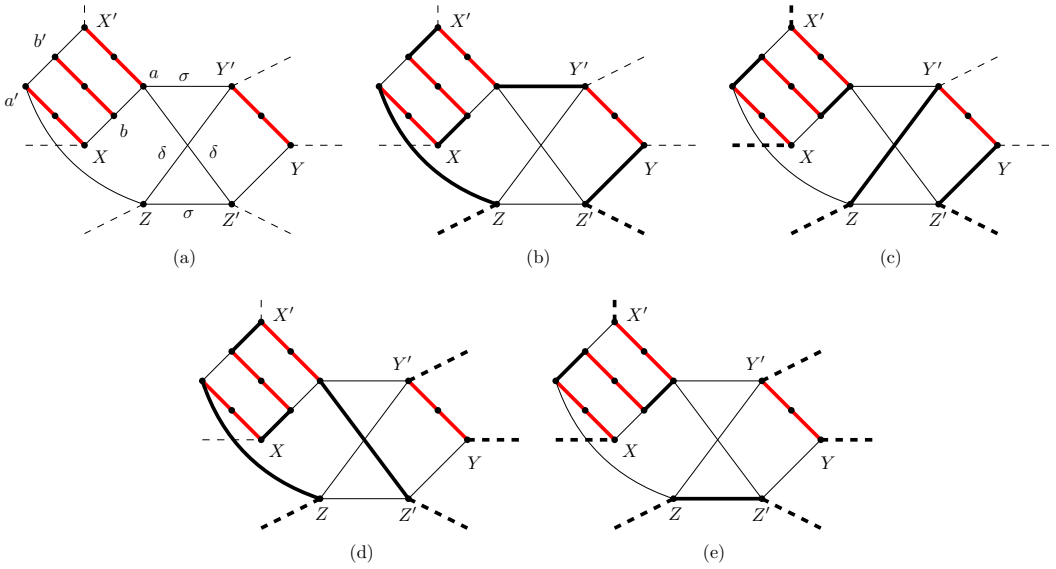

Figure 5 (a) A (4,2)-simple gadget. Bold red edges are incident to degree-two vertices. Dashed edges are external edges. $Y'a$ and ZZ' are same-set edges with same-set weight σ, while $Z'a$ and $Y'Z$ are different-set edges with different-set weight δ. (b)–(e) show the subtours (1)–(4).

We start with the parity gadgets. We call a parity gadget a *simple gadget*, if the parity gadget only allows subtours (1)–(4) (and no other subtours), independent of other gadgets equipped in the graph G. If a simple gadget is an (r_x, r_y)-parity gadget we call it an (r_x, r_y)-simple gadget. Note that a simple gadget is a strict gadget. The next result shows that a $(4, 2)$-simple gadget exists (and by symmetry, we also have a $(2, 4)$-simple gadget). The proof is given in [7].

▶ **Lemma 9.** *The gadget as depicted in Figure 5 is a* $(4, 2)$*-simple gadget.*

We can now prove Lemma 8. We use the reduction from Max-Cut/Flip to TSP/k-Opt as described in Section 3. By Theorem 3 we may assume H to have maximum degree four.

We now construct a valid $(k-1)$-labeling. Firstly, we assign an orientation on the H-edges, such that every degree-four H-vertex has exactly two incoming edges and two outgoing edges. Specifically, we repeat the following procedure: Until all H-edges have an orientation, we take a maximal (possibly closed) walk in the subgraph of unoriented H-edges, and we orient the edges along the walk. It is easy to see that the orientation is as desired.

Next, for every directed H-edge z with head x and tail y, we label (x, z) and (y, z) with four and two, respectively. By Lemma 9, there exists a simple gadget corresponding to these labels. Our construction guarantees that up to this point the label sum of every H-vertex is at most 12. Next, for each H-vertex, we assign a nonnegative label to the H-vertex, such that the label sum at the H-vertex is exactly $k - 1$. This is possible because $k \geq 13$. Hence, we obtain a valid $(k - 1)$-labeling.

Further, since we use only simple gadgets, the labeling above satisfies the condition of Lemma 7. Then by Theorem 3 and Lemma 7, we obtain Lemma 8.

5 All-exp property for $k \geq 9$

In this section, we prove the following statement.

▶ **Lemma 10.** *TSP/k-Opt has the all-exp property for* $k \geq 9$.

We use the reduction in Section 3, with two extra ingredients. Firstly, we look into the construction by Michel and Scott [15]. The graph for the instance is constructed inductively as follows (see Figure 6 for an illustration):

- The base graph F_0 consists of a single edge $v_{0,1}v_{0,8}$ with weight 7.
- The graph F_n contains a path of eight new vertices $v_{n,1}, v_{n,2}, v_{n,3}, v_{n,4}, v_{n,5}, v_{n,6}, v_{n,7}, v_{n,8}$ that appear in the path in that order. The weights of the edges along the path from $v_{n,1}$ to $v_{n,8}$ are $7 \cdot 8^n, 5 \cdot 8^n, 5 \cdot 8^n, 3 \cdot 8^n, 3 \cdot 8^n, 8^n, 8^n$. Next, we connect F_n to F_{n-1} as follows: We add edges connecting $v_{n-1,1}$ to $v_{n,2}, v_{n,4}$, and $v_{n,6}$, with weights $8^n, -8^n$, and 8^n, respectively. Finally, we add edges connecting $v_{n-1,8}$ to $v_{n,3}, v_{n,5}$, and $v_{n,7}$, with weights 1, -1, and 1, respectively.

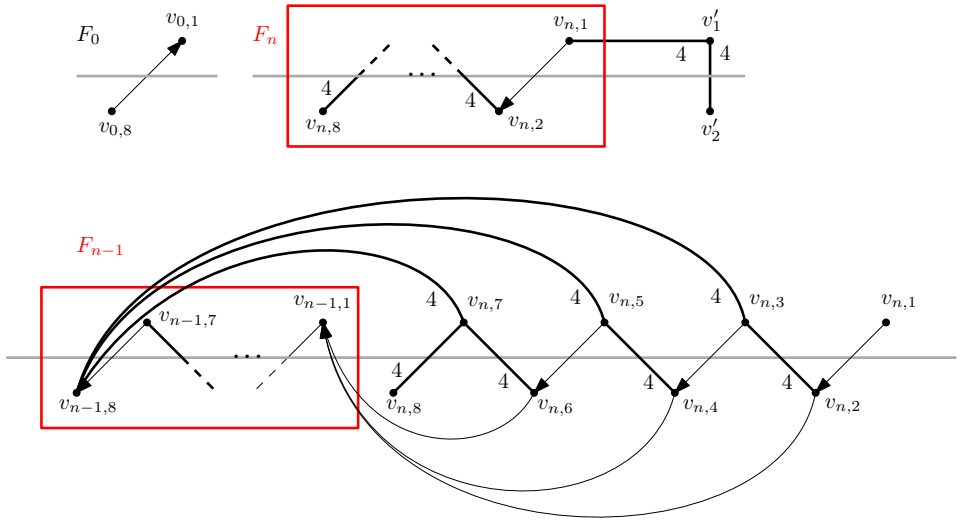

Figure 6 Michel-Scott construction of a Max-Cut instance that has an exponentially long improving flip sequence. Vertices on one side of the horizontal line are in the same set of the initial cut. We show here a valid $(k-1)$-labeling L and its gadget arrangement, for $k \geq 9$. Only labels $L(\cdot, \cdot)$ with value other than two are specified. All labels to vertices have suitable values to ensure the label sum at each vertex is $k-1$. Bold edges indicate simple gadgets, and the directed edges are flexible gadgets. The arrows indicate the direction of the forcing rule (i.e., if the gadget equipped to a directed edge is strict at the tail, then it is forced to be strict at the head).

The final graph H_n consists of all the graphs $F_0, \ldots, F_n$ and the connecting edges, as well as two new vertices v_1' and v_2' and two new edges $v_{n,1}v_1'$ and $v_1'v_2'$ with weights 8^{n+1} and $2 \cdot 8^{n+1}$, respectively. The initial cut of H_n is as follows: One set of the cut contains exactly v_1' and all vertices $v_{i,j}$ such that j is odd. The other set contains the remaining vertices.

Michel and Scott [15] showed that there exists a unique maximal improving flip sequence L_n from the aforementioned cut of H_n. The sequence is described recursively as follows: $L_0 = v_{0,1}v_{0,8}$, and $L_n = v_{n,1}v_{n,2}L_{n-1}v_{n,3}v_{n,4}L_{n-1}v_{n,5}v_{n,6}L_{n-1}v_{n,7}v_{n,8}$.

Secondly, we introduce the *flexible gadget*, a $(2,2)$-parity gadget as depicted in Figure 3. Note that it is not a simple gadget, because besides the subtours (1)–(4), there are other subtours, as shown in Figure 3. However, the following lemma (for a proof see [7]) shows that a suitable equipping of the flexible and simple gadgets can force the flexible gadgets to use only the subtours (1)–(4), and hence, they are strict:

▶ **Lemma 11.** *Suppose in the reduction in Section 3, we only equip simple, flexible, and XOR gadgets. If the H-edges corresponding to the flexible gadgets form a forest in H, then all parity gadgets are strict.*

To prove Lemma 10 we use the reduction from Section 3, with some specialization. Firstly, for the Max-Cut/Flip instance, we use the graph H_n as the graph H, for $n \geq 1$, and we use the corresponding weight and initial cut as described above. Secondly, we use the following labeling L: (See Figure 6 for a depiction of the labeling and gadget assignment.)

- For $i \in \{1, \ldots, n\}$ and $q \in \{3, 5, 7\}$, we have $L(v_{i,q}, v_{i,q}v_{i-1,8}) = 4$;
- For $i \in \{1, \ldots, n\}$ and $q \in \{2, 4, 6\}$, we have $L(v_{i,q}, v_{i,q}v_{i,q+1}) = 4$;
- $L(v_{n,8}, v_{n,8}v_{n,7}) = 4$;
- $L(v'_1, v_{n,1}v'_1) = L(v'_1, v'_1v'_2) = 4$;
- $L(x, z) = 2$, for all other pairs of an H-vertex x and an H-edge z not mentioned above and
- $L(v_{n,8}) = L(v_{n,1}) = k - 5$; $L(v'_2) = k - 3$; for other H-vertex x, we have $L(x) = k - 9$. (As $k \geq 9$, these labels are nonnegative.)

For every H-edge xy, if $L(x, xy) = L(y, xy) = 2$, we equip the flexible gadget to xy. Otherwise, we use the $(4, 2)$-simple gadget as described in Lemma 9 instead.

Observe that the labeling above is a valid $(k-1)$-labeling. Further, consider the subgraph of H containing all H-edges corresponding to the flexible gadgets. This subgraph is a forest with the leaves: $v_{0,8}$, $v_{n,1}$, $v_{n,3}$, $v_{n,5}$, $v_{j,3}$, $v_{j,5}$, $v_{j,7}$, and $v_{j,8}$ for $j \in \{1, \ldots, n-1\}$. By Lemma 11, all parity gadgets are strict.

Then Lemma 10 follows from Theorem 3 and Lemma 7.

6 All-exp property for $k \geq 5$

In this section, we prove Theorem 1 that asserts the all-exp property of TSP/k-Opt for $k \geq 5$. This proof is similar to that of Lemma 10 with a few changes. Firstly, we modify the Michel-Scott construction for the Max-Cut/Flip instance. In particular, we replace certain edges by paths of odd length. Secondly, we introduce a new gadget, called the *double gadget* that simulates two adjacent edges simultaneously. Lastly, we do not insist that all gadgets are strict. However, we argue that with our chosen initial tour, we cannot encounter a subtour other than subtours (1)–(4) in any parity gadget by a k-swap sequence.

6.1 Modified Michel-Scott construction

See Figure 7 for a depiction of the modification explained in this section. Recall the construction by Michel and Scott [15] and the unique maximal improving flip sequence L_n in Section 5. Let p be an odd number that is at least three. We observe that for any consecutive pair (v, v') in the sequence L_n, vv' is an edge in H_n and (v', v) is not a contiguous subsequence of L_n. In that case, for such consecutive pair (v, v'), we orient the edge vv' in H_n from v to v'. Then we obtain a partial orientation $\overrightarrow{H}_n$ of H_n.

For $i \in \{0, \ldots, n\}$ and $q \in \{1, \ldots, 7\}$, note that the vertex $v_{i,q}$ only has one out-neighbor $v_{i',q'}$ in $\overrightarrow{H}_n$, for some i', q'. We replace the edge $v_{i,q}v_{i',q'}$ by a path of length p $(v_{i,q}, u^1_{i,q,q'}, \ldots, u^{p-1}_{i,q,q'}, v_{i',q'})$, with $p-1$ new vertices $u^1_{i,q,q'}, \ldots, u^{p-1}_{i,q,q'}$. The weights of the new edges and which set of the cut the new vertices belong to depend on the sign of the weight of the original edges. In particular, let ω be the original weight of $v_{i,q}v_{i',q'}$ and ε be a very small number (say, 2^{-n}), and define $u^0_{i,q,q'} := v_{i,q}$ and $u^p_{i,q,q'} := v_{i',q'}$. If $\omega > 0$, then we assign the weights for the edges along the path in decreasing order: for $j = 0, \ldots, p-1$, the edge $u^j_{i,q,q'}u^{j+1}_{i,q,q'}$ has weight $\omega - j\varepsilon$. Further, we assign $u^j_{i,q,q'}$ to the same set of the cut as $v_{i,q}$ for j even, and to that as $v_{i',q'}$ for j odd. If $\omega < 0$, we assign the weights for the edges along the path in increasing order: for $j = 0, \ldots, p-1$, the edge $u^j_{i,q,q'}u^{j+1}_{i,q,q'}$ has weight

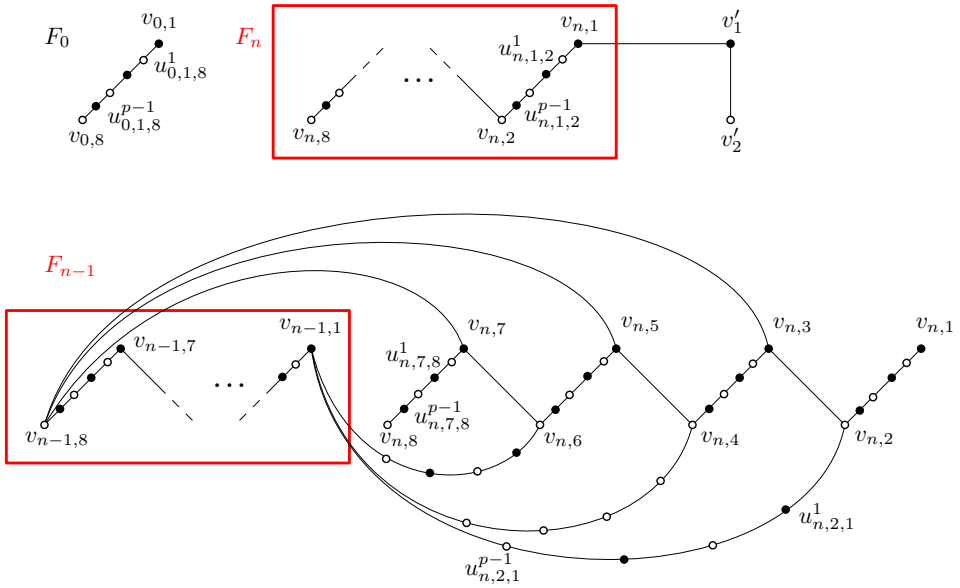

Figure 7 Modified Michel-Scott construction, where we replace certain edges in Figure 6 with paths of length p. Here, we indicate the sets of the initial cut by the colors of the vertices.

$\omega + j\varepsilon$. Further, we assign $u^j_{i,q,q'}$ to the same set of the cut as $v_{i,q}$, for all $j \in [p-1]$. The resulting (undirected) graph, weight, and cut after all replacements are the graph H, the weight w, and the initial cut χ_0 that we will use for the reduction.

We can show (for a proof see [7]) that the uniqueness property carries over to the new instance.

▶ **Lemma 12.** *There is a unique maximal improving flip sequence L'_n from the cut χ_0 of H, and this sequence is exponentially long.*

6.2 Double gadget

Let xy and xt be two H-edges. Denote $z := xy$. A *double gadget* replaces a gateway YY' of y, a gateway TT' of t, the z-edge ZZ', and a subpath (X, X_1, X_2, X') of the second-set path of x, where XX_1 and X_2X' are two gateways of x. Note that the vertices X_1 and X_2 are removed from the graph G, when we equip the double gadget to the pair xy and xt. Further, the xt-edge is not replaced by any gadget. As the third edge in a path of length five in G, the xt-edge is then used in every tour of G. We define the external and internal edges of the double gadget similar to those of parity gadgets.

A double gadget has to guarantee at least eight possible subtours (with subtours defined analogously to subtours defined in Definition 4). A $\{Z, Z'\}$-path is always present in these subtours. The eight subtours corresponds to all possibilities of containing an $\{X, X'\}$-path, a $\{Y, Y'\}$-path, or a $\{T, T'\}$-path.

Let $\sigma(x, y)$ and $\delta(x, y)$ be the same-set and different-set weights for the edge xy, respectively (i.e., they correspond to the weights when x and y are in the same set and in different sets). The numbers $\sigma(x, t)$ and $\delta(x, t)$ are defined analogously. For each of the eight subtours, the total weight of the internal edges in the subtour is the sum of two numbers, a_{xy} and a_{xt}. a_{xy} takes value $\sigma(x, y)$ if an $\{X, X'\}$-path and a $\{Y, Y'\}$-path are both present or both absent; and it takes value $\delta(x, y)$ if exactly one of these paths is present. a_{xt} is defined analogously.

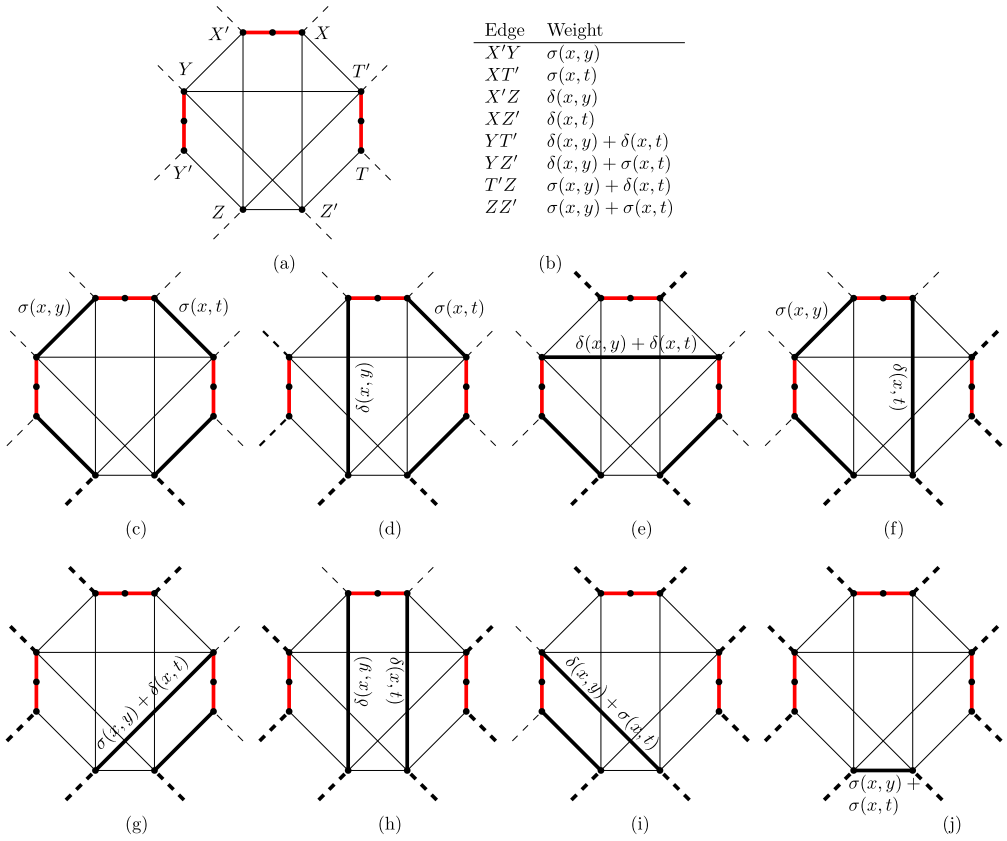

Figure 8 A (2,2,2)-double gadget (a) and the listing of edges with nonzero weights (b). The other panels show the eight subtours when the gadget is locally strict, including the nonzero weights of the edges in the subtours.

We extend the definition of an (r_x, r_y)-parity gadget to an (r_x, r_y, r_t)-double gadget in the obvious way, e.g., r_x is the number of internal edges that have to be removed if in a subtour an $\{X, X'\}$-path is added.

In the following proof, we use the (2,2,2)-double gadget as depicted in Figure 8. One can easily verify that the graph is indeed a (2,2,2)-double gadget. Note that the gadget also allows subtours other than those shown in the figure. However, we will show later that these other subtours do not appear in the improving swap sequence of concern.

6.3 Proof of Theorem 1

We use the reduction described in Section 3, from the Max-Cut instance (H, w) and the initial cut χ_0 indicated in Section 6.1. In the construction of the Max-Cut instance, we use a constant p which is odd and more than $2k$, where we recall that p is the length of the paths that replace certain edges.

We then define a suitable labeling by using the $(2, 2, 2)$-double gadgets, the flexible gadgets, the $(4, 2)$-simple gadgets, and the XOR-gadgets. The crucial idea here is that a double gadget can be used to label two incident edges. As a result, each H-vertex can now be incident to at most three labels, including one label corresponding to the XOR gadget. Accordingly, we can bring the label sum down to as low as four.

Next, we argue that although the flexible gadget and the $(2, 2, 2)$-double gadget allow many subtours, we only encounter a limited subset of these subtours. For this we introduce the notion of local strictness and show that we can get a result similar to Lemma 7. With this we can prove Theorem 1. See [7] for the details of this proof.

7 PLS-Completeness for $k \geq 17$

In this section, we prove the PLS-completeness of TSP/k-Opt for $k \geq 17$. With this result we not only improve the value $k \geq 14,208$ from Krentel [13, 8]. We also present the first rigorous PLS-completeness proof for TSP/k-Opt as Krentel's proof has a substantial gap. He assumes without proof that no edges of infinite weight can appear in a local optimum. The definition of PLS-completeness requires that the function g maps local optima to local optima. Therefore, either one has to show that a local optimum cannot contain edges of infinite weight, or one has to show how to extend the definition of the function g to local optima that contain edges of infinite weight. Both are not done in the paper of Krentel [13], and there is no obvious way how to fill this gap. For our reduction we can prove in Lemma 14 below that local optima cannot contain edges of infinite weight. There seems not to be a generic way to prove such a result for arbitrary TSP instances as for example those constructed by Krentel [13]. A result similar to Lemma 14 was obtained by Papadimitriou [19] for the Lin-Kernighan heuristic.

▶ **Theorem 2.** *TSP/k-Opt is PLS-complete for $k \geq 17$.*

Our proof of Theorem 2 follows closely the proof of Lemma 8. However, there are three key differences. Firstly, while the all-exp property is known to hold for Max-Cut instances with maximum degree four (Theorem 3), the PLS-completeness of Max-Cut/Flip is only known for maximum degree five:

▶ **Theorem 13** ([4]). *Max-Cut/Flip is PLS-complete, even when restricted to graphs of maximum degree five.*

Secondly, we impose certain structure on the graph G in the reduction. Particularly, we specify which gateways a parity gadget can replace.

Lastly, recall that the TSP instance requires a complete graph G_∞, which we obtain from G by adding the missing edges, which we also call the *non-edges*. By choosing suitable weights for the non-edges we will be able to prove in Lemma 14 that no locally optimal tour of G_∞ can contain a non-edge.

Proof of Theorem 2. We use the reduction from Max-Cut to TSP as described in Section 3. By Theorem 13, we can assume in the Max-Cut instance (H, w), that H is a graph of maximum degree five.

We assign an orientation on the H-edges such that each degree-five vertex has in-degree at most three. We can get such an orientation by repeating the following procedure: Until all H-edges have an orientation, we take a maximal (possibly closed) walk in the subgraph of unoriented H-edges, and we orient the edges along the walk. For every directed H-edge z with head x and tail y, we label (x, z) and (y, z) with four and two, respectively. Next, for each H-vertex x, we assign an integer label to x, such that the label sum at x is $k - 1$. This label is nonnegative, as $k \geq 17$. Corresponding to these labels we use the $(4, 2)$-simple gadgets from Lemma 9 and the XOR-gadgets. Hence, this is a valid $(k - 1)$-labeling. We denote it by L.

Next, we specify the gadget arrangement corresponding to L as follows. Recall that n is the number of H-vertices. Let $x^1, \ldots, x^n$ be the H-vertices. For every H-vertex x, we assign the XOR gadget of order $L(x)$ to x. Let ψ be the increasing lexicographical order of the H-edges with respect to the H-vertex indices. That is, for $i < i'$ and $j < j'$, the H-edge $x^i x^{i'}$ precedes the H-edge $x^j x^{j'}$ in the order ψ, if either $i < j$ or $i = j$ and $i' < j'$. Then we equip the parity gadgets according to the labeling L, such that when we go along the second-set path for each H-vertex x from x_ℓ to x_r, the H-edges corresponding to the related gadgets appear in their order in ψ. We equip the gadgets such that for a (4,2)-simple gadget g related to an H-vertex t, either the vertex X or Y in g is adjacent to either t_ℓ or a vertex in a gadget that is also related to t and precedes g in ψ.

Let G and w be the resulting graph and edge weight function. We have the following lemma (for a proof see [7]).

▶ **Lemma 14.** *For $k \geq 3$ there exists a complete graph G_∞ with a corresponding edge weight function w' obtained from G and w by adding the missing edges with suitable weights, such that for the TSP/k-Opt instance consisting of (G_∞, w'), all locally optimal tours only contain edges of G.*

For a given tour τ we can map it to a cut σ as follows: For each H-vertex x we put x into the first set if τ uses the left first-set edge. Otherwise we put x into the second set. Assume we have a tour τ that is a local optimum but the corresponding cut is not a local optimum. By Lemma 14 the tour τ contains only edges from G. By using arguments similar to those used in the proof of Lemma 7 we can conclude that τ is not a local optimum, a contradiction.

Then Theorem 2 follows from Theorem 13. ◀

8 Conclusion

We have shown that for $k \geq 5$ the k-Opt algorithm for TSP has the all-exp property, i.e. it has exponential running time for all possible pivot rules (Theorem 1). Moreover, we proved that TSP/k-Opt is PLS-complete for $k \geq 17$ (Theorem 2). In both cases we drastically lowered the so far best known value for k which was $\gg 1000$. It was mentioned (without explaining the details) in [13] that there is a connection between the PLS-completeness of a problem and the all-exp property. This connection was made precise by Schäffer and Yannakakis [21] who introduced the notion of *tight* PLS-completeness. They proved that the tight PLS-completeness of a problem implies the all-exp property. Our PLS-completeness result for TSP/k-Opt relies on the PLS-completeness of Max-Cut/Flip for graphs with maximum degree five [4]. As for the latter the tight PLS-completeness is not known we do not get tight PLS-completeness for TSP/k-Opt.

We put some effort into getting the constant in Theorem 1 as small as possible. In contrast, the constant in Theorem 2 very likely can be lowered to 15 by using our techniques from Section 6. However, this would require substantially more involved proofs. Finally we would like to mention (as already observed by Krentel [13]) that our results also hold for *metric* TSP as one can add a sufficiently large constant to all edge weights.

Optimal PSPACE-Hardness of Approximating Set Cover Reconfiguration

Shuichi Hirahara
National Institute of Informatics, Tokyo, Japan

Naoto Ohsaka
CyberAgent, Inc., Tokyo, Japan

Abstract

In the Minmax Set Cover Reconfiguration problem, given a set system $\mathcal{F}$ over a universe $\mathcal{U}$ and its two covers $\mathcal{C}^{\mathsf{start}}$ and $\mathcal{C}^{\mathsf{goal}}$ of size k, we wish to transform $\mathcal{C}^{\mathsf{start}}$ into $\mathcal{C}^{\mathsf{goal}}$ by repeatedly adding or removing a single set of $\mathcal{F}$ while covering the universe $\mathcal{U}$ in any intermediate state. Then, the objective is to minimize the maximum size of any intermediate cover during transformation. We prove that Minmax Set Cover Reconfiguration and Minmax Dominating Set Reconfiguration are PSPACE-hard to approximate within a factor of $2-\frac{1}{\mathrm{polyloglog}\, N}$, where N is the size of the universe and the number of vertices in a graph, respectively, improving upon Ohsaka (SODA 2024) [32] and Karthik C. S. and Manurangsi (2023) [26]. This is the first result that exhibits a sharp threshold for the approximation factor of any reconfiguration problem because both problems admit a 2-factor approximation algorithm as per Ito, Demaine, Harvey, Papadimitriou, Sideri, Uehara, and Uno (Theor. Comput. Sci., 2011) [23]. Our proof is based on a reconfiguration analogue of the FGLSS reduction [12] from *Probabilistically Checkable Reconfiguration Proofs* of Hirahara and Ohsaka (STOC 2024) [19]. We also prove that for any constant $\varepsilon \in (0,1)$, Minmax Hypergraph Vertex Cover Reconfiguration on $\mathrm{poly}(\varepsilon^{-1})$-uniform hypergraphs is PSPACE-hard to approximate within a factor of $2-\varepsilon$.

1 Introduction

1.1 Background

In the field of reconfiguration, we study the reachability and connectivity over the space of feasible solutions under an adjacency relation. Given a *source problem* that asks the existence of a feasible solution, its *reconfiguration problem* requires to decide if there exists a *reconfiguration sequence*, namely, a step-by-step transformation between a pair of feasible solutions while always preserving the feasibility of any intermediate solution. One of the reconfiguration problems we study in this paper is Set Cover Reconfiguration [23], whose source problem is Set Cover. In the Set Cover Reconfiguration problem, for a set system $\mathcal{F}$ over a universe $\mathcal{U}$ and its two covers $\mathcal{C}^{\mathsf{start}}$ and $\mathcal{C}^{\mathsf{goal}}$ of size k, we seek a reconfiguration sequence from $\mathcal{C}^{\mathsf{start}}$ to $\mathcal{C}^{\mathsf{goal}}$ consisting only of covers of size at most $k+1$, each of which is obtained from the previous one by adding or removing a single set of $\mathcal{F}$. Countless reconfiguration problems have been defined from a variety of

source problems, including Boolean satisfiability, constraint satisfaction problems, and graph problems. Studying reconfiguration problems may help elucidate the structure of the solution space of combinatorial problems [13].

The computational complexity of reconfiguration problems has the following trend: a reconfiguration problem is likely to be PSPACE-complete if its source problem is intractable (say, NP-complete); e.g., Set Cover [23], 3SAT [13], and Independent Set [16, 17]; a source problem in P frequently induces a reconfiguration problem in P; e.g., Spanning Tree [23] and 2SAT [13]. Some exception are however known; e.g., 3Coloring [7] and Shortest Path [6]. We refer the readers to the surveys by Nishimura [30] and van den Heuvel [35] and the Combinatorial Reconfiguration wiki [20] for more algorithmic and hardness results of reconfiguration problems.

To overcome the computational hardness of a reconfiguration problem, we consider its *optimization version*, which affords to relax the feasibility of intermediate solutions. For example, Minmax Set Cover Reconfiguration [23] is an optimization version of Set Cover Reconfiguration, where we are allowed to use any cover of size greater than $k+1$, but required to minimize the *maximum size of any covers* in the reconfiguration sequence (see Section 4.1 for the formal definition). Solving this problem approximately, we may be able to find a "reasonable" reconfiguration sequence for Set Cover Reconfiguration that consists of covers of size at most, say, 1% larger than $k+1$. Unlike Set Cover, which is NP-hard to approximate within a factor smaller than $\ln n$ [10, 11, 27], Minmax Set Cover Reconfiguration admits a 2-factor approximation algorithm due to Ito, Demaine, Harvey, Papadimitriou, Sideri, Uehara, and Uno [23, Theorem 6]. An immediate question is: *Is this the best possible?*

Here, we summarize known hardness-of-approximation results on Minmax Set Cover Reconfiguration. Ohsaka [32] showed that Minmax Set Cover Reconfiguration is PSPACE-hard to approximate within a factor of 1.0029 assuming the Reconfiguration Inapproximability Hypothesis [31], which was recently proved [19, 26]. Karthik C. S. and Manurangsi [26] proved NP-hardness of the $(2-\varepsilon)$-factor approximation for any constant $\varepsilon \in (0,1)$. Both results are not optimal: Ohsaka's factor 1.0029 is far smaller than 2, while Karthik C. S. and Manurangsi's result is not PSPACE-hardness. This leaves a tantalizing possibility that there may exist a polynomial-length reconfiguration sequence that achieves a 1.0030-factor approximation for Minmax Set Cover Reconfiguration, and hence the approximation problem may be in NP. Note that the PSPACE-hardness result of Ohsaka [32] disproves the existence of a polynomial-length witness (in particular, a polynomial-length reconfiguration sequence) for the 1.0029-factor approximation under the assumption that NP $\neq$ PSPACE.

1.2 Our Results

We present optimal results of PSPACE-hardness of approximation for three reconfiguration problems. Our first result is that Minmax Set Cover Reconfiguration is PSPACE-hard to approximate within a factor smaller than 2, improving upon Ohsaka [32, Corollary 4.2] and Karthik C. S. and Manurangsi [26, Theorem 4]. This is the first result that exhibits a sharp threshold for the approximation factor of any reconfiguration problem: approximating within any factor below 2 is PSPACE-complete and within a 2-factor is in P [23].

▶ **Theorem 1.1** (informal; see Theorem 4.1)**.** *For a set system $\mathcal{F}$ of universe size N and its two covers $\mathcal{C}^{\mathsf{start}}$ and $\mathcal{C}^{\mathsf{goal}}$ of size k, it is* PSPACE*-complete to distinguish between the following cases*:

- (*Completeness*) *There exists a reconfiguration sequence from* $\mathcal{C}^{\mathsf{start}}$ *to* $\mathcal{C}^{\mathsf{goal}}$ *consisting only of covers of size at most* $k+1$.
- (*Soundness*) *Every reconfiguration sequence contains a cover of size greater than* $(2-\varepsilon(N))(k+1)$, *where* $\varepsilon(N) \coloneqq (\mathrm{polyloglog}\, N)^{-1}$.

In particular, Minmax Set Cover Reconfiguration *is* PSPACE*-hard to approximate within a factor of* $2-\varepsilon(N)$.

As a corollary of Theorem 4.1 along with [32], the following PSPACE-hardness of approximation holds for Dominating Set Reconfiguration, which also admits a 2-factor approximation [23] (please refer to [32] for the problem definition).

▶ **Corollary 1.2** (from Theorem 4.1 and [32, Corollary 4.3]). Minmax Dominating Set Reconfiguration *is* PSPACE*-hard to approximate within a factor of* $2-\frac{1}{\mathrm{polyloglog}\, N}$, *where* N *is the number of vertices in a graph.*

Our third result is a similar inapproximability result for Hypergraph Vertex Cover Reconfiguration, which is defined analogously to Set Cover Reconfiguration. Minmax Hypergraph Vertex Cover Reconfiguration is easily shown to be 2-factor approximable [23]; we prove that this is optimal.

▶ **Theorem 1.3** (informal; see Theorem 4.3). *For any constant* $\varepsilon \in (0,1)$, *a* $\mathrm{poly}(\varepsilon^{-1})$*-uniform hypergraph, and its two vertex covers* $\mathcal{C}^{\mathsf{start}}$ *and* $\mathcal{C}^{\mathsf{goal}}$ *of size* k, *it is* PSPACE*-complete to distinguish between the following cases*:

- (*Completeness*) *There exists a reconfiguration sequence from* $\mathcal{C}^{\mathsf{start}}$ *to* $\mathcal{C}^{\mathsf{goal}}$ *consisting only of vertex covers of size at most* $k+1$.
- (*Soundness*) *Every reconfiguration sequence contains a vertex cover of size greater than* $(2-\varepsilon)(k+1)$.

In particular, Minmax Hypergraph Vertex Cover Reconfiguration *on* $\mathrm{poly}(\varepsilon^{-1})$*-uniform hypergraphs is* PSPACE*-hard to approximate within a factor of* $2-\varepsilon$.

We highlight here that the size of hyperedges in a Hypergraph Vertex Cover Reconfiguration instance of Theorem 4.3 depends (polynomially) only on the value of ε^{-1}, whereas the size of subsets in a Set Cover Reconfiguration instance of Theorem 4.1 may depend on the universe size N.

Proofs marked with $*$ are omitted and can be found in the full version of this paper [18].

1.3 Proof Overview

At a high level, our proofs of Theorems 1.1 and 1.3 are given by combining the ideas developed in [19, 31, 32, 26]. Karthik C. S. and Manurangsi [26] proved NP-hardness of the $(2-\varepsilon)$-factor approximation of Minmax Set Cover Reconfiguration as follows.

1. Starting from the PCP theorem for NP [3, 4], they applied the FGLSS reduction [12] to prove NP-hardness of the $\mathcal{O}(\varepsilon^{-1})$-factor approximation of an intermediate problem, which we call Max Partial 2CSP.
2. The $\mathcal{O}(\varepsilon^{-1})$-factor approximation of Max Partial 2CSP is reduced to the $(2-\varepsilon)$-factor approximation of a reconfiguration problem, which we call Label Cover Reconfiguration (Problem 2.3).
3. Label Cover Reconfiguration can be reduced to Minmax Set Cover Reconfiguration via approximation-preserving reductions of Lund and Yannakakis [27] and Ohsaka [32].

Here, Max Partial 2CSP is defined as follows. The input consists of a graph $G = (\mathcal{V}, \mathcal{E})$, a finite alphabet Σ, and constraints $\psi_e \colon \Sigma^2 \to \{0, 1\}$ for each edge $e \in \mathcal{E}$. A *partial assignment* is a function $f \colon \mathcal{V} \to \Sigma \cup \{\bot\}$, where the symbol $\bot$ indicates "unassigned." The task is to maximize the fraction of assigned vertices in a partial assignment f that *satisfies* ψ_e for every $e = (v, w) \in \mathcal{E}$; i.e., $\psi_e(f(v), f(w)) = 1$ if $f(v) \neq \bot$ and $f(w) \neq \bot$.

To improve this NP-hardness result to PSPACE-hardness, we replace the starting point with the PCRP (Probabilistically Checkable Reconfiguration Proof) system of Hirahara and Ohsaka [19], which is a reconfiguration analogue of the PCP theorem. We also replace Max Partial 2CSP with its reconfiguration analogue, which we call Partial 2CSP Reconfiguration (Problem 2.2). The proof of PSPACE-hardness is outlined as follows.

1. Starting from the *PCRP theorem* for PSPACE [19], we apply the FGLSS reduction [12] to prove PSPACE-hardness of Partial 2CSP Reconfiguration (Sections 3.1 and 3.2).
2. We reduce Partial 2CSP Reconfiguration to Label Cover Reconfiguration (Section 3.3).
3. We reduce Label Cover Reconfiguration to Minmax Set Cover Reconfiguration by the reductions of [32, 27] (Section 4.1).

The second and third steps are similar to the previous work [26]. Our main technical contribution lies in the first step, which we explain below.

Roughly speaking, the PCRP theorem [19] shows that any PSPACE computation on inputs of length n can be encoded into a sequence $\pi^{(1)}, \cdots, \pi^{(T)} \in \{0, 1\}^{\mathrm{poly}(n)}$ of exponentially many proofs such that any adjacent pair of proofs $\pi^{(t)}$ and $\pi^{(t+1)}$ differs in at most one bit, and each proof $\pi^{(t)}$ can be probabilistically checked by reading $q(n)$ bits of the proof and using $r(n)$ random bits, where $q(n) = \mathcal{O}(1)$ and $r(n) = \mathcal{O}(\log n)$. The FGLSS reduction [12] transforms such a proof system into a graph $G = (\mathcal{V}, \mathcal{E})$, an alphabet Σ, and constraints $(\psi_e)_{e \in \mathcal{E}}$ such that each vertex $v \in \mathcal{V} \coloneqq \{0, 1\}^{r(n)}$ corresponds to a coin flip sequence of a verifier, each value $\alpha \in \Sigma = \{0, 1\}^{q(n)}$ corresponds to a local view of the verifier, and the constraints ψ_e check the consistency of two local views of the verifier. This reduction works in the case of the PCP theorem and proves NP-hardness of Max Partial 2CSP [26]. However, the reduction does not work in the case of the PCRP theorem: We need to ensure that the reconfiguration sequence of proofs $\pi^{(1)}, \cdots, \pi^{(T)}$ is transformed into a sequence of partial assignments $f^{(1)}, \cdots, f^{(T)}$, each adjacent pair of which differs in at most one vertex. The issue is that changing one bit in the original proof $\pi^{(t)}$ may result in changing the assignments of many vertices in a partial assignment $f^{(t)} \colon \mathcal{V} \to \Sigma \cup \{\bot\}$.

To address this issue, we employ the ideas developed in [31, 32], called the *alphabet squaring trick*, and modify the FGLSS reduction as follows. Given a verifier that reads $q(n)$ bits of a proof, we define the alphabet as $\Sigma = \{0, 1, 01\}^{q(n)}$. Intuitively, the symbol "01" means that we are taking 0 and 1 simultaneously. This enables us to construct a reconfiguration sequence of partial assignments $f^{(1)}, \cdots, f^{(T)}$ from a reconfiguration sequence of proofs $\pi^{(1)}, \cdots, \pi^{(T)}$. Details can be found in Section 3.2.

1.4 Related Work

Ito, Demaine, Harvey, Papadimitriou, Sideri, Uehara, and Uno [23] showed that optimization versions of SAT Reconfiguration and Clique Reconfiguration are NP-hard to approximate, relying on NP-hardness of approximating Max SAT [15] and Max Clique [14], respectively. Note that their NP-hardness results are not optimal since SAT Reconfiguration and Clique Reconfiguration are PSPACE-complete. Toward PSPACE-hardness of approximation for reconfiguration problems, Ohsaka [31] proposed the *Reconfiguration Inapproximability Hypothesis* (RIH), which postulates that a reconfiguration analogue of

Constraint Satisfaction Problem is PSPACE-hard to approximate, and demonstrated PSPACE-hardness of approximation for many popular reconfiguration problems, including those of 3SAT, Independent Set, Vertex Cover, Clique, Dominating Set, and Set Cover. Ohsaka [32] adapted Dinur's gap amplification [9] to demonstrate that under RIH, optimization versions of 2CSP Reconfiguration and Set Cover Reconfiguration are PSPACE-hard to approximate within a factor of 0.9942 and 1.0029, respectively.

Very recently, Hirahara and Ohsaka [19] and Karthik C. S. and Manurangsi [26] announced the proof of RIH independently, implying that the above PSPACE-hardness results hold *unconditionally*. Karthik C. S. and Manurangsi [26] further proved that (optimization versions of) 2CSP Reconfiguration and Set Cover Reconfiguration are NP-hard to approximate within a factor smaller than 2, which is numerically tight because both problems are (nearly) 2-factor approximable. Our result partially resolves an open question of [26, Section 6]: "*Can we prove tight* PSPACE*-hardness of approximation results for GapMaxMin-2-*CSP_q *and Set Cover Reconfiguration?*"

Other reconfiguration problems whose approximability was investigated include those of Set Cover [23], Subset Sum [22], and Submodular Maximization [33]. We note that optimization variants of reconfiguration problems frequently refer to those of *the shortest reconfiguration sequence* [29, 5, 24, 25], which are orthogonal to this study.

2 Preliminaries

2.1 Notations

For a nonnegative integer $n \in \mathbb{N}$, let $[n] \coloneqq \{1, 2, \ldots, n\}$. Unless otherwise specified, the base of logarithms is 2. A *sequence* $\mathscr{S}$ of a finite number of objects $S^{(1)}, \ldots, S^{(T)}$ is denoted by $(S^{(1)}, \ldots, S^{(T)})$, and we write $S^{(t)} \in \mathscr{S}$ to indicate that $S^{(t)}$ appears in $\mathscr{S}$. Let Σ be a finite set called *alphabet*. For a length-n string $\pi \in \Sigma^n$ and a finite sequence of indices $I \subseteq [n]^*$, we use $\pi|_I \coloneqq (\pi_i)_{i \in I}$ to denote the restriction of π to I. The *Hamming distance* between two strings $f, g \in \Sigma^n$, denoted by $\Delta(f, g)$, is defined as the number of positions on which f and g differ; namely,

$$\Delta(f, g) \coloneqq \left| \left\{ i \in [n] \;\middle|\; f_i \neq g_i \right\} \right|. \tag{2.1}$$

2.2 Reconfiguration Problems on Constraint Graphs

Constraint Graphs. In this section, we formulate reconfiguration problems on constraint graphs. The notion of *constraint graph* is defined as follows.

▶ **Definition 2.1.** A *q-ary constraint graph* is defined as a tuple $G = (\mathcal{V}, \mathcal{E}, \Sigma, \Psi)$ such that
- $(\mathcal{V}, \mathcal{E})$ is a q-uniform[1] hypergraph called the *underlying graph*,
- Σ is a finite set called the *alphabet*, and
- $\Psi = (\psi_e)_{e \in \mathcal{E}}$ is a collection of q-ary *constraints*, where each $\psi_e \colon \Sigma^e \to \{0, 1\}$ is a circuit.

A binary constraint graph is simply referred to as a *constraint graph*. ⌟

For an *assignment* $f \colon \mathcal{V} \to \Sigma$, we say that f *satisfies* a hyperedge $e = \{v_1, \ldots, v_q\} \in \mathcal{E}$ (or a constraint ψ_e) if $\psi_e(f(e)) = 1$, where $f(e) \coloneqq (f(v_1), \ldots, f(v_q))$, and f *satisfies* G if it satisfies all the hyperedges of G. In the qCSP Reconfiguration problem, for a q-ary constraint

[1] A hypergraph is said to be *q-uniform* if each of its hyperedges has size exactly q.

graph G and its two satisfying assignments f^{start} and f^{goal}, we are required to decide if there exists a reconfiguration sequence from f^{start} to f^{goal} consisting only of satisfying assignments for G, each adjacent pair of which differs in at most one vertex. qCSP Reconfiguration is PSPACE-complete in general [13, 23]; thus, we formulate its two optimization versions.

Partial 2CSP Reconfiguration. For a constraint graph $G = (\mathcal{V}, \mathcal{E}, \Sigma, \Psi = (\psi_e)_{e\in\mathcal{E}})$, a *partial assignment* is defined as a function $f\colon \mathcal{V} \to \Sigma \cup \{\bot\}$, where the symbol $\bot$ indicates "unassigned." We say that a partial assignment $f\colon \mathcal{V} \to \Sigma \cup \{\bot\}$ *satisfies* edge $e = (v, w) \in \mathcal{E}$ if $\psi_e(f(v), f(w)) = 1$ whenever $f(v) \neq \bot$ and $f(w) \neq \bot$. The *size* of f, denoted by $\|f\|$, is defined as the number of vertices whose value is assigned; namely,

$$\|f\| \coloneqq \left|\left\{v \in \mathcal{V} \;\middle|\; f(v) \neq \bot\right\}\right|. \tag{2.2}$$

For two satisfying partial assignments f^{start} and f^{goal} for G, a *reconfiguration partial assignment sequence from f^{start} to f^{goal}* is a sequence $F = (f^{(1)}, \dots f^{(T)})$ of satisfying partial assignments such that $f^{(1)} = f^{\mathsf{start}}$, $f^{(T)} = f^{\mathsf{goal}}$, and $\Delta(f^{(t)}, f^{(t+1)}) \leqslant 1$ (i.e., $f^{(t)}$ and $f^{(t+1)}$ differ in at most one vertex) for all t. For any reconfiguration partial assignment sequence $F = (f^{(1)}, \dots, f^{(T)})$, we define $\|F\|_{\min}$ as

$$\|F\|_{\min} \coloneqq \min_{1\leqslant t\leqslant T} \|f^{(t)}\|. \tag{2.3}$$

Partial 2CSP Reconfiguration is formally defined as follows:

▶ **Problem 2.2** (Partial 2CSP Reconfiguration)**.** For a constraint graph $G = (\mathcal{V}, \mathcal{E}, \Sigma, \Psi)$ and its two satisfying partial assignments $f^{\mathsf{start}}, f^{\mathsf{goal}}\colon \mathcal{V} \to \Sigma \cup \{\bot\}$, we are required to find a reconfiguration partial assignment sequence F from f^{start} to f^{goal} such that $\|F\|_{\min}$ is maximized. ⌟

Let $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}})$ denote the maximum value of $\frac{\|F\|_{\min}}{|\mathcal{V}|}$ over all possible reconfiguration sequences F from f^{start} to f^{goal}; namely,

$$\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \coloneqq \max_{F=(f^{\mathsf{start}},\dots,f^{\mathsf{goal}})} \frac{\|F\|_{\min}}{|\mathcal{V}|}. \tag{2.4}$$

Note that $0 \leqslant \mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \leqslant 1$. For every numbers $0 \leqslant s \leqslant c \leqslant 1$, $\textsc{Gap}_{c,s}$ Partial 2CSP Reconfiguration requests to determine for a constraint graph G and its two satisfying partial assignments f^{start} and f^{goal}, whether $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \geqslant c$ or $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) < s$. Note that we can assume $\|f^{\mathsf{start}}\| = \|f^{\mathsf{goal}}\| = |\mathcal{V}|$ when $c = 1$.

Label Cover Reconfiguration. For a constraint graph $G = (\mathcal{V}, \mathcal{E}, \Sigma, \Psi = (\psi_e)_{e\in\mathcal{E}})$, a *multi-assignment* is defined as a function $f\colon \mathcal{V} \to 2^{\Sigma}$. We say that a multi-assignment f *satisfies* edge $e = (v, w) \in \mathcal{E}$ if there exists a pair $(\alpha, \beta) \in f(v) \times f(w)$ such that $\psi_e(\alpha, \beta) = 1$. The size of f, denoted by $\|f\|$, is defined as the sum of $|f(v)|$ over all $v \in \mathcal{V}$; namely,

$$\|f\| \coloneqq \sum_{v\in\mathcal{V}} |f(v)|. \tag{2.5}$$

For two satisfying multi-assignments f^{start} and f^{goal} for G, a *reconfiguration multi-assignment sequence from f^{start} to f^{goal}* is a sequence $F = (f^{(1)}, \dots, f^{(T)})$ of satisfying multi-assignments such that $f^{(1)} = f^{\mathsf{start}}$, $f^{(T)} = f^{\mathsf{goal}}$, and

$$\sum_{v\in\mathcal{V}} \left|f^{(t)}(v) \triangle f^{(t+1)}(v)\right| \leqslant 1 \quad \text{for all } t. \tag{2.6}$$

For any reconfiguration multi-assignment sequence $F = (f^{(1)}, \dots, f^{(T)})$, we define $\|F\|_{\max}$ as

$$\|F\|_{\max} \coloneqq \max_{1 \leqslant t \leqslant T} \|f^{(t)}\|. \tag{2.7}$$

Label Cover Reconfiguration is formally defined as follows.[2]

▶ **Problem 2.3** (Label Cover Reconfiguration)**.** For a constraint graph $G = (\mathcal{V}, \mathcal{E}, \Sigma, \Psi)$ and its two satisfying multi-assignments $f^{\mathsf{start}}, f^{\mathsf{goal}} \colon \mathcal{V} \to 2^{\Sigma}$, we are required to find a reconfiguration multi-assignment sequence F from f^{start} to f^{goal} such that $\|F\|_{\max}$ is minimized. ⌟

Let $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}})$ denote the minimum value of $\frac{\|F\|_{\max}}{|\mathcal{V}|+1}$ over all possible reconfiguration multi-assignment sequences F from f^{start} to f^{goal}; namely,

$$\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \coloneqq \min_{F=(f^{\mathsf{start}}, \dots, f^{\mathsf{goal}})} \frac{\|F\|_{\max}}{|\mathcal{V}|+1}. \tag{2.8}$$

Note that $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \geqslant \frac{|\mathcal{V}|}{|\mathcal{V}|+1}$. For every numbers $1 \leqslant c \leqslant s$, $\mathrm{Gap}_{c,s}$ Label Cover Reconfiguration requests to determine whether $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \leqslant c$ or $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) > s$ for a constraint graph G and its two satisfying multi-assignments f^{start} and f^{goal}. Note that we can assume $\frac{\|f^{\mathsf{start}}\|}{|\mathcal{V}|+1} = \frac{\|f^{\mathsf{goal}}\|}{|\mathcal{V}|+1} \leqslant 1$ when $c = 1$.

2.3 Probabilistically Checkable Reconfiguration Proof Systems

First, we formally define the notion of *verifier*.

▶ **Definition 2.4.** A *verifier* with *randomness complexity* $r \colon \mathbb{N} \to \mathbb{N}$ and *query complexity* $q \colon \mathbb{N} \to \mathbb{N}$ is a probabilistic polynomial-time algorithm V that given an input $x \in \{0,1\}^*$, tosses $r = r(|x|)$ random bits R and uses R to generate a sequence of $q = q(|x|)$ queries $I = (i_1, \dots, i_q)$ and a circuit $D \colon \{0,1\}^q \to \{0,1\}$. We write $(I, D) \sim V(x)$ to denote the random variable for a pair of the query sequence and circuit generated by V on input $x \in \{0,1\}^*$ and r random bits, and write $(I, D) = V(x, R)$ when we wish to fix the random bits R. Denote by $V^{\pi}(x) \coloneqq D(\pi|_I)$, where $(I, D) = V(x, R)$ for $R \sim \{0,1\}^r$, the random variable for the output of V on input x given oracle access to a proof $\pi \in \{0,1\}^*$. We say that $V(x)$ *accepts* a proof π if $V^{\pi}(x) = 1$; i.e., $D(\pi|_I) = 1$ for $(I, D) \sim V(x)$. ⌟

We proceed to the definition of *Probabilistically Checkable Reconfiguration Proofs* (PCRPs) due to Hirahara and Ohsaka [19], which offer a PCP-type characterization of PSPACE. For any pair of proofs $\pi^{\mathsf{start}}, \pi^{\mathsf{goal}} \in \{0,1\}^{\ell}$, a *reconfiguration sequence from* π^{start} *to* π^{goal} is a sequence $(\pi^{(1)}, \dots, \pi^{(T)}) \in (\{0,1\}^{\ell})^*$ such that $\pi^{(1)} = \pi^{\mathsf{start}}$, $\pi^{(T)} = \pi^{\mathsf{goal}}$, and $\Delta(\pi^{(t)}, \pi^{(t+1)}) \leqslant 1$ (i.e., $\pi^{(t)}$ and $\pi^{(t+1)}$ differ in at most one bit) for all t.

▶ **Theorem 2.5** (PCRP theorem [19, Theorem 5.1])**.** *For any language L in* PSPACE*, there exists a verifier V with randomness complexity $r(n) = \mathcal{O}(\log n)$ and query complexity $q(n) = \mathcal{O}(1)$, coupled with polynomial-time computable functions $\pi^{\mathsf{start}}, \pi^{\mathsf{goal}} \colon \{0,1\}^* \to \{0,1\}^*$, such that the following hold for any input $x \in \{0,1\}^*$:*

- *(Completeness) If $x \in L$, there exists a reconfiguration sequence $\Pi = (\pi^{(1)}, \dots, \pi^{(T)})$ from $\pi^{\mathsf{start}}(x)$ to $\pi^{\mathsf{goal}}(x)$ over $\{0,1\}^{\mathrm{poly}(|x|)}$ such that $V(x)$ accepts every proof with probability 1; namely,*

$$\forall t \in [T], \quad \mathbb{P}\Big[V(x) \text{ accepts } \pi^{(t)}\Big] = 1. \tag{2.9}$$

[2] This problem can be thought of as a reconfiguration analogue of Min Rep [8].

- (*Soundness*) *If* $x \notin L$*, every reconfiguration sequence* $\Pi = (\pi^{(1)}, \dots, \pi^{(T)})$ *from* $\pi^{\mathsf{start}}(x)$ *to* $\pi^{\mathsf{goal}}(x)$ *over* $\{0,1\}^{\mathrm{poly}(|x|)}$ *includes a proof that is rejected by* $V(x)$ *with probability more than* $\frac{1}{2}$*; namely,*

$$\exists t \in [T], \quad \mathbb{P}\Big[V(x) \text{ accepts } \pi^{(t)}\Big] < \frac{1}{2}. \tag{2.10}$$

We further introduce the notion of regular verifier. We say that a verifier is *regular* if each position in its proof is equally likely to be queried.[3]

▶ **Definition 2.6.** For a verifier V and an input $x \in \{0,1\}^*$, the *degree* of a position i of a proof is defined as the number of times i is queried by $V(x)$ over $r(|x|)$ random bits; namely,

$$\left|\left\{R \in \{0,1\}^{r(|x|)} \;\middle|\; i \in I_R\right\}\right| = \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[i \in I\Big] \cdot 2^{r(|x|)}, \tag{2.11}$$

where r is the randomness complexity of V and I_R is the query sequence generated by $V(x,R)$. A verifier V is said to be Δ-*regular* if the degree of every position is exactly equal to Δ. ⌟

3 Subconstant Error PCRP Systems and FGLSS Reduction

We construct a bounded-degree PCRP verifier with subconstant error using Theorem 2.5 in Section 3.1, and prove PSPACE-hardness of approximation for Partial 2CSP Reconfiguration and Label Cover Reconfiguration by the FGLSS reduction [12] in Sections 3.2 and 3.3, respectively.

3.1 Bounded-degree PCRP Systems with Subconstant Error

Starting from Theorem 2.5, we first obtain a regular PCRP verifier for any PSPACE language, whose proof uses the degree reduction technique due to Ohsaka [31].

▶ **Proposition 3.1** (∗)**.** *For any language* L *in* PSPACE*, there exists a* Δ*-regular PCRP verifier* V *with randomness complexity* $r(n) = \mathcal{O}(\log n)$*, query complexity* $q(n) = \mathcal{O}(1)$*, perfect completeness, and soundness* $1-\varepsilon$*, for some constant* $\Delta \in \mathbb{N}$ *and* $\varepsilon \in (0,1)$*.*

Subsequently, using a randomness-efficient sampler over expander graphs (e.g., [21, Section 3]), we construct a *bounded-degree* PCRP verifier with *subconstant error*.

▶ **Proposition 3.2.** *For any language* L *in* PSPACE *and any function* $\delta\colon \mathbb{N} \to \mathbb{R}$ *with* $\delta(n) = \Omega(n^{-1})$*, there exists a bounded-degree PCRP verifier* V *with randomness complexity* $r(n) = \mathcal{O}(\log \delta(n)^{-1} + \log n)$*, query complexity* $q(n) = \mathcal{O}(\log \delta(n)^{-1})$*, perfect completeness, and soundness* $\delta(n)$*. Moreover, for any input* $x \in \{0,1\}^*$*, the degree of any position is* $\mathrm{poly}(\delta(|x|)^{-1})$*.*

Verifier Description. Our PCRP verifier is described as follows. By Proposition 3.1, let V be a Δ-regular PCRP verifier for a PSPACE-complete language L with randomness complexity $r(n) = \mathcal{O}(\log n)$, query complexity $q(n) = q \in \mathbb{N}$, perfect completeness, and soundness $1-\varepsilon$, where $\Delta \in \mathbb{N}$ and $\varepsilon \in (0,1)$. The proof length, denoted by $\ell(n)$, is polynomially bounded

[3] Note that regular verifiers are sometimes called *smooth* verifiers, e.g., [34]. Since the term "regularity" is compatible with that of (hyper)graphs, we do not use the term "smoothness" but "regularity."

since $\ell(n) \leqslant q(n)2^{r(n)} = \mathrm{poly}(n)$. Hereafter, for any $r(n)$ random bit sequence R, let I_R and D_R respectively denote the query sequence and circuit generated by $V(x, R)$. Given a function $\delta\colon \mathbb{N} \to \mathbb{R}$ with $\delta(n) = \Omega(n^{-1})$, we construct the following verifier $\widetilde{V}$:

Bounded-degree verifier $\widetilde{V}$ with subconstant error.

Input: a Δ-regular verifier V with soundness $1-\varepsilon$, a function $\delta\colon \mathbb{N} \to \mathbb{R}$, and an input $x \in \{0,1\}^n$.
Oracle access: a proof $\pi \in \{0,1\}^{\ell(n)}$.
1: construct a (d, λ)-expander graph X over vertex set $\{0,1\}^{r(n)}$ with $\frac{\lambda}{d} < \frac{\varepsilon}{4}$.
2: let $\rho \coloneqq \left\lceil \frac{2}{\varepsilon} \ln \delta(n)^{-1} \right\rceil = \mathcal{O}(\log \delta(n)^{-1})$.
3: uniformly sample a $(\rho-1)$-length random walk $\mathbf{R} = (R_1, \ldots, R_\rho)$ over X using $r(n) + \rho \cdot \log d$ random bits.
4: **for each** $1 \leqslant k \leqslant \rho$ **do**
5: execute $V(x)$ on R_k to generate a query sequence $I_{R_k} = (i_1, \ldots, i_q)$ and a circuit $D_{R_k}\colon \{0,1\}^q \to \{0,1\}$.
6: **if** $D_{R_k}(\pi|_{I_{R_k}}) = 0$ **then**
7: declare reject.
8: declare accept.

Correctness. The perfect completeness and soundness for a fixed proof $\pi \in \{0,1\}^{\ell(n)}$ are shown below, whose proof relies on the property about random walks over expander graphs due to Alon, Feige, Wigderson, and Zuckerman [2].

▷ Claim 3.3 (∗). If $V(x)$ accepts π with probability 1, then $\widetilde{V}(x)$ accepts π with probability 1. If $V(x)$ accepts π with probability less than $1-\varepsilon$, then $\widetilde{V}(x)$ accepts π with probability less than $\delta(n)$.

We are now ready to prove Proposition 3.2.

Proof of Proposition 3.2. We first show the perfect completeness and soundness. Suppose $x \in L$, then there exists a reconfiguration sequence $\Pi = (\pi^{(1)}, \ldots, \pi^{(T)})$ from $\pi^{\mathsf{start}}(x)$ to $\pi^{\mathsf{goal}}(x)$ such that $\mathbb{P}[V(x) \text{ accepts } \pi^{(t)}] = 1$ for all t. By Claim 3.3, we have that $\mathbb{P}[\widetilde{V}(x) \text{ accepts } \pi^{(t)}] = 1$ for all t. Suppose $x \notin L$, then for every reconfiguration sequence $\Pi = (\pi^{(1)}, \ldots, \pi^{(T)})$ from $\pi^{\mathsf{start}}(x)$ to $\pi^{\mathsf{goal}}(x)$, it holds that $\mathbb{P}[V(x) \text{ accepts } \pi^{(t)}] < 1-\varepsilon$ for some t. By Claim 3.3, we have $\mathbb{P}[\widetilde{V}(x) \text{ accepts } \pi^{(t)}] < \delta(n)$ for such t.

Since $\rho = \mathcal{O}(\log \delta(n)^{-1})$, the randomness complexity of $\widetilde{V}$ is equal to $\widetilde{r}(n) = r(n) + \rho \cdot \log d = \mathcal{O}(\log \delta(n)^{-1} + \log n)$, and the query complexity is $\widetilde{q}(n) = q(n) \cdot \rho = \mathcal{O}(\log \delta(n)^{-1})$. Note that d and λ may depend only on ε, and a (d, λ)-expander graph X over $\{0,1\}^{r(n)}$ can be constructed in polynomial time in $2^{r(n)} = \mathrm{poly}(n)$, e.g., by using an explicit construction of near-Ramanujan graphs [28, 1].

Observe finally that $\widetilde{V}$ queries each position $i \in [\ell(n)]$ of a proof with probability equal to

$$\mathop{\mathbb{P}}_{\mathbf{R}}\left[\bigvee_{1 \leqslant k \leqslant \rho} \left(i \in I_{R_k}\right)\right]. \tag{3.1}$$

Since V is Δ-regular, it holds that

$$\mathop{\mathbb{P}}_{R \sim \{0,1\}^{r(n)}}\left[i \in I_R\right] = \frac{\Delta}{2^{r(n)}}. \tag{3.2}$$

Using the fact that each R_k is uniformly distributed over $\{0,1\}^{r(n)}$, we bound Eq. (3.1) as follows:

$$\mathop{\mathbb{P}}_{\mathbf{R}}\left[\bigvee_{1\leqslant k\leqslant \rho}\left(i\in I_{R_k}\right)\right] \underbrace{\leqslant}_{\text{union bound}} \sum_{k\in[\rho]}\mathop{\mathbb{P}}_{\mathbf{R}}\left[i\in I_{R_k}\right] = \frac{\rho\cdot\Delta}{2^{r(n)}} = \mathcal{O}\left(\frac{\log\delta(n)^{-1}}{2^{r(n)}}\right). \tag{3.3}$$

Consequently, the degree of each position i with respect to $\widetilde{V}$ is at most

$$\begin{aligned}\mathop{\mathbb{P}}_{\mathbf{R}}\left[\bigvee_{1\leqslant k\leqslant \rho}\left(i\in I_{R_k}\right)\right]\cdot 2^{\widetilde{r(n)}} &= \mathcal{O}\left(\frac{\log\delta(n)^{-1}}{2^{r(n)}}\right)\cdot 2^{r(n)+\rho\cdot\log d}\\ &= \mathcal{O}(\log\delta(n)^{-1})\cdot 2^{\mathcal{O}(\log\delta(n)^{-1})}\\ &= \mathrm{poly}(\delta(n)^{-1}),\end{aligned} \tag{3.4}$$

which completes the proof. ◀

3.2 FGLSS Reduction and PSPACE-hardness of Approximation for Partial 2CSP Reconfiguration

We now establish the FGLSS reduction from Proposition 3.2 and show that Partial 2CSP Reconfiguration is PSPACE-hard to approximate within a factor arbitrarily close to 0.

▶ **Theorem 3.4.** *For any function $\varepsilon\colon\mathbb{N}\to\mathbb{R}$ with $\varepsilon(n)=\Omega\left(\frac{1}{\mathrm{polylog}\, n}\right)$, $\mathrm{Gap}_{1,\varepsilon(N)}$ Partial 2CSP Reconfiguration with alphabet size $\mathrm{poly}(\varepsilon(N)^{-1})$ is PSPACE-complete, where N is the number of vertices.*

Reduction. We describe a reduction from a bounded-degree PCRP verifier to Partial 2CSP Reconfiguration. Define $\delta(n) \coloneqq \frac{\varepsilon(\mathrm{poly}(n))}{2}$, whose precise expression is given later. For any PSPACE-complete language L, let V be a bounded-degree PCRP verifier of Proposition 3.2 with randomness complexity $r(n)=\mathcal{O}(\log\delta(n)^{-1}+\log n)$, query complexity $q(n)=\mathcal{O}(\log\delta(n)^{-1})$, perfect completeness, and soundness $\delta(n)$. The proof length $\ell(n)$ is polynomially bounded. Suppose we are given an input $x\in\{0,1\}^n$. Let $\pi^{\mathsf{start}},\pi^{\mathsf{goal}}\in\{0,1\}^{\ell(n)}$ be the two proofs associated with $V(x)$. Because the degree of V is bounded by $\mathrm{poly}(\delta(n)^{-1})$, for some constant $\kappa\in\mathbb{N}$, we have

$$\mathop{\mathbb{P}}_{(I,D)\sim V(x)}\left[i\in I\right] \leqslant \frac{\delta(n)^{-\kappa}}{2^{r(n)}} \text{ for any } i\in[\ell(n)]. \tag{3.5}$$

Hereafter, for any $r(n)$ random bit sequence R, let I_R and D_R denote the query sequence and the circuit generated by $V(x,R)$, respectively. Construct a constraint graph $G=(\mathcal{V},\mathcal{E},\Sigma,\Psi)$ as follows:

$$\mathcal{V} \coloneqq \{0,1\}^{r(n)}, \tag{3.6}$$

$$\mathcal{E} \coloneqq \left\{(R_1,R_2)\in\mathcal{V}\times\mathcal{V}\;\middle|\; I_{R_1}\cap I_{R_2}\neq\emptyset\right\}, \tag{3.7}$$

$$\Sigma \coloneqq \left\{\{0\},\{1\},\{0,1\}\right\}^{q(n)}, \tag{3.8}$$

$$\Psi \coloneqq \{\psi_e\}_{e\in\mathcal{E}}, \tag{3.9}$$

where we define $\psi_{R_1,R_2} : \Sigma \times \Sigma \to \{0,1\}$ for edge $(R_1, R_2) \in \mathcal{E}$ so that $\psi_{R_1,R_2}(f(R_1), f(R_2)) = 1$ for an assignment $f : \mathcal{V} \to \Sigma$ if and only if the following three conditions are satisfied:

$$\forall \alpha \in \prod_{i \in I_R} f(R_1)_i, \quad D_{R_1}(\alpha) = 1, \tag{3.10}$$

$$\forall \beta \in \prod_{i \in I_R} f(R_2)_i, \quad D_{R_2}(\beta) = 1, \tag{3.11}$$

$$\forall i \in I_{R_1} \cap I_{R_2}, \quad f(R_1)_i \subseteq f(R_2)_i \text{ or } f(R_1)_i \supseteq f(R_2)_i. \tag{3.12}$$

Here, for the sake of notation simplicity, we consider $f(R)$ as if it were indexed by I_R (rather than $[q(n)]$); namely, $f(R) \in \{\{0\},\{1\},\{0,1\}\}^{I_R}$. Thus, $f(R)$ for each $R \in \mathcal{V}$ corresponds the local view of $V(x, R)$.

For any proof $\pi \in \{0,1\}^{\ell(n)}$, we associate it with an assignment $f_\pi : \mathcal{V} \to \Sigma$ such that

$$f_\pi(R) \coloneqq \Big(\{\pi_i\}\Big)_{i \in I_R} \text{ for all } R \in \mathcal{V}. \tag{3.13}$$

Note that $f_\pi(R) \in \{\{0\},\{1\}\}^{I_R}$. Constructing two assignments f^{start} from π^{start} and f^{goal} from π^{goal} by Eq. (3.13), we obtain an instance $(G, f^{\mathsf{start}}, f^{\mathsf{goal}})$ of Partial 2CSP Reconfiguration. Observe that f^{start} and f^{goal} satisfy G and $\|f^{\mathsf{start}}\| = \|f^{\mathsf{goal}}\| = |\mathcal{V}|$. Note that $N \coloneqq |\mathcal{V}| \leqslant n^c$ for some constant $c \in \mathbb{N}$. Letting $\delta(n) \coloneqq \frac{\varepsilon(n^c)}{2} = \Omega\left(\frac{1}{\operatorname{polylog} n}\right)$ ensures that the alphabet size is $|\Sigma| = \mathcal{O}(3^{q(n)}) = \operatorname{poly}(\varepsilon(N)^{-1})$. This completes the description of the reduction.

Correctness. We first prove the completeness.

▶ **Lemma 3.5** (Completeness). *If $x \in L$, then* $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) = 1$.

Proof. It is sufficient to consider the case that π^{start} and π^{goal} differ in exactly one position, say, $i^\star \in [\ell(n)]$; namely, $\pi^{\mathsf{start}}_{i^\star} \neq \pi^{\mathsf{goal}}_{i^\star}$ and $\pi^{\mathsf{start}}_i = \pi^{\mathsf{goal}}_i$ for all $i \neq i^\star$. Note that f^{start} and f^{goal} may differ in two or more vertices. Consider a reconfiguration partial assignment sequence F from f^{start} to f^{goal} obtained by the following procedure:

Reconfiguration sequence F from f^{start} to f^{goal}.

1: **for each** $R \in \mathcal{V}$ such that $i^\star \in I_R$ **do**
2: change the $i^{\star\text{th}}$ entry of R's current value from $f^{\mathsf{start}}(R)_{i^\star} = \{\pi^{\mathsf{start}}_{i^\star}\}$ to $\{0,1\}$.
3: **for each** $R \in \mathcal{V}$ such that $i^\star \in I_R$ **do**
4: change the $i^{\star\text{th}}$ entry of R's current value from $\{0,1\}$ to $f^{\mathsf{goal}}(R)_{i^\star} = \{\pi^{\mathsf{goal}}_{i^\star}\}$.

Observe that any partial assignment f° of F satisfies G for the following reasons:

- Since $f^\circ(R)_{i^\star} \subseteq \{0,1\} = \{\pi^{\mathsf{start}}_{i^\star}, \pi^{\mathsf{goal}}_{i^\star}\} = f^{\mathsf{start}}(R)_{i^\star} \cup f^{\mathsf{goal}}(R)_{i^\star}$ when $i^\star \in I_R$, f° satisfies Eqs. (3.10) and (3.11).
- Letting $K \coloneqq \{f^\circ(R)_{i^\star} \mid i^\star \in I_R\}$, we find K to be either $\{\{0\}\}$, $\{\{1\}\}$, $\{\{0,1\}\}$, $\{\{0\},\{0,1\}\}$, or $\{\{1\},\{0,1\}\}$ by construction; i.e., f° satisfies Eq. (3.12).

Since $\|f^\circ\| = |\mathcal{V}|$, it holds that $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \geqslant \frac{\|F\|_{\max}}{|\mathcal{V}|} = 1$, completing the proof. ◀

▶ **Lemma 3.6** (Soundness). *If $x \notin L$, then*

$$\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) < \delta(n) + \frac{q(n) \cdot \delta(n)^{-\kappa}}{2^{r(n)}}. \tag{3.14}$$

The proof of Theorem 3.4 follows from Lemmas 3.5 and 3.6 because for any sufficiently large n such that $\frac{q(n)\cdot\delta(n)^{-\kappa}}{2^{r(n)}} \leqslant \delta(n)$ (note that $\delta(n) = \Omega\left(\frac{1}{\mathrm{polylog}\, n}\right)$), the following hold:

- (Perfect completeness) If $x \in L$, then $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) = 1$;
- (Soundness) If $x \notin L$, then $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) < 2\delta(n) = \varepsilon(N)$.

Proof of Lemma 3.6. We prove the contrapositive. Suppose $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \geqslant \Gamma$ for some $\Gamma \in (0,1)$, and there is a reconfiguration partial assignment sequence $F = (f^{(1)}, \dots, f^{(T)})$ from f^{start} to f^{goal} such that $\|F\|_{\min} = \mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}})$. Define then a (not necessarily reconfiguration) sequence $\Pi = (\pi^{(1)}, \dots, \pi^{(T)})$ over $\{0,1\}^{\ell(n)}$ such that each proof $\pi^{(t)}$ is determined based on the *plurality vote* over $f^{(t)}$; namely,

$$\pi_i^{(t)} \coloneqq \operatorname*{argmax}_{b\in\{0,1\}} \left|\left\{R \in \mathcal{V} \;\middle|\; i \in I_R \text{ and } b \in f^{(t)}(R)_i\right\}\right| \text{ for all } i \in [\ell(n)], \tag{3.15}$$

where ties are broken so that 0 is chosen. In particular, $\pi^{(1)} = \pi^{\mathsf{start}}$ and $\pi^{(T)} = \pi^{\mathsf{goal}}$. Observe the following:

▶ **Observation 3.7.** *For any $t \in [T]$ and $R \in \mathcal{V}$, it holds that*

$$f^{(t)}(R) \neq \bot \implies D_R(\pi^{(t)}|_{I_R}) = 1. \tag{3.16}$$

Since $\mathbb{P}_{R\sim\mathcal{V}}[f^{(t)}(R) \neq \bot] = \|f^{(t)}\| \geqslant \Gamma$, by Observation 3.7, we have that for all t,

$$\mathbb{P}\Big[V(x) \text{ accepts } \pi^{(t)}\Big] = \mathop{\mathbb{P}}_{R\sim\{0,1\}^{r(n)}}\Big[D_R(\pi^{(t)}|_{I_R}) = 1\Big] \geqslant \mathop{\mathbb{P}}_{R\sim\mathcal{V}}\Big[f^{(t)}(R) \neq \bot\Big] \geqslant \Gamma. \tag{3.17}$$

Unfortunately, Π is *not* a reconfiguration sequence because $\pi^{(t)}$ and $\pi^{(t+1)}$ may differ in two or more positions. Since $f^{(t)}$ and $f^{(t+1)}$ differ in a single vertex $R \in \mathcal{V}$, we have $\pi_i^{(t)} \neq \pi_i^{(t+1)}$ only if $i \in I_R$, implying $\Delta(\pi^{(t)}, \pi^{(t+1)}) \leqslant |I_R| = q(n)$. Using this fact, we interpolate between $\pi^{(t)}$ and $\pi^{(t+1)}$ to find a valid reconfiguration sequence $\Pi^{(t)}$ such that $V(x)$ accepts every proof of $\Pi^{(t)}$ with probability $\Gamma - o(1)$.

▷ Claim 3.8. There exists a reconfiguration sequence $\Pi^{(t)}$ from $\pi^{(t)}$ to $\pi^{(t+1)}$ such that for every proof π° of $\Pi^{(t)}$,

$$\mathbb{P}\Big[V(x) \text{ accepts } \pi^\circ\Big] \geqslant \Gamma - \frac{q(n)\cdot\delta(n)^{-\kappa}}{2^{r(n)}}. \tag{3.18}$$

Concatenating $\Pi^{(t)}$'s of Claim 3.8 for all t, we obtain a valid reconfiguration sequence Π from π^{start} to π^{goal} such that

$$\min_{1\leqslant t\leqslant T} \mathbb{P}\Big[V(x) \text{ accepts } \pi^{(t)}\Big] \geqslant \Gamma - \frac{q(n)\cdot\delta(n)^{-\kappa}}{2^{r(n)}}. \tag{3.19}$$

Substituting $\delta(n) + \frac{q(n)\cdot\delta(n)^{-\kappa}}{2^{r(n)}}$ for Γ, we have that if $\mathsf{MaxPar}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \geqslant \delta(n) + \frac{q(n)\cdot\delta(n)^{-\kappa}}{2^{r(n)}}$, then $V(x)$ accepts every proof $\pi^{(t)}$ of Π with probability at least $\delta(n)$; i.e., $x \in L$. This completes the proof of Lemma 3.6. ◀

What remains to be done is to prove Observation 3.7 and Claim 3.8.

Proof of Observation 3.7. Suppose $f^{(t)}(R) \neq \bot$ for some $t \in [T]$ and $R \in \mathcal{V}$. We will show that $\pi_i^{(t)} \in f^{(t)}(R)_i$ for every $i \in I_R$. Define

$$K \coloneqq \left\{f^{(t)}(R')_i \;\middle|\; \exists R' \in \mathcal{V} \text{ s.t. } i \in I_{R'} \text{ and } f^{(t)}(R') \neq \bot\right\}. \tag{3.20}$$

Then, any pair $\alpha, \beta \in K$ must satisfy that $\alpha \subseteq \beta$ or $\alpha \supseteq \beta$ because otherwise, $f^{(t)}$ would violate Eq. (3.12) at edge (R_1, R_2) such that $i \in R_1 \cap R_2$, $f^{(t)}(R_1)_i = \alpha$, and $f^{(t)}(R_2)_i = \beta$, which is a contradiction. For each possible case of K, the result of the plurality vote $\pi_i^{(t)}$ is shown below, implying that $\pi_i^{(t)} \in f^{(t)}(R)_i$.

K	$\{\}$	$\{\{0\}\}$	$\{\{1\}\}$	$\{\{0,1\}\}$	$\{\{0\},\{0,1\}\}$	$\{\{1\},\{0,1\}\}$
$\pi_i^{(t)}$	0	0	1	0	0	1

Since $f^{(t)}(R)$ must satisfy a self-loop $(R, R) \in \mathcal{E}$, by the definition of $\psi_{R,R}$, we have

$$\forall \alpha \in \prod_{i \in I_R} f^{(t)}(R)_i, \quad D_R(\alpha) = 1, \tag{3.21}$$

On the other hand, it holds that

$$\pi^{(t)}|_{I_R} \in \prod_{i \in I_R} f^{(t)}(R)_i, \tag{3.22}$$

implying $D_R(\pi^{(t)}|_{I_R}) = 1$, as desired. ◀

Proof of Claim 3.8. Recall that $\pi^{(t)}$ and $\pi^{(t+1)}$ may differ in at most $q(n)$ positions. Consider any trivial reconfiguration sequence $\Pi^{(t)}$ from $\pi^{(t)}$ to $\pi^{(t+1)}$ by simply changing at most $q(n)$ positions on which $\pi^{(t)}$ and $\pi^{(t+1)}$ differ. By construction, any proof π° of $\Pi^{(t)}$ differs from $\pi^{(t)}$ in at most $q(n)$ positions, say, $I^\circ \in \binom{[\ell(n)]}{\leqslant q(n)}$. Then, we derive the following:

$$\begin{aligned}
&\mathbb{P}\Big[V(x) \text{ accepts } \pi^\circ\Big] \\
&= \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[D(\pi^\circ|_I) = 1\Big] \geqslant \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[D(\pi^\circ|_I) = 1 \text{ and } I \cap I^\circ = \emptyset\Big] \\
&= \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[D(\pi^{(t)}|_I) = 1 \text{ and } I \cap I^\circ = \emptyset\Big] \\
&= \underbrace{\mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[D(\pi^{(t)}|_I) = 1\Big]}_{=\mathbb{P}\left[V(x) \text{ accepts } \pi^{(t)}\right] \geqslant \Gamma} - \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[D(\pi^{(t)}|_I) = 1 \text{ and } I \cap I^\circ \neq \emptyset\Big] \\
&\geqslant \Gamma - \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[I \cap I^\circ \neq \emptyset\Big].
\end{aligned} \tag{3.23}$$

Recall that $\mathbb{P}_{(I,D)\sim V(x)}[i \in I] \leqslant \frac{\delta(n)^{-\kappa}}{2^{r(n)}}$ for any $i \in [\ell(n)]$ by assumption. Since $|I^\circ| \leqslant q(n)$, taking a union bound, we have

$$\mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[I \cap I^\circ \neq \emptyset\Big] \leqslant \sum_{i \in I^\circ} \mathop{\mathbb{P}}_{(I,D)\sim V(x)}\Big[i \in I\Big] \leqslant \frac{q(n) \cdot \delta(n)^{-\kappa}}{2^{r(n)}}, \tag{3.24}$$

implying that

$$\mathbb{P}\Big[V(x) \text{ accepts } \pi^\circ\Big] \geqslant \Gamma - \frac{q(n) \cdot \delta(n)^{-\kappa}}{2^{r(n)}}. \tag{3.25}$$

This completes the proof. ◁

3.3 Reducing Partial 2CSP Reconfiguration to Label Cover Reconfiguration

Subsequently, we show PSPACE-hardness of approximation for Label Cover Reconfiguration by reducing from Partial 2CSP Reconfiguration, whose proof is similar to [26]. Note that Label Cover Reconfiguration admits a 2-factor approximation, similarly to Minmax Set Cover Reconfiguration (see Section 4.1).

▶ **Theorem 3.9** (∗). *For any function* $\varepsilon\colon \mathbb{N} \to \mathbb{R}$ *with* $\varepsilon(n) = \Omega\left(\frac{1}{\operatorname{polylog} n}\right)$, $\textsc{Gap}_{1,2-\varepsilon(N)}$ Label Cover Reconfiguration *with alphabet size* $\operatorname{poly}(\varepsilon(N)^{-1})$ *is* PSPACE*-complete, where* N *is the number of vertices. In particular,*

- *for any constant* $\varepsilon \in (0,1)$, $\textsc{Gap}_{1,2-\varepsilon}$ Label Cover Reconfiguration *with constant alphabet size is* PSPACE*-complete, and*
- $\textsc{Gap}_{1,2-\frac{1}{\operatorname{polyloglog} N}}$ Label Cover Reconfiguration *with alphabet size* $\operatorname{polyloglog} N$ *is* PSPACE*-complete.*

4 Applications

In this section, we apply Theorem 3.9 to show optimal PSPACE-hardness of approximation results for Minmax Set Cover Reconfiguration (Theorem 4.1) and Minmax Hypergraph Vertex Cover Reconfiguration (Theorem 4.3).

4.1 PSPACE-hardness of Approximation for Set Cover Reconfiguration

We first prove that Minmax Set Cover Reconfiguration is PSPACE-hard to approximate within a factor smaller than 2. Let $\mathcal{U}$ be a finite set called the *universe* and $\mathcal{F} = \{S_1, \ldots, S_m\}$ be a family of m subsets of $\mathcal{U}$. A *cover* for a set system $(\mathcal{U}, \mathcal{F})$ is a subfamily of $\mathcal{F}$ whose union is equal to $\mathcal{U}$. For any pair of covers $\mathcal{C}^{\mathsf{start}}$ and $\mathcal{C}^{\mathsf{goal}}$ for $(\mathcal{U}, \mathcal{F})$, a *reconfiguration sequence from* $\mathcal{C}^{\mathsf{start}}$ *to* $\mathcal{C}^{\mathsf{goal}}$ is a sequence $\mathscr{C} = (\mathcal{C}^{(1)}, \ldots, \mathcal{C}^{(T)})$ of covers such that $\mathcal{C}^{(1)} = \mathcal{C}^{\mathsf{start}}$, $\mathcal{C}^{(T)} = \mathcal{C}^{\mathsf{goal}}$, and $|\mathcal{C}^{(t)} \triangle \mathcal{C}^{(t+1)}| \leqslant 1$ (i.e., $\mathcal{C}^{(t+1)}$ is obtained from $\mathcal{C}^{(t)}$ by adding or removing a single set of $\mathcal{F}$) for all t. In Set Cover Reconfiguration [23], for a set system $(\mathcal{U}, \mathcal{F})$ and its two covers $\mathcal{C}^{\mathsf{start}}$ and $\mathcal{C}^{\mathsf{goal}}$ of size k, we are asked to decide if there is a reconfiguration sequence from $\mathcal{C}^{\mathsf{start}}$ to $\mathcal{C}^{\mathsf{goal}}$ consisting only of covers of size at most $k+1$. Next, we formulate its optimization version. Denote by $\mathsf{opt}(\mathcal{F})$ the size of the minimum cover of $(\mathcal{U}, \mathcal{F})$. For any reconfiguration sequence $\mathscr{C} = (\mathcal{C}^{(1)}, \ldots, \mathcal{C}^{(T)})$, its *cost* is defined as the maximum value of $\frac{|\mathcal{C}^{(t)}|}{\mathsf{opt}(\mathcal{F})+1}$ over all $\mathcal{C}^{(t)}$'s in $\mathscr{C}$; namely,[4]

$$\mathsf{cost}_{\mathcal{F}}(\mathscr{C}) \coloneqq \max_{\mathcal{C}^{(t)} \in \mathscr{C}} \frac{|\mathcal{C}^{(t)}|}{\mathsf{opt}(\mathcal{F}) + 1}, \tag{4.1}$$

In Minmax Set Cover Reconfiguration, we wish to minimize $\mathsf{cost}_{\mathcal{F}}(\mathscr{C})$ subject to $\mathscr{C} = (\mathcal{C}^{\mathsf{start}}, \ldots, \mathcal{C}^{\mathsf{goal}})$. For a pair of covers $\mathcal{C}^{\mathsf{start}}$ and $\mathcal{C}^{\mathsf{goal}}$ for $(\mathcal{U}, \mathcal{F})$, let $\mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}})$ denote the minimum value of $\mathsf{cost}_{\mathcal{F}}(\mathscr{C})$ over all possible reconfiguration sequences $\mathscr{C}$ from $\mathcal{C}^{\mathsf{start}}$ to $\mathcal{C}^{\mathsf{goal}}$; namely,

$$\mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}}) \coloneqq \min_{\mathscr{C} = (\mathcal{C}^{\mathsf{start}}, \ldots, \mathcal{C}^{\mathsf{goal}})} \mathsf{cost}_{\mathcal{F}}(\mathscr{C}). \tag{4.2}$$

For every $1 \leqslant c \leqslant s$, $\textsc{Gap}_{c,s}$ Set Cover Reconfiguration requests to distinguish whether $\mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}}) \leqslant c$ or $\mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}}) > s$.

[4] Here, division by $\mathsf{opt}(\mathcal{F}) + 1$ is derived from the nature that we must first add at least one set whenever $|\mathcal{C}^{\mathsf{start}}| = |\mathcal{C}^{\mathsf{goal}}| = \mathsf{opt}(\mathcal{F})$ and $\mathcal{C}^{\mathsf{start}} \neq \mathcal{C}^{\mathsf{goal}}$.

For the sake of completeness, we here present a 2-factor approximation algorithm for Minmax Set Cover Reconfiguration of [23]:[5]

2-factor approximation for Minmax Set Cover Reconfiguration.

1: ▷ *start from* $\mathcal{C}^{\mathsf{start}}$. ◁
2: insert each set of $\mathcal{C}^{\mathsf{goal}} \setminus \mathcal{C}^{\mathsf{start}}$ into the current cover in any order.
3: discard each set of $\mathcal{C}^{\mathsf{start}} \setminus \mathcal{C}^{\mathsf{goal}}$ from the current cover in any order.
4: ▷ *end with* $\mathcal{C}^{\mathsf{goal}}$. ◁

Our main result is stated below, whose proof uses a gap-preserving reduction from Label Cover Reconfiguration to Minmax Set Cover Reconfiguration [32, 27].

▶ **Theorem 4.1.** $\mathrm{Gap}_{1,2-\frac{1}{\mathrm{polyloglog}\, N}}$ Set Cover Reconfiguration *is* PSPACE*-complete, where* N *is the universe size. In particular,* Minmax Set Cover Reconfiguration *is* PSPACE*-hard to approximate within a factor of* $2 - \frac{1}{\mathrm{polyloglog}\, N}$.

Theorem 4.1 along with [32] implies that Minmax Dominating Set Reconfiguration is PSPACE-hard to approximate within a factor of $2 - \frac{1}{\mathrm{polyloglog}\, N}$, where N is the number of vertices (see Corollary 1.2).

Proof of Theorem 4.1. The reduction from Label Cover Reconfiguration to Minmax Set Cover Reconfiguration is almost the same as that due to Lund and Yannakakis [27] and Ohsaka [32]. Let $(G = (\mathcal{V}, \mathcal{E}, \Sigma, \Psi), f^{\mathsf{start}}, f^{\mathsf{goal}})$ be an instance of Label Cover Reconfiguration with N vertices and alphabet size $|\Sigma| = \mathrm{polyloglog}\, N$, where $\|f^{\mathsf{start}}\| = \|f^{\mathsf{goal}}\| = |\mathcal{V}|$. Define $B \coloneqq \{0,1\}^{\Sigma}$. For each $\alpha \in \Sigma$ and $S \subseteq \Sigma$, we construct $\overline{Q_\alpha} \subset B$ and $Q_S \subset B$ according to [32] in $2^{\mathcal{O}(|\Sigma|)}$ time. Let $\prec$ be an arbitrary order over V. Create an instance of Minmax Set Cover Reconfiguration as follows. For each vertex $v \in \mathcal{V}$ and each value $\alpha \in \Sigma$, we define $S_{v,\alpha} \subset \mathcal{E} \times B$ as

$$S_{v,\alpha} \coloneqq \left(\bigcup_{e=(v,w)\in\mathcal{E}: v\prec w} \{e\} \times \overline{Q_\alpha} \right) \cup \left(\bigcup_{e=(v,w)\in\mathcal{E}: v\succ w} \{e\} \times Q_{\pi_e(\alpha)} \right), \tag{4.3}$$

where $\pi_e(\alpha) \coloneqq \{\beta \in \Sigma \mid \psi_e(\alpha,\beta) = 1\}$. Then, a set system $(\mathcal{U}, \mathcal{F})$ is defined as

$$\mathcal{U} \coloneqq \mathcal{E} \times B \text{ and } \mathcal{F} \coloneqq \left\{ S_{v,\alpha} \;\middle|\; v \in \mathcal{V}, \alpha \in \Sigma \right\}. \tag{4.4}$$

For a satisfying multi-assignment $f\colon \mathcal{V} \to 2^{\Sigma}$ for G with $\|f\| = |\mathcal{V}|$,[6] we associate it with a subfamily $\mathcal{C}_f \subset \mathcal{F}$ such that

$$\mathcal{C}_f \coloneqq \left\{ S_{v,\alpha} \;\middle|\; v \in \mathcal{V}, \alpha \in f(v) \right\}, \tag{4.5}$$

which is a minimum cover for $(\mathcal{U}, \mathcal{F})$ [32]; i.e., $|\mathcal{C}_f| = |\mathcal{V}| = \mathsf{opt}(\mathcal{F})$. Constructing minimum covers $\mathcal{C}^{\mathsf{start}}$ from f^{start} and $\mathcal{C}^{\mathsf{goal}}$ from f^{goal} by Eq. (4.5), we obtain an instance $((\mathcal{U}, \mathcal{F}), \mathcal{C}^{\mathsf{start}}, \mathcal{C}^{\mathsf{goal}})$ of Minmax Set Cover Reconfiguration. This completes the description of the reduction.

[5] Similarly, a 2-factor approximation algorithm can be obtained for Minmax Dominating Set Reconfiguration and Minmax Hypergraph Vertex Cover Reconfiguration.
[6] In other words, each $f(v)$ is a singleton.

Here, we will show that

$$\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) = \mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}}), \tag{4.6}$$

which implies the completeness and soundness; for this, we use the following lemma [32].

▶ **Lemma 4.2** ([32, Observation 4.4; Claim 4.7]). *Let $f\colon \mathcal{V} \to 2^{\Sigma}$ be a multi-assignment and $\mathcal{C} \subseteq \mathcal{F}$ be a subfamily such that for any $v \in \mathcal{V}$ and $\alpha \in \Sigma$, $\alpha \in f(v)$ if and only if $S_{v,\alpha} \in \mathcal{C}$. Then, f satisfies an edge $e = (v, w) \in \mathcal{E}$ if and only if $\mathcal{C}$ covers $\{e\} \times B$. In particular, f satisfies G if and only if $\mathcal{C}$ covers $\mathcal{E} \times B$. Moreover, it holds that $\|f\| = |\mathcal{C}|$.*

We first show that $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \geqslant \mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}})$. For any reconfiguration multi-assignment sequence $F = (f^{(1)}, \dots, f^{(T)})$ from f^{start} to f^{goal} such that $\|F\|_{\max} = \mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}})$, we can construct a reconfiguration sequence $\mathscr{C} = (\mathcal{C}_{f^{(1)}}, \dots, \mathcal{C}_{f^{(T)}})$ from $\mathcal{C}^{\mathsf{start}}$ to $\mathcal{C}^{\mathsf{goal}}$ by Eq. (4.5). By Lemma 4.2, each $\mathcal{C}_{f^{(t)}}$ covers $\mathcal{U}$; thus, $\mathscr{C}$ is a valid reconfiguration sequence from $\mathcal{C}^{\mathsf{start}}$ to $\mathcal{C}^{\mathsf{goal}}$. Moreover, $\mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}}) \leqslant \mathsf{cost}_{\mathcal{F}}(\mathscr{C}) = \|F\|_{\max} = \mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}})$, as desired. We then show that $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \leqslant \mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}})$. For any reconfiguration sequence $\mathscr{C} = (\mathcal{C}^{(1)}, \dots, \mathcal{C}^{(T)})$ from $\mathcal{C}^{\mathsf{start}}$ to $\mathcal{C}^{\mathsf{goal}}$ such that $\mathsf{cost}_{\mathcal{F}}(\mathscr{C}) = \mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}})$, we can construct a sequence $F = (f^{(1)}, \dots, f^{(t)})$ of multi-assignments such that $f^{(t)}\colon \mathcal{V} \to 2^{\Sigma}$ is defined as follows:

$$f^{(t)}(v) \coloneqq \left\{ \alpha \in \Sigma \;\middle|\; S_{v,\alpha} \in \mathcal{C}^{(t)} \right\} \text{ for all } v \in \mathcal{V}. \tag{4.7}$$

By Lemma 4.2, each $f^{(t)}$ satisfies G; thus, F is a valid reconfiguration multi-assignment sequence from f^{start} to f^{goal}. Moreover, $\mathsf{MinLab}_G(f^{\mathsf{start}} \leftrightsquigarrow f^{\mathsf{goal}}) \leqslant \|F\|_{\max} = \mathsf{cost}_{\mathcal{F}}(\mathscr{C}) = \mathsf{cost}_{\mathcal{F}}(\mathcal{C}^{\mathsf{start}} \leftrightsquigarrow \mathcal{C}^{\mathsf{goal}})$, which completes the proof of Eq. (4.6).

Since $|\Sigma| = \operatorname{polyloglog} N$, the reduction takes polynomial time in N, and it holds that $|\mathcal{U}| = |\mathcal{E} \times B| = \mathcal{O}(N^2 \cdot 2^{\operatorname{polyloglog} N}) = \mathcal{O}(N^3)$; i.e., $N = \Omega(|\mathcal{U}|^{\frac{1}{3}})$. By Theorem 3.9, $\textsc{Gap}_{1,2-\frac{1}{\operatorname{polyloglog} N}}$ Label Cover Reconfiguration with alphabet size $\operatorname{polyloglog} N$ is PSPACE-complete; thus, $\textsc{Gap}_{1,2-\frac{1}{\operatorname{polyloglog}|\mathcal{U}|}}$ Set Cover Reconfiguration is PSPACE-complete as well, accomplishing the proof. ◀

4.2 PSPACE-hardness of Approximation for Hypergraph Vertex Cover Reconfiguration

We conclude this section with a similar inapproximability result for Minmax Hypergraph Vertex Cover Reconfiguration on $\mathcal{O}(1)$-uniform hypergraphs. Minmax Hypergraph Vertex Cover Reconfiguration is defined analogously to Minmax Set Cover Reconfiguration; refer to the full version [18] for the formal definition. Our inapproximability result is shown below, whose proof reuses the reduction of Theorem 4.1.

▶ **Theorem 4.3** (∗). *For any constant $\varepsilon \in (0, 1)$, $\textsc{Gap}_{1,2-\varepsilon}$ Hypergraph Vertex Cover Reconfiguration on $\operatorname{poly}(\varepsilon^{-1})$-uniform hypergraphs is* PSPACE*-complete. In particular,* Minmax Hypergraph Vertex Cover Reconfiguration *on $\operatorname{poly}(\varepsilon^{-1})$-uniform hypergraphs is* PSPACE*-hard to approximate within a factor of $2 - \varepsilon$.*

Abstract

Consider a matroid equipped with a labeling of its ground set to an abelian group. We define the label of a subset of the ground set as the sum of the labels of its elements. We study a collection of problems on finding bases and common bases of matroids with restrictions on their labels. For zero bases and zero common bases, the results are mostly negative. While finding a non-zero basis of a matroid is not difficult, it turns out that the complexity of finding a non-zero common basis depends on the group. Namely, we show that the problem is hard for a fixed group if it contains an element of order two, otherwise it is polynomially solvable.

As a generalization of both zero and non-zero constraints, we further study F-avoiding constraints where we seek a basis or common basis whose label is not in a given set F of forbidden labels. Using algebraic techniques, we give a randomized algorithm for finding an F-avoiding common basis of two matroids represented over the same field for finite groups given as operation tables. The study of F-avoiding bases with groups given as oracles leads to a conjecture stating that whenever an F-avoiding basis exists, an F-avoiding basis can be obtained from an arbitrary basis by exchanging at most $|F|$ elements. We prove the conjecture for the special cases when $|F| \leq 2$ or the group is ordered. By relying on structural observations on matroids representable over fixed, finite fields, we verify a relaxed version of the conjecture for these matroids. As a consequence, we obtain a polynomial-time algorithm in these special cases for finding an F-avoiding basis when $|F|$ is fixed.

1 Introduction

Several combinatorial optimization problems involve additional constraints, such as parity, congruency, and exact-weight constraints [35, 41, 42, 43, 44]. These constraints are subsumed by *group-label constraints* defined as follows: the ground set E is equipped with a labeling $\psi\colon E \to \Gamma$ to an abelian group Γ and a solution $X \subseteq E$ must ensure that the sum of the labels of its entries is not in a prescribed forbidden set $F \subseteq \Gamma$, i.e., $\psi(X) \coloneqq \sum_{e\in X} \psi(e) \notin F$. We call such a solution *F-avoiding*.

Particularly important special cases of group-label constraints include the *non-zero* ($F = \{0\}$) and *zero* ($F = \Gamma \setminus \{0\}$) constraints, where F-avoiding sets are referred to as *non-zero* and *zero*, respectively. The non-zero constraint has been extensively studied for path problems on graphs as it generalizes constraints on parity and topology. This line of research includes packing non-zero A-paths [12] as well as finding a shortest odd s–t path [46, Section 29.11e], a shortest non-zero s–t path [25], and an F-avoiding s–t path with $|F| \leq 2$ [28]. For these problems, some literature allows Γ to be non-abelian since the order of operations can be naturally defined for paths. Problems related to non-zero perfect bipartite matchings in $\mathbb{Z}_2$ have also been dealt with, see [1, 18, 26]. The zero constraint, or, slightly more generally, the group-label constraint with $|\Gamma \setminus F| = 1$, can encode the congruency and exact-weight constraints by setting Γ to be a cyclic group $\mathbb{Z}_m$ and the integers $\mathbb{Z}$, respectively. Examples of problems whose congruency-constrained versions have been studied include submodular function minimization [42], minimum cut [43], and integer linear programming with totally unimodular coefficients [41]. For the last problem, Nägele, Santiago, and Zenklusen [41] gave a randomized strongly polynomial-time algorithm to test the existence of an F-avoiding feasible solution, where the group is $\mathbb{Z}_m$ with prime m and $|F| \leq 2$, implying the congruency constraint if $m = 3$.

The exact-weight constraint was first considered for the matching problem by Papadimitriou and Yannakakis [44]. Mulmuley, Vazirani, and Vazirani [40] gave a randomized polynomial-time algorithm for solving the problem using an algebraic technique. Derandomizing this algorithm is a major open problem and there is a collection of partial results for it, see e.g. [6, 18, 22, 49, 52]. Other exact problems include arborescences, matchings, cycles [2], and independent sets or bases in a matroid [11, 16, 45].

In this work, we explore group-label constraints for matroid bases and matroid intersection. Throughout the paper, we assume that any group Γ is abelian without mentioning it. In the problems Non-Zero Basis and Zero Basis, we are given a matroid M on a ground set E and a group labeling $\psi\colon E \to \Gamma$, and we are to find a non-zero or zero basis, respectively, or to correctly report that no such basis exists. In F-avoiding Basis, along with the matroid M and labeling ψ, we are also given a forbidden label set $F \subseteq \Gamma$, and we need to find an F-avoiding basis, that is, a basis B with $\psi(B) \notin F$. In Non-Zero Common Basis, Zero Common Basis, and F-avoiding Common Basis, instead of a single matroid, we are given two matroids M_1 and M_2 on a common ground set E and seek a non-zero, zero,

and F-avoiding common basis, respectively. We also tackle the weighted variants of these problems, referred to as Weighted Non-Zero Basis for example, where we are to find a feasible solution minimizing a given weight function $w\colon E \to \mathbb{R}$.

We note that the target label 0 in the non-zero and zero problems can be changed to an arbitrary group element $g \in \Gamma$ by appending a coloop to the ground set with label $-g$. Regarding the input of the group, we consider the following three types: (i) operation and zero-test oracle, (ii) operation table of a finite group, and (iii) a fixed finite group. Unless otherwise stated, we assume that a group is given as the oracles and the matroids are given as independence oracles. In this case, by a polynomial-time algorithm, we mean an algorithm making polynomially many elementary steps, group operations, and independence oracle calls. If the group is finite and is given by its operation table, then the running time of a polynomial-time algorithm can depend polynomially on the group size.

Our research follows the recent initiative by Liu and Xu [35], who addressed Zero Basis[1]. They conjectured that, given the existence of a zero basis, for any non-zero basis B, there is a zero basis B^* such that $|B^* \setminus B| \leq D(\Gamma) - 1$, where $D(\Gamma)$ denotes the Davenport constant of Γ (see Section 6.3 for definition), which is upper-bounded by $|\Gamma|$. Liu and Xu proved the conjecture for cyclic groups $\Gamma = \mathbb{Z}_m$ with the order m being a prime power or the product of two primes, with the aid of an additive combinatorics result by Schrijver and Seymour [47], deriving an FPT algorithm parameterized by $|\Gamma| = m$ for Zero Basis. In Theorem 6.6, we give a counterexample to this conjecture for groups with $\mathbb{Z}_2^d$ with $d \geq 4$.

The non-zero constraint is closely related to *lattices* studied by Lovász [37]. The *lattice* generated by vectors $\{v_1, \ldots, v_n\} \subseteq \mathbb{R}^n$ is the set $\{\sum_{i=1}^n \lambda_i v_i \mid \lambda_1, \ldots, \lambda_n \in \mathbb{Z}\}$. For a set family $\mathcal{F} \subseteq 2^E$, let $\mathrm{lat}(\mathcal{F})$ denote the lattice generated by the characteristic vectors of $\mathcal{F}$. Every lattice has a *lattice basis* $A = \{a_1, \ldots, a_n\} \subseteq \mathbb{Z}^E$, which is a set of linearly independent vectors generating it. Since $\mathcal{F}$ and its lattice basis A generate the same lattice, $\mathcal{F}$ has a non-zero member if and only if A has a non-zero member, i.e., $\psi(a_i) := \sum_{e \in E} a_i(e)\psi(e) \neq 0$ for some i. This implies that if a basis of $\mathrm{lat}(\mathcal{F})$ can be computed in polynomial time, then the existence of a non-zero member of $\mathcal{F}$ can be decided in polynomial time. Such set families $\mathcal{F}$ include matroid bases [45], common bases of a matroid and a partition matroid having two classes [45], and perfect matchings [37, 38].

Below, we summarize our results for each problem.

Non-Zero Basis. The tractability of Non-Zero Basis can be derived from the above lattice argument together with a characterization of base lattices [45]. We observe that for any zero basis B, there exists a non-zero basis B^* such that $|B^* \setminus B| \leq 1$, provided that at least one non-zero basis exists. A weighted variant of this statement is shown in the same way. This result generalizes an algorithm for Weighted Zero Basis with $\Gamma = \mathbb{Z}_2$ by Liu and Xu [35].

Non-Zero Common Basis. We show in Theorems 3.7 and 6.1 that Non-Zero Common Basis is polynomially solvable if and only if Γ does not contain $\mathbb{Z}_2$ as a subgroup. Our hardness proof for $\Gamma = \mathbb{Z}_2$ is based on an information-theoretic argument using sparse paving matroids, which is independent of the $\mathsf{P} \neq \mathsf{NP}$ conjecture. The polynomial-time algorithm for $\Gamma \not\geq \mathbb{Z}_2$ is a modification of the negatively directed cycle elimination algorithm for weighted matroid intersection [9]. In Theorem 3.9, we also give a 2-approximation algorithm for Weighted Non-Zero Common Basis if $\Gamma \not\geq \mathbb{Z}_2$ and the weight function is nonnegative. Finally, in Theorems 3.11 and 3.12, we solve Weighted

[1] Called *Group-Constrained Matroid Base* (GCMB) in [35].

Non-Zero Common Basis for an arbitrary group when both matroids are partition matroids or one of the matroids is a partition matroid defined by a partition having two classes.

F-avoiding Basis and Common Basis. If the group is fixed and finite, (Weighted) F-avoiding Basis reduces to polynomially many instances of (weighted) matroid intersection [35]. On the other hand, it follows from the results of [16] that F-avoiding Basis requires exponentially many independence oracle queries if F is part of the input and the group is finite and is given as an operation table, while the same hardness of F-avoiding Common Basis follows from our Theorem 6.1 even if the group is fixed and finite. Regarding positive results for F-avoiding problems, our contribution is twofold. First, using similar ideas as in [11, 51], in Theorem 4.2 we give a randomized algebraic algorithm for F-avoiding Common Basis in case where the matroids are represented over the same field and the group is finite and is given as an operation table. We observe in Theorem 4.3 that the algorithm can be derandomized in certain cases, including F-avoiding Basis for graphic matroids. Second, we turn to the study of F-avoiding Basis for cases where $|F|$ is fixed and the group is given by an oracle. Motivated by the work of Liu and Xu [35], we propose Conjecture 5.1 stating that if at least one F-avoiding basis exists, then each basis can be turned into an F-avoiding basis by exchanging at most $|F|$ elements. The validity of the conjecture follows from the results of [35] for groups of prime order. We show that the conjecture also holds if Γ is an ordered group (Theorem 5.6) or if $|F| \leq 2$ (Theorem 5.18). By introducing a novel relaxation of strong base orderability, in Theorem 5.11 we show that a relaxation of the conjecture holds for $\mathrm{GF}(q)$-representable matroids for every fixed prime power q. In Theorem 5.17, we prove a somewhat stronger version of this result for graphic matroids. In each of these special cases, we obtain the polynomial solvability of F-avoiding Basis for fixed F.

Zero Basis and Zero Common Basis. The zero constraint for $\Gamma = \mathbb{Z}$ corresponds to the exact-weight constraint, implying that many problems are NP-hard, in particular, Zero Basis is NP-hard even for uniform matroids (Theorem 6.2). It follows from the results of [16] that Zero Basis requires exponentially many independence oracle queries for a finite group given by operation table. We show the same hardness of Zero Common Basis for any fixed nontrivial group (Theorem 6.4). On the other hand, we obtain positive results from the aforementioned results on F-avoiding problems. In particular, Zero Basis is polynomially solvable if the group is fixed and finite [35], Theorem 4.2 implies a randomized polynomial-time algorithm for Zero Common Basis for matroids represented over the same field if Γ is finite and is given as an operation table, and using the results of [35], Theorem 5.11 implies an FPT algorithm for Zero Basis when parameterized by $|\Gamma|$ if the matroids are representable over a fixed, finite field.

Other work related to group-labeled matroids

Bérczi and Schwarcz [5] showed the hardness of partitioning into common bases, see also [4, 24] for later results. A natural relaxation of that problem gives rise to problems related to Non-Zero Common Basis for the group $\mathbb{R}/\mathbb{Z}$. This relation is explained in the full version.

It is straightforward to verify that the family of non-zero subsets of a set satisfies the axiom of *delta-matroids*, which are a generalization of matroids introduced by Bouchet [8]. From this viewpoint, Non-Zero Basis offers a tractable special case of the intersection of a matroid and a delta-matroid. We note that the intersection of a matroid and a delta-matroid is intractable in general, as it encompasses matroid parity. Kim, Lee, and Oum [29] defined a delta-matroid, called a Γ-*graphic delta-matroid*, from a graph equipped with a labeling of

vertices to an abelian group Γ. In the definition, they employ a constraint similar to but different from non-zero. Exploring the relationship between Γ-graphic delta-matroids and our findings is left for future work.

Organization

The rest of this paper is organized as follows. Section 2 provides preliminaries on groups and matroids. Section 3 deals with non-zero problems. Section 4 provides an algebraic algorithm for F-avoiding Common Basis for represented matroids. Section 5 studies F-avoiding Basis if $|F|$ is fixed. Section 6 includes our hardness results for each of the problems. Finally, Section 7 concludes this paper enumerating open problems.

2 Preliminaries

Let $\mathbb{N}$, $\mathbb{Z}_{\geq 0}$, $\mathbb{Z}$, $\mathbb{Q}$, $\mathbb{R}_{\geq 0}$, and $\mathbb{R}$ denote the set of positive integers, nonnegative integers, integers, rationals, nonnegative reals, and reals, respectively. We let $[n] \coloneqq \{1, \dots, n\}$ for $n \in \mathbb{Z}_{\geq 0}$. For a set S, we simply write $S \setminus \{x\}$ as $S - x$ for $x \in S$ and $S \cup \{y\}$ as $S + y$ for $y \notin S$. For a set E and $r \in \mathbb{Z}_{\geq 0}$, we let $\binom{E}{r} \coloneqq \{ S \subseteq E \mid |S| = r \}$.

In this paper, all groups are implicitly assumed to be abelian. We use the additive notation for the operations of groups except in Section 4. For $m \in \mathbb{N}$, let $\mathbb{Z}_m = \{0, \dots, m-1\}$ denote the cyclic group of order m. For groups Γ_1 and Γ_2, we mean by $\Gamma_1 \leq \Gamma_2$ that Γ_1 is a subgroup of Γ_2. A group Γ is said to be *ordered* if Γ is equipped with a total order $\leq$ compatible with the operation of Γ in the sense that $a \leq b$ implies $a + c \leq b + c$ for all $a, b, c \in \Gamma$. A *labeling* is a function $\psi \colon E \to \Gamma$ from a set E to a group Γ, and we let $\psi(S) \coloneqq \sum_{x \in S} \psi(x)$ for $S \subseteq E$. Let $\mathrm{GF}(q)$ denote the finite field of q elements for a prime power q.

We follow [14] for basic terminologies on graphs such as paths and cycles. The vertex and edge sets of a graph G are denoted by $V(G)$ and $E(G)$, respectively. Similarly, $V(D)$ denotes the vertex set of a directed graph D, and $A(D)$ denotes its arc set. Given a weight function $w \colon A(D) \to \mathbb{R}$ and a subgraph C of D, the *weight* of C is defined as $w(C) \coloneqq w(A(C))$. A weight function w is said to be *conservative* if D does not contain a directed cycle of negative weight.

We refer the reader to [20, 46] for basics on matroid optimization. A *matroid* M consists of a finite ground set $E(M)$ and a nonempty set family $\mathcal{B}(M) \subseteq 2^{E(M)}$ such that for any $B_1, B_2 \in \mathcal{B}(M)$ and $x \in B_1 \setminus B_2$, there exists $y \in B_2 \setminus B_1$ such that $B_1 - x + y \in \mathcal{B}(M)$. Elements in $\mathcal{B}(M)$ are called *bases*. The next basis exchange property was proved by Brualdi [10], see also [46, Theorem 39.12].

▶ **Lemma 2.1** (Brualdi [10]). *If B and B' are bases of a matroid M, then there exists a bijection $\phi \colon B \setminus B' \to B' \setminus B$ such that $B - e + \phi(e)$ is a basis for each $e \in B \setminus B'$.*

Following [20], we define a *partition matroid* as a direct sum of uniform matroids and a *unitary partition matroid* as a direct sum of rank-1 uniform matroids. We note that several authors refer to the latter object as partition matroids. Given a matrix A over some field, we denote by $M(A)$ the matroid defined on the column indices of A where a set is a basis of $M(A)$ if the corresponding columns form a basis of the vector space spanned by the columns of A. Given a connected graph G, its *cycle matroid* $M(G)$ is the matroid whose ground set is $E(G)$ and whose bases are the edge sets of the spanning trees of G. If $M = M(A)$ for a matrix A over a field $\mathbb{F}$ or a graph A, we say that M is $\mathbb{F}$-*representable* or *graphic*, respectively.

3 Non-Zero Basis and Common Basis

3.1 Non-Zero Basis

In this section, we consider (Weighted) Non-Zero Basis. The following theorem can be derived from the description of the lattices of matroid bases by Rieder [45]. In what follows we give a direct proof of the result.

▶ **Theorem 3.1.** *Let M be a matroid and $\psi\colon E(M) \to \Gamma$ a group labeling. The following are equivalent:*

(i) *all bases of M have the same label,*
(ii) *M has a basis B such that $\psi(B') = \psi(B)$ holds for each basis B' with $|B \setminus B'| \leq 1$, and*
(iii) *ψ is constant on each component of M.*

Proof. It is clear that (i) implies (ii) and (iii) implies (i). In what follows, we show that (ii) implies (iii). Let B be a basis such that $\psi(B') = \psi(B)$ holds for each basis B' with $|B \setminus B'| \leq 1$. Let G_B denote the bipartite graph with bipartition $(B, E(M) \setminus B)$ and edge set $\{\, xy \mid x \in B, y \in E(M) \setminus B, B - x + y \in \mathcal{B}(M) \,\}$. By the assumption on B, it follows that $\psi(x) = \psi(y)$ for each edge xy of G_B. Then, ψ is constant on each connected component of the graph G_B, and thus (iii) follows by using that the connected components of the graph G_B coincide with the components of the matroid M [32]. ◀

Note that Theorem 3.1(iii) provides a characterization for "NO" instances of Non-Zero Basis, while Theorem 3.1(ii) provides a simple algorithm for this problem. Liu and Xu [35] gave the following simple and constructive algorithm for Weighted Zero Basis with $\Gamma = \mathbb{Z}_2$, for which the zero and non-zero constraints are equivalent, without decomposing the matroid into components. First, find a minimum weight basis $B \in \mathcal{B}(M)$, and if $\psi(B) \neq 0$, then we are done. Otherwise, consider all the bases of the form $B - x + y$ with $x \in B$ and $y \in E(M) \setminus B$. Among these bases, if there is none with a non-zero label, then there does not exist a non-zero basis, otherwise, choose a non-zero basis of minimum weight among the considered ones. Actually, this algorithm works correctly for Weighted Non-Zero Basis for any group, and the proof of [35, Proposition 1] can be modified to show its correctness. In what follows, we give a different proof of this fact.

▶ **Lemma 3.2.** *Let M be a matroid, $\psi\colon E(M) \to \Gamma$ a group labeling, and $w\colon E(M) \to \mathbb{R}$ a weight function. Then, for any minimum-weight basis B, there exists a minimum-weight non-zero basis B^* such that $|B \setminus B^*| \leq 1$, provided that at least one non-zero basis exists.*

Proof. Let B' be a minimum-weight non-zero basis with $|B \setminus B'|$ being minimal. If $B = B'$ then we are done, otherwise $\psi(B) = 0$. According to the symmetric exchange axiom, we can choose $x \in B \setminus B'$ and $y \in B' \setminus B$ such that $B - x + y$ and $B' + x - y$ are both bases. As $0 \neq \psi(B) + \psi(B') = \psi(B - x + y) + \psi(B' + x - y)$, one of $B - x + y$ and $B' + x - y$ must be non-zero. Suppose $\psi(B - x + y) \neq 0$. Since $w(B) + w(B') = w(B - x + y) + w(B' + x - y)$ and $w(B)$ has the minimum weight, we have $w(B - x + y) \leq w(B')$, which implies $w(B - x + y) = w(B')$ by $\psi(B - x + y) \neq 0$. Thus, we can take $B^* = B - x + y$. If $\psi(B' + x - y) \neq 0$, then it can be shown in the same way that $B' + x - y$ is a minimum-weight non-zero basis, contradicting the assumption that B' is a minimum-weight non-zero basis closest to B. ◀

We obtain the following from Lemma 3.2.

▶ **Theorem 3.3.** Weighted Non-Zero Basis *can be solved in polynomial time.*

3.2 Non-Zero Common Basis

3.2.1 Polynomial-time Algorithm with $\mathbb{Z}_2 \not\leq \Gamma$

In this section, we show the polynomial solvability of Non-Zero Common Basis when $\mathbb{Z}_2 \not\leq \Gamma$, that is, Γ does not contain any element of order two. Later, we will show in Theorem 6.1 that the problem is hard if $\mathbb{Z}_2 \leq \Gamma$. Our algorithm is a modification of the weighted matroid intersection algorithm given by Krogdahl [30, 31, 32] and independently by Brezovec, Cornuéjols, and Glover [9].

We will use the following result on directed graphs. While several works concentrated on finding non-zero paths and cycles in group-labeled graphs [25], their setting does not seem to include group-labeled digraphs. Therefore, we give a proof of the next result in the full version. While this result may be of independent interest, it will later be applied as a subroutine.

▶ **Theorem 3.4.** *Let D be a digraph, $\psi\colon A(D) \to \Gamma$ a group labeling, and $w\colon A(D) \to \mathbb{R}$ a conservative weight function. Then, there is a polynomial-time algorithm that returns a non-zero directed cycle in D which is shortest with respect to w or correctly reports that D contains no non-zero directed cycle.*

We note that the problem of finding an odd directed path is NP-hard even in the unweighted case [33]. In contrast to Theorem 3.4, the key distinction here lies between walks and paths: while a walk can include a directed cycle to change a group label, a path cannot. Consequently, a Dijkstra-style algorithm for finding an odd directed path must track not only the last vertex but also all intermediate vertices, leading to an exponential increase in running time.

Let M_1 and M_2 be matroids on a common ground set E and $\psi\colon E \to \Gamma$ a group labeling. Given a common basis B, we define the digraph $D_{M_1,M_2}(B)$ on the vertex set E and the labeling ψ' on its arcs as follows. For each $x \in B$ and $y \in E \setminus B$ such that $B - x + y \in \mathcal{B}(M_1)$, we add an arc xy to $D_{M_1,M_2}(B)$ with label $\psi'(xy) \coloneqq \psi(y)$. Similarly, for each $x \in B$ and $y \in E \setminus B$ such that $B - x + y \in \mathcal{B}(M_2)$, we add an arc yx and with label $\psi'(yx) \coloneqq -\psi(x)$.

▶ **Lemma 3.5.** *Let M_1 and M_2 be matroids on a common ground set E and $\psi\colon E \to \Gamma$ a group labeling. Let B and B' be common bases of M_1 and M_2 such that $\psi(B) = 0$ and $\psi(B') \neq 0$. Then, $D_{M_1,M_2}(B)$ contains a non-zero directed cycle C with $V(C) \subseteq B \triangle B'$.*

Proof. By Lemma 2.1, $D_{M_1,M_2}(B)$ contains a collection P_1 of $|B \setminus B'|$ pairwise vertex-disjoint arcs from $B \setminus B'$ to $B' \setminus B$ and a collection P_2 of $|B \setminus B'|$ pairwise vertex-disjoint arcs from $B' \setminus B$ to $B \setminus B'$. The union of P_1 and P_2 has label $\psi(B' \setminus B) - \psi(B \setminus B') = \psi(B') - \psi(B) = \psi(B') \neq 0$ and consists of pairwise vertex-disjoint directed cycles in $D_{M_1,M_2}(B)$, hence it contains a non-zero directed cycle. ◀

The following result and proof are analogous to that of [9, Theorem 2]. In that result, a weight function is given instead of a labeling, and the constraint "non-zero" is replaced by "negative". In our setting, the proof only works if we assume $\mathbb{Z}_2 \not\leq \Gamma$, as we need to guarantee that if we decompose an arc set having label $2\psi'(C)$ for some non-zero directed cycle C, then at least one member of the decomposition has non-zero label. We give the proof in the full version.

▶ **Lemma 3.6.** *Let Γ be a group such that $\mathbb{Z}_2 \not\leq \Gamma$. Let M_1 and M_2 be matroids on a common ground set E, $\psi\colon E \to \Gamma$ a group labeling, and B a common basis. If C is a non-zero directed cycle of $D_{M_1,M_2}(B)$ whose vertex set is inclusion-wise minimal among non-zero directed cycles, then $B \triangle V(C)$ is a common basis.*

Combining Lemmas 3.5 and 3.6, we obtain the main result of the section.

▶ **Theorem 3.7.** *Let Γ be a group such that $\mathbb{Z}_2 \not\leq \Gamma$. Let M_1 and M_2 be matroids on a common ground set E, $\psi\colon E \to \Gamma$ a group labeling, and B_0 a zero common basis. Then, M_1 and M_2 have a non-zero common basis if and only if $D_{M_1,M_2}(B_0)$ contains a non-zero directed cycle. Moreover,* Non-Zero Common Basis *is polynomially solvable.*

Proof. If there exists a non-zero common basis B^*, then $D_{M_1,M_2}(B_0)$ contains a non-zero directed cycle by Lemma 3.5. Conversely, if $D_{M_1,M_2}(B_0)$ contains a non-zero directed cycle, then let C be a minimum length non-zero directed cycle. Then, Lemma 3.6 implies that $B^* \coloneqq B \triangle V(C)$ is a common basis, and we have $\psi(B^*) = \psi(B_0) + \psi'(C) = \psi'(C) \neq 0$.

This provides the following algorithm for Non-Zero Common Basis. First, we find a common basis B_0. If no common basis exists or B_0 is non-zero, we are done. Otherwise, we find a minimum length non-zero directed cycle C in $D_{M_1,M_2}(B_0)$ using Theorem 3.4. If no non-zero directed cycle exists then we report that there is no non-zero common basis, otherwise we output $B_0 \triangle V(C)$. ◀

We turn to the study of Weighted Non-Zero Common Basis. Given two matroids M_1 and M_2 on a common ground set E, a common basis B, and a weight function $w\colon E \to \mathbb{R}$, we define the weight function w' on the arcs of $D_{M_1,M_2}(B)$ as follows. For each arc xy such that $x \in B$, $y \in E \setminus B$ and $B - x + y \in \mathcal{B}(M_1)$ we define $w'(xy) \coloneqq w(y)$, and for each arc yx such that $x \in B$, $y \in E \setminus B$ and $B - x + y \in \mathcal{B}(M_2)$ we define $w'(yx) \coloneqq -w(x)$. Then, B is a minimum-weight common basis if and only if w' is conservative [31, 21, 9], see also [46, Theorem 41.5]. We observe the following relationship between the weight of a shortest non-zero directed cycle in $D_{M_1,M_2}(B)$ and the weights of non-zero common bases of M_1 and M_2. Its simple proof can be found in the full version.

▶ **Lemma 3.8.** *Let M_1 and M_2 be matroids on a common ground set E, $\psi\colon E \to \Gamma$ a group labeling, and $w\colon E \to \mathbb{R}$ a weight function. Let B_0 be a minimum-weight common basis and assume that $\psi(B_0) = 0$. Let C be a shortest non-zero directed cycle in $D_{M_1,M_2}(B_0)$ with respect to w'. Then, $w(B_0 \triangle V(C)) \leq w(B^*)$ holds for each non-zero common basis B^*.*

We note that Lemma 3.8 generalizes Lemma 3.2, as in the special case $M_1 = M_2$ each arc of $D_{M_1,M_2}(B_0)$ is bidirectional, thus a shortest non-zero directed cycle consists of two vertices.

In Lemma 3.8, the weight of C is measured by w' (which takes negative values on some arcs), so $V(C)$ is not necessarily inclusion-wise minimal among the vertex sets of non-zero directed cycles. Thus, it does not yield an algorithm for Weighted Non-Zero Common Basis. In fact, the complexity of the problem remains open for a group Γ with $\mathbb{Z}_2 \not\leq \Gamma$. Nevertheless, we use Lemma 3.8 to give a 2-approximation if the weight function w is nonnegative. The proof of the result is given in the full version.

▶ **Theorem 3.9.** *Let Γ be a group with $\mathbb{Z}_2 \not\leq \Gamma$. Let M_1 and M_2 be matroids on a common ground set E, $\psi\colon E \to \Gamma$ a group labeling, and $w\colon E \to \mathbb{R}_{\geq 0}$ a weight function. Then, there exists a polynomial-time algorithm that computes a non-zero common basis B that satisfies $w(B) \leq 2w(B^*)$ for every non-zero common basis B^* or correctly outputs that there exists no non-zero common basis.*

3.2.2 Certificate for All Common Bases Being Zero

Given a strongly connected digraph having labels on its arcs, the fact that all directed cycles have label zero can be certified by a certain labeling of its vertices. Using this result and assuming a property of the matroid pair ensuring strong connectivity, we get a characterization for all directed cycles of $D_{M_1,M_2}(B)$ having label zero, which is analogous

to the weight-splitting theorem of Frank [19]. By Theorem 3.7, this provides the following certificate for the "NO" instances of Non-Zero Common Basis if $\mathbb{Z}_2 \not\leq \Gamma$. We give details in the full paper.

▶ **Theorem 3.10.** *Let M_1 and M_2 be matroids on a common ground set E and the same rank r. Assume that $r_{M_1}(X) + r_{M_2}(E \setminus X) > r$ holds for every $\emptyset \neq X \subsetneq E$. Let B be a common basis of M_1 and M_2, and $\psi\colon E \to \Gamma$ a group labeling. Then, $D_{M_1,M_2}(B)$ contains no non-zero directed cycle if and only if there exist labelings $\psi_1, \psi_2\colon E \to \Gamma$ such that $\psi = \psi_1 + \psi_2$ and ψ_i is constant on each connected component of M_i for $i = 1, 2$.*

3.2.3 Partition matroids

When both matroids are partition matroids, we can drop the assumption $\mathbb{Z}_2 \not\leq \Gamma$ from Theorem 3.7 and extend it to the weighted setting. The proof of the next result is given in the full version.

▶ **Theorem 3.11.** Weighted Non-Zero Common Basis *is polynomially solvable if M_1 and M_2 are partition matroids.*

Given a graph G and a function $b\colon V(G) \to \mathbb{Z}_{\geq 0}$, a *perfect b-matching* is an edge set $F \subseteq E(G)$ such that $d_F(v) = b(v)$ for each $v \in V$. If G is bipartite, then its perfect b-matchings form the family of common bases of two partition matroids. Therefore, Theorem 3.11 can be formulated as having a polynomial-time algorithm for finding a minimum weight non-zero perfect b-matching in a bipartite graph with weights and labels on its edges. For perfect matchings and the group $\mathbb{Z}_2$, the idea of essentially the same algorithm as ours was briefly mentioned in [26], where the authors noted that it can also be derived from results of [1]. A formal description of the algorithm and a proof of its correctness were given in [18] for a special weight function.

Next, we consider the special case of Weighted Non-Zero Common Basis when we only assume that one of the matroids is a partition matroid. Without further assumptions, this problem is not easier than the general one: a construction similar to that of Harvey, Király and Lau [23] shows that the general problem can be reduced to the special case when one of the matroids is a unitary partition matroid and all partition classes have size two. In what follows, we will consider the case when the partition matroid is defined by a partition having two classes. In this special case, the polynomial solvability of Non-Zero Common Basis follows from the corresponding lattice basis characterization of Rieder [45]. We extend this result by solving the weighted version of the problem.

▶ **Theorem 3.12.** Weighted Non-Zero Common Basis *is polynomially solvable if M_2 is a partition matroid defined by a partition having two classes.*

The proof of the theorem is given in the full version. The proof of both Theorem 3.11 and Theorem 3.12 relies on Lemma 3.8 by observing that the special property of the matroid pair guarantees that $B_0 \triangle V(C)$ is a common basis whenever B_0 is a minimum-weight common basis having label zero and C is a shortest non-zero directed cycle in $D_{M_1,M_2}(B)$.

4 Algebraic Algorithm for F-avoiding Basis and Common Basis

We present a randomized polynomial-time algorithm for F-avoiding Common Basis for representable matroids given as matrices over a field $\mathbb{F}$ and a finite group Γ given as an operation table. Our algorithm is a generalization of the exact-weight matroid intersection algorithm for representable matroids by Camerini, Galtiati, and Maffioli [11]. A similar algebraic algorithm has also been considered by Webb [51, Section 3.7].

Before describing the algorithm, we introduce needed algebraic notions and results. We assume that the arithmetic operations and the zero test over $\mathbb{F}$ can be performed in constant time. In this section, we use the multiplicative notation for the operation of Γ, and let e denote the group unit (zero) of Γ instead of 0. The *group ring* $K[\Gamma]$ of Γ over a field K is the set of formal K-coefficient linear combinations of the elements in Γ, i.e., $K[\Gamma] \coloneqq \{ \sum_{g\in\Gamma} a_g g \mid a_g \in K \ (g \in \Gamma) \}$. The addition and multiplication of $f = \sum_{g\in\Gamma} a_g g \in K[\Gamma]$ and $h = \sum_{g\in\Gamma} b_g g \in K[\Gamma]$ are naturally defined as $f + h = \sum_{g\in\Gamma}(a_g + b_g)g$ and $fh = \sum_{g,g'\in\Gamma} a_g b_{g'} gg'$. With these operations, $K[\Gamma]$ forms a commutative ring, containing K as a subring under the natural identification $K \ni a \mapsto ae \in K[\Gamma]$. Note that the operations of $K[\Gamma]$ and the zero test can be performed in polynomially many operations of K and Γ.

For finite sets R and C, we mean by an $R \times C$ *matrix* a matrix of size $|R| \times |C|$ whose rows and columns are identified with R and C, respectively. We simply write $[r] \times C$ as $r \times C$ for $r \in \mathbb{Z}_{\geq 0}$. Given a ground set E and a labeling $\psi\colon E \to \Gamma$, we define an $E \times E$ diagonal matrix D_ψ as follows: for every $j \in E$, we set the (j, j) diagonal entry of D_ψ as $x_j\psi(j)$, where x_j is an indeterminate (variable) whose actual value comes from $\mathbb{F}$. Then, D_ψ is regarded as a matrix over the group ring $\mathbb{F}(\{x_e\}_{e\in E})[\Gamma]$, where $\mathbb{F}(\{x_e\}_{e\in E})$ denotes the rational function field over $\mathbb{F}$ in $|E|$ indeterminates $\{x_e\}_{e\in E}$.

The following is a modification of a claim of Tomizawa and Iri [50], who first used the Cauchy–Binet formula in the context of linear matroid intersection.

▶ **Lemma 4.1.** *Let $\mathbb{F}$ be a field, M_1 and M_2 $\mathbb{F}$-representable matroids with the common ground set E and the same rank r, A_k an $r \times E$ matrix representing M_k for $k = 1, 2$, and $\psi\colon E \to \Gamma$ a labeling. Let $\Xi = A_1 D_\psi A_2^\top$. Then, the coefficient of $g \in \Gamma$ in $\det(\Xi)$ is a non-zero polynomial in $\{x_j\}_{j\in E}$ if and only if a common basis with label g exists.*

Proof. By the Cauchy–Binet formula, we can expand $\det(\Xi)$ as

$$\det(\Xi) = \sum_{B\in\binom{E}{r}} \det(A_1[B]) \det(A_2[B]) \prod_{j\in B} x_j \cdot \psi(B), \tag{1}$$

where $A_k[B]$ denotes the submatrix of A_k obtained by extracting the columns in B for $k = 1, 2$. Observe that $\det(A_1[B]) \det(A_2[B])$ is non-zero if and only if B is a common basis of M_1 and M_2, and the terms coming from different common bases do not cancel out thanks to the factor $\prod_{j\in B} x_j$, proving the claim. ◀

Lemma 4.1 together with the Schwartz–Zippel lemma [36, 48, 53], division-free determinant algorithm [27], search-to-decision reduction, and the field extension for small fields give rise to a randomized algebraic algorithm for F-avoiding Common Basis. The proof of the result is given in the full version.

▶ **Theorem 4.2.** *Let $\mathbb{F}$ be a field and M_1 and M_2 $\mathbb{F}$-representable matroids with the common ground set E. There is a randomized algorithm that, given matrices A_1 and A_2 over $\mathbb{F}$ representing M_1 and M_2, respectively, the operation table of a finite abelian group Γ, a group labeling $\psi\colon E \to \Gamma$, and a forbidden label set $F \subseteq \Gamma$, solves F-avoiding Common Basis in expected polynomial time.*

A *Pfaffian pair* is a pair of $r \times n$ matrices A_1, A_2 such that $\det(A_1[B]) \det(A_2[B])$ is a non-zero constant for any common basis B [51]. This property implies that if $\mathbb{F} = \mathbb{Q}$ and matroids are given as a Pfaffian pair, then no cancel-out occurs in the summands of $\det(\Xi)$ in the equation (1) even if we substitute 1 for all x_i. Therefore, we can derandomize the algorithm given in Theorem 4.2. Examples of common bases of matroid pairs representable by Pfaffian pairs include spanning trees, regular matroid bases, arborescences, perfect matchings in Pfaffian-orientable bipartite graphs, and node-disjoint S–T paths in planar graphs [39].

▶ **Theorem 4.3.** *F-avoiding Common Basis is polynomially solvable for $\mathbb{Q}$-representable matroids if matroids are given as a Pfaffian pair and a group is given as the operation table.*

We can also generalize Theorem 4.2 to a randomized pseudo-polynomial-time algorithm for the weighted problem as follows. See the full version for the proof.

▶ **Theorem 4.4.** *Let $\mathbb{F}$ be a field and M_1 and M_2 $\mathbb{F}$-representable matroids on a common ground set E. There is a randomized algorithm that, given matrices A_1 and A_2 over $\mathbb{F}$ representing M_1 and M_2, respectively, the operation table of a finite abelian group Γ, a group labeling $\psi\colon E \to \Gamma$, a forbidden label set $F \subseteq \Gamma$, and a weight function $w\colon E \to \mathbb{Z}$, solves Weighted F-avoiding Common Basis in pseudo-polynomial time in expectation. The algorithm can be derandomized if $\mathbb{F} = \mathbb{Q}$ and (A_1, A_2) is a Pfaffian pair.*

5 F-avoiding Basis with Fixed $|F|$

As we will see in Theorem 6.3, Zero Basis is hard for groups given by operation tables. This implies the hardness of F-avoiding Basis if the set F of forbidden labels is part of the input. In this section, we study the problem when F has a fixed size. Note that in contrast to the setting of Section 4, we assume that Γ is given as an operation oracle (and it is not necessarily finite).

Related to the notion of k-closeness recently introduced by Liu and Xu [35], we propose the following conjecture.

▶ **Conjecture 5.1.** *Let M be a matroid, $\psi\colon E(M) \to \Gamma$ a labeling, and $F \subseteq \Gamma$ a finite collection of forbidden labels. Then, for any basis B, there exists an F-avoiding basis B^* with $|B \setminus B^*| \leq |F|$, provided that at least one F-avoiding basis exists.*

Note that Lemma 3.2 (applied with a constant weight function) implies that Conjecture 5.1 holds for $|F| = 1$. A tightness example for Conjecture 5.1 can be found in the full version. We can relax Conjecture 5.1 as follows.

▶ **Conjecture 5.2.** *There exists a function $f\colon \mathbb{N} \to \mathbb{N}$ with the following property: If M is a matroid, $\psi\colon E(M) \to \Gamma$ is a group labeling, and $F \subseteq \Gamma$ is a finite collection of forbidden labels, then, for any basis B, there exists an F-avoiding basis B^* with $|B \setminus B^*| \leq f(|F|)$, provided that at least one F-avoiding basis exists.*

Conjectures 5.1 and 5.2 have algorithmic implications due to the following simple observation.

▶ **Lemma 5.3.** *Let α be a fixed positive integer. Further, let M be a matroid, $\psi\colon E(M) \to \Gamma$ a group labeling, and $F \subseteq \Gamma$ a finite collection of forbidden labels, such that, for any basis B, there exists an F-avoiding basis B^* with $|B \setminus B^*| \leq \alpha$, provided that at least one F-avoiding basis exists. Then, an F-avoiding basis of M can be found in polynomial time, if one exists.*

Proof. We first compute an arbitrary basis B of M. Then, for every $X \subseteq B$ and every $Y \subseteq E(M) \setminus B$ with $|X| = |Y| \leq \alpha$, we test whether $(B \setminus X) \cup Y$ is an F-avoiding basis of M. As there are at most $1 + n^\alpha$ choices for each of X and Y, the desired running time follows. If we find an F-avoiding basis during this procedure, we return it. Otherwise, no F-avoiding basis exists by assumption. ◀

The following is an immediate consequence of Lemma 5.3.

▶ **Corollary 5.4.** *If Conjecture 5.2 holds, then F-avoiding Basis is solvable in polynomial time if $|F|$ is fixed.*

Liu and Xu [35] defined a finite group Γ to be *k-close* for an integer $k \geq 1$, if for any matroid M, group labeling $\psi\colon E(M) \to \Gamma$, element $g \in \Gamma$ and basis B, there exists a basis B^* with $|B \setminus B^*| \leq k$ and $\psi(B^*) = g$, provided that M has at least one basis with label g. Observe that Conjecture 5.1 would imply $(|\Gamma|-1)$-closeness, and Conjecture 5.2 would imply $f(|\Gamma|-1)$-closeness of each finite group Γ for some function $f\colon \mathbb{N} \to \mathbb{N}$. This would imply an FPT algorithm for Zero Basis when parameterized with $|\Gamma|$ due to the following result, which is a consequence of [35, Theorem 1].

▶ **Theorem 5.5** (see Liu–Xu [35]). *Assume that for each finite group Γ, there exists an integer k such that Γ is k-close. Then,* Zero Basis *is in FPT for finite groups when parameterized by $|\Gamma|$.*

Liu and Xu [35] observed that if all subgroups of Γ satisfy a conjecture by Schrijver and Seymour [47], then Γ is $(|\Gamma|-1)$-close. By the results of DeVos, Goddyn, and Mohar [13], this implies that any cyclic group Γ is $(|\Gamma|-1)$-close whose order is a prime power or the product of two primes. The proof of [35, Theorem 4] does not seem to generalize to our setting. Thus, it is not clear whether the conjecture of Schrijver and Seymour implies Conjecture 5.1. If Γ has prime order, then Liu and Xu [35, Theorem 3] gave a simpler proof of $(|\Gamma|-1)$-closeness. That proof also generalizes to show that Conjecture 5.1 holds for such groups.

Using the results of Lemos [34], we can also prove that Conjecture 5.1 holds for *ordered groups*, which is a group Γ equipped with a total order $\leq$ on Γ such that $a \leq b$ implies $a + c \leq b + c$ for all $a, b, c \in \Gamma$. The result is restated in the following theorem, whose proof can be found in the full version.

▶ **Theorem 5.6.** *Let M be a matroid, $\psi\colon E(M) \to \Gamma$ a labeling to an ordered group Γ, $F \subseteq \Gamma$ a finite collection of forbidden labels, B a basis of M, and suppose that M has an F-avoiding basis. Then, there exists an F-avoiding basis B^* of M with $|B^* \setminus B| \leq |F|$.*

5.1 Strongly Base Orderable Matroids and Relaxations

In this section, we introduce a relaxed notion of strong base-orderability, called (α, k)-weak base orderability, where α and k are positive integers. In Section 5.1.1, we define this notion and show its relation to strong base-orderability and group-restricted bases. In Section 5.1.2 and Section 5.1.3, we conclude results for matroids representable over fixed finite fields and graphic matroids, respectively.

5.1.1 (α, k)-Weakly Base Orderable Matroids

A matroid is called *strongly base orderable* if for any two bases B_1, B_2, there exists a bijection $\varphi\colon B_1 \setminus B_2 \to B_2 \setminus B_1$ such that $(B_1 \setminus Z) \cup \varphi(Z)$ is a basis for each $Z \subseteq B_1 \setminus B_2$. For some positive integer k, we say that the ordered basis pair (B_1, B_2) has the *k-exchange property* if there exist pairwise disjoint nonempty subsets $X_1, \ldots, X_k \subseteq B_1 \setminus B_2$ and $Y_1, \ldots, Y_k \subseteq B_2 \setminus B_1$ such that $\left(B_1 \setminus \bigcup_{i \in Z} X_i\right) \cup \bigcup_{i \in Z} Y_i$ is a basis for each $Z \subseteq [k]$. For positive integers α and k, we define a matroid M to be *weakly (α, k)-base orderable* if the ordered pair (B_1, B_2) has the k-exchange property for any two bases B_1, B_2 of M with $|B_1 \setminus B_2| \geq \alpha$. We note that (α, k)-weak base orderability is a relaxation of *k-base orderability* defined by Bonin and Savitsky [7], and our definition of the k-exchange property differs from their definition of k-exchange-ordering. Observe that strongly base orderable matroids are precisely the matroids that are (k, k)-weakly base orderable for each $k \geq 1$.

For a matroid M and two disjoint bases B_1, B_2 of M with $B_1 \cup B_2 = E(M)$, we say that (B_1, B_2) is a *basis partition* of M. For a basis B of a matroid M, we say that a minor M' of M is a *B-minor* if it is obtained by contracting some elements of B and deleting some elements of $E(M) \setminus B$. We use the following simple observation later, whose proof can be found in the full version.

▶ **Lemma 5.7.** *Let B_1 and B_2 be two bases of a matroid M. Further, let M' be a B_1-minor of M such that (B_1', B_2') is a basis partition of M' and has the k-exchange property for some $k \in \mathbb{N}$, where $B_i' \coloneqq B_i \cap E(M')$ for $i = 1, 2$. Then (B_1, B_2) has the k-exchange property in M.*

The following result is our main motivation to consider weak base orderability. It establishes a connection between weak base orderability and Conjecture 5.2.

▶ **Theorem 5.8.** *Let M be a matroid, $\psi\colon E(M) \to \Gamma$ a group labeling, and $F \subseteq \Gamma$ a finite collection of forbidden labels. If M is $(\alpha, |F|+1)$-weakly base orderable, then for each basis B, there exists an F-avoiding basis B^* with $|B \setminus B^*| \leq \alpha - 1$, provided that at least one F-avoiding basis exists.*

For the proof, we need the following result, which is most likely routine; see the full version for the proof.

▶ **Proposition 5.9.** *Let S be a finite set, $\psi\colon S \to \Gamma$ a group labeling, and $0 \notin F \subseteq \Gamma$ satisfying $|F| \leq |S| - 1$. Then, there exists some nonempty $S' \subseteq S$ with $\psi(S') \notin F$.*

Proof of Theorem 5.8. Let $k \coloneqq |F|$ and let B be a basis and B' an F-avoiding basis minimizing $|B' \setminus B|$. If $|B' \setminus B| \leq \alpha - 1$, there is nothing to prove. We may hence suppose that $|B' \setminus B| \geq \alpha$. Then, as M is $(\alpha, k+1)$-weakly base orderable, there exist pairwise disjoint nonempty subsets $X_1, \dots, X_{k+1} \subseteq B' \setminus B$ and $Y_1, \dots, Y_{k+1} \subseteq B \setminus B'$ such that $\left(B' \setminus \bigcup_{i \in Z} X_i\right) \cup \bigcup_{i \in Z} Y_i$ is a basis for each $Z \subseteq [k+1]$. We define $\psi'\colon [k+1] \to \Gamma$ by $\psi'(i) = \psi(Y_i) - \psi(X_i)$ for all $i \in [k+1]$. Observe that $0 \notin F' \coloneqq \{ f - \psi(B') \mid f \in F \}$, as B' is an F-avoiding basis. It hence follows from Proposition 5.9 that there exists some nonempty $Z \subseteq [k+1]$ with $\psi'(Z) \notin F'$. Let $B'' \coloneqq \left(B' \setminus \bigcup_{i \in Z} X_i\right) \cup \bigcup_{i \in Z} Y_i$. By the definition of $X_1, \dots, X_{k+1}$ and $Y_1, \dots, Y_{k+1}$, we obtain that B'' is a basis of M. Further, we have $\psi(B'') = \psi(B') + \psi'(Z) \notin F$. Finally, we have $|B'' \setminus B| < |B' \setminus B|$ since Z is nonempty. This contradicts the choice of B'. ◀

As strongly base orderable matroids are (k, k)-weakly base orderable for any $k \geq 1$, we also get the following.

▶ **Corollary 5.10.** *Strongly base orderable matroids satisfy Conjecture 5.1.*

A connection of the results obtained in this section with certain orderings of elements of matroids introduced by Baumgart [3] can be found in the full version.

5.1.2 Matroids Representable over Finite Fields

In this section, we prove that the concept of weakly base orderability allows us to deal with a large class of matroids, namely all those which are representable over a fixed finite field. More precisely, we prove the following result.

▶ **Theorem 5.11.** *There is a function $f\colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ such that for every prime power q, every $\mathrm{GF}(q)$-representable matroid is weakly $(f(q,k), k)$-orderable for any positive integer k.*

On a high level, the proof works in the following way. First, relying on results of [15] on the existence of certain submatrices of large matrices over finite fields, we show that every $\mathrm{GF}(q)$-representable matroid has a certain substructure. We then show that this substructure has the desired property. From this, we can conclude the theorem.

In order to find this substructure, we deal with the matrices representing the matroids in consideration. We first need some notation for these matrices. For two matrices A and A', we say that A contains A' as a *permuted submatrix* if A' can be obtained from A by deleting and permuting rows and columns. For a square matrix, we refer by its *size* to its number of rows. Let q be a prime power. We say that a triple (α, β, γ) of elements of $\mathrm{GF}(q)$ is *feasible* if $\alpha \neq \beta$ and at least one of $\beta \neq 0$ and $\gamma \neq 0$ hold. For a triple (α, β, γ) and a positive integer t, the (α, β, γ)*-diagonal matrix* of size t is the $t \times t$ matrix $A = (A_{ij})$ such that for $i, j \in [t]$, we have $A_{ij} = \alpha$ if $i < j$, $A_{ii} = \beta$ if $i = j$, and $A_{ij} = \gamma$ if $i > j$. We now collect some properties of (α, β, γ)-diagonal matrices. We first need the following result showing that (α, β, γ)-diagonal matrices can always be found in sufficiently large matrices over a fixed finite field. The following result can easily be concluded from a slightly weaker result due to Ding, Oporowski, Oxley, and Vertigan [15]. Its detailed proof can be found in the full version.

▶ **Proposition 5.12.** *There is a computable function $f_1 \colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ with the following property: Let q be a prime power, t a positive integer, and A a matrix over $\mathrm{GF}(q)$ having at least $f_1(q, t)$ columns no two of which are identical. Then, A contains a permuted square submatrix A' of size t which is (α, β, γ)-diagonal for a feasible triple (α, β, γ).*

We are now ready to give the following result showing that every sufficiently large matroid that is representable over a fixed finite field has a certain substructure. The approach is to choose a matrix representing the matroid and find a particular submatrix in this matrix using Proposition 5.12. After, we show that a minor represented by this matrix can be obtained by applying certain deletions and contractions. The detailed proof can be found in the full version.

▶ **Lemma 5.13.** *There is a computable function $f_1 \colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ with the following properties: Let q be a prime power, k a positive integer, M a $\mathrm{GF}(q)$-representable matroid of rank at least $f_1(q, k)$ and (B_1, B_2) a basis partition of M. Then, there exists a B_1-minor M' of M that can be represented by a matrix of the form $[I_k \ A]$, where I_k is the identity matrix of size k and A is an (α, β, γ)-diagonal matrix for a feasible triple (α, β, γ), and the columns of I_k correspond to the elements of B_1' and those of A correspond to the elements of B_2', where $B_i' \coloneqq B_i \cap E(M')$ for $i = 1, 2$.*

We will prove Theorem 5.11 by showing that matroids representable by a very specific class of matrices satisfy its conclusion. For this, we need a statement showing that certain matrices are nonsingular, which we derive from an explicit formula for the determinants of (α, β, γ)-triangular matrices due to Efimov [17]. The detailed proof can be found in the full version.

▶ **Proposition 5.14.** *Let q be a prime power, (α, β, γ) a feasible triple, t a multiple of $q(q-1)$, and A the (α, β, γ)-diagonal matrix of size t. Then, A is nonsingular.*

We are now ready to conclude the result for the specific class of matroids.

▶ **Lemma 5.15.** *There is a computable function $f_2 \colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ with the following properties: Let q be a prime power, k a positive integer, and M a matroid that can be represented by $[I \ A]$ over $\mathrm{GF}(q)$, where I is an identity matrix of size $f_2(q, k)$ and A is an (α, β, γ)-diagonal*

matrix of the same size for a feasible triple (α, β, γ)*. Next, let* B_1 *and* B_2 *be the subsets of* $E(M)$ *corresponding to* I *and* A*, respectively. Then,* (B_1, B_2) *is a basis partition of* M *and has the* k*-exchange property.*

Proof. Let f_2 be the function defined by $f_2(q,k) \coloneqq q(q-1)k$ for all positive integers q and k. By Proposition 5.14, we have that A is nonsingular and hence (B_1, B_2) is a basis partition of M. For $i \in [k]$, let X_i be the subset of B_1 and Y_i be the subset of B_2 that corresponds to the columns of indices $q(q-1)(i-1)+1$ to $q(q-1)i$ of I and A, respectively. For $Z \subseteq [k]$, let $B_Z \coloneqq \left(B_1 \setminus \bigcup_{i \in Z} X_i\right) \cup \bigcup_{i \in Z} Y_i$. It suffices to prove that B_Z is a basis of M for every $Z \subseteq [k]$. To this end, consider some fixed $Z \subseteq [k]$. Observe that the matrix obtained from restricting $[I\ A]$ to the columns corresponding to B_Z can be transformed into a matrix of the form $A^* = \begin{bmatrix} I' & A_1 \\ O & A' \end{bmatrix}$ by exchanging rows and columns. Here, I' is the identity matrix of size $q(q-1)(k-|Z|)$, O is a zero matrix, A' is an (α, β, γ)-diagonal matrix of size $q(q-1)|Z|$, and A_1 is an arbitrary matrix. As the size of A' is divisible by $q(q-1)$, we obtain by Proposition 5.14 that A' is nonsingular. It follows that A^* is nonsingular, and hence B_Z is independent. As $|B_Z| = |B_1|$ by construction, we obtain that B_Z is a basis of M. This finishes the proof. ◀

Finally, we combine Lemmas 5.7, 5.13, and 5.15 to conclude Theorem 5.11.

Proof of Theorem 5.11. We prove the statement for the function $f\colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ defined by $f(q,k) \coloneqq f_1(q, f_2(q,k))$ for each $k \in \mathbb{N}$ and prime power q. Let B_1 and B_2 be bases of a $\mathrm{GF}(q)$-representable matroid M with $|B_1 \setminus B_2| \geq f(q,k)$. We need to prove that (B_1, B_2) has the k-exchange property. Let $M' \coloneqq M / (B_1 \cap B_2) \setminus (E(M) \setminus (B_1 \cup B_2))$. Further, for $i = 1, 2$, let $B_i' \coloneqq B_i \cap E(M')$ and observe that (B_1', B_2') is a basis partition of M'. It follows from Lemma 5.13 that there exists a B_1'-minor M'' of M' that can be represented by a matrix of the form $[I\ A]$, where I is the identity matrix of size $f_2(q,k)$, A is an (α, β, γ)-diagonal matrix of size $f_2(q,k)$ for a feasible triple (α, β, γ) and the columns of I and A correspond to the elements of B_1'' and B_2'', respectively, where $B_i'' \coloneqq B_i' \cap E(M'')$ for $i = 1, 2$. We now obtain from Lemma 5.15 that (B_1'', B_2'') is a basis partition of M'' and has the k-exchange property in M''. As M'' is a B_1-minor of M, we now obtain from Lemma 5.7 that (B_1, B_2) has the k-exchange property in M. ◀

Combining Theorems 5.8 and 5.11, Lemma 5.3, and Theorem 5.5, we get the following.

▶ **Corollary 5.16.** *Let* q *be a prime power,* M *a* $\mathrm{GF}(q)$*-representable matroid,* $\psi\colon E \to \Gamma$ *a group labeling and* $F \subseteq \Gamma$ *a finite set of forbidden labels. When* $|F|$ *is fixed,* F-avoiding Basis *is solvable in polynomial time. Moreover, if* $|\Gamma|$ *is finite, then* Zero Basis *is in FPT when parameterized by* $|\Gamma|$*.*

We note that Corollary 5.16 is not implied by Theorem 4.2. The former applies to arbitrary groups, while the latter is limited to finite groups given by an operation table. Furthermore, Corollary 5.16 gives a deterministic polynomial-time algorithm, in contrast to the randomized algorithm in Theorem 4.2.

5.1.3 Graphic matroids

As a strengthening of the k-exchange property, we say that the basis pair (B_1, B_2) of a matroid has the *elementary* k*-exchange property* if there exist k-element subsets $X \subseteq B_1 \setminus B_2$ and $Y \subseteq B_2 \setminus B_1$ and a bijection $\varphi\colon X \to Y$ such that $(B_1 \setminus Z) \cup \varphi(Z)$ is a basis for each $Z \subseteq X$. Note that this is equivalent to requiring $|X_i| = |Y_i| = 1$ for each $i \in [k]$ in the

definition of the k-exchange property. We define a matroid M to be *elementarily* (α, k)*-weakly base orderable* if (B_1, B_2) has the elementary k-exchange property for any pair of basis B_1 and B_2 with $|B_1 \setminus B_2| \geq \alpha$.

It turns out that all regular matroids are elementarily $(f(k), k)$-weakly base orderable for some large function $f\colon \mathbb{N} \to \mathbb{N}$, while the same is not true for binary matroids. The proofs of these results can be found in the full version. As graphic matroids are regular, they are elementarily $(f(k), k)$-weakly base orderable for some large function $f\colon \mathbb{N} \to \mathbb{N}$. We give a proof in the full version, independent from the proof of Theorem 5.11, which shows that for graphic matroids, there exists such a function f satisfying $f(k) = O(k^3)$.

▶ **Theorem 5.17.** *Graphic matroids are elementarily* $(3k^3, k)$*-weakly base orderable for any* $k \geq 1$.

5.2 Two forbidden labels

The objective of this section is to prove the following restatement of the case $|F| = 2$ of Conjecture 5.1. Its proof can be found in the full version. Vaguely speaking, we first reduce the problem to matroids on six elements and then combine some earlier results with a particular treatment for the cycle matroid of K_4.

▶ **Theorem 5.18.** *Let M be a matroid, $\psi\colon E(M) \to \Gamma$ a group labeling, and let F be a 2-element subset of Γ. For any basis B, there exists an F-avoiding basis B^* such that $|B \setminus B^*| \leq 2$, provided that there exists at least one F-avoiding basis.*

6 Hardness and Negative Results

In this section, we give the algorithmic hardness results and counterexamples contained in this work. Sections 6.1 and 6.2 contain algorithmic intractability results and Section 6.3 contains a counterexample to a conjecture of Liu and Xu [35]. All proofs can be found in the full version.

6.1 Hardness of Non-zero Common Basis with $\mathbb{Z}_2 \leq \Gamma$

We here show that Non-Zero Common Basis is intractable for any group Γ such that $\mathbb{Z}_2 \leq \Gamma$. This implies that the condition on Γ in Theorem 3.7 is crucial indeed.

▶ **Theorem 6.1.** Non-Zero Common Basis *requires an exponential number of independence queries for any fixed group Γ such that $\mathbb{Z}_2 \leq \Gamma$.*

Our proof of Theorem 6.1 provides a new and simpler proof of the result of Bérczi and Schwarcz [5] showing that the problem of partitioning the ground set into common bases is hard. In addition to this new proof, we also describe the relation of a relaxation of that problem to a problem on non-zero common bases via dual lattices in the full version.

6.2 Hardness of Zero Basis

In this section, we show two hardness results for Zero Basis. The first one shows that the problem is hard even for uniform matroids by using the hardness of the well-known Subset Sum problem.

▶ **Theorem 6.2.** Zero Basis *is* NP-hard *for a uniform matroid and $\Gamma = \mathbb{Z}$.*

It can be derived from [16, Theorem 1.3] that Zero Basis is also hard for finite groups given as operation tables.

▶ **Theorem 6.3** (see Doron-Arad–Kulik–Shachnai [16, Theorem 1.3]). Zero Basis *requires an exponential number of independence queries for a finite group* Γ *given as an operation table.*

Recall that (Weighted) Zero Basis is solvable if Γ is a fixed, finite group [35]. In contrast, Theorem 6.1 implies that Non-Zero Common Basis is hard for any fixed group Γ such that $\mathbb{Z}_2 \leq \Gamma$. By modifying that proof, the hardness of Zero Common Basis follows even when the assumption $\mathbb{Z}_2 \leq \Gamma$ is dropped.

▶ **Theorem 6.4.** Zero Common Basis *requires an exponential number of independence queries for any nontrivial fixed group* Γ.

6.3 Counterexample to a Conjecture of Liu and Xu

Liu and Xu [35] proposed a conjecture which is even stronger than the implications from Conjectures 5.1 and 5.2. In order to state their conjecture, we need the following definition. For a finite abelian group Γ its *Davenport constant* $D(\Gamma)$ is defined as the minimum value such that every sequence of elements from Γ of length $D(\Gamma)$ contains a nonempty subsequence with sum 0. Liu and Xu proposed the following conjecture.

▶ **Conjecture 6.5** (Liu–Xu [35]). *Let* Γ *be a finite abelian group. Then,* Γ *is* $(D(\Gamma)-1)$*-close.*

We provide a counterexample for Conjecture 6.5. More precisely, we prove the following result.

▶ **Theorem 6.6.** *Let* $\Gamma = \mathbb{Z}_2^d$ *for some* $d \geq 4$. *Then,* Γ *is not* $(D(\Gamma)-1)$*-close.*

7 Conclusion

In this work, we have treated several problem settings on finding bases of group-labeled matroids whose labels satisfy certain conditions. Many questions remain open. In Section 3.2, we deal with Weighted Non-Zero Common Basis for groups Γ with $\mathbb{Z}_2 \not\leq \Gamma$ and give an approximation algorithm and exact algorithms for some special cases. However, the general complexity of Weighted Non-Zero Basis for $\mathbb{Z}_2 \not\leq \Gamma$ remains open. In Section 4, randomized algebraic algorithms turn out to be a powerful tool for finding bases and common bases of certain labels. It would be interesting to see whether more of the problems that can be solved by these randomized algorithms can also be solved deterministically. For example, one could consider Non-Zero Common Basis for arbitrary groups when one of the matroids is graphic, and the other one is a partition matroid. Finally, while Conjectures 5.1 and 5.2 remain wide open, the following stronger conjecture can be formulated analogously to the notion of strongly k-closeness introduced by Liu and Xu [35]. Note that the conjecture holds for $|F| = 1$ by Lemma 3.2, and it can also be shown that it holds for strongly base orderable matroids.

▶ **Conjecture 7.1.** *Let* M *be a matroid on a ground set* E, $\psi\colon E \to \Gamma$ *a group labeling,* $F \subseteq \Gamma$ *a finite subset, and* $w\colon E \to \mathbb{R}$ *a weight function. Suppose that* M *has an* F*-avoiding basis. Then, for any minimum weight basis* B*, there exists a minimum weight* F*-avoiding basis* B^* *such that* $|B \setminus B^*| \leq |F|$.

Abstract

We show the first near-linear time randomized algorithms for listing all minimum vertex cuts of polylogarithmic size that separate the graph into at least *three* connected components (also known as *shredders*) and for finding the *most shattering* one, i.e., the one maximizing the number of connected components. Our algorithms break the quadratic time bound by Cheriyan and Thurimella (STOC'96) for both problems that has been unimproved for more than two decades. Our work also removes an important bottleneck to near-linear time algorithms for the vertex connectivity augmentation problem (Jordan '95) and finding an even-length directed cycle in a graph, a problem shown to be equivalent to many other fundamental problems (Vazirani and Yannakakis '90, Robertson et al. '99). Note that it is necessary to list only minimum vertex cuts that separate the graph into at least three components because there can be an exponential number of minimum vertex cuts in general.

To obtain a near-linear time algorithm, we have extended techniques in local flow algorithms developed by Forster et al. (SODA'20) to list shredders on a local scale. We also exploit fast queries to a pairwise vertex connectivity oracle subject to vertex failures (Long and Saranurak FOCS'22, Kosinas ESA'23). This is the first application of using connectivity oracles subject to vertex failures to speed up a static graph algorithm.

1 Introduction

Given an undirected graph G with n vertices and m edges, a *minimum vertex cut* is a smallest set of vertices whose removal disconnects G. The *vertex connectivity* of G is the size of any minimum vertex. The problem of efficiently computing vertex connectivity and finding a corresponding minimum vertex cut has been extensively studied for more than half a century [16, 25, 9, 8, 12, 7, 21, 1, 19, 5, 22, 4, 13, 14, 11, 2]. Let k denote the vertex connectivity of G. Recently, a $\tilde{\mathcal{O}}(m + nk^3)$-time algorithm was shown in [10], which is near-linear when $k = \mathcal{O}(\text{polylog}(n))$. Then, an almost-linear $\mathcal{O}(m^{1+o(1)})$-time algorithm for the general case was finally discovered [18, 3]. In this paper, we show new algorithms for two closely related problems:

1. Find a *most-shattering* minimum vertex cut, i.e., a minimum vertex cut S such that the number of (connected) components of $G \setminus S$ is maximized over all minimum vertex cuts.
2. List all minimum vertex cuts S such that $G \setminus S$ has at least three components.

In the latter problem, the restriction to at least three components is natural for polynomial-time algorithms. This is because there are at most n many minimum vertex cuts whose removal results in at least three components [15], but the total number of minimum vertex cuts can be exponential or, more specifically, at least $2^k(n/k)^2$ [24][1]. We say that a vertex set S is a *separator* if $G \setminus S$ is not connected and a *shredder* if $G \setminus S$ has at least three components. An s-separator (s-shredder) is a separator (shredder) of size s. In other words, the second problem is to list all k-shredders[2].

The state-of-the-art algorithm for both Problems 1 and 2 was discovered by Cheriyan and Thurimella [6] and runs in $\mathcal{O}(k^2n^2 + k^3n\sqrt{n})$ time. This bound has remained unimproved for over two decades. Their approach inherently requires quadratic time because their algorithm makes $\Omega(n + k^2)$ max flow calls. Naturally, one may ask whether a subquadratic algorithm exists.

Our Contribution

We answer the above question in the affirmative by showing a randomized algorithm for listing all k-shredders and computing a most shattering min-cut in near-linear time for all $k = \mathcal{O}(\text{polylog}(n))$. Our main results are stated below.

▶ **Theorem 1.1.** *Let $G = (V, E)$ be an n-vertex m-edge undirected graph with vertex connectivity k. There exists an algorithm that takes G as input and correctly lists all k-shredders of G with probability $1 - n^{-97}$ in $\mathcal{O}(m + k^5 n \log^4 n)$ time.*

▶ **Theorem 1.2.** *Let $G = (V, E)$ be an n-vertex m-edge undirected graph with vertex connectivity k. There exists a randomized algorithm that takes G as input and returns a most shattering minimum-cut (if one exists) with probability $1 - n^{-97}$. The algorithm runs in $\mathcal{O}(m + k^5 n \log^4 n)$ time.*

▶ Remark 1.3. The $k^5 n \log^4 n$ term in both theorems can be improved to $k^3 n^{1+o(1)}$ using a pairwise vertex connectivity oracle developed by Long and Saranurak in [20], which is faster for large values of k.

Given recent developments in fast algorithms for computing vertex connectivity, one might expect that some of these modern techniques (e.g. local flow [23, 10], sketching [18], expander decomposition [26]) will be useful for listing shredders and finding most shattering min-cuts. It turns out that they are indeed useful, but *not enough*.

We have extended the techniques developed for local flow algorithms [10] to list k-shredders and compute the number of components that they separate. Specifically, our local algorithm lists k-shredders that separate the graph in an unbalanced way in time *proportional to the smaller side* of the cut. To this end, we generalize the structural results related to shredders from [6] to the local setting. To carry out this approach, we bring a new tool into the area – our algorithm queries a pairwise connectivity oracle subject to vertex failures [20, 17]. Surprisingly, this is the first application of using connectivity oracles subject to vertex failures to speed up a static graph algorithm.

---

[1] Both problems are specific to vertex cuts; recall that every minimum *edge* cut always separates a graph into two components.

[2] E.g. in a tree, vertices with degree at least three are 1-shredders. In the complete bipartite graph $K_{k,k}$ with $k \geq 3$, both the left and right halves of the bipartition are k-shredders.

2 Technical Overview

Let $G = (V, E)$ be an n-vertex m-edge undirected graph with vertex connectivity k. Cheriyan and Thurimella developed a deterministic algorithm called `All-`k`-shredders`$(\cdot)$ that takes G as input and lists all k-shredders of G in $\mathcal{O}(knm + k^2\sqrt{n}m)$ time. They improved this bound by using the sparsification routine developed in [22] as a preprocessing step. Specifically, there exists an algorithm that takes G as input and produces an edge subgraph G' on $\mathcal{O}(kn)$ edges such that all k-shredders of G are k-shredders of G' and vice versa. The algorithm runs in $\mathcal{O}(m)$ time. Using this preprocessing step, they obtained the bound for listing all k-shredders in $\mathcal{O}(m) + \mathcal{O}(k(kn)n + k^2\sqrt{n}(kn)) = \mathcal{O}(k^2n^2 + k^3n\sqrt{n})$ time.

In this paper, we resolve a bottleneck of `All-`k`-shredders`$(\cdot)$, improving the time complexity of listing all k-shredders from $\mathcal{O}(knm + k^2\sqrt{n}m)$ to $\mathcal{O}(k^4m\log^4 n)$. Using the same sparsification routine, our algorithm runs in $\mathcal{O}(m + k^5n\log^4 n)$ time. The proofs of the theorems and lemmas presented here have been omitted to the full version of the paper.

2.1 The Bottleneck

A key subroutine of `All-`k`-shredders`$(\cdot)$ is a subroutine called `Shredders`$(\cdot,\cdot)$ that takes a pair of vertices (x, y) as input and lists all k-shredders that separate x and y. This subroutine takes $\mathcal{O}(m)$ time plus the time to compute a flow of size k, which is at most $\mathcal{O}(mk)$ time. The idea behind `All-`k`-shredders`$(\cdot)$ is to call `Shredders`$(\cdot,\cdot)$ multiple times to list all k-shredders. `All-`k`-shredders`$(\cdot)$ works as follows. Let Y be an arbitrary set of $k + 1$ vertices. Any k-shredder S will either separate a pair of vertices in Y, or separate a component containing $Y \setminus S$ from the rest of the graph.

For the first case, they call `Shredders`(u, v) for all pairs of vertices $(u, v) \in Y \times Y$. This takes $\mathcal{O}(k^2)$ calls to `Shredders`$(\cdot,\cdot)$, which in total runs in $\mathcal{O}(k^3m)$ time. For the second case, we can add a dummy vertex z and connect z to all vertices in Y. Notice that any k-shredder S separating a component containing $Y \setminus S$ from the rest of the graph must separate z and a vertex $v \in V \setminus (Y \cup S)$. We can find these k-shredders by calling `Shredders`(z, v) for all $v \in V \setminus Y$. The bottleneck of Cheriyan's algorithm is listing k-shredders that fall into the second case. They call `Shredders`$(\cdot,\cdot)$ $\Omega(n)$ times as $|V \setminus Y| = n - \mathcal{O}(k) = \Theta(n)$ for small values of k. This step is precisely where the quadratic $\mathcal{O}(knm)$ factor comes from. To bypass this bottleneck, we categorize the problem into different cases and employ randomization.

2.2 Quantifying a Notion of Balance

Let S be a k-shredder of G. A useful observation is that if we obtain vertices x and y in different components of $G \setminus S$, then `Shredders`(x, y) will list S. To build on this observation, one can reason about the relative *sizes* of the components of $G \setminus S$ and employ a random sampling approach. Let C denote the "largest" component of $G \setminus S$. If C does not greatly outsize the remaining components, we can obtain two vertices in different components of $G \setminus S$ without too much difficulty. To capture the idea of relative *size* between components of $G \setminus S$, we define a quantity called *volume*. This definition is used commonly throughout the literature, but we have slightly altered it here.

▶ **Definition 2.1** (Volume). *For a vertex set Q, we refer to the* volume *of Q, denoted by* $\mathrm{vol}(Q)$*, to denote the quantity*

$$\mathrm{vol}(Q) = |\{(u, v) \in E \mid u \in Q\}|.$$

If $\mathcal{Q}$ is a collection of disjoint vertex sets, then we define the volume of $\mathcal{Q}$ as the quantity

$$\mathrm{vol}(\mathcal{Q}) = \mathrm{vol}\left(\bigcup_{Q\in\mathcal{Q}} Q\right).$$

For convenience, we will say that a k-shredder S admits *partition* $(C, \mathcal{R})$ to signify that C is the largest component of $G \setminus S$ by volume and $\mathcal{R}$ is the set of remaining components. We will also say $x \in \mathcal{R}$ to denote a vertex in a component of $\mathcal{R}$. We can categorize a k-shredder S by comparing the volume ratio between the largest component of $G \setminus S$ and the union of remaining components (the ratio between $\mathrm{vol}(C)$ and $\mathrm{vol}(\mathcal{R})$).

▶ **Definition 2.2** (Balanced/Unbalanced k-Shredders). *Let S be a k-shredder of G with partition $(C, \mathcal{R})$. We say S is* balanced *if $\mathrm{vol}(\mathcal{R}) \geq m/k$. Conversely, we say S is* unbalanced *if $\mathrm{vol}(\mathcal{R}) < m/k$.*

Suppose that S is a k-shredder with partition $(C, \mathcal{R})$. Building on our discussion above, if S is balanced, then C does not greatly outsize the rest of the graph (by a factor of k at most). Conversely, if S is unbalanced, then C greatly outsizes the rest of the graph.

2.3 Listing Balanced k-Shredders via Edge Sampling

Listing all balanced k-shredders turns out to be straightforward via random edge sampling. Let S be a k-shredder that admits partition $(C, \mathcal{R})$. Suppose that S is balanced. The idea is to sample an edges (x, x') and (y, y') such that x and y are in different components of $G \setminus S$. Then, `Shredders`(x, y) will list S. Intuitively, this approach works because we know that each component of $G \setminus S$ cannot be too large, as S is a balanced k-shredder. Hence, if we sample two edges (x, x') and (y, y') at random, the probability that x and y live in different components of $G \setminus S$ is some constant. We can then boost the success probability by repeating the procedure for a polylogarithmic number of times. The formal statement is given below.

▶ **Lemma 2.3.** *Let $G = (V, E)$ be an n-vertex m-edge undirected graph with vertex connectivity k. There exists a randomized algorithm that takes G as input and returns a list $\mathcal{L}$ that satisfies the following. If S is a balanced k-shredder of G, then $S \in \mathcal{L}$ with probability $1 - n^{-100}$. Additionally, every set in $\mathcal{L}$ is a k-shredder of G. The algorithm runs in $\mathcal{O}(k^2 m \log n)$ time.*

Because handling balanced k-shredders is simple, we omit the algorithm for listing balanced k-shredders and its analysis. We will primarily focus on our methods of listing unbalanced k-shredders.

2.4 Listing Unbalanced k-Shredders via Local Flow

Unbalanced k-shredders are more difficult to list than balanced k-shredders. For balanced k-shredders S with partition $(C, \mathcal{R})$, we can obtain two vertices in different components of $G \setminus S$ without much difficulty. This is no longer the case for unbalanced k-shredders, mainly because $\mathrm{vol}(\mathcal{R})$ may be arbitrarily small. Hence, most sampled edges will be incident to C. To handle unbalanced k-shredders, we introduce a new structural definition.

▶ **Definition 2.4** (Capture). *Let S be an unbalanced k-shredder of a graph $G = (V, E)$ with partition $(C, \mathcal{R})$. Consider an arbitrary tuple (x, ν, Π), where x is a vertex in V, ν is a positive integer, and Π is a set of paths. We say that the tuple (x, ν, Π)* captures *S if the following holds.*

1. *x is in a component of $\mathcal{R}$.*
2. *$\frac{1}{2}\nu < \mathrm{vol}(\mathcal{R}) \leq \nu$.*
3. *Π is a set of k openly-disjoint simple paths, each starting from x and ending at a vertex in C, such that the sum of lengths over all paths is at most $k^2\nu$.*

At a high level, we will spend some time constructing random tuples (x, ν, Π) in the hopes that one of the tuples captures S. The main result is stated below.

▶ **Lemma 2.5.** *Let G be a graph with vertex connectivity k. Let (x, ν, Π) be a tuple where x is a vertex, ν is a positive integer, and Π is a set of paths. There exists a deterministic algorithm that takes (x, ν, Π) as input and outputs a list $\mathcal{L}$ of k-shredders and one set U such that the following holds. If S is a k-shredder that is captured by (x, ν, Π), then $S \in \mathcal{L}$ or $S = U$. The algorithm runs in $\mathcal{O}(k^2\nu \log \nu)$ time.*

What is most important about this result is that we have constructed an algorithm that can identify k-shredders on a *local* scale. This means it spends time proportional to an input volume parameter ν instead of a global quantity like n or m. The idea behind Lemma 2.5 is to modify `Shredders`$(\cdot, \cdot)$ using recent advancements in local flow algorithms.

2.5 Verification via Pairwise Connectivity Oracles

In our algorithm, we will obtain a list of k-shredders and a list of unverified sets. The union of these two sets will include all k-shredders of G with high probability. However, within the list of unverified sets, there may be some false k-shredders. To filter out the false k-shredders, we utilize a pairwise connectivity oracle subject to vertex failures developed by Kosinas in [17]. To determine whether an unverified set S is a k-shredder, we will make some pairwise connectivity queries between vertex pairs (u, v) to determine whether u, v are disconnected in $G \setminus S$. These local queries, along with some more structural observations, will help us determine whether $G \setminus S$ contains at least three components.

3 Preliminaries

This paper concerns finite, undirected, and unweighted graphs with vertex connectivity k. We use standard graph-theoretic definitions. Let $G = (V, E)$ be a graph with vertex connectivity k. For a vertex subset $S \subseteq V$, we use $G \setminus S$ to denote the subgraph of G induced by removing all vertices in S. A *connected component* (component for short) of a graph refers to any maximally-connected subgraph, or the vertex set of such a subgraph. Suppose that S is a k-shredder of G. The *largest component* of $G \setminus S$ is the component with the greatest *volume*, where volume is defined in Definition 2.1. We break ties arbitrarily. For convenience, we will say that a k-shredder S admits partition $(C, \mathcal{R})$ to signify that C is the largest component of $G \setminus S$ and $\mathcal{R}$ is the set of remaining components. We will also write $x \in \mathcal{R}$ to indicate a vertex in a component of $\mathcal{R}$.

For a vertex subset $Q \subseteq V$, we define the set of neighbors of Q as the set $N(Q) = \{v \in V \setminus Q \mid (u, v) \in E, u \in Q\}$. For vertex subsets $Q_1, Q_2 \subseteq V$, we define $E(Q_1, Q_2) = \{(u, v) \in E \mid u \in Q_1, v \in Q_2\}$.

Let π be a simple path in G. We refer to the *length* of π as the number of edges in π. Suppose π starts at a vertex $x \in V$. We say the *far-most endpoint* of π to denote the other endpoint of π. Although all paths we refer to are undirected, our usage of the far-most endpoint will be unambiguous. Let x and y be two arbitrary vertices in π. We denote $\pi[x \rightsquigarrow y]$ as the subpath of π from x to y. We denote $\pi(x \rightsquigarrow y)$ as the subpath $\pi[x \rightsquigarrow y]$ *excluding* the

vertices x and y. We say two paths π, π' are *openly-disjoint* if they share no vertices except their endpoints. Let Π be a set of paths. Then, Π is openly disjoint if all pairs of paths in Π are openly disjoint. We say $v \in \Pi$ to denote a vertex among one of the paths in Π and $(u, v) \in \Pi$ to denote an edge used by one of the paths in Π.

4 Cheriyan and Thurimella's Algorithm

We will use $\texttt{Shredders}(\cdot, \cdot)$ as a subroutine and extend it to a *localized setting*. To do this, we need to review the terminology and ideas presented in [6].

▶ **Theorem 4.1** ([6, Algorithm 2]). *Let G be an n-vertex m-edge undirected graph with vertex connectivity k. Let x and y be two distinct vertices. There exists a deterministic algorithm $\texttt{Shredders}(\cdot, \cdot)$ that takes (x, y) as input and returns all k-shredders of G separating x and y in $\mathcal{O}(km)$ time.*

At a high level, $\texttt{Shredders}(\cdot, \cdot)$ works as follows. Let x and y be two vertices in a k-vertex-connected graph G. Firstly, we use a flow algorithm to obtain a set Π of k openly-disjoint simple paths from x to y. Observe that any k-shredder S of G separating x and y must contain exactly one vertex from each path of Π. More crucially, at least one component of $G \setminus S$ must also be a component of $G \setminus \Pi$. That is, for some component Q of $G \setminus \Pi$, we have $N(Q) = S$. This is the main property that $\texttt{Shredders}(\cdot, \cdot)$ exploits. It lists potential k-shredders by finding components Q of $G \setminus \Pi$ such that $|N(Q)| = k$ and $N(Q)$ consists of exactly one vertex from each path in Π (see Figure 1).

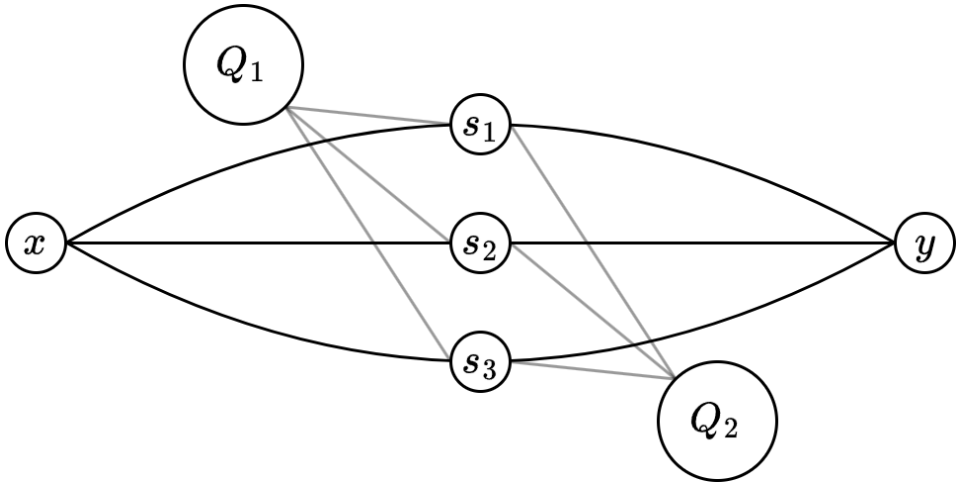

Figure 1 Let Π be the set of three openly-disjoint simple paths from x to y. A call to $\texttt{Shredders}(x, y)$ will identify $N(Q_1) = N(Q_2)$ as potential 3-shredders.

We can state these facts formally with the following definitions.

▶ **Definition 4.2** (Bridge). *A* bridge Γ *of* Π *is a component of $G \setminus \Pi$ or an edge $(u, v) \in E$ such that $(u, v) \notin \Pi$, but $u \in \Pi$ and $v \in \Pi$.*

If Γ is an edge, we define $\text{vol}(\Gamma) = 1$. Otherwise, $\text{vol}(\Gamma)$ is defined according to Definition 2.1.

▶ **Definition 4.3** (Attachments). *Let Γ be a bridge of Π. If Γ is a component of $G \setminus \Pi$, then the set of* attachments *of Γ is the vertex set $N(\Gamma)$. Otherwise, if Γ is an edge $(u, v) \in E$, the set of* attachments *of Γ is the vertex set $\{u, v\}$.*

For convenience, we refer to a single vertex among the attachments of Γ as an attachment of Γ. For a path $\pi \in \Pi$, we denote $\pi(\Gamma)$ as the set of attachments of Γ that are in π. If Q is an arbitrary vertex set, then we use $\pi(Q)$ to denote the set $Q \cap \pi$. If $\pi(Q)$ is a singleton set, then we may use $\pi(Q)$ to represent the unique vertex in $Q \cap \pi$. In all contexts, it will be clear what object the notation is referring to.

▶ **Definition 4.4** (k-Tuple). *A set S is called a k-tuple with respect to Π if $|S| = k$ and for all $\pi \in \Pi$, we have $|S \cap \pi| = 1$.*

We adopt the following notation as in $\texttt{Shredders}(\cdot,\cdot)$. If a component Γ of $G \setminus \Pi$ is such that $N(\Gamma)$ forms a k-tuple with respect to Π, then $N(\Gamma)$ is called a *candidate k-shredder* or *candidate* for short. In general, not all candidates are true k-shredders. To handle this, $\texttt{Shredders}(\cdot,\cdot)$ performs a *pruning* phase by identifying fundamental characteristics of false candidates. To identify false candidates, we formalize some of the key definitions in [6].

▶ **Definition 4.5** (δ_π). *Let π be a path starting from a vertex x. For a vertex $v \in \pi$, we define $\delta_\pi(v)$ as the distance between x and v along path π.*

▶ **Definition 4.6** (Straddle). *Let Γ_1, Γ_2 be two bridges of Π. We say Γ_1* straddles *Γ_2 (or Γ_2 straddles Γ_1) if there exist paths $\pi, \pi' \in \Pi$ such that there exist vertex pairs $(v_1, v_2) \in \pi(\Gamma_1) \times \pi(\Gamma_2)$ satisfying $\delta_\pi(v_1) < \delta_\pi(v_2)$ and $(u_1, u_2) \in \pi'(\Gamma_1) \times \pi'(\Gamma_2)$ satisfying $\delta_{\pi'}(u_1) > \delta_{\pi'}(u_2)$.*

See figure Figure 2 for an example.

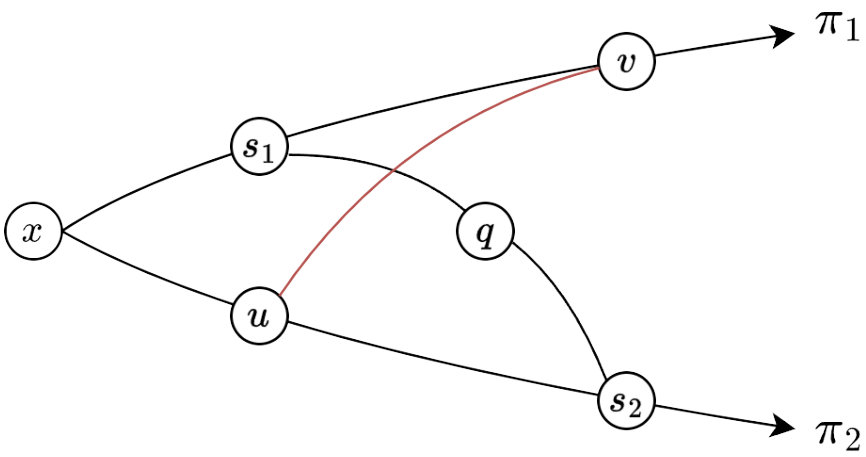

Figure 2 Here we have $\Pi = \{\pi_1, \pi_2\}$. The candidate k-shredder $\{s_1, s_2\}$ is straddled by the edge (u, v) because $\delta_{\pi_2}(u) < \delta_{\pi_2}(s_2)$ and $\delta_{\pi_1}(v) > \delta_{\pi_1}(s_1)$.

It is useful to note that Definition 4.6 is still well-defined even for candidates (i.e. we can use the $\preceq, \succeq$ operators to compare bridges to candidates and candidates to candidates).

Candidate Pruning

The crucial observation is that a candidate S reported by $\texttt{Shredders}(x, y)$ is a k-shredder of G if and only if no bridge of Π straddles S. Hence, to prune false candidates, $\texttt{Shredders}(x, y)$ finds all bridges of Π that are straddled using standard sorting and interval merging. These notions are formalized in the following two lemmas.

▶ **Lemma 4.7.** *Let x and y be two distinct vertices and let Π denote a set of k openly disjoint simple paths from x to y. Let S be a candidate with respect to Π. Then, S is a k-shredder separating x and y if and only if no bridge of Π straddles S.*

▶ **Lemma 4.8.** *Let x be a vertex in G and let Π denote a set of k openly disjoint simple paths starting from x whose sum of lengths over all paths is at most ℓ. Let $\mathcal{C}, \mathcal{B}$ be a set of candidates and a set of bridges of Π, respectively. There exists a deterministic algorithm that, given $(\mathcal{C}, \mathcal{B}, \Pi)$ as input, lists all candidates $S \in \mathcal{C}$ such that S is not straddled by another candidate in $\mathcal{C}$ nor by any bridge in $\mathcal{B}$. The algorithm runs in $\mathcal{O}(k|\mathcal{C}| \log |\mathcal{C}| + \ell + \mathrm{vol}(\mathcal{B}))$ time.*

Challenges

Fix an unbalanced k-shredder S with partition $(C, \mathcal{R})$. Unfortunately, the same probabilistic approach we used for listing balanced k-shredders does not work here. Specifically, if we sample two edges $(x, x'), (y, y')$, the probability that x and y are in different components of $G \setminus S$ can be arbitrarily small. What this dilemma implies is that we must spend at least a linear amount of time just to collect samples. More critically, we must spend a sublinear amount of time processing an *individual* sample to make any meaningful improvement. This time constraint rules out the possibility of calling $\texttt{Shredders}(\cdot, \cdot)$ per sample. Instead, we must develop a *localized* version of $\texttt{Shredders}(\cdot, \cdot)$ that spends time relative to a parameter of our choice, instead of a global value such as m or n.

In detail, consider an unbalanced k-shredder S with partition $(C, \mathcal{R})$. Observe that there must exist a power of two 2^i such that $2^{i-1} < \mathrm{vol}(\mathcal{R}) \leq 2^i$. If we sample $\tilde{\mathcal{O}}(m/2^i)$ edges (x, y), we will sample a vertex $x \in \mathcal{R}$ with high probability due to the classic hitting set lemmas. The goal is to spend only $\tilde{\mathcal{O}}(\mathrm{poly}(k) \cdot 2^i)$ time processing each sample to list S. Suppose that such a local algorithm exists. Although we do not know the exact power of two 2^i, we know that $\mathrm{vol}(\mathcal{R}) < \frac{m}{k}$. Hence, we can simply try all powers of two up to $\frac{m}{k}$. This gives us the near-linear runtime bound:

$$\sum_{i=0}^{\lceil \log \frac{m}{k} \rceil} \tilde{\mathcal{O}}\left(\frac{m}{2^i}\right) \cdot \tilde{\mathcal{O}}(\mathrm{poly}(k) \cdot 2^i) = \sum_{i=0}^{\lceil \log \frac{m}{k} \rceil} \tilde{\mathcal{O}}(\mathrm{poly}(k) \cdot m) = \tilde{\mathcal{O}}(\mathrm{poly}(k) \cdot m).$$

5 Local Techniques

Let S be an unbalanced k-shredder with partition $(C, \mathcal{R})$. Our challenge is to list S in time relative to a parameter of our choice rather than the size of the entire graph. To achieve this, we will implement a local search procedure from a sampled vertex. To formalize the procedure, recall Definition 2.4.

Suppose that we have obtained a tuple (x, ν, Π) that captures S. Let Q denote the component in $\mathcal{R}$ containing x. It is straightforward to see that all remaining components of $\mathcal{R} \setminus \{Q\}$ will also be components of $G \setminus \Pi$. Thus, we may attempt to explore components of $G \setminus \Pi$ and apply Lemma 5.3 (a local version of Lemma 4.7) and Lemma 4.8 to list S. An important distinction from $\texttt{Shredders}(\cdot, \cdot)$ is that in this case, Π is no longer a set of k openly-disjoint simple paths from x to a single vertex y, but rather from x to some vertices in C.

▶ **Lemma 2.5.** *Let G be a graph with vertex connectivity k. Let (x, ν, Π) be a tuple where x is a vertex, ν is a positive integer, and Π is a set of paths. There exists a deterministic algorithm that takes (x, ν, Π) as input and outputs a list $\mathcal{L}$ of k-shredders and one set U such that the following holds. If S is a k-shredder that is captured by (x, ν, Π), then $S \in \mathcal{L}$ or $S = U$. The algorithm runs in $\mathcal{O}(k^2 \nu \log \nu)$ time.*

Our goal is to show that the inner workings of `Shredders`$(\cdot, \cdot)$ can be efficiently translated to our localized setting. We show how to implement this in Algorithm 1. A major caveat concerns the set U. We can think of U as an *unverified set*. Why U exists is a consequence of locality. Essentially, because the algorithm in Lemma 2.5 is time-limited by a volume parameter ν, we may discover a set U but not have enough time to verify whether U is a k-shredder. We first state two helpful lemmas that will provide some understanding of how Algorithm 1 works. These lemmas summarize and translate a large portion of Section 4 in terms of our new setting.

▶ **Fact 5.1.** *Let S be a k-shredder with partition $(C, \mathcal{R})$ captured by (x, ν, Π). For every path $\pi \in \Pi$, we have $|S \cap \pi| = 1$.*

▶ **Lemma 5.2.** *Let S be a k-shredder with partition $(C, \mathcal{R})$ captured by (x, ν, Π). Let Q denote the component in $\mathcal{R}$ containing x. Every component in $\mathcal{R} \setminus \{Q\}$ is a component of $G \setminus \Pi$.*

▶ **Lemma 5.3.** *Let S be a k-shredder with partition $(C, \mathcal{R})$ captured by (x, ν, Π). Then, no bridge of Π straddles S.*

Algorithm Outline

Consider Algorithm 1. At a high level, Algorithm 1 works as follows. Let (x, ν, Π) be a tuple given as input to the algorithm. For each path $\pi \in \Pi$, we can traverse the path from x to the far-most endpoint of π. At a given vertex $u \in \pi$, we can explore the bridges of Π attached to u using a breadth-first search (BFS). While doing so, we maintain a list of bridges of Π. We also maintain a list of candidate k-shredders of Π by checking whether the attachment set of a bridge forms a k-tuple. Among the list of candidate k-shredders, false candidates are then pruned correctly and efficiently via Lemma 5.3 and Lemma 4.8. So far, we have not deviated from `Shredders`$(\cdot, \cdot)$.

The key modification is to impose a restriction on the number of edges we are allowed to explore via BFS. We can explore at most ν edges along each path. Suppose we are processing a vertex u along path π. If the number of edges explored for this path exceeds ν while exploring bridges of Π attached to u, we terminate early and mark u as an *unverified vertex*. Intuitively, the unverified vertex u serves as a boundary of exploration. It signifies that bridges attached to u were not fully explored, so we flag u and treat it with extra caution during a later step. While this may seem dubious, the key is that we are concerned only with k-shredders that are *captured* by (x, ν, Π). Let S be a k-shredder with partition $(C, \mathcal{R})$. For each path $\pi \in \Pi$, if we walk in increasing distance from x and explore attached bridges of Π, observe that it is impossible to visit more than $\text{vol}(\mathcal{R})$ edges prior to reaching a vertex in S. Since $\text{vol}(\mathcal{R}) \leq \nu$, this implies we must either identify S as a candidate k-shredder, or as the unverified set U.

At the end of processing all the paths in Π, we will have obtained a list of bridges of Π, a list of candidate k-shredders of Π, and an *unverified set* consisting of all the unverified vertices. The final step is to black box Lemma 4.8 to prune false candidates among the list of candidate k-shredders.

Algorithm 1 Finding the unbalanced k-shredders with small components containing x.

Input: x - a sample vertex
ν - volume parameter
Π - a set of k openly disjoint paths starting from x
Output: $\mathcal{L}$ - a list of k-shredders captured by (x, ν, Π)
U - an unverified set

$\mathcal{L} \leftarrow \varnothing$
$U \leftarrow \varnothing$
for each path $\pi \in \Pi$ **do**
    reset explored edges and vertices to null
    for each vertex $u \in \pi$ in increasing distance from x **do**
        if u is the far-most endpoint of π **then**
            $U \leftarrow U \cup \{u\}$
            break
        explore all unexplored bridges of Π attached to u with BFS:
            terminate early the moment more than ν edges are explored
        if BFS terminated early **then**
            $U \leftarrow U \cup \{u\}$
            break
        else
            for each bridge Γ explored by BFS **do**
                if the attachment set A of Γ forms a k-tuple of Π **then**
                    $\mathcal{L} \leftarrow \mathcal{L} \cup \{A\}$
if $x \in U$ **then**
    return $(\varnothing, \varnothing)$

prune false k-shredders in $\mathcal{L} \cup \{U\}$ using Lemma 4.8
$F \leftarrow$ the set of far-most endpoints of all paths in Π
if U was not pruned $U \cap F = \varnothing$ **then**
    return $(\mathcal{L}, U)$
else
    return $(\mathcal{L}, \varnothing)$

We state two more lemmas that will be useful in the later sections.

▶ **Lemma 5.4.** *Suppose that Algorithm 1 on input (x, ν, Π) returns an unverified set U such that $U \neq \varnothing$. Then, U is a k-separator. Specifically, let z be the far-most endpoint of an arbitrary path $\pi \in \Pi$. Then, x and z are not connected in $G \setminus U$.*

▶ **Lemma 5.5.** *Suppose that Algorithm 1 returns a nonempty unverified set U on input (x, ν, Π). Let Q denote the component of $G \setminus U$ containing x. There exists a modified version of Algorithm 1 that also computes* $\mathrm{vol}(Q)$ *in $\mathcal{O}(k\nu)$ time.*

6 Resolving Unverified Sets

We now address the case where Algorithm 1 returns an unverified set U on input (x, ν, Π). The difference between U and the list of returned k-shredders $\mathcal{L}$ is that the algorithm did not find a component Q of $G \setminus \Pi$ such that $N(Q) = U$. In some sense, this means that

we "lose" a component of $G \setminus U$. The danger in guessing that U is a k-shredder is that U might only be a k-separator. Imagine that $G \setminus U$ has exactly two components: C_1 and C_2. If $\text{vol}(C_2) \gg \text{vol}(C_1)$, then it becomes quite challenging to determine whether there exists a third component of $G \setminus U$ in $\mathcal{O}(\text{vol}(C_1))$ time. To cope with this uncertainty, we make another structural classification.

▶ **Definition 6.1** (Low-Degree, High-Degree). *Let S be a k-shredder with partition $(C, \mathcal{R})$. Let ν be the unique power of two satisfying $\frac{1}{2}\nu < \text{vol}(\mathcal{R}) \leq \nu$. We say that S has* low-degree *if there exists a vertex $s \in S$ such that $\deg(s) \leq \nu$. Otherwise, we say S has* high-degree.

One aspect of this definition may seem strange: we have specifically described ν as a power of two. This is because in the later sections, we will use geometric sampling to capture k-shredders. The sampling parameters we use will be powers of two. Hence, we have imposed this slightly arbitrary detail on Definition 6.1. For now, all that matters is that $\frac{1}{2}\nu < \text{vol}(\mathcal{R}) \leq \nu$.

Organization

There are two main lemmas for this section. Lemma 6.3 handles low-degree unverified sets and is presented in Section 6.1. Lemma 6.7 handles high-degree unverified sets and is presented in Section 6.2. The idea is that after Algorithm 1 returns an unverified set U, we will use Lemma 6.3 to test whether U is a low-degree k-shredder. If not, we will leave keep U as a potential high-degree k-shredder. After all unverified sets have been returned, we use Algorithm 3 to extract all high-degree k-shredders from the remaining unverified sets.

6.1 Low-Degree

Suppose that U is a low-degree k-shredder with partition $(C, \mathcal{R})$. Suppose that the tuple (x, ν, Π) captures U and Algorithm 1 reports U as an unverified set. Our goal is to design an algorithm that confirms U is a k-shredder in the same time complexity as Algorithm 1 up to $\text{polylog}(n)$ and $\text{poly}(k)$ factors.

Lemma 5.4 gives us two vertices in different components of $G \setminus U$: x and z (where z is the far-most endpoint of any path in Π). Since U is a k-shredder, there must exist a third component of $G \setminus U$ and every vertex in U must be adjacent to a vertex in this third component. Because U is low-degree, there must exist a vertex $u \in U$ with $\deg(u) \leq \nu$. The idea is to scan through the edges adjacent to this low-degree vertex u and find an edge (u, y) such that y is neither connected to x nor z in $G \setminus U$. To make the scanning procedure viable, we need to efficiently answer pairwise connectivity queries in $G \setminus U$. The key ingredient is a result obtained by Kosinas in [17]. Specifically, the following holds.

▶ **Theorem 6.2.** *There exists a deterministic data structure for an undirected graph G on n vertices and m edges with $\mathcal{O}(km \log n)$ preprocessing time that supports the following operations.*

1. *Given a set F of k vertices, perform a data structure update in time $\mathcal{O}(k^4 \log n)$.*
2. *Given a pair of vertices (x, y) return* `true` *if x is connected to y in $G \setminus F$ in time $\mathcal{O}(k)$.*

We defer the method of capturing k-shredders for later. For now, let us assume that the tuple (x, ν, Π) captures a k-shredder U and U is reported as an unverified set by Algorithm 1. We show an auxiliary algorithm that will be helpful in listing low-degree k-shredders.

▶ **Lemma 6.3.** *After preprocessing the input graph using the data structure from Theorem 6.2, there exists a deterministic algorithm that takes in as input (x, ν, Π, U), where U is an unverified set returned by Algorithm 1 on input (x, ν, Π). The algorithm outputs* `true` *if U is a k-shredder and there exists a vertex $u \in U$ such that $\deg(u) \leq \nu$ in $\mathcal{O}(k^4 \log n + k\nu)$ time.*

▶ Remark 6.4. In [20], Long and Saranurak showed the existence of a pairwise connectivity oracle subject to vertex failures with $\mathcal{O}(k^2 n^{o(1)})$ update time and $\mathcal{O}(k)$ query time. Our usage of Kosinas's oracle involves making one update operation with a set of size k and $\mathcal{O}(\nu)$ many connectivity queries. Using Long and Saranurak's version, we can improve the dependency on k in the time complexity of Algorithm 2 to $\mathcal{O}(k^2 n^{o(1)} + k\nu)$ time.

Algorithm Outline

As mentioned above, the idea is to scan through the edges adjacent to u in order to find a vertex y such that y is neither connected to x nor z in $G \setminus U$. We will be utilizing Theorem 6.2 to determine whether a pair of vertices (x, y) are connected in $G \setminus U$. Pseudocode is given in Algorithm 2.

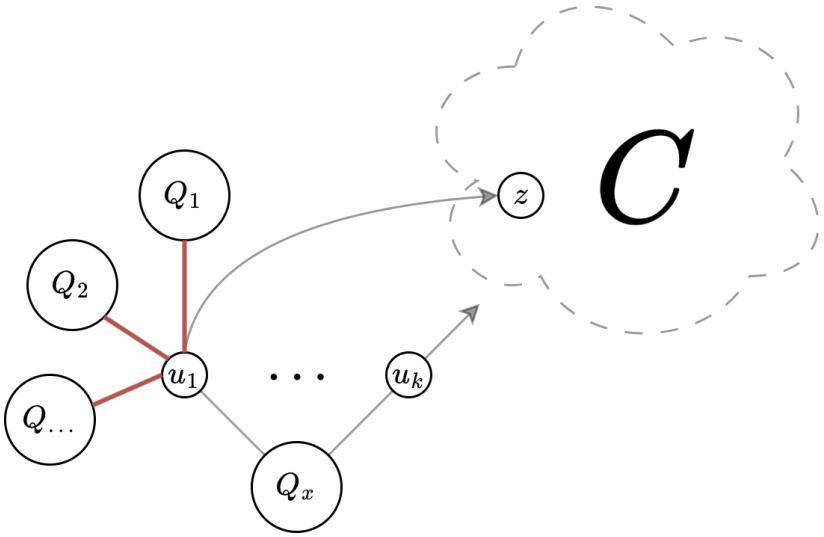

Figure 3 Here the set $U = \{u_1, \dots, u_k\}$ was reported as an unverified set. Suppose there exist a vertex v_1 without loss of generality such that $\deg(u_1) \leq \nu$. Then, we can simply scan through the neighbors of u_1 in $\mathcal{O}(\nu)$ iterations to obtain an edge incident to a component of $G \setminus U$ that is not Q_x nor C.

6.2 High-Degree

It is quite difficult to determine locally whether U is a high-degree k-shredder. We can no longer hope for a low-degree vertex $u \in U$ and scan through its edges to find a third component of $G \setminus U$. To tackle high-degree k-shredders reported as unverified sets, our idea is to ignore them as they are reported and filter them later using one subroutine. Let U be a high-degree k-shredder with partition $(C, \mathcal{R})$. Let ν be the power of two satisfying $\frac{1}{2}\nu < \mathrm{vol}(\mathcal{R}) \leq \nu$. Every vertex $x \in \mathcal{R}$ has $\deg(x) \leq \nu$ because $\mathrm{vol}(\mathcal{R}) \leq \nu$. Furthermore, every vertex $u \in U$ has $\deg(u) > \nu$ because U is high-degree. We can exploit this structure by noticing that U forms a "wall" of high-degree vertices. That is, if we obtain a vertex $x \in \mathcal{R}$, we can use BFS seeded at x to explore a small area of vertices with degree at most ν. The high degree vertices of U would prevent the graph traversal from escaping the component of $G \setminus U$ containing x. At the end of the traversal, the set of explored vertices would compose a component Q of $G \setminus U$ and we can report that $N(Q) = U$ might be a high-degree k-shredder. To obtain a vertex $x \in \mathcal{R}$, we can use the classic hitting set lemmas via random edge sampling.

Algorithm 2 Auxiliary algorithm for low-degree k-shredders.

Input: x - a sample vertex
ν - volume parameter
Π - a set of k openly-disjoint paths starting from x
U - unverified set returned by Algorithm 1 on (x, ν, Π)
Output: `true` if (1) and (2) are satisfied, `false` otherwise
(1) U is a k-shredder
(2) there exists a vertex $u \in U$ such that $\deg(u) \leq \nu$

if all vertices in U have degree greater than ν **then**
  return `false`
$u \leftarrow$ a vertex in U with $\deg(u) \leq \nu$
$\pi \leftarrow$ the path in Π containing u
$z \leftarrow$ the far-most endpoint of π

$\Phi \leftarrow$ the pairwise connectivity oracle from Theorem 6.2 (already preprocessed)
update Φ on vertex failure set U
for each edge (u, y) adjacent to u such that $y \notin U$ **do**
  $q_{x,y} \leftarrow$ connectivity query between x and y in $G \setminus U$
  $q_{y,z} \leftarrow$ connectivity query between y and z in $G \setminus U$
  if $q_{x,y}$ is `false` **and** $q_{y,z}$ is `false` **then**
    return `true`
return `false`

▶ **Lemma 6.5** (Hitting Set Lemma). *Let Q be a set of vertices. Let ν be a positive integer satisfying $\frac{1}{2}\nu < \mathrm{vol}(Q) \leq \nu$. If we independently sample $400\frac{m}{\nu}\log n$ edges (u, v) uniformly at random, we will obtain an edge (u, v) such that $u \in Q$ with probability $1 - n^{-100}$.*

We are not finished yet, as we need to connect this idea with the unverified sets reported by Algorithm 1. Suppose that U was reported by Algorithm 1 on input (x, ν, Π). We have that x is in some component Q of $G \setminus U$. Our goal is to sample a vertex y in a *different* component Q' of $G \setminus U$. As described above, we can exploit the fact that U is a high-degree k-shredder by exploring low-degree vertices in the neighborhood of y to recover Q'. At this point, we have essentially recovered two components of $G \setminus U$: Q and Q'. To make further progress, we present a short, intuitive lemma.

▶ **Lemma 6.6.** *Let U be a k-separator. Let Q, Q' be two distinct components of $G \setminus U$. Then U is a k-shredder if and only if $\mathrm{vol}(Q) + \mathrm{vol}(Q') + |E(U, U)| < m$.*

We are finally ready to handle high-degree k-shredders reported as unverified sets. We present the main result.

▶ **Lemma 6.7.** *There exists a randomized Monte Carlo algorithm that takes as input a list $\mathcal{U}$ of tuples of the form (x, ν, Π, U), where U is an unverified set returned by Algorithm 1 on (x, ν, Π). The algorithm returns a list of k-shredders $\mathcal{L}$ that satisfies the following. If $(x, \nu, \Pi, U) \in \mathcal{U}$ is a k-tuple such that U is a high-degree k-shredder, then $U \in \mathcal{L}$ with probability $1 - n^{-100}$. The algorithm runs in $\mathcal{O}(k^2 m \log^2 n)$ time.*

Algorithm Outline

We summarize the argument made above. Fix a tuple (x, ν, Π, U) in $\mathcal{U}$ such that U is a high-degree k-shredder with partition $(C, \mathcal{R})$. Let ν denote the unique power of two satisfying $\frac{1}{2}\nu < \mathrm{vol}(\mathcal{R}) \leq \nu$. Because U is high-degree, we have for all $u \in U$, $\deg(u) > \nu$. Let Q

denote the component of $G \setminus U$ containing x. Suppose we have obtained a vertex y in a component $Q' \in \mathcal{R} \setminus \{Q\}$. Since all vertices in Q' have degree at most ν, the idea is to explore all vertices connected to y that have degree at most ν. Because $N(Q') = U$ and each vertex in U has degree greater than ν, we will compute Q' as the set of explored vertices. After computing Q', we will have obtained two components of $G \setminus U$: Q and Q'. In order to confirm that U is a k-shredder, all that is left to do is to make sure that Q and Q' are not the only components of $G \setminus U$. Lemma 6.6 implies this can be done by verifying that $\text{vol}(Q) + \text{vol}(Q') + |E(U, U)| < m$. Now, the final step is to find such a vertex y. We use a random sampling procedure for this task. Consider Algorithm 3. We omit the proofs of correctness and time complexity.

Algorithm 3 Extracting all high-degree k-shredders from unverified sets.

Input: $\mathcal{U}$ - a list of tuples of the form (x, ν, Π, U)
Output: $\mathcal{L}$ - a list of k-shredders that satisfies the following:
if $(x, \nu, \Pi, U) \in \mathcal{U}$ is such that U is a high-degree k-shredder,
then $U \in \mathcal{L}$ with probability $1 - n^{-100}$

$\mathcal{L} \leftarrow \varnothing$
for $i \leftarrow 0$ to $\lceil \log\left(\frac{m}{k}\right) \rceil$ **do**
  $\nu' \leftarrow 2^i$
  for $400\frac{m}{\nu'} \log n$ times **do**
    independently sample an edge (y, z) uniformly at random
    $Q' \leftarrow$ set of vertices explored by BFS seeded at y:
      ignore vertices v such that $\deg(v) > \nu'$
      terminate early the moment more than ν' edges are explored
    if BFS terminated early **then**
      skip to next sample
    else if there exists a tuple $(x, \nu, \Pi, U) \in \mathcal{U}$ such that $N(Q') = U$ **then**
      $Q \leftarrow$ component of $G \setminus U$ containing x
      if $x \notin Q'$ **and** $\text{vol}(Q) + \text{vol}(Q') + |E(U, U)| < m$ **then**
        $\mathcal{L} \leftarrow \mathcal{L} \cup \{U\}$
return $\mathcal{L}$

7 Capturing and Listing Unbalanced k-Shredders

In the previous sections, we showed an algorithm that takes as input a tuple (x, ν, Π), and lists all k-shredders that are captured by (x, ν, Π) as well as an unverified set. We then showed how to resolve unverified sets using casework on the structural properties of k-shredders. There is one piece of the puzzle left: the method for capturing unbalanced k-shredders. For this, we will leverage random sampling and recent developments in local flow algorithms as in [10].

7.1 Leveraging Local Flow Algorithms

Let S be an unbalanced k-shredder with partition $(C, \mathcal{R})$. At a high level, we use geometric sampling to obtain a seed vertex $x \in \mathcal{R}$ and a volume parameter ν satisfying $\frac{1}{2}\nu < \text{vol}(\mathcal{R}) \leq \nu$. This obtains two items necessary for capturing S. We are still missing a set of k openly-disjoint paths Π, each starting from x and ending at a vertex in C such that the sum of lengths over all paths is at most $k^2\nu$. This is precisely a core tool developed in [10].

▶ **Definition 7.1** (Vertex Cut). *A vertex cut (L, S, R) of a graph $G = (V, E)$ is a partition of V such that for all vertex pairs $(u, v) \in L \times R$, u is not connected to v in $G \setminus S$.*

▶ **Theorem 7.2** ([10, implicit in Theorem 4.1]). *Let $G = (V, E)$ be an undirected n-vertex m-edge graph with vertex connectivity k. Let (L, S, R) be a vertex cut of G such that $\mathrm{vol}(R) < \frac{m}{k}$. There exists a randomized algorithm `LocalVC`$(\cdot, \cdot)$ that takes as input a pair (x, ν) where x is a vertex in R and ν is a positive integer satisfying $\frac{1}{2}\nu < \mathrm{vol}(R) \leq \nu$. The algorithm outputs a set Π of k openly-disjoint paths such that each path satisfies the following.*
1. *The sum of lengths over all paths in Π is at most $k^2\nu$.*
2. *The path starts from x and ends at a vertex in L.*

The algorithm outputs Π with probability $1/4$ in $\mathcal{O}(k^2\nu)$ time.

Theorem 4.1 of [10] only states that their algorithm returns a vertex cut. But they also construct the set of paths Π. Their algorithm is simple, and we will briefly explain it here. First, we perform the standard vertex-splitting reduction and reduce the problem to finding *directed edge-disjoint* paths instead. To find the first path, we perform any graph search, says DFS, from a vertex x to explore $k\nu$ volume and sample a random endpoint y_1 among all explored edges. Note that y_1 is in L with probability at least $1 - 1/k$ since $\mathrm{vol}(R) \leq \nu$. Then, we reverse the direction of edges on the path from x to y_1 in the DFS tree and obtain a "residual" graph. Then, we repeat the process in the residual graph to construct the next path from x to y_2. After k iterations, the endpoints $y_1, \ldots, y_k$ of these k paths are in L with probability $(1 - 1/k)^k \geq 1/4$. These paths in the residual graphs can be decomposed (like the flow-decomposition) into k directed edge-disjoint paths in the original graph whose total length is $k^2\nu$. These, in turn, correspond k openly vertex-disjoint paths by the standard reduction in the beginning.

Notice how the output of the algorithm described in Theorem 7.2 directly corresponds to Definition 2.4. Let R denote the union of all components in $\mathcal{R}$. Notice that (C, S, R) forms a vertex cut such that $\mathrm{vol}(R) < \frac{m}{k}$. The idea is to obtain a seed vertex $x \in R$ using a linear amount of random samples. For each sample, we can directly apply `LocalVC`$(\cdot, \cdot)$ to obtain the desired set of paths. Furthermore, we can boost the success rate of the algorithm by repeating it a polylogarithmic number of times. In the following section, we formalize this idea.

7.2 The Algorithm for Unbalanced k-Shredders

The main result is stated below.

▶ **Lemma 7.3.** *There exists a randomized algorithm that takes as input $G = (V, E)$, an n-vertex m-edge undirected graph with vertex connectivity k. The algorithm correctly lists all unbalanced k-shredders of G with probability $1 - n^{-98}$ in $\mathcal{O}(k^4 m \log^4 n)$ time.*

We first give a high level outline for listing unbalanced k-shredders. Let S be an unbalanced k-shredder with partition $(C, \mathcal{R})$. With geometric sampling, by the hitting set lemma we will sample a vertex $x \in \mathcal{R}$ with a volume parameter ν that satisfies $\frac{1}{2}\nu < \mathrm{vol}(\mathcal{R}) \leq \nu$. Then, we use Theorem 7.2 to obtain a set of k openly-disjoint paths Π, each starting from x and ending at a vertex in C such that the sum of lengths over all paths is at most $k^2\nu$. We now have a tuple (x, ν, Π) that captures S. After capturing S, we call Algorithm 1 to list S as a k-shredder or an unverified set. In the latter case, we can verify whether S is a low-degree k-shredder using Algorithm 2. If this verification step fails, S must be a high-degree k-shredder. In this case, we can add S to a global list of unverified sets. This list will be processed after all unbalanced k-shredders have been captured. Lastly, we can extract all high-degree k-shredders from the list of unverified sets using Algorithm 3. Pseudocode describing this process is given in Algorithm 4.

Algorithm 4 Listing all unbalanced k-shredders of a graph.

Input: $G = (V, E)$ - an undirected k-vertex-connected graph
Output: $\mathcal{L}$ - a list containing all unbalanced k-shredders of G

$\mathcal{L} \leftarrow \varnothing$ ▷ *list of k-shredders*
$\mathcal{U} \leftarrow \varnothing$ ▷ *unverified sets*
$\Phi \leftarrow$ initialize a pairwise connectivity oracle as in [17]

for $i \leftarrow 0$ to $\lceil \log \left(\frac{m}{k}\right) \rceil$ **do**
  $\nu \leftarrow 2^i$
  for $400 \frac{m}{\nu} \log n$ times **do**
    independently sample an edge (x, y) uniformly at random
    for $100 \log n$ times **do**
      $\Pi \leftarrow \texttt{LocalVC}(x, \nu)$ as in [10]
      $(\mathcal{L}_{local}, U) \leftarrow$ call Algorithm 1 on input (x, ν, Π)
      $\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{L}_{local}$
      if $U \neq \varnothing$ **then**
        call Algorithm 2 on input (x, ν, Π, U)
        if Algorithm 2 returned `true` **then**
          $\mathcal{L} \leftarrow \mathcal{L} \cup \{U\}$
        else
          $\mathcal{U} \leftarrow \mathcal{U} \cup \{(x, \nu, \Pi, U)\}$

$\mathcal{L}_{high-degree} \leftarrow$ call Algorithm 3 on input $\mathcal{U}$
$\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{L}_{high-degree}$
return $\mathcal{L}$

8 Listing All k-Shredders

At last, we are ready to present the algorithm for listing all k-shredders. See Algorithm 5.

▶ **Lemma 8.1.** *Let $G = (V, E)$ be an n-vertex m-edge undirected graph with vertex connectivity k. There exists a randomized algorithm that takes G as input and correctly lists all k-shredders of G with probability $1 - n^{-97}$ in $\mathcal{O}(k^4 m \log^4 n)$ time.*

The idea is that we can classify any k-shredder as either balanced or unbalanced. We have described how to use random edge sampling to handle the former case, and Algorithm 4 handles the latter case. Because the algorithm for listing balanced k-shredders is quite trivial, we have omitted its pseudocode. Given Lemma 8.1, Theorem 1.1 follows by the standard sparsification [22].

9 Most Shattering Min-Cut

We have presented a randomized near-linear time algorithm that lists all k-shredders with high probability, but we have not yet shown how to count the number of components each k-shredder separates. Counting components proves to be a bit trickier than it was in [6]. What we will do is modify our algorithms such that whenever we list a k-shredder S, we also return the number of components of $G \setminus S$. We will do this for Algorithm 1, Algorithm 2, and Algorithm 3. Note that if there are no k-shredders of G, we can simply return a k-separator of G. This can be done in $\tilde{\mathcal{O}}(m + nk^3)$ time as shown in [10].

Algorithm 5 Listing all k-shredders of a graph.

Input: $G = (V, E)$ - an undirected k-vertex-connected graph
Output: $\mathcal{L}$ - a list of all k-shredders of G

1: $\mathcal{L} \leftarrow \varnothing$

2: $\mathcal{L}_{balanced} \leftarrow$ edge sampling and `Shredders`$(\cdot, \cdot)$
3: $\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{L}_{balanced}$

4: $\mathcal{L}_{unbalanced} \leftarrow$ call Algorithm 4 on input G
5: $\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{L}_{unbalanced}$

6: **return** $\mathcal{L}$

9.1 Counting Components in the Local Algorithm

At a high level, we can modify Algorithm 1 as follows. Suppose Algorithm 1 identifies a candidate k-shredder S on line 16. By line 13, all bridges of Π attached to some vertex $s \in S$ must have been explored. The modification is as follows. We can keep a dictionary M whose keys are candidate k-shredders (in k-tuple form) mapped to nonnegative integers initialized to zero. For each bridge Γ of Π attached to s, if Γ is a component of $G \setminus \Pi$ such that $N(\Gamma) = S$, then we increment $M[S]$. We claim that if $S \in \mathcal{L}$ is a k-shredder captured by (x, ν, Π), then $M[S] + 2$ is the number of components of $G \setminus S$.

▶ **Lemma 9.1.** *Suppose that Algorithm 1 returns $(\mathcal{L}, U)$ on input (x, ν, Π). There exists a modified version of Algorithm 1 such that for each k-shredder $S \in \mathcal{L}$ that is captured by (x, ν, Π), the modified version also computes the number of components of $G \setminus S$. The modification requires $\mathcal{O}(k^2\nu)$ additional time, subsumed by the running time of Algorithm 1.*

9.2 Counting Components for Low-Degree Unverified Sets

If Algorithm 2 returned `true` on input (x, ν, Π, U), then U is a k-shredder with a vertex $u \in U$ such that $\deg(u) \leq \nu$. Notice that all components of $G \setminus U$ must contain a vertex that is adjacent to u. Immediately, we have that the number of components of $G \setminus U$ is upper bounded by ν, as $\deg(u) \leq \nu$. However, looking at two arbitrary edges $(u, v_1), (u, v_2)$ adjacent to u, it is unclear whether v_1 and v_2 are in the same component of $G \setminus U$. Although we can query whether v_1 and v_2 are connected in $G \setminus U$ in $\mathcal{O}(k)$ time, we cannot afford to make these queries for all pairs of vertices in $N(u)$. Such a procedure would require us to make $\mathcal{O}(\nu^2)$ many queries, which is too costly. To solve this issue, we use a convenient property of DFS trees to bypass making $\mathcal{O}(\nu^2)$ connectivity queries. Much of the machinery was inspired by [17], so we omit the details.

▶ **Lemma 9.2.** *Suppose that Algorithm 2 returns `true` on input (x, ν, Π, U). There exists a modified version of Algorithm 2 that also computes the number of components of $G \setminus U$. The modification requires $O(k^2\nu)$ additional time, subsumed by the running time of Algorithm 2.*

9.3 Counting Components for High-Degree Unverified Sets

Recall from Section 6.2 that the key observation is that S forms a wall of high-degree vertices. We exploited this by sampling vertices in $\mathcal{R}$ and exploring regions of vertices with low degree. The idea is that S will restrict the graph exploration within one component of $\mathcal{R}$, and we can

recover that component. We can actually extend this idea a bit further to count the number of components in $\mathcal{R}$. For all components $Q \in \mathcal{R}$, our algorithm will eventually sample a vertex $x \in Q$. By exploring low-degree vertices, we will recover Q. We can verify that $N(Q)$ is a k-shredder as by now we have listed all of them. Hence, we will eventually count all components of $G \setminus S$ throughout the sampling and exploring procedure.

▶ **Lemma 9.3.** *Suppose that Algorithm 3 returns a list $\mathcal{L}$ of k-shredders on input $\mathcal{U}$. There exists a modified version of Algorithm 3 such that for each k-shredder $S \in \mathcal{L}$, the modified version also computes the number of components of $G \setminus S$. The modification requires $\mathcal{O}(m \log^2 n)$ additional time, subsumed by the time complexity of Algorithm 3.*

Given Lemmas 9.1–9.3, we can compute a most shattering minimum-cut with high probability in $O(k^4 m \log^4 n)$ time and, hence, Theorem 1.2 follows by the standard sparsification [22].

Abstract

In the MaxSAT with Cardinality Constraint problem (CC-MaxSAT), we are given a CNF-formula Φ, and a positive integer k, and the goal is to find an assignment β with at most k variables set to true (also called a weight k-assignment) such that the number of clauses satisfied by β is maximized. Maximum Coverage can be seen as a special case of CC-MaxSat, where the formula Φ is monotone, i.e., does not contain any negative literals. CC-MaxSat and Maximum Coverage are extremely well-studied problems in the approximation algorithms as well as the parameterized complexity literature.

Our first conceptual contribution is that CC-MaxSat and Maximum Coverage are equivalent to each other in the context of FPT-Approximation parameterized by k (here, the approximation is in terms of the number of clauses satisfied/elements covered). In particular, we give a randomized reduction from CC-MaxSat to Maximum Coverage running in time $\mathcal{O}(1/\epsilon)^k \cdot (m+n)^{\mathcal{O}(1)}$ that preserves the approximation guarantee up to a factor of $(1-\epsilon)$. Furthermore, this reduction also works in the presence of "fairness" constraints on the satisfied clauses, as well as matroid constraints on the set of variables that are assigned true. Here, the "fairness" constraints are modeled by partitioning the clauses of the formula Φ into r different colors, and the goal is to find an assignment that satisfies at least t_j clauses of each color $1 \leq j \leq r$.

Armed with this reduction, we focus on designing FPT-Approximation schemes (FPT-ASes) for Maximum Coverage and its generalizations. Our algorithms are based on a novel combination of a variety of ideas, including a carefully designed probability distribution that exploits sparse coverage functions. These algorithms substantially generalize the results in Jain et al. [SODA 2023] for CC-MaxSat and Maximum Coverage for $K_{d,d}$-free set systems (i.e., no d sets share d elements), as well as a recent FPT-AS for Matroid Constrained Maximum Coverage by Sellier [ESA 2023] for frequency-d set systems.

1 Introduction

Two problems that have gained considerable attention from the perspective of Parameterized Approximation [11] are the classical MaxSAT with cardinality constraint (CC-MaxSat) problem and its monotone version, the Maximum Coverage problem. In the CC-MaxSat problem, we are given a CNF-formula Φ over m clauses and n variables, and a positive integer k, and the objective is to find a weight k assignment that maximizes the number of satisfied clauses. We use $\mathsf{var}(\Phi)$ and $\mathsf{cla}(\Phi)$ to denote the set of variables and clauses in Φ, respectively. An *assignment* to a CNF-formula Φ is a function $\beta : \mathsf{var}(\Phi) \to \{0, 1\}$. The *weight* of an assignment β is the number of variables that have been assigned 1.

The classical Maximum Coverage problem is a special case of the CC-MaxSat problem. Indeed, it is a monotone variant of CC-MaxSat, where negated literals are not allowed. An input to the Maximum Coverage problem consists of a family of m sets, $\mathcal{F}$, over a universe U of size n, and an integer k, and the goal is to find a subfamily $\mathcal{F}' \subseteq \mathcal{F}$ of size k such that the number of elements *covered* (belongs to some set in $\mathcal{F}'$) by $\mathcal{F}'$ is maximized. Observe that when the goal is to cover every element in U, the Maximum Coverage problem corresponds to Set Cover. A natural question that has guided research on these problems is whether CC-MaxSat or Maximum Coverage admits an algorithm with running time $f(k)n^{\mathcal{O}(1)}$? That is, whether CC-MaxSat or Maximum Coverage is fixed parameter tractable (FPT) with solution size k? Unfortunately, these problems are W[2]-hard [9]. That is, we do not expect these problems to admit an algorithm with running time $f(k)n^{\mathcal{O}(1)}$. This negative result sets the platform for studying these problems from the viewpoint of Parameterized Approximation [11]. It is well known that both CC-MaxSat and Maximum Coverage admit a polynomial time $(1 - \frac{1}{e})$-approximation algorithm [26], which is in fact optimal. [10]. So, in the realm of Parameterized Approximation, we ask does there exist an $\epsilon > 0$, such that CC-MaxSat or Maximum Coverage admits an approximation algorithm with factor $(1 - \frac{1}{e} + \epsilon)$ and runs in time $f(k, \epsilon)n^{\mathcal{O}(1)}$. While there has been a lot of work on Maximum Coverage [17, 20, 25, 15, 24], Jain et al. [17] studied CC-MaxSat and designed a standalone algorithm for the problem. Our first result, a bit of a surprise to us, shows that in the world of Parameterized Approximation, CC-MaxSat and Maximum Coverage are *"equivalent"*.

▶ **Theorem 1.1** (Informal). *Let $\epsilon > 0$. There is a polynomial time randomized algorithm that given an instance (Φ, k) of CC-MaxSat produces an instance $(U, \mathcal{F}, k)$ of* Maximum Coverage *such that the following holds with probability $\frac{1}{2}(\frac{\epsilon}{2})^k$. Given a $(1 - \epsilon)\mathsf{OPT}_{\mathsf{cov}}$ solution to $(U, \mathcal{F}, k)$ we can obtain a $(1-\epsilon)\mathsf{OPT}_{\mathsf{sat}}$ solution to (Φ, k) in polynomial time. Here, $\mathsf{OPT}_{\mathsf{cov}}$ ($\mathsf{OPT}_{\mathsf{sat}}$) denotes the value of the maximum number of covered elements (satisfied clauses) by a k-sized family of subsets (weight k assignment).*

Theorem 1.1 allows us to focus on Maximum Coverage, rather than CC-MaxSat, at the expense of $\epsilon^{-\mathcal{O}(k)}$ in the running time. Further, there is no assumption on the input formulas in Theorem 1.1. This reduction immediately implies faster algorithms for CC-MaxSat by utilizing the known good algorithms for Maximum Coverage [17, 20, 25, 15, 24]. The Maximum Coverage problem has been generalized in several directions by adding either fairness constraints or asking our solution to be an independent set of a matroid. In what follows, we take a closer look at progresses on Maximum Coverage and its generalizations and then design algorithms that generalize and unify all the known results for CC-MaxSat and Maximum Coverage.

1.1 Tractability Boundaries for Maximum Coverage

Cohen-Addad et al. [8] studied Maximum Coverage and showed that there is no $\epsilon > 0$, such that Maximum Coverage admits an approximation algorithm with factor $(1 - \frac{1}{e} + \epsilon)$ and runs in time $f(k, \epsilon)(m + n)^{\mathcal{O}(1)}$ [2]. Later, this was also studied by Manurangsi [20], who obtained the following strengthening over [8]: for any constant $\epsilon > 0$ and any function h, assuming Gap-ETH, no $h(k)(n + m)^{o(k)}$ time algorithm can approximate Maximum Coverage with n elements and m sets to within a factor $(1 - \frac{1}{e} + \epsilon)$, even with a promise that there exist k sets that fully cover the whole universe. This negative result sets the contour for possible positive results. In particular, if we hope for an FPT algorithm that improves over a factor $(1 - \frac{1}{e})$ then we must assume some additional structure on the input families. This automatically leads to the families wherein each set has bounded size, or each element appears in bounded sets which was considered earlier.

Skowron and Faliszewski [25] showed that, if we are working on set families, such that each element in U appears in at most p sets, then there exists an algorithm, that given an $\epsilon > 0$, runs in time $(\frac{p}{\epsilon})^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$ and returns a subfamily $\mathcal{F}'$ of size k that is a $(1-\epsilon)$-approximation. These kind of FPT-approximation algorithms are called FPT-approximation Schemes (FPT-ASes). For $p = 2$, Manurangsi [20] independently obtained a similar result. Jain et al. [17] generalized these two settings by looking at $K_{d,d}$-free set systems (i.e., no d sets share d elements). They also considered $K_{d,d}$-free formulas (that is, the clause-variable incidence bipartite graph of the formula excludes $K_{d,d}$ as an induced subgraph). They showed that for every $\epsilon > 0$, there exists an algorithm for $K_{d,d}$-free formulas with approximation ratio $(1 - \epsilon)$ and running in time $2^{\mathcal{O}((\frac{dk}{\epsilon})^d)}(n + m)^{\mathcal{O}(1)}$. For, Maximum Coverage on $K_{d,d}$-free set families, they obtain an FPT-AS with running time $(\frac{dk}{\epsilon})^{\mathcal{O}(dk)} n^{\mathcal{O}(1)}$. Using these results together with Theorem 1.1 we get the following.

▶ **Corollary 1.2.** *Let $\epsilon > 0$. Then, CC-MaxSat admits a randomized* FPT-AS *with running time $(\frac{dk}{\epsilon})^{\mathcal{O}(dk)} n^{\mathcal{O}(1)}$ on $K_{d,d}$-free formulas. Furthermore, if the size of clauses is bounded by p or every variable appears in at most p clauses then CC-MaxSat admits randomized* FPT-AS *with running time $(\frac{p}{\epsilon})^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$. Both results hold with constant probability.*

We note that the deterministic version of the first result in the corollary was given in [21] in a recent independent work.

Corollary 1.2 follows by utilizing Theorem 1.1 and repurposing the known results about Maximum Coverage ([17, 5, 25, 20]). We will return to the case of $K_{d,d}$-free set systems later. Apart from extending the classes of set families where Maximum Coverage admits FPT-ASes, the study on the Maximum Coverage problem has been extended in many directions.

[2] Throughout the paper, the approximation factor will refer to the number of elements covered/number of satisfied clauses, unless explicitly stated otherwise

1.1.1 Matroid Constraints

Note that Maximum Coverage is a special case of submodular function maximization subject to a cardinality constraint. In the latter problem, we are given (an oracle access to) a submodular function $f : 2^V \to \mathbb{R}_{\geq 0}$ [3], and the goal is to find a subset $U \subseteq V$ that maximizes $f(U)$ over all subsets of size at most k. Indeed, coverage functions are submodular and monotone (i.e., adding more sets cannot decrease the number of elements covered). There has been a plethora of work on monotone submodular maximization subject to cardinality constraints, starting from Wolsey [27]. In a further generalization, we are interested in monotone submodular maximization subject to a matroid constraint – in this setting, we are given a matroid $\mathcal{M} = (U, \mathcal{I})$ [4] via an *independence oracle*, i.e., an algorithm that answers queries of the form "Is $P \in \mathcal{I}$?" for any $P \subseteq U$ in one step, and we want to find an independent set $S \in I$ that maximizes $f(S)$. Note here that a uniform matroid of rank k [5] exactly captures the cardinality constraint. Calinescu et al. [6] gave an optimal $(1 - 1/e)$-approximation.

More recently, Huang and Sellier [15] and Sellier [24] studied the problem of maximizing a coverage function subject to a matroid constraint, called Matroid Constrained Maximum Coverage. In this problem, which we call M-MaxCov (M for "matroid" constraint), we are given a set system $(U, \mathcal{F})$ and a matroid $\mathcal{M} = (\mathcal{F}, I)$ of rank k, and the goal is to find a subset $\mathcal{F}' \subseteq \mathcal{F}$ such that $\mathcal{F}' \in I$ and $\mathcal{F}'$ maximizes the number of elements covered. Note that M-MaxCov is a generalization of Maximum Coverage. In the latter paper, Sellier [24] designed an FPT-AS for M-MaxCov, running in time $(d/\epsilon)^{\mathcal{O}(k)} \cdot (m+n)^{\mathcal{O}(1)}$ for frequency-d set systems. Note that this result generalizes that of [25, 20] from a uniform matroid consraint to an arbitrary matroid constraint of rank k.

Analogous to M-MaxCov, one can define a matroid constrained version of CC-MaxSat, called M-MaxSAT. In this problem, we are given a CNF-SAT formula Φ and a matroid $\mathcal{M}$ of rank k on the set of variables. The goal is to find an assignment that satisfies the maximum number of clauses, with the restriction that, the set of variables assigned 1 must be an independent set in $\mathcal{M}$. Note that M-MaxSAT generalizes M-MaxCov as well as CC-MaxSat. We obtain the following result for M-MaxSAT, by combining the results on a variant of Theorem 1.1 with the corresponding result on M-MaxCov.

▶ **Theorem 1.3.** *There exists an* FPT-AS *for M-MaxSAT parameterized by k, d, and ϵ, on d-CNF formulas, where k denotes the rank of the given matroid.*

1.1.2 Fairness or Multiple Coverage Constraints

Now we consider an orthogonal generalization of Maximum Coverage. Note that an optimal solution for Maximum Coverage may leave many elements uncovered. However, such a solution may be deemed *unfair* if the elements are divided into multiple colors (representing, say, people of different demographic groups), and the set uncovered elements are biased against a specific color. To address these constraints, the following generalization of Maximum Coverage, which we call F-MaxCov (F stands for "fair"), has been studied in the literature. Here, we are given a set system $(U, \mathcal{F})$, a coloring function $\chi : U \to [r]$, a

[3] $f : 2^V \to \mathbb{R}$ is submodular if it satisfies $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ for all $A, B \subseteq V$

[4] Recall that a matroid is a pair $\mathcal{M} = (U, \mathcal{I})$, where U is the ground set, and $\mathcal{I}$ is a family of subsets of U satisfying the following three axioms: (i) $\emptyset \in \mathcal{I}$, (ii) If $A \in \mathcal{I}$, then $B \in \mathcal{I}$ for all subsets $B \subseteq A$, and (iii) for any $A, B \in \mathcal{I}$ with $|B| > |A|$, then there exists an element $e \in B \setminus A$ such that $A \cup \{e\} \in \mathcal{I}$.

[5] Rank of a matroid is equal to the maximum size of any independent set in the matroid.

coverage requirement function $t : [r] \to \mathbb{N}$, and an integer k; and the goal is to find a subset $\mathcal{F}' \subseteq \mathcal{F}$ of size at most k such that, for each $i \in [r]$, the union of elements in $\mathcal{F}'$ is at least $t(i)$ (or t_i).

Since F-MaxCov is a generalisation of Maximum Coverage, it inherits all the lower bounds known for Maximum Coverage. Furthermore, we can mimic the algorithm for Maximum Coverage (Partial Set Cover) parameterized by t (where you want to cover at least t elements with k sets) [5] to obtain an algorithm for Partition Maximum Coverage parameterized by $\sum_{j\in[r]} t_j$. However, the problem is NP-hard even when $t_j \leq 1$, $j \in [r]$, via a simple reduction from Set Cover.

F-MaxCov has been studied under multiple names in the approximation algorithms literature; however much of the focus has been on approximating the *size* of the solution, rather than the coverage. Notable exception include Chekuri et al. [7] who gave a "bicriteria" approximation, that outputs a solution of size at most $\mathcal{O}(\log r/\epsilon)$ times the optimal size, and covers at least $(1 - 1/e - \epsilon)$ fraction of the required coverage of each color. Very recently, Bandyapadhyay et al. [3] recently designed an FPT-AS for F-MaxCov for the set systems of frequency 2, running in time $2^{\mathcal{O}(\frac{rk^2 \log k}{\epsilon})} \cdot (m+n)^{\mathcal{O}(1)}$. We obtain the following result on F-MaxCov.

▶ **Theorem 1.4.** *There exists a randomized* FPT-AS *for F-MaxCov running in time* $\left(dr\left(\frac{\log k}{\epsilon}\right)^r\right)^{\mathcal{O}(k)} \cdot (m+n)^{\mathcal{O}(1)}$*, on set systems with frequency bounded by* d*.*

Note that this result generalizes the result of [3] to frequency-d set systems, and in the case of $d = 2$, our running time is faster than that of [3] (albeit our algorithm is randomized).

One can also define *fair* version of CC-MaxSat in an analogous way, which we call F-MaxSAT. In this problem, we are given a CNF-formula Φ, a coloring function $\chi : \mathsf{cla}(\Phi) \to [r]$, a coverage demand function $t : [r] \to \mathbb{N}$, and an integer k. The goal is to find a weight-k assignment that satisfies at least $t(j)$ (also denoted as t_j) clauses of each color $j \in [r]$. By combining Theorem 1.4 with a slightly more general version of the reduction theorem (Theorem 1.1) also yields FPT-AS for F-MaxSAT with a similar running time.

1.2 Our New Problem: Combining Matroid and Fairness Constraints

As discussed in the previous subsections, Maximum Coverage has been generalized in two orthogonal directions, namely, matroid constraints on the sets chosen in the solution, and fairness constraints on the elements covered by the solution. Although the corresponding variants of CC-MaxSat have not been studied in the literature, we mentioned that our techniques readily imply FPT-ASes for these problems for many "sparse" formulas. Given this, the following natural question arises.

> Can we find good approximations for the variants of CC-MaxSat (resp. Maximum Coverage) that combines the two orthogonal generalizations, namely, matroid constraint on the variables assigned 1, and fairness constraints on the satisfied clauses (resp. matroid constraint on the sets chosen in the solution, and fairness constraints on the elements covered)?

In the following, we formally define the common generalization of M-MaxSAT and F-MaxSAT, which we call (M, F)-MaxSAT.

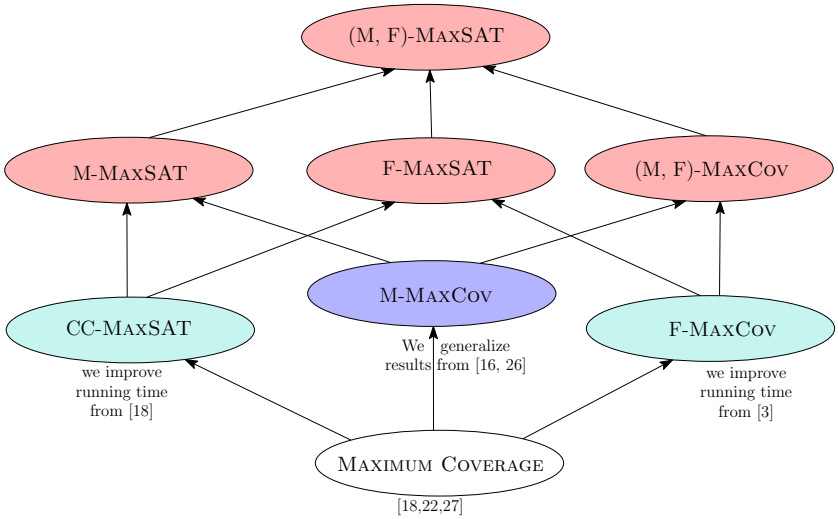

Figure 1 If there is an arrow of the form $A \to B$, then problem B generalizes problem A. FPT-ASes for the problems in red bubbles are not known in the literature, and we study in this paper. For all the other problems FPT-ASes are known in the literature for some cases. This paper improves the results in cyan and blue.

(M, F)-MaxSAT
Input. A CNF-SAT formula Φ where the clauses $\mathsf{cla}(\Phi)$ of Φ are partitioned into r colors. Each color $j \in [r]$ has an associated demand t_j. Additionally, we are provided the independence oracle to a matroid $\mathcal{M} = (\mathsf{var}(\Phi), I)$ of rank k.
Question. Does there exist an assignment $\Psi : \mathsf{var}(\Phi) \to \{0, 1\}$, such that
- The number of clauses satisfied by Ψ of color j is at least t_j, for each $j \in [r]$,
- The set of variables assigned 1 must be independent in $\mathcal{M}$, i.e., $\Psi^{-1}(1) \in I$.

In the special case where the CNF-SAT formula is monotone (i.e., does not contain negated literals), we obtain (M, F)-MaxCov, which generalizes all the variants of Maximum Coverage discussed earlier. We obtain the following result for (M, F)-MaxCov.

▶ **Theorem 1.5.** *There exists a randomized* FPT-AS *for (M, F)-MaxCov on set systems with maximum frequency d, that runs in time $\left(\frac{d \log k}{\epsilon}\right)^{\mathcal{O}(kr)} \cdot (m+n)^{\mathcal{O}(1)}$ and returns a $(1-\epsilon)$-approximation with at least a constant probability.*

Finally, by reducing (M, F)-MaxSAT on d-CNF formulas to (M, F)-MaxCov with frequency d set systems, using the randomized reduction, and then using the results of Theorem 1.5, we obtain our most general result, as follows.

▶ **Theorem 1.6.** *There exists a randomized* FPT-AS *for (M, F)-MaxSAT on d-CNF formulas, that runs in time $\left(\frac{d \log k}{\epsilon}\right)^{\mathcal{O}(kr)} \cdot (m+n)^{\mathcal{O}(1)}$ and returns a $(1-\epsilon)$-approximation with at least a constant probability.*

We give a summary of how the various problems are related to each other, and a comparison of our results with the literature in Figure 1.

1.3 Related Results

Max k-VC or Partial Vertex Cover has been extensively studied in Parameterized Complexity. In this problem we are given a graph and the task is to select a subset of k vertices covering as many of the edges as possible. The problem is known to be approximable within 0.929 and is hard to approximate within 0.944, assuming UGC [20]. Max k-VC is known to be W[1]-hard [14], parameterized by k, but admits FPT algorithms on planar graphs, graphs of bounded degeneracy, $K_{d,d}$-free graphs, and bipartite graphs, parameterized by k [1, 13, 18]. Indeed, it is among the first problems to admit FPT-AS [23, 20, 25]. It is also known to have "lossy kernels" [23, 19], a lossy version of classical kernelization.

Bera et al. [4] considered the special case of Partition Vertex Cover, where the set of edges of a graph are divided into r colors, and we want to find a subset of vertices that covers at least a certain number of edges from each color class. For this problem, they gave a polynomial-time $\mathcal{O}(\log r)$-approximation algorithm. Hung and Kao [16] generalized this to F-MaxCov, and gave a $\mathcal{O}(d \log r)$-approximation, where each element of the universe is contained in at most d sets (i.e., d is the maximum *frequency*). Bandyapadhyay et al. [2] studied this problem under the name of Fair Covering, and designed a $\mathcal{O}(d)$-approximation, but their running time is XP in the number of colors. Chekuri et al. [7] designed a general framework for F-MaxCov, yielding tight approximation guarantees for a variety of set systems satisfying certain property; in particular, they improve the approximation guarantee for frequency-d set systems to $\mathcal{O}(d + \log r)$, which is tight in polynomial time.

2 Overview of Our Results and Techniques

2.1 Reduction from CC-MaxSat to Maximum Coverage: An overview of Theorem 1.1

This theorem is essentially a randomized *approximation-preserving reduction* from CC-MaxSat to Maximum Coverage. Given an instance $\mathcal{I} = (\Phi, k)$ of CC-MaxSat, we first compute a random assignment Ψ that assigns a variable independently to be 1 with probability $p = \epsilon/2$ and 0 with probability $1 - p$. Let V^* be the set of at most k variables set to be 1 by an optimal assignment Ψ^*. It is straightforward to see that, the probability that all the variables in V^* are set to be 1 by the random assignment Ψ is p^k – we say that this is the good event $\mathcal{G}$. Now, consider a clause that is satisfied negatively by Ψ^*, i.e., a clause C that contains a negative literal $\neg x$ and $\Psi^*(x) = 0$. It is also easy to see that, conditioned on the good event $\mathcal{G}$, the probability that such a clause C is also satisfied negatively by Ψ is at least $1 - p$. Thus, the expected number of clauses that are satisfied negatively by Ψ, conditioned on $\mathcal{G}$, is at least $1 - p$ times the number of clauses satisfied negatively by Ψ^*. Markov's inequality implies that, with probability at least $1/2$, the actual number of such clauses is close to its expected value. Thus, conditioned on $\mathcal{G}$, and the previous event, we can focus on the positively satisfied clauses (note that the probability that both of these events occur is at least $1/2 \cdot (\epsilon/2)^k$. To this end, we can eliminate all the negatively satisfied clauses, and we can also prune the remaining clauses by eliminating any negative literals and the variables that are set to 0 by Ψ. Thus, all the remaining clauses only contain positive literals, which can be seen as an instance $\mathcal{I}'$ of Maximum Coverage. Furthermore, conditioned on $\mathcal{G}$, the variables set to 1 by Φ^* correspond to a family $\mathcal{F}^*$ of size k, and the elements covered by $\mathcal{F}^*$ correspond to the set of clauses satisfied only positively by Φ^*. Thus, if we find a $(1 - \epsilon)$-approximate solution to $\mathcal{I}'$, and set the corresponding variables to 1, and the rest of the variables to 0, then we get a weight-k assignment that satisfies at least $(1 - \epsilon) \cdot \mathsf{OPT}_{sat}$ clauses. Note that this reduction, combined with the algorithm of [17] gives the proof of Corollary 1.2.

Furthermore, this reduction is robust enough that it can accommodate the fairness constraints on the clauses, as defined above. To be precise, one can give a similar reduction from $\mathcal{C}$-MaxSAT to $\mathcal{C}$-MaxCov, where $\mathcal{C} \in \{\text{M, F, (M, F)}\}$ – note that when we have fairness constraints, the success probability now becomes $(r/\epsilon)^{\mathcal{O}(k)}$. Essentially, these reductions translate a constraint on the variables set to 1 (for CC-MaxSat and variants), to the corresponding family of sets (for Maximum Coverage and variants). Thus, at the expense of a multiplicative $(r/\epsilon)^{\mathcal{O}(k)}$ factor in the running time, we can focus on Maximum Coverage and its variants, which is what we do in this section, as well as in the paper. As a warm-up, we start in Section 2.2 with the vanilla Maximum Coverage on frequency-d set systems (where our algorithms *do not* improve over the known algorithms in the literature), and give a complete formal proof. Then, we will gradually introduce the ideas required to handle fairness (Section 2.3) and matroid (Section 2.4) constraints – first separately, and then together. Finally, in Section 2.5, we briefly discuss the ideas required to these results to $K_{d,d}$-free set systems and multiple matroid constraints.

2.2 Deterministic and Randomized Branching using a Largest Set

To introduce our ideas in a clean and gradual way, we start with the simplest setting of Maximum Coverage where the maximum frequency of the elements is bounded by d. Recall that we are given an instance $(U, \mathcal{F}, k)$ and the goal is to find a sub-family of $\mathcal{F}$ of size k that covers the maximum number of elements. For any sub-family $\mathcal{R} \subseteq \mathcal{F}$, let $U(\mathcal{R})$ denote the subset of elements covered by $\mathcal{R}$, and $\mathsf{OPT}_k(\mathcal{R})$ denote the maximum number of elements that can be covered by a subset of $\mathcal{R}$ of size k. Further, for a set $S \in \mathcal{F}$, we denote by $\mathcal{F} - S$, the family obtained by removing S, as well as the elements of S from each of the remaining sets. Our approach is inspired by the approaches of Skowron and Faliszewski [25] and Manurangsi [20] who show that $\mathcal{O}(kd/\epsilon)$ sets of the largest size is guaranteed to contain a $(1-\epsilon)$-approximate solution. This naturally begs the question, "*why not start by adding the largest set into the solution?*" (in a sense, the following presentation is closer in spirit to Jain et al. [17].) Let us inspect this question more closely. Let L be a largest set in $\mathcal{F}$. By looking at the contribution of coverage of each set in an optimal solution, say $\mathcal{O}$, we can easily see that $|L| \geq \frac{\mathsf{OPT}_k(\mathcal{F})}{k}$. We say that a set $S \in \mathcal{F}$ is *heavy* w.r.t. L if $|L \cap S| \geq \frac{\epsilon|L|}{k}$ (note that L is heavy w.r.t. itself). However, since the frequency of each element is bounded by d, each element in L can appear in at most d (in fact, $d-1$) sets $L \cap S$ for different $R \in \mathcal{F}$. This implies that at most $\frac{kd}{\epsilon}$ sets in $\mathcal{F}$ are heavy w.r.t. L.

Algorithm. Our algorithm simply branches on the sets in $\mathcal{H}(L)$, which is the family of heavy sets w.r.t. L. Specifically, in the branch corresponding to a heavy set $S \in \mathcal{H}(L)$, we include it in the solution, and recursively call the algorithm on the residual instance $(U \setminus S, \mathcal{F} - S, k-1)$. If any of the sets in $\mathcal{O}$ is heavy w.r.t. L, then in the branch corresponding to such a set yields an approximate solution via induction. The main idea is that, if no set in $\mathcal{O}$ is heavy w.r.t. L, then the branch corresponding to L yields a good solution. This is justified as the effect of any of the $k-1$ sets in $\mathcal{O}$ is too small. For the sake of clarity, we formally analyze this algorithm below via induction.

We want to show that, for a given input $(U', \mathcal{F}', k')$ the recursive algorithm returns a family $\mathcal{R} \subseteq \mathcal{F}'$ of size k' such that $|U'(\mathcal{R})| \geq (1-\epsilon) \cdot \mathsf{OPT}_{k'}(\mathcal{F}')$. The base case for $k' = 0$ is trivial, since the algorithm returns an empty set. Suppose that the claim is true for all inputs with budget $k-1$, and we want to prove it for $(U, \mathcal{F}, k)$. Let $\mathcal{O}$ denote an optimal solution of size k with $|\mathsf{OPT}_k(\mathcal{F})| = |U(\mathcal{O})|$.

Approximation Ratio in the Easy Case. If $\mathcal{O} \cap \mathcal{H}(L) \neq \emptyset$, then there exists a branch corresponding to a set $S \in \mathcal{O} \cap \mathcal{H}(L)$. This is the *easy case* (for the analysis). In this case, $\mathsf{OPT}_{k-1}(\mathcal{F} - S) = \mathsf{OPT}_k(\mathcal{F}) - |S|$, and hence the approximation ratio is:

$$\begin{aligned}\frac{|S| + (1-\epsilon)\mathsf{OPT}_{k-1}(\mathcal{F} \setminus S)}{\mathsf{OPT}_k(\mathcal{F})} &= \frac{|S| + (1-\epsilon)(\mathsf{OPT}_k(\mathcal{F}) - |S|)}{\mathsf{OPT}_k(\mathcal{F})} \\ &\geq \frac{(1-\epsilon)(\mathsf{OPT}_k(\mathcal{F})}{\mathsf{OPT}_k(\mathcal{F})} = (1-\epsilon)\end{aligned}$$

Approximation Ratio in the Hard Case. The more hard case (for analysis) is when $\mathcal{O} \cap \mathcal{H}(S) = \emptyset$. In this case, we argue that the branch that includes the element L is good enough. As in the easy case, we first lower bound the value of $\mathsf{OPT}_{k-1}(\mathcal{F} - L)$. By counting the unique contributions to the solution, there exists a *light* set $S_l \in \mathcal{O}$ such that for $\mathcal{O}' = \mathcal{O} \setminus \{S_l\}$, it holds $|U'(\mathcal{O}')| \geq \frac{k-1}{k} \cdot \mathsf{OPT}_k(\mathcal{F})$. Because no set in $\mathcal{O}$ is heavy w.r.t. L, it follows that for each $R \in \mathcal{O}'$, it holds that $|R \cap L| < \frac{\epsilon|L|}{k}$, and therefore by counting it holds that $|U(\mathcal{O}') \cap L| < \epsilon \cdot |L|$. Therefore,

$$\mathsf{OPT}_{k-1}(\mathcal{F} \setminus L) \geq |U'(\mathcal{O}') \setminus L| \geq |U(\mathcal{O}')| - |U(\mathcal{O}') \cap L| \geq \frac{k-1}{k} \cdot \mathsf{OPT}_k(\mathcal{F}) - \epsilon \cdot |L|.$$

Therefore, the approximation ratio of the branch that includes L is as follows.

$$\begin{aligned}\frac{|L| + (1-\epsilon)\mathsf{OPT}_{k-1}(\mathcal{F} - L)}{\mathsf{OPT}_k(\mathcal{F})} &= \frac{|L| + (1-\epsilon)\left(\frac{k-1}{k} \cdot \mathsf{OPT}_k(\mathcal{F}) - \epsilon \cdot |L|\right)}{\mathsf{OPT}_k(\mathcal{F})} \\ &\geq \frac{|L| + (1-\epsilon)\left(\frac{k-1}{k} \cdot \mathsf{OPT}_k(\mathcal{F})\right) - \epsilon|L|}{\mathsf{OPT}_k(\mathcal{F})} \\ &= \frac{(1-\epsilon)|L| + (1-\epsilon)\left(\frac{k-1}{k} \cdot \mathsf{OPT}_k(\mathcal{F})\right)}{\mathsf{OPT}_k(\mathcal{F})} \\ &\geq \frac{(1-\epsilon)(\mathsf{OPT}_k(\mathcal{F})}{\mathsf{OPT}_k(\mathcal{F})} = (1-\epsilon)\end{aligned}$$

The second last inequality holds from the fact that $|L| \geq \frac{\mathsf{OPT}_k(\mathcal{F})}{k}$.

This leads to a deterministic $(1-\epsilon)$-approximation algorithm with running time $((\frac{kd}{\epsilon})^k) \cdot (n+m)^{\mathcal{O}(1)}$.

Insight into the probabilistic branching

A closer inspection of the analysis reveals that the reason L may not a good choice is that the sets of $\mathcal{O}$ *together* cover more than a certain threshold fraction of elements covered by L. We utilize this idea through a smoothening process that captures the effect of the size of the intersection of a set S with L in a more nuanced manner. Let us define the weight $h_L(S)$ of a set $S \in \mathcal{F} \setminus \{L\}$ as $h_L(S) = \frac{|S \cap L|}{|L|}$. Our algorithm now instead does "randomized branching", i.e., it samples one set to be included in the solution according to some probability distribution, and then continues recursively. Note that the single run of the algorithm finishes in polynomial time. The probability distribution used by the algorithm is as follows: the set L is sampled with probability $1/2$, and any other set $S \in \mathcal{F} \setminus \{L\}$ is sampled with probability proportional to its weight $h(S)$ (the constant of proportionality is chosen such that this is a valid probability distribution, that is, the probabilities sum up to 1). In particular, observe that $\sum_{S \in \mathcal{F} \setminus \{L\}} h_L(S) \leq \frac{d|L|}{|L|} = d$. Thus, the probability of selecting S is at least $\frac{h_L(S)}{2d}$. Note that due to the way the weights $h_L(S)$ are defined, the sets with a large intersection with L have a greater chance of being sampled, as compared to the sets with a small intersection with L.

We will show that the algorithm returns a $(1-\epsilon)$-approximate solution with probability at least $(\frac{\epsilon}{2d})^k$, and runs in polynomial time. This implies that by repeating the algorithm $(\frac{2d}{\epsilon})^k$ times, we obtain a $(1-\epsilon)$-approximation with probability at least a positive constant. This leads to a randomized algorithm with running time $\mathcal{O}^*((\frac{2d}{\epsilon})^k)$.

The proof is again by induction. We want to show that, for any input $(U', \mathcal{F}', k')$, the algorithm returns a solution $\mathcal{R} \subseteq \mathcal{F}'$ of size k' such that $|U'(\mathcal{R})| \geq (1-\epsilon) \cdot \mathsf{OPT}_{k'}(\mathcal{F}')$, with probability at least $(\frac{\epsilon}{2d})^{k'}$. We reuse much of the notation from the previous analysis. Let $\mathcal{O}$ be an optimal solution of size k. First, the case when $L \in \mathcal{O}$, since our algorithm samples and includes L in the solution with probability 1/2. Then, conditioned on this event (that is, L being sampled), the approximation ratio analysis proceeds similarly to the *easy case* of the previous analysis. By induction, the recursive algorithm returns a $(1-\epsilon)$-approximate solution with probability at least $(\frac{\epsilon}{2d})^{k-1}$. Thus, overall, the algorithm returns a $(1-\epsilon)$-approximation with probability at least $\frac{1}{2}(\frac{\epsilon}{2d})^{k-1} \geq (\frac{\epsilon}{2d})^k$.

Now suppose $L \notin \mathcal{O}$. As before, let $S_l \in \mathcal{O}$ be a light set as defined earlier, and $\mathcal{O}' = \mathcal{O} \setminus \{S_l\}$. We analyze by considering the following two cases: either (i) $|U(\mathcal{O}') \cap L| \leq \epsilon \cdot |L|$, or (ii) $|U(\mathcal{O}') \cap L| > \epsilon \cdot |L|$.

In case (i), we are effectively in the same situation as the *hard case* of the previous analysis – as before, the algorithm samples L with probability at least 1/2, and as argued in the *hard case*, conditioned on the previous event, the branch corresponding to L returns a $(1-\epsilon)$-approximate solution, but now with probability at least $(\frac{\epsilon}{2d})^{k-1}$ by induction. Therefore, we obtain an $(1-\epsilon)$-approximate solution with probability at least $\frac{1}{2}(\frac{\epsilon}{2d})^{k-1} \geq (\frac{\epsilon}{2d})^k$.

In case (ii), we have that $|U(\mathcal{O}') \cap L| > \epsilon \cdot |L|$. Notice that,

$$\sum_{S \in \mathcal{O}'} |S \cap L| > \epsilon.$$

This implies that

$$\sum_{S \in \mathcal{O}'} h_L(S) = \sum_{S \in \mathcal{O}'} \frac{|S \cap L|}{|L|} \geq |U(\mathcal{O}') \cap L| > \epsilon |L|.$$

Therefore, the total weight of the sets in $\mathcal{O}'$ is at least ϵ. Therefore, the probability that the algorithm samples a set from $\mathcal{O}'$ is at least $\frac{\epsilon}{2d}$. Conditioned on this event, the approximation ratio analysis now proceeds as in the *easy case*, and the algorithm returns a $(1-\epsilon)$-approximate solution with probability at least $\frac{\epsilon}{2d}(\frac{\epsilon}{2d})^{k-1} = (\frac{\epsilon}{2d})^k$.

2.3 Handling fairness constraints via the Bucketing trick

The aforementioned idea of prioritizing the largest set L, or sets that are heavy w.r.t. it, fails to generalize when we have multiple coverage constraints in F-MaxCov. This is simply because there is no notion of "the largest set" even when we want to cover elements of *two* different colors, each with different coverage requirements. To handle such multiple coverage constraints, our idea is to use multidimensional-knapsack-style bucketing technique to group the sets of $\mathcal{F}$ into *approximate equivalence classes*, called *bags* for short. At a high level, all the vertices belonging to a particular bag contain *approximately equal* (i.e., within a factor of $(1+\epsilon)$) number of elements of *all* of the r colors. Thus, in isolation, any two sets L_1 and L_2 belonging to the same bag are interchangeable, since we tolerate an ϵ-factor loss in the coverage. Since the total number of bags can be shown to be $\left(\frac{\log k}{\epsilon}\right)^{\mathcal{O}(rk)}$, and hence we can "guess" a bag $\mathcal{B}$ containing a set from a solution $\mathcal{O}$. However, due to different amount

of overlap with an optimal solution $\mathcal{O}$, two sets $L_1, L_2 \in \mathcal{B}$ may not be interchangeable w.r.t. $\mathcal{O}$. That is, if $L_1 \in \mathcal{O}$, then $\mathcal{O} \setminus \{L_1\} \cup \{L_2\}$ may not be a good solution. However, assuming that we have correctly guessed a bag that intersects with $\mathcal{O}$, we can then select a set $L \in \mathcal{B}$, and define the heavy sets (for deterministic algorithm) or weights $h_L(\cdot)$ (for the randomized algorithm) w.r.t. L. Note that, since we have multiple coverage constraints, we cannot simply look at the total size of the intersection $|S \cap L|$. Instead, we need to tweak the notion of *heaviness* that takes into account the number of elements of each color in the intersection $S \cap L$. To summarize, we need two additional ideas to handle multiple colors in F-MaxCov: (1) "guessing" over buckets, and (2) a suitable generalization of the notion of heaviness. Modulo this, the rest of the analysis is again similar to the *easy* and *hard* cases as before. Using these ideas, we can prove the first part of Theorem 1.4.

2.4 Handling Matroid Constraints

First, we consider M-MaxCov (note that this is an orthogonal generalization of Maximum Coverage, without multiple coverage constraints), where the solution is required to be an independent set in the given matroid $\mathcal{M} = (\mathcal{F}, I)$ of rank k. We assume that we are given an *oracle access* to $\mathcal{M}$ in the form of an algorithm that answers the queries of the form "Is $\mathcal{R}$ an independent set?" for any subset $\mathcal{R} \subseteq \mathcal{F}$. Let us revisit the initial deterministic FPT-AS for Maximum Coverage and try to generalize it to M-MaxCov. Recall that this algorithm branches on each set $S \in \mathcal{H}(L)$, where L is a largest set. The analysis of easy case goes through even in presence of the matroid constraint, since we branch on a set from an optimal solution $\mathcal{O}$. However, in the hard case, our analysis replaces a $S_l \in \mathcal{O}$ with L, and argues that the branch corresponding to L returns a $(1-\epsilon)$-approximate solution. However, this does not work for M-MaxCov, since $(\mathcal{O} \setminus \{S_l\}) \cup \{L\}$ may not be an independent set in $\mathcal{M}$. To summarize, although L handles the coverage constraints (approximately), it may fail to handle the matroid constraint. In fact, it may just so happen that L is not a good set *at all*, in the sense that, for *any* set $S \in \mathcal{O}$, $(\mathcal{O} \setminus \{S\}) \cup \{L\}$ is not independent in $\mathcal{M}$, which is crucial for the induction to go through.

To solve this issue, we resort to the bucketing idea as in the fair coverage case (thus, the subsequent arguments generalize to (M, F)-MaxCov in a straightforward manner; although let us stick to the special case of M-MaxCov for now). Indeed, branching w.r.t. the largest set L is an overkill – it suffices to pin down a bag $\mathcal{B}$ containing a set in $\mathcal{O}$ (it does not even have to be the largest set), by "guessing" from $\mathcal{O}\left(\frac{\log k}{\epsilon}\right)$ bags. However, we again cannot select an arbitrary set $S \in \mathcal{B}$ and define heavy sets w.r.t. S, precisely due to the matroid compatibility issues mentioned earlier. Therefore, we resort to the idea of *representative sets* from matroid theory [22] [6] Assuming our guess for $\mathcal{B}$ is correct, there exists some $S \in \mathcal{B} \cap \mathcal{O}$. However, we cannot further "guess" S, since the size of the bag may be too large. Instead, we compute a inclusion-wise maximal independent set $\mathcal{B}' \subseteq \mathcal{B}$. Note that the size of $\mathcal{B}'$ is at most k, and it can be computed using polynomially many queries to the independence oracle. However, it may very well happen that $S \notin \mathcal{B}'$. Nevertheless, using matroid properties, we can argue that, there exists a set $S' \in \mathcal{B}'$, such that $(\mathcal{O} \setminus \{S\}) \cup \{S'\}$ is an independent set. Thus, $\mathcal{B}'$ is a *representative set* of $\mathcal{B}$. Furthermore, since both S and S' come from the same bag, they cover approximately the same number of elements. Thus, our modified deterministic

[6] Although this is a powerful hammer in its full generality – which we do use to handle multiple matroid constraints – our specialized setting lets us use much simpler arguments to handle single matroid constraint in M-MaxCov/(M, F)-MaxCov.

algorithm works as follows. First, it computes maximal independent set $\mathcal{B}' \subseteq \mathcal{B}$, and for each $S' \in \mathcal{B}'$, it computes the heavy family $\mathcal{H}(S')$. Then, it branches over all sets in $\bigcup_{S' \in \mathcal{B}'} \mathcal{H}(S')$. If one of the branches corresponds to branching on a set from $\mathcal{O}$, then the analysis is similar to the easy case. Otherwise, we know that $(\mathcal{O} \setminus \{S\}) \cup \{S'\}$ is an $(1-\epsilon)$-approximate solution that is also an independent set. Therefore, the branch corresponding to S' yields the required $(1-\epsilon)$-approximation. We can improve the running time via doing a randomized branching in two steps: first we pick a set $S'' \in \mathcal{B}'$ uniformly at random, and then we perform the probabilistic branching using the weights $h_{S''}(\cdot)$.

Both deterministic and randomized variants incur a further multiplicative overhead of $(\frac{k \log k}{\epsilon})^k$ due to first guessing a bag, and then computing a representative set $\mathcal{B}' \subseteq \mathcal{B}$ of the bag, and thus do not improve over the results of Sellier [24] in terms of running time for M-MaxCov. However, this idea naturally generalizes to (M, F)-MaxCov, with the appropriate modifications in bucketing (as mentioned in the previous paragraph) to handle the multiple coverage requirements of different colors. This leads to the proof of Theorem 1.5.

2.5 Further Extensions

The ideas mentioned in the previous subsections can be extended to even more general settings in a couple of ways. First, we describe how to extend the ideas from frequency-d set systems for Maximum Coverage to $K_{d,d}$-free set systems, i.e., set system $(U, \mathcal{F})$, where no d sets in $\mathcal{F}$ contain d elements of U in common. Note that frequency-d set systems are $K_{d+1,d+1}$-free. Then, we describe how the linear algebraic toolkit of *representative sets* can be used to handle multiple (linear) matroid constraints.

$K_{d,d}$-free Set Systems

Next, we consider $K_{d,d}$-free set systems $(U, \mathcal{F})$, where no d sets of $\mathcal{F}$ contain d common elements of U. To design the FPT-AS on $K_{d,d}$-free set systems, we combine the bucketing idea along with the combinatorial properties of $K_{d,d}$-free graphs to bound the number of heavy neighbors of a set. To this end, however, we need to modify the precise definition of *heaviness* (as in Jain et al. [17]). This leads to a somewhat cumbersome branching algorithm that handles colors differently based on their coverage requirement. For colors with small coverage requirement, we highlight the covered vertices using the standard technique of *label coding*[7]. Now, vertices in a bag cover the elements with the same label and for colors with high coverage requirements, the sizes of the sets in the same bag are "almost" the same. Then, we pick an *arbitrary* set L from the bag $\mathcal{B}$, and we branch on (suitably defined) *heavy* sets w.r.t. S. Since the number of heavy sets is bounded by a function of k, d, and ϵ, this leads to a deterministic version of Theorem 1.4 to $K_{d,d}$-free set systems. Note that since frequency-d set systems is a special case of this, this implies a deterministic FPT-AS in this case; however with a much worse running time compared to Theorem 1.4. This leads to the proof of Theorem 1.5.

[7] The technique is better known as *color coding*. However, this creates an unfortunate clash of terminology – these *colors* have nothing to do with the original colors corresponding to coverage constraints. Bandyapadhyay et al. [3] instead use the term "label coding", and we also adopt the same terminology

Handling Multiple Matroid Constraints

Our results on M-MaxCov and (M, F)-MaxCov can be generalized to handle multiple matroid constraints on the solution, in the case when the matroids are *linear* or representable[8]. In this more general problem, we are given q linear matroids $\mathcal{M}_1, \mathcal{M}_2, \ldots, \mathcal{M}_q$, where $\mathcal{M}_i = (\mathcal{F}, I_i)$, each of rank at most k, and the solution S is required to be independent in all q matroids, i.e., $S \in \bigcap_{i \in [q]} I_i$. In this case, we can use linear algebraic tools ([22, 12]) to compute a representative set of size qk instead of k, and the computation requires $2^{\mathcal{O}(qk)} \cdot n^{\mathcal{O}(1)}$ time. Thus, FPT-ASes for this problem now have a factor of q in the exponent.

Note that our FPT-AS improves upon the polynomial-time approximation guarantee of $1 - 1/e$ of Calinescu et al. [6] for monotone submodular maximization subject to a matroid constraint, in the special case of $K_{d,d}$-free coverage functions. To the best of our knowledge, this is the largest class of monotone submodular functions and matroid constraints for which the lower bound of $1 - 1/e$ can be overcome, even in FPT time. Further, the analogous results to (M, F)-MaxSAT generalize these results to maximization of non-monotone/non-submodular functions.

3 Preliminaries

For a positive integer q, let $[q] \coloneqq \{1, 2, \ldots, q\}$.

Convention. We consistently use index j to refer to a color from the range $[r]$, and may often write "for a color j" instead of "for a color $j \in [r]$". Finally, for a coverage requirement function t (resp. variations such as $t', \widetilde{t}$), and a color j, we shorten $t(j)$ to t_j (resp. $t'_j, \widetilde{t}_j$).

4 Reduction from (M, F)-MaxSAT to (M, F)-MaxCov

In this section, we begin with a polynomial time approximate preserving randomized reduction from F-MaxSAT to F-MaxCov. The success probability of the reduction is $\mathcal{O}((\epsilon/r)^k)$. Recall that in the F-MaxSAT problem, given a CNF-formula Φ with $\chi : \mathsf{cla}(\Phi) \to [r]$, a coverage demand function $t : [r] \to \mathbb{N}$ and an integer k, the goal is to find an assignment of weight at most k that satisfies at least $t(i)$ (also denoted as t_i) clauses of color class i (an assignment Ψ satisfying these properties is called *optimal weight k assignment*).

We begin with some basic definitions. Let Φ be a CNF-formula. By $\mathsf{var}(\Phi)$ and $\mathsf{cla}(\Phi)$, we denote the set of variables and clauses in the formula Φ, respectively. An assignment to a CNF-formula Φ is a function $\Psi : \mathsf{var}(\Phi) \to \{0, 1\}$. The weight of an assignment is the number of variables that have been assigned 1. By $T(\Psi)$ and $F(\Psi)$, we denote the set of variables assigned 1 and 0 by the assignment Ψ, respectively. For a clause $c \in \mathsf{cla}(\Phi)$, $\mathsf{var}(c)$ is the set of variables that occur in the clause c as a positive or negative literal. Similarly, for a set of clauses $C \in \mathsf{cla}(\Phi)$, $\mathsf{var}(C)$ is the set of variables that occur as a positive or negative literal in a clause $c \in C$.

Our reduction (Algorithm 1) takes an instance (Φ, χ, t, k) of F-MaxSAT as input. It constructs a random assignment Ψ by setting each variable to 1 with probability p and 0 with probability $1 - p$. It constructs a new formula by first removing the set of clauses that are

[8] A matroid $\mathcal{M} = (E, \mathcal{I})$ is representable over a field $\mathbb{F}$ if there exists a matrix M such that there exists a bijection between E and the columns on M with the property that, a subset $E' \subseteq E$ is independent in $\mathcal{M}$ iff the corresponding set of columns are linearly independent over $\mathbb{F}$.

Algorithm 1 Reduction Algorithm($\mathcal{I} = (\Phi, \chi, t, k)$ of F-MaxSAT).

1: Construct a random assignment Ψ as follows. For each variable $x \in \mathsf{var}(\Phi)$, independently set $\Psi(x)$ to 1 with probability p and 0 with probability $1-p$. ▷ We will later set $p = \frac{\epsilon}{2r}$.
2: Construct a new formula Φ' as follows:
- Let $N \subseteq \mathsf{cla}(\Phi)$ be the set of clauses that are satisfied negatively by Ψ. Then, $\mathsf{cla}(\Phi') = \mathsf{cla}(\Phi) \setminus N$.
- For each $c \in \mathsf{cla}(\Phi')$, remove all the variables in c that occur either as a negative literal or set to 0 by Ψ.
- For each $c \in \mathsf{cla}(\Phi')$, add $\mathsf{var}(c)$ to $\mathsf{var}(\Phi')$.

3: Construct an instance $\mathcal{J}_\Psi = (\mathcal{U}, \mathcal{F}, \chi', t', k')$ of F-MaxCov as follows:
- Set $\mathcal{U} = \mathsf{cla}(\Phi')$.
- For each $v \in \mathsf{var}(\Phi')$, add a set f_v to $\mathcal{F}$ where $f_v = \{c \in \mathsf{cla}(\Phi') \colon v \in \mathsf{var}(c)\}$.
- For each $c \in \mathsf{cla}(\Phi')$, if the corresponding element in $\mathcal{U}$ is e_c, set $\chi'(e_c) = \chi(c)$.
- Set $t'(i) = t(i) - \frac{|N \cap \chi^{-1}(i)|}{1-\epsilon}$ for each $i \in [r]$.
- Set $k' = k$.

satisfied negatively by Ψ, followed by removing negative literals from the remaining clauses. It reduces the formula to an instance $(\mathcal{U}, \mathcal{F}, \chi', t', k')$ of F-MaxCov as described in Step 3 of Algorithm 1. Clearly, this reduction takes polynomial time.

Next, we prove the correctness of our reduction. For a Yes-instance $\mathcal{I}$ of F-MaxSAT, let $\Psi^\star$ be an optimal weight k assignment. Let $N^\star$ be the set of clauses satisfied negatively by $\Psi^\star$, i.e., every clause in $N^\star$ contains a negative literal that is set to 1, and let $P^\star$ be the set of clauses satisfied only positively by $\Psi^\star$, i.e., every clause in $P^\star$ contains a positive literal that is set to 1 and no negative literal in this clause is set to 1. By $N_i^\star$, we mean the set of clauses in color class i satisfied negatively by $\Psi^\star$ and by $P_i^\star$, we mean the set of clauses in color class i satisfied only positively by $\Psi^\star$. We call a random assignment, constructed in Algorithm 1, *good* if each variable in $T(\Psi^\star)$ (positive variables under $\Psi^\star$) is assigned 1 by Ψ, i.e., $T(\Psi^\star) \subseteq T(\Psi)$, which occurs with probability at least p^k. For a good assignment Ψ, let N_i denote the set of clauses in color class i satisfied negatively by Ψ and P_i denote the set of clauses in color class i satisfied only positively by Ψ. We say that an event $\mathcal{G}$ is *good* if a good assignment Ψ is generated in Algorithm 1. We begin with the following claim.

▷ Claim 4.1. Given a Yes-instance $\mathcal{I}$ of F-MaxSAT, with probability at least 1/2, a good assignment Ψ satisfies at least $(1-\epsilon)|N_i^\star|$ clauses negatively, for each $i \in [r]$.

Proof. Let (Φ, χ, t, k) be a Yes-instance of F-MaxSAT. Let Ψ be a good assignment, which occurs with probability at least p^k. We show that Ψ satisfies at least $(1-\epsilon)|N^\star|$ clauses negatively, with probability at least 1/2. Let X_i be the number of clauses in $N_i^\star$ that are satisfied negatively by Ψ. We define an indicator random variable x_j, for each $j \in [|N_i^\star|]$, as follows.

$$x_j = \begin{cases} 1 & \text{clause } c_j \in N_i^\star \text{ is satisfied negatively by } \Psi \\ 0 & \text{otherwise} \end{cases}$$

$$\mathsf{Pr}(x_j|\mathcal{G}) = \mathsf{Pr}(\text{clause } c_j \in N_i^\star \text{ is satisfied negatively by } \Psi|\mathcal{G}) \geq (1-p)$$

$$\mathbb{E}[X_i|\mathcal{G}] = \sum_{j \in [|N_i^\star|]} x_j \times \mathsf{Pr}(x_j|\mathcal{G}) \geq (1-p)|N_i^\star|$$

Let $Y_i = |N_i^\star| - |N_i|$, where N_i is the set of clauses satisfied negatively by Ψ. Note that,

$$Y_i = |N_i^\star| - |N_i| \leq |N_i^\star \setminus N_i| = |N_i^\star| - X_i$$

Thus,

$$\mathbb{E}[Y_i|\mathcal{G}] \leq |N_i^\star| - \mathbb{E}[X_i|\mathcal{G}] \leq p|N_i^\star|$$

Since $Y_i \geq 0$, we can use Markov's inequality and get

$$\mathsf{Pr}(Y_i \geq 2rp|N_i^\star||\mathcal{G}) \leq \frac{\mathbb{E}[Y_i]}{2rp|N_i^\star|} \leq \frac{1}{2r}$$

Since $Y_i = |N_i^\star| - |N_i|$, we get

$$\mathsf{Pr}(|N_i| \leq (1-2rp)|N_i^\star||\mathcal{G}) \leq \frac{1}{2r}$$

By union bound,

$$\mathsf{Pr}\left(\exists i \in [r], |N_i| \leq (1-2rp)|N_i^\star||\mathcal{G}\right) \leq \sum_{i\in[r]} \mathsf{Pr}(|N_i| \leq (1-2rp)|N_i^\star||\mathcal{G}) \leq \frac{1}{2}$$

This implies that

$$\mathsf{Pr}\left(\forall i \in [r], |N_i| > (1-2rp)|N_i^\star||\mathcal{G}\right) \geq \frac{1}{2}$$

Setting $p = \frac{\epsilon}{2r}$ gives us the required result, i.e., with probability at least $1/2$, for all colors $i \in [r]$, $|N_i| > (1-\epsilon)|N_i^\star|$. ◁

▶ **Lemma 4.2.** *If $\mathcal{I} = (\Phi, \chi, t, k)$ is a yes-instance of F-MaxSAT, then with probability at least $(\frac{\epsilon}{2r})^k$, the reduced instance $\mathcal{J}_\Psi = (\mathcal{U}, \mathcal{F}, \chi', t', k')$ is a yes-instance of F-MaxCov.*

Proof. Let $\mathcal{I}$ be a Yes-instance of F-MaxSAT and let $\Psi^\star$ be an optimal weight k assignment. Further, let $N^\star$ be the set of clauses satisfied negatively by $\Psi^\star$, i.e., every clause in $N^\star$ contains a negative literal that is set to 1, and let $P^\star$ be the set of clauses satisfied only positively by $\Psi^\star$, i.e., every clause in $P^\star$ contains a positive literal that is set to 1 and no negative literal in this clause is set to 1. Then, there exists a set $V_{P^\star} \subseteq \mathsf{var}(P^\star)$ of size at most k that satisfies all the clauses in $P^\star$ positively, i.e., for each clause in $P^\star$, there is a variable in $V_{P^\star}$ that occurs as a positive literal in it and is assigned 1 under $\Psi^\star$. Let Ψ be a good assignment which is generated with probability at least $(\frac{\epsilon}{2r})^k$. Since Ψ is a good assignment, $T(\Psi^\star) \subseteq T(\Psi)$ and $F(\Psi) \subseteq F(\Psi^\star)$. Hence, $P^\star \subseteq P$. Thus, $P^\star \subseteq \mathcal{U}$ and for each variable in $\mathsf{var}(P^\star)$, we have a set in the family $\mathcal{F}$. Let $Z = \{f_v \in \mathcal{F} \colon v \in V_{P^\star}\}$. We claim that Z is a solution to $\mathcal{J}_\Psi$. Clearly, Z covers at least $|P_i^\star|$ elements in $\mathcal{U}$, for each $i \in [r]$. We claim that $t_i' \leq |P_i^\star|$. Since $\Psi^\star$ is a solution to $\mathcal{I}$, it satisfies t_i clauses for each $i \in [r]$. Since $t_i = |P_i^\star| + |N_i^\star|$, due to Claim 4.1, we know that $t_i \leq |P_i^\star| + \frac{|N_i|}{1-\epsilon}$. Thus, $|P_i^\star| \geq t_i - \frac{|N_i|}{1-\epsilon}$. Since $t_i' = t_i - \frac{|N_i|}{1-\epsilon}$, $t_i' \leq |P_i^\star|$. This completes the proof. ◀

▶ **Lemma 4.3.** *Assume that $\mathcal{I} = (\Phi, \chi, t, k)$ is a yes-instance of F-MaxSAT. If there exists $(1-\epsilon)$-approximate solution for $\mathcal{J}_\Psi = (\mathcal{U}, \mathcal{F}, \chi', t', k')$, where Ψ is a good assignment, then there exists $(1-\epsilon)$-approximate solution for $\mathcal{I}$ with probability at least $\frac{1}{2}$.*

Proof. Let $\Psi^\star$ be an optimal assignment. Due to Claim 4.1, Ψ satisfies at least $(1-\epsilon)|N_i^\star|$ clauses negatively, for each $i \in [r]$, with probability at least $1/2$. Let S be a $(1-\epsilon)$-approximate solution to $\mathcal{J}_\Psi$. We construct an assignment σ as follows: if $f_x \in S$, then $\sigma(x) = 1$, otherwise 0. We claim that σ is a $(1-\epsilon)$-approximate solution to $\mathcal{I}$. Due to the construction of $\mathcal{J}_\Psi$, note that $\mathcal{F}$ does not contain a set corresponding to the variable that is set to 0 by Ψ. Thus, if $\Psi(x) = 0$, then $\sigma(x) = 0$. Hence, σ satisfies at least $(1-\epsilon)|N_i^\star|$ clauses negatively, for each $i \in [r]$, with probability at least $1/2$. Next, we argue that σ satisfies at least $(1-\epsilon)|P_i^\star|$ clauses only positively, for each $i \in [r]$. Since S is a $(1-\epsilon)$-approximate solution to $\mathcal{J}_\Psi$, for each $i \in [r]$, S covers at least $(1-\epsilon)t_i'$ elements. Recall that $\mathcal{U}$ contains an element corresponding to each clause in $\cup_{i\in[r]} P_i$. Thus, σ satisfies at least $(1-\epsilon)t_i'$ clauses only positively for each $i \in [r]$. Recall that $t_i' = t_i - \frac{|N_i|}{1-\epsilon}$. Thus, $|P_i| + |N_i| \geq (1-\epsilon)(t_i - \frac{|N_i|}{1-\epsilon}) + |N_i| = (1-\epsilon)t_i$. Hence, σ is a factor $(1-\epsilon)$-approximate solution for $\mathcal{I}$. ◀

Due to Lemma 4.2 and 4.3, we have the following result.

▶ **Theorem 4.4.** *There exists a polynomial time randomized algorithm that given a* Yes*-instance $\mathcal{I}$ of F-MaxSAT generates a* Yes*-instance $\mathcal{J}$ of F-MaxCov with probability at least $(\frac{\epsilon}{2r})^k$. Furthermore, given a factor $(1-\epsilon)$-approximate solution of $\mathcal{J}$, it can be extended to a $(1-\epsilon)$-approximate solution of $\mathcal{I}$ with probability at least $1/2$.*

Note that if the variable-clause incidence graph of the input formula belongs to a subgraph closed family $\mathcal{H}$, then the incidence graph of the resulting instance of F-MaxCov will also belong to $\mathcal{H}$. Thus, due to Theorem 4.4 and Theorem 1.2 in [17], we have the following result, which is an improvement over Theorem 1.1 in [17].

▶ **Theorem 4.5.** *There is a randomized algorithm that given a* Yes*-instance $\mathcal{I}$ of* CC-Max-SAT*, where the variable-clause incidence graph is $K_{d,d}$-free, returns a factor $(1-\epsilon)$-approximate solution with probability at least $(1-\frac{1}{e})$, and runs in time $(\frac{rdk}{\epsilon})^{\mathcal{O}(dk)}(n+m)^{\mathcal{O}(1)}$.*

The $(\frac{r}{\epsilon})^{\mathcal{O}(k)}$ factor in the running time of the algorithm in Theorem 4.5 comes by repeating the algorithm in Theorem 4.4, followed by Theorem 1.2 in [17], independently $(\frac{r}{\epsilon})^{\mathcal{O}(k)}$ many times. This also boosts the success probabilty to at least $(1-\frac{1}{e})$.

▶ Remark 4.6. Note that the reduction from F-MaxSAT to F-MaxCov also works in presence of matroid constraint(s) on the set of variables assigned 1. Recall that in the former (resp. latter) problem, we are given a matroid $\mathcal{M}$ on the set of variables (resp. sets), and the set of at most k variables assigned 1 (resp. at most k sets chosen in the solution) is required to be an independent set in $\mathcal{M}$. This follows from the fact that the randomized algorithm preserves the optimal independent set in the set cover instance with good probability.

5 Conclusion

In this paper, we designed FPT-approximation schemes for (M, F)-MaxSAT, which is a generalization of the CC-MaxSat problem with fairness and matroid constraints. In particular, we designed FPT-AS for the classes of formulas where the maximum frequency of a variable in the clause is bounded by d, and more generally, for $K_{d,d}$-free formulas. Our algorithm for F-MaxCov on the set systems of frequency bounded by d is substantially faster compared to the recent result of Bandyapadhyay et al. [3], even for the special case of $d = 2$. We use a novel combination of the bucketing trick and a carefully designed probability distribution in order to obtain this faster FPT-AS.

Our work naturally leads to the following intriguing questions. Firstly, our approximation-preserving reduction from CC-MaxSat (and variants) to Maximum Coverage (and variants) is inherently randomized. Is it possible to derandomize this reduction? A similar

question of derandomization is also interesting for our aforementioned algorithm for F-MaxCov on bounded-frequency set systems. In this case, can we design an FPT-AS for the problem running in time single-exponential in k?

Abstract

A parameterized string (p-string) is a string over an alphabet $(\Sigma_s \cup \Sigma_p)$, where Σ_s and Σ_p are disjoint alphabets for static symbols (s-symbols) and for parameter symbols (p-symbols), respectively. Two p-strings x and y are said to parameterized match (p-match) if and only if x can be transformed into y by applying a bijection on Σ_p to every occurrence of p-symbols in x. The indexing problem for p-matching is to preprocess a p-string T of length n so that we can efficiently find the occurrences of substrings of T that p-match with a given pattern. Let σ_s and respectively σ_p be the numbers of distinct s-symbols and p-symbols that appear in T and $\sigma = \sigma_s + \sigma_p$. Extending the Burrows-Wheeler Transform (BWT) based index for exact string pattern matching, Ganguly et al. [SODA 2017] proposed parameterized BWTs (pBWTs) to design the first compact index for p-matching, and posed an open problem on how to construct the pBWT-based index in compact space, i.e., in $O(n \lg |\Sigma_s \cup \Sigma_p|)$ bits of space. Hashimoto et al. [SPIRE 2022] showed how to construct the pBWT for T, under the assumption that $\Sigma_s \cup \Sigma_p = [0..O(\sigma)]$, in $O(n \lg \sigma)$ bits of space and $O(n \frac{\sigma_p \lg n}{\lg \lg n})$ time in an online manner while reading the symbols of T from right to left. In this paper, we refine Hashimoto et al.'s algorithm to work in $O(n \lg \sigma)$ bits of space and $O(n \frac{\lg \sigma_p \lg n}{\lg \lg n})$ time in a more general assumption that $\Sigma_s \cup \Sigma_p = [0..n^{O(1)}]$. Our result has an immediate application to constructing parameterized suffix arrays in $O(n \frac{\lg \sigma_p \lg n}{\lg \lg n})$ time and $O(n \lg \sigma)$ bits of working space. We also show that our data structure can support backward search, a core procedure of BWT-based indexes, at any stage of the online construction, making it the first compact index for p-matching that can be constructed in compact space and even in an online manner.

1 Introduction

A *parameterized string* (*p-string*) is a string over an alphabet $(\Sigma_s \cup \Sigma_p)$, where Σ_s and Σ_p are disjoint alphabets for *static symbols* (*s-symbols*) and for *parameter symbols* (*p-symbols*), respectively. Two p-strings x and y are said to *parameterized match* (*p-match*) if and only if x can be transformed into y by applying a bijection on Σ_p to every occurrence of p-symbols in x. For example with $\Sigma_s = \{\mathtt{a}, \mathtt{b}\}$ and $\Sigma_p = \{\mathtt{X}, \mathtt{Y}, \mathtt{Z}\}$, two p-strings `aXYbZXaY` and `aZYbXZaY` p-match because `aXYbZXaY` can be transformed into `aZYbXZaY` by replacing `X`, `Y` and `Z` with `Z`, `Y` and `X`, respectively. The concept of p-matching was introduced by Baker aiming at software maintenance and plagiarism detection [1, 2, 3], and has been extensively studied in the last decades (see a recent survey [28] and references therein).

The indexing problem for p-matching is to preprocess a p-string T of length n so that we can efficiently find the occurrences of substrings of T that p-match with a given pattern. Solutions proposed for this problem adapt and extend indexes initially devised for exact string pattern matching, e.g., parameterized suffix trees [1, 25, 2, 3], parameterized suffix arrays [8, 20, 4, 12], parameterized suffix trays [14], parameterized DAWGs [31], parameterized position heaps [9, 11, 13] and parameterized Burrows-Wheeler transforms (pBWTs) based indexes [16, 24, 18].

Among these indexes, pBWT-based indexes are the most space economic, consuming $n \lg |\Sigma_s \cup \Sigma_p| + O(n)$ bits [16] or $2n \lg |\Sigma_s \cup \Sigma_p| + 2n + o(n)$ bits with a simplified version proposed in [24]. Let σ_s and respectively σ_p be the numbers of distinct s-symbols and p-symbols that appear in T and $\sigma = \sigma_s + \sigma_p$. The pBWT-based index of T can be constructed via the parameterized suffix tree of T for which $O(n(\lg \sigma_s + \lg \sigma_p))$-time or randomized $O(n)$-time construction algorithms are known [25, 7, 26], but the intermediate memory footprint of $O(n \lg n)$ bits could be intolerable when it is significantly larger than the resulting index. Hashimoto et al. [19] showed how to compute the pBWT of [24] for T, under the assumption that $\Sigma_s \cup \Sigma_p = [0..O(\sigma)]$, in $O(n \lg \sigma)$ bits and $O(n \frac{\sigma_p \lg n}{\lg \lg n})$ time in an online manner while reading the symbols of T from right to left. Here we note that the work of [19] lacks details in terms of pBWT-based index construction because any pBWT-based index to date [16, 24, 18] requires additional data structures other than the pBWT, and the pBWTs alone does not seem to be enough to support p-matching queries efficiently.

In this paper, we refine the algorithm of [19] to work in $O(n \lg \sigma)$ bits and $O(n \frac{\lg \sigma_p \lg n}{\lg \lg n})$ time in a more general assumption that $\Sigma_s \cup \Sigma_p = [0..n^{O(1)}]$. While working in compact space, i.e., $O(n \lg \sigma)$ bits, it achieves $o(n\sigma_p)$ time when $\sigma_p = \omega(\lg n)$. This is of great interest because the time complexity of $o(n\sigma_p)$ has not been achieved in the construction for p-matching indexes even in the offline setting unless we resort to a fast construction algorithm for parameterized suffix trees using $O(n \lg n)$ bits. In particular, the currently best worst-case result for the direct construction of parameterized suffix arrays is $O(n\sigma_p)$ time and $O(n \lg n)$ bits of working space [12]. Since our online-built data structure for T can be used to compute the parameterized suffix array of T in $O(n \frac{\lg \sigma_p \lg n}{\lg \lg n})$ time, we obtain a new way to construct parameterized suffix arrays in $O(n \frac{\lg \sigma_p \lg n}{\lg \lg n})$ time and $O(n \lg \sigma)$ bits of working space.

We also show that our data structure can support backward search, a core procedure of BWT-based indexes, at any stage of the online construction, making it the first compact index for p-matching that can be constructed in compact space and even in an online manner. This cannot likely be achieved with the previous work [19] due to the lack of support for 2D range counting queries in the data structure it uses.

Our computational assumptions are as follows:

- We assume a standard Word-RAM model with word size $\Omega(\lg n)$.
- Each symbol in $(\Sigma_s \cup \Sigma_p)$ is represented by $O(\lg n)$ bits, namely, a symbol is from the universe $[0..n^{O(1)}]$.
- We can check membership for a given symbol ($\in \Sigma_s \cup \Sigma_p$) in Σ_s and Σ_p in $O(1)$ time, e.g., by having some flag bits or thresholds separating both alphabet sets.
- The order of two s-symbols can be determined in $O(1)$ time based on their bit representations.

An index of a p-string T for p-matching is to support, given a pattern w,

1. the *counting query* that asks to compute the number of occurrences of substrings in T that p-match with w and
2. the *locating query* that asks to compute the positions of these counted occurrences in T.

The number of occurrences returned for a locating query of w is the answer to the counting query of w. Since these occurrences can be at arbitrary positions of T in general, the time complexity for the locating query depends usually on the number of these occurrences. In contrast, most indexes based on the BWT can answer counting queries in time independent to this number, by levering the so-called *backward search*. By using backward search, our time complexities for both queries resemble those of other BWT-based indexes, with some additional logarithmic terms. In detail, our main result is as follows:

▶ **Theorem 1.** *For a p-string T of length n over an alphabet $(\Sigma_s \cup \Sigma_p)$ of size $n^{O(1)}$, an index of T for p-matching can be constructed online in $O(n\frac{\lg \sigma_p \lg n}{\lg\lg n})$ time and $O(n \lg \sigma)$ bits of space, where σ_s and respectively σ_p are the numbers of distinct s-symbols and p-symbols used in the p-string and $\sigma = \sigma_s + \sigma_p$. At any stage of the online construction, it can support the counting queries in $O(m\frac{\lg \sigma_p \lg n}{\lg\lg n})$ time, where m is the length of a given pattern for queries. By building an additional data structure of $O(\frac{n}{\Delta}\lg n)$ bits of space for a chosen parameter $\Delta \in \{1, 2, \ldots, n\}$ the locating queries can be supported in $O(m\frac{\lg \sigma_p \lg n}{\lg\lg n} + \mathsf{occ}\frac{\Delta \lg n}{\lg\lg n})$ time, where occ is the number of occurrences to be reported.*

We also obtain the following result for constructing the parameterized suffix array:

▶ **Theorem 2.** *For a p-string T of length n over an alphabet $(\Sigma_s \cup \Sigma_p)$ of size $n^{O(1)}$, the parameterized suffix array of T can be constructed in $O(n\frac{\lg \sigma_p \lg n}{\lg\lg n})$ time and $O(n \lg \sigma)$ bits of space, where σ_s and respectively σ_p are the numbers of distinct s-symbols and p-symbols used in the p-string and $\sigma = \sigma_s + \sigma_p$.*

2 Preliminaries

2.1 Basic notations and tools

We denote with $\lg = \log_2$ the logarithm with base two. An integer interval $\{i, i+1, \ldots, j\}$ is denoted by $[i..j]$, where $[i..j]$ represents the empty interval if $i > j$.

Let Σ be an ordered finite *alphabet*. An element of Σ^* is called a *string* over Σ. The length of a string w is denoted by $|w|$. The empty string ε is the string of length 0, that is, $|\varepsilon| = 0$. Let $\Sigma^+ = \Sigma^* - \{\varepsilon\}$ and $\Sigma^k = \{x \in \Sigma^* \mid |x| = k\}$ for any non-negative integer k. The concatenation of two strings x and y is denoted by $x \cdot y$ or simply xy. When a string w is represented by the concatenation of strings x, y and z (i.e., $w = xyz$), then x, y and z are called a *prefix*, *substring*, and *suffix* of w, respectively. A substring x of w is called *proper* if $x \neq w$.

The i-th symbol of a string w is denoted by $w[i]$ for $1 \leq i \leq |w|$, and the substring of a string w that begins at position i and ends at position j is denoted by $w[i..j]$ for $1 \leq i \leq j \leq |w|$, i.e., $w[i..j] = w[i]w[i+1]\cdots w[j]$. For convenience, let $w[i..j] = \varepsilon$ if $j < i$; further let $w[..i] = w[1..i]$ and $w[i..] = w[i..|w|]$ denote abbreviations for the prefix of length i and the suffix starting at position i, respectively. For two strings x and y, let $\mathsf{lcp}(x, y)$ denote the length of the longest common prefix between x and y. We consider the lexicographic order over Σ^* by extending the strict total order $<$ defined on Σ: x is lexicographically smaller than y (denoted as $x < y$) if and only if either x is a proper prefix of y or $x[\mathsf{lcp}(x, y) + 1] < y[\mathsf{lcp}(x, y) + 1]$ holds. In this paper, we will ignore the former case since we mainly consider the lexicographic order between distinct strings that have a sentinel (end-marker) at the end of the strings so that x cannot be a proper prefix of y.

For any string w, character c, and position i ($1 \leq i \leq |w|$), $\mathsf{rank}_c(w, i)$ returns the number of occurrences of c in $w[..i]$ and $\mathsf{select}_c(w, i)$ returns the i-th occurrence of c in w. For $1 \leq i \leq j \leq |w|$, a *range minimum query* $\mathsf{RmQ}_w(i, j)$ asks for $\arg\min_{i \leq k \leq j}\{w[k]\}$. We also consider *find previous/next queries* $\mathsf{FPQ}_p(w, i)$ and $\mathsf{FNQ}_p(w, i)$, where p is a predicate either in the form of "c" (equal to c), "$< c$" (less than c) or "$\geq c$" (larger than or equal to c): $\mathsf{FPQ}_p(w, i)$ returns the largest position $j \leq i$ at which $w[j]$ satisfies the predicate p. Symmetrically, $\mathsf{FNQ}_p(w, i)$ returns the smallest position $j \geq i$ at which $w[j]$ satisfies the predicate p. For example with the integer string $w = [2, 5, 10, 6, 8, 3, 14, 5]$, $\mathsf{FNQ}_5(w, 4) = 8$, $\mathsf{FNQ}_6(w, 4) = 4$, $\mathsf{FPQ}_5(w, 4) = 2$, $\mathsf{FNQ}_{<5}(w, 4) = 6$, $\mathsf{FPQ}_{<5}(w, 4) = 1$, $\mathsf{FNQ}_{\geq 9}(w, 4) = 7$ and $\mathsf{FPQ}_{\geq 9}(w, 4) = 3$.

If the answer of $\mathsf{select}_c(w, i)$, $\mathsf{FPQ}_p(w, i)$ or $\mathsf{FNQ}_p(w, i)$ does not exist, it is just ignored. To handle this case of non-existence, we would use them in an expression with min or max: For example, $\max\{1, \mathsf{FPQ}_p(w, i)\}$ returns 1 if $\mathsf{FPQ}_p(w, i)$ does not exist.

Dynamic strings should support insertion/deletion of a symbol to/from any position as well as fast random access. We use the following result:

▶ **Lemma 3** ([29]). *A dynamic string of length n over an alphabet $[0..U]$ can be implemented while supporting random access, insertion, deletion,* rank *and* select *queries in $(n + o(n)) \lg U$ bits of space and $O(\frac{\lg n}{\lg \lg n})$ query and update times.*

Dynamic binary strings equipped with rank and select queries can be used as a building block for the dynamic wavelet matrix [6] of a string over an alphabet $[0..U]$ to support queries beyond rank and select. The idea is that each of the other queries can be simulated by performing one of the building block queries on every level of the wavelet matrix, which has $\lceil \lg U \rceil$ levels, cf. [32, Section 6.2.].

▶ **Lemma 4.** *A dynamic string of length n over an alphabet $[0..U]$ with $U = O(n)$ can be implemented while supporting random access, insertion, deletion,* rank, select, RmQ, FPQ *and* FNQ *queries in $(n + o(n))\lceil \lg U \rceil$ bits of space and $O(\frac{\lg U \lg n}{\lg \lg n})$ query and update times.*

2.2 Parameterized strings

Let Σ_s and Σ_p denote two disjoint sets of symbols. We call a symbol in Σ_s a *static symbol* (*s-symbol*) and a symbol in Σ_p a *parameter symbol* (*p-symbol*). A *parameterized string* (*p-string*) is a string over $(\Sigma_s \cup \Sigma_p)$. Let \$ be the smallest s-symbol, which will be used as an end-marker of p-strings. Let ∞ represent a symbol that is larger than any integer, and let $\mathbf{N}_\infty = \mathbf{N}_+ \cup \{\infty\}$ be the set of positive integers $\mathbf{N}_+$ including infinity (∞). Logically we assume that $\mathbf{N}_\infty \cap \Sigma_s = \emptyset$ and $(\mathbf{N}_\infty \cup \Sigma_s)$ is an ordered alphabet such that all s-symbols are smaller than any element in $\mathbf{N}_\infty$. For practical implementations, we require that s-symbols and integers can be distinguished in constant time (e.g., by shifting the ranges of the domains). Also, the conceptual symbol ∞ can be treated as the finite value $\sigma_p + 1$.

For any p-string w the *p-encoded string* $\langle w \rangle$ of w, also proposed as $\texttt{prev}_\infty(w)$ in [24], is the string in $(\mathbf{N}_\infty \cup \Sigma_s)^{|w|}$ such that

$$\langle w \rangle[i] = \begin{cases} w[i] & \text{if } w[i] \in \Sigma_s, \\ \infty & \text{if } w[i] \in \Sigma_p \text{ and } w[i] \text{ does not appear in } w[..i-1], \\ i - j & \text{otherwise,} \end{cases}$$

where j is the largest position in $[1..i-1]$ with $w[i] = w[j]$. To put in words, we transformed each occurrence of a p-symbol into the distance to the previous occurrence of the same p-symbol, or ∞ if it is the leftmost occurrence. Two p-strings x and y p-match if and only if $\langle x \rangle = \langle y \rangle$. On the one hand, the transformation from w to $\langle w \rangle$ is *prefix-consistent*, i.e., $\langle w \rangle = \langle wc \rangle[..|w|]$ for any symbol $c \in (\Sigma_s \cup \Sigma_p)$. On the other hand, $\langle w \rangle$ and $\langle cw \rangle[2..]$ differ if and only if $c \in \Sigma_p$ occurs in w. If it is the case, the leftmost occurrence h of c in w is the unique position such that $\langle w \rangle$ and $\langle cw \rangle[2..]$ differ with $\langle w \rangle[h] = \infty$ and $(\langle cw \rangle[2..])[h] = \langle cw \rangle[h+1] = h$, i.e., $h = \mathsf{select}_c(w, 1)$ and $h + 1 = \mathsf{select}_c(cw, 2)$.

For any p-string w, let $|w|_p$ denote the number of distinct p-symbols in w, i.e., $|w|_p = \mathsf{rank}_\infty(\langle w \rangle, |w|)$. We define a function π that maps a non-empty p-string $w \in (\Sigma_s \cup \Sigma_p)^+$ to an element in $(\Sigma_s \cup [1..|w|_p])$ such that $\pi(w)$ is $w[1]$ if $w[1]$ is an s-symbol; otherwise $\pi(w)$ is the number of *distinct* p-symbols in $w[..h+1]$, where $h+1$ is either the position of the second occurrence of $w[1]$ in w or $|w|$ if $w[1]$ is unique in w. More formally,

$$\pi(w) = \begin{cases} w[1] & \text{if } w[1] \in \Sigma_s, \\ |w[..h+1]|_p & \text{otherwise,} \end{cases}$$

where $h + 1 = \min\{|w|, \mathsf{select}_{w[1]}(w, 2)\}$. In the second case, $\pi(w)$ is considered to represent the rank of p-symbol $w[1]$ when p-symbols are sorted in increasing order of the leftmost positions they appear in $w[2..]$, considering the rank of p-symbols not in $w[2..]$ to be $|w|_p$. If $\mathsf{select}_{w[1]}(w, 2)$ exists, it holds that $h = \mathsf{select}_\infty(\langle w[2..] \rangle, \pi(w))$. For convenience, we extend the domain of π to handle the empty string with $\pi(\varepsilon) = \$$.

For two p-strings x and y, $\mathsf{lcp}^\infty(\langle x \rangle, \langle y \rangle)$ denotes the number of ∞'s in the longest common prefix of $\langle x \rangle$ and $\langle y \rangle$.

Our algorithm heavily relies on the properties of the p-string encoding and π. For any p-strings x and y, Table 1 shows a complete list of cases for $\mathsf{lcp}(\langle x \rangle, \langle y \rangle)$, $\mathsf{lcp}^\infty(\langle x \rangle, \langle y \rangle)$ and the lexicographic order between $\langle x \rangle$ and $\langle y \rangle$. The correctness immediately follows from the definition of the p-string encoding and π (see Figure 1 for illustrations). It is worth noting that Case (B3) is the only case in Cases (B1)-(B4) where we have $\langle y \rangle < \langle x \rangle$, i.e., the lexicographic order is changed after extension.

By Table 1, we have the following corollaries:

▶ **Corollary 5.** *For any p-strings x and y, $\mathsf{lcp}^\infty(\langle x \rangle, \langle y \rangle) \leq \mathsf{lcp}^\infty(\langle x[2..] \rangle, \langle y[2..] \rangle) + 1$.*

▶ **Corollary 6.** *For any p-strings x and y with $\pi(x) = \pi(y)$, $\langle x \rangle < \langle y \rangle$ if and only if $\langle x[2..] \rangle < \langle y[2..] \rangle$.*

▶ **Corollary 7.** *For any p-strings x and y (whether $\langle x[2..] \rangle < \langle y[2..] \rangle$ or $\langle x[2..] \rangle > \langle y[2..] \rangle$) with $\pi(x) \leq \mathsf{lcp}^\infty(\langle x[2..] \rangle, \langle y[2..] \rangle)$ and $\pi(x) < \pi(y)$, it holds that $\langle x \rangle < \langle y \rangle$. Note that $\pi(x)$ and/or $\pi(y)$ can be s-symbols.*

Table 1 All cases for $\mathsf{lcp}(\langle x\rangle, \langle y\rangle)$, $\mathsf{lcp}^{\infty}(\langle x\rangle, \langle y\rangle)$ and the lexicographic order between $\langle x\rangle$ and $\langle y\rangle$ for p-strings x and y over $(\Sigma_s \cup \Sigma_p)$ with $\lambda = \mathsf{lcp}(\langle x[2..]\rangle, \langle y[2..]\rangle) < \min\{|x|, |y|\}$, $e = \mathsf{lcp}^{\infty}(\langle x[2..]\rangle, \langle y[2..]\rangle)$ and $\langle x[2..]\rangle < \langle y[2..]\rangle$. On the one hand, a case starting with letter A assumes that at least one of $\pi(x)$ and $\pi(y)$ is in Σ_s, while on the other hand, a case starting with letter B assumes that none of $\pi(x)$ and $\pi(y)$ is in Σ_s. We let $h = \mathsf{select}_{x[1]}(x, 2) - 1$ in Case (B2) and $h' = \mathsf{select}_{y[1]}(y, 2) - 1$ in Case (B3), both of which always exist because the conditions of Cases (B2) and (B3) imply that $\pi(x) \neq \infty$ and $\pi(y) \neq \infty$, respectively.

Let T be a p-string that has the smallest s-symbol \$ as its end-marker, i.e., $T[|T|] =$ \$ and \$ does not appear anywhere else in T. The suffix rank function $\mathsf{R}_T : [1..|T|] \to [1..|T|]$ for T maps a position i $(1 \leq i \leq |T|)$ to the lexicographic rank of $\langle T[i..]\rangle$ in $\{\langle T[j..]\rangle \mid 1 \leq j \leq |T|\}$. Its inverse function $\mathsf{R}_T^{-1}(i)$ returns the starting position of the lexicographically i-th p-encoded suffix of T. [1]

The *parameterized Burrows-Wheeler Transform (pBWT)* of T is the string L_T of length $|T|$ over $(\Sigma_s \cup [1..|T|_p])$ such that $\mathsf{L}_T[i] = \pi(T[\mathsf{R}_T^{-1}(i) - 1..]))$, where we assume that $T[0..] =$ \$. Another string F_T of length $|T|$ is defined as $\mathsf{F}_T[i] = \pi(T[\mathsf{R}_T^{-1}(i)..])$. [2] Since $\{T[\mathsf{R}_T^{-1}(i)..] \mid 1 \leq i \leq |T|\} = \{T[\mathsf{R}_T^{-1}(i) - 1..] \mid 1 \leq i \leq |T|\}$ is equivalent to the set of all non-empty suffixes of T, F_T is a permutation of L_T.

[1] R_T^{-1} and R_T are essentially equivalent to parameterized suffix arrays and inverse parameterized suffix arrays, respectively.

[2] Previous studies [16, 24, 19] define pBWTs based on sorted cyclic rotations, but our suffix-based definition is more suitable for online construction to prevent unnecessary updates on F_T and L_T.

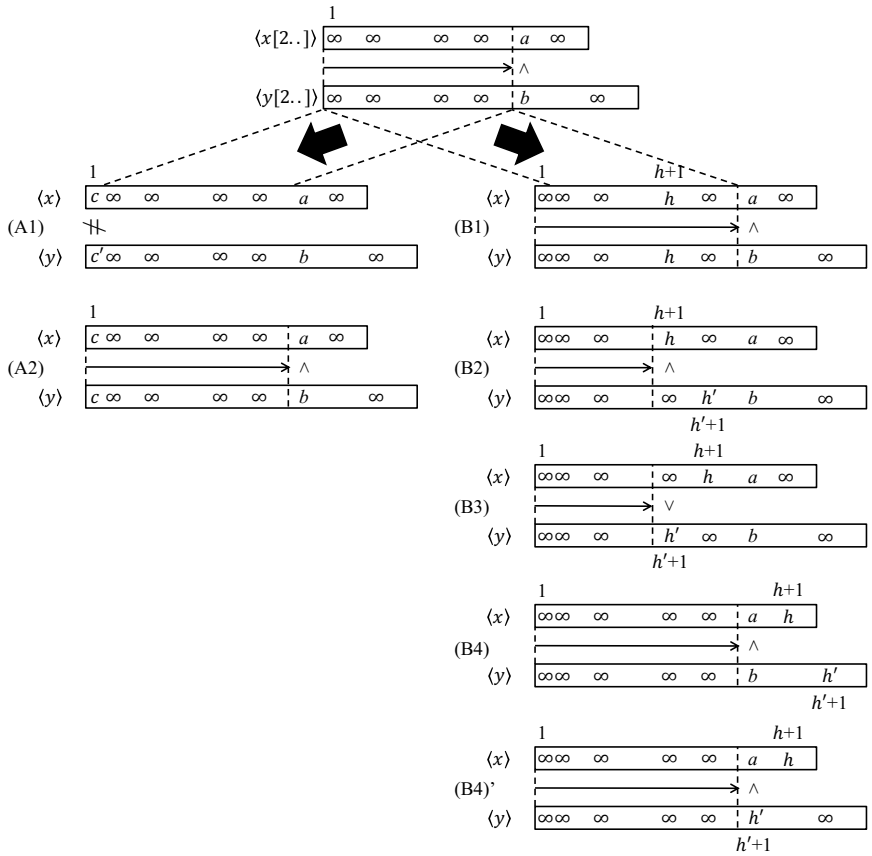

Figure 1 Illustrations for the cases of Table 1. The two bold diagonal arrows on the top separate the cases starting with letter A (left side) from the others, starting with B (right side). Each horizontal right-facing arrow represents the longest common prefix of two p-encoded strings, and the lexicographic order between them is determined by the following p-encoded symbols. Particularly, we let $a = \langle x[2..]\rangle[\lambda+1]$ and $b = \langle y[2..]\rangle[\lambda+1]$, where $\lambda = \mathsf{lcp}(\langle x[2..]\rangle, \langle y[2..]\rangle)$. Since $a < b$, it holds that $a \le \lambda$ while $b \le \lambda$ or $b = \infty$. For Case (B1), $h = \mathsf{select}_{x[1]}(x,2) - 1 = \mathsf{select}_{y[1]}(y,2) - 1$. For Case (B2)-(B4) and (B4)', $h = \mathsf{select}_{x[1]}(x,2) - 1$ and $h' = \mathsf{select}_{y[1]}(y,2) - 1$, some of which are not necessarily defined (when $\pi(x)$ or $\pi(y)$ is ∞) but assumed to be present in illustrations. Case (B4)' illustrates the case with $b = \infty$ and $h' = \lambda + 1$, which is included in Case (B4).

The so-called LF-mapping LF_T maps a position i to $\mathsf{R}_T(\mathsf{R}_T^{-1}(i) - 1)$ if $\mathsf{R}_T^{-1}(i) > 1$, and otherwise $\mathsf{R}_T(|T|) = 1$. By definition and Corollary 6, we have:

▶ **Corollary 8.** *For any p-string T and any integers i, j with $1 \le i < j \le |T|$, $\mathsf{LF}_T(i) < \mathsf{LF}_T(j)$ if $\mathsf{L}_T[i] = \mathsf{L}_T[j]$.*

Thanks to Corollary 8, it holds that $\mathsf{LF}_T(i) = \mathsf{select}_c(\mathsf{F}_T, \mathsf{rank}_c(\mathsf{L}_T, i))$, where $c = \mathsf{L}_T[i]$. The inverse function FL_T of LF_T can be computed by $\mathsf{FL}_T(i) = \mathsf{select}_c(\mathsf{L}_T, \mathsf{rank}_c(\mathsf{F}_T, i))$, where $c = \mathsf{F}_T[i]$.

Let LCP_T^∞ be the string of length $|T|$ such that $\mathsf{LCP}_T^\infty[1] = 0$ and $\mathsf{LCP}_T^\infty[i] = \mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(i-1)..]\rangle, \langle T[\mathsf{R}_T^{-1}(i)..]\rangle)$ for every $1 < i \le |T|$. An example of all explained arrays is given in Table 2.

3 Online construction algorithm

To construct our index for p-matching online, we maintain F_T, L_T, and LCP^∞_T with dynamic data structures while prepending a symbol to the current p-string T. The details of the data structures will be presented in Subsection 3.3. In what follows, we focus on a single step of updating T to $\hat{T} = cT$ for some symbol c in $\Sigma_s \cup \Sigma_p$. Note that F_T, L_T and LCP^∞_T are strongly related to the sorted p-encoded suffixes of a p-string and $\hat{T} = cT$ is the only suffix that was not in the suffixes of T. Let $k = \mathsf{R}_T(1)$ and $\hat{k} = \mathsf{R}_{\hat{T}}(1)$. In order to deal with the new emerging suffix $\hat{T}$, we compute the lexicographic rank $\hat{k}$ of $\langle\hat{T}\rangle$ among the non-empty p-encoded suffixes of $\hat{T}$. Then $\mathsf{F}_{\hat{T}}$ and $\mathsf{L}_{\hat{T}}$ can be obtained by replacing \$ in L_T at k by $\pi(\hat{T})$ and inserting \$ and $\pi(\hat{T})$ into the $\hat{k}$-th position of L_T and F_T, respectively. In Subsection 3.1, we propose our algorithm to compute $\hat{k}$. For updating LCP^∞, we have to compute the lcp^∞-values for $\langle\hat{T}\rangle$ with its lexicographically adjacent p-encoded suffixes, which will be treated in Subsection 3.2.

3.1 How to compute $\hat{k}$

Unlike previous work [19] that computes $\hat{k}$ by counting the number of p-encoded suffixes that are lexicographically smaller than $\langle\hat{T}\rangle$, we get $\hat{k}$ indirectly by computing the rank of a lexicographically closest (smaller or larger) p-encoded suffix to $\langle\hat{T}\rangle$. The lexicographically smaller (resp. larger) closest element in $\{\langle T[i..]\rangle \mid 1 \le i \le |T|\}$ to $\langle\hat{T}\rangle$ is called the *p-pred* (resp. *p-succ*) of $\langle\hat{T}\rangle$. If the lexicographic rank of the p-pred (resp. p-succ) of $\langle\hat{T}\rangle$ is k_- (resp. k_+), then it holds that $\hat{k} = k_+ = k_- + 1$.

We start with the easy case that the prepended symbol c is an s-symbol.

▶ **Lemma 9.** *Let $\hat{T} = cT$ be a p-string with $c \in \Sigma_s$. If $p := \mathsf{FPQ}_c(\mathsf{L}_T, k)$ exists, the rank k_- of the p-pred of $\hat{T}$ is $\mathsf{LF}_T(p)$. Otherwise, $k_- = \mathsf{select}_b(\mathsf{F}_T, \mathsf{rank}_b(\mathsf{F}_T, |T|))$, where b is the largest s-symbol that appears in T and is smaller than c.*

Proof. By Case (A2) of Table 1, the lexicographic order of p-encoded suffixes starting with c does not change by removing their first characters, which are all c. If p exists, $\langle T[\mathsf{R}_T^{-1}(p)..]\rangle$ is the lexicographically smaller closest p-encoded suffix to $\langle T\rangle$ that is preceded by c. Hence, $\langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(p))..]\rangle = \langle c(T[\mathsf{R}_T^{-1}(p)..])\rangle$ is the p-pred of $\langle cT\rangle = \langle\hat{T}\rangle$, which means that $k_- = \mathsf{LF}_T(p)$.

If p does not exist, it implies that $\langle\hat{T}\rangle$ is the lexicographically smallest p-encoded suffix that starts with c. Since $\langle\hat{T}\rangle$ lexicographically comes right after the p-encoded suffixes starting with an s-symbol smaller than c, k_- is the last occurrence of b in F_T, that is, $k_- = \mathsf{select}_b(\mathsf{F}_T, \mathsf{rank}_b(\mathsf{F}_T, |T|))$. ◀

In the rest of this subsection, we consider the case that c is a p-symbol. If T contains no p-symbol, it is clear that $k_- = |T|$. Hence, in what follows, we assume that there is a p-symbol in T.

Since $\langle\hat{T}\rangle$ has the longest lcp-value with its p-pred or p-succ among all the suffixes of T, we search for such p-encoded suffixes of T using the following lemmas to leverage the information stored in LCP^∞_T.

▶ **Lemma 10.** *Given two positions i and j with $1 \le i < j \le |T|$,*

$$\mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(i)..]\rangle, \langle T[\mathsf{R}_T^{-1}(j)..]\rangle) = \mathsf{RmQ}_{\mathsf{LCP}^\infty_T}(i+1, j).$$

Algorithm 1 Algorithm to compute the maximal interval $[l..r]$ such that $\mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(i)..]\rangle, \langle T[\mathsf{R}_T^{-1}(j)..]\rangle) \geq e$ for any $j \in [l..r]$. It returns $[i..i]$ if $e > |T[\mathsf{R}_T^{-1}(i)..]|_p$.

```
1 Function GetMI(i, e):
2     l ← max{1, FPQ_{<e}(LCP^∞_T, i)};
3     r ← min{|T|, FNQ_{<e}(LCP^∞_T, i + 1) − 1};
4     return [l..r];
```

Proof. By Lemma 1 of [22], $\mathsf{lcp}(x,z) = \min\{\mathsf{lcp}(x,y), \mathsf{lcp}(y,z)\}$ for any strings $x < y < z$, and thus, $\mathsf{lcp}^\infty(x,z) = \min\{\mathsf{lcp}^\infty(x,y), \mathsf{lcp}^\infty(y,z)\}$. Since LCP_T^∞ holds the lcp^∞-values of lexicographically adjacent p-encoded suffixes, we get $\mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(i)..]\rangle, \langle T[\mathsf{R}_T^{-1}(j)..]\rangle) = \min\{\mathsf{LCP}_T^\infty[g]\}_{g=i+1}^{j} = \mathsf{RmQ}_{\mathsf{LCP}_T^\infty}(i+1, j)$ by applying the previous argument successively. ◀

▶ **Lemma 11.** *For given $i, e \in [1..n]$, if $e \leq |T[\mathsf{R}_T^{-1}(i)..]|_p$, then Algorithm 1 computes the maximal interval $[l..r]$ such that $\mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(i)..]\rangle, \langle T[\mathsf{R}_T^{-1}(j)..]\rangle) \geq e$ for any $j \in [l..r]$. If $e > |T[\mathsf{R}_T^{-1}(i)..]|_p$, then Algorithm 1 returns $[i..i]$.*

▶ **Lemma 12.** *Algorithm 2 correctly returns $\hat{k}$.*

Proof.

Outline. Let $h_i = \mathsf{select}_\infty(\langle T\rangle, i)$ for any $1 \leq i \leq \min\{|T|_p, \pi(\hat{T})\}$, and $h_i = |T|+1$ for any $i > \min\{|T|_p, \pi(\hat{T})\}$. Also let $\lambda = \max\{\mathsf{lcp}(\langle \hat{T}\rangle, \langle T[i..]\rangle) \mid 1 \leq i \leq |T|\}$. Although Algorithm 2 does not intend to compute the exact value of λ, it checks if λ falls in $[h_e..h_{e+1}]$ in decreasing order of e starting from $\min\{\pi(\hat{T}), \max\{\mathsf{LCP}_T^\infty[k], \mathsf{LCP}_T^\infty[k+1]\}\}$. One of the necessary conditions to have $\mathsf{lcp}(\langle \hat{T}\rangle, \langle T[i..]\rangle) > h_e$ is that $\mathsf{lcp}(\langle T\rangle, \langle T[i+1..]\rangle) \geq h_e$, or equivalently $\mathsf{lcp}^\infty(\langle T\rangle, \langle T[i+1..]\rangle) \geq e$. Line 2 computes the maximal interval $[l..r]$ that represents the ranks of the p-encoded suffixes having an lcp^∞-value larger than or equal to e. The basic idea is to find a p-encoded suffix in $\{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=l}^{r}$ that comes closest to $\langle \hat{T}\rangle$ when extended by adding its preceding symbol. Here let us call $\langle T[\mathsf{R}_T^{-1}(p)-1..]\rangle$ the *extended suffix* of $\langle T[\mathsf{R}_T^{-1}(p)..]\rangle$. When Algorithm 2 decreases e to the value with $\lambda \in [h_e+1..h_{e+1}]$, $\hat{k}$ is returned in one of the if-then-blocks at Lines 4, 5, 8 and 13.

If $\mathsf{lcp}(\langle \hat{T}\rangle, \langle T[i..]\rangle) = h_{\hat{e}}$ for an integer $\hat{e}$, there are two possible scenarios (see Figure 2 for an illustration):

(H1) $\mathsf{lcp}^\infty(\langle T\rangle, \langle T[i+1..]\rangle) \geq \hat{e}$ and either $\pi(\hat{T}) > \pi(T[i..]) = \hat{e}$ or $\pi(T[i..]) > \pi(\hat{T}) = \hat{e}$, and

(H2) $\mathsf{lcp}(\langle T\rangle, \langle T[i+1..]\rangle) = h_{\hat{e}} - 1$ and both $\pi(\hat{T})$ and $\pi(T[i..])$ are at least $\hat{e}$.

Case (H1) is processed in one of the if-then-blocks at Lines 6 and 18 when $e = \hat{e}$. while Case (H2) at Lines 4, 5, 8 and 13 when $e = \hat{e} - 1$. Note that p-encoded suffix of Case (H1) is never farther from $\langle \hat{T}\rangle$ than that of Case (H2) because the lexicographic order between $\langle \hat{T}\rangle$ and $\langle T[i..]\rangle$ is determined by ∞ and $h_{\hat{e}}$ at $h_{\hat{e}}+1$ in Case (H1), while it is by ∞ and something smaller than $h_{\hat{e}}$ in Case (H2). Since Algorithm 2 processes Case (H1) first, it guarantees that the algorithm finds the closer one first.

In what follows, we delve into the details of each code block.

If-then-block at Line 3. The case with $e = \pi(\hat{T})$ is treated differently than other cases in the if-then-block at Line 3 since $h_{\pi(\hat{T})}$ is the unique position where $\langle T\rangle[h_{\pi(\hat{T})}] = \infty$ turns into $\langle \hat{T}\rangle[h_{\pi(\hat{T})}+1] = h_{\pi(\hat{T})}$. For a p-encoded suffix $\langle T[\mathsf{R}_T^{-1}(q')..]\rangle \in \{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=l}^{r}$, having $\mathsf{L}_T[q'] = \pi(\hat{T})$ is necessary and sufficient for its extended suffix $\langle T[\mathsf{R}_T^{-1}(q')-1..]\rangle$ to have an lcp-value larger than $h_{\pi(\hat{T})}$ with $\langle \hat{T}\rangle$. By Corollary 6, p-encoded suffixes satisfying this condition must preserve their lexicographic order after extension, and hence, it is enough to search for the closest one ($q \leftarrow \mathsf{FPQ}_e(\mathsf{L}_T, k)$ or $q \leftarrow \mathsf{FNQ}_e(\mathsf{L}_T, k)$) to $\langle T\rangle$ and compute the rank of its

extended suffix by $\mathsf{LF}_T(q)$. If Lines 4 and 5 do not return a value, we know that $\lambda \leq h_{\pi(\hat{T})}$. The if-block at Line 6 checks if there exists a p-encoded suffix $\langle T[i{+}1..]\rangle$ that satisfies the condition of Case (H1) to be $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[i..]\rangle) = h_{\pi(\hat{T})}$. It is enough to find one $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$ with $\mathsf{L}_T[q] > \pi(\hat{T})$ because it is necessary and sufficient to have $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle) = h_{\pi(\hat{T})}$ and $\langle\hat{T}\rangle[h_{\pi(\hat{T})}+1] = \infty \neq h_{\pi(\hat{T})} = \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle[h_{\pi(\hat{T})}+1]$. Note that there could be two or more p-encoded suffixes that satisfy the condition and their lexicographic order may change by extension. In the then-block at Line 6, the algorithm computes the rank of the lexicographically smallest p-encoded suffix that has an lcp^∞-value larger than $\pi(\hat{T})$ with $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle = \langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q))..]\rangle$, which is the p-succ of $\langle\hat{T}\rangle$ in this case.

Precondition to enter Line 7. The case with $e \neq \pi(\hat{T})$ is processed in the else-block at Line 7. Here, it is good to keep in mind that when we enter this else-block, $\mathsf{lcp}^\infty(\langle T\rangle, \langle T[i..]\rangle) \leq e$ or $\pi(T[i-1..]) \leq e$ holds for any proper suffix $T[i..]$ of T, since otherwise $\hat{k}$ must be reported in a previous round of the foreach loop.

If-then-block at Line 8. When the if-condition at Line 8 holds, $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$ is the lexicographically smaller closest p-encoded suffix to $\langle T\rangle$ such that $\mathsf{lcp}^\infty(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle) \geq e+1$, or equivalently $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle) > h_e$. Note that $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle < \langle\hat{T}\rangle$ must hold, since otherwise, $T[\mathsf{R}_T^{-1}(q)-1..]$ and $\langle\hat{T}\rangle$ would fall into Case (B3) with $\mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle, \langle\hat{T}\rangle) = \pi(\hat{T})$, and $\hat{k}$ should be reported at Line 6 in a previous round. For any p-encoded suffix in $\{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=q+1}^{k-1}$ its extended suffix is lexicographically smaller than $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$ due to Corollary 7, and never closer to $\langle\hat{T}\rangle$ than $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$. If $|T[\mathsf{R}_T^{-1}(q)..]|_p \geq e+1$, the interval $[l'..r']$ computed at Line 9 is the maximal interval such that every p-encoded suffix in $\{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=l'}^{r'}$ shares the common prefix of length $h' := \mathsf{select}_\infty(\langle T[\mathsf{R}_T^{-1}(q)..]\rangle, e+1)$ with $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$. In the case with $|T[\mathsf{R}_T^{-1}(q)..]|_p = e$, `GetMI(`$q$`,` $e+1$`)` returns $[q..q]$ and let us define h' to be $|T[\mathsf{R}_T^{-1}(q)..]|$.

Since any $\langle T[i..]\rangle \in \{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=1}^{l'-1}$ has an lcp-value smaller than h' with $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$, it follows from Table 1 that $\langle T[i-1..]\rangle < \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$. Also, for any $\langle T[i..]\rangle \in \{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=k+1}^{|T|}$, the aforementioned precondition to enter the else-block at Line 7 implies that $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle < \langle T[i-1..]\rangle < \langle\hat{T}\rangle$ cannot happen: If $\mathsf{lcp}^\infty(\langle T\rangle, \langle T[i..]\rangle) < e$ or $\pi(T[i-1..]) \leq e$, then $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[i-1..]\rangle) \leq h_e < \mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle)$ leads to the conclusion. For the remaining case with $\mathsf{lcp}^\infty(\langle T\rangle, \langle T[i..]\rangle) = e$ and $\pi(T[i-1..]) > e$, it holds that $\langle\hat{T}\rangle < \langle T[i-1..]\rangle$ due to Case (B4) of Table 1.

In the previous paragraph we have confirmed that the lcp-value between $\langle\hat{T}\rangle$ and its p-pred is at most h', which implies that the p-pred is the largest p-encoded suffix that is prefixed by $x := \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle[..h']$. If $q' \leftarrow \mathsf{FPQ}_{\geq e+2}(\mathsf{L}_T, r')$ computed at Line 10 is in $[l'..r']$, $\langle T[\mathsf{R}_T^{-1}(q')-1..]\rangle = \langle T[\mathsf{LF}_T(q')..]\rangle$ is prefixed by $x\cdot\infty$ and the p-pred is the largest p-encoded suffix that is prefixed by $x\cdot\infty$, which can be computed by $\max \mathtt{GetMI}(\mathsf{LF}_T(q'), e+2)$ because $\langle T[\mathsf{R}_T^{-1}(q')-1..]\rangle[..h'+1] = \langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q')..]\rangle[..h'+1] = x\cdot\infty$ contains exactly $e+2$ ∞'s. If $q' \notin [l'..r']$, the p-pred is the largest p-encoded suffix that is prefixed by $x\cdot h'$ (or $x\cdot\$$ for the case with $|T[\mathsf{R}_T^{-1}(q)..]|_p = e$), which is $\langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q))..]\rangle$.

If-then-block at Line 13. When the if-condition at Line 13 holds, $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$ is the lexicographically larger closest p-encoded suffix to $\langle T\rangle$ such that $\mathsf{lcp}^\infty(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q){-}1..]\rangle) \geq e+1$, or equivalently $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle) > h_e$. Note that $\langle\hat{T}\rangle < \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$ must hold, since otherwise, $\langle\hat{T}\rangle$ and $T[\mathsf{R}_T^{-1}(q)-1..]$ would fall into Case (B3) with $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle) = h_{\hat{e}}$ for some $\hat{e} > e$, and $\hat{k}$ should be reported at Line 18 of a previous round. For any p-encoded suffix in $\{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=k+1}^{q-1}$ its extended suffix is lexicographically smaller than $\langle\hat{T}\rangle$ due to Corollary 7, and never come lexicographically between $\langle\hat{T}\rangle$ and $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$. If $|T[\mathsf{R}_T^{-1}(q)..]|_p \geq e+1$, the interval $[l'..r']$ computed

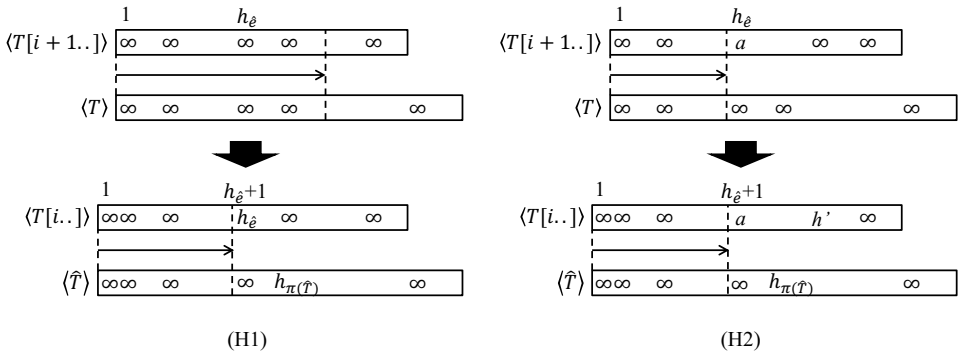

Figure 2 Illustration for Cases (H1) and (H2) in which $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[i..]\rangle) = h_{\hat{e}}$ for an integer $\hat{e}$. The left part shows one of the situations for Case (H1) where $\mathsf{lcp}^{\infty}(\langle T\rangle, \langle T[i+1..]\rangle) \geq \hat{e}$ and $\pi(\hat{T}) > \pi(T[i..]) = \hat{e}$. The right part shows one of the situations for Case (H2) where $\mathsf{lcp}(\langle T\rangle, \langle T[i+1..]\rangle) = h_{\hat{e}} - 1$, $\pi(\hat{T}) > h_{\hat{e}}$ and $\pi(T[i..]) > h_{\hat{e}}$.

at Line 14 is the maximal interval such that every p-encoded suffix in $\{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=l'}^{r'}$ shares the common prefix of length $h' := \mathsf{select}_{\infty}(\langle T[\mathsf{R}_T^{-1}(q)..]\rangle, e+1)$ with $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$. In the case with $|T[\mathsf{R}_T^{-1}(q)..]|_p = e$, `GetMI(`$q$, $e+1$`)` returns $[q..q]$ and let us define h' to be $|T[\mathsf{R}_T^{-1}(q)..]|$.

For any $\langle T[i..]\rangle \in \{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=1}^{k-1}$, the aforementioned precondition to enter the else-block at Line 7 implies that $\langle T[i-1..]\rangle < \langle\hat{T}\rangle$ because Case (B3) of Table 1 cannot hold under the condition of $\mathsf{lcp}^{\infty}(\langle T\rangle, \langle T[i..]\rangle) \leq e$ or $\pi(T[i-1..]) \leq e$. For any $\langle T[i..]\rangle \in \{\langle T[\mathsf{R}_T^{-1}(p)..]\rangle\}_{p=r'+1}^{|T|}$, we show that $\langle\hat{T}\rangle < \langle T[i-1..]\rangle < \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$ cannot happen: Note that $\mathsf{lcp}^{\infty}(\langle T[\mathsf{R}_T^{-1}(q)..]\rangle, \langle T[i..]\rangle) \leq e$ by definition, and $\mathsf{lcp}^{\infty}(\langle T[\mathsf{R}_T^{-1}(q)..]\rangle, \langle T[i..]\rangle) < e$ implies $\mathsf{lcp}^{\infty}(\langle T\rangle, \langle T[i..]\rangle) = \mathsf{lcp}^{\infty}(\langle T[\mathsf{R}_T^{-1}(q)..]\rangle, \langle T[i..]\rangle)$. If $\mathsf{lcp}^{\infty}(\langle T[i..]\rangle, \langle T[\mathsf{R}_T^{-1}(q)..]\rangle) < e$ or $\pi(T[i-1..]) \leq e$, $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[i-1..]\rangle) \leq h_e < \mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle)$ leads to the conclusion. For the remaining case with $\mathsf{lcp}^{\infty}(\langle T[i..]\rangle, \langle T[\mathsf{R}_T^{-1}(q)..]\rangle) = e$ and $\pi(T[i-1..]) > e$, it holds that $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle < \langle T[i-1..]\rangle$ due to Case (B4) of Table 1.

In the previous paragraph we have confirmed that the lcp-value between $\langle\hat{T}\rangle$ and its p-succ is at most h', which implies that the p-succ is the smallest p-encoded suffix that is prefixed by $x := \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle[..h']$. If $q' \leftarrow \mathsf{FNQ}_{e+1}(\mathsf{L}_T, l')$ computed at Line 15 is in $[l'..r']$, the p-succ is the smallest p-encoded suffix that is prefixed by $x \cdot h'$ (or $x \cdot \$$ for the case with $|T[\mathsf{R}_T^{-1}(q)..]|_p = e$), which is $\langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q'))..]\rangle$. If $q' \notin [l'..r']$, the p-succ is the smallest p-encoded suffix that is prefixed by $x \cdot \infty$, which can be computed by $\min$ `GetMI(`$\mathsf{LF}_T(q), e+2$`)` because $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle[..h'+1] = \langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q))..]\rangle[..h'+1] = x \cdot \infty$ contains exactly $e+2$ ∞'s.

If-then-block at Line 18. When we enter the if-then-block at Line 18, it is guaranteed that $\lambda \leq h_e$. In order to check if there exists a p-encoded suffix $\langle T[i+1..]\rangle$ that satisfies the condition of Case (H1) to be $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[i..]\rangle) = h_e$, the algorithm computes $q \leftarrow \mathsf{FPQ}_e(\mathsf{L}_T, r)$. If $q \in [l..r]$, $\langle T[\mathsf{R}_T^{-1}(q)..]\rangle$ is the lexicographically largest p-encoded suffix that satisfies the condition, and by Corollary 6, its extended suffix $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$ must be the largest one to have $\mathsf{lcp}(\langle\hat{T}\rangle, \langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle) = h_e$. Therefore, $\langle T[\mathsf{R}_T^{-1}(q)-1..]\rangle$ is the p-pred of $\langle\hat{T}\rangle$, and $\hat{k} = 1 + \mathsf{LF}_T(q)$. ◀

Algorithm 2 Algorithm to compute $\hat{k}$.

```
1  foreach e ← min{π(T̂), max{LCP∞_T[k], LCP∞_T[k+1]}} down to 1 do
2      [l..r] ← GetMI(k, e);
3      if e = π(T̂) then
4          if (q ← FPQ_e(L_T, k)) ∈ [l..r] then return 1 + LF_T(q) ;
5          if (q ← FNQ_e(L_T, k)) ∈ [l..r] then return LF_T(q) ;

```

3.2 How to maintain $\mathsf{LCP}^{\infty}_{T}$

Suppose that we have $k = \mathsf{R}_T(1)$, $\hat{k} = \mathsf{R}_{\hat{T}}(1)$, L_T, F_T. We show how to compute the lcp^{∞}-values of $\langle \hat{T} \rangle$ with its p-pred $\langle T[\mathsf{R}_T^{-1}(\hat{k}) - 1..] \rangle$ and p-succ $\langle T[\mathsf{R}_T^{-1}(\hat{k})..] \rangle$ to maintain $\mathsf{LCP}^{\infty}_{T}$.

We focus on $\mathsf{lcp}^{\infty}(\langle \hat{T} \rangle, \langle T[\mathsf{R}_T^{-1}(\hat{k})..] \rangle)$ because the other one can be treated similarly. We apply Table 1 by setting $x = \hat{T}$ and $y = T[\mathsf{R}_T^{-1}(\hat{k})..]$ if $k < \mathsf{FL}_T(\hat{k})$ (otherwise we swap their roles for x and y). In order to get $\mathsf{lcp}^{\infty}(\langle x \rangle, \langle y \rangle)$, all we need are $\pi(x) = \pi(\hat{T})$, $\pi(y) = \mathsf{F}[\hat{k}]$ and $e = \mathsf{lcp}^{\infty}(\langle x[2..] \rangle, \langle y[2..] \rangle)$. For the computation of e we use Lemma 10, i.e., $e = \mathsf{lcp}^{\infty}(\langle x[2..] \rangle, \langle y[2..] \rangle) = \mathsf{RmQ}_{\mathsf{LCP}^{\infty}_{T}}(k+1, \mathsf{FL}_T(\hat{k}))$.

3.3 Dynamic data structures and analysis

Let σ_s and respectively $\sigma_p := |T|_p$ be the numbers of distinct s-symbols and p-symbols that appear in T and $\sigma = \sigma_s + \sigma_p$. We consider constructing F_T, L_T and $\mathsf{LCP}^{\infty}_{T}$ online for a p-string T of length n over an alphabet $(\Sigma_s \cup \Sigma_p)$ of size $n^{O(1)}$. To this end, we introduce data structures for implementing our algorithm, which we presented in the previous subsections.

To obtain our claimed space bounds of $O(n \lg \sigma)$ bits, we maintain a naming function that maps the set of distinct s-symbols indexed in the pBWT from Σ_s to the range of ranks $[1..\sigma_s]$. By doing so, we can represent and store each s-symbol in the pBWT by its rank. Thus, each s-symbol in F_T and L_T consumes $O(\lg \sigma_s)$ bits instead of $O(\lg n)$ bits.

In the following we present two alternative implementations for the naming function. The first one imposes a new order on the s-symbols such that the computed F_T and L_T arrays may arrange s-symbols differently than the standard pBWT built on the plain s-symbols. The second one keeps the order of the s-symbols, but needs an additional scan of the input text T to determine the order *prior to* the computation of the pBWT.

1. Our first approach updates the naming function in the same online fashion as computing the pBWT. To this end, we represent the naming function by a dynamic associative array using $O(\sigma_s \lg n) = O(n \lg \sigma_s)$ bits of space and taking $O(\frac{\lg \sigma_s}{\lg \lg \sigma_s})$ operation time like [21]. Setting initially $\sigma_s = 0$, we update σ_s and the naming function whenever we read a new s-symbol. In detail, when we read a new s-symbol with integer representation x with a yet-undefined rank (meaning it is not yet stored in the associative array), we increment σ_s by one, and insert the integer key x associated with the value σ_s into the associative array. The assignment of the ranks is done in a *first come first served* order, meaning that the order of two s-symbols is determined by whose rightmost occurrence in the text has the larger text position (since we build the pBWT online reading symbols from the right end). Changing the alphabet order neither invalidates the LF-mapping nor the backward search.[3] However, there is a subtle caveat in that this approach needs to know σ_s in advance (or at least a close upper bound σ'_s with $\sigma'_s = c\sigma$ for a constant $c \geq 1$). Otherwise, we need to spend some extra time on reconstructing all dynamic data structures working with s-symbols. That is because, for steady increases of σ_s, there is point where we no longer can represent a s-symbol rank in just $\lceil \lg \sigma_s \rceil$ bits, but need $1 + \lceil \lg \sigma_s \rceil$ bits instead. Instead of rebuilding all data structures storing s-symbol ranks on every increase of $\lceil \lg \sigma_s \rceil$, we initially accommodate each s-symbol with $2\lceil \lg \sigma_s \rceil$ bits, and double this space whenever necessary.[4] By doing so, the number of bits per s-symbol increases from constant to $\Theta(\lg \sigma_s)$ exponentially, and thus the number of total rebuilding steps is bounded by $O(\lg \lg \sigma_s)$, where σ_s denotes the final number of distinct s-symbols indexed by the pBWT. Thus the final construction time stated in Theorem 1 becomes $O(n \frac{(\lg \sigma_p + \lg \lg \sigma_s) \lg n}{\lg \lg n})$, based on the fact that querying or updating the dynamic data structures representing F_T and L_T needs $O(\frac{\lg n}{\lg \lg n})$ time per entry, as we will later see in Lemma 13.
   For computing b in Lemma 9 for a given s-symbol c, we process as follows. Given c has been assigned the rank r, then $b = r - 1$. Otherwise, c has not been ranked, and thus $b = \sigma_s$ since c will receive a rank larger than all other s-symbols indexed in the pBWT.
2. However, if this imposed order is not desirable in some setting, it is possible to assign ranks reflecting the initial order of Σ_s. For that, we note that the aforementioned implementation [21] also supports a sorted traversal of the keys. Thus, it is sufficient to (a) build this associative array while scanning the entire text T, (b) reassign each key a new rank determined by a sorted traversal of the associative array, and finally (c) start the pBWT computation. This, of course, needs to read T twice instead of once.
   Unfortunately, since we keep the initial alphabet order of the s-symbols, determining b in Lemma 9 becomes nontrivial. For computing the value of b, we maintain the set of s-symbols used in the currently computed pBWT by a dynamic fusion tree [34] taking $O(\sigma_s \lg n) = O(n \lg \sigma_s)$ bits. The fusion tree allows us then to compute b in $O(\frac{\lg \sigma_s}{\lg \lg \sigma_s})$ time.

Next, we maintain F_T by a dynamic string of Lemma 3 supporting random access, insertion, rank and select queries in $O(\frac{\lg n}{\lg \lg n})$ time and $O(n \lg \sigma)$ bits of space. For LCP^{∞}_T we maintain a dynamic string of Lemma 4 to support random access, insertion, RmQ, FPQ and FNQ queries in $O(\frac{\lg \sigma_p \lg n}{\lg \lg n})$ time and $O(n \lg \sigma_p)$ bits of space.

[3] Changing the alphabet order for optimizing the compressibility of the BWT is actually an actively researched topic [5].

[4] While this seems like a standard trick for amortizing the costs of dynamic arrays, the amortization argument does not hold here in general because the cost parameter σ_s and the array length n can be independent. For instance, imagine that we first read $n/2$ times the same s-symbol from the input, and then start to read only distinct s-symbols.

If we build a dynamic string of Lemma 4 for L_T, the query time would be $O(\frac{\lg \sigma \lg n}{\lg \lg n})$. Since our algorithm does not use RmQ, FPQ and FNQ queries for s-symbols, we can reduce the query time to $O(\frac{\lg \sigma_p \lg n}{\lg \lg n})$ as follows. We represent L_T with one level of a wavelet tree, where a bit vector partitions the alphabet into Σ_s and $[1..|T|_p]$ and thus has pointers to X_T and Y_T storing respectively the sequence over Σ_s and that over $[1..|T|_p]$ of L_T. We represent the former and the latter by the data structures described in Lemmas 3 and 4, respectively, since we only need the aforementioned queries such as RmQ on Y_T. Then, queries on L_T can be answered in $O(\frac{\lg \sigma_p \lg n}{\lg \lg n})$ time using $O(n \lg \sigma)$ bits of space.

In addition to these dynamic strings for F_T, L_T and LCP^{∞}_T, we consider maintaining another dynamic string Z_T, a string that is obtained by extracting the leftmost occurrence of every p-symbol in T. Note that $|Z_T| = \sigma_p \leq n$. A dynamic string Z_T of Lemma 3 enables us to compute $\pi(cT)$ for a p-symbol c by $\pi(cT) = \min\{\infty, \mathsf{select}_c(Z_T, 1)\}$ in $O(\frac{\lg \sigma_p}{\lg \lg \sigma_p})$ time and $O(\sigma_p \lg \sigma_p)$ bits of space.

We are now ready to prove the following lemma.

▶ **Lemma 13.** *F_T, L_T and LCP^{∞}_T for a p-string of length n over an alphabet $(\Sigma_s \cup \Sigma_p)$ of size $n^{O(1)}$ can be constructed online in $O(n\frac{\lg \sigma_p \lg n}{\lg \lg n})$ time and $O(n \lg \sigma)$ bits of space, where σ_s and respectively σ_p are the numbers of distinct s-symbols and p-symbols used in the p-string and $\sigma = \sigma_s + \sigma_p$.*

Proof. We maintain the dynamic data structures of $O(n \lg \sigma)$ bits described in this subsection while prepending a symbol to the current p-string. For a single step of updating T to $\hat{T} = cT$ with $c \in (\Sigma_s \cup \Sigma_p)$, we compute $\hat{k} = \mathsf{R}_{\hat{T}}(1)$ as described in Subsection 3.1 and obtain $\mathsf{F}_{\hat{T}}$ and $\mathsf{L}_{\hat{T}}$ by replacing \$ in L_T at $k = \mathsf{R}_T(1)$ by $\pi(\hat{T})$ and inserting \$ and $\pi(\hat{T})$ into the $\hat{k}$-th position of L_T and F_T, respectively. LCP^{∞}_T is updated as described in Subsection 3.2.

If $c \in \Sigma_s$, the computation of $\hat{k}$ based on Lemma 9 requires a constant number of queries. If $c \in \Sigma_p$, Algorithm 2 computes $\hat{k}$ invoking $O(2 + e - \hat{e})$ queries, where $e = \max\{\mathsf{LCP}^{\infty}_T[k], \mathsf{LCP}^{\infty}_T[k+1]\}$ and $\hat{e} = \max\{\mathsf{LCP}^{\infty}_{\hat{T}}[\hat{k}], \mathsf{LCP}^{\infty}_{\hat{T}}[\hat{k}+1]\}$. The value e can be seen as a potential held by the current string T, which upper bounds the number of queries. The number of queries in a single step can be $O(\sigma_p)$ in the worst case when e and $\hat{e}$ are close to σ_p and respectively 0, but this will reduce the potential for later steps, which allows us to give an amortized analysis. Since a single step increases the potential at most 1 by Corollary 5, the total number of queries can be bounded by $O(n)$.

Since we invoke $O(n)$ queries that take $O(\frac{\lg \sigma_p \lg n}{\lg \lg n})$ time each, the overall time complexity is $O(n\frac{\lg \sigma_p \lg n}{\lg \lg n})$. ◀

4 Extendable compact index for p-matching

In this section, we show that L_T, F_T and LCP^{∞}_T can serve as an index for p-matching.

First we show that we can support backward search, a core procedure of BWT-based indexes, with the data structures for L_T, F_T and LCP^{∞}_T described in Subsection 3.3. For any p-string w, let *w-interval* be the maximal interval $[l..r]$ such that $\langle T[\mathsf{R}_T^{-1}(p)..]\rangle$ is prefixed by $\langle w \rangle$ for any $p \in [l..r]$. We show the next lemma for a single step of the backward search, which computes *cw-interval* from w-interval.

▶ **Lemma 14.** *Suppose that we have data structures for L_T, F_T and LCP^{∞}_T described in Subsection 3.3. Given w-interval $[l..r]$ and $c \in (\Sigma_s \cup \Sigma_p)$, we can compute cw-interval $[l'..r']$ in $O(\frac{\lg \sigma_p \lg n}{\lg \lg n})$ time.*

Proof. We show that we can compute cw-interval from w-interval using a constant number of queries supported on L_T, F_T and $\langle \hat{T} \rangle$, which takes $O(\frac{\lg \sigma_p \lg n}{\lg \lg n})$ time each.

- When c is in Σ_s: A p-encoded suffix $\langle T[\mathsf{R}_T^{-1}(p)-1..]\rangle = \langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(p))..]\rangle$ is prefixed by $\langle cw\rangle$ if and only if $\langle T[\mathsf{R}_T^{-1}(p)..]\rangle$ is prefixed by $\langle w\rangle$ and $\mathsf{L}_T[p] = c$. In other words, $\mathsf{LF}_T(p) \in [l'..r']$ if and only if $p \in [l..r]$ and $\mathsf{L}_T[p] = c$. Then it holds that $l' = \mathsf{LF}_T(\mathsf{FNQ}_c(\mathsf{L}_T, l))$ and $r' = \mathsf{LF}_T(\mathsf{FPQ}_c(\mathsf{L}_T, r))$ due to Corollary 6.
- When c is a p-symbol that appears in w: Similar to the previous case, $\mathsf{LF}_T(p) \in [l'..r']$ if and only if $p \in [l..r]$ and $\mathsf{L}_T[p] = \pi(cw)$. Then it holds that $l' = \mathsf{LF}_T(\mathsf{FNQ}_{\pi(cw)}(\mathsf{L}_T, l))$ and $r' = \mathsf{LF}_T(\mathsf{FPQ}_{\pi(cw)}(\mathsf{L}_T, r))$ due to Corollary 6.
- When c is a p-symbol that does not appear in w: Let $e = |w|_p$. Since $p \in [l..r]$ and $\mathsf{L}_T[p] > e$ are necessary and sufficient conditions for $\mathsf{LF}_T(p)$ to be in $[l'..r']$, we can compute $r' - l' + 1$, the width of $[l'..r']$, by counting the number of positions p such that $\mathsf{L}_T[p] > e$ with $p \in [l..r]$. This can be done with 2D range counting queries, which can also be supported with the wavelet matrix of Lemma 4. If $s = \mathsf{FNQ}_{\geq e+1}(\mathsf{L}_T, l)$ is in $[l..r]$, it holds that $r' - l' + 1 \neq 0$ and $\mathsf{LF}_T(s) \in [l'..r']$. Note that $\mathsf{LF}_T(s)$ is not necessarily l' because p-encoded suffixes $\langle T[\mathsf{R}_T^{-1}(p)..]\rangle$ with $\mathsf{L}_T[p] > e$ in $[l..r]$ do not necessarily preserve the lexicographic order when they are extended by one symbol to the left, making it non-straightforward to identify the position l'.
  To tackle this problem, we consider

  $$[l_e..r_e] = \mathtt{GetMI}(s, e) \text{ and } [l'_{e+1}..r'_{e+1}] = \mathtt{GetMI}(\mathsf{LF}_T(s), e+1),$$

  and show that $l' = l'_{e+1} + x$, where x is the number of positions p in $[l_e..l-1]$ with $\mathsf{L}_T[p] > e$. Observe that $[l..r] \subseteq [l_e..r_e]$ and $[l'..r'] \subseteq [l'_{e+1}..r'_{e+1}]$ by definition, and that $\mathsf{LF}_T(p) \in [l'_{e+1}..r'_{e+1}]$ if and only if $p \in [l_e..r_e]$ and $\mathsf{L}_T[p] > e$ (see Figure 3 for an illustration). Also, it holds that $\langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(p))..]\rangle < \langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q))..]\rangle$ for any $p \in [l_e..l-1]$ and $q \in [l..r]$ satisfying $\mathsf{L}_T[p] > e$ and $\mathsf{L}_T[q] > e$ because $\mathsf{lcp}^\infty(\langle T[\mathsf{R}_T^{-1}(p)..]\rangle, \langle T[\mathsf{R}_T^{-1}(q)..]\rangle) = e$, and they fall into Case (B4) of Table 1. Similarly for any $p \in [l..r]$ and $q \in [r+1..r_e]$ satisfying $\mathsf{L}_T[p] > e$ and $\mathsf{L}_T[q] > e$, we have $\langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(p))..]\rangle < \langle T[\mathsf{R}_T^{-1}(\mathsf{LF}_T(q))..]\rangle$. Hence, $l' = l'_{e+1} + x$ holds.

This concludes the proof. ◀

We are now ready to prove Theorem 1, which we restate here:

▶ **Theorem 1.** *For a p-string T of length n over an alphabet $(\Sigma_s \cup \Sigma_p)$ of size $n^{O(1)}$, an index of T for p-matching can be constructed online in $O(n\frac{\lg \sigma_p \lg n}{\lg\lg n})$ time and $O(n \lg \sigma)$ bits of space, where σ_s and respectively σ_p are the numbers of distinct s-symbols and p-symbols used in the p-string and $\sigma = \sigma_s + \sigma_p$. At any stage of the online construction, it can support the counting queries in $O(m\frac{\lg \sigma_p \lg n}{\lg\lg n})$ time, where m is the length of a given pattern for queries. By building an additional data structure of $O(\frac{n}{\Delta}\lg n)$ bits of space for a chosen parameter $\Delta \in \{1, 2, \ldots, n\}$ the locating queries can be supported in $O(m\frac{\lg \sigma_p \lg n}{\lg\lg n} + \mathsf{occ}\frac{\Delta \lg n}{\lg\lg n})$ time, where occ is the number of occurrences to be reported.*

Proof of Theorem 1. If we only need counting queries, Lemmas 13 and 14 are enough: While we build L_T, F_T and LCP_T^∞ online, we can compute w-interval $[l..r]$ for a given pattern w of length m using Lemma 14 successively m times, spending $O(m\frac{\lg \sigma_p \lg n}{\lg\lg n})$ time in total.

Since $\{\mathsf{R}_T^{-1}(i) \mid i \in [l..r]\}$ is the set of occurrences of w in T, we consider how to access $\mathsf{R}_T^{-1}(i)$ in $O(\frac{\Delta \lg n}{\lg\lg n})$ time to support locating queries. As is common in BWT-based indexes, we employ a sampling technique (e.g., see [10]): For every $\Theta(\Delta)$ text positions we store the values so that if we apply LF/FL-mapping to i successively at most $\Theta(\Delta)$ times we hit one of the sampled text positions. A minor remark is that since our online construction proceeds from right to left, it is convenient to start sampling from the right-end of T and store the distance to the right-end instead of the text position counted from the left-end of T.

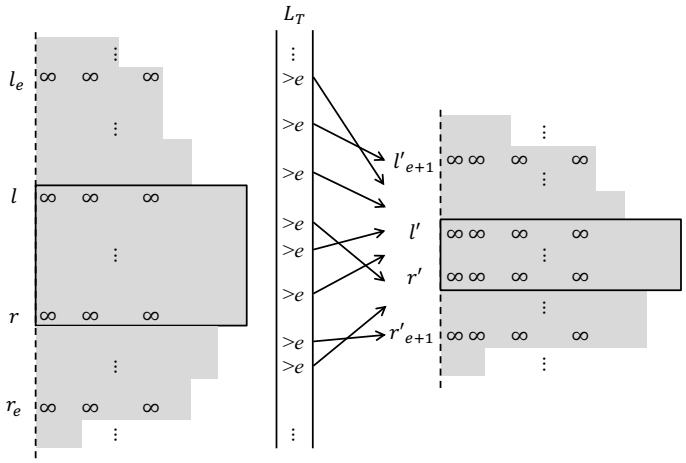

Figure 3 Illustration for the computation of cw-interval $[l'..r']$ from w-interval $[l..r]$ for the case when c is a p-symbol that does not appear in w with $e = |w|_p = 3$. The left (resp. right) part shows sorted p-encoded suffixes around $[l..r]$ (resp. $[l'..r']$) with grayed areas representing the longest common prefix between w (resp. cw) and each p-encoded suffix. The figure illustrates that each position $p \in [l_e..l-1]$ with $\mathsf{L}_T[p] > e$ is mapped to $[l'_{e+1}..l'-1]$ by the LF-mapping.

During the online construction of the data structures for L_T, F_T and LCP^{∞}_T, we additionally maintain a dynamic bit vector of length n and a dynamic integer string V_T of length $O(n/\Delta)$, which marks the sampled positions and stores sampled values, respectively. We implement V_T with the dynamic string of Lemma 3 in $O(\frac{n}{\Delta}\lg n)$ bits with $O(\frac{\lg n}{\lg\lg n})$ query times. In order to support LF/FL-mapping in $O(\frac{\lg n}{\lg\lg n})$ time, we also maintain L_T by an instance of the dynamic string of Lemma 3. Using these data structures, we can access $\mathsf{R}^{-1}_T(i)$ in $O(\frac{\Delta\lg n}{\lg\lg n})$ time as we use LF/FL-mapping at most $O(\Delta)$ times. This leads to the claimed time bound for locating queries. ◀

5 Constructing parameterized suffix arrays in compact space

The parameterized suffix array of a p-string T of length n is the n-length integer array PSA_T with $\mathsf{PSA}_T[i] = \mathsf{R}^{-1}_T(i)$ for any $1 \le i \le n$. We now prove Theorem 2:

▶ **Theorem 2.** *For a p-string T of length n over an alphabet $(\Sigma_s \cup \Sigma_p)$ of size $n^{O(1)}$, the parameterized suffix array of T can be constructed in $O(n\frac{\lg\sigma_p\lg n}{\lg\lg n})$ time and $O(n\lg\sigma)$ bits of space, where σ_s and respectively σ_p are the numbers of distinct s-symbols and p-symbols used in the p-string and $\sigma = \sigma_s + \sigma_p$.*

Proof of Theorem 2. Using Lemma 13, we can build F_T and L_T in $O(n\frac{\lg\sigma_p\lg n}{\lg\lg n})$ time and $O(n\lg\sigma)$ bits of working space, which supports the LF-mapping in $O(\frac{\lg\sigma_p\lg n}{\lg\lg n})$ time. After reserving $n\lg n$ bits space for the array PSA_T, we fill PSA_T in decreasing order of its values starting from $\mathsf{PSA}_T[1] = n$. By definition of the LF-mapping, given a position i with $\mathsf{PSA}_T[i] = x > 1$, the position i' with $\mathsf{PSA}_T[i'] = x-1$ can be computed by $i' = \mathsf{LF}_T(i)$. Therefore, all values of PSA_T can be filled with n applications of the LF-mappings, leading to $O(n\frac{\lg\sigma_p\lg n}{\lg\lg n})$ time in total. ◀

6 Concluding remarks

We have proposed a construction of a BWT-based compact index for p-matching, which works in compact space and in an online manner. BWT-based indexes have been proposed for other generalized pattern matching like structural pattern matching [17], order preserving matching [15], Cartesian tree matching [23], palindrome pattern matching [30] and circular parameterized pattern matching [33]. Generalized pattern matching listed above has a common feature that their underlying equivalent relations are substring consistent [27]. Since previous work has shown that similar techniques can often be applied to this class of generalized pattern matching, it is of great interest to see if the techniques presented in this paper can also be used for constructing other BWT-based indexes.

Abstract

We consider the PageRank problem in the dynamic setting, where the goal is to explicitly maintain an approximate PageRank vector $\pi \in \mathbb{R}^n$ for a graph under a sequence of edge insertions and deletions. Our main result is a complete characterization of the complexity of dynamic PageRank maintenance for both multiplicative and additive (L_1) approximations.

First, we establish matching lower and upper bounds for maintaining additive approximate PageRank in both incremental and decremental settings. In particular, we demonstrate that in the worst-case $(1/\alpha)^{\Theta(\log \log n)}$ update time is necessary and sufficient for this problem, where α is the desired additive approximation. On the other hand, we demonstrate that the commonly employed ForwardPush approach performs substantially worse than this optimal runtime. Specifically, we show that ForwardPush requires $\Omega(n^{1-\delta})$ time per update on average, for any $\delta > 0$, even in the incremental setting.

For multiplicative approximations, however, we demonstrate that the situation is significantly more challenging. Specifically, we prove that any algorithm that explicitly maintains a constant factor multiplicative approximation of the PageRank vector of a directed graph must have amortized update time $\Omega(n^{1-\delta})$, for any $\delta > 0$, even in the incremental setting, thereby resolving a 13-year old open question of Bahmani et al. (VLDB 2010). This sharply contrasts with the undirected setting, where we show that $\operatorname{poly}\log n$ update time is feasible, even in the fully dynamic setting under oblivious adversary.

1 Introduction

The notion of PageRank was introduced by Brin and Page 25 years ago to rank web search results [7]. Since then, computing the PageRank of a network has become a fundamental task in data mining [23]. At a high level, PageRank is a probability distribution over the vertices

of a directed graph which assigns higher probability to more "central" vertices; see Section 2 for a formal definition. We write $\pi \in \mathbb{R}^n$ to denote PageRank probability vector, where π_i is the probability mass on the i-th vertex. Due to its importance, it has been studied extensively in a number of computational models. In this paper, we consider the PageRank problem in the dynamic setting, in which the goal is to maintain an approximate PageRank vector $\tilde{\pi} \in \mathbb{R}^n$ of a graph undergoing a sequence of edge insertions and deletions. We focus primarily on explicit maintainance of the PageRanks, meaning that the algorithm explicitly maintains $\tilde{\pi}$ in its memory contents at all time steps; we remark that all prior algoriths for the problem of maintaining all PageRanks in the dynamic setting have been of this form.

We consider *three* different settings, which differ in the allowed sets of operations. In the *incremental* setting, edges can only be added to the graph. Analogously, in the *decremental* setting, edges can only be deleted. The most general setting is the *fully dynamic* setting in which we allow both types of updates. We also consider two notions of approximation. A $1+\alpha$ *multiplicative approximation* to the PageRank vector π is a vector $\tilde{\pi}$, such that for every vertex v it holds $\tilde{\pi}_v \in [(1-\alpha)\pi_v, (1+\alpha)\pi_v]$. An *additive* α *approximation* is a vector $\tilde{\pi}$ such that $\|\tilde{\pi} - \pi\|_1 \leq \alpha$.[1] We note that a multiplicative guarantee is strictly stronger, as a multiplicative $1+\alpha$ approximation implies an additive α approximation.

Previous work on dynamic PageRank [4, 11, 24, 5, 10] resulted in two main approaches to the problem. The first one is based on sampling random walks. Specifically, it is well-known that one can approximate PageRank by sampling $O(\log n)$ random walks of length $O(\log n)$ from each vertex in the graph (see Algorithm 1).

In a seminal paper, Bahmani et al. [4] showed that this approach can be made dynamic. Specifically, the algorithm of Bahmani et al. maintains a *multiplicative* $1+\alpha$ approximation of incremental (or decremental) PageRank when the updates *arrive in a random order*. However, their analysis crucially relies on the random arrival of updates, and it was not clear whether this assumption could be removed. The authors of [4] explicitly posed the question of whether it is possible to extend their results for multiplicative approximations to the case of adversarially ordered updates; to date, this question has remained open.

The second approach to computing dynamic PageRank is a dynamic version of the ForwardPush algorithm [25, 1, 9], which is a variant of a classical local push approach proposed by [3]. This algorithm was developed for the problem of maintaining Personalized PageRank, but can also be naturally used to maintain an additive PageRank approximation. While this approach is highly effective in practice, no running time bounds faster than running a static algorithm from scratch after each update have been developed for maintaining PageRank using the dynamic ForwardPush method.[2]

Thus, despite the above line of work, many fundamental questions regarding the computational cost of maintaining PageRank in a dynamic setting remain open. Specifically, it is still open whether there exists an algorithm for maintaining a approximation to PageRank in $o(n)$ time per update. This question is open even if one considers only incremental or decremental updates, or if one allows additive approximation. In this paper, we answer each of these open questions. More precisely, we characterize the complexity of solving the dynamic PageRank problem in each of these settings by providing new upper and lower bounds.

---

[1] Note that this coincides with the total variational distance between distributions.

[2] We note that the paper introducing the dynamic ForwardPush algorithm gives a good running time bound for running the algorithm in *undirected* graphs. However, this bound only holds for computing Personalized PageRank from a *uniformly random* source vertex. Even though PageRank can be reduced to Personalized PageRank, the reduction requires computing Personalized PageRank from a *fixed* vertex, and so the bound does not carry over.

1.1 Our contributions

We provide new lower and upper bounds on the complexity of explicitly maintaining an approximate PageRank vector both under additive and multiplicative approximation. Throughout this section, we use n to denote the number of vertices in a graph, m to denote the number of edges and ϵ to denote the jumping probability used to define PageRank.[3]

1.1.1 Additive Approximation

We provide (essentially) matching lower and upper bounds for explicitly maintaining additive approximation of PageRank in both incremental and decremental setting.

▶ **Theorem 1.** *Fix $\epsilon \in (0.01, 0.99)$. For any sufficiently large $n \geq 1$ and any α such that $1/\alpha = n^{o(1/\log\log n)}$, any algorithm which explicitly maintains α-additive approximation of PageRank must run in $n \cdot (1/\alpha)^{\Omega(\log\log n)}$ total time.*

Our lower bound, which we prove in Section 3.1, is obtained by constructing a graph and an update sequence for which the PageRank vector undergoes a large number of significant changes. The changes to the vector are large to the point that even an approximate PageRank vector must be often updated in linear time. We note that the lower bound, and all other lower bounds that we state, applies to the setting when the PageRank vector is maintained explicitly, i.e., after each update algorithm outputs the changes that the PageRank vector undergoes.

We note that it is easy to come up with an example in which a single edge update significantly changes the PageRanks of a large fraction of vertices (see Figure 1). This immediately rules out efficient incremental and decremental algorithms that maintain approximate PageRank with *worst-case* update time guarantees. This also rules out fully dynamic algorithms with amortized update time guarantees. However, proving a strong lower bound for the *amortized* update time bound in the incremental or decremental setting is far more involved, as it requires showing a long sequence of updates in which, on average, every edge insertion (or deletion) changes the PageRank of many vertices.

We complement our lower bound with the following algorithmic result proved in Section 5.

▶ **Theorem 2.** *For any $\epsilon \in (0, 1)$, there is an algorithm that with high probability explicitly maintains an α additive approximation of PageRank of any graph G in either incremental or decremental setting. The algorithm processes the entire sequence of updates in $O(m) + n \cdot (1/\alpha)^{O_\epsilon(\log\log n)}$ total time and works correctly against an oblivious adversary.*

Furthermore, we study the complexity of the dynamic ForwardPush algorithm [25]. This algorithm, when run with parameter $\tilde{\alpha}$ maintains an $\tilde{\alpha} \cdot m$ additive approximation to PageRank (and so to obtain α additive approximation, one needs to use $\tilde{\alpha} = \alpha/m$). By using a similar construction of a hard instance, we show that the algorithm takes $\Omega(n^{2-\delta})$ time, for any $\delta > 0$, to handle a sequence of $O(n)$ operations, even in incremental or decremental settings (see Theorem 9).

[3] The probability of not-jumping (in our notation, $1 - \epsilon$) is sometimes called the *damping factor* of PageRank.

1.1.2 Multiplicative Approximation

Our next result is a lower bound showing that any algorithm explicitly maintaining a constant multiplicative approximation to PageRank, even in the incremental or decremental setting, must in the worst case take $\Omega(n^{2-\delta})$ total time, for any $\delta > 0$, to process a sequence of n updates to an n-vertex graph. Specifically, we prove the following in Section 3.2:

▶ **Theorem 3.** *There exists a sequence of $\Theta(n)$ edge insertions applied to an initially empty graph on n vertices for which the following holds. For any constant $\delta > 0$, any algorithm that maintains a vector $\tilde{\pi} \in \mathbb{R}^n$ such that $(1/2)\pi_v < \tilde{\pi}_v \leq 2\pi_v$ at all time steps, must take time $\Omega(n^{2-\delta})$ to process the sequence. In particular, the amortized update time of any such algorithm is $\Omega(n^{1-\delta})$.*

We note that, by symmetry, the above theorem also applies to the decremental setting.

Theorem 3 gives a negative resolution to the 13-year-old open question of Bahmani et al. [4], who asked whether their polylogarithmic update time bounds for maintaining PageRank under a sequence of updates coming in *random* order can be extended to the general case. Previously, the only negative results for this problem were given by Lofgren [12] who showed that the specific algorithm of Bahmani et al. requires $\Omega(n^c)$ update time for some $c \in (0, 1)$, but this did not rule out the existence of a better algorithm. We extend this lower bound to *every* algorithm which explicitly maintains an approximate PageRank vector, and strengthen the bound from $\Omega(n^c)$ to $\Omega(n^{1-\delta})$ for any $\delta > 0$.

To complement the above lower bound, in Section 6, we give a simple analysis of the Bahmani et al. algorithm in *undirected* graphs, and show that in this case maintaining multiplicative approximation can be done in polylogarithmic time per update even in the fully dynamic setting. This algorithm also assumes an oblivious adversary. While the analysis is based on a simple observation, to the best of our knowledge it has not been explicitly given before.

▶ **Theorem 4.** *For any $\epsilon \in (0, 1)$, there is an algorithm that with high probability explicitly maintains a $1 + \alpha$ multiplicative approximation of PageRank of any undirected graph G in the fully dynamic setting. The algorithm handles each update in $O(\log^5 n/(\epsilon^2\alpha^2))$ time and works correctly against an oblivious adversary.*

It is an open question whether it is possible to design dynamic PageRank algorithms that bypass our lower bounds, for example, by not maintaining PageRank explicitly or looking beyond worst-case bounds and studying restricted graph classes.

1.2 Related Work

The dynamic PageRank problem has been studied in a number of recent works [4, 5, 11, 24, 8, 17, 18, 13, 19, 20, 9] studying both the theoretical and empirical aspects of the problem. One line of study considered the incremental and decremental settings with updates performed in *random* order [4, 24] and obtained algorithms that achieve $O(\log n/\epsilon)$ update time. The result of [24] is applicable in a non-random order as well, although in that case it requires $\Omega(d_v)$ running time per update done on a vertex v of degree d_v. Bahmani et al. [5] analyze their algorithm in a random graph model in which high PageRank vertices are more likely to receive new neighbors. We note that attempts at designing faster algorithms have been undertaken in [11] as well as [24]. However, these algorithms come with no provable approximation guarantees.

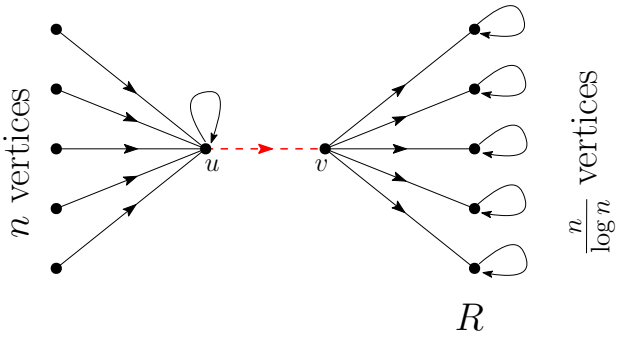

Figure 1 An example illustrating that maintaining multiplicative approximation or even an L_1 approximation of PageRank in the worst case requires $\Theta(n/\log n)$ running time even after a single deletion/insertion of edge uv. For details, see Section 1.3.

Another line of work [2, 14, 15, 25, 21] focuses on computing Personalized PageRank, which is PageRank computed from the point of view of a single vertex. For instance, [15] show that if each entry of a Personalized PageRank is lower-bounded by δ, then the Personalized PageRank of a vertex can be approximated in time $O(\sqrt{d/\delta})$, where d is the average graph degree.

Finally, PageRank was also studied in the context of sublinear algorithms [6, 22]. For instance, for a graph on m edges and omitting poly dependence on $\log m$ and α^{-1}, the very recent algorithm presented in [22] requires $O(n^{1/2} \cdot \min\{m^{1/4}, \Delta^{1/2}\})$ running time for approximating the PageRank of a single vertex, where Δ is the maximum degree in the graph.

1.3 Impossibility of Non-Trivial Worst-Case Bounds

A wealth of literature on designing dynamic algorithms for approximate PageRank, including our results, focuses on *amortized* running time complexity. It is natural to wonder whether non-trivial worst-case update running times do not exists due to lack of techniques or due to fundamental reasons. As our example in Figure 1 illustrates, non-trivial update running times are not possible even on very sparse graphs and even if one's goal is to maintain an L_1-approximate PageRank vector.

Namely, on the one hand, for the graph G in Figure 1, it can be shown that $\pi_u, \pi_v \in \Omega(\epsilon)$ and $\pi_x \in \Omega((\log n)/n)$ for each vertex $x \in R$. On the other hand, consider graph G' obtained from G, i.e., from the graph in Figure 1, by removing the red-dashed (u, v) edge, and let π' be the PageRank of G'. It is not hard to show that $\pi'_u \in \Omega(1)$, $\pi'_v \in O(\epsilon/n)$ and $\pi'_x \in O(1/n)$ for each $x \in R$. This example illustrates the following: there exists a directed graph in which after *a single* edge removal one has to update $\Omega(n/\log n)$ vertices if the goal is to maintain a multiplicative and even an L_1 approximation of the PageRank for sufficiently small constant ϵ. Moreover, if random walks are used to estimate the PageRank – which to the best of our knowledge is the only other used approach than Power method – then maintaining an additive or multiplicative approximate PageRank of a single vertex still requires $\Omega(n)$ worst-case time. To see that, observe that there are $\Theta(n)$ times more random walks passing through v in G than in G'.

Algorithm 1 An algorithm for computing approximate PageRank using random walks.
Input: A graph G, and parameters ϵ, α and ℓ.

1: Sample a set W of $R = \lceil \frac{9 \ln n}{\epsilon \alpha^2} \rceil$ random walks starting from each vertex of G. Each walk length is chosen from geometric distribution with parameter $1 - \epsilon$.
2: Remove from W all walks longer than ℓ.
3: **for** $v \in V$ **do**
4: $\quad \mathbf{X}_v \leftarrow$ the number of times the walks from W visit v.
5: $\quad \tilde{\pi}(v) \leftarrow \frac{\mathbf{X}_v}{|W|/\epsilon}$.
6: **end for**
7: Return $\tilde{\pi}$

1.4 Organization of the Paper

The rest of this paper is organized as follows. In Section 2 we formally define PageRank and review a random-walk based algorithm for approximating it in the static setting. In Section 3 we give the lower bounds on the time required to explicitly maintain PageRank and on the running time of the dynamic ForwardPush algorithm. Section 4 reviews the algorithm for approximating PageRank by maintaining random walks. While the algorithm is essentially the same as the algorithm by Bahmani et al. [4], we present a full analysis, since the previous papers on dynamic PageRank did not prove the correctness of this approach. In the following two sections we analyze this algorithm in two settings. First, in Section 5 we show that this algorithm achieves near-optimal update time while maintaining additive approximation to PageRank. Second, in Section 6 we present a simple analysis showing that in undirected graphs maintaining even a constant multiplicative approximation to PageRank in the fully dynamic setting is possible with polylogarithmic update time.

2 Preliminaries

We begin by defining the PageRank of a directed graph $G = (V, E)$. Formally, the PageRank of G, denoted by $\pi \in \mathbb{R}^n_{\geq 0}$, is the stationary distribution of a random walk on G, where at each step the walk *jumps* to another uniformly random vertex with probability $\epsilon \in (0, 1)$. The jump probability ϵ is a parameter, which we will fix for the remainder. If $\deg(i)$ is the out-degree of the i-th vertex in V, then the corresponding non-symmetric transition matrix $M \in \mathbb{R}^{n \times n}$ has entries $M_{i,j} = \frac{\epsilon}{n} + (1 - \epsilon)\frac{1}{\deg(i)}$ if $(i, j) \in E$, and $M_{i,j} = \epsilon/n$ otherwise. We make the standard assumption (required for PageRank to be well-defined) that each vertex has $\deg(i) \geq 1$, which can be accomplished by adding self-loops.

PageRank can be approximated by sampling $O(\log n/\epsilon)$ relatively short random walks from each vertex. One such approach is provided as Algorithm 1, for which the following can be shown.

▶ **Proposition 5** ([4, 16]). *Let π be the PageRank vector of a graph G. The estimate $\tilde{\pi}$ computed by Algorithm 1 (with $\ell = \infty$) satisfies (a) for all $v \in V$ we have $\mathbb{E}[\tilde{\pi}_v] = \pi_v$, and (b) with probability $1 - 1/\operatorname{poly}(n)$, simultaneously for all $v \in V$, we have $\tilde{\pi}_v = (1 \pm \alpha)\pi_v$.*

3 Lower Bounds

In this section we present our lower bounds for maintaining explicit approximation to PageRank and for the running time of the dynamic ForwardPush algorithm [25]. We now describe a generic construction of a hard instance, which we instantiate with different parameters in each of the individual lower bounds. Throughout the section, we consider the case of $\epsilon \in (0.01, 0.99)$, which is the usual case in the applications of PageRank.

The Graph. The graph G is a union of the graphs H, R, S_0, S_1. First, H is a directed tree. Each non-leaf vertex v has exactly t children, with p^i parallel directed edges from v to the i-th child of v (where i is 0-based). We require that $p \geq \max(1/\epsilon, 2)$. Hence, the total-out degree of each internal vertex in H is $O(p^t)$. The depth of H is d, and so H has $\Theta(t^d)$ vertices and $\Theta(t^d \cdot p^t)$ edges.

The graph R consists of $n/4$ vertices v, each with no in-edges, and each with a single out edge vr where r is the root of the directed tree H. Finally, the sets S_0, S_1 are both directed star graphs on $s+1$ vertices (with the edges directed away from the center of the star), where S_i has the center c_i for $i \in \{0, 1\}$. Additionally, each leaf of S_0 and S_1 has a single outgoing edge, which is a self-loop. We then order the leaf vertices of H as $\ell_1, \ell_2, \ldots$, and create a directed edge from ℓ_i to $c_{i \bmod 2}$. We will set the parameters, such that the total number of vertices in H, R, S_0, and S_1 is less than n. One can then add an additional $O(n)$ isolated vertices (with self-loops), so that the total number of vertices is precisely n.

Update Sequence The initial graph has all vertices and edges of H, R, S_0, S_1, except that each non-leaf vertex of H only has an edge to its leftmost child (i.e., one with index 0). Observe that each vertex has at least one outgoing edge, and so PageRank is well-defined.

The update sequence is as follows. Let $v_1, \ldots, v_{|H|}$ be the sequence of vertices visited on a pre-order traversal of H, such that $\ell_1, \ell_2, \ldots$ is a subsequence of $v_1, \ldots, v_{|H|}$. We insert the edges of H in $|H|$ rounds: in the ith round we insert all incoming edges of v_i (unless they have already been in the graph from the beginning).

To prove the lower bounds, we use the following way of interpreting PageRank, which is a continuous version of Algorithm 1 and follows from Proposition 5. Each vertex has some *probability mass*, which it either generates or receives from its in-neighbors. Specifically, each vertex of the graph generates a probability mass of $1/n$. A $1-\epsilon$ fraction of the probability mass of a vertex v (either generated by v or incoming to v from other vertices) is divided uniformly among the outgoing edges of v and sent to the neighbors of v. The PageRank of each vertex is exactly ϵ fraction of its probability mass.

Note that if a vertex is on a cycle, some probability mass enters it multiple times. In this case, each time the mass enters the vertex, it increases the total probability mass. In particular, we have the following.

▶ **Observation 6.** *Let v be a vertex, whose only outgoing edge is a self loop. Assume that v receives a probability mass of p along its incoming edges other than the self-loop. Then, the PageRank of v is $p + 1/n$.*

▶ **Lemma 7.** *Consider the graph G^τ obtained right after inserting all edges on the path from R to ℓ_i. Let m_i be the probability mass that reaches ℓ_i from R in G^τ. Then $m_i \geq (1-\epsilon)^{2d+2}/4$.*

Moreover, out of the probability mass that reaches the leaves of H from R, at least $(1-1/p)^d$ fraction reaches ℓ_i.

Proof. Observe that a path from any vertex $u \in R$ to ℓ_i first follows the edge to r, which is the only outgoing edge of u, and then, thanks to the order of adding edges of H, at each step uses the rightmost edge of each vertex in H. Consider an internal vertex $w \in H$. By the construction it has p^i edges to the ith child (0-based). Assuming that we have added edges to j children so far, we have that there are p^{j-1} edges to the rightmost child and so the fraction of outgoing edges of w that go to the rightmost child is:

$$p^{j-1} / \left(\sum_{k=0}^{j-1} p^k \right) = p^{j-1} \cdot \frac{p-1}{p^j - 1} \geq p^{j-1} \cdot \frac{p-1}{p^j} = 1 - 1/p. \tag{1}$$

The path from w to ℓ_i has $d+1$ edges. At each step $1-\epsilon$ fraction of the probability mass is forwarded to the children, out of which, as shown above, at least $1-1/p \geq 1-\epsilon$ fraction follows the path to ℓ_i. Hence, the fraction of probability mass that reaches ℓ_i from w is $(1-\epsilon)^{2d+2}$. Since vertices of R generate a total probability mass of $1/4$, we get the desired.

The second claim follows directly from Equation (1) and the fact that H has depth d. ◀

3.1 Lower Bound for Maintaining Additive Approximation

We first show the following auxiliary lemma which we will use to argue when an additive α-approximate PageRank vectors must be updated in linear time.

▶ **Lemma 8.** *Consider four vectors $v^1, \tilde{v}^1, v^2, \tilde{v}^2 \in \mathbb{R}^n$, such that $\|v^1 - \tilde{v}^1\|_1 \leq \alpha$, $\|v^2 - \tilde{v}^2\|_1 \leq \alpha$ and v^1 and v^2 differ by at least $100 \cdot \alpha/n$ on at least $n/4$ coordinates. Then $\tilde{v}^1$ and $\tilde{v}^2$ differ on $\Omega(n)$ coordinates.*

Proof. The proof goes by contradiction. Assume that $\tilde{v}^1$ and $\tilde{v}^2$ differ on at most $n/1000$ coordinates. Thus, they have at least $0.999 \cdot n$ coordinates in common. Moreover, $\|v^1 - \tilde{v}^1\|_1 \leq \alpha$ implies that v^1, and $\tilde{v}^1$ differ by more than $10 \cdot \alpha/n$ on less than $0.1 \cdot n$ coordinates. Clearly, a similar property is satisfied by v^2, and $\tilde{v}^2$.

Let I be the set of coordinates where

1. $\tilde{v}^1$ and $\tilde{v}^2$ are equal (there are at least $0.999 \cdot n$ such coordinates),
2. v^1 and v^2 differ by at least $100 \cdot \alpha/n$ (at least $n/4$ such coordinates),
3. v^1 and $\tilde{v}^1$ differ by at most $10 \cdot \alpha/n$ (at least $0.9 \cdot n$ coordinates),
4. v^2 and $\tilde{v}^2$ differ by at most $10 \cdot \alpha/n$ (at least $0.9 \cdot n$ coordinates).

Observe that since the vectors have n coordinates, I is nonempty. By using first the triangle inequality, and then items 2-4 above, for any coordinate $i \in I$ we have

$$\begin{aligned} |\tilde{v}_i^1 - \tilde{v}_i^2| &\geq |v_i^1 - v_i^2| - |v_i^1 - \tilde{v}_i^1| - |v_i^2 - \tilde{v}_i^2| \\ &\geq 100 \cdot \alpha/n - 10 \cdot \alpha/n - 10 \cdot \alpha/n \\ &= 80 \cdot \alpha/n. \end{aligned}$$

which contradicts item 1. The lemma follows. ◀

▶ **Theorem 1.** *Fix $\epsilon \in (0.01, 0.99)$. For any sufficiently large $n \geq 1$ and any α such that $1/\alpha = n^{o(1/\log\log n)}$, any algorithm which explicitly maintains α-additive approximation of PageRank must run in $n \cdot (1/\alpha)^{\Omega(\log\log n)}$ total time.*

Proof. We instantiate our construction using the following parameters. The number of edges from a vertex to its ith child is $(1/\epsilon)^i$ ($p = 1/\epsilon$). Each vertex of H has $t = 1/2 \cdot \log_p n$ children. The tree H has depth $d = \frac{\log(101\alpha)}{2\log(1-\epsilon)} - 2 \geq 1$. Note that $d = \Theta(\log(1/\alpha))$. Finally, S_0, S_1 have $s = n/4$ leaves.

Let us now bound the size of the graph. The number of leaves of H is

$$t^d = (1/2 \cdot \log_{1/\epsilon} n)^d = \left(\frac{\log n}{2\log 1/\epsilon}\right)^{\Theta(\log(1/\alpha))} = \log^{\Theta(\log(1/\alpha))} n = (1/\alpha)^{\Theta(\log\log n)}, \qquad (2)$$

where in the third step we use the fact that $\frac{\log n}{2\log 1/\epsilon} = \log^{\Theta(1)} n$ for sufficiently large n.

R, S_0 and S_1 have $n/4$ vertices each. By Equation (2) and the assumption on α, H has $o(n)$ vertices, and so with the additional isolated vertices, the graph has exactly n vertices.

The number of edges incident to R, S_0 and S_1 is $O(n)$. The number of children of each internal vertex of H is

$$\Theta(p^t) = \Theta(p^{1/2 \cdot \log_p n}) = \Theta(n^{1/2}).$$

Thus, the total number of edges in H is $(1/\alpha)^{\Theta(\log\log n)} \cdot n^{1/2} = n^{o(1)} \cdot \Theta(n^{1/2})$. Hence, we conclude that the graph has n vertices and $O(n)$ edges.

Observe that as we add edges, leaves $\ell_1, \ell_2, \ldots$ become reachable from R exactly in the order of their indices. Fix any leaf ℓ_j of H. Denote by π^b and π^a, respectively, the PageRank vectors just before ℓ_j is reachable from R and just after all edges on the path from R to ℓ_j are added.

We use the interpretation of PageRank based on probability mass. Before ℓ_j is reachable from R, it may receive probability mass only from its ancestors in H. Hence,

$$\pi^b_{\ell_j} \leq (d+1)/n = \Theta(\log(1/\alpha))/n = o(\log n)/n.$$

Moreover, since PageRank is a ϵ fraction of the probability mass entering each vertex, by Lemma 7,

$$\pi^a_{\ell_j} \geq \epsilon \cdot (1-\epsilon)^{2d+2}/4 = \epsilon \cdot (1-\epsilon)^{\frac{\log(101\alpha)}{\log(1-\epsilon)}-2}/4 = 101 \cdot \epsilon \cdot \alpha \cdot (1-\epsilon)^{-2}.$$

The increase to PageRank of ℓ_j is thus at least $\pi^a_{\ell_j} - \pi^b_{\ell_j} \geq 100 \cdot \epsilon \cdot \alpha(1-\epsilon)^{-2}$. Hence, after the insertion there is at least $100\alpha(1-\epsilon)^{-2}/4$ "new" probability mass at ℓ_j. Since every two hop path from j leads to a leaf in $S_{j \bmod 2}$, each of these leaves will receive a least

$$100 \cdot \alpha \cdot (1-\epsilon)^{-2}/4 \cdot (1-\epsilon)^2/s = 100 \cdot \alpha/(4s).$$

new probability mass (since only $(1-\epsilon)$ fraction of the probability mass is transferred along each hop). By Observation 6 all of that probability mass ends up increasing the PageRank of the leaf. Therefore the PageRank of each of these s leaves increases by $100 \cdot \alpha/(4s) = 100 \cdot \alpha/(4 \cdot n/4) = 100 \cdot \alpha/n$.

We now use Lemma 8 with $v_1 = \pi^b$, $v_2 = \pi^a$ and $\tilde{v}_1$ and $\tilde{v}_2$ being any PageRank vectors giving α-additive approximation and infer that $\Omega(n)$ coordinates of any approximate PageRank vector must be updated in order to maintain α-additive approximation. This happens for each leaf of H, and so by Equation (2) the Lemma follows. ◀

3.2 Lower Bound for Maintaining Multiplicative Approximation

▶ **Theorem 3.** *There exists a sequence of $\Theta(n)$ edge insertions applied to an initially empty graph on n vertices for which the following holds. For any constant $\delta > 0$, any algorithm that maintains a vector $\tilde{\pi} \in \mathbb{R}^n$ such that $(1/2)\pi_v < \tilde{\pi}_v \leq 2\pi_v$ at all time steps, must take time $\Omega(n^{2-\delta})$ to process the sequence. In particular, the amortized update time of any such algorithm is $\Omega(n^{1-\delta})$.*

Proof. We instantiate our construction as follows. Each non-leaf vertex v of H has exactly $t = \delta/2 \log n/\log\log n$ children, with $(\log^2 n)^i$ parallel directed edges from v to the i-th child of v ($p = \log^2 n$). It follows that the total outdegree of each internal vertex in H is $O(n^\delta)$. The depth of H is set to be $d = \log_t(n^{1-2\delta}) = \Theta(\log n/\log\log n)$, so that H has $n^{1-2\delta}$ vertices, and the total number of edges in H is $O(n^{1-\delta})$. Finally, both S_0 and S_1 have $s = n^{1-2\delta}$ vertices.

Fix a leaf ℓ_j of H and consider the state of the algorithm right after all on the path from the root of H to ℓ_j have been added. By Lemma 7, the probability mass entering ℓ_j is at least.

$$(1-\epsilon)^{2d+2}/4 = (1-\epsilon)^{\Theta(\log n/\log\log n)} = n^{\Theta(-1/\log\log n)}.$$

Out of this probability mass a constant fraction reaches the leaves of $S_{j \bmod 2}$. In particular, the PageRank of each such leaf is at least $\epsilon \cdot n^{\Theta(-1/\log\log n)}/n^{1-2\delta} \geq n^{-\delta}$.

Moreover, out of the probability mass from R the fraction that reaches ℓ_j is at least

$$(1-1/p)^d = (1-1/\log^2 n)^{\Theta(\log n/\log\log n)} \geq 1 - 1/\log n.$$

out of all probability mass that reaches the leaves of H from R. Observe that compared to this probability mass (which is a constant), the total probability mass generated by all vertices of H is negligible. As a result, the ratio of probability mass that reaches $S_{j \bmod 2}$ to the probability mass that reaches $S_{(j+1) \bmod 2}$ is

$$\frac{1-1/\log n}{1/\log n} = \Theta(\log n).$$

This implies that when we add all edges on a path from R to ℓ_j, the PageRanks of leaves of $S_{j \bmod 2}$ increase by a factor of $\Theta(\log n)$ and so the PageRank estimates of all these $\Omega(n^{1-2\delta})$ vertices must be changed. Since a total of $m = O(n)$ edges are added, and since this occurs once for each of the $\Omega(n^{1-\delta})$ leaf vertices in H, we obtain a total of $\Omega(n^{2-3\delta})$ PageRank estimate updates, which is the desired result after rescaling δ by a constant. ◀

3.3 Lower bound for the ForwardPush algorithm

▶ **Theorem 9.** *Consider running the ForwardPush [25] algorithm whose error parameter is set to ensure that the algorithm maintains additive α approximation of PageRank. For any $\delta > 0$, each sufficiently large $n \geq 1$ and $\epsilon \in (0.01, 0.99)$ there exists a graph on n vertices and a sequence of $O(n)$ edge insertions, such that the algorithm runs in $\Omega(n^{2-\delta})$ time.*

Proof. We use our construction with the same settings as in the proof of Theorem 3. Specifically, $t = \delta/2 \log n/\log\log n$, $p = \log^2 n$, $d = \log_t(n^{1-2\delta}) = \Theta(\log n/\log\log n)$ and $s = n^{1-2\delta}$.

The ForwardPush algorithm can be explained using the probability mass interpretation. The algorithm maintains a *residual* on each vertex u, denoted by R_u. This residual can be positive or negative. Initially, the residual of each vertex is $1/n$.

The residual is a probability mass that still has to be pushed to the neighbors of u. The algorithm maintains two invariants

1. $|R_u| \leq \gamma \deg(u)$ for each vertex $u \in V$, where γ is an accuracy parameter.
2. If we keep pushing the residuals, the PageRank estimates converge to the exact PageRank values.

For any vertex u that violates the invariant, that is satisfies $|R_u|/\deg(u) > \gamma$, the algorithm executes a *push* operation, which takes time $\Theta(\deg(u))$ and pushes a $1-\epsilon$ fraction of the residual to the outneighbors of u and uses a ϵ fraction of the residual to increase the PageRank of u. The residual of u is then set to 0. Upon an insertion of an edge uv, the algorithm decreases R_u by $\Delta = \Theta(\pi_u)/\deg(u)$ and increases R_v by Δ. Then, it restores the invariant by executing push operations.

In the following part of the proof we use the following observation, which follows from the second algorithm invariant.

▶ **Observation 10.** *Fix a vertex v and denote by D_v the set of vertices that have a directed path to v. We assume $v \in D_v$. Then, the total additive error of the PageRank estimate maintained by the ForwardPush algorithm is at most $\sum_{u \in D_v} |R_u|$.*

By using the second algorithm invariant, we get that ForwardPush ensures that the total additive error is $\sum_{u \in V} |R_u| \leq \sum_{u \in V} \gamma \deg(u) = \gamma m$. Therefore, to ensure an additive α approximation of PageRank, we set $\gamma m \leq \alpha$, implying $\gamma \leq \alpha/m$. We note that it is easy to come up with an example where this analysis is tight up to a constant factor.

We now analyze ForwardPush algorithm on our hard instance. Since the number of edges in our graph is $\Theta(n)$, we invoke ForwardPush with the approximation parameter $\gamma = \Theta(1/n)$. We claim that with this value of γ, the residual values are propagated often enough so that over $\Theta(n)$ edge insertions described above, ForwardPush makes $\Omega(n^{2-\delta})$ updates.

We use the observations from the proof of Theorem 3 that the PageRank of a vertex c_i ($i \in \{0, 1\}$) is $n^{\Theta(-1/\log\log n)}$ and, as we add edges, increases by a $\Theta(\log n)$ factor each time we fully add a path from R to a leaf ℓ_j, such that $i = j \bmod 2$.

We now use Observation 10 to show that the ForwardPush maintains a constant factor approximate of the PageRank estimates of c_0 and c_1. Indeed, these vertices can only be reached from R, H or from themselves. We now bound the residuals of these vertices. The residuals of the vertices of R are set to 0 the moment each of these vertices performs the first push operation and are then never updated. The residual of each vertex v of H satisfies $|R_v|/\deg(v) \leq \alpha/m$ which implies $|R_v| \leq \Theta(\deg(v))/m = \Theta(n^{\delta-1})$. Finally, the residual of c_0 (and, similarly c_1) satisfies $|R_{c_0}|/\deg(c_0) \leq \alpha/m$, which gives $|R_{c_0}| \leq \Theta(n^{1-2\delta})/m = \Theta(n^{-2\delta})$. By applying Observation 10 we have that the additive error the PageRank estimates of c_0 and c_1 is at most

$$\Theta(n^{\delta-1}) \cdot \Theta(n^{1-2\delta}) + \Theta(n^{-2\delta}) = \Theta(n^{-\delta}).$$

These additive errors are negligible comared to the PageRanks of these vertices, which is $n^{\Theta(-1/\log\log n)}$. Hence, the algorithm maintains constant-factor estimates of the PageRanks of c_0 and c_1. As a result, when the exact PageRank values change by a factor of $\Theta(\log n)$, the algorithm updates their estimates. However, the ForwardPush algorithm only updates a PageRank estimate of a vertex u when either it executes a push operation on u or adds an outgoing edge from u. Since all outgoing edges of c_0 and c_1 have been added in the beginning, we get that the algorithm executes a push operation on c_0 for half of leaves of H. Each such operation takes $\Theta(\deg(c_0)) = \Theta(n^{1-2\delta})$ time and so the overall running time of the algorithm is $\Theta(n^{1-2\delta} \cdot n^{1-2\delta}) = \Theta(n^{2-4\delta})$ which, after tweaking δ by a constant factor, gives the desired. ◀

4 Approximating PageRank by Maintaining Dynamic Random Walks

In this section we review the algorithm for approximating PageRank by maintaining random walks. This algorithm is a dynamic version of Algorithm 1 and has been previously described by Bahmani et al. [4]. We provide a detailed proof of correctness of the algorithm, which to the best of our knowledge has not been included in any prior work.

The algorithm relies on maintaining $O_\epsilon(n \log n)$ random walks and re-sampling their parts as necessary. In this section, we present data structures that we use to efficiently maintain and re-sample those random walks. Section 4.1 presents our approach on an edge insertion, while Section 4.2 describes how our algorithms handle edge deletions. We being by describing the problem setup.

Setup. Following Proposition 5, to approximate the PageRank it suffices to sample $R = O(\log n/(\epsilon\alpha^2))$ PageRank walks from each vertex. A PageRank walk is a random walk w, whose length ℓ_w is sampled from geometric distribution with parameter $1 - \epsilon$. Even though a

given walk may get re-routed after edge insertions or deletions, it is crucial that the the length of each walk remains **fixed** throughout the entire execution of the algorithm. Otherwise, it is easy to construct examples where the lengths of the maintained walks no longer follow the right distribution.

We maintain two types of data structures. For each each vertex v and $t = 0 \dots O(\log n/\epsilon)$, we maintain a binary search tree $S_{v,t}$ which stores all the walks whose t-th vertex if v. For each edge e, we maintain the binary search tree W_e consisting of the walks passing through e.

4.1 Edge Insertion

When an edge (u, v) is inserted, we re-sample some of the walks passing through u. This re-sampling is done by first performing rejection sampling on each walk and, second, by choosing an appropriate position where each of the rejected walks should be re-sampled. Choosing an appropriate position from where to re-sample w is trivial in case when w passes through u once. However, it might be the case that w passes through that vertex multiple times, and a more careful consideration is required. At a high level, we iterate through all segments of w and for each segment of w that leaves u we toss a coin. Then, with probability $1/d_u$, where d_u is the degree of u after the update, we reroute w starting from the considered segment, and terminate the update procedure for w.

Each walk has a unique ID associated with it. These IDs are integers ranging from 1 through the number of walks we maintain. Each vertex and each edge keeps track of which walks are passing through them.

Given a vertex v and integers i and t, it will be convenient to be able to sample the i-th walk whose t-th vertex is v. It will become clear why such operation is needed when we describe how to handle edge insertions. To be able to implement this operation efficiently, we store the IDs of walks whose t-th vertex is v in a binary tree; we use $S_{v,t}$ to refer to this binary tree. Then, the i-th walk can be easily fetched via a search within that tree. The maximum value of t to consider is upper-bounded by the maximum length of the walks.

Assume that we insert an edge $e = (u, v)$. Let d_u be the out-degree of u *after* adding e. Consider a walk w that at some point got to u and continued to u's neighbors. If e was present in the graph at that point, with probability $1/d_u$ the walk w would have continued along e, and with probability $1 - 1/d_u$ the walk w would have chosen some other neighbor of u. However, w was sampled before e was in the graph, and our aim now is to correct this distribution and account for the insertion of e. The idea is to use rejection sampling, which we provide as Algorithm 2.

The for-loop on Line 3 of Algorithm 2 is in an efficient way of selecting walks passing through u and v that need to be re-sampled. Since the length of each walk follows a geometirc distribution with parameter $1 - \epsilon$, it is easy to see that with high probability the walks have length $O(\log n/\epsilon)$, and hence $\ell \in O(\log n/\epsilon)$.

Remark: To the best of our understanding, on an insertion of an edge (u, v), the prior work [24] re-samples a walk passing through u from the first occurrence of u in the walk, if there is any such occurrence (for details, see [24]). Such re-sampling does not account for the case when a walk passes through u multiple times and leads to biases in randomness.

4.2 Edge Deletions

Algorithm 3 presents our procedure executed after deleting an edge.

Let e be a deleted edge, and let $W_e \subseteq W$ be the list of walks passing through e. Clearly each $w \in W_e$ needs to be rerouted. The following lemma states that W updated by executing Algorithm 3 is a set of independent random walks.

Algorithm 2 A procedure executed after edge $e = (u, v)$ is inserted.

1: $W \leftarrow \emptyset$
2: Let ℓ be the length of longest generated walk.
3: **for** $t = 1 \dots \ell$ **do**
4: Sample each walk from $S_{u,t}$ with probability $1/d_u$ in the following way. First, select an integer $r_{u,t}$ from the binomial distribution with parameters $|S_{u,t}|$ and $1/d_u$. Second, select $r_{u,t}$ integers uniformly at random and without repetition from $[1, |S_{u,t}|]$. Then, for each of those integers i select the i-th walk from $S_{u,t}$. If e is an undirected edge, apply the same steps for $S_{v,t}$.
5: For each walk w selected in the last step such that $w \notin W$, add w to W and label w by t.
6: **end for**
7: **for** each $w \in W$ **do**
8: Let j be the label remembered for w on Line 5.
9: Generate walk w' with the following properties:
- The walks w and w' have the same length.
- The vertex-prefixes of length j of w and w' are the same.
- After that prefix, if w has more than j vertices, w' walks along e.
- The remaining edges of w' are chosen randomly, i.e., the rest of w' is a newly generated random walk.

10: Update the data structures by removing w and inserting w'.
11: **end for**

Algorithm 3 A procedure executed after edge e is deleted.

1: Let $W_e \subseteq W$ be the list of walks passing through e.
2: **for** $w \in W_e$ **do**
3: Let w_p be the longest prefix of w not containing e.
4: Let w' be a walk of length $|w|$ such that w' has w_p as its prefix, and the remainder of w' is a random walk.
5: To update W, remove w from W and the corresponding data structures, and insert w'.
6: **end for**

▶ **Lemma 11.** *Let W be the set of walks that our algorithm maintains. Assume that e gets deleted, and let W' be the updated list of walks as described in Algorithm 3. If W consists of random walks sampled independently, then W' is also a set of random walks sampled independently.*

Proof. The edges of walks throughout the algorithm are sampled independently of each other, so walks are independent by construction. We focus on showing how deletion of an edge affects randomness of a single walk.

Consider a walk $w \in W$ originating at vertex w_1. Let w_i be the i-th vertex of w, $w_{1\dots i}$ be the prefix of length i of w, and k be the length of w. Walk w is random iff for each $i \geq 2$ and each $u \in N(w_{i-1})$ it holds

$$\Pr\left[w_i = u \mid w_{1\dots i-1}\right] = \frac{1}{d(w_{i-1})}. \tag{3}$$

Let w' be the updated walk w, $d'(v)$ be the updated degree of vertices after e gets deleted and u' be a neighbor of w'_{i-1} after deletion of e. Note: we are **not** assuming that w contains e, so it might be the case that $w = w'$. We want to show that $\Pr\left[w'_i = u' \mid w'_{1\dots i-1}\right] = 1/d'(w'_{i-1})$. We have

$$\begin{aligned}
&\Pr\left[w'_i = u' \mid w'_{1\dots i-1}\right] && (4)\\
=&\Pr\left[w'_i = u' \mid w'_{1\dots i-1}, e \in w_{1\dots i}\right] \cdot \Pr\left[e \in w_{1\dots i}\right] && (5)\\
&+ \Pr\left[w'_i = u' \mid w'_{1\dots i-1}, e \notin w_{1\dots i}\right] \cdot \Pr\left[e \notin w_{1\dots i}\right]. && (6)
\end{aligned}$$

Analyzing (5)**.** We first handle (5). Recall that w' is constructed by keeping only the prefix of w up to the first occurrence of e, and the rest of the walk of w' is random and independent of any other state of the algorithm (see Algorithm 3). Hence, we have

$$\Pr\left[w'_i = u' \mid w'_{1\dots i-1}, e \in w_{1\dots i}\right] = \frac{1}{d'(w'_{i-1})}.$$

Analyzing (6)**.** Now consider term (6). If $w_{1\dots i}$ does not contain e, then $w'_{1\dots i} = w_{1\dots i}$ and we have

$$\begin{aligned}
&\Pr\left[w'_i = u' \mid w'_{1\dots i-1}, e \notin w_{1\dots i}\right]\\
=&\Pr\left[w_i = u' \mid w_{1\dots i-1}, e \notin w_{1\dots i-1}, e \neq \{w_{i-1}, w_i\}\right].
\end{aligned}$$

There are two cases:

(a) Case $w_{i-1} \notin e$: from (3) we have

$$\begin{aligned}
&\Pr\left[w_i = u' \mid w_{1\dots i-1}, e \notin w_{1\dots i-1}, e \neq \{w_{i-1}, w_i\}, w_{i-1} \notin e\right]\\
=&\Pr\left[w_i = u' \mid w_{1\dots i-1}, e \neq \{w_{i-1}, w_i\}, w_{i-1} \notin e\right]\\
=&\frac{1}{d(w_{i-1})} = \frac{1}{d'(w_{i-1})} = \frac{1}{d'(w'_{i-1})}.
\end{aligned}$$

In the last chain of equalities we used that once we condition on $w_{1\dots i-1}$, then (3) is a function of only w_{i-1} and not on any other content of $w_{1\dots i-1}$, e.g., whether $e \in w_{1\dots i-1}$ or not.

Note: The choice of e is independent of our data structures and the randomness the algorithm uses. However, in the case of non-oblivious adversary, i.e., in case of the adversary who sees the state of our algorithm, the updated edge e could be chosen based on the randomness used to generate w, and hence the above sequence of equalities would not hold.

(b) Case $w_{i-1} \in e$: we have the following

$$\begin{aligned}
&\Pr\left[w_i = u' \mid w_{1\dots i-1}, e \notin w_{1\dots i-1}, e \neq \{w_{i-1}, w_i\}, w_{i-1} \in e\right]\\
=&\frac{\Pr\left[w_i = u' \wedge e \neq \{w_{i-1}, w_i\} \mid w_{1\dots i-1}, e \notin w_{1\dots i-1}, w_{i-1} \in e\right]}{\Pr\left[e \neq \{w_{i-1}, w_i\} \mid w_{1\dots i-1}, e \notin w_{1\dots i-1}, w_{i-1} \in e\right]}\\
=&\frac{1/d(w_{i-1})}{(d(w_{i-1})-1)/d(w_{i-1})} = \frac{1}{d(w_{i-1})-1} = \frac{1}{d'(w'_{i-1})}.
\end{aligned}$$

Showing (3) for w'. The analysis of (5) and (6) together with (4) implies

$$\begin{aligned}&\Pr\left[w'_i = u' \mid w'_{1\dots i-1}\right]\\ =&\frac{1}{d'(w'_{i-1})}\cdot\Pr\left[e \in w_{1\dots i}\right] + \frac{1}{d'(w'_{i-1})}\cdot\Pr\left[e \notin w_{1\dots i}\right]\\ =&\frac{1}{d'(w'_{i-1})}.\end{aligned}$$

◀

4.2.1 Re-sampling Walks from Scratch

We now give a simple example that shows why re-sampling affected walks from scratch after a deletion would not properly maintain random walks. We note that this approach was suggested as a valid alternative by Bahmani et al. [4].

Consider a path graph on 5 vertices; let the graph be $1-2-3-4-5$. Consider a random walk w of length 2 originating at vertex 3 and visiting vertices w_1, w_2, w_3, i.e., $w_1 = 3$. Next, a deletion of $e = \{4,5\}$ occurs. Let w' be obtained from w as follows: if w contains e, then w' is a new random walk of length 2 originating at 3; otherwise, w' equals w. Now, if we denote the vertices on w' by w'_1, w'_2, w'_3, we have

$$\begin{aligned}\Pr\left[w'_2 = 4\right] =& \Pr\left[w'_2 = 4 \mid \{4,5\} \notin w\right]\Pr\left[\{4,5\} \notin w\right]\\ &+ \Pr\left[w'_2 = 4 \mid \{4,5\} \in w\right]\Pr\left[\{4,5\} \in w\right]\\ =& \Pr\left[w_2 = 4 \mid \{4,5\} \notin w\right]\Pr\left[\{4,5\} \notin w\right]\\ &+ \Pr\left[w'_2 = 4 \mid \{4,5\} \in w\right]\Pr\left[\{4,5\} \in w\right]\\ =& \Pr\left[w_2 = 4 \text{ and } \{4,5\} \notin w\right] + \frac{1}{2}\cdot\frac{1}{4}\\ =& \frac{1}{4} + \frac{1}{8}.\end{aligned}$$

However, for w' to be random it should hold $\Pr\left[w'_2 = 4\right] = 1/2$.

5 Near-Optimal Additive Approximation Algorithm

In this section, we analyze the algorithm from Section 4 in the context of dynamically maintaining *additive* approximation of PageRank. Namely, we show that when considering the incremental or decremental setting for directed graphs, an α additive PageRank approximation can be maintained in $(1/\alpha)^{O_\epsilon(\log\log n)}$ amortized update time, even for an adversarially chosen graph and a sequence of edge updates. Perhaps surprisingly, Theorem 1 shows that, for a constant ϵ, this running time complexity is essentially tight.

▶ **Theorem 2.** *For any $\epsilon \in (0,1)$, there is an algorithm that with high probability explicitly maintains an α additive approximation of PageRank of any graph G in either incremental or decremental setting. The algorithm processes the entire sequence of updates in $O(m) + n \cdot (1/\alpha)^{O_\epsilon(\log\log n)}$ total time and works correctly against an oblivious adversary.*

Our new analysis is based on two ideas. First, we show that if we *limit the lengths* of walks in Algorithm 1 to a constant, we obtain a constant additive approximation of the PageRank vector. This is thanks to the fact that a constant fraction of all walks have length $O(1/\epsilon)$, and so this truncation only affects a constant factor of the walks.

▶ **Lemma 12.** *Let π be the PageRank of a directed graph G. Then, with high probability, Algorithm 1 for $\ell = \lceil 2/\epsilon \cdot \log(2/(\alpha\epsilon))\rceil$ outputs a vector π_{ADD} such that $\|\pi - \pi_{ADD}\|_1 \le 5\frac{\alpha}{1-\epsilon}$.*

To keep the flow of high-level ideas uninterrupted, the proof of Lemma 12 is given in Section 5.1.

The second idea is an observation which bounds the maximum number of times a walk can be affected by adding edges (edge deletions can use a symmetric argument). To explain the idea let us see what happens when we want to maintain a random outgoing edge e of a vertex undergoing insertions of outgoing edges. Clearly when we insert the d-th outgoing edge we need to update e to be equal to d with probability $1/d$. By a harmonic sum argument, the expected number of times e needs to be updated in the course if k insertions is only $O(\log k)$. We generalize this argument to walks of length ℓ as follows.

▶ **Lemma 13.** *Let G be a directed graph undergoing edge insertions (or deletions). The total number of times a random walk of length ℓ is being regenerated is bounded by $O(\log^{\ell} n)$ in expectation.*

Proof. We are going to prove this bound by induction, i.e., let us denote by $f(i)$ the upper bound on expected number of times the walk of length i is regenerated. Consider a random walk w of length 1 starting in a vertex v. Consider insertion of an edge incident to v. The probability that w is regenerated at this moment is $1/d_v$. As we consider incremental setting the expected number of times w is regenerated is bounded by

$$f(1) = \sum_{i=1}^{n} \frac{1}{i} \leq \ln n.$$

Now consider a walk w of length ℓ starting at v. Similarly as above we can bound the number of changes to w as

$$f(\ell) = \sum_{i=1}^{n} \frac{1}{i} \cdot f(\ell - 1) \leq \ln n \cdot f(\ell - 1) = \ln^{\ell} n,$$

what finishes the proof. Symmetric argument can be applied in the decremental case. ◀

The above lemma implies that for $\ell = \lceil 2/\epsilon \cdot \log(2/(\alpha\epsilon)) \rceil$ the amortized cost of maintaining each walk is $(1/\alpha)^{O(\log\log n)}$ for a constant ϵ. As we generate $O(n \log n)$ walks in Algorithm 1 the total cost of maintaining $5\alpha/(1-\epsilon)$-approximation in incremental or decremental setting is $O(m + n \cdot (1/\alpha)^{O(\log\log n)})$.

5.1 Proof of Lemma 12

Define $\hat{\ell} = \lceil 2/\epsilon \cdot \log(2/(\alpha\epsilon)) \rceil$. Let $\tilde{\pi}$ be the output of Algorithm 1 for $\ell = \infty$, and π_{ADD} the output for $\ell = \hat{\ell}$. As discussed, it is known, e.g., see [4, 16], that $|\pi_v - \tilde{\pi}_v| \leq \alpha\pi_v$. As $\sum_v \pi_v = 1$, this further implies $\|\pi - \tilde{\pi}\|_1 \leq \alpha$.

Next, we compare π_{ADD} and $\tilde{\pi}$. Difference between these two vectors can be expressed by the following two quantities: (1) $|W|$, which in turn affects the scaling on Line 5; and (2) the value of $\mathbf{X}_v$, which affects the numerator on Line 5. We analyze both of these quantities.

Analysis for $|W|$. For $\ell = \hat{\ell}$, a walk has length at most $\hat{\ell}$ with probability $\epsilon \sum_{j=0}^{\hat{\ell}} (1-\epsilon)^j = 1 - (1-\epsilon)^{\hat{\ell}+1} \geq 1 - \epsilon/2$, where we used that $1 - x \leq e^{-x}$ for $x \in [0, 1/2]$. Hence, $\mathbb{E}[|W|] \geq nR(1 - \epsilon/2)$. By using a Chernoff bound we can prove that with high probability it holds $|W| \geq nR(1-\epsilon)$. The proof proceeds as follows. In the summation above, there are only ℓ different values of j that affect $\mathbb{E}[|W|]$. For a fixed j, the contribution to $|W|$ can be expressed as a sum of **independent** 0/1 random variables – a random variable per each

of the nR walks, denoting whether the given walk has length length j or not. Hence, for a fixed j we apply the Chernoff bound to show it concentrates well, and then by the union bound over all ℓ values of j we get the desired concentration for $|W|$.

Analysis for $\mathbf{X}_v$. By definition, π_{ADD} only accounts for the contribution to $\mathbf{X}_v$ by the appearances of v which are within walks of length at most ℓ; $\mathbf{X}_v$ is defined in Algorithm 1. Let $\mathbf{Y}_v$ be the appearances of v for which π_{ADD} does not but $\tilde{\pi}$ does account for.

Now, we upper-bound $\sum_v \mathbf{Y}_v$:

$$\begin{aligned}
\mathbb{E}\left[\sum_v \mathbf{Y}_v\right] =& nR(1-\epsilon)^{\hat{\ell}+1}\cdot(\hat{\ell}+1) + \sum_{j=\hat{\ell}+2}^{\infty} nR(1-\epsilon)^j \\
\leq& 2nR\alpha + nR(1-\epsilon)^{\hat{\ell}+2}\sum_{j=0}^{\infty}(1-\epsilon)^j \\
=& 2nR\alpha + \frac{nR}{\epsilon}(1-\epsilon)^{\ell+2} \\
\leq& 2nR\alpha + nR\epsilon\alpha^2/4 \\
\leq& 3nR\alpha.
\end{aligned}$$

In the derivation above, we used $(1-\epsilon)^{\hat{\ell}+1}(\hat{\ell}+1) \leq (\alpha\epsilon/2)^2(\hat{\ell}+1) \leq (\alpha\epsilon/2)^2 2\hat{\ell} \leq 2\alpha$. To prove that $\sum_v \mathbf{Y}_v \leq 4nR\alpha$ with high probability, it suffices to proceed the same way as for our analysis of $\mathbb{E}[|W|]$. In the analysis, we need the observation that $\sum_{j>c\log n/\epsilon} nR(1-\epsilon)^j < 1/n$ for a sufficiently large constant c. In other words, there are only $O(\log n)$ different values of j that substantially contribute to $\sum_v \mathbf{Y}_v$ and over which is needed to take the union bound.

Our analysis now implies that additive approximation of Algorithm 1 for $\ell = \hat{\ell}$ is with high probability upper-bounded by $\frac{\alpha}{1-\epsilon} + 4\frac{\alpha\epsilon}{1-\epsilon} \leq 5\frac{\alpha}{1-\epsilon}$. The first term is coming from the fact that π_{ADD} is computed by rescaling $\mathbf{X}_v$ by $|W|/\epsilon \geq (1-\epsilon)nR/\epsilon$ as opposed to rescaling by nR/ϵ, as it is done when computing $\tilde{\pi}$. The second term is coming from the fact that the loss between $\tilde{\pi}$ and π_{ADD} in the numerator of Line 5 is at most $4nR\alpha$ with high probability, which is divided by $|W|/\epsilon \geq nR(1-\epsilon)/\epsilon$.

6 Efficient Multiplicative Approximation in Undirected Graphs

In this section, we describe how to maintain approximate PageRank of undirected graphs under edge deletions and insertions even if the goal is to maintain a multiplicative approximation. Our approach takes $\operatorname{polylog} n$ time per update and is also based on the algorithm from Section 4.

▶ **Theorem 4.** *For any $\epsilon \in (0,1)$, there is an algorithm that with high probability explicitly maintains a $1+\alpha$ multiplicative approximation of PageRank of any undirected graph G in the fully dynamic setting. The algorithm handles each update in $O(\log^5 n/(\epsilon^2\alpha^2))$ time and works correctly against an oblivious adversary.*

Our analysis relies on the following (folklore) claim, which states that the number of the walks passing through an edge is fairly small.

▶ **Lemma 14** (Folklore). *Let G be an undirected graph. Consider a set of random walks W of length $\ell < n$ each, such that there are d_v walks originating at vertex v. Then, with high probability an edge e is contained in $O(\ell \cdot \log n)$ of those walks.*

Proof. Observe that the number of walks in W originating at each vertex v is proportional to the stationary distribution of v. Hence, the number of walks of W whose i-th vertex is v in expectation equals d_v, for each $1 \leq i \leq \ell$. Therefore, the number of walks of W whose i-th edge is $e = \{u, v\}$ (either as $u \to v$ or $v \to v$) in expectation equals 2, for each $1 \leq i \leq \ell$.

Let $X_{e,i}$ be the number of walks whose i-th edge equals i. From our discussion, $\mathbb{E}[X_{e,i}] = 2$. Also, $X_{e,i}$ is a sum of 0/1 independent random variables $Y_{v,j,i}$, where $Y_{v,j,i}$ means that the i-th edge of the j-th walk originating at v equals e. Hence, by applying the Chernoff bound, we obtain that with high probability it holds that $X_{e,i} \in O(\log n)$. By taking the union bound over all $1 \leq i \leq \ell$ and over all the vertices, we prove the desired claim. ◀

As a direct consequence of Lemma 14 we obtain the following claim.

▶ **Corollary 15.** *Consider $n \cdot t$ independent random walks of length $\ell \in O(\log n/\epsilon)$ such that from each vertex there are t walks originating. Then, with high probability an edge e is contained in $O(t \log^2 n/\epsilon)$ of those walks.*

In Section 4, we describe how to update our data structures in $O(\ell \cdot \log n)$ time per an update of an ℓ-length walk. Since Algorithm 1 runs $t = R = O(\log n/(\epsilon\alpha^2))$ random walks per vertex, by Corollary 15 there are $O(\log^3 n/(\epsilon\alpha^2))$ walks passing through each edge. Thus by the fact that walks have lengths $O(\log n/\epsilon)$ with high probability, the dynamic algorithm requires $O(\log^5 n/(\epsilon^2\alpha^2))$ time for each update, which yields Theorem 4.

A Sublinear Time Tester for Max-Cut on Clusterable Graphs

Agastya Vibhuti Jha
École polytechnique fédérale de Lausanne, Switzerland

Akash Kumar[1]
Indian Institute of Technology, Bombay, India

Abstract

One natural question in the area of sublinear time algorithms asks whether we can distinguish between graphs with max-cut value at least $1-\varepsilon$ from graphs with max-cut value at most $1/2+\varepsilon$ in the adjacency list model where we can make degree queries and neighbor queries. Chiplunkar, Kapralov, Khanna, Mousavifar, and Peres (FOCS' 18) showed that in graphs of bounded degree, one cannot hope for a factor $1/2+\varepsilon$ approximation to the max-cut value in time $n^{1/2+o(\varepsilon)}$. Recently, Peng and Yoshida (SODA '23) obtained $o(n)$ time algorithms which can distinguish expanders with max-cut value at least $1-\varepsilon$ from expanders with small max-cut value (their running time is $n^{1/2+O(\varepsilon)}$). In this paper, going beyond the results of Peng-Yoshida, we develop sublinear time algorithms for this problem on clusterable graphs (which is a graph class with a good community structure). Our algorithms run in $\approx n^{0.5001+O(\varepsilon)}$ time.

A natural extension of Peng-Yoshida approach does not seem to work for clusterable graphs. Indeed, their random walk based technique tracks the ℓ_2 length of random walk vectors and they exploit the difference in the length of these vectors to tell apart expanders with large cut value from expanders with small cut-value. Such approaches fail to be reliable when graph has loosely connected clusters. Taking inspiration from [4], we exploit the more refined geometry of spectra of clusterable graphs which leads to our sublinear time implementation. We prove a novel spectral lemma which shows that in a spectral expander $2-\lambda_{n-1} \geq \Omega(\lambda_2)$. This lemma is leveraged to show that there is a suitable difference between spectra of clusterable graphs with large cut value and spectra of clusterable graphs with small cut value. We use this gap to obtain our sublinear time implementation. To do this, we obtain a nuanced understanding of the eigenvector structure of clusterable graphs and in particular, we show that the eigenvectors of the normalized Laplacian of a clusterable graph, corresponding to eigenvalues which are close to 2 have a small infinity norm.

1 Introduction

Max-Cut is a fundamental algorithmic problem and has several applications in computer science. In this problem, we are given a graph $G=(V,E)$ as input and we are asked to find a bipartition $(S,\overline{S})$ of vertices which has the maximum number of edges going across. Let

[1] Part of this work was done when the author was a postdoc at EPFL.

Max-Cut(G) denote the fraction of edges cut by the maximizing bipartition. The decision version of Max-Cut was shown to be NP-Complete by Karp in his famous list of 21 problems in [11]. A 0.878 approximation algorithm for Max-Cut was achieved in the seminal work of [8] which was shown to be tight assuming the unique games conjecture.

While Max-Cut is interesting on general graphs, it is also intriguing when restricted to important graph classes. For instance, [2] provided algorithms for finding cuts in expanders with Max-Cut(G) $\geq 1-\gamma$ (for some sufficiently small $\gamma > 0$) that are crossed by at least $(1 - O(\gamma))$ fraction of the edges, which improves (in small γ regime) upon the Goemans-Williamson bound of $(1 - O(\sqrt{\gamma}))$ fraction of edges. In another direction, more relevant to this paper, a crucially important step was taken by [9] who presented algorithms for testing bipartiteness in bounded-degree graphs, assuming query access to the adjacency list of the input. This algorithm decides in sublinear time whether the input bounded-degree graph has Max-Cut(G) $= 1$ or whether has Max-Cut(G) $< 1-\gamma$. The authors also proposed a two-step rule of thumb for approaching a wide variety of property testing problems in bounded-degree graphs, which involves developing property testing algorithms assuming the input graph is an expander, and then using tools from expander decompositions to break the graph into a collection of expanding components with inverse-polylogarithmic expansion.

Until recently however, no sublinear time algorithms were known for approximating Max-Cut even on expanding graphs which approximate the cut-value to within a factor better than 1/2. This was remedied by [13] who gave sublinear algorithms for approximating Max-Cut on expanders in the adjacency list model. In this work, we focus on the adjacency list model and provide sublinear time algorithms for Max-Cut on a natural relaxation of expanders, namely, the family of $(k, \varphi, \varepsilon)$-clusterable graphs. Briefly, a degree d-bounded graph $G = (V, E)$ is $(k, \varphi, \varepsilon)$-clusterable if the vertex set can be partitioned into k sets, each with *inner conductance* at least φ and *outer conductance* at most ε. This graph class has been considered in several recent works on property testing [5, 4, 7]. Our main theorem (informal version below) concerns this graph class and asserts the following:

▶ **Theorem 1.** *Fix $k \in \mathbb{N}, \varphi < 1$ and $0 < \varepsilon, \gamma < \delta\varphi^2$ where $\delta = 10^{-5}$. Then there exists an algorithm which on input a $(k, \varphi, \varepsilon)$-clusterable graph runs in time $\approx n^{1/2+100\delta+O(\varepsilon/\varphi^2)}$ and returns*

- *Yes, if Max-Cut(G) $\geq 1-\gamma$*
- *No, if Max-Cut(G) $\leq 1/2+\gamma$*

Broadly speaking, this problem of distinguishing clusterable graphs with large max-cut value from clusterable graphs with small max-cut value is a special sub-problem of the more general question which seeks to develop tolerant testers for max-cut. Some complexity considerations related to the Unique Games Conjecture seem to suggest that this problem does not admit a $(1-\gamma, 1-\sqrt{\gamma})$ tolerant tester in the adjacency list query model. [3] even showed that there is no sublinear time algorithm for the Max-Cut problem with approximation ratio better than 16/17. It is an open question to chase down the parameter range for which one might expect a sublinear time algorithm for a better than one-half approximation of Max-Cut on a class of graphs richer than expanders. Our results can be viewed as taking the first step in this direction.

2 Preliminaries

In the following, we will let $G = (V, E)$ denote a graph.

▶ **Definition 2.** *The normalized adjacency matrix $\bar{\boldsymbol{A}}$ is $\boldsymbol{D}^{-1/2}\boldsymbol{A}\boldsymbol{D}^{-1/2}$, where $\boldsymbol{D}$ is the diagonal of degrees. The normalized Laplacian is $\bar{\boldsymbol{L}} = \boldsymbol{I} - \bar{\boldsymbol{A}}$.*

The *random walk associated with* G is defined to be the random walk with transition matrix $\boldsymbol{AD}^{-1}$. Note that, unlike the previous works in *property-testing*, we do a *non-lazy* walk over G.

▶ **Definition 3** ([10], Rayleigh Quotient). *Let $\boldsymbol{A}$ be a matrix in $\mathbb{R}^{n\times n}$ and let $\boldsymbol{x}$ be a non-zero vector in $\mathbb{R}^n$. Then, the Rayleigh quotient of $\boldsymbol{x}$ with respect to $\boldsymbol{A}$ is defined as:*

$$\mathcal{R}_{\boldsymbol{A}}(\boldsymbol{x}) = \frac{\boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x}}{\boldsymbol{x}^T\boldsymbol{x}}.$$

- For any arbitrary matrix $\boldsymbol{B}$ in $\mathbb{R}^{n\times n}$, we use $\mu_1 \leq \mu_2 \leq \ldots \leq \mu_n$ to denote its eigenvalues in ascending order, and $\nu_1 \geq \nu_2 \geq \ldots \geq \nu_n$ to denote its eigenvalues in descending order.
- Given a graph $G = (V, E)$, we let $\mathbf{1}_x \in \mathbb{R}^V$ to denote the indicator vector for a vertex x in V. For a multi-set of vertices $\{x_1, x_2, \ldots x_k\}$, we let $S \in \mathbb{R}^{n\times k}$ denote the matrix of indicators, where the j^{th} column of S is the vector $\mathbf{1}_{x_j}$ for $1 \leq j \leq k$.
- (*Informal*) Given a graph $G = (V, E)$, and its normalized Laplacian $\bar{\boldsymbol{L}}$, we will refer to the eigenvectors with corresponding eigenvalues close to 0 (resp. eigenvalues close to 2) as the *clusterability* eigenvectors (resp. *Max-Cut* eigenvectors). The notion of close to 0 (resp. close to 2) will be made clear in the context.

▶ **Theorem 4** ([10], Spectral Theorem). *Let $\boldsymbol{A}$ be a real symmetric matrix. Then, there exists an orthonormal basis of $\mathbb{R}^n$ consisting of eigenvectors of $\boldsymbol{A}$ and all the eigenvalues of $\boldsymbol{A}$ are real.*

▶ **Theorem 5** ([10], Courant-Fischer). *Let $\boldsymbol{A}$ be a real symmetric matrix in $\mathbb{R}^{n\times n}$, let $\lambda_1 \leq \lambda_2 \leq \ldots \leq \lambda_n$ be its eigenvalues. Then, for any $1 \leq k \leq n$,*

$$\lambda_k = \min_{\mathcal{U}} \max_{x\neq 0}\{\{R_{\boldsymbol{A}}(\boldsymbol{x}) \mid \boldsymbol{x} \in \mathcal{U}\} \mid dim\, \mathcal{U} = k\},$$

and

$$\lambda_{n-k+1} = \max_{\mathcal{U}} \min_{\boldsymbol{x}\neq 0}\{\{R_{\boldsymbol{A}}(\boldsymbol{x}) \mid \boldsymbol{x} \in \mathcal{U}\} \mid dim\, \mathcal{U} = k\}.$$

▶ **Lemma 6** ([10], Weyl's Inequality). *Let $\boldsymbol{A}$ and $\boldsymbol{E}$ be real symmetric matrices in $\mathbb{R}^{n\times n}$. Then, for all $i \in \{1, 2, \ldots, n\}$,*

$$\lambda_i(\boldsymbol{A}) + \lambda_{min}(\boldsymbol{E}) \leq \lambda_i(\boldsymbol{A} + \boldsymbol{E}) \leq \lambda_i(\boldsymbol{A}) + \lambda_{max}(\boldsymbol{E}).$$

▶ **Lemma 7** ([10]). *For any $m \times n$ matrix $\boldsymbol{A}$ and $n \times m$ matrix $\boldsymbol{B}$, the multisets of nonzero eigenvalues of $\boldsymbol{AB}$ and $\boldsymbol{BA}$ are the same. In particular, if one of $\boldsymbol{AB}$ and $\boldsymbol{BA}$ is positive semi-definite, then $\mu_h(\boldsymbol{AB}) = \mu_h(\boldsymbol{BA})$.*

▶ **Lemma 8** (Folklore). *Let $\boldsymbol{A}$ and $\boldsymbol{B}$ denote two positive semidefinite matrices in $\mathbb{R}^{n\times n}$. Then $\nu_{max}(\boldsymbol{AB}) \leq \nu_{max}(\boldsymbol{A})\,\nu_{max}(\boldsymbol{B})$.*

▶ **Definition 9.** *Given a graph $G = (V, E)$ and a set $S \subseteq V$, we define $vol(S) = \sum_{i\in S} deg(i)$.*

▶ **Definition 10** (Inner and Outer Conductance). *Let $G = (V, E)$ be a graph. For a set $S \subseteq C \subseteq V$, we define the conductance of S within C as $\varphi^C_{in}(S) = \frac{|E(S,C\setminus S)|}{\sum_{i\in S} deg(i)} = \frac{|E(S,C\setminus S)|}{vol(S)}$. The inner conductance of a set $C \subseteq V$ is defined as*

$$\varphi_{in}(C) = \min_{\substack{S\subseteq C \\ 0<vol(S)\leq vol(C)/2}} \varphi^C_{in}(S).$$

We define the outer conductance of a set $C \subseteq V$ to be $\varphi_{out}(C) = \frac{|E(C,V\setminus C)|}{vol(C)}$.

▶ **Theorem 11** (Cheeger's Inequality, Folklore). *Let G be a graph. Let $\bar{\boldsymbol{L}}$ denote its normalized Laplacian. Then,*

$$\frac{\phi^2(G)}{2} \leq \lambda_2 \leq 2\phi(G),$$

where λ_2 denotes the second smallest eigenvalue of the normalized Laplacian of G.

▶ **Definition 12** ((k,φ,ε)-clusterable graphs). *A graph $G=(V,E)$ is said to admit a (k,φ,ε)-clustering if there exists a partition of V into k sets $C_1, C_2, \ldots C_k$ such that each C_i satisfies $\varphi_{in}(C_i) \geq \varphi$ and $\varphi_{out}(C_i) \leq \varepsilon$ and for all $i,j \in [k]$ it holds that $\frac{|C_i|}{|C_j|} = O(1)$.*

When the parameters φ and ε are clear from the context, we will often refer to these graphs as k-clusterable graphs and sometimes even as clusterable graphs when the parameter k is also clear from the context. [7] consider clusterable graphs where $\varepsilon/\varphi^2 \leq \delta := 10^{-5}$. We also consider a similar parameter regime.

▶ **Theorem 13** ([7], Clusterability Eigengap). *Let G be a graph that admits a (k,φ,ε)-clustering. Let $0 \leq \lambda_1 \leq \lambda_2 \leq \ldots \lambda_n$ denote the spectrum of its normalized Laplacian. Then, $\lambda_k \leq 2\varepsilon$ and $\lambda_{k+1} \geq \varphi^2/2$.*

3 Technical Overview

The algorithmic problem of getting a better than $1/2$ approximation algorithm for the max-cut-value of a degree bounded graph was ushered to the frontlines of research in sublinear-time algorithms in the work of [4]. This paper shows that any algorithm that returns an estimate to the max-cut-value that is at least $1/2+\varepsilon$ must make an $n^{1/2+\Omega(\varepsilon)}$ number of queries to the adjacency list of G. After this work, one natural next step is to ask whether there are algorithms that approximate max-cut to within some approximation factor better than $1/2$ on some rich enough class of interesting graphs. A progress was reported on this endeavor in the work of [13] who obtained a such an estimate to the max-cut-value on expanders of bounded degree.

As our starting point, we describe at a high level, the approach used in [13] for deciding whether the max-cut value of an input expander is large or whether it is small. The starting point of this work adapts the techniques used in the pioneering work of [9] to obtain a tester for deciding whether Max-Cut(G) is close to 1 or bounded away from 1 on expanders. One can think of a φ-expander as a (k,φ,ε)-clusterable graph with $k=1$ and $\varepsilon=0$ (see Definition 12). Let us now describe the high level ideas that underlie Peng-Yoshida algorithm. In particular, [13] note that on an expanding instance with large max-cut value, the following distributions over end-points of ℓ length lazy walks are fairly far:

- $\mathcal{D}_{v,e}$: The end-point distribution supported over vertices reached in an ℓ-step walk with the effective length (that is, number of steps left after deleting all loops) being an even number.
- $\mathcal{D}_{v,o}$: The end-point distribution supported over vertices reached in an ℓ-step walk with the effective length being an odd number.

As mentioned ealier, the intuition behind this argument comes from [9] which considers the case where Max-Cut(G) $= 1$. In this case, note that the distributions are disjointly supported and thus indeed the ℓ_2^2 distance between the distributions is large.

While the Peng-Yoshida algorithm extends the Goldreich-Ron bipartiteness testing algorithm in a very elegant way, unfortunately, this algorithm does not extend to the (k,φ,ε)-clusterable case even for $k=2$. To see this, let us take the following graph. It contains two

disjoint isomorphic $(1/\varepsilon - 2)$-regular[2] bipartite φ-expanders which are sparsely connected (and we will describe what these corss-edges are momentarily). We denote the first bipartite graph as (A_1, B_1) and the other one as (A_2, B_2) where $|A_1| = |B_1| = |A_2| = |B_2| = n/4$. Next, we connect A_1 and A_2 with a perfect matching and we also connect A_1 and B_2 with another perfect matching. We also add a perfect matching between B_1 and A_2 and another one between B_1 and B_2. In all, this gives us a $1/\varepsilon$-regular $(2, \varphi, \varepsilon)$-clusreable graph which has $\mathsf{Max\text{-}Cut(G)} = 1 - O(\varepsilon)$. Now, consider performing a lazy walk of logarithmic length from *any* start vertex in this instance. Note that the walk reveses its "polarity" once every $2/\varepsilon$ steps in expectation. In particular, this means that the distributions $\mathcal{D}_{v,o}$ and $\mathcal{D}_{v,e}$ are fairly close and one can no longer use the distance between these distributions as a reliable indicator for whether the max-cut-value is large or whether it is small.

We want to circumvent this obstacle and obtain a better than 1/2-approximation to max-cut-value in sublinear time for k-clusterable graphs. To this end, for the ease of presentation in this overview, it will be convenient to make the following simplications listed in the remark below.

▶ Remark 14. We emphasize that all the simplifications made in this remark are only for the ease of presentation in this overview. Our main result (Theorem 16) and its proof does not rely on these simplifications.

1. *We will assume that graph is d-regular.*
2. *We will assume that all clusters in the input k-clusterable graph have the same size.*
3. *Recall we are trying to distinguish $(k, \varphi, \varepsilon)$-clusterable graphs with max-cut-value at least $1 - \gamma$ from graphs with max-cut-value at most $1/2 + \gamma$. It will additionally be convenient to assume that $\varphi = \Omega(1)$ and that ε and γ are sufficiently small constants with $\gamma = \Theta(\varepsilon)$. As stated in Theorem 16, we only need to have both ε and γ being at most $\delta\varphi^2$.*

Now, towards getting a better than 1/2 approximation to the max-cut-value, let us consider the following intuition: Suppose we are given a k-clusterable graph G with high max-cut-value. That is, we are told that $\mathsf{Max\text{-}Cut(G)} \geq 1 - \gamma$. In this case, by averaging, one notices that G has at least $\ell := 2k/3$ clusters which have induced max-cut-value at least $1 - O(\gamma)$. Now consider the graph that one gets after doing a two-step non-lazy walk on G. This is the graph G^2 where one puts a (parallel) edge between every pair of vertices between which there is a path of length two. Consider what this process does to a component with high induced max-cut-value. Intuitively, since (almost) all the edges run between the maximizing bipartition in this component, we get two sparsely connected components – one induced on each bipartition. And both of these bipartitions induce expanders as well. This way, we get one additional sparse cut in G^2 corresponding to every component with large induced max-cut-value. In particular, this means the $(k + \ell)$-th smallest eigenvalue of the Normalized Laplacian of G^2 is close to zero. Thus, this intuition suggests that one can track the $(k + \ell)$-th smallest eigenvalue of the normalized Laplacian of the graph which results after a non-lazy walk of some even length. Indeed, our algorithms are built off on this intuition.

Towards showing that this algorithm can reliably distinguish between k-clusterable graphs G with $\mathsf{Max\text{-}Cut(G)} \geq 1 - \gamma$ and k-clusterable graphs with $\mathsf{Max\text{-}Cut(G)} \leq 1/2 + \gamma$ (recall we assumed $\gamma = \Theta(\varepsilon)$ in Remark 14), we need to understand the spectra of instances in both of these regimes. Additionally, we need to show that the graph spectra in these two cases are appreciably different that a non-lazy random walk based algorithm can detect this difference. We now outline our algorithm. The algorithm proceeds by taking a multiset

[2] We ignore the integrality issues.

$S \subseteq V$ of samples with $|S| = poly(k) \cdot n^{O(\varepsilon)}$ in the hope of getting enough vertices from every cluster. Next up, setting the length of the walk to be $t = \frac{C \log n}{\varphi^2}$, the algorithm computes the Gram Matrix of collision probabilities $\boldsymbol{W}_S = (\boldsymbol{M}^t \boldsymbol{I}_S)^T (\boldsymbol{M}^t \boldsymbol{I}_S) \in \mathbb{R}^{|S| \times |S|}$ (here $\boldsymbol{I}_S$ denotes the identity matrix restricted to vertices of S). Finally, the algorithm just checks whether the $(k+\ell)$-th largest eigenvalue of $n/s \cdot \boldsymbol{W}_S$ is at least $n^{-O(\varepsilon)}$. If yes, the algorithm reports that the graph had max-cut-value close to 1 otherwise it reports that the graph had max-cut-value close to 1/2. In the following remark, we collect the remaining ingredients our analysis relies upon. In the remainder of the tech-overview we elaborate upon the ideas stressed in this remark.

▶ Remark 15. The intuition here comes from considering the matrix $\boldsymbol{W} = (\boldsymbol{M}^t)^T(\boldsymbol{M}) = \boldsymbol{M}^{2t}$. For a set $S \subseteq V$, we let $\boldsymbol{W}_S$ denote the matrix we obtain when we restrict the matrix $\boldsymbol{W}$ to rows and columns indexed by S.

1. *In Theorem 20, we show the following two items.*
   a. *If* Max-Cut(G) $\geq 1-\gamma$, *then the $(k+\ell)$-th eigenvalue of $\boldsymbol{M}^{2t}$ is at least $(1-\varepsilon)^{2t}$ which by the choice of $t = \frac{C \log n}{\varphi^2}$ means we get a lower bound of $n^{-O(\varepsilon)}$ on the $(k+\ell)$-th largest eigenvalue of $\boldsymbol{W}$.*
   b. *If* Max-Cut(G) $\leq 1/2+\gamma$, *we show the $(k+\ell)$-th largest eigenvalue of $\boldsymbol{W}$ is at most $(1-O(\varphi^2))^{2t}$ which by the choice of t can be shown to be at most n^{-C}.*
2. *Finally, one shows that the eigenvalues of $\boldsymbol{W}$ are very close to the corresponding eigenvalues of $n/s \cdot \boldsymbol{W}_S$. This goes via an application of Matrix Bernstein Bounds. Using these bounds requires a little more understanding of the eigenvector structure of the Laplacian of Clusterable instances with high max-cut-value which we also develop.*

Towards showing Item 1.(a) and Item 1.(b) mentioned in Remark 15, it is helpful to introduce a little notation. Let $\nu_1 \geq \nu_2 \geq \cdots \geq \nu_n$ denote the eigenvalues of the random walk matrix $\boldsymbol{M}$. For showing item 1.(a), note that using the easy direction of higher order Cheeger, we already have $\nu_k(\boldsymbol{M}) \geq 1 - 2\varepsilon$. In case 1.(a), we also know Max-Cut(G) $\geq 1-\varepsilon$ which additionally means that the last ℓ eigenvalues of $\boldsymbol{M}$ are close to -1 (and in particular we have $\nu_{n-\ell+1} \leq -1 + O(\varepsilon)$). This is because G has ℓ nearly bipartite components and therefore, we have ℓ disjointly supported vectors all of which have Rayleigh Quotient close to -1. In all, this means that $(k+\ell)$-th largest eigenvalue of $\boldsymbol{M}^{2t}$ is at least $(1-O(\varepsilon))^{2t}$ as desired.

Towards showing Item 1.(b), we prove an important *eigengap transportation* lemma (Lemma 21) in spectral graph theory which asserts that for any expander graph on n vertices we have $\lambda_{n-1} < 2 - \Omega(\lambda_2)$ (recall that λ's denote the eigenvalues of the Normalized Laplacian). Although, fairly intuitive, this seems to be a novel result. Indeed, a direct adaptation of techniques from [14] produces a bound saying $\lambda_{n-1} \leq 2 - \Omega(\lambda_2^2)$ as obtained in [12]. One can use this lemma to conclude that in case 1.(b), where Max-Cut(G) $\leq 1/2+\varepsilon$, $\nu_{n-k+1} \gg -1$. Additionally, since G has such a small max-cut-value, we can show that there at least $\ell := 2k/3$ clusters in G which have induced max-cut-value close to 1/2. It can be shown that corresponding to every one of these ℓ components, we have an additional eigenvalue of $\boldsymbol{M}$ which is bounded away from -1. In all, using Lemma 21, we get $\nu_{k+\ell}(\boldsymbol{M}^{2t}) \leq (1 - O(\varphi^2)^{2t}$ as desired.

Finally, we turn to item 2 in Remark 15. Towards relating eigenvalues of $\boldsymbol{W}$ and $n/s \cdot \boldsymbol{W}_S$ using Matrix Bernstein, we need to control the Euclidean length of columns of $\boldsymbol{M}^{2t}$. Thus, we want to understand collision statistics of random walks performed from all start vertices in G. We do this by following techniques used in [4, 7] which encounters a similar situation. The main goal in [4] was to test k-clusterability and lazy walks were fine for this objective. The main idea there was to show that the eigenvectors of the random walk matrix corresponding to

eigenvalues close to 1 (that is, eigenvectors which reveal clusterability information) are mostly uniform, in absolute value, over the corresponding cluster. [7] formalize this by proving an ℓ_∞ norm bound on such eigenvectors which is later leveraged towards understanding the collision statistics of random walk behaviors from an arbitrary pair a, b of vertices. Oversimplifying a little, this allows them to approximate powers of random walk matrices which can then be used to test for an eigengap which in turn allows us to test clusterability. However, bounding this Euclidean length in our situation requires a more nuanced adaptation of techniques from [4] since our walks are non-lazy and we need to track eigenvectors of the random walk matrix with corresponding eigenvalue close to -1.

Indeed, we show a similar statement for such eigenvectors. This is done by proving ℓ_∞ norm bounds on these eigenvectors which we later use to approximate appropriate powers of random walk matrices. Again, using the same oversimplification as above, this allows us to approximate powers of random walk matrices which we then use to distinguish clusterable graphs with large max-cut value from clusterable graphs with small max-cut value. More precisely, what we show that the eigengaps between the original clusterable graphs (one with large max-cut value and the other one with a small max-cut value) are preserved under sampling. And this finishes the high level description of our approach. As a final aside, there are a few additional technical challenges/interesting features of this work which we enumerate below.

- **Challenges in Bounding Euclidean Length of Random Walk Vectors:** Recall that in [4], the goal was to test k-clusterability. To this end, [4] exploits that for a k-clusterable graph, there is a large gap between the k-th largest eigenvalue (which is at least $1 - 2\varepsilon$) and $(k+1)$-st largest eigenvalue (at most $1 - \varphi^2/2$)) of the random walk matrix, $\boldsymbol{M}$. On the other hand, in graphs which are far from being k-clusterable, the $(k+1)$-st eigenvalue of the random walk matrix is also reasonably large and this can be used a reliable estimator to distinguish between the two cases. However, in our setup, there is no such sharp threshold after which we necessarily witness any sharp drop between two successive eigenvalues of $\boldsymbol{M}$. And therefore, this non-existence of an eigengap between successive eigenvalues remains a problem with $\boldsymbol{M}^{2t}$ as well. Indeed, if $\mathsf{Max\text{-}Cut(G)}$ is large, we can have more than ℓ clusters with relatively large induced max-cut-value (say with value at least $(1 - 1000\varepsilon)$) – and each of these clusters implies a yet another large eigenvalue of $\boldsymbol{M}$. To allay this, we consider all eigenvectors with eigenvalue at least $1 - \delta\varphi^2$ and we leverage our ℓ_∞ bounds on the eigenvectors to upperbound the contribution to $\|\boldsymbol{M}^t \mathbf{1}_x\|_2^2$ from such eigenvectors. For other eigenvectors, the contribution to the walk length can be handled by choosing walk length suitably (which depends inversely on the δ value we choose). This also explains why our analysis carries the parameter δ around.
- **Showing an Eigengap in Presence of Crossedges:** Remark 15 emphasizes that we have an eigenvalue gap between the two cases, 1(a) and 1(b). However, recall that we wanted to consider instances with outer conductance ε and the instance just described had outer conductance 0. Two problems emerge when we consider instances with large outer conductance. All of the argument so far assumes there are no cross edges running between these k components. We show when an ε fraction of cross edges between various components are added, the $(k+\ell)$-th eigenvalue of $\boldsymbol{M}^{2t}$ *still remains* a reliable indicator for the max-cut-value. This does not follow immediately from Frobenius norm bounds on the Laplacian corresponding to the cut edges.
- **Necessity of Non-Lazy Walks:** An essential feature of our algorithm is that it crucially involves performing non-lazy random walks. To the best of our knowledge, there is no other work in sublinear algorithms where analyzing non-lazy walks is tied with the algorithmic guarantees in such a fundamental way. Classic results in property testing

Algorithm 1 TestMaxCut$(G, k, \varphi, \varepsilon, d)$ ▷ Need: $\varepsilon/\varphi^2 \leq \delta = \frac{1}{10^5}$, a constant $\chi \gg 1$.
▷ Set constants $a = \frac{2000 \cdot \chi \cdot d^4}{\delta}$, $b = \frac{4000 \cdot \chi^2 d^8}{\delta^2}$.

$\ell = \lceil 2k/3 \rceil$
$\xi = n^{-a \cdot \varepsilon/\varphi^2}$.
$s = 10^{20} k^4 d^6 \cdot n^{80\delta + b \cdot \varepsilon^2/\varphi^4}$
$t = 10/\delta \cdot 1/\varphi^2 \cdot \chi d^3 \log n$.
Sample s vertices from V uniformly at random. Let S be the multiset of sampled vertices.
Compute $\boldsymbol{Z} = (n/s) \left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\boldsymbol{S}\right)^T \left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\boldsymbol{S}\right)$ using the oracle.
$\mu_{thres} = \frac{0.99}{d} \cdot n^{-2000 \cdot \varepsilon \cdot \chi d^4 \delta^{-1} \varphi^{-2}}$.
if $\nu_{k+\ell}(Z) \geq \mu_{thres}$ **then**
  Accept G.
else
  Reject G.

on bounded degree graphs often make the simplification of making the graph regular by adding loops (which again makes any random walks considered lazy). However, we unfortunately cannot use this simplification of adding loops as this again risks shrinking the eigengap our approach hopes to exploit. Thus, for non-regular input graphs, *our analysis can not even assume the random walk Matrix $\boldsymbol{M}$ to be symmetric* (a common assumption which can be made if G could be made regular by adding loops).

4 Algorithm Under the Oracle Assumption

The goal of this section is to present an algorithm for testing Max-Cut(G) under a simplifying assumption. We assume that we have the following oracle at our disposal: the oracle takes a vertex v as input, and returns $\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\mathbf{1}_v$.

5 Proof Under the Oracle Assumption

We state below the main theorem which asserts that the above algorithm is a bonafide distinguisher which reliably tells apart graphs with large max-cut-value from graphs with small max-cut-value. This provides the proof of correctness for the algorithm described in Section 4.

▶ **Theorem 16.** *Let $G = (V, E)$ be a $(k, \varphi, \varepsilon)$-clusterable graph where*
- *The maximum degree of G is at most some constant, d.*
- *$\varepsilon \leq \frac{\delta \cdot \varphi^2}{10^4 \cdot d^4 \cdot \chi}$.*
  Here $\delta = 10^{-5}$ and $\chi > 1$ is sufficiently large.

Then the algorithm TestMaxCut$(G, k, \varphi, \varepsilon, d)$ runs in time $\frac{\chi \cdot d^3 \cdot \log n}{\varphi^2} n^{1/2 + 100\delta + O(\varepsilon/\varphi^2)}$ and with probability at least $2/3$, returns
- *Accept if Max-Cut(G) $\geq 1 - \varepsilon$.*
- *Reject if Max-Cut(G) $\leq 1/2 + \varepsilon$.*

▶ Remark 17. As noted in item 3 of Remark 14, one can show Theorem 16 assuming both $\varepsilon, \gamma \ll \delta\varphi^2$ (where $\delta = 10^{-5}$). It is more easily shown assuming $\gamma \leq \varepsilon$ which is what the theorem above assumes.

Towards proving this, we first prove the following theorem:

▶ **Theorem 18.** *Let $G = (V, E)$ be a $(k, \varphi, \varepsilon)$-clusterable graph where*
- *The maximum degree of G is at most some constant, d.*
- *$\varepsilon \leq \frac{\delta \cdot \varphi^2}{10^4 \cdot d^4 \cdot \chi}$. Here $\delta = 10^{-5}$ and $\chi > 1$ is sufficiently large.*

Then with probability taken over its internal randomness, 1 satisfies the following.
- *If Max-Cut(G) $\geq 1 - \varepsilon$, $\nu_{k+\ell}\left(\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\boldsymbol{S}\right)^T\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\boldsymbol{S}\right)\right) \geq \frac{0.99}{d} \cdot n^{-2000 \cdot \varepsilon \cdot \chi d^4 \delta^{-1} \varphi^{-2}}$ with probability at least $2/3$,*
- *If Max-Cut(G) $\leq 1/2 + \varepsilon$, $\nu_{k+\ell}\left(\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\boldsymbol{S}\right)^T\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\boldsymbol{S}\right)\right) \leq n^{-100}$,*

The proof of Theorem 16 is immediate by Theorem 18.

Proof of Theorem 16. As ε is upper bounded by $10^{-4}\delta\varphi^2\chi^{-1}d^{-4}$, in the YES case our estimator is lower bounded by $0.99d^{-1} \cdot n^{-2000 \cdot \varepsilon \cdot \chi d^4 \delta^{-1} \varphi^{-2}}$ with probability at least $2/3$. While in the NO case, our estimator is upper bounded by n^{-100} with probability 1. ◀

We begin by stating the following proposition:

▶ **Proposition 19.** *Let $G = (V, E)$ be a bounded degree $(k, \varphi, \varepsilon)$-clusterable graph with ε at most $10^{-4}\delta\varphi^2\chi^{-1}d^{-4}$ where $\delta = 10^{-5}$ and d is the degree bound. Then,*
1. *If Max-Cut(G) $\geq 1 - \varepsilon$, then at least $\lceil 2k/3 \rceil$ of the clusters have induced Max-Cut value at least $(1 - 10\varepsilon d)$.*
2. *If Max-Cut(G) $\leq 1/2 + \varepsilon$, then at least $\lceil 2k/3 \rceil$ of the clusters have induced Max-Cut value at most $(1/2 + 10\varepsilon d)$.*

N.B. In the following, we will denote $\lceil 2k/3 \rceil$ by ℓ for simplicity.

A simple markov argument shows that in the case with large max-cut value, most of the clusters are nearly bipartite (far from bipartite in the case with small max-cut value resp.).

5.1 Eigengaps in the Spectrum of Random Walk Matrix

For simplicity of the reader, we collect all the parameters we use throughout the paper.
- $\delta = 10^{-5}$.
- $\chi > 1$. a sufficiently large constant.
- A degree bound, d.
- $k \in \mathbb{N}$, the number of clusters in our $(k, \varphi, \varepsilon)$ clusterable graph.
- $\ell = \lceil 2k/3 \rceil$.
- A bound on ε, namely $\varepsilon \leq \delta\varphi^2/(10^4 d^4 \chi)$.

We state the main result of this section below. The proof is given in the appendix. In this section, we will prove one key lemma (Lemma 21) which is crucially used in proving the theorem below.

▶ **Theorem 20.** *Let G be a bounded degree graph that admits a $(k, \varphi, \varepsilon)$-clustering such that $\varepsilon \leq \delta \cdot \varphi^2/\left(10^4 \chi d^4\right)$ where d is the degree bound (and $\delta = 10^{-5}$). Then,*
1. *If Max-Cut(G) $\geq 1 - \varepsilon$, then $\nu_{k+\ell}\left(\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\right)^T\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\right)\right) \geq (1 - 100\varepsilon d)^{2t}/d$,*
2. *If Max-Cut(G) $\leq 1/2 + \varepsilon$, then $\nu_{k+\ell}\left(\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\right)^T\left(\boldsymbol{D}^{-1/2}\boldsymbol{M}^t\right)\right) \leq \left(1 - \varphi^2/\left(100\chi d^3\right)\right)^{2t}$,*

where t is any even number.

We begin by proving the key technical lemma required in the proof of Theorem 20.

▶ **Lemma 21** (Eigengap Transportation). *Let $G = (V, E)$ be a bounded degree graph, and $0 \leq \lambda_1 \leq \lambda_2 \leq \ldots \lambda_n \leq 2$ denote the spectrum of $\boldsymbol{L}_G$. Then $\lambda_{n-1} \leq 2 - \frac{\lambda_2}{\chi \cdot d^2}$, where d is the degree bound and χ is an absolute constant.*

Let us do a little setup before we prove Lemma 21. Suppose $\boldsymbol{v}_{n-1}, \boldsymbol{v}_n$ denote the last two eigenvectors of $\bar{\boldsymbol{L}} = \boldsymbol{I} - \boldsymbol{D}^{-1/2}\boldsymbol{A}\boldsymbol{D}^{-1/2}$. Suppose for a sufficiently small $\gamma > 0$, we have for every $\boldsymbol{x} \in span(\boldsymbol{v}_{n-1}, \boldsymbol{v}_n)$, $R(\boldsymbol{x}) \geq 2 - \gamma$. We will show that in this case we also have $\lambda_2 \leq O(\gamma d^2)$ where d is the maximum degree in the graph G. Before we prove this result, we first develop some intuition which will help with the formal proof which is presented in Section Subsubsection 5.1.2.

5.1.1 Intuition for Proving Lemma 21

Towards getting some intuition, it will be helpful to assume that the graph is d-regular. Denote the eigenvectors corresponding to λ_{n-1} (resp λ_n) as $\boldsymbol{v}_{n-1}$ (resp $\boldsymbol{v}_n$). Recall that in this (d-regular) case the eigenvector corresponding to λ_1 is given $\boldsymbol{v}_1 = \mathbf{1}/\sqrt{n}$. As mentioned above, we would like to produce a vector $\boldsymbol{x} \perp \boldsymbol{v}_1$ with small Rayleigh Quotient. Consider a d-regular graph with two disjoint bipartite components each on n vertices – denoted $G_1 = (L_1, R_1, E_1)$ and $G_2 = (L_2, R_2, E_2)$. The eigenvectors $\boldsymbol{v}_{n-1}, \boldsymbol{v}_n$ satisfy:

$$\boldsymbol{v}_{n-1}(u) = \begin{cases} +1/\sqrt{n} \text{ if } u \in L_2 \\ -1/\sqrt{n} \text{ if } u \in R_2 \\ 0 \text{ Otherwise.} \end{cases} \quad \text{and} \quad \boldsymbol{v}_n(u) = \begin{cases} +1/\sqrt{n} \text{ if } u \in L_1 \\ -1/\sqrt{n} \text{ if } u \in R_1 \\ 0 \text{ Otherwise.} \end{cases} \tag{1}$$

Now consider the vector $\boldsymbol{x}$ (resp $\boldsymbol{y}$) obtained by reversing the signs of all entries in the vector $\boldsymbol{v}_n$ (resp $\boldsymbol{v}_{n-1}$). Thus, the vector $\boldsymbol{x}$ equals a copy of the all-ones vector over G_1 and $\boldsymbol{y}$ equals a copy of all-ones vector over G_2 where $\boldsymbol{x}$ and $\boldsymbol{y}$ have disjoint supports and thus $\langle \boldsymbol{x}, \boldsymbol{y} \rangle = 0$. This gives a two-dimensional space of vectors with small Rayleigh Quotient which in turn means $\lambda_2 = 0$. While taking the absolute values gives a vector with small Rayleigh Quotient, in general, we cannot expect this to produce vectors with disjoint supports. Suppose we only have the vector $\boldsymbol{y}$ we obtained above by taking the absolute values of every entry in $\boldsymbol{v}_{n-1}$. Suppose we want to use only this vector towards bounding λ_2. The difficulty is this vector is not orthogonal to $\boldsymbol{v}_1$ as all coordinates in both of these vectors are all positive. To fix this, we subtract off a multiple of the projection of the $\boldsymbol{y}$ along the all-ones vector to obtain a vector $\boldsymbol{z} \perp \mathbf{1}$. We would like to bound the Rayleigh Quotient of $\boldsymbol{z}$. Since all the coordinates in $\boldsymbol{z}$ are a shift of corresponding coordinates in $\boldsymbol{y}$ (by the same additive amount) the numerator of the corresponding Rayleigh Quotients of the two vectors are equal. Towards bounding the Rayleigh Quotient, the main idea is to lower bound the length of $\boldsymbol{z}$ after this shift. This is precisely what we achieve in Lemma 27. Details follow.

5.1.2 Proof of Lemma 21

The high-level idea in the argument is to exhibit a two-dimensional subspace all vectors in which have a small Rayleigh Quotient with respect to the Laplacian. We already know $\boldsymbol{D}^{1/2}\mathbf{1}$ is one such vector. So, it suffices to produce a vector $\boldsymbol{t} \perp \boldsymbol{D}^{1/2}\mathbf{1}$ which has a small Rayleigh Quotient. At a high-level, our proof uses the following strategy. If a suitable non-linear transform applied to vectors $\boldsymbol{v}_{n-1}$ or $\boldsymbol{v}_n$ does not give us the desired vector $\boldsymbol{t}$, then that same transform applied to an equal weight linear combination of $\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}$ and $\boldsymbol{D}^{-1/2}\boldsymbol{v}_n$ gives us the desired vector $\boldsymbol{t}$.

Let $R(\boldsymbol{x}) = R_{\bar{\boldsymbol{L}}}(\boldsymbol{x})$. Note that the map $\boldsymbol{x} \to \boldsymbol{D}^{1/2}\boldsymbol{x}$ is a bijection and as noted in [15], this means

$$\lambda_{n-1} = \max_{\substack{S \subseteq \mathbb{R}^n \\ S \text{ 2-dimensional}}} \min_{\boldsymbol{x} \in S \setminus 0} R_{\bar{\boldsymbol{L}}}(\boldsymbol{x}) \tag{2}$$

$$= \max_{\substack{S \subseteq \mathbb{R}^n \\ S \text{ 2-dimensional}}} \min_{\boldsymbol{x} \in S \setminus 0} R_{\bar{\boldsymbol{L}}}(\boldsymbol{D}^{1/2}\boldsymbol{x}) \tag{3}$$

$$= \frac{\sum_{(u,v)\in E}(\boldsymbol{x}_u - \boldsymbol{x}_v)^2}{\sum d_v \boldsymbol{x}_v^2}. \tag{4}$$

The following observation is immediate.

▶ **Observation 22.** *Suppose $\lambda_{n-i+1}(\bar{\boldsymbol{L}}) \geq 2 - \gamma$. Let $S = span(\boldsymbol{v}_{n-i+1}, \boldsymbol{v}_{n-i+2}, \ldots, \boldsymbol{v}_n)$. Consider a i-dimensional subspace $S' = span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-i+1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-i+2}, \ldots \boldsymbol{D}^{-1/2}\boldsymbol{v}_n) \subseteq \mathbb{R}^n$. Then, for all non-zero vectors $\boldsymbol{x} \in S'$, we have $R(\boldsymbol{D}^{1/2}\boldsymbol{x}) \geq 2 - \gamma$.*

▷ Claim 23. Let $\boldsymbol{x} \in span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_n)$. Now consider the vector $\boldsymbol{x}' = |\boldsymbol{x}|$ obtained by letting $\boldsymbol{x}'(u) = |\boldsymbol{x}(u)|$ for each $u \in V$. Then, $R(\boldsymbol{D}^{1/2}\boldsymbol{x}') \leq \gamma$.

Proof. Since $\boldsymbol{x} \in S \stackrel{\text{def}}{=} span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_n)$, by Observation 22, it holds that $R(\boldsymbol{D}^{1/2}\boldsymbol{x}) \geq 2-\gamma$. This means $\sum_{(u,v)\in E}(\boldsymbol{x}(u)+\boldsymbol{x}(v))^2 \leq \gamma \sum d_v \boldsymbol{x}_v^2$. Note that $\|\boldsymbol{D}^{1/2}\boldsymbol{x}'\|_2 = \|\boldsymbol{D}^{1/2}\boldsymbol{x}\|_2$ as the two vectors have same absolute value in each coordinate. We will show that $R(\boldsymbol{D}^{1/2}\boldsymbol{x}') = \frac{\sum_{(u,v)\in E}\left(\boldsymbol{x}'(u)-\boldsymbol{x}'(v)\right)^2}{\sum d_v \boldsymbol{x}'(v)^2} \leq \gamma$ which will settle the claim. To do this, pick an edge $(u, v) \in E$ and note that we have the following cases.

1. **Case 1:** $\boldsymbol{x}'(u) = \boldsymbol{x}(u), \boldsymbol{x}'(v) = \boldsymbol{x}(v)$. In this case, we note that $\left(\boldsymbol{x}'(u) - \boldsymbol{x}'(v)\right)^2 \leq \left(\boldsymbol{x}(u) + \boldsymbol{x}(v)\right)^2$.
2. **Case 2:** $\boldsymbol{x}'(u) = -\boldsymbol{x}(u), \boldsymbol{x}'(v) = -\boldsymbol{x}(v)$.
   In this case as well, it holds that $\left(\boldsymbol{x}'(u) - \boldsymbol{x}'(v)\right)^2 \leq \left(\boldsymbol{x}(u) + \boldsymbol{x}(v)\right)^2$.
3. **Case 3 and 4:** $\boldsymbol{x}'(u) = -\boldsymbol{x}(u), \boldsymbol{x}'(v) = \boldsymbol{x}(v)$ and vice versa. In this case it holds that $\left(\boldsymbol{x}'(u) - \boldsymbol{x}'(v)\right)^2 = \left(\boldsymbol{x}(u) + \boldsymbol{x}(v)\right)^2$.

Thus, it follows that in all, we have $R(\boldsymbol{D}^{1/2}\boldsymbol{x}') = \frac{\sum_{(u,v)\in E}\left(\boldsymbol{x}'(u)-\boldsymbol{x}'(v)\right)^2}{\sum d_v \boldsymbol{x}'(v)^2} \leq \gamma$ which settles the claim. ◁

Thus, given any vector $\boldsymbol{x} \in S \stackrel{\text{def}}{=} span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_n)$ we can produce a vector $\boldsymbol{x}'$ for which $\boldsymbol{D}^{1/2}\boldsymbol{x}'$ has small Rayleigh Quotient. However, this vector is not orthogonal to the trivial eigenvector $\boldsymbol{D}^{1/2}\mathbf{1}$ of $\boldsymbol{L}$. To fix this, we obtain a vector $\boldsymbol{t}$ in two steps. As a first step, consider the following vector obtained by shifting $\boldsymbol{x}'$ around which is orthogonal to the all ones vector, $\mathbf{1}$:

$$\boldsymbol{s} = \boldsymbol{x}' - \|\boldsymbol{x}\|_1 \cdot \frac{\mathbf{1}}{n}.$$

To obtain a vector orthogonal to $\boldsymbol{D}^{1/2}\mathbf{1}$, consider the vector $\boldsymbol{t} = \boldsymbol{D}^{-1}\boldsymbol{s}$. Observation 26 shows that this vector is orthogonal to $\boldsymbol{D}^{1/2}\mathbf{1}$. One notes that $\boldsymbol{t}$ does not necessarily have small length and this is an obstacle to upperbound $R(\boldsymbol{D}^{1/2}\boldsymbol{t})$. To handle this, we make the following definition.

▶ **Definition 24.** *Let $\alpha > 0$ be a sufficiently small constant. Take a unit vector $\boldsymbol{x} \in \mathbb{R}^n$. Consider the vector $\boldsymbol{s}$ obtained by taking absolute values in each coordinate and then shifting it to obtain a vector orthogonal to all 1's vector. That is,*

$$\boldsymbol{s}(i) = |\boldsymbol{x}(i)| - \frac{\|\boldsymbol{x}\|_1}{n}.$$

Let $\boldsymbol{t} = \boldsymbol{D}^{-1}\boldsymbol{s}$. The vector $\boldsymbol{x}$ is called (α, d)-bad if $\|\boldsymbol{t}\|_2 < \alpha/d$. If $\|\boldsymbol{t}\|_2 \geq \alpha/d$, then the vector $\boldsymbol{x}$ is not (α, d)-bad and is called (α, d)-good. If the parameter d is clear from context, we will call such these vectors α-good or α-bad.

We make the following observations about (α, d)-good vectors.

▶ **Observation 25.** *Let $\boldsymbol{x} \in \mathbb{R}^n$ be a unit vector. Obtain the vector $\boldsymbol{s} = |\boldsymbol{x}| - \|\boldsymbol{x}\|_1 \cdot \frac{\mathbf{1}}{n}$ and the vector $\boldsymbol{t} = \boldsymbol{D}^{-1}\boldsymbol{s}$. If $\|\boldsymbol{t}\| \geq \beta$, then $\|\boldsymbol{s}\|_2 \geq \beta$. Also, if $\|\boldsymbol{s}\| \geq \alpha$, then $\boldsymbol{t}$ is α-good.*

Proof. Note that $\|\boldsymbol{t}\|_2^2 = \sum \boldsymbol{s}_i^2/d_i \leq \sum \boldsymbol{s}_i^2 = \|\boldsymbol{s}\|_2^2$. Thus, if $\|\boldsymbol{t}\|_2 \geq \beta$, $\|\boldsymbol{s}\|_2 \geq \|\boldsymbol{t}\|_2 \geq \beta$. In the other direction, we are told $\|\boldsymbol{s}\|_2^2 = \sum \boldsymbol{s}_i^2 \geq \alpha^2$. Note that $\|\boldsymbol{t}\|_2^2 = \sum \boldsymbol{s}_i^2/d_i^2 \geq \|\boldsymbol{s}\|_2^2/d^2$ and the result follows. ◀

▶ **Observation 26.** *Let $\boldsymbol{x} \in \mathbb{R}^n$ be a unit vector. Let $\boldsymbol{t}$ be a vector obtained as above. We have $\boldsymbol{D}^{1/2}\boldsymbol{t} \perp \boldsymbol{D}^{1/2}\mathbf{1}$.*

Proof. Note

$$\langle \boldsymbol{D}^{1/2}\boldsymbol{t}, \boldsymbol{D}^{1/2}\mathbf{1}\rangle = \langle \boldsymbol{t}, \boldsymbol{D}\mathbf{1}\rangle = \sum \boldsymbol{t}_i d_i = \sum \boldsymbol{s}_i = 0.$$ ◀

In the rest of this section, we will prove the following lemma.

▶ **Lemma 27.** *Let $\alpha > 0$ be a sufficiently small constant. Then there exists a vector $\boldsymbol{x} \in span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_n)$ which is α-good.*

With this lemma in hand, Lemma 21 follows as an immediate corollary.

Proof of Lemma 21. By Lemma 27, there exists a vector $\boldsymbol{x} \in span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_n)$ which is α-good. As before, define the vectors $\boldsymbol{s}$ and $\boldsymbol{t}$. Recall from Observation 26 that $\boldsymbol{D}^{1/2}\boldsymbol{t} \perp \boldsymbol{D}^{1/2}\mathbf{1}$. Towards showing that $\lambda_2 \leq O(\gamma d^2)$, it suffices to show that $R(\boldsymbol{D}^{1/2}\boldsymbol{t}) \leq O(\gamma d^2)$. First, let us note that $\boldsymbol{x}$ being α-good, we have $\|\boldsymbol{t}\|_2 = \left\|\boldsymbol{D}^{-1}\boldsymbol{s}\right\|_2 \geq \alpha/d$. Letting $\boldsymbol{x}' = |\boldsymbol{x}|$, by Claim 23, we know $\sum_{(u,v)\in E} \left(\boldsymbol{x}'(u) - \boldsymbol{x}'(v)\right)^2 \leq \gamma \sum d_v \boldsymbol{x}'(v)^2$. And since $\boldsymbol{s}$ is obtained by shifting each coordinate in $\boldsymbol{x}'$ by the same amount, it follows that

$$\sum_{(u,v)\in E} \left(\boldsymbol{s}(u) - \boldsymbol{s}(v)\right)^2 = \sum_{(u,v)\in E} \left(\boldsymbol{x}'(u) - \boldsymbol{x}'(v)\right)^2.$$

Next, write

$$R(\boldsymbol{D}^{1/2}\boldsymbol{t}) = \frac{\sum_{(u,v)\in E}(\boldsymbol{t}_u - \boldsymbol{t}_v)^2}{\sum d_v \boldsymbol{t}_v^2}.$$

We observe that for each edge $(u, v) \in E$, $(\boldsymbol{t}_u - \boldsymbol{t}_v)^2 \leq (\boldsymbol{s}_u - \boldsymbol{s}_v)^2$. Finally, note $\sum d_v \boldsymbol{t}_v^2 \geq \sum \boldsymbol{t}_v^2 = \|\boldsymbol{t}\|_2^2 \geq \alpha^2/d^2$. Thus, it follows that $R(\boldsymbol{D}^{1/2}\boldsymbol{t}) \leq \gamma d^2/\alpha^2$. This means that $\lambda_2 \leq R(\boldsymbol{D}^{1/2}\boldsymbol{t}) \leq \gamma \cdot d^2/\alpha^2$. ◀

Now, in the rest of this document, we will prove Lemma 27. The following claim will be useful.

▷ Claim 28. Suppose $\boldsymbol{x}$ is an α-bad vector of unit length (in l_2). Let

$$\boldsymbol{s} = |\boldsymbol{x}| - \|\boldsymbol{x}\|_1 \cdot \frac{\mathbf{1}}{n}$$

(where $|\boldsymbol{x}|$ is a vector with $|\boldsymbol{x}|(u) = |\boldsymbol{x}(u)| \forall u \in V$.) Then $\|\boldsymbol{s}\|_1 \geq \left(1 - \alpha^2/4\right)\sqrt{n}$.

Proof. By the definition of bad vectors and Observation 25, we have $\|\boldsymbol{s}\|_2 \leq \alpha$. On expanding out,

$$\|\boldsymbol{s}\|_2^2 = \sum_{i \in V} \left(\boldsymbol{x}(i)^2 + \frac{\|\boldsymbol{x}\|_1^2}{n^2} - \frac{2|\boldsymbol{x}(i)| \cdot \|\boldsymbol{x}\|_1}{n} \right) = \left(\|\boldsymbol{x}\|_2^2 - \frac{\|\boldsymbol{x}\|_1^2}{n} \right) = \left(1 - \frac{\|\boldsymbol{x}\|_1^2}{n} \right) \leq \alpha^2.$$

Rearranging, this gives $\|\boldsymbol{x}\|_1 \geq \sqrt{n} \cdot \sqrt{1 - \alpha^2}$. For sufficiently small α, and taking Taylor expansion, this gives

$$\|\boldsymbol{x}\|_1 \geq \left(1 - \frac{\alpha^2}{4}\right) \cdot \sqrt{n} \tag{5}$$

◁

Now suppose $\boldsymbol{x}$ is indeed an α-bad vector. Since, $\boldsymbol{x}$ is a unit vector with $\|\boldsymbol{x}\|_1$ pretty close to $\sqrt{n}$, it follows that the absolute value of $\boldsymbol{x}$ in each coordinate is almost $1/\sqrt{n}$. This is shown below.

▷ Claim 29. Suppose $\boldsymbol{x}$ is an α-bad vector with $\|\boldsymbol{x}\|_2 = 1$. Let $\beta > 0$ be sufficiently small. Then for at least $\left(1 - \alpha^2/2\beta^2\right) \cdot n$ coordinates in $i \in [n]$, it holds that

$$\frac{1-\beta}{\sqrt{n}} \leq |\boldsymbol{x}(i)| \leq \frac{1+\beta}{\sqrt{n}}.$$

Proof. From Claim 28, it follows that $\|\boldsymbol{x}\|_1 \geq (1 - \alpha^2/4)\sqrt{n}$. This means

$$\begin{aligned}
\frac{\|\boldsymbol{x}\|_1}{\sqrt{n}} = \sum_{i \in [n]} |\boldsymbol{x}(i)| \cdot \frac{1}{\sqrt{n}} &\geq (1 - \alpha^2/4) \\
\implies 1/2 + 1/2 - \sum_{i \in [n]} |\boldsymbol{x}(i)|/\sqrt{n} &\leq \alpha^2/4 \qquad (6) \\
\implies \frac{1}{2} \cdot \sum_{i \in [n]} |\boldsymbol{x}(i)^2| + \frac{1}{2} \cdot \sum_{i \in [n]} \left(\frac{1}{\sqrt{n}}\right)^2 - \sum_{i \in [n]} |\boldsymbol{x}(i)|/\sqrt{n} &\leq \alpha^2/4 \qquad (7) \\
\implies \sum_{i \in [n]} \left(|\boldsymbol{x}(i)| - \frac{1}{\sqrt{n}} \right)^2 &\leq \frac{\alpha^2}{2} \qquad (8)
\end{aligned}$$

Now let

$$B_{\boldsymbol{x}} = \{i \in [n] : |\boldsymbol{x}(i)| \geq \frac{1+\beta}{\sqrt{n}}\} \cup \{i \in [n] : |\boldsymbol{x}(i)| \leq \frac{1-\beta}{\sqrt{n}}\}.$$

Note that for each such $i \in B_{\boldsymbol{x}}$, we have that $(|\boldsymbol{x}(i)| - 1/\sqrt{n})^2 \geq \beta^2/n$. Together with (8), this means that $|B_{\boldsymbol{x}}| \leq \frac{1}{2} \cdot \left(\frac{\alpha}{\beta}\right)^2 n$ which settles the claim. ◁

Thus, Claim 28 means that if a vector $\boldsymbol{x}$ is α-bad, it would have a pretty large l_1 mass which as shown in Claim 29 means that $\boldsymbol{x}$ takes on values close to $\pm\frac{1}{\sqrt{n}}$ almost everywhere in the support. This gives us all the ammunition we need to prove Lemma 27. We will proceed by contradiction. That is, we will produce a vector $\boldsymbol{x} \in S \stackrel{\text{def}}{=} span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}, \boldsymbol{D}^{-1/2}\boldsymbol{v}_n)$ with small l_1 norm. And this means this vector is α-good. Details follow.

Proof of Lemma 27. For ease of indexing, let $\boldsymbol{z}_1 = \boldsymbol{D}^{-1/2}\boldsymbol{v}_n, \boldsymbol{z}_2 = \boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1}$. If either of $\boldsymbol{z}_1, \boldsymbol{z}_2$ is α-good, we choose that vector and the proof is finished. So, suppose both $\boldsymbol{z}_1, \boldsymbol{z}_2$ are α-bad. In this case, let S denote the $span(\boldsymbol{z}_1, \boldsymbol{z}_2) = span(\boldsymbol{D}^{-1/2}\boldsymbol{v}_n, \boldsymbol{D}^{-1/2}\boldsymbol{v}_{n-1})$. We normalize all non-zero vectors in S to have length 1. We will show that the unit vector $\boldsymbol{x} = \frac{1}{\sqrt{2}}(\boldsymbol{z}_1 + \boldsymbol{z}_2) \in S$ is in fact α-good. By way of contradiction, suppose $\boldsymbol{x}$ is α-bad and thus by Claim 28 $\|\boldsymbol{x}\|_1$ is close to $\sqrt{n}$. We will obtain a contradiction to this. Set a parameter $\beta = \sqrt{\alpha}$ and define the set of "bad" coordinates in $\boldsymbol{z}_1$ as

$$B_1 = \left\{ i \in [n] \colon |\boldsymbol{z}_1(i)| \geq \frac{(1+\beta)}{\sqrt{n}} \text{ OR } |\boldsymbol{z}_1(i)| \leq \frac{(1-\beta)}{\sqrt{n}} \right\}.$$

Similarly, define B_2 as the set of bad coordinates in $\boldsymbol{z}_2$. By Claim 29, note that $|B_1|, |B_2|$ both have size at most $\alpha/2n$. Let $B = B_1 \cup B_2$ and set $G = [n] \setminus B$. Note that $\boldsymbol{z}_1 \perp \boldsymbol{z}_2$ and thus

$$\langle \boldsymbol{z}_1, \boldsymbol{z}_2 \rangle = 0 = \sum_{i \in [n]} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i) = \sum_{i \in B} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i) + \sum_{i \in G} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i) \tag{9}$$

We will show that the first term above is small in absolute value (and therefore, so is the second term). For notational convenience, denote the restriction of $\boldsymbol{z}_1$ on B as $\boldsymbol{z}_{1,B} \in \mathbb{R}^{|B|}$. Similarly, define $\boldsymbol{z}_{1,G}, \boldsymbol{z}_{2,B}$, and $\boldsymbol{z}_{2,G}$. By Cauchy Schwartz,

$$\left| \sum_{i \in B} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i) \right| \leq \|\boldsymbol{z}_{1,B}\|_2 \|\boldsymbol{z}_{2,B}\|_2 \tag{10}$$

We now upperbound the right hand side by upperbounding each of the two norms above. We do this, for instance for $\boldsymbol{z}_{1,B}$ by noting $1 = \|\boldsymbol{z}_1\|_2^2 = \|\boldsymbol{z}_{1,G}\|_2^2 + \|\boldsymbol{z}_{1,B}\|_2^2$ and noting that for each $i \in G$, $\boldsymbol{z}_1(i)^2 \geq \frac{(1-\beta)^2}{n}$. This way, we get

$$\|\boldsymbol{z}_{1,B}\|_2^2 \leq 1 - \frac{(1-\beta)^2}{n} \cdot |G| \leq 1 - \frac{(1-\sqrt{\alpha})^2}{n} \cdot (1-\alpha)n \leq 1 - (1-\alpha) \cdot (1 - 2\sqrt{\alpha}) \leq 3\sqrt{\alpha}.$$

The second inequality uses that $\beta = \sqrt{\alpha}$. Similarly, $\|\boldsymbol{z}_{2,B}\|_2^2 \leq 3\sqrt{\alpha}$ as well. This means $\langle \boldsymbol{z}_{1,B}, \boldsymbol{z}_{2,B} \rangle \leq 3\sqrt{\alpha}$. Thus, the inner product of $\boldsymbol{z}_{1,B}$ and $\boldsymbol{z}_{2,B}$ is indeed small in magnitude and the same holds for the inner product of $\boldsymbol{z}_{1,G}$ and $\boldsymbol{z}_{2,G}$ which means the restrictions to the good parts of $\boldsymbol{z}_1$ and $\boldsymbol{z}_2$ are nearly orthogonal. We will now show that $\|\boldsymbol{x}\|$ is small and thus, by Claim 28, $\boldsymbol{x}$ cannot be α-bad. To this end, write

$$\|\boldsymbol{x}\|_1 = \frac{1}{\sqrt{2}} \cdot \sum_{i \in G} |\boldsymbol{z}_1(i) + \boldsymbol{z}_2(i)| + \sum_{i \in B} |\boldsymbol{z}_1(i) + \boldsymbol{z}_2(i)|.$$

Let $P = \{i \in G \colon \boldsymbol{z}_1(i), \boldsymbol{z}_2(i) \text{ have the same sign.}\}$ and let $N = G \setminus P$. We have

$$\begin{aligned} \|\boldsymbol{x}\|_1 =& \frac{1}{\sqrt{2}} \cdot \sum_{i \in P} |\boldsymbol{z}_1(i) + \boldsymbol{z}_2(i)| + \sum_{i \in N} |\boldsymbol{z}_1(i) + \boldsymbol{z}_2(i)| + \sum_{i \in B} |\boldsymbol{z}_1(i) + \boldsymbol{z}_2(i)| \\ \leq& \frac{1}{\sqrt{2}} \left(\frac{2 + 2\beta}{\sqrt{n}} \right) \cdot |P| + \frac{1}{\sqrt{2}} \cdot 2\beta \cdot |N| + \sum_{i \in B} |\boldsymbol{z}_1(i) + \boldsymbol{z}_2(i)| \end{aligned}$$

We now bound the RHS above. For the last term, note that by triangle inequality and Cauchy Schwatrz,

$$\sum_{i \in B} |\boldsymbol{z}_1(i)| + \boldsymbol{z}_2(i)| \leq \|\boldsymbol{z}_{1,B}\|_1 + \|\boldsymbol{z}_{2,B}\|_1 \leq (\|\boldsymbol{z}_{1,B}\|_2 + \|\boldsymbol{z}_{2,B}\|_2) \cdot \sqrt{|B|}$$

which is at most $2\sqrt{3} \cdot \sqrt[4]{\alpha} \cdot \sqrt{n} \leq 4\sqrt[4]{\alpha} \cdot \sqrt{n}$. Finally, we will show that $|P| \approx |N| \approx n/2$ from which it will follow that $\|\boldsymbol{x}\|_1 \approx \left(1/\sqrt{2} + O(\sqrt[4]{\alpha})\right) \cdot \sqrt{n}$ which is multiplicatively bounded away from $\sqrt{n}$ (and thus implies $\boldsymbol{x}$ cannot be α-bad).

To see this, recall $\beta = \sqrt{\alpha}$ and that

$$3\beta \geq \left|\sum_{i \in G} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)\right| \geq \left|\left|\sum_{i \in P} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)\right| - \left|\sum_{i \in N} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)\right|\right|.$$

We will show if $|P| \notin [n/2 \pm 10\beta \cdot n]$ then the absolute inner product restricted to the good coordinates is much larger than 3β which means that both $|P|$ and $|N|$ have size around $n/2$.

Suppose $|P| \geq n/2 + \delta n$. Note

$$\left|\sum_{i \in P} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)\right| \geq \frac{(1-\beta)^2}{n}|P| \geq \frac{(1+\beta^2-2\beta)}{n} \cdot \left(\frac{n}{2} + \delta n\right) \geq (1-2\beta)\left(\frac{1}{2} + \delta\right).$$

The last term can be expanded as $(1/2) - \beta + \delta - 2\delta\beta$.

Also, note

$$\left|\sum_{i \in N} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)\right| \leq \frac{(1+\beta)^2}{n} \cdot |N| \leq \frac{(1+\beta^2+2\beta)}{n} \cdot \left(\frac{n}{2} - \delta n\right) \leq (1+3\beta)\left(\frac{1}{2} - \delta\right).$$

The last term can be expanded as $(1/2) + 3\beta/2 - \delta - 3\delta\beta$.

For $\delta = 10\beta$, using

- $|\sum_{i \in G} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)| \geq |\sum_{i \in P} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)| - |\sum_{i \in N} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)|$.
- The above lowerbound on $|\sum_{i \in P} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)|$, and
- The above upperbound on $|\sum_{i \in N} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)|$

we conclude $|\sum_{i \in G} \boldsymbol{z}_1(i)\boldsymbol{z}_2(i)| \geq 15\beta$ which is a contradiction. A similar contradiction is reached when $|P| \leq n/2 - \delta n$ (for $\delta = 10\beta$). Thus, overall we have $n/2 - 10\beta n \leq |P|, |N| \leq n/2 + 10\beta n$. Plugging back the upperbounds on $|P|$ and $|N|$ in

$$\|\boldsymbol{x}\|_1 \leq \frac{\sqrt{n}}{\sqrt{2}}\left((2+2\beta) \cdot (1/2 + 10\beta) + 2\beta \cdot (1/2 + 10\beta)\right) + 4\sqrt[4]{\alpha}n \leq \frac{\sqrt{n}}{\sqrt{2}} \cdot (1 + 8\sqrt[4]{\alpha}).$$

The last inequality uses that $\beta = \sqrt{\alpha}$. This confirms that $\boldsymbol{x}$ is α-good as desired. ◀

6 Discussion and Concluding Remarks

As mentioned in the tech-overview, the remainder of the proof is deferred to the arXiv version. In this last section, we want to explain why exploring the better than 1/2 approximability of max-cut over clusterable graphs seems to be an important step. Indeed, as one might already see, the current paper only presents an algorithm achieving better than a factor 1/2 approximation for clusterable graphs. After the seminal work of Goldreich and Ron ([9]), and the recent work of Peng and Yoshida ([13]), the question of obtaining a better than 1/2 approximation algorithms for max-cut in sublinear time got ushered to the frontiers of research. Perhaps the most natural graph class to extend a better than 1/2 approximation guarantee on, is the class of *low threshold rank* graphs as defined in the seminal work of [1].

However, it is important to consider the nuances of the problem: the problem asks –given a graph with small threshold rank, is its max-cut value close to 1 or is it close to 1/2. Approaching this problem in the sublinear time regime appears highly non-trivial and it seems

the current techniques have some limitations. For instance, one might try a Peng-Yoshida style approach which leverages the ℓ_2 distance between distributions induced by walks of odd-lengths and even-lengths. However, as we described in our tech-overview, this technique does not *even* extend to the case of graphs with threshold rank 2 (since clusterable graphs form a sub-class of low-threshold rank graphs). The spectral approach pioneered in the work of Chinplunkar et al. in FOCS 18, (which was refined in our submission), attempts to relate the cut-value of the graph to an appropriate eigenvalue close to -1. This approach fails for low-threshold rank graphs. Since, even for graphs with threshold rank 2, there could be 2 small bipartite components, which would lead to 2 eigenvalues being -1. Thus, it is not immediately clear, if there is an appropriate eigenvalue which is a good indicator of the actual max-cut value.

Taking inspiration from the celebrated work of [6], [5] defined the notion of a (k, φ)-clusterable graphs which has more immediate relevance for the property-testing community. With all of this in mind, we think this is an important stepping stone towards obtaining better than 1/2 approximation algorithms for max-cut on low threshold rank graphs. In particular, getting a handle on the "combinatorics of low-threshold rank graphs" and understanding the structure of small non-expanding sets therein appears quite hard. Clusterable graphs help us leverage a much neater structure and improve our understanding of how random walks might behave in non-expanding graphs, without making the problem of testing max-cut on them trivial.

Abstract

We consider a generalized poset sorting problem (GPS), in which we are given a query graph $G = (V, E)$ and an *unknown poset* $\mathcal{P}(V, \prec)$ that is defined on the same vertex set V, and the goal is to make as few queries as possible to edges in G in order to fully recover $\mathcal{P}$, where each query (u, v) returns the relation between u, v, i.e., $u \prec v$, $v \prec u$ or $u \not\sim v$. This generalizes both the poset sorting problem [Faigle et al., SICOMP 88] and the generalized sorting problem [Huang et al., FOCS 11].

We give algorithms with $\tilde{O}(n \operatorname{poly}(k))$ query complexity when G is a complete bipartite graph or G is stochastic under the Erdős-Rényi model, where k is the *width* of the poset, and these generalize [Daskalakis et al., SICOMP 11] which only studies complete graph G. Both results are based on a unified framework that reduces the poset sorting to partitioning the vertices with respect to a given pivot element, which may be of independent interest. Moreover, we also propose novel algorithms to implement this partition oracle. Notably, we suggest a randomized BFS with vertex skipping for the stochastic G, and it yields a nearly-tight bound even for the special case of generalized sorting (for stochastic G) which is comparable to the main result of a recent work [Kuszmaul et al., FOCS 21] but is conceptually different and simplified.

Our study of GPS also leads to a new $\tilde{O}(n^{1-1/(2W)})$ competitive ratio for the so-called weighted generalized sorting problem where W is the number of distinct weights in the query graph. This problem was considered as an open question in [Charikar et al., JCSS 02], and our result makes important progress as it yields the first nontrivial sublinear ratio for general weighted query graphs (for any bounded W). We obtain this via an $\tilde{O}(nk + n^{1.5})$ query complexity algorithm for the case where every edge in G is guaranteed to be comparable in the poset, which generalizes a $\tilde{O}(n^{1.5})$ bound for generalized sorting [Huang et al., FOCS 11].

1 Introduction

We consider a generalized poset sorting problem and obtain various new algorithmic results. In the *generalized poset sorting* problem (GPS), we are given an undirected *query graph* $G = (V, E)$ and an unknown *poset* $\mathcal{P} = (V, \prec)$. The goal is to fully recover the poset $\mathcal{P}$, that is, to figure out the relation between all $x, y \in V$, through the smallest number of queries to the edges in G. Here, when the algorithm makes a query $(u, v) \in E$, the relation of u and v in the poset, i.e., $u \prec v$, $v \prec u$ or $u \not\sim v$ (which stands for u and v are not comparable), is returned. [1]

When the comparison graph G is a complete graph, GPS reduces to a special case called the *poset sorting* problem which was suggested by [11]. This poset sorting is a fundamental problem since it captures the presence of incomparable elements in a partially ordered set which does not have a linear ordering. For this problem, an algorithm with optimal $\Theta(nk + n \log n)$ query complexity was given in [10] where k is the *width* of the poset (the width of a poset is defined as the size of its largest antichain).[2] However, this $\tilde{O}(nk)$ bound heavily relies on the fact that G is complete, and does not work for our general case where the query graph G can have missing edges (u, v) which forbid the query of the relation between u and v (we shall provide a more detailed technical discussion later).

In fact, the missing edges in the query graph already introduce significant challenges even when the poset $\mathcal{P}$ is a total order (where every two elements are comparable). This special case (general graph G and total order) is called *generalized sorting* whose study was initiated by [18]. The state-of-the-art algorithm for this generalized sorting needs to use $\tilde{O}(\sqrt{mn})$ queries [22] for general graphs G, far from matching the $\Theta(n \log n)$ bound for the classic sorting. On the other hand, a parallel research theme aims to explore whether $\tilde{O}(n)$ query complexity can be obtained for generalized sorting on special graph families. Notably, such algorithms were obtained for complete bipartite graphs [1, 7, 2, 21] and Erdős-Rényi stochastic graphs [18, 22].

Our focus. Thus, a fundamental question is to figure out which families of query graphs G admit algorithms with the optimal $\tilde{O}(nk)$ queries (to match that for the complete graphs [10]) for GPS, where k is the width of the poset. An ideal goal is to achieve this $\tilde{O}(nk)$ bound for general query graphs, but as we mentioned, even for the total order case it is already difficult to improve over $\sqrt{mn}$. Therefore, we instead focus on complete bipartite and Erdős-Rényi stochastic query graphs, which are fundamental cases and were very well studied in the special case of generalized sorting. Moreover, we also study how GPS connects to other settings, especially its implications for variants of generalized sorting. This connection is plausible since a natural way for sorting is to build a partially sorted solution and then solve the remaining sub-problem, and this sub-problem may often be modeled as a poset sorting problem.

Technical challenges. However, designing algorithms for GPS turns out to be nontrivial and requires new approaches. Below, we briefly discuss why the existing techniques from tightly related problems, including poset sorting and generalized sorting problems, cannot be readily applied.

---

[1] To make sure the problem is well-defined, we need to define the correspondence between $\mathcal{P}$ and query results of G, see Section 3 for more details.

[2] Throughout, $\tilde{O}(f) := O(f \operatorname{poly} \log f)$.

- **Techniques from poset sorting.** The missing edges in G can increase the query complexity of existing algorithms for poset sorting [11, 10]. In these algorithms, the overall framework is to incrementally add elements to the current sorting, and when an element x is to be added, a binary search is used to figure out the relation between x and every other element added so far. A crucial step to bound the query complexity is that there always exists a path cover of size k (which is the width) in the induced subgraph of the added elements, and this ensures only k binary search suffices. While this is true for complete graphs, the width k can no longer upper bound the size of the path cover only by using edges in an induced subgraph of a general G.
- **Techniques from generalized sorting.** Incomparable edges $(u, v) \in E$ ($u \not\sim v$) reveal very little information about ordering, hence algorithms for generalized sorting should avoid querying these edges. However, existing algorithms [18, 23, 22] for generalized sorting (designed for general query graph G) relies on a rough estimation of the relation between elements, and "useful" edges may be wrongly classified as incomparable edges. If this happens, then it is very difficult to detect the "useful" edge without querying a lot of incomparable edges, making existing algorithms less efficient.

1.1 Our Results

We give efficient algorithms for GPS that make $\tilde{O}(n \operatorname{poly}(k))$ queries for Erdős-Rényi stochastic query graphs (Theorem 1.1) and complete bipartite query graphs (Theorem 1.2), where k is the width of the poset throughout (see Section 3 for formal definitions of these query graph models). These are the first results for GPS parameterized by the width of the poset k, and the query complexity bound is nearly-optimal in n (and up to a factor of k). We obtain our results via a unified framework and it may be of independent interest (will be discussed in Section 4). These results are our main technical contributions.

▶ **Theorem 1.1** (Erdős-Rényi Stochastic Graphs). *There exists an algorithm that solves GPS on Erdős-Rényi stochastic query graphs and width-k posets using $\tilde{O}(nk^2)$ queries with high probability. This holds regardless of the probability parameter $0 < p \leq 1$ in Erdős-Rényi $G(n, p)$.*

Roughly, the Erdős-Rényi stochastic query graph is a union of an adversarily choosen base graph and an Erdős-Rényi graph $G(n, p)$. Although our bound for Erdős-Rényi stochastic query graph does not depend on p, it still relies on the structural property of the Erdős-Rényi graph where edges are i.i.d. generated. This case of Erdős-Rényi query graph has been well studied in (total order) generalized sorting (i.e., $k = 1$), where [18] and [22] are milestones. Compared with [18], our result is significantly better than their $\min\{np^{-2}, n^{1.5}\sqrt{p}\}$, especially that our algorithm is $\tilde{O}(n)$ regardless of p and theirs can obtain near-linear query complexity only for a very limited range of p. On the other hand, compared to the more recent work [22] whose bound is $O(n \log(np))$, our result is worse by a $\operatorname{poly} \log n$ factor. However, our slightly worse bound generalizes to poset sorting and is also technically different. See Section 4 for a more detailed discussion. Finally, we remark that a unique feature of [22] is that when p is very small, say $p = 1/n$, then the complexity of sorting can even be better than $O(n \log n)$ which is the well-known lower bound for classic sorting. We leave it as an open question to figure out if one can achieve a similar bound for GPS with Erdős-Rényi query graphs.

▶ **Theorem 1.2** (Complete Bipartite Graphs). *There exists an algorithm that solves GPS on complete bipartite query graphs and width-k posets using $\tilde{O}(nk)$ queries with high probability.*

This result for complete bipartite graphs is tight up to $\text{poly}(\log n)$ factors, since the $\Omega(nk)$ lower bound for complete query graph in [10] still holds in the complete bipartite case. Our result is also a generalization of a series work of nuts-and-bolts problems [1, 7, 2, 21], and our bound for $k = 1$ nearly matches the state-of-the-art bound for this problem (up to poly log factors, compared to the best $O(n \log n)$ result in (total order) generalized sorting problem on complete bipartite graphs by [21]). Note that there is a difference between the nuts-and-bolts problem and the generalized sorting problem on complete bipartite graphs, where the nuts-and-bolts problem has an additional assumption that every node is assigned an edge with the query result "equal". With the help of the "equal" edge, a natural randomized quicksort-like algorithm achieves the query complexity $O(n \log n)$, by an $O(n)$ partition algorithm to partition nodes based on a randomly selected pivot. However, if the "equal" edge is not provided, it is already a non-trivial task to design a partition algorithm. This is also noted by [21], and they resolve the missing "equal" edges and design an $O(n \log n)$ sorting algorithm with some other indirect methods. However, this indirect method does not yield a partition algorithm, and we find it hard to generalize these indirect methods to the setting of poset. In our result, we devised a partition algorithm for complete bipartite graphs without "equal" edges, and this type of partiton algorithm was unknown even for the total order setting. This partition step turns out to be useful and naturally generalizable to posets.

Weighted generalized sorting. Apart from the significance in its own right, another important implication of GPS is that it can be used as an intermediate step for other (total order) sorting problems. We showcase this idea by presenting new results for the weighted generalized sorting problem.

In the weighted (total order) generalized sorting problem, the query graph is weighted (with weight function $w : E \to \mathbb{R}_{\geq 0}$), and each query $(u, v) \in E$ incurs a weighted cost $w(u, v)$ instead of a unit cost. Since the objective is weighted, we measure the performance of the algorithm using the *competitive ratio* [16], defined as the total cost incurred by the algorithm divided by $\sum_i w(v_i, v_{i+1})$ ($v_1 \prec \ldots \prec v_n$ is the total order), which is the cost of cheapest proof, i.e. comparing every consecutive elements in the sorted order. We obtain the following result for weighted generalized sorting.

▶ **Theorem 1.3.** *There exists an algorithm that solves the weighted (total order) generalized sorting problem with competitive ratio $\tilde{O}(n^{1-1/(2W)})$, where W is the number of distinct weights in the graph.*

Indeed, obtaining nontrivial bounds for this weighted generalized sorting has been suggested as an *open question* by [9], and it received significant attention in various subsequent works [16, 3, 4, 13, 14]. However, these existing works mostly focus on understanding certain special cases of weights, such as bounded number of distinct weights [4, 13, 14] or structured/random weights [16, 17, 3]. For the general case, we are only aware of an $O(n)$ ratio [16], which is trivial in the unweighted case since one can query all edges, but is already nontrivial in the weighted setting.

Our result makes progress on the weighted generalized sorting problem, and our bound implies a strictly sublinear ratio when the number of distinct weights is bounded (and the weights can take any non-negative values). This improves over the known $O(n)$ ratio in [16], and our ratio also matches ratios for several notable special cases. When $W = 1$ which reduces to (total order) generalized sorting, our bound matches the $\tilde{O}(n^{1.5})$ query complexity in [18] which is the state-of-the-art for dense graphs (for sparse graphs a $\sqrt{mn}$ bound was

obtained in [22], where m is the number of edges in the query graph). Moreover, we give an improved analysis of our algorithm for the case when the weights are well-separated, and this result matches an $\tilde{O}(n^{3/4})$ ratio, obtained in a recent work [13, 14], for the case when the weights are picked from $\{0, 1, n, \infty\}$ (where ∞ weight can be interpreted as "missing edge" in the query graph in our case).

▶ Remark 1.4. In several previous works [16, 18, 22] it has been mentioned that the ratio for finding a maximum element in a weighted query graph is $\Omega(n)$, and this seems to suggest that $\Omega(n)$ is also a lower bound for sorting (since sorting implies finding the maximum). However, this is not true, for two reasons. One is that the ratio in the maximum-finding problem is defined with respect to the cost of a minimum-weight certificate for the maximum, which can be much smaller than the $\sum_i w(v_i, v_{i+1})$ cost for identifying total order in sorting. Secondly, the hard instance in the lower bound of maximum-finding [16] only uses three types of weights, and by our upper bound, this type of instance cannot be hard for sorting. A similar discussion of this gap was also made in [13, 14]. In fact, a further implication of our result is that, in order to prove $\Omega(n)$ lower bound for weighted generalized sorting, one must use at least $\Omega(\log n)$ distinct weights in the hard instance.

Auxiliary problem: GPS with comparable edges (GPSC). As we mentioned, GPS is used as an important intermediate step for obtaining Theorem 1.3. In particular, we consider a special case of GPS whose query graph consists of *comparable* edges only, i.e., $(u, v) \in E$ only if $u \prec v$ or $v \prec u$, and we call this special case the GPS with comparable edges (GPSC). Due to the fact that GPSC is in between GPS and (total order) generalized sorting, and that it may be useful for other sorting problems, the result of this problem, stated below, may be of independent interest.

▶ **Theorem 1.5** (GPSC). *There exists an algorithm that solves GPSC on general query graphs and width-k posets using $\tilde{O}(nk + n^{1.5})$ queries with high probability.*[3]

As mentioned, Theorem 1.5 is a crucial subroutine for Theorem 1.3, but to obtain a sublinear ratio for weighted generalized sorting (provided that the number of distinct weights is bounded), any $n^{2-\epsilon}$ query bound for GPSC suffices, although it may lead to a worse constant in the exponent of n in the ratio (i.e., worse than $O(n^{1-1/(2W)})$ but still $o(n)$). We give a detailed overview on how this can be used to obtain Theorem 1.3 in Section 4.

▶ Remark 1.6 (Comparison to [13, 14]). A recent work [13] independently studies similar problems that are relevant to our results.[4] The meta problem suggested in their paper is a weighted version of the GPSC problem, which they call universal sorting. This weighted GPSC model is more general than the unweighted GPSC (which is the model of our Theorem 1.5), but is incomparable with GPS which we focus on. However, due to a lower bound of $\Omega(n)$ for the universal sorting model, their concrete results/upper bounds only deal with special cases. We compare with each of their main results in the following; in short, all their results concern problems that are either special cases or immediate extensions of ours, but the bounds may not be comparable (i.e., they may obtain better bounds for special cases or use a different measure of complexity).

[3] This algorithm may run in exponential time.

[4] [14] is another version of [13] and is to appear in ITCS'24. We focus on [13] since [14] only contains a subset of results of [13].

- **Weighted generalized sorting with special weights** [13, Theorem 1]. They study a special case of weighted generalized sorting, where all weights are among $\{0, 1, F\}$ ($F > n^{3/4}$), and they achieve a $\tilde{O}(n^{3/4})$ competitive ratio. Our algorithm for general weights achieves the same competitive ratio for this special case.
- **Bichromatic sorting** [13, Theorem 2]. They study a special case of weighted generalized sorting, where the comparison costs are among $\{1, \alpha, \beta\}$ and are assigned to query graph in a structured way. They achieve a nearly optimal ratio of $O(\log^3 n)$ for this special case, and our general algorithm for weighted generalized sorting (our Theorem 1.3) can also be applied which yields a ratio of $O(n^{5/6})$.
- **GPSC with weight-0 edges** [13, Theorem 6]. They propose an algorithm for GPSC that additionally allows weight-0 edges. This algorithm is used as a subroutine in their sorting algorithm. Our algorithm for GPSC (our Theorem 1.5), even though not explicitly stated to be able to handle the weight-0 edges, can still be applied by treating all weight-0 edges as weight-1. Hence, we still obtain the same bound of $\tilde{O}(nk + n^{1.5})$ as in no weight-0 edges, and this is actually better than their $O(n^{1.5}k \log n)$ bound.
- **GPSC on complete bipartite graphs** [13, Theorem 22]. They study GPSC problem on complete bipartite graphs. They measure the performance by instance optimality instead of query complexity, and their algorithm is $O(\log^3 n)$ instance optimal. Since GPSC is a special case of GPS problem, our algorithm for GPS problem on complete bipartite graphs (our Theorem 1.2) can be applied which yields a query complexity of $\tilde{O}(nk)$. This is also a near optimal result because optimal solution requires $\Omega(nk)$ queries in the worst case.

1.2 Technical Contribution

We give a highlight of technical challenges and our technical contributions. A more detailed overview of the proof can be found in Section 4.

A general framework for GPS. Previous algorithms for generalized sorting [18, 23, 22] use an incremental method to iteratively discover the (nearly-)minimum element, but this does not work directly in GPS due to incomparable edges and non-unique minimal elements. We develop a general framework for GPS, which reduces GPS to finding a linear extension, and we further show this linear extension can be found by a quicksort-like algorithm proposed by [18, 10]. The quicksort-like algorithm relies on a partition algorithm that receives as input a subgraph and a pivot, and it partitions the subgraph into three parts: less than, larger than, and incomparable to the pivot. We require the partition algorithm to have a refined query complexity that only depends on the width of the part of the input subgraph (to the partition algorithm) that is comparable to the pivot. This refined property of partition algorithms enables us to obtain $\tilde{O}(nk)$ query complexity for the quicksort-like algorithm. Hence, this framework is capable of obtaining (nearly) tight bounds when combined with carefully designed partition algorithms (for instance, for Erdős-Rényi query graphs and complete bipartite graphs), which may be of independent interest.

Novel partition algorithms for Erdős-Rényi graphs based on stochastic BFS. Our partition algorithm for Erdős-Rényi graphs is based on a stochastic BFS, where the key idea is to skip a vertex from the BFS queue if that vertex has been visited by sufficiently many other vertices. This still guarantees the correctness with high probability due to the property of Erdős-Rényi graph. To make sure we trim most vertices in a few iterations, we also run the BFS in a random order of vertices. Previously, algorithms for Erdős-Rényi graphs were only known

for generalized sorting (without considering a poset), and the techniques are not readily applicable. In particular, the framework of [18] requires an algorithm with a subquadratic query complexity for general query graph, which is not available in GPS. Another recent work [22] uses a very different approach, but the efficiency of one of its subroutines relies on the uniqueness of the minimal element. Hence it is highly nontrivial to generalize to the poset setting while achieving subquadratic complexity.

Weighted generalized sorting via new algorithms for GPSC. To achieve the $\tilde{O}(n^{1-\frac{1}{2W}})$ competitive ratio, we partition the edge set into cheap and expensive edges according to a threshold, and the two cases are balanced and solved by one of the following two algorithms: a) a new sorting algorithm that may receive a partially sorted graph (i.e. a partial order) as extra input and the competitive ratio depends on the width of the input partial order; and b) a new GPSC algorithm as in Theorem 1.5. In our new GPSC algorithm, we employ the framework of sorting with predictions [18, 23, 22] (which was proposed for generalized sorting), where we construct a prediction graph that "guesses" the direction of the edges, and make decisions and refine the prediction in an iterative manner. To achieve better query complexity, we devise a stronger predictor that has an "everywhere" guarantee for each vertex, as opposed to having a collective bound on the total number of wrongly predicted edges, as considered in [23, 22].

1.3 Related Work

Parameterization other than the width of the poset which we use was also considered in the literature, and they are generally not comparable to our results. In [5, 6], the GPS is parameterized by the number of missing edges $q = \binom{n}{2} - m$ (where m is the number of edges in the query graph) while there is no restriction on the poset, and nearly-tight bounds were obtained with respect to q. In a recent work [24], the query graph can be general but the poset is assumed to be a tree and is parameterized by the maximum degree d, and they also obtained nearly tight query complexity bounds.

In addition to generalized sorting problems, other related problems were also considered. Examples include noisy sorting/selection [12, 8, 15] and generalized/weighted selection [16, 20, 3, 10].

2 Preliminaries

Throughout, we use $\mathcal{P} = (V, \prec)$ to denote a poset, and we let $k_{\mathcal{P}}$ denote the width of $\mathcal{P}$. By Dilworth's Theorem, a poset of width k can be decomposed to k chains, say $\mathcal{C} = \{C_1, C_2, \ldots, C_k\}$, where the elements are comparable to each other on each chain. Suppose $\mathcal{P} = (V, \prec)$ is the underlying poset of GPS problem, we directly use k to denote $k_{\mathcal{P}}$. For every $X \subseteq V$, let k_X denote the width of poset $(X, \prec)$. For every $X \subseteq V, v \in X$, let $X_{\prec v}, X_{\nsim v}, X_{\succ v}$ denote the elements of X that are smaller than v, incomparable with v and larger than v respectively. Recall that $x \nsim y$ denotes "x is incomparable with y". For some set X, denote the set of permutations of X by $\mathrm{perm}(X)$. For every set X with a total order $(X, \prec)$ and every $x \in X$, define $\mathrm{rank}_X(x) = |\{y \in X \mid y \prec x\}| + 1$ as the rank of x. Similarly, let $\mathrm{rank}_{\mathbf{p}}(x)$ be the rank of x in permutation $\mathbf{p}$.

For a graph $G = (V, E)$ and a vertex subset $S \subseteq V$, denote $G[S]$ as the induced subgraph of G on S, whose vertex set is S and the edge set is $\{(u, v) \in E : u, v \in S\}$. Given a directed acyclic graph (DAG) $\vec{G}(V, \vec{E})$, let $\mathcal{P}(\vec{G})$, which stands for induced poset of $\vec{G}$, be a poset $\mathcal{P}'(V, \prec)$, such that $\forall u, v \in V$, $u \prec v$ if and only if there is a directed path from u to v in

$\vec{G}$. This implies that $u \not\prec v$ if and only if u cannot reach v and v cannot reach u in $\vec{G}$. By Dilworth's Theorem, a DAG can be covered by k paths, and these paths form a path cover of $\vec{G}$, where k is the width of $\mathcal{P}(\vec{G})$, i.e., every vertex is contained in at least one path (and may be contained in multiple paths).

3 Models

Generalized poset sorting (GPS). Formally, in the GPS problem, we are given an n-element underlying (unknown) poset $\mathcal{P} = (V, \prec)$ and a graph $G = (V, E)$. An oracle receives queries of the form $(u, v) \in E$, and returns the relation of u, v in $\mathcal{P}$. The goal of GPS is to use the minimum number of queries to fully recover $\mathcal{P}$, i.e., $\forall u, v \in V$, correctly determine the relation of u, v in $\mathcal{P}$.

Model of query graphs in GPS. To make sure the problem is well-defined, e.g., G has sufficient edges to recover $\mathcal{P}$, we need to add some further constraints on the query graph G. Specifically, we enforce the following: let $\vec{E} := \{(u, v) \in E : u \prec v\}$ and $\vec{G} = (V, \vec{E})$ (noting that $\vec{G}$ is defined with respect to both G and $\mathcal{P}$) then

$$\mathcal{P} = \mathcal{P}(\vec{G}). \tag{1}$$

This is well-defined if G is deterministic (for instance G is a complete bipartite graph), but for stochastic case enforcing this directly may cause randomness issues. Hence, we discuss how we define the Erdős-Rényi stochastic query graph in more detail in the following.

Model of query graphs in GPS: Erdős-Rényi stochastic case. Let $G(n, p)$ denote the Erdős-Rényi random graph with n vertices and probability parameter $0 \leq p \leq 1$. Specifically, this $G(n, p)$ is generated by independently adding an undirected edge (u, v) with probability p for every vertex pair $u \neq v$. Clearly, this random graph is unlikely to be able to uniquely identify $\mathcal{P}$. Hence, we still wish to enforce the property stated in (1). Specifically, we need to add to the Erdős-Rényi graph a *minimal* DAG G_{base} which is a "base graph". Here, we say a DAG $\vec{G}$ is minimal if there is no redundant edge in $\vec{G}$, where we call an edge $u \to v$ redundant if we have $\exists x \notin \{u, v\}$, $u \to x$ and $x \to v$. Formally, we have the following definition, and it indeed satisfies (1) (stated in Fact 3.2).

▶ **Definition 3.1.** *Fix some minimal DAG $\vec{G}_{\text{base}}$ such that $\mathcal{P} = \mathcal{P}(\vec{G}_{\text{base}})$, denoting its underlying undirected graph as G_{base}, the Erdős-Rényi stochastic query graph G is a union of G_{base} and $G(n, p)$.*

▶ **Fact 3.2.** *The random query graph $G = (V, E)$ defined in Definition 3.1 satisfies* (1) *with probability* 1*, namely,* $\Pr[\mathcal{P} = \mathcal{P}(\vec{G})] = 1$ *where* $\vec{G} := \{(u, v) \in E \mid u \prec v\}$.

Indeed, this definition can be viewed as a generalization of the stochastic setting in the (total order) generalized sorting [18, 22], here they use a directed Hamiltonian Path as a base graph (which is the only minimal choice in the total order setting).

Generalized poset sorting with comparable edges (GPSC). In this model, all edges in G are comparable edges. Specifically, when an edge in E is queried, the answer will only be $v \prec u$ or $u \prec v$, corresponding to $\mathcal{P}$. We remark that when $\mathcal{P}$ is a total order set, then the model draws back to the generalized sorting model, so GPSC is already a generalization of generalized sorting.

Weighted generalized (total order) sorting. In this model, the poset is total order, and the query graph is weighted by a weight function $w : E \to \mathbb{R}_{\geq 0}$. We aim to minimize the sum of costs we pay to solve the GPS under this setting. We evaluate our algorithms by the competitive ratio, which is the maximum ratio taken over all possible inputs, measured by the cost of the algorithm, denoted as ALG, divided by OPT which is the sum of costs $\sum_i w(v_i, v_{i+1})$ where $(v_1, \ldots, v_n)$ is the total order defined by $\mathcal{P}$.

4 Proof Overview

Due to space limit, we give a sketch for the proofs of main results in this section, and the full proof, except for a more detailed presentation of our main framework (in Section 5), can be found in the full version.

A general framework for generalized poset sorting. As mentioned, we obtain algorithms for GPS via a new unified framework. In this framework, we first reduce the GPS to finding a *linear extension* (Lemma 5.1). A linear extension for the poset $\mathcal{P} = (V, \prec)$ is a total order such that $\forall x, y \in V$, if $x \prec y$ then x appears before y in the total order. Finding a linear extension is an interesting problem in its own right, and it has also been studied in [18, 10]. However, previous studies did not establish the connection between GPS and linear extension, which we do in our framework.

To find the linear extension, we employ a quicksort-like algorithm to randomly select a pivot element $v \in V$ and partition the elements into three parts, elements smaller than v, elements incomparable with v and elements larger than v. Given this partition, one can compute the linear extension of these three parts recursively and combine them in the order of smaller-incomparable-larger to obtain the linear extension of $\mathcal{P}$.

This quicksort-like algorithm was also used in [10] to find a linear extension for complete query graphs. While their analysis may be adapted to the general query graph case, it only leads to sub-optimal bounds with respect to k. We give new analysis to this quicksort-like algorithm, and we are able to obtain an improved dependence in k, provided that the partition algorithm have a refined query complexity that only depends on the width of the part of the input subgraph (to the partition algorithm) that is comparable to the pivot (see Lemmas 5.3 and 5.4 for more details). We manage to design partition algorithms with refined query complexity for both Erdős-Rényi and complete bipartite query graphs.

Now we explain our new steps in the analysis to the quicksort-like algorithm. In [10], it is observed that the depth of the recursion tree is $O(k + \log n)$. This is good enough for complete query graphs, since the partition step can be done in $O(n)$, and this, combined with the depth of the recursion tree, translates to an $O(nk + n \log n)$ bound. However, when G is not a complete graph, the partition problem often requires $\Omega(n)$ queries, say $O(nk^c)$ queries, then the analysis in [10] leads to an $\tilde{O}(nk^{c+1})$ bound, which introduces an additional k factor. In order to avoid this additional k factor, we require partition algorithms to use $O(nk_v^c)$ queries that depend on k_v, which denotes the width of elements comparable with pivot vertex v. A crucial observation is that, if k_v is small, then the partition algorithm uses few queries, and if k_v is large, then the next pivot v' (in the incomparable part) is likely to have a small $k_{v'}$.

Partition algorithms. For the partition step, if it were the complete graph case, we could directly query the relations between the pivot and every other element using $n - 1$ queries. However, this simple but efficient bound is no longer easily obtainable when the query graph

is not complete. Nonetheless, we introduce novel ideas for this partition step, and we manage to obtain algorithms that use $\tilde{O}(nk^2)$ queries for Erdős-Rényi query graphs and $\tilde{O}(nk)$ queries for complete bipartite query graphs.

Partition algorithms: Erdős-Rényi graphs. It is helpful to interpret the problem as a graph problem. We define a directed graph $\vec{G}$ from G, by defining the direction of every edge $(u, v) \in E$ according to the relation between u, v, i.e. the direction is $u \to v$ if and only if $u \prec v$. Then for every vertex u, u is smaller than the pivot vertex if and only if there exists a path from u to pivot in $\vec{G}$. Hence, the partition problem reduces to finding all vertices that can be reached from the pivot vertex. This graph problem may be solved using BFS, but a vanilla BFS needs to query all edges, which is too costly. To resolve this issue, we design a variant of BFS that can make use of the structure of Erdős-Rényi graphs, called Skip-BFS.

We start by giving the overall intuition by assuming we are given a chain decomposition of the poset (which is of size k, guaranteed by Dilworth's Theorem). An important property of Erdős-Rényi $G(n, p)$ is that, if we select $O(p^{-1} \log n)$ arbitrary vertices, then every vertex is adjacent to at least one selected vertex[5]. Hence, if we select the $O(p^{-1} \log n)$-largest vertices from each chain in the chain decomposition of the poset then every vertex has outgoing edges to at least one selected vertex. Exploring (the neighbors of) these selected vertices only takes $\tilde{O}(kp^{-1} \cdot np) = \tilde{O}(nk)$ queries, and this finishes the partition.

However, the chain decomposition is not known to our algorithm a priori. Thus, we need a method to gauge whether a vertex is worth exploring, i.e., it is sufficiently large in its chain. To this end, Skip-BFS maintains a counter $c[v]$ for each vertex v, which is initialized as some parameter $R = \Theta(\log n)$. Then, if some vertex v becomes the current vertex for which we start to explore its neighbors, we decrease the counter $c[u]$ by 1 for every v's neighbor u such that u is smaller than v. When the counter of some vertex u is decreased to 0, we skip this vertex u by removing it from the BFS queue. Such u can be safely skipped since Skip-BFS has already explored $R \geq \Omega(\log n)$ vertices that are larger than u, and these vertices are likely to cover all incoming vertices of u. To see this, since u's counter is decreased $R \geq \Omega(\log n)$ times, we already visited $O(p^{-1} \log n)$ vertices that are larger than u, and that each such vertex connects to p fraction of vertices smaller than u. Hence, these already-visited $O(p^{-1} \log n)$ vertices connect to/cover all vertices that are smaller than u. Finally, to guarantee the efficiency of this process, we need to explore vertices in a random order for each BFS step (in step i we explore all vertices with distance i from the starting vertex), in order to trim most u's in only a few steps. This eventually leads to an $\tilde{O}(nk^2)$ time partition algorithm for Erdős-Rényi query graphs.

Compared with the approach in [22] who gave an algorithm for the total order case that uses $O(n \log(np))$ queries which is tight, our bound is comparable, but our approach is conceptually different. In fact, it is unclear if their approach can be efficiently generalized to the poset case. In their algorithm, they repeatedly find the minimum vertex of the current graph and remove it. To find the minimum vertex, they identify a set of candidate vertices and then trim the wrong ones by testing if there is an incoming edge, which requires querying the edges between the candidates and other vertices. However, in GPS, there are multiple minimal vertices, and it is nontrivial to bound the number of candidates and the adjacent edges to query since one cannot stop before one is certain that the surviving candidates are minimal. Hence, it is nontrivial to generalize their approach to GPS using even subquadratic queries.

[5] This does not always happen and only with high probability, but in the following discussions we ignore this and talk about the typical behavior.

Partition algorithm: complete bipartite graphs. Suppose the two parts of the bipartite graph are A and B, and suppose the pivot is $b \in B$. Let $A_{\succ b}$ and $B_{\succ b}$ be the elements in A and B that are greater than b, respectively. We focus the discussion on finding the elements that are larger than b, i.e., $A_{\succ b} \cup B_{\succ b}$. Since the graph is complete bipartite, it is easy to obtain $A_{\succ b}$, but it is nontrivial to obtain $B_{\succ b}$ since one cannot directly compare any other point in B with the pivot b. A natural idea to deal with this is to find the minimal elements in $A_{\succ b}$ so that one can figure out $B_{\succ b}$ from these elements. However, finding the minimal element is technically nontrivial even in the total order setting (whose minimal is unique), let alone there may be multiple minimal elements in posets. Indeed, the existing algorithm for the total order setting does not seem to make progress on this simple and fundamental task, and they solved the problem via other indirect methods [1, 7, 2, 21]. We provide a completely new algorithm to find the minimal elements for poset in bipartite complete graphs, which is a technical contribution to the study of sorting and selection for bipartite graphs.

We first devise a FindMin procedure that finds a "local" minimal element in $A_{\succ b}$ (the "local" is due to the fact that we may make iterative calls and only run the procedure on an induced subgraph). Then, we apply this FindMin iteratively to both find the minimal elements of $A_{\succ b}$ and construct $B_{\succ b}$. In particular, every time we run FindMin to obtain a vertex a, we try to find $B_{\succ a}$ and expand the currently found $B_{\succ b}$, and remove a from A to continue. Each iteration takes $\tilde{O}(n)$ queries. Then, using the property and the randomness of FindMin, the new element a' that we find must be smaller than a if they are comparable, and this also shrinks the distance from a to the pivot by a constant factor with good probability. Finally, if one takes one chain in a chain decomposition, this entire process would typically run on a vertex from this chain for $O(\log n)$ iterations. Summing over k chains, the total query time is $\tilde{O}(nk)$ in the typical case.

GPSC. Recall that there are no incomparable edges in the query graph (which means every edge $(u, v) \in E$ satisfies either $u \prec v$ or $v \prec u$) of the GPSC problem. This conceptually simplifies the problem since this avoids the issue of gaining essentially no information from querying an incomparable edge. Technically, this allows us to apply techniques/frameworks developed for generalized sorting problems, which crucially relies on the information gained from querying an edge. Specifically, we use an idea proposed in [18] and further developed in [22], where one first constructs a prediction graph which "guesses" the direction/relation of all edges in the query graph. Then, an incremental algorithm that iteratively adds a currently "minimal" element, i.e., an element u with a small number of "incoming edges" (which are the edges (v, u) such that $v \prec u$) in the prediction, is employed to generate the sorting.

To apply this framework to GPSC, especially to achieve a linear dependence in k, we cannot use [18, 22] in a black-box way, since we need a stronger predictor such that it has a bounded number of wrongly predicted edges *everywhere*: $\forall v$, there are $\tilde{O}(\sqrt{n})$ wrongly predicted edges among all adjacent edges to v. This is stronger than the previously designed predictors [18, 22], since [18] only guarantees an $\tilde{O}(\sqrt{n})$ absolute error for the in-degree of every vertex (instead of the edge predictions), and [22] only guarantees an overall number of wrong edges (instead of our "everywhere" guarantee). We manage to obtain such a stronger predictor.

Then, with this predictor, we iteratively maintain a current set A of sorted vertices, and we show it is possible to identify a key vertex $v \in A$, whose incoming vertices (with respect to the prediction) can be partitioned into $X_v \subseteq A$ and $Y_v \subseteq V \backslash A$, such that the poset induced by X_v still has width k, and that $|Y_v| = O(\sqrt{n})$ (by the stronger guarantee of the predictor).

This, together with the fact that X_v can be decomposed into k chains, implies that one can verify/discover all incoming edges (from the predictor) to v using $O(k \log n + \sqrt{n})$ queries. In total, this entire iterative process of updating A happens $O(n)$ times, which leads to our final query bound $\tilde{O}(nk + n^{1.5})$.

Weighted generalized sorting. We start with designing an $O(k \operatorname{poly} \log n)$-competitive algorithm $\mathcal{A}$, whose input consists of a chain decomposition (of the total order) of size k in addition to the weighted query graph (and the underlying total order), for weighted generalized sorting. Notice that one can always feed a trivial chain decomposition of size n to $\mathcal{A}$ and obtain $\tilde{O}(n)$ competitive ratio, which is already nontrivial as we mention in Section 1.1. Although the algorithm by [16] can also achieve an $O(n)$ ratio for weighted generalized sorting, it only works for the case when all chains are single nodes (i.e., $k = n$), hence it is not useful for obtaining a sublinear ratio.

Next, we employ a threshold algorithm to "combine" $\mathcal{A}$ with Theorem 1.5 to obtain a sublinear ratio when the number of distinct weights is bounded. Suppose the weights are $w_1 < \ldots < w_W$. We use a threshold parameter $1 \leq \tau \leq W$, and define G_τ as the subgraph of the query graph with edge weights *at most* w_τ. We also consider the poset $\mathcal{P}_\tau$ induced by G_τ, and let k_τ denote its width. We start with running Theorem 1.5 on $(G_\tau, \mathcal{P}_\tau)$ and ignoring the weight, which takes $\tilde{O}(nk_\tau)$ queries (assuming $k_\tau \geq \sqrt{n}$ in this discussion), and it generates a chain decomposition of $\mathcal{P}_\tau$. Notice that this chain decomposition of $\mathcal{P}_\tau$ is also a chain decomposition of $\mathcal{P}$ since they are supported on the same element set. Then, we feed this chain decomposition to $\mathcal{A}$, and use the output of $\mathcal{A}$ as the result. The entire algorithm achieves an $\tilde{O}(\frac{nk_\tau \cdot w_\tau}{\mathrm{OPT}} + k_\tau)$ ratio, and we can further show this ratio is at most $O(\frac{nw_\tau}{w_{\tau+1}})$ (assuming that k_τ is not the dominating factor), which depends on the "gap" between two adjacent weights. The final result can be achieved by fine-tuning of τ to minimize this ratio: if all weights are of a small gap, then one can view it as the unweighted case and run Theorem 1.5 directly, and otherwise, we have a significant gap which still allows a sublinear ratio.

5 A General Framework for Generalized Poset Sorting

In this section, we present our framework for GPS. As mentioned, this framework consists of two steps: it first reduces GPS to finding a linear extension, and eventually reducing the task of finding a linear extension to constructing a partition oracle. We start with formally defining the mentioned linear extension problem and the partition problem. We establish two sets of technical lemmas that relate GPS with linear extension Lemma 5.1 and the partition problem Lemmas 5.3 and 5.4, respectively.

Linear extension problem. In linear extension problem, there is an underlying poset $\mathcal{P} = (V, \prec)$ and query graph $G = (V, E)$. The algorithm receives G as input and has access to an oracle, which accepts queries u, v such that $(u, v) \in E$ and answers the relation of u, v in $\mathcal{P}$. The algorithm needs to compute a linear extension of $\mathcal{P}$ by making as few queries as possible. We call $p_1, p_2, \ldots, p_n \in \operatorname{perm}(V)$ a linear extension of $\mathcal{P}$ if and only if for every $1 \leq i < j \leq n$, $p_i \not\succ p_j$ (i.e. either $p_i \prec p_j$ or $p_i \nsim p_j$).

▶ **Lemma 5.1** (Linear Extension to Poset). *There exists an algorithm that given a linear extension of the underlying width-k poset $\mathcal{P}$ solves GPS in $\tilde{O}(nk)$ queries.*

Lemma 5.1 shows that given any linear extension of $\mathcal{P}$, we can solve $\mathcal{P}$ using $\tilde{O}(nk)$ queries. Specifically, our algorithm maintains a vertex set X such that all directions of edges in $G[X]$ is determined. Initially, X is empty. The vertices are added to X by their order in the linear

extension. When vertex v is added to X, our algorithm needs to determine all directions of edges between X and v. In the proof of Lemma 5.1, we show that X can always be decomposed into at most k paths. For every vertex v and every path $P = p_1 \prec p_2 \prec \ldots \prec p_s$, there exists a, b such that

- For every $1 \leq i \leq a$, $p_i \prec v$.
- For every $a < i < b$, $p_i \nsim v$.
- For every $b \leq i \leq s$, $p_i \succ v$.

a, b can be found by binary search. Hence the directions of edges between X and v can be determined in $O(k \log n)$ queries. Our algorithm is shown as Algorithm 1.

Algorithm 1 Constructing GPS using Linear Extension.

```
procedure GPS(p)
    input: p, a linear extension of 𝒫
    for i ← 1, 2, ..., n − 1 do
        let X_i be {p_1, p_2, ..., p_i}
        compute a path cover of induced subgraph G⃗[X_i], denoted by P_1, P_2, ..., P_{w_i} (w_i
    denotes the width of poset 𝒫(G⃗[X_i]))
        determine the directions of edges between X_i and p_{i+1} by applying binary search
    between P_j and p_{i+1} for every 1 ≤ j ≤ w_i
    end for
end procedure
```

▶ **Lemma 5.2.** *For every linear extension $p_1, p_2, \ldots, p_n$ of $\mathcal{P}$ and every $1 \leq i \leq n$, we have $\mathcal{P}(\vec{G}[X_i]) = (X_i, \prec)$ where $X_i = \{p_1, p_2, \ldots, p_i\}$.*

Proof. To prove $\mathcal{P}(\vec{G}[X_i]) = (X_i, \prec)$, we show that for every $u, v \in X_i$, $u \prec v$ if and only if u can reach v in $\vec{G}[X_i]$.

- If u can reach v in $\vec{G}[X_i]$, then u can also reach v in $\vec{G}$, which implies $u \prec v$.
- If $u \prec v$, then there exists a path $u \to q_1 \to q_2 \to \ldots \to q_\ell \to v$ in $\vec{G}$. For every $1 \leq j \leq \ell$, suppose $q_j \notin X_i$, let $q_j = p_a, v = p_b$, we have $p_a \prec p_b$ and $b \leq j < a$, which contradicts the definition of linear extension. Hence we have $q_1, q_2, \ldots, q_\ell \in X_i$, which implies u can reach v in $\vec{G}[X_i]$. ◀

Proof of Lemma 5.1. By Lemma 5.2, for every $1 \leq i < n$, $\mathcal{P}(\vec{G}[X_i]) = (X_i, \prec)$. The width of poset $(X_i, \prec)$ is no more than k since $X_i \subseteq V$. Hence, for every i, all directions of edges between $p_1, p_2, \ldots, p_i$ and p_{i+1} can be determined by applying at most k binary searches on the path cover of $\vec{G}[X_i]$. Clearly, this entire process takes $O(nk \log n)$ queries in total, which finishes the proof. ◀

Partition problem. The partition algorithm is defined on an underlying DAG $\vec{G} = (V, \vec{E})$ and a query graph $G = (V, E)$. Notice that partition algorithm is a pure graph problem (there is no poset in the problem definition). The algorithm receives G and vertex $p \in V$ as input and has access to an oracle, which accepts queries u, v such that $(u, v) \in E$ and answers the relation of u, v in $\vec{G}$. There are three possible relations, u can reach v, v can reach u, neither u nor v can reach each other. The algorithm needs to compute $V_{\to p}, V_{\nrightarrow p}, V_{\leftarrow p}$ by making as few queries as possible, where

- $V_{\to p} = \{u \in V \mid u \neq p, u \text{ can reach } p\}$
- $V_{\leftarrow p} = \{u \in V \mid u \neq p, p \text{ can reach } u\}$
- $V_{\nrightarrow p} = \{u \in V \mid u \neq p, \text{neither } u \text{ nor } p \text{ can reach each other}\}$

The following two lemmas reduce the problem of finding linear extensions to finding a partition of the elements with respect to a given pivot. These two versions of lemmas are essentially the same, except that one allows the partition oracle to make mistakes and with a randomized query complexity (but needs to succeed with high probability), and the other requires the correctness (with probability 1) and a good query complexity in expectation. We need these two since we find it is not trivial to convert one to the other, and our downstream algorithms may need both of them.

▶ **Lemma 5.3.** *If for every $X \subseteq V$ and $p \in X$, $\textsc{Partition}(G[X], p)$ correctly outputs $X_{\to p}, X_{\nleftrightarrow p}, X_{\leftarrow p}$ within $O(|X|(k_{X_{\prec v}} + k_{X_{\succ v}})f(n,k))$ queries with probability $1-\varepsilon$ (f is some function of n, k), then $\textsc{Part-to-LE}(V)$ outputs a linear extension of $\mathcal{P}$ in $O(nkf(n,k)\log^2 n)$ queries with probability of at least $1 - n\varepsilon - 2n^{-6}$.*

▶ **Lemma 5.4.** *If for every $X \subseteq V$ and $p \in X$, $\textsc{Partition}(G[X], p)$ always correctly outputs $X_{\to p}, X_{\nleftrightarrow p}, X_{\leftarrow p}$ and uses $O(|X|(k_{X_{\prec v}} + k_{X_{\succ v}})f(n,k))$ queries in expectation, then $\textsc{Part-to-LE}(V)$ outputs a linear extension of $\mathcal{P}$ in $O(nkf(n,k)\log^2 n)$ queries in expectation.*

Abstract

We study the k-connectivity augmentation problem (k-CAP) in the single-pass streaming model. Given a $(k-1)$-edge connected graph $G = (V, E)$ that is stored in memory, and a stream of weighted edges (also called links) L with weights in $\{0, 1, \ldots, W\}$, the goal is to choose a minimum weight subset $L' \subseteq L$ of the links such that $G' = (V, E \cup L')$ is k-edge connected. We give a $(2+\epsilon)$-approximation algorithm for this problem which requires to store $O(\epsilon^{-1} n \log n)$ words. Moreover, we show the tightness of our result: Any algorithm with better than 2-approximation for the problem requires $\Omega(n^2)$ bits of space even when $k = 2$. This establishes a gap between the optimal approximation factor one can obtain in the streaming vs the offline setting for k-CAP.

We further consider a natural generalization to the fully streaming model where both E and L arrive in the stream in an arbitrary order. We show that this problem has a space lower bound that matches the best possible size of a spanner of the same approximation ratio. Following this, we give improved results for spanners on weighted graphs: We show a streaming algorithm that finds a $(2t-1+\epsilon)$-approximate weighted spanner of size at most $O(\epsilon^{-1} n^{1+1/t} \log n)$ for integer t, whereas the best prior streaming algorithm for spanner on weighted graphs had size depending on $\log W$. We believe that this result is of independent interest. Using our spanner result, we provide an optimal $O(t)$-approximation for k-CAP in the fully streaming model with $O(nk + n^{1+1/t})$ words of space.

Finally we apply our results to network design problems such as Steiner tree augmentation problem (STAP), k-edge connected spanning subgraph (k-ECSS) and the general Survivable Network Design problem (SNDP). In particular, we show a single-pass $O(t \log k)$-approximation for SNDP using $O(kn^{1+1/t})$ words of space, where k is the maximum connectivity requirement.

1 Introduction

In the (weighted) *k-connectivity augmentation* problem (k-CAP), given a $(k-1)$-edge-connected n-vertex graph $G = (V, E)$ (possibly with parallel edges) together with a set of weighted candidate edges (also called *links*) denoted by $L \subseteq \binom{V}{2}$ and their weights

$w\colon L \to \{0, 1, \ldots, W\}$, the goal is to find a minimum weight subset $S \subseteq L$ of the links such that $(V, E \cup S)$ is k-edge-connected. Augmenting connectivity is a crucial task for enhancing network reliability which can be used for strengthening the resilience of a network and ensuring uninterrupted access for all users. k-CAP is among the most elementary questions in Network Design, which is an important area of discrete optimization. The iterative rounding method of [29] provides a 2-approximation for a more general problem of *survivable network design* problem (SNDP). Untill very recently, nothing better than 2 approximation was known even for weighted *tree augmentation problem* (TAP). In a recent development, weighted k-CAP has witnessed breakthroughs with approximation factors below 2 [48, 49, 50]. The state-of-the-art for weighted k-CAP is $1.5 + \epsilon$ approximation.

In this work, we consider weighted k-CAP in the streaming model, which is one of the most common models for processing real-time and large-scale data. A graph streaming algorithm operates by processing a sequence of graph edges presented in any order (or in some applications in random order), reading them one by one. The primary objective is to design algorithms that can process the entire edge sequence and output an approximately efficient solution, making just one (or a few passes), while utilizing limited memory resources. Ideally, the space usage of the algorithm should be significantly smaller than the size of the n-vertex input graph (with possibly $O(n^2)$ edges), preferably $O(n \cdot \text{polylog}(n))$ memory, which is referred to as the *semi-streaming* model [18].

While graph problems such as minimum spanning tree [2, 47, 42], matching [39, 25, 5, 4, 30], spanners, sparsifiers and shortest paths [19, 7, 15, 2, 33, 28, 20, 21] have received significant attention in the streaming model, the connectivity augmentation problem, has received comparatively very limited study in this context. Prior to our result, only testing k-connectivity in streaming was studied [52, 13, 47], which showed that testing k-edge-connectivity in streaming requires $\tilde{\Theta}(nk)$ space in one pass, and $\tilde{\Theta}(n)$ space in two passes [46, 3]. See Appendix C for more discussion on related work.

1.1 Our Computational Models

In this work, we study graph augmentation problems in the streaming model of computation. The input to the k-CAP problem consists of two pieces of information, namely the $(k-1)$-connected network G and the set of links that can be used to augment connectivity.

Link arrival streaming. In the link arrival streaming model the graph G is presented to the algorithm first, and the cost of storing it does not count towards the space complexity of the algorithm. This is akin to the oracle model that is routinely used to study submodular function maximization in the streaming model (e.g., in [6, 43]): One thinks of having an oracle for the function being maximized. For submodular function maximization it is not always clear how to implement this oracle in small space, but in our case the actual cost of storing a sufficient representation of the graph G can be easily made $O(nk)$, and, with some work, even $O(n)$, as we now explain.

Note that a minimally k-connected graph has size $O(nk)$. So if the graph has larger size, one can process the edges of G (even in a streaming fashion) using a k-connectivity certificate of G that preserves all cuts of value at most k, and store this compact representation in $O(nk)$ space. Finally, one can apply even a more efficient preprocessing that preserves a similar information via a *cactus* graph with $O(n)$ edges. Then the problem becomes streaming *cactus augmentation*. The cactus augmentation problem itself is a well-studied problem in particular for designing approximation algorithms for k-CAP. To simplify the notation, throughout the paper, we assume the latter compact representation of size $O(n)$.

Fully streaming. Besides the most natural link arrival model defined above, we study the more general model where the edges of G and the links that can be used for augmentation may arrive in an interleaved fashion. This model is quite general: in particular, it allows for the edges of G to arrive *after* the links, in which case the algorithm must maintain a compressed representation of the stream of links that allows augmenting any given graph G presented later!

For the other graph problems studied in this paper, namely spanner, SNDP and k-edge connected spanning subgraph (k-ECSS), we consider the standard edge arrival streams in which edges of the input graph arrives one by one in an arbitrary order stream.

1.2 Our Results

In this paper, we focus on insertion-only streams, and provide the first streaming algorithms for k-CAP in link arrival streams and fully streaming. Table 1 summarizes our results.

Graph augmentation in link arrival. We show tight results for weighted k-CAP in link arrival streams (see first row in Table 1). Note that, while we can achieve a factor $2+\epsilon$ approximation in $O(\frac{n}{\epsilon}\log n)$ words of space, our lower bound shows that getting better than 2 approximation requires $\Omega(n^2)$ bits of memory. This establishes a gap between the streaming setting and the offline setting where strictly better than 2 approximation algorithms are known (e.g., see [50]). An easy argument shows that $\Omega(n)$ bits of space is necessary for achieving any approximation for k-CAP in link arrival streams (Proposition 2.12 in the full versoin), so our algorithm has nearly-tight space complexity. If one picks a k-connectivity certificate as the compact representation of G, the space complexity of the upper bound becomes $O(nk+\frac{n}{\epsilon}\log n)$.

Further, we study the Steiner tree augmentation problem (STAP) which is a generalization of the tree augmentation problem (TAP) in link arrival streams and provide matching upper and lower bounds (See the second row in Table 1). While our lower bound holds for link arrival streams, our algorithm works even in the more general fully streaming too. We remark that, while in the offline setting TAP and STAP admit similar approximations [45], there is a gap in their complexities in the streaming model.

Graph augmentation in fully streaming. We further show matching upper and lower bounds (up to a polylog(n) factor) for k-CAP in the fully streaming setting (see the lower section in the first row of Table 1). The main component in our algorithm for solving k-CAP is an improved streaming algorithm for constructing *spanners on weighted graphs*. In particular, our upperbound implies that spanner is an optimal "universal" augmentation set for k-CAP.

Improved streaming spanner in weighted graphs. Given an n-vertex graph $G=(V,E)$ with a weight function $w\colon E\to\{0,\dots,W\}$, a subgraph $H\subseteq G$ is a t-spanner of G if for every $(u,v)\in E$, the shortest uv-path in H has weight at most $t\cdot w(uv)$. In streaming spanner, which is a well-studied problem [7, 15, 2, 33, 20], edges of E arrive in an arbitrary order stream. While by using the standard weight-based partitioning trick, constructing an $O(t)$-spanner in $O(n^{1+1/t}\cdot\log W)$ words of space in one pass over the stream is straightforward (e.g., mentioned in [21]), it was not known whether the dependence on $\log W$ is crucial.[2]

[2] We remark that our contribution in removing the dependence on $\log W$ from the number of edges in spanner (and consequently from k-CAP) is conceptually interesting, as most graph streaming algorithms are mainly designed for unweighted graphs, and extending them to the weighted case typically incurs a $\log W$ loss.

Table 1 Summary of our results for k-CAP, STAP, Spanner and SNDP in steaming models. All our problems are *weighted*. The space upper bounds are measured in words, while the lower bounds are in bits. We use $\tilde{O}(f)$ to mean $O(f \cdot \text{polylog} f)$ (it does not hide $\log W$ factors). All our algorithms are deterministic, whereas all lower bounds hold for randomized algorithms with constant success probability.

Problem	Pass	Approx.	Space	Stream	Notes
k-CAP	1	$2+\epsilon$	$O(\frac{n}{\epsilon}\log n)$	link arrival	Theorem 1
		$2-\epsilon$	$\Omega(n^2)$ bits		Theorem 10
		$O(t)$	$\tilde{O}(kn+n^{1+\frac{1}{t}})$	fully streaming	Theorem 15
			$\Omega(kn+n^{1+\frac{1}{t}})$ bits		Theorem 11
STAP	1	$O(t)$	$\tilde{O}(n^{1+\frac{1}{t}})$	fully streaming	Corollary 20
			$\Omega(n^{1+\frac{1}{t}})$ bits	link arrival	Corollary 21
Spanner	1	$O(t)$	$\tilde{O}(n^{1+\frac{1}{t}})$	edge arrival	Theorem 16
			$\Omega(n^{1+\frac{1}{t}})$ bits		Erdős' girth conjecture
SNDP	1	$O(t\log k)$	$\tilde{O}(kn^{1+\frac{1}{t}})$	edge arrival	Theorem 25
		$O(t)$	$\Omega(n^{1+\frac{1}{t}})$ bits		Corollary 21
k-ECSS	k	$O(\log k)$	$O(kn\log n)$	edge arrival	Corollary 26

Exploiting an even-odd bucketing approach, we provide a streaming algorithm with space complexity $O(n^{1+1/t}\cdot\log\min(W,n))$ words which by the well-known Erdős girth conjecture is basically the best one can hope for up to logarithmic factors. We further apply this even-odd bucketing to the k-CAP problem in the link arrival setting, and obtain a (more technical) algorithm (Theorem 1) with no dependence on $\log W$ in its space complexity.

Streaming SNDP. Finally, we describe an application of our results for designing the *first* one-pass streaming algorithms for the problem in insertion only edge arrival streams, where the edges of the input graph arrive in an arbitrary order stream.
